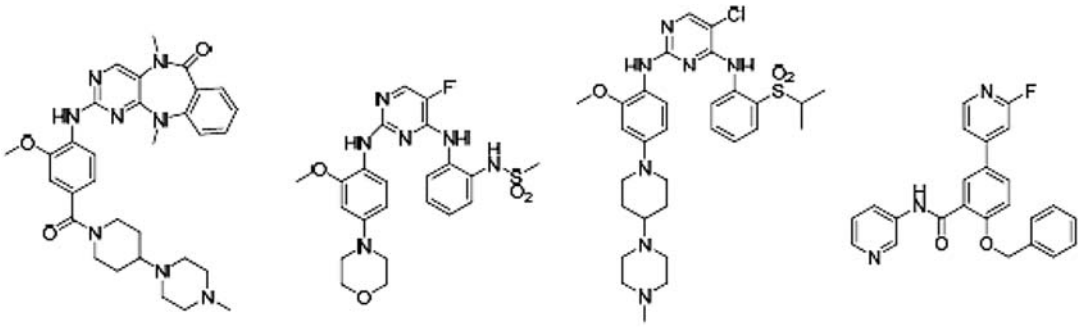
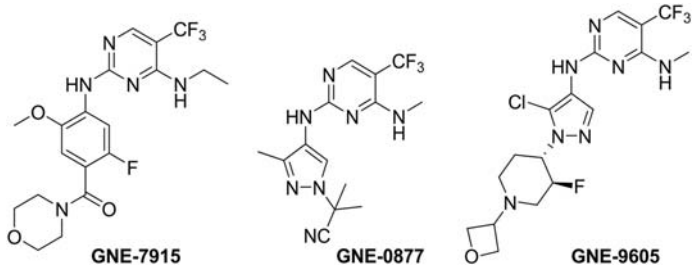
As an attractive therapeutic target for the treatment of PD, LRRK2 has received increased attention in academic institutions and in the pharmaceutical industry. Multiple programs have been launched in different institutions and several small molecule LRRK2 inhibitors have been identified in recent years. Early reported LRRK2 inhibitors include staurosporine, K252A7, sunitinib, H-11529, and GW5074.[38–40] These compounds, however, are nonspecific inhibitors against LRRK2. More recently, LRRK2-IN-1 was identified and exhibited excellent activity and selectivity.[41] In biochemical assays with 0.1 mM ATP concentration, this compound inhibited both wild-type LRRK2 and G2019S mutant with activities (IC_{50}) of 13 nM and 6 nM, respectively. In addition, it inhibited only 12 kinases in a 442-kinase panel assay with a score of < 10% of the DMSO control at a concentration of 10 μM. As a tool compound, LRRK2-IN-1 has demonstrated that the inhibition of LRRK2 induces the dephosphorylation of Ser910/Ser935 and the accumulation of LRRK2 within aggregate structures in mice kidneys. In contrast, no dephosphorylation of LRRK2 Ser910 or Ser935 was observed in brain tissue, indicating that LRRK2-IN-1 is likely unable to efficiently cross the BBB. CZC-251469 is another potent, highly selective, and metabolically stable LRRK2 inhibitor.[33] It has been demonstrated that CZC-251469 prevents mutant LRRK2-induced injury of cultured rodent and human neurons with midnanomolar potency. This agent, however, displayed poor brain penetration (~4%), which limited its utility in PD models and eventual translation into human clinical trials.



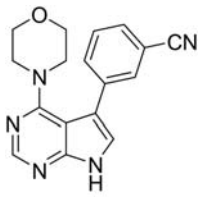
Recently, it was reported that TAE684, a previously reported inhibitor of ALK, is also a potent inhibitor of LRRK2 kinase activity (IC_{50} of 7.8 nM against wild-type LRRK2, 6.1 nM against the G2019S mutant).[42] At a concentration of 0.1–0.3 μM in cells TAE684 substantially inhibits Ser910 or Ser935 phosphorylation of both wild-type LRRK2 and G2019S mutants. The mouse pharmacokinetic (PK) profile of TAE684 demonstrated excellent oral bioavailability (83%), a half-life of 11.3 h and excellent plasma exposure (AUC of 6374 h ng mL^{-1}) at a dose of 10 mg kg^{-1}. Furthermore, TAE684 exhibited a brain-to-plasma AUC ratio of 2, indicating its superior BBB penetration property. In addition, complete Ser910 or Ser935 dephosphorylation of LRRK2 in the kidney and spleen at an oral dose of 50 mg kg^{-1} and slightly lower effects at 10 mg kg^{-1} were observed. Unfortunately, no inhibition of Ser910 or Ser935 phosphorylation of LRRK2 was observed in the mouse brain.

In 2012, a research group from GlaxoSmithKline reported a novel LRRK2 inhibitor GSK2578215A.[43] This agent exhibited biochemical IC_{50}s of around 10 nM against both wild-type LRRK2 and the G2019S mutants. GSK2578215A also substantially inhibited Ser910 or Ser935 phosphorylation of both wild-type LRRK2 and G2019S mutants at a concentration of 0.3–1.0 μM in cells. Evaluation of the PK profile of GSK2578215A in wild-type mice demonstrated that the compound achieved exposure in the brain with a brain-to-plasma ratio of 1.9. However, GSK2578215A exhibits low oral bioavailability (12%), short half-life (1.14 h), and limited plasma exposure (AUC = 635.3 h ng mL^{-1}) at an oral dose of 10 mg kg^{-1}. Complete Ser910 or Ser935 dephosphorylation of LRRK2 was observed in the kidney and spleen after intraperitoneal (i.p.) injections with 100 mg kg^{-1} of GSK2578215A in normal mice. Again, despite the significant exposure of GSK2578215A in the brain, no inhibition of LRRK2 Ser910 or Ser935 phosphorylation was observed in the brain, a finding similar to that observed for TAE684. Recently, Estrada et al. at Genentech Inc. reported the first BBB-penetrant, CNS-active, highly selective LRRK2 inhibitor, GNE-7915.[44] GNE-7915 demonstrated excellent LRRK2 inhibitory activity in biochemical (K_i = 1 nM) and cellular assays (IC_{50} = 9 nM) and high selectivity in a kinase panel screen. In addition, GNE-7915 exhibited excellent in vitro DMPK and in vivo rat PK profiles including good brain penetration in rats (unbound brain/unbound plasma AUC ratio = 0.50 and CSF/unbound plasma AUC ratio = 0.60). Furthermore, GNE-7915 was dosed to BAC transgenic mice expressing human LRRK2 protein with the G2019S PD mutation via either a single oral dose (p.o.) or i.p. injection. A robust, concentration-dependent knockdown of pLRRK2 in the brain was observed after an oral dose of 15 and 50 mg kg^{-1} and an i.p. dose of 10 and 50 mg kg^{-1}. GNE-7915 was also tolerable in the genotoxic study and 7-day repeat-dose toxicity studies in rats (10, 50, and 100 mg kg^{-1}) and cynomolgus monkeys (10, 25, and 65 mg kg^{-1}).



In an effort to improve aqueous solubility and eliminate the potential ortho-quinone-imine reactive metabolite formation of GNE-7915, the Genentech group successfully designed aminopyrazole inhibitors GNE-0877 and GNE-9605.[45] GNE-0877 and GNE-9605 exhibited excellent potency in cellular assays (3 and 19 nM of IC_{50}s, respectively) and good selectivity in kinase panel screening. Furthermore, GNE-0877 showed clearance of 44 mL min^{-1} kg^{-1} and oral bioavailability of 88% at a dose of 50 mg kg^{-1} in rats. Crystalline GNE-0877 also demonstrated good thermodynamic solubility (solubility = 100 μg mL^{-1} under neutral conditions). Importantly, the absence of P-gp efflux (efflux ratio = 0.8) translated to an in vivo rat-free brain/plasma AUC ratio (0.6) and corresponding CSF/free plasma AUC ratio (0.9). However, GNE-0877 was found to be a reversible CYP1A2 inhibitor (IC_{50} = 0.7 μM) although this compound did not exhibit time-dependent inhibition of CYP1A2. Additional profiling suggested that GNE-0877 was a pan inducer of CYP enzymes in human hepatocytes. Another LRRK2 inhibitor GNE-9605, which possessed

the same pyrimidine unit as GNE-0877 but with a different substitution pattern on the pyrazole moiety, was also described. A basic piperidine, which is a favorable fragment for solubility and brain penetration, was incorporated into GNE-9605. It was very potent toward LRRK2 in both biochemical ($K_i = 2.0$ nM) and cellular assays and highly selective in kinase panel screening. This agent is not a CYP inhibitor or inducer of any major CYP isoforms. In addition, in vivo rat PK studies with GNE-9605 demonstrated a total plasma clearance of 26 mL $min^{-1} kg^{-1}$ with excellent oral bioavailability (90%). Unbound brain-to-plasma and CSF-to-unbound plasma AUC ratios of GNE-9605 were between 0.5 and 1.0, respectively.



PF-06447475

More recently, Pfizer scientists reported a novel LRRK2 inhibitor PF-06447475.[46] This agent exhibited IC_{50} values against wild-type LRRK2 at 3 nM and the G2019S mutant at 11 nM in biochemical assays and 25 nM of IC_{50} in LRRK2 whole cell assay. PF-06447475 achieved approximately equal distribution of the free drug between rat brain, plasma, and kidney tissues. However, despite high permeability and moderate clearance, oral bioavailability was poor across species. Therefore, this agent was not progressed into clinic.

7.10.5.2 Cyclin-Dependent Kinase 5

Cyclin-dependent kinase 5 (CDK5) is a proline-directed serine/threonine kinase belonging to the family of cyclin-dependent kinases. It requires association with a regulatory partner, p35 and p39, for kinase activation. CDK5 plays a pivotal role in the development of the CNS. In addition to maintaining neuronal architecture, CDK5 plays an important role in the regulation of synaptic plasticity, neurotransmitter release, neuron migration, and neurite outgrowth.[47–50] The hyperactivity of CDK5 has been linked to the development of AD. Although CDK5 is important in the development of CNS and neuronal survival, many questions, such as what is the precise mechanism in disease progression, remain unanswered. Brain-penetrant CKD5 inhibitors have not yet been reported.

7.10.5.3 Mitogen-Activated Protein Kinase Kinase 1/2

MEK is a Ser/Thr protein kinase that phosphorylates extracellular signal-regulated kinase (ERK) in the Ras/Raf/MEK/ERK pathway. Mitogen-activated protein kinase kinase 1/2 (MEK1/2) has been an attractive therapeutic target in drug development for the treatment of a number of cancers. Highly selective and potent MEK1/2 inhibitors have been identified and assessed in recent years. Trametinib received US FDA approval in 2013 for the treatment of melanoma. Several other inhibitors are in clinical trials for cancer therapy.[51,52] Although oncology is the major area of focus, MEK1/2 has been investigated as a potential CNS target. Several MEK1/2 kinase inhibitors such as PD-98059, U0126, and PD198306 have shown efficacy in treating preclinical animal models of cerebral ischemia, traumatic brain injury, and neuropathic pain.[53] However, no MEK1/2 inhibitors for the treatment of CNS disorders are currently under clinical investigation, partly because the precise mechanism by which MEK inhibition relates to CNS disorders still remains unknown. Several inhibitors such as PD325901, cobimetinib (GDC-0973), and trametinib, designed for cancer therapy, have been screened and demonstrated that their brain penetration levels were very low.[6,54,55] The unfavorable physicochemical properties of these agents such as excessive HBDs might limit their brain exposure. Both cobimetinib and trametinib were determined to be substrates of the P-gp efflux transporter.

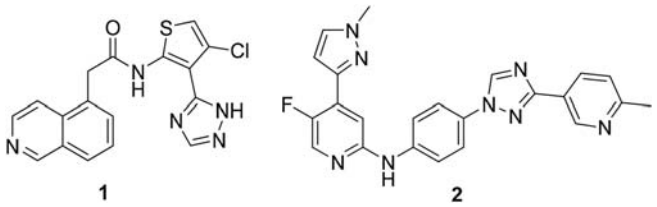
Trametinib

7.10.5.4 c-Jun N-Terminal Kinase

The c-jun N-terminal kinases (JNKs) are members of the MAPK family and they regulate the serine/threonine phosphorylation of several transcription factors when they are activated in response to a variety of stress-based stimuli such as cytokines, ultraviolet irradiation, heat shock, fatty acids, and osmotic shock. Despite the fact that JNK1 and JNK2 are expressed throughout the body, JNK3 is predominantly expressed in the brain and at lower levels in the heart and testis. Recent studies have suggested that JNK1 plays a central role in the development of obesity-induced insulin resistance and JNK2 is linked to autoimmune disorders such as RA and asthma. On the other hand, JNK3 has been shown to play an important role in the brain, by mediating neurodegeneration, such as beta amyloid processing, Tau phosphorylation, and neuronal apoptosis in AD, as well as mediating neurotoxicity in a rodent model of PD. Therefore, interest in developing selective JNK inhibitors as therapeutics for CNS disorders has been increasing over the past few years although no JNK kinase inhibitors are currently under clinical investigation.[56,57] A recent excellent review article described several brain-penetrant JNK3 kinase inhibitors.[58]



In 2011, Bowers et al. reported the JNK inhibitor 1.[59] This compound exhibited a favorable combination of potency, selectivity for JNK over p38α and ERK2 (JNK3 $IC_{50}=11$ nM, JNK1 $IC_{50}=14$ nM, JNK2 $IC_{50}=43$ nM, p38α $IC_{50}>50$ μM, and ERK2 $IC_{50}>50$ μM in biochemical assays), metabolic stability, permeability, and P-gp efflux. It was dosed to mice in kainic acid animal model study and the effect of JNK inhibition was tested. Pretreatment with a single, oral dose of compound 1 at 300 mg kg^{-1} resulted in a significant 51% reduction of phospho-c-jun in the hippocampus of FVB mice 4 h after an i.p. injection of 25 mg kg^{-1} kainic acid, indicating the in vivo effect on JNK activity of the inhibitor. The brain penetration level of this compound, however, was not reported. In the same year, Noel et al. independently disclosed a novel JNK inhibitor 2.[60] This agent displayed IC_{50} of 0.2 μM against JNK3 and >20 μM against p38α. The concentrations of the compound were determined at 9 and 10 μM in mouse plasma and in mouse brain, respectively, 2 h after IP dosing of 10 mg kg^{-1}. In addition, the compound exhibited good oral bioavailability (69%) and moderate terminal half-life ($T_{1/2}=2.3$ h).

7.10.5.6 Casein Kinase 1

Casein kinase 1 (CK1) is a Ser/Thr kinase that is ubiquitously expressed in eukaryotic organisms.[61] Seven CK1 isoforms (α, β, γ1, γ2, γ3, δ, and ε), highly homologous within their kinase domains and significantly different in the length and primary structure of their N-terminal and C-terminal noncatalytic domains, have been characterized.[62–65] Recent review articles have summarized the pharmacology studies that linked CK1 to several CNS-associated disorders, such as movement- and motivation-related behaviors, acceleration of the mammalian clock in brain regions and peripheral tissues, and AD.[66,67] AD is associated with the accumulation of the neurotoxic peptide amyloid-β (Aβ), which is produced by the sequential cleavage of amyloid precursor protein by the aspartyl protease β-secretase and the presenilin-dependent protease γ-secretase. Elevated CK1 activity has been reported to be associated with the pathological accumulation of the tau protein.[68] Inhibition of CK1 has been shown to reduce fibrillar lesions and to inhibit the production of the neurotoxic peptide (Aβ).

CKI-7 was the first reported CK1 inhibitor, which was characterized as an ATP-competitive inhibitor. However, this agent displayed poor selectivity against CK1 isoforms and was not suitable to proceed as a drug candidate. PF-4800567 and PF-670462 are the first reported brain-penetrable CK1 inhibitors.[69] Activity results of both compounds are summarized in **Table 2**. When tested in an in vitro assay against purified CK1ε and CK1δ, PF-4800567 had an IC_{50} of 32 nM for CK1ε, whereas its CK1δ IC_{50} was 711 nM, 22-fold less potent than toward CK1ε. In contrast, PF-670462, an inhibitor of both CK1ε and CK1δ, showed a small preference in the opposite direction and was approximately sixfold more potent toward CK1δ.

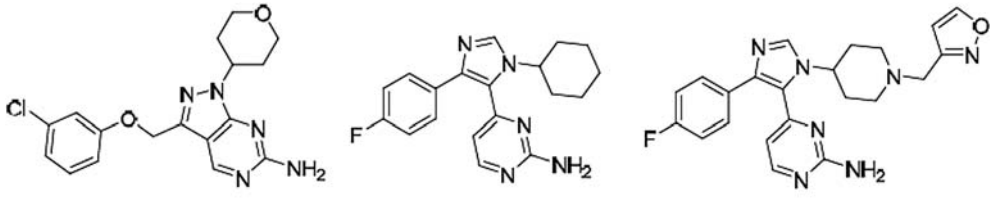
The in vivo PKs of PF-4800567 and PF-670462 were determined in C57BL/6J mice at a single 100 mg kg^{-1} subcutaneous dose. The results are shown in **Table 3**. The brain-to-plasma ratios were constant throughout the period of 24 h with an average value of 2.1 and 1.3 for PF-4800567 and PF-670462, respectively.

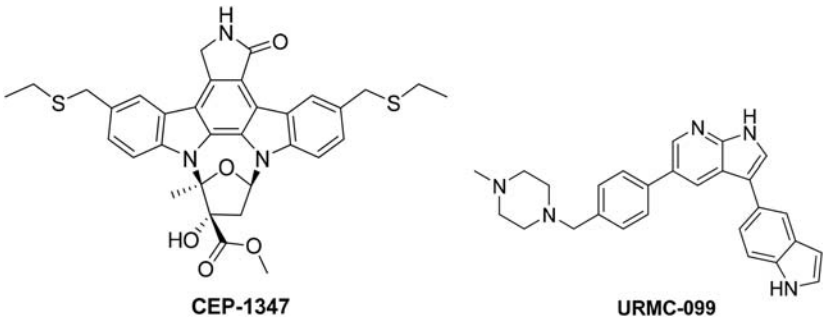
More recently, the efficacy of PF-670462 against alcoholism in rats was reported.[70] CK1ε/δ inhibition with PF-670462 decreased the alcohol deprivation effect dose-dependently and prevented alcohol intake during the days following treatment.



PF-5006739 is another CK1δ/ε inhibitor.[71] The crystal structure of the complex of PF-5006739 and CK1δ has revealed that the aminopyrimidine moiety binds to residue Leu85 in the hinge area by two-point hydrogen bonding. PF-5006739 exhibited potency against CK1δ and ε at a nanomolar range (CK1δ $IC_{50} = 3.9$ nM; CK1ε $IC_{50} = 17$ nM) in enzymatic assays and in whole cell screening ($EC_{50} = 15.2$ and 83 nM, respectively). PF-5006739 exhibited P_{app} value of 22×10^{-6} cm s^{-1} in permeability assay. Its MDR1 efflux ratio is 3.2. The maximum free concentration of PF-5006739 in the mouse brain was estimated to be 117 nM, with sufficient free drug exposure to cover the whole cell EC_{50} at a 10 mg kg^{-1} subcutaneous dose. PF-5006739 also demonstrated in vivo responses downstream of CK1δ/ε inhibition. It dose-dependently modulated circadian rhythm in both nocturnal and diurnal animal models.

7.10.5.7 Mixed-Lineage Kinase

Mixed lineage kinases (MLKs) are members of a large family of MAPK kinase kinases that activate MAPKs, including JNK, ERK 1/2, ERK5/BMK1, and p38.[72] MLK3 is the most widely expressed MLK family member. It is expressed in neurons and activates a neuronal cell death signal transduction pathway.[73,74] Inhibition of MLK3 has been a strategy for the prevention or treatment of neurodegenerative diseases such as AD and PD.[75,76]



CEP-1347 is a semisynthetic inhibitor in the MLK family. As a tool compound, it demonstrated the promotion of neuronal survival at dosages that inhibit activation of the JNKs in primary embryonic cultures and differentiated PC12 cells after trophic withdrawal in animal models.[77–84] CEP-1347 was advanced into clinical investigation stage and was found to be safe and well tolerable

Table 4 Blood–brain barrier penetration data of URMC-099 (C-57/BL/6 mice, i.v., 10 mg kg^{-1})

The New Small-Molecule Mixed-Lineage Kinase 3 Inhibitor URMC-099 Is Neuroprotective and Anti-inflammatory in Models of Human Immunodeficiency Virus-Associated Neurocognitive Disorders. *J. Neurosci.* **2013**, *33*(24), 9998–10010.

during 4 weeks in PD patients. Unfortunately, it failed to show efficacy in phase II clinical trials for early stage PD.[85] The brain exposure of CEP-1347 was not reported. However, the undesired properties such as high molecular weight (MW = 615) could limit its BBB penetration.

URMC-099, a new MLK3 inhibitor, possesses more favorable CNS drug-like properties with molecular weight of 421 Da, c log *P* of 3.8, c log *D* of 2.5, and PSA of 51 $Å^2$.[86] As a result, this agent exhibited excellent brain penetration in mice at an intravenous (i.v.) dose of 10 mg kg^{-1}. The brain and plasma levels were measured at three time points utilizing averages from three mice per time point (Table 4). The brain/plasma ratios across the three time points are fairly consistent. In addition, further PK evaluation in mice indicated that this agent displayed the clearance rate of 1.8 L $h^{-1}kg^{-1}$, volume of distribution of 5.6 L kg^{-1}, terminal half-life of 2.1 h, and bioavailability of 41%. This potent (IC_{50} = 14 nM) compound inhibits LPS-induced TNFα release in microglial cells, human immunodeficiency virus 1 (HIV-1) Tat-induced release of cytokines in human monocytes, and the upregulation of phospho-JNK in Tat-injected brains of mice. The antiinflammatory and neuroprotective effects of URMC-099 in multiple murine and rodent models of HIV-associated neurocognitive disorders were also demonstrated.[87]

7.10.5.8 Death-Associated Protein Kinase 1

Death-associated protein kinase (DAPK1) is a serine/threonine protein kinase that participates in apoptotic cell death, growth factor signaling, and autophagy.[88,89] It consists of a protein kinase domain, a calcium–calmodulin binding region, an ankyrin repeat domain, two putative P loops, a cytoskeletal binding region, and a death domain.[90] Emerging evidence suggests that elevated DAPK1 activity is linked to neuronal injury, such as ischemic injury and seizure-related injury.[91–93] Therefore, DAPK1 has been proposed as a target in CNS drug discovery and several DAPK1 inhibitors have been identified recently (3–6).[94–97] All these compounds, however, are in an early stage of the drug discovery process. No brain penetration data were reported and no DAPK1 inhibitors are in clinical investigation to date.

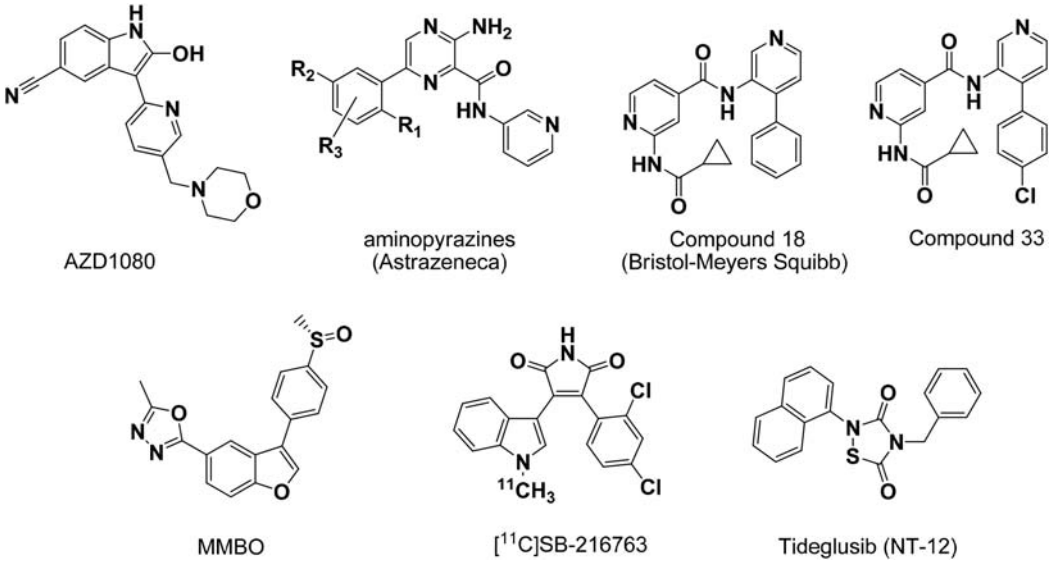
DAPK1 IC_{50} = 250 nM

7.10.5.9 Glycogen Synthase Kinase 3

In the late 1970s, two constitutively active isoforms of glycogen synthase kinase 3 (GSK3), with 98% homology in their catalytic domains, were identified in mammals: GSK3α and GSK3β.[98] The expression of GSK3 isoforms was found with greater abundance

in the brain compared to other tissues. GSK3 was originally identified as one of the kinases that modulates the activity of glycogen synthase (GS) for the conversion of glucose to glycogen.[99] Other kinases involved in the deactivation of GS are PKA, AMPK, and CK2. Upstream signaling, including the insulin or Wnt pathways, controls the activity of GSK3. GSK3α is inactivated by phosphorylation at Ser21 while GSK3β is inactivated at Ser9. The initial recognition of GSK3's regulation of GS suggested the possibility of using GSK3 inhibitors for treating diabetes mellitus type 2. Other therapeutically useful indications by the inhibition of GSK3 include bipolar disorder, inflammation, neuropathic pain, cancers, and fragile X syndrome (FXS).[100–104] However, much of the research focus was toward identifying GSK3 inhibitors for neurodegenerative AD.[105,106] The pathological link between GSK3 and AD was suggested when the involvement of GSK3β isoform in Tau protein phosphorylation was discovered. One of the histological hallmarks of AD is the formation of neurofibrillary tangles (NFTs) and intraneuronal aggregates of paired helical filaments. Hyperphosphorylation of Tau protein at the microtubule-binding motif by GSK3 leads to Tau protein aggregation (formation of NFTs) and microtubule destabilization within brain cells. Other important functions of GSK3 within the CNS include the regulation of the neuronal network's synaptic plasticity that may have an effect on depression, memory, and learning. In light of the multiple biological functions of GSK3β in the brain, the effort to identify clinically useful brain-penetrant GSK3β inhibitors has been intensified in the past few years. Although most of the inhibitors reported in the literature were claimed GSK3β selective, the selectivity between GSK3α and GSK3β isoforms is minimal because of the high homology of their kinase domains. Developing an isoform-selective GSK3β kinase inhibitor presents great challenges and pan-GSK inhibitors may not be disadvantageous. The first GSK3 inhibitor identified was lithium, which has been used to safely treat bipolar disorder for over 60 years. Readers who are interested in the history of using lithium for the treatment of bipolar disorder are referred in Refs. [107,108]. Over the years, numerous GSK3 inhibitors have been reported. The following section will focus on the recent development of potent synthetic small molecule GSK3 inhibitors with disclosed data on brain penetration.



AstraZeneca reported a low-molecular-weight (MW = 334 g mol^{-1}) GSK3 inhibitor, AZD1080, which was in the phase I clinical trial targeting AD.[109] In an animal model, AZD1080 was able to rescue synaptic plasticity deficits in rodent brains after animals were challenged with a low dose of MK-801 (a N-Methyl-D-Aspartate (NMDA) blocker for behavioral testing). The ability of AZD1080 to penetrate the BBB was evaluated using an in vitro bovine endothelial cell assay. The high permeability (8×10^{-3} cm min^{-1}) of AZD1080 determined in the assay predicted that AZD1080 could achieve significant brain exposure in vivo. A PK/PD study in a rat model with AZD1080 with the administration of 3 and 10 μmol kg^{-1} of AZD1080 showed a 38% and 48% maximum inhibitory effect of tau phosphorylation (Thr-231) in hippocampus at 6 h. AZD1080 could achieve a 0.5–0.8 brain-to-plasma ratio at C_{max} in rats. Although AZD1080 possessed two HBDs; its other physicochemical properties were within the range for a good brain penetrant (e.g., MW = 334). The morpholine moiety of AZD1080 could help improve drug solubility and brain penetration. Tertiary amines are one of the common structural elements that can be found in numerous CNS pharmaceuticals. Unfortunately, further development of AZD1080 was halted due to nephrotoxicity observed in a phase I clinical trial.[107]

Another different chemotype targeting GSK3 reported by AstraZeneca was aminopyrazine.[110] The same in vitro bovine endothelial cell assay was used to evaluate the compound's brain penetration ability. Given the presence of an amino group on a pyrazine core and an amide functionality (both can act as HBDs), poor permeability was expected. However, good measured permeability in both Caco-2 and bovine endothelial cell assays was observed. These data suggest that the masking of the HBDs through intramolecular interaction could be beneficial for both oral absorption and brain penetration. Although compounds in this pyrazine series were identified with good in vitro permeability, in vivo confirmation of their brain-to-plasma ratio was not reported.

Recently, researchers at Bristol-Meyers Squibb reported a bis-amide series of GSK3 inhibitors.[111] In their case, a vinblastine-resistance carcinoma (KBV) cell line with overexpression of human tau protein was used in compounds profiling for target activity

and permeability. Using the same cell line in assays with or without a P-gp inhibitor (tariquidar), the compound's permeability was evaluated and used as guidance for predicting brain penetration efficacy. Compounds with efflux ratio >2 were believed to have a low chance for good brain penetration. An amide is reported as one of the structural moieties that favors P-gp efflux because amide compounds tend to have more HBDs and a high polar surface area. It was interesting that most of the compounds reported in the bis-amide series had a high passive permeability and efflux ratios <2, despite the presence of two amide functionalities in the scaffold. Several lead compounds, such as compounds 18 and 33, were tested in vivo in a transgenic mouse AD model with elevated pTau levels. At oral doses of 10 and 30 mg kg^{-1}, both compounds showed dose-response activity and brain-to-plasma ratios of 0.2–0.3 and ≥ 0.5, respectively. The liability associated with those compounds was high PK variability probably due to their high clearance and the metabolic instability in mouse plasma. However, the same instability was not observed in human plasma.

A benzofuran scaffold GSK3 inhibitor, MMBO, was published by researchers at Takeda focusing on AD.[112,113] MMBO was classified as a brain-penetrant potent GSK3 inhibitor superior to lithium. An oral dose of 3 mg kg^{-1} of MMBO in C57BL/6N mice showed a brain-to-plasma ratio (AUC) = 1.6. In addition, MMBO showed a dose-dependent in vivo efficacy and the measured Tau phosphorylation (pT205-tau) in the hippocampus of mice was decreased maximally after 30 min of dose administration, which corresponded to T_{max}. The physicochemical properties of low molecular weight (338), tPSA (60 $Å^2$), and without HBDs were all in favor of MMBO being a good brain penetrant.

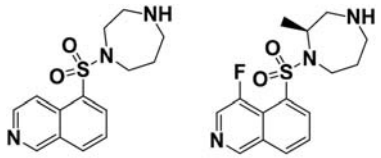
For a successful CNS drug development program, it is key to quantify compound's brain exposure for a PK/PD/efficacy correlation. A commonly used technique to quantify tissues drug exposure is the use of radiotracers in positron emission tomography (PET). Some GSK3 inhibitor PET tracers had been reported and they had demonstrated limited BBB penetration. Their unfavorable physicochemical properties for brain penetration such as their high PSA and/or the presence of an excess number of HBDs might be the culprit for the observation. Recently, Aigbirhio et al. reported a successful case study using [^{11}C]SB-216763 as a brain-penetrant GSK-3 inhibitor radiotracer.[114] The arylindole maleimide SB216763 is a potent GSK-3 inhibitor with $K_i = 9$ nM and $IC_{50} = 34$ nM. PET imaging study in a nonhuman primate showed SB216763 to have significant brain uptake and the highest exposure is in thalamus, striatum, cortex, and cerebellum areas in the brain. Uniform distribution of the radiotracer within the brain revealed by PET imaging also suggests the ubiquitous distribution of GSK3 in brain tissue.

Tideglusib (NT-12) is the most advanced GSK3 inhibitor ever reported in a phase II clinical trial.[115,116] Evidence has indicated that tideglusib is an irreversible non-ATP-competitive GSK3 inhibitor. Preclinical models have confirmed that tideglusib could decrease tau phosphorylation and lower brain amyloid plaque. Although no PK data have been released on tideglusib to understand its brain penetrative ability, the small MW and high lipophilicity may predict a favorable brain exposure. Recent data release from the ARGO phase II study showed that tideglusib had an acceptable safety profile but unfortunately, no clinical benefit was observed in this trial for AD.

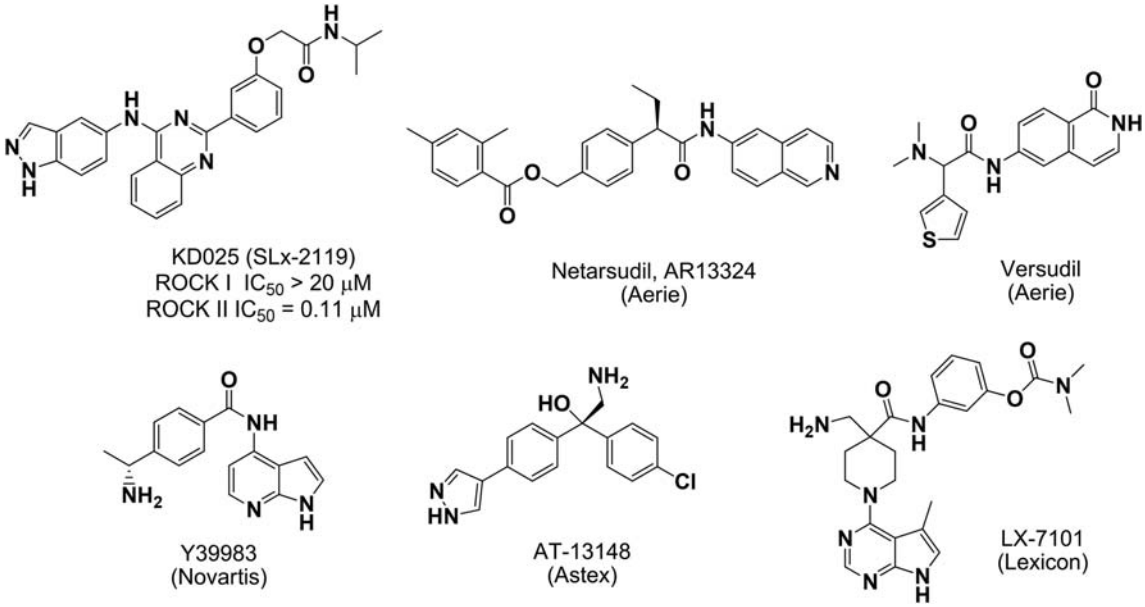
Over the past years, many GSK3 inhibitors with different scaffolds and inhibition modes have been developed. However, candidates successfully moved into clinical trials were scarce. The negative results in the recent clinical trial observed in tideglusib suggested that there are challenges ahead to validate anti-GSK3 as an intervention point for treating neurodegenerative disorders such as AD.

7.10.5.10 Rho-Associated Protein Kinase

Rho-associated protein kinases (ROCKs) are the downstream effectors of the small GTPase RhoA.[117] A recent review by Feng gave a comprehensive summary for a large number of ROCK inhibitors developed in the past decades.[118] Two isoforms, ROCK I and II, were identified as ~160 kDa serine/threonine kinases. The expressions of both ROCKs are considered ubiquitous, but a higher expression of ROCK II was found in the brain compared to ROCK I. ROCK's kinase activity is auto-inhibited by its carboxy terminal. Interaction with GTPase RhoA activates ROCKs by binding to the Rho-binding domain located in the coiled-coil region of ROCK proteins and conformational changes release the auto-inhibitory carboxy terminal from the kinase domain. A number of downstream effectors of ROCKs have been identified and their biological functions on smooth muscle cell contraction, cell proliferation, adhesion, and migration have been delineated. Because of the important functions of ROCKs in the regulation of the cytoskeleton of cells, ROCK inhibitors have been proposed for the treatment of cardiovascular, respiratory, and renal diseases including hypertension, asthma, chronic obstructive pulmonary disease (COPD), inflammatory bowel disease, glaucoma, age-related macular degeneration, optical nerve and spinal cord injuries, stroke, and AD. In 1995, Japan approved the first ROCK inhibitor Fasudil (Eril®) for the treatment of cerebral vasospasm, followed by China in 2010 for the same indication.[119] Fasudil was notably the first small molecule kinase inhibitor approved for clinical use 40 years later after the discovery of protein kinases in 1954. In 2014, another structurally similar ROCK inhibitor, ripasudil, reached the market place for very different indications. Ripasudil (Glanatec®) was approved, also in Japan, as a twice daily dosing eye drop for glaucoma and ocular hypertension treatment. Research in developing ROCK inhibitors has been intensified in the past decade and numerous ROCK inhibitors have been reported either in preclinical or in different phases of clinical trials.[120] The most advanced AR13324 is in phase III for the same indications as for ripasudil. Some examples of other ROCK inhibitors currently in clinical trials are KD-025, Y39983, AT13148, LX-7101, and a few others. Although ROCK inhibitors have successfully been proven for some clinical use, continuous systemic inhibition of ROCKs may be problematic. Major safety concerns related to systemic ROCK inhibition include the induction of significant hypotension and a reversible reduction in lymphocyte counts. ROCK I, but not ROCK II, is believed to be related to the observed toxicity. Almost all reported inhibitors are pan-ROCK inhibitors, with the exception of KD-025 which shows higher inhibitory activity for ROCK II.



The biological functions of ROCKs related to the CNS have been explored in the last decade.[121,122] The RhoA/ROCK signaling axis regulates myelin-associated axon growth inhibitors, including Nogo, myelin-associated glycoprotein, oligodendrocyte-myelin glycoprotein, and repulsive guidance molecule. Following nerve injuries or developing neurological disorders, ROCKs are activated and neurite growth is inhibited. Inhibiting ROCK's signaling may abolish the effects of the axon growth inhibitors and promote axonal growth for recovery. On this basis, ROCK inhibitors may be therapeutically important for the treatment of some neurodegenerative disorders and brain/spinal cord injuries.



Although therapeutic effects have been demonstrated in animal models for targeting ROCK inhibition in numerous CNS diseases, successful use of ROCK inhibitors in clinical trials for CNS-related neurodegenerative diseases has yet to be reported. One probable reason may be the toxicity related to ROCK I inhibition and the fact that designing a ROCK II isoform-selective inhibitor is extremely challenging. Currently, SLx-2119 (KD-025) is the most advanced ROCK II isoform-selective inhibitor designed by researchers at Surface-Logix Inc. in order to reduce the ROCK I-related toxicity (e.g., hypotension). KD-025 is about 200-fold more potent against ROCK II ($IC_{50} = 105$ nmol L^{-1}) compared to ROCK I ($IC_{50} = 24$ μmol L^{-1}). Since the physicochemical properties and in vivo data of those ROCK inhibitors were not detailed in any publications, their CNS penetration could not be evaluated. The marketed drug Fasudil has been reported to have therapeutic effects against several CNS disorders in clinical and animal models. However, Fasudil was found to have low brain penetration and special strategies, such as liposome preparation, myelin injection, or prodrug, to enhance CNS penetration have been exploited for CNS targeting. The aforementioned ROCK II-selective inhibitor KD-025 was recently studied in focal cerebral ischemia in mice.[123,124] At a dose of 100 mg kg^{-1}, total KD-025 concentration (AUCs) in plasma and brain tissue are 51.93 and 2.37 (h μg mL^{-1}), respectively. Although the peak level of KD-025 in plasma and brain tissue is more than 10-fold of the ROCK II IC_{50}, inhibitors with a significantly higher free plasma-to-brain ratio are more desirable. Until the CNS penetration and selectivity issues can be properly addressed with newer ROCK II-selective inhibitors,[9] intervening in the ROCK signaling pathway in the clinical setting for the treatment of medically unmet CNS-related disorders such as AD and PD will remain challenging.

7.10.5.11 p38 Mitogen-Activated Protein Kinase

Cellular signaling through one of the three major MAPK (ERKs, JNKs, p38s), the cytoplasmic p38 MAPK, is activated in response to stress stimuli and proinflammatory cytokines (e.g., interleukins and TNFα). The importance of p38 MAPK as a therapeutic target in inflammatory diseases and cancer has been recognized since 1994 soon after it was first isolated and characterized as a 38 kDa protein, which regulates proinflammatory cytokine syntheses. The rationale of using p38 MAPK inhibitors as therapeutics has been the focus of

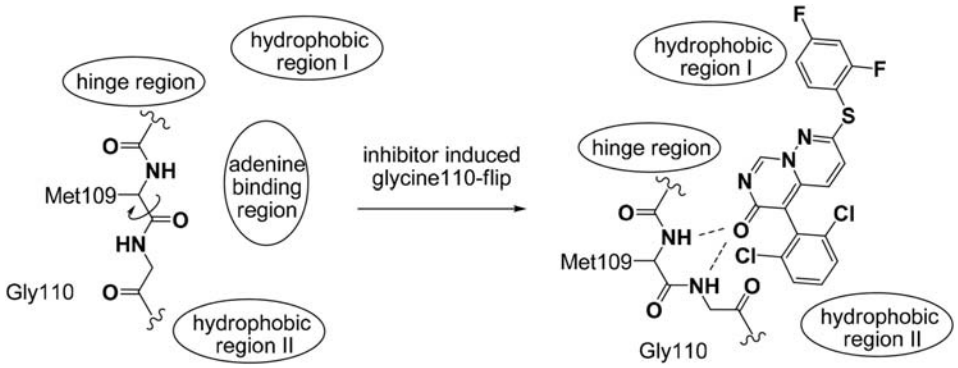


Fig. 5 Gly110 flip induced by inhibitor binding to the ATP-binding pocket. Reproduced from Fischer, S.; Koeberle, S. C.; Laufer, S. A. p38a Mitogen-Activated Protein Kinase Inhibitors, a Patent Review (2005–2011). *Expert Opin. Ther. Pat.* **2011**, *21* (12), 1843–1866.

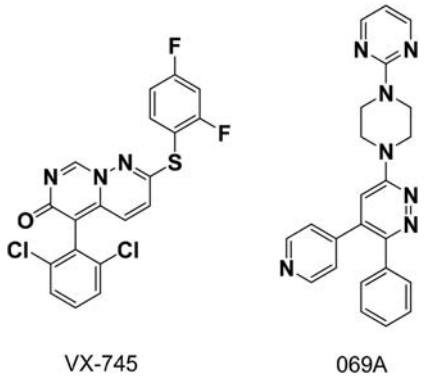
several excellent reviews.[125–130] The original development of p38 inhibitors was motivated by an interest in targeting peripheral inflammatory diseases such as RA, cancer, and COPD.[131,132] However, the efficacy of p38 MAPK inhibition is compromised by the observation that a feedback loop mechanism, which led to the activation of other proinflammatory pathways, such as JNK. In addition, studies have shown that p38 MAPK may act as a tumor suppressor in some cell types and its inhibition may cause tumorigenesis. Recent understanding of several CNS disease pathologies suggested that the activation of p38 MAPK was responsible for disease progression. Proinflammatory cytokines produced *via* p38α MAPK activation are implicated in CNS ailments such as Alzheimer disease (AD), PD, multiple sclerosis (MS), neuropathic pain, neuronal injury, and depression.[133–139] In Alzheimer's disease, for example, hyperphosphorylation of the Tau protein by p38α MAPK is thought to cause Tau protein aggregation (formation of NFTs), which leads to microtubule destabilization within brain cells. Recently, the p38α MAPK signaling pathway was suggested to be important for effecting CNS axons myelination and remyelination in diseases such as MS and periventricular leukomalacia.[140]

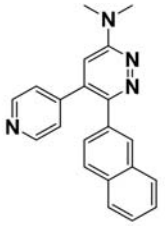
The p38 MAPK has four isoforms (α, δ, γ, δ). Based on sequence homology, the four isoforms can be separated into two groups, group I (α and β) and group II (γ and δ). The most studied isoform p38α is mainly responsible for the biosynthesis of proinflammatory cytokines. Over the past 20 years, extensive efforts by major pharmaceutical companies and smaller outfits have produced numerous p38α MAPK inhibitors for preclinical and clinical testing. For a clinically useful p38α inhibitor, besides selectivity among other off-targets, the main hurdle was to achieve selectivity over other p38 isoforms. Up-to-date, small molecule p38α MAPK inhibitors involved interaction with the ATP-binding pocket and selectivity was achieved with a design using three key strategies. The first and the most selective strategy involved the use of the so-called glycine flip with Gly110 at the hinge (Fig. 5). When a suitable hydrogen bond acceptor (e.g., a carbonyl) of the inhibitor was directed toward Gly110 within the hinge motif, the glycine's amide bond (HBD) rotated to engage a hydrogen bond with the carbonyl of the inhibitor. Such a bond flip along the hinge region is only possible for a small amino acid such as glycine; hence, it imposed a high selectivity of the inhibitor among other kinases. The second approach for a selective inhibitor design made use of a Aspartic acid-Phenylalanine-Glycine (DFG)-pocket in an inactive state of the enzyme. When an enzyme was in its inactive state (DFG-out), the DFG motif rotates outward into the ATP-binding pocket. An inhibitor designed with an extended moiety could occupy the space vacated by the DFG motif. The third strategy involved the use of p38's gatekeeper residue, Thr160. The small amino acid Thr160 in p38 allowed the designs of inhibitors with substituents large enough to reach the hydrophobic region I. Kinases with larger gatekeeper residues would not accommodate such inhibitors. Summarized in the following sections are different chemotypes which use the three aforementioned methods for the design of selective p38α MAPK inhibitors. The availability of p38 X-ray crystallographic structural data also facilitated the design of novel inhibitors. Drug discovery efforts targeting p38α MAPK were mainly focused on targeting peripheral diseases such as RA. Unfortunately, a p38α MAPK inhibitor has not achieved regulatory agency approval for such a disease indication. Toxicity appears to be the main reason for their clinical failure.



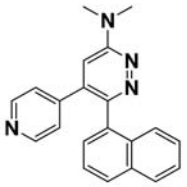
VX-745 069A

Due to earlier p38α MAPK inhibitors, which showed signs of CNS toxicity in a preclinical animal study, nonbrain-penetrant p38α MAPK inhibitors have been the focus in the past decades and less effort was dedicated to CNS. CNS toxicity was reported in a dog study for VX-745, and the development of the compound was discontinued in the early 2000s. Interestingly, VX-745 reemerged recently as an effective tool to target AD. EIP Pharma reported a preclinical study using VX-745 as an antagonist to modulate the effects of microglia-mediated inflammatory responses related to p38α MAPK activation.[141] The total drug concentration of VX-745 brain-to-plasma ratio is about 1.7 in rats after a single oral dose. The same brain-to-plasma ratio was also observed in dogs after 2 weeks of dosing with VX-745. In the same dog study, a $K_{p,uu,csf}=2$ was achieved. The low molecular weight (MW = 436), polar surface area (tPSA = 45), and the absence of HBDs all favor VX-745 as a brain penetrant.

In 2007, Munoz et al. reported a brain-penetrant p38α MAPK inhibitor 069A with a pyridazine scaffold.[133] Experimental values of lipophilicity and aqueous solubility were used to predict brain penetration of newly designed compounds. The experimentally determined c log *P* and solubility for 069A were 3.18 and 9.54 μg mL^{-1}, respectively. The solubility value of 9.54 μg mL^{-1} translated to a log *S* = −2.02 and a c log *P* = 3.18 are both within the preferred range for good brain penetration. In addition, compound 069A has MW = 395, tPSA = 68, and with no HBDs. All of these physicochemical properties of 069A support its being a good brain penetrant. In an in vivo efficacy study using an AD-relevant mouse model, compound 069A was able to suppress excess proinflammatory cytokine upregulation (IL-1, TNFα, and S100B) and improved neurological outcome was observed. Comparable total exposure of 069A to both plasma and the brain tissue was observed after an oral dose of 2.5 mg kg^{-1} to C57Bl/6 mice.

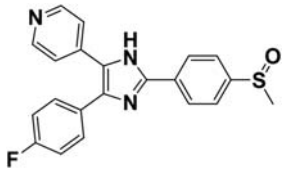


MW-108
p38α MAPK Ki = 114 nM
Kp (brain/blood) = 0.9



MW-181
p38α MAPK Ki = 114 nM
Kp (brain/blood) = 0.7

A similar brain-penetrant pyridazine-based chemical probe p38α inhibitor MW-108 was reported by Watterson et al. in a study of synaptic dysfunction in neurodegenerative diseases.[142] MW-108 is a selective p38α small molecule inhibitor with favorable CNS drug-like physicochemical properties (MW = 326; cPSA = 41.9; c log *P* = 3.4). In a PK study, a brain-to-blood ratio of 0.9 was achieved at C_{max} after an oral dose. A similar analog MW-181 (MW = 326; cPSA = 41.9; c log *P* = 3.4) with an isomeric naphthalene substitution also showed good penetration (brain-to-blood ratio = 0.7). In an in vivo animal model relevant to AD, attenuation of $A\beta_{42}$-induced synaptic and cognitive dysfunction by MW-108 administration was observed.



SB203580

A trisubstituted imidazole SB203580 has been the most investigated tool compound in preclinical CNS disease models.[134] However, the imidazole core was believed to be the culprit for severe hepatotoxicity and different scaffolds were used in later inhibitor designs. Drug delivery to the CNS was also limited for the trisubstituted imidazole series and resorted to unconventional dosing routes. I.c.v./intrathecal/osmotic infusions into cisterna magna were reported to have been used in those studies.

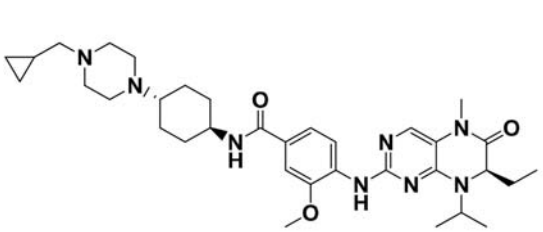
Very few p38α MAPK inhibitors have ever been advanced into clinical trials to target CNS diseases.[143] A few compounds related to pain treatment and major depressive disorders were tested in phase II/III clinical trials but subsequent development was discontinued. The development of p38α MAPK inhibitors for the treatment of RA has been slowed by the lack of clinical efficacy and toxicity associated with the drug candidates. Another disease focus for p38α MAPK inhibitors is for COPD. With more specific tissue delivery of the inhibitors, systemic toxicity observed with early generation compounds could be minimized. Targeting CNS diseases with p38α MAPK inhibitors is still in its infancy, and more understanding of the underlying biology associated with those CNS diseases related to the p38α signaling pathway is needed. Developing more brain-penetrant p38α MAPK inhibitors in the future will no doubt be very helpful but challenging.

7.10.5.12 Polo-Like Kinase 2

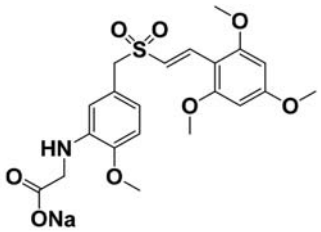
The Polo-like kinases (PLKs) family consists of five members (PLK1–5).[144] They belong to the serine/threonine protein kinase family primarily expressed in dividing cells and are essential in cell cycle control and in the regulation of mitosis. Unlike

PLK1–4, PLK5 is different in that it lacks a functional kinase domain and is not involved in cell cycle control.[145] All PLKs possess binding motifs called "polo-boxes," which interact specifically with their corresponding substrates.

The most studied member, PLK1, was a key kinase in directing mitotic entry, centrosome maturation and separation, formation of the bipolar spindle, transition from metaphase to anaphase, and the initiation of cytokinesis. Not only being overexpressed in a number of human tumor tissues, PLK1 is also activated in response to DNA damage and replication stress.[146–151] Since the biological function of PLK1 is key to cell division, the inhibition of PLK1 signaling is expected to have an antimitotic effect on rapidly dividing tumor cells. In addition, embryonic lethality was observed in PLK1 knockout mouse.

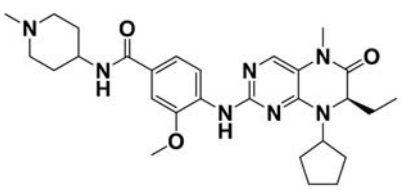


Volasertib (BI-6727)

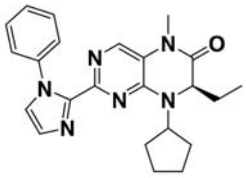


Rigosertib (ON-01910)

Several PLK inhibitors have entered clinical trials and two of them have recently reached phase III clinical trials for hematological malignancies, including Acute Lymphoblastic Leukemia (ALL), acute myeloid leukemia (AML), Chronic Lymphocytic Leukemia (CLL), Chronic Myeloid Leukemia (CML), and myelodysplastic syndrome (MDS).[152–154] Volasertib, in combination with cytarabine, is being evaluated in older patients with AML who are ineligible for intensive induction therapy. Rigosertib, a dual PLK/PI3K inhibitor, is being investigated in patients with MDS. Clinical observations however showed PLK1 inhibitors inevitably causing undesirable myelosuppressive toxicities. In this regard, more isoform-selective PLK inhibitors were needed as useful therapeutic agents. More importantly, different members in the PLK family have been suggested to have opposite functions. For example, the function of PLK1 is inhibited as a consequence of DNA damage-induced ATM signaling while PLK3 is activated by the same signal.



BI-2536



compound 9

Besides oncology, PLKs have been implicated in certain neurodegenerative diseases. One member of the PLKs family, Polo-like kinase 2 (PLK2), is of special interest for targeting CNS diseases.[155] PLK2 is believed to play an important role in the neurological disorder, PD. Phosphorylation of α-synuclein at Ser-129 represents one of the key proteins in the pathology of PD, and PLK2 has been implicated as a major contributor to the formation of phosphor-S129 α-synuclein. α-Synuclein is a major component in Lewy bodies, which was found in intracytoplasmic dopaminergic neurons. Lewy bodies are considered the prime histological marker for PD. The design of isoform-selective PLK2 inhibitors is essential for targeting CNS diseases to avoid the potential toxicity associated with PLK1 inhibition in dividing cells. Because of the high homology of PLK isoforms, developing an isoform-selective PLK2 inhibitor for the treatment of PD is very challenging. Researchers at Boehringer Ingelheim first reported a selective PLK inhibitor, BI-2536, which showed > 10,000 fold selectivity against a panel of other kinases. Unfortunately, PLK1/PLK2 selectivity was not achieved with BI-2536 (PLK2/PLK1 selectivity = 0.10). Scientists at Elan Pharmaceutical later analyzed the crystal structure of BI-2536 bound to PLK2, which revealed that selectivity could be achieved by exploiting the PLK2-specific gatekeeper + 2 Tyr-161 residue in the kinase ATP-binding pocket (**Fig. 6**).[156–157] Different heterocyclic rings at C2 of the pteridinone core achieved optimization of PLK2 selectivity over other PLK isoforms. Crystal structure analysis showed an edge-to-face interaction between the C2-heteroaryls and Tyr-161, which improved both the compound's PLK2 activity and their selectivity against PLK1 and PLK3. Based on the crystal information, two similar chemical series, a pteridinone and a tricyclic pteridinone, were reported as PLK2 isoform-selective inhibitors.

In the first report, design criteria favoring metabolic stability and CNS penetration were included. Design criteria included are: (1) incorporation of fluorine atoms, (2) lowering the compounds' c log *P* to improve metabolic stability, (3) selecting compounds with high permeability and low P-gp efflux for favorable CNS penetration. Ultimately, optimization resulted in compound 10 (PLK2/PLK1 selectivity = 193) as a brain-penetrant PLK2-selective inhibitor, which showed in vivo activity. In a rat model, compound 37 was able to reduce phospho-S129 α-synuclein by 41–45% at 6 h after a single oral dose of 100 and 200 mg kg^{-1}. The brain-to-plasma level at 6 h was determined to be 0.36 and 0.28 at 100 mg kg^{-1} and 200 mg kg^{-1}, respectively. The total drug

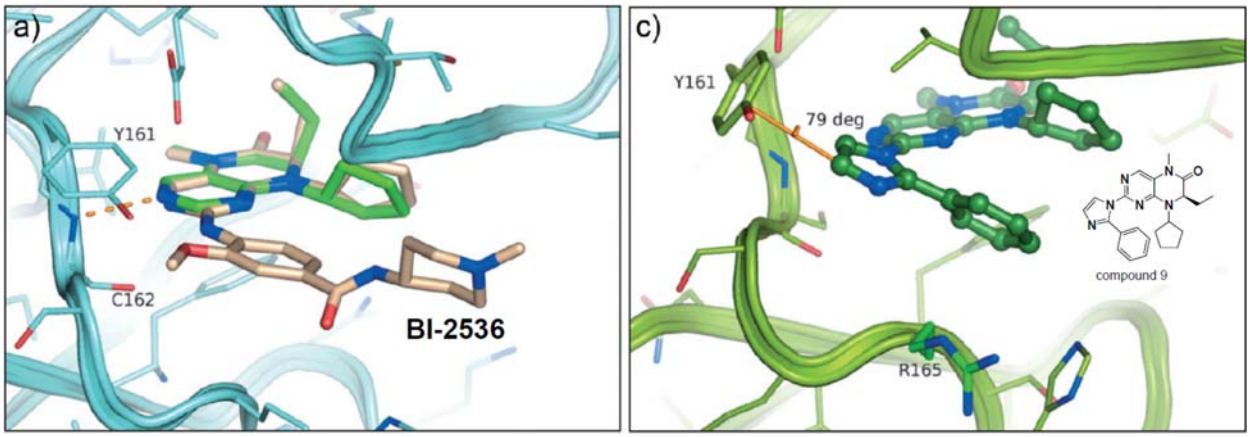


Fig. 6 Binding of BI-2536 and Compound 9 to PLK2. Reproduced from Aubele, D. L.; Hom, R. K.; Adler, M.; Galemmo, R. A., Jr.; Bowers, S.; Truong, A. P.; Pan, H.; Beroza, P.; Neitz, R. J.; Yao, N.; Lin, M.; Tonn, G.; Zhang, H.; Bova, M. P.; Ren, Z.; Tam, D.; Ruslim, L.; Baker, J.; Diep, L; Fitzgerald, K.; Hoffman, J.; Motter, R.; Fauss, D.; Tanaka, P.; Dappen, M.; Jagodzinski, J.; Chan, W.; Konradi, A. W.; Latimer, L.; Zhu, Y. L.; Sham, H. L.; Anderson, J. P.; Bergeron, M.; Artis, D. R. Selective and Brain-Permeable Polo-Like Kinase-2 (Plk-2) Inhibitors That Reduce a-Synuclein Phosphorylation in Rat Brain. *ChemMedChem* **2013**, *8* (8), 1295–1313. (a) Plk-2 protein is shown with cyan carbon atoms, the structure of BI2536 in pink, (c) Compound 9: PDB code 4I6F, 2.9 Å resolution, showing the corresponding edge-to-face angle.

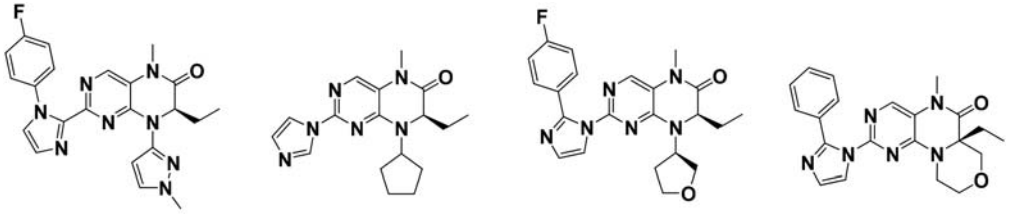
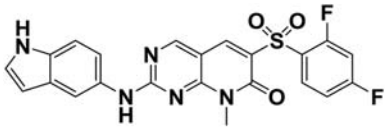
exposure at these two dosing levels was well above the PLK2 cellular IC_{50} value. Unfortunately, the free drug concentration and $K_{p,uu}$ were not available.



Another PLK2-selective inhibitor based on a tricyclic pteridinone was detailed in a second publication by the same group at Elan.[157] After optimization, three short-listed compounds (11, 12, and 13) were evaluated in vivo for brain exposure in mouse (i.v.) and PK in rat (i.v./p.o.). Compounds 11, 12, and 13 showed total brain/plasma AUC ratios of 1.7, 0.03, and 0.3, respectively. Taking into account of other DMPK parameters, the tricyclic pteridinone, compound 13, was identified with high PLK2 potency ($IC_{50} = 39$ nM) together with a PLK2/PLK1 selectivity ratio = 700. A subsequent target engagement (phospho-S129 α-synuclein) study with a single oral dose of compound 13 in rats at 100 or 200 mg kg^{-1} resulted in 34.5% and 41.4% decrease of phospho-S129 α-synucleins level, respectively, in the cerebral cortex. Although the free drug concentrations of the compound were not reported, the total concentration of compound 13 in the rat brain at 6 h was fivefold (@100 mg kg^{-1}) and sevenfold (@200 mg kg^{-1}) higher than the PLK2 IC_{50} value. With the properties of a non-P-gp substrate with good permeability and oral bioavailability, compounds 10 and 13 have become useful tools to aid the understanding of the role of PLK2/α-synuclein system in the pathology of PD.



ON1231320
PLK2 selective
(Onconova)

Recently, another PLK2-selective chemotype, pyrido[2,3-d]pyrimidine, was reported by researchers at Onconova Therapeutics.[158] Phenotypic screening of a library of compounds using cell death as a readout identified ON1231320 as a PLK2-specific small molecule inhibitor. The identified isoform-selective PLK2 inhibitor ON1231320 caused apoptotic cell death in cultured tumor cell lines and showed significant tumor growth inhibition in a triple-negative breast tumor xenograft model (MDA-MB-231). Since the inhibitors reported by the authors are primarily targeting peripheral human tumors, CNS exposure information for this class of PLK2-selective inhibitors is not available.

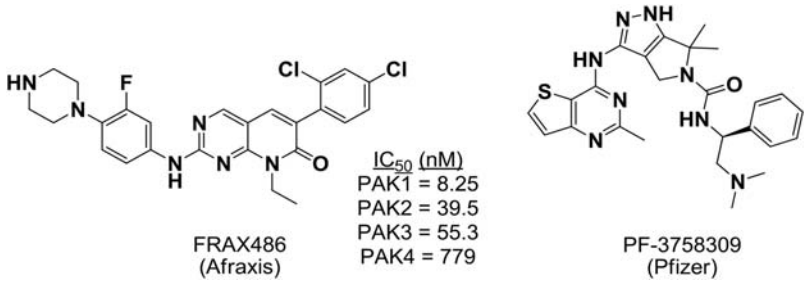
In addition to PLK1 and PLK2, the structurally distinct isoform PLK4 (with only one polo-box instead of two) was also found to be overexpressed in triple-negative breast cancer with basal-like subtype and upregulation of PLK4 causes centriole overduplication.[159,160] Several potent and selective PLK4 inhibitors have been reported and tumor growth inhibition was observed in a preclinical mouse xenograft model with a triple-negative breast cancer cell line (MDA-MB-468). The rest of the PLKs—PLK3 and PLK5—are considered to be tumor suppressors and they regulate cellular responses to DNA damage and cellular stress. No selective PLK3 and PLK5 inhibitors have been reported. In the past few years, most PLK inhibitors were developed for oncology focusing on peripheral diseases and their brain penetration levels were not reported. However, it would be beneficial to patients if some of the developed PLK inhibitors could penetrate the CNS in order to treat metastatic tumors therein.

7.10.5.13 p21-Activated Kinase

p21-activated kinases (PAKs), a family of serine/threonine kinases, were identified as effectors of small GTPase-activating proteins such as Ras-related C3 botulinum toxin substrate 1 (Rac1) and cell division control protein 42 (Cdc42) in 1994.[161] The PAKs are classified into two subgroups (group I: PAK1–3; group II: PAK4–6) based on protein sequence and structural homology.[162] Expression of PAK in different tissues was characterized in rodents and it was found that PAKs are expressed at significant levels in the brain. Activation of PAK occurs *via* the binding of Rac1 or Cdc42 to their N-terminal regulatory domain (the CRIB motif). Research has suggested that PAK plays important roles in both neurodegenerative diseases and cancers. Historically, group I PAK1–3 have been the main focus of the research community and much of the understanding of PAK biology was from PAK1–3. Because of the important roles of group 2 PAK4–6 in many fundamental cellular processes, recent research focus on PAK4–6 is on oncology indications.[163–165]

In neurodegenerative diseases such as Alzheimer disease (AD), dysregulation of PAK1 and PAK3 is associated with the buildup of amyloid (Aβ) extracellular plaques and intraneuronal NFTs. Huntingtin protein aggregation is enhanced by PAK1 activity in HD. Abnormal activation of PAK1 is also related to a family of genetic diseases called neurofibromatosis caused by dysfunctional NF1/NF2 genes.[166] PAK3 gene mutations found in fetal and adult brain tissues are believed to be responsible for X-linked mental retardation. FXS, a form of mental illness, was recently found to be related to the activation of the RAC/PAK signaling.[167] In some human tumor cells, PAKs are overexpressed and amplified, which transduce signal *via* Ras, Raf, NFκB, Akt, Bad, and p53 to effect cell proliferation, survival, anti-apoptosis, and invasion. As the biological roles of PAKs become clearer in relation to the aforementioned diseases, therapeutic intervention with selective PAK inhibitors might be a useful strategy.[168]

Paradoxically, some PAK activities were recently found to have a positive impact in some disease settings where compounds with agonistic rather than inhibitory activity might be desirable. A recent study suggested that the inhibition of the RAC/PAK axis induced autism-like deficits in normal mice,[169] and in another study, PAK1/2 kinase activity was shown to be essential for neurite growth.[170] The cardiac protective function of PAK1 was also recently highlighted in an animal study.[171] PAK1 may function in preventing arrhythmogenesis associated with ischemia/reperfusion injury.



Recently, Rudolph et al. published a perspective review on the current status of PAK inhibitors.[162] Most reported structural types are ATP-competitive binders and only a few allosteric PAK inhibitors have been identified so far. The only PAK inhibitor with reported CNS penetration information is FRAX486, which was developed by Afraxis to study FXS in *Fmr1* KO mice.[167] FRAX486 is a pyrido[2,3-d]pyrimidine-7-one derivative with selectivity against group I PAK1–3. The subcutaneous injection of a dose of 20 mg kg^{-1} FRAX486 to mice achieved PAK1,2,3 coverage in the brain of about 36, 7.6, and 5.4 folds, respectively, based on the total drug concentration. In addition, FRAX486 can achieve total drug concentration in the brain tissue that is higher than in plasma (**Fig. 7**). However, the free fractions of the compound in the brain tissue and in plasma were not reported in this study to reveal the $K_{p,uu}$ value. Nevertheless, an injection of FRAX486 was able to reverse the phenotypes in the *Fmr1* KO mice model for FXS in a dose-dependent manner.

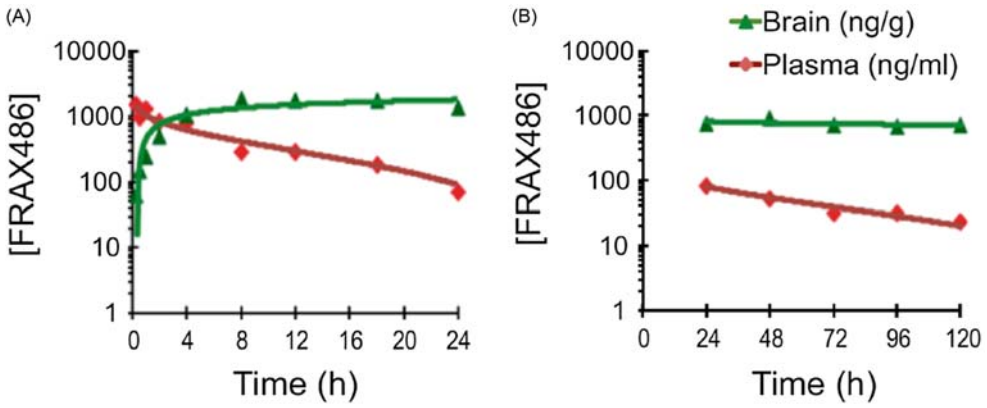


Fig. 7 Pharmacokinetics of FRAX486. (A) A single s.c. injection; (B) daily administration of 20 mg kg^{-1}. Adapted from Dolan, B. M.; Duron, S. G.; Campbell, D. A.; Vollrath, B.; Shankaranarayana Rao, B. S.; Ko, H. Y.; Lin, G. G.; Govindarajan, A.; Choi, S. Y.; Tonegawa, S. Rescue of Fragile X Syndrome Phenotypes in Fmr1 KO Mice by the Small-Molecule PAK Inhibitor FRAX486. *Proc. Natl. Acad. Sci. USA* **2013**, *110*(14), 5671–5676.

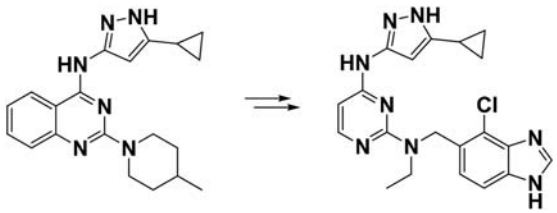
Although the importance of PAKs in CNS diseases as mentioned earlier has been proposed, the majority of the PAK inhibitors reported are antitumor agents, including both group 1 and 2 PAKs. For example, researchers at Pfizer focused on designing potent PAK4 inhibitors with a pyrroloaminopyrazole scaffold targeting colon, ovarian, and pancreatic tumors.[172,173] PF-3758309 (PAK4 $K_d = 2.7$ nM) was advanced into phase I clinical trials for solid tumors but was eventually discontinued due to poor human PKs. Optimization to increase permeability and reduce the efflux ratio due to P-gp-mediated efflux were the focus of the design of the next-generation compounds; however, no brain penetration data of the newly designed compounds were reported.



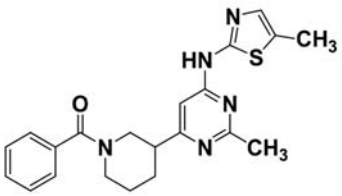
14
PAK1 Ki = 100 nM
PAK4 Ki = 49 nM

15
PAK1 Ki = 5 nM
PAK4 Ki = 547 nM

The Genentech group focused on developing selective PAK1 inhibitors for the luminal B subtype of breast cancer, which is known to have focal amplification of PAK1. Structure Activity Relationship (SAR) development was described in detail for improving PAK1 selectivity over Group 2 PAKs.[174,175] Starting with PAK4-selective lead compound 14, replacing the quinazoline core in 14 with a pyrimidine scaffold and changing the piperidine to a substituted benzimidazole, the researchers were able to identify compounds which are PAK1-selective inhibitors as demonstrated in compound 15. Most compounds reported therein have an efflux liability, which may impede their brain penetration ability. Interestingly, the highlighted compound 15 is not a P-gp substrate (MDCK P_{app} AB:BA = 7.4/11.1). Further optimization of this series is needed to minimize off-target activity against Aurora A. Although many kinase inhibitors are primarily developed against peripheral tumors as shown in this section and other sections, brain metastasis is one of the reasons for treatment resistance in certain types of cancers such as in lung and breast carcinomas. Developing a kinase inhibitor that has sufficient brain penetration will undoubtedly be beneficial for patients who have developed brain metastasis.

7.10.5.14 Dual Leucine Zipper Kinase

Dual leucine zipper kinase (DLK, MAP3K12), one of the upstream regulators of JNK, has recently been proposed as an alternative target for treating neurodegenerative diseases, such as Alzheimer's and Parkinson's.[176] The expression of DLK is neuronal-specific and animal models have demonstrated that DLK plays an important regulatory role in neuronal degeneration. Genentech researchers conducted a high-throughput screening using an enzymatic inhibition assay of DLK kinase domain catalytic activity followed by a measurement of p-JNK levels in a DLK overexpressed cell-based assay for lead identification.[1] Based on the physicochemical properties required for brain penetration, compound 16 was selected for optimization.



16
DLK IC_{50} = 0.035 μM
p-JNK IC_{50} = 0.641 μM
MDR1 BA/AB = 2.2; AB = 4.3 X10^6 cm s^{-1}

ClogP and ClogD = 3.9
LipE = 3.6
tPSA = 71
cpKa = 6.8
HBD = 1
MW = 398
CNS MPO score = 4.2

Lead optimization was focused around replacing the potential toxicophore aminothiazole and reducing metabolic liability. Including design parameters, such as maintaining PSA < 80 Å^2, avoiding HBD, and adjusting basicity, can lead to favorable brain penetrants. The aminothiazole moiety was successfully replaced by 2-amino-4-cyanopyridine with a slight loss in potency. Modification of the central pyrimidine core to pyridine reduced tPSA by more than 10 units. Further optimization on compound 17 by replacing the benzamide moiety with an oxetane gave a potent DLK inhibitor compound 18 (GNE-3511) with desirable PK properties (Table 5). The oxetane was essential for reducing the basicity of the piperidine nitrogen to reduce efflux liability.

In a PTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine)-induced phosphorylation of c-Jun PD model, a dose-dependent reduction of p-c-Jun positive neurons was observed in brain tissue with compound 18. PK analysis in rodents showed that compound 18 is brain penetrant with a $K_{p,uu} = 0.7$ in rat at 6 h (Table 6). Compound 18 was the first selective DLK inhibitor reported with in vivo brain penetration activity so far. The availability of tools like compound 18 will allow for a better understanding of the DLK biology and its implication in neurodegenerative diseases.

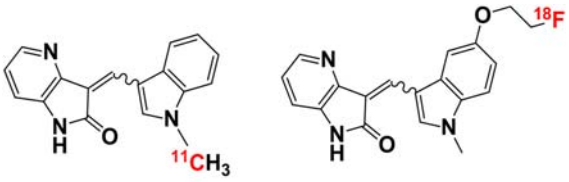
7.10.5.15 Tropomyosin Receptor Kinase

Tropomyosin receptor kinases (Trks) are believed to be possible druggable targets for both neurological diseases and cancers.[177] There exist three Trk isoforms (TrkA, TrkB, and TrkC). Each Trk isoform is activated by its own ligands. Ligands such as nerve growth factor, brain-derived neurotropic factor and neurotrophin-4/5, and neurotrophin-3 activate TrkA, TrkB, and TrkC, respectively. Several Trk isoform-selective inhibitors have been reported but no related CNS penetration data are available. The development of Trk-selective brain-penetrant PET ligands can help understanding of target distribution in brain tissue and target occupancy by inhibitors. Recently, brain-penetrant 3-indolydene 4-aza-2-oxindole-based [^{11}C] and [^{18}F] radiolabeled ligands against Trk have been reported.[178] Several design parameters related to brain penetration were considered: (1) BBB permeation and neuroreceptor imaging binding potential (ideally BP $= B_{max}/K_d > 10$), (2) molecular weight (MW) ≤ 305, (3) calculated distribution coefficient (c log $D_{7.4}$) in the range of 2.0–3.5, (4) topological polar surface area of 30–80 Å^2, and (5) HBD ≤ 1. Eventually, potent pan-Trk inhibitors [^{11}C]-19 and [^{18}F]-20 were chosen as the early generation ligands for development as Trk PET probes.



(*E*)/(*Z*)-[^{11}C]-**19**
[^{11}C]-GW441759

(*E*)/(*Z*)-[^{18}F]-**20**

PET imaging studies in rodents with compounds 19 and 20 showed high level of brain uptake but nonspecific distribution within the CNS. Obvious drawbacks with compounds 19 and 20 are the isomeric alkene functionalities in addition to the metabolic instability of the "labeled" alkyl groups. Thus, further structural optimization may be necessary to provide better tools to improve the understanding of Trk biology in the CNS.

7.10.5.16 Epidermal Growth Factor Receptor

NSCLC accounts for more than 85% of all lung cancer cases and is one of the leading causes of cancer death worldwide.[179] It is estimated that in 2014 there were 224,210 new lung cancer cases and 159,260 NSCLC related deaths in the United States alone.[180] Genetic aberrations in the tyrosine kinase domain of EGFR have been identified as one of the key drivers of NSCLC progression.[181] EGFR kinase inhibitors, such as gefitinib, erlotinib, and afatinib, deliver significant patient benefit and have been approved for the treatment of advanced NSCLC with EGFR activating mutations.[182–185]

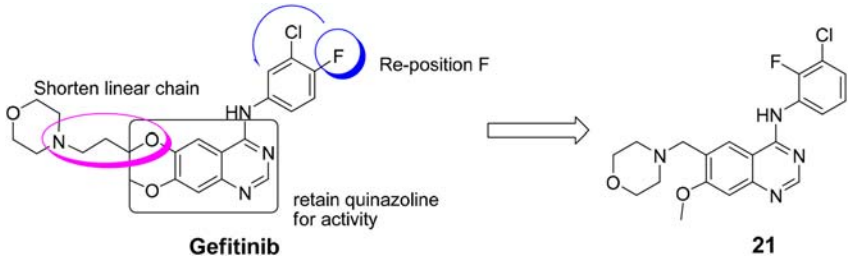
An increased incidence of CNS metastases has been reported as patients live longer with treatment and with the improvement of imaging technology and routine screening.[186,187] Studies have suggested that around 40–50% of patients with lung cancer will develop CNS metastases, including brain metastases and leptomeningeal metastases, in their life span.[188,189] Currently approved drugs can neither effectively treat lung cancer CNS metastases nor prevent the development of metastases under standard dosing regimens, due to their limited BBB penetration of the currently marketed compounds.[190,191] For patients with symptomatic brain metastases, selective use of radiation therapy and surgery are still the mainstay of treatment, but provide limited benefit.[192,193] Given the effectiveness of EGFR TKIs in treating tumors in the lung, there is a major unmet medical need for an agent which can effectively penetrate the CNS and treat tumors in brain tissue.

In order to design a brain-penetrant EGFR kinase inhibitor, scientists at the AstraZeneca Innovation Center in China re-engineered Gefitinib, a nonbrain-penetrant EGFR kinase inhibitor, by creating an intra-molecular hydrogen bonding interaction between F and adjacent NH, reducing the polar surface area and molecular weight of the molecule, and decreasing the number of rotatable bonds to give lead compound 21 (**Table 7**).[194] As a result, good CNS drug-like properties, such as a low efflux ratio (0.33) and good permeability ($P_{app,A\ to\ B} = 32 \times 10^{-6}$ cm s^{-1}), were achieved. Encouragingly, this compound exhibited inhibitory potency (IC_{50}) at 3.8 and 6.6 nM in PC-9 and H3255 cell line EGFR phosphorylation assays, which were comparable to that of gefitinib (at 6.2 and 6.5 nM, respectively). Furthermore, compound 21 demonstrated an acceptable human CYP450 inhibition profile ($IC_{50} > 10$ μM for CYP2C9, CYP2D6, and CYP3A4) and low hERG inhibition liability (hERG $IC_{50} = 17$ μM, patch clamp assay). More importantly, the preferred CNS drug-like properties of the compound translated into much improved brain and CSF penetration ($K_{puu,brain}$ and $K_{puu,CSF}$ were 0.47 and 0.76, respectively). Furthermore the compound showed reasonable exposure in both brain and blood ($AUC_{0-7\ h}$ at 2 mg kg^{-1} were 1013 and 834 nM h, respectively). The excellent in vitro potency and promising CNS penetration results were achieved while maintaining reasonable PK properties in rats (oral bioavailability 44%, elimination half-life 1.1 h, clearance 59 mL min^{-1} kg^{-1}, and volume of distribution at steady state 2.8 L kg^{-1}).

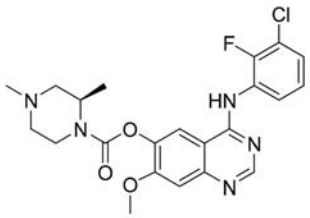
Table 7 Properties of Gefitinib and compound 21

Compound	*Gefitinib*	*21*
Molecular weight	446.7	402.9
PSA (Å^2)	62.6	53.5
Rotatable bonds[a]	10	7
Exon 19Del pEGFR IC_{50} (nM)	6.2	4.6
L858R pEGFR IC_{50} (nM)	6.5	4.2
MDCKII–MDR1 P_{app}, A to B (10^{-6} cm s^{-1})	8.3	32
Efflux ratio	3.0	0.33
$f_{u,blood}$ (%)	3.3	7.8
$f_{u,brain}$ (%)	0.39	3.0
$K_{puu,brain}$	0.021	0.47
$K_{puu,CSF}$	0.088	0.76

[a]The rotatable bond number is calculated using the equation of $N_{rot} = N_{rot,ac} + \Sigma(size - 4 - N_{ring,ac} - N_{fused})$, where N_{rot} is the rotatable bond number in the molecule, $N_{rot,ac}$ is the number of rotatable acyclic bonds, *Size* is the size of the nonaromatic ring, $N_{rig,cyc}$ is the number of rigid bonds within the ring, and N_{fused} is the number of bonds which belong to more than one ring system.
Reproduced from Zeng, Q.; Wang, J.; Cheng, Z.; Chen, K.; Johnström, P.; Varnäs, K.; Li, D. Y.; Yang, Z. F.; Zhang, X. Discovery and Evaluation of Clinical Candidate AZD3759, a Potent, Oral Active, Central Nervous System-Penetrant, Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitor. *J. Med. Chem.* **2015**, *58*(20), 8200−8215.



The further optimization of this compound led to the discovery of the clinical candidate AZD3759, a compound with an improved DMPK profile and enhanced brain exposure. AZD3759 achieved excellent levels of CNS penetration as demonstrated by $K_{puu,brain}$ and $K_{puu,CSF}$ around unity (both $K_{puu,brain}$ and $K_{puu,CSF}$ are 1.3). This compound possesses optimal CNS–drug-like properties, while maintaining the same binding mode as Gefitinib. It was found that the terminal basic nitrogen atom in the piperazine moiety promotes solubility and also brain penetration. AZD3759 exhibited excellent potency against EGFR activating mutants (L858R and Exon 19Del) and a good PK profile with moderate blood clearance at 17 mL min^{-1} kg^{-1} and the volume of distribution at 5.2 L kg^{-1}. The intrinsic clearance (Cl_{int}) is 11.4 μL min^{-1} 10^{-6} cells in human hepatocytes and the predicted clearance of the agent in human is 7.7 mL min^{-1} kg^{-1} by in vitro–in vivo extrapolation (IVIVe).[195,196] The liver blood flow (LBF) method with blood protein binding correction was applied to generate individual estimates of unbound human hepatic clearance ($CL_{hepatic}$) using available data from the preclinical studies in each species.[197–199] Using the LBF method, the predicted human clearance from rats is 8.1 mL min^{-1} kg^{-1}, which is very similar to that derived from IVIVe. Following oral dosing in rats at 2 mg kg^{-1}, absorption of AZD3759 was rapid with blood C_{max} of 0.58 μM achieved at 1.0 h. Subsequently, blood concentrations of AZD3759 declined mono-exponentially with a mean elimination half-life of 4.3 h, which was close to the same parameter obtained from i.v. dosing (4.1 h). The bioavailability following an oral dose in rats was 91%.



AZD3759

L858R pEGFR IC_{50} = 7.2 nM
Exon 19Del pEGFR IC_{50} = 7.4 nM
$K_{puu,brain}$ = 1.3
$K_{puu,CSF}$ = 1.3

To substantiate the PK and CNS penetration data in rats, the brain distribution of AZD3759 was further investigated in monkeys by microdosing PET.[200] Radio-labeled [^{11}C]-AZD3759 (0.28 μg, 150 MBq and 0.35 μg, 155 MBq, respectively) was injected into

Table 8 Unbound brain/plasma ratio for [^{11}C]-AZD3759 in cynomolgus monkey[a]

	Injected mass and radioactivity	V_T *(mL cm^{-3})*	$f_{u,\ plasma}$ [b]	$f_{u,\ brain}$ [c]	$C_{u,\ brain}/C_{u,\ plasma}$
PETA	0.28 μg, 150 MBq	3.0	0.12	0.02	0.50
PETB	0.35 μg, 155 MBq	3.7	0.14	0.02	0.53

[a]PET microdosing studies were performed after a single dose of [^{11}C]-AZD3759 (phosphate buffered saline, pH 7.4) *via* intravenous bolus route.
[b]The unbound fraction in plasma was determined in the PET experiment using ultrafiltration.
[c]Data obtained from in vitro equilibrium dialysis of rat brain homogenate were used as an estimate of the unbound fraction in monkey brain tissue.

Discovery and Evaluation of Clinical Candidate AZD3759, a Potent, Oral Active, Central Nervous System-Penetrant, Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitor. *J. Med. Chem.* **2015**, *58*(20), 8200−8215.

two male cynomolgus monkeys (PETA and PETB, respectively). The PET distribution volume (V_T) was estimated for the whole brain region using the two-tissue compartment model. The distribution volume and estimated free brain to plasma partition coefficient ($C_{u,brain}/C_{u,plasma}$) are summarized in **Table 8**. The partition coefficient values (0.50 and 0.53 for PETA and PETB, respectively) indicated that AZD3759 penetrated extensively into monkey brain tissue. PET images (**Fig. 8**) for both monkeys also suggested that the radio-labeled compound was well distributed throughout the brain.

In late 2015 the FDA approved Tagrisso (AstraZeneca), which is an irreversible EGFR inhibitor for nonsmall lung cancer with L858R, Exon19Del activating mutants, and the T790M resistance mutation. Its clinical investigations for the treatment of brain metastases are ongoing. Recently, Bao et al. from Hansoh Pharmaceuticals reported a compound code named HS-10269 (structure not disclosed), which is also a T790M mutant active EGFR inhibitor.[201] The brain penetration results in mice of Tagrisso and HS-10269 are shown in **Table 9**.

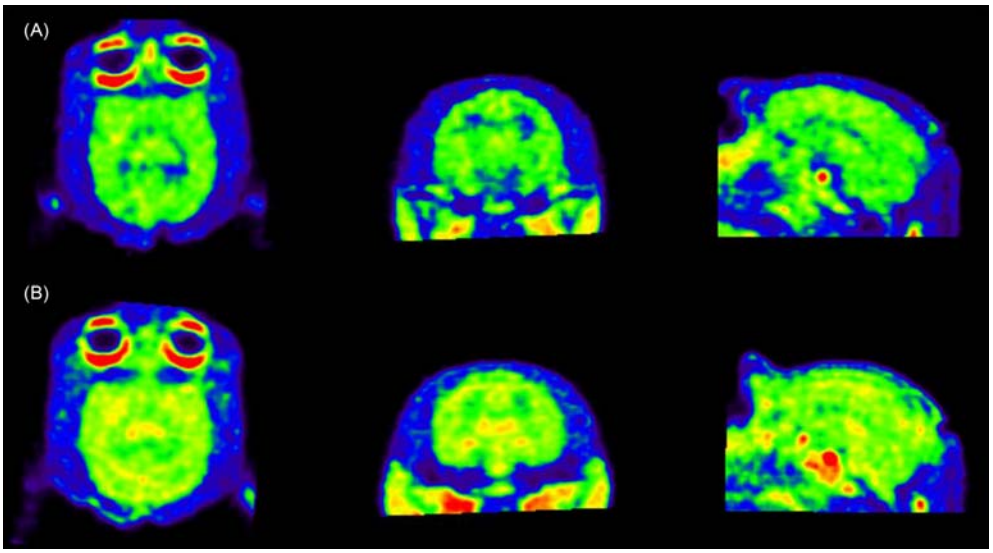


Fig. 8 Color-coded PET images showing the distribution of radioactivity in the monkey brains following administration of [^{11}C]-AZD3759. Reproduced from Bao, R.; Gao, P.; Zhang, F.; Tong, Z.; Yu, H.; Xu, Y. Discovery of a Third-Generation EGFR Inhibitor, Which Is Highly Selective and Potent Against Both Resistant and Activating EGFR Mutations for NSCLC Therapy. In *Annual Meeting of the American Association for Cancer Research,* New Orleans, Louisiana (LA), Apr 16–20, 2016; Abstract nr 3063.

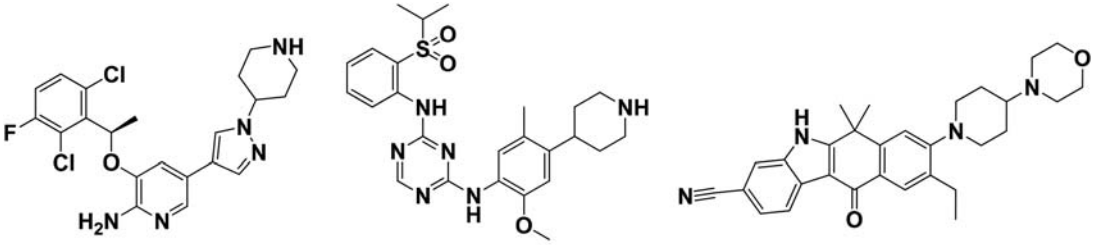
AZD9291 (Tagrisso)

HS-10269 has a similar in vitro activity profile to AZD9291 (Tagrisso). Total HS-10269 drug brain-to-plasma ratio is ~1.4 at 6 h time point, after a single dose of 5 mg kg^{-1} in mice which is lower compared to that with AZD9291 (brain-to-plasma ratio = 6.8).

7.10.5.17 Anaplastic Lymphoma Kinase

ALK, which belongs to the insulin receptor superfamily, was first discovered in 1994 and has subsequently been linked to a subtype of non-Hodgkin lymphoma.[202] Chromosomal translocation results in the expression of a fusion protein of the nucleophosmin to the truncated form of ALK, which is constitutively activated the cytoplasmic ALK kinase activity and led to aberrant downstream signaling. Lung cancer represents the highest cancer death among all cancer types and the oncogenic addiction through the ALK signaling pathway accounted for about 8% as the driver mutation in this cancer type.[203] The main ALK-related driver mutation involves a fusion protein of the N-terminal of echinoderm microtubule-associated protein-like 4 and the intracellular portion of ALK (EML4–ALK), which renders the kinase activity of the protein constitutively activated. The quest for clinically useful ALK inhibitors has intensified over the past decade.[204–208] The first ALK fusion protein kinase inhibitor, crizotinib (Xalkori), was approved by the US FDA in 2011 for the treatment of NSCLC. In addition to anti-ALK, Crizotinib also has activity against the kinases ROS and MET. Ceritinib (Zykadia), the second ALK inhibitor for the same patient group, was approved by the US FDA in 2014. Similar to crizotinib, ceritinib is also a multi-kinase inhibitor with activity against ROS. In 2015, the third ALK inhibitor Alectinib (Alecensa), also targeting crizotinib resistant patients, gained US FDA approval for treating NSCLC with ALK abnormality. Unlike crizotinib and ceritinib, alectinib is a more selective ALK inhibitor and does not act against ROS and/or MET. Although initially effective, resistance to the approved ALK inhibitors nevertheless will emerge due to mutations and/or tumor metastasis to distal organs which the current drugs show limited access. The CNS represents the most common site of metastasis and up to 60% of NSCLC patients either present with CNS disease at first diagnosis, or they eventually develop brain and/or leptomeningeal metastases during the course of therapy. Therefore, developing inhibitors, which can treat both peripheral and CNS malignancies, are urgently needed.[209]



Crizotinib (Pfizer)

Ceritinib (Novartis)

Alectinib, CH5424802 (Roche)

The importance of multidrug transporters (P-gp and BCRP) in the systemic and brain availability of ceritinib was studied by Schinkel et al. Using genetic strains of P-gp and BCRP transporter knockout mice as well as the co-administration of zosuquidar (a P-gp inhibitor) and/or Ko143 (a BCRP inhibitor) with ceritinib in mice, the authors showed that the oral bioavailability of ceritinib was not significantly affected in the absence of P-gp and/or BCRP.[210] Saturation of transporters in the gastrointestinal tract by the oral administration of ceritnib might limit the effect of transporter efflux on the absorption of ceritinib, therefore resulting in oral exposure. However, the concentration of ceritinib in the mouse brain was significantly increased (62-fold) in a P-gp knockout mouse study. A double knockout of both P-gp and BCRP provided another threefold increase in ceritinib brain exposure (193-fold). The results strongly suggested that both P-gp and BCRP restrict ceritinib's access to the CNS. Importantly, the concentration of ceritinib did not show a relevant increase in either the liver or kidneys.

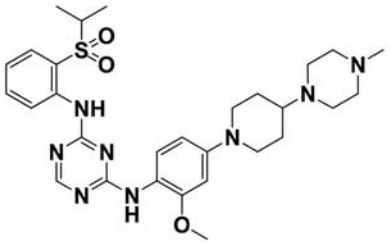
In a recent study by Kodama et al. with alectinib in a preclinical intracranial metastases model, alectinib showed superior antitumor efficacy compared to the first-generation ALK inhibitor crizotinib.[211–213] Both survival benefit and tumor regression were observed in the alectinib group at an oral daily dose of 60 mg kg^{-1}. The higher CNS activity of alectinib could be explained by the fact that it is not a P-gp substrate (Caco-2 B − A/A − B = 1.32) while crizotinib is a substrate for P-gp. A ^{14}C-labeled alectinib study in rats confirmed that a brain-to-plasma ratio of 0.63–0.94 was achieved at T_{max}. Comparing the physicochemical properties of all three approved ALK inhibitors, alectinib has the lowest tPSA value, the lowest number of HBDs, and the highest c log *P*, suggesting that alectinib would have the highest brain penetration of the three. Another phase I ALK inhibitor, ASP3026 (discontinued in 2014),

which is structurally similar to ceritinib, had been studied for its brain penetration by PET ^{11}C-labeling.[214,215] A quantitative measurement of [^{11}C]ASP3026 showed a higher drug concentration in tumors Standard Uptake Value (SUV = 3.0) compared to brain parenchyma (SUV = 0.8). In addition, a PK study on ASP3026 showed a brain-to-plasma ratio = 0.72 ($AUC_{0-24\ h}$) after an oral dose of 10 mg kg^{-1} in mice. In a similar experiment, a much lower brain-to-plasma ratio = 0.18 ($AUC_{0-24\ h}$) was observed for crizotinib. The higher brain penetration and tumor concentration of ASP3026 might be the result of the presence of extra basic nitrogen.

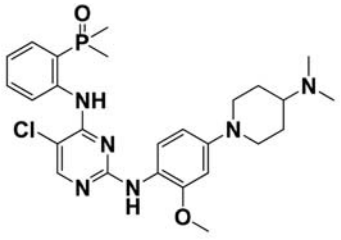
Another ALK inhibitor TAE684 (ALK IC_{50} = 3 nM; LRRK2 IC_{50} = 6.8 nM), which is structurally very similar to ASP3026, was reported to have a K_p = 2 though it did not demonstrate target modulation.[42,216,217] It was speculated that free drug concentration in the brain was not enough to cause any biological response based on the free drug hypothesis.

A recent review by Klempner et al. gave an overview of current ALK inhibitors and their CNS activity.[209] Poor CSF-to-plasma drug concentration has been reported for crizotinib and alectinib. Although intracranial responses were observed in both untreated and patients with brain metastasis who were previously treated with alectinib, the overall response rate was significantly lower than the systemic overall response rate. This might suggest suboptimal target engagement due to insufficient free drug concentration within the CNS, which hence results in disease progression.

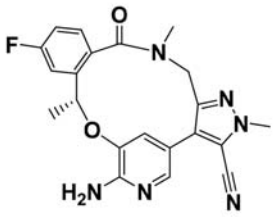
PF-06463922, a macrocyclic analog of crizotinib, was specifically designed as an ALK-mutants active and brain-penetrant dual ALK-ROS inhibitor.[218] At the outset of the design of the next-generation brain-penetrant ALK inhibitors, transporter-mediated efflux should be minimized in order to lead to higher drug concentrations within the CNS and tumor cells. Overexpression of efflux transporters is a common resistance mechanism adopted by cancer cells to evade therapeutic agents. The expression of efflux transporters, such as P-gp and BCRP in particular, along the BBB is a way to protect the brain from exogenous contaminants. Several critical parameters, including lipophilic efficiency, log *D*, and molecular weight (MW), were incorporated into the design of new compound to achieve the goal of discovering brain-penetrant ALK inhibitors. Macrocyclic compounds provided several attributes favoring CNS Absorption, Distribution, Metabolism, and Excretion (ADME) properties, including less flexible conformation (reinforced binding), reduced number of rotatable bonds, and more compact structures compared to their acyclic counterparts. With the key structural information provided by inhibitor bound cocrystals, the novel approach of employing macrocycles was proven to be a viable strategy. The U-shaped binding conformation of crizotinib brought the halogen-substituted phenyl ring in close proximity with the pyrazole. Optimization, by forming an amide macrocycle, ultimately provided PF-06463922 as an ALK inhibitor with activity against the L1169M mutant (pALK-L1169M cell IC_{50} = 21 nM). PF-06463922 is stable in an in vitro human liver microsome assay (< 8), is highly permeable, is not a P-gp substrate [MDR ER (B − A/A − B) = 1.5], and has a log *D* value of 2.3. A preclinical rat PK study with PF-06463922 showed a half-life of 2.7 h with 100% bioavailability. At an oral dose of 10 mg kg^{-1}, PF-06463922 demonstrated a free brain-to-plasma AUC ratio = 0.21. Exposure of PF-06463922 in CSF is also significant with free CSF-to-plasma AUC ratio = 0.31 which may have an important therapeutic value for leptomeningeal metastatic cancer in the ALK disease setting. It was found that amide macrocycles in the PF-06463922 series were superior in CNS penetration compared to ether macrocycles. The amide-macrocycles display significantly lower lipophilicity (log *D* = 2–3), exhibit low clearance, and are not P-gp substrates. It was estimated that the solvent-accessible areas (SASAs) for macrocyclic compounds are about 10% less than their acyclic analogs within the same range of molecular weight. SASA has been suggested as a better descriptor for molecular size than molecular weight as a way of predicting CNS penetration. The authors also discussed analysis of > 115,000 compounds from the Pfizer compound collection with MDR BA/AB efflux ratio data. They concluded that one should focus on compounds with a log *D* range from 2 to 3 with a minimal number of HBDs, and a lower molecular weight (or SASA) in order to favor CNS penetration.



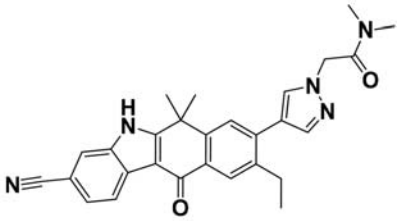
ASP3026
(Astellas)



AP26113
(Ariad)



PF-06463922
(Pfizer)

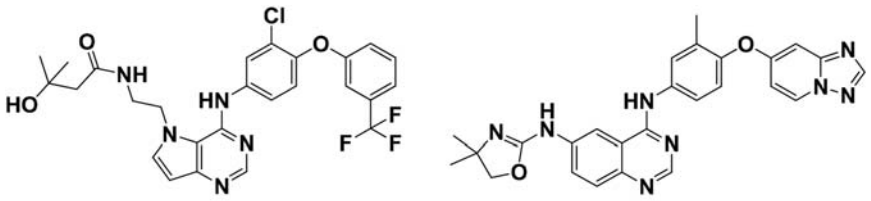


JH-VIII-157-02
EML4-ALK (WT) IC_{50} = 2 nM
EML4-ALK (G120R) IC_{50} = 2 nM
mouse brain-to-plasma ratio = 0.1

A newer generation of ALK inhibitors targeting resistance mutation continues to emerge in the literature. Although most reports provide superior activity against crizotinib resistant mutations, their brain penetration still requires improvement. Gary et al. recently disclosed an alectinib analog, JH-VIII-152-02, which targets the G1202R and other mutations, which were resistant to both alectinib and ceritinib.[219] Although JH-VIII-152-02 has good oral bioavailability and a half-life of 1.69 h, its brain-to-plasma ratio is only 0.1 at 2 h after a 10 mg kg^{-1} oral dose. Another ALK inhibitor, Brigatinib (AP26113), is now in a phase II clinical trial with a secondary objective measuring CNS response in the setting of brain metastases.[207] More understanding of the physicochemical properties of these new comers in the ALK-targeted therapeutic area will be important and helpful for designing CNS-penetrable compounds for other diseases.

7.10.5.18 Human Epidermal Growth Factor Receptor 2

The accurate measurement of free drug concentration in the CNS is important for the development of a valid PK/PD model for CNS diseases. However, developing such an accurate and reliable analytical method is not without difficulties, especially for highly protein-bound lipophilic molecules. TAK-285 (HER2 $IC_{50} = 17$ nM; EGFR $IC_{50} = 23$ nM) was a dual HER2/EGFR kinase inhibitor developed for the treatment of metastatic breast cancer with overexpression of HER2. In a preclinical animal model, microdialysis was used to determine the free drug concentration in rat brain tissue.[220,221] The adsorption of TAK-285 (>99% plasma protein bound) to the microdialysis apparatus tubing unfortunately hindered the accurate measurement of free drug concentration. Optimization of the assay protocol, by adding bovine serum albumin (4% w/v) to the perfusion fluids and using a flow rate (from 1.0 to 0.5 μL min^{-1}), allowed more reliable detection of TAK-285 in the rat brain. Using AUC curve values, the brain-to-blood ratio ($K_{p,uu,brain} = 0.24$) for unbound TAK-285 was determined. Unfortunately, further clinical development of TAK-285 targeting brain metastasis for breast cancer patients has not yet been reported.



Another HER2 small molecule kinase inhibitor reported to have CNS activity is ONT-380 (original Arry-380).[222–225] ONT-380 is a selective HER2 inhibitor (HER2 $K_i = 1.8$ nM; EGFR $K_i = 72$ nM) with high selectivity against EGFR, another member in the Erbb family. A compound such as ONT-380, which has low activity against wild-type EGFR, is believed to have a better tolerability profile. Inhibition of wild-type EGFR correlated with adverse events including diarrhea and skin rashes when patients are treated with EGFR inhibitors. ONT-380 has been reported to have about a 30% overall response rate in a phase I clinical trial focusing on brain metastasis in HER2 positive breast cancer patients. Analysis of the CNS activity of ONT-380 is complicated by the presence of an active metabolite (AR00440993), which was considered to be a brain penetrant (**Fig. 9**). However, the structure of the elusive brain-penetrant metabolite was not disclosed. Further evaluation of ONT-380 in a phase II clinical trial is currently in the planning stages.

Shionogi recently reported S-222611 (structure not disclosed) as an orally active, reversible, dual EGFR/HER2 inhibitor.[226] In a preclinical study, S-222611 (25–100 mg kg^{-1}) showed better efficacy compared to lapatinib (50–200 mg kg^{-1}) in the intracranial implantation brain metastasis model with BT474 breast cancer cells. Unfortunately, no details of the brain exposure for S-222611 were included in the report; hence it is not possible to relate exposure of the drug to the observed efficacy in the CNS.

One of the greatest hurdles to developing brain-penetrant therapeutics is the lack of CNS drug exposure data in the clinical setting. In a rare instance, the drug disposition of capecitabine (and metabolites) and lapatinib in surgically resected brain metastases from metastatic breast cancer patients was investigated.[227,228] Although the results showed high variability, both capecitabine (and metabolites) and lapatinib showed significant drug concentrations in the resected brain tumor tissues from patients, even though lapatinib was classified as a nonbrain penetrant in a preclinical model, due to the fact that it is a P-gp substrate. In this study, brain tumor tissue-to-serum ratio of lapatinib in a range of 0.19–9.8 was observed.

With only a few brain-penetrant HER2 inhibitors such as TAK-285 and ONT-380 reported, further discovery of brain-penetrant HER2 inhibitors to treat breast cancer patients with HER2 overexpression and brain metastases is urgently needed.

7.10.5.19 Phosphoinositide 3-Kinase

GBM is a form of primary brain malignancy for which therapeutic intervention is desperately in need. The current standard of care includes surgery, radiotherapy, and cytotoxic chemotherapy drugs. In GBM, aberrant PI3K signaling is implicated in more than 80% of cases. One of the common mechanisms of PI3K pathway signaling dysregulation in GBM is through PI3Kα amplification or mutations. Researchers at Genentech recently disclosed two classes of brain-penetrant pan-PI3K inhibitors originating from their nonbrain-penetrant PI3K inhibitor assets, namely the thienopyrimidine and the purine-based series.[229] Design criteria for new inhibitors were focused on reducing efflux transporter liability (P-gp and BCRP) compared to the original leads. It was demonstrated that minimizing the number of HBDs could reduce the chance of molecules becoming efflux transporter substrates (Table 10).

Throughout the lead optimization process, a CNS MPO scoring system was used to guide compound design. The MPO scoring system assigns a score between 0 (low chance of being brain penetrant) and 6 (high) to a compound based on a weighted formula from the six descriptors (c log *P*, c log *D*, MW, TPSA, HBDm, and pK_a). A correlation between high MPO scores and low efflux liability was observed in the thienopyrimidine series. Based on the design criteria and MPO scores, several compounds with good PI3Kα activity were identified and were confirmed to be brain penetrant, in vivo. It was emphasized that an "out-of-range" parameter can sometimes be compensated by other parameters included in the composite MPO scoring system and thus a compound should not be precluded from CNS penetration assessment. Eventually, compounds 22 (PI3Kα $K_{iapp} = 1$ nM) and 23 (PI3Kα $K_{iapp} = 2$ nM) were selected for in vivo study in the U-87 MG/M GBM subcutaneous xenograft model, which is a surrogate for an intracranial model. A dose-dependent inhibition of tumor growth was observed in this model, together with evidence of downstream target modulation (pAKT and pS6RP).

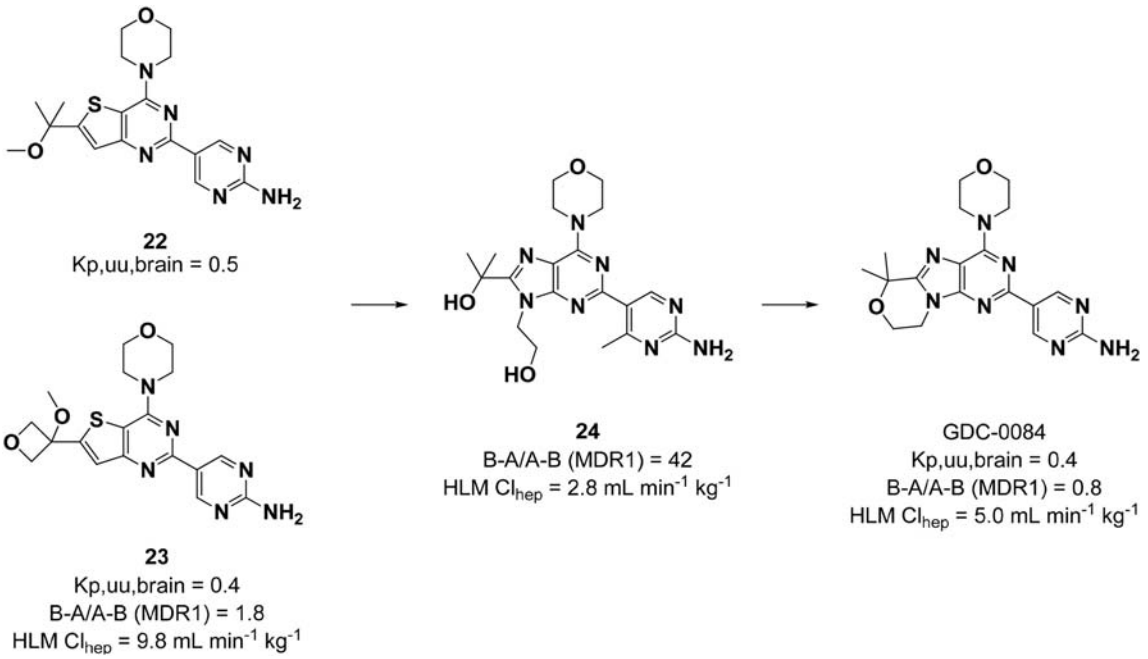
The Design and Identification of Brain Penetrant Inhibitors of Phosphoinositide 3-Kinase α. *J. Med. Chem.* **2012**, *55*(18), 8007−8020.



Unfortunately, the thienopyrimidine compound 23 was not further developed because it was predicted to have high clearance in humans. Recently, the same research group disclosed purine-based, brain-penetrant, scaffold of PI3Kα inhibitors which addressed the metabolic issues of the previously disclosed thienopyrimidine series.[230] Utilizing the same SAR from the thienopyrimidine series, a purine-based series with good PI3Kα potency and human microsomal stability was identified. The original concern that high PSA would adversely affect brain penetration for the purine-based scaffold was dispelled as compounds from the purine series were shown not to be P-gp or BCRP substrates, displaying low efflux ratios. Optimization of lead compound 24 (PI3Kα $K_{iapp} = 3$ nM), using the same design criteria described previously for the thienopyrimidine series, led to the development candidate GDC0084 (PI3Kα $K_{iapp} = 2$ nM). Cyclization of the hydroxyethyl substituent to the isopropanol moiety in 24, to form a tricyclic ring

system, significantly reduced the efflux liability observed with compound 24. In addition to having good metabolic stability, GDC0084 is also a good brain penetrant with $K_{p,uu,brain} = 0.4$ in mice. Dose-dependent inhibition of tumor growth was observed, and tumor regression was achieved at a daily subcutaneous dose of 17.5 mg kg^{-1} in an in vivo GBM U87 MG/M xenograft model in mice. Further evidence to support the CNS penetration of GDC0084 was demonstrated by a dose-dependent modulation of pAKT in the brain tissue of normal mice. Based on its PI3Kα activity and good pharmaceutical properties, GDC0084 was selected as a clinical development candidate for the treatment of glioblastoma, targeting the aberrant PI3K signaling pathway. Due to the current lack of effective treatment for a devastating disease like glioblastoma, a highly brain-penetrant inhibitor targeting the relevant oncogenic PI3K signaling pathway will definitely provide another option to benefit patients.

7.10.20 Ataxia-Telangiectasia Mutated Kinase

In addition to PI3Kα (5.18) mentioned earlier, another potentially important targeted therapy for glioblastoma is chemosensitization for radiotherapy. Irradiation of tumors causes both a single- and double-strand DNA break. The inhibition of the cellular repair mechanism of the damaged DNA can be lethal to all cells. ATM is one of the key components for cells to respond to such DNA damage. Thus, inhibiting ATM should sensitize tumors to radiotherapy.

Durant et al. at AstraZeneca recently presented potent inhibitors of the ATM.[231]

The original lead AZ31 is not CNS penetrant ($K_{p,uu} = 0.07$) due to its poor physicochemical properties with a high PSA = 99. AZ31 is also a P-gp transporter substrate with efflux ratio = 10.7 in a MDCK-MDR1 assay (**Table 11**). Structural modification of AZ32 focused on reducing PSA (reduce number of O-atoms) and eliminating the efflux liability (by reducing the number of HBDs) and resulted in the identification of AZ32 ($K_{p,uu} = 0.26$), which has greatly improved brain penetration. In this case, reducing the number of HBDs has a profound effect on the compound's efflux liability. Although AZ32 is less potent against ATM in the cellular assay, its physicochemical properties are another example to support the guidelines discussed previously on what makes for a good brain penetration (e.g., low MW, PSA, and not a transporter substrate). Further potency optimization in this series will provide important validation tools to test the hypothesis that ATM inhibition together with radiotherapy will be beneficial for patients with GBM.

7.10.6 Assessment of CNS Exposure in Drug Discovery

7.10.6.1 Barriers Within CNS System

Sufficient exposure at the site of action is responsible for pharmacological activity and ultimately delivers the desired therapeutic effects during the course of disease. For most organs, there is no restriction on compound diffusion between blood and extracellular space, consequently leading to a steady state of free drug equilibrium. However, the brain is separated from blood by the barriers, which regulate homeostasis and prevent the entry of exogenous and harmful compounds into the brain.[232,233] There are two important barriers to protect the brain, namely the BBB and the blood–cerebrospinal fluid barrier (BCSFB).

The BBB consists of monolayer of polarized endothelial cells, situated in the brain microvasculature, with a large surface area but tight intercellular junctions. Therefore the BBB acts as a major barrier to CNS penetration for compounds which are the subject of

transcellular diffusion. Efflux transporters in the BBB, such as P-gp and BCRP, present a hurdle to efficient brain delivery. The BCSFB creates a similar barrier at the choroid plexus epithelium, which is situated between fenestrated blood vessels and the CSF, but it is 5000 times smaller in surface area than BBB and less important with regard to drug uptake into the brain.[234,235]

Retrospective analysis of human brain exposure was performed on a set of 32 structurally diversified Pfizer candidate drugs with clinical data by Di et al. The results demonstrated that those compounds with high passive permeability, were not efflux transporter substrates and showed good CNS distribution in preclinical animals at equilibrium, predicted good human brain penetration.[236] Consistent with this, the current strategy for CNS drug discovery relies on optimizing permeability and reducing efflux across BBB in vitro. The ratio of unbound drug in brain to unbound drug in plasma was used to determine the extent of in vivo brain penetration in rodents, which allows optimization cycles to balance physiochemical properties for favorable CNS penetration and achieve high unbound brain concentration. Additionally, brain PKs provides guidance design of subsequent pharmacological studies and thereafter enhances the understanding of target engagement. Integrated approaches are established to build SAR and to design compounds with favorable physiochemical properties and therefore identify compounds with an optimal extent of brain penetration.

This section does not give a full overview of all the techniques and models available today, but focuses on the assays widely used across the pharmaceutical industry and some of the new techniques available due to recent advances in technology.

7.10.6.2 In Vitro Methodology to Identify Permeability and Efflux Liability at BBB

BBB permeability is expressed in the same units (mL $min^{-1}g^{-1}$ brain) as cerebral blood flow (CBF), which will limit the maximal amount of compound delivered to the brain.[237] Obviously, compounds with low passive permeability tend to have low free brain exposure given that most systemically exposed drugs will be carried away by CBF if drug permeability is less than CBF, 0.15–0.6 mL $min^{-1}g^{-1}$ brain.[238] For example, mannitol has low passive permeability, less than 1 μL $min^{-1}g^{-1}$ brain, and consequently shows a low $K_{puu,brain}$ (0.01). In contrast, caffeine (not P-gp substrate) with a passive permeability of 13 μL $min^{-1}g^{-1}$ brain shows a much better $K_{puu,brain}$ (1.0).[239] It has been reported that 46 of 48 CNS drugs have an apparent permeability of greater than 15×10^{-6} cm s^{-1}, and non-CNS drugs show a sevenfold higher incidence of having permeability $< 15 \times 10^{-6}$ cm s^{-1}.[240] Thus, this cut-off value has been recommended by the authors to help predict CNS candidates. However, data accumulated so far suggest that permeability criteria have been considered as one of the important parameters to be optimized during the screening cascade for the CNS drug project. However, high value passive permeability alone cannot deliver good brain penetration when active efflux processes in the BBB are involved in drug transport.[241]

It is desirable to have an in vitro methodology to identify high efflux liability in a screening cascade, for example by capturing asymmetric drug transport in a quantitative manner and identifying the potential of BBB efflux. There is a great potential for human in vitro BBB models to make a large impact on the evaluation of BBB permeability and efflux potential as complements to human in vivo assessment. Unfortunately, primary and immortalized brain endothelial cells are not suitable for routine screening due to the fact that they have loose junctions, down-regulated transporter expression, and are costly.[242] MDCK cells are neither endothelial cells nor do they originate from the brain; however the tight junctions of the MDCK monolayer provide transcellular permeability which correlates well with in vivo BBB permeation.[242] BBB efflux can be predicted by using an MDCK monolayer transfected with P-gp or BCRP transporters. The rate of transcellular transport and the susceptibility of a drug to efflux are expressed as an apparent permeability coefficient (P_{app})

$$P_{app} = \frac{dC}{dt} \times \frac{V_r}{A \times C_0}$$

where dC/dt represents the concentration change with time in the receiver chamber, V_r is the volume of the receiver chamber, A is the surface area of a semi-permeable membrane, and C_0 is the initial concentration in the donor chamber.

An efflux ratio (ER) can also be calculated from the bidirectional permeability assessment.

$$ER = \frac{P_{app\ (basolateral\ to\ apical)}}{P_{app\ (apical\ to\ basolateral)}}$$

It is beneficial to establish the correlation between the efflux ratio observed in the in vitro assay of choice and $K_{puu,brain}$ obtained in vivo. Once a predictive relationship has been established, more confidence can be built on these first tier assays, such as P-gp efflux, to filter out compounds that fail to meet the cut-off value. When running the assay, it is desirable to test compounds at a reasonable concentration, for example 1 μM.

BCRP expression at the human microvascular vessel is slightly higher than P-gp. P-gp is a dominant efflux transporter and can prevent the entry of drugs into brain, but some non-P-gp substrates still have limited brain penetrance in rodents. Cooperative effects between P-gp and BCRP have been reported for dual substrates, which further limits the entry of compounds into the brain.[243,244] Thus, MDCK cells transfected with both P-gp and BCRP transporters enable one to simultaneously detect the efflux liability of both P-gp and BCRP at BBB. Unpublished data from AZ have found that 37 out of 48 non-P-gp substrate compounds ($ER < 2$ in MDCK–MDR1 assay) still demonstrated poor CNS penetration in rodents in vivo ($K_{puu,brain} < 0.5$). However a higher efflux ratio ($ER > 2$), in doubly transfected MDCK cells, was found to predict poor CNS penetration ($K_{puu,brain} < 0.5$). (Internal data not published.) Thus, we believe that the inclusion of efflux from both P-gp and BCRP could significantly increase the throughput and sensitivity to identify BBB efflux liability from an in vitro platform.

7.10.6.3 In Vivo Methodology to Measure the Extent of Brain Penetration

The extent of brain delivery should be considered separately from BBB permeability. The extent of brain delivery can be estimated in vivo by the ratio of $C_{u,brain}$ to $C_{u,plasma}$ at a steady state, alternatively the ratio of free AUC_{brain} to free AUC_{plasma} following a single dose. Meanwhile, CSF serves as a surrogate for free brain concentration that can be represented in the following equation.

$$K_{puu,brain} = \frac{C_{u,brain\ (steady\ state)}}{C_{u,plasma\ (steady\ state)}} = \frac{\text{free AUC}_{brain}}{\text{free AUC}_{plasma}}$$

There are only two in vivo methodologies to directly measure free drug levels in the CNS, namely intracerebral micro-dialysis and CSF sampling. The technique of microdialysis enables sampling and collecting of small molecular weight substance from the interstitial space of brain; however it suffers from several limitations including invasiveness, low throughput, the requirement of surgical skills, and nonspecific binding to the device for highly lipophilic compounds. On the plus side, microdialysis can directly measure free drug concentration in a specific region in the brain CSF; it is sometimes used as a surrogate for unbound drug concentrations in brain interstitial fluid. CSF samples are usually taken via lumbar puncture in humans and from the cisterna magna in nonclinical species, such as rodents and nonhuman primates. The CSF-to-plasma ratio can vary along the path of CSF flow since drug exchange may be different at different sampling sites. Therefore, a CSF readout should be interpreted with caution since there are many factors governing the equilibrium between brain and CSF;[245] however, it is still best if the compounds show high permeability and are not a substrate of BBB transporters. $K_{puu,CSF}$ can be estimated using the following equation.

$$K_{puu,CSF} = \frac{C_{u,CSF\ (steady\ state)}}{C_{u,plasma\ (steady\ state)}} = \frac{\text{free AUC}_{CSF}}{\text{free AUC}_{plasma}}$$

In order to come up with suitable methods of a higher capacity, unbound brain concentrations can be calculated by combining in vivo whole brain measurements with in vitro estimates of the unbound/free fraction in brain tissue. Typically, animals are orally administrated with test compounds, and plasma and brain samples are harvested at predefined time points. Alternatively, test compounds are infused intravenously until steady state is reached, and plasma and brain tissues are taken at only one, that is, the terminal, time point. Homogenization of the brain destroys the tissue and thus this method cannot reveal drug levels in a specific brain region. In vitro equilibrium dialysis of brain homogenate can determine free fractions in brain tissue and plasma in a high-throughput manner. There was a poor correlation between $f_{u,brain}$ and $f_{u,plasma}$ given that there were different levels of lipids and proteins present in plasma and brain tissue. The in vivo brain penetration study determines the total brain to plasma ratio. Thus, the ratio of $f_{u,brain}$ to $f_{u,plasma}$ varies significantly with physiochemical properties. K_p reflects both the extent of the brain penetration and the partition coefficient mainly driven by relative binding ratios between brain and plasma tissue; thus the optimization of K_p for better brain penetration generally ends with a compound with high lipophilicity as already discussed in many papers.[236]

$$K_p = K_{puu,brain} \times \frac{f_{u,brain}}{f_{u,plasma}}$$

A simple animal model, namely short oral absorption, attempts to address multiple DMPK properties in one assay with a minimum number of animals (one animal per time point), such as brain penetration, oral exposure, and the extent of hepatic extraction.[246] Blood samples are taken via portal vein, and cardiac puncture, while brain tissue in addition to CSF from cisterna magna is taken from individual animals at a pre-defined time point. The extent of hepatic extraction can be roughly estimated from the ratio of blood concentrations in the portal vein relative to the cardiac sample (extraction ratio $= 1 - C_{cardiac}/C_{portal\ vein}$). For brain penetration assessment, time course profile of brain concentration provides dynamic brain penetration data and more accurately measures brain penetration as compared to a single time point approach since distribution equilibrium may not be achieved at single time point and data could be misleading. For example, K_p value at 2 h time point may underestimate brain penetrance of AZ-2 (**Fig. 10**).

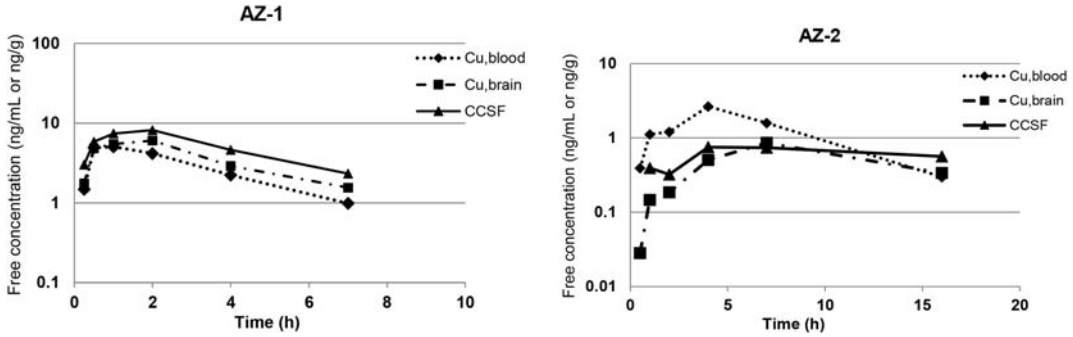

Fig. 10 The graph on the left demonstrates the parallel or overlap of free blood, free brain, and CSF concentrations; the graph on the right shows delayed T_{max} in free brain and CSF concentrations as compared to free blood.

Noninvasive techniques, such as PET, have multiple applications. PET allows the direct measurement of brain uptake and BBB permeability in humans, which is not feasible for other approaches. Following a trace dose of radiolabeled (^{11}C and ^{18}F) test compound, administrated intravenously, PET can monitor bio-distribution of the test compound into the brain and plasma and offer a readout of the brain partition coefficient K_p. After correcting for the unbound fraction in plasma and brain, the extent of brain penetration can be estimated.[247,248] Secondly, targeting specific PET tracers can serve as a biomarker for early disease diagnosis and disease progression monitoring given that the expression levels of neurological targets may alter during the course of the progression of a neurological disease, even before clinical symptoms present. Several PET tracers for Aβ plaque have been approved by the FDA for the diagnosis of AD.[249] In neurological disease, the tight junctions of the BBB may have become compromised and expression levels of efflux transporters may alter as well. To understand the scientific rationale of drug resistance in patients and to stratify patients for appropriate treatments, a metabolically activated, ^{18}F labeled PET tracer was developed to monitor P-gp and BCRP functions.[250] These efforts toward the advancement of noninvasive PET imaging enable us to directly monitor the alterations of drug disposition in the CNS due to the compromisation of the BBB in the course of disease.

However, a drawback of PET is that it is not able to differentiate between the parent molecule and metabolites in brain tissue. This shortcoming can be overcome by mass spectrometry imaging (MSI) since mass spectrometry can differentiate between metabolites and parent, if they have different molecular weights, based upon their m/z values or different mass transitions. The spatial distribution of multiple molecules can thus be obtained simultaneously in a given tissue slice. Signals from heme proteins have been used as robust MSI markers to localize the boundaries between the tissue blood vessels. Multiplex imaging of heme distribution has been related to the distribution of the therapeutics and their metabolites and ultimately utilized to provide a spatial/temporal map of drug transit into the brain parenchyma.[251] If a target site is located in the interstitial space of the brain and is accessible, microdialysis is available to measure the unbound concentration. No method exists to measure the intracellular unbound drug concentration if the target site is inside the cell. Current imaging tools allow one to obtain the total amount of drug in the vicinity of the target. Pharmacodynamic responses or modulation of biomarkers can be used as a readout for active concentrations in the target site. Another approach is PBPK modeling to enhance the understanding of intracellular disposition of drugs and link it to pharmacodynamic changes and thereafter therapeutic efficacy.

7.10.7 Conclusion and Future Perspectives

Research efforts during the past decades have provided scientists with a much deeper understanding of the underpinning biology of both proliferative and neurodegenerative diseases. Protein kinases have been demonstrated as key players in either activating or deactivating various proteins, via phosphorylation, for normal cell function. However, hyperphosphorylated proteins have been linked to protein aggregation and ultimately lead to tissue inflammation in disorders such as AD. Therefore the inhibition of an aberrant protein phosphorylation status may provide an avenue to control disease. Although there have been many successful developments in the use of kinase inhibitors in oncology, efforts to develop kinase inhibitors for noncancer-related diseases have been less successful. There are 29 FDA approved kinase inhibitors available but only two are for noncancer-related diseases. More importantly, no successful kinase inhibitor for neurodegenerative diseases has yet been approved. This data reflects the difficulties in developing kinase inhibitors to target diseases beyond oncology. Even in the oncology area, a need for brain-penetrant kinase inhibitors as a potential therapy is of equal importance. Brain metastasis is one of the pathways for disease progression. Although kinase inhibitors are successful in controlling peripheral diseases, their CNS efficacy is usually not realized. One of the key reasons may be due to the challenges of incorporating target potency and selectivity within the desired CNS DMPK parameters. Over the years, the required physicochemical properties to favor CNS penetration have become better understood. It is clear that the currently used kinase inhibitor chemical scaffolds may not be suitable for CNS penetration.

New chemistry design strategies are necessary to develop brain-penetrable compounds. Several theoretical models have been developed in the past few years to help medicinal chemists to achieve their goals of developing drug candidates that achieve effective CNS penetration. In addition, only a small fraction of all kinases have been studied. More kinases may be involved in the pathology of CNS diseases than is currently recognized. If more than one signaling pathway is involved in the underlying diseases, selective multikinase inhibition may be more efficacious and beneficial. The recent development of many in vitro/in vivo DMPK methodologies has also facilitated more efficient and productive workflows for the identification of compounds with desirable CNS penetration properties. Ultimately, the key lies in designing new chemical scaffolds, which will lead to more candidates entering clinical studies by biologists/physicians for proof-of-concept studies. We should be optimistic that some of the research efforts may result in the creation of medicines for the treatment of patients with CNS diseases in the near future.

7.11.1 Introduction

This article will focus on the medicinal chemistry of ligands selective for the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor which have been reported in the last decade. The AMPA receptor (AMPAR) is a ligand gated ion channel of the glutamate family, which plays a pivotal role in the biological processes that underpin learning and memory. This renders the AMPA ion channel a highly attractive target for the treatment of cognitive impairment, in particular for conditions linked to reduced levels of glutamate neurotransmission. Excess levels of glutamate are also detrimental and can lead to potentially serious adverse conditions, most notably seizures, which are in part attributed to overstimulation of the AMPAR. Hence, inhibitors of the AMPA ion channel have also been researched and represent an attractive option for the treatment of epilepsy. In addition, high levels of glutamate have strongly been linked with neurodegenerative processes underlying a number of diseases. The majority of work during the last decade has focused on the identification of positive allosteric modulators (PAMs), which will be the main focus of this article. The medicinal chemistry of negative modulators was thoroughly reviewed in the second edition of *Comprehensive Medicinal Chemistry*,[1] and little or no new work has been reported during recent years. However, it is worth mentioning that a number of the compounds previously reported have been progressed into clinical studies, where they have shown encouraging results in epilepsy studies.[2] A brief summary is contained in the section "**AMPA Receptor Antagonists**" together with a description of a recent, novel approach to the identification of AMPA antagonists involving targeting transmembrane AMPA receptor regulatory proteins (TARPs).

7.11.2 AMPA Receptor Function and Structure

7.11.2.1 Glutamate and Its Implication in Neuropsychiatric and Neurological Disorders

In the mammalian central nervous system (CNS), fast excitatory signaling is mediated through binding of the neurotransmitter glutamate, released from presynaptic terminals, to glutamatergic receptors widely distributed on postsynaptic neurons and glia.[3] Fast synaptic neurotransmission plays a major role in controlling diverse sensory, behavioral and cognitive processes, including learning and memory. Glutamate binds to two distinct classes of receptors: ionotropic (ion channels) and metabotropic (G-protein coupled receptors).[4] Three types of ionotropic glutamate receptors (iGluRs) have been identified and are named according to the chemical entity originally discovered to selectively activate each channel: AMPA, NMDA (*N*-methyl-D-aspartate), and kainate ((3*S*,4*S*)-3-(carboxymethyl)-4-isopropenyl-L-proline).[5] Although they share common structural features and act by depolarizing the postsynaptic membrane in response to glutamate, each type of iGluRs has distinct kinetic and pharmacological properties, and plays a disparate role in cognition. iGluRs are involved in several aspects of nervous system development and function, and glutamate neurotransmission dysfunction has been linked to the pathophysiology of several psychiatric and neurological disorders, such as schizophrenia, mood disorders, epilepsy, Alzheimer's disease, and Parkinson's disease.[6–8] As a result,

alteration of glutamatergic neurotransmission with small-molecule drugs attracted the interest of the pharmaceutical research community, since it could possibly lead to the discovery of innovative treatments for a range of diseases. However, the complex pharmacology of the glutamatergic signaling pathway and the absence of highly selective chemical probes have restricted major advancement in this area of neuroscience for many years. Recent developments in the understanding of this multireceptor physiological pathway,[9] the expanding knowledge on the structure and composition of the AMPAR complexes,[10] and the identification of novel, rationally designed, AMPAR ligands with targeted pharmacokinetic profiles represent great promise and could lead to new therapies for a number of neurological and psychiatric conditions in the near future.

Hypofunction of fast excitatory synaptic transmission has been linked to cognition deficit, a major symptom in Alzheimer's disease and schizophrenic patients.[6] In the case of schizophrenia, it has been proposed that the disease predominantly originates from NMDA receptors' (NMDARs) glutamatergic synaptic underactivity, with nonselective NMDAR antagonists, such as ketamine, causing schizophrenia-like symptoms in healthy volunteers.[11,12] In addition, postmortem analysis of schizophrenic hippocampus has revealed a subnormal density of AMPARs and an increased concentration of the glutamate receptor antagonist *N*-acetylaspartyl glutamate, emphasizing the link with hypoglutamatergic neurotransmission.[13] Dynamic regulation of AMPARs in postsynaptic membranes and activation of the receptor are intimately associated with synaptic plasticity, a mechanism believed to underlie learning and memory.[14,15] Under normal physiological conditions, repetitive AMPAR stimulation induces postsynaptic neuronal membrane depolarization, provoking colocalized NMDARs activation through release of the Mg^{2+} block. This enhances NMDAR Ca^{2+}-gating,[16] which concomitantly with AMPAR-mediated cation influx (Na^{+} and K^{+}) eventually results in synapse strengthening, an effect named synaptic plasticity.[15,17] In turn, the increased NMDAR synaptic signaling influences receptor trafficking and additional AMPARs are inserted into the synapses.[18] The rapid response of the AMPAR enables accurate transmission of high-frequency presynaptic impulse.

7.11.2.2 Structure and Modulation of AMPA Receptors

Similarly, to the other iGluRs, AMPARs have a modular tetrameric architecture, organized as dimers of dimers.[19,20] Four different subunits (GluA1 to GluA4), composed of about 900 amino acids and sharing 65%–75% sequence homology, can combine to form homo- or heterodimers, which subsequently combine to form a heterotetramer, composed of at least two types of subunits.[21] Distribution of AMPAR subunits in the CNS has been demonstrated to be uneven between the various brain regions, with different cellular expression within each region.[22] Although they are not expressed by nerve cells, recombinant AMPAR homotetramers are fully functional and have been used to study the structure and pharmacology of the channel. Over the last decade, single electron microscopy and X-ray crystallography have enabled researchers to develop a better understanding of the structure and assembly of the AMPAR subunits.[23] Until recently, only the structure of extracellular subregions of the AMPAR complex and the structure of functional homotetramers in complex with ligands had been resolved by X-ray crystallography.[23,24] These studies provided insights into the mechanism and conformational changes, that occur during AMPAR-gating, and resulted in the elaboration of possible gating models.[24,25] The combined use of X-ray crystallography and cryogenic electron microscopy has now enabled scientists to obtain structural information for GluA2-containing AMPAR heteromers and has revealed new insights into the dynamic arrangement of the extracellular region of the receptor.[26] Each subunit is composed of an extracellular domain, a transmembrane domain and an intracellular domain.[27] The extracellular domain comprises a large *N*-terminal region with binding sites for regulatory proteins, and a ligand binding domain (LBD) consisting of two discontinuous polypeptides, S1 and S2 arranged in a clamshell motif allowing glutamate binding. The LBD is responsible for agonist and antagonist recognition. The transmembrane section is composed of three α-helices (TM1, TM3, and TM4) and a re-entrant hairpin loop (TM2), which constitute part of the cation conducting pore and contribute to the receptor tetrameric assembly.[28] The intracellular section of each subunit displays the C-terminal domain, which possesses interaction sites for a range of accessory proteins, contributing to AMPARs trafficking and regulation of the receptor kinetics.[29–32] Experiment data suggest that the amino-terminal domain (NTD) is critical in regulating the subunit assembly, and, as a result, it has attracted a lot of attention to determine the molecular basis guiding the receptor oligomerization.[20] The NTD has also been shown to control other processes, such as receptor trafficking, channel gating, agonist potency, and allosteric modulation. The traditional gating view is based on the assumption that the LBD is highly mobile and adopts a close clamshell conformation upon binding of an agonist. This conformational change induces disruption of transmembrane segment interactions and formation of a cation pore.

A diverse range of subunit assemblies can lead to functional AMPARs. The composition of the channel in vivo is extremely complicated and influences receptor kinetics and glutamate binding. Despite this diversity in composition, the signaling properties of AMPARs are dominated by the GluA2 subunit, which has been detected in the majority of the receptor complexes.[26] An extra layer of structural diversity arises from the presence of sites of posttranslational modifications and the existence of splice isoforms, known as flip (i) (Ser775; UniProt ascension number P42262-2) and flop (o) (Asn775; UniProt ascension number P42262-1).[33,34] The flip/flop variation, found in the S2 subdomain of the LBD, controls the kinetics of channel closure and desensitization, the reduction of AMPAR-mediated currents in the continuous presence of glutamate.[35,36] Incorporation of flip or flop isoforms in a tetrameric complex is influenced by transmembrane proteins.[29]

In view of the connection of glutamatergic neurotransmission dysfunction with diverse neurological and psychiatric disorders, generation of glutamate receptor ligands has been of interest and a range of different approaches have been

investigated. In particular, according to the mechanism of synaptic plasticity and the causes of cognitive deficit in diseases, such as schizophrenia, enhancement of AMPAR-mediated synaptic transmission has been extensively explored.[37,38] Originally, direct or partial AMPAR agonists were sought, but it quickly became clear that such compounds were associated with a high risk of toxicity following overexcitation of the receptor signaling.[39,40] This approach precluded the precise and refined spatial and temporal control, required for optimal cognitive functioning, and was overcome by the discovery of AMPAR PAMs, termed potentiators, which lack intrinsic activity in the absence of glutamate. Nonetheless, when AMPARs are functionally activated *via* binding of the endogenous substrate, they enhance the agonistic effect by modulating the channel's biophysical properties.[41] Potentiators enhance AMPAR response through two distinct effects on synaptic currents: inhibiting desensitization and/or slowing deactivation.[42] Unlike orthosteric agonists, PAMs maintain the magnitude and/or duration of channel opening during synaptic activity. However, AMPAR potentiators can still cause excitotoxicity, resulting in motor coordination disruption and/or convulsion,[43,44] and therefore carefully determining preclinical therapeutic indexes (TIs) of these molecules is critical for onward development. The majority of modulators described to date have limited subunit selectivity but excellent selectivity against the other ionotropic and metabotropic glutamate receptors. It has been hypothesized that some AMPAR subtypes might govern the "positive" pharmacology of AMPAR PAMs whereas other subtypes might cause the undesired adverse events. Hence, selectively targeting the "positive" subtypes would prevent side-effects and offer an optimal TI. Unfortunately, it is currently impossible to biologically test this assumption. Recent structural studies have revealed a marked vertical compression in AMPAR heteromers, giving rise to novel NTD/LBD interfaces, which may enable subunit-specific allosteric modulation. Alteration of receptor signaling with NTD ligands has been successfully explored with NMDARs. On the other hand, inhibition or negative modulation of AMPARs is an attractive strategy to mediate CNS disorders characterized by excessive neuronal activity. Hence, AMPAR antagonists which dampen aberrant neurotransmission have been developed to treat stroke and epilepsy. However, a number of clinical trials with this class of drug have indicated a narrow therapeutic window and shown associated side-effects, such as ataxia, sedation, and dizziness.[45]

After years of intense research, recent studies have established that AMPARs are part of macromolecular complexes with a large molecular diversity.[46] The complexes result from the assembly of the GluA heterotetramer with auxiliary proteins, including the transmembrane AMPAR regulatory proteins (TARPs), the cornichon homologs, and the CKAMP44 protein.[47] The finding that AMPARs are heteromultimeric in nature indicates that the receptor functions beyond glutamate binding may be largely influenced by non-GluA subunit constituents, which increase the ability of neurons to tune the response to presynaptic excitation. In particular, it has been established that members of the TARP family of proteins dramatically regulate AMPAR trafficking, gating, and pharmacology, but also control sensitivity to AMPAR ligands.[47–49] TARPs comprise γ2 (stargazing), γ3, γ4, γ5, γ7, and γ8 subunits, which are differentially localized in specific neuronal and glial populations throughout the CNS.[50,51] Recently, the molecular architecture of the AMPAR–TARP-γ2 complex has been reported in two separate studies and defines the molecular basis for TARP modulation of AMPAR gating and pharmacology.[52,53] The stoichiometry of the TARP–AMPAR complex is still unclear, but distinct interactions between the two component TMDs have been elucidated. Electrostatic interactions between the "palm" section of TARPs and the lower part of the AMPAR LBD also contribute to the complex formation. It is assumed that the contraction of AMPARs upon activation enhances this electrostatic attraction, accounting for the TARP-mediated stabilization of the opened state AMPARs.[53] Interaction mapping studies have also revealed that the distal AMPAR NTD also possesses TARP interaction regions, which impact on AMPAR gating.[54] An increasing number of studies into neuropsychiatric and neurodegenerative illnesses are demonstrating an emerging pathological role for TARPs. Members of the TARP protein family have distinct regional expression across the CNS, resulting in physiologic differentiation of the AMPAR activity.[55] This discrete distribution provides the innovative and attractive opportunity to modulate AMPARs in specific brain regions to access modulators with potential therapeutic advantage, which would not globally affect synaptic transmission.[56] This would be achieved by identifying TARP-dependent AMPAR ligands and a similar strategy has recently been successfully implemented by Lilly and Janssen in their search for safer AMPAR antagonists for the treatment of epilepsy,[57,58] demonstrating that accessory proteins are novel pharmacological targets. Positive emission tomography studies with a range of AMPAR modulators have indicated that different concentrations of potentiators are required to selectively activate the CNS regions associated with procognitive and undesired effects, suggesting a potential role of localized auxiliary proteins, resulting in AMPAR complexes with different biophysical properties.[59]

The LBD of the channel has an opened bilobate structure which closes upon binding of glutamate, initiating the gating cascade.[60,61] According to X-ray cocrystal structures of positive modulators bound to the LBD of AMPAR, all potentiators bind at the S1S2 interface of the LBD, resulting in increased stability of the closed glutamate-bound dimer.[62] Several studies have demonstrated that the isolated LBD possesses similar pharmacological properties to the native membrane-bound AMPAR.[63] This has enabled significant advance in the understanding of the biophysical and structural properties of the channel, allowing structure-based drug design (SBDD) of agonists and antagonists, but also the identification of binding sites for PAMs.[64] Irrespective of their mechanistic properties and mode of action, AMPAR potentiators have been shown to enhance glutamatergic synaptic activity in several in vitro experiments both on recombinant and on native tissue preparation,[17,65] and improve cognition in preclinical animal models and in small but not all clinical trials.[66–70] In addition, AMPAR PAMs have been therapeutically beneficial to treat a range of neuropsychiatric and neurological conditions in animal models, such as anxiety, attention-deficit hyperactivity disorder (ADHD), Parkinson's disease, and depression.[71–75]

7.11.3 AMPA Receptor Positive Allosteric Modulators

7.11.3.1 Clinical Studies With AMPAR Potentiators

A number of candidates have been identified that have entered clinical development. Encouragingly no major mechanism-related safety issues have been reported and some compounds have shown promising efficacy in early patient-based studies, however, no compounds have yet demonstrated sufficient efficacy to merit large scale efficacy studies. Table 1 summarizes compounds that have entered clinical evaluation many of which have been terminated.

Cortex pioneered early work in the area and reported encouraging results with early compounds such as CX516, which demonstrated positive effects in studies with healthy volunteers[70] and as an adjunct therapy in patients with schizophrenia.[76,77] Unfortunately, CX516 failed to demonstrate efficacy in a number of later studies when tested in patients with mild cognitive impairment,[78] autism[79], or Alzheimer's disease.[80] A later compound, CX717 (structure currently unknown) was also progressed to clinical studies, where it failed to demonstrate beneficial effects in healthy subjects,[88] but showed some efficacy in ADHD patients.[89] Cortex were unable to obtain funding to follow up on the positive results seen in patients with ADHD, but they are currently developing CX717 for respiratory depression (Table 2). Cortex have also taken a third compound CX691 into the clinic either alone or following licensing deals with other companies, but the compound failed to demonstrate beneficial effects.[81–83] Organon, Lilly, and GlaxoSmithKline (GSK) have also progressed molecules into the clinic but all have reported negative data.[78,84–87] Understanding why some compounds have shown hints of efficacy, yet others have failed, is an important challenge and the answer will be key in the design of the next generation of AMPA modulators.

A number of AMPAR modulators remain under clinical investigation (Table 2). Cortex is again leading the way, but has changed therapeutic focus to respiratory conditions, and recently the company name changed to RespireRx. They are currently progressing three compounds for sleep apnea and drug-induced respiratory depression.[91] The only company currently known to be active in the psychiatry area is Pfizer with a compound PF-4958242 **11** in phase I studies. A total of 11 phase I studies have been conducted over an extended period,[90] many of these studies focus on pharmacokinetic evaluation and investigation of drug–drug interaction potential, suggesting that there are potentially a number of safety concerns with the compound. The results of one study with PF-04958242 have been published, where it failed to show beneficial effects in treating age-related hearing loss.[92]

Table 1 AMPAR positive modulators clinically evaluated but whose progression has been terminated

Molecule	*Trial*	*Status*
CX516 (**2**) Ampalex	Cognitive performance in healthy young and aged volunteers[70,76]	Improved cognitive performance
	CX516 added to Clozapine, Olanzapine, or Risperidone in patients with schizophrenia[77]	Inconsistent cognitive benefits
	Efficacy and safety of CX516 in elderly participants with mild cognitive impairment[78]	Completed
	Effects of CX516 on functioning in fragile X syndrome and autism[79]	Completed
	Treatment of Alzheimer's disease with CX516[80]	Completed
CX691 (**3**)	Cardiac safety study of phase I and phase II ORG24448 patients[81]	95 patients Completed
ORG24448	Depression: 8 week treatment, includes PET analysis	180 patients
SCH900460	Excluded patients with propensity for seizure following EEG assessment[82]	Completed
Faramaptor	TUNRS NIMH-funded cognitive impairments in schizophrenia: 8 weeks adjunctive therapy to existing atypical antipsychotic medication[83]	Terminated
ORG26576 (**4**)	Phase II major depressive disorder: 54 patients[84] Part 1: 100–600 mg bid up to 16 days Part 2: 30 subjects; high dose group and low dose group; 28 days dosing	Completed
	ADHD: 60 patients[85]; 100–300 mg BID; 8 weeks	Completed
LY451395 (**7**) (Mibampator)	Aggression and agitation in Alzheimer's disease: 132 patients; 3 mg bid 12 weeks[78]	Comparable to placebo on all endpoint except Frontal Systems Behavior Inventory where a significant improvement was demonstrated ($p=0.007$) (38)
	Alzheimer's disease: 200 patients[86]	Negative
GSK729327 (**9**)	Phase I: safety and tolerability in healthy volunteers: 79 volunteers, 1–6 mg[87]	Completed

Table 2 AMPAR potentiators still under clinical investigation in 2016

Molecule	*Trial*	*Status*
CX717	DARPA-funded small scale trial in healthy volunteers subjected to simulated night shift work[88]	No improvement in cognitive performance
	ADHD small (n=23–28) study of 200 mg bid and 800 mg bid for 3 weeks in adults with moderate-severe symptoms	Significant improvements at highest dose on hyperactivity and inattention indices
	Drug-induced respiratory depression	Pending
CX1739	Sleep apnea	No effect on mean apnea/hypopnea index, however significantly reduced apnea time
	Drug-induced respiratory depression	
CX1942	Respiratory depression (intravenous)	Pending
PF-04958242 (**11**)	Phase I[90]	On-going

7.11.3.2 Chemotypes of AMPAR Positive Allosteric Modulators

A number of excellent comprehensive reviews, describing the historical chemotypes originally explored as selective AMPAR positive modulators (Fig. 1), have been published in recent years.[93–95] Briefly, three major classes have been explored: the benzamides, the thiadiazines, and the phenethyl sulfonamides. Chronologically, the benzamide series, derived from the nootropic agent aniracetam **1**, was first investigated and developed by Cortex into derivatives such as CX516 **2**, CX691 **3**, and ORG26576 **4**, which were all tested in the clinic. Then the thiadiazine series, originating from the diuretic agent cyclothiazide **5**, was also extensively investigated, leading to Servier's clinical candidate S-18986 **6**. Finally, a class of phenethyl sulfonamides, discovered by Lilly, generated significant interest with a number of subsequent patent applications from several pharmaceutical companies also covering sulfonamide

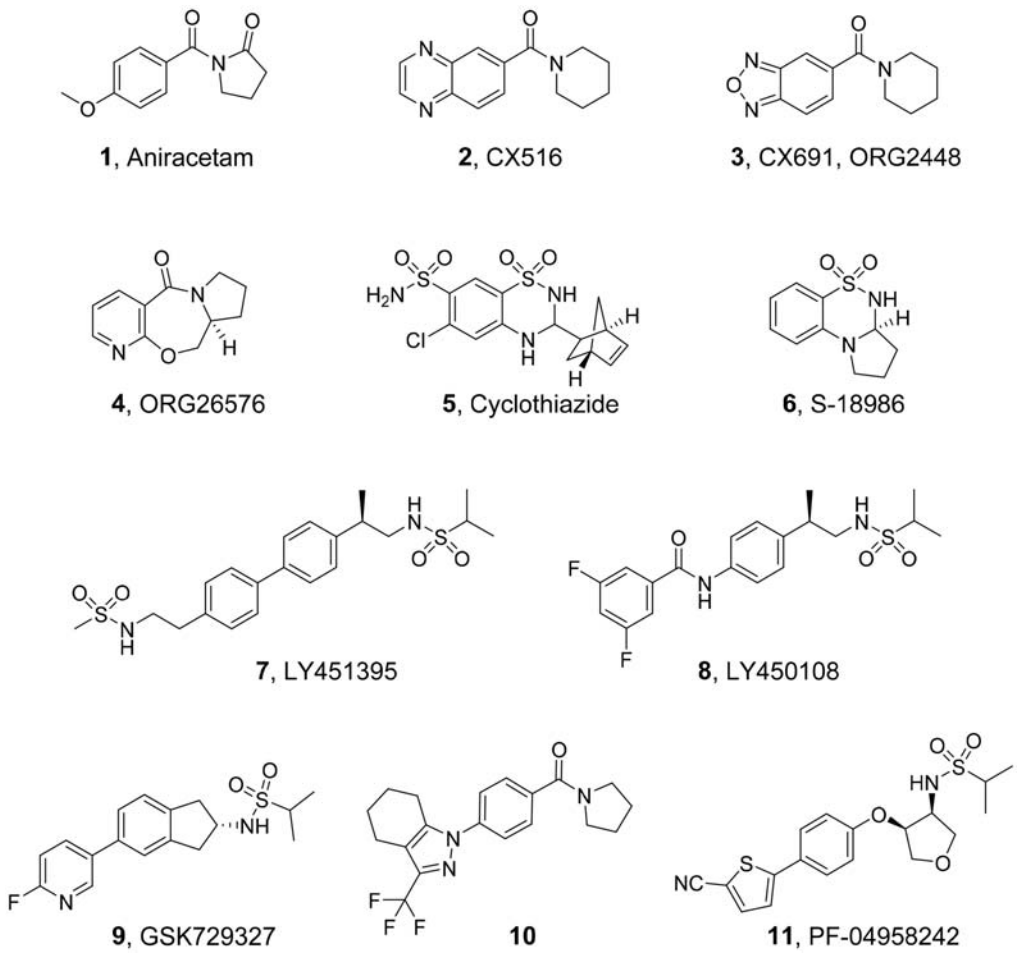

Fig. 1 Representative chemotypes of AMPAR positive allosteric modulators.

derived structures. This class has yielded candidate compounds including LY451395 **7** and LY450108 **8** from Lilly, GSK729327 **9** from GSK and PF-04958242 **11** from Pfizer. In recent years, GSK also filed a number of patents describing novel AMPAR potentiators, all displaying a trifluoromethylpyrazole group, and later reported the discovery of clinical candidate **10**, a benzamide derivative with a fused trifluoromethylpyrazole scaffold at the *para* position.[96] It is worth noting that since, trifluoromethylpyrazole derivatives have become common functionality in AMPAR potentiator structures that have been claimed by a number of pharmaceutical groups and can be considered as the latest class of AMPA PAMs. Over time the modulators developed have become increasingly more potent for the AMPAR, with the original benzamides being weaker than the phenethylsulfonamides.[93]

As highlighted in our 2015 review of the AMPAR potentiator patent literature,[97] a number of novel chemotypes have recently been discovered, some of which are suggested to have a different mode of action and potentially a different clinical profile. This article will concentrate on new developments reported in the scientific literature over the last ten years and not fully covered by previous reviews. We will mainly focus on the new core templates, some derived from high-throughput screens (HTS), with an emphasis on structure–activity relationships (SARs), drug metabolism and pharmacokinetics (DMPK) properties, and pharmacological profiles of these series. While only GSK and Pfizer have described in detail the discovery and profiles of development candidates (**9**, **10**, and **11**),[59,96,98] other organizations have published descriptions of a range of different chemotypes for which no development has been reported. It is also interesting to note that many recent scientific articles and patents in this area have been published by academic groups with a reduced number coming from industrial laboratories, this perhaps has been influenced by the decision of many companies to withdraw from the neuroscience area, and also in some cases the move of experts in this area from industry to the academic sector.

7.11.3.3 Recent Medicinal Chemistry of AMPAR Potentiators

7.11.3.3.1 Two novel templates from GSK

Between 2005 and 2010, GSK have filed a large number of patent applications for novel AMPAR modulators, indicating strong interest from the company in this area of neuroscience.[99–110] In the period covered by this article, they published three scientific articles, each focusing on a different chemotype.[96,98,111]

In a short communication,[111] they reported the discovery of a series of *N*-substituted pyrrolidines and tetrahydrofurans (THF), related to the phenethyl sulfonamide modulators described by Lilly. One may assume that this exploratory work, based on existing literature, was conducted when the company first started to develop an interest in this area and can be considered as GSK's initial attempt to identify AMPAR positive modulators. The original Lilly phenethyl sulfonamide series generally suffered from poor physicochemical properties, such as low solubility, high polar surface area (PSA), and high lipophilicity, which might have contributed to the failure of the compounds which progressed to the clinic (LY451395 **7** and LY450108 **8**). By introducing heteroatoms on the phenethyl moiety, using a 3,4-disubstituted pyrrolidine (**Fig. 2**) or a 3,4-disubstituted THF (**Fig. 3**) linker, and exploring replacement for the *N*-phenyl methanesulfonamide motif, the GSK team attempted to modulate these undesired properties. Interestingly the reported pyrrolidine linker derivatives have *trans* relative stereochemistry whereas the THF linker derivatives have *cis* relative stereochemistry. This renders direct comparisons between the two subseries challenging and it is assumed that direct matched-pairs have not been prepared, since according to the authors these stereochemistry were only selected because of their synthetic tractability. The compounds were screened for their ability to potentiate glutamate-induced calcium influx against recombinant hGluA2i receptors in a fluorometric imaging plate reader (FLIPR)-based assay, with the maximal response of cyclothiazide defined as 100%.

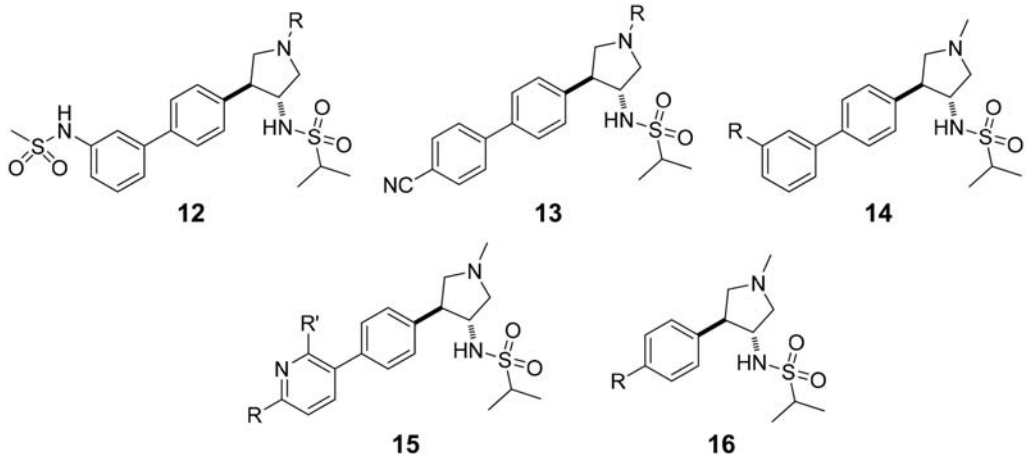

Fig. 2 Representative structures of the pyrrolidine-linked *iso*propylsulfonamide derivatives.

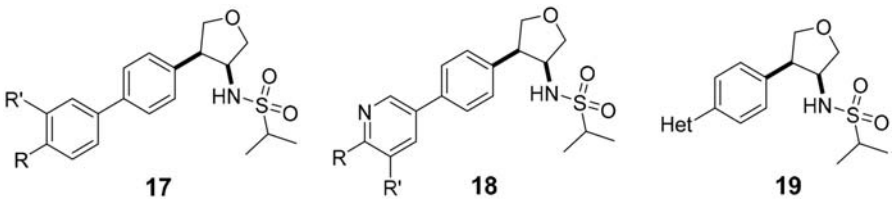

Fig. 3 Representative structures of the tetrahydrofuran-linked *iso*propylsulfonamide derivatives.

Rigidification of the linker and introduction of a heteroatom in this part of the template was well tolerated since the first derivative prepared **12** (R = Me) induced strong potentiation of the hGluA2i recombinant receptor (EC_{50} = 0.3 μM, Asym Max = 124%). Different substituents on the pyrrolidine nitrogen atom were investigated (**12** and **13**, R = Me, Et, ^{i}Pr, Ph) and showed that *N*-methylated pyrrolidines afforded the best activities, with bulkier groups leading to decreased potentiation. Reduction of the PSA was examined by replacing the *meta* methylsulfonamide moiety by a *para* nitrile, as in **13** or various *meta* substituents, as in **14**, such as a methylsulfone, an acetamide, a methylketone, or a trifluoromethyl group. All of these modifications resulted in at least a 10-fold loss in potency. Changing the phenyl ring for a pyridyl, **15** (R = R′ = H) or a substituted pyridyl **15** (R = H, R′ = F or R = F, R′ = H) produced compounds with higher EC_{50}s than **12** (R = Me), in the micromolar range (2.5–5 μM). Thiophenes were also explored as potential phenyl replacements but afforded weaker compounds (**16**, R = 2-thiophene, EC_{50} = 20 μM; **16**, R = 3-thiophene, EC_{50} = 3.2 μM, Fig. 2).

A major downside of the majority of these pyrrolidine-linked *iso*propylsulfonamides was an undesired off-target inhibition of the hERG cardiac channel. Despite a reduction in lipophilicity, these molecules contain a basic center, a common feature in compounds with affinity for hERG, and some derivatives were very potent hERG inhibitors, such as **12** (R = Ph, hERG IC_{50} = 1.3 μM) or **15** (R = F, R′ = H, hERG IC_{50} = 1.0 μM), Fig. 2. An increase in solubility was successfully achieved, with compound **12** (R = Me) and **13** (R = Me), Fig. 2, which achieved levels of >9 mg/mL and >2.7 mg/mL, respectively. Intrinsic clearance was high in both rat and human liver microsomes (RLM and HLM) for *N*-methylated derivatives, with *N*-dealkylation being identified as a major route of metabolism. Compounds with larger *N*-substituents generally achieved good microsomal stability but had similar or higher affinity for hERG relative to AMPAR. It was hypothesized that substituting the pyrrolidine ring by a THF could mitigate the hERG and metabolic liabilities of this series and afford selective compounds with a better pharmacokinetic profile.

All the THF analogs reported (seven in total) showed excellent potentiation of the AMPAR (EC_{50} 112%) and were significantly more active than the *N*-methyl pyrrolidine derivatives. This could be explained by the reduced steric bulk of the THF and also possibly by the different relative stereochemistry. The calculated lipophilicity and PSA of the THF derivatives was lower than that of the pyrrolidine analogs. With the exception of **17** (R = CN, R′ = H) and **18** (R = F, R′ = H), Fig. 3, all the molecules in this subseries had more than 100-fold selectivity for hGluA2i over hERG. Unfortunately, only a limited set of in vitro DMPK data was reported for these THF modulators and it is impossible to know if these molecules successfully achieved the targeted properties discussed earlier. Indeed, the intrinsic clearance of only two analogs, **18** (R = H, R′ = F) and **19** (Het = 2-(5-F)-pyridyl), Fig. 3, was disclosed and both compounds had high turnover in RLM. In addition, no solubility or CNS permeability data are given for the THF derivatives.

The limited success in identifying AMPAR modulators with desirable physicochemical and pharmacokinetic properties starting from a literature chemotype probably prompted GSK to identify their own chemical hits through screening of in-house compound libraries. Hence in a second publication from 2010, scientists at GSK reported the discovery and optimization of indane clinical candidate **9**.[98] From this publication, it appears that the indane series was the first novel chemical core extensively explored by GSK in their search for AMPAR positive modulators. Interestingly in addition to high potency, scientists at GSK were also targeting a specific pharmacokinetic profile, which would deliver high unbound compound concentrations. In this respect, the article not only presents the SAR around the indane core but also detailed in vitro and in vivo DMPK data, which led to the selection of the clinical candidate.

The exploratory work in this series started with the identification of lead amino indane **20**, Table 3, a rigid analog of the phenethyl series, which comprises the two sulfonamide moieties of Lilly's clinical candidate LY451395 **7**. Compound **20** induced significant potentiation of the AMPAR-mediated response against recombinant hGluA2i receptors in a FLIPR-based fluorescent-indicator dye assay (pEC_{50} = 6.1, Asym Max = 123%). Owing to its encouraging calculated physicochemical properties (see Table 3), lead **20** was profiled in an array of in vitro assays, and found to have acceptable rat protein plasma binding (95.9%) and good selectivity for AMPAR over closely related ion channels. Additionally, it did not cause CYP450 inhibition at low concentrations but was identified as a moderate P-gp substrate with a moderate efflux ratio (ER = 5.8) in a MDCK–MDR1 permeability assay. This was assumed to be caused by the high PSA (92 Å^2) and resulted in low CNS penetration in a rat oral pharmacokinetic study (Table 1, brain:blood ratio = 0.1) despite good systemic exposure.

With the preliminary SAR indicating that modulation of the *iso*propylsulfonamide moiety was not tolerated, attention turned to modification of the phenyl ring. Deletion of the *meta* substituent and introduction of *ortho* or *para* groups led to a significant reduction in potency. A broad range of alternative *meta* substituents were investigated but none retained the activity of compound

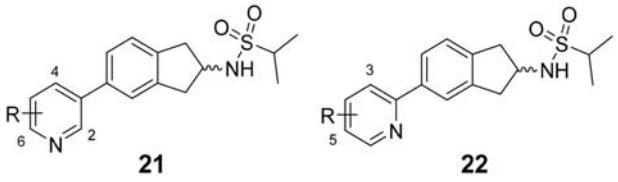
20, with the exception of sulfonamide derivatives (secondary and tertiary), but which also maintained undesirable high PSA. In vivo exposure of some of these potent analogs was determined in rat pharmacokinetic studies but similarly to **20** all suffered from poor CNS penetration. As a result, a number of aromatic rings with significantly lower PSA was explored, with the objective to reduce affinity for P-gp while maintaining high free drug concentration and good potency. This led to the identification of 3-pyridyl and 2-pyridyl indane analogs (Fig. 4: **21**, R = H and **22**, R = H), Fig. 4. Although, unsubstituted 3-pyridyl analog **21** (R = H) had lower potency in the FLIPR assay (pEC_{50} = 4.8, Asym Max = 101%), inhibited CYP1A2 (IC_{50} = 0.6 μM) and was moderately stable in rat microsomes (Cli = 2.1 mL/min/g), it possessed significantly improved physicochemical properties, such as lower PSA (59 Å^2), molecular weight (316 g/mol), and clogP (2.3). These pyridyl derivatives were deemed interesting starting points for the identification of compounds with improved CNS penetration and a series of close analogs was prepared. To avoid an increase of the PSA (PSA < 60 Å^2), pyridyl substituents were limited to alkyl and halo groups.

In the 3-pyridyl indane series, represented by **21**, Fig. 4, introduction of a single substituent at any position of the pyridyl ring reduced CYP450 inhibition, but only *para*-substitution provided stronger potentiators (**21**, R = 6-F, pEC_{50} = 5.3, Asym Max = 106%; **21**, R = 6-Me, pEC_{50} = 5.5, Asym Max = 107%). Intrinsic clearance across this set of substituted 3-pyridyl analogs was variable, all compounds had noticeably higher human microsomal turnover than the unsubstituted pyridyl **21** (R = H) and the fluoro analogs were generally more stable than the methyl substituted pyridines. The same pattern in terms of potency (**22**, R = 5-F, pEC_{50} = 5.2, Asym Max = 114%; **22**, R = 5-Me, pEC_{50} = 5.5, Asym Max = 90%), CYP450 inhibition and microsomal stability was observed in the 2-pyridyl indane series, represented by **22**. To validate the initial hypothesis that a reduction in PSA would increase CNS exposure, a selection of compounds from these series (**21** and **22**) with lower PSA than **20** were assessed in rat in vivo pharmacokinetic studies and found to have significantly improved brain to blood ratios (**21**, R = 2-F, brain:blood ratio = 1.5; **22**, R = 6-Me, brain:blood ratio = 1.4).

The exploratory work described above was conducted using racemic mixtures of indanes, comprising *R* and *S* enantiomers. Testing of single enantiomers indicated that the *S* enantiomers were significantly more potent, hence further exploration and characterization then focused on derivatives with the *S* stereochemistry. Three enantiomerically pure modulators (Fig. 5: **9**, **23**, and **24**) were profiled in detail. Indanes **9**, **23**, and **24** all produced good potentiation of AMPAR in the FLIPR assay, did not inhibit the CYP450 isoforms tested and retained the good microsomal clearance of the racemic mixtures, with methyl derivative **23** having higher intrinsic turnover than fluoro derivatives **9** and **24**. In a whole-cell patch clamp electrophysiology assay, these compounds also showed clear potentiation of AMPAR-mediated currents over a range of concentrations in HEK293 cells expressing hGluA2i homomeric receptors. Furthermore, all three derivatives (**9**, **23**, and **24**) had excellent selectivity against a wide range of ion channels, enzymes, and GPCRs. When tested in two in vivo behavioral cognition models, compounds **9** and **24** had a significant effect. Administration of both compounds at 0.3 mg/kg (PO) improved recognition memory in male rats, in the 24 h delay-induced deficit in a novel object recognition (NOR) experiment.[112] In the passive avoidance task assay,[113] modulator **9** attenuated the scopolamine-induced amnesic effect when administered at 3 and 10 mg/kg (PO), while compound **24** was active at 1 and



21 **22**

Fig. 4 Chemical structure of the racemate pyridyl indane derivatives.

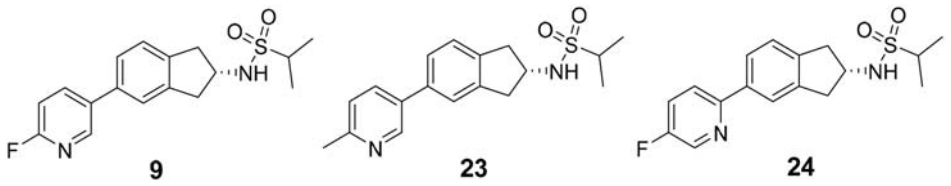


Fig. 5 Structure of the three enantiopure indanes extensively profiled.

3 mg/kg (PO). Based on the efficacy and DMPK data, only derivatives **9** and **24** were progressed to safety and tolerability studies. From these studies (no direct comparison is given), **9** was selected as the development compound.

The binding mode of the indane series was determined from a 1.8 Å resolution crystal structure of the functional hGluA2i S1S2 LBD in complex with modulator **9** (PDB code 2xhd; Fig. 6). The compound was found to bind in an analogous manner to the phenethyl sulfonamides described by Lilly: the *iso*propylsulfonamide moiety points into one of the two deep hydrophobic pockets present at the dimer interface, having displaced a network of four water molecules, and the sulfonamide NH makes a hydrogen bond with the backbone carbonyl of Pro515. The aromatic ring of the indane core sits in a narrow tunnel between the two lobs of the binding pocket, while the fluoropyridyl ring points toward the top of the symmetrical end of the inverted U-shaped binding pocket and is only making hydrophobic contacts with the protein.

Clinical candidate **9** had low equilibrium solubility ($\leq$0.1 mg/mL) across the range of pH (2–10) and physiological fluids (water, simulated gastric fluid, and simulated intestinal fluid) tested, but high permeability (P_{app} (+inh) = 688 nm/s; ER = 1.1), which delivered an attractive pharmacokinetic profile across different species. Indeed, **9** had good oral bioavailability (51%–61%) and low blood clearance (3%–11% liver blood flow) in the three preclinical species tested (rat, dog, and monkey). In addition to these suitable developability properties, compound **9** had excellent solid and solution stability under a range of conditions and did not induce time-dependent inhibition of CYP450. Furthermore, no formation of glutathione conjugates was detected, eliminating the potential liability associated with the presence of the α-fluoropyridine. AMPAR modulator **9** induced weak PXR activation in both rat and human, and as such only had a low propensity for drug–drug interactions through induction of CYP3A4. The in vitro plasma protein binding of the compound was measured in five species (mouse, rat, dog, monkey, and human), found to be moderate (from 79.5% to 90.8%) with low interspecies variability, and was fitting with the targeted pharmacokinetic profile sought by the GSK group.

A metabolite identification study was conducted using in vitro rat, dog, monkey, and human microsomes. Five metabolites were observed at low abundance relative to the parent drug, and all metabolites detected in HLM were also present in the other microsomal species. Three metabolites resulted from hydroxylation of the aliphatic part of the indane ring and one of these was a major metabolite across all species. Oxidation of the *iso*propyl moiety was also detected but represented a minor route. Aryl hydroxylation was the final metabolic route identified and was only significant in rat microsomes. Furthermore, development compound **9** was not genotoxic in the selected in vitro genetic toxicity screens and did not exhibit any cardiovascular risk in an in vitro hERG assay or following single oral dosing up to 2.5 mg/kg in cynomolgus monkeys. Finally, clinical candidate **9** had no observed adverse effect levels and acceptable safety margins in preclinical safety screening up to 6 weeks. All of these results prompted evaluation of **9** in the clinic.

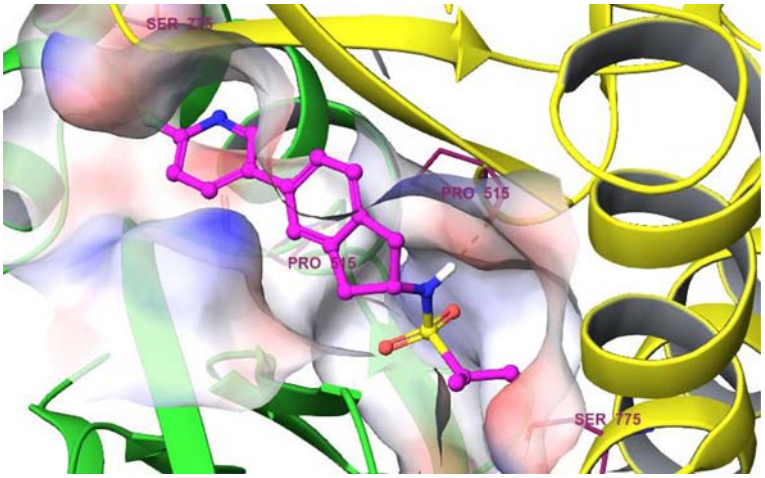

Fig. 6 X-ray crystal structure of clinical candidate 9 in complex with hGluA2i S1S2 LBD (PDB code 2xhd, 1.8 Å resolution). All the X-ray images presented in this review were generated using Maestro, version 10.5, Schrödinger, LLC, New York, NY, 2016.

An initial phase I study was conducted in healthy volunteers to explore the safety and tolerability of the candidate, as well as its pharmacokinetics in human. Two dosing regimens were investigated: single doses (0.25–6 mg) and multiple doses of 0.1 mg administered daily for 28 days. In both cases, indane **9** was rapidly absorbed (C_{max} reached between 0.5 and 3 h postadministration) and had a very long half-life (107–168 h). This resulted from a very low apparent oral clearance and a large apparent volume of distribution, in excess of total body water. This pharmacokinetic profile was not predicted from preclinical species and prevented further clinical evaluation of the compound. Importantly, both dosing regimens were well tolerated with no safety issues raised or withdrawal caused by adverse events.

In a third publication from 2011, GSK reported the identification of a novel chemical series originating from a HTS and optimized using ligand-bound X-ray crystal structures.[96] The optimization work in that series led to the identification of a second clinical candidate, compound **10**. The HTS was run using a FLIPR-based fluorescent-indicator dye protocol in HEK cells expressing recombinant hGluA2i receptors, indicating the ability of the screened molecules to potentiate glutamate-induced calcium influx. Despite a moderate AMPAR potentiation ($pEC_{50}=4.6$, Asym Max = 94%) in the FLIPR assay relative to other hits, compound **25** (Fig. 8) was selected as an attractive starting point from the screen output because of its superior preliminary developability profile. Indeed, hit **25** had good physicochemical properties (MWt = 337 g/mol and logD = 3.0) and performed well in a battery of in vitro assays. The molecule had moderate protein binding (plasma and brain), was devoid of significant CYP450 inhibitory activity, and had good selectivity against a range of ion channels, receptors, and enzymes. Low kinetic solubility and high metabolic turnover in microsomes (rat Cli = 12.7 mL/min/g; human Cli = 3.5 mL/min/g) were identified as the major shortcomings of **25** and resulted in low systemic exposure ($AUC_{0-t}=78$ ng h/mL) when the compound was tested in a rat pharmacokinetic assay. However in that assay hit **25** had good CNS exposure (brain:blood AUC_{0-t} ratio = 1.3), suggesting high permeability.

In order to rapidly identify a development candidate, the screening cascade used in the optimization work not only relied on in vitro functional efficacy screens (FLIPR assay and electrophysiology), but also extensively on calculated physicochemical properties. Unusually for a membrane-bound ion channel target, X-ray crystallography was also routinely employed enabling SBDD and a focused exploration of chemical space to quickly access highly potent modulators and ultimately, the identification of a clinical candidate. The crystal structure of tetrahydroindazole **25** in complex with the rat GluA2i S1S2 LBD and glutamate was determined at 1.55 Å (PDB code 2xx8; Fig. 7), and indicated that the phenyl ring sits at the S1–S2 interface on the twofold axis, similarly to other AMPAR PAMs. The trifluoromethyl group occupies one end of the inverted U-shaped binding pocket, making hydrophobic contacts with the protein, and has displaced the same cluster of four water molecules as the isopropyl group in compound **9**, while the carbonyl of the amide points down into the symmetrical end of the inverted U, making a hydrogen bond with one of the four water molecules. The aliphatic part of the tetrahydroindazole heterocycle makes contact with solvent, suggesting that modification of this ring might be tolerated, but such changes may not impact potency. Several serine residues (Ser518, Ser750, and Ser775), which can interact with a small-molecule modulator *via* hydrogen bonding, are detected in the binding pocket from the crystal structure, but were not exploited by hit **25**. The dimethylamide group was identified as amenable for modification and as a handle to potentially reach Ser750, Ser775 or the water molecules as hydrogen bonding partners.

The hit optimization campaign focused on improving potency, solubility, and metabolic stability. The high metabolic clearance of compound **25** was assumed to be caused by the dimethylamide moiety and other acyclic amides (Fig. 8: **26**, R = CH_2CH_2Ph or R = Bu) where one of the methyl groups was replaced by a larger substituent were prepared. These derivatives retained similar potency to **25** but had reduced solubility and similar or higher microsomal instability. Attention then turned to cyclic amides (Fig. 8: **10** and **27** (X = CH_2 or O)), which were predicted to fit optimally in the binding pocket according to the crystal structure of **25** (Fig. 7) and were expected to have reduced metabolic instability. Interestingly in the FLIPR assay pyrrolidine derivative **10** was

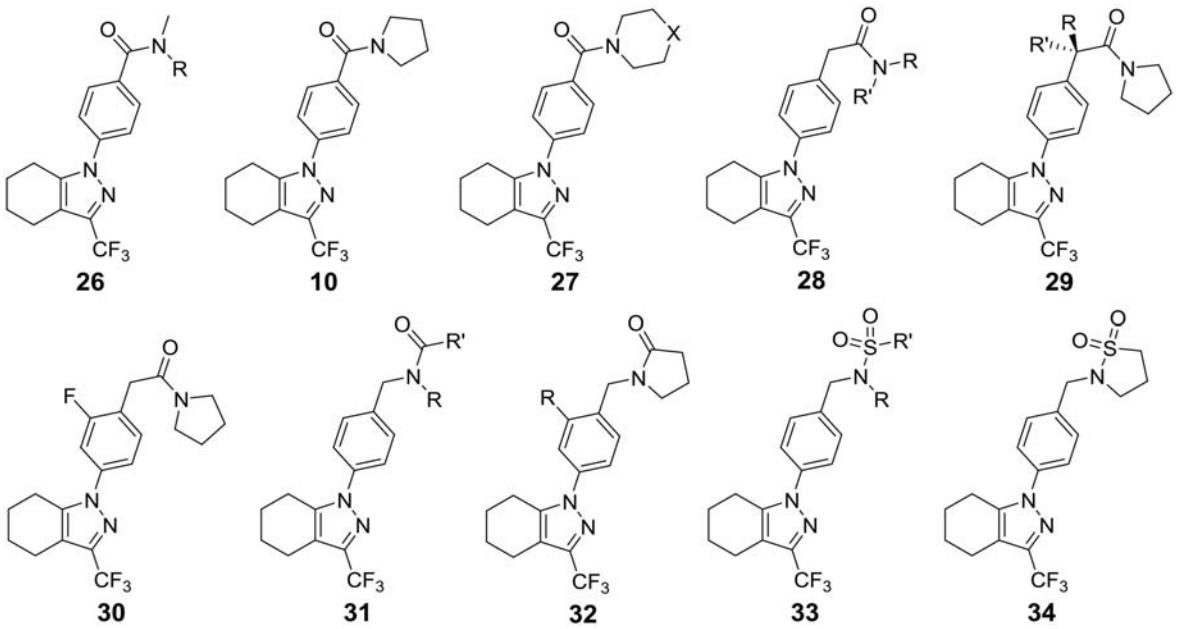

Fig. 8 Chemical structures of the tetrahydroindazole derivatives investigated during the lead optimization program.

more potent than **25** ($pEC_{50}=5.0$, Asym Max = 123%), while 6-membered ring analogs **27** were less active (X = CH_2, $pEC_{50}<4$, Asym Max = 100%; X = O, $pEC_{50}<4.7$, Asym Max = 81%). Despite its moderate potency, morpholine derivative **27** (X = O) had an attractive profile since it retained similar solubility to **25**, did not cause CYP450 inhibition and had significantly improved metabolic stability in both RLM and HLM (rat Cli < 0.5 mL/min/g; human Cli = 1.3 mL/min/g). Encouragingly, compound **10** was also more stable than **25** when tested in microsomes (rat Cli = 2.4 mL/min/g; human Cli < 0.5 mL/min/g). Derivatives **10** and **27** (X = O) had good physicochemical properties (MWt < 380 g/mol and logD < 3.1), high permeability in an artificial membrane permeability assay (**10**, 415 nm/s; **27** (X = O), 455 nm/s) and moderate to high rat plasma and brain protein binding. Owing to their favorable in vitro profile, compounds **10** and **27** (X = O) were progressed to rat in vivo pharmacokinetic studies and found to have good systemic exposure (**10**, $AUC_{0-t}=472$ ng h/mL; **27** (X = O), $AUC_{0-t}=1984$ ng h/mL) with reduced blood clearance relative to the HTS hit. Both compounds also retained high CNS penetration (brain:blood AUC_{0-t} ratio > 1) comparable to **25**. Interestingly, a cocrystal structure of amide **10** (PDB code 2xx7; Fig. 9) showed a similar binding mode to compound **25**, with an unpredicted reorientation of the amide carbonyl and differences in the network of water molecules. The carbonyl group of **10** makes a hydrogen bond with a water molecule, sitting at the top of the benzene ring, which is itself makes a second hydrogen bond

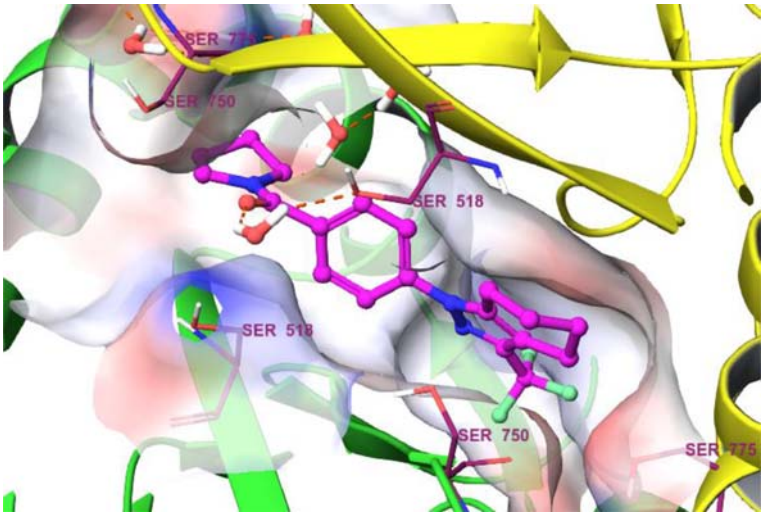

Fig. 9 X-ray crystal structure of pyrrolidine amide 10 in complex with the hGLuA2i S1S2 LBD (PDB code 2xx7, 2.2 Å resolution).

with Ser518. In the meantime, the pyrrolidine ring has displaced one of the four water molecules found at the end of the inverted U-shaped binding pocket.

Replacement of the amide moiety with a sulfonamide, a ketone or a sulfone was also investigated but afforded compounds with lower or at best similar potency to hit **25**. Kinetic solubility of these derivatives was also low. Owing to the difficulties in balancing high potency and DMPK properties, introduction of a linker atom between the phenyl and the amide group was explored as this modification was suggested to be tolerated by docking studies. Such molecules were expected to have an increased flexibility that would lead to superior solubility. The homologated analog of **25**, compound **28** (Fig. 8: R = R′ = Me), induced a substantial increase in calcium influx in the FLIPR assay ($pEC_{50} = 5.7$, Asym Max = 107%) but retained high microsomal turnover. The SAR in this series appeared to be quite narrow since a close acyclic homologated amide **28** (Fig. 8: R = ^{c}Pen, R′ = H) had reduced efficacy and very high microsomal clearance (rat and human Cli > 45 mL/min/g). The successful improvement in metabolic stability with cyclic amides **10** and **27** (X = O), prompted the GSK team to look at similar structural transformation in the homologated series (**29** and **30**). Derivative **29** (Fig. 8: R = R′ = H) maintained the improved potency of **28** (Fig. 8: R = R′ = Me) ($pEC_{50} = 5.5$, Asym Max = 82%) but also the undesired high microsomal instability (rat Cli = 14.6 mL/min/g; human Cli = 24.9 mL/min/g). When both compounds were tested in a rat in vivo pharmacokinetic experiment, moderate systemic exposure and high blood clearance were observed, emphasizing the need to identify compounds with much improved metabolic stability. The initial attempt to enhance metabolic stability focused on blocking the benzylic position of **29** (R = R′ = H), a likely site of metabolism, by the introduction of small alkyl and fluorine groups. Monomethyl, cyclopropyl, mono and bis-fluorinated analogs **29** were prepared, but all gave reduced potency relative to methylene benzylic modulator **29** (R = R′ = H) and retained high metabolic turnover. The methylene spacer not only created a potential site of metabolism but also increased the electron density of the phenyl ring, making it more prone to oxidation. Lowering the aromatic electron density by introducing substituents was considered, but was limited to fluorine atoms since the crystal structure of **29** (R = R′ = H) (PDB code 2xxh; Fig. 10) indicated that the benzene ring was in a narrow channel and that large substituents would not be tolerated. Fluorophenyl analog **30**, Fig. 8, was synthesized and had superior potency to **29** (R = R′ = H) ($pEC_{50} = 5.9$, Asym Max = 79%), slightly better human microsomal stability but significantly reduced solubility.

The lack of success in identifying homologated amides with a favorable in vitro DMPK profile prompted scientists at GSK to consider reversed amides with an embedded benzylamine core motif (Fig. 8: **31** and **32**). Tertiary, **31** (R = R′ = Me) and secondary, **32** (Fig. 8, R = H, R′ = Et and R = H, R′ = Me), acyclic amides were prepared and found to be highly potent ($pEC_{50} > 5.6$), but retained high to moderate intrinsic clearance in both RLM and HLM (3.3 < Cli < 22.4 mL/min/g). With the previous success of cyclic amides **10** and **27** (X = O) to yield compounds with reduced turnover, pyrrolidinone **32** (R = H) was synthesized and induced excellent potentiation of the AMPA ion channel ($pEC_{50} = 6.0$, Asym Max = 132%). Despite similar moderate rat microsomal clearance to **10** (Cli = 2.4 mL/min/g), modulator **32** (Fig. 8, R = H) had lower systemic exposure ($AUC_{0-t} = 231$ ng h/mL) and notably higher estimated blood clearance when tested in rats in vivo. Blocking a potential site of metabolism by introduction of a fluorine on the phenyl ring in **32** (R = F) successfully afforded a potent compound ($pEC_{50} = 6.0$, Asym Max = 112%) with slightly higher intrinsic stability in microsomes (rat Cli = 2.0 mL/min/g; human Cli = 2.9 mL/min/g). However this did not translate to a remarkably superior in vivo pharmacokinetic profile and compound **32** (Fig. 8, R = F) did not achieve the blood and brain levels observed with **10**. The majority of the reversed amides retained some undesired CYP450 inhibition, and solubility in this series was variable with the cyclic derivatives being the most soluble. Replacement of the amide moiety by sulfonamides, such as in **33** (Fig. 8: R = H or Me, R′ = Me or ^{c}Pr or ^{i}Pr) or in **34** (Fig. 8), produced active compounds, although moderately less potent than the amide analogs, but lacking any CYP450 inhibitory activity. These compounds also successfully achieved moderate to high microsomal stability in both rat and human microsomes (Cli < 2.5 mL/min/g) but were unfortunately, for the vast majority, too poorly soluble to be tested in vivo.

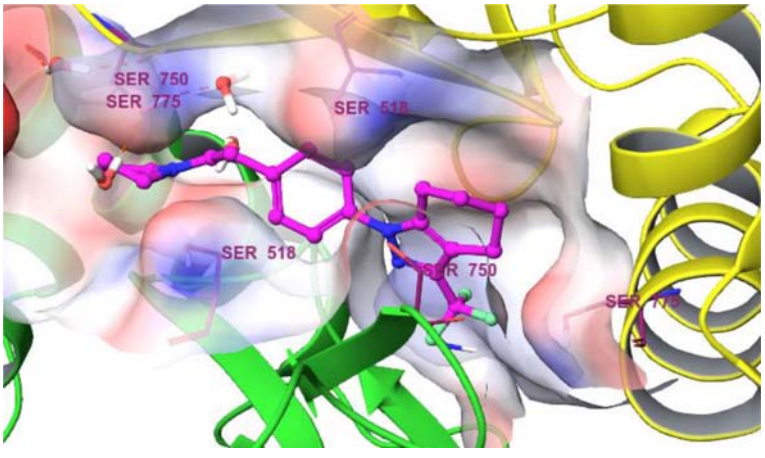

Fig. 10 X-ray crystal structure of homologated amide 29 with the hGLuA2i S1S2 LBD (PDB code 2xxh, 1.5 Å resolution).

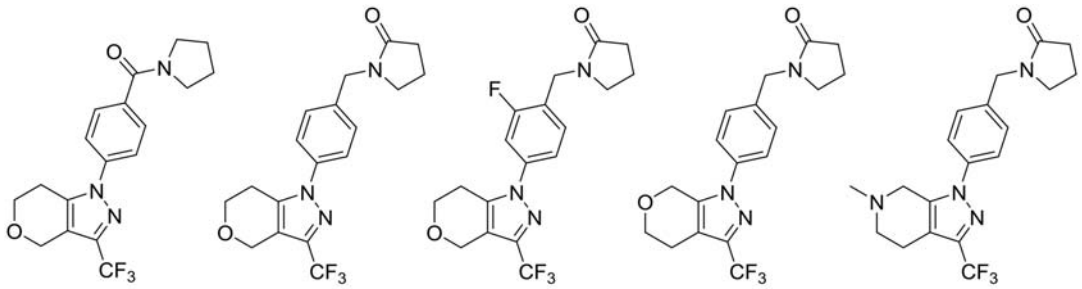

Fig. 11 Indazole derivatives containing a heteroatom in the saturated ring.

Having failed to identify compounds with low in vitro and in vivo turnover using a range of strategies, a selection of compounds was progressed to an in vitro metabolite identification study to develop a better understanding of the metabolic liabilities of the series. Interestingly the saturated part of the tetrahydroindazole was detected as a major site of metabolism and stabilization of this heterocycle was subsequently investigated. Introduction of heteroatoms (oxygen or nitrogen) in the aliphatic part of the tetrahydroindazole moiety was explored (**Fig. 11**) and successfully delivered active compounds with much improved in vitro properties. Overall, modulators **35**–**39**, **Fig. 11**, had lower intrinsic clearance in rat and human microsomes, higher solubility, lower logD, higher free fraction in both plasma and brain, and did not inhibit CYP450 enzymes. This resulted in high oral exposure, with low blood clearance and good CNS penetration, when the compounds were tested in rat pharmacokinetic experiments. These molecules, alongside the ones which previously gave the best exposures when profiled in vivo ($AUC_{0-t} > 400$ ng h/mL), were tested in electrophysiology, selectivity, developability, and early toxicology screens. From the results of these assays (data not disclosed), a set of five molecules (**10**, **27** (X = O), **33** (R = H, R′ = Me), **35**, and **37**), with excellent wider selectivity and clear potentiation of AMPAR-mediated currents in patch clamp assays, were identified as potential development candidates.

As mentioned earlier, AMPAR positive modulators have a tendency to induce convulsion, a recognized side-effect of this class of drugs.[43] The maximum electroshock seizure threshold (MEST) assay enables the identification of compounds which reduce seizure threshold and possess an undesirable proconvulsant activity.[114] The five selected compounds were profiled in MEST experiments and found to be devoid of any proconvulsant adverse effects. With the exception of compound **33** (R = H, R′ = Me), all the modulators were clean in preliminary genotoxic screens and were subsequently tested in in vivo cognition models. In the passive avoidance task model,[113] only modulators **10**, **35**, and **37** attenuated the scopolamine-induced amnesic deficit while modulator **27** (X = O) showed no effect. The three active molecules were then assessed in the NOR experiment,[112] a second in vivo behavioral model to evaluate cognition. In this model, only compound **10** showed a significant procognitive effect when administered at doses ranging from 0.1 to 1 mg/kg (PO). Hence tetrahydroindazole derivative **10**, which was identified early in the program, was selected as the preclinical candidate and evaluated further in a battery of in vitro and in vivo assays.

Similarly to hit **25**, development candidate **10** exhibited low solubility in water, simulated gastric fluid and fasted simulated intestinal fluid. Nonetheless the compound had excellent solution stability in all media tested and also high solid stability over time. In addition, compound **10** did not induce time-dependent inhibition of CYP450 isoforms 2D6 and 3A4, and did not inhibit hERG currents at 10 μM. Intrinsic turnover of the molecule was studied in both microsomes and hepatocytes across five different species: rat, dog, minipig, monkey, and human. Microsomal and hepatocyte clearances were correlated well and highlighted interspecies differences, with low to moderate instability in rat, dog, and human, and high turnover in minipig and monkey. In vivo pharmacokinetic profiling of modulator **10** in four species (rat, dog minipig, and monkey) indicated good tissue distribution, with a volume of distribution at steady state in excess of total body water, a rapid oral absorption (0.5–1 h) and variable blood clearance across species (moderate in rat and high in the others). This resulted in short half-lives (0.5–1.6 h) and moderate to low oral bioavailability (2%–54%). The general good agreement between in vitro and in vivo clearances suggested a likely high systemic exposure in humans. In single and repeat dose oral toxicity studies of up to 4 weeks in rats and dogs, the clinical candidate exhibited a safe profile, giving a large therapeutic window. Surprisingly, AMPAR PAM **10** never entered clinical evaluation and GSK did not report or patent further exploratory work in the trifluoromethylpyrazole series.

7.11.3.3.2 HTS and hybridization strategies by Pfizer

Pfizer is another pharmaceutical group which has shown a strong interest in AMPAR modulation and has filed four patent applications between 2008 and 2010.[115–118] The company has published the most recent scientific literature in the area, with three journal articles since 2013,[59,119,120] and is probably the last pharmaceutical group to have joined the race to discover and commercialize an AMPAR PAM. In these recent publications, Pfizer describes the discovery and optimization of two chemical series, one of which has led to the discovery of clinical candidate PF-04958242,[59] believed to be the only AMPAR potentiator still actively evaluated in clinical trials for neurological disorders.

The majority of AMPAR modulators described in the literature were identified and characterized in vitro using recombinant systems, which do not reproduce the structural complexity of AMPARs found in vivo (see section **Introduction**) and possess

a risk that data generated using homotetrameric receptors will not translate reliably to native tissues. To mitigate this risk early, Pfizer developed an assay employing mouse embryonic stem (mES) cell-derived neurons, which are expected to represent more accurately the considerable heterogeneity of composition of AMPARs found in biological organisms and afford composite pharmacological values.[121] This assay, which was optimized for a HTS campaign and ran on a FLIPR platform, provided two quantifiable parameters: an EC_{50} obtained from a 9-point concentration-response curve and a maximal efficacy percentage (E_{max}), normalized to the average response to 100 μM of AMPA in the presence of 32 μM of cyclothiazide, which was defined as 100%. Screening the Pfizer compound library using this newly developed assay led to the identification of dihydroisoxazole (DHI) hit **40**, **Table 4**.[119] Despite showing moderate potency in the FLIPR mES assay ($EC_{50} = 4.4$ μM), modulator **40** had favorable calculated physicochemical properties and was, as a result, profiled in an array of in vitro DMPK assays (see **Table 4**). Interestingly, compound **40** had good permeability with no P-gp liability and moderate clearance in HLM, confirming that it was an attractive starting point for an optimization program that would primarily focus on improving the potency while maintaining optimal CNS physicochemical and ADME (absorption, distribution, metabolism, and excretion) properties.

A cocrystal structure of DHI **40** with the LBD of hGluA2o was determined (PDB code 4lz7; **Fig. 12**) and revealed that the phenyl ring sits on the twofold axis and that the acetamide projects into one of the deep hydrophobic pockets, similar to the *iso*propyl sulfonamide group in LY451395 **7**. The pyrrolidine ring approaches Asn775 but does not participate in any distinct interaction. Intriguingly, unlike GSK researchers, scientists at Pfizer did not comment on the network of water molecules present at the dimer interface of the two LBD subunits and their potential displacement or interaction with modulator **40**.

From this crystal structure, it was initially suggested that replacement of the acetamide by a sulfonamide could afford molecules with superior binding affinity since docking of a sulfonamide group provided a better fit for the hydrophobic pocket. The *iso*propylsulfonamide of the phenethyl series was introduced on the DHI core, giving **41** (**Fig. 13**), which was 35-fold more active than **40**

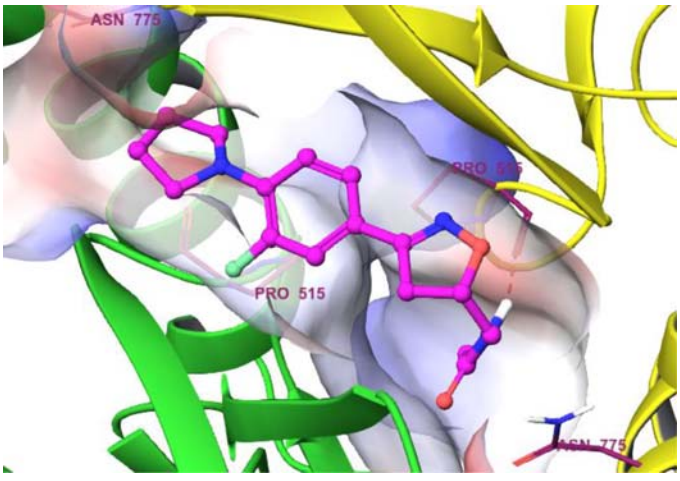

Fig. 12 X-ray crystal structure of DHI hit 40 with the hGLuA2o S1S2 LBD (PDB code 4lz7, 2.1 Å resolution).

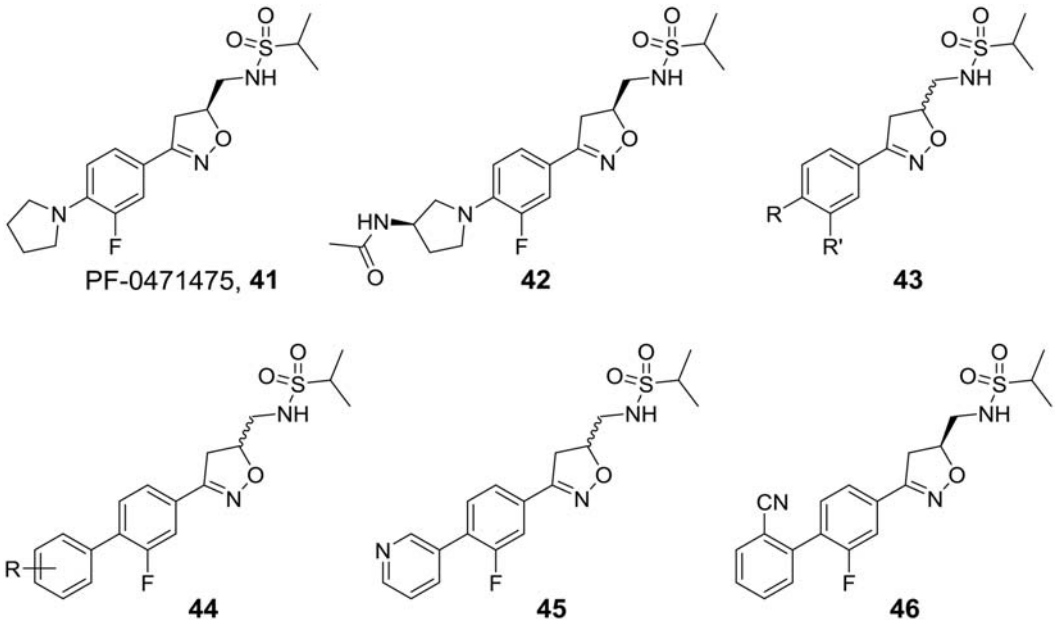

Fig. 13 Representative structures of DHI derivatives prepared during the lead optimization campaign.

($EC_{50}=123$ nM, $E_{max}=147\%$), confirming the design hypothesis. Compound **41** retained desirable CNS drug-like properties (MWt = 369 g/mol, clogP = 3.0, TPSA = 79 Å^2), had moderate predicted human blood clearance (Cl = 13.5 mL/min/kg), showed good permeability with no P-gp efflux in the MDR1-MDCK assay ($P_{app}=18.6\times10^{-6}$ cm/s, ER = 1.45). The enantiomer of **41** was significantly less active, confirming that molecules with the *S* stereochemistry provided the best fit in the binding pocket. A variety of small amides and sulfonamides were prepared to probe the SAR of this part of the scaffold, but all induced a loss of potency. Replacing the amide with carbamates or ureas was also unsuccessfully investigated. Removal of the pyrrolidine produced an inactive compound (Fig. 13: **43**; R = H, R′ = F; $EC_{50}>32$ μM), while des-fluoro racemate **43** (R = pyrrolidine, R′ = H) was only slightly less active ($EC_{50}=253$ nM, $E_{max}=169\%$) but was attractively slightly less lipophilic (clogP = 2.75).

Docking of **41** into the crystal structure of **40** was performed to help identify additional means to increase the functional potency of this series, and indicated that the second symmetrical hydrophobic pocket could be accessed through substitution of the pyrrolidine. Hence an acetamide was introduced at the 3-position of the pyrrolidine affording **42**, Fig. 13, an exceptionally active potentiator ($EC_{50}<10$ nM, $E_{max}=143\%$), whose postulated binding interactions were confirmed by X-ray cocrystal structure (Fig. 14, PDB code 4lz8). A tritiated form of this potent modulator was prepared to develop an in-house AMPAR competition binding assay.

The development of a low nanomolar potentiator which occupies both hydrophobic pockets of the LBD was done at the expense of the physicochemical properties of **42** (MWt = 427 g/mol, TPSA = 109 Å^2) and resulted in poor permeability and P-gp mediated efflux ($P_{app}=3.9\times10^{-6}$ cm/s, ER = 12.1). Consequently, compound **42** had low CNS exposure in a mouse pharmacokinetic study,

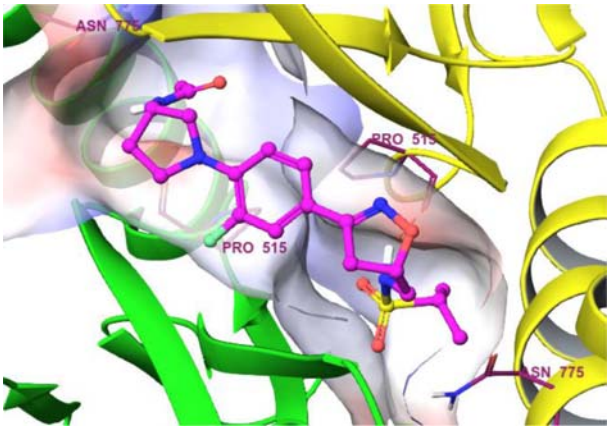

Fig. 14 X-ray crystal structure of compound 42 with the hGLuA2o S1S2 LBD (PDB code 4lz8, 1.85 Å resolution).

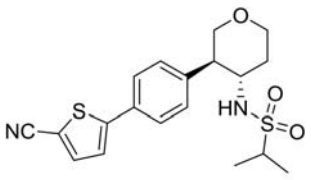
precluding its use in vivo. Therefore the SAR around the pyrrolidine ring was revisited with the objective to obtain compounds with lower TPSA and also to remove the aniline moiety which represented well-documented concerns.[122,123] From the crystal structure of **40** and **42**, it appeared that replacing the pyrrolidine with a second aromatic ring would be tolerated, and a series of biaryl derivatives was prepared. While phenyl analog **44** (Fig. 13, R = H) had low affinity for AMPARs ($EC_{50} = 3.2$ μM, $E_{max} = 138\%$), pyridyl derivative **45**, Fig. 13, retained acceptable potency ($EC_{50} = 294$ nM, $E_{max} = 157\%$). Molecular modeling of the biaryl template suggested that a nitrile group at the *ortho* position of the distal aromatic could access the hydrophobic pocket, providing superior binding affinity. This design hypothesis was confirmed since racemate **44** (Fig. 13, R = 2-CN) had similar potency to **41** ($EC_{50} = 87$ nM, $E_{max} = 152\%$) and the *S*-enantiomer **46** was again the most potent ($EC_{50} < 10$ nM). Modulator **46** retained good calculated physicochemical properties (MWt = 401 g/mol, clogP = 3.8, TPSA = 100 $Å^2$), had moderate predicted human hepatic clearance (Cl = 9.67 mL/min/kg) and was highly permeable ($P_{app} = 29.1 \times 10^{-6}$ cm/s; ER = 1.18). Disappointingly, no additional ADME, selectivity or in vivo pharmacokinetic data were given for this very promising compound. In addition, it should be noted that no solubility or CYP450 inhibitory data are communicated on any of the compounds described earlier.[119]

In this publication, detailed pharmacokinetics and pharmacodynamics were only reported for compound **41**, despite modulator **46** being in appearance the most attractive compound. In their in vivo assessment, the Pfizer group demonstrated a marked interest to the unbound brain compound concentration ($C_{b,u}$), which determines AMPAR LBD interactions, and developed a $C_{b,u}$-normalized AMPAR-mediated exposure-response continuum to define an acute dose rodent-based TI. Such studies were carried out since AMPAR overstimulation has been associated with excitotoxicity[39,43,44] and for this reason defining the toxicity threshold in rodents was viewed as crucial by Pfizer scientists before advancing any drug of this pharmacological class to large animal safety and efficacy models.

Potentiator **41** had high rat protein plasma binding (97.3%) and rat brain tissue binding in brain homogenates (98.6%). In a rat pharmacokinetic study, following single subcutaneous (SC) dosing (0.2 mg/kg), compound **41** had a short terminal half-life ($t_{1/2} = 0.4$ h), a total brain to total plasma concentration ratio of 1.04 and an unbound brain to unbound plasma concentration ratio of 0.54, confirming that DHI **41** was CNS-penetrant. The convulsion liability, a recognized side-effect of AMPAR PAMs,[44] was first studied in CD-1 mice and detected 5–11 min postdose in one third of the animals following SC administration of 0.32 mg/kg of **41** and in all animals at a higher dose (0.56 mg/kg, SC). Bioanalysis of brain samples from these mice indicated that a 2.1 nM mean $C_{b,u}$ of potentiator induced convulsion. The same study was repeated in Sprague-Dawley rats where the exposure convulsion threshold was similar with a toxic $C_{b,u}$ of 2.3 nM.

The efficacy of potentiator **41** was first assessed in a modified version of the cerebellum cyclic guanosine monophosphate (cGMP) assay, published by Lilly[124] to evaluate the effect of their AMPAR modulators on the accumulation of cGMP, a downstream messenger involved in a signaling cascade regulating excitatory neurotransmission and neuroplasticity. It was determined that cGMP levels increased with statistical significance in CD-1 mouse cerebellum 30 min after SC dosing of 0.32 mg/kg of **41**, corresponding to a mean $C_{b,u}$ of 0.4 nM. Surprisingly, it is not mentioned if the effect of **41** on cGMP elevation occurred in a dose-dependent manner and as mentioned earlier, this same dosing regimen (0.32 mg/kg, SC) also induced convulsion in one third of the mice, supporting the idea that lower doses must have been investigated but for which no result is reported. Urethane-anesthetized rats, treated with the NMDAR antagonist MK-801, which induces a schizophrenic state, were used as an in vivo model to measure the nootropic electrophysiological effects of **41** administered intravenously. A minimal effective dose of 0.003 mg/kg (IV) of **41** was required to significantly reverse the MK-801-induced schizophrenic effect. From a pilot rat IV pharmacokinetic study (0.01 mg/kg), it was extrapolated that the reversal effect, which occurred after 5 min, corresponded to a $C_{b,u}$ of 0.004 nM, giving a 500-fold TI for convulsion relative to procognitive electrophysiological enhancement in rats. In the majority of the pharmacokinetic and pharmacodynamic experiments described earlier, DHI **41** was administered subcutaneously and no justification was given in this first publication for choosing this preferred mode of administration, which is not desired for clinical evaluation. However in a subsequent article,[120] it was mentioned that SC administration was predominantly used to control the variability in C_{max} and prevent the generation of any potential first-pass active metabolites. Pfizer did not mention if further biological studies were being undertaken with this compound, such as in vivo cognition behavioral experiments, or assessment of memory related effects in nonrodent species or if focus had shifted to potentiator **46**. No additional data have been reported on either compound since 2013. From this study, it should be noted that the use of SBDD positively informed GluA2-based SAR and allowed the group to quickly prepare potent modulators.

In a second publication from 2013,[120] Pfizer presented extensive efficacy and safety profiling on a single compound, PF-04778574 **47** (Fig. 15), which was originally disclosed in a patent[115] and for which no medicinal chemistry rational design



PF-04778574, **47**

Fig. 15 Chemical structure of PF-04778574.

has yet been revealed. As previously mentioned, AMPAR overstimulation can be excitotoxic and AMPAR potentiators have been associated with marked adverse events in preclinical studies.[43] Conscious of this risk, Pfizer designed a sequence of in vitro and in vivo assays to aid the selection of preclinical species to assist in the identification of safe compounds early in lead optimization campaigns and understand potentiator exposures causing desired versus harmful effects. In this article, the Pfizer scientists reported how they applied their safety and efficacy assessment cascade to carefully define a PF-04778574 mechanism-based TI in mice and study its translatability from rodents to higher-order species, by developing an interspecies exposure-response model.

In the in vitro mES FLIPR assay, which was used for the screening campaign in the work described earlier, PF-04778574 concentration-dependently enhanced *S*-AMPA calcium influx through the heterogeneous mixture of AMPARs expressed ($pEC_{50} = 6.05 \pm 0.19$ and $E_{max} = 162\% \pm 24\%$). In the in-house competitive binding assay, modulator PF-04778574 had a Ki of 85 nM and was also found to be devoid of any agonistic effect in three different assays, corroborating the assumed mode of action. Results from these two experiments confirmed that PF-04778574 was a subtype-independent AMPAR PAM. As expected, the compound also potentiated the effect of *S*-AMPA on HEK293 cells expressing either recombinant hGluA2i or hGluA2o in a FLIPR assay, with similar efficacy on both isoforms (flip: $pEC_{50} = 7.35 \pm 0.11$ and $E_{max} = 111\% \pm 6\%$; flop: $pEC_{50} = 7.05 \pm 0.07$ and $E_{max} = 112\% \pm 5\%$), demonstrating an absence of selectivity between these two receptor subtypes. Whole-cell patch clamp electrophysiology on primary cultures of rat cortical neurons, expressing native populations of AMPARs, was used to study the functional potency of PF-04778574 on *S*-AMPA-evoked currents. In that assay, PF-04778574 clearly increased the electric current induced by 30 μM of *S*-AMPA from a concentration of 30 nM and had an EC_{50} of 282 nM.

The protein plasma binding of PF-04778574 was measured across a range of species (CD-1 mice, Sprague-Dawley rats, beagle dogs, cynomolgus monkeys) and found to be moderate (91.2% –95.2%). Interestingly the brain tissue binding was markedly higher (98.0%) and considered species-independent.[125] These two parameters were used to calculate the unbound drug concentration in the plasma ($C_{p,u}$) and the brain ($C_{b,u}$) from measured total plasma and total brain concentrations. To reduce the number of animals sacrificed in the efficacy and safety pharmacodynamic studies, $C_{b,u}$:$C_{p,u}$ ratios in four animal models (mouse, rat, dog, and monkey) were experimentally determined to subsequently allow calculation of a $C_{b,u}$ from a measured $C_{p,u}$, when brain tissues were not collected. This conversion of a $C_{p,u}$ into a $C_{b,u}$ relies on the assumption that $C_{b,u}$:$C_{p,u}$ ratios are constant over time, which is not always the case. The free drug ratios determined in neuropharmacokinetic experiments ranged from 0.42 (mouse) to 0.73 (monkey), indicating good CNS permeability and low interspecies variability from rodents to large animals (< 1.7-fold differences). A number of acute pharmacokinetic experiments in different animal models, using alternative mode of administration and various doses of PF-04778574, were then conducted to obtain a selection of dose–$C_{b,u}$–time relationships.

From these experiments, it should be noted that following intravenous administration of PF-04778574 (0.2 mg/kg) in rat, the blood clearance was more than twice in excess of total liver blood flow (Cl = 250 mL/min/kg), the volume of distribution was high ($V_d = 4.59$ L/kg) and the half-life very short ($t_{1/2} = 0.24$ h), indicating poor systemic stability of PF-04778574 in rats. The compound was noticeably more stable in dogs following oral dosage (0.1 mg/kg) with a moderate blood clearance (Cl = 8.01 mL/min/kg), a high volume of distribution ($V_d = 2.1$ L/kg), and a moderate half-life ($t_{1/2} = 3.1$ h). PF-04778574 was rapidly absorbed in dogs ($T_{max} = 0.75$ h) and had acceptable systemic exposure ($C_{max} = 56.0$ ng/mL and $AUC_{0-\infty} = 210$ ng h/mL). In monkeys, PF-04778574 was administered subcutaneously at two doses (0.1 and 0.32 mg/kg) affording a moderate mean half-life ($t_{1/2} = 3.4$ h) and a T_{max} around 2 h. Positively, maximal plasma drug concentration (C_{max}) and $AUC_{0-\infty}$ values suggested linear pharmacokinetics across this dosing range. Unfortunately, no in vitro clearance assessments in microsomes or hepatocytes were given and it is impossible to say if the overall high in vivo metabolic turnover of PF-04778574 could have been predicted from the in vitro data.

Once all the pharmacokinetic studies had been carried out, modulator PF-04778574 was characterized in a selection of in vivo pharmacodynamic models to correlate the unbound brain drug concentration ($C_{b,u}$) with the observed pharmacological effects. To rule out any non-AMPAR-mediated in vivo pharmacological effect, PF-04778574 was screened at 10 μM against a panel of 118 enzymes and receptors, and found to express a high degree of selectivity for the AMPAR with only minimal inhibitory activity on the dopamine transporter ($IC_{50} = 0.95$ μM).

The in vivo efficacy of PF-04778574 was first assessed in the cGMP assay similarly to compound **41**. cGMP elevation in the cerebellum of CD-1 mice occurred dose-dependently and was statistically significant from a SC dose of 0.32 mg/kg of drug, the other doses evaluated being 0.1 and 1 mg/kg SC. Using the pharmacokinetic models developed in CD-1 mice and assuming linear pharmacokinetics across the doses tested, it was determined that $C_{b,u}$ superior to 1.7 nM would induce a significant increase in cerebellar cGMP levels. In this article, Pfizer also suggested that changes in cerebellar cGMP levels correlate with the potential of compounds to display adverse events. However it should be noted that this assay was originally developed to study the efficacy of the AMPAR modulators but not their safety.[124] In urethane-anesthetized rats, a dose of 0.1 mg/kg (IV) of PF-04778574 significantly overcame the electrophysiological hypoglutamatergic conditions induced by the NMDAR antagonist MK-801. The restorative effect occurred between 5 and 25 min postdose and was projected to correspond to $C_{b,u}$ ranging between 0.98 and 0.35 nM, respectively. Additionally, a 0.03 mg/kg dose (IV) of the compound, translating to a maximal projected $C_{b,u}$ of 0.30 nM, was ineffective in this assay, indicative of a minimal effective $C_{b,u}$ close to 0.30 nM. Since modulator **47** improved impaired synaptic transmission over a large concentration range, it was then tested in a behavioral cognition model, the monkey ketamine-disrupted spatial delayed response task.[68] In this behavioral model, PF-04778574 was tested over a 100-fold dose range (0.001, 0.01, and 0.1 mg/kg, SC), but only significantly reversed the ketamine-induced impaired performance at 0.01 mg/kg (SC), suggesting that the compound had a hormetic exposure-response,[126] typical of nootropic drugs. From the pharmacokinetic model

experiments in primate, this dose projected to a mean $C_{b,u}$ of 0.38 nM. Interestingly the readouts of the two in vivo efficacy models were consistent and suggested that **47** induced procognitive effects from an unbound brain drug concentration of around 0.35 nM.

The amplitude of adverse events caused by AMPAR potentiators is generally progressive, first manifesting as disruption of motor coordination and ultimately leading to convulsion. The tremorgenic potential of AMPAR modulator **47** was evaluated in mice undergoing an accelerating rotarod assay 30 min postdose. In this assay, low doses (0.178 and 0.32 mg/kg, SC) were not associated with a decrease animal fall latency and only a dose of 0.56 mg/kg (SC) of PF-04778574, projecting to a $C_{b,u}$ of 4.8 nM, induced statistically meaningful motor deficits. In addition to the motor coordination disruption observed in the rotarod test, a number of tremorgenic events were unexpectedly recorded during the initial pharmacokinetic studies. Hence general tremor was observed in dogs at $C_{b,u}$ ranging from 6.0 to 15.6 nM and movement-related tremor/ataxia was detected in monkeys at $C_{b,u}$ ranging from 8.0 to 24.1 nM. In these two species, the $C_{b,u}$ inducing tremorgenic side-effects were similar but were two to three times higher than in mice. Convulsion, a more severe side-effect, which has been associated with a significant number of AMPAR PAMs, was assessed in dose-response studies across three species (mice, rats, and dogs) to evaluate a potential interspecies consistency in $C_{b,u}$ causing convulsions. In CD-1 mice, among the three doses tested (1, 1.78, and 3 mg/kg, SC), only the highest two induced general convulsions and this extrapolated to a minimal convulsion-causing $C_{b,u}$ of 9.6 nM. The delay to observe convulsions following dosing was greater for the 1.78 mg/kg (SC) group (23 min) relative to the 3.2 mg/kg (SC) group (7 min), which was consistent with the "threshold" nature of this adverse event. In rats, the two highest doses evaluated (3.2 and 5.6 mg/kg, SC) induced convulsions and the same dose-dependent adverse event delay as in mice was observed. The convulsive-exposure threshold in this species translated to a projected $C_{b,u}$ of 10.7 nM. In dogs, tremorgenic events were observed at the low doses investigated (0.2 and 0.25 mg/kg, PO), but generalized convulsions only occurred following a dose of 0.5 mg/kg (PO) of **47**, corresponding to a $C_{b,u}$ of 17.4 nM. The PF-04778574 $C_{b,u}$ causing convulsion was consistent in rodents (9.6 and 10.7 nM), slightly higher in dogs (17.4 nM) and could be expected to be even higher in primates, since tremorgenic events happened at doses of up to 24.1 nM.

The data generated showed that motor coordination disruption was the dose-capping adverse effect and that PF-04778574 showed adequate separation between $C_{b,u}$ linked to efficacy and harmful effects with TI of 7–13, 16–29, and 22–42 in mice, dogs, and monkeys, respectively. Overall, the exposure-response physiological effects were mainly consistent across species, suggesting a translatable relationship from rodent to higher-order species. Escalating unbound brain concentrations progressively led from efficacy to cerebellar cGMP elevation to motor coordination disruptions to convulsion. From these studies and a number of subsequent assumptions, the scientists at Pfizer concluded that PF-04778574, with a projected 8–16-fold TI in humans for self-limiting tremor, might be safely evaluated clinically as a nootropic drug in schizophrenic patients. Despite this conclusion, the compound never entered clinical evaluation and no further results with this AMPAR potentiator have been reported since 2013.

In a final publication from 2015, scientists at Pfizer reported the discovery, SAR and optimization of clinical candidate PF-04958242 **11**.[59] In addition to the identification of new templates from HTS such as the DHI series described previously, Pfizer also explored modification of Lilly's biaryl *iso*propylsulfonamide LY451646 **48** (Fig. 16), with the objective to discover a series with improved efficacy, selectivity, and metabolic stability relative to **48**. Synthetic tractability strongly influenced chemistry route design to enable library synthesis and quick expansion of the SAR around the biaryl scaffold. From their initial studies with AMPAR modulators, the scientists at Pfizer understood the importance of identifying compounds with low human pharmacokinetic

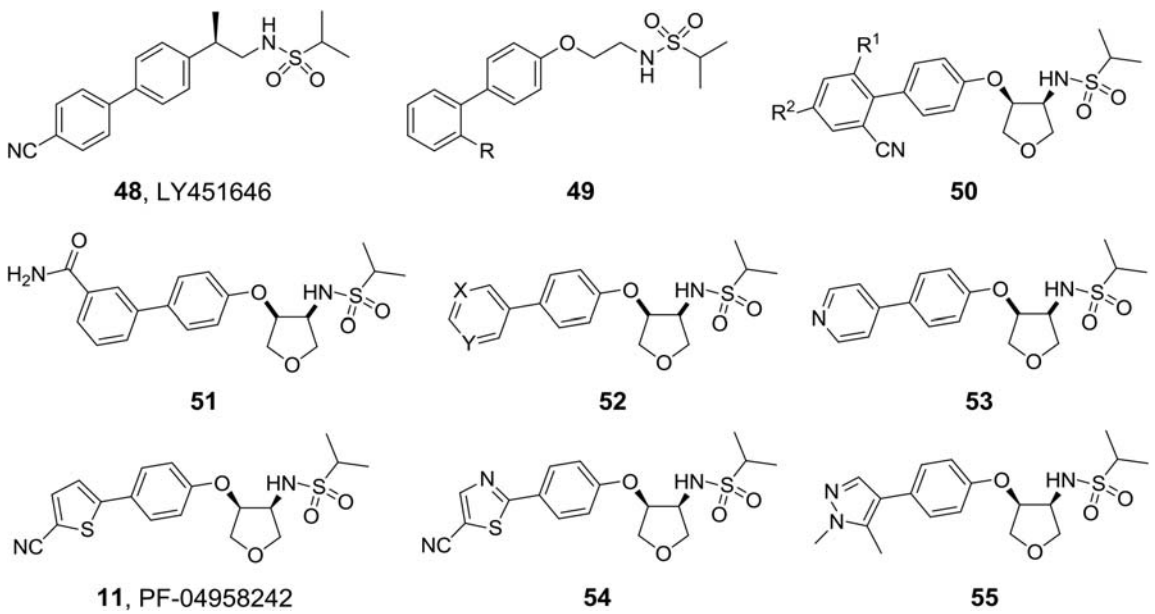


Fig. 16 Representative structures of the derivatives investigated during the lead optimization which led to the identification of PF-04958242.

variability to accurately predict the C_{max} and prevent occurrence of threshold-mediated adverse events.[127] With this in mind, physicochemical properties of virtual targets imparting ADME properties were carefully examined to only prepare compounds likely to develop into good oral CNS drugs with the targeted pharmacokinetic profile.

LY451646 **48** was tested in the FLIPR mES assay developed by Pfizer to set a benchmark and only produced moderate activity ($EC_{50}=3.4$ μM, $E_{max}=132\%$). A number of initial design hypotheses, including investigation of different vectors around the central aryl ring, replacement of the middle benzene with a heteroaliphatic ring and sulfonamide variation/replacement were unsuccessfully explored and afforded inactive compounds. Modulation of the linker was more successful, in particular introduction of an oxygen between the phenyl and the two-carbon linker resulted in active modulators, such as **49** (Fig. 16). In this ether subset, *para*-substitution was preferred, mimicking the SAR of the all-carbon linker series. Interestingly while the unsubstituted distal aromatic analog **49** (R = H) had similar potency to **48** but was significantly less efficacious ($EC_{50}=2.44$ μM, $E_{max}=32\%$), introduction of an *ortho*-cyano **49** (R = CN) had an opposite effect, giving a less potent compound with greater efficacy ($EC_{50}=7.35$ μM, $E_{max}=218\%$), suggesting a potential functionally favorable contact of the cyano with the AMPAR LBD interface.

The X-ray crystal structure of LY451646 **48** in complex with the LBD of hGluA2o (PDB code 4lz5) indicated that the *iso*propylsulfonamide NH forms a hydrogen bond with the carbonyl oxygen of Pro515 and occupies one of the deep lipophilic pockets, similarly to modulators of the sulfonamide class. The biaryl core was sitting along the twofold axis, projecting to the symmetrical binding pocket. Docking of **49** (R = CN) into this crystal structure indicated that the *ortho*-cyano was ideally positioned to access the symmetrical hydrophobic space occupied by the *iso*propylsulfonamide at the other end of the inverted U-shaped binding pocket. This binding model prompted the team at Pfizer to conformationally restrict the amido-alkoxyethane linker to preorganize the ligand for binding and obtain potentiators with superior pharmacological activity. Hence a number of *cis* and *trans* 1,2-dihalo 5- and 6-membered rings were designed and prepared. Examination of the physicochemical properties of these molecules and consideration of prior findings from GSK on an almost identical series, incited Pfizer to focus on *cis*-THF ether analogs.

A significant improvement in functional efficacy was observed following the introduction of the THF-ether linker and chiral separation indicated that the (3*S*,4*S*)-isomers were notably more potent than their (3*R*,4*R*)-counterparts. Despite high functional efficacy ($EC_{50}=217$ nM, $E_{max}=143\%$) and good permeability with no P-gp efflux in the in vitro MDR1–MDCK assay ($P_{app}=32.3\times10^{-6}$ cm/s; ER = 1.39), compound **50** (Fig. 16: $R^1=H$, $R^2=H$) suffered from undesirable high turnover in HLM (Cli = 158 mL/min/kg). To improve the metabolic stability, fluorine atoms were introduced on the distal phenyl, which was a likely source of CYP450-mediated hydroxylation, and afforded functionally active compounds with improved but still suboptimal human microsomal turnover, such as **50** ($R^1=F$, $R^2=H$, $EC_{50}=14.1$ nM, $E_{max}=126\%$, Cli = 89 mL/min/kg) and **50** ($R^1=H$, $R^2=F$, $EC_{50}<10$ nM, $E_{max}=190\%$, Cli = 39 mL/min/kg). Addition of polar groups to the phenyl ring successfully lowered the clearance but concomitantly induced a reduction of potency (Fig. 16: **51**, $EC_{50}=1.11$ μM, $E_{max}=102\%$) and negatively impacted properties governing CNS permeability (**51**, $P_{app}=17.4\times10^{-6}$ cm/s; ER = 7.84). Replacement of the *ortho*-cyanophenyl with 6-membered heteroaromatics such as **52** (Fig. 16: X = N, Y = C, or X = Y = N) and **53** caused a reduction of clogP and delivered compounds with low HLM clearance, high permeability, no P-gp liability and acceptable functional potency ($0.62<EC_{50}<1.16$ μM, $110<E_{max}<161\%$). A selection of substituted 5-membered heteroaromatic derivatives (Fig. 16: **11**, **54**, **55**) was also synthesized and afforded compounds with superior functional activity compared to the 6-membered heteroaromatics. Of these compounds, potentiator **11** which had good activity in the FLIPR mES assay ($EC_{50}=310$ nM, $E_{max}=110\%$), low HLM clearance (Cli < 8 mL/min/kg) and high predicted CNS exposure from the MDR1–MDCK assay ($P_{app}=19.3\times10^{-6}$ cm/s; ER = 1.05) was selected for further profiling.

An X-ray cocrystal structure of **11** bound to the LBD interface of hGluA2o (PDB code 4x48, Fig. 17) indicated that the *iso*propylsulfonamide was making similar contacts with the protein as **48**, and that the cyano group was in the vicinity of Asn775 possibly impacting on the flip/flop selectivity of modulator **11**.

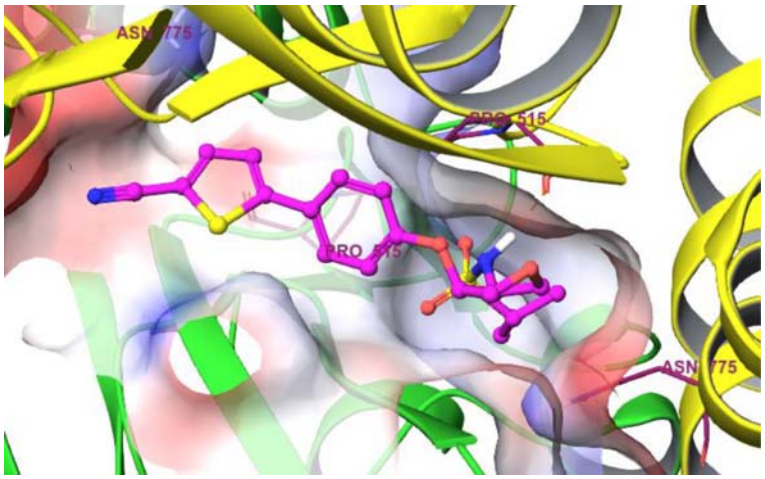

Fig. 17 X-ray crystal structure of 11 bound to hGluA2o S1S2 LBD (PDB code 4x48, 1.89 Å resolution).

The in vitro potency and efficacy of PF-04958242 **11** was assessed in a selection of assays to evaluate its species, subunit and splice variant selectivity profile. Although no data are given, the authors mentioned that **11** was equipotent in mouse and human ES cell-derived neurons, indicating interspecies uniformity. In cells expressing recombinant hGluA2 receptors, compound **11** increased *S*-AMPA-mediated Ca^{2+} influx with some selectivity for the flip (hGluA2i (Ser775), $EC_{50} = 24$ nM, $E_{max} = 124\%$) over the flop isoform (hGluA2o (Asn775), $EC_{50} = 880$ nM, $E_{max} = 124\%$). In a whole-cell patch clamp electrophysiology experiment on primary cultures of rat cortical neurons, modulator **11** significantly enhanced *S*-AMPA-evoked current ($EC_{50} = 43 \pm 10$ nM). To ascertain that the pharmacological effects observed when testing PF-04958242 in vivo were solely AMPAR-mediated, the selectivity of **11** was determined against a panel of 118 human-based ion channels, receptors, and enzymes. At the concentration tested (10 μM), compound **11** had good selectivity for AMPAR with detectable affinity for only three other receptors and enzymes, the most potent interaction being with the serotonin transporter (Ki = 530 nM). The plasma protein binding of **11** was moderate in the three species tested (rat: 95.2%; dog: 93.0%; monkey: 89%) while its rat brain protein binding was relatively high (98.1%), consistent with the moderate calculated lipophilicity of **11** (clogP = 3.54). Inhibition of seven major CYP450 isoforms by modulator **11** was low, with only detectable inhibition of CYP2D6 ($IC_{50} = 18$ μM). Unfortunately only this limited set of in vitro ADME properties was given, and important parameters, such as compound solubility, hERG inhibition, CYP induction, reactivity with glutathione, and genotoxicity, were not discussed.

A similar approach to the one used to study the effects of PF-04778574 in vivo was employed and $C_{b,u}$ (unbound brain concentrations) were calculated for each animal/dose/time/administration mode to establish a $C_{b,u}$-normalized AMPAR-mediated exposure-response continuum for clinical candidate **11**, enabling the assessment of AMPAR-dependent activities related to nootropic effects and safety. Single-dose neuropharmacokinetic experiments were conducted in CD-1 mice and Sprague-Dawley rats to determine $C_{b,u}$:$C_{p,u}$ ratios, treated as constant over time, and subsequently allow calculation of a $C_{b,u}$ from a measured $C_{p,u}$ at multiple time-points. The experimentally measured C_b:C_p and $C_{b,u}$:$C_{p,u}$ ratios ranged from 0.59 to 1.5, confirming the good CNS permeability of **11**, as predicted by the MDR1-MDCK assay. The neuropharmacokinetic experiments in rat (1 mg/kg, SC; 0.01 mg/kg, IV) indicated that **11** had similar terminal half-life, ranging from 0.53 h to 0.76 h, and T_{max} (0.75 h) in plasma, cerebrospinal fluid, and brain. Following intravenous administration in rat (0.2 mg/kg), PF-04958242 had very high blood clearance (Cl = 169 mL/min/kg), very short half-life ($t_{1/2} = 0.31$ h), high volume of distribution ($V_d = 3.6$ L/kg), and low systemic exposure ($AUC_{0-\infty} = 20.1$ ng h/mL), indicating poor plasma stability in rats. When administered orally to rats (3 mg/kg), **11** was rapidly absorbed ($T_{max} = 0.25$ h), had a longer half-life ($t_{1/2} = 0.84$ h) and acceptable systemic exposure ($C_{max} = 134.0$ ng/mL and $AUC_{0-\infty} = 175$ ng h/mL), gave rat oral bioavailability of 58%. In higher-order species, the half-life was greater ($t_{1/2} = 6.21$ h in dogs (0.1 mg/kg, PO), $t_{1/2} = 12.3$ h in monkey (0.032 mg/kg, SC)), the C_{max} was lower and the systemic exposure consistent (in dogs, $C_{max} = 23.9$ ng/mL and $AUC_{0-\infty} = 158$ ng h/mL; in monkeys, $C_{max} = 6.87$ ng/mL and $AUC_{0-\infty} = 149$ ng h/mL).

Elevation of cerebellar cGMP in CD-1 mice occurred dose-dependently 30 min after administration of compound **11** and was statistically significant from a dose of 1 mg/kg (SC). From the neuropharmacokinetic models previously established in CD-1 mice following SC dosing of **11**, it was determined that a projected $C_{b,u}$ of 6.7 nM induced cGMP elevation in CD-1 mice cerebellum. In urethane-anesthetized rats, a dose of 0.01 mg/kg (IV) of **11** significantly overcame the electrophysiological hypoglutamatergic conditions induced by the NMDAR antagonist MK-801, projecting to $C_{b,u}$ ranging between 0.23 and 0.18 nM. The compound was then tested in a second behavioral cognition model, the ketamine-disrupted spatial working memory in the radial arm maze, in which it attenuated the ketamine-evoked memory loss at doses ranging from 0.0032 to 0.032 mg/kg (SC), protecting to $C_{b,u}$ between 0.029 and 0.29 nM according to the SC rat pharmacokinetic study. Higher doses (0.1 and 0.32 mg/kg, SC) were ineffective, indicating a hormetic exposure-response for this nootropic agent.

The tremorgenic potential of potentiator **11** was assessed in C57BL/6J mice undergoing an accelerating rotarod assay 30 min postdose. In this test, low doses (0.1 and 0.178 mg/kg) were safe and only 0.32 mg/kg (SC) of PF-04958242, projecting to a $C_{b,u}$ of 10.8 nM, induced statistically meaningful motor deficits. The convulsion liability of potentiator **11** was not described, although it can be assumed from the previous studies that $C_{b,u}$ superior to 10.8 nM will be required to cause convulsion. From these studies, PF-04958242 had a 37-fold TI in rodents.

The intrinsic turnover of **11** was studied in rat and dog hepatocytes (rat Cli ≤ 63.6 mL/min/kg and dog Cli ≤ 7.4 mL/min/kg) and found to be consistent with the respective in vivo clearance. The good agreement between in vitro and in vivo clearances, and the moderate human hepatocyte clearance of the molecule (Cli ≤ 7.1 mL/min/kg) suggested a likely moderate to high systemic exposure in humans. Metabolite identification studies, indicated that compound **11** underwent similar turnover in dog and human systems, with THF hydroxylation and *O*-dealkylation identified as the major routes of metabolism. Studies using major recombinant human cytochrome P450 isoforms indicated that hepatic turnover *via* CYP2C19 and CYP3A4 would be the predominant human clearance pathways.

These positive results prompted Pfizer to evaluate PF-04958242 in 90 day regulatory toxicology studies in rats and dogs, in which clinical candidate **11** achieved adequate TIs, suggesting that the compound could be safely evaluated in the clinic. Simcyp software was used to project clinical pharmacokinetic parameters from experimentally determined preclinical data and predicted an efficacious dose of 0.3 mg with a 12 h dosing interval. At the time of publication, AMPAR potentiator **11** had been tested in 11 phase I clinical trials and found to be safe and well tolerated in healthy volunteers, in patients with age-related sensorineural hearing loss and schizophrenic subjects on stable doses of antipsychotics and other psychotropic medications. The authors claimed that further clinical studies would focus on evaluating the nootropic effects of **11** in select neurodisease populations.

7.11.3.3.3 Evolution and optimization of the Cortex CX614 series

Cortex has worked in the area of AMPAR positive modulators for many years and has progressed several compounds into clinical trials, as described in the introduction of this article (see Tables 1 and 2). Nonetheless, the company has only published a limited number of medicinal chemistry papers and the majority of the chemical information was until recently contained within patents.[128–132] In particular, the structures of the early development compounds (CX516, CX546, CX614, and CX691, Fig. 18) are in the public domain, but little information, describing the SAR and DMPK properties of these molecules, has been disclosed. Four recent publications from the Cortex group describe the discovery of some later compounds, based on CX614 as a starting point.[133–136]

In the first scientific article,[135] the authors described the design of CX614 **57**, using an understanding of the mode of binding of aniracetam **1** to the AMPA protein and the application of conformational restriction to the benzamide scaffold to increase potency to low micromolar levels and obtain compounds with superior chemical stability. The pharmacological effect of the modulators developed by Cortex was evaluated using patch clamp electrophysiology on cultured rat hippocampal neurons. The activities were reported as EC_{2x}, defined as the concentration of potentiator required to double the current flow through the perfused neuron.

Initial work centered on exploration of the importance of the fused dioxane ring present in CX614. Close analogs indicated that the oxygen at position 1 was essential for activity; analogs, in which this oxygen had been replaced, were significantly less active, with the exception of a compound with a carbonyl group at position 1 which retained activity. On the contrary, the SAR exploration demonstrated that the oxygen at position 4 was not required for AMPAR potentiation. Hence, the introduction of a carbonyl group at position 4, together with a fused pyrrolidine, to increase the rigidity of the modulator, encouragingly produced a more potent derivative (**58**, $EC_{2x}=0.06$ μM) than CX614. The positive results with this symmetrical molecule prompted further work, which initially focused on simple *N*-alkyl analogs **59**. Biological evaluation of an array of compounds (**59**, R=alkyl) showed that a small alkyl group was optimal for potency, with the methyl derivative being the most active ($EC_{2x}=0.1$ μM). Analogs bearing larger groups, including cycloalkyls and branched alkyls, had reduced activity, while the unsubstituted analog (**59**, R=H, $EC_{2x}=5$ μM) had similar potency to CX614. AMPAR modulators from this series were also tested in a ligand binding assay, where a good correlation with the electrophysiology data was observed. Some of the molecules with good activity in the hippocampal neuron electrophysiology assay were tested in a rat hippocampal slice preparation, where weak activity was observed.

In a second paper,[136] Cortex published further SAR studies around the *N*-substituent of **59**. Initial work focused on short alkyl chains bearing substituents. Starting from the *N*-ethyl derivative (**59**, R=Et, Fig. 18) work investigated the effect of introducing a range of functionality on the terminal carbon atom. A wide array of groups was tolerated, the majority of substituents afforded compounds with similar potency to the *N*-ethyl derivative (**59**, R=Et, $EC_{2x}=0.2$ μM). Two modifications, which showed small increase in potency, were the introduction of the chemically reactive groups azide (**59**, R=$N_3(CH_2)_2$–, $EC_{2x}=0.08$ μM) and isothiocyanate (**59**, R=$NCS(CH_2)_2$–, $EC_{2x}=0.06$ μM). Extending the chain length by one carbon atom and appending a nitrile group resulted in a potent butanenitrile derivative (**59**, R=$NC(CH_2)_3$–, $EC_{2x}=0.05$ μM). This work indicated that a wide range of *N*-substituents is tolerated with retention of potency, possibly suggesting that these groups do not interact with the target protein.

Further studies investigated the effect of aromatic groups on the terminus of the alkyl chain (**60**, R=$Ar(CH_2)_n$). Modulation of the chain length was initially studied (Ar=phenyl, **60a–60d**) and the activity found to be optimal with two carbon atoms

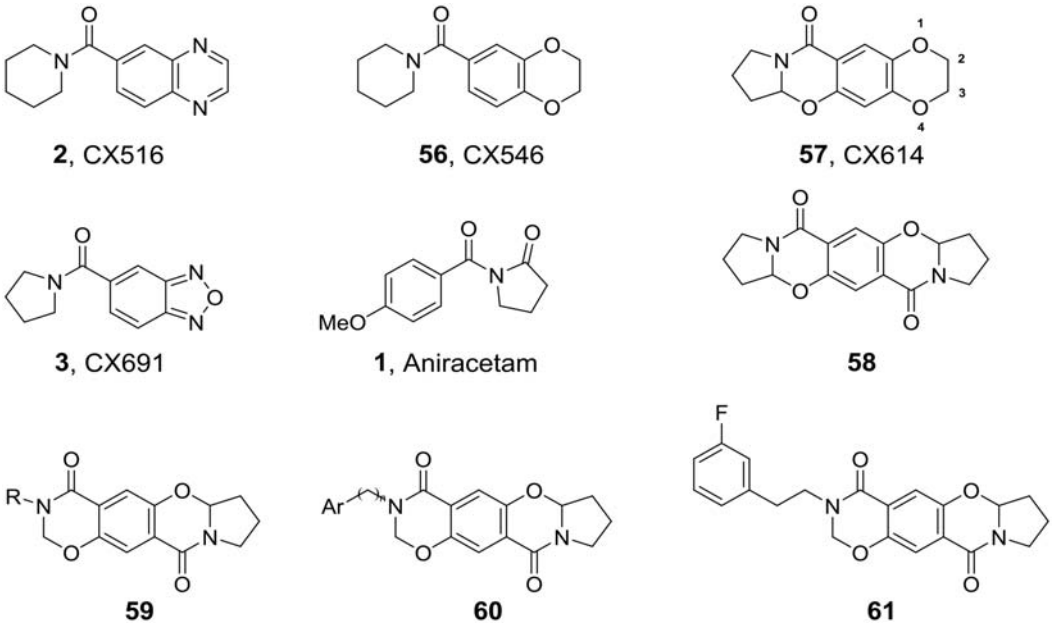

Fig. 18 Evolution of the AMPAR modulators, described by Cortex, containing the benzamide motif.

(**60c**, $EC_{2x}=0.25$ μM), longer (**60d**) and shorter (**60b**) chains gave compounds with activity similar to CX614 (Table 5). In this optimized two carbon linker series, introduction of small halogen substituents (**60e** and **60f**) at the *meta* position of the phenyl ring resulted in a 10-fold increase in potency, larger or more polar groups (**60 g** and **60 h**) led to reduced activity or at best retention. Appending substituents at the *ortho* or *para* position of the phenyl ring reduced potency in all cases (**60i** and **60j**). Interestingly, bis-meta substitution was tolerated and the 3,5-difluorophenyl derivative **60k** had high potency in both the electrophysiology ($EC_{2x}=0.005$ μM) and the binding assay (Ki = 0.3 μM). Following exploration of the SAR of substitution around the phenyl ring, the final area of investigation looked at phenyl replacement with heterocycles, all linked to the core through a two carbon chain. Six-membered heteroaromatic did not provide any advantages with the three regioisomeric pyridines (**60l–60n**) being equipotent to the unsubstituted phenyl analog (Table 5). The general trend among unsubstituted 5-membered heterocycles was a raise in potency, typically 10-fold compared to the pyridyl groups. The limited range of substituents, described for each heterocycle, make it difficult to draw conclusions regarding the SAR. However, there is a suggestion that in the case of the pyrazoles described, introduction of a small lipophilic group, such as chlorine, provided a further increase in potency.

In a subsequent publication,[133] Cortex scientists mentioned phenethyl compound **61**, Fig. 18, stating that despite its very good potency in a rat in vitro electrophysiology assay ($EC_{2x}=0.011$ μM), it was only weakly active when tested in an in vivo electrophysiology experiment, similar to related compounds. High clearance was suggested to explain the discrepancy between in vitro potency and in vivo efficacy. Metabolite identification studies in RLM showed the major sites of metabolism to be the ethyl chain and the saturated carbon atoms of the oxazinone and pyrrolidine rings. The initial strategy adopted to improve the metabolic stability was to substitute the alkyl chain linking the phenyl group to tetracyclic core, such as in **62** and **63** (Fig. 19). Substitution adjacent to the phenyl group represented by **62**, Fig. 19, resulted in a large reduction of the in vitro potency of all analogs. Substitution of the methylene adjacent to the tetracyclic core, represented by **63**, Fig. 19 (X = H, $R^1=CO_2Me$, $R^2=H$; X = F, R^1 = ethynyl, $R^2=H$), did result in compounds with similar potency to the parent compound (**61**, Fig. 18), but, unfortunately, these derivatives failed to demonstrate superior metabolic stability.

The second strategy investigated was to replace the oxazinone ring with pyrimidinone (Fig. 19: **64**, X = CH) or triazinone rings (Fig. 19: **64**, X = N). This approach proved successful with both the pyrimidinone and the triazinone showing similar effects in an in vivo electrophysiology assay at 5 mg/kg (IP), when compared to **61**, which showed very little response. The SAR of the pyrimidinones and triazinones regarding chain substitution matched that described for **62** and **63**, with small lipophilic groups on the carbon atom adjacent to the heterocycle producing increased potency, but substituents adjacent to the phenyl ring not being tolerated. Replacement of the pendant 3-fluorophenyl group with a 2-tetrazolyl group resulted in improved potency in the in vivo electrophysiology assay. This was particularly evident in the triazinone series and was also reported to correlate with increased exposure. Having identified compounds with superior metabolic stability, Cortex focused on removing the chiral center present in the pyrrolidinooxazinone motif, this was achieved by substituting the nitrogen of the oxazinone with a cyclopropyl group. Combining the achiral ring system with the modifications, which resulted in optimal metabolic stability and potency, afforded

65 (Fig. 19), which was active in a rat native tissue electrophysiology assay ($EC_{2x}=0.46$ μM), produced an increase in the amplitude of fEPSP in vivo (39% at 5 mg/kg, IP) and induced LTP in the rat (1 mg/kg, IP).

The main issue with compound **65**, Fig. 19, was its short plasma half-life (0.27 h) and in a fourth publication[134] Cortex described how the pharmacokinetic profile of this series was optimized. In addition to the short half-life, it was also suggested that **65** had low brain penetration, although no data were presented to support this. Initially investigation of the core ring system was performed, and replacement of the oxazinone with either pyrimidinone or triazinone was investigated, leading to the discovery of compound **66** (Fig. 20), which had an encouraging profile. Potentiator **66** was 100% bioavailable in the rat with a good half-life in all species (rat: $t_{1/2}=1.7$ h; dog: $t_{1/2}=3$ h; monkey $t_{1/2}=9.5$ h), and retained the electrophysiological profile of **65** ($EC_{2x}=0.28$ μM; 37% increase in fEPSP amplitude at 5 mg/kg, IP). All four possible combinations of pyrimidinone and triazinone were prepared with **66** having the best profile. Extensive SAR investigations were subsequently performed looking at modifications of the tetrazole, pendant methyl, and cyclopropyl groups. Few transformations gave a profile superior to **66**. Wider SAR investigation showed that dimeric tetrazole **67** (Fig. 20) was more potent than **66** ($EC_{2x}=0.016$ μM; 59% increase in fEPSP amplitude at 1 mg/kg, IP), but no pharmacokinetic data were provided on the later compound. Since the publication of these data, Cortex has not published any further medicinal chemistry papers.

7.11.3.3.4 Optimization of an HTS-derived hit by Organon using SBDD

Organon (now Merck) have published four patent applications between 2008 and 2010,[137–140] and shortly after published a series of papers[141–143] which describe the discovery of advanced lead compounds derived from a screening hit, compound **68**, Fig. 22.

In the first publication,[143] they describe the profile of **68** (Fig. 22) and strategies used to improve the in vitro developability profile with retention of potency. AMPAR modulator **68** had very encouraging in vitro functional potency ($pEC_{50}=6.7$; calcium assay in HEK cells overexpressing hGluA1) but was poorly soluble (<1 mg/L) and highly unstable in both rat and human liver microsomes (Cli >270 μL/min/mg). To direct the medicinal chemistry, the group utilized X-ray structures of compounds in complex with the LBD of the hGluA2i subunit. Analysis of the binding mode of **68** (PDB code 3O28, Fig. 21) indicated that the key interactions potentially responsible for the activity were predominantly hydrophobic and were those made by (a) the trifluoromethyl on the tetrahydroindazole and also (b) the cyclohexyl ring of the tetrahydrobenzothiophene.

Initial efforts concentrated on opening of the saturated ring of the tetrahydrobenzothiophene which resulted in dimethyl or methyl and ethyl thiophene analogs (Fig. 22: **69**) or introduction of heteroatoms into the saturated ring (Fig. 22:**70**). These analogs all exhibited reduced potency (≈ 30-fold) but encouragingly a modest increase in kinetic solubility (10 mg/L) in some cases. Introduction of an oxygen atom into the saturated ring produced compound **70** which retained potency, but still showed poor solubility and microsomal stability. Attempts to modify the saturated ring of the tetrahydroindazole gave similar results and truncation

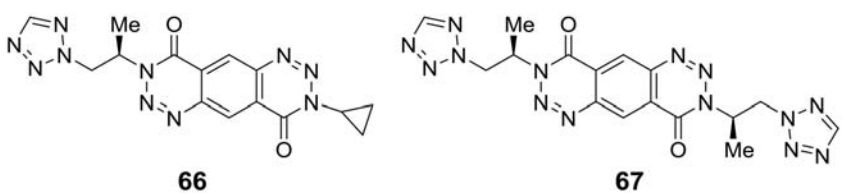

Fig. 20 Tetrazole derivatives with improved DMPK profiles.

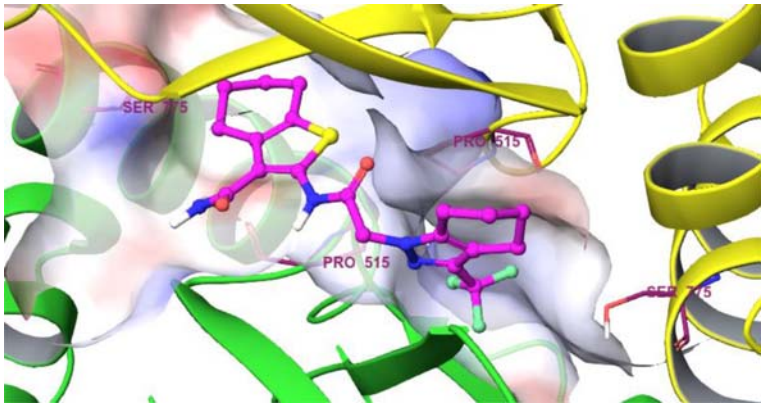

Fig. 21 X-ray structure of hit compound 68 in complex with the S1S2 LBD of hGluA2i (PDB code 3O28, 2.0 Å resolution).

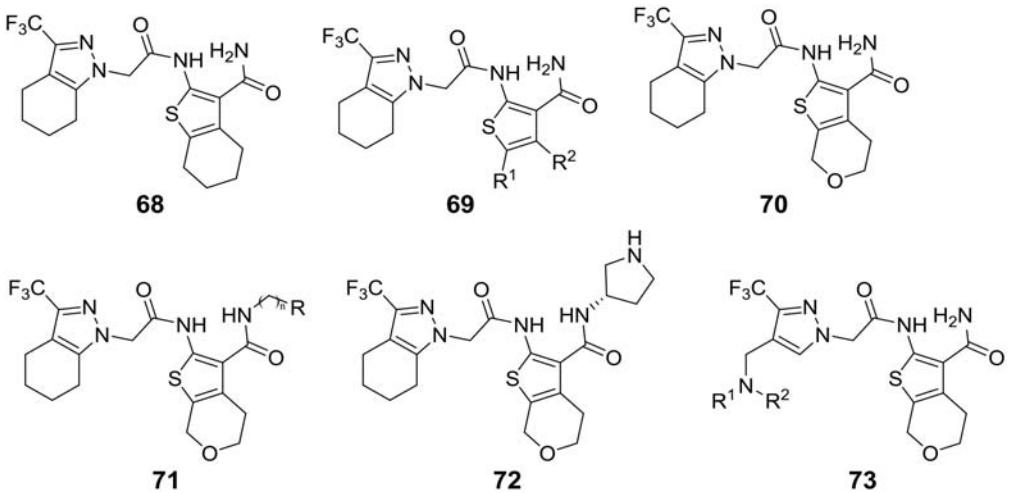

Fig. 22 Key compounds in the optimization of screening hit 68 published by Organon.

was generally poorly tolerated. Active compounds were obtained when the system was fully aromatized preferably with nitrogen atoms in the 6-membered ring, but this failed to improve the developability characteristics.

Further examination of the structural information revealed a hydrophilic pocket close to the space occupied by the primary amide function. Thus, a series of analogs were prepared in which various groups were appended to the amide of **71** (Fig. 22). One of the early analogs (**71**, R = NMe_2, $n = 2$) showed modest potency ($pEC_{50} = 5.2$) but was successfully crystallized with the hGluA2 LBD (PDB code 3O29, Fig. 23). Analysis of the structure revealed a weak interaction with an aspartic acid residue (Asp781), which had the potential for further optimization. Interestingly both the tetrahydroindazole and the tetrahydrobenzothiophene moieties occupied similar regions to the hit **68**.

Further modification led to a more potent analog (**71**, R = NH_2, $n = 3$; $pEC_{50} = 6.4$) which also showed an improved developability profile (solubility: 38 mg/L; Cli = 17 μL/min/mg (HLM), Cli = 77 μL/min/mg (RLM)). The ADME properties still required work as the permeability (Caco-2 assay) was low, but encouragingly the compound was not a P-gp substrate (A–B = 34 nm/s, B–A = 55 nm/s). Unfortunately, when **71** (R = NH_2, $n = 3$) was tested in an in vivo rat pharmacokinetic study, the poor permeability contributed to low oral bioavailability (7.7%) and poor CNS penetration (brain to plasma ratio = 0.05), despite having moderate blood clearance (21 mL/min/kg). Further analysis of X-ray data suggested that conformationally constrained analogs, would bind well to the protein. Compound **72** (Fig. 22) was prepared and showed good potency ($pEC_{50} = 6.6$), which was slightly superior to the corresponding enantiomer ($pEC_{50} = 5.8$). **72** possessed promising solubility (20 mg/L) and microsomal stability (Cli = 41 μL/min/mg (HLM), Cli = 50 μL/min/mg (RLM)). However, the permeability was still low, as was bioavailability (3.8%) despite low in vivo clearance (2.3 mL/min/kg, rat). Surprisingly the brain to plasma ratio was found to be 1:1.

Following extensive exploration of the tetrahydrobenzothiophene motif, which failed to deliver molecules with the desired in vivo profile, attention focused on the tetrahydroindazole group.[142] Structural data suggested that introduction of polar groups in this region was possible and could potentially interact with two key residues, namely Pro515 and Ser750. Compounds with an

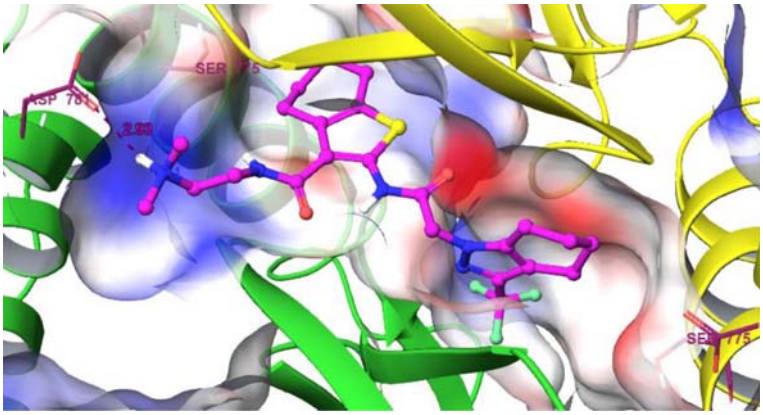

Fig. 23 Biostructure of lead 71 (R = NMe_2, n = 2) bound to the S1S2 LBD of hGluA2i (PDB code 3O29, 2.02 Å resolution).

opened saturated ring and basic functionality appended to the pyrazole ring were modeled and appeared to have the greatest potential. A series of analogs **73** (Fig. 22) was prepared; a wide variety of small alkyl groups were tolerated and good activity ($pEC_{50} \geq 6$) was observed with both secondary and tertiary amines. Two secondary amines were chosen for further study: **73**, R^1 = Me, R^2 = H; pEC_{50} = 6.5, Cli < 12 μL/min/mg (RLM), Cli = 33 μL/min/mg (HLM) and kinetic solubility = 65 mg/L and **73**, R^1 = Et, R_2 = H; pEC_{50} = 6.1, Cli < 19 μL/min/mg (RLM), Cli < 12 μL/min/mg (HLM) and kinetic solubility = 107 mg/L, Fig. 22. The pharmacokinetics of both compounds were studied in vivo and showed improved oral bioavailability in the rat compared to previous analogs (R^1 = Me, F = 15%; R^1 = Et, F = 43%). The ethyl compound was progressed further but found to have low CNS penetration (brain to plasma ratio = 0.05). However, despite the poor CNS penetration, it showed positive effects in a rat in vivo electrophysiology assay, increasing the amplitude of evoked activity at a dose of 0.3 mg/kg (IV). The crystal structure of **73** (R^1 = Et, R_2 = H) bound to the S1S2 LBD of hGluA2i was obtained and confirmed the initial designed hypothesis (PDB code 3O6H, Fig. 24). The authors conclude by saying that at the time of publication the advanced compound was under detailed investigation and further results will be published at a later date.

In the final publication,[141] further evolution of the template to structurally diverse scaffolds was explored using a hybridization strategy (Fig. 25). Structural components of other reported AMPA modulators were combined with key elements of the newly discovered scaffold, in order to identify a back-up series. The work resulted in the identification of compound **77**, Fig. 25. Examination of available X-ray structures suggested that **74** (hGluA1 pEC_{50} = 6.4, solubility = 20 mg/L) had the potential to be hybridized with the previously reported Lilly compound (LY451646, **48**) by replacing the cyanophenyl group with the pyrazole moiety of **74** to give **75**, Fig. 25. The results were initially encouraging with **75** having the desired in vitro profile (pEC_{50} = 6.3, solubility = 73 mg/L and Cli < 12 μL/min/mg (rat and human)), combined with reasonable permeability (Caco-2) and no evidence of transporter interaction. However, the in vivo rat profile was less than desired with moderate-high plasma clearance (49.7 mL/min/kg). It was hypothesized that introducing a conformational constraint might reduce CYP-mediated metabolism leading to decreased clearance.

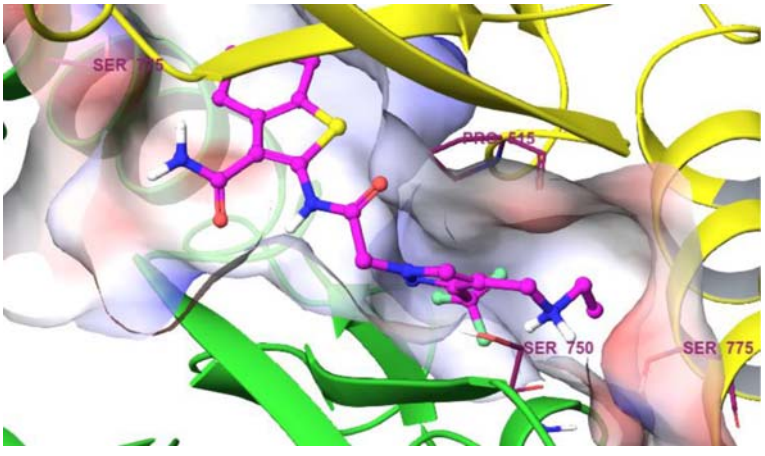

Fig. 24 X-ray structure of 73 (R^1 = Et, R^2 = H) in complex with the S1S2 LBD of hGluA2i (PDB code 3O6H, 2.1 Å resolution).

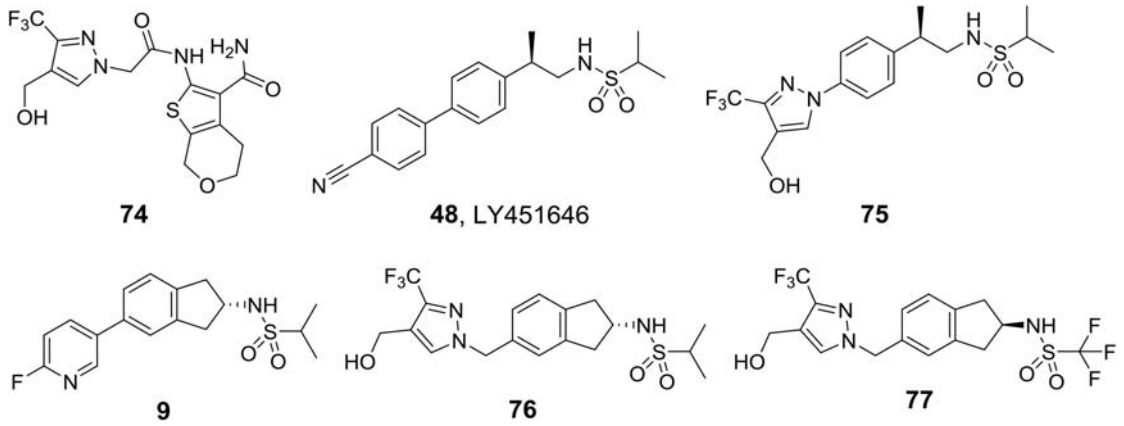

Fig. 25 Advanced compounds from Organon and comparison with similar templates from other groups.

A second hybridization strategy was employed to achieve the conformational restraint, incorporating features of a template described by GlaxoSmithKline 9[98] producing **76** (PDB code 3PMW, Fig. 26). A linker was introduced between the indane and the pyrazole as molecular modeling suggested the directly linked pyrazole would not fit the binding site optimally. Derivative **76** had a very encouraging profile ($pEC_{50}=6.3$, Cli = 31 μL/min/mg (RLM), 23 μL/min/mg (HLM)), improved in vivo clearance (21.6 mL/min/kg, rat) and excellent oral bioavailability ($F\%=95$). Having identified **76** as a promising new scaffold, the Organon group explored further the SAR around the template. Changing the stereochemistry of these compounds had little effect on the overall profile. The pyrazole ring could be replaced by other 5-membered heterocycles including furan and pyrrole. A range of substituents in place of the alcohol were tolerated including hydrophobic groups, such as an additional trifluoromethyl, and polar groups, such as secondary amines. Exploration of the sulfonamide demonstrated that a wide range of hydrophobic groups were tolerated in this position including aromatic groups, such as methoxyphenyl and trifluoromethyl pyrazole. Compound **77**, Fig. 25, resulted from this exploration and it was noted that replacement of the isopropyl sulfonamide by the corresponding trifluoromethyl analog gave a compound which retained much of the potency of **76** but with further improved metabolic stability. The profile of **77** is as follows: $pEC_{50}=5.6$, solubility = 83 mg/L, Cli < 12 μL/min/mg (RLM and HLM), in vivo (rat) Cl = 1.9 mL/min/kg, $t_{1/2}=7.4$ h, $F\%=100$, and evidence of good CNS penetration. No report describing the in vivo pharmacological effects of the AMPAR potentiators is described in these three papers and it is unclear if these series are still being developed.

A recent publication from one of the Organon authors currently working at the University of Strathclyde described another hybridization strategy,[144] in which the hydroxymethyl pyrazole used in the design of **77** is combined with a template related to those previously described by Cortex to produce hybrid **79** (Fig. 27). Only in vitro activity data are described in an electrophysiology assay with compounds being tested on both flip and flop isoforms of GluA2. Modulator **79** is significantly more potent than **74** and shows activity at both receptor subtypes. Also described in the paper are the sulfonamide analog **80** (Fig. 27) and the compound in which the pyrazole is directly attached to the tricyclic core, **81** (Fig. 27), both compounds are less potent than **79**.

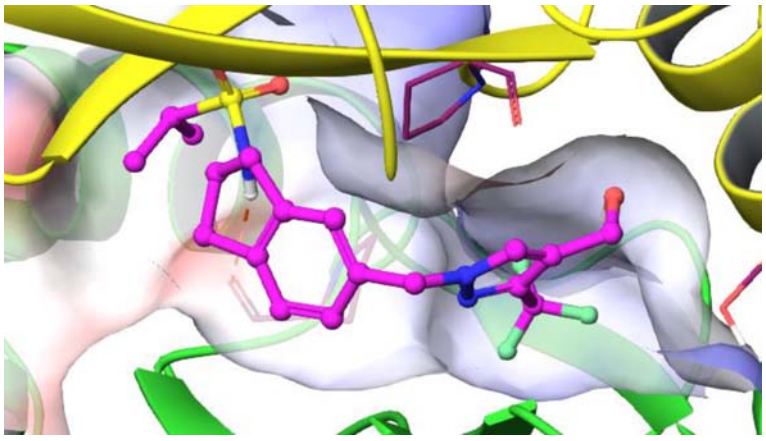

Fig. 26 X-ray structure of 76 bound to the S1S2 LBD of hGluA2i (PDB code 3PMW, 2.2 Å resolution).

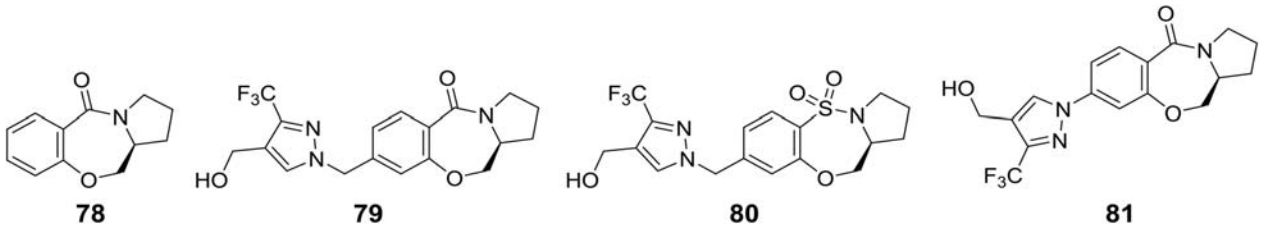

Fig. 27 Conformationally restrained molecules published by the University of Strathclyde.

7.11.3.3.5 Work from other pharmaceutical and academic groups

A number of groups at the universities of Liege, Copenhagen, and Modena have published work centered around the cyclothiazide core **5**, Fig. 1.[145–152] Servier also worked for many years on this template but have not described any new chemotypes related to this scaffold in the period covered by this article. This work has been comprehensively reviewed elsewhere.[153]

Takeda have demonstrated an interest in this area of neuroscience through a significant number of patent applications between 2009 and 2012 (Fig. 28).[154–159] However, until now, no scientific publication reporting on their strategy and discovery of advanced AMPAR PAMS has been published. Lilly which had a strong interest in the area before 2010[160–163] seems to have stopped working on AMPAR PAMS, since no patent or scientific articles originating from them has been reported in the last 10 years.

7.11.4 AMPA Receptor Antagonists

The medicinal chemistry of AMPAR negative modulators was thoroughly reviewed in the second edition of *Comprehensive Medicinal Chemistry*[1] and little or no new work has been reported during recent years. AMPAR antagonists have been shown to be potent anticonvulsants and, as a result, have been developed as antiseizure agents. A number of the compounds previously reported have been progressed into clinical studies where they have shown encouraging results in epilepsy studies. One molecule perampanel **87**[164] has reached the market with a number of others currently in late stage clinical trials: selurampanel **88**, talampanel **89**, and GYKI 53784 **90** (Fig. 29).[165]

A recent, novel approach, to the identification of AMPA negative modulators has recently been published, by both Lilly and Janssen.[57,58] It involves targeting of AMPAR accessory proteins, more precisely TARPs, and represent an innovative approach to

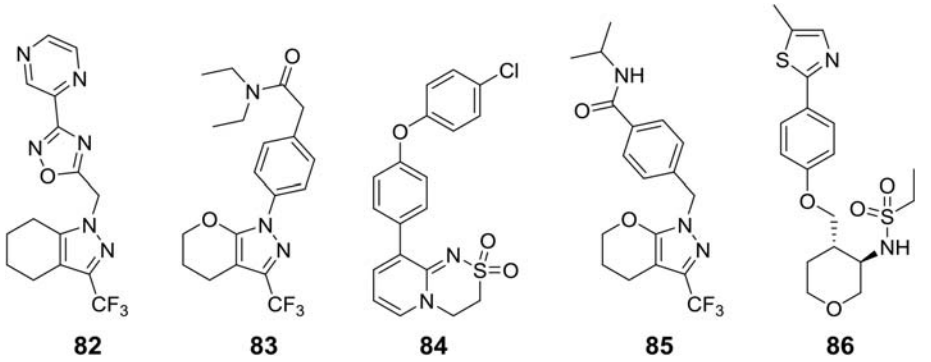

Fig. 28 Representative structures of the AMPAR modulators claimed by Takeda.

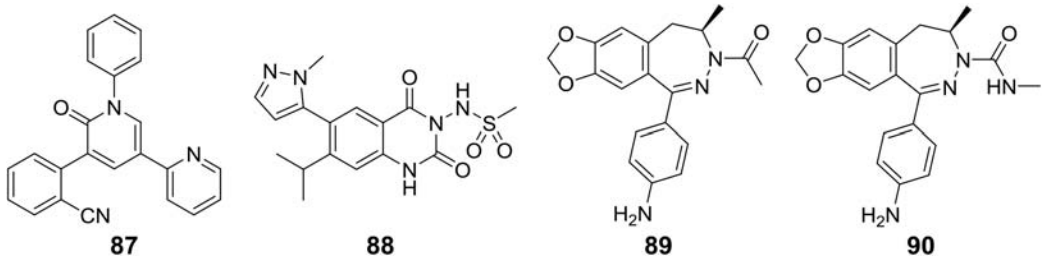

Fig. 29 Advanced AMPA negative allosteric modulators.

modulate AMPAR in specific brain regions. Indeed, while relative concentrations of GluA subunits vary between brain regions, they are generally present throughout the brain and inhibition in specific brain compartments is challenging to achieve. To date, no AMPAR inhibitors have been found to exhibit regional specificity or AMPAR subunit selectivity.

Since AMPAR are ubiquitously expressed within the CNS, general AMPAR antagonists have very narrow therapeutic windows and are associated with side effects, such as motor impairment, dizziness, ataxia, and falling.[166] The variable regional expression of members of the TARP protein family across the CNS provide the opportunity to identify AMPAR modulators dependent on the co-expression of AMPAR with a specific TARP protein.[167] For instance, TARP-γ8 has significantly higher expression within the hippocampus relative to other major brain areas, while TARP-γ2 is mainly found in the cerebellum. Since the hippocampus is the region of the brain associated with the etiology of epilepsy and the cerebellum the region controlling motor function, the identification of a selective AMPAR–TARP-γ8 antagonist selective over TARP-γ2 could provide a therapeutic advantage over previously reported AMPA negative modulators that bind to the LBD. In addition, hippocampal excitotoxicity caused by kainate, an AMPAR partial agonist, is overturned in TARP-γ8 knockout mice.[168] Hence, ligands targeting the AMPAR–TARP-γ8 complex are of interest and two pharmaceutical companies have recently reported the identification of selective TARP-γ8 modulators. The novel class of AMPAR antagonists is assumed to work by disrupting the interaction between TARP-γ8 and the pore-forming region of the GluA subunits. These molecules, which represent the first AMPAR modulators to exhibit regional specificity, have an encouraging preclinical profile and the potential for progression to clinical evaluation.

A screening campaign was initiated at Lilly to identify compounds which inhibited calcium entry (FLIPR assay) into CHO cells, exclusively expressing AMPAR complexes formed a recombinant of GluA1 tetramer (flip isoform) and TARP-γ8. Cell lines, expressing alternative AMPAR complexes, composed of the GluA1 homotetramer and other single TARPs, were generated and used to assess selectivity for the GluA1–TARP-γ8 complex. The screen identified phenol **91** (Fig. 30) which was modestly potent (TARP-γ8 $IC_{50} = 2.97$ μM), selective over TARP-γ2 ($IC_{50} \geq 83$ μM), but was unstable in rat and human liver microsomes (81% and 84% metabolism, respectively, following 5 min incubation). Hepatocyte studies also indicated the presence of phase II metabolism. Unsurprisingly, when tested in vivo (rat), **91** had a clearance well in excess of liver blood flow (234 mL/min/kg). The first stage of hit optimization focused on reducing the phase II metabolic liability, and a series of phenol isosteres were prepared (Fig. 30: **92**, **93**, and **94**). Encouragingly, all three compounds were more potent than the original hit (TARP-γ8 $IC_{50} = 0.147$ μM (**92**), 0.35 μM (**93**), 0.07 μM (**94**)). While compound **92** was poorly stable in both rat and human liver microsomes, the other two compounds had improved stability: **93** 52% and 65% metabolism in rat and human liver microsomes respectively following 5 min incubation and **94** 36% and 32% metabolism in rat and human liver microsomes respectively. Analog **94** was progressed to an in vivo pharmacokinetic study in rats where it showed encouraging blood clearance (61 mL/min/kg). However, when **92**, **93**, and **94** were profiled against a panel of cytochrome P450 enzymes, it was discovered that all three compounds were potent inhibitors of CYP1A2, with IC_{50} values of 0.22, 0.23, and 0.36 μM, respectively. CY1A2 was also shown to be the predominant metabolic enzyme for all three compounds.

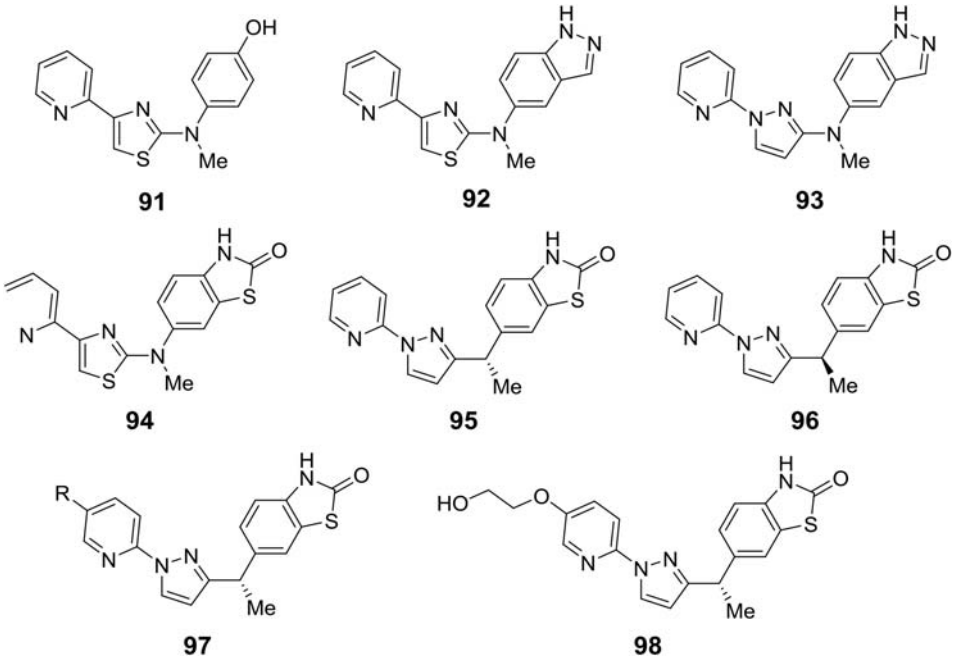

Fig. 30 Selective AMPA modulators which act through binding to TARPγ-8.

The Lilly group used structure-based design to solve this issue by predicting binding modes of the three compounds at the CYP enzyme. They hypothesized that replacing the nitrogen atom of the tertiary amine linker in **92**, **93**, and **94** by a sp^3-hybridized carbon should not affect the binding to the AMPA protein since it would maintain the overall shape and size of the molecules, but would distort the planarity of the molecule sufficiently to reduce the potential to bind to CYP1A2. The enantiomeric carbon linked compounds **95** and **96** were prepared (Fig. 30). Encouragingly both compounds showed little or no inhibition of CYP1A2, having IC_{50} values of >10 and 4.67 μM respectively, but retained activity in the TARP-γ8 assay and were highly selective over TARP-γ2. Unfortunately, both compounds displayed poor metabolic stability both in vitro and in vivo having clearances greater than liver blood flow in rats. Using in silico methods to predict sites of metabolism indicated that the main site of oxidative metabolism was the pyridine ring. A series of analogs, exemplified by **97**, were prepared from which **98**, LY3130481, Fig. 30, emerged as the preferred molecule. Compound **98** showed encouraging potency in the TARP-γ8 assay ($IC_{50}=0.065$ μM) with no detectable activity at TARP-γ2 or affinity for GluA1 protein. Modulator **98** has an encouraging pharmacokinetic profile in the rat with low clearance (11 mL/min/kg), high bioavailability (97%) and was highly efficacious in the PTZ epilepsy model ($ED_{50}=1.7$ mg/kg). Importantly, **98** was clearly differentiated in its side effect profile from agents which act elsewhere at the AMPAR, such as perampanel. When tested in the inverted screen model, **98** showed little potential to alter climbing behavior at low doses and had an inverted index (ratio of TD_{50} in inverted screen model to ED_{50} in PTZ test) superior to 58, much greater than perampanel which showed and index of 0.4.

Similarly to Lilly, Janssen initiated a HTS campaign targeting the AMPAR–TARP-γ8 complex. Hits were identified and following extensive medicinal chemistry optimization led to the discovery of JNJ-55511118 **99** and JNJ-56022486 **100** (Fig. 31). No publication describing the optimization campaign behind these molecules has yet been disclosed. In a calcium flux assay, **99** and **100** inhibited glutamate-evoked calcium influx in HEK293 cells, expressing GluAx subunit and TARP-γ8. In the absence of TARP-γ8 or in the presence of other TARP subunits, little or no inhibition was observed, demonstrating the selectivity of these molecules. The broad selectivity of JNJ-55511118 **99** and JNJ-56022486 **100** was evaluated at 1 μM against a panel of 52 receptors, ion channels and transporters. Both compounds were highly selective, with at least 100-fold selectivity against all tested targets. The effect and selectivity of other TARP family members was confirmed using patch clamp electrophysiology in CHO cells expressing heterologous GluA1o–TARP-γ8. A similar effect on glutamate-evoked currents was recorded on neuronal cells, with no effect on cerebellar granule cells expressing native AMPAR–TARP-γ2, and a significant inhibition on hippocampal neurons expressing native AMPAR–TARP-γ8. These positive results indicate that the presence of other interaction partners in the native system does not affect the binding of the compounds or their functional impact. Extensive additional electrophysiological studies were conducted and concluded that JNJ-55511118 does not cause dissociation of TARP-γ8 from the AMPAR, but modifies the protein-protein interaction between these two components of the receptor complex.

From a radioligand binding assay, the binding affinity (K_i) of JNJ-55511118 **99** and JNJ-56022486 **100** was found to be 26 and 19 nM respectively. In brain slices, the tritiated version of 100 was shown to bind at high concentrations to regions of high TARP-γ8 expression. The in vivo pharmacokinetic profile of both molecules was evaluated in rat and mouse, and JNJ-55511118 **99** showed the best profile in these studies, prompting further in vivo experiments to focus on that compound. Compound **99** had good oral bioavailability, with acceptable clearance (4.8 mL/min/kg) and volume of distribution (1.8 L/kg) in rats. It also demonstrated high CNS penetration and high target occupancy following oral dosing in both rat and mouse. Free fraction of JNJ-55511118 in rat and mouse plasma was generally low (1.48% and 0.88%, respectively), as was the free fraction in rat brain tissue (0.24%).

JNJ-55511118 **99** showed strong anticonvulsant properties in the corneal kindling and PTZ models in mice, and in the amygdala kindling model in rats. The compound also demonstrated partial protection in the 6 Hz and MES tests in mice. Potential side effects of **99** on learning and memory, resulting from AMPAR negative modulation in the hippocampus, were tested in rats using two cognition models (V-maze and Morris water maze). Although JNJ-55511118 induced memory impairment in both tests, the effect was significantly milder to that caused by the NMDAR antagonists dizocilpine and phencyclidine. Positively, other severe side effects, such as loss of motor coordination or sedation, were not observed in animals dosed with AMPAR modulator **99**, even when saturating doses were used.

Inhibition of excitatory neurotransmission with AMPAR–TARP-γ8 modulators, such as LY3130481 and JNJ-55511118, has a strong potential clinical utility top prevent convulsion, in particular in patients whose epilepsy has a strong hippocampal component. The absence of effect in the midbrain and hindbrain with such inhibitors is expected to attenuate seizures without the side effects seen with classical anticonvulsants, such as sedation or ataxia.

7.11.5 Conclusion and Future Perspective

The large number of publications on AMPAR potentiators within the period covered by this article proves that it remains a fertile area of drug discovery and that interest will remain for the foreseeable future. It appears that the field has learnt from the failure of the early AMPAR PAMs which entered clinical evaluation and that more precise and defined properties are now sought. The use of SBDD has clearly assisted a number of projects and allowed the identification of very potent potentiators, active at very low doses in cognition behavioral models in vivo. Some pharmaceutical groups such as Pfizer and GSK have also aimed for a specific pharmacokinetic profile with the objective to achieve large TI, low intersubject pharmacokinetics variability and prevent the occurrence of the recognized adverse events associated with AMPAR modulators. We can expect a number of compounds derived from series described in this review to enter clinical evaluation in the next few years, thus expectation of positive readouts of clinical trial data continues. The recent report from Lilly scientists of ligands which modulate AMPA function through binding to TARPs offers a novel strategy to modulate the channel function and potentially a pathway to the identification of modulators with greater safety profiles.

7.11.6 Conflict of Interest

S. Ward holds a grant from the Wellcome Trust entitled "Transforming the treatment of schizophrenia: Design and development of AMPA receptor modulators with a much improved safety profile as novel drugs for treating the cognitive dysfunction associated with schizophrenia and other CNS disorders."

The authors have no other relevant affiliations or financial involvement with any organization or entity with a financial interest in or financial conflict with the subject matter or materials discussed in the manuscript apart from those disclosed.

Acknowledgment

The authors thank Dr Ben Wahab for crystal structure processing and computational support.

7.12.1 Introduction

7.12.1.1 T2D Background

The incidence of Type 2 Diabetes (T2DM) is increasing rapidly in both the developed and developing world. The disease is characterized by hyperglycemia as a consequence of increased insulin resistance and a deterioration of the ability of the pancreas to compensate through increased insulin secretion.[1] For the majority of T2DM patients, the etiology is exacerbated by underlying excess body weight and obesity.[2] While, several therapeutics have been developed for control of elevated blood glucose levels, including sulfonyl ureas and metformin, these are not generally associated with weight-loss that would contribute to improvement in the underlying disease state.[3] One class of therapeutics that has shown promise in this respect is the glucagon-like peptide 1 receptor (GLP-1R) agonists.[4] In addition to effective glucose control through increased insulin secretion and decreased glucagon secretion, the most prominent of these, liraglutide (Novo Nordisk), has been shown to provide dose-dependent weight loss. Liraglutide is approved for T2DM at a subcutaneously approved dose of up to 1.8 mg/day. At a relatively higher 3.0 mg/day subcutaneous dose, liraglutide has recently been shown to provide meaningful body weight reduction in both diabetic and non-diabetic obese subjects.[5]

7.12.1.2 GLP-1 History and Background

GLP-1 was initially identified in the early 1980s and was subsequently shown to increase insulin secretion from the pancreatic β-cells in a glucose-dependent manner.[6] GLP-1 is secreted from intestinal endocrine cells in response to a meal, stimulating a postprandial release of insulin.[7] Human studies comparing matched levels of glucose following intravenous versus oral administration indicated that an oral glucose challenge provides a much greater increase in secreted insulin, a phenomenon known as the incretin effect, leading to early efforts to develop GLP-1 as a drug.[8,9] However, due to rapid cleavage and inactivation by the peptidase, DPP-4, the native peptide does not lend itself to development as a therapeutic agent[10]. Therefore, DPP-4 inhibitors were identified that target GLP-1 action through stabilization of the endogenous hormone. These compounds have proven effective at controlling hyperglycemia, particularly in combination with metformin, which has been shown to potentiate the release of endogenous GLP-1.[11,12]

In parallel to the development of DPP-4 inhibitors, more stable analogs of the native GLP-1 hormone were sought. Exenatide, a synthetic version of the hormone exendin-4 identified from the saliva of the Gila monster, was the first peptide GLP-1 agonist to be commercialized.[13] Exenatide is a longer peptide than GLP-1, but shares approximately 55% homology.[14] Most notably, the position 2 alanine of GLP-1, which is the site of cleavage by DPP-4, is a glycine in exenatide. This mutation, together with other sequence changes, provides significant resistance to peptidase-mediated degradation, thus significantly enhancing the plasma half-life.

A number of modified GLP-1 and exenatide-based analogs have since been identified, taking different approaches to provide enhanced duration of action.[15] Together with amino acid alternations, these include conjugation to PEG, albumin, Fc fragments, and acyl modifications. In addition, alternative delivery systems to subcutaneous injection have also been trialed, including transdermal patches and, more notably, subcutaneous osmotic minipumps.[16,17]

7.12.2 Mechanism of Action

7.12.2.1 GLP-1 Synthesis and Expression

GLP-1 is synthesized and subsequently processed from the preproglucagon gene in the intestinal endocrine cells.[18] In the α-cell, preproglucagon is processed into active glucagon and the major proglucagon fragment, while in intestinal L-cells in the gut, the pro-hormone is processed by the enzyme PC1/3 into GLP-1, GLP-2, and glicentin and oxyntmodulin.[19] The GLP-1 peptide was discovered in the early 1980s, sharing approximately 50% sequence homology with glucagon, and was later shown to induce glucose-stimulated insulin secretion from pancreatic β-cells.[6] Active, circulating GLP-1 is found in two forms, predominantly GLP-1(7–36 amide) and to a lesser extent, GLP-1(7–37).[20] The peptide is rapidly inactivated by the enzyme DPP-4, via truncation the N-terminal His-Ala dipeptide, a discovery which led to the DPP-4 inhibitor class of drugs, which thus prolong the lifetime of the active form of the peptide.[10,21] Removal of the two N-terminal amino acids completely abrogates agonist activity of both forms of GLP-1. A similar truncation of exendin-4, from Gila monster venom, results in the GLP-1 receptor (GLP-1R) antagonist exendin9-39.[14,22]

7.12.2.2 GLP-1 Synthesis and Expression

The GLP-1R is expressed in multiple tissues, including pancreatic islets, the brain, and GI tract.[23,24] GLP-1R is a $G_{\alpha s}$-coupled family B GPCR, characterized by a large extracellular domain.[25,26] Activation of the receptor on the pancreatic β-cell results in an increase in cAMP, activation of PKA, and an increase in insulin biosynthesis.[7,27] Under hyperglycemic conditions, the downstream effect of cAMP accumulation results in an increase in insulin secretion from the β-cell. Under normal conditions, stimulation of insulin secretion via activation of the GLP-1R occurs in a glucose-dependent fashion.[28] However, under euglycemic or even hypoglycemic conditions, concomitant exposure of rat pancreas to GLP-1 and a sulfonylurea results in increased insulin secretion. This indicates that the glucose sensitive response of GLP-1 is controlled by the K_{ATP} channel.[29–31]

In addition to stimulating cAMP through $G_{\alpha s}$, the GLP-1R has also been shown to stimulate other cellular pathways.[7] For example, stimulation of mouse β-cells with GLP-1 increases intracellular Ca^{2+}, likely mediated by PI-3 kinase, resulting in transcriptional changes that include increased insulin biosynthesis.[32] It has been demonstrated that prolonged exposure to GLP-1 may result in cumulative effects that include enhanced β-cell survival.[33,34]

GLP-1 may also play a role in control of fasting glycemia through inhibition of glucagon secretion.[35,36] While the mechanism of suppression is not well understood, in addition to stimulating insulin secretion, the use of GLP-1 analogs in diabetic patients may serve to diminish the rise in postprandial glucagon often observed in these patients.[37]

7.12.3 Effects on Food Intake

7.12.3.1 Inhibition of Feeding in Rodents and Humans

GLP-1R is expressed in the hypothalamus, the center of regulation of feeding.[38] Elegant studies involving intracerebroventricular (ICV) administration of GLP-1 to fasted rats resulted in inhibition of food intake.[39] Interestingly, inhibition of feeding in diabetic rodents can also be achieved following peripheral administration of long-acting GLP-1R agonists, such as liraglutide. While, liraglutide may cross the blood-brain barrier, evidence suggests that GLP-1 receptors in the arcuate nucleus may play a role in mediating food intake effects.[40]

In humans, a number of studies have demonstrated that GLP-1 dose dependently reduces food intake and slows gastric emptying.[41] This has been shown in type 2 diabetics as well as obese and healthy subjects.[42,43] Furthermore, prolonged activation of the receptor results in reduced bodyweight, most likely as a result of suppressed gastric emptying and decreased food intake. [44]

Together, the biological effects on insulin secretion, hepatic glucose production, food intake, and body weight make activation of the GLP-1R an ideal target for treatment of obesity and T2DM. However, the short half-life and physical properties of the endogenous ligand present multiple challenges to developing a suitable therapeutic agent.[45]

7.12.4 Interactions With the GLP-1R

7.12.4.1 Brief Overview of GLP-1 Structure

The GLP-1R was first cloned in the early 1990s.[46] It has been characterized as a family B GPCR with a predicted seven alpha helix transmembrane domain and an extracellular N-terminal domain. While a structure of the intact receptor is yet to be published, in 2007 Runge et al. expressed the isolated N-terminal domain and determined the X-ray crystal structure bound to the GLP-1 analog, exendin(9–39).[47] The structure indicated that the central alpha helix of exendin(9–39) forms both hydrophobic and hydrophilic interactions within a ligand-binding groove in the extracellular domain of the receptor. Binding of GLP-1 to its receptor is believed to be a two-step process. The first part is recruitment of the peptide to the N-terminal domain and the second is the interaction of the N-terminal region of the peptide with seven transmembrane cores of the receptor.[48]

7.12.5 GLP-1R Agonists

GLP-1R agonists, exenatide, lixisenatide, liraglutide, dulaglutide, and albiglutide have been approved for the treatment of T2DM.[49,50] Structures of these GLP-1 analogs and natural GLP-1 are shown in Fig. 1. Natural GLP-1 is an incretin hormone produced by intestinal L-cells and released in response to food intake to induce insulin secretion from pancreatic β-cells.

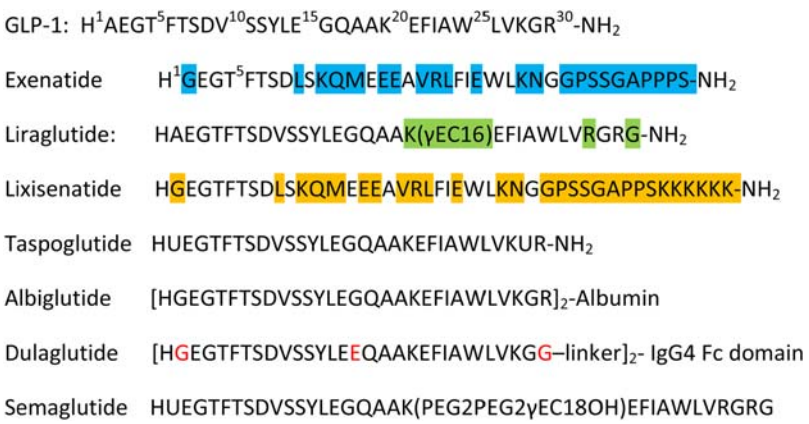

Fig. 1 Sequence of natural GLP-1 and its analogs.

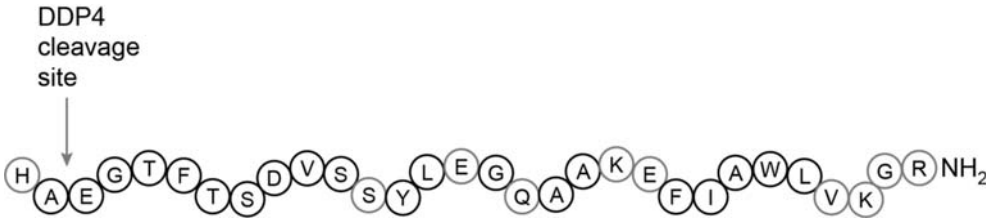

Fig. 2 DDP4 cleavage site of GLP-1.

GLP-1(7–36) amide is a biologically active form of GLP-1 and it binds to GLP-1R to trigger conformational change of the receptor, which in turn produces an increase in secondary messengers such as cAMP and Ca^{2+} levels. Natural GLP-1 has a very short half-life in plasma and it is degraded by serum protease DDP4 (Fig. 2) and other enzymes such as NEP, kallikurin, and plasmin. Therefore, to increase the plasma stability of the peptide and in turn to increase the $T_{1/2}$, scientists have used strategies such as DDP4 inhibitors, alteration of the *N*-terminal AA sequence to prevent degradation by DPP-4, and also design of sequences by attaching fatty acids that bind tightly to human serum albumin. [51–53]

7.12.6 Structure Activity Relationships of GLP-1

Adelhorst and co-workers as well as others investigated the importance of each residue on the GLP-1 backbone using alanine scanning, and these studies have shown that the *N*-terminal end of the GLP-1 is critical for receptor activation.[54] Furthermore, these studies also demonstrated that the C-terminal end residues of GLP-1 are responsible for binding to extracellular domain.

Pos 1. Histidine was found to be a key and important residue for GLP-1R binding and activation. This amino acid is present in all the GLP-1 agonists. The presence of this intact *N*-terminal α-amino group is required for DPP-4 cleavage, and modifications of *N*-terminal His can confer resistance to proteolysis. Also, *N*-methylation, α-methylation, des-amination, and imidazole lactic acid confer stabilization against DPP-4 proteolysis. Complete removal of histidine resulted in loss of activity. Replacement of histidine with other positive-charged amino acids Arginine and Lysine resulted in significantly reduced activity. However, histidine can be substituted for Phenylalanine with minimum loss of activity indicating importance of interaction of aromatic group with the receptor.

Pos 2. At the N-terminal end, modification to the second AA (Ala) has been extensively investigated to address metabolic instability due to processing by DPP-4. Substitution of Ala for Gly as in liraglutide is only slightly detrimental to GLP-1 activity and it improved the stability to DPP-IV. Replacement of Ala with polar AAs such as Ser provided modest resistance to proteolysis with approximately 10-fold loss of activity toward GLP-1R. Sterically hindered amino acids such as Leu and isoLeu resulted in a significant loss of potency. Substitution of Aib (2-aminobutyric acid) gave comparable binding and activity to native GLP-1 with complete resistance to DPP-4. In addition, both D- and L-Ala exhibited similar potency and activity and thus stereochemical configuration has minimal effect on activity.[55]

Pos 3. Negatively charged amino acids Glu and Asp are important for receptor interaction and they confer good receptor binding affinity and potency. Replacement of Glu with a basic amino acid such as Lys resulted in significant loss of potency. Substitution with Ala, Ser, and Val resulted in reduced potency. The stereochemical configuration is very critical for this position and thus replacement with D-Glu led several fold reduction in potency. Replacement of Glu with Pro, Phe, and Tyr showed comparable insulinotropic effect relative to GLP-1; however with slight loss of potency and binding affinity.

Pos 4. Gly at pos4 is very important for interaction with GLP-1R and all the GLP-1 agonists prepared to-date all have Gly at this position.

Pos 5, 6, 7, and 8 are represented by Thr, Phe, Thr, and Ser, respectively, and this combination of sequence is key for activity.

Pos 9. Negatively charged amino acid Asp is critical for activity and the only alternate AA that is tolerated here is Glu with slight loss in affinity. D-Asp substitution gave significant loss of binding affinity indicating importance of stereochemical configuration.

Pos 10–15. Val at pos10 can be replaced with Tyr, Ala, and other hydrophobic amino acids with some loss in affinity and activity. Substitution of position 12 Ser with Ala did not affect receptor binding and activity while replacement with Lys gave fourfold reduction in binding affinity. Replacement of Glu at pos 15 with smaller amino acids such as Gly and Ala resulted in significantly reduced affinity. Ser at pos11, Tyr at pos13, and Leu at pos14 are important for GLP-1R binding and activity.

Pos 16–20. Gly at pos16 can be replaced by a variety of other amino acids including branched amino acids without loss of activity. Aib is well tolerated at this position and exhibited binding affinity and potency comparable to GLP-1. Lys at pos20 has been used as a conjugation site for attaching fatty acids directly or via γ-glutamyl spacer to prolong the half-life by means of increased albumin binding. Similarly, conjugation with PEG2 linker also provided long $T_{1/2}$ with minimal loss of activity. Gln at pos17, Ala at pos18, and Ala at pos19 are critical for GLP-1 activity.

Pos 21–25. Glu at pos21 can be replaced with other amino acids with very minimal loss of GLP-1R binding. Pos21 can also be replaced with Lys, a basic amino acid without loss of activity. Phe at pos22 is an important AA for both receptor binding and activity

and can be replaced with hexafluoroleucine with modest loss in GLP-1 activity. lle at pos23 is also important for receptor binding and can be replaced with hexafluoroleucine. Ala at pos24 and Trp at pos25 are both critical for GLP-1 activity.

Pos 26–31. Leu at pos26 is also an important residue for activity and can be replaced with hexafluoro analog with slight loss of potency and affinity. Similarly, Val at pos27 is an important AA and is present in both natural and synthetic GLP-1 agonists. Lys at pos28 is found to be another good conjugation site for PEGylation and lipidation with only a twofold loss in potency relative to Lys at pos20. Gly at pos29 can be substituted for Aib to provide more potent GLP-1 agonist with excellent resistance to DPP-IV. This alteration was important in the discovery of taspoglutide. Arg at pos30 and Gly at pos31 are critical for GLP-1R binding and activation.

The endogenous GLP-1 is rapidly cleaved by serum proteases, particularly dipeptidyl peptidase 4 (DPP-4) at the His-Ala position as mentioned before. Therefore, therapeutic utility of natural GLP-1 is very limited. This difficulty can be overcome by using metabolically stable GLP-1 analogs or DPP-IV inhibitors. Also, a number of other strategies have been introduced including pegylation, D-amino acids, α,α-dialkylated aminoacids, β-amino acids, *N*-alkylated amino acids, stapling, and other conformational restriction to protect the peptides from proteolysis.[16,56] Exenatide showed a terminal half-life of ~2.4 h after subcutaneous administration and was consequently dosed 10 μg twice daily.[57]

7.12.6.1 Exenatide

The first GLP-1 agonist (exenatide) brought to the market for the treatment of diabetes (Fig. 3). It has Gly at pos2 and it provides stability to DPP-4-mediated degradation. In addition leucine at pos21 and serine at pos39 form a compact conformation that shields the side chain of Trp25 from solvent exposure that results in increased peptide stability and α-helicity.

7.12.6.2 Lixienatide

Lixisenatide contains amino acid residues similar to Exenatide at positions 1 to 39 with one less proline and additional six Lys residues at the C-terminal end (Fig. 4). Lixisenatide exhibiting a terminal half-life of 3 h is dosed 20 μg once daily. Lixisenatide showed improved HbA1c reduction in combination with metformin compared to exenatide with less hypoglycemia.

7.12.6.3 Taspoglutide

Taspoglutide is closely similar to natural GLP-1 analog with presence of Aib at positions 2 and 29 (Fig. 5). These modifications provided stability to DPP-4 and other plasma enzymes such as kallikerin and plasmin. In phase 3 studies the sustained release formulation of taspoglutide showed very good profile with consistent HbA1c reductions, however further progress on this molecule was terminated due to immunogenicity issues as well as allergic reactions at the injection site.

7.12.6.4 Liraglutide

Liraglutide is structurally similar to natural GLP-1(7–37) with 97% identical amino acid residues to natural hormone (Fig. 6). It differs at position 28 with Arg instead of Lys and in addition palmitic acid is conjugated via glutamate spacer at Lys in position 20. This fatty acid conjugation provides the prolonged duration of action facilitated by binding to serum albumin as well self-association at the subcutaneous space. Furthermore, the tight albumin binding action protects liraglutide sequence from DPP-4 and NEP enzymatic degradation. The mean plasma half-life in humans is 11–13 h. Once daily human dose of 1.2 mg provides good glycemic control and with increasing doses up to 1.8 mg show significant improvements in HbA1c reduction compared to exenatide (1.1% vs. 0.79%). Further increase in dose of up to 3 mg of liraglutide gave ~6% weight reduction in overweight Type 2 diabetics compared to placebo.

Fig. 4 Sequence of lixisenatide.

Fig. 5 Sequence of taspoglutide.

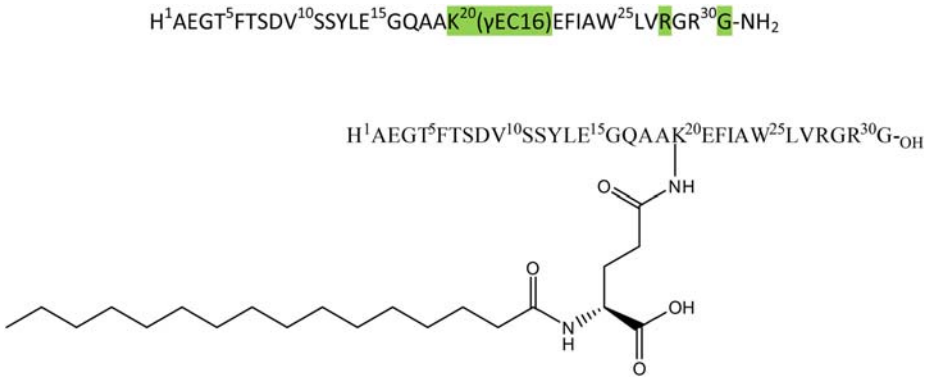

Fig. 6 Sequence and structure of liraglutide.

7.12.6.5 Semaglutide

Semaglutide is a long-acting GLP-1 agonist from Novo Nordisk, currently in phase 3 clinical trials as a once weekly treatment for T2DM (Fig. 7).[58] Semaglutide's structure differs from liraglutide at two places. Pos2 Gly is substituted with Aib (U) and this modification provides significant protection to enzymatic degradation by DPP-4. In addition, a modified fatty acid chain and the two PEG2 spacers turned out to be optimal for both in vitro and in vivo prolonged duration of action. As a result of these two modifications, the half-life for semaglutide in human is 160 h and a dose of 0.2 mg and above dose dependently reduced HbA1c by 1.7%. More importantly, semaglutide is currently being investigated in clinical trial for once daily oral treatment.

7.12.6.6 Albiglutide

In albiglutide, two copies of GLP-1 analog fused as repeat units to *N*-terminus of human serum albumin in a recombinant manner (Fig. 8). The GLP-1 analog has Gly instead of Ala at position 2 to provide resistance to DPP-4. These tandem repeat units of GLP-1 analog are critical and provide improved potency upon conjugation to albumin. Albiglutide has a half-life of 6–8 days in humans and it demonstrated good efficacy in humans with HbA1c reduction of 0.78% from baseline.

7.12.6.7 Dulaglutide

Dulaglutide is developed by Eli Lilly and is a recombinant fusion protein consists of two GLP-1 peptides covalently linked by a small peptide to human IgG4 Fc domain (Fig. 9). Ala at pos2 and Arg at pos30 are replaced with Gly to provide protection from DPP-4

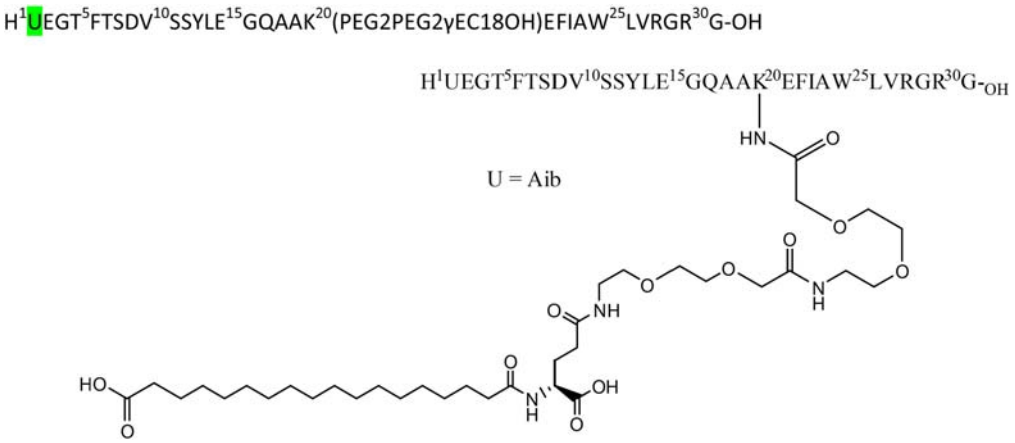

Fig. 7 Sequence and structure of semaglutide.

Fig. 8 Sequence of albiglutide.

Fig. 9 Sequence of dulaglutide.

cleavage as well as to maintain potency. Glu at pos16 provides improved potency. Dulaglutide has a half-life of ~4 days and showed significant dose-dependent reduction in HbA1c of 1.5% at 1.5 mg dose after 12 weeks.

7.12.7 Summary of GLP-1R Agonist Toxicity

All approved GLP-1R agonist drugs are modified GLP-1-like peptides, which are expected to have high specificity and low risk of off-target effects. Common findings observed in nonclinical toxicity studies of GLP-1R agonists are pharmacologically mediated reductions in food consumption accompanied by decreased body weight gain and/or body weight loss.[59–62] Food restriction in rats, significantly affecting body weight in the absence of any pharmacologic treatment, is associated with changes in hematology and serum chemistry parameters as well as histopathologic changes.[63] This association makes it particularly challenging to determine which changes observed after treatment with GLP-1R agonists are primary effects and which are secondary to effects on food consumption and body weight. Despite these challenges, several class effects, common to GLP-1R agonists, have emerged in nonclinical and/or clinical studies.

7.12.7.1 Gastrointestinal Effects

Administration of GLP-1R agonists is associated with gastrointestinal (GI) symptoms such as nausea and vomiting. These GI effects are believed to be mediated by local stimulation of GI tract, activation of GLP-1Rs in the central nervous system, and/or peripheral stimulation of the vagal afferent leading to a polysynaptic activation of neurons in the hypothalamus and brain stem.[64,65] In animal studies, including animal models of nausea, nausea and/or vomiting were observed in monkeys after albiglutide or dulaglutide treatment,[60,62,66] in pigs after liraglutide treatment,[67] and in cats and mice after exenatide treatment.[68,69] Clinically, patients have discontinued treatment due to adverse GI effects; however, gradual dose escalation doses of new patients has been shown to lessen these GI effects.

7.12.7.2 Heart Rate Effects

Increased heart rate is another common finding in animal studies for GLP-1 or GLP-1R agonists.[61,62,70] Even though GLP-1Rs are expressed in the cardiac sinoatrial node, the exact mechanisms mediating these hemodynamic changes are still under investigation.[71–73] A small increase in heart rate (a few beats per minute) is also the most common finding in the patients and is usually associated with nausea and a small blood pressure decrease.[74,75] Even though changes in heart rate are associated with increased cardiac mortality, recent preliminary data from large cardiovascular outcome trial of Victoza® (LEADER),[76] which spanned a period of up to 5 years and included more than 9000 adult T2DM patients, showed superior reduction in major adverse cardiovascular events including cardiovascular death, non-fatal myocardial infarction, or non-fatal stroke. A previous cardiovascular outcome study of lixisenatide (ELIXA)[77] did not demonstrate an increase or decrease in the rate of cardiovascular events compared to placebo.

7.12.7.3 Thyroid C-Cell Tumor

Class labeling GLP-1R agonists marketed in the United States include a black box warning for risk of thyroid C-cell tumors.[62,78–81] This warning is based on the increased incidence of thyroid C-cell adenomas and/or carcinomas observed in rodents treated for 2 years with GLP-1R agonists. These tumors were sometimes observed at clinically relevant exposures. It has been hypothesized that thyroid C-cell hyperplasia, adenomas and/or carcinomas observed in repeat dose toxicity studies, or carcinogenicity studies in rats and/or mice are likely due to the activation of GLP-1Rs on rodent thyroid C-cells.[78,80] The relevance of these findings to other species is not known. Activation of GLP-1Rs receptor in rodent thyroid C-cells was associated with transient elevations in calcitonin levels.[78,82] Neither elevated calcitonin levels nor thyroid C-cell tumors were observed in monkeys given liraglutide for up to 87 weeks.[78] Little or no significant rise in calcitonin levels was identified in long-term clinical studies of liraglutide.[82,83] The density of GLP-1Rs on C-cells of rodents has been reported to be higher than that observed in monkey or human thyroid.[73,78,84,85] Taken together, these data suggest but do not prove that the thyroid C-cell tumors observed in rats and mice treated with GLP-1R agonists may be a rodent-specific phenomena; however, the relevance of these findings to human remains uncertain.[66]

7.12.7.4 Pancreatitis

Xu and colleagues have reported that GLP-1Rs are expressed on pancreatic ductal cells of rats and humans and have demonstrated that treatment of diabetic rodents and isolated human pancreatic islets with exendin-4, a long-acting GLP-1R agonist, increases β-cell differentiation/proliferation.[86,87] Although these data suggest that GLP-1R agonists could have a beneficial effect on

pancreatic function, pancreas has been identified as a potential target organ of toxicity. Pancreatitis has not been observed in mice, rats, or monkeys in repeated toxicity studies with liraglutide[88], exenatide,[59] and dulaglutide[80]. However, low-grade chronic pancreatitis was noted in rats treated with exenatide and elevated GLP-1 levels were suspected to cause pancreatitis in a transgenic rat model of T2DM.[89,90] In contrast, prolonged exposure of Zucker diabetic fatty rats to liraglutide did not reveal any evidence of drug-induced pancreatitis.[91] Clinically, isolated cases of acute pancreatitis have been reported in T2DM patients treated with GLP-1R agonists including exenatide and liraglutide;[82,92] however, an exposure-response relationship for the increased incidence of pancreatitis was not evident in clinical trials of GLP-1R agonsits. [93] It is well known that T2DM patients have up to three times higher risk for pancreatitis than patients without diabetes,[94] suggesting a better understanding of the relationship between treatment with GLP-1R agonists and pancreatitis is needed.[95,96]

7.12.7.5 Gall Bladder Events

For high-dose liraglutide, gall bladder has been identified as another potential target organ of toxicity based on clinical observations of cholelithiasis and cholecystitis in Saxenda®-treated subjects.[81] In most nonclinical toxicity studies, no adverse effects were observed in the gall bladders of animals administered GLP-1R agonists. However, an increased incidence of cholecystitis was observed in mouse gall bladder after repeated dosing of dulaglutide[62] and liraglutide[61]. Although treatment with liraglutide[61] was associated with other gall bladder findings such as abnormal contents and/or dilation/distention enlargement of the gall bladder in mouse, usually there were no histomorphologic correlates to these macroscopic observations. It should be noted that T2DM patients have almost twofold greater risk of biliary disease than patients without diabetes,[94] and substantial or rapid weight loss itself can increase the risk of cholelithiasis.[81] Increased incidences of cholelithiasis and cholecystitis were observed in patients treated with high-dose liraglutide (>1.8 mg) for weight management but not in patients treated with lower dose liraglutide (≤ 1.8 mg) for management of T2DM.[61,81] Furthermore, exposure-response analysis of several liraglutide clinical trials with more than 4000 patients did not reveal any relationship between liraglutide exposure and the incidence of documented gall bladder events.[93]

7.12.7.6 ADA Generations

Formation of anti-drug antibodies (ADA) has been reported for several GLP-1R agonists. The carcinogenic potential of albiglutide could not be assessed due the formation of ADA.[60] Monkeys treated with exenatide developed ADA within one month of treatment.[59]. At high titers, these anti-exenatide antibodies altered pharmacokinetics but did not affect the pharmacologic activity (reduced body weight effect) or toxicity in the monkey studies. Clinically ADA formation was more frequently identified in exenatide once weekly (~45% low titer, 12% high titer at 24–30 weeks) than exenatide BID (~32% low titer, 5% high titer at 30 weeks).[97,98] The incidence of injection site reactions appears higher in subjects with ADAs as compared to those without ADAs (24% vs. 15%). No significant correlation has been observed between low titer antiexenatide antibodies and efficacy, but higher titer antibodies were associated with a statistically significant attenuation in HbA1c reduction.[97] Potential ADA-related hypersensitivity, skin reactions, and GI symptoms have been described in a few patients ($<1\%$) in clinical phase 3 clinical studies of taspoglutide.[98,99] Low incidences of ADA formation (4–10%, low titers) have been reported for liraglutide but did not have a significant impact on efficacy and safety.[61]

7.12.8 Future Directions

There has been tremendous progress made in the discovery of novel GLP-1 agonists. Almost all of approved products are injectable as either once daily or once weekly subcutaneous treatment. In addition, Novo-Nordisk and vIV therapeutics are developing newer oral GLP-1 agents that can provide clear advantage in the GLP-1 space. The ongoing clinical studies will determine whether these new oral drugs will be advantageous in terms of safety and efficacy compared to current treatment options. The clinical use of GLP-1 agonists is moving greatly toward the direction of combination with other agents such as insulin and incretins. Coformulation is one of the attractive approaches to provide better glycemic efficacy and additional weight loss and CV benefits. IDegLira as developed by Novo Nordisk is one of the examples of co-formulation approach. In addition to Novo, a number of other companies have the potential to develop co-administration regimens of insulin with incretins. Sanofi has access to insulin glargine (Lantus) and the GLP-1R agonist lixisenatide. In addition, Roche is in early development with GLP-1R/GIPR dual agonist, which could also be combined with human insulin. Similarly, Lilly is seeking approval of basal PEGylated insulin analog (peglyspro), which could be combined with recently approved dulaglutide. The ongoing studies will determine the clinical efficacy, tolerability, and superiority compared to already available GLP-1 agents.

7.13.1 Introduction

Diabetes is a chronic disease that affects nearly 400 million individuals worldwide, the majority of these being Type 2 diabetics, whose disease is driven by insulin insufficiency and peripheral insulin resistance. A wealth of therapies are employed to treat this disease, but all come with the potential for serious events such as hypoglycemia, and most cause increases in body weight (BW) that further exacerbates the disease. New mechanisms are sorely needed that maintain their efficacy as the disease progresses, possess a low risk of serious adverse events, are weight neutral at a minimum,[1] and decrease the metabolic and cardiovascular risk factors associated with the disease.

Each day, all of the glucose in the blood, roughly 180 g, enters the kidney, is filtered by the glomerulus, and is then reabsorbed in the proximal tubule of the kidney by sodium–glucose cotransporters (SGLTs) that effectively recover >99% of the filtered amount. However, in diabetics, the high levels of glucose being filtered can exceed the capacity of the SGLTs to recover the glucose leading to glucosuria, the spillage of glucose into the urine. As glucosuria is not harmful to the patient and is an excellent way of eliminating excess energy, the inhibition of SGLTs has become a recent focus of the pharmaceutical industry as a way of reducing glucose levels. This should provide a novel way of reducing the hyperglycemia associated with diabetes and potentially provide benefit to a multitude of metabolic diseases.

The theoretical benefits of inhibiting SGLTs for diabetes and metabolic diseases are

- low risk for hypoglycemia as glucosuria decreases as blood glucose levels normalize;
- an effective treatment independent of insulin levels or sensitivity (will work in all patients!);
- the ability to pass 180 g (720 kcal) of glucose/day, the body's daily glucose requirement;
- reduction in glucose levels and glucose toxicity, therefore sparing the pancreatic beta cell;
- beneficial effects on hypertension and cardiovascular disease via reductions in blood pressure;
- weight loss, reducing stress on the body and improving cardiovascular risk factors.

7.13.2 Sodium–Glucose Cotransporters

The sodium–glucose transporters are a family of transporters from the SLC5 gene family that couple sodium to the transport of sugars most often glucose, galactose, and mannose and, in addition, myoinositol and short-chain fatty acids. Unlike the GLUTs that are facilitative glucose transporters and simply assist in moving glucose down a concentration gradient, the SGLTs are capable of collecting and transporting glucose against a concentration gradient, using the electrochemical force of the sodium gradient to accomplish this. The Na^+/K^+ pump continually maintains the gradient by pumping sodium out of the cell at the basolateral membrane. SGLTs work similarly in either proximal tubule cells or intestinal cells transporting glucose into the requisite cell at the luminal surface followed by GLUT-mediated transport of glucose into the bloodstream at the basolateral membrane. The main SGLTs of interest are SGLT1, a high-affinity/low-capacity transporter, and SGLT2, a low-affinity/high-capacity transporter. Substrates bind in an ordered fashion with Na^+ binding first, followed by a conformational change that opens up the site for glucose to bind.

The location of the high-capacity SGLT2 in the upper S1–S2 segment of the kidney proximal tubule functions to rapidly reabsorb the majority of the glucose (~90%). The high-affinity SGLT1 in the lower S3 segment acts to collect any remaining glucose (~10%) escaping SGLT2. The process is very efficient with >99% of the glucose recovered and a loss into urine of <0.5 g day^{-1} up to a filtered serum concentration near 11 mM (200 mg dL^{-1}). When this transport maximum (T_m) is reached, glucose begins passing the transporters and reaches the bladder to be excreted in the urine, one of the more common ways of identifying early-stage diabetics.[2] This threshold for glucose is altered in diabetics due to increased expression of SGLT2 ($T_{m\text{-}Glucose}=420$ vs. 317 mg min^{-1} in normal patients), and this increased preservation of glucose by the kidney only serves to exacerbate the diabetic condition. SGLT1 is also found in all three segments of the small intestine and is solely responsible for glucose and galactose absorption from the intestinal brush border of the gut. Some of the properties of SGLTs are shown in Fig. 1.[3]

7.13.2.1 Human SGLT Loss-of-Function Patients

Familial renal glucosuria (FRG) is a consequence of genetic defects in renal SGLT2 that results in varying amounts of glucose excreted in the urine.[4] In general, FRG is a mild disorder with patients living normal lives, experiencing no resulting kidney disease

	SGLT1 K_i (mM)	SGLT2 K_i (mM)

or early kidney failure and hypoglycemia or hypovolemia only rarely. Homozygous and multidefect heterozygous individuals can pass anywhere from 10 to 162 g of glucose per day depending on the extent of the defect or truncation of the protein, whereas heterozygous individuals appear normal and show only a very mild glucosuria ($<10\ g\ day^{-1}$). The rather benign nature of this defect along with the lack of any long-term pathophysiology associated with FRG, in addition to the ability to pass calories with a low chance of hypoglycemia, is the main reason that SGLT2 inhibition is a recent target for pharmaceutical intervention. Interestingly, FRG patients do not experience urinary tract infections, a concern reported with SGLT2 inhibitors investigated in clinic, suggesting that glucose levels in themselves are not responsible for these infections.[2]

Glucose–galactose malabsorption (GGM) is a genetic defect in SGLT1 protein, and to varying degrees, these patients are glucose-intolerant. The most severe cases are commonly diagnosed at birth due to severe osmotic diarrhea that is life-threatening unless glucose, galactose, and lactose are excluded from the diet. A study of GGM patients indicates that the defect is normally a missense mutation, most commonly D28N, which prevents viable SGLT1 from reaching the cell membrane. The outcome is that sugar and Na^+ along with the ~250 molecules of water/glucose molecule that would be normally absorbed in the upper intestinal tract are passed further down into the intestine. The nonabsorbed sugar and Na^+ extract water from the intestinal cells due to osmotic forces resulting in osmotic diarrhea. Bacteria further down in the gut exacerbate the situation as they metabolize the excess sugar releasing hydrogen and methane as by-products. GGM patients may also experience a minor renal glucosuria reflective of the role SGLT1 plays in the kidney.[5] In a study of GGM patients from an Amish population, it is observed that as these patients age, their glucose intolerance eases and they are able to tolerate carbohydrate in their diets by their teenage years.[6] It is uncertain whether this is an adaptive change in glucose transporter subtype or simply improved management of sugar disposal as probiotics accelerate the tolerance.[7] Finally, the amount of water absorbed along with sodium and glucose through SGLT1 in the intestine is significant and has been employed as an oral rehydration therapy in severely dehydrated cholera patients employing a salt/glucose solution.

7.13.2.2 SGLT Knockout Animals

SGLT1 knockout mice ($SGLT1^{-/-}$) are found to experience similar symptoms to GGM patients with an inability to absorb glucose and galactose, resulting in diarrhea when these carbohydrates are present in the diet.[8] In $SGLT1^{-/-}$ mice, little if any compensation through overexpression of GLUT transporters is reported as suggested elsewhere in response to hyperglycemia. $SGLT1^{-/-}$ mice do not exhibit glucose-induced activation of insulin release through GLP-1 and GIP indicating that glucose transport into L and K cells through SGLT1 may be necessary in order to trigger these responses. A minor reduction in renal glucosuria is observed in $SGLT1^{-/-}$ mice (~3%) as would be expected based on SGLT1's role in the kidney.

$SGLT2^{-/-}$ mice are healthy and show a similar growth rate compared with wild-type (wt) littermates except for being modestly hyperphagic and consuming twice the normal daily amounts of water.[9] Renal SGLT2 mRNA expression is absent although GLUT1 and GLUT2 expression is normal. SGLT1 expression and protein are reduced unexpectedly by 40% in $SGLT2^{-/-}$ mice compared with wt mice suggesting that under these conditions, a reduction in glucose reabsorption in early segments of the proximal tubule does not result in a compensatory increase in SGLT1 protein and glucose uptake in later segments of the proximal tubule. Reabsorption of glucose early in the proximal tubule is roughly 78% of the filtered load in wt mice and 0% in $SGLT2^{-/-}$ mice indicating

total loss of SGLT2 activity. Cumulative reabsorption assessed later in the proximal tubule totaled 93% of the filtered load in wt mice vs. 21% in SGLT2$^{-/-}$ mice indicating SGLT1 activity is still present and perhaps contributing more than expected to glucose recovery. Reabsorption is reduced overall suggested as a mechanism to protect the later proximal tubule from glucose toxicity. Systolic blood pressure (SBP), estimated glomerular filtration rate (eGFR), hematocrit, and plasma osmolality are normal as are plasma and urine levels of Na^+ and K^+, although modest changes in renin and aldosterone may reflect adjustments that prevent volume depletion. Knockout of SGLT2 on top of a diabetic *db*/*db* mouse background is hyperphagic (+20%) with a threefold increase in urine output and a 500-fold increase in glucosuria. However, even on a high-fat diet, these animals are protected from hyperglycemia and have preserved β-cell function and normal insulin sensitivity.[10] In another group, SGLT2$^{-/-}$ mice subsequently subjected to streptozotocin-induced diabetes showed protection from hyperglycemia, increased glucosuria, and renal hyperfiltration, an early marker of renal injury.[11] This suggests that pharmacological inhibition of SGLT2 should also prevent the renal injury common in diabetic patients by reducing glucose flux through the proximal tubule, thereby preventing proximal tubule hypertrophy and maintaining normal eGFR.[12]

7.13.2.3 Other SGLTs

SGLT3 is also found in the proximal tubule, shares 70% identity to SGLT1, and is located distal to SGLT1.[13] Examination of the function of SGLT3 indicates it is not a glucose/carbohydrate transporter but instead serves as a glucose-stimulated Na^+ transporter (see **Table 1**). SGLT3 expression is elevated in diabetes, which may lead to enhanced Na^+ transport postulated to promote hyperfiltration and ultimately renal damage. This suggests that inhibiting the SGLTs including SGLT3 in the proximal tubule could be beneficial in diabetics as it could also prevent the renal injury characteristic of advanced diabetes. However, none of the inhibitors described thus far inhibit SGLT3 in any significant way. Examination of the amino acid sequence of SGLT3 compared with SGLT1/2 indicates that a single-point change of glutamine-457 to glutamate (Q457E) relegates SGLT3 to the role of a glucose sensor/Na^+ transporter rather than glucose transporter. Interestingly, restoring glutamine-457 (E457Q) in SGLT3 protein reinstates its glucose transport function.[14] SGLT3 is also found in cholinergic neurons of the small intestine and the neuromuscular junction of skeletal muscle suggesting a role in the regulation of muscle contraction.[15]

SGLT4 is mainly expressed in the intestine and kidney with mannose as the preferred substrate. Mannose undergoes glomerular filtration by the kidney and is necessary for the normal glycosylation of proteins, making a specific mannose transporter necessary in the kidney.[16]

SGLT5 is expressed primarily in the S3 segment of the kidney proximal tubule and is responsible for fructose reabsorption after glomerular filtration. SGLT5$^{-/-}$ mice show complete elimination of Na^+-dependent fructose (and mannose) reuptake from the proximal tubule.[17] As metabolism of fructose in the liver leads to the synthesis and accumulation of liver triglycerides (TG) resulting in nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH), it is thought that selective inhibition of renal SGLT5 would be an appropriate treatment for these diseases. Surprisingly, the SGLT5$^{-/-}$ mice demonstrate an exacerbated fatty liver phenotype coexisting with increased hepatic insulin resistance. Marketed SGLT2-selective inhibitors are in general biased against SGLT5, although remogliflozin appears only 16-fold selective signifying an added benefit for treating metabolic syndrome is possible.[18]

SGLT6, also referred to as SMIT2, is expressed primarily in the brain and CNS and is responsible for myoinositol transport and has been associated with infantile convulsion diseases.[19]

7.13.2.4 SGLT Structure and Glucose-Binding Motif

Prior to the advent of crystallographic information, the binding of various sugar analogs provided a basic understanding of the requirements of sugar binding to the different SGLTs (see **Table 2**). AMG (α-methylglucose), a nonmetabolized glucose analog

Table 1 Characteristics of other SGLT homologues

D-Fructose	No interaction	D-Mannose	No interaction

used in cell assays to assess glucose transport, and D-glucose and D-galactose all bind to hSGLT1 in the 0.5–1 mM range. Removing the anomeric hydroxyl in 1-deoxyglucose (1DOG) results in a 10-fold shift in affinity to 10 mM. 2DOG and 3DOG lose another order of magnitude in binding affinity indicating the importance of these two hydroxyls to the binding of the sugar. Replacement of the 2- or 3-hydroxyls with fluorine shows opposing results with 2F2DOG remaining > 100 mM, while 3F3DOG recovers some of its binding (9 mM). 3-*O*-Methyl glucose (3OMG) retains affinity (3.5 mM) compared with 3DOG. Interestingly, 4DOG is no different than glucose, while the corresponding F-analog, 4F4DOG, actually gains some affinity (0.070 mM) compared to glucose itself. 6DOG and 6F6DOG are nearly equivalent binders indicating that in comparison with the 2- and 3-hydroxyls that are vital, the 4- and 6-positions are much less critical to tight binding to the transporter. However, the C6 methylene does appear important for affinity as the corresponding xylose derivatives are transported poorly. Fructose and mannose do not bind and are not transported. An understanding of these attributes can potentially provide an advantage in modifying the binding affinity and physiochemical properties of inhibitors. The low-affinity transporter, SGLT2, exhibits weaker binding constants with AMG and D-glucose at ~5 mM and does not interact with D-galactose.[5]

SGLTs' secondary structure is composed of 14 transmembrane (TM) helices with both the C- and N-terminal ends in the extracellular matrix. Although no crystal structures exist for human SGLT1/SGLT2 proteins, a homology model built using an X-ray of the bacterial galactose transporter from *Vibrio parahaemolyticus*[20] is available and employed to better understand the sugar binding site and the possible aglycone binding site.[21] The bacterial sugar binding site consists of residues from TM helices 1, 2, 6, 7, and 10. The Na^+ binding site is located ~10 Å away and is composed mainly of serine interactions S354/S355 and backbone carbonyls of A62, I65, and A361 in TM helices 1 and 8. The homology model for hSGLT1 indicates key interactions between each of the hydroxyls and protein as shown in Fig. 2.

As with ion channels, the SGLT transporters are dependent on the membrane potential, which accelerates initial sodium binding and leads to transport of more glucose at higher potentials. Na^+ is suggested to bind first, which then allows for a conformational change that exposes the sugar binding site. Subsequent to sugar binding, a conformational shift of the 12- and 6-helices opens the transporter pocket to the inside of the cell where the sodium ions and glucose diffuse out of the pocket. Na^+ is the best ion trigger for SGLT1 with a $k_{0.5}$ of 4 mM. Li^+ ($k_{0.5} = 12$ mM) is somewhat weaker and H^+, which is almost 1000-fold more potent ($k_{0.5} = 0.007$ mM), is also possible, but neither are important physiologically due to a 10–100-fold decrease in sugar binding

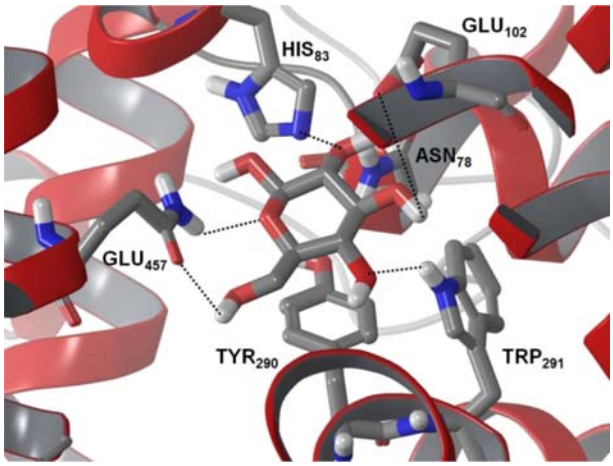

Fig. 2 Glucose binding interactions from homology model of hSGLT1 (from bacterial X-ray).

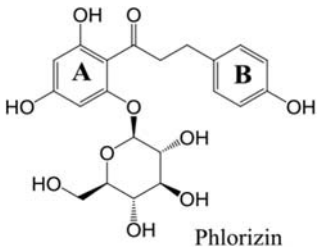
affinity. Expression of the high-affinity/low-capacity SGLT1 transporter in the gut, where large concentrations of glucose are present, is unexpected, although, as SGLT1 is located throughout the entire length of the small intestine, transporter efficiency is most relevant.

7.13.2.5 Inhibitor Binding Characteristics



Phlorizin

Initial small-molecule X-ray and computational analyses of the binding conformations of various inhibitors, of which phlorizin is the prototype (see O-glycosides), suggest that the distal B-ring either can adopt a position coplanar with the proximal A-ring and sugar or can fold up over the A-ring. Adoption of a model where B-ring is folded up over A-ring would increase the overall space occupied by the molecule, allowing a better filling of the intended cavity. This supports the observation that simple single ring phenylglycosides are transported, while other inhibitors with a sufficiently large aglycone are not transported. Examination of the SGLT homology model suggests the aglycone may bind in the loop between helices 13 and 14 corresponding to residues 604–610 in rabbit SGLT1. This sequence contains an FCG motif that is conserved across all SGLT isoforms.[22] A key residue in inhibitor binding in rabbit SGLTs, rbCys608, also shows equivalent human homologues, hSGLT1 (Cys610) and hSGLT2 (Cys615). Mutation of this residue in hSGLT1 (C610K) results in a significant loss of AMG transport and a corresponding 10-fold decrease in phlorizin binding.[23] In contrast, mutation of the equivalent residue in hSGLT2 (C615K) maintains AMG transport along with a twofold improvement in phlorizin binding. Along with other mutations that have been studied, this argues that these residues are key in forming a hydrophobic binding pocket but do not possess direct H-bonding interactions with the aglycone portion of SGLT inhibitors.

Comparisons of the activity of known SGLT inhibitors have shown clear discrimination over hSGLT3, hSGLT4, hSGLT6, and hSMIT1 with varying selectivity against hSGLT1 and hSGLT5 (see **Table 3**).[24] Homology is relatively high among family members with 67–84% similarity (50–70% identity) although species differences in homologues have been observed to vary activity 10-fold.

In general, all SGLT selectivity ratios as reported are determined in cell-based assays with the transporter overexpressed and with IC_{50}s based on steady-state conditions. However, when looking deeper into the initial rate constants, the selectivity can be quite different. Whereas steady-state IC_{50}s do provide a relative selectivity ratio, that is, >1200-fold for dapagliflozin, they do not explain the initial rate constants where dapagliflozin is shown to have only ~100-fold selectivity over SGLT1.[25] The overall effect an inhibitor has on SGLTs requires an understanding of the various on and off rate constants where in this case, the very slow off rate of dapagliflozin against SGLT2 and relatively short off rate against SGLT1 helps explain the actual selectivity (see **Table 4**). This could explain a continued effect on glucosuria after plasma concentrations have fallen below their IC_{50}s for compounds such as dapagliflozin, in addition to the vastly different doses of different SGLT2 inhibitors required for efficacy given that all known inhibitors have similar low nM binding affinities.

Table 3 hSGLT IC_{50}s and selectivity against other known homologues

Compound	*hSGLT2 IC_{50}*	*Selectivity relative to SGLT2*					
		hSGLT1	*hSGLT3*	*hSGLT4*	*hSGLT5*	*hSGLT5*	*hSMIT1*

7.13.2.6 Expression Levels of Glucose Transporters With Disease

7.13.2.6.1 Kidney

Hyperglycemia, whether in animal models or humans, leads to concomitant increases in mechanisms that increase or preserve carbohydrate energy reserves. In diabetic ZDF rats, the expression levels of renal SGLT1 and SGLT2 are increased 1.6- and 4.8-fold, respectively.[26] In other models of diabetes, increased renal SGLT2 mRNA levels and activity are driven by hyperglycemia, are under the control of HNF-1, and are reversed by normalizing glucose levels.[27] Renal proximal tubule cells collected from diabetic patients show a concomitant fourfold increase in SGLT2 mRNA and a threefold increase in GLUT2 mRNA compared with nondiabetic patients indicating an adaptive change to maximize glucose recovery. These cells demonstrate a threefold increase in AMG uptake.[28]

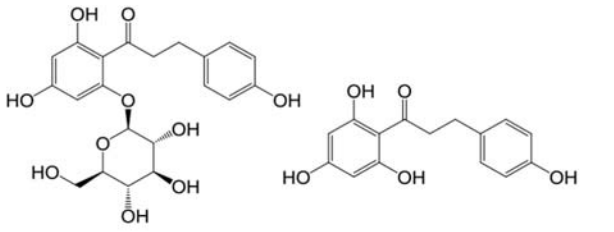
7.13.2.6.2 Intestine

A similar increase in glucose uptake is observed in the intestine of diabetic individuals. This is due to both hypertrophy of the small intestine's absorptive surface and an increase in the quantity of transporters SGLT1 and/or GLUT2 at the brush border and basolateral membrane, respectively. Using antibody recognition, a 4.3-fold increase in SGLT1 protein in brush border membrane (BBM) vesicles is found in diabetic vs. normal patients corresponding to a 3.3-fold increase in glucose transport capacity. The question of whether GLUT transporter expression at the BBM surface also plays a role has been investigated comparing phloretin-/phlorizin-[29] and cytochalasin B[30]-dependent transport with the body of evidence currently suggesting SGLT1 and not GLUT as the major effector of transport. As an added observation, GGM would not be as serious a condition in infants if the GLUTs were able to mediate transport. Indications of additional regulation involving phosphorylation through PKA/PKC are also suggested.[31]

7.13.3 SGLT Inhibitors

The potential effect of SGLT2 inhibitors in reducing glucose levels in diabetic patients has resulted in a wealth of agents entering the clinic and on the market. The purpose of this section is to highlight the genesis of various chemotypes both in terms of chemical diversity and summarize their clinical outcomes.[32]

7.13.3.1 O-Glycosides



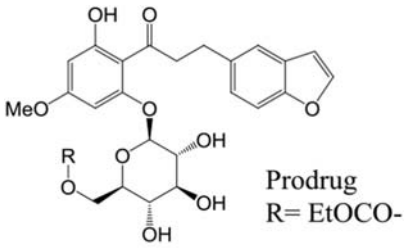
Phlorizin
SGLT2 IC_{50} 21 nM
SGLT1 IC_{50} 290 nM

Phloretin
SGLT2 IC_{50} 25000 nM
SGLT1 IC_{50} 50000 nM
GLUT IC_{50}~400 nM

Phlorizin, isolated originally from the bark of apple trees, is a potent inhibitor of human SGLT1 (290 nM) although this is species-dependent with the IC_{50} being an order of magnitude more potent (12 nM) in rat and considerably less potent against rabbit SGLT1 (760 nM). Phlorizin is an even better inhibitor of human SGLT2 (21 nM), the low-affinity/high-capacity transporter.[33] Phlorizin suffers from poor bioavailability requiring rather large oral doses in order to assess its effect on SGLT2 in the kidney, which results

in significant inhibition of SGLT1 in the gut along with the accompanying diarrhea observed in GGM patients. IV administration to patients at doses above 12 mg kg^{-1} results in complete inhibition of glucose reuptake by the kidney.[34] In addition to poor exposure when delivered orally, phlorizin is also unstable due to hydrolysis of the O-glycosidic bond by intestinal glucosidases, generating the aglycone, phloretin. Phloretin is well absorbed and has a variety of functions including inhibition of the GLUT transporters and uncoupling of oxidative phosphorylation. As the GLUTs are the major cellular glucose transporters, their inhibition could severely compromise a tissue's ability to maintain essential energy supplies, thereby making phlorizin unsuitable as a potential agent for the treatment of diabetes. Phlorizin has been shown to block glucose uptake into the brain and specifically glucose uptake into glucose-sensitive neurons in the hypothalamus. Injection of phlorizin into the brain of normal rats causes a marked increase in food intake although injection into the brains of ZDF rats has no effect.[35] For these reasons, it would be prudent to keep SGLT inhibitors out of the brain.[36] The recent evaluation of apple cider in healthy volunteers, which contains a plethora of polyphenolic compounds including phlorizin, confirms sufficient exposures to affect increases in glucosuria along with reductions in blood glucose and plasma insulin.[37] Phlorizin is the starting point for design of all sugar-containing SGLT inhibitors.

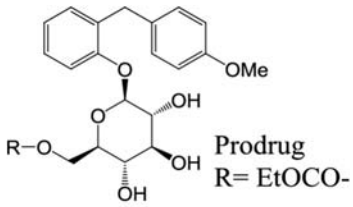
7.13.3.2 T-1095 (hSGLT2 $IC_{50} = 4.4$ nM: hSGLT1 $IC_{50} = 260$ nM)



T1095 R=H

T-1095 provides a modest improvement over phlorizin in terms of activity/selectivity by derivatization of one of the hydroxyls as a methyl ether and incorporation of the phenol oxygen into a benzofuran ring. It appears to be hydrolytically more stable and overcomes the poor bioavailability of phlorizin by using a carbonate prodrug situated on the 6-position of the sugar. As it is expected that the prodrug will be absorbed intact to be cleaved in the liver, this would serve to both limit the effect on SGLT1 in the gut and increase the plasma exposure of active drug.

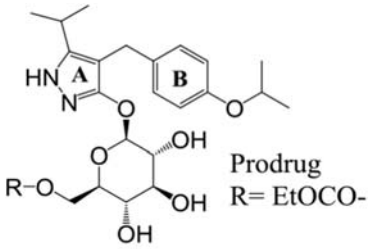
7.13.3.3 Sergliflozin (hSGLT2 $IC_{50} = 7.5$ nM: hSGLT1 $IC_{50} = 2100$ nM)



Sergliflozin R=H

Sergliflozin is the next key compound, maintaining a β-O-glycoside similar to phlorizin and T-1095 but reconstituting the aglycone to remove the phenols and make the compound more drug-like. Selectivity is improved with a ratio of 200-fold over SGLT1. Sergliflozin is still an O-glucoside and requires a prodrug to escape glucosidases in the gut and achieve sufficient exposures. Early clinical outcomes show glucosuria of approximately 20 g day^{-1} in healthy volunteers and 36 g day^{-1} in T2DM patients, along with a reduction in glucose area under the curve (AUC) during an oral glucose tolerance test (OGTT) when administered at 500 mg day^{-1}. The activity is limited due to poor exposure with a short half-life and would require frequent dosing in order to be a successful drug.[38] A study of carbocyclic versions of sergliflozin indicates that removal of the ring oxygen substantially improves stability to glucosidases. Even though half-life and efficacy improve, selectivity and other physiochemical liabilities limit clinical advancement.[39]

7.13.3.4 Remogliflozin (hSGLT2 IC_{50} = 12.4 nM: hSGLT1 IC_{50} = 6500 nM)

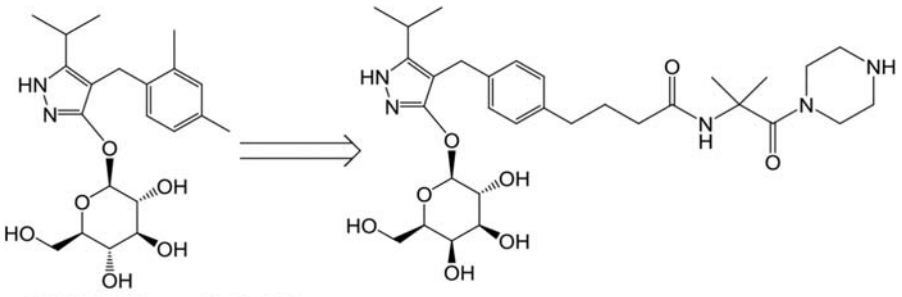


Remogliflozin R=H

Remogliflozin substitutes the A-ring phenyl with a pyrazole and is optimized for improved properties although it still requires dosing as a prodrug to avoid cleavage by the glucosidases.[40] A report of the early clinical studies looks promising with 1000 mg QD dosing in diabetic patients resulting in a urinary glucose excretion (UGE) of 165 g day^{-1}, nearly that of the maximum filtered load of 180 g day^{-1}. Unfortunately, this dose only results in a minor reduction in fasting plasma glucose (FPG) of 5.4 mg dL^{-1}, which is puzzling. Doses of 100 mg BID and 1000 mg BID produce roughly equivalent daily UGE values of 91.6 and 103 g/24 h and FPG reductions of 23.4 and 41.4 mg dL^{-1}, respectively.[41] Subsequent 12-week studies confirm reductions in HbA1c of 0.73–1.07% with doses ranging from 50 to 1000 mg QD.[42]

7.13.3.5 SGLT1-Selective Analogs of Remogliflozin (hSGLT2 IC_{50} = 1730 nM: hSGLT1 IC_{50} = 50 nM)

This template was further investigated with the goal of generating selective SGLT1 agents. With suitable modifications, 24-fold selective SGLT1 agents with improved intestinal stability are identified, showing no effect on renal glucosuria and complete inhibition of carbohydrate absorption during an OGTT.[43] Continued efforts to improve activity and stability are needed as glucosidases are still an issue in vivo leading to the expected aglycone cleavage and producing undesirable pharmacology. Along with further improvements in stability, the aglycone portion is modified with functional groups that prevent absorption should cleavage occur. These compounds proved superior to acarbose, an alpha-glucosidase inhibitor, in preventing glucose absorption in animal models and with reduced side effects (diarrhea).[44]

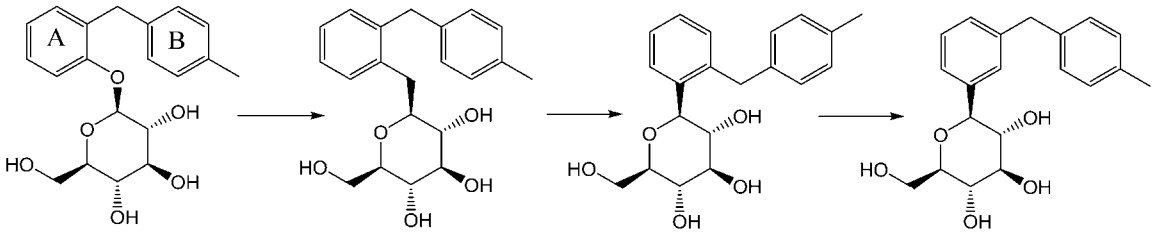


SGLT2 IC_{50}= 6010nM
SGLT1 IC_{50}= 246nM

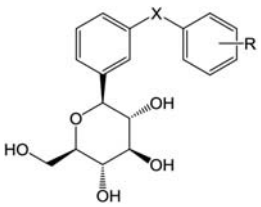
SGLT2 IC_{50}= 1730nM
SGLT1 IC_{50}= 50nM

7.13.4 Origin of C-Glucoside

In an attempt to reduce the instability of the O-glycosides, a conservative O- to C-replacement on the sergliflozin template loses nearly 60-fold potency against SGLT2. Removing the oxygen altogether generates the first C-arylglycoside where the activity tumbles even further to 4000 nM. However, examination of a pharmacophore model suggests that shifting the B-ring connectivity from an orthobenzyl to a metabenzyl should better approximate the O-glycoside conformation. Indeed, this allows recovery of most of the activity of the original structure while more importantly removing the instability inherent in the O-glycosides.[30]



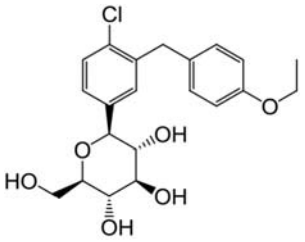
Initial optimization of the newly identified aglycone reveals that alteration of the aromatic linker along with suitable substitution of the B-ring produces effects on both potency and selectivity over SGLT1.[45]



Cmpd	*hSGLT IC_{50} (nM) (hSGLT2 selectivity ratio over hSGLT1)*				
	X = CH_2	X = Bond	X = CH_2CH_2	X = S	X = O
R = H	190	623	710		
R = 4-Me	22 (600-fold)	290 (30-fold)	430 (20-fold)	69 (100-fold)	540 (15-fold)
R = 3-Me	510	1200	970		

7.13.4.1 Dapagliflozin (hSGLT2 IC_{50} = 1.1 nM: hSGLT1 IC_{50} = 1400 nM)

Additional rounds of optimization of the A-ring and the B-ring give the best combination of potency and selectivity in dapagliflozin with selectivity over hSGLT1 of 1200:1.



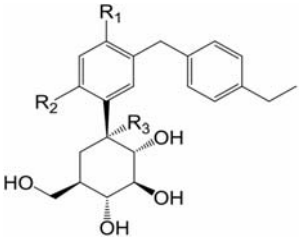
Dapagliflozin

Early clinical evaluation reveals that at doses of 5–100 mg day^{-1}, glucosuria reaches a maximum of 82 g day^{-1} on day one and then moderates to 64 g day^{-1} as the hyperglycemia normalizes, resulting in less glucose to filter and excrete. This is the first reported example where drug-induced glucosuria is limited providing only 44% of the total possible 180 g of glucose recovered each day. On day 13, fasting serum glucose is reduced by 15.4 mg dL^{-1}, and an OGTT allows a 17.4% reduction in glucose AUC compared with placebo control.[46] Hypoglycemia is observed in 10% of the patients, although metformin cotherapy could contribute to this. As dapagliflozin is highly selective and unlikely to inhibit SGLT1 activity in the gut, the reduction in OGTT is likely in response to glucosuria and improved insulin-mediated glucose disposal due to reduced glucotoxicity. Longer-term studies demonstrate consistent reductions in HbA1c of 0.72–0.66% as monotherapy with corresponding decreases in BW of up to 2.2 kg and SBP of up to 4 mmHg.[47] In more recent examinations in diabetic patients, dapagliflozin increases glucosuria by 78–91 g glucose/day, enhances whole-body glucose disposal, primarily in the muscle, decreases insulin levels as a result of decreased hyperglycemia, and counters glucose toxicity increasing insulin sensitivity. Unexpectedly, an increase in endogenous glucose production (EGP) in response to increases in glucagon occurs.[48] Increases in both glucagon levels (23%) and EGP result in an increase of ~47 g glucose/day offsetting the effect of glucosuria and reducing the expected effect on plasma glucose by 50%. As other SGLT inhibitors also show this increase in EGP

following drug treatment, this effect along with the limitations on glucosuria noted earlier significantly undercuts the overall benefit to patient.

Dapagliflozin was evaluated in both naive early-stage diabetics and late-stage diabetics on insulin therapy with similar renal function. Although dapagliflozin is effective in both groups, higher starting FPG, HbA1c, and weight translate into better outcomes on glucosuria, HbA1c reductions, and weight loss in the late-stage patients.[49]

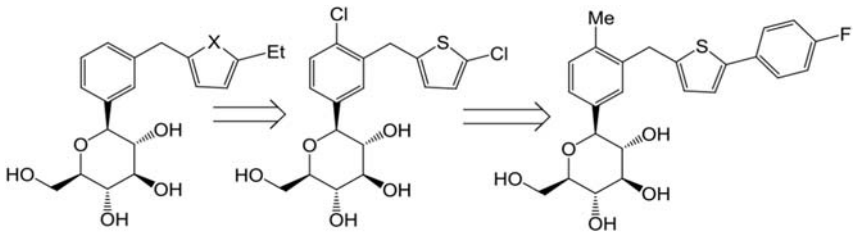
Carba-analogs of the C-linked glycosides are also interesting. In this case, retention of the hydroxyl at the previous anomeric center (R3) gives varying effects on potency but always improves the SGLT2 selectivity. Addition of a group at the C6 center of the A-ring (R2) improves selectivity dramatically but unexpectedly only when the C4-position (R1) is vacant in contrast to previous findings by others.[50]



R_1	R_2	R_3	hSGLT2 IC_{50}	Selectivity
H	H	H	49	670
OMe	H	H	8.3	61
OMe	H	OH	100	310
H	OMe	H	12	6100
H	OMe	OH	14	>7100
OMe	OMe	H	8.5	530
OMe	OMe	OH	10	860

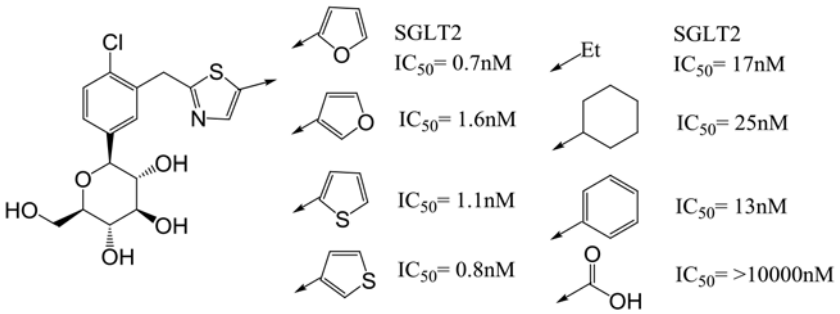
7.13.4.2 Canagliflozin (hSGLT2 IC_{50} = 4.4 nM: hSGLT1 IC_{50} = 684 nM)

Soon after the discovery of C-aryl glycosides as preferential to O-glycosides, an explosion of SAR commenced. Replacement of the B-ring phenyl as in phlorizin and dapagliflozin with heteroaromatics proves equally attractive. Although the initial furan was disappointing, the thiophene shows much better activity, while pyrazole and pyridine are ~10-fold weaker.[51] Optimization of the A-ring substituents shows that chloro and methyl substitutions provide a significant advantage. Aromatic substitution of the thiophene proves even better both in terms of in vivo activity and chemical stability and provides the clinical candidate canagliflozin.[52]



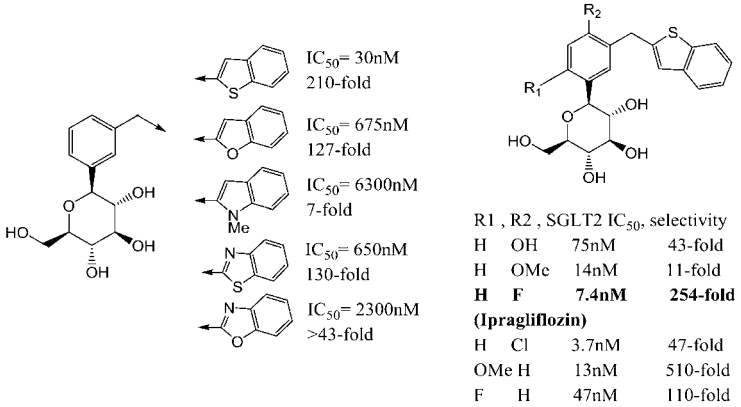
As canagliflozin has only a modest selectivity of ~155-fold over SGLT1, one could expect that at higher dose regimens, it would begin to show some of the positive and negative effects of SGLT1 inhibition in the gut. Patients administered 300 mg of canagliflozin show a 20% inhibition of glucose uptake in the gut over the first 2 h. However, this is followed by a substantial increase in glucose uptake of 34% over the next 4 h producing a 6% net reduction in intestinal glucose uptake as compared with the first 6 h.[53] Delayed gastric emptying, as assessed by acetaminophen absorption is observed in this study although it is insufficient to explain the entirety of the effect. Increases in gut peptides GLP-1 and PYY with corresponding reductions in GIP suggest that inhibition of SGLT1 is delaying glucose absorption sufficient to trigger these responses by L cells. As the delay of early glucose absorption is then countered by a faster rate at later times, this transient effect would not result in a real inhibition of total glucose uptake, but would reduce the postprandial glucose spike and trigger an incretin response; and perhaps, independent of the kidney effects has a beneficial effect on glucose homeostasis. However, as a hydrogen breath test is negative, this suggests little if any glucose persists into the lower gut where bacteria would metabolize it releasing hydrogen in the process.

Continuation of this heterocyclic SAR expansion provides additional subnanomolar compounds when the B-ring is a suitably decorated thiazole. Further substitution of the thiazole with a simple alkyl chain or aromatic does not increase potency, although furans and thiophenes show considerable improvement.[54] Additional heteroatoms in either of the heterocyclic rings do not provide any further benefit. The need for the aglycone to consist of a nonpolar somewhat planar assembly is clear. Attempts to instill solubilizing polar groups such as carboxylic acid are entirely unacceptable even as a B-ring substituent. The furan and thiophene compounds with maximal potency still possess poor physiochemical properties that preclude clinical examination.



7.13.4.3 Ipragliflozin (hSGLT2 IC_{50} = 7.4 nM: hSGLT1 IC_{50} = 1880 nM)

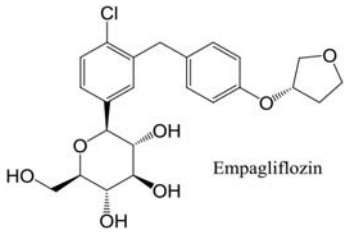
Expanding the scope of the B-ring to fused aromatics results in limited success, with benzothiophene proving the best option, although 10–100-fold losses of activity are observed with modest changes in heterocycle. Optimization of the A-ring substituents leads to the discovery of clinical candidate ipragliflozin. Additional evaluation of R_1 substitution, generally ignored since phlorizin, suggests that this position can also tolerate substitution to generate improved SGLT2-selective agents.[55]



R1	R2	SGLT2 IC_{50}	selectivity
H	OH	75nM	43-fold
H	OMe	14nM	11-fold
H	**F**	**7.4nM**	**254-fold**
(Ipragliflozin)			
H	Cl	3.7nM	47-fold
OMe	H	13nM	510-fold
F	H	47nM	110-fold

Initial dose-range finding trials in diabetic patients provide a maximum placebo-adjusted reduction in FPG of 60 mg dL^{-1} along with reductions in BW and SBP. Gastrointestinal disorders are common and reported in 50% of the study population. A 12-week study of ipragliflozin dosed from 12.5 to 150 mg provides a placebo-adjusted HbA1c reduction of 0.61–1.31% (placebo HbA1c increases by 0.5%). FPG is reduced by 27.6–58.9 mg dL^{-1}, and a reduction in BW of 1.61 kg is observed at the highest dose. Adverse events (AEs) are typical of this class including GI, UTI, and polyuria.[56]

7.13.4.4 Empagliflozin (hSGLT2 IC_{50} = 3.1 nM: hSGLT1 IC_{50} = 8300 nM)



No publications examining the SAR of empagliflozin exist, but it would appear the efforts are aimed at optimizing the 4-position of the B-ring. When examined in diabetic patients, the highest dose of 25 mg produces placebo-corrected reduction in HbA1c of 0.70%, with FPG reduction of 24 mg dL^{-1}, and modest effects on weight loss (2.1 kg) and SBP (3.4 mm) over 12 weeks of treatment. Modest reductions in eGFR are noted as have been observed with other SGLT2 inhibitors and are reversible once treatment is discontinued. Examination of individual patients suggests that those with normal eGFR have no change during treatment, while patients with hyperfiltration, a hallmark of early diabetes, do see a reduction. Significant loss of efficacy is observed in patients with progressively worsening eGFR with a 50% reduction in glucosuria in stage-3 chronic kidney disease (CKD) and total loss in stage-4 CKD typical of SGLT2/kidney centric agents.[57]

7.13.4.5 Tofogliflozin (hSGLT2 IC_{50} = 2.9 nM: hSGLT1 IC_{50} = 8444 nM)

Efforts toward tofogliflozin focus on the orientation between the sugar and the aglycone using a pharmacophore approach based on known SGLT inhibitors. This exercise suggests that insertion of a spiro-sugar connection maintains the proper shape and provides novelty of structure. Optimization of the remaining aglycone follows the traditional bibenzyl path with slightly different outcomes.

			SGLT2 IC_{50} (nM)	*Selectivity SGLT1/2*
Dapagliflozin			1.3	800
	R1	R2		
Tofogliflozin	Et	H	2.9	2912
1	iPr	H	3.2	3855
2	F	H	123	152
3	CN	H	118	691
4	Et	Cl	1.3	122
5	Et	Me	1.4	90

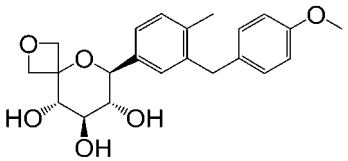
Interestingly, 4-substitutions on the A-ring degrade selectivity and so are intentionally absent. Electron-withdrawing groups on the B-ring (compounds 2 and 3) are also found detrimental to both selectivity and activity.[58] Comparative in vivo studies select tofogliflozin over other analogs due to superior PK parameters, with improved exposure and reduced clearance. A 52-week trial in diabetics demonstrates a reduction in HbA1c of approximately 0.67% at both 20 and 40 mg QD doses against patients own baseline values (no placebo controls). Modest effects on TG, HDL-C, LDL-C, and SBP are observed along with increases in eGFR. Ketone bodies, a new safety concern for this class of compounds, nearly double (108–211 μmol L^{-1}) in the tofogliflozin-treated groups.[59]

Close derivatives of spiro glucoside are also prepared where the spiro-ring oxygen is replaced with carbon. This effort produces clearly the most selective compounds to date due to near total loss of SGLT1 activity. These compounds, however, are rapidly cleared in vivo, which limits their effects on glucosuria in rats.[60]

Cmpd	*X*	*SGLT IC_{50} (nM)*	*Selectivity SGLT1/2*
	Dapagliflozin	6.7	132[a]
	$-CH_2-$	0.3	18,667
	$-CHOH-$	40	3450
	$-CHF-$	0.9	56,667
	$-CHOMe-$	1.8	55,000
	$-CH_2CH_2-$	33	>6060

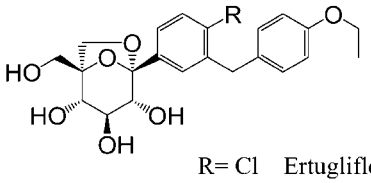
[a]Selectivity values for dapagliflozin are usually ~1000 as reported elsewhere.

7.13.4.6 Ertugliflozin (hSGLT2 IC_{50} = 0.88 nM: hSGLT1 IC_{50} = 1960 nM)



SGLT2 IC_{50} 6.98 nM
SGLT1 IC_{50} 1540nM
HLM Cl= 12 uL/min/mg
HHep Cl= 44 uL/min
Rat plasma Cl = 22 mL/min/kg

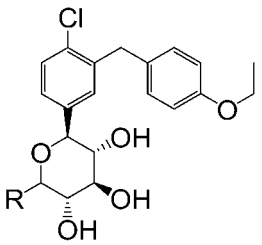
This approach investigates modification of the sugar rather than the aglycone. Starting with sequential modification and removal of hydroxyls around the ring, the critical requirement of the C2 and C3 hydroxyls for binding coupled with flexibility at the C4 and C5 positions is soon rediscovered.[61] The first spirocyclic sugar has relatively good potency, sufficient selectivity, low microsomal clearance, and good physiochemical properties and oral exposures. However, clearance in human hepatocytes is much higher than observed in microsomes, possibly due to the lack of an H-bond donor in the 5 position, and, in addition, effects on UGE in a rat model are unimpressive.

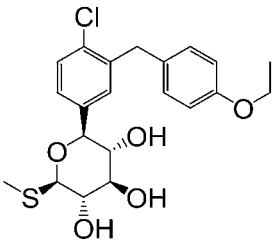


R= Me	R= Cl Ertugliflozin
SGLT2 IC_{50} 1.07 nM	SGLT2 IC_{50} 0.93 nM
SGLT1 IC_{50} 506nM	SGLT1 IC_{50} 2050nM
HLM Cl= <8 uL/min/mg	HLM Cl= 12 uL/min/mg
HHep Cl= <2.1 uL/min	HHep Cl= 4.5 uL/min
Rat plasma Cl=37 mL/min/kg	Rat plasma Cl=4 mL/min/kg

An alternate bicyclic series proves much more amenable with regard to acceptable activity and in vitro clearance. The first compound (R=Me) has the appropriate activity with good microsomal and human hepatocyte stability but inordinately high in vivo rat clearance. Employing the dapagliflozin aglycone then provides ertugliflozin with near 2000-fold selectivity and good in vitro and in vivo PK characteristics.[62] The authors claim that this substitution pattern at the C5 position of the sugar solves supposed issues with genotoxicity that are common in previous compounds tested across the industry using the standard in vitro micronucleus assay.[63] Clinical evaluation of ertugliflozin in diabetic patients over 12 weeks demonstrates placebo-adjusted reductions of HbA1c (0.72%), FPG (32 mg dL^{-1}), and BW (1.9 kg) at the highest dose (25 mg). Reductions in SBP (3.4 mm) and DBP (2.6 mm) are observed along with reductions in fasting insulins indicating relief of glucotoxicity. Serum lipids (cholesterol, LDL, and HDL) are increased similar to other SGLT2i. AEs are moderate across dosing groups, and UTIs, common with SGLT2i compounds, are only seen in the 10 mg group, notably the only group with near equal distribution of women.[64]

7.13.4.7 Sotagliflozin (Lexicon LX4211) (hSGLT2 IC_{50} = 1.8 nM: hSGLT1 IC_{50} = 36 nM)





R,	hSGLT2 IC_{50}
βOMe	14nM
αOMe	4800nM
β OiPr	33nM
β OBn	620nM

LX4211
hSGLT2 IC_{50}= 1.8nM
hSGLT1 IC_{50}= 36nM

LX4211 is the first compound reported that intentionally adds SGLT1 inhibition to its profile. Addition of SGLT1 could potentially improve glucosuria further over the nine SGLT2-selective agents as explained earlier. However, SGLT1 in the kidney is only reported to account for 10% of the glucose recovery, questioning whether this effect would be measurable. Inhibition of SGLT1's effect on reducing or eliminating glucose uptake in the intestine has the potential to be truly meaningful if it does not produce the diarrhea observed in the SGLT1-deficient GGM patients. This approach utilizes a different sugar, xylose, which ultimately reduces the C5 methanol unit of glucose to an alcohol. Stereochemistry at the C5 position requires the β-configuration as the α-configuration lost more than 100-fold in activity. Activity also degrades with increasing size of the alkoxy unit.[65] The clinical candidate, LX4211, has a thioether substituent at C5, an interesting choice as one would expect that increased metabolism would limit exposures.

The effects of LX4211 in a 4-week trial show promising results with reductions in FPG of 39 and 55 mg dL^{-1} at the 150 and 300 mg dose levels, respectively, along with corresponding reductions in HbA1c of 0.66 and 0.76 (placebo-corrected).[66] Additional reductions in LDL and HDL are also observed in contrast to most SGLT2-selective agents. Activation of the GLP-1 pathway is evident, which also

improves glucose homeostasis by improving insulin action and delaying gastric emptying. An assessment of timing of dose with effect on postprandial glucose levels indicates that LX4211's effect is dependent on the presence of compound in the gut irrespective of systemic concentrations.[67] A 12-week study supports HbA1c reductions of 0.83%, similar to values seen with the SGLT2-selective agents, although with only a 29 mg dL^{-1} drop in FPG.[68] BID dosing provides the best weight loss of 2.6% (200 mg BID @ 12 weeks). As BID dosing should inhibit gut SLGT1 at least enough to cover an additional meal, the effect is somewhat disappointing as it did not differentiate from SGLT2-selective agents. AEs are generally mild with reports of urinary tract infections (UTIs) and diarrhea, but these did not differentiate from placebo. The lack of significant intestinal effects expected with gut SGLT1 inhibition suggests either that the concern is overblown or that LX4211 has only transient effects in the gut similar to that observed with canagliflozin.

7.13.4.8 Luseogliflozin TS071 (hSGLT2 IC_{50} = 2.3 nM: hSGLT1 IC_{50} = 3990 nM)

Me	2.3nM	293-fold
Cl	1.8nM	684-fold

R,	hSGLT2 IC_{50}	SGLT1/2	
H	38nM	2640-fold	
OMe	11nM	395-fold	
Me	2.3nM	1770-fold	(luscogliflozin)

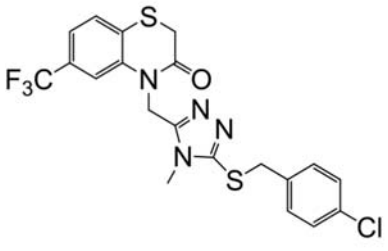
Conversion of the pyranose ring O to S results in similar SAR as seen previously including A-ring 4-substitution preferences. The addition of a methoxy group in the 6-position of the A-ring leads to improvement in potency and selectivity ultimately resulting in luseogliflozin as the clinical candidate.[69] Early clinical trials with luseogliflozin show reductions in HbA1c of 0.82% (placebo-adjusted) at the highest dose of 5 mg along with reductions in FPG of 27 mg dL^{-1}.[70] BW losses and SBP reductions of 1.7 kg and ~6.6 mmHg are in line with other SGLT2 inhibitors. AEs are minimal, and UTIs are not observed, although the patient population is skewed toward men in all groups. As with other SGLT2 inhibitors, decreases in insulin are matched by increases in glucagon, although not triggered by hypoglycemia as glucose levels remain above 100 mg dL^{-1} assessed by continuous glucose monitoring.[71]

7.13.4.9 A-Ring Replacements

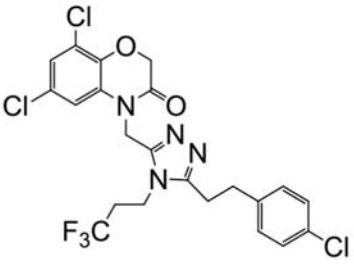
Very few replacements of the A-ring are described. In these manuscripts, two different indole replacements, one as an N-glycoside and the other as a C-glycoside, produce moderate activity although selectivity remains elusive.[72] A similar attempt utilizing a thiophene, ordinarily considered a direct phenyl replacement, produces compounds of only modest activity.[73]

7.13.4.10 Nonnucleoside Inhibitors

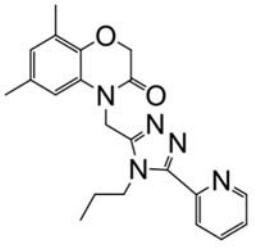
Little if any effort has been directed toward finding nonglucoside SGLT inhibitors, although one effort uncovered a rather potent starting point using high throughput screening (HTS).[74] This series was then optimized to eliminate metabolic liabilities and improve potency.



hSGLT2 IC_{50} = 1400nM
hSGLT1 IC_{50} = 7000nM



hSGLT2 IC_{50} = 10nM
hSGLT1 IC_{50} = 6300nM



hSGLT2 IC_{50} = 12nM
hSGLT1 IC_{50} NA

Through the course of these efforts, very little change in SGLT1 inhibition is observed with the best compounds showing approximately 1000-fold selectivity of SGLT2/1 similar to that of dapagliflozin. Although metabolic liabilities are partially addressed, the compound still does not meet development criteria, and further, SAR minimizes many of these liabilities while retaining SGLT2 potency and increasing solubility.[75]

7.13.5 Limitations on Effects of SGLT Inhibitors

Ever since SGLT2 inhibitors have been evaluated in clinic, a significant limitation becomes apparent with inhibitors providing only 30–50% of the 180 g maximum possible glucosuria per day. Potential reasons for this have been postulated resulting in various scenarios that could account for this deficiency, although currently no single explanation accounts for this reduced effect on glucosuria.[76]

7.13.5.1 Target Engagement

Examination of different agents suggests that varying dosing regimens generate sufficient systemic exposure to fully inhibit SGLT2 although activity does persist longer with some inhibitors potentially due to slower off rates. Another limitation is the ability of the inhibitor to physically reach the target, the luminal side of the transporter in the proximal tubule, and disposition of the inhibitor once dissociated from the transporter. As very few inhibitors are recovered as unchanged drug in the urine, most are likely reabsorbed and only eliminated after metabolism indicating repeated access to target is not an issue. Although overexpression of SGLT2 transporters in response to hyperglycemia is expected, a deficiency of drug is unlikely as dose adjustment would be expected to compensate. Other less likely scenarios posit whether newly expressed SGLT2 transporters, as a result of hyperglycemia, could be in a different location anatomically or are inserted into the membrane in such a way as to be blind to SGLT2 inhibitors but not to glucose.

7.13.5.2 Competition With Glucose

Increasing concentrations of glucose in the proximal tubule as a result of hyperglycemia could compete with the inhibitor, although as the activity of most known inhibitors is low nM, while the binding constant for glucose is $\sim$5 mM, a million-fold less, it is unlikely that glucose itself could effectively compete with most of the known inhibitors.

7.13.5.3 Other Transporters

Expression of other glucose transporters such as GLUTs on the BBM has been considered and tested extensively, although current evidence suggests that this potential bypass mechanism to enhance glucose absorption is not functional. Otherwise, one would expect GGM patients to be able to express transporters to absorb glucose making their side effects less severe. Alternatively, the remaining SGLT1 could simply take the place of SGLT2 and reabsorb the majority of the glucose; however, this is not shown to be the case in terms of expression or transport rate and as well with the dual SGLT1/2 inhibitor, LX4211.

7.13.5.4 Patients With Kidney Damage

One of the accompanying comaladies associated with diabetes is kidney disease that presents initially with hyperfiltration but then proceeds with continual reductions in eGFR that eventually leads to kidney failure.[77] This is driven by increased glucose flux through the proximal tubule cells, which triggers a hypertrophic phase aided by paracrine factors, EGF, and angiotensin II. This causes an increase in reactive oxygen species leading to tubule cell damage and ultimately apoptosis. Hyperglycemia is shown to increase the levels and transport capacity of the SGLT transporters and results in even larger flux through the tubule cell.[78] In the development of SGLT inhibitors, a question remains as to whether they will prevent or protect the kidney from this pathophysiology.[79] As SGLT2 inhibitors work in the kidney, a question of loss of efficacy with decreasing renal function is an important consideration in this patient population. As proximal tubule cells collected from diabetic patients elicit a reduction in oxidative stress and apoptosis when exposed to various SGLT inhibitors, there is hope that this effect will be observed in patients as well. However, to date, it would appear that most SGLT2 inhibitors cause a modest reduction in eGFR. The effect of dapagliflozin and other SGLT2 inhibitors on glucosuria, however, is severely encumbered ($>$5-fold) under conditions of moderate to severe renal impairment.[80]

7.13.5.5 Drug Metabolism and Clearance

The extent of exposure of a particular agent can also be altered based on both renal function and individual drug metabolism and clearance pathways. Although the exposure profiles of most of the SGLT2 inhibitors do not vary extensively with changes in renal function, exposure maximums increase as clearance is generally reduced. Multiple elimination pathways are preferred so as not to stress one pathway or result in changes in exposure or clearance of other drugs (DDI). The metabolism and route of elimination of dapagliflozin were extensively studied in normal patients and patients with varying stages of kidney disease. In the case of dapagliflozin, the primary route of metabolism is phase-2 glucuronidation at the 3 position of the sugar with 61% of this metabolite being

recovered in the urine of patients. Decreasing eGFR nearly doubles the drug AUC as renal clearance decreases. As less than 1% of unchanged drug is cleared renally and as drug effect requires the drug be on the luminal side of the transporter where the drug could be easily excreted, a reabsorption pathway in the lower proximal tubule is necessary. Many of the known SGLT2 inhibitors, such as canagliflozin, empagliflozin, ertugliflozin, and ipragliflozin, are extensively glucuronidated prior to excretion, although empagliflozin is excreted to some extent as unchanged drug in the urine (28.6%) and tofogliflozin is predominantly excreted in the urine as unchanged drug and oxidative metabolites.[81,82]

7.13.5.6 Increased Glucagon Response

Additional studies with dapagliflozin and empagliflozin[83] demonstrate that increases in glucagon and EGP occur upon drug treatment and produce significant limitations in the agent's effect on hyperglycemia in diabetic patients. Using tracer studies in diabetic patients, reductions in postprandial glucose levels would be fourfold greater if enhanced EGP did not compensate. Although the actual cause of this is unknown, it could be a direct consequence of lower glucose levels attenuating insulin release, which subsequently reduces glucose uptake in insulin-sensitive tissues along with a maintained or higher glucagon–insulin ratio that induces glucose production. It is possible that immediate corrections of the diabetic phenotype by SGLT2 inhibitors through improvements in glucose toxicity, insulin sensitivity, hyperinsulinemia, and glucose uptake are not immediately sensed in the pancreas where islet hyperplasia results in increased islet cell mass. The reduction in insulin release from the β-cell may remove the local paracrine restraint on the α-cell allowing for either maintained or even larger glucagon release from the α-cell. An alternative explanation suggests SGLTs as the major glucose transporters on the α-cell,[84] and as a result, inhibition of transport into the α-cell signals an intracellular hypoglycemia resulting in increased glucagon release. As the addition of phlorizin, a dual SGLT1/2 inhibitor, has no additional effect on glucagon release, the effects are likely SGLT2-selective.

7.13.6 Potential Safety Concerns

7.13.6.1 Hypoglycemia

One of the biggest concerns of patients and physicians is the potential for hypoglycemia with any therapy for diabetes, and many of the current standards of care do have this potential especially when combined with other therapies. The potential for hypoglycemia with the known SGLT2 inhibitors has proved very low, an expected finding as the drug effect is dependent on blood glucose levels and hepatic glucose production will maintain euglycemia.

7.13.6.2 Urinary Tract Infections

Urinary tract and genitourinary infections, predominantly fungal *candidiasis* and bacterial infections, respectively, could be expected to limit the use of SGLT inhibitors in the diabetic population. These infections are considered a direct result of the increased glucose passing through the bladder due to inhibition of glucose reuptake by SGLTs. Indeed, an increased incidence of infections is observed with SGLT inhibitors, which are much more often reported in women ($>85\%$ of reported cases) than men likely due to anatomical considerations and are usually mild and self-treated. More recent clinical trials have sought to limit the number of patients entering the evaluation with a history of UTI in order to assess the actual drug-related increase in these events. Diabetics are more prone to these types of infections due to increased adherence of bacteria to the uroepithelial cells and account for why the FRG population with extensive glucosuria does not experience infections. Secondly, a glucose-rich environment has been shown to affect leukocyte function altering immune function and promoting a higher risk of infections in diabetics.[85]

7.13.6.3 Diabetic Ketoacidosis (DKA)

Moderate ketosis is common when glucose is scarce and the alternative is burning fat to satisfy the body's energy needs. Ketone bodies such as β-hydroxybutyrate occur normally in circulation and are an energy source for the brain when glucose levels are low. DKA occurs when enough ketone bodies are present that acidification of the blood results. Many diabetics will experience an occasional bout of DKA with 10% of Type 1 diabetics experiencing DKA at least once a year. The present concern focuses on significant DKA in the absence of hyperglycemia due to the effects of the SGLT2 inhibitors on glucose levels, which make it difficult for health care professionals to recognize the symptoms and treat the patient accordingly. Clinical studies with SGLT2i including dapagliflozin, empagliflozin, and others have shown that the frequency of DKA is very low, $<0.1\%$, and further profiling of the affected patients indicates many present as either Type 2 diabetics who are on insulin therapy or Type 1 diabetics who either have been misdiagnosed or are trying to reduce their insulin use by reducing their glucose levels with SGLT2i (off label). In Type 2 diabetics who are normally hyperinsulinemic due to whole-body insulin resistance, SGLT2i reduces glucose levels resulting in a rapid drop of insulin levels. This results in glucagon excess that drives lipolysis and fatty acid oxidation increasing the likelihood of ketoacidosis. This effect is further exacerbated due to increased levels of unabsorbed sodium in the proximal tubule that activate the sodium-monocarboxylate carrier increasing recovery of ketone bodies that would normally be excreted in the urine.[86] It is important that a better means for identifying euglycemic DKA be available for both patients and physicians in order to correctly diagnose this potentially life-threatening condition.[87]

7.13.6.4 SGLT in Heart

Cardiac myocytes can burn either fatty acid or glucose in order to meet energy needs. Although fatty acids are the preferential fuel under conditions where oxygen supply is plentiful, under situations such as ischemia where oxygen supply is low, glucose becomes the preferred substrate. SGLT1 mRNA has been identified in the sarcolemma of cardiac myocytes in rodents and humans although its function is unclear as both GLUT1 and GLUT4 are also highly expressed.[88] Addition of insulin to mice results in no change in SGLT1 mRNA levels although it produces a near sevenfold increase in cardiac 2DOG uptake indicative of the action of insulin-sensitive GLUT4 transporters. This transport capacity is reduced by ~50% when phlorizin is added suggesting SGLT1 could be playing a role in glucose uptake. Insulin is shown to have a dramatic effect on the force of contraction in both ischemic and dilated cardiomyopathic human heart strips and is related to increases in GLUT4 translocation to the cell surface. GLUT4 mRNA is increased as an adaptive change in cardiomyopathy without changes in GLUT1 or SGLT1 expression, although SGLT inhibitors do have an effect to reduce contractive force in failing hearts perhaps as an adaptive change due to the lack of sufficient insulin action through GLUTs.[89] As these studies use phlorizin as the SGLT1 inhibitor, which breaks down to generate phloretin, a GLUT inhibitor, these effects are difficult to ascribe to SGLT1 alone. However, as the effects of GLUT4 are reduced under conditions of insulin resistance present in Type 2 diabetes, an increase in SGLT1 could occur as an adaptive change to maintain the necessary glucose uptake when conditions necessitate.

7.13.7 Added Beneficial Effects

7.13.7.1 Effects on Blood Pressure

Hypertension comes with an increased risk of stroke, coronary artery disease, nephropathy, retinopathy, and neuropathy, and the risk increases substantially in patients with diabetes. Any additional effect a drug may have that reduces blood pressure (BP) would have a beneficial outcome to the patient. The UK Prospective Diabetes study shows a 32% risk reduction for diabetes-related death and a 44% reduction for stroke when patients are under tight BP control.[90] A comprehensive compilation of BP effects for different SGLT2 inhibitors during the course of clinical trials suggests reductions in both systolic and diastolic BP of 3–5 mmHg and 1–3 mmHg, respectively.[91,92] This reduction in BP is likely due to inhibition of SGLT that increases Na^+ on the luminal side of the proximal tubule and promotes osmotic diuresis leading to a reduction in plasma volume and an increase in urine output. Interestingly, add-on cotherapies such as sitagliptin, metformin, and sulfonylureas tend to reduce or actually reverse the beneficial effect of SGLT2 inhibition on BP. This seemingly positive effect on BP must be managed carefully in poorly controlled elderly patients concurrently on hypertension medications where extensive BP reduction has the potential to lead to dizziness and syncope resulting in falls and potential bone fractures.

7.13.7.2 Added GLP-1 Effects

In a cell model of intestinal L cells, the presence of SGLT1 allows for glucose uptake, metabolism, and activation of GLP-1 release.[93] Processes that drive glucose further down in the small intestine toward the ileum such as α-glucosidase inhibitors or SGLT1 inhibitors are shown to activate this pathway in the distal L cell. In contrast, direct effects of phlorizin, which inhibits SGLT1, prevent GLP-1 release in this cell line suggestive of SGLT1-mediated glucose uptake in these cells in order to activate the incretin response. As LX4211 elicits a GLP-1 response in vivo, it would appear that the SGLT1 inhibitors do not likely remain in the lumen of the intestine as far down as the ileum and are absorbed earlier, although they likely delay the absorption of glucose that reaches the L cell and activates GLP-1 and the other incretins, GIP, and PPY.

7.13.7.3 Weight Loss

All of the SGLT2 inhibitors elicit effects on weight loss, usually 1–3 kg, which represents about 2–3% of BW and goes along with the intended mechanism of reducing metabolic excess by excreting glucose. Whereas this is insufficient BW reduction as a registrable endpoint for an obesity indication, it certainly plays a part in risk reduction from a cardiovascular and diabetic standpoint. The hope is that adding SGLT1 inhibition would not only increase glucosuria from the kidney but also prevent glucose absorption from the diet triggering incretin responses, and this could substantially increase the potential weight loss. Unfortunately, the only dual SGLT1/2 inhibitor, LX4211, does not appear to differentiate from the SGLT2-selective agents and produces a similar 2–3% reduction in BW.

7.13.8 Summary

As the effects of the SGLT2 inhibitors are directed specifically to enhancing glucosuria, it appears that the reduction of metabolic load reduces glucose toxicity and is disease-modifying, which drives other positive effects such as reduced insulin levels, increased beta cell insulin content, improved insulin sensitivity, and enhanced postprandial glucose disposal.[94] Additional therapeutic interventions such as insulin or insulin secretagogues increase the possibility of hypoglycemia, and increased vigilance for possible euglycemic

diabetic ketoacidosis needs to be managed moving forward. Adverse events such as UTIs, thought to be limiting early on, seem to be manageable, and the incidence seems to wane over time. Additional benefits on BW and BP could further prevent disease progression and improve cardiovascular risk factors. This has recently been borne out in studies in Type 2 diabetic patients at high risk of cardiovascular events when administered empagliflozin and produces a 38% relative risk reduction of death from cardiovascular causes over the 4-year study duration.[95] Although the limitations of efficacy based on incomplete glucosuria and the compensating glucagon effects are significant and need to be better understood and addressed, this therapy is showing considerable benefit and is an important tool in the arsenal used to manage diabetes. Glucagon-driven ketogenesis resulting in DKA in a small number of patients is serious but suggests agents that also activate GLP-1 and maintain sufficient insulin effect could potentially counter these effects. Other side effects of SGLT inhibition not discussed earlier include increased LDL levels, predicted for a long time to be a negative risk factor for cardiovascular diseases, and effects on electrolytes that can lead to loss of bone density, and these will need to be factored into the risk–benefit analysis of this new drug class. Although most agents maximize their selectivity against SGLT1, a few explore whether additional benefit can be gleaned from inhibiting SGLT1, including activation of GLP-1 pathway along with reductions in glucose uptake from the gut further reducing metabolic load. Whether this can be accomplished without increasing gastrointestinal complications is yet to be seen.

7.14.1 Introduction

Type 2 diabetes mellitus (T2DM) is a complex metabolic disease that is characterized by hyperglycemia and reduced insulin biosynthesis/secretion in the context of whole-body insulin resistance. A hallmark of the disease is the inability of insulin-producing β-cells in the pancreas to cope with the increased secretory demand of insulin-resistant organs and tissue, which over time leads to a vicious cycle of progressive loss of glycemic control and β-cell dysfunction. This relentless decline in pancreatic β-cell function due to increased metabolic stress underlies the progressive nature of T2DM. Both lifestyle factors such as overeating and physical inactivity that cause obesity and a genetic predisposition to β-cell dysfunction play significant roles in the etiology of T2DM. The ensuing chronic hyperglycemia, if left untreated, can lead to serious microvascular complications including retinopathy, nephropathy, and peripheral vascular disease. In addition, metabolic derangements such as dyslipidemia and hypertension that often accompany T2DM increase the risk of cardiovascular complications including atherosclerosis, myocardial infarction, heart failure, and stroke.

The global epidemic of diabetes afflicts more than 415 million people, and its worldwide prevalence is anticipated to exceed 642 million by 2040.[1] T2DM is the leading cause of kidney disease, nontraumatic amputations, and new cases of blindness. Approximately 5 million people aged between 20 and 79 years died from diabetes in 2015, equivalent to one death every 6 s.[1] A large majority of people with diabetes live in developing nations, and their numbers are projected to exceed 274 million by 2040 in India and China alone.[1] In the United States, 29.1 million people (9.3% of the population) have diabetes, 27.8% of whom are undiagnosed.[2] It is estimated that one out of every three adults in the United States could have diabetes by 2050.[3] In addition to the human toll, diabetes confers a significant financial burden to society. The estimated annual global cost of treating diabetes was $673 billion in 2015, and it is expected to exceed $750 billion in 2040.[1] In the United States alone, the direct medical cost to treat diabetes was $176 billion in 2012, with an additional $69 billion in indirect costs due to lost productivity and early death.[3]

Based on their mechanisms of action, 12 classes of oral and injectable medications are currently approved for the treatment of T2DM.[4] Unfortunately, none of these agents halt disease progression, and the initial correction of hyperglycemia with current oral agents is typically not sustained beyond a few years. Hence, initial oral monotherapy is typically followed by oral combination therapies and subsequently by the addition of insulin or other injectable agents to control blood glucose. Several established oral T2DM therapies are associated with significant side effects such as hypoglycemia (sulfonylureas), weight gain (sulfonylureas and TZDs), GI intolerance (metformin), and increased risk of fractures, bladder cancer, and cardiovascular morbidity (TZDs). Over the last decade, however, dipeptidyl peptidase 4 (DPP-4) inhibitors (gliptins) have emerged as a new class of oral agents with good efficacy and few side effects, including a low risk of hypoglycemia and no weight gain. Sitagliptin, the first marketed DPP-4 inhibitor,[5,6] and the gliptin class in general have consequently enjoyed significant clinical and commercial success. Together with the injectable glucagon-like peptide-1 (GLP-1) analogs, these medicines work to increase the activation of incretin receptors, which are key molecular targets involved in glucose-stimulated insulin secretion (GSIS) and energy homeostasis. Specifically, DPP-4 inhibitors inhibit cleavage and inactivation of the peptide incretin hormones GLP-1 and glucose-dependent insulinotropic polypeptide (GIP) by the serine protease, DPP-4. The stabilized endogenous circulating GLP-1 and GIP incretins increase signaling via their cognate G protein-coupled receptors, resulting in enhanced GSIS from islets and improved glucose control with a low risk of hypoglycemia.

The biology of incretins, the pharmacology of DPP-4 inhibitors, and their clinical use in the treatment of T2DM have all been well reviewed elsewhere.[7–10] Beyond its catalytic activity, the complex biology of DPP-4 as a multidomain cell surface protein identical to the T-cell activation antigen CD26, which interacts with multiple proteins, has also been recently summarized.[11] This review in contrast focuses primarily on a comparison of the medicinal chemistry and clinical pharmacology of the DPP-4 inhibitors. It summarizes marketed gliptins, compounds in development, and natural DPP-4 inhibitors. The first section introduces incretins and reviews relevant aspects of the human biology and structure of DPP-4 to provide the necessary context for the second section that reviews the synthesis and pharmaceutical properties of the various gliptins.

7.14.2 Scientific Rationale for DPP-4 Inhibitors in the Treatment of Type 2 Diabetes

The observation that oral nutrients (glucose) stimulate higher levels of insulin secretion in humans than an intravenous isoglycemic infusion led to development of the incretin concept[12,13] and identification of an entero-insular axis,[14] wherein gut-derived factors (intestine secretion insulin, incretins) enhance GSIS from pancreatic β-cells. Subsequent reports in human subjects of potent insulinotropic activity for the gut-derived peptides GIP[15] (secreted by enteroendocrine K cells of the proximal intestine[16]) and GLP-1[17] (secreted from L cells primarily in the ileum[18]) and elucidation of their primary sequences[19,20] led to intense interest in peptide incretins and associated pathways as potential therapeutic targets for the treatment of T2DM. The insulinotropic activities of GLP-1 and GIP are additive and fully account for the incretin effect in healthy human subjects.[21,22] Early research efforts focused primarily on GLP-1, however, after demonstration of its preserved incretin activity in T2DM subjects[23] unlike that of GIP, which is significantly diminished in the diabetic state.[23,24]

GLP-1 and GIP signal through activation of corresponding Gs protein-coupled receptors that rapidly increase intracellular cAMP and calcium levels in β-cells and stimulate glucose-dependent insulin secretion.[25–28] Of note, the bioactive forms of circulating GLP-1 (GLP-1[7–36]-amide and GLP-1[7–37]) and GIP (GIP[1–42]) are rapidly degraded in human plasma and in vivo[29–32] with clearance half-lives of only a few minutes.[33] Proteolytic removal of two residues from the N-terminal of each peptide results in the formation of inactive des-dipeptidyl metabolites.[34–36] With identification of the inactivating protease in both instances as the cell surface-associated dipeptidyl peptidase 4 (DPP-4),[36] two strategies emerged for the development of incretin-based therapeutics for T2DM: the pursuit of injectable DPP-4-resistant GLP-1 peptide mimetics as incretin replacement therapy and the development of oral small-molecule DPP-4 inhibitors to increase pools of endogenous active GLP-1 and GIP. Although there is considerable overlap in the pharmacologies of these two classes of incretin-based therapeutics, important differences regarding the modest weight loss and gastrointestinal side effects observed for the GLP-1 class derive from pharmacological activation of the GLP-1 receptor by supraphysiological levels of exogenously administered peptides, in contrast to DPP-4 inhibitors, which effect physiological activation of GLP-1 and GIP receptors by their endogenous ligands, are weight-neutral and well tolerated in comparison.

7.14.3 Biology of DPP-4

7.14.3.1 Gene Structure, Expression, and Related Enzymes

Dipeptidyl peptidase 4 [EC3.4.14.5] was first identified in 1966 as an aminopeptidase with the relatively unique ability to cleave a prolyl amide bond.[37] As a serine protease with an α,β hydrolase fold, DPP-4 is representative of the peptidase family S9b and together with prolyl endopeptidase (PEP, S9a) and acylaminoacyl peptidase (S9c) comprises the prolyl oligopeptidase family.[38] DPP-4 is also identical to the T-cell activation antigen cluster of differentiation (CD) 26.[39] DPP-4 is a type II transmembrane protein consisting of short cytoplasmic and transmembrane domains, a flexible stalk region, and a predominant extracellular domain (residues 40–766) containing the C-terminal active site, a cysteine-rich area, and a glycosylated region. The enzyme exists predominantly as a homodimer,[40] formation of which is required for enzyme activity. DPP-4 can also form heterodimers with related peptidases such as fibroblast-activating protein-α (FAP/seprase), each enzyme retaining its activity within such complexes.[41,42] The human DPP-4 gene is located on chromosome 2 and consists of 26 exons spanning 70 kb.[43–45] DPP-4 is a ubiquitous enzyme, present

on epithelial and endothelial cells, and expressed in numerous tissues including the liver, gut, placenta, lung, and kidney.[45,46] The enzyme is shed from the plasma membrane as soluble circulating DPP-4, the activity of which can be readily detected in human plasma and serum.[47] DPP-4 is the founding member of the DPP-4 activity and/or structural homologue (DASH) family of peptidases (dipeptidyl peptidase 4 activity and/or structure homologues),[48] which includes FAP/seprase,[41] dipeptidyl peptidase II/quiescent cell proline dipeptidase (DPP-II/QPP),[49] dipeptidyl peptidase 8 (DPP-8),[50] and dipeptidyl peptidase 9,[51] all of which cleave prolyl amide bonds within peptide substrates.[52–54] While DPP-4 is widely expressed and is a cell surface-associated or soluble peptidase, the remaining DASH family members are either restricted in expression or activity (FAP/seprase) or intracellular in localization (DPP-II/QPP, DPP-8, and DPP-9). Hence, DPP-4 has relatively better access to diverse circulating and secreted bioactive peptides as potential substrates, several of which, in addition to GLP-1 and GIP, are physiological substrates that are regulated by the enzyme.

7.14.3.2 Substrate Specificity

In vitro, DPP-4 is a prolyl-aminodipeptidase that cleaves NH_2-X-Pro dipeptides from the amino terminus of peptide substrates. Although Pro is the preferred P1 residue (using the protease active site nomenclature of Schechter and Berger[55]), DPP-4 can also cleave peptides that contain a penultimate Ala at the N-terminal (e.g., GLP-1 and GIP). Incubation of soluble DPP-4 with positional-scanning libraries[56] of dipeptides conjugated to 7-amino-4-carbamoylmethylcoumarin (AMC) as a fluorogenic reporter of cleavage has confirmed the P1 Pro/Ala specificity of DPP-4 while revealing a relatively relaxed specificity for the P2 position (i.e., for the amino terminal residue of the substrate).[53] The peptidase is unable to cleave Pro–Pro bonds but otherwise accommodates diverse residues at the P1′ position adjacent to the scissile amide. Not surprisingly, the in vitro cleavage by DPP-4 of numerous bioactive peptides, hormones, neuropeptides, and chemokines that contain the canonical X-Pro/Ala amino terminal sequence has been reported,[57–59] and corresponding hypotheses have been generated for diverse roles of this peptidase in human physiology and disease. A key limitation of these studies, however, is that they typically use conditions of limited physiological relevance for in vivo substrate cleavage (e.g., supraphysiological concentrations of DPP-4 and substrate and/or prolonged incubation times). In addition, efficient cleavage of a specific peptide by DPP-4 in vitro or upon pharmacological infusion of the exogenous peptide in animals or human subjects has limited bearing on whether the peptidase and its putative endogenous substrate are otherwise exposed to each other in vivo for similar cleavage to occur physiologically. Indeed, redundant or other specific proteolytic pathways may be more relevant to the in vivo clearance of a particular putative DPP-4 substrate. Of note, very few of the bioactive substrates tested in vitro have been shown to satisfy all of the following prerequisites necessary to qualify as physiologically relevant substrates that are regulated by DPP-4 cleavage, namely, (1) demonstration of in vivo cleavage of the *endogenous* peptide by DPP-4, (2) blockade of this cleavage by administration of a DPP-4 inhibitor or in animals genetically deficient in DPP-4, (3) concomitant increase in endogenous levels of intact peptide, and (4) modulation of endogenous peptide bioactivity as a consequence of DPP-4 cleavage or its blockade. A key challenge in this regard has been the lack of suitable assays to measure levels of intact versus cleaved peptides with the requisite selectivity and sensitivity necessitated by the low abundance of these putative endogenous substrates. Our discussion therefore focuses only on those bioactive peptides that have been established as physiologically relevant substrates regulated by DPP-4 cleavage in humans. We also discuss select peptides, however, that may be processed by DPP-4 in humans but for which additional clinical data are needed to unequivocally establish their contributory role to the established pharmacology of DPP-4 inhibitors.

7.14.3.3 Processing of Glucagon Superfamily Peptides

With demonstration of GLP-1 and GIP as short-lived physiological incretins and identification of DPP-4 as the key inactivating enzyme, intense efforts led to the development of small-molecule DPP-4 inhibitors and demonstration of antihyperglycemic efficacy of these agents in rodents.[60,61] Proof of concept in humans was subsequently obtained upon demonstration of glucose-lowering efficacy in a 4-week study in diabetic subjects using the DPP-4 inhibitor NVP-DPP728.[62] Since then, the cumulative preclinical and clinical data for DPP-4 inhibitors indicate that the acute antihyperglycemic efficacy of these agents can be fully accounted for by stabilization of the incretin substrates GLP-1 and GIP.[7,63] Infusion of the GLP-1 receptor antagonist exendin (9–39) in diabetic subjects reverses the acute glucose-lowering efficacy of sitagliptin by only 50%,[64] highlighting the importance of both GLP-1 and GIP as physiological incretins. This finding is also consistent with the complete lack of acute glucose-lowering efficacy of a DPP-4 inhibitor in double incretin receptor knockout (DIRKO) mice lacking both GLP-1 and GIP receptors.[65]

It is possible that DPP-4 substrates besides GLP-1 and GIP contribute to the long-term efficacy of DPP-4 inhibitors since the peptidase can cleave and inactivate additional glucagon superfamily peptides in vitro with catalytic efficiencies comparable to that of GLP-1 and GIP cleavage.[66] For most of these peptides, however, including growth hormone-releasing hormone (GHRH), glucagon-like peptide-2 (GLP-2), and gastrin releasing peptide, increased in vivo bioactivity as a physiological substrate that is stabilized by DPP-4 inhibition appears unlikely.[67–69] Intriguingly, oxyntomodulin (Oxm) and pituitary adenylate cyclase-activating polypeptide (1–38) (PACAP38) are also efficiently cleaved by DPP-4 in vitro despite both peptides containing a P1 serine residue.[66] Endogenous Oxm has insufficient bioactivity to act as a physiological hormone,[70] although long-acting DPP-4-resistant Oxm analogs are being actively pursued as dual GLP-1/glucagon receptor agonists for the treatment of obesity and diabetes.[71,72] Exogenously infused PACAP38 is rapidly cleaved by DPP-4 in mice but not in DPP-4-deficient animals.[66] The acute insulinotropic activity of PACAP38 is also augmented by a DPP-4 inhibitor in mice.[69] Since the peptide also stimulates glucagon secretion, which

counteracts insulin action, its role in islet function remains unclear. Additional clinical data are therefore needed to determine whether PACAP38 contributes to the long-term metabolic effects of DPP-4 inhibitors.

7.14.3.4 Cleavage of Neuropeptide Y and Peptide YY

Neuropeptide Y (NPY) is a 36-residue peptide produced in the hypothalamus and secreted into cerebrospinal fluid. The peptide plays several roles in the central and peripheral nervous system, including the regulation of energy intake, stress, and vascular remodeling.[73,74] NPY and the related peptide YY (PYY), which is secreted by GLP-1-producing L cells in the gut following a meal, mediate their actions through a family of related receptors (Y1R–Y5R). Both peptides are cleaved by DPP-4 in vitro,[75] and the corresponding metabolites (NPY(3–36) and PYY(3–36)) show increased selectivity for Y2R versus Y1R activation; PYY(3–36) is a potent anorectic peptide in humans due to its Y2R agonist activity.[76]

While there is no clinical evidence for a role of NPY in the action of DPP-4 inhibitors, increased levels of intact NPY(1–36) and increased Y1R activation/peripheral sympathetic tone have been recently invoked to explain skin lesions and necrosis observed in cynomolgus monkeys treated with the DPP-4 inhibitor vildagliptin.[77] In the absence of measurements of endogenous NPY in this study, however, and given the lack of cutaneous toxicity in primates treated with sitagliptin, it is unlikely that these findings reflect NPY stabilization as a mechanism-based class effect for all DPP-4 inhibitors. In addition, NPY is cleaved by multiple DASH peptidases in vitro,[78] suggesting the potential for redundant proteolytic clearance pathways of the intact peptide in vivo. As an alternate hypothesis, off-target inhibition of the related DASH family dipeptidyl peptidases DPP-8 and DPP-9 had previously been shown to associate with the preclinical toxicity of nonselective DPP-4 inhibitors in rats and dogs.[79] Sitagliptin, a highly selective DPP-4 inhibitor, does not exhibit any of these liabilities. The importance of DPP-4 inhibitor selectivity for safety has been questioned,[80,81] but the predominantly intracellular localization of DPP-8 and DPP-9[82] and the challenge of isolating their activities from that of other DASH family members have precluded a valid assessment of the endogenous inhibition of these enzymes by the various gliptins and any corresponding active metabolites. Notwithstanding, activity-based dipeptidyl peptidase profiling studies in rats and cynomolgus monkeys have identified DPP-8 and DPP-9 expression and activity in lymphoid cells, in epithelial and capillary endothelia of multiple tissues, and in the skin of both species.[83] These data are more consistent with the view that the observed experimental differences in preclinical toxicity of various gliptins reflect different off-target activities and selectivities of the inhibitors and/or their active metabolites (as determined by species-dependent biodistribution, intracellular permeability, and access to various intracellular compartments and DASH peptidases), although local stabilization of putative DPP-4 substrates such as NPY by select gliptins such as vildagliptin that distribute widely into tissue and extravascular spaces cannot be discounted.

Endogenous levels of PYY(1–36) and PYY(3–36) have been measured using specific immunoassays after a standard mixed meal in T2DM subjects administered sitagliptin or placebo for 12 weeks.[68] While the ratio of intact to cleaved PYY increased ~50% to 0.78 with DPP-4 inhibition, levels of total PYY and PYY(3–36) both decreased after treatment by 25% and more than 60%, respectively, likely due to negative feedback on PYY-secreting cells. The same study reported no differences in the levels of endogenous intact GLP-2 with sitagliptin treatment. Hence, PYY but not GLP-2 appears be an endogenous DPP-4 substrate in humans. The absence of increased PYY(3–36) levels, however, is consistent with the weight-neutral profile of DPP-4 inhibitors in the clinic, and the peptide remains unlikely to contribute to the long-term efficacy of DPP-4 inhibitors.

7.14.3.5 Chemokine and Cytokine Substrates

Chemokines are cytokines that modulate the chemotaxis of responsive cells. Several chemokines and cytokines contain an N-terminal X-Pro dipeptide sequence that is efficiently cleaved in vitro by DPP-4,[58] often with changes in bioactivity of the signaling molecule.[84,85] Since these molecules play a key role in cell recruitment and immunity and given that DPP-4 is identical to the T-cell coactivation antigen CD26, numerous hypotheses have been made regarding both the potential therapeutic utility and liability of DPP-4 inhibitors in modulating T cell and immune function.[86] Pharmacological infusions of exogenous cytokines that are in vitro substrates of DPP-4, such as granulocyte-macrophage colony-stimulating factor (GM-CSF) and erythropoietin (Epo), result in increased bioactivity in DPP-4-deficient mice compared with wild-type animals. Consistent with these observations, increased CSF activity and hematopoiesis after chemotherapy or radiation have been reported in DPP-4-deficient mice or in mice treated with sitagliptin, although endogenous cytokine levels were not measured in these studies.[85] Despite numerous studies in cell-based systems and in preclinical models of immune disease, however, a definitive role for the catalytic activity of DPP-4 in human immune function has yet to be established.[87] The only chemokine for which there is good evidence of in vivo processing by DPP-4 in preclinical species is stromal cell-derived factor 1α (SDF-1α, CXCL12). Increased levels of endogenous intact SDF-1α and decreased levels of the des-dipeptidyl fragment have been measured in rhesus monkeys treated with the DPP-4 inhibitor MK-0626 using immunoenrichment and mass spectrometry assays with the requisite sensitivity and selectivity.[88] Similar results have also been reported in DPP-4-deficient mice.[89] SDF-1α is a pro-inflammatory chemokine that signals through its receptor chemokine receptor type 4 (CXCR4) and regulates homing of hematopoietic stem/progenitor cells during various physiological processes including organogenesis and tumor metastasis.[90] T-cell (T)-tropic HIV-1 strains use CXCR4 as the entry coreceptor, and the intact SDF-1α ligand blocks HIV entry.[91] A study in a limited number of T2DM subjects has reported that treatment with sitagliptin increases the number of $CD34^{+}CXCR4^{+}$ cells that are responsive to SDF-1α.[92] Plasma levels of SDF-1α were decreased by 50% after 12 weeks of treatment, however, similar to the negative feedback observed for PYY secretion in humans. Additional clinical studies

are needed to determine whether SDF-1α or other cytokines contribute to the pharmacology of DPP-4 inhibitors, although the excellent clinical safety profile of these agents is reassuring,[93] as is a preliminary report that sitagliptin does not appear to compromise immune or virological status in HIV-infected individuals.[94]

7.14.3.6 Processing of Vasoactive Peptides

Brain natriuretic peptide (BNP) is a 32-residue cardioactive peptide secreted by the ventricles of the heart in response to mechanical stretch. The peptide promotes natriuresis and reduces vascular resistance and venous pressure.[95] Cleavage of the amino-terminal Ser-Pro dipeptide of intact BNP by DPP-4 in vitro produces BNP (3–32),[96] which exhibits reduced vasodilatory and natriuretic activity when infused in dogs.[97] Vasodilation induced by BNP infused in healthy subjects, however, is not potentiated by the administration of sitagliptin.[98]

Substance P (SP, tachykinin) is an 11-residue sensory neuropeptide that is ubiquitously distributed and is associated with numerous physiological and pathological processes including vasodilation, nociception, emesis, depression, angioedema, and adverse cardiac remodeling.[99,100] DPP-4 processing results in sequential removal of Arg-Pro and Lys-Pro dipeptide sequences from the amino terminus of SP to produce SP[3–11] and SP[5–11], respectively, the latter being further cleaved by aminopeptidase M.[101] SP is also a substrate for angiotensin-converting enzyme (ACE) and neutral endopeptidase (NEP).[102] Plasma levels of SP were doubled in DPP-4-deficient mice,[103] however, suggesting modulation of endogenous SP bioactivity. In T2DM subjects, increased levels of SP have been suggested to contribute to the rare cases of angioedema that have been reported for gliptin therapy,[103] especially in the background of ACE inhibitors being used to treat hypertension, which is common in diabetes. Infused SP increases heart rate and sympathetic activity in healthy volunteers only after coadministration of both sitagliptin and an ACE inhibitor (enalapril) and not when each agent is administered individually.[104] In addition, sitagliptin does not potentiate SP-induced cutaneous wheal and flare responses[105] in human subjects, consistent with clearance of SP by the other proteolytic pathways.

The potential modulation of cardioactive peptides such as SP, NPY, and/or SDF-1α has been invoked[106] to explain an increased risk of heart failure hospitalization related to treatment with the DPP-4 inhibitor saxagliptin in high cardiovascular disease (CVD)-risk T2DM patients.[107] No such signal for increased heart failure risk has been observed in the cardiovascular outcomes trial for sitagliptin,[108] however, suggesting that this is not a class effect. While the neutral cardiovascular safety profile of sitagliptin is reassuring, ongoing trials with linagliptin in high CVD-risk T2DM patients[109,110] should provide further experience into the use of gliptins in high-risk populations.

7.14.4 Crystal Structure of DPP-4

The X-ray crystal structure of recombinant soluble human DPP-4 bound to the dipeptide mimetic inhibitor valine pyrrolidide reveals a homodimeric enzyme with each subunit comprising an N-terminal eight-bladed β-propeller domain and a classical C-terminal α/β hydrolase domain.[111] A large cavity of ~30–45 Å in the α/β hydrolase domain incorporates a small pocket containing the peptidase active site, with the catalytic triad (Ser630, Asp708, and His740) located at the interface of the two domains. The active site can be accessed by two passages – one funnel-shaped tunnel defined by the propeller domain that extends from the lower face of the propeller to the active site is itself connected to a second larger opening on the side, at the interface of the propeller and hydrolase domains. The side entrance is calculated to have negative electrostatic potential, which interacts favorably with the positively charged amino-termini of peptide substrates to facilitate their entry into the active site. The crystal structure of DPP-4 bound to a fragment of NPY[112] confirms that two acidic residues (Glu205 and Glu206) within a short α-helix insertion protruding from the propeller domain toward the active site anchor the amino-terminus of the substrate via salt bridges to align the peptide for cleavage. This α-helix together with residues Tyr 662 and Tyr666 restricts the size of the P1 residue that can be accommodated in the S1 pocket, explaining the restricted P1 selectivity of DPP-4. The P2 residue of the substrate points into the large cavity, interacting with water molecules partially occupying the S2 pocket and making no specific contacts with the enzyme, consistent with the broad specificity of the hydrophobic S2 subsite. The catalytic Ser630 residue is located within a "nucleophilic elbow" (Gly-Trp-Ser630-Tyr-Gly) and oriented by a network of hydrogen bonds with proximal residues. The oxyanion hole that stabilizes the tetrahedral intermediate is formed by Tyr547 and the backbone NH of Tyr631. The carbonyl oxygen of the P1′ residue hydrogen bonds to Arg125, which together with residues Phe357, Tyr547, Pro550, Tyr631, and Tyr666, forms the hydrophobic S2 pocket.

The common binding pockets and key interactions of the various gliptins with residues at the DPP-4 active site (discussed in the next section) predict similar pharmacologies of these inhibitors, which is confirmed by the similar glucose-lowering efficacies of these compounds in the clinic[113] that correlate with the extent of plasma DPP-4 inhibition. The latter is a useful pharmacodynamic (PD) marker for efficacy.[114] It should be emphasized that in the absence of standardized plasma DPP-4 activity assays and methods of analyzing DPP-4 inhibition data, varying extents of plasma DPP-4 inhibition (typically uncorrected for assay dilution and for the competitive effects of added substrate) have been reported for the various gliptins. Upon correction for these effects,[115] however, all marketed gliptins likely achieve similar and effective (>95%) inhibition of plasma DPP-4 activity at their prescribed doses.

7.14.5 DPP-4 Inhibitors

7.14.5.1 Approved and Marketed DPP-4 Inhibitors

Currently, 10 orally active DPP-4 inhibitors have been approved for the treatment of T2DM (Table 1, Fig. 1). These are sitagliptin **1**, gemigliptin **2**, evogliptin **2a**, omarigliptin **3**, vildagliptin **4**, saxagliptin **5**, teneligliptin **6**, anagliptin **7**, linagliptin **8**, alogliptin **9**, and trelagliptin **10**. These approved drugs[116,117] can be grouped into three structural classes, namely, β-amino butanoic acid derivatives **1**,**2**, pyrrolidine analogs **3**–**7**, and pyrimidone/xanthine analogs **8**–**10**. The preclinical pharmacokinetic (PK) profiles of the approved DPP-4 inhibitors are summarized in Table 2. These drugs have different half-lives in the clinic, corresponding to oral dosing regimens ranging from twice-daily (vildagliptin), to once-weekly (trelagliptin and omarigliptin), to once-daily for the remaining seven DPP-4 inhibitors. A metaanalysis[129] of six of the above DPP-4 inhibitors (alogliptin, dutogliptin, linagliptin, saxagliptin, sitagliptin, and vildagliptin) as monotherapy or in combination therapy with metformin in patients with T2DM has shown that the combination therapy displays better efficacy than metformin monotherapy alone, which in turn achieves slightly greater reductions in hemoglobin A1c (HbA1c), fasting plasma glucose (FPG), and body weight than DPP-4 inhibitor monotherapy. Gliptin monotherapy was associated with a lower risk of adverse cardiovascular events, hypoglycemia, and gastrointestinal adverse effects compared with metformin monotherapy, while combination therapy did not increase the number of such adverse events. Hence, DPP-4 inhibitors are well suited in combination with metformin as second-line agents.

7.14.5.1.1 β-Amino butanoic acid derivatives

7.14.5.1.1.1 Sitagliptin (MK-0431, Merck)

Sitagliptin **1**, a triazolopiperazine derivative containing a β-amino amide moiety, was the first DPP-4 inhibitor approved by the US FDA in 2006. It is a potent DPP-4 inhibitor ($IC_{50} = 18$ nM) and has good selectivity over DPP-8 ($IC_{50} \sim 48{,}000$ nM), DPP-9 ($IC_{50} > 100{,}000$ nM), and other DASH peptidases.[118] Sitagliptin exhibits excellent oral bioavailability in preclinical species (100% in dogs and 61% in rats at a dose of 2 mg kg^{-1}). Administration of single oral doses of sitagliptin in lean mice reduced the blood glucose excursion in an oral glucose tolerance test (OGTT) in a dose-dependent manner from 0.1 mg kg^{-1} (23% reduction) to 3.0 mg kg^{-1} (55% reduction) when administered 60 min before an oral dextrose challenge (5 g kg^{-1}). In a parallel experiment in lean mice, its PD profile was determined; plasma DPP-4 inhibition, compound concentration, and active GLP-1 levels were measured 20 min after a dextrose challenge. Reduction of blood glucose excursion at 1 mg kg^{-1} corresponded to a plasma sitagliptin concentration of 190 nM and 69% inhibition of plasma DPP-4 activity. A 3 mg kg^{-1} dose, corresponding to a plasma concentration of 600 nM, provided 84% inhibition of plasma DPP-4. Maximal glucose-lowering efficacy at 3 mg kg^{-1} was accompanied by a two- to threefold increase in plasma active GLP-1 levels, analogous to what is observed upon glucose

Table 1 Approval dates and potencies of marketed DPP-4 inhibitors

Common name	*Originator*	*Status*	*Dose (dosing frequency)*	*DPP-4 IC_{50} and K_i (nM)*
1 Sitagliptin	Merck & Co.	Approved by US FDA 2006	25/50/100 mg (QD)	$IC_{50} = 18$ $K_i = 9$ Reversible, slow binding
2 Gemigliptin	LG Life Sciences Ltd.	Approved by Korea FDA 2012	50 mg (QD)	$IC_{50} = 16$ $K_i = 15.2$ Reversible
2a Evogliptin	Dong-A	Approved in Korea 2015	5 mg (QD)	$IC_{50} = 0.9$
3 Omarigliptin	Merck	Approved in Japan 2015	12.5/25 mg (QW)	$IC_{50} = 1.6$ Reversible, long acting
4 Vildagliptin	Novartis	Approved by EMEA 2008	50 mg (BID or QD)	$IC_{50} = 3.5$ $K_i = 17$ Reversible, covalently bound inhibitor
5 Saxagliptin	Bristol–Myers Squibb	Approved by US FDA 2009	2.5/5 mg (QD)	$IC_{50} = 3.37$ $K_i = 0.6$ Reversible, covalent bound
6 Teneligliptin	Mitsubishi Tanabe Pharma	Approved in Japan 2012	20/40 (QD)	$IC_{50} = 0.37$
7 Anagliptin	Sanwa Kagaku Kenkyushu/Kowa	Approved in Japan 2013	200/400 mg (QD)	$IC_{50} = 3.3$ Reversible, covalently bound
8 Linagliptin	Boehringer Ingelheim/Lilly	Approved by US FDA 2011	5 mg (QD)	$IC_{50} = 1.0$ Reversible, long acting
9 Alogliptin	Takeda/Furiex	Approved by US FDA 2013	6.25/12/5/25 mg (QD)	$IC_{50} = 7$ Reversible, long acting
10 Trelagliptin	Takeda/Furiex	Approved in Japan 2015	100 mg (QW)	$IC_{50} = 4$ Reversible, long acting

challenge in DPP-4-deficient mice. Acute lowering of blood glucose was also demonstrated in diet-induced obese (DIO) mice, which are hyperglycemic and hyperinsulinemic, and shows impaired glucose tolerance similar to that observed in T2DM.[118,119]

Based on X-ray studies, the trifluorophenyl moiety of sitagliptin fits into the S1 pocket of the DPP-4 active site, and the binding orientation of the amide carbonyl is reversed relative to that of α-amino acid scaffold-containing peptidomimetic inhibitors. The β-amino amide moiety binds in the S2 pocket. The primary amino group forms a salt bridge and hydrogen bonding interactions with Glu205 and Glu206 and with Tyr662, respectively. The carbonyl group exhibits a water bridge hydrogen-bonding interaction

with Tyr547. The triazolopiperazine moiety occupies the S2 extended pocket and stacks against Phe357. The trifluoromethyl group exhibits interactions with Arg358 and Ser209.[118]

Sitagliptin has good oral bioavailability of 87% in the clinic[130] and a terminal half-life ($T_{1/2}$) of 10–12 h at doses of 25–100 mg.[131] The drug is 80% renally cleared as the parent compound,[131] and exposure is 2.3- to 4.5-fold higher in patients with moderate to severe renal insufficiency, including end-stage renal disease.[132] Hence, a dose adjustment is recommended in such patients, with the nominal 100 mg dose being reduced to 50 mg or even 25 mg depending on the degree of renal dysfunction.[133] Sitagliptin inhibits plasma DPP-4 activity by over 80% for 24 h (corresponding to estimated in vivo plasma DPP-4 inhibition of $>90\%$) at doses ≥ 100 mg in healthy subjects.[131] Postprandial active GLP-1 levels are increased two- to threefold, but total GLP-1 levels are decreased, suggestive of negative feedback as has been reported for PYY. In patients with T2DM, a single 200 mg dose of sitagliptin inhibited plasma DPP-4 activity by 90% over 24 h and doubled active GLP-1 and GIP levels in response to oral glucose challenges at 2 and 24 h post dose, resulting in significant reductions in glucose excursions.[134] A once-daily treatment regimen was further supported by phase II studies in T2DM patients, where similar HbA1c and FPG reductions from baseline were obtained after 12 weeks of dosing with 100 mg qd and 50 mg bid.[283] Sitagliptin was well tolerated with single doses up to 800 mg and multiple doses up to 400 mg day^{-1} over 28 days.[133] In a 24-week phase III study in T2DM patients (HbA1c mean baseline 8.0%) treated with sitagliptin 100 or 200 mg, similar placebo-subtracted reductions in HbA1c (-0.8% and -0.9%), fasting plasma glucose (FPG, -17 and -21 mg dL^{-1}), and 2 h postprandial glucose (PPG, -47 and -54 mg dL^{-1}) were obtained with hypoglycemia incidence similar to placebo,[135] supporting the rationale for a recommended dose of 100 mg in patients with normal renal function. Rates of overall adverse events (AEs) with sitagliptin treatment in clinical trials have been similar to placebo, typically including nasopharyngitis, upper respiratory tract infection, and headache.[133] Add-on therapy studies have demonstrated the benefits of adding sitagliptin therapy to metformin or pioglitazone (-0.7% incremental HbA1c reductions from a baseline of $\sim 8.0\%$), although addition to a sulfonylurea (glimepiride) resulted in a higher incidence of hypoglycemia compared with placebo.[285] Sitagliptin and glipizide both reduced HbA1c by 0.7% when added to metformin (mean baseline HbA1c 7.5%), demonstrating noninferiority of sitagliptin to a sulfonylurea.[136] In addition, the incidence of hypoglycemia was significantly reduced with sitagliptin (5%) compared with glipizide (32%), and sitagliptin-treated patients lost 1.5 kg after 52 weeks compared with patients on glipizide who gained 1.1 kg. These data underscore the superior safety and tolerability profile of sitagliptin, which induces glucose-dependent insulin secretion in contrast to a conventional sulfonylurea secretagogue.

Sitagliptin increased the number of insulin-positive pancreatic β-cells, islet insulin content, and GSIS and reduced glucagon-positive α-cells in a high-fat-fed streptozotocin (STZ)-induced mouse model of diabetes.[137] In the clinic, sitagliptin improved HOMA-β, the proinsulin-to-insulin ratio, the insulinogenic index, and the overall responsiveness of the β-cell to glucose.[133] Islet-protective effects leading to disease modification similar to that observed in animal models, however, have not been observed in the clinic to date for sitagliptin or for the gliptin class in general.

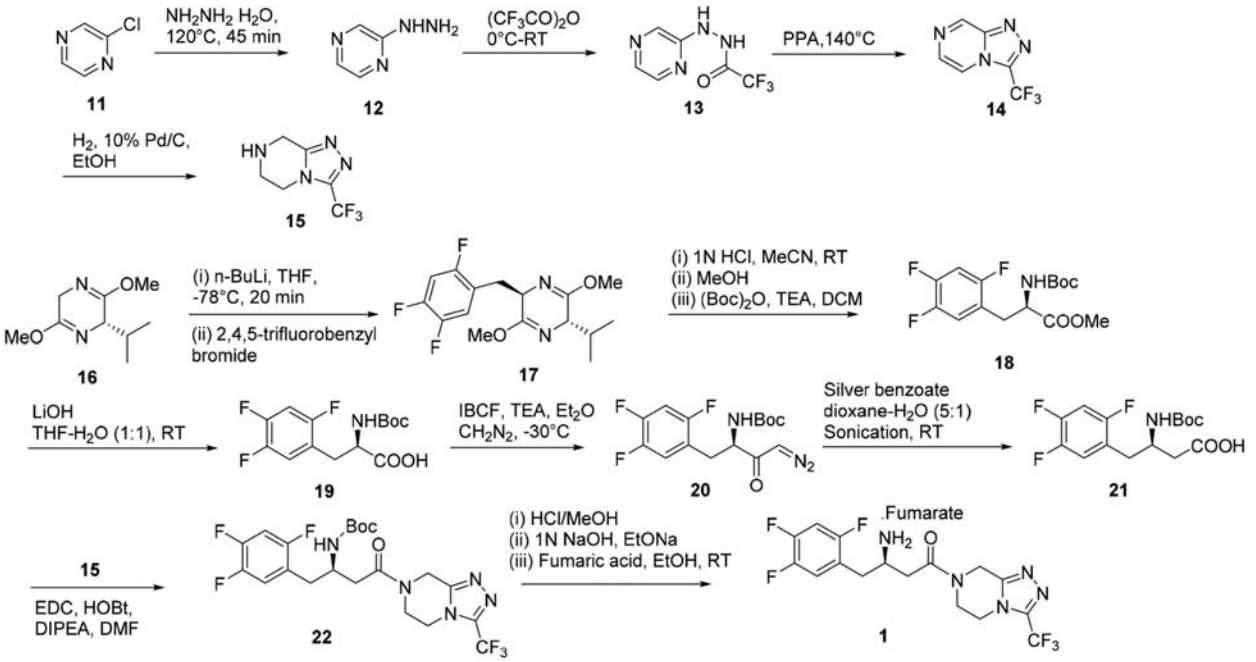
The cardiovascular safety of sitagliptin was evaluated over a median follow-up of 3 years in Trial Evaluating Cardiovascular Outcomes with Sitagliptin (TECOS) in patients with T2DM and established CVD.[108] Sitagliptin was noninferior to placebo for the primary composite cardiovascular endpoint of cardiovascular death, nonfatal myocardial infarction, nonfatal stroke, or hospitalization for unstable angina. In addition, rates of hospitalization for heart failure, which had raised concern after prior cardiovascular outcomes trials with two other gliptins, were the same for the two groups. There were also no significant differences in rates of pancreatitis or pancreatic cancer, which had been suggested as potential mechanism-based adverse effects of GLP-1 receptor activation.[138] TECOS was therefore a key trial in establishing the long-term safety profile of sitagliptin in high-risk populations.

Three approaches for the synthesis of sitagliptin are outlined in Schemes 1–3. Each method involves coupling the trifluorophenyl-containing "left-hand" moiety with the triazolopiperazine moiety **15**. Triazolopiperazine **15** was prepared from chloropyrazine **11** by treatment with hydrazine to generate hydrazinopyrazine **12** followed by conversion to compound **13** by acylation with trifluoroacetic anhydride (TFAA). Intramolecular cyclization of compound **13** with polyphosphoric acid gave compound **14**, which on catalytic hydrogenation over Pd/C provided the desired triazolopiperazine **15**.

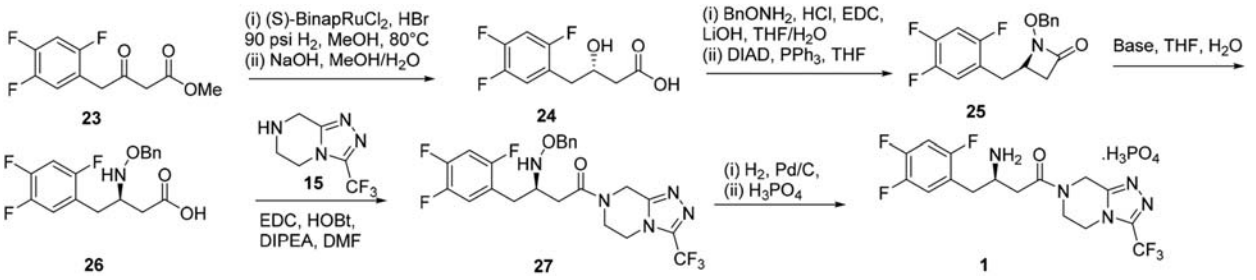
In the first synthetic approach to sitagliptin, treatment of the Schollkopf reagent **16** with 2,4,5-trifluorobenzyl bromide gave compound **17**, which upon treatment with acid and Boc protection gave the ester **18**, which was subsequently converted to the Boc-protected amino acid **19**. Using a mixed anhydride procedure, intermediate **19** was converted to the diazoketone **20** using diazomethane. **20** was converted subsequently to the desired β-amino acid **21** by sonication in the presence of silver benzoate.[139] Coupling of **21** with triazolopiperazine intermediate **15** followed by Boc deprotection provided sitagliptin **1**, which was converted to the corresponding hemifumarate salt (Scheme 1).[118]

The first step of another method for synthesis of sitagliptin is asymmetrical reduction of β-ketoester **23** with the (*S*)-BinapRuCl2 complex and a catalytic amount of HBr in methanol followed by hydrolysis to provide the β-hydroxy acid **24**. Subsequently, lactam **25** was synthesized by coupling of **24** with $BnONH_2 \cdot HCl$ using N-(3-dimethylaminopropyl)-N-ethylcarbodiimide hydrochloride (EDC), followed by cyclization with diisopropyl azodicarboxylate (DIAD) and PPh_3.[140] Treatment of **25**, a catalytic amount of 0.1% sodium hydroxide, directly provided the β-amino acid **26**, which was coupled with triazolopiperazine **15** using EDC·HCl and N-methylmorpholine to give compound **27**. Hydrogenation of **27** using Pd/C and treatment with phosphoric acid provided the phosphate salt of sitagliptin 1 (Scheme 2).

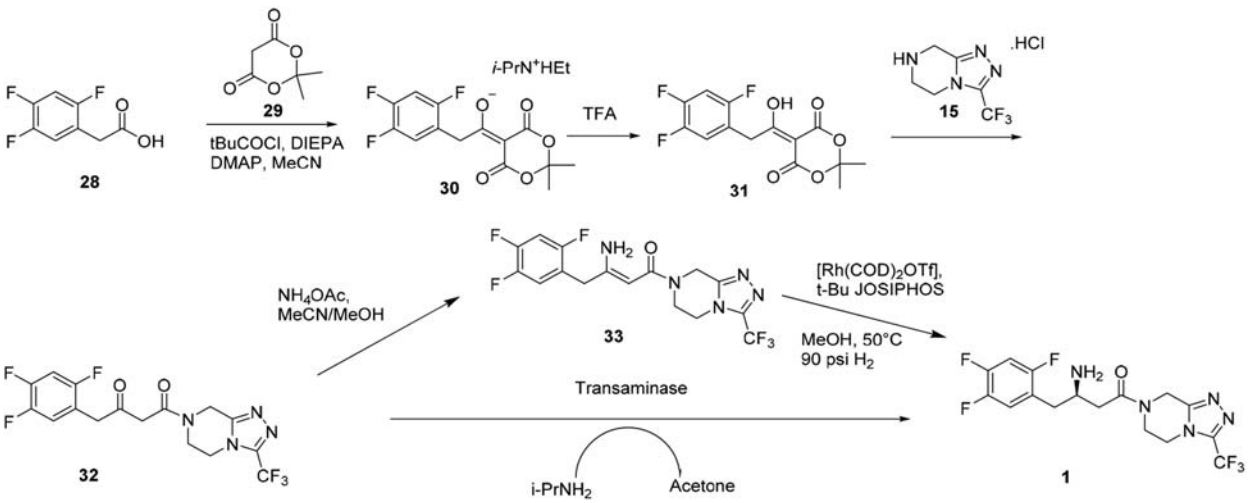
A third approach for the synthesis of sitagliptin is outlined in Scheme 3. Trifluorophenylacetic acid **28** was converted to a mixed anhydride with pivaloyl chloride. Subsequent treatment with Meldrum's acid **29**, dipropyamine ethyl amine (DIPEA), and a catalytic amount of dimethylamino pyridine (DMAP) in acetonitrile provided the Meldrum adduct **30**. Treatment of **30** with



Scheme 1 First-generation approach for sitagliptin synthesis.



Scheme 2 Second approach to sitagliptin synthesis.



Scheme 3 Third approach to sitagliptin synthesis.

trifluoroacetic acid (TFA) gave compound **31**. Reaction of **31** with the HCl salt triazolopiperazine **15** gave β-keto amide **32**, which upon further treatment with ammonium acetate in methanol gave the enamine amide, dehydrositagliptin **33**. Finally, sitagliptin **1** with 95% ee was synthesized by enantioselective hydrogenation of **33** in the presence of [Rh(COD)2OTf] 12,13 and tBu JOSIPHOS in excellent yield.[141,142] An efficient biocatalytic process[141] to replace the rhodium-catalyzed asymmetrical enamine reduction for the large-scale manufacture of sitagliptin has been reported. The authors applied a substrate walking, modeling, and mutation approach to create a transaminase with marginal activity for the synthesis of the chiral amine and then further engineered via directed evolution for efficient, economical, and environmentally benign processes for the manufacture of pure sitagliptin (**Scheme 3**).

7.14.5.1.1.2 Gemigliptin (LC15-0444, LG Life Sciences)

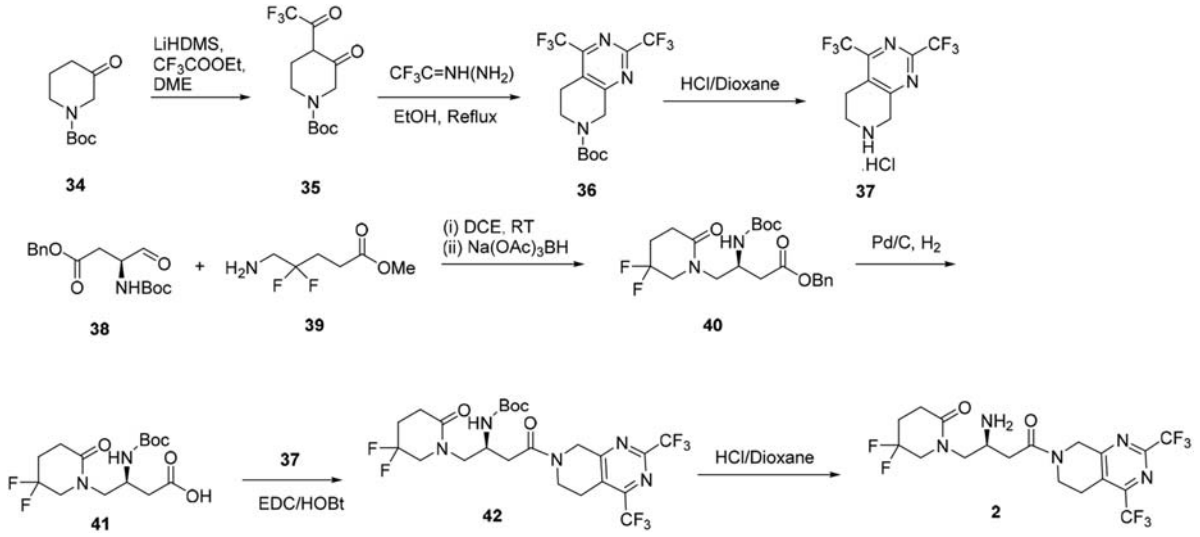
Gemigliptin (LC15-0444) tartrate sesquihydrate is a potent, selective, competitive, and long-acting DPP-4 inhibitor discovered by modifying compounds from published patents. It was approved by the Korean Food and Drug Administration (KFDA) in June 2012. Gemigliptin is 3000-fold selective for DPP-4 ($IC_{50} = 16$ nM) over other proteases such as DPP-8 and DPP-9. The absorption, distribution, metabolism, and excretion of gemigliptin were examined following single oral administration of (14)C-labeled gemigliptin to rats. The (14)C-labeled gemigliptin was rapidly absorbed after oral administration, and its bioavailability was 95.2% (by total radioactivity). Distribution to specific tissues other than the digestive organs was not observed. Within 7 days after oral administration, 43.6% of the administered dose was excreted via urine, and 41.2% was excreted via feces. Biliary excretion of the radioactivity was about 17.7% for the first 24 h. After oral administration of gemigliptin to rats, the in vivo metabolism of gemigliptin was investigated in bile, urine, feces, plasma, and liver samples. The major metabolic pathway was hydroxylation, and the major circulating metabolites were dehydrated and hydroxylated metabolites.[127,143] Gemigliptin was rapidly absorbed after single oral dosing, and the compound was eliminated with a half-life of 3.6, 5.2, and 5.4 h in the rat, dog, and monkey, respectively. Gemigliptin produced a dose-dependent inhibition of plasma DPP-4 activity, with 80% inhibition of plasma DPP-4 activity observed at plasma gemigliptin levels of 9, 7, and 2 ng mL^{-1} in rats, dogs, and monkeys, respectively. Gemigliptin improved glycemic control after a single dose during an OGTT and reduced HbA1c levels following chronic treatment in high-fat diet (HFD)-fed mice.[127,144]

In clinical studies, gemigliptin was well tolerated in both a single ascending dose (SAD) study[145] from 25 to 600 mg and a multiple ascending dose (MAD) study[146] from 200 to 600 mg in healthy Korean male subjects. It was readily absorbed after single oral dosing with median T_{max} at 2.0 h (0.5–5.1 h) post dose and mean terminal elimination half-life of 16.7–21.3 h at all dose levels. Gemigliptin exhibited linear PK properties over the range of 50–400 mg in the SAD study and dose-dependently inhibited of plasma DPP-4 in both studies.

The efficacy and safety of gemigliptin (50, 100, or 200 mg once daily) in patients with T2DM were evaluated in a placebo-controlled, double-blind phase II study in Korea.[147] At week 12, gemigliptin significantly reduced HbA1c (placebo-subtracted reduction of 0.68–0.92% from a baseline of ~8.2%) and FPG at all doses compared with placebo, without significant differences among doses. Glucose tolerance was also significantly improved at all doses compared with placebo based on the results from an OGTT performed at week 12. Gemigliptin was well tolerated, and the incidences of AEs were not different from placebo. The efficacy of 50 mg gemigliptin as monotherapy was assessed in a 24-week phase III study in patients with T2DM.[148] Placebo-subtracted HbA1c reduction of 0.71% (baseline HbA1c ~8.2%) and corresponding FPG reduction of 19.80 mg dL^{-1} were observed. The HbA1c-lowering effects of gemigliptin were proportional to the baseline HbA1c as reported with other DPP-4 inhibitors. The overall incidence rates for AEs were similar in both gemigliptin and placebo groups.

The efficacy of gemigliptin (25 mg twice daily or 50 mg once daily) as a combination therapy was assessed in a 24-week phase III study in patients with T2DM inadequately controlled with metformin alone.[149] Sitagliptin 100 mg was used as an active comparator. At week 24, both dose regimens of gemigliptin were noninferior to sitagliptin. The proportion of patients achieving HbA1c <7% with gemigliptin 25 mg twice daily (50%) or 50 mg once daily (54%) was comparable to that of sitagliptin (49%). There were significant decreases in FPG and postprandial glucose, improvements in glucose tolerance during OGTT, and increases in GLP-1 and β-cell sensitivity to glucose. There was no increased risk of AEs with gemigliptin compared with sitagliptin. Unlike sitagliptin, however, which does not interfere with the P450 cytochrome enzymes and has no reported significant drug–drug interactions, gemigliptin is a substrate of both CYP3A4 and P-glycoprotein. Coadministration of a single dose of gemigliptin (50 mg) and multiple once-daily doses of ketoconazole (400 mg), a strong inhibitor of CYP3A4 and P-glycoprotein, increased total active drug exposure by 1.94-fold based on both the systemic exposure and the relative activities of gemigliptin and active metabolite. Rifampin (600 mg once daily), a strong inducer of CYP3A4 and P-glycoprotein, significantly decreased the total drug exposure by 70%. These data suggest that gemigliptin may need a dose adjustment when coadministered with drugs that alter CYP3A4 activity.[150] In addition, coadministration of multiple once-daily doses of gemigliptin (200 mg) and pioglitazone (30 mg) decreased the plasma C_{max} and area under the curve (AUC) of pioglitazone by 16% and 15%, respectively, while it caused no alteration in the PKs of gemigliptin.[151]

Analogous to the synthesis of sitagliptin, the synthesis of gemigliptin **2** (**Scheme 4**) involved coupling[152,153] of two key intermediates, dihydropyrido[3,4-d] pyrimidine **37** and β-amino acid **41**, using EDC/hydroxybenzotriazole (HOBt) to yield **42** followed by Boc deprotection. Treatment of the enolate made from compound **34** using LHMDS and adding trifluoroacetate gave **35**, which upon reflux condition gave **36**. Boc deprotection of **36** afforded the key intermediate **37**. Cyclization of **38** with **39** yielded the β-amino derivative **40**. Benzyl deprotection of **40** using Pd/C gave the desired intermediate **41**.



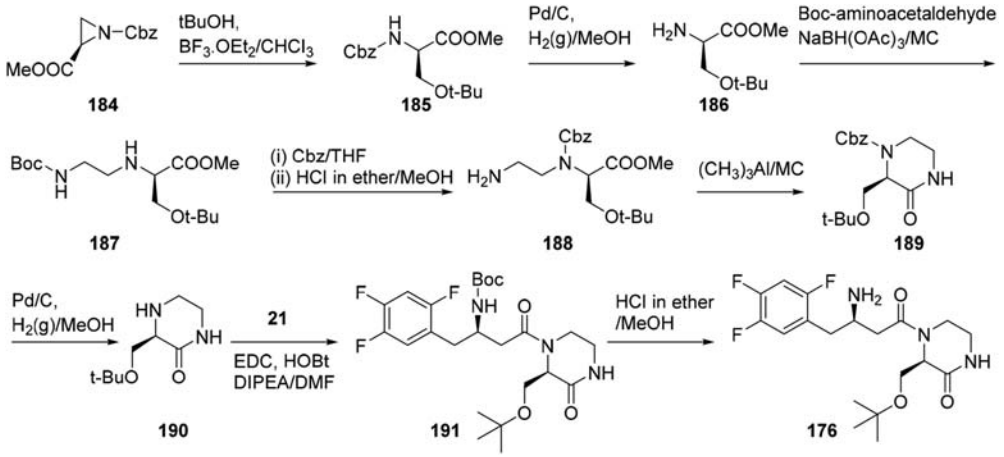
Scheme 4 Synthetic approach for gemigliptin.

7.14.5.1.1.3 Evogliptin (DA-1229, Dong-A)

Evogliptin (DA-1229) is a long-acting DPP-4 inhibitor and a β-amino amide-containing piperazine-2-one derivative[154] discovered by pharmaceutical in Korea. Evogliptin (5 mg oral dose) has been approved by the South Korean Ministry of Food and Drug Safety in October 2015. Evogliptin is a potent ($IC_{50} = 0.98$ nM), reversible, competitive, long-acting DPP-4 inhibitor and is selective (6000-fold) against other proteases such as DPP-8 and DPP-9. X-ray structure analysis reveals that the trifluorophenyl ring of evogliptin occupies the hydrophobic S1 pocket at the active site of DPP-4 and interacts with Tyr547, Tyr662, and Tyr666. The β-amino amide group binds at the S2 pocket where the amine group forms a salt bridge and hydrogen bonds with the side chains of Glu205 and Tyr662. The piperazine-2-one moiety occupies the S2 extended pocket. Evogliptin (0.1–3 mg kg^{-1}) dose-dependently inhibited plasma DPP-4, increased levels of insulin and GLP-1, and lowered blood glucose levels in mice. Evogliptin effected >80% of DPP-4 inhibition at 24 h following a single dose of 100 mg kg^{-1} in mice maintained on a HFD.[154]

In a phase I trial,[286] evogliptin achieved >80% plasma DPP-4 inhibition after a single dose of 5.0 mg. In a phase II trial, evogliptin was efficacious, safe, and well tolerated at all doses.[288] Evogliptin treatment produced a significant reduction in HbA1c levels of 0.56%, 0.66%, and 0.61% at doses of 2.5, 5.0, and 10.0 mg, respectively.

Synthesis of evogliptin started with the preparation of piperazine-2-one moiety **190** from the boron trifluoride-catalyzed ring opening of N-protected aziridine carboxyl ester **184** with tertiary butanol. The resulting compound **185**, after hydrogenation, gave compound **186**, which after reductive amination with sodium triacetoxyborohydride followed by Boc deprotection, and cbz protection provided compound **188** via **187**. Compound **188** was conducted using trimethylaluminum followed by cbz deprotection that gave the key intermediate **188**. The coupling of this key intermediate with β-amino acid **21** offered **191**, which after Boc deprotection using hydrochloride in ether provided evogliptin **176** (Scheme 5).[154] Long-term treatment with evogliptin for 8 weeks in mice maintained on a HFD showed significant improvement in impaired glucose tolerance and insulin resistance.[287]



Scheme 5 Synthesis of evogliptin.

7.14.5.1.1.4 Omarigliptin (MK-3102, Merck)

Omarigliptin (MK-3102) 3 is a novel long-acting aminotetrahydropyran-based DPP-4 inhibitor targeted at achieving better medication compliance in T2DM patients. It was designed by replacing the middle "linker" in sitagliptin with a rigid cyclohexylamine/aminotetrahydropyran moiety. It exhibits an order of magnitude-enhanced potency (DPP-4 $IC_{50} = 1.6$ nM) compared with sitagliptin and has excellent selectivity ($IC_{50} > 67$ μM) against the other DASH peptidases.[125] It is a once-weekly oral antidiabetic agent as opposed to most other existing gliptin therapies, which are administered once or twice daily. Omarigliptin has a clinical half-life of 11–22 h and oral bioavailability of 100% in rat and dog.[155]

In X-ray studies conducted with a trifluorophenyl analog of omarigliptin, the inhibitor binds in the DPP-4 active site analogous to sitagliptin and shares the same interactions. The 2-F atom in the trifluorophenyl group occupies the S1 pocket and hydrogen bonds with the side chain of Arg125. The aminotetrahydropyran group binds at the S2 pocket where the primary amine group makes salt bridges with the carboxylates of Glu205 and Glu206. The fused ring π–π stacks with the side chain of Phe347.[125,155]

In an OGTT in lean mice, omarigliptin significantly reduced blood glucose excursion in a dose-dependent manner from 0.01 mg kg^{-1} (7% reduction in glucose AUC) to 0.3 mg kg^{-1} (51% reduction). The efficacy of glucose lowering in this model was similar to that achieved with sitagliptin. In the corresponding PD assay, plasma DPP-4 activity was inhibited by 85% at the 0.3 mg kg^{-1} dose. In addition, the administration of omarigliptin dose-dependently increased plasma concentrations of active GLP-1 in this study, with maximal increase observed at the 0.3–1 mg kg^{-1} doses.[155]

Omarigliptin dose-dependently inhibited plasma DPP-4 activity in healthy subjects and in patients with T2DM, with 80.7% plasma DPP-4 inhibition at the prescribed clinical dose of 25 mg and a doubling of postprandial 4 h-weighted mean active GLP-1 levels compared with placebo.[156] Omarigliptin is rapidly absorbed in healthy volunteers with a bioavailability of ≥74%. At steady state following three weekly doses of omarigliptin 25 mg, AUC was 22.3 μmol L^{-1} h^{-1}, C_{max} was 701 nM, T_{max} was 1.5 h, and the half-life was 82.5 h.[156] In a 12-week dose range-finding study in T2DM patients, omarigliptin (25 mg once weekly) significantly reduced HbA1c (placebo-subtracted reduction of 0.72% from a baseline of 8.1%).[12] Plasma DPP-4 activity was inhibited by 80.7% at trough. Omarigliptin is generally well tolerated with safety and efficacy comparable to that of sitagliptin.[156] Omarigliptin was approved in Japan in 2015, but its filing in the United States was recently abandoned due to business reasons.[157]

The synthesis of omarigliptin illustrated in Scheme 6 involved the coupling of methylsulfonylpyrrolopyrazole **48** and tetrahydropyranone **56b**. The pyrrolopyrazole intermediate **43** was made by heating a solution of the Boc-protected ketone **45** with *N*,*N*-dimethylformamide dimethyl acetal (DMF-DMA) to form the enamine **44**, which was subsequently dissolved in ethanol and heated under pressure with hydrazine then heated with hydrogen chloride in dry ethyl acetate. Neutralization with aqueous sodium hydroxide gave **43**. The methyl sulfonyl pyrrolopyrazole **48** was made from the Boc-protected intermediate **46** by sequential treatment with sodium hydride, methane sulfonyl chloride, and deprotection with benzene sulphonic acid and neutralization with ammonium hydroxide.

The tetrahydropyranone intermediates **56a** and **56b** were made in the following manner. The nitroketone **51** was made by reacting aldehyde **49** with nitromethane in the presence of a catalytic amount of sodium hydroxide as a base and oxidizing the resulting nitroalcohol **50** with Jones or Dess–Martin reagent. Heating the nitroketone **51** with 3-iodo-2-(iodomethyl)prop-1-ene gave the pyran **52**, which, when reduced with sodium borohydride, gave a mixture of racemic trans-**53** and racemic *cis*-**54** isomers, which were separated by flash column chromatography. The *cis* isomer **54** was readily converted to the transisomer **53** by treatment with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU). The nitro-substituted pyrans **53** were then reduced using zinc and hydrochloric acid. The resulting amines were protected as Boc derivatives by treatment with di-*tert*-butyl dicarbonate and separated by chiral column chromatography to give **55a** and **55b**. Treatment of **55b** with osmium tetroxide and *N*-methylmorpholine *N*-oxide followed by treatment with sodium periodate gave ketone **56b**.[125]

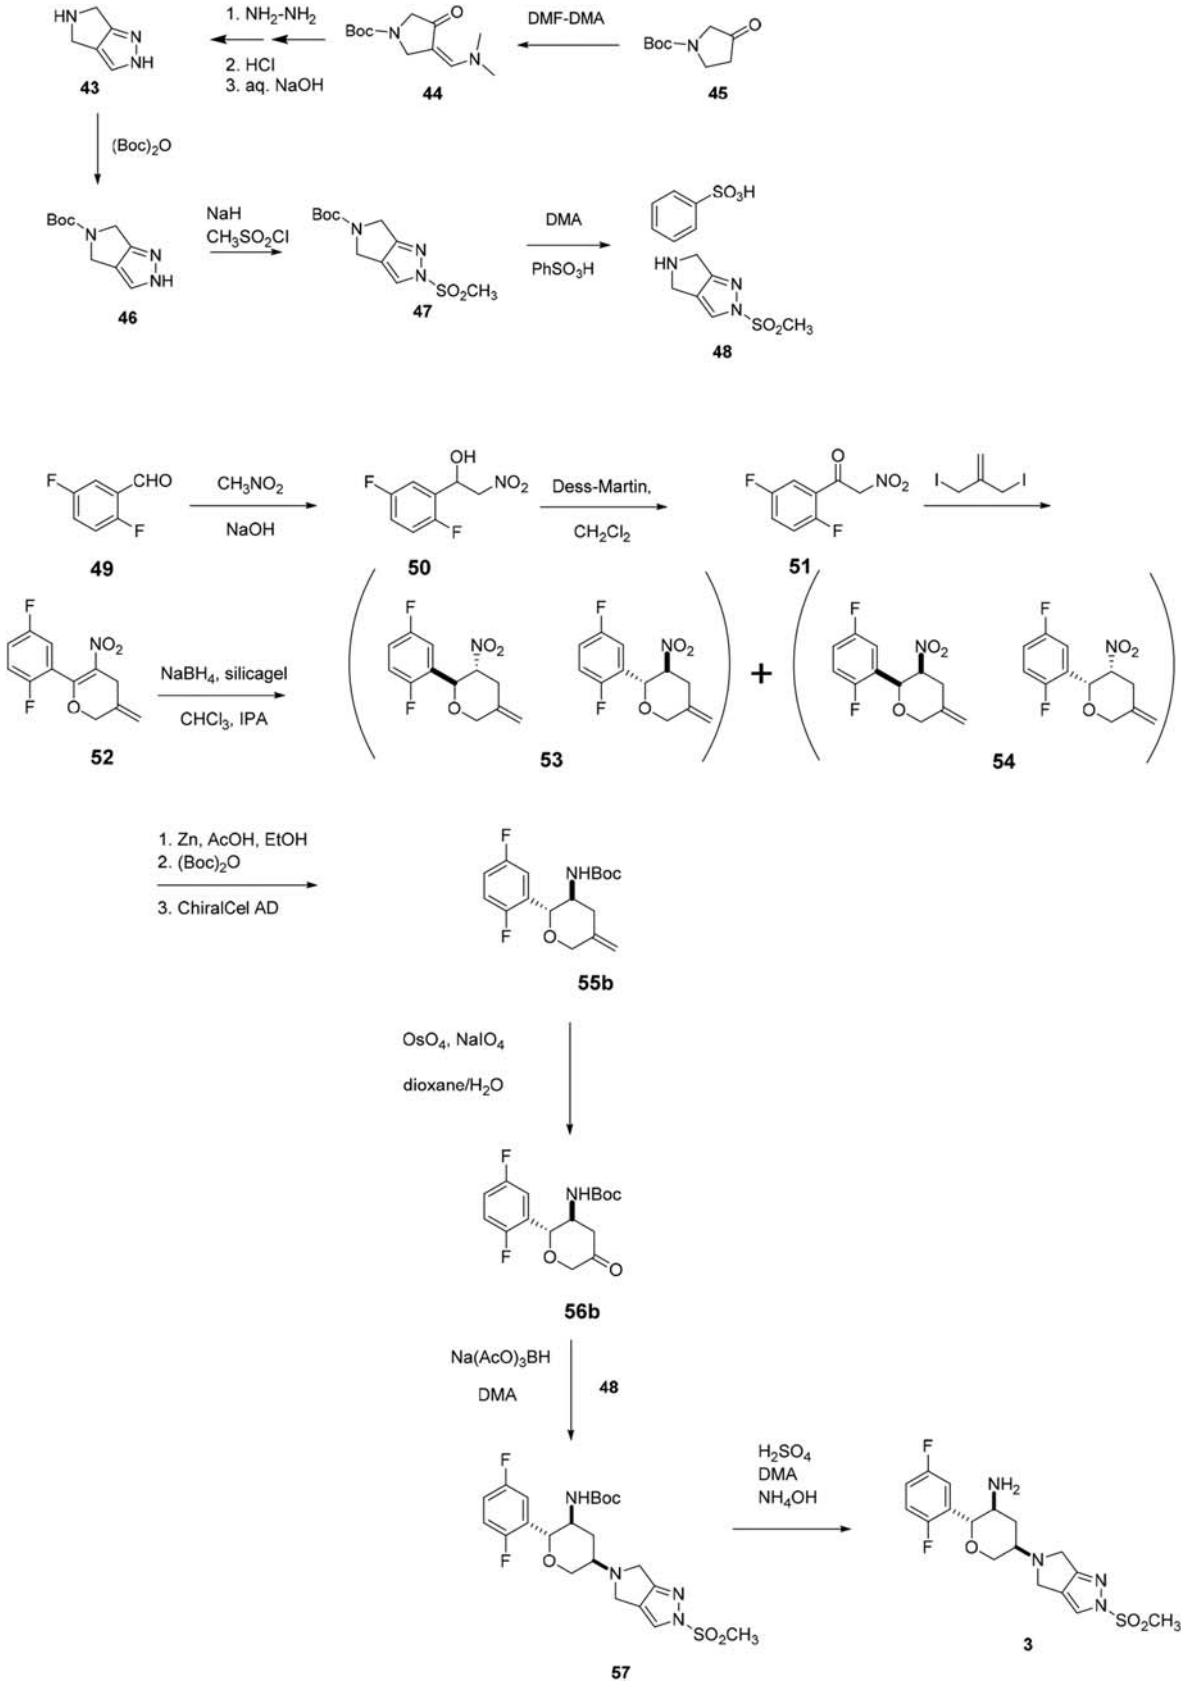
A second convergent manufacturing route of omarigliptin (MK-3102) synthesis[158] through a diastereoselective reductive amination of pyranone **56b** with a mesylated pyrazole **48** followed by deprotection of a Boc group is displayed in Scheme 7.

The synthesis of the pyranone **56b** relies on three Ru-catalyzed reactions: (1) a DKR reduction of a rac-α-aminoketone to set the two contiguous stereogenic centers, (2) a cycloisomerization of a bis-homopropargylic alcohol to a dihydropyran, and, finally, (3) a Ru-catalyzed oxidation of a pyranol to the desired pyranone. The regioselective synthesis of an *N*-Boc-1-mesyl pyrazole fragment was achieved via base-promoted mesyl group isomerization to afford 30:1 selectivity. A highlight of the endgame process development is telescoping a Boc deprotection and reductive amination followed by direct crystallization of the penultimate intermediate from the reaction mixture.

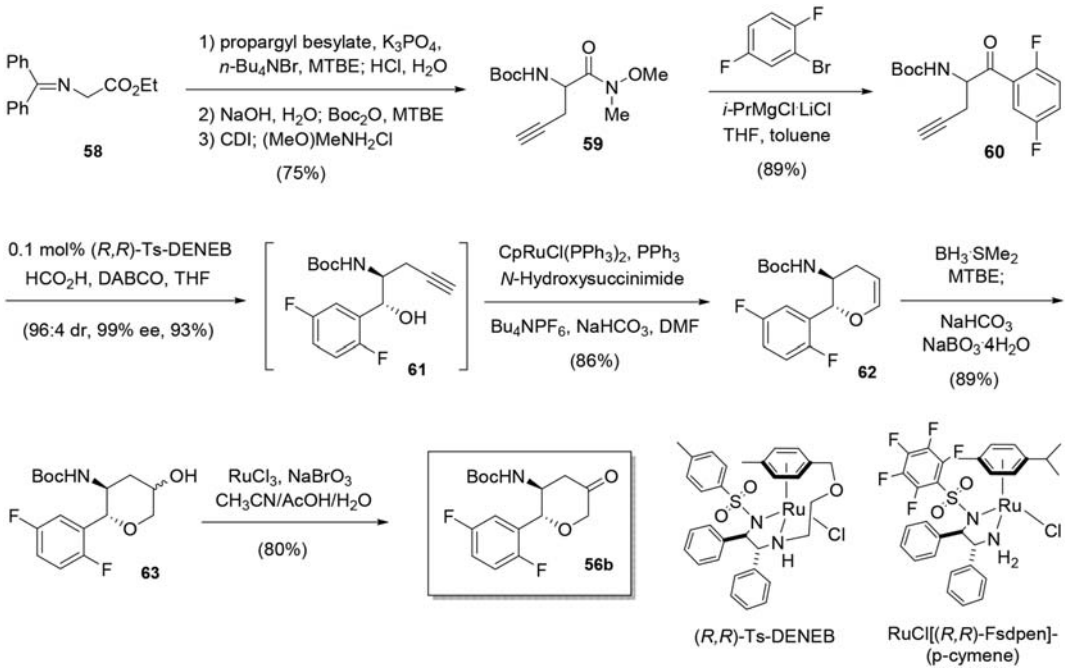
7.14.5.1.2 Pyrrolidine analogs

7.14.5.1.2.1 Vildagliptin (LAF-237, Novartis)

Vildagliptin (LAF-237) **3**, the first gliptin of the cyanopyrrolidine class approved for the treatment of T2DM, is a substrate mimic. Vildagliptin is potent (DPP-4 $IC_{50} = 3.5$ nM) and has modest selectivity over DPP-8 (>250-fold) and DPP-9 (23-fold) but is highly selective against other peptidases such as DPP-II and FAP. Vildagliptin was discovered in an attempt to enhance the half-life and potency of a prior-generation inhibitor NVP-DPP-728,[159] which has a short half-life due to formation of an imidate through internal cyclization between the P2-binding amino functionality and the P1-binding nitrile group. Incorporation of a bulky adamantyl group at the glycine nitrogen resolved this drawback and improved PKs. The absolute oral bioavailability of vildagliptin was >90% in cynomolgus monkeys following a 1 μmol kg^{-1} oral dose. Clearance from plasma was ~1.5 L h^{-1} kg^{-1} with



Scheme 6 Synthesis of omarigliptin.



Scheme 7 Process manufacturing route to omarigliptin intermediate pyranone 56b.

a moderate volume of distribution at steady state (0.7 L kg^{-1}). The C_{max} was 293 nM at 72 min, and the terminal elimination half-life was 90 min, longer than that of NVP-DPP-728.[120]

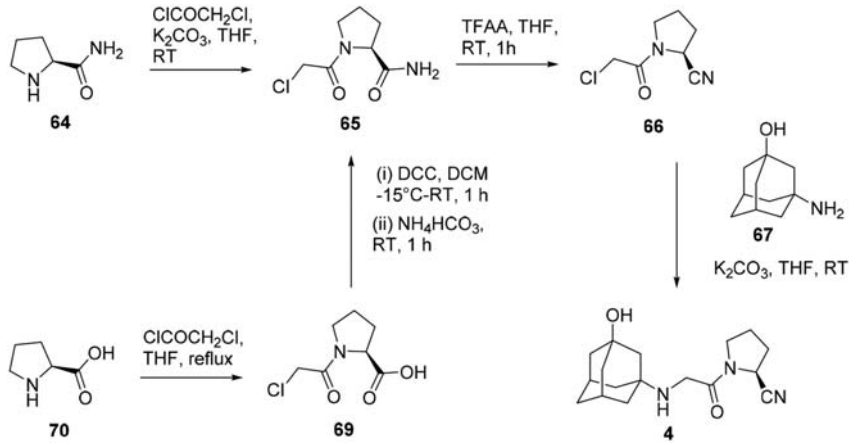
Vildagliptin in an OGTT dosed at 10 μmol kg^{-1} PO 15 min prior to a glucose challenge in obese Zucker (*fa/fa*) rats inhibited plasma DPP-4 activity by >90%, increased active GLP-1 levels fivefold and peak insulin levels approximately twofold, and decreased glucose excursion compared with control-treated rats.[120]

The cyanopyrrolidine moiety of vildagliptin occupies the S1 pocket at the DPP-4 active site. Like saxagliptin, the nitrile group is stabilized through covalent imidate adduct formation with the hydroxyl of catalytic Ser630. The imidate nitrogen–hydrogen bonds with the side chain of Tyr547. The hydrophobic adamantyl moiety occupies the S2 pocket. The hydroxyl-substituent hydrogen bonds with His126 and Ser209 via bridging water molecules. The carbonyl group interacts via hydrogen bonds with the side chain of Asn710, and the secondary amine group is stabilized through salt bridge interactions with Glu205 and Glu206.[160]

Vildagliptin is rapidly absorbed in healthy subjects and T2DM patients with a T_{max} of 1.5 h and a bioavailability of 85% after oral administration.[161] Modeling suggests two absorption sites with lag times of 0.2 and 2.5 h,[162] indicating that vildagliptin may be absorbed via a paracellular pathway. Vildagliptin has a high volume of distribution in healthy subjects (71 L) indicating that it distributes extensively into extravascular spaces. The nitrile moiety in vildagliptin is rapidly hydrolyzed in vivo, likely by DPP-4, to the inactive carboxylic acid metabolite LAY151, which is the major clearance mechanism for the drug. The remaining 33% of vildagliptin total body clearance is via the kidneys as parent (23%) or metabolites. The mean half-life of vildagliptin after multiple doses in T2DM patients is 1.3–2.4 h. Hence, unlike most other gliptins, vildagliptin has to be administered twice daily. There have been no reports of any significant drug–drug interactions with vildagliptin.

In a 24-week dose range-finding phase II study in T2DM patients, vildagliptin (50 mg qd, 50 mg bid, and 100 mg qd) produced placebo-subtracted reductions in HbA1c of 0.5%, 0.7%, and 0.9%, respectively (from a mean baseline HbA1c of 8.4%).[163] Adverse events were similar to that in the placebo group, and no changes in body weight or hypoglycemia were observed. Pooled phase III monotherapy data for vildagliptin 50 mg bid and 100 mg qd from placebo- and active-controlled trials reveal good glucose-lowering efficacy (adjusted mean HbA1c reductions of 1% and 1.1%, respectively) that is consistent with the relatively high corresponding HbA1c baselines of 8.7% and 8.5%.[164] Vildagliptin 50 mg bid was approved by the European Medicines Agency in 2008 as monotherapy and combination therapy with other antihyperglycemic agents, but the drug remains commercially undeveloped in the United States.

Two methods of vildagliptin synthesis are outlined in Scheme 8. In the first method, the amino group of L-prolinamide **64** was acylated using chloroacetyl chloride to give compound **65**, which was converted to compound **66** by dehydration with TFAA. Finally, reaction of 3-hydroxy-1-amino adamantine **67** with **66** gave vildagliptin **4**.[120] An alternative route for the synthesis of intermediate **65** involved the direct *N*-acylation of L-proline **70** with chloroacetyl chloride to afford the chloroacetamide **69**, which was converted to amide **65** by using *N*,*N*′-dicyclohexylcarbodiimide (DCC) and ammonium bicarbonate.[284]



Scheme 8 Combined synthesis of vildagliptin.

7.14.5.1.2.2 Saxagliptin (BMS-477118, Bristol–Myers Squibb*)*

Saxagliptin (**5**) is a substrate-mimicking pyrrolidine-based DPP-4 inhibitor. It contains a cyanomethanoproline moiety at the P1 site and a large hydrophobic adamantyl moiety at the P2 site to fit the S2 pocket. Saxagliptin is highly potent (DPP-4 $K_i = 0.6$ nM) and moderately selective against other DASH peptidases (i.e., DPP-8, DPP-9, FAP, etc.). Like vildagliptin, saxagliptin forms a reversible covalent bond with the catalytic serine residue of DPP-4. This has been used to explain the high potency of saxagliptin versus other gliptins that do not make covalent interactions with DPP-4.[165,166] In addition, the high degree of branching and the presence of a fused cyclopropane scaffold prevent internal cyclization and enhance chemical stability.[121,165,166] Saxagliptin is administered once daily and was approved by US FDA in 2009 either as monotherapy or in combination with other antidiabetic agents.[121]

The PKs of saxagliptin was evaluated in rats, dogs, and monkeys.[167] Saxagliptin was rapidly absorbed and had good bioavailability (50–75%) in the species tested. The plasma clearance (CLp) of saxagliptin was higher in rats (115 mL min^{-1} kg^{-1}) than in dogs (9.3 mL min^{-1} kg^{-1}) and monkeys (14.5 mL min^{-1} kg^{-1}) and was predicted to be low to moderate in humans. The plasma elimination half-life was between 2.1 and 4.4 h in rats, dogs, and monkeys, and both metabolism and renal excretion contributed to overall elimination. The primary metabolic clearance pathway of saxagliptin involved the formation of a pharmacologically active 5-hydroxyl metabolite, which is a reversible DPP-4 inhibitor with twofold lower potency than saxagliptin.[121]

The volumes of distribution for saxagliptin observed in rats, dogs, and monkeys range from 1.3 to 5.2 L kg^{-1}. The in vitro serum protein binding was low ($\leq$30%) in rats, dogs, monkeys, and humans. After intra-arterial administration of saxagliptin to Sprague-Dawley and Zucker diabetic fatty rats, higher levels of saxagliptin and metabolite were observed in the intestine relative to plasma. Saxagliptin displays prolonged PD effects relative to its plasma PK profile, presumably due to a combination of contributions from the active hydroxyl metabolite, distribution of saxagliptin and its metabolite to the intestinal tissue, and slow dissociation of both molecules from DPP-4.[167]

The acute preclinical efficacy of saxagliptin was evaluated in Zucker *fa*/*fa* rats in an OGTT.[121] Saxagliptin (0.3–3 μmol kg^{-1} and 0.13–1.3 mg kg^{-1} PO) dose-dependently increased glucose clearance in this model, and maximal responses in reducing glucose excursion were associated with plasma DPP-4 inhibition of approximately 60%. Saxagliptin was also evaluated in the *ob*/*ob* mouse.[121] An OGTT was performed at 1 h after oral administration of drug at 1, 3, or 10 μmol kg^{-1}. Saxagliptin dose-dependently elevated plasma insulin at 15 min postglucose challenge, with concomitant improvement in the glucose clearance curves at 60 min post challenge.

The cyanopyrrolidine moiety of saxagliptin occupies the S1 pocket of DPP-4 and establishes a covalent bond interaction between the cyano group and side chain of Ser630.[168] The cyclopropyl moiety contributes to binding through hydrophobic interactions with Tyr666. The hydrophobic hydroxyl adamantly group binds at the S2 pocket. The hydroxyl group enhances potency by forming a direct hydrogen bond with the side chain of Tyr547. As with peptide substrates, the primary amine group of saxagliptin in the S2 pocket establishes salt bridges with the carboxylic groups of Glu205 and Glu206.

Saxagliptin exhibited similar PKs in healthy subjects (dosed 40, 100, 150, 200, 300, or 400 mg once daily) and in patients with T2DM (dosed 40, 100, 150, 200, 300, or 400 mg once daily).[169] Drug exposure was dose-proportional, as was exposure to the active 5-hydroxy metabolite BMS-510849, which was 1.7- to 6.9-fold higher than that of the parent molecule. Both saxagliptin and BMS-510849 are cleared from the plasma by the kidney with half-lives of 2.2–3.8 h and 3–7.4 h, respectively.[169] Both, parent drug (12–29% of the administered dose) and active metabolite (21–52% of the dose) were recovered in the urine. Saxagliptin elevated postprandial intact GLP-1 levels up to threefold and dose-dependently inhibited plasma DPP-4 activity (by ~80% to >95%), with maximal DPP-4 inhibition at saxagliptin doses $\geq$150 mg.

In a 12-week study in drug-naive T2DM patients with BMI $\leq$ 37 kg m^{-2}, saxagliptin (2.5, 5, 10, 20, or 40 mg once daily) dose-dependently reduced HbA1c (−0.72% to −0.90%) compared with placebo (−0.27%) from a mean baseline HbA1c of 7.9%.[170] In a 24-week study in drug-naive T2DM subjects, saxagliptin 2.5, 5, or 10 mg once-daily dose-dependently reduced HbA1c compared

with placebo (placebo-subtracted HbA1c reductions of 0.62, 0.65, and 0.73 from a mean baseline of approximately 8.0%).[171] The rates of AEs were similar for treatment and placebo groups, with the most common adverse events (>5% for all saxagliptin groups) being upper respiratory tract infection, headache, urinary tract infection, nasopharyngitis, and sinusitis. Skin AEs were reported more frequently in the treatment groups than in the placebo group, with rash (3.6% in the treatment groups vs. 1.1% in placebo) and pruritus (1.3% in the treatment groups vs none in the placebo) being most common.

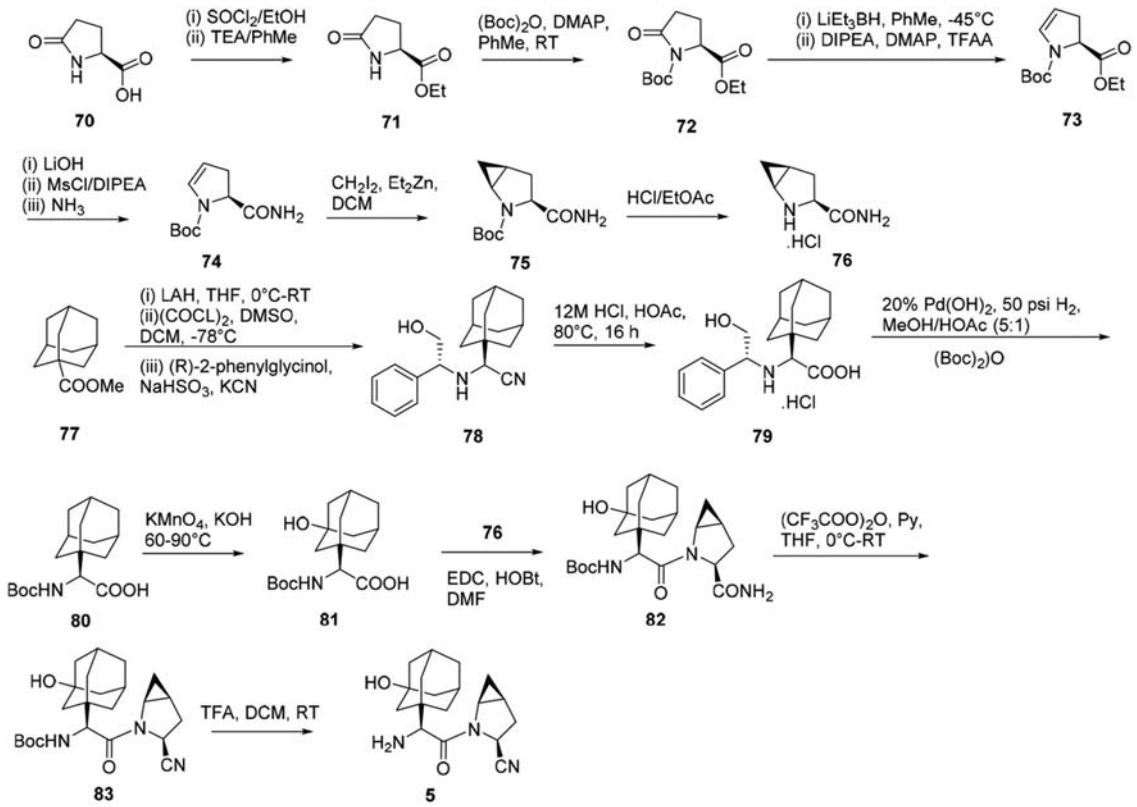
The cardiovascular safety of saxagliptin was evaluated in the saxagliptin assessment of vascular outcomes recorded in patients with diabetes mellitus-thrombolysis in myocardial infarction 53 trial (SAVOR-TIMI 53) cardiovascular outcomes study in T2DM subjects, 70% of whom were also on metformin.[172] Saxagliptin met the primary safety objective of noninferiority but did not meet the primary efficacy objective of superiority for a composite endpoint of cardiovascular death, nonfatal myocardial infarction, or nonfatal ischemic stroke. Although there was no increase in all-cause mortality in the trial, the rate of hospitalization for heart failure was 27% higher in the saxagliptin group (3.5%) than placebo (2.8%, $P=0.007$), resulting in an FDA label warning regarding heart failure risk in susceptible populations.[173]

Saxagliptin is made from two key intermediates—the methanoprolinamide **76** and hydroxyadamantylglycine **81**. The methanoprolinamide intermediate **76** was prepared from L-pyroglutamic acid **70**. Compound **70** was esterified to **71**, Boc-protected to yield **71**, and converted to intermediate **73**. Compound **73** was converted into **74** through an amidation reaction. Using a Simmons–Smith cyclization, compound **74** was converted into Boc-protected methanoprolinamide **75**, which after Boc deprotection provided the desired intermediate **76**.

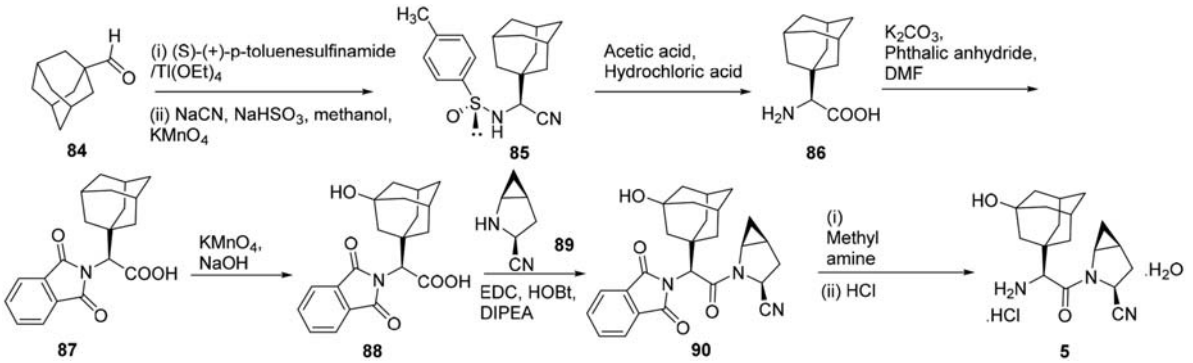
The synthesis of intermediate **81** began from adamantine carboxylic acid methyl ester **77**. Reduction to the aldehyde and its condensation with (R)-2-phenylglycinol and KCN provided compound **78**. Compound **80** was obtained from **78** following acid hydrolysis, hydrogenation-mediated removal of the chiral auxiliary, and Boc protection. Hydroxylation of compound **80** gave the desired intermediate **81**. Thus, saxagliptin **5** was synthesized by coupling of key intermediates, **76** and **81**, using an EDC protocol followed by subsequent TFAA-mediated conversion of amide to nitrile and Boc deprotection (**Scheme 9**).[121]

An asymmetrical synthetic method to make saxagliptin is outlined in **Scheme 10**. Synthesis started with adamantine-1-carboxaldehyde **84** followed by condensation with (*S*)-(+)-*p*-toluenesulfonamide and NaCN to give compound **85**. After acid hydrolysis, compound **86** was subjected to phthalic anhydride protection to give **87**. Hydroxylation of **87** afforded the key intermediate **88**, which was coupled with methanopyrrolidine intermediate **89** to give **90**. Methyl amine-mediated deprotection of phthalic deprotection gave saxagliptin **5**.[174,175]

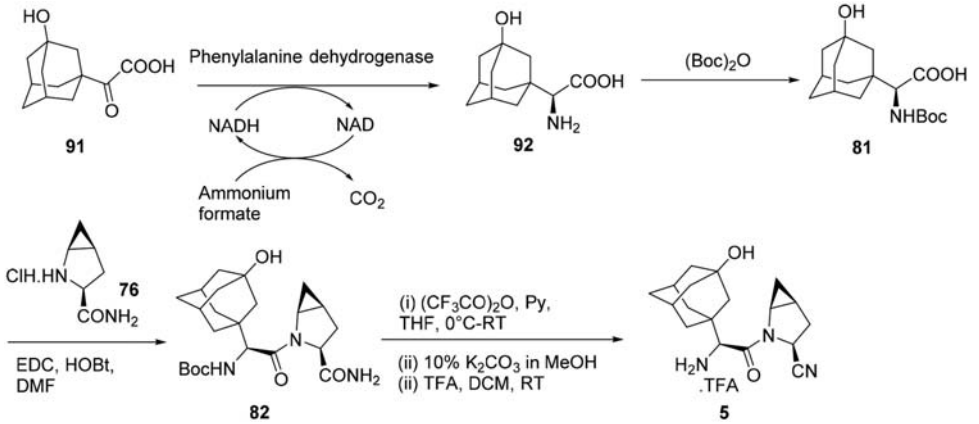
A third enzymatic approach to saxagliptin synthesis is shown in **Scheme 11**. The key intermediate (*S*)-*N*-Boc-3-hydroxyadamantylglycine **92** was obtained from 2-(3-hydroxy-1-adamantyl)-2-oxoacetic acid **91** by reductive amination with



Scheme 9 First method to saxagliptin synthesis.



Scheme 10 Second method to saxagliptin synthesis.



Scheme 11 Third method to saxagliptin synthesis.

a phenylalanine dehydrogenase enzyme. Boc protection followed by coupling with **76** and conversion to the nitrile and deprotection afforded saxagliptin **5**.[176,177]

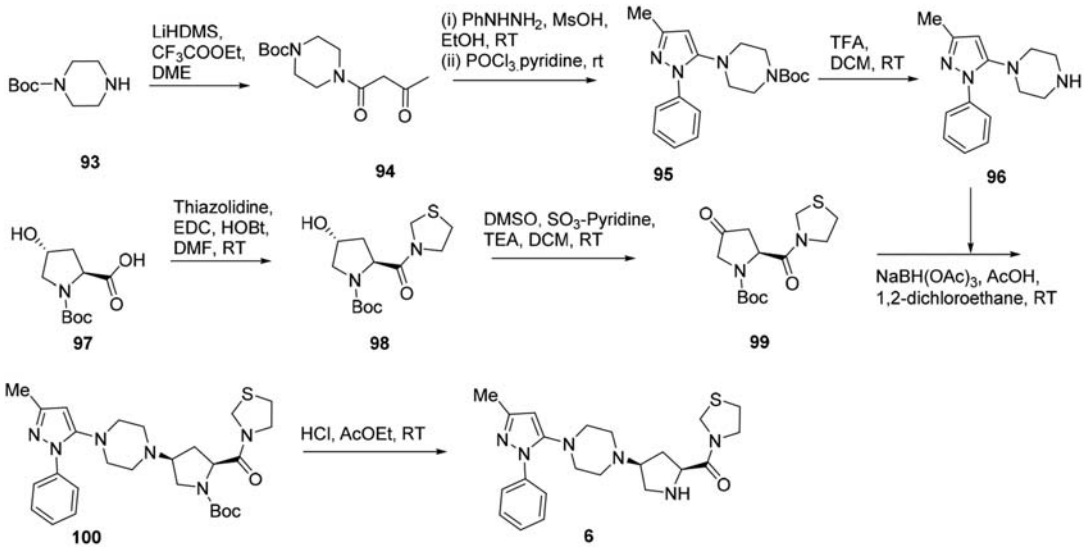
7.14.5.1.2.3 Teneligliptin (MP-0513, Mitsubishi Tanabe)

Teneligliptin **6** is a proline-based constrained bicyclic heteroarylpiperazine-derived DPP-4 inhibitor. It is extremely potent (DPP-4 $IC_{50} = 0.37$ nM) and selective against DPP-8 (703-fold) and DPP-9 (1460-fold). It has recently been approved in Japan for the treatment of T2DM. Oral administration of teneligliptin (HBr salt) to rats and monkeys at each dose of 0.1, 0.3, and 1.0 mg kg^{-1} reached maximal plasma concentrations (C_{max}) at 0.75–0.88 h in rats and 0.50–1.38 h in monkeys, with corresponding half-lives of 8–16 and 15–19 h. Its bioavailability was 63–86% in rats and 44–83% in monkeys. Drug exposure was dose-proportional, and teneligliptin was mainly excreted into feces via bile in both species.[126]

Teneligliptin (HBr salt) when administered orally to Wistar rats at a dose of 0.03, 0.1, 0.3, or 1 mg kg^{-1} effected dose-dependent, fast-onset, and long-lasting DPP-4 inhibitory activity. Greater than 50% inhibition of plasma DPP-4 level was sustained at a single oral dose of 1 mg kg^{-1} for up to 24 h. In Zucker fatty rats pretreated with compound at doses from 0.03 to 1 mg kg^{-1} in an OGTT, teneligliptin dose-dependently lowered glucose excursions to levels similar to that in lean controls. A 0.03 mg kg^{-1} oral dose of teneligliptin produced >35% DPP-4 inhibition compared with predosing values.[126]

X-ray studies reveal that the thiazolidine moiety of teneligliptin binds to the hydrophobic S1 pocket of DPP-4, while the substituted proline occupies the S2 pocket. The amine functionality of the proline establishes salt bridge interactions with Glu205 and Glu206. The carbonyl group makes a hydrogen-bonding interaction with the side chain of Asn710. The (1-phenylpyrazol-5-yl)piperazine fragment of teneligliptin has been termed an "anchor lock domain" and binds more deeply into the S2 pocket. The pyrazolyl ring is stacked with Phe357. The piperazinyl ring fragment interacts with the Phe357 residue through a CH–n interaction. The phenyl group attached to the pyrazolyl ring forms hydrophobic interactions with Ser209 and Arg358.[126]

Teneligliptin is rapidly absorbed in healthy subjects, with a T_{max} of 1.33 h and an elimination half-life of 26.9 h following a radiolabeled 20 mg dose.[178] The drug is ~78–80% protein-bound in plasma. Teneligliptin is metabolized by CYP3A4 and flavin monooxygenases 1 and 3 to metabolites of uncharacterized biological activity, including a major thiazolidine-1-oxide derivative (14.7% of total AUC). At least 90% of the total radiolabeled dose was excreted by 216 h (45.4% in the urine and the rest in feces). Approximately 21% of teneligliptin is excreted in urine as parent drug. Teneligliptin is a weak CYP2D6, CYP3A4, and FMO inhibitor



Scheme 12 Synthesis of teneligliptin.

in vitro but did not show any significant drug–drug interactions when coadministered with ketoconazole, metformin, or canagliflozin in healthy subjects.[179] The efficacy of teneligliptin as monotherapy and combination therapy was assessed in T2DM patients in phase II and III trials conducted in Japan and Korea. After 12 weeks of treatment, teneligliptin 20 or 40 mg once daily produced placebo-subtracted HbA1c reductions of 0.9% and 1%, respectively, from corresponding HbA1c mean baselines of 7.8% and 7.7%,[180] similar to efficacy observed in this population for the gliptin class in general. Pooled phase III data from two open-label nonplacebo-controlled monotherapy trials indicate that teneligliptin (20 mg once daily, titrated to 40 mg if inadequate efficacy was observed) reduced HbA1c by 0.63% from a baseline of approximately 7.7%.

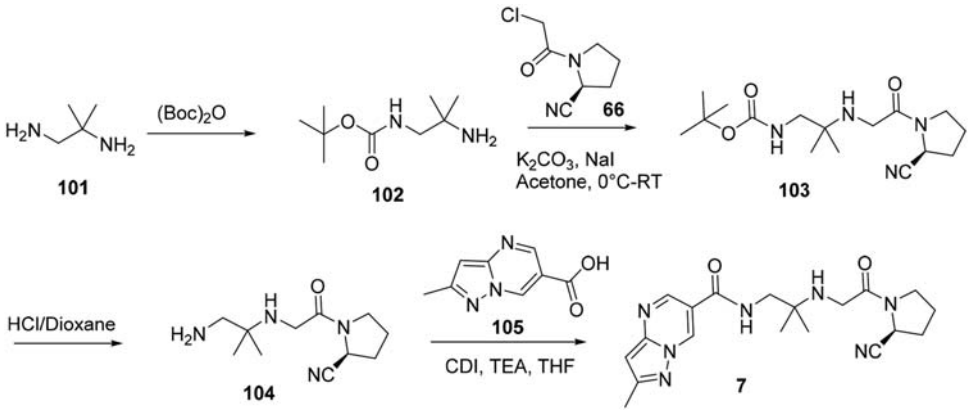
Synthesis of teneligliptin **6** (**Scheme 12**) involved the reductive amination of ketone **99** with amine **96** (to afford only the *cis* isomer of compound **100**) and subsequent Boc removal.[126] Intermediate **96** was prepared by treating Boc piperazine **93** with ketene. Subsequent dehydration and cyclodehydration of the resulting β-ketoamide with phenyl hydrazine and phosphorus oxychloride in pyridine, respectively, were followed by Boc deprotection. Intermediate **99** was prepared by coupling of *N*-Boc-*trans*-4-hydroxy-L-proline **97** with thiazolidine followed by oxidation with dimethyl sulfoxide and sulfur trioxide.

7.14.5.1.2.4 Anagliptin (SK-0403, Sanwa Kagaku Kenkyusho)

Anagliptin **7** is a 2-methyl pyrazolopyrimidine-derived cyanopyrrolidine-based DPP-4 inhibitor. It is potent (DPP-4 $IC_{50} = 3.8$ nM) and more than 10,000-fold selective for DPP-4 against DPP-8 and DPP-9.[128] In PK studies,[128] anagliptin had a clearance of 0.65 L h^{-1} kg^{-1} and oral bioavailability of 100% in beagle dogs while showing a relatively higher clearance of 2.00 L h^{-1} kg^{-1} and moderate oral bioavailability of 23% in rats. In bile duct-cannulated rats, 30% and 40% of drug was excreted unchanged from the urine in the 24 h period after IV administration at doses of 1 and 5 mg kg^{-1}, respectively, with recovery of ~13–14% of the doses in bile. Similarly, in dogs dosed at 1 mg kg^{-1} IV, 32% and 24% of anagliptin was excreted unchanged from urine and feces, respectively, in the 24 h period after drug administration. Parent compound was primarily eliminated into urine, and biliary excretion was more significant in dogs than in rats.

In male Wistar/ST rats at oral doses of 0.1, 0.3, 1, or 3 mg kg^{-1}, anagliptin dose-dependently inhibited plasma DPP-4 activity, with sustained inhibition of >90% at 3 mg kg^{-1} over the course of a 2 h OGTT. A significant reduction in glucose AUC was observed at the 1 and 3 mg kg^{-1} doses, with increased insulin levels at 10 min postglucose challenge suggesting augmentation of active GLP-1 levels.[128]

Anagliptin is rapidly absorbed following a 100 mg radiolabeled oral dose in healthy male subjects, with a T_{max} of approximately 1.8 h and a biexponential elimination profile with a terminal half-life of 4.37 h.[181] Hence, like vildagliptin, anagliptin has to be administered twice daily. The drug is moderately protein bound (~37%). Hydrolysis of the cyanopyrrolidine to the corresponding inactive acid, likely in part by DPP-4, forms a major metabolite in vivo (22.3% of the radiolabeled AUC), which has a longer terminal half-life of 9.88 h.[181] Excretion of the radiolabeled dose was primarily by active renal secretion of anagliptin and its acid metabolite in the urine (73.2%), with 25% of the administered dose recovered in feces. In a 24-week phase III study in T2DM patients conducted in Korea, anagliptin 100 or 200 mg bid produced similar placebo-subtracted HbA1c reductions of 0.73% and 0.74%, respectively, from a mean baseline HbA1c of 7.1%.[182] The safety profile was typical for the class, with nonsignificantly higher incidences of pharyngitis, rhinitis, and upper respiratory tract infections compared with placebo. Anagliptin has been approved for use in Japan for the treatment of type 2 diabetes.[183]



Scheme 13 Synthesis of anagliptin.

The synthesis of anagliptin is summarized in Scheme 13. The selective Boc protection of 2-amino-2-methylpropylamine **101** with Boc anhydride followed by coupling with (*S*)-1-(2-chloroacetyl)pyrrolidine-2-carbonitrile **66** gave compound **103**. After deprotection of the Boc group, compound **103** was coupled with pyrazolo[1,5-a]pyrimidinecarboxylic acid **105** to afford anagliptin **7** in excellent yield.[128]

7.14.5.1.3 Pyrimidinedione/xanthine analogs

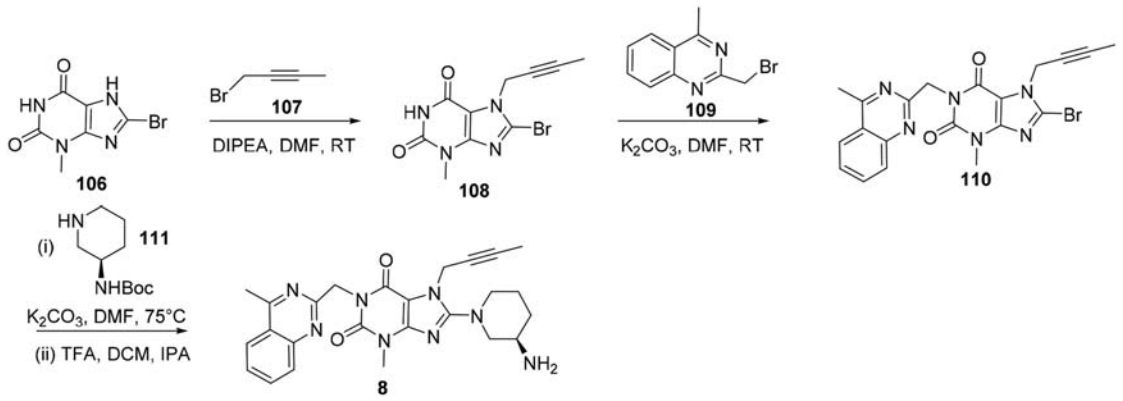
7.14.5.1.3.1 Linagliptin (BI-1356, Boehringer Ingelheim)

Linagliptin **8** is a xanthine-based DPP-4 inhibitor. It is highly potent with an IC_{50} of 1.0 nM and is highly selective for DPP-4 over DPP-8 (10,000-fold), DPP-9 (>10,000-fold), and other related peptidases.[123,184,185] Oral bioavailability of linagliptin is reported to be 15–51% in rats, with the drug having a volume of distribution of 5.4–40 L kg^{-1}, a clearance of 37–56 mL min^{-1} kg^{-1}, and a relatively long half-life of 36 h.[123,186] Corresponding values in monkeys are 51%, 16 mL kg^{-1} min^{-1}, and 41 h.[123] The drug is not appreciably metabolized in vivo, with about 80% of radiolabeled linagliptin in the plasma appearing as the parent compound in mice, rats, and humans.[187] After 14 days of repeated oral dosing with radiolabeled linagliptin in rats, approximately 90% of the radioactivity was recovered in the feces, and only ~1% was found in the urine.[188] Multiple oral doses of linagliptin (1, 2.5, 5, or 10 mg qd for 12 days) were administered to patients with type 2 diabetes. The T_{max} was 1–3 h post dose after both single and multiple dosing, and drug exposure (linagliptin AUC) and maximal concentration (C_{max}) values increased dose-dependently but in a less than dose-proportional manner. Steady state was attained within 2–5 days, with only modest drug accumulation (accumulation ratio, 1.18–2.03). At steady state, linagliptin was cleared at a rate of 14–70 mL min^{-1}, and the elimination half-life ranged from 113 to 130 h. Renal excretion of linagliptin was low across all doses, being <1% on day 1 and remaining below 6% on day 12.[189]

Single doses of linagliptin dose-dependently inhibited plasma DPP-4 activity in normal Han–Wistar rats by >70% at 1 mg kg^{-1} and by ~90% at 3 and 10 mg kg^{-1}, measured 7 h post dose.[185] Similar results were obtained in diabetic *db*/*db* mice.[123] In obese insulin-resistant Zucker rats, linagliptin reduced glucose excursion during an OGTT, both when dosed 30 min before the glucose challenge and when dosed 24 h before testing. Acute glucose lowering was associated with increases in intact GLP-1 and insulin levels.[185] In the high-fat diet/STZ-induced mouse model of type 2 diabetes, chronic administration of linagliptin (1, 3, or 10 mg kg^{-1} once daily for 4 weeks) dose-dependently inhibited plasma DPP-4 activity by 59–87% at trough. Oral glucose tolerance was improved to a similar extent after 17 days of treatment at all doses and was associated with improvements in HbA1c after 4 weeks. Basal intact GLP-1 levels 16 h after drug administration were dose-dependently increased up to threefold on day 28.[190] In male Zucker diabetic fatty (ZDF) rats, once-daily administration of linagliptin (3 mg kg^{-1}) for 5 weeks increased intact GLP-1 levels and reduced glucose excursion by ~50% in an OGTT performed at the end of the treatment. In female ZDF rats, which are less severely diabetic, treatment with linagliptin for 7.5 weeks dose-dependently improved glucose tolerance, with the highest dose (3 mg kg^{-1}), leading to a significant reduction in HbA1c.[190]

X-ray crystal structure analysis of the DPP-4-linagliptin complex has revealed that the S1 pocket of DPP-4 is occupied by the butynyl group of linagliptin and the S2 pocket is occupied by the amino piperidine moiety. The amino group of the latter establishes a salt bridge with Glu205 and Glu206 and hydrogen bonds with Tyr662. The aromatic uracil moiety forms a π–π interaction with Tyr547. The carbonyl group at C-6 elicits a hydrogen bond with Tyr631. These interactions enhance binding avidity. The π–π interaction between the quinazoline phenyl and Trp629 is responsible for the enhanced selectivity profile of linagliptin.[123]

Linagliptin is well tolerated with no hypoglycemia in healthy subjects at doses up to 600 mg. The drug exhibits biliary excretion with a terminal half-life of 180 h.[191] In a 12-day study in male T2DM subjects, linagliptin (1, 2.5, 5, or 10 mg once daily) dose-dependently inhibited plasma DPP-4 activity, with >80% inhibition achieved in seven of the eight patients in the 5 mg dose group and in all nine patients in the 10 mg dose group.[189] Moderate accumulation was observed, with the accumulation half-life decreasing with dose from ~24 h at 1 mg dose to ~9 h for the 10 mg dose group. Linagliptin dose-dependently reduced glucose



Scheme 14 Synthesis of linagliptin.

excursions and increased active GLP-1 levels during an OGTT both on day 1, and, more markedly, on day 13, reflecting the time to steady state, which ranged between 4 and 6 days for doses up to 5 mg. In a 24-week phase III study in T2DM subjects, linagliptin (5 mg once daily) improved glycemic control with a placebo-subtracted HbA1c reduction of 0.69% from a mean baseline of 8.00%.[192] The drug was well tolerated, with an adverse event profile similar to that of the placebo group. Linagliptin 5 mg was approved by the US FDA in 2011.

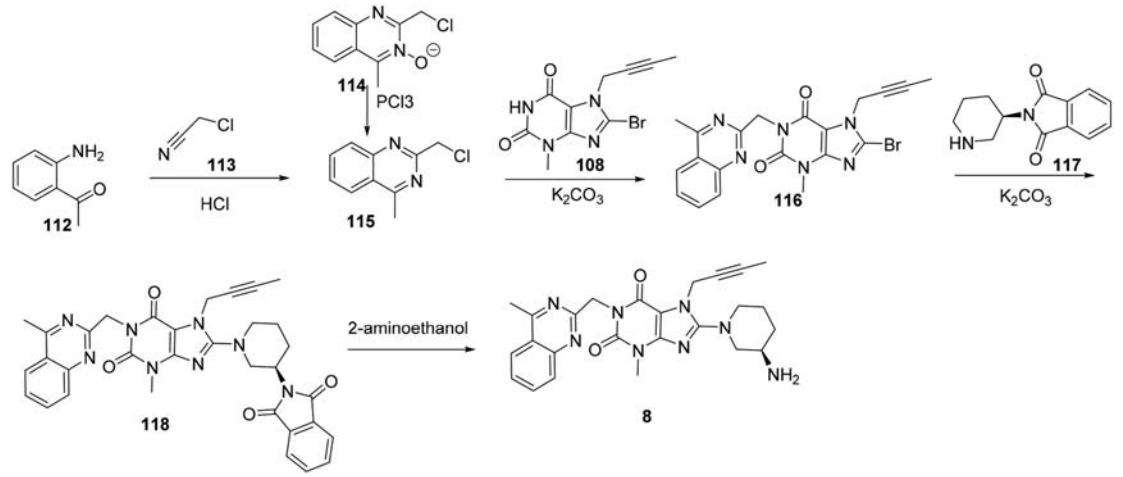
Linagliptin reduced kidney fibrosis in STZ-induced diabetic mice independent of glycemic control[193] and inhibited the high glucose-induced increase of the profibrotic cytokine TGFβ1 in human kidney proximal tubular cells.[194] These effects on the TGF-β axis have been attributed to a molecule-specific effect of linagliptin, since they are reportedly not recapitulated by sitagliptin.[195] Linagliptin is currently being assessed for cardiovascular and renal outcomes in T2DM patient in the cardiovascular and renal microvascular outcome study With linagliptin in patients with type 2 diabetes mellitus trial (CARMELINA)[196] and against glimepiride for cardiovascular outcomes in the cardiovascular outcome trial of linagliptin versus glimepiride in type 2 diabetes trial (CAROLINA).[109]

The synthesis of linagliptin presented in **Scheme 14** begins with N-7 alkylation of xanthine analog **106** with 1-bromo-2-butyne **107** to afford compound **108**. N-1 alkylation of **108** with **109** resulted in compound **110**, which on nucleophilic substitution at C-8 by 3-aminopiperidine **111** and subsequent Boc deprotection afforded linagliptin **8**.[123]

An alternative[197–200] route for the synthesis of linagliptin shown in **Scheme 15** involved the preparation of a key intermediate **115** via either the cyclization of 2-aminoacetophenone **112** with chloroacetonitrile **113** or the reaction of quinazoline oxide **114** with PCl_3. N-1 alkylation of **108** with **115** gave the compound **116**. Linagliptin **8** was prepared by nucleophilic substitution at the C-8 position of **116** by piperidine derivative **117** followed by deprotection with 2-aminoethanol.

7.14.5.1.3.2 Alogliptin (SYR-322, Takeda)

Alogliptin 9 is a quinazolinone-based potent inhibitor of DPP-4 exhibiting an IC_{50} of ~6.9 nM and >10,000-fold selectivity for DPP-4 over the other DASH peptidases.[122,201] Alogliptin exhibited favorable PK and PD profiles in rats, dogs, and monkeys.[201]



Scheme 15 Second route to the synthesis of linagliptin.

Alogliptin was absorbed rapidly (T_{max} values of 0.4–2.3 h across preclinical species) and exhibited oral bioavailability of 45–88%.[201] Plasma DPP-4 inhibition occurred dose-dependently and rapidly (within 15 min post dose) in all species. Plasma DPP-4 inhibition was sustained in rats (43% DPP-4 inhibition at 12 h following a 10 mg kg^{-1} dose), dogs (65% DPP-4 inhibition at 12 h following a 3 mg kg^{-1} dose), and monkeys (>80% DPP-4 inhibition at 24 h following doses of 2, 10, or 30 mg kg^{-1}), supportive of a once-daily dosing regimen.

Administration of alogliptin to Zucker *fa/fa* rats (0.3–10 mg kg^{-1}) maximally inhibited plasma DPP-4 activity by >90% at all doses, with >65% DPP-4 inhibition measured 24 h after the 10 mg kg^{-1} dose. Alogliptin plasma concentrations of ~5.5 ng mL^{-1} (16.2 nM) were sufficient to inhibit plasma DPP-4 activity by at least 80%. Alogliptin dose-dependently inhibited plasma DPP-4 activity, increased GLP-1 levels, augmented early-phase insulin secretion, and reduced blood glucose excursion in response to an oral glucose challenge. Maximal PD effects were observed at the 10 mg kg^{-1} dose in these animals.[122,201,202]

X-ray studies revealed that the cyanobenzyl group of alogliptin occupies the S1 pocket of DPP-4 and interacts with Arg125. The aminopiperidine scaffold of alogliptin binds into the S2 pocket by making a salt bridge interaction with the carboxylate groups of Glu205 and Glu206. The carbonyl group hydrogen bond with the backbone amide of Tyr631 and the central uracil core forms a π–π interaction with the side chain of Tyr547.[122,124]

In healthy subjects and T2DM patients, alogliptin had a T_{max} of 1–2 h, absolute bioavailability of 100%, and a large volume of distribution (greater than total body water), suggesting wide distribution in tissues.[203,204] The drug was well tolerated at all doses tested from 25 to 800 mg. The drug is minimally metabolized to N-demethylated and N-acetylated derivatives (<1% and <6% of the dose, respectively) and is actively secreted in the urine (60–71%) as parent drug.[205] CYP2D6 and CYP3A4 are the major metabolizing enzymes for alogliptin, but given the minimal metabolism, there have been no reports of any significant drug–drug interactions. The drug has an elimination half-life of 12.5–21 h.[204] In healthy subjects, alogliptin maximally inhibited plasma DPP-4 activity by 93.3–98.8% at all doses tested, with 24 h mean DPP-4 inhibition ranging from 74.3% to 97.0%. Multiple doses of alogliptin (25, 100, and 400 mg once daily) over 14 days inhibited DPP-4 activity by >81% at trough,[205] further supporting the rationale for once-daily dosing. The efficacy of alogliptin monotherapy (12.5 or 25 mg once daily) in T2DM patients was assessed in a 26-week phase III study.[206] The two doses produced placebo-subtracted HbA1c reductions of 0.54% and 0.57%, respectively, from a mean HbA1c baseline of 7.9%. The drug was well tolerated with AEs typical of the class (headache, infection, and gastrointestinal) and comparable to placebo. The incidence of headache (6.8–7.5%) and skin-related events (12.8–15.2%, mainly pruritus) was higher than the placebo group (4.7% and 6.3%, respectively). Alogliptin was approved in Japan in 2010 and by the US FDA in 2013. The recommended drug dosage is 25 mg once daily in patients with normal renal function and 12.5 or 6.25 mg once daily in patients with moderate or severe renal impairment.[207]

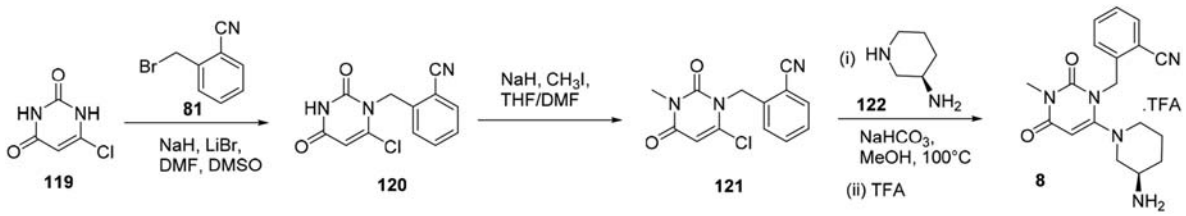
The cardiovascular safety of alogliptin was assessed in patients with established ACS in the examination of cardiovascular outcomes with alogliptin versus standard of care in patients with type 2 diabetes mellitus and acute coronary syndrome trial (EXAMINE).[208] The noninferiority primary composite endpoint for death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke was achieved. There was a statistically nonsignificant increased risk of hospitalization for heart failure resulting in a label warning,[173] although all-cause mortality was not increased in the trial.

The synthesis of alogliptin is shown in **Scheme 16**. 4-Chlorouracil **119** was reacted with 2-(bromomethyl) benzonitrile and afforded compound **120**.[209] Methylation of **120** followed by nucleophilic substitution with 3-(R)-aminopiperidine **122** gave alogliptin **8** as the TFA salt.[122,210]

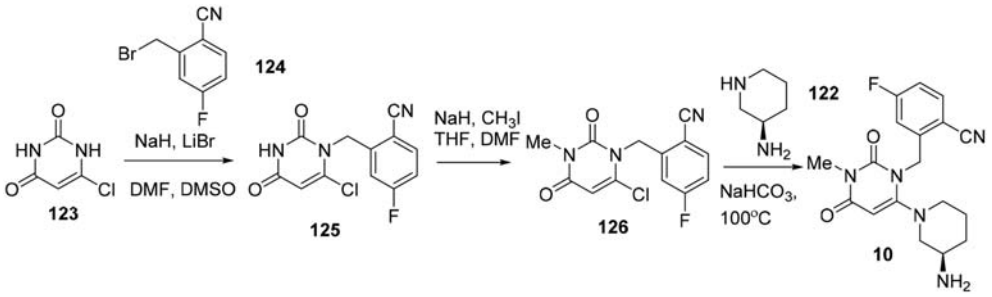
7.14.5.1.3.3 Trelagliptin (SYR-472, Takeda/Furiex)

Trelagliptin **10** is a fluorinated analog of alogliptin. It is a long-acting DPP-4 inhibitor amenable for once-weekly oral administration.[124] It is potent (IC_{50} = 4 nM) with high selectivity (>100,000) against DPP-8 and other related enzymes. Trelagliptin effects a sustained PD effect in dogs and inhibited >80% plasma DPP-4 activity at 24 h after a single oral dose of 7 mg kg^{-1}. It also exhibited favorable PK profiles in dogs and monkeys with half-lives of 4.8 and 8 h, respectively, and oral bioavailability of 90–105%. Trelagliptin 1 mg kg^{-1} exhibited acute antihyperglycemic efficacy in an OGTT conducted in Zucker *fa/fa* rats, with a reduction in glucose excursion and augmented plasma insulin levels.[124]

Due to its structural similarity to alogliptin, trelagliptin exhibits similar interactions with the active site of DPP-4.[124] The aminopiperidine moiety forms salt bridges with Glu205 and Glu206, while the fluorocyanobenzyl group occupies the hydrophobic S1 pocket and interacts with Arg125. The carbonyl at the 2-position forms an important hydrogen bond with the backbone NH of Tyr631 and the uracil core π-stacks with Tyr547.



Scheme 16 Synthesis of alogliptin.



Scheme 17 Synthetic approach toward trelagliptin.

Trelagliptin is rapidly absorbed in healthy subjects following a 100 mg dose, with a T_{max} of 1.3 h.[211] The mean elimination half-life was 18.5–54.3 h. Trelagliptin is metabolized by CYP2D6, and the drug is mainly renally cleared. The marketed dose of 100 mg once weekly is recommended to be reduced to 50 mg in patients with moderate renal impairment.[211] In a phase II dose range-finding study, trelagliptin reduced HbA1c in a dose-dependent manner when administered once weekly for 12 weeks at doses of 12.5–200 mg in Japanese T2DM patients.[212] A maximum placebo-subtracted HbA1c reduction of ~0.9% was obtained at the 100 and 200 mg doses from a baseline of ~8.2%. In a 24-week phase III trial in Japanese T2DM patients, trelagliptin 100 mg once weekly was noninferior to alogliptin 25 mg once daily.[213] Trelagliptin was well tolerated with no serious AEs considered to be related to treatment. It was approved in Japan for the treatment of T2DM in 2014.

Synthesis of trelagliptin is outlined in Scheme 17. Selective alkylation of chlorouracil **123**, followed by methylation, provided compound **126**. The displacement of chloride with 3-(R)-aminopiperidine **122** afforded trelagliptin **10**.[124]

7.14.5.2 DPP-4 Inhibitors in Phase III

Five potent, safe, and well-tolerated peptidomimetic DPP-4 inhibitors are reported to have entered phase III clinical trials as summarized in Table 3. These molecules are dutogliptin (**13**), gosogliptin (**9**), denagliptin (**11**), melogliptin (**10**), and retagliptin (**12**).

7.14.5.2.1 Dutogliptin (PHX1149, Phenomix Corp)

Dutogliptin (PHX1149) **127** is a boronic acid-based DPP-4 inhibitor. Dutogliptin is a highly water-soluble (>2 g mL^{-1}) DPP-4 inhibitor with 15- to 319-fold selectivity over other members of the DPP family and a DPP-4 IC_{50} of 25 nM.[214,215] PK and PD studies indicate that PHX1149 inhibits DPP-4 enzymatic activity across preclinical species in a time- and dose-dependent manner.[214] In a single-dose study of PHX1149 at 50, 100, 200, 300, or 500 mg in healthy male subjects after an overnight fast, mean drug AUC increased in a dose-proportional manner with a median T_{max} of 2–4 h.[215] The half-life for PHX1149 was ~10–13 h. Dose-dependent maximal inhibition of DPP-4 ranging from 64% to 92% was observed 2–4 h post dose. Near-maximal DPP-4 inhibition for 24 h was observed at the 300 and 500 mg doses, and the EC_{50} and EC_{90} values for DPP-4 inhibition by PHX1149 in vivo were ~10 and ~100 ng mL^{-1}, respectively.[215]

Dutogliptin was evaluated in a 12-week phase II study in T2DM patients not optimally controlled with metformin and/or thiazolidinediones.[216] Patients were randomized to receive oral doses of dutogliptin 200 mg and 400 mg once daily. Placebo-subtracted reductions from baseline in HbA1c were 0.34% and 0.52%, from a baseline HbA1c of ~8.4%, and dutogliptin also significantly reduced FPG. The incidence of AEs was similar in treatment and placebo groups, with slightly more headache, arthralgia, sinusitis, and dizziness occurring in the 400 mg group compared with placebo.

Synthesis of dutogliptin begins with pyrrolidine **132**, which, after Boc protection, gave **133**. Treatment of **133** with *sec*-butyllithium and trimethoxyborane resulted in **134**, which, on reaction with (+)-pinanediol, followed by Boc deprotection provided key intermediate **135**. Another core intermediate **138** was prepared from N-protected 3-aminopyrrolidine **136** via alkylation, cbz protection, and hydrolysis of the methyl ester. The coupling of pyrrolidine intermediate **135** with **138** provided **139**, which after cbz and (+)-pinanediol deprotection with hydrogenation and phenyl boronic acid, respectively, afforded dutogliptin **127**.[217] Alternative routes for the synthesis of dutogliptin[218,219] have also been reported (Scheme 18).

7.14.5.2.2 Gosogliptin (PF-00734200, Pfizer)

Gosogliptin **128** is a diprolyl-derived piperazine-containing DPP-4 inhibitor with an IC_{50} of 13 nM and 100-fold selectivity over DPP-II and DPP-8.[220] In rats and dogs, gosogliptin had a half-life of 2.5 and 2.9 h, respectively, with corresponding bioavailability of 109% and 95%.[220,221] In cynomolgus monkey, the half-life of gosogliptin was 7.6 h, with 71% bioavailability.

The X-ray crystal structure of gosogliptin bound to DPP-4 confirms that the hydrophobic difluoropyrrolidide moiety binds to the S1 pocket where it forms hydrophobic interactions with Trp659, Val 656, Tyr631, Ser630, Tyr666, and Tyr662. One of the fluorines forms a hydrogen bond with either Ser630 or the backbone amide of Tyr631. The remaining part of the inhibitor occupies the S2 pocket where the secondary amine of the pyrrolidine makes a salt bridge with the carboxylates of Glu206 and Glu205. The

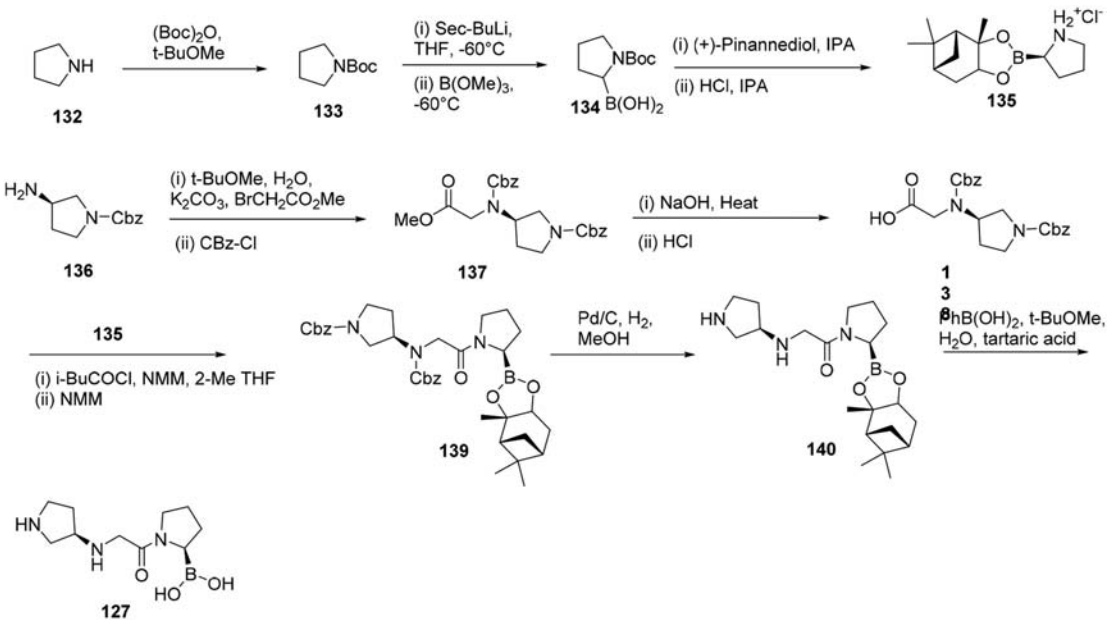
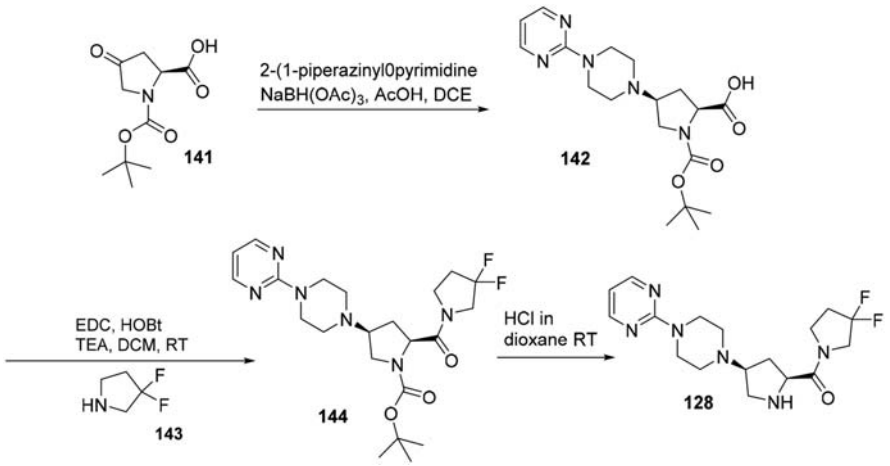


Scheme 18 Synthesis of dutogliptin.



Scheme 19 Synthesis of gosogliptin.

pyrimidine moiety binds in the S2 extended pocket and forms a π–π stacking interaction with the side chain of Phe357, which is responsible for enhancing selectivity.[220]

Gosogliptin was rapidly absorbed in healthy subjects with a mean T_{max} of 1 h and a mean half-life of 63.5 h.[221] Gosogliptin was renally cleared with a cumulative excretion in urine of 76.8% after a single dose. Radiolabeled gosogliptin undergoes moderate metabolism in humans, with parent drug representing 48.9% of total excreted radioactivity and hydroxylation at the 5′ position of the pyrimidine ring by CYP3A4 and CYP2D6 representing a major metabolite (20.6% of the dose).[221] In healthy Japanese subjects, administration of gosogliptin 20 mg once daily for 6 days inhibited DPP-4 activity at steady state by ~75% and enhanced GLP-1 levels twofold after a standardized meal.[222]

In a 12-week add-on study in T2DM patients inadequately controlled with metformin, gosogliptin 20 or 30 mg once daily resulted in placebo-subtracted HbA1c reductions of 0.79% and 0.92% reductions, respectively. The difference in HbA1c reduction between the two doses was not statistically significant.[223]

Gosogliptin was synthesized as shown in Scheme 19. The stereoselective reductive amination reaction of ketone **141** with 2-pyrimidylpiperazine in the presence of triacetoxyborohydride afforded only the *cis* isomer **142**. Coupling **142** with 3,3-difluropyrrolidine **143** using an EDC/HOBt protocol followed by Boc deprotection with HCl in dioxane afforded gosogliptin **128**.[220]

7.14.5.2.3 Denagliptin (GSK-823093, GlaxoSmithKline)

Denagliptin **129** belongs to the cyanofluoropyrrolidine class of DPP-4 inhibitors. It inhibits human DPP-4 with an IC_{50} of 22 nM.[224] Modeling studies show that denagliptin binds in the active site of DPP-4 as a substrate-based inhibitor and forms five strong hydrogen bonds with the side chains of Glu205, Glu206, Asn710, Tyr662, and Arg125.[225]

In phase I studies, denagliptin (25 mg) was rapidly absorbed, with maximal DPP-4 inhibition after 30 min and >80% DPP-4 inhibition after 24 h. In a 7-day, multiple-dose, phase IIA study, denagliptin produced sustained DPP-4 inhibition and elevated levels of GLP-1 and insulin and exhibited no body weight gain.[224]

Denagliptin was synthesized from bisfluorobiphenyl **145**, which was first converted to hydroxy acid **146** and then into acid **148** by successive treatment with H_2SO_4 and catalytic hydrogenation. Compound **148** was converted into oxazolidine amide **149**. Compound **149** on the introduction of an azide moiety provided compound **150**, which after hydrolysis followed by subsequent reduction to amine, and Boc protection gave the desired intermediate **152**. Finally, the coupling of **152** with 4-fluoro-2-pyrrolidinecarbonitrile **153** followed by Boc deprotection afforded denagliptin **129** (Scheme 20).[226,227]

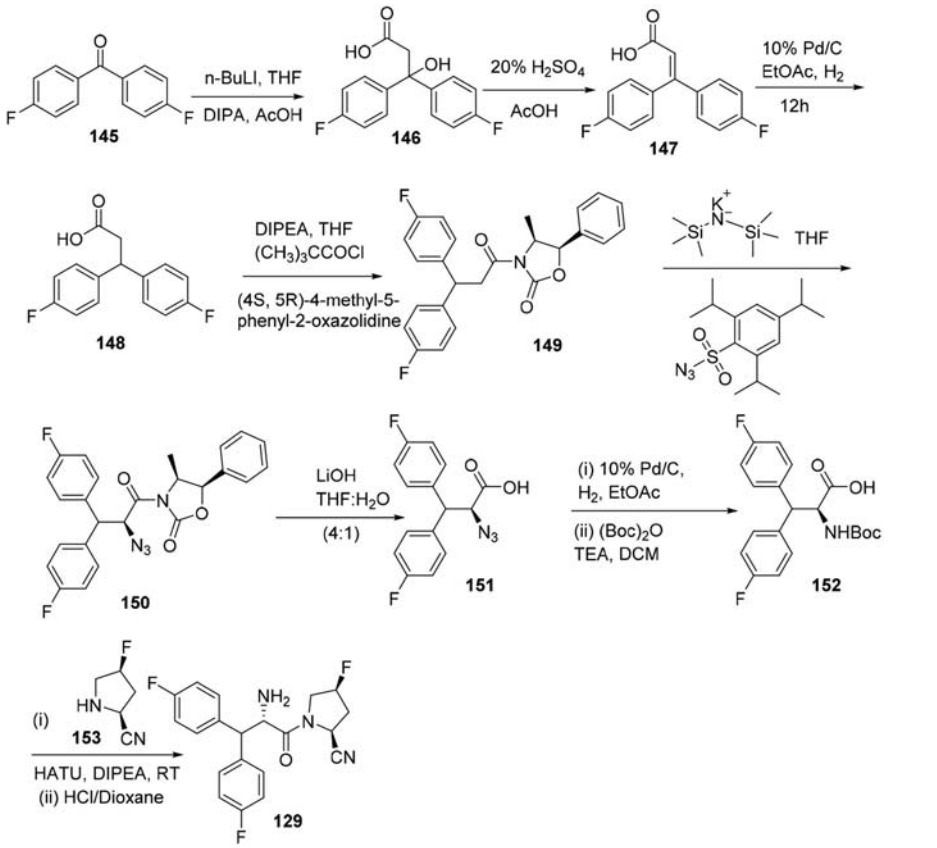
7.14.5.2.4 Melogliptin (GRC 8200, Glenmark)

Melogliptin **130** is a potent DPP-4 inhibitor (IC_{50} = 1.6 nM) containing a triazole moiety. It is 10,000-fold selective against DPP-8 and DPP-9.[228,229] The binding mode of melogliptin with DPP-4 has not been reported, but it likely binds similarly to other substrate mimetics. At a dose of 5 mg kg^{-1}, melogliptin exhibited half-lives of 1.28, 4.31, and 2.15 h with 50–95% bioavailability across preclinical species.[230]

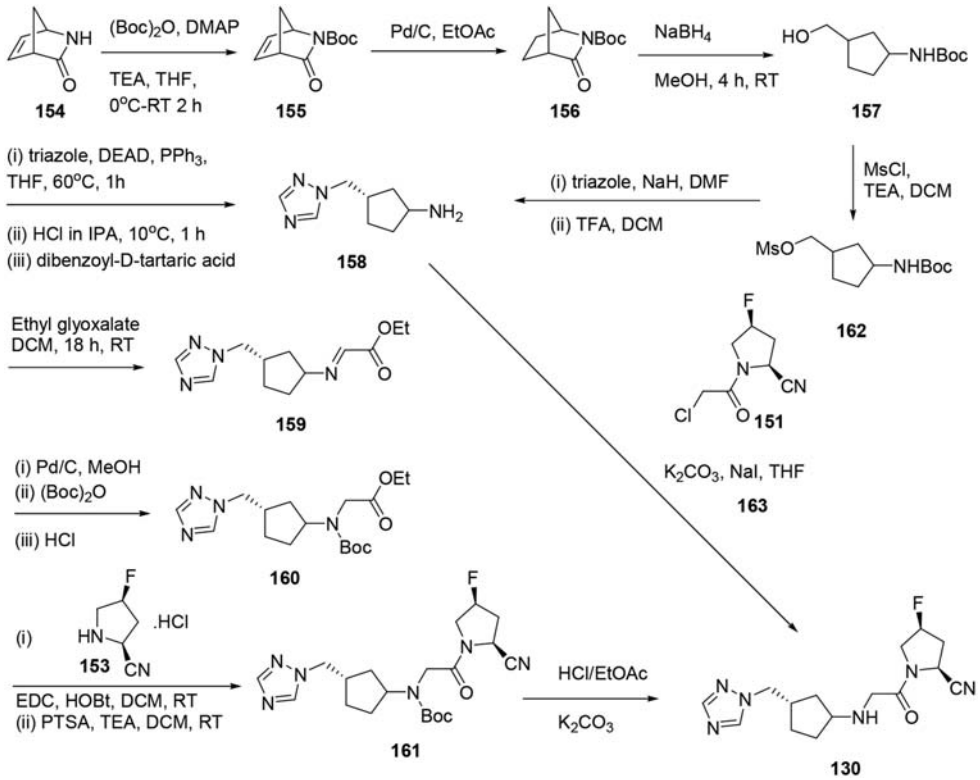
A single oral dose of melogliptin (3 mg kg^{-1}) resulted in a 30% reduction of glucose and twofold enhanced insulin levels in *db*/*db* mice.[228] In overnight fasted beagle dogs, a single oral dose of melogliptin 5 mg kg^{-1} maximally inhibited DPP-4 activity within 1 h and achieved >90% inhibition within 1 h.[228]

In phase II clinical studies, melogliptin 50 mg twice daily or 100 mg once daily inhibited plasma DPP-4 activity by more than 90% within an hour of dosing and reduced HbA1c by 0.75% and 0.60%, respectively.[231]

The synthesis of melogliptin is illustrated in Scheme 21. It starts with Boc protection of ketone **154** to give compound **155**. After palladium-catalyzed reduction of **155**, the resulting compound **156** was reduced with sodium borohydride to give amino alcohol



Scheme 20 Synthesis approach of denagliptin.



Scheme 21 Synthesis of melogliptin.

157. Compound **158** was prepared via Mitsunobu reaction followed by Boc deprotection and resolution with dibenzoyl D-tartaric acid. Compound **158** after reductive amination and successive Boc protection provided **160** via **159**. Coupling with **153** followed by Boc deprotection then afforded melogliptin **130**.[229]

A second route toward melogliptin synthesis began with the mesylation of compound **157** shown on the right hand side of Scheme 21, to yield **162**, which on reaction with triazole using sodium hydride followed by Boc deprotection afforded compound **158**. Finally, coupling of **158** with chloroacetamide **163** gave melogliptin **130**.[232]

7.14.5.2.5 Retagliptin (SP-2086, Jiangsu Hengrui Medicine)

Retagliptin **131**, a tetrahydro-imidazo[1,5-a] pyrazine analog of sitagliptin. It is twice as potent as sitagliptin ($IC_{50} = 8$ nM) and has good selectivity against DPP-8 (>3000-fold) and DPP-9 (>9000-fold).[233,234]

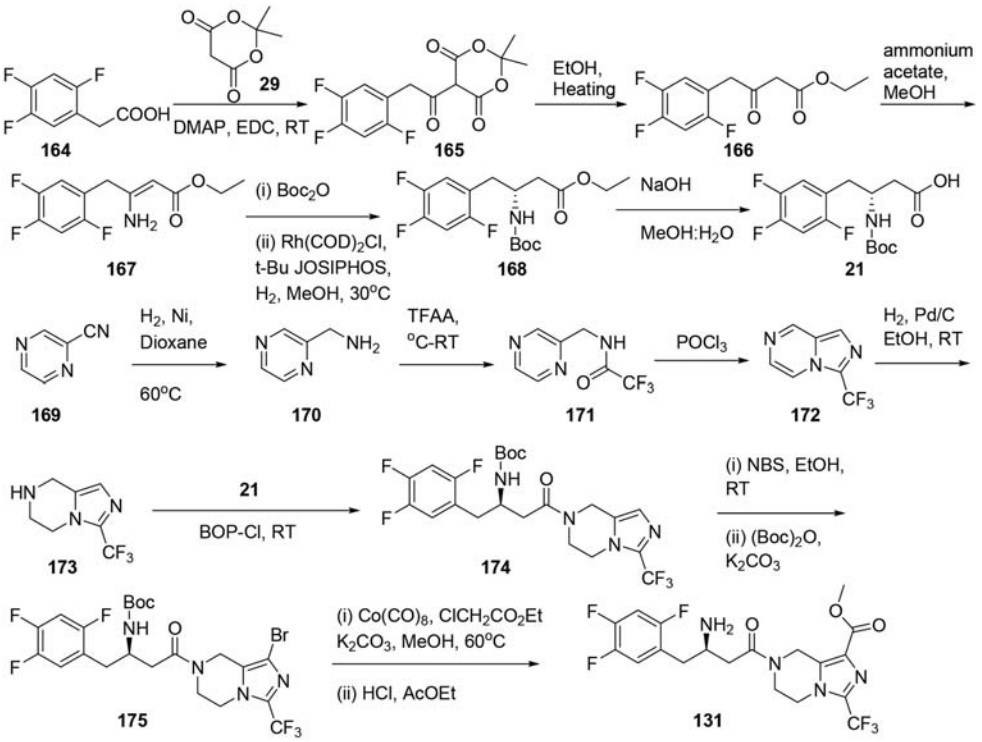
In clinical studies, retagliptin exhibited a half-life of 1.5 h, and treatment of T2DM patients resulted in meaningful reductions in plasma glucose and HbA1c. It is currently undergoing phase III clinical trials.[234]

The synthesis of retagliptin, which is similar to the method described earlier for sitagliptin, is illustrated in Scheme 22. The sequence involved the preparation of two important intermediates **21** and **173**. The β-amino acid intermediate **21** was synthesized from compound **164**. Treatment with 2,2-dimethyl-[1,3]dioxane-4,6-dione **29** in the presence of DMAP and EDC followed by subsequent heating in ethanol, treatment with ammonium acetate in methanol, Boc protection, stereocontrolled hydrogenation, and hydrolysis afforded intermediate **21** via intermediates **165**, **166**, **167**, and **168**. The tetrahydro-imidazo[1,5-a]pyrazine moiety **173** was prepared from pyrazine-2-carbonitrile **169**, which, following Ni-catalyzed hydrogenation followed by acylation with TFAA, gave compound **171** via **170**. The intramolecular cyclization of compound **171** with phosphorous oxytrichloride gave compound **172**, which on catalytic hydrogenation over Pd/C provided the tetrahydro-imidazo[1,5-a]pyrazine intermediate **173**. The coupling of **21** with **173** provided compound **174**. Treatment with *N*-bromosuccinimide subsequently yielded **175**, which was Boc-protected and successively treated with ethyl chloroacetate in the presence of octacarbonyldicobalt and potassium carbonate. Final Boc deprotection afforded retagliptin **131**.[235,236]

7.14.5.3 DPP-4 Inhibitors in Phase II

Seven DPP-4 inhibitors reported in phase II clinical trials are shown in Table 4. These are R-1579 (carmegliptin, **177**), P32/98 **178**, TS-021 **179**, AMG-222 **180**, NVP-DPP728 **181**, R-1438 **182**, and Ro-0730699 **183**.

Carmegliptin (R-1579) jointly developed by Roche and Chugai comprises a tricyclic moiety. It is a potent DPP-4 inhibitor ($IC_{50} = 6.8$ nM) with >100-fold selectivity over DPP-8 and DPP-9 and >2000-fold selectivity over DPP-II and FAP. Carmegliptin exhibits balanced hepatic and renal excretion with an IV half-life of 6.8 h and 33% oral bioavailability in cynomolgus monkeys. In



Scheme 22 Synthesis of retagliptin.

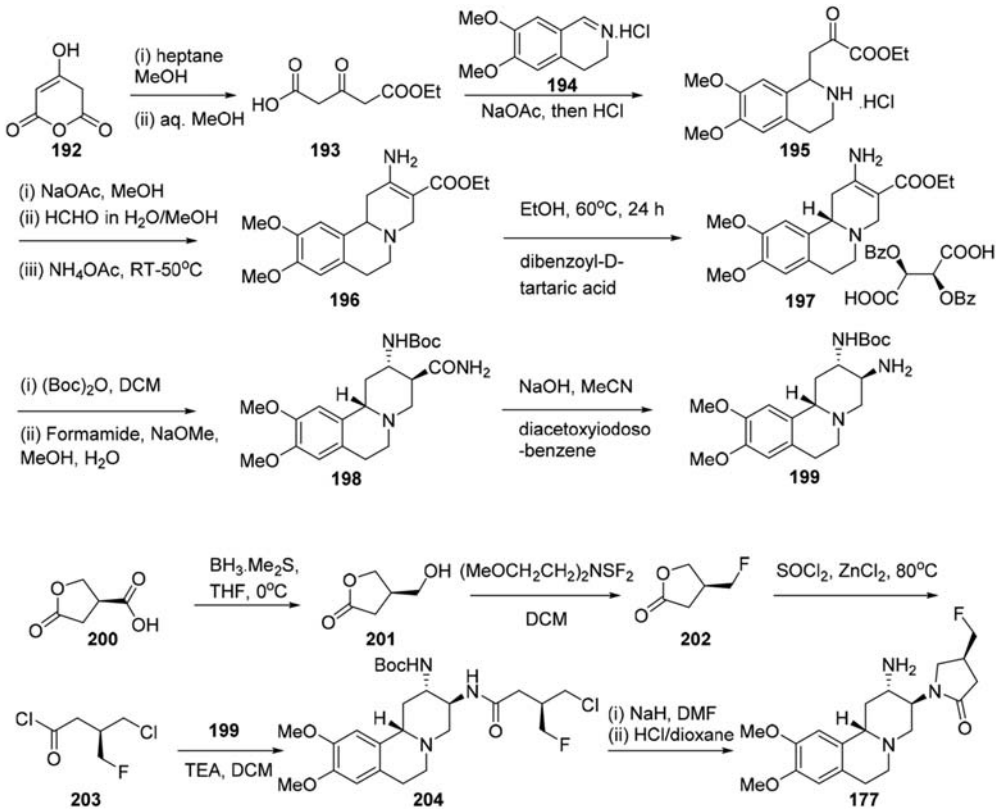
Table 4 DPP-4 inhibitors in phase II

DPP-4 inhibitors	*Structure*	*Generic/common name*	*Originator*	*IC_{50} and K_i (nM)*
177 R-1579 (Ro-4876904)		Carmegliptin	F Hoffman-La Roche	$IC_{50}=6.8$
178 P32/98		Isoleucine thiazolidide	Probiodrug AG	$IC_{50}=420$ $K_i=80$
179 TS-021		Cyanopyrrolidine analog	Taisho Pharmaceutical Co Ltd./Eli Lilly	$IC_{50}=5.34$ $K_i=4.96$
180 AMG-222 (ALS-2-0426)		Cyanopyrrolidine analog	Alantos Pharmaceuticals and Amgen Inc.	–
181 NVP-DPP-728		Cyanopyrrolidine analog	Novartis	$IC_{50}=22$ $K_i=11$
182 R-1438		Aminomethylpyridine derivative	Roche	$K_i=0.1$
183 Ro-0730699		Cyanopyrrolidine derivative	F Hoffman-La Roche	$IC_{50}=75$ $K_i=80$

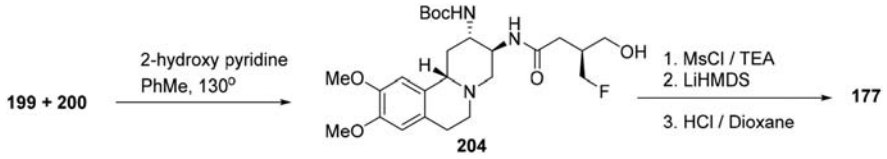
an OGTT performed in Zucker fatty (*fa/fa*) rats, treatment with carmegliptin (0.3 mg kg^{-1}) resulted in reduced glucose excursion. At a single oral dose of 3 mg kg^{-1}, DPP-4 inhibition reached 40% and 60% 24 and 48 h post dose, respectively. Phase I and II clinical studies have assessed the safety and efficacy of carmegliptin with once-daily dosing.[237] Inhibition of various CYP isozymes and hERG channel inhibition are the major challenges in advancing this compound.

X-ray crystal structure analysis reveals that the 4-fluoromethyl pyrrolidinone moiety of carmegliptin binds in the hydrophobic S1 pocket at the active site of DPP-4. The lactam carbonyl hydrogen bonds with Tyr662 and with the amino side chain of Asn710 and forms a cation–dipole interaction with the guanidine side chain of Arg125. These interactions highlight the similarity between this amide carbonyl group and the carbonyl moiety of substrate-based inhibitors. The tricyclic moiety of carmegliptin appears to fit well into the S2 pocket. The amine group forms a salt bridge with Glu205 and Glu206 and a hydrogen bond with Arg125.

The synthesis of carmegliptin is described in **Scheme 23**. The pyridoisoquinoline amine **199** was prepared from the anhydride **192** via several transformations that included a chiral resolution of **196** to furnish **197**. Compound **197** was converted to **198**, which on treatment with diacetoxyiodosobenzene afforded the desired intermediate **199**. Another key intermediate, acid chloride **203**, was prepared from (*S*)-paraconic acid **200**.[289] The reduction of **200** with borane-dimethyl sulfide complex gave the hydroxymethyl lactone **201**. Since compound **201** is known to racemize rather readily,[238] it was immediately treated with bis(2-methoxyethyl) aminosulfur trifluoride,[239] which gave fluoromethyl lactone **202**. Reaction of **202** with thionyl chloride in the presence of zinc chloride



Scheme 23 Synthesis of carmegliptin.



Scheme 24 Second approach for Synthesis of carmegliptin.

provided acid chloride **203** intermediate. The reaction of pyridoisoquinoline amine **199** with acid chloride **203** afforded the compound **204**, which after treatment of sodium hydride followed by Boc deprotection gave carmegliptin **177**.[237]

An alternative route for the synthesis of carmegliptin is outlined in Scheme 24[240,241]

Among the other compounds in early development, P32/98 **178** was discontinued due to adverse findings in animal toxicity studies.[79] NVP-DPP-728 **181** does not appear to provide any advantages over vildagliptin in terms of potency or safety.[159] Compound **183** is an investigational cyanopyrrolidine containing DPP-4 inhibitor with a half-life of 2.3 h and 90% oral bioavailability.[242] Compound **180** is another N-substituted cyanopyrrolidine derivative with a large bulky group at the P1 site. TS-021 **179** is an N-substituted substrate-mimicking glycine containing cyanopyrrolidine-based inhibitor. X-ray crystallographic studies revealed the binding mode of **179** in which the cyanopyrrolidine moiety fits neatly into the S1 pocket and the 2-hydroxy-1,1-dimethylethyl moiety occupies the pocket containing His126, Ser201, Phe357, and Arg358 residues.[290] All of these inhibitors have undergone evaluation for dose-ranging efficacy and tolerability.

7.14.5.4 DPP-4 Inhibitors in Phase I

DPP-4 inhibitors currently undergoing phase I clinical trials based on their potency, selectivity, tolerability, efficacy, and preclinical safety are ABT-279 **205**, ABT-341 **206**, E-3024 **208**, SSR-162369 **211**, TAK-100 **207**, ER-319711 **209**, GSK-23A, and imigliptin **212** **210** (Table 5).

ABT-279 **205** was demonstrated to be a safe and effective DPP-4 inhibitor in ongoing phase I trials. 5-Ethynyl substitution on the cyanopyrrolidine ring of ABT-279 was responsible for the improvement in selectivity over related peptidases such as DPP-8 and

[a]Blank cell, data not reported.

DPP-9.[243] ABT-341 **206** is a cyclohexene-based constrained phenethylamine inhibitor of DPP-4. It is potent and selective, and its structure is very similar to sitagliptin. Clinical candidate **206** is orally efficacious and has thus far been deemed safe for the treatment of T2DM patients.[244a] Compound E-3024 **208** exhibits modest potency ($IC_{50}=100$ nM) and high selectivity (>1000-fold).[244b] Its development was discontinued due to observation of rash in healthy volunteers.[244b] SSR-162369 **211** is a bicyclic 8-pyrrolidinoxanthine derivative resembling sitagliptin. It is potent with a DPP-4 IC_{50} of 18 nM.[116,245] TAK-100 **207** is a 3-pyridylacetic acid derivative. It is also potent with a DPP-4 IC_{50} of 5.3 nM and high selectivity (>100,000-fold) against other DASH peptidases. In dogs at a dose of 0.5 mg kg^{-1}, PO, the compound completely inhibited the activity of plasma DPP-4 within 1 h and exhibited 30% inhibition of DPP-4 after 24 h. X-ray studies of TAK-100 bound to the DPP-4 enzyme revealed interactions between the primary amino group and Glu205 and Glu206 residues. The *p*-tolyl group fits into the S1 pocket. The neopentyl group is bound to Phe357 through hydrophobic interactions. The carboxyl group interacts with the side chains of Ser630 and His740. This moiety also forms a salt bridge with the side chain of Arg125.[246]

ER-319711 **209** is an 8-oxo-purine-derived DPP-4 inhibitor. It is potent and selective. In studies comparing the compound with **208**, **209** appears to have a longer glucose-lowering profile suggesting more sustained competitive inhibition of DPP-4.[247]

GSK-23A **210** is a fluorocyanopyrrolidine derivative with a bulky side chain. The steric and electronic effects within a molecule are responsible for the extraordinarily long half-life in buffer (1733 h).[116]

Imigliptin **212** is a pyridinylimidazolone scaffold-based potent ($IC_{50}=9$ nM) and selective (>10,000-fold against DPP-8 and DPP-9) inhibitor of DPP-4. It was discovered via scaffold hopping from alogliptin. It has oral bioavailabilities of 97%, 89%, and 86% in rat, dog, and monkey, respectively. Long-term administration of imigliptin to *db*/*db* mice demonstrated significant lowering of plasma triglycerides and HbA1c and elevated GLP-1 levels. It has good physicochemical properties and a good safety profile. It is currently undergoing phase I clinical trials in China.[248]

7.14.5.5 DPP-4 Inhibitors in Preclinical Development

More than 25 DPP-4 inhibitors have been reported to be in preclinical development (Table 6).

Compounds **213–215**, **217**, and **219**[249] are all cyanopyrrolidine derivatives. In general, these DPP-4 inhibitors in preclinical development are potent and selective. During an OGTT in Zucker fatty rats, RBx-0597 **215** increased the insulin response and ameliorated blood glucose levels.[249] RBx-0597 inhibited human, mouse, and rat plasma DPP-4 activity with IC_{50} values of 32, 31, and 39 nM, respectively. RBx-0597 exhibited significant selectivity (150- to 300-fold) over DPP-8, DPP-9, and other proline-specific proteases (>200- to 2000-fold). Kinetic analysis revealed that RBx-0597 is a competitive and slow-binding DPP-4 inhibitor. In *ob*/*ob* mice, RBx-0597 (10 mg kg^{-1}) inhibited plasma DPP-4 activity up to 50% at 8 h post dose and showed a significant glucose-lowering effect that was sustained through 12 h. The compound also significantly increased active GLP-1 and insulin levels. It showed a favorable PK profile (CLp, 174 mL min^{-1} kg^{-1}, $T_{1/2}$ 0.28 h, T_{max} 0.75 h, and V_{ss} 4.13 L kg^{-1}) in Wistar rats, with oral bioavailability of 65%.[250]

ASP-8497 **214** is potent with DPP-4 IC_{50} of 5.3 nM and excellent selectivity against DPP-8 and DPP-9. Compound **214** inhibits DPP-4 activity in a competitive fashion and significantly reduced glucose excursion during an OGTT in STZ-treated mice.[251] Des-fluoro-sitagliptin **216** is also a potent DPP-4 inhibitor (DPP-4 $IC_{50}=27$ nM) and is highly selective against DPP-8 ($IC_{50}=69{,}000$ nM), DPP-9 ($IC_{50}>100{,}000$ nM), and other DASH peptidases ($IC_{50}>100{,}000$ nM).[79] The inhibitor preserved pancreatic β-cell mass and function in a HFD (STZ)-induced mouse model of type 2 diabetes.[252]

Table 6 DPP-4 inhibitors in preclinical development[a]—cont'd

DPP-4 inhibitors	*Structure*	*Originator*	*IC_{50} and K_i (nM)*
PHX-1004		Phenomix	
PSN-IV/119-1		Prosidion	$IC_{50}=0.2$
222		Point Therapeutics	$K_i=1.8$
PT-630			
RBx-0597		Daiichi Sankyo	$IC_{50}=32$
S-40010		Servier	$IC_{50}=2$
S-40755		Servier	
SNT-189379		Santhera Pharmaceuticals	
223		Syrrx	$IC_{50}=4$
Syrrx-106124			

[a]Blank cell, data not reported.

DSR12727 **218** is a potent and selective inhibitor (DPP-4 $IC_{50}=1.1$ nM) with moderate inhibition of CYP3A. It has good PD and PK profiles.[253]

Compound **220** is a potent inhibitor and selective over DPP-II, DPP-8, and DPP-9. It has good PK properties. The crystal structure of its complex with DPP-4 confirms that the pyrrolidine ring occupies the S1 pocket and the fluoride atom interacts with the side chain of Tyr631. The carbonyl oxygen interacts with the hydroxyl group of Tyr631. Both nitrogens of the oxadiazole ring form hydrogen bonds with Arg125 and His740. The secondary amine forms salt bridges with Glu205 and Glu206.[254]

LY 2463665 **221** is a novel ethanolamine inhibitor of DPP-4. It is a potent DPP-4 inhibitor ($IC_{50}=7$ nM) and is selective versus other DASH peptidases (>10,000-fold selectivity against DPP-II, DPP-8, and DPP-9). It shows good PD and PK profiles. It exhibits bioavailabilities of 63% and 76% in rats and dogs with half-lives of 2.5 and 5.7 h, respectively. Like sitagliptin, it exhibits reversible binding to the DPP-4 active site. The aromatic group occupies the S1 pocket.[255]

Compound **223** is a quinazolinone-based potent and selective DPP-4 inhibitor with an IC_{50} of 4.0 nM. The cyanobenzyl moiety occupies the S1 pocket of DPP-4 and interacts with Arg125. The carbonyl group hydrogen bonds with the side chain of Tyr631. The bicyclic heterocycle stacks with Tyr547. The inhibitor achieves 50% plasma DPP-4 inhibition at 12 h following a 10 mg kg^{-1} dose. It lowered glucose excursion and OGTT in mice.[256]

7.14.6 Natural DPP-4 Inhibitors

7.14.6.1 Natural Products as DPP-4 Inhibitors

Several natural dipeptides and tripeptides have been reported to be weak DPP-4 inhibitors. These include several peptides previously identified in dry-cured ham extracts or known to be products of DPP-4 action, which were synthesized and assayed for DPP-4 inhibition. Peptides with amino acid sequences KA and AAATP showed extremely weak DPP-4 inhibitory activity (IC_{50} values of 6.27 and 6.47 mM, respectively). Dipeptides AA, GP, and PL and peptides AAAAG, ALGGA, and LVSGM were also DPP-4 inhibitors, although to an even lesser degree. These findings suggest the potential of Spanish dry-cured ham to be a natural precursor of DPP-4 inhibitory peptides, albeit of very low inhibitory potencies.[257]

Hemorphins are endogenous peptides belonging to the family of "atypical" opioid peptides released sequentially from hydrolyzed hemoglobin, which interact with DPP-4. Hemorphin-7 (H7) is slowly cleaved by the enzyme (k_{cat}/K_M of 137 $mM^{-1}s^{-1}$), but the peptide also acts as a competitive DPP-4 inhibitor. These blood-derived peptides may represent endogenous regulators of enzyme activity.[258]

The diprotins A (Ile-Pro-Ile) and B (Val-Pro-Leu), isolated from culture filtrates of *Bacillus cereus* BMF673-RF1, with IC_{50} values of 1.1 and 5.5 μg mL^{-1}, respectively, also represent natural peptidyl inhibitors of DPP-4.[259] Other examples of reported peptidyl inhibitors include the five sequences HPIK, LPLP, LPVP, MPLW, and GPFP, which inhibited DPP-4 activity with IC_{50} values between 76 and 120 μM.[260] Peptides isolated from tuna cooking juice inhibited DPP-4 with IC_{50} values of 78–116 μM.[261] The peptide Ile-Pro-Ala (also called β-lactosin A) was identified in β-lactoglobulin hydrolysate and inhibited DPP-4 with an IC_{50} value of 49 μM.[262] Another peptide Val-Ala-Gly-Thr-Trp-Tyr, also derived from β-lactoglobulin, was active against DPP-4 with an IC_{50} value of 174 μM.[263] Dipeptide LA and tripeptide IPA isolated from bovine whey are reported to be weak DPP-4 inhibitors ($IC_{50}=454$

and 49 μM, respectively). Two peptides, Gly-Pro-Ala-Glu and Gly-Pro-Gly-Ala, isolated from Atlantic salmon skin gelatin showed inhibition of DPP-4 with IC_{50} values of 49.6 and 41.9 μM, respectively.[264] Peptides derived from amaranth seed proteins after enzymatic digestion also exhibited DPP-4 inhibitory activity ($IC_{50} = 1.1$ mg mL^{-1}).[265]

In addition to peptidyl DPP-4 inhibitors, there are reports of nonpeptide natural products as potential DPP-4 inhibitors. In silico modeling of the xanthone class compound glucosylxanthone, used in traditional Indian medicine, suggests that glucosylxanthone and its analogs may bind to the DPP-4 active site, although no inhibitory data were reported.[266] Triuret, a product of uric acid and peroxynitrite, has been reported to inhibit cell-associated and human recombinant DPP-4. Increasing or decreasing intracellular peroxynitrite levels enhances or decreases the ability of uric acid to inhibit cell-associated DPP-4, respectively.[267]

Organometallic ruthenium(II) complexes of curcumin were evaluated for their DPP-4 inhibitory activity, with the most potent (arene)ruthenium(II) complex having a K_i of ~20 μM.[268]

The DPP-4 inhibitory activities of several flavonoids and phenols (**224–239**,[269] **240**,[270] **241–245**,[271] and **246**[272]) are shown in Fig. 2. Most of these compounds are more potent DPP-4 inhibitors than the positive control diprotin A (Ile-Pro-Ile, $IC_{50} = 4.21 \pm 2.01$ μM).

As shown in Fig. 3, various alkaloids have been reported to be DPP-4 inhibitors (**247–254**[273]).

7.14.6.2 DPP-4 Inhibitors From Natural Extracts

Several natural extracts are reported as inhibitors of DPP-4 activity. However, their inhibitory activities are much lower than those of any of the synthetic compounds in clinical development.

Various alcohol, organic, and water extracts of *Capsicum annuum*, *Capsicum* in Solanaceae, *Rosa gallica*, and *Uncaria tomentosa* are reported to inhibit DPP-4.[273] A hot water extract of *S. chinensis* fruits also inhibited human DPP-4 ($IC_{50} = 10.8 \pm 1.5$ mg mL^{-1}).[274]

The *Castanospermum australe* Cunn. seed (CAS) extract gave a DPP-4 IC_{50} value of 13.96 μg mL^{-1}, while the standard used in the assay, diprotin A, had an IC_{50} value of 1.543 μg mL^{-1}. It was also reported that a 150 mg kg^{-1} dose of the extract normalizes hyperglycemia in T2DM rats.[275] In addition, 16,17-dihydro-17b-hydroxy isomitraphylline (DHIM), an indole alkaloid isolated from *Mitragyna parvifolia*, dose-dependently inhibits DPP-4 in vitro (5, 10, and 20 μg of DHIM inhibits 18%, 56%, and 68% of DPP-4 activity, respectively). Diabetic rats treated with DHIM (100 mg kg^{-1}) for 8 weeks exhibited markedly reduced plasma glucose concentrations and increased glucose tolerance in response to glucose loading. GLP-1 and IL-10 levels were also significantly increased in treated animals.[275]

Grape seed procyanidin extract (GSPE, Vitaceae) inhibits DPP-4 activity in vitro by ~70% upon incubation of the enzyme with 200 mg L^{-1} GSPE. GSPE also weakly inhibits rat intestinal DPP-4 and plasma DPP-4 activities at the same concentration.[276]

Three plants, *Pterocarpus marsupium* (Leguminosae) (PM), *Eugenia jambolana* (Myrtaceae) (EJ), and *Gymnema sylvestre* (Asclepiadaceae) (GS), used in traditional medicine in India, are commonly used for the treatment of hyperglycemia. Their extracts display concentration-dependent inhibition of DPP-4. At an extract concentration of 1000 μg mL^{-1}, both PM and EJ exhibited potent inhibitory activity of DPP-4 with IC_{50} values of 274 and 279 μg mL^{-1}, respectively.[277]

Anthocyanins (ANC) isolated from blueberry–blackberry wine blends (Ericaceae) were investigated for their DPP-4 inhibitory effects in vitro.[269] ANC fractions strongly inhibited DPP-4 activity (IC_{50} values ranging from 0.07 to >300 μM).

Crude extracts of sponge *Xestospongia muta* and the sea anemones *Bunodosoma granulifera* and *Bartholomea annulata* exhibited potent DPP-4 inhibitory activities, with IC_{50} values of 0.80, 1.20, and 0.138 mg mL^{-1}, respectively.[278]

Three kinds of traditional Chinese medicine from Xinjiang, *Trigonella foenum-graecum* L. (Leguminosae) (TF), *Cicer arietinum* L. (Leguminosae) (CA), and *Punica granatum* L. (Leguminosae) (PG), inhibited DPP-4 activity with IC_{50} values of 0.03, 0.09, and 0.19 mg mL^{-1}, respectively.[279]

The extracts of three traditional Chinese herbs, *Hirudo* (Annelida), *Poria cum Radix Pini* (Polyporaceae), and *Buddleja officinalis* Maxim. (Buddlejaceae), were identified as having DPP-4 inhibitory activity. At a concentration of 300 mg L^{-1}, the extent of DPP-4 inhibition by the extracts was 27%, 27%, and 44%, respectively.[280]

7.14.7 Summary

The gliptin class of therapeutics represents a valuable tool in the armamentarium of oral antihyperglycemic agents available to the primary care physician for the treatment of T2DM. While postmarketing surveillance has revealed rare instances of serious side effects such as Stevens–Johnson syndrome (an exfoliative skin condition) associated with sitagliptin or alogliptin use[205,281] and severe joint pain,[282] which appears to be a class effect and is typically relieved after discontinuation of drug, amenability to combination with metformin or other antihyperglycemic agents, an overall excellent safety profile, and glucose dependency of the incretin mechanism have rendered the gliptins popular as monotherapy and add-on therapy. Despite their structural diversity, these agents leverage common interactions in binding to the DPP-4 active site and exhibit similar antihyperglycemic efficacies in the clinic. Long-term cardiovascular outcome data have reinforced the attractive safety profile of sitagliptin while raising some questions regarding saxagliptin and alogliptin use in high-risk patient populations. The recently launched once-weekly DPP-4 inhibitors offer added convenience to T2DM patients facing a large pill burden and may help sustain the clinical and commercial success of the gliptins in the face of newer oral agents such as the SGLT-2 inhibitors.

7.15.1 General Overview

7.15.1.1 Hemostasis and Thrombosis

The circulation of blood guarantees the supply of oxygen and nutrients, as well as the disposal of catabolic products. Therefore, the integrity of blood vessels is essential at all times. When the vascular integrity is compromised, a highly efficient repair mechanism is activated at the site of injury resulting in the formation of a repair seal to prevent further blood loss. This fundamental biological process is defined as hemostasis.[1] It is mediated by three main components: the endothelial cells, the platelets, and the coagulation system. The endothelial cell layer defines the surface of the blood vessels and thus the interface to the flowing blood. Platelets circulate in a resting state but are able to adhere to the damaged or activated endothelial surface and then stick to each other to form platelet aggregates that seal the damaged surface. Finally, the coagulation system is responsible for the generation of fibrin fibers that stabilize the platelet aggregates. The coagulation cascade and the platelet activation and aggregation are interdependent biological processes: activation of the coagulation cascade leading to efficient formation of fibrin fibers is dependent on the negatively charged membrane surface of activated platelets. On the other hand, platelet activation and stabilization of platelet aggregates depend upon the final product of the coagulation cascade, thrombin.[2] In fact, the key coagulation protease thrombin is responsible for the generation of fibrin fibers, and it is also the most potent activator of platelets.[3] The importance of each

component in the hemostatic system changes with the rheological condition: under high shear rate, that is, in fast-flowing or arterial blood, platelets play a central role, whereas under low shear rate, that is, in slow blood flow characteristic for veins, formation of fibrin clots by the coagulation system is assuming a more dominant role.[4] Although these systems are usually discussed in isolation, it is important to realize that they are mutually dependent and thus cannot optimally perform in the absence of the counterpart.

If the size of a repair seal is exaggerated, such (partially) occlusive platelet/fibrin aggregates, known as platelet- or fibrin-rich thrombi, can block the blood supply to downstream organs, causing ischemic disorders.

Thrombosis is the result of a pathological deviation of one or several components involved in hemostasis. Such deviation can be caused by a plethora of environmental or genetic factors. A differentiation between venous and arterial blood flow is important. In arterial blood vessels, age, gender, race, diabetes mellitus, and a family history of thrombotic events represent risk factors that cannot be influenced and may shift the hemostatic system toward a prothrombotic state. In addition, lifestyle factors such as obesity, hyperlipidemia, smoking, and physical immobilization also contribute to the deviation of the hemostatic system toward higher risk of thrombosis.[5] The effect of these risk factors is thought to be twofold. First, excessive platelet reactivity to activators shifts the balance toward an increased risk of occlusive thrombosis.[6] Second, in a very slow but steady process, these environmental factors trigger changes in the endothelial cell lining of the vascular system and thus support the process of atherosclerosis. Formation of atherosclerotic plaques is triggered by an accumulation of lipid vesicles within the wall of the blood vessels. Macrophages invade the vessel wall and phagocytose the lipids forming the so-called foam cells that accumulate and contribute to the growth of atherosclerotic plaques. With increasing age and size of these plaques, the risk of direct obstruction of blood flow can become symptomatic.[7] Furthermore, if atherosclerotic plaques fissure or rupture, usually triggered by mechanical stress by fast-flowing blood in a partially occluded artery, a prothrombotic surface is exposed, which can initiate the formation of an occlusive platelet thrombus.

7.15.1.2 Pathology of Thrombotic Diseases

Depending on the anatomical location, a limitation of blood flow can have diverse clinical outcomes: occlusion of blood flow to the heart muscle reduces heart performance, which manifests in dyspnea (shortness of breath), vertigo (dizziness), numbness, nausea, or pain. The symptoms of occlusion of blood vessels in the heart are generally described as acute coronary syndrome (ACS). Depending on the stability and induced damage of the vessel occlusion, ACS is further qualified as ST-elevated myocardial infarct (STEMI), non-ST-elevated myocardial infarct (NSTEMI), and unstable angina pectoris (UA). In STEMI, complete and stable vessel occlusion with resultant infarction (death) of distal tissues induces a change in the electrocardiogram (ECG) visible as a change in the ST part of the ECG. In NSTEMI, no functional consequence on the ECG is evident indicating that the vessel occlusion is partial or recent. However, NSTEMI is also associated with an elevation of troponin I or troponin T concentration in blood. The troponins are cytosolic proteins of cardiac muscles and are released into the circulation upon cardiac damage.[8] In contrast, UA is defined by transient signs of the aforementioned symptoms without elevation of troponin levels.[9]

In analogy to coronary blood vessels, if an occlusion arises in the brain, the events are classified as transient ischemic attacks (TIA) or as ischemic stroke if a permanent occlusion of brain arteries occurs. In addition, the occlusion of a peripheral artery in the lower extremities manifests as transient limitation of blood flow and hence leg pain (intermittent claudication) or with stable occlusion as peripheral arterial occlusive disease (PAOD), respectively.

In venous blood vessels, risk factors for the formation of venous thrombi are similar to arterial thrombi. Risk factors that cannot be influenced include genetic predisposition for enhanced coagulation activity, age, gender, race, diabetes mellitus, cancer, orthopedic surgery, and long-term immobilization of patients. Lifestyle factors, which could theoretically be controlled, include obesity, physical inactivity, smoking, and the use of contraceptives.[10] The clinical manifestation of venous thrombosis is different to arterial thrombosis. Occlusion of a vein, usually in the leg, defined as deep vein thrombosis (DVT), results in symptoms such as swollen legs, numbness, redness, and pain in the area of the occlusion. Since veins represent blood vessels with a relatively large diameter, clots can break off from deep vein wall and can be flushed over large distances into the right side of the heart. The right heart chamber pumps the blood into the lung for reoxygenation and thus into the more narrow blood vessels of the lung. There, clots can occlude a pulmonary arterial bed and cause pulmonary embolism (PE). Alternatively, such a clot can be flushed into the brain and cause an embolic stroke. Together, DVT and PE are summarized as venous thromboembolism (VTE). The anti-VTE approaches are described in detail in Book Chapter 7.07. Advances in Anticoagulants.

7.15.1.3 Epidemiology and Antithrombotic Market

Ischemic thrombotic vascular disease is the leading cause of death in developed countries.[11] Despite advances in treatment and prevention, ACS represents an enormous medical, social, and economic burden worldwide. Globally, ACS resulting from myocardial infarction is responsible for almost half of all deaths related to cardiovascular diseases. ACS also claims a high toll in terms of treatment-related and indirect economic costs.[12]

Venous thromboembolism (VTE) represents a significant source of morbidity and mortality. VTE is a common disorder, with an estimated annual incidence of approximately 5–12 cases per 10,000. The prognosis for patients who develop VTE is exacerbated by the risk of recurrent VTE, post-thrombotic syndrome, and chronic pulmonary hypertension as a long-term complication of PE.[13]

The global market of antithrombotics was estimated to exceed 23 billion US dollars in 2013 and is expected to grow in the future.[14] The antiplatelet market is still dominated by clopidogrel, which in 2010 grossed peak sales of over 9 billion US dollars.[15] In light of such significant rewards, efforts within the pharmaceutical industry are benevolently supported. However, the future

success of novel antiplatelet drugs depends on a clear demonstration of excellent efficacy in combination with an improved bleeding risk profile.

In the next sections, after an introduction into platelet biology and a broad overview of the major antiplatelet targets, efforts in medicinal chemistry to generate novel antiplatelet drugs are reviewed. A vast amount of literature that summarizes the different approaches of the past decades is already available.[16] Therefore, in this article, established antiplatelet drugs are described briefly, while the focus is placed on more recent developments.

7.15.2 Introduction Into Platelet Function

7.15.2.1 Formation of Platelets

Platelets, also called thrombocytes, are generated by large progenitor cells known as megakaryocytes. Megakaryocytes release platelets as a result of a complex maturation process. First, megakaryocytes become multinucleated or polyploid and accumulate proteins and membranes. Then, in a cytoskeleton-driven process, they form long branched protrusions termed proplatelets. As these nascent platelets mature, granules and selected organelles are delivered from the megakaryocyte core into the proplatelet tip that then undergoes fission to release platelets. Platelets are devoid of a cell nucleus[17]; nevertheless, they can synthesize proteins *de novo* since they contain messenger RNA.[18] One megakaryocyte may protrude as many as 10–20 proplatelets. Nonactivated, resting platelets circulate as biconvex discoid (lens-shaped), a form defined by internal microtubule and actin cytoskeleton, with an average diameter of 2–4 μm. In healthy individuals, the normal platelet number, usually referred as "platelet count," is 150,000–400,000 per cubic millimeter or $150–400 \times 10^9$ platelets per liter.[19] An average of 10^{11} platelets is produced daily in a healthy adult with an average lifetime of about 10 days.

7.15.2.2 Endothelial Cell Layer and Extracellular Matrix

In the vasculature, the interface between circulating blood and the vessel wall consists of a single layer of endothelial cells. The release of inhibitory mediators, such as nitric oxide (NO), endothelial ADPase (CD39), and prostacyclin (PGI_2), from these endothelial cells contributes to keep circulating platelets in a resting state. Nitric oxide and PGI_2 inhibit platelet activation through intraplatelet signaling, whereas endothelial ADPase degrades ADP, one of the key activators of platelets.

The extracellular matrix (ECM) below the endothelium forms a scaffold that keeps the histological structure of the vessel wall in shape and consists of a complex network of elastic fibers to support vessel stability. ECM is mainly constituted by collagen, laminin, fibronectin, and elastin. The collagens are the most abundant proteins in the ECM where fibril-forming collagens (types I, II, III, V, and XI) represent the most abundant forms.[20]

When the endothelial layer is disrupted and the underlying subendothelial matrix is exposed to the blood flow (e.g., after rupture of an atherosclerotic plaque) or when inflammation perturbs the endothelium, platelets adhere to the ECM and become activated. In addition, the exposed ECM also contains tissue factor (TF). TF exerts its biological activity by forming a catalytic enzyme complex with the coagulation factor VII (FVII). If exposed to blood, it binds to the inactive FVII leading to the active complex TF/FVIIa and subsequent formation of thrombin. As outlined in the preceding text, the relative importance of platelets and the coagulation system for the repair of vascular injuries depends on the rheological conditions.

7.15.2.3 Platelet Adhesion, Activation, Aggregation, and Thrombus Stabilization

Upon adhesion to the ruptured endothelium, platelets become activated via an intraplatelet signaling cascade induced by the adhesion receptors (outside-in signaling). For example, the collagen adhesion receptors trigger synthesis of thromboxane A_2 (TXA_2) via the enzyme cyclooxygenase-1 (COX-1). TXA_2 is then secreted and activates nearby platelets via binding to their thromboxane receptor (TP) and thus contributes to the amplification of platelet aggregation leading to thrombus formation. Furthermore, most adhesion receptors trigger transactivation of other integrin receptors (inside-out signaling). In the active conformation, these integrins can interact with their ECM ligands and thus contribute to the stabilization of the platelet thrombus. Moreover, activated platelets change the composition of the outer membrane resulting in the upregulation of negatively charged phospholipids (mainly phosphatidylserine (PS)) exposed toward the extracellular space. The γ-carboxyglutamic acid (Gla)-containing domain of coagulation factors can interact with the negatively charged membrane that accelerates the coagulation cascade activity.[21] In addition, activated platelets release the content of their dense and alpha-granules.[22] Dense granules contain small molecules such as ADP, ATP, GDP, serotonin, pyrophosphates, and magnesium and calcium ions.[23] Alpha-granules release soluble proteins such as von Willebrand factor (vWF), fibrinogen, thrombospondin, coagulation factors V, XI, and XIII, and prothrombin and, by fusing with the platelet membrane, increase the number of surface receptors, that is, the fibrinogen receptor $\alpha_{IIb}\beta_3$, the collagen receptor GPVI, and the adhesion receptor P-selectin.[24] The released molecules and exposed receptors are major contributors to further activation and recruitment of additional platelets into the initiated platelet thrombus. Specifically, these molecules either activate platelets that are in close proximity of the growing thrombus and thus recruit more platelets or bind to the surface of activated platelets as linker molecules to support thrombus growth or stabilization. For example, ADP binds and activates the purinergic receptors $P2Y_1$ and $P2Y_{12}$ that induce an intraplatelet signaling cascade leading to the activation of resting platelets.

The most important cross-linker is fibrinogen, which binds to the integrin $\alpha_{IIb}\beta_3$ on the surface of platelets and is thus essential for thrombus formation and stabilization.

The platelet response is intertwined at several levels with the coagulation cascade that results in an amplification of the prothrombotic activity. For example, leukocytes, such as monocytes and neutrophils, adhere to the activated platelets and expose the surface molecule TF upon complex formation with FVIIa, one of the strongest activators of the coagulation cascade.[25] In addition, coagulation factors, which are also released from alpha-granules, cooperate with TF to form thrombin. Thrombin activates the receptors PAR-1 and PAR-4 and thereby triggers intraplatelet signaling and further activation of platelets. Finally, thrombin proteolytically cleaves fibrinogen to form fibrin, which then can assemble into a fibrin mesh.

A pleiotropy of additional proteins, enzymes, and receptors has been described to participate in platelet adhesion, activation, aggregation, and stabilization. The precise function of many of these molecules is either not yet fully understood or they have varying importance depending on the specific condition of platelet activation. Rheological conditions, the composition of the prothrombotic surface, the inflammatory status of the endothelial cell layer, and the extent of involvement of the coagulation system might modulate the importance of these factors. While these biological processes are sometimes contradictorily or even confusingly described in the literature, their complexity could be an incentive for the generation of new therapeutic opportunities. Whereas in past decades the focus had been mainly on platelets in thrombotic diseases, recent research suggests additional function of platelets in immunology and tumor biology (see Section **Role of Platelets Outside Hemostasis**). In these processes, different signaling pathways might be more relevant, potentially resulting in novel opportunities for antiplatelet drugs in nonatherothrombotic diseases.

7.15.2.4 Inhibition of Platelet Aggregation

Platelets have been described to contribute to hemostasis and thrombosis since their discovery by Bizzozero in the 1880s.[26] More recently, atherosclerotic lesions in combination with occlusive platelet thrombi have been found in patients with ischemic cardiac death.[27] Inhibition of platelet aggregation is recognized as an effective strategy for the prevention of thrombosis in patients with atherosclerotic disease in the coronary, peripheral, and cerebrovascular circulation.[28] The aforementioned signaling molecules and receptors are among the most important and best studied drivers of thrombus formation in arterial blood flow and thus have been the focus of successful antithrombotic strategies. Briefly, COX-1 is irreversibly inhibited by aspirin, the most widely used agent for prevention of atherothrombotic diseases. The ADP receptor $P2Y_{12}$ is inhibited by the irreversible antagonists, clopidogrel and prasugrel, and the reversible antagonists ticagrelor and cangrelor, which are used for the treatment and prevention of ACS.[28b] The fibrinogen receptor $\alpha_{IIb}\beta_3$ is inhibited by the monoclonal antibody abciximab and by two small molecules tirofiban and eptifibatide, which are used for inhibition of platelet activity in an acute clinical setting. Most recently, the PAR-1 inhibitor vorapaxar gained approval for the prevention of atherothrombotic disease in patients with previous MI.[16d] The properties of these agents and novel development for these targets will be discussed in detail in the following sections.

Furthermore, inhibitors of the coagulation system known as anticoagulants have arisen as powerful antithrombotics. Anticoagulants have been shown to be effective in the treatment and prevention of VTE. However, long-term treatment with anticoagulant therapies in ACS patients was so far only successful with low-dose rivaroxaban, an inhibitor of the coagulation factor Xa. Rivaroxaban has recently been approved by the European Medicines Agency (EMA) but not by the Food and Drug Administration (FDA) for the secondary prevention after ACS.[29] Long-term anticoagulation in addition to dual antiplatelet therapy (DAPT) is required in 5–10% of patients for other conditions, such as atrial fibrillation, mechanical valves, and thromboembolic diseases, but is associated with an increase in major bleeding complications. Bleeding complications separate into minor bleedings like gum or nosebleeds and major bleedings leading to a drop of hemoglobin and the need for medical intervention such as red cell transfusion to guarantee survival.[30] Major bleedings are associated with reduced long-term survival and consequently limitation of bleeding risk is paramount. Therefore, for combination treatments, the safest possible agents and minimal duration of anticoagulant therapy are essential.[31]

7.15.2.5 Assay Systems to Monitor Platelet Inhibition

Inhibition of platelet function can be quantified by multiple assay systems. The classical platelet function assay is termed light transmission aggregometry (LTA). By differential centrifugation, blood cells are separated from platelets to generate platelet-rich plasma (PRP). Resting platelets are in a discoid shape and light transmission through a PRP-containing cuvette is low. However, upon the addition of a soluble platelet activator (ADP, thrombin, collagen, and TXA_2) in combination with stirring, platelets start to aggregate and the transmission of light through the cuvette is increased, hence allowing indirect quantification of platelet aggregation.[32] The quality of PRP preparation and reproducible execution of the protocol is essential to generate reliable results in this very sensitive assay. Although a low-throughput method, LTA still represents the gold standard for investigation of platelet function since inhibition of LTA has been shown to correlate with the antithrombotic effect in vivo. To allow medium throughput in a clinical setting, this principle has been adapted to a whole-blood aggregation assay (VerifyNow®).[33]

Two alternative functional tests using whole blood were developed based on the principle of impedance (time variation in an electric circuit). Two silver electrodes continuously measure the change in impedance in whole blood. Upon stimulation, platelets aggregate and adhere to the electrodes leading to a proportional increase in impedance. The change of impedance over time is graphically displayed and compared relative to control or samples containing various inhibitor concentrations. The identical principle has now been adapted to allow multiple measurements in parallel (Multiplate).[34]

Another functional test system aspirates blood through a capillary that is coated with ADP, collagen, or epinephrine. The platelet activators induce the formation of a platelet plug that closes the capillary (platelet function analyzer).[35] Time to occlusion has been shown to correlate with the extent of platelet inhibition.[36]

Alternatively, platelet activation can be monitored by quantification of intracellular signaling activity. One assay quantifies the phosphorylation of the vasodilator-stimulated phosphoprotein (VASP) that correlates with the extent of platelet activation and inhibition.[37] If the drug target is a G protein-coupled receptor (GPCR), inhibition of G protein signaling can be quantified using labeled GTPγS. Upon activation of the GPCR, labeled GTPγS binds to the G protein. Since GTPγS is not hydrolyzable, the labeled G proteins accumulate and can be quantified. Prevention of accumulation of labeled G protein correlates with inhibition of the GPCR.

Furthermore, the direct binding affinity of antagonists to target proteins can be measured using radiolabeled ligands of the target protein. However, to prevent misinterpretation, the binding affinity of the antagonist has to be put in relation with the binding affinity of the radioligand. Moreover, GTPγS accumulation or binding with radiolabeled ligand is performed in most cases with recombinant cell lines.

7.15.2.6 Experimental Thrombosis Models In Vivo

To confirm antithrombotic activity in animals, various models have been established.[38] The rat ferric chloride ($FeCl_3$) model is one of the most frequently used thrombosis models. In the anesthetized rat, the carotid artery is gently dissected free of connective tissue and a small piece of filter paper, soaked in $FeCl_3$ solution, is topically applied. $FeCl_3$ destroys the endothelial cell layer of the carotid artery and thus induces the formation of an occlusive platelet-rich thrombus. The decrease in blood flow is quantified using a Doppler flow probe.[39] All marketed antiplatelet agents have shown antithrombotic efficacy in this model.[40] In the same animals, quantification of bleeding time, after transection of the rat tail, is often used to evaluate potential side effects on hemostasis. However, in rat, tail bleeding time is reported to vary according to the antithrombotic agent and specific method applied.[41] Therefore, methods to quantify the volume of blood loss after a standardized surgical wound have also been established.[42]

Alternatively, thrombus formation can be induced by mechanical damage of the artery. In the method described by Folts et al. (Folts model), mechanical squeezing of the artery with forceps replaces $FeCl_3$ and induces thrombus formation. In the Folts model, occlusive thrombi are mechanically dislodged to reopen the blood flow. The number of occlusion/reopening cycles (cyclic flow variation) is then compared under various concentrations of antiplatelet agents.[43]

7.15.3 Overview of Current Treatment and Unmet Medical Need

7.15.3.1 Clinical Use of Antiplatelet Drugs

Treatment guidelines for ACS patients are based on a vast amount of clinical evidence. For historical and cultural reasons, not all treatment recommendations are identical. In this paragraph, we summarize the general treatment principles of the North American and European guidelines.

Patients with a STEMI are treated based on the capabilities of the hospital.[44] If the hospital is equipped to perform surgical intervention to reopen the occluded artery, defined as percutaneous intervention (PCI), STEMI patients receive PCI as fast as possible. Briefly, a catheter is inserted into the artery of the leg or the arm and advanced into the heart and finally into the occluded artery. With the help of a small balloon, the occluded artery is dilated to reestablish blood flow. To stabilize the reopened part of the artery, a metal mesh may be inserted into this specific section of the coronary artery (stent placement).

In a non-PCI-capable hospital, patients can be treated with a fibrinolytic agent. Fibrinolytic enzymes, such as tPA and streptokinase, are able to proteolytically cleave fibrin fibers and thus contribute to the dissolution of the occluding thrombus. This therapy, however, is only possible within a narrow time window of up to 6 hours after onset of symptoms. If a fibrinolytic therapy is no longer possible, the patient has to be transported to a hospital with PCI capabilities. Alternatively, if coronary anatomy is not amenable to PCI, coronary artery bypass graft (CABG) surgery is recommended. In this surgical intervention, a healthy artery or vein from the patient (usually from the leg) is grafted upstream and downstream of the blocked coronary artery to form a bypass around the blocked portion of the coronary artery. This creates a new path for oxygen-rich blood to feed the heart muscle and reestablish proper performance.

To support surgical therapy, adjunctive antithrombotic therapy is the standard of care. In all cases, the administration of aspirin (75–325 mg) is recommended to start before procedure and to continue thereafter indefinitely. During surgical intervention until revascularization, anticoagulation with unfractionated heparin, fractionated heparin (enoxaparin), or a synthetic pentasaccharide (fondaparinux) is recommended. In addition, DAPT with $P2Y_{12}$ receptor inhibitors (clopidogrel, prasugrel, and ticagrelor) should start as early as possible or at the time of PCI and continue for at least 12 months. Alternatively, intravenous application of $\alpha_{IIb}\beta_3$ receptor antagonists (abciximab, tirofiban, and eptifibatide) may be used for short-term platelet inhibition (up to 3 days) in combination with anticoagulation therapy. Secondary prevention is then continued with DAPT as described in the preceding text.[44] For UA/NSTEMI patients, treatment guidelines advocate aspirin as soon as possible after hospital presentation, with unlimited duration if tolerated.[45] UA/NSTEMI patients are subsequently treated either invasively with PCI or following a conservative, noninvasive strategy with antiplatelet medication. During invasive PCI, antiplatelet medication follows the same guidelines as described in the preceding text for STEMI patients. For conservative strategies, antiplatelet treatment is limited to DAPT.[45,46]

Treatment guidelines for stroke are well defined.[47] Intravenous application of recombinant tissue-type plasminogen activator (r-tPA) defines the cornerstone of early thrombolysis treatment of acute ischemic stroke. For optimal efficacy, thrombolytic therapy is limited to the first 6 h after onset of symptoms. Three antiplatelet regimens have demonstrated substantial reductions in secondary event risk and are currently recommended by consensus panels: aspirin monotherapy, the combination of aspirin plus extended-release dipyridamole, and clopidogrel monotherapy.[48]

The management of PAOD is multidisciplinary, involving primary care physicians and vascular specialists with varying expertise in diagnostic and treatment modalities. PAOD describes a broad spectrum of diseases from asymptomatic to severe limb ischemia. If the anatomical situation allows, surgical removal of occlusive thrombus or bypass surgery is recommended. In addition, antiplatelet therapy with aspirin, clopidogrel or dipyridamole, and cilostazol is deemed useful to reduce the risk of MI, stroke, or death.[49]

7.15.3.2 Need for Novel Antiplatelet Approaches

The current strategy for treatment and prevention of ACS has significantly reduced morbidity and mortality in this patient population. Unhealthy food choices and sedentary lifestyles in the industrialized world elevate the risk of atherothrombotic disease and thus partially offset the progress achieved by the joint efforts of pharmaceutical and medical research.

The first antiplatelet drug aspirin reduced major cardiovascular events (death, MI, and urgent revascularization) by 22%.[50] The combination of clopidogrel on top of aspirin further decreased major cardiovascular events by an additional 20%.[51] As a next step, prasugrel on top of aspirin achieved a higher platelet inhibition and thus an additional 19% risk reduction of cardiovascular events.[52] Moreover, each improvement in efficacy was accompanied with a statistically significant increase in major bleedings. Nevertheless, despite a higher risk in major bleedings, each of these studies demonstrated a clear medical benefit with a sufficient therapeutic window, which supported market approval and broad use in ACS patients. However, the long-term consequences of increased rates of major bleedings were illustrated by recent post hoc analyses of antiplatelet clinical trials.[53] These analyses revealed that a strong association between major bleeding and increased long-term mortality exists in ACS patients. Therefore, improved antiplatelet agents that are fully effective but show a reduced propensity of major bleeding will be essential to ameliorate current therapeutic strategies.

At present, clopidogrel in combination with aspirin remains the cornerstone of treatment in ACS. However, despite the significant benefits of DAPT, a considerable number of patients experience adverse events such as bleeding and thrombosis. Since the active principle of clopidogrel is a metabolite, and metabolic activation of clopidogrel can be a limiting factor in humans, large interindividual variability of antiplatelet effects is reported. On average, clopidogrel inhibits platelet function only by 40% with a variability of 0 to 80% inhibition.[16b] Those patients with high on-treatment platelet reactivity, that is, $<20\%$ inhibition, are at a higher risk of a thrombotic event.[54] Various approaches have been chosen in the past decades to generate novel antiplatelet therapies with reduced risk of bleeding and improved pharmacokinetic and pharmacodynamic profiles; however, success has been scarce. Encouraging examples are the orally active, reversible $P2Y_{12}$ antagonists ticagrelor and cangrelor and the PAR-1 antagonist vorapaxar.[53a,55] In addition, many more creative approaches for the optimization of known principles or the evaluation of novel targets are still ongoing.

7.15.4 Overview of Targets for Antiplatelet Therapy

7.15.4.1 Platelet Adhesion and Aggregation Receptors

Platelets circulate in a resting state; nevertheless, they can immediately adhere to exposed ECM. The major constituents of the subendothelial matrix, which bind and activate platelets, are collagen, vWF, vitronectin, fibronectin, and laminin.

On the surface of platelets, the most important adhesion receptors are the two main collagen receptors GPVI and integrin $\alpha_2\beta_1$, the vWF receptor GPIb, and the vitronectin receptor integrin $\alpha_V\beta_3$. The two integrins $\alpha_5\beta_1$ and $\alpha_6\beta_1$ are the receptors for fibronectin and laminin, respectively. The key integrin $\alpha_{IIb}\beta_3$ interacts with vWF immobilized on collagen, when acting as an adhesion receptor, and with fibrinogen to trigger aggregation.

Integrin $\alpha_2\beta_1$ is important for the adhesion to collagen, whereas GPVI is required for collagen-induced platelet activation.[56] Upon damage of the endothelial surface, vWF circulating in the blood binds to the exposed collagen fibers and serves as an adhesion partner for the GPIb-V-IX receptor complex. The importance of the GPIb-V-IX receptor complex is increasing with the velocity of the blood. At high blood flow in narrow blood vessels, the role of the GPIb-V-IX receptor is critical for platelet adhesion and thus in the initiation of thrombus formation.[57]

Adhesion receptors are the key initiators of intraplatelet signaling inducing new interactions responsible for the stabilization of platelet adhesion, platelet–platelet contact, platelet spreading, and granule release or clot retraction.[26,58] Ultimately, integrin $\alpha_{IIb}\beta_3$, the most important receptor for fibrinogen, is activated leading to platelet aggregation.

Due to their central role in platelet adhesion and in the early phase of the platelet activation or aggregation process, adhesion receptors have been targeted in antiplatelet approaches (**Table 1** and Section **Antagonists of the Adhesion Receptors**). From a drug discovery perspective, the most successful approach is integrin $\alpha_{IIb}\beta_3$, the major cross-linker between platelets responsible for aggregation (see Section **Integrin $\alpha_{IIb}\beta_3$ Antagonists**).

Table 1 Adhesion and aggregation receptors and selection of corresponding antagonists

Protein	*Receptor*	*Antagonists*	*Marketed*
Collagen	GPVI	Kistomin	No
	$\alpha_2\beta_1$	Revacept	Clin. Dev.
		Various	No
vWF	GPIb-V-IX	Aptamers, proteins, monoclonal antibodies, and nanobodies	Clin. Dev.
Fibrinogen/vWF	$\alpha_{IIb}\beta_3$	Abciximab	Yes
		Eptifibatide	Yes
		Tirofiban	Yes
		RUC-4	Preclin. Dev.

Table 2 The role of GPCRs on platelet activation and inactivation

Agonist	*GPCR*	*G protein*	*Effect on platelets*
ADP	$P2Y_1$	Gq	Activation
	$P2Y_{12}$	Gi	Activation
Thrombin	PAR-1	Gq	Activation
	PAR-4	Gq	Activation
PGE_2	EP3	Gi	Activation
Serotonin	$5\text{-}HT_{2A}$	Gq	Activation
TXA_2	TP	Gq	Activation
PGI_2	IP	Gs	Inactivation
PGD_2	DP1	Gs	Inactivation

Overview of GPCRs described for the activation or inactivation of platelets. Their most relevant associated G protein and their effect on signaling are listed. The GPCRs currently targeted by marketed antiplatelet drugs are highlighted in gray.

7.15.4.2 GPCRs as Receptors of Released Signaling Molecules

Upon adhesion, platelet activation is followed by the release of signaling molecules such as ADP, TXA_2, and thrombin. This triggers an amplification of the hemostatic process through a mechanism initiated by GPCRs.

GPCRs on the platelet surface display differential responses resulting in either further platelet activation or inactivation. As presented in Table 2, these GPCRs fall into two categories. Platelet-activating GPCRs are $P2Y_1$, $P2Y_{12}$, PAR-1, PAR-4, EP3, $5\text{-}HT_{2A}$, and TP. GPCRs that trigger the inactivation of platelets are the prostaglandin receptors IP (PGI_2 receptor) and DP1 (PGD_2 receptor). Most of these important GPCRs have been targeted by the pharmaceutical industry and will be discussed in Section Antagonists of GPCRs.

7.15.4.3 Mechanism of Intracellular Signaling and Key Intracellular Enzymes

Upon interaction with agonists, GPCRs undergo conformational changes and consequently trigger the activation of the bound heterotrimeric G protein complex ($G\alpha\beta\gamma$).[59] Upon GPCR activation, the $G\alpha$ subunit exchanges bound GDP by GTP. As a consequence, the $G\alpha$ subunit detaches from both the GPCR and the $\beta\gamma$ subunits and binds to its downstream signaling partner. Since the $G\alpha$ subunits exist in multiple variations, the ensuing downstream signal is different (Fig. 1). Specifically, the $G\alpha i$ subunit (Gi) inhibits adenylyl cyclase (AC) and thus causes a lowering of cyclic AMP (cAMP). In contrast, the $G\alpha s$ subunit (Gs) activates AC, which leads to elevated cAMP. The third major $G\alpha$ protein $G\alpha q$ (Gq) induces the activation of phospholipase $C\beta$ ($PLC\beta$), which generates inositol phosphate-3 (IP3) leading to an elevation of intraplatelet calcium (Ca^{2+}) levels.[60] Both mediators Ca^{2+} and cAMP play a critical role in platelet stimulation: high calcium and low cAMP levels in the platelet cytosolic space allow full activation of platelets. In contrast, low calcium and high cAMP levels keep the platelet in a resting state.

As shown in Table 2, antiplatelet strategies seek to either stimulate Gi-bound GPCRs, which elevate cAMP, or inhibit Gs-bound GPCRs, which would diminish cAMP concentrations. Alternatively, prevention of cAMP degradation can also interfere with platelet activation. The hydrolysis of cyclic nucleotides such as cAMP and cGMP yields the inactive 5′-AMP and 5′-GMP, respectively, and is mediated by phosphodiesterases (PDEs; Fig. 2). Inhibition of platelet-specific PDEs has already been validated as an antiplatelet approach with two PDE inhibitors approved as antithrombotic drugs.

Cyclooxygenase (COX), also named prostaglandin-endoperoxide synthase, is a pivotal enzyme in the biosynthesis of prostanoids, such as prostacyclin (PGI_2) and TXA_2. In general, after stimulation of a cell, phospholipases are activated and cleave cell membrane phospholipids to liberate arachidonic acid (AA). AA is then converted by COX into PGH_2, a precursor for the prostanoids PGF_2, PGE_2, PGI_2, and PGD_2 and TXA_2. The synthesis of specific prostanoids from PGH_2 depends on the context of activation

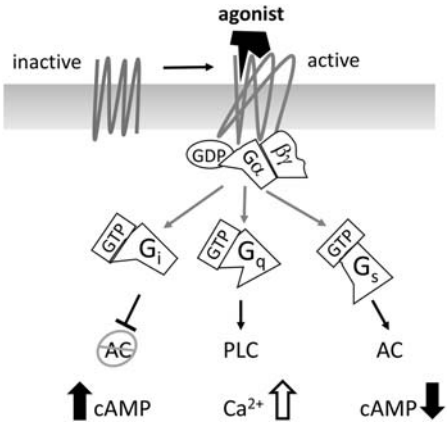

Fig. 1 Schematic representation of G protein-mediated signaling. Binding of an agonist to the GPCR induces a transformation of the GPCR from the inactive to the active conformation, hence triggering an activation of the bound G protein. The G protein is a heterotrimeric protein with three subunits α, β, γ. Only Gα exists in three major forms, termed Gi, Gs, and Gq. Upon activation, the Gα subunit exchanges bound GDP by GTP, detaches from the GPCR, and releases the βγ subunit. Activation and release of Gi result in the suppression of AC activity, while active Gs positively regulates AC, leading to a reduction or increase in cAMP, respectively. Active Gq triggers an increase in the intraplatelet calcium concentration (via activation of PLC and formation of IP3; see also **Fig. 3**). GPCR is symbolically drawn as 7-transmembrane spiral. The membrane surface of platelets is graphically displayed as a *thick gray bar*.

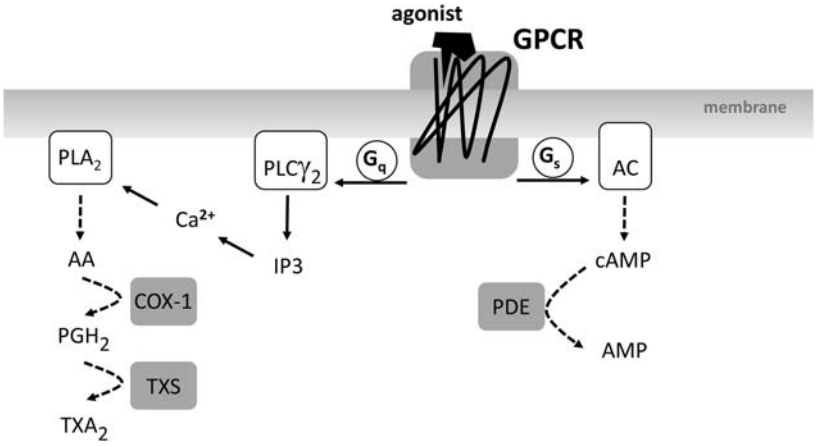

Fig. 2 Schematic representation of GPCR-induced intraplatelet signaling. Agonist binding induces conformational changes allowing an interaction with intracellular G proteins (see also **Fig. 1**). Gs proteins activate AC leading to increased concentrations of cytosolic cAMP. cAMP is hydrolyzed by PDEs into the (inactive) AMP. Gq proteins activate $PLC\gamma_2$, which cleaves phospholipids to liberate IP3 and DAG. IP3 triggers elevation of intraplatelet calcium concentration, which activates phospholipase A_2 (PLA_2). PLA_2 hydrolyses phospholipids to liberate arachidonic acid (*AA*). AA is converted by COX-1 into PGH_2, which, in platelets, is converted by TXS into TXA_2. *Black arrows* indicate an activation step. The dashed arrows point to the formation of an enzymatic product. Current pharmacological targets for the inhibition of platelet activation are highlighted in *gray*.

and the cell type. In thrombosis, two pathways are dominant: (a) in endothelial cells, PGI_2 is mainly produced, and released PGI_2 contributes to the inactivation of circulating platelets, and (b) in platelets, after the activation via the collagen receptor GPVI or thromboxane receptor TP, PGH_2 is converted into TXA_2 by thromboxane synthase (TXS). Secreted TXA_2 is one of the most important activators of circulating platelets and thus of the recruitment of platelets into growing thrombi. Consequently, the prostanoids and TXA_2 biosynthesis pathway contain two targets for antiplatelet approaches: COX-1 and TXS (**Fig. 2**).

Following binding to the exposed ECM ligands, adhesion receptors interact with intracellular effector proteins triggering a signaling cascade.[56,61] Examples of effector proteins are members of the Src kinase family, such as Lyn, Fyn, and Syk.[62] These tyrosine kinases activate phosphoinositol-3-kinase (PI3Kβ) and phospholipase $C\gamma_2$ ($PLC\gamma_2$), which convert membrane lipids into inositol phosphate-3 (IP3) and diacylglycerol (DAG). While IP3 triggers the release of intracellular calcium from internal stores into the platelet cytosol, DAG activates protein kinase C (PKC). Calcium and PKC signaling converge in the induction of granule secretion. In addition, calcium and DAG bind to the nucleotide exchange factor CalDAG-GEF1, which triggers the GTP binding protein Rap1 to exchange GDP by GTP resulting in an active conformation.[63] Active Rap1 associates with the linker protein RIAM (Rap1-GTP-interacting adapter molecule) and talin-1. This ternary complex binds to the

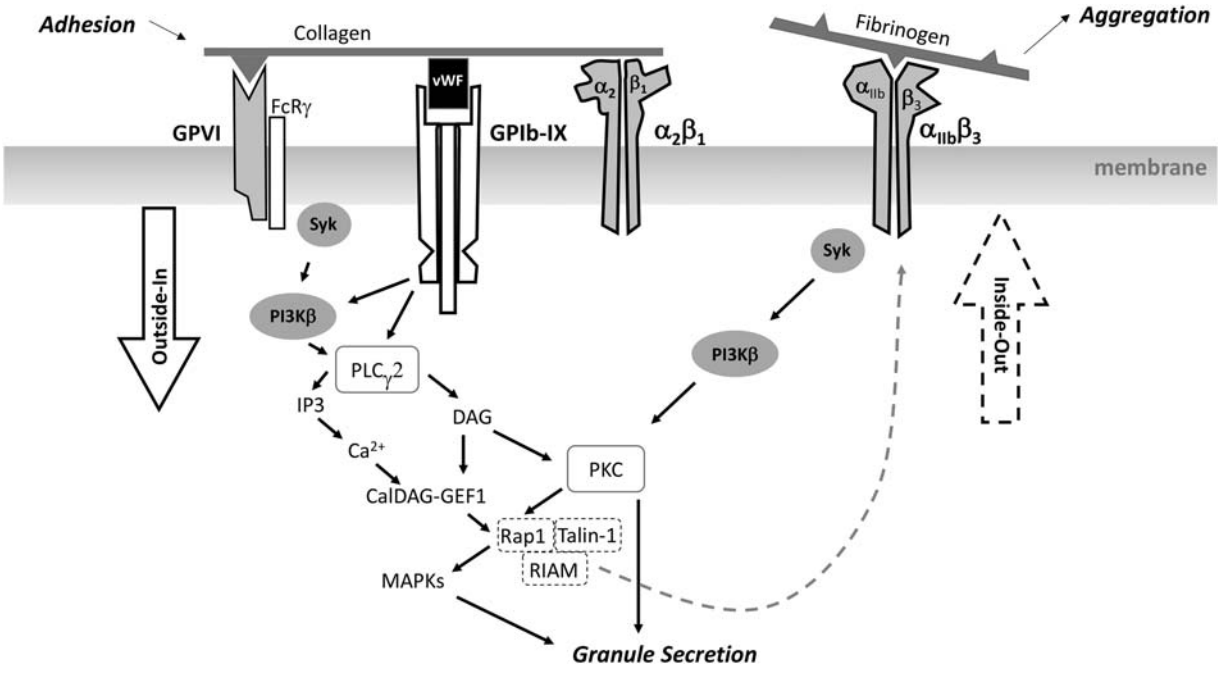

Fig. 3 Intraplatelet signaling induced by adhesion receptors. Adhesion receptors bind to collagen either directly ($\alpha_2\beta_1$, GPVI) or via a linker protein (*vWf*). GPVI using the subunit FcRγ activates Syk, which in turn activates PI3Kβ. PI3Kβ activates PLCγ_2, which cleaves phospholipids releasing IP3 and DAG. IP3 binds and stimulates calcium channels on the surface of intraplatelet organelles to release calcium (Ca^{2+}). Calcium is a key element for platelet activation; thus, this signaling event is termed outside-in signaling. Calcium and DAG bind to CalDAG-GEF1, a nucleotide exchange factor for the GTP binding protein Rap1. CalDAG-GEF1 in turn triggers the formation of the Rap1/RIAM/talin-1 complex, which binds to the intracellular part of integrins, inducing the high-affinity conformation and thus binding of extracellular ligands (inside-out signaling). In parallel, DAG activates PKC and active Rap1 leads to the activation of mitogen-activated protein kinases (*MAPK*s). Both pathways contribute to the phosphorylation of other signaling molecules essential for granule secretion. Upon binding of fibrinogen, additionally induced conformational changes within integrin $\alpha_{IIb}\beta_3$ trigger an interaction with intracellular linker molecules among which Syk activation leads to activation of PI3Kβ. PI3Kβ activates PKC and thus also contributes to the amplification of platelet activation. *Arrows* indicate an activation step within the cascade. Intracellular protein or receptor shapes filled in *gray* indicate current targets of antiplatelet approaches. Integrin $\alpha_{IIb}\beta_3$ is shown as an aggregation receptor only.

intracellular part of integrin $\alpha_{IIb}\beta_3$ triggering the high-affinity conformation with subsequent fibrinogen binding and platelet aggregation (Fig. 3).[64]

Interference with intraplatelet signaling is intended to prevent inside-out signaling and thus initiation of platelet aggregation. Since primary adhesion to exposed ECM is still possible, it is postulated that such an approach is antithrombotic with minimal effect on hemostasis. Antiplatelet approaches targeting enzymes of intraplatelet signaling will be discussed in Section Inhibitors of Intracellular Enzymes.

7.15.5 Antagonists of GPCRs

7.15.5.1 Purinergic Receptor Antagonists

Extracellular nucleotides are ubiquitous signaling molecules, acting via the P2 purinergic receptors. Platelets express three P2 receptor subtypes, the ATP-gated $P2X_1$ cation channel and the ADP-dependent $P2Y_1$ and $P2Y_{12}$ G protein-coupled receptors.[65] Large amounts of ATP released from cells following vascular injury trigger the opening of the $P2X_1$ channel. This results in calcium ion influx leading to shape change, movement of secretory granules, and low levels of $\alpha_{IIb}\beta_3$ integrin activation.[66] $P2X_1$ can also synergize with several other receptors to amplify signaling and functional events in platelets. In addition, when platelets adhere to a prothrombotic surface, they get activated and release the content of their granules including adenosine diphosphate (ADP). ADP stimulates platelet activation through $P2Y_1$ and $P2Y_{12}$.[67]

Coactivation of these two receptors is necessary for normal ADP-induced platelet aggregation; however, they have different functions. In response to ADP, $P2Y_1$ mediates a rise in cytoplasmic calcium that results in platelet shape change and weak, reversible aggregation. Upon ADP binding, $P2Y_{12}$ inhibits AC causing a lowering of cAMP, hence promoting platelet aggregation.[68] Studies with $P2Y_{12}$ knockout mice have demonstrated that the main role of $P2Y_{12}$ is the amplification of aggregation and stabilization of platelet thrombi.[69] $P2Y_{12}$ is also involved in the potentiation of platelet secretion induced by other agents through various intracellular pathways.

The $P2X_1$ receptor is widely distributed, for instance, on smooth muscle cells in different hollow organs (e.g., urinary bladder, artery, intestine, and vas deferens).[70] The $P2Y_1$ receptor is expressed on platelets and in the heart, blood vessels, and various smooth muscles as well as the prostate, ovary, and brain. In contrast, $P2Y_{12}$ is mainly found on platelets and subregions of the brain.[71]

7.15.5.1.1 $P2Y_{12}$ antagonists

In preclinical animal models, inhibition of $P2Y_{12}$ prevented experimental thrombosis with only limited effect on bleeding parameters.[72] Importantly, inhibition of $P2Y_{12}$ as an antiplatelet approach was validated in multiple clinical studies. Several $P2Y_{12}$ antagonists have been demonstrated to effectively reduce the risk of adverse cardiovascular events in patients with ACS and patients undergoing PCI.[68,73] In current treatment guidelines, $P2Y_{12}$ antagonists define the cornerstone therapy for patients with ACS. However, the search for even better $P2Y_{12}$ antagonists is still ongoing. Current efforts are focused on a new generation of molecules with reduced bleeding risk, reduced variability of antiplatelet effects, and preferentially once-a-day treatment. Excellent reviews and book chapters have comprehensively covered the discovery, pharmacology, and clinical use of $P2Y_{12}$ antagonists.[73b,74] In this section, we will provide a short summary of the current available drugs and give an overview of the recent medicinal chemistry efforts with a broad selection of diverse chemical scaffolds.

7.15.5.1.1.1 Indirect $P2Y_{12}$ antagonists: the thienopyridine family

Earlier $P2Y_{12}$ antagonists were developed without knowledge of their pharmacological target. Later studies showed their indirect way of action, that is, they require metabolic activation for biological activity. Three indirect antagonists of the thienopyridine family, which block the ADP-induced platelet activation and aggregation, have reached the market: the orally active ticlopidine, clopidogrel, and prasugrel (Fig. 4).

The first representative of this class was discovered in 1972 at Porcor (later Sanofi) in an effort to find new antiinflammatory drugs based on tinoridine (**1**), a compound previously described by the Yoshitomi company.[75] They chose a phenotypic screening approach: the analogs, synthesized in gram amounts, were directly tested in a wide range of in vivo and ex vivo rodent models, including the ADP-induced platelet aggregation ex vivo assay. In this assay, surprisingly high antiplatelet activity was measured, and one of the most potent analogs, ticlopidine (**2**), was selected for clinical development. It successfully completed several advanced clinical trials and consequently gained global approval in 1991 for the primary and secondary prevention of stroke. Unfortunately, in patients, ticlopidine led to rare but serious hematologic side effects (e.g., thrombocytopenia purpura and neutropenia), and the need for a safer derivative became an urgent priority.

The Sanofi researchers synthesized thousands of analogs and advanced unsuccessfully eight of them into phase I clinical trials before identifying the desired molecule bearing an (*S*)-carboxylic methyl ester at the benzylic position of ticlopidine. Clopidogrel (**3**) was demonstrated to be superior to aspirin in the secondary prevention of vascular events in a huge clinical trial (CAPRIE).[76] Clopidogrel was launched in 1998 worldwide and quickly eclipsed its predecessor ticlopidine due to its higher safety and efficacy profile. In combination with aspirin, it became the therapeutic cornerstone for ACS patients and is widely used during PCI interventions. Clopidogrel rose to the second best-selling drug after atorvastatin before becoming generic in 2012.

Interestingly, clopidogrel and its predecessor ticlopidine were brought to the market without knowledge of their precise biochemical mechanism of action. This mystery could be solved in 2001 with the cloning of the $P2Y_{12}$ receptor and its unequivocal identification as the biological target of the thienopyridines.[77] All thienopyridines are prodrugs that undergo metabolic conversion in the liver to generate the active species. For clopidogrel, the major part of the oral dose (c. 85%) is converted through enzymatic ester hydrolysis in the intestine to the inactive carboxylate derivative. After absorption of the remaining dose, different cytochrome P450 isoforms (mainly CYP2C19) oxidize the thiophene ring to form the intermediate thiolactone (2-oxo-clopidogrel, **6**), which is converted in a second step by CYP-mediated ring opening to an unstable and biologically active metabolite (Fig. 5).[78] $P2Y_{12}$ is covalently modified by the thiol group of the metabolite **7** forming a disulfide bridge with $Cys97^{3.25}$ as a primary attachment site. This metabolite is generated only in small amounts (< 10% of the dose), which leads to a slow onset of the pharmacological effect (up to

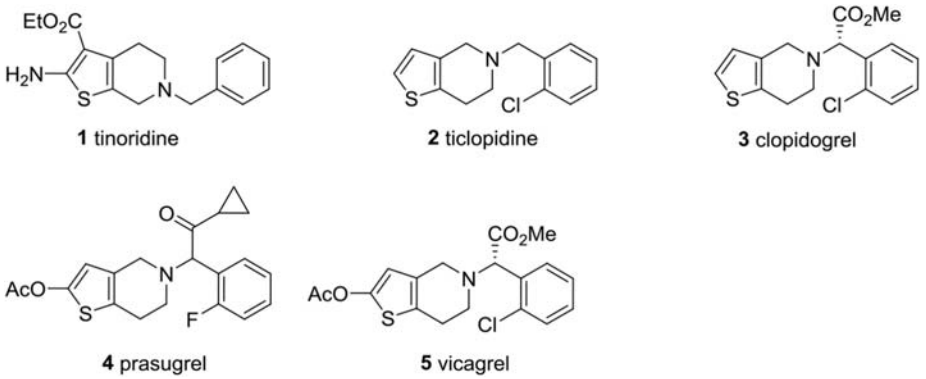

Fig. 4 From tinoridine to ticlopidine and further development to clopidogrel, prasugrel, and hybrid molecule vicagrel.

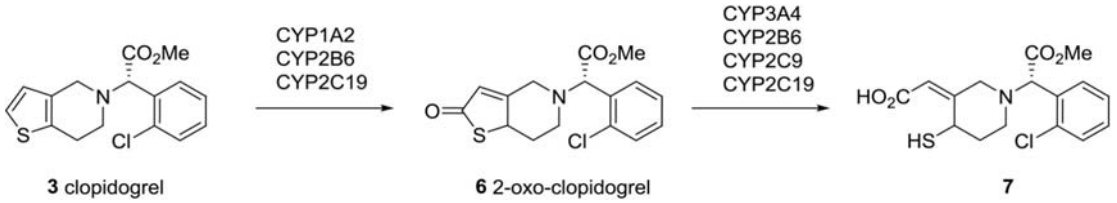

Fig. 5 Metabolism of clopidogrel: CYP-mediated thiophene ring oxidation to 2-oxo-clopidogrel (**6**) followed by a second CYP-mediated oxidation to the active thiol metabolite **7**. Analogous transformations are suggested for ticlopidine. For clopidogrel and 2-oxo-clopidogrel, the inactivation occurs through ester cleavage by carboxyesterases to the corresponding inactive acid. Prasugrel follows after hydrolysis of its acetate, the same second oxidation step as 2-oxo-clopidogrel.

4 days required to achieve steady-state concentration). When high levels of receptor inhibition are rapidly required, a loading dose of 300–600 mg followed by the regular 75 mg clopidogrel dose is prescribed. As for aspirin, irreversible inhibition of the receptor lasts for the lifetime of the platelets, and full restoration of platelet activity may require 7–10 days after the last dosage.

The clinical success of clopidogrel has been overshadowed by the observation that up to 30% of the patients do not achieve the expected level of platelet inhibition ("clopidogrel resistance").[79] The factors contributing to the variable response to this drug are manifold, that is, genetic polymorphism of drug transporter proteins and metabolic enzymes or drug–drug interactions. However, the major determinant for clopidogrel resistance is CYP2C19 polymorphism, which occurs in 30–55% of patients. Loss-of-function variants of CYP2C19 lead to poor conversion of clopidogrel to the active metabolite, and as a consequence, patients showing "high on-treatment platelet reactivity" (i.e., platelets that respond to ADP, despite ongoing anti-$P2Y_{12}$ treatment) are at a higher risk of recurrence of cardiovascular events. Large clinical trials to identify poor responders through platelet function tests with the goal to adjust the dose of clopidogrel were so far unsuccessful.[80]

Consequently, efforts shifted toward the development of compounds relying less on CYP-mediated metabolism. Prasugrel (CS-747, **4**) is a third-generation thienopyridine brought to the market in 2009 by Daiichi Sankyo/Eli Lilly[72b] (**Fig. 4**). The methyl ester moiety of clopidogrel is replaced by a cyclopropyl ketone, which renders the chiral center configurationally labile. Thus, prasugrel has been developed as a racemate. However, similar to its predecessors, it still requires metabolism for biological activity. In contrast to clopidogrel, the crucial thiolactone is provided with less variability by a rapid carboxyesterase-mediated acetate cleavage that takes place already in the intestine. This intermediate undergoes CYP-mediated ring opening to the active metabolite. The higher potency of prasugrel compared with clopidogrel is reflected by the clinical dose of 10 mg/day with a loading dose of 60 mg. In a large clinical phase III trial with ACS patients, prasugrel showed increased efficacy compared with clopidogrel albeit at the cost of higher incidence of major bleeding events in high-risk patients.[81] This safety drawback limits its clinical use.

Two recent studies have described attempts at increasing the systemic exposure of the active metabolite of clopidogrel (**7**). In the first study, a hybrid molecule (vicagrel, **5**) bearing the acetate functionality of prasugrel grafted onto the thiophene ring of clopidogrel was investigated by Shan et al. (**Fig. 4**).[82] Due to faster esterase metabolism, the bioavailability in rats of 2-oxo-clopidogrel (**6**) starting from vicagrel was four- to sixfold higher than with clopidogrel. Vicagrel could therefore overcome the high variability in the pharmacological response due to CYP2C19 polymorphism and thus may attenuate clopidogrel resistance. However, the advantage of vicagrel over prasugrel has yet to be demonstrated since vicagrel showed a lower potency in an ADP-induced platelet aggregation assay in rats. In the second study, the observation of oxidative metabolism at the piperidine ring of clopidogrel, mediated by CYP3A4/5, revealed a novel side pathway decreasing the production of the oxo-clopidogrel intermediate.[83] Based on these findings, Zhu et al. subsequently deuterated the piperidine ring of clopidogrel that moved the metabolism to the thiophene ring, ultimately leading to higher concentration of the deuterated version of metabolite **7**.[84]

7.15.5.1.1.2 The direct $P2Y_{12}$ antagonists

Direct antagonists do not require metabolic activation and therefore display faster onset and offset of action. This is a beneficial profile whenever the recovery of platelet function is required, such as in emergency surgeries or during unforeseen bleeding events. In addition, direct antagonists might cause less bleeding than the irreversible inhibitors since the $P2Y_{12}$ receptor remains responsive to high local concentrations of ADP.[42b,85]

7.15.5.1.1.2.1 Nucleotides analogs: cangrelor, ticagrelor, and regrelor

The audacious decision to launch at Fisons Pharmaceuticals (became the Charnwood site within AstraZeneca) a medicinal chemistry program based on ATP (**8**) paid off with the approval of two drugs, cangrelor (**9**) and ticagrelor (**10**).[86] ATP was known as a competitive albeit weak antagonist of ADP-induced platelet aggregation (later defined as partial agonist of $P2Y_{12}$). It was thus hypothesized that the agonistic and antagonistic behaviors of ADP and ATP, respectively, were derived from the additional negative charges arising from the terminal phosphate in ATP (**Fig. 6**).[87] To avoid the hydrolysis of ATP, which would lead to the agonistic nucleotide ADP, a dichloromethylene bridge was grafted between the β/γ phosphate units. Thioether substitution on the 2-position of the purine ring proved beneficial for affinity and selectivity over other P2 subtypes. The introduction of a lipophilic substituent onto the N6 atom increased the affinity. However, larger side chains (approximately four carbon atoms and longer) led to an

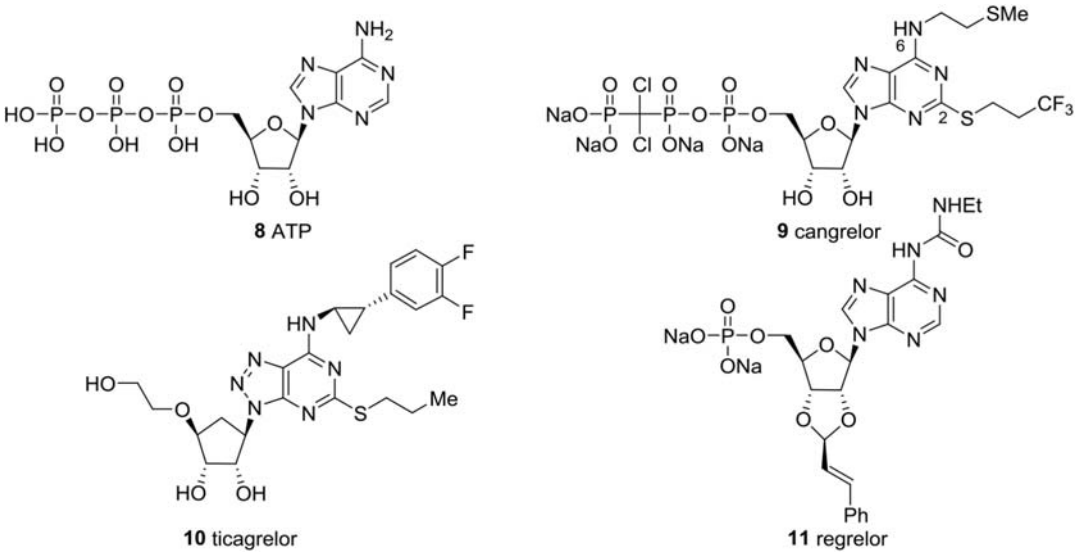

Fig. 6 From ATP to cangrelor (tetrasodium salt) and ticagrelor; the AMP derivative regrelor (disodium salt).

undesired prolonged half-life in dogs. Finally, the optimized combination of substituents resulted in cangrelor (AR-C69931MX), which showed high antiplatelet activity on human platelets (Fig. 6).[88] An infusion during PCI intervention was chosen as primary treatment modality based on the favorable i.v. profile of cangrelor with both its rapid onset (3–6 min) and offset (30–60 min) of action. In large phase III clinical studies (the CHAMPION trials), cangrelor significantly decreased the number of ischemic events during PCI.[89] Despite the minor prolongation of bleeding time at maximally effective antithrombotic doses in a dog model, the occurrence of major bleeding in humans was similar to clopidogrel, along with increased rates of minor bleedings. Cangrelor (out-licensed by AstraZeneca to The Medicines Company) became after the FDA and EMA approval in 2015 the latest addition in the armamentarium of antithrombotic agents.

To develop an orally bioavailable ATP analog, efforts were directed to the replacement of the labile and charged triphosphate side chain of ATP by nonacidic groups.[90] Careful optimization of the hydrophobic substituents of the heterocyclic scaffold, that is, propylthioether and *trans*-2-difluorophenyl cyclopropylamine, enhanced the affinity to the $P2Y_{12}$ receptor. The potentially labile ribose sugar unit was replaced by a cyclopentyl carbocycle, and an additional affinity-enhancing nitrogen was introduced in the purine moiety. The clinical candidate, a neutral cyclopentyl-triazolo-pyrimidine analog, is referred to as ticagrelor (AZD-6140; Fig. 6). Originally described as noncompetitive with respect to ADP, the most recent studies showed that ticagrelor displayed surmountable and competitive antagonism against $P2Y_{12}$.[91] Ticagrelor was evaluated clinically in large patient populations (the PLATO trial)[53a] by AstraZeneca and received marketing authorization in 2010 by the EMA and 1 year later by the FDA for the prevention of atherothrombotic events in patients with ACS.[92] In the PLATO trial, ticagrelor showed an increased effectiveness to lower the rate of death from vascular causes, MI, or stroke compared with clopidogrel, albeit with higher incidence of major bleeding unrelated to CABG. Interestingly, ticagrelor was linked to a significant decrease in overall mortality (see Section Importance of selectivity of receptor and ligand). This finding was however not replicated in other studies.[93] Ongoing clinical trials will help to refine the use of ticagrelor in ACS patients.[16d]

An interesting add-on from the AstraZeneca team is the development of an antibody fragment (Fab) as antidote for ticagrelor.[94] The Fab displays a significantly higher affinity (20 pM) for ticagrelor than ticagrelor shows for its target $P2Y_{12}$. The antidote normalizes bleeding in mice treated with ticagrelor. If this finding translates to humans, it will be an important asset for patients undergoing emergency surgeries.

Several groups have described ticagrelor analogs; however, to the best of our knowledge, no clinical development has been reported.[95]

In 2008, Inspire Pharmaceuticals described AMP/ADP nucleotide and dinucleoside polyphosphate analogs as $P2Y_{12}$ antagonists.[96] Some dinucleoside polyphosphates are endogeneously produced and released into extracellular space where they are able to stimulate several P2 receptors. Recently, their binding mode in the $P2Y_{12}$ receptor was proposed based on its X-ray crystal structure (see Section $P2Y_{12}$ X-ray structure and structure-based modeling).[97] In the course of their work, lipophilic substitution of the ribose ring of AMP by a cinnamaldehyde acetal and apolar N6-urea modification provided the potent antagonist regrelor (INS50589, **11**; $IC_{50} = 16$ nM in the ADP-induced platelet aggregation assay with washed platelets),[96] which was further developed as i.v. drug for CABG surgery (Fig. 6). Its clinical phase II was terminated due to bleeding complications.

7.15.5.1.1.2.2 Sulfonylurea/amide derivatives: AZD1283 and elinogrel

A medicinal chemistry program at Portola Pharmaceuticals aiming at novel $P2Y_{12}$ antagonists started with an HTS hit bearing a crucial sulfonylurea moiety. After SAR optimization, elinogrel (PRT-060128, **12**; acquired in 2009 by Novartis) emerged as an

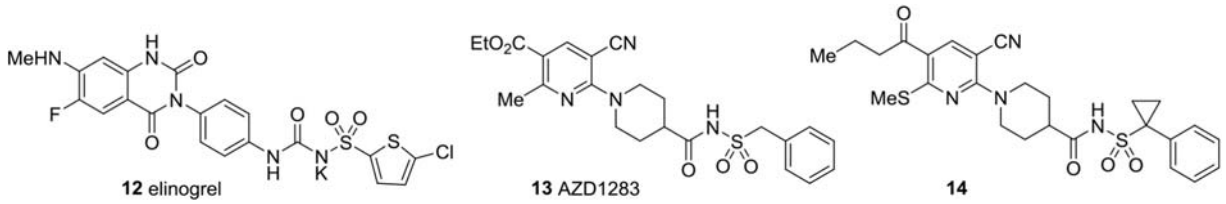

Fig. 7 Elinogrel (potassium salt) with *N*-phenyl quinazoline-2,4-dione and a chlorothiophene subunit connected by the mildly acidic sulfonylurea motif. The acylsulfonamide **13** (AZD1283) and the close derivative **14** with propyl ketone functionality.

in vitro potent ($K_i = 20$ nM) and selective antagonist, showing good activity in the ADP-induced platelet aggregation assay ($IC_{50} = 3–5$ μM) (Fig. 7). It was subsequently developed for both i.v. and oral administration for ACS patients and prevention of secondary thrombotic events,[98] where it has been tested in phase II clinical trials. No public information is available regarding the reasons behind the discontinuation of elinogrel by Portola Pharmaceuticals in 2012.

In 2013, AstraZeneca disclosed the optimization of ethyl 6-aminonicotinate acyl sulfonamides and the selection of their clinical candidate **13** (AZD1283; Fig. 7).[99] The antithrombotic efficacy was assessed in a modified Folts dog model (cyclic flow reduction model), wherein the femoral artery blood flow is measured after mechanical damage of the endothelium followed by c. 80% stenosis. The therapeutic index (TI) of AZD1283 was calculated from the antithrombotic efficacy (ED_{50}) and from the dose leading to 3.5-fold increased bleeding time ($ED_{BT>3.5}$). AZD1283 ($TI > 10$) compared favorably with clopidogrel ($TI = 2.3$) and ticagrelor ($TI > 5.2$). A cocrystal structure of AZD1283 in $P2Y_{12}$ was recently solved (see Section **$P2Y_{12}$ X-ray structure and structure-based modeling**).[97] The clinical development of AZD1283 was stopped for undisclosed reasons in 2012.

In the course of a follow-up program, AstraZeneca explored bioisosteres for the ester functionality of AZD1283.[100] In particular, enhanced stability was desired as its ethyl ester is converted by esterases into inactive metabolites. The closely related propyl ketone derivative **14** showed multiple advantages over AZD1283 in terms of antiplatelet activity and metabolic stability.[101] However, in the modified Folts model in dogs, full inhibition of platelet aggregation was linked with a significant increase in bleeding time, in sharp contrast to the clean profile of AZD1283. It is speculated that the different binding kinetics might account for the unexpected bleeding side effects seen with compound **14** (Fig. 7).

7.15.5.1.1.2.3 Evolution of the Berlex lead compound

In 2007, scientists from Berlex disclosed the antiplatelet effect of the reversible antagonist **15** (BX-667) and its biologically active metabolite **16** (BX-048; Fig. 8).[102] BX-667 inhibits ADP-induced platelet aggregation in human whole blood ($IC_{50} = 97$ nM)

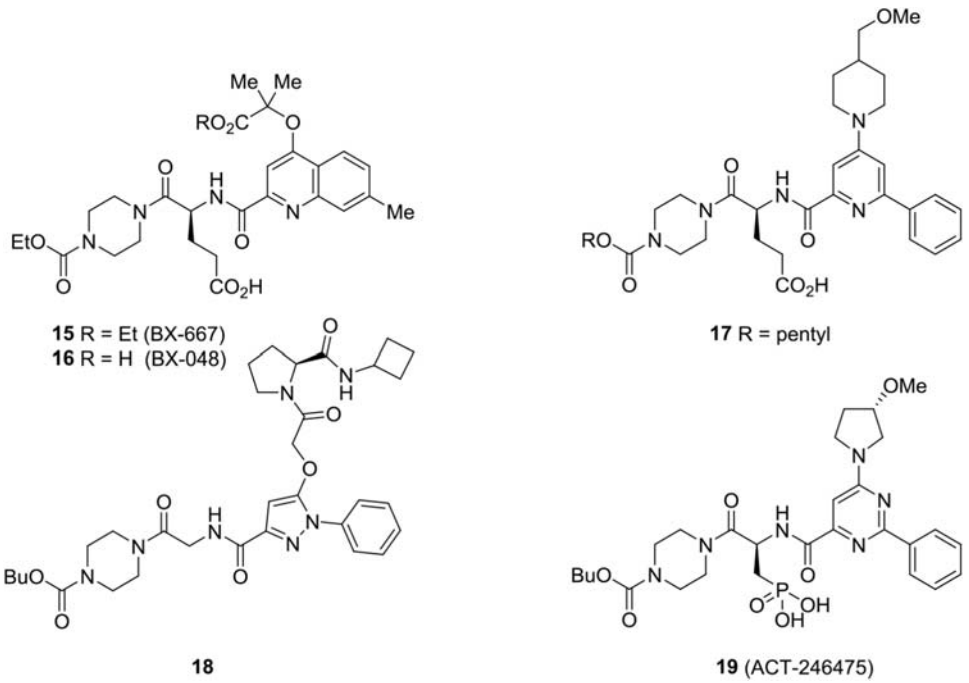

Fig. 8 Medicinal chemistry efforts around the Berlex lead structures (**15** and **16**): representative compounds from Pfizer (**17**), Sanofi (**18**), and Actelion (**19**).

with negligible effect on collagen-induced platelet activation. Both compounds were also able to inhibit AA-induced platelet aggregation albeit at much higher concentrations than those needed after ADP stimulation. Compounds **15** and **16** were studied in three experimental models of thrombosis (A-V shunt model, rat carotid artery injury ($FeCl_3$) model, and dog cyclic flow model), and a wider therapeutic index (less bleeding at maximal efficacy) was achieved with BX-667 compared with clopidogrel. Nevertheless, no further development has been reported for either compound.

The quinoline glutamic acid scaffold of BX-667 and BX-048 was the starting point for an intense medicinal chemistry quest by several companies for improved $P2Y_{12}$ antagonists.

Pfizer published a series of papers whereby the quinoline ring of BX-667 was exchanged with either a pyridine or a pyrimidine heterocycle.[103] Relying on a parallel chemistry approach (polymer-assisted solution-phase synthesis), hundreds of derivatives could be efficiently synthesized. Inhibition of platelet aggregation was assessed in a human PRP assay with ticagrelor as benchmark. The pharmacokinetic profile and the potency of the compounds could be modulated by varying the 4-position of the pyridine. In contrast to most tested substituents, the methoxymethylene-substituted piperidine moiety in compound **17** led to a low clearance in the rat via excretion as unchanged drug in the bile. Compound **17** was found to be orally efficacious in the rat $FeCl_3$ model, where it dose-dependently prevented thrombus formation (Fig. 8).

In 2014, Sanofi reported a detailed SAR study where the glutamic acid piperazine lead structure from Berlex BX-667 was kept constant and the quinoline was replaced by a phenylpyrazole (Fig. 8).[104] To strengthen their investigation, a homology model of $P2Y_{12}$ based on the related $CXCR_4$ receptor was built for structure-based alignment with the Berlex compound. The 5-position of the pyrazole was extensively optimized, and an *N*-acetyl (*S*)-proline cyclobutyl amide moiety was found to deliver highly active antagonists in the glutamic acid series. Surprisingly, with this specific pyrazole substituent, the amino acid could be reduced to a simple glycine spacer while keeping the activity both in the binding assay (**18**, $K_i = 7.7$ nM) and in the ADP-induced platelet aggregation assay in human PRP (**18**, $IC_{50} = 30$ nM).

Actelion recently reported a knowledge-based approach building on the combination of the Berlex compound and a substructure of ticagrelor.[105] Optimization of the substituent at the 4-position of the pyrimidine ring as a replacement of the Berlex quinoline provided compounds with promising biological activity. The glutamic side chain was optimized leading to phosphonate-based antagonists with excellent ex vivo potency in the platelet aggregation assay in human plasma. Specifically, compound **19** (ACT-246475) was profiled to be a reversible and potent $P2Y_{12}$ antagonist with an exceptional selectivity profile (Fig. 8).[42c] ACT-246475 inhibits ADP-induced platelet aggregation in vitro with an apparent IC_{50} of 14 nM. To the best of our knowledge, ACT-246475 currently represents the most potent and selective $P2Y_{12}$ antagonist available. In addition, in a rat thrombosis model, direct comparison of ACT-246475 with clopidogrel, at comparable antithrombotic efficacy, confirmed a clearly improved blood loss profile. Furthermore, preclinical profiling of ACT-246475 confirmed an in vitro and in vivo safety profile that supported further evaluation in humans.[106]

7.15.5.1.1.2.4 Miscellaneous scaffolds

An HTS campaign at Sanofi, resulting in a low micromolar range hit, was the starting point to identify a new series for a clopidogrel follow-up program[107] (Fig. 9). Thorough optimization of the hit **20** yielded the following notable structural improvements: (i) introduction of a ketone motif as metabolically stable ester replacement on the pyrazole, (ii) rigidification and scaffold hopping by switching from an ortho-aminoanisole moiety to an indole ring, (iii) substitution of the indole ring with an optimized carboxamide instead of carboxylic acids to lower the interspecies differences in biological activity and to improve oral bioavailability, and finally (iv) removal of a mutagenic anilinic structural element. The resulting preclinical candidate **21** (SAR216471) is highly potent

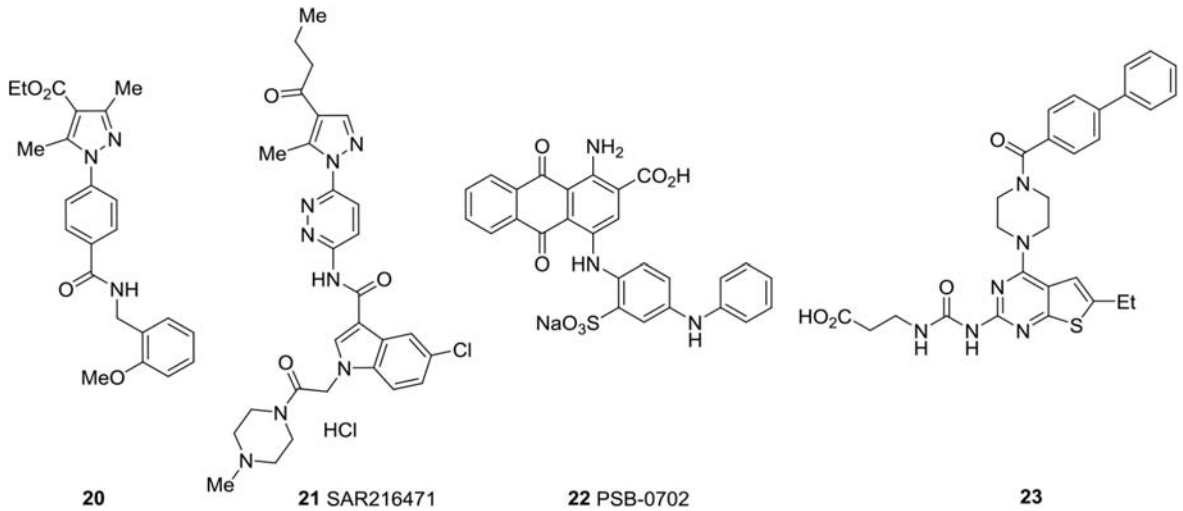

Fig. 9 From the HTS hit **20** to SAR216471 (**21**, Sanofi), PSB-0702 (**22**, University of Bonn), and thienopyrimidine **23** (Pfizer).

in the binding ($IC_{50} = 17$ nM) and in the aggregation assays ($IC_{50} = 108$ nM in human PRP) and has moderate bioavailability in rat but sustained inhibition of platelet aggregation in vivo. The rat tail bleeding experiment revealed a favorable safety profile with the highest therapeutic index in comparison with clopidogrel, prasugrel, and ticagrelor.[108] No recent clinical development has been reported for SAR216471.

The University of Bonn described anthraquinone-derived $P2Y_{12}$ antagonists, thus further demonstrating the capacity of the receptor to accommodate diverse and large ligands.[109] This compound class originates from the dye "reactive blue 2," which interacts with various nucleotide binding proteins, including the P2 family. The most active analog of this series, compound **22** (PSB-0702), exhibits a K_i value of 21 nM and is at least 100-fold selective versus other P2 receptor subtypes (**Fig. 9**).

Potent thienopyrimidines were described by Pfizer and in a patent by Millennium.[110] As it has been observed previously with many compound series, protein binding of the antagonist can lead to a decrease in its activity when measured in human PRP. In the Pfizer thienopyrimidines, as exemplified by compound **23,** highly polar and acidic groups were required to balance out the strong protein binding effect of the biphenyl group (**Fig. 9**).

7.15.5.1.1.3 $P2Y_{12}$ X-ray structures and structure-based modeling

In 2014, X-ray crystal structures of the $P2Y_{12}$ receptor were solved in complex with three different ligands: (i) the non-nucleotide antagonist **13** (AZD1283; **Fig. 7**); (ii) the full agonist 2MeSADP (**24b**; **Fig. 10**; $EC_{50} = 0.3$ nM), which is a more potent close analog of ADP (**24a**, $EC_{50} = 69$ nM); and (iii) the corresponding ATP derivative and partial agonist 2MeSATP.[97,111] The receptor structures in complex with antagonist **13** (AZD1283) or agonists (2MeSADP and 2MeSATP) show markedly different conformations, with an inward shift of two transmembrane helices (TM6 and TM7) toward the agonists making their binding pocket more contracted. In addition, the agonist-bound pocket is closed by an extracellular loop forming a lid through polar interactions. In contrast, binding of the non-nucleotide antagonist AZD1283 prevents lid closure. Two distinct binding pockets could be visualized: pocket 1 (bordered by TM3–7) accommodates the earlier described ligands in different orientations. Thus, AZD1283 and 2MeSADP overlap partially, with superimposition of their nicotinate and adenine moieties, and their aromatic ring undergoes π–π stacking interactions with Tyr105. Pocket 2 (bordered by TM1-3/7) is empty in the AZD1283 structure and may bind diadenosine tetraphosphate and the metabolites of the thienopyridines.

We can anticipate that the availability of structural data of receptor–ligand complexes will reinvigorate the structure-based drug design effort on the $P2Y_{12}$ receptor. Modeling based on these structures has already proposed different binding modes of several ligands described in the preceding text.[112] Moreover, the possibility to target both the orthosteric and allosteric binding sites opens up rich avenues for future drug development programs.

7.15.5.1.1.4 Importance of selectivity of receptor and ligand

Recent studies have challenged the previously restricted expression pattern of $P2Y_{12}$, which is now no longer believed to be confined to platelets and subregions of the brain.[71] This finding may be reflected by numerous extraplatelet effects of $P2Y_{12}$ receptor antagonists described in recent clinical trials.[113] In this context, inhibition of $P2Y_{12}$ on neurons is one of the proposed hypotheses for the observed dyspnea side effect during ticagrelor treatment.[114] Besides the expression pattern of the receptor, the target selectivity of the antagonists plays an important role in the therapeutic efficacy and safety. Comparison of clopidogrel and prasugrel with $P2Y_{12}$ knockout mice suggests that some of the excess bleeding associated with thienopyridines may be due to off-target effects.[69] For ticagrelor, the beneficial effect on mortality observed in the PLATO trial could be due in part to its effect on the adenosine concentration. More specifically, ticagrelor has been found to inhibit the cellular uptake of adenosine, likely by inhibition of equilibrative nucleoside transporter 1 (ENT1). Thus, an additional antiplatelet effect by ticagrelor is mediated by the increase in adenosine levels.[115]

In summary, the fine-tuning of both target selectivity and beneficial polypharmacology represents a great challenge that may lead to new $P2Y_{12}$ antagonists with improved therapeutic window.

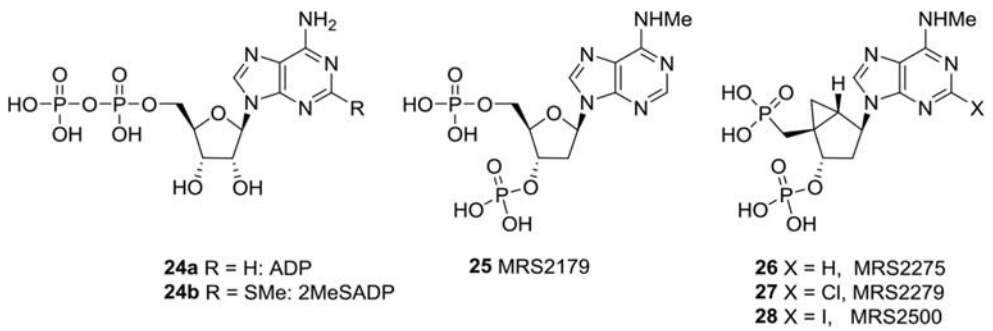

Fig. 10 Endogenous ligand ADP (**24a**) with the closed ADP analog 2MeSADP (**24b**) and adenine nucleotide-based $P2Y_1$ antagonists (**25**–**28**).

7.15.5.1.1.5 Future prospects of $P2Y_{12}$ antagonists

One major unmet goal in $P2Y_{12}$-based therapies is to determine for all patients the optimal therapeutic window in order to maximize therapeutic efficacy while minimizing safety issues (e.g., bleeding).[73a] An important aspect is the level and mode (reversible vs. irreversible) of $P2Y_{12}$ inhibition and its link to excessive bleeding.[85] Will it be therefore possible with newer agents to keep the high level of antiplatelet activity of ticagrelor and decrease its bleeding risk? In combination with a once-daily oral profile and optimized target selectivity, this challenging goal would potentially represent a significant step forward. The duration of therapy, use of dual or triple therapy (e.g., with aspirin and/or an additional antiplatelet agent), and stratification of patients (e.g., diabetes patients) can still be optimized with the current treatment modalities. Finally, although prior trials to improve efficacy, for instance, by testing the platelet reactivity to identify patients with clopidogrel resistance, were so far inconclusive, new concepts in individualized therapy are still being proposed.[116]

7.15.5.1.2 $P2Y_1$ antagonists

In 2001, Léon et al. demonstrated that the deletion of $P2Y_1$ using a $P2Y_1$ knockout mouse led to an antithrombotic effect in a model of thrombin-dependent acute thromboembolism. Similarly, the selective antagonist **25** (MRS2179; **Fig. 10**) showed antithrombotic efficacy in the same model using wild-type mice.[117] Moreover, MRS2179 potentiated the antithrombotic effect of clopidogrel in several in vivo models.[118] Therefore, the $P2Y_1$ receptor represents an attractive target for antiplatelet compounds, alone or in combination with a $P2Y_{12}$ antagonist.

7.15.5.1.2.1 Adenine nucleotide-based antagonists

Several research groups described the discovery of a series of adenine nucleotide-based $P2Y_1$ receptor antagonists that inhibit ADP-induced platelet aggregation, such as **25** (MRS2179), **26** (MRS2275), and **27** (MRS2279; **Fig. 10**).[119] The chemical and enzymatic stability of these tool compounds is suboptimal, which limits their usefulness as potential oral drugs.

7.15.5.1.2.2 Non-nucleotide-based antagonists

7.15.5.1.2.2.1 Bristol-Myers Squibb (BMS)

In search for novel $P2Y_1$ antagonists, scientists at BMS performed an HTS with >1 million compounds using a binding assay with [^{33}P]-2MeSADP as ligand.[120] This campaign uncovered the diarylurea **29** showing high affinity for $P2Y_1$ ($K_i = 75$ nM) and a selectivity >1000-fold against $P2Y_{12}$ (**Fig. 11**). Initial SAR led to the discovery of **30** (BPTU; $K_i = 6$ nM), which showed potency in the ADP-induced platelet aggregation assay in human PRP ($IC_{50} = 2.1$ μM). BPTU provided a significant reduction in thrombus weight in a rat arterial thrombosis model with a limited effect on bleeding. The antithrombotic and bleeding profiles of BPTU were

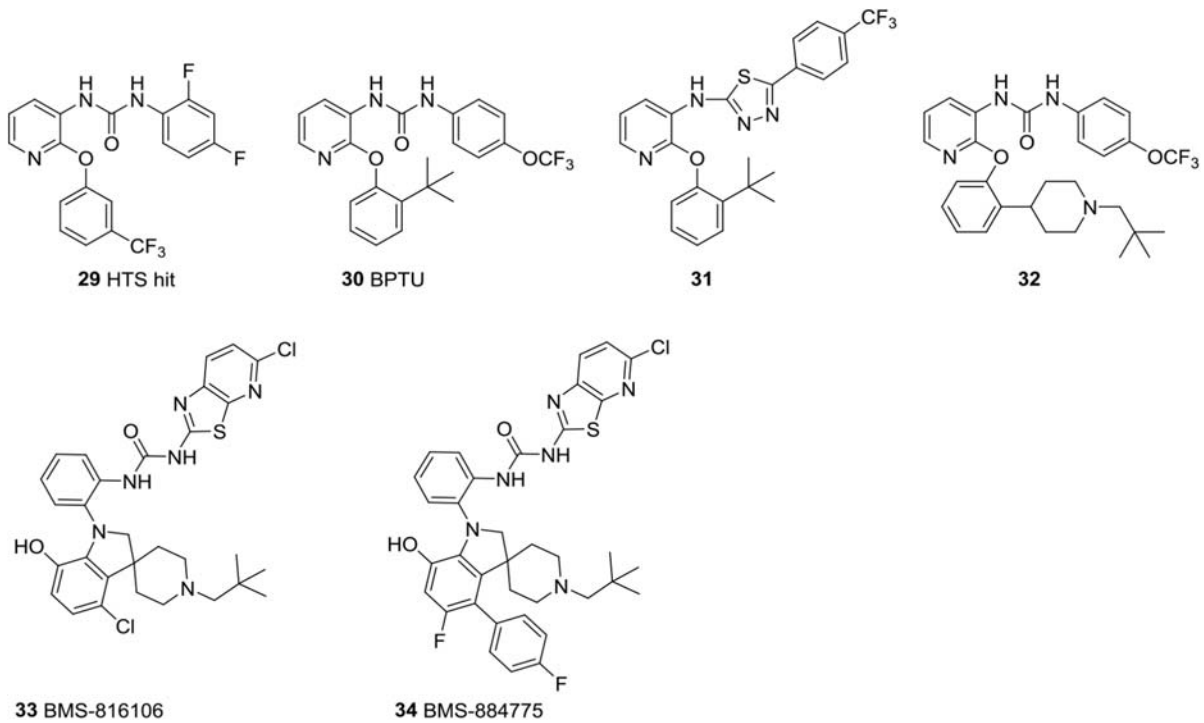

Fig. 11 BMS $P2Y_1$ antagonist program: HTS hit **29** leading to **30** (BPTU), compound **31** containing a urea surrogate, compounds with a basic amino group **32**, **33** (BMS-816106), and **34** (BMS-884775).

favorable in comparison with clopidogrel. However, the compound suffered from low aqueous solubility and high protein binding in human plasma, the latter likely due to a high lipophilicity.

Additional SAR studies targeted the low aqueous solubility of BPTU. Since the urea motif may be detrimental, surrogates were identified, such as aminothiazole or aminothiadiazole moieties[121] (**31**, $K_i = 7$ nM). Alternatively, the introduction of polar groups, such as basic amines, gave compounds such as **32,** which showed a much higher aqueous solubility while retaining affinity and potency ($K_i = 16$ nM and $IC_{50} = 2.4$ μM in human PRP).[122]

In parallel, structural modifications to constrain the tert-butylphenoxy-pyridine region of BPTU were explored, culminating with the introduction of an indoline ring combined with a spiropiperidine moiety.[123] Additional SAR optimization finally led to **33** (BMS-816106), which showed high activity in the FLIPR and platelet aggregation assays (IC_{50} values of 0.12 and 130 nM, respectively), good solubility, and promising PK parameters.[124] The chlorine atom in para position to the solubilizing hydroxyl group decreased the electron density of the 7-hydroxyl indoline ring and led to a high liver microsomal stability and a low level of glutathione addition to the hydroxyindoline moiety. BMS-816106 demonstrated a robust antithrombotic effect with an improved bleeding profile compared with clopidogrel in rat.

Further derivatization of the indoline ring culminated in the discovery of BMS-884775 (**34**, IC_{50} values of 0.12 and 180 nM in FLIPR and platelet aggregation assays, respectively).[125] Its volume of distribution was low, which might reduce potential off-target effects since $P2Y_1$ is expressed widely in the body. BMS-884775 demonstrated antithrombotic efficacy with less bleeding compared with prasugrel in the rabbit models of electrically induced carotid artery thrombosis and cuticle bleeding. To the best of our knowledge, no clinical development of these two advanced molecules has been reported.

7.15.5.1.2.2.2 Pfizer and GlaxoSmithKline (GSK)

An HTS campaign at Pfizer afforded a series of moderately potent diarylurea hits very similar to the BMS hit **29**. Extensive optimization led to the identification of compound **35** ($K_i = 90$ nM), which showed efficacy in a rat ferric chloride arterial thrombosis model (**Fig. 12**).[126] In a similar approach, scientists at GSK reported compounds **36** and **37** as lead $P2Y_1$ antagonists (K_i values of 70 and 140 nM, respectively).[127]

7.15.5.1.2.3 Biologics

Scientists at Western University, Pomona, postulated that an antibody targeting the binding site of ADP within the second extracellular loop of $P2Y_1$ could be used as a function-blocking agent for platelet activation.[128] To test this hypothesis, a rabbit polyclonal antibody was generated against the second extracellular loop of human $P2Y_1$, abbreviated as EL2Ab. It competitively displaced [^{3}H]-MRS2500 ([^{3}H]-**28**; **Fig. 10**) from $P2Y_1$ and dose-dependently inhibited ADP-induced human platelet aggregation in vitro. In a ferric chloride carotid injury thrombosis model in mice, EL2Ab prolonged the time to thrombus occlusion, similarly to MRS2500 (**28**). However, EL2Ab prolonged the tail bleeding in mice, indicating that it impairs hemostasis. Further characterization of the therapeutic window of this approach is required.

7.15.5.1.2.4 Dual $P2Y_1$/$P2Y_{12}$ antagonists

A team at the Boston Children's Hospital reported the discovery of dual $P2Y_1$/$P2Y_{12}$ antagonists based on diadenosine 5′, 5‴-P^1,P^4-tetraphosphate (Ap_4A), an endogenous signaling molecule found in platelet dense granules.[129] Interestingly, compound **38** (**Fig. 12**) inhibited ADP-induced platelet aggregation at a concentration much lower than that required to inhibit either $P2Y_1$ or $P2Y_{12}$ activity, suggesting a synergistic effect. In contrast to Ap_4A, which has a half-life of a few minutes in human blood,[130] compound **38** retained molecular and functional integrity for at least 3 h.[131] The authors conclude that such compounds would cause a rapid onset of platelet inhibition with a rapid clearance from the bloodstream and consequently may be of use when emergency surgery is needed.

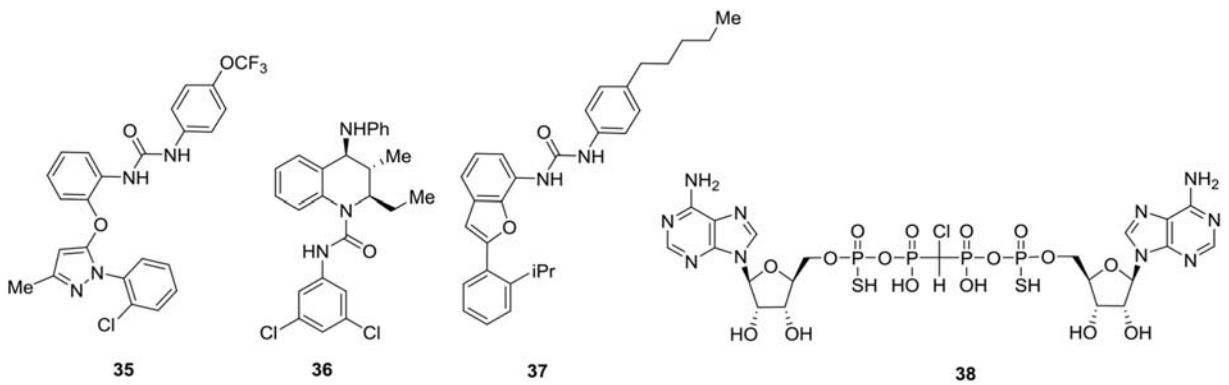

Fig. 12 $P2Y_1$ antagonists reported by Pfizer (**35**), GSK (**36**, **37**), and Boston Children's Hospital (**38**).

7.15.5.1.2.5 X-ray structures

X-ray crystal structures of the human $P2Y_1$ receptor in complex with the nucleotide analog MRS2500 (**28**) or with the nonnucleotide antagonist BPTU (**30**) have been recently solved.[132] MRS2500 is located in a pocket close to the extracellular surface, which is lined up by amino acids from the N-terminus, helices VI and VII, and the extracellular loop 2. In contrast, the $P2Y_1$-BPTU crystal structure surprisingly reveals that BPTU binds at the lipid interface of the transmembrane domain instead of interacting within the helical bundle. The superficial binding pocket, formed by helices I–III and the extracellular loop 1, accommodates BPTU through hydrophobic interactions with a single H bond to the urea carbonyl functionality. Although MRS2500 and BPTU bind to distinct sites in $P2Y_1$, these two ligands stabilize the receptor in similar inactive conformations. The existence of an external hydrophobic binding site suggests that the entry of the allosteric BPTU antagonist occurs through the lipid membrane. This observation opens up new opportunities to target novel allosteric sites outside of the canonical ligand binding pocket.

7.15.5.1.2.6 Summary

Based on in vivo data generated in thrombosis and bleeding models, targeting the $P2Y_1$ receptor represents a relevant strategy for an alternative or a complementary treatment to current antiplatelet drugs. Unfortunately, as of today, the few ongoing drug discovery programs failed to deliver small-molecule $P2Y_1$ antagonists for clinical development. The broad tissue distribution of the receptor and the lack of clinical data represent significant hurdles for the validation of $P2Y_1$ as an antiplatelet target.

7.15.5.1.3 $P2X_1$ antagonists

Only few $P2X_1$ antagonists have been reported.[133] Most are derived from suramin (**39**), a polysulfonated drug used in the treatment of African river blindness (onchocerciasis) and African trypanosomiasis (sleeping sickness). In this context, polysulfonate **40** (NF449) so far represents the most potent and selective antagonist of $P2X_1$ (Fig. 13).[134] In a mouse model of thromboembolism, the chemical probe NF449 decreased intravascular platelet aggregation without prolongation of the bleeding time.[135]

7.15.5.2 Protease-Activated Receptor (PAR) Antagonists

7.15.5.2.1 PAR-1 antagonists

7.15.5.2.1.1 Mechanism of action

In addition to its pivotal role in the coagulation cascade, thrombin directly stimulates platelets via proteolytic activation of specific GPCRs called protease-activated receptors (PARs).[136] Of the four PAR subtypes, only PAR-1 and PAR-4 are expressed on human platelets and only PAR-1 is activated at low thrombin concentrations. Thrombin docks through its positively charged anion binding exosite I to two regions located in the N-terminus of PAR-1, the hirudin-like domain ($K^{51}YEPF^{55}$) and the anionic cluster ($E^{57}DEE^{60}$).[137] Subsequently, thrombin activates PAR-1 by specifically cleaving the N-terminus of the receptor, thus exposing a new N-terminal peptide that begins with the sequence $S^{42}FLLRN^{47}$. This new N-terminus acts as a tethered peptide agonist that binds intramolecularly to the transmembrane core of the receptor, thereby initiating conformational changes and an intracellular signaling cascade. This irreversible "self-activation" of PAR-1 translates into a high local concentration of the tethered agonist peptide (estimated to be 0.4 mM), which is a challenge for the development of high potency antagonists.

Since a PAR-1 antagonist would selectively block the thrombin-mediated platelet activation without inhibiting the fibrin formation or platelet activation by other activators, such as ADP, TXA_2, and collagen, a PAR-1 antagonist might achieve potent antiplatelet activity compared with aspirin and ADP antagonists. Alternatively, a PAR-1 antagonist administered in combination with another antiplatelet agent might lead to higher efficacy in reducing recurrent thrombotic cardiovascular events in ACS patients.

An extensive review enumerating PAR-1 antagonist programs was published in 2006.[138] Therefore, in this article, we will concentrate on recent data and activities, with emphasis on the discovery of vorapaxar, currently, the only approved PAR-1 antagonist.

7.15.5.2.1.2 Vorapaxar (SCH-530348)

Vorapaxar is a first-in-class orally active PAR-1 antagonist discovered by scientists at Schering-Plough and later on developed by Merck. It originated from an HTS performed at Schering-Plough that identified a racemic synthetic analog (±)-**42** of the natural

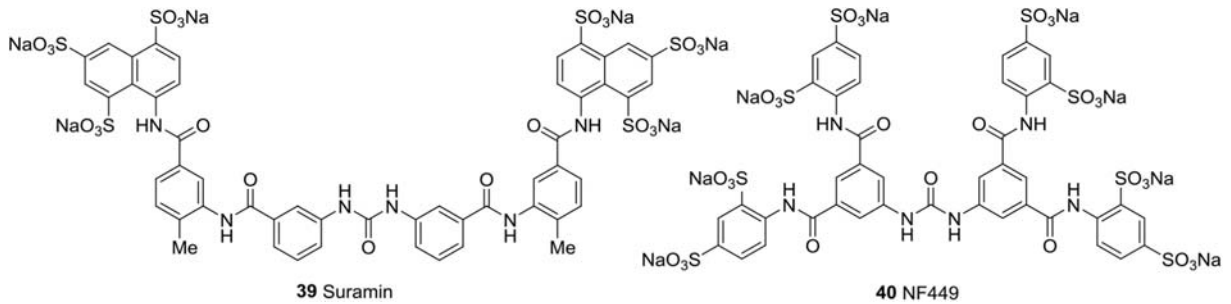

Fig. 13 The $P2X_1$ antagonists suramin and NF449.

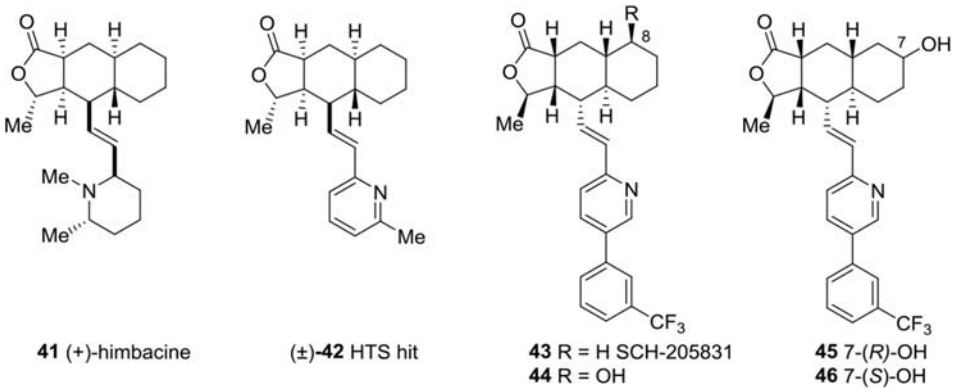

Fig. 14 Racemic HTS hit (±)-**42** derived from (+)-himbacine (**41**) and the ent-himbacine series **43**–**46**.

product (+)-himbacine (**41**) as a hit for the PAR-1 antagonist program (Fig. 14).[139] Optimization of the *ent*-himbacine series started with the pyridine ring and unraveled SCH-205831 (**43**) with a K_i of 2.7 nM against PAR-1.

SCH-205831 showed high oral bioavailability in rat and monkey as well as complete and sustained inhibition of platelet aggregation after a 3 mg/kg oral administration in an ex vivo cynomolgus monkey model. Metabolic profiling revealed three monohydroxylated metabolites **44**–**46** with high circulating levels in several animal species.[140] Further in vivo studies suggested an autoinduction pattern for the hepatic enzymes that might not allow the adequate drug exposure needed for the toxicology studies. Consequently, the development of SCH-205831 was stopped.

The scientists at Schering-Plough adopted two concepts to improve upon **43**. The first approach was to further optimize the structure of the metabolites themselves. The observed low clearance of metabolite **44** in the rat was possibly due to the steric hindrance around the hydroxyl group, which would prevent efficient conjugation and excretion. Therefore, varying the position of the hydroxyl moiety could lead to an analog with higher clearance. In the second approach, the metabolically labile positions 7 and 8 of SCH-205831 were blocked to force the metabolism at alternative sites. The outcome of these efforts was the selection of **45**, devoid of the drawbacks linked to liver enzyme induction. Compound **45** showed a K_i of 11 nM against PAR-1 in the binding assay. It was threefold more potent in the cynomolgus monkey ex vivo platelet aggregation inhibition model than its prototype **43** with an efficacious oral dose of 1 mg/kg. However, an unacceptable off-target activity at the CB2 receptor was observed later in a GPCR counter-screen ($K_i = 38$ nM). The Schering team further optimized the heteroaryl region, that is, the pyridyl ring and its substitution pattern, and in parallel, heteroatoms were incorporated into the C-ring with the goal to modify its metabolic pattern and to increase the overall polarity of the compounds (Fig. 15).[141]

Compound **47** ($IC_{50} = 25$ nM in the binding assay) showed complete inhibition of platelet aggregation at a 1 mg/kg oral dose up to 6 h in the cynomolgus monkey model, comparable with **45**. Nevertheless, considerable amounts of hydroxylated lactol metabolites **48** were quantified in monkey plasma, which led to the termination of this series. Decahydroisoquinoline analogs, in particular ethyl carbamate **49**, showed promising in vitro binding affinities against PAR-1 ($K_i = 4.5$ nM). In the ex vivo platelet aggregation inhibition model in cynomolgus monkeys, **49** exhibited excellent efficacy at a 3 mg/kg oral dose, still inhibiting platelet aggregation by 70% at 24 h. More importantly, contrary to SCH-205831 and **47**, no major hydroxylated metabolite was found in monkey plasma and the metabolic profile of **49** proved to be clean.

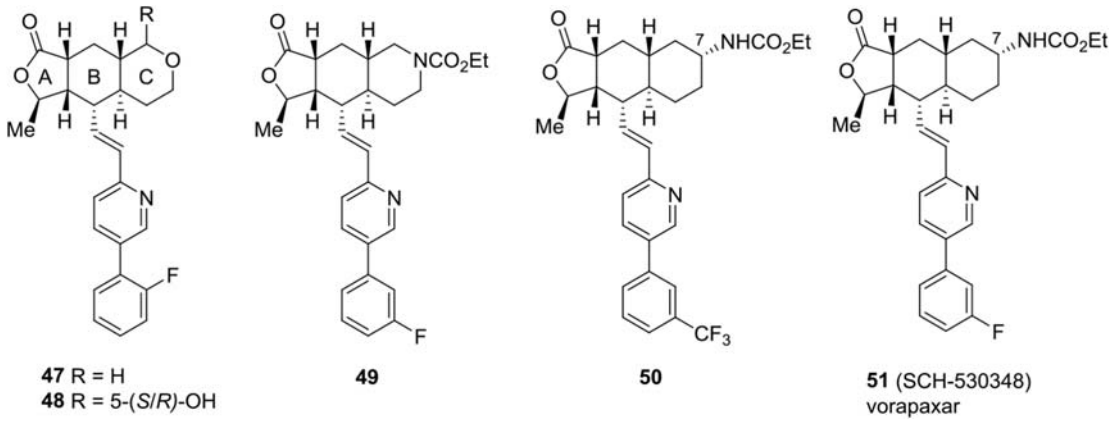

Fig. 15 Further modifications of the C-ring leading to vorapaxar.

A further modification of the C-ring was the replacement of the 7-OH group present in compound **45** by a carbamate group.[142] The optimization of the carbamate chain and of the pyridyl aryl substituent culminated in compounds **50** and **51** displaying similar binding affinity and impressive efficacy in the ex vivo platelet aggregation inhibition model in cynomolgus monkeys, that is, 100% inhibition at 0.1 mg/kg oral dose with 24 h duration. Based on a lower lipophilicity compared with **50** (F-phenyl vs. CF_3-phenyl), compound **51** (SCH-530348, vorapaxar) was further developed in preclinical and clinical studies.

Vorapaxar is a reversible, competitive antagonist with a dissociation half-life of about 20 h allowing effective competition against the tethered ligand. The K_i was 8.1 nM against PAR-1 in the binding assay. The compound showed potent inhibition of thrombin-induced platelet aggregation ($IC_{50} = 47$ nM), whereas no inhibition of platelet aggregation induced by other agonists such as ADP, collagen, and a standard TXA_2 mimetic (U46619) was observed. Vorapaxar was inactive in the PAR-2, PAR-3 binding, and PAR-4 functional assays.

A high-resolution crystal structure of vorapaxar bound to human PAR-1 was reported in 2012.[143] The binding pocket is superficial with a small surface exposed to the aqueous solvent. Vorapaxar may access the binding pocket through the lipid bilayer, possibly between TM6 and TM7, similarly to retinal and S1P with rhodopsin and $S1P_1$, respectively. Despite molecular dynamics simulations and the knowledge of the key amino acids influencing agonist peptide affinity, the mechanism of activation of PAR-1 remains poorly understood.

Vorapaxar was approved in the United States in 2014 for the reduction of thrombotic cardiovascular events in patients with a history of MI or peripheral arterial disease (PAD).[144] In 2015, the drug was approved in the EU for the reduction of atherothrombotic events in adult patients with a history of MI. Vorapaxar is formulated in a 2.5 mg once-daily tablet and is given in combination with aspirin and/or clopidogrel. A black box warning was issued by the FDA regarding an increased bleeding risk in patients with a history of stroke, TIA, intracranial hemorrhage, or active pathological bleeding. Approval of vorapaxar was based on two phase III trials, the TRA2°P-TIMI50 study in patients with MI, PAD, or ischemic stroke and the TRACER study in NSTEMI ACS population.[145] Overall, vorapaxar on top of standard antiplatelet therapy (i.e., aspirin and $P2Y_{12}$ antagonist) significantly reduced the risk of cardiovascular death or ischemic events in patients with a history of MI or ischemic stroke or PAD. Nevertheless, it is associated with an increased risk of bleeding, including serious and potentially fatal bleeding events. Vorapaxar is rapidly and fully absorbed after oral administration in humans, and 80% inhibition of PAR-1 is achieved after one week of treatment at the recommended dose.[146]

The team at Merck is actively searching for follow-up molecules.[147] Notably, efforts addressing vorapaxar's low aqueous solubility led to the discovery of SCH-602539 (**52**; **Fig. 16**).[148] Other vorapaxar analogs were reported by a research group in Korea in collaboration with LG Life Sciences whereby the tricyclic ring was replaced by a bicyclic octahydroindene core.[149] For instance, compounds **53** and **54** showed high potency in the radioligand binding assay and in the platelet aggregation assay (**Fig. 16**).

7.15.5.2.1.3 Atopaxar (E-5555, Eisai)

Atopaxar (**55**, E-5555) is a reversible, orally active PAR-1 antagonist discovered by scientists at Eisai (**Fig. 16**). Atopaxar showed an IC_{50} of 19 nM in the binding assay and in vitro inhibited human platelet aggregation induced by thrombin with an IC_{50} value of 64 nM.[150] The antithrombotic property of atopaxar given orally was studied in a model of photochemically induced thrombosis in guinea pigs. Atopaxar at doses of 30 and 100 mg/kg significantly prolonged the time to occlusion of the femoral artery, demonstrating an antithrombotic effect. Atopaxar administered orally at doses of 30, 300, and 1000 mg/kg did not prolong bleeding time in guinea pigs.

Four phase II clinical trials were performed for the oral treatment of ACS and coronary artery disease (CAD). The LANCELOT ACS study demonstrated that treatment with atopaxar was associated with a significant reduction in the early ischemia without a significant increase in major or minor bleeding.[151] Nevertheless, the development of the compound was discontinued in 2012, possibly due to transient dose-dependent transaminase elevation and cardiotoxicity that were observed with the highest doses of atopaxar.

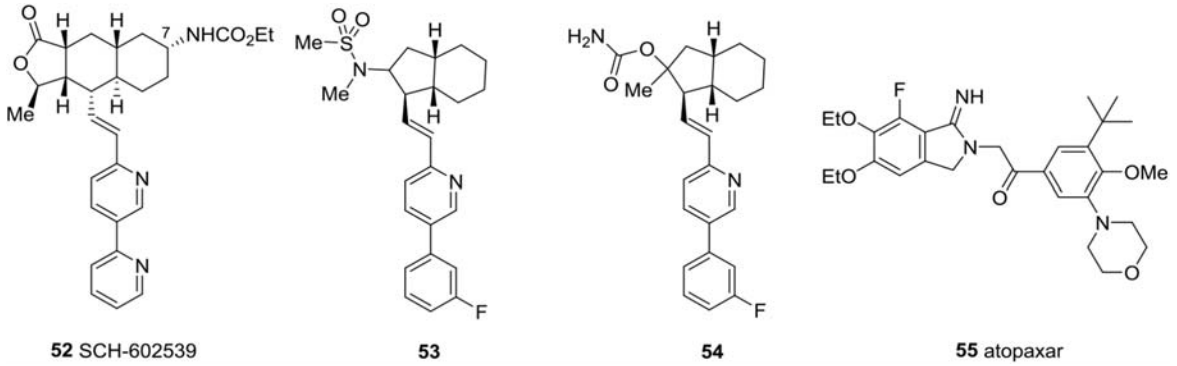

Fig. 16 Modifications of vorapaxar leading to SCH-602539 (**52**) and compounds **53–54;** structure of atopaxar (**55**).

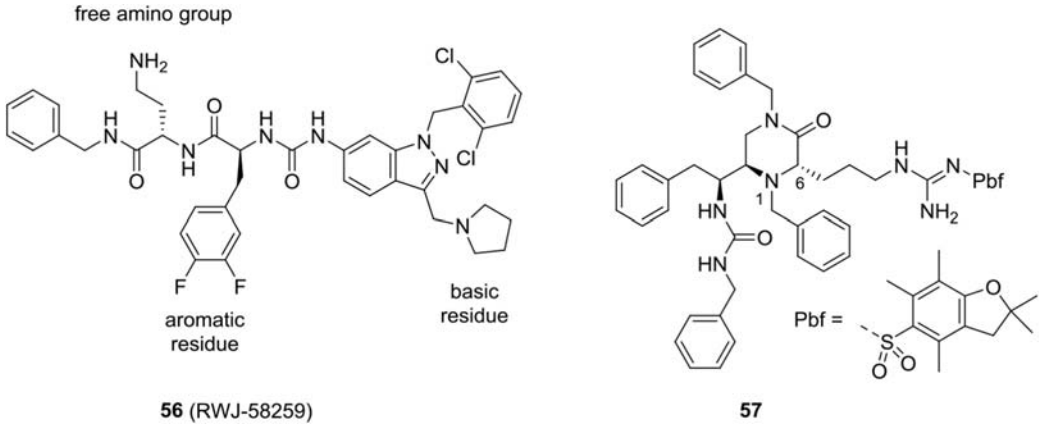

Fig. 17 Peptidomimetic PAR-1 antagonists developed based on the "three-point model," by Johnson & Johnson (RWJ-58259, **56**) and CSIC (**57**).

7.15.5.2.1.4 PZ-128

PZ-128, developed by the Tufts Medical Center (the United States), is a palmitoylated pepducin that targets the cytoplasmic side of PAR-1 and inhibits binding of the G proteins.[152] The structure of PZ-128 mimics the predicted inactive conformation of the third intracellular loop of PAR-1. PZ-128 suppressed platelet aggregation and arterial thrombosis in guinea pigs and baboons and had a synergistic effect in combination with clopidogrel. Full recovery of platelet function occurred after 24 h. Moreover, PZ-128 had no effect on bleeding or coagulation parameters in primates or in blood from patients undergoing PCI. A phase I study is currently evaluating the safety, tolerability, and pharmacodynamics of PZ-128 in patients with vascular disease or with two or more CAD risk factors.

7.15.5.2.1.5 Compounds in early phases

The first generation of peptidomimetic PAR-1 antagonists from Johnson & Johnson was designed based on the SFLLRN motif of the tethered ligand of PAR-1. Three substructures in the tethered peptide were shown to be essential for binding to PAR-1, that is, a free amino group, an aromatic residue, and a basic residue. This "three-point model" eventually led to the discovery of **56** (RWJ-58259) with an IC_{50} value of 150 nM in the binding assay (**Fig. 17**).[153] This compound was not further developed most likely due to low oral bioavailability.

The Spanish research group CSIC used a diversity-oriented synthesis strategy to prepare small libraries with different scaffolds able to orient one to two aromatic and basic groups at variable distances. A first series of peptide-based ureas and thioureas were prepared, including analogs of RWJ-58259.[154] Some protected peptide-based ureas displayed weak antagonistic activity in the TRAP-induced human platelet aggregation assay. In a second step, the pseudodipeptide-based piperazinone scaffold was introduced as to conformationally restrict the urea derivatives.[155] No clear SAR emerged and none of the analogs showed significant antiaggregation activity. The most active compound **57**, wherein the guanidine moiety is protected with a Pbf group, showed 57% inhibition at 150 μM in the TRAP-induced human platelet aggregation assay (**Fig. 17**).

Scientists at Pierre Fabre identified cinnamoyl piperazine and low-molecular-weight imidazole hits as novel PAR-1 antagonists following HTS.[156] Optimization of these two hits delivered compounds **58–60** that were potent in vitro in the FLIPR assay and ex vivo in the agonist peptide SFLLR-induced platelet aggregation assay and displayed high antithrombotic activity in an arteriovenous extracorporal shunt model in rats after i.v. administration (**Fig. 18**).

Among them, **58** (F-16618) was selected based on its reasonable water solubility and DMPK properties and characterized in more depth. F-16618 was found to have strong antithrombotic activity in vivo in several models with no major effects on physiological hemostasis.[157]

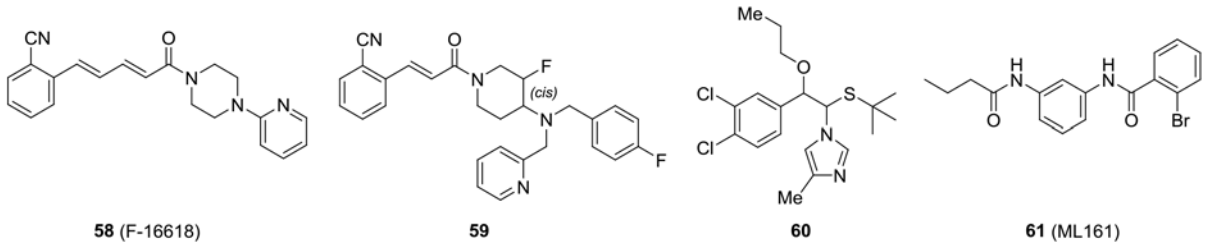

Fig. 18 PAR-1 antagonists developed at Pierre Fabre (**58–60**) and at the Broad Institute of MIT and Harvard (**61**).

Following an HTS screen performed at the Broad Institute of MIT and Harvard, ML161 (**61**) was postulated to inhibit PAR-1 in an allosteric manner (Fig. 18). This feature might provide selective modulation of downstream pathways, thereby potentially decreasing the bleeding risk in the setting of an anti-PAR-1 therapy.[158]

7.15.5.2.1.6 Summary

Despite preclinical and early clinical work indicating that the inhibition of PAR-1 does not interfere with the formation of the first layer of platelets (primary hemostasis) at the damaged vessel wall nor prolong bleeding time, clinical trials of vorapaxar combined with standard antiplatelet therapy showed an increased number of bleeding events. Therefore, current market approval is limited to a clearly defined subpopulation of ACS patients. Additional studies are needed to understand the reasons behind the increase in bleeding and to identify treatment regimens or combinations and patient populations who might optimally profit together with an acceptable increase of bleeding risk. In this regard, two phase IV clinical trials of vorapaxar are reported to be in preparation, on top of prasugrel or ticagrelor, and in patients with diabetes mellitus.

7.15.5.2.3 PAR-4 antagonists

7.15.5.2.3.1 Mechanism of action

PAR-4 lacks the hirudin-like domain found in PAR-1 and has therefore a lower affinity to thrombin. Both receptors differ in their intracellular signaling, which affects their role in thrombus formation. While PAR-1 induces a sharp and short-lived rise in cytosolic calcium and $\alpha_{IIb}\beta_3$ activation, PAR-4 causes a steady and sustained rise in calcium and $\alpha_{IIb}\beta_3$ activation that largely depends on $P2Y_{12}$. PAR-4 and $P2Y_{12}$ heterodimerization may be one mechanism by which the two receptors synergize to stabilize platelet-rich thrombi.[159] An interesting clinical observation was that among patients undergoing CABG surgery, which is associated with excess thrombin generation, bleeding was not increased. To explore the roles of PAR-1 and PAR-4 in thrombin-induced platelet activation, as part of the TRACER study, further studies were conducted in patients receiving vorapaxar or placebo and in healthy volunteers.[160] This study showed that vorapaxar inhibited the PAR-1-mediated component of thrombin-induced calcium mobilization but did not inhibit the PAR-4-mediated delayed increase in intracellular calcium. The authors suggested that under conditions of particularly high thrombin levels, PAR-1-selective antagonists may result in clinical benefits and that the remaining PAR-4 response would help maintain hemostasis. However, the role of PAR-4 in thrombosis and hemostasis is still unclear, and the need for potent and selective PAR-4 antagonists remains.

7.15.5.2.3.2 Clinical and preclinical programs

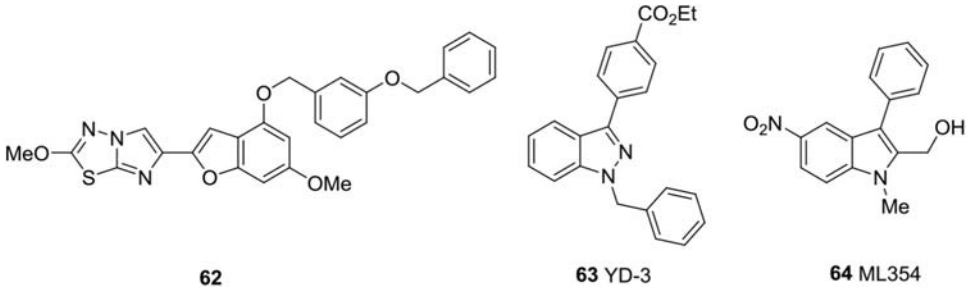
A phase I clinical study of BMS-986120 assessing safety, tolerability, and pharmacokinetics in healthy subjects has been completed. A second phase I single-dose study is planned to evaluate the effect of BMS-986120 on thrombus formation in an ex vivo thrombosis chamber model, in comparison with aspirin and clopidogrel.

The structure of BMS-986120 has not been publicly revealed. Three patents were published in 2013 disclosing PAR-4 antagonists for the inhibition of platelet aggregation.[161] In particular, a dose–response experiment with compound **62** was performed in the cynomolgus monkey electrically induced arterial thrombosis model, demonstrating in vivo antithrombotic efficacy (Fig. 19).[162]

Compound **63** (YD-3), reported by a research group in Taiwan in 2000, was the first nonpeptidic and selective PAR-4 antagonist.[163] A structural similarity search around the indazole moiety was conducted on the Vanderbilt compound repository unraveling **64** (ML354), with a similar binding affinity as YD-3 in the hundred nanomolar range and a selectivity > 100 versus PAR-1 (Fig. 19). This lead is currently under optimization.[164]

7.15.5.3 EP_3 Antagonists

The prostaglandin PGE_2 (**65**) is involved in various physiological processes, such as inflammation, pain, fever, gastroprotection, and labor.[165] The pharmacological effect of PGE_2 is determined by four receptor subtypes EP_{1-4} and by their tissue distribution. In platelets, the proaggregatory effect of PGE_2 on EP_3 is balanced by the antiplatelet activity of EP_2 and EP_4. As PGE_2 is induced under inflammatory conditions, targeting EP_3 should reduce thrombosis at atherosclerotic sites, which constitutes a state of chronic



62 **63** YD-3 **64** ML354

Fig. 19 Patent example (**62**) from BMS, the first nonpeptidic selective PAR-4 antagonist **63** (YD-3) and follow-up compound **64** (ML354).

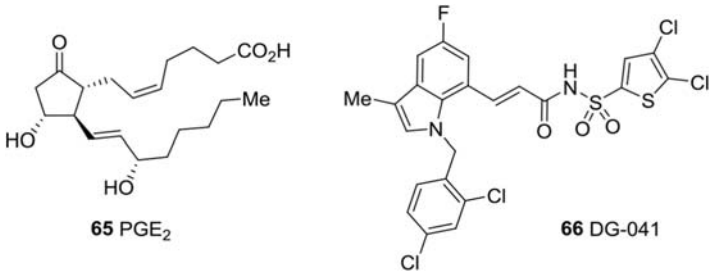


Fig. 20 The natural ligand of EP_3 PGE_2 and the EP_3 antagonist DG-041 (deCODE genetics).

inflammation.[166] In contrast, antagonizing EP_3 should not affect the platelet response to a vessel injury, since collagen and thrombin are the main drivers of platelet activation, while PGE_2 is not induced. As a result, a better safety profile would be expected compared with conventional antiplatelet agents.[167]

deCODE genetics initially identified EP_3 as a target by isolating variants in the gene encoding the EP_3 receptor that significantly increased the risk of PAD.[168] Based on the common pharmacophore of PGE_2 and other early known EP_3 ligands, new EP_3 antagonists were designed bearing a central indole ring as a replacement for the cyclopentanone core of PGE_2 and projecting two arms with apolar anionic and hydrophobic moieties in a 1,7-disubstituted pattern (Fig. 20).[169] Substitution of the indole core with a methyl group and a fluorine atom increased the metabolic stability. Among all tested substituents, the 4,5-dichlorothiophene moiety in combination with the 2,4-dichlorophenyl ring provided adequate in vitro potency along with low plasma protein binding. Compound **66** (DG-041) displayed noncompetitive antagonism of EP_3 due to a slow off-rate and therefore quasi-irreversible binding to the receptor. Importantly, dithiothreitol treatment showed that DG-041 did not behave as a Michael acceptor. Therefore, the formation of a covalent adduct is unlikely. The selectivity against other prostanoid receptors was measured, and no relevant inhibition of the IP receptor was found. As PGE_2 alone does not induce platelet aggregation, the biological activity was measured with collagen as coagonist in an LTA assay. This experimental setting should mimic the specific environment of a ruptured plaque. In different murine models, DG-041 reduced thrombosis without affecting hemostasis.[170] DG-041 was evaluated up to phase IIa clinical trials, but no further development has been reported so far.

7.15.5.4 5-HT_{2A} Antagonists

Following platelet activation, serotonin (5-hydroxytryptamine (5-HT)) is released by dense granules and binds to specific cell surface receptors on neighboring platelets. At least 14 members of serotonin receptors have been described, all belonging to the GPCR family with the exception of the ligand-gated ion channel 5-HT_3.[171] Many receptors are found in the brain, where they mediate the excitatory and inhibitory action of the neurotransmitter serotonin. This has attracted the pharmaceutical community, and as a result, many drugs modulating these receptors have been brought to the market for a variety of indications, such as depression, psychosis, and anorexia.

On platelets, the prominent serotonin receptor is 5-HT_{2A}, which in the brain is the target of psychedelic drugs (e.g., LSD). Serotonin is only a weak activator of platelets and per se is not sufficient to induce platelet aggregation.[172] However, in combination with other agonists, it contributes to the amplification of the platelet response. Preventing the amplification without interfering with the initiation of platelet aggregation should result in a greater separation of bleeding and thrombosis.

Early 5-HT_{2A} receptor antagonists including ketanserin (**67**) and sarpogrelate (**68**) have been shown to reduce restenosis after coronary stenting (Fig. 21). In addition, sarpogrelate (Mitsubishi Tanabe) has been used in some Asian countries for the treatment of PAD. The beneficial effect of 5-HT_{2A} receptor antagonists on the narrowing of arteries could be based on a synergy of an antiplatelet effect, vasodilation, and the inhibition of vascular smooth muscle cell proliferation. So far, serotonin receptor

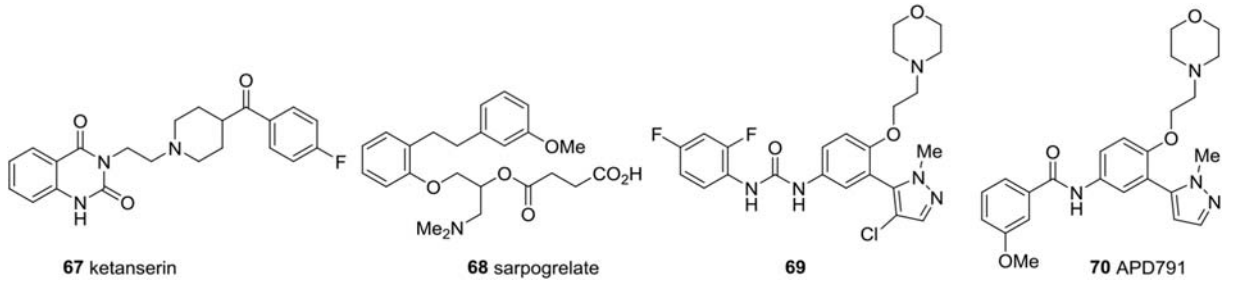

Fig. 21 Ketanserin, sarpogrelate, chloropyrazol **69**, and APD791 (Arena Pharmaceuticals).

antagonists did not achieve FDA approval as antiplatelet agents. The reasons for the challenging development of early-generation antagonists could be the lack of specificity for the 5-HT_{2A} receptor subtype and the complex role of serotonin in many diseases and general homeostasis. Despite positive animal studies, the validity of 5-HT_{2A} as an antithrombotic target for humans has not yet been ascertained and awaits confirmation through clinical trials.[173]

Recently, Arena Pharmaceuticals modified compounds from their own 5-HT_{2A} insomnia program with the goal to improve the selectivity and pharmacokinetic profile of previous 5-HT_{2A} blockers. The discovered functional inverse agonist **69** showed high 5-HT_{2A} selectivity (2700-fold) versus 5-HT_{2C} and low hERG channel inhibition (**Fig. 21**).[174] In a second optimization round, the urea motif was removed to increase the solubility at neutral pH, which led to compound **70** (APD791, temanogrel). In addition to binding assays, compounds were assessed for their antagonistic potential in the serotonin-mediated amplification of ADP-stimulated human platelet aggregation.[175] The low basicity of the morpholine ring of APD791 was key for a reduced hERG interaction. However, the morpholine ring undergoes microsomal ring opening leading to two biologically active metabolites.[176] In the Folts dog model of coronary stenosis, APD791 effectively blocked thrombosis without increasing bleeding time.[177] Despite the short half-life of the clinical candidate APD791 (0.9 h in dogs), the two metabolites may have contributed to the enhanced duration of action (58% inhibition of serotonin-mediated aggregation after 24 h). Finally, limited CNS partitioning in rat was measured, which is beneficial to minimize side effects in the brain. The highly selective and orally active 5-HT_{2A} antagonist APD791 is currently undergoing clinical phase I studies to assess pharmacokinetics, pharmacodynamics, and safety when coadministered with aspirin and clopidogrel.

7.15.5.5 TP Antagonists

The hallmark of platelet activation after adhesion onto collagen is the activation of thromboxane synthesis. PGH_2 is preferentially converted by the thromboxane synthase (TXS) into thromboxane A_2 (TXA_2), which is secreted into the surrounding space of activated platelets (**Fig. 2**).[178] TXA_2 can bind to the thromboxane receptor (TP) on the surface of resting platelets in close proximity. Binding of TXA_2 to TP then triggers signaling through Gq resulting in an elevation of intraplatelet calcium concentrations and hence unleashing further intraplatelet signaling and activation of the platelets.[179]

Blunting of TXA_2 production via inhibition of COX-1 by aspirin is the most successful approach to interfere with atherothrombotic diseases. Alternatively, inhibition of the binding of TXA_2 to its receptor TP was also explored. However, the majority of TP antagonists have been stopped at an early clinical stage due to lack of efficacy and toxicity issues.[180] Terutroban (S-18886, Servier) was the most advanced TP antagonist for antithrombotic therapy. A large phase III clinical trial revealed no benefit for terutroban when compared with aspirin, and its development was terminated. Recently, terutroban analogs have been reported displaying a novel carboxylic group bioisostere.[181] Other TP antagonists currently under clinical investigation have indications outside the antiplatelet field, such as ifetroban (Cumberland Pharmaceuticals), which is in phase II for patients with hepatorenal syndrome. In addition, the inhibitor EV-077/SER150 with TP and TXS dual mode of action (Evolva; outlicensed to Serodus) is evaluated in a clinical phase II study for efficacy in patients with diabetic nephropathy.

7.15.5.6 IP Antagonists

PGI_2 binds to and activates the IP receptor that stimulates AC resulting in elevation of intracellular cAMP.[182] In platelets, activation of IP is essential to keep platelets in a resting state. Elevated cAMP concentrations also lead to the relaxation of smooth muscle cells and thus vasodilation. Therefore, the effect of PGI_2 is twofold: antithrombotic by inhibition of platelet activation and vasodilatory on blood vessels.

PGI_2 is an IP agonist with a very short half-life. Hence, efforts of pharmaceutical research have produced analogs with improved chemical and metabolic stability for use in patients.

7.15.6 Inhibition of Platelet Adhesion and Aggregation

7.15.6.1 Integrin $\alpha_{IIb}\beta_3$ Antagonists

7.15.6.1.1 First-generation antagonists

Stimulation of platelets, independent of the mechanism of activation, always results in the transformation of inactive integrin $\alpha_{IIb}\beta_3$ (glycoprotein GPIIb/IIIa) into its active fibrinogen binding conformation and thus in the initiation of platelet aggregation. This function made $\alpha_{IIb}\beta_3$ a prime target for effective antiplatelet therapy within the pharmaceutical industry for a decade beginning in the late 1980s.[183] Three drugs were successfully developed, all of which are administered intravenously (**Fig. 22**): the human/murine chimeric antibody fragment abciximab (Johnson & Johnson–Eli Lilly) specific for an epitope on the β_3 subunit was the first to be approved in 1994; in 1998, the cyclic heptapeptide eptifibatide (**71**, Merck) was approved, which is derived from the snake venom barbourin; and finally, in the same year, the small molecule tirofiban (**72**, Merck) received as well market approval. These drugs have been widely applied in the treatment of ACS patients. However, compared with the newer $P2Y_{12}$ antagonists, their high antithrombotic efficacy goes along with an increased risk of thrombocytopenia and major bleedings. Therefore, these $\alpha_{IIb}\beta_3$ drugs are preferentially used in high-risk patients undergoing PCI.

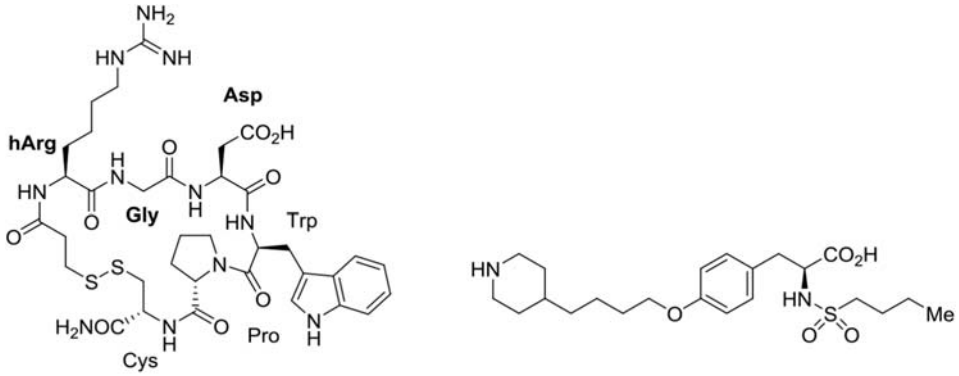

Fig. 22 Eptifibatide contains six amino acids and one mercaptopropionyl (des-amino cysteinyl) residue that forms a disulfide bridge with the cysteine amide. The modified RGD sequence is labeled in bold (*hArg*=homoarginine). Tirofiban mimics with its piperidine and its carboxylic acid moiety the Arg and Asp amino acids of the RGD sequence. The carboxylate group of tirofiban coordinates the Mg^{2+} ion, and the protonated piperidine ring undergoes charge-assisted H-bond interactions with the Asp224.

In contrast to the i.v. drugs, oral $\alpha_{IIb}\beta_3$ antagonists showed little to no benefit in several clinical phase III trials with an unexpected increase in thrombotic events. This resulted in increased mortality in the treatment arms and thus in a discontinuation of the oral antagonist programs across the pharmaceutical industry.[26]

7.15.6.1.2 Mechanism of action of integrins and ligand binding mode

The integrin $\alpha_{IIb}\beta_3$ belongs to a large family of α/β heterodimeric transmembrane proteins that fulfill important roles in cell–cell or cell–extracellular matrix interactions. Integrins are able to transmit signals bidirectionally across the cell membrane. Signaling pathways from numerous agonists of platelet activation (e.g., thrombin, TXA_2, and ADP) converge to activate $\alpha_{IIb}\beta_3$ resulting in fibrinogen cross-linking and platelet aggregation. The "inside-out" signaling is initiated by the binding of the intracellular protein talin to the cytoplasmic tail of the β_3 subunit. Upon this activation event, the integrin undergoes major conformational changes that are described in a simplified fashion thereafter.[184] From the inactive bent conformation in which the extracellular ligand binding domain is masked, $\alpha_{IIb}\beta_3$ converts into an intermediate partially activated ("primed") extended state. In the primed state, the "headpiece" of $\alpha_{IIb}\beta_3$ exposes and opens progressively its binding sites for the docking of the ligand. Finally, upon binding to fibrinogen or other ligands, the integrin switches to a fully extended ligand-bound state, where the rearrangement of the intracellular tails (e.g., tail separation) enables the binding of adaptor proteins (e.g., Syk and $G\alpha_{13}$) and the generation of "outside-in" signaling. Outside-in signaling stabilizes the thrombus and is involved in platelet spreading, granule secretion, and clot retraction (**Fig. 3**).[61,185]

Tirofiban and eptifibatide have been designed based on the RGD (Arg-Gly-Asp) or KGD (Lys-Gly-Asp) sequence found in natural ligands of $\alpha_{IIb}\beta_3$ (e.g., fibrinogen), which enables recognition by the receptor (**Fig. 22**). The binding mode of these antagonists has been elucidated by X-ray crystal structures of receptor–ligand complexes.[186] The basic amine group of the ligands mimics the arginine in the RGD sequence and binds Asp224 in the α_{IIb} subunit, while the carboxyl group replaces the aspartate, which is coordinated to a Mg^{2+} ion in the metal ion-dependent adhesion site (MIDAS) at the β_3 subunit. During complexation of these antagonists, a conformational change of the integrin exposes new epitopes, termed ligand-induced binding sites, which can be detected experimentally by antibodies. In some patients, similar neoepitopes can also be recognized by preformed antibodies. This interaction may lead to antibody-mediated removal of platelets from the circulation resulting in a thrombocytopenia side effect.

7.15.6.1.3 Novel approaches in $\alpha_{IIb}\beta_3$ antagonism

Various hypotheses have been put forward to explain the mortality increase with oral antagonists, but so far, the negative outcome of all different tested drugs could not be attributed to one single factor.[183b,187] RGD sequence-derived inhibitors induce after binding to the integrin a switch to an activated receptor conformation. Some compounds indeed show partial agonistic behavior. For oral antagonists with short half-lives, it was also postulated that the natural ligand agonist (fibrinogen) would directly activate the "primed" receptor after dissociation of the drug. Either effects, partial agonism, or insufficient target engagement with priming of the receptor could lead to outside-in signaling and platelet aggregation. In addition, the low bioavailability of some of the oral antagonists may have resulted in incomplete receptor blockade putting the patients at risk for recurrent thrombosis.

Two novel approaches are currently being pursued in the development of $\alpha_{IIb}\beta_3$ antagonists, which should hopefully lead to compounds with an improved safety profile[61]: (a) antagonist binding to the extracellular domain without eliciting the conformational change leading to receptor activation (in this case, platelet aggregation would still be circumvented due to blockade of the fibrinogen–receptor interaction and outside-in signaling inhibition) and (b) antagonist binding to the intracellular domain.

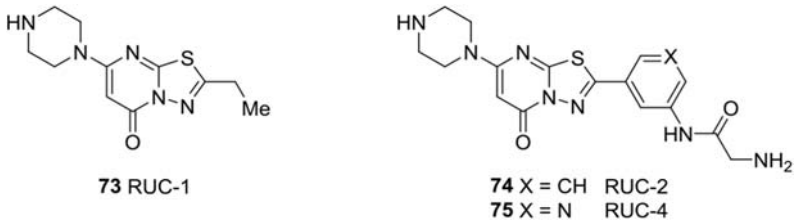

Fig. 23 Novel antagonists of the closed $\alpha_{IIb}\beta_3$ form: RUC-1, RUC-2, and RUC-4 (**73**–**75**).

In the first approach, an HTS screen of >30,000 compounds was performed by Blue et al. to identify novel inhibitors of platelet aggregation.[188] The thiadiazolo-pyrimidinone hit **73** (RUC-1; Fig. 23) was shown to possess promising affinity ($IC_{50} = 13$ μM) for the $\alpha_{IIb}\beta_3$ receptor and high selectivity over other related integrins. In contrast to previous peptidomimetic $\alpha_{IIb}\beta_3$ antagonists that bind to the open form of the integrin, X-ray data confirmed that the inhibitor RUC-1 binds only to the α_{IIb} subunit with no interaction with the Mg^{2+} ion in the β_3 MIDAS region, thus preventing the opening of the headpiece and the adoption of a high-affinity ligand binding conformation.[189] Along the same lines, the ~100-fold more active analog **74** (RUC-2, 90 nM) showed no major conformational changes in the β_3 subunit.[190] It shared the same binding mode as RUC-1, but in addition displaced with its primary amine the Mg^{2+} ion by binding to Glu220, which normally is coordinated to Mg^{2+} in the MIDAS domain.[191] Finally, the exchange of the phenyl ring of RUC-2 by a pyridine ring led to the derivative **75** (RUC-4),[192] showing similar activity but with a more favorable solubility and PK profile. RUC-4 has been further investigated in different animal models of thrombosis, where it protects the mice against thrombus development. For patients experiencing myocardial infarction, a timely exposure to antiplatelet agents is critical for positive outcome. An intramuscular injection of RUC-4 has therefore been proposed by Coller and coworkers as prehospital emergency treatment.[192] Further optimization using pharmacophore modeling identified related $\alpha_{IIb}\beta_3$ antagonists with high affinity for the closed conformation.[193]

The second approach encompasses the intracellular inhibition of the inside-out signaling by targeting the interaction between talin and the cytoplasmic tail of $\alpha_{IIb}\beta_3$. Different cell-permeable peptides containing talin binding sequences have been designed (e.g., palmitoylated peptides)[194] that showed promising antithrombotic activity. However, it is still unclear if this approach would lead to a separation of the antithrombotic activity from the bleeding side effect.

Alternatively, the outside-in signaling, which is believed to be responsible for the formation of an occlusive thrombus from a primary layer of platelets, could be targeted exclusively. In this approach, adhesion to the endothelial lesion and the subsequent primary thrombus formation, both depending on the inside-out mechanism, would not be impeded. This should prevent the undesired bleeding side effects. The ligand-induced outside-in signaling requires $G\alpha_{13}$ docking to the integrin in the same region as talin.[195] A myristoylated (m) ExE motif peptide has been described to disrupt the binding of $G\alpha_{13}$ to $\alpha_{IIb}\beta_3$.[195b] Thus, the hexapeptide m-FEEERA inhibits the early phase of outside-in signaling without interfering with the talin-dependent inside-out mechanism. In two mice models of thrombosis, this novel peptidic agent inhibited occlusive thrombosis without causing bleeding. However, to the best of our knowledge, no small-molecule inhibitors of intracellular $\alpha_{IIb}\beta_3$ tails have been reported so far. Nevertheless, this approach might represent a further step toward the development of $\alpha_{IIb}\beta_3$ antagonists with improved safety profile.

7.15.6.2 Antagonists of the Adhesion Receptors

The initial steps of thrombus formation involve platelet rolling, tethering, and adhesion to the site of vessel injury. Adhesion to the subendothelial exposed collagen is mainly dependent on two platelet receptors: the GPVI immunoglobulin receptor and its coadhesion receptor, the integrin $\alpha_2\beta_1$ (GPIa–IIa). In contrast to the restricted expression pattern of GPVI on platelets and megakaryocytes, $\alpha_2\beta_1$ is also found on epithelial cells, selected immune cells, and a large variety of mesenchymal cells. Several platelet adhesion receptors introduced in Section Platelet Adhesion and Aggregation Receptors have been the target of pharmacological interventions.[196] However, to the best of our knowledge, small-molecule inhibitors have only been described for $\alpha_2\beta_1$.

7.15.6.2.1 $\alpha_2\beta_1$ antagonists

Mouse models revealed diverse potential implications of $\alpha_2\beta_1$ in human diseases, such as infection, immunity, and cancer, with a role in metastasis and angiogenesis. The rationale for targeting $\alpha_2\beta_1$ in thrombosis is supported by the observation that its low expression level in humans is associated with only mild bleeding diathesis, in contrast to the strong bleeding disorder observed in the $\alpha_{IIb}\beta_3$ deficiency subjects (Glanzmann's thrombasthenia). Furthermore, $\alpha_2\beta_1$ gene polymorphism resulting in higher surface-level expression of the $\alpha_2\beta_1$ receptor has been linked to increased risk of myocardial infarction.[196]

The recognition of collagen, and more specifically of the binding sequence GFOGER (where O is hydroxyproline) in type I collagen, is mediated by a MIDAS motif in the αI (insertion) domain. This insertion domain is also common to eight other integrins but is not present in $\alpha_{IIb}\beta_3$ integrin. Binding of collagen triggers a signaling cascade that promotes further platelet adhesion and their subsequent activation and aggregation.

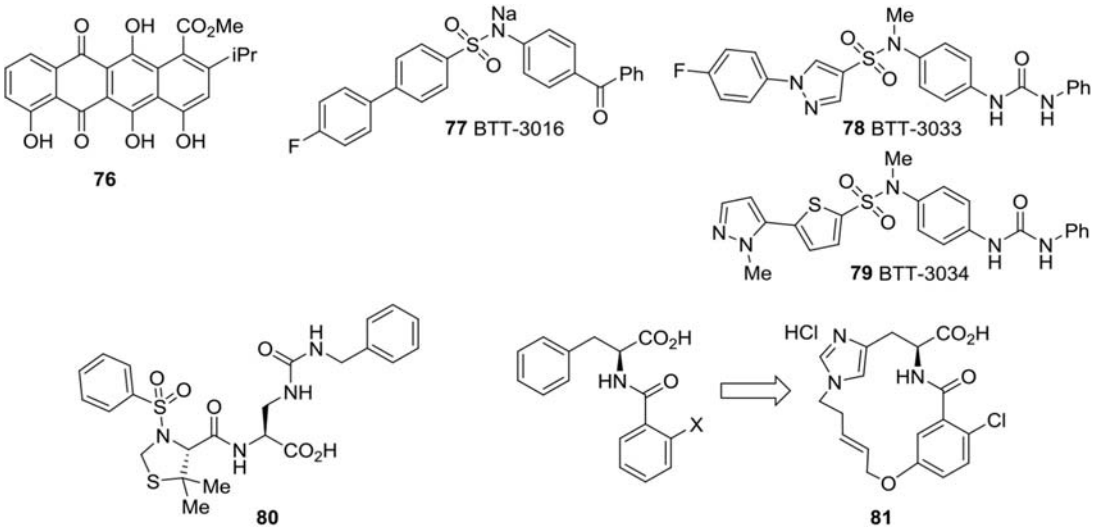

Fig. 24 Collaboration Turku/Jyväskylä Universities with Biotie Therapies: polyketide representative **76** and compounds **77–79**; compound **80** (DeGrado); from the common L-Phe-N-aroyl motif to the 15-membered macrocycle **81** (Sanofi).

From docking experiments of academic and commercial compound libraries, tetracyclic aromatic polyketides were found to be suitable candidates for binding into the closed conformation of the α_2I domain of $\alpha_2\beta_1$. These compounds exemplified by compound **76** (Fig. 24) were able to coordinate to the Mg^{2+} ion (directly or indirectly via water molecules) complexed in the MIDAS domain and showed competitive inhibition against type I collagen with IC_{50} values of 7.5–12 μM.[197] Further structure-based design at the same binding site and lead optimization resulted in a novel potent tool compound **77** (BTT-3016) of the diphenylsulfonamide series. BTT-3016 showed selectivity across the β1 integrin subtypes,[198] and it inhibited thrombus formation in the carotid artery injury model in mice. The bleeding time prolongation in the mouse tail bleeding model was comparable with aspirin. In a next optimization round, a phenylurea moiety replaced the benzophenone substituent, and (hetero)arylpyrazoles were chosen as a substitute for the biphenyl unit. Both compounds **78** (BTT-3033) and **79** (BTT-3034) inhibited cell adhesion to rat tail type I collagen in the submicromolar range. However, only BTT-3033 blocked platelet adhesion under blood flow conditions suggesting two different binding modes, an assumption supported by site-directed mutagenesis.[199] Interestingly, the two inhibitors recognize different $\alpha_2\beta_1$ conformations, and under blood flow conditions, only the targeting of the nonactivated conformation of $\alpha_2\beta_1$ was effective in blocking platelet adhesion.

DeGrado and coworkers combined molecular fragments of previously known $\alpha_4\beta_1$ and $\alpha_{IIb}\beta_3$ integrin inhibitors that led to a series of novel prolyl-2,3-4-diaminopropionic acid (DAP) derivatives with selectivity over other β_1 integrins.[200] Further optimization of the proline ring led to the discovery of thiazolidine-based inhibitors with high affinity (e.g., **80**, $IC_{50} = 12$ nM) toward $\alpha_2\beta_1$ and selectivity toward other platelet integrins (Fig. 24).[201] Based on biochemical studies, it was deduced that the DAP antagonists bind to a second MIDAS site in the β_1I-like domain. Blocking of this allosteric site prevented the opening of the αI-domain in the α_1 subunit to an active collagen binding conformation. In the ferric chloride-induced carotid artery injury model, total time to occlusion for compound **80** (60 mg/kg) was similar to aspirin (10 mg/kg).

In 2014, Sanofi described novel macrocyclic rings that incorporate as a key binding element the L-phenylalanine-N-aroyl motif inspired from $\alpha_4\beta_1$ and $\alpha_2\beta_7$ antagonists.[202] The carboxylic group of these early antagonists binds to the Mg^{2+} ion in the integrin MIDAS domain. The compounds were tested in a collagen interaction solid phase assay using the extracellular part of $\alpha_2\beta_1$. After some optimization, wherein one phenyl was replaced by an imidazole ring, highly active antagonists of $\alpha_2\beta_1$ were obtained (e.g., **81**; $IC_{50} = 4$ nM) with potent activity as well on other β_1 integrins (Fig. 24). The binding mode was rationalized by docking compound **81** to the β_1 MIDAS domain of crystallized $\alpha_5\beta_1$. Disappointingly, the series showed poor cellular permeability and high plasma clearance.

These preliminary studies support $\alpha_2\beta_1$ as an interesting antithrombotic target. Interference with protein–protein interaction was successfully achieved by targeting the α_2I domain. Alternatively, the allosteric pocket in the β_1 subunit could be efficiently targeted with notable selectivity over other integrins. Major efforts are still required to advance new $\alpha_2\beta_1$ integrin antagonists toward clinical evaluation.

7.15.6.2.2 GPVI antagonists

The collagen receptor GPVI is the major platelet receptor that binds to collagen with high affinity and initiates intraplatelet signaling leading to platelet aggregation.[203] The most advanced antagonist is revacept (advanceCor), which is a dimeric GPVI-Fc fusion protein in phase II for the treatment of ischemic stroke and TIA. Preclinical experiments with monoclonal antibodies or genetically modified mice confirmed the essential role of GPVI in collagen-induced platelet activation.[58] Therefore, inhibition of GPVI represents a novel opportunity to interfere with the initiation of thrombus formation.[204]

7.15.6.2.3 vWF and GPIb receptor antagonists

So far, no small-molecular-weight inhibitors of vWF nor of the GPIb-V-IX receptor complex have been reported. Aptamers, monoclonal antibodies, and nanobodies (e.g., ALX-0081) have been generated and have confirmed that targeting the vWF-GPIb-V-IX receptor complex could be a reasonable antithrombotic strategy.[16g,205] Anfibatide (Lee's Pharmaceutical), a snake venom-derived GPIb antagonist, is currently in clinical phase II in ACS patients.[206] Novel approaches or technologies might be needed to enable the identification of small-molecular-weight compounds as GPIb-V-IX receptor inhibitors.[207]

7.15.7 Inhibitors of Intracellular Enzymes

7.15.7.1 COX Inhibitors

COX inhibitors, commonly referred to as nonsteroidal antiinflammatory drugs (NSAIDs), can been classified either based on their chemical structure or by their selectivity profile toward the two cyclooxygenase enzyme isoforms COX-1 and COX-2.[208] For decades, their broad pharmacological effects as analgesic, antipyretic, antiinflammatory, or antiplatelet agents have made them indispensable for human health. The expression pattern of the COX isoforms influences the pharmacological effects of the inhibitors. While COX-2 is inducible under inflammatory conditions, COX-1 is constitutively expressed with high concentrations found in gastric epithelial cells and in platelets.

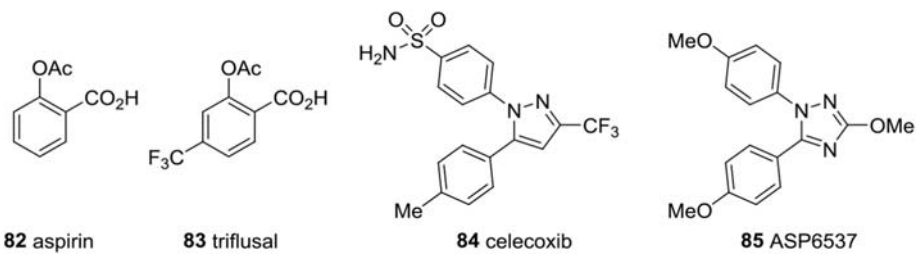
7.15.7.1.1 Aspirin

High doses of aspirin (**82**, acetylsalicylic acid (ASA)) blunt the synthesis of prostanoids in many tissues, and thus, aspirin is effective to limit prostanoid-mediated inflammation, pain, and thrombosis (Fig. 25).[209] However, long-term treatment with high-dose aspirin is restricted by side effects such as gastric bleeding and impairment of kidney function.[210] Therefore, low-dose regimens of aspirin have been evaluated. Several trials have consistently demonstrated a relevant reduction in cardiovascular events in ACS patients.[50] Due to its good safety profile, aspirin (75–325 mg) is unanimously recommended by health agencies for the prevention of cardiovascular events in ACS patients. Nevertheless, aspirin is a specific (and irreversible) inhibitor of COX-1 and thus ineffective in reducing platelet activation stimulated by other factors such as ADP or thrombin. Therefore, it is usually combined with a $P2Y_{12}$ antagonist.

In contrast, the net benefit of aspirin for the primary prevention of thrombotic events is not clearly established.[211] Particularly, the risk of gastrointestinal and other major bleedings needs to be taken into account when prescribed to healthy individuals. Therefore, primary prevention of ACS with aspirin has not been advocated by health authorities.

The mechanism of action of aspirin involves the transfer of its acetyl group to the hydroxyl group of Ser529 in human COX-1. Aspirin inhibits as well the other isoform COX-2, albeit with lower potency than COX-1 (c. 170-fold selectivity).[212] By such irreversible blockade, the catalytic site of COX enzymes becomes inaccessible to the substrate AA, and hence, the enzymatic conversion to PGG_2 and PGH_2 is hindered. Consequently, the level of PGH_2 that can be converted to TXA_2 in platelets by TXS decreases. It is postulated that the biosynthesis of the prothrombotic TXA_2 should be reduced by $>95\%$ to achieve complete inhibition of platelet aggregation. Being devoid of a nucleus, platelets lack the machinery for protein resynthesis. Thus, the inactivation of COX-1, the major isoform in platelets, lasts for the life span of the platelets (7–10 days). In other cells, irreversible inactivation of COX by aspirin is only of transient nature since they can regenerate COX enzymes through de novo synthesis.

Similar to clopidogrel, aspirin has been linked to high response variability.[213] Indeed, many patients experience recurrent adverse cardiovascular events despite ongoing aspirin therapy ("clinical resistance/treatment failure"). In secondary prevention, aspirin reduces by c. 25% the risk of ACS versus placebo as reported in a large meta-analysis by the Antiplatelet Trialists' Collaboration (ATC).[211] The underlying reasons for its limited efficacy are multifactorial and reflect to a certain extent the heterogeneous nature of the thrombotic diseases, that is, many signaling pathways are responsible for platelet aggregation. Other postulated causes encompass COX-1 polymorphism or higher platelet turnover, drug–drug interactions (e.g., active site competition with ibuprofen leading to decreased aspirin activity), aspirin metabolism or efflux mechanisms, and alternative TXA_2 production. Nevertheless, the "laboratory" resistance of aspirin, as defined by its inability to inactivate COX-1 with an adequate dose, remains a relatively rare phenomenon ($<5\%$). While the contributions of all these individual factors are still a matter of debate, patient compliance and



82 aspirin **83** triflusal **84** celecoxib **85** ASP6537

Fig. 25 The COX inhibitors aspirin and triflusal; representative selective COX-2 (celecoxib) and COX-1 inhibitors (ASP6537, Astellas).

pharmacokinetic variability arising, for example, from different aspirin formulations are believed to be major drivers of clinical treatment resistance.

7.15.7.1.2 Triflusal

Triflusal (**83**) is a structural variant of aspirin bearing an additional trifluoromethyl group (**Fig. 25**).[214] Its mechanism of action is similar to aspirin with preferential inactivation of COX-1. It is marketed by Uriach Pharma in some countries for the secondary prevention of ACS as well as to reduce graft occlusion after a coronary bypass. In 2008, based on a favorable efficacy and safety profile, the European Stroke Organization recommended the use of triflusal after strokes and TIA as an alternative to the combination of aspirin and dipyridamole or clopidogrel alone.[215] Triflusal is currently being compared in a clinical trial with clopidogrel for the secondary prevention of ischemic stroke patients based on the CYP2C19 polymorphism.[16i]

7.15.7.1.3 Recent developments

Inhibition of prostaglandin synthesis in the gastrointestinal mucosa is one of the main mechanisms of mucosal damage by NSAIDs and aspirin in particular.[216] The low but clearly increased risk of GI ulceration and bleeds contributes to the reduced patient compliance. Several possibilities have been explored to lower the gastric side effects of aspirin, namely, the development of (i) selective COX-1 inhibitors, (ii) aspirin prodrugs, and (iii) NO hybrids.

7.15.7.1.3.1 Selective COX-1 inhibitors

During the development of improved antiinflammatory drugs, it was initially believed that COX-1 was solely responsible for the gastric side effects of older generation NSAIDs, and therefore, selective COX-2 inhibitors (coxibs, e.g., celecoxib, **84**) were introduced. However, selective COX-2 inhibitors were found to increase adverse cardiovascular side effects that resulted in the withdrawal of rofecoxib (Merck).[217] It was suggested that COX-2 inhibition by the coxibs reduces the production of PGI_2, which possesses antiplatelet activity. This phenomenon may explain why high doses of aspirin have no additional antithrombotic effects compared with low-dose aspirin since simultaneous full inhibition of both COX isoforms may abolish the production of protective PGI_2.

In contrast to the well-defined pharmacology of selective COX-2 inhibitors, the therapeutic advantage of selective COX-1 inhibitors has been only rarely demonstrated. A review from 2010 covers the earlier published examples.[218] The findings that COX-1 knockout mice do not spontaneously develop gastric ulcers[219] and that highly selective COX-2 inhibitors have low gastrointestinal side effects suggest that gastric irritation is linked with the dual inhibition of both enzyme isoforms. Building on these findings, Astellas published the pharmacological profile of ASP6537 (**85**), a diaryltriazole derivative structurally derived from COX-2 inhibitors (**Fig. 25**).[220] The high selectivity profile of ASP6537 (>140,000-fold selective for COX-1 over COX-2) using recombinant human COX enzymes translates into a TXA_2/PGI_2 balance favorably shifted toward TXA_2 production, compared with aspirin. In addition, a significantly higher antithrombotic effect in an induced carotid arterial thrombosis model was measured, and no ulcerogenic effect at an efficacious antithrombotic dose could be observed. ASP6537 (licensed to Cardeus Pharmaceuticals) may be of benefit in both primary and secondary prevention of ACS events. Other recent selective COX-1 inhibitors have been disclosed by Vitale et al. with the investigation of diarylisoxazoles.[221] They could show that the right choice of lipophilic substituents on the central isoxazole determines the high COX-1 selectivity (>1000-fold over COX-2). The binding mode was rationalized by docking simulations using the COX-1 crystal structure.

7.15.7.1.3.2 Aspirin prodrugs

Masking the carboxylic group of aspirin through a prodrug approach would ideally abolish COX inhibition in the GI tract and yield a nonacidic molecule that would spare the gastrointestinal tract. The realization of this concept is challenged by a metabolic issue: in contrast to aspirin, neutral aspirin esters are substrates for butyrylcholinesterase (BuChE) in human plasma. Instead of the desired ester cleavage, a shift to the acetate hydrolysis is observed leading to the undesired formation of salicylic esters. One solution to this problem was proposed by Gilmer and coworkers by using isosorbide as a prodrug moiety (**Fig. 26**).[222] The sugar linker hinders the

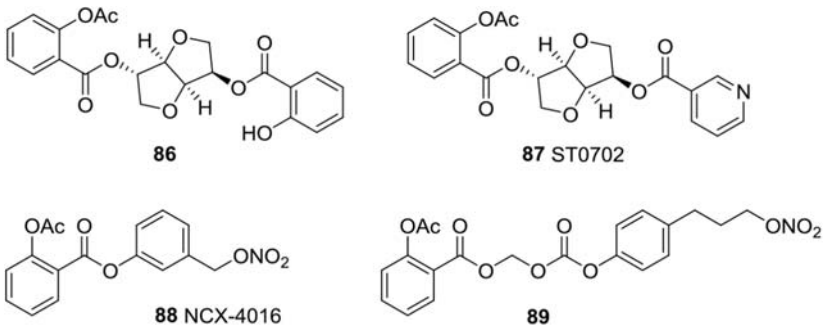


Fig. 26 Isosorbide-derived aspirin prodrugs with salicylate **86** and niacin moieties (**87**, ST0702); NO–aspirin hybrid drugs: compound **88** (NCX-4016) and acyloxymethyl carbonate-based prodrug **89**.

substrate recognition of BuChE, which would cleave the acetate group to the inactive salicylic ester. The aspirin production in **86** is very efficient, with 80–85% conversion. The close analog **87** (ST0702, Solvotrin Therapeutics) possesses a nicotinic acid (niacin) moiety replacing the salicylic acid of **86**.[223] It effectively inhibits human platelet aggregation and is in preclinical development with colorectal cancer as primary indication. In this setting, it is hoped that the released aspirin will have an impact on the platelet-mediated cancer cell metastasis and will concomitantly reduce the prothrombotic state of the disease.[224]

7.15.7.1.3.3 NO–aspirin hybrids

The gaseous messenger nitric oxide (NO) plays an essential role in human physiology, in particular in the cardiovascular system.[225] In blood vessels, the endothelium releases NO, which stimulates the increase in intracellular cGMP in platelets. This mechanism leads to decreased ability of platelet aggregation and to the maintenance of hemostasis[226] In the gastric tract, NO shows a protective effect on the mucosal membrane through multiple mechanisms that could counteract the GI side effects of COX inhibitors. Based on these beneficial effects, combinations of aspirin or other NSAIDs with an NO donor were proposed. This concept has been intensively investigated[227] with a particularly appealing strategy based on the hybrid drug concept (**Fig. 26**), in which aspirin is linked via its carboxylic group to an NO-releasing moiety. Double cleavage of these mutual prodrugs should ideally yield the two desired pharmacological agents in an equimolar ratio. An early compound **88** (NCX-4016, Nicox) has been evaluated up to phase II clinical trials.[228] However, the faster esterase-mediated acetate cleavage compared with the carboxylic ester results in an inhibitory effect on platelet aggregation arising only from the release of NO. Thus, NCX-4016 does not qualify as a "true" aspirin prodrug. Another type of prodrug from the NO–aspirin class of compounds besides the isosorbide moiety[229] has been described by the University of Turin, Italy, with the introduction of (nitrooxyacyloxy)methyl esters and related carbonates of aspirin.[230] The representative prodrug **89** is able to release aspirin quickly in human serum and inhibits collagen-induced platelet aggregation of human PRP.

Despite tremendous efforts, the development of new COX inhibitors with improved antiplatelet and safety profiles compared with aspirin remains a major challenge. However, it is remarkable that being on the market for so long, clinical trials with aspirin are still ongoing to further delimit its potential benefits (i.e., specific patient populations) either as monotherapy or as combination therapy.

7.15.7.2 TXS Inhibitors

Long-term treatment with high-dose aspirin can cause adverse effects such as gastric bleeding. Therefore, the quest for alternative approaches targeting TXA_2 formation has been initiated. In the past decades, the pharmaceutical industry focused on thromboxane synthase (TXS), the enzyme responsible for the conversion of PGH_2 into TXA_2. However, following inhibition of TXS, the PGH_2 produced during prostanoid biosynthesis accumulates and activates the TP receptor. This effect offsets the benefit of TXS inhibition and may explain the negative clinical trial results with TXS inhibitors.[231]

7.15.7.3 PDE Inhibitors

The cytosolic enzymes phosphodiesterases (PDEs) cleave the phosphodiester bond in the second messenger molecules cAMP and cGMP. So far, 11 different families of PDE have been described. In human platelets, the phosphodiesterases PDE2, PDE3, and PDE5 are the key enzymes responsible for cAMP (PDE2/3) and cGMP (PDE2/5) degradation, thereby limiting the intracellular concentration of cAMP and cGMP, respectively.[232]

The PDE3 inhibitor cilostazol (**90**) interferes with cAMP degradation and subsequent platelet activation and is in clinical use for the treatment of intermittent claudication (**Fig. 27**).[233] Cilastazol also antagonizes adenosine uptake and is a weak inhibitor of PDE5. The old drug dipyridamole (**91**) is characterized as a weakly selective PDE5 inhibitor and elevates thus intraplatelet cGMP.[234] It is approved by the FDA in combination with aspirin for the secondary prevention of stroke.[235]

The PDE3 inhibitor **92** (K-134, Kiowa) has been tested for PAD (intermittent claudication) and improved the walking distance in patients.[236] The dual PDE (of unspecified subtype) and $P2Y_{12}$ antagonist **93** (BF061) is an adenosine derivative recently described as a novel antiplatelet agent with similar activity compared with clopidogrel with less bleeding in animal models.[237]

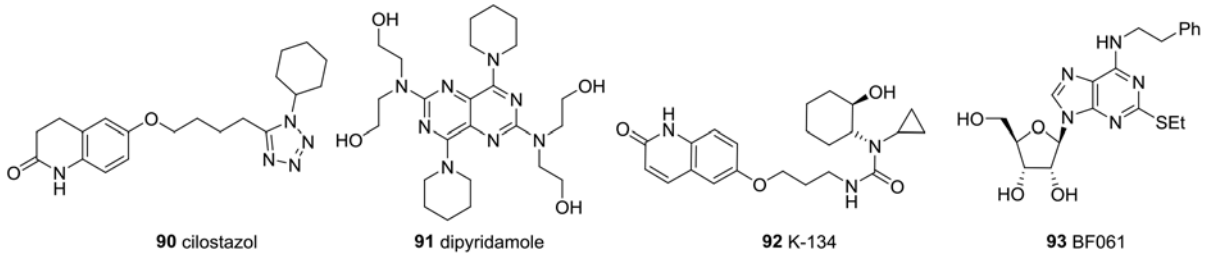

Fig. 27 The marketed PDE inhibitors cilostazol and dipyridamole; early development compounds K-134 (Kiowa) and BF061.

As PDEs display broad distribution in the body, future challenges for novel PDE drugs targeting platelets lie in the design of isoform-specific inhibitors.

7.15.7.4 Kinase Inhibitors

7.15.7.4.1 PI3Kβ inhibitors

PI3Kβ, a member of the PI3K lipid kinase family, has recently been described as a new target for antithrombotic therapy.[238] It is ubiquitously expressed and has been implicated in tumor cell proliferation. In platelets, PI3Kβ is a downstream effector of various cell surface receptors, including GPIb, GPVI, and $P2Y_{12}$.[239] Together with other PI3K isoforms, it regulates signaling of integrins such as $\alpha_{IIb}\beta_3$ (inside-out and outside-in signaling; **Fig. 3**). High shear stress as occurring in narrowed arteries during atherothrombosis activates PI3Kβ, which triggers enhanced $\alpha_{IIb}\beta_3$ adhesive contacts resulting in platelet aggregation. Inhibition of the catalytic subunit 110β of PI3Kβ could selectively decrease pathological thrombus formation while keeping the homeostatic machinery of platelets intact. In 2005, Jackson et al. reported the development of a 110β isoform-selective inhibitor based on compound **94** (LY294002), an early nonselective kinase blocker (**Fig. 28**).[238] After systematic SAR studies, the pyrido[1,2-a]pyrimidin-4-one **95** (TGX-221) was identified as a potent ($IC_{50} = 5$ nM) and selective inhibitor for 110β over a large kinase panel. Importantly, the morpholine ring was kept constant as it is crucial for binding to the hinge region. In a variety of animal models, TGX-221 inhibited thrombus formation with no significant increase in bleeding. Minor structural modifications culminated in the clinical candidate **96** (AZD6482), which was investigated by AstraZeneca up to phase I clinical trials, but no further development has been reported (**Fig. 28**). Similarly to TGX-221, AZD6482 is potent ($IC_{50} = 10$ nM) and selective for PI3Kβ with a short half-life in various species (5–43 min in humans). Owing to its short-acting profile, AZD6482 was administered in a 3 h infusion in human volunteers and showed good tolerability.[240] At maximal antiplatelet effect, it elicited no increase in bleeding time or blood loss. AZD6482 was also evaluated clinically in combination with aspirin or clopidogrel.[241] As a single agent, its antiplatelet effect ranked it between $P2Y_{12}$ and COX_1 antagonists. However, the most effective combination was observed with aspirin, providing enhanced antiplatelet effect with less bleeding complications compared with the clopidogrel–aspirin dual therapy. Short-acting intravenous antiplatelet inhibitors could be of value in the emergency treatment of ischemic stroke or for patients undergoing PCI.

Recently, AstraZeneca published a series of papers describing the follow-up program of AZD6482. The goal was to achieve once-daily oral dosing by improving the bioavailability and the metabolic stability of AZD6482.[242] Another key criterion during the optimization was the selectivity toward 110β over the other isoform 110α, the latter being critical for insulin signaling. Indeed, AZD6482 slightly increased plasma insulin levels in man, which could be linked to its PI3Kα inhibition ($IC_{50} = 0.87$ μM). While this was no issue during short infusions, it was believed that a cleaner profile would be needed for chronic antithrombotic therapies. It was known from TGX-221 that the carboxylic group could be removed without loss of potency but at the expense of an increased lipophilicity and metabolic instability. Therefore, removal of the carboxylic function to avoid the issue of acyl glucuronidation, reintroduction of a polar moiety (hydroxyethylcarboxamide), and exchange of the undesired anilinic nitrogen by an oxygen atom yielded **97** with an improved pharmacokinetic profile. In PRP, the selectivity between the α/β isoforms was sharply increased compared with AZD6482 (25-fold vs. 3.1-fold). Finally, the preclinical candidate **97** was tested in the modified Folts model in dogs to evaluate the safety margin, and no significant bleeding was observed.

Another approach relied on a virtual screening campaign of the AstraZeneca fragment library based on a 110β homology model of the crystallized 110γ structure.[242] The fragment **98** ($IC_{50} = 34$ μM) was chosen as a valid starting point. Introduction of a naphthyl

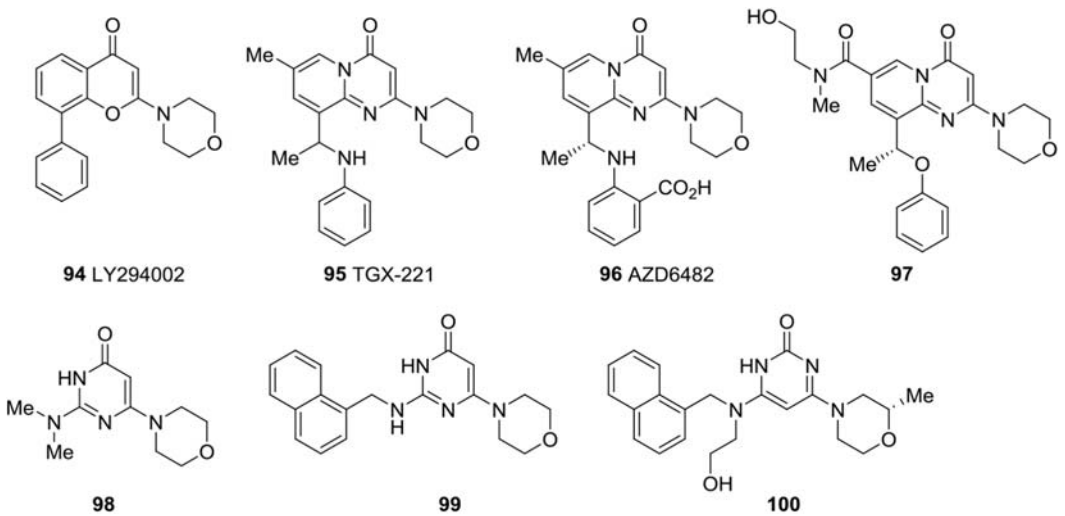

Fig. 28 PI3Kβ inhibitors. From the morpholinochromenone **94** (LY294002) to TGX-221 (**95**) and AZD6482 (**96**). Clinical candidate **97** from AstraZeneca. Follow-up compounds **99** and **100** based on the virtual screening hit **98**.

moiety for binding into the selectivity pocket gave the potent lead compound **99** ($IC_{50}=93$ nM), which however displayed low metabolic stability (Fig. 28). Three additional optimization rounds including a shift of the nitrogen within the pyrimidinone core, the introduction of a hydroxyethyl substituent to target the ribose binding subpocket, and a variation of the substituent engaging the hinge region gave **100**. Compound **100** was potent against 110β ($IC_{50}=38$ nM) and inhibited ADP-induced platelet aggregation in whole-blood effectively ($IC_{50}=2.1$ μM). It showed increased 110α/β selectivity translating in minimized risk for insulin resistance. As for AZD6482, a more favorable thrombosis–bleeding separation window was apparent in PK/PD experiments in dogs compared with other antiplatelet agents, such as ticagrelor and clopidogrel.

The enthusiasm for PI3Kβ as an antithrombotic target has been dampened recently by the observation that PI3Kβ activity is required for the stabilization of the thrombus at a high shear rate.[243] In animal models, the inhibition or absence of PI3Kβ in platelets resulted in thrombus instability that led to their enhanced detachment from the vasculature. A defective outside-in signaling from $\alpha_{IIb}\beta_3$ may account for the weakened interplatelet interactions that is required for thrombus consolidation. It is unclear whether these findings may translate into increased emboli and undesired secondary ischemic events during therapeutic intervention.

7.15.7.4.2 Other kinases

Besides PI3Kβ or its isoforms α/γ, other kinase classes have been proposed as antiplatelet targets. Three TAM receptor tyrosine kinases (Tyro3, Axl, and Mer) bind the extracellular protein Gas6 (growth arrest-specific-6), a member of a coagulation factor family. On the platelet surface, Gas6–TAM interaction may activate the integrin $\alpha_{IIb}\beta_3$ in synergy with ADP through a PI3K-dependent mechanism resulting in platelet aggregation. On endothelial cells, Gas6 is an important contributor to the surface expression of TF and therefore to the initiation of the clotting cascade.[244] A recent study from the University of North Carolina on the development of Mer inhibitors has been published.[245] The lead compound **101** (UNC2881; Fig. 29) showed high inhibitory potency on Mer ($IC_{50}=4.3$ nM) with >50-fold selectivity over Axl and Tyro3 ($IC_{50}=360$ and 250 nM, respectively) and activity in the collagen-induced platelet aggregation assay, suggesting a potential use of Mer inhibitors as antiplatelet agents.

Syk is an intracellular kinase with scaffolding properties, which is activated after engagement of several adhesion or aggregation receptors (Fig. 3). Syk plays as well a role in leukocyte recruitment to inflammatory sites. In 2011, Portola Pharmaceuticals reported the selective Syk inhibitor **102** (PRT-060318), which inhibited arterial thrombosis in various animal species and did not affect the bleeding time.[246]

7.15.8 New Frontiers in Antiplatelet Therapy

7.15.8.1 Role of Platelets Outside Hemostasis

7.15.8.1.1 Platelets in inflammation and immunity

Platelets interact with almost all known immune cells and are postulated to play a key role in inflammation and immunity.[247] Dense and alpha-granules contain proinflammatory mediators, such as P-selectin, CD40L, TGF-β, and several growth factors. These signals stimulate other cells to produce proinflammatory cytokines and chemokines, such as IL-1β, IL-8, TNFα, and CCL2.[248]

The role of platelets in various pathological conditions has been described. For example, observational studies suggest that antiplatelet therapy is associated with a reduction in mortality from sepsis.[249] Furthermore, elevated levels of circulating platelet–leukocyte aggregates have been reported in patients with atherothrombosis suggesting a possible role of platelets in inflammation. Not surprisingly, aspirin and $P2Y_{12}$ antagonists possess antiinflammatory action in various experimental systems and clinical conditions.[248]

Pulmonary arterial hypertension (PAH) is a progressive disease that involves pathological remodeling, vasoconstriction, and thrombosis. Although the presence of thrombotic lesions in the pulmonary vasculature is a common pathological finding in PAH, the role of platelets is controversial. Activated platelets may interact with the pulmonary arterial wall and contribute to the functional and structural alterations of pulmonary vessels by releasing vasoactive and mitogenic factors. Further studies are needed to fully understand the role of platelets in the establishment and progression of PAH.[250]

Systemic sclerosis (SSc) is an inflammatory disease of unknown etiology characterized by widespread organ dysfunction due to fibrosis and ischemia. Enhanced activation of platelets and increased tendency to aggregation have long been observed in SSc

patients. Further research has to clarify if aberrant platelet functionality represents the cause or the consequence of initiation and perpetuation of SSc.[251]

Increasing evidence points to an important role for platelets and their secreted products in the pathogenesis of allergic diseases. A variety of changes in platelet function have been observed in patients with asthma, such as alterations in platelet secretion, expression of surface molecules, aggregation, and adhesion. Moreover, platelets have been found to actively contribute to most of the characteristic features of asthma, including bronchial hyperresponsiveness, bronchoconstriction, airway inflammation, and airway remodeling.[252]

Interaction of platelets with viruses is a described pathophysiological phenomenon. Multiple mechanisms are involved including virus-induced platelet destruction, inappropriate platelet activation, and impaired megakaryopoiesis. Viruses can bind platelets through specific receptors that lead to functional alterations of both the platelet and the involved virus.[253]

Furthermore, platelets express a wide range of potential bacterial receptors, including complement receptors, FcγRII (antibody receptor), and Toll-like receptors (danger signal receptor). Platelets are essential for the formation of neutrophil extracellular traps (expelled DNA net), resulting in bacterial clearance by trapping bacteria and concentrating antibacterial factors.[254] Current literature suggests that the interplay of platelets and bacteria is much more complex than currently understood and awaits exciting discoveries.

In conclusion, the identification of platelets in various inflammatory mechanisms suggests an important role in the regulation of innate and adaptive immunity and in the recognition of pathogens.

7.15.8.1.2 Platelets in cancer

Platelet-released factors or platelet-mediated processes play a role in tumor growth and tumor metastasis.[255] An increase in platelet number and activity is seen in patients with tumors. In this context, high platelet number is correlated with low overall survival and poor prognosis. Preclinical data suggest a cross talk between circulating tumor cells and platelets in the blood, thus facilitating tumor metastases through direct interactions and secreted bioactive proteins.[256] In addition, platelets form aggregates with tumor cells in the blood, thereby protecting them from host immune surveillance through physical shielding or release of immunosuppressive signals.[257] Furthermore, inhibitors of the COX enzymes effectively inhibit cancer formation and progression and thus suggest an involvement of platelets or platelet-derived signals.[258]

In summary, a better understanding of the role of platelets in the pathogenesis of these diseases might offer novel opportunities for innovative disease-specific antiplatelet approaches.

7.15.8.2 Emerging Antiplatelet Targets

The newly uncovered role of platelets in inflammation, immunity, and tumor biology offers new insights and thus potentially novel targets. Moreover, recently optimized technologies allow revisiting basic aspects of platelet function and thus have the potential to revive efforts on already well-known targets. In addition, improvements in the methodology of proteomics lead to higher sensitivity and throughput and are expected to unravel novel targets.[259]

In the next paragraph, recently described novel approaches and targets are briefly outlined, and a selection of targets with reported low-molecular-weight molecules is presented in Fig. 30. Available information suggests an important role of these targets

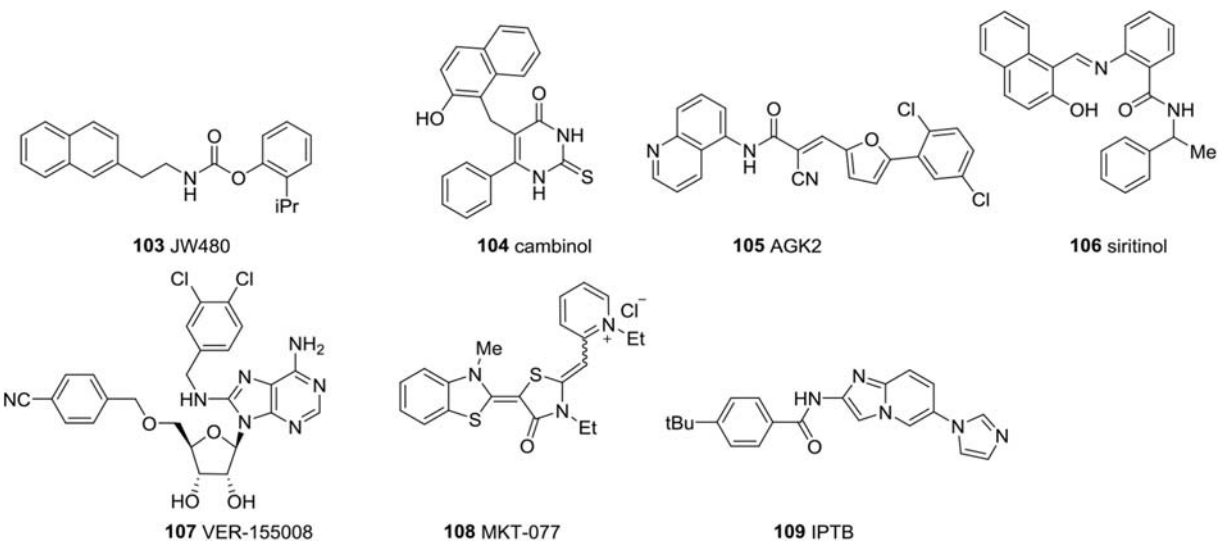

Fig. 30 A selection of inhibitors for various novel antiplatelet targets: JW480 (inhibitor of serine hydrolase); the sirtuin inhibitors cambinol, AGK2, and sirtinol; the HSP70 inhibitors VER-155008 and MKT-077 and IPTB (ASK1 inhibitor).

in platelet function. However, the precise mechanism and the impact of inhibition on the general safety profile and on overall bleeding risk await further investigation.

In a chemoproteomic approach,[260] the new serine hydrolase (AADACL1) was identified as being involved in the regulation of platelet activity. The specific inhibitor JW480 (**103**)[261] was confirmed to inhibit platelet aggregation in vitro and prevents arterial occlusion in an animal thrombosis model.[262]

Clozapine, the antipsychotic of choice for treatment-resistant schizophrenia, has been demonstrated to interfere with platelet function and thus might be the starting point to uncover a novel antiplatelet target.[263]

Protein acetylation is regulated by the activity of acetyltransferases and deacetylases, including sirtuins. Inhibitors of sirtuins, such as cambinol (**104**), AGK2 (**105**), and sirtinol (**106**), were shown to interfere with platelet function.[264] Characterization of the proteins and pathways responsible for this antiplatelet effect awaits further clarification.

Tetrahydrobiopterin (BH4), a cofactor for catecholamines, serotonin, and nitric oxide biosynthesis, was shown to inhibit platelet aggregation by enhancing local NO production within platelets.[265]

Inhibition of the heat shock protein HSP70 with the tool compounds VER-155008 (**107**) and MKT-077 (**108**) suppressed platelet spreading on fibrinogen- but not on collagen-coated surfaces. It was proposed that HSP70 is involved in the regulation of the inside-out signaling of $\alpha_{IIb}\beta_3$ integrin and thus defines a potentially novel antiplatelet approach.[266]

Further profiling of intraplatelet signaling revealed that IPTB (**109**), an inhibitor of the signaling protein ASK1, interfered with platelet aggregation and prevented arterial occlusion in an experimental model of thrombosis.[267]

Many more enzymes, signaling molecules, and surface receptors are expressed in human platelets.[268] In many cases, a potential role in the regulation of platelet function has been proposed based on the reported role of these proteins in other cell types and tissues. So far, mechanistic confirmation has been limited by the availability of research tools or by the inability to find low-molecular-weight inhibitors. We await reinforced efforts toward antiplatelet drugs and are excited to follow future progress in the identification of novel targets.

7.15.9 Conclusion

The last decades have witnessed a major decrease in mortality from cardiovascular diseases, and new antiplatelet drugs have contributed significantly to the medical progress. To interfere with pathological thrombus formation, different stages of the platelet response can be pharmacologically targeted: the adhesion of platelets to the subendothelial layer, the amplification of their biological response through GPCRs, and the concomitant intracellular enzymatic activity that culminates in platelet aggregation. In recent years, new drugs, such as ticagrelor, cangrelor, prasugrel, and vorapaxar, have entered the market and extended the standard treatment of ACS patients with clopidogrel and aspirin. In the field of antithrombotics, the key parameter to control is unwanted bleeding, which defines an upper limit in the optimal therapeutic dose. Therefore, efficacious drugs with a further improved therapeutic window are still needed. Recent studies have provided new antithrombotic targets, and the role of platelets beyond hemostasis has opened up new fields of research.

Acknowledgments

The authors thank Kurt Hilpert, Nathalie Meyer-Schaller, Dorte Renneberg, and Jodi Williams for the critical review of the book chapter.

7.16.1 Introduction

Hemostasis is a process that stops bleeding via clot formation in the event of vascular injury. Conversely, thrombosis is the abnormal propagation of clotting resulting in occlusion of a blood vessel. Clotting is highly regulated to maintain the balance between thrombosis and hemorrhage. In certain pathological states, inappropriate coagulation predominates with serious implications. Arterial thrombosis can lead to myocardial infarction and ischemic stroke, and is the leading cause of mortality and morbidity worldwide, accounting for a combined 25% of all deaths.[1] In a venous setting, deep vein thrombosis (DVT) may result in leg swelling and life-threatening pulmonary embolism (PE), if a clot is dislodged. Overall, effective treatment for thrombosis-related cardiovascular disease remains a major unmet medical need.

Anticoagulant drugs are the primary strategy for the prevention and treatment of thrombosis and its accompanying complications. For about 60 years, the only available anticoagulants were heparin and warfarin. Although both have potent antithrombotic activity, each has limitations.[2] Heparin, a highly sulfated glycosaminoglycan originally isolated from canine liver extracts, is not orally bioavailable and thus requires parenteral administration. With the advent of low molecular weight heparin (LMWH), which is administered subcutaneously, challenges of variable bioavailability and duration of action experienced with unfractionated heparin were overcome. Until recently, warfarin, a vitamin K antagonist (VKA) that acts by preventing maturation of several coagulation proteases through inhibition of vitamin K epoxide reductase, was the only orally bioavailable anticoagulant. Although an efficacious anticoagulant, warfarin is less than an ideal drug due to delayed onset of activity, drug–drug interactions, dietary restrictions, and a narrow therapeutic index, which can result in suboptimal time in therapeutic range, necessitating strict patient monitoring. These limitations spurred research to discover improved anticoagulant drugs that are orally bioavailable with predictable activity, but at the same time do not increase bleeding or require monitoring.

The sequence of enzymatic events leading to clot formation is depicted in the coagulation cascade, a model originally proposed 50 years ago.[3,4] The coagulation cascade model has evolved to consist of three phases: initiation, amplification, and propagation,[5] and is split into the extrinsic and intrinsic pathways (**Fig. 1**). The two pathways converge at the common pathway, in which Factor X (FX) is converted to Factor Xa (FXa). FXa along with its cofactor Va (FVa) then converts prothrombin to thrombin. Thrombin converts fibrinogen to fibrin, which in turn forms the basis for the fibrin clot. Initiation of coagulation occurs in the extrinsic

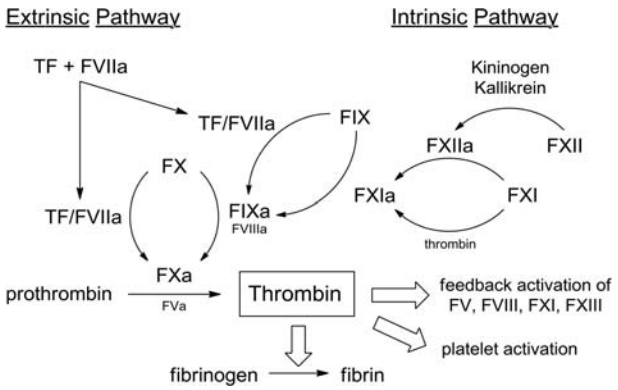

Fig. 1 A representation of the coagulation cascade.

pathway when tissue factor (TF) is exposed upon blood vessel wall injury or atherosclerotic plaque rupture and forms a complex with factor VIIa (FVIIa). The TF/FVIIa complex activates factor IX (FIX) and FX to factor IXa (FIXa) and FXa, respectively. The intrinsic pathway is primarily responsible for the amplification phase of coagulation. This pathway is initiated by the activation of factor XII (FXII) to factor XIIa (FXIIa), facilitated by kininogen and plasma kallikrein. FXIIa activates factor XI (FXI) to factor XIa (FXIa), which in turn activates FIX to FIXa. FIXa forms a complex with factor VIIIa (FVIIIa), which then activates FX to FXa. Additional conversion of FXI to FXIa also occurs via feedback activation by thrombin. Thrombin has multiple functions, including conversion of fibrinogen to fibrin, platelet activation and feedback activation of factor V (FV), factor VIII (FVIII), FXI, and factor XIII (FXIII), which together lead to the propagation of clot formation.

Medicinal chemistry efforts have targeted multiple steps of the coagulation cascade for the discovery of anticoagulant drugs. The main challenge in the anticoagulant drug development effort is balancing antithrombotic efficacy with bleeding safety. The various coagulation targets offer unique profiles with regard to this efficacy/bleeding dichotomy. Significant drug discovery advances have been made, but there continues to be the need for drugs that allow for increased efficacy without dose limitations due to bleeding risk. This review will cover new antithrombotic agents, including inhibitors of thrombin and FXa, several of which have reached the market, as well as inhibitors of TF/FVIIa, FIXa, and FXIa, some of which are currently in development, and highlight the major findings in the quest for better and safer antithrombotic agents since 2006.

7.16.2 Thrombin Inhibitors

7.16.2.1 Target Validation and Proof of Concept

Efforts to identify novel anticoagulants targeting specific serine proteases in the coagulation cascade were initially focused on direct inhibition of thrombin by virtue of its key role both in the formation of fibrin clots and in activation of platelets. Early thrombin inhibitors were i.v. administered polypeptides based on hirudin, a 65-amino acid polypeptide isolated from the salivary gland of the medicinal leech.[6] Two recombinant forms of hirudin, lepirudin and desirudin, were approved for clinical use in the treatment of heparin-induced thrombocytopenia (HIT) and prevention of venous thromboembolism (VTE) in patients undergoing hip-replacement surgery, respectively.[7] A third agent related to hirudin, bivalirudin, a synthetic 20-amino acid polypeptide analog that binds to both the active site and the GPIbα-binding site of thrombin, is approved as an alternate to heparin in patients undergoing percutaneous coronary intervention (PCI).[8]

7.16.2.2 Small-Molecule Direct Thrombin Inhibitors

Structurally, the active site of thrombin, in common with other serine proteases, includes an S1 specificity pocket with Asp189 at the bottom creating a preference for substrates with a basic P1 group.[9,10] Due to an insertion loop that includes Tyr61A, Pro60B, Pro60C, and Trp60D that is unique to thrombin, the S2 pocket in thrombin is relatively small, and the natural substrates typically have small, hydrophobic residues such as proline at P2. The S3/4 pocket is formed by the residues Leu99, Ile174, and Typ215 and accommodates aromatic residues such as Tyr and Phe. In common with other serine proteases is the catalytic triad of Asp102, His57, and Ser195. Hence, medicinal chemistry efforts to identify small-molecule direct thrombin inhibitors (DTIs) focused on Arg–Pro–Phe peptidomimetics and incorporated acid groups to interact with the residues of the catalytic triad. This resulted in the identification of small-molecule inhibitors, such as argatroban (**1**, Fig. 2), a parenteral agent currently approved for the treatment of patients with HIT.[11]

The search for orally bioavailable DTIs was hampered for many years by the presence of the highly basic P1 Arg mimic in combination with the carboxylic acid substituent, which resulted in zwitterionic molecules with poor oral exposure.[12] Ultimately, this lack of oral absorption was addressed using prodrugs. The first such compound to reach the market was ximelagatran (**3**, Fig. 2), a double

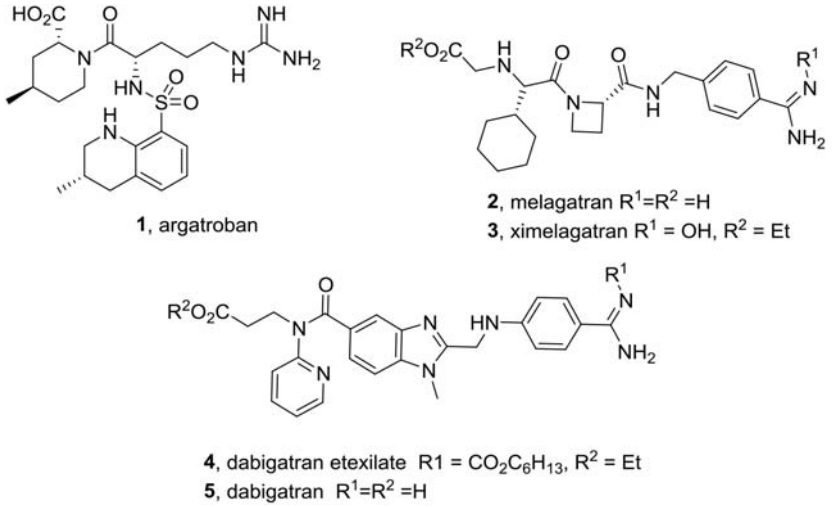

Fig. 2 Small-molecule DTIs: argatroban, ximelagatran, and dabigatran etexilate.

prodrug of melagatran (**2**),[13] which was launched in Europe in 2004, but was subsequently withdrawn from the market due to drug-induced liver toxcity.[14]

A second oral DTI, dabigatran etexilate (**4**, Fig. 2), also a double prodrug of a benzamidine-based inhibitor, dabigatran (**5**), was launched in Europe in 2008 for prevention of VTE[15] and in the United States in 2010 for prevention of stroke and systemic embolism in atrial fibrillation patients (SPAF).[16] Dabigatran etexilate is currently the only orally bioavailable DTI on the market. Dabigatran is a potent inhibitor of thrombin with Ki = 4.5 nM. On oral administration of the double prodrug in humans, the oral bioavailability of **5** is ~6.5%. Concerns over bleeding risk in patients taking DTIs[17,18] led to the introduction of idarucizumab (BI 655075), an antibody fragment that binds to the thrombin-binding site of dabigatran and is a specific antidote for dabigatran recently approved in the United States.[19]

Examples of other DTIs that were advanced into clinical trials are shown in Fig. 3. Efficacy in rat models of venous and arterial thrombosis was demonstrated with AR-H067637 (**7**), the active metabolite of AZD0837 (**6**), with minimal to no increase in bleeding observed.[20] In a Phase II clinical trial, **6** had a good safety profile with low incidence of bleeding and demonstrated effective anticoagulation using standard clotting time measurements.[21] Pyrrolidine LB30870 (**8**) was more potent than melagatran and

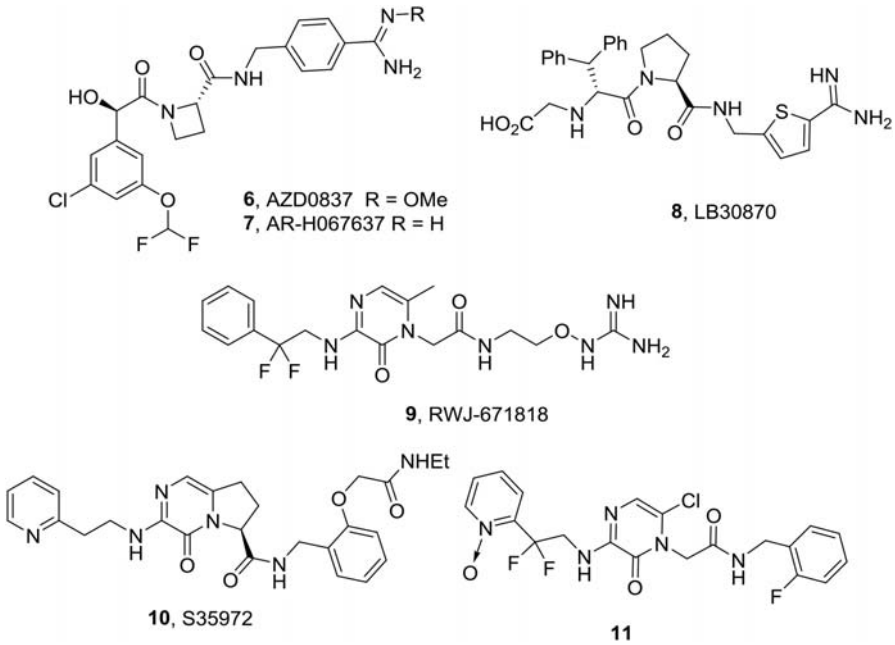

Fig. 3 Examples of additional DTI clinical candidates.

argatroban in inhibiting thrombin in vitro, with a comparable on-rate and slower off-rate compared with melagatran, and showed dose-dependent antithrombotic efficacy in animal models of venous thrombosis.[22] In a Phase I clinical trial to assess pharmacokinetic (PK), pharmacodynamic (PD), and food effects in healthy male subjects, **8** was well tolerated, but showed nonlinear oral PK with a significant, negative food effect.[23]

Ultimately with the aid of structure-based drug design (SBDD), novel DTIs with nonpeptidic scaffolds, less-basic P1 groups, and no acid functionality were identified that obviated the need for prodrugs in order to achieve oral bioavailability. A variety of strategies were explored to replace the basic benzamidine group. RWJ-671818 (**9**, Fig. 3), a pyrazinone core molecule with a weakly basic oxyguanidine P1 group, is a potent inhibitor of thrombin with Ki = 1.3 nM.[24] It is 100% bioavailable in dogs with good stability in human liver microsomes. Compound **9** was highly efficacious in vivo in the electrolytic-mediated carotid arterial thrombosis (ECAT) and DVT models in rats and in the arterial venous (A-V) shunt model in dogs. A Phase I human clinical trial to assess safety, tolerability, PK, and PD of a single oral dose of **9** in healthy male volunteers was completed, and results were described as promising, but no further development has been reported. S35972 (**10**, Fig. 3) is another weakly basic DTI, which is highly selective for thrombin over other serine proteases and shows comparable in vitro potency to dabigatran.[25] Good oral bioavailability was demonstrated with **10** in dogs (F% > 70%), as well as efficacy in both venous and arterial models of thrombosis in the rat, with no food effect. Better efficacy and less bleeding in a rat arterial thrombosis model was reported for **10** when compared with dabigatran etexilate. Based on its positive preclinical profile, **10** was advanced into Phase I clinical trials and was found to be well tolerated at effective anticoagulant doses.[25] In pyrazinone compound **11** (Fig. 3), a pyridine N-oxide was used to impart improved aqueous solubility over a previous lead compound to afford a compound suitable for further clinical development.[26]

While the majority of the effort in anticoagulant research eventually shifted to other targets in the coagulation cascade, additional orally bioavailable DTIs using diverse P1 groups have been reported in the literature. Compounds with pyridone and pyrazinone cores and aminopyridine and imidazole P1 moieties, **12** and **13**, respectively, (Fig. 4) demonstrated modest oral exposure in dogs.[27] Replacement of the P3 imidazole with substituted phenyl groups provided **14** with thrombin Ki = 1.5 nM and excellent trypsin selectivity.[28] The corresponding pyridine N-oxide provided a twofold improvement in functional activity as measured by the activated partial thromboplastin time (aPTT) assay.

In another series of compounds, replacement of the oxyguanidine P1 with 3-(6-methyl-2-aminopyridine) in a series of chlorofluorophenylacetamide P2 thrombin inhibitors provided **15**[29] (Fig. 5) with thrombin Ki = 0.7 nM. In a related series, cyanofluorophenylacetamide **16** was a potent inhibitor with thrombin Ki = 1.2 nM and good oral exposure in dogs (F% = 49%), but lacked oral bioavailability in rats.[30] A thiomorpholine inhibitor **17** with thrombin Ki = 1.1 nM was identified from a screen of six-membered ring heterocycle cores, but while slightly more selective had poor PK compared with the analogous pyrrolidine-based compound **18** (Fig. 5).[31] Benzamidine compound **19**, bearing a benzoxazinone core, was also a potent and selective inhibitor of thrombin in vitro with Ki = 2.6 nM.[32]

Fluorinated dabigatran derivatives **20** and **21** (Fig. 6) where the pyridine ring of **5** was replaced by a substituted *ortho*-fluorobenzene ring, or the terminal benzamidine ring was substituted with fluorine, provided compounds with similar in vitro potency to **5** and in vivo activity of the corresponding double prodrugs **22** and **23** comparable to **4**.[33] N-ethyl analogs **24–26** (Fig. 6) with fluoro-, difluoro-, and trifluoro-substituted methylbenzene rings in place of the pyridyl ring of **5** were also found to be potent DTIs when compared with **1** in vitro.[34] HY023016 (**27**, Fig. 6), a novel tetramethylpyrazine dabigatran prodrug, was efficacious in two animal models of venous thrombosis in rats and demonstrated a lesser effect on bleeding in a mouse tail bleeding model compared with dabigatran etexilate.[35]

Outside the realm of small-molecule inhibitors, both cyclic peptides[36] and DNA aptamers[37,38] have been proposed as thrombin inhibitors which would offer both high specificity and affinity.

7.16.3 Factor Xa Inhibitors

7.16.3.1 Target Validation and Proof of Concept

Proof of concept for FXa as an anticoagulant target was provided by polypeptide inhibitors, antistasin, isolated from the salivary glands of the Mexican leech,[39] and the tick anticoagulant peptide (TAP),[40] both of which were shown to be slow, tight-binding inhibitors of FXa. The gradual shift of research focus from thrombin to FXa began in earnest as early preclinical data comparing

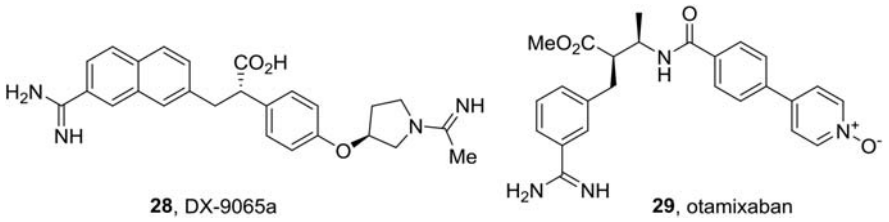

Fig. 7 Benzamidine FXa inhibitors: DX-90651 and otamixaban.

DTIs to selective FXa inhibitors in animal models of thrombosis demonstrated similar or improved efficacy with less bleeding compared with thrombin inhibitors.[41–43] Ensuing clinical success with indirect FXa inhibitors, such as the pentasaccharide fondaparinux, lent further support to the FXa mechanism.[39,44] Early clinical experience with small-molecule FXa inhibitors was obtained with parenteral agents, such as DX-9065a (**28**)[45] and otamixaban (**29**),[46,47] which contain strongly basic amidine moieties and have insufficient oral bioavailability (see **Fig. 7**).

Efforts to identify orally bioavailable direct FXa inhibitors, which have continued over more than two decades, resulted in the identification of numerous novel small-molecule FXa inhibitors. Similar to thrombin inhibitors, this research transitioned from small peptidic inhibitors of FXa to peptidomimetics anchored by a highly basic benzamidine P1 and ultimately to less-basic or neutral small-molecule inhibitors.[48] Extensive systematic structure-activity relationship (SAR) studies beginning from weak inhibitors identified from high-throughput screening, and SBDD using X-ray structures of early inhibitors bound in the active site of FXa, resulted in the identification of potent inhibitors. Key structural features of the FXa-binding site exploited by small-molecule inhibitors are a generally hydrophobic S1 recognition pocket with Asp189 and Tyr228 at the bottom, a hydrophobic S4 pocket formed by residues Phe174, Tyr99, and Trp215 and backed by a "cation hole" formed by the carbonyls of Lys96 and Glu97 that will accommodate positively charged P4 moieties; and backbone interactions with the intervening residues 214–217.[49] While the early benzamidine and other basic P1 groups formed key H-bonding interactions with Asp189, many of the neutral P1 inhibitors instead form hydrophobic interactions with Tyr228 through Cl, Me, or OMe substituents. In addition, the Cys191–Cys220 disulfide bridge above the S1 pocket provides an additional hydrophobic area that is accessed by some small-molecule inhibitors. Further optimization provided compounds with good oral bioavailability and optimal PK profiles suitable for once or twice a day dosing. Large clinical trials comparing FXa inhibitors to the standard of care have now established the safety and efficacy of the FXa mechanism in patients.[50] Currently three FXa inhibitors have been approved and marketed, while several others have entered or completed Phase I and II clinical trials, and the clinical pharmacology of the various compounds has been reviewed.[51]

7.16.3.2 Marketed Factor Xa Inhibitors

Rivaroxaban (**30**, **Fig. 8**),[52] the first FXa inhibitor to be approved for clinical use, utilizes an oxazolidinone core linking a chlorothiophene P1 group and a phenylmorpholinone P4 moiety while forming H-bonds to Gly219, an intervening residue in the active site of FXa. Rivaroxaban is an orally bioavailable, potent, and highly selective inhibitor of FXa with Ki = 0.4 nM. Selectivity over other serine protease is > 10,000 fold. In preclinical animal models of thrombosis, rivaroxaban was efficacious in both venous and arterial models without significant prolongation of bleeding times. Human oral bioavailability is very high (80–100% after a 10 mg dose) with a terminal half-life of 7–11 h.[52] In a large clinical trial comparing rivaroxaban to warfarin in patients with nonvalvular atrial

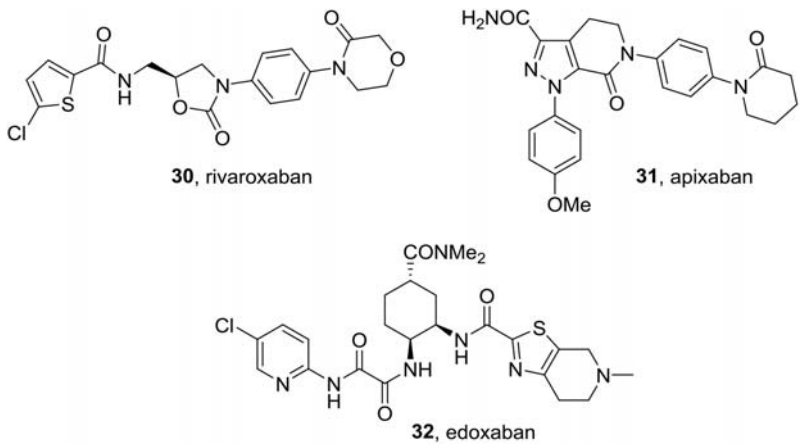

Fig. 8 Marketed FXa inhibitors: rivaroxaban, apixaban, and edoxaban.

fibrillation, rivaroxaban administered once daily was noninferior to warfarin in the prevention of stroke and systemic embolism (SPAF) with similar bleeding occurence.[53]

Apixaban (**31**, Fig. 8),[54] the second FXa inhibitor approved, incorporates a rigid bicyclic tetrahydropyrazolopyridinone core to optimally position its 4-methoxyphenyl P1 and phenylpiperidone P4 groups, while forming key H-bonding interactions to the intervening residues. It is a potent, highly selective FXa inhibitor with FXa Ki = 0.08 nM and >30,000-fold selectivity over other coagulation proteases. In dogs, apixaban demonstrated favorable PK with a small volume of distribution, low clearance, moderate half-life, and good oral bioavailability.[55] Dose-dependent antithrombotic effects in animal models of arterial and venous thrombosis were observed without excessive increase in bleeding times.[56] Apixaban has a terminal half-life in humans of 8–15 h and >50% oral bioavailability and is given twice a day to minimize peak-to-trough fluctuations, which appears to provide a more optimal benefit-to-risk profile.[57] In a clinical trial in 18,201 patients comparing apixaban to warfarin for SPAF, apixaban was superior to warfarin for prevention of stroke and systemic embolism with less bleeding and reduced mortality.[58] In a separate study, apixaban was also shown to be superior to aspirin for SPAF without significant increase in major bleeding.[59]

Edoxaban (**32**, Fig. 8),[60] the third FXa inhibitor to be approved, utilizes a substituted 1,2-diaminocyclohexane core with a chloropyridine P1 and an *N*-methyl-tetrahydrothiazolopyridine P4 group. Its FXa Ki is 0.56 nM with >10,000-fold selectivity for FXa. Oral absorption in rats and monkeys was superior to **28**, and dose-dependent inhibition of thrombus formation was observed in animal models without significant prolongation of bleeding time at an antithrombotic dose. In humans, the terminal half-life is 9–11 h with 50% oral bioavailability. Edoxaban dosed once daily demonstrated noninferiority versus warfarin for SPAF with less bleeding and lower risk of death from a cardiovascular cause.[61,62] The major route of clearance is renal, with 50% of drug excreted unchanged in the urine.[63]

In addition to the above key SPAF trials, these three FXa inhibitors have been assessed in multiple Phase III trials for treatment and prevention of VTE, DVT, or PE and have demonstrated either noninferior or superior efficacy and safety as compared to the standard of care.[64] Indirect analyses of the accumulated trial data suggest, however, that apixaban has a better margin of safety with respect to bleeding.[65] A recent meta-analysis of the combined data from four major SPAF trials with the new oral anticoagulants (dabigatran etexilate, rivaroxaban, apixaban, and edoxaban) found an overall favorable benefit/risk profile, with significant decrease in the incidence of stroke, intracranial bleeding, and mortality.[66] In this pooled analysis, the risk of major bleeding was similar to warfarin.

7.16.3.3 Additional FXa Inhibitors Assessed in Clinical Trials

Razaxaban (**33**, Fig. 9),[67] a forerunner to apixaban, was the first small-molecule oral FXa compound to establish clinical proof of concept (PoC) for the FXa mechanism[68] and advanced through Phase II trials before being superseded by apixaban. Razaxaban has an FXa Ki = 0.19 nM with excellent selectivity over other serine proteases. A unique feature of **33** was the aminobenzisoxazole P1, which was designed using SBDD to provide trypsin selectivity by taking advantage of the larger S1 pocket of FXa. Betrixaban (**34**, Fig. 9),[69] which has completed successful Phase II trials for VTE and SPAF,[70] is an anthranilamide-based compound with a chloropyridine P1 and dimethylbenzamidine P4 group. It is a potent inhibitor of FXa (Ki = 0.12 nM) with a high volume of distribution, long half-life, minimal renal clearance, and low hepatic metabolism.[71] A Phase III study for extended VTE thromboprophylaxis in medical patients is still ongoing.

Optimization of the pyrrolidine N-substituent, which projects into the S1β-pocket of FXa in a series of (3*R*,4*R*)-pyrrolidine-3,4-dicarboxamide core molecules, provided R1663 (**35**, Fig. 9).[72] This inhibitor had good PK and oral bioavailability across multiple species with >33-fold selectivity over other serine proteases. Data from Phase I trials has been reported,[73] and Phase II trials with this compound have since been initiated in Russia.

Letaxaban (**36**, Fig. 9)[74] incorporates a 2-hydroxyethylsulfone moiety to link a chloronaphthyl P1 with a 4-piperidinyltetrahydropyrimidinone P4 group. The tetrahydropyrimidinone P4 group of **36** was discovered from extensive SAR to identify a replacement heterocycle to address a metabolic vulnerability observed in an earlier imidazoimidazolone lead compound. Compound **36** has an FXa IC_{50} = 3.5 nM with favorable PK in monkeys and potent antithrombotic efficacy in a rabbit model of venous thrombosis without affecting bleeding time.[75] Letaxaban was progressed through Phase II clinical trials, but has since been discontinued. Darexaban (**37**, Fig. 9),[76] a phenylene diamine with 4-methoxyphenyl P1 and phenyldiazine P4, is a modestly potent FXa inhibitor with a Ki = 31 nM, which progressed through Phase III clinical trials before being discontinued.[77] Glucuronidation of the phenol in **37** after oral administration leads to the formation of a highly metabolically stable, active metabolite (FXa IC_{50} = 28.6 nM) that plays a major role in the potent anticoagulant activity in plasma.[76]

Eribaxaban[78] (**38**, Fig. 9) is a D-proline-based FXa inhibitor which incorporates a chlorophenyl P1 in combination with a fluorophenylpyridinone P4 group and has a FXa IC_{50} = 0.32 nM. The compound showed good preclinical properties and was advanced through Phase II clinical trials before development was halted.[79] The results of a Phase II proof of concept study with LY517717 (**39**, Fig. 9)[80] were also reported, but no further development is evident. GW813893 (**40**),[81] a pyrrolidinone-based molecule with a 5-chlorothiophene-2-ethenyl P1 and morpholine amide P4 group, was also reportedly advanced into clinical trials based on encouraging preclinical data in animal models,[82] but no results or further development has been reported. Positive results from a first in human (FIH) trial with FXa inhibitor, DY-807f, were recently reported, but the structure of this compound was not disclosed.[83]

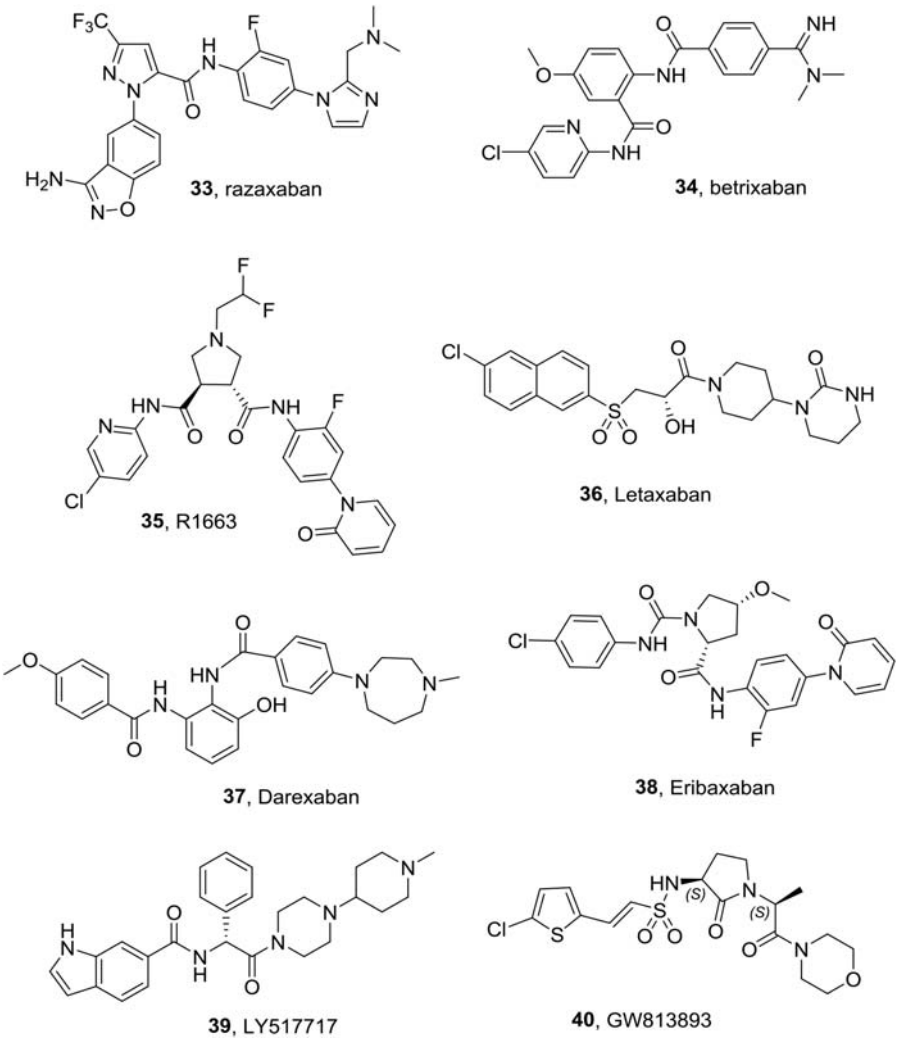

Fig. 9 Structures of additional FXa inhibitors that progressed to clinical trials.

7.16.3.4 Preclinical FXa Inhibitors

Many additional small-molecule inhibitors of FXa that have not advanced to clinical trials have also been described. Potent in vitro inhibition of FXa can be achieved with a wide variety of scaffolds in combination with structurally diverse P1 and P4 moieties, and detailed reviews of the field are available.[48,84,85] Finding drug candidates with the ideal combination of potency, PK and PD, with a good margin of safety is much more challenging and was the cornerstone of the successful efforts that resulted in the FXa inhibitors described earlier. The range of structural diversity explored in the search for viable FXa inhibitors is a testament to the ingenuity of the medicinal chemist. The following additional examples provide a brief survey of recently disclosed novel, potent, and selective inhibitors of FXa, many of which are also efficacious in animal models of thrombosis after oral administration.

A conformationally constrained analog of rivaroxaban (**41**, Fig. 10),[86] which incorporates a novel [6,6,5] tricyclic ring system designed to maintain the preferred coplanar relationship between the oxazolidinone ring and the pendant phenyl, was reported to have improved in vitro and in vivo potency in animal models of thrombosis with similar increase in bleeding times compared with rivaroxaban. The compound had high oral bioavailability in dogs (F% = 92%) and was well tolerated in a 2-week toxicity study in rats.

Various analogs of apixaban have been explored, including triazolinone **42** (Fig. 10), which exhibits a unique binding mode extending the triazolinone ring deeper into the S1 pocket as a result of movement of Asp189 to create a larger pocket.[87] Potential backups to apixaban with gem-dimethyl P4 moieties replacing the terminal lactam were also explored. Compounds **43** and **44** (Fig. 10) had the best combination of FXa affinity, PK, and oral bioavailability, but did not differentiate from apixaban.[88]

In the edoxaban series, compounds with alternate P1 groups were explored including 5-chloroindole compound **45**, which was evaluated as a potential clinical candidate, and chloroisoquinoline **46**,[89] which also incorporates a novel dihydropyrrolo[3,4-*d*]thiazolyl P4 group (See Fig. 11). Compared to **45**, compound **46** showed a reduced food effect in both monkeys and dogs, which was attributed to its greatly improved solubility at both pH 1.2 and 6.8.

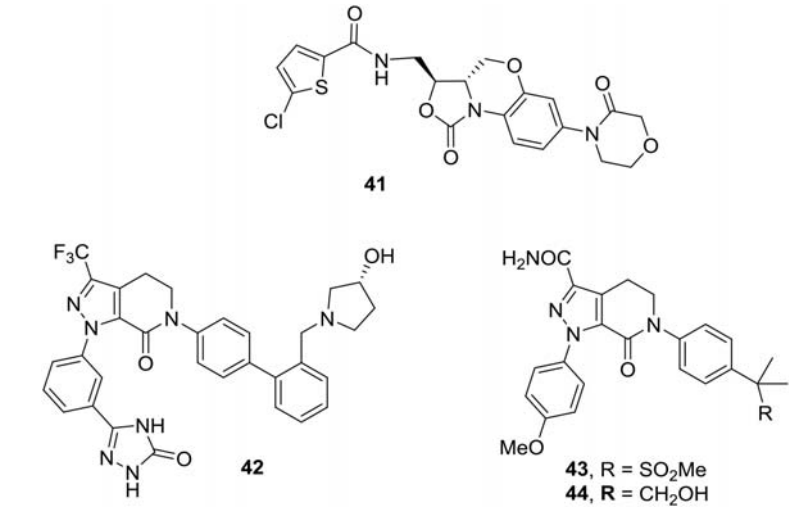

Fig. 10 Analogs of rivaroxaban and apixaban.

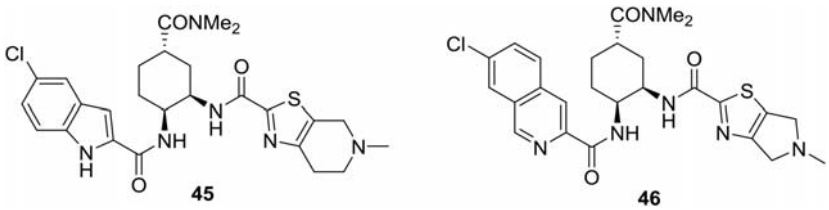

Fig. 11 Analogs of edoxaban.

The biphenylsulfonamide P4, previously pioneered in early examples in the pyrazole series, which led to apixaban, was also used successfully in the SBDD of early examples in the eribaxaban series, such as compound **47** (Fig. 12).[90] Additional analogs of eribaxaban with disubstitution at the 4-position of the central pyrrolidine ring were explored in an attempt to increase the projected human half-life.[91] This was achieved with compound **48** by incorporating a 2,4-difluorophenyl group at this position to achieve a projected human t½ of 23 h compared to 6 h for eribaxaban. An FXa X-ray crystal structure of **48** compared with eribaxaban shows good overlap of the two structures with the aryl group extended above the S1 pocket such that the *ortho*-fluoro substituent occupies the disulfide region. Compound **49**, which uses the P4 of eribaxaban and the P1 of rivaroxaban in combination with a pyrrolidine scaffold, was evolved from a weakly active aminothiazole lead.[92] Further optimization of this series resulted in the identification of clinical candidate, **35** shown earlier.[72]

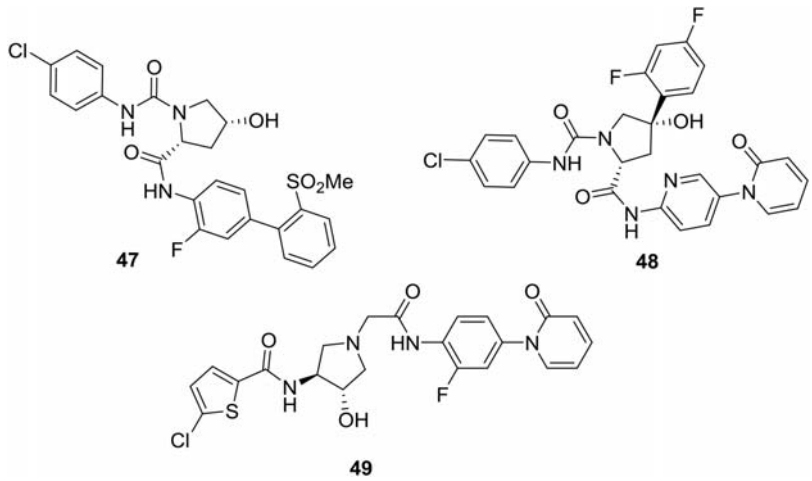

Fig. 12 Analogs of eribaxaban.

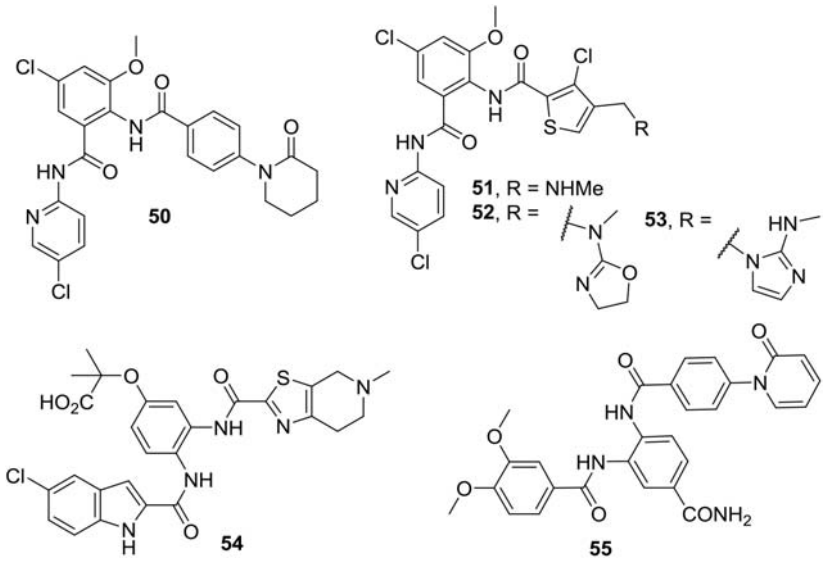

Fig. 13 Analogs of betrixaban.

Numerous examples of anthranilamide-based compounds, of which betrixaban is the most advanced, have been disclosed. The examples depicted in Fig. 13 serve to show the diversity of P1 and P4 groups and substitution patterns on the central phenyl ring that can be combined using this scaffold (ie, **50**[93] and **51–53**[94]), as well as the related phenylene diamine scaffold (ie, **54**[95] and **55**[96]), to provide potent inhibitors of FXa.

To further improve the properties of GW813913, biaryl substituted pyrrolidinones, such as compound **56** (Fig. 14),[97] a subnanomolar inhibitor of FXa that incorporates the P4 group of razaxaban, was prepared. The P1 group of GW813913 was also successfully used in combination with an aminomethyl pyrrolidine core and 4-pyridylpiperidine P4 group in compound **57**.[98]

Various analogs of letaxaban that lack the β-hydroxy group on the ethylsulfone linker and incorporate novel P4 groups were explored. Potent, selective, orally bioavailable inhibitors, such as **58**,[99] **59**,[100] and **60**,[101] (Fig. 15) with reduced CYP3A4 inhibition over earlier analogs were identified as interesting lead molecules.

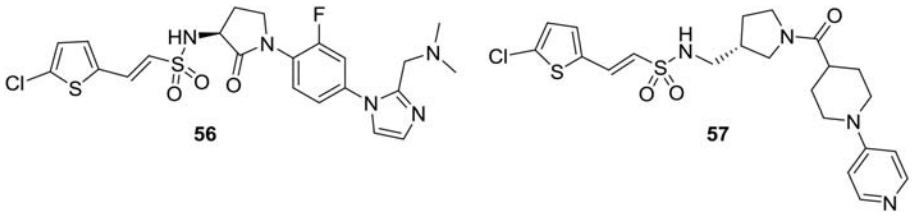

Fig. 14 Analogs of GW813913.

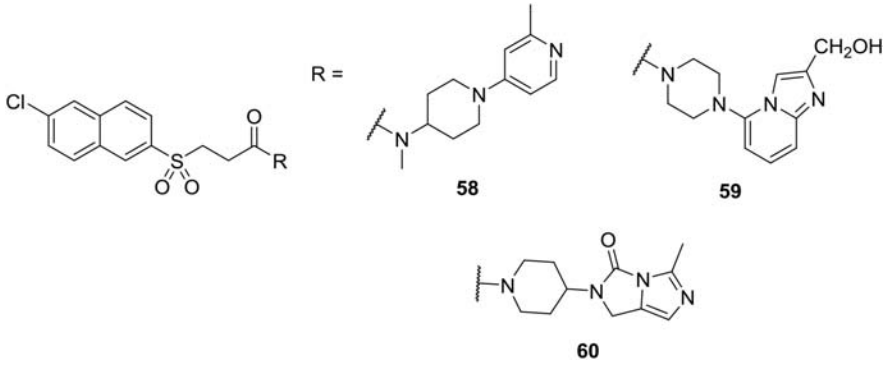

Fig. 15 Analogs of letaxaban.

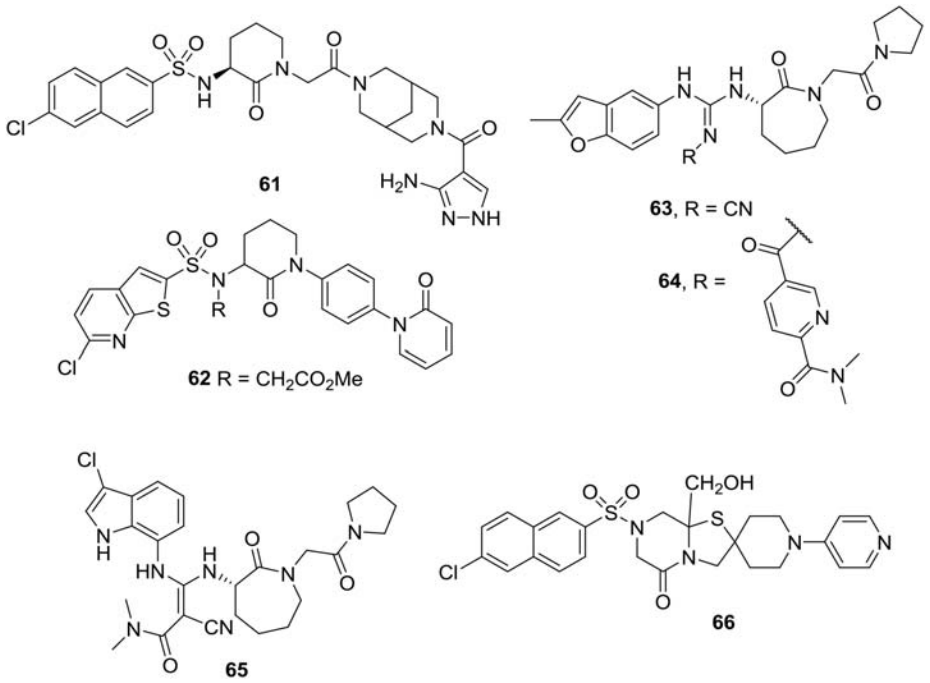

Fig. 16 FXa analogs with alternate cores.

Potent FXa inhibitors have also been reported with lactam cores, such as aminopiperidones **61**[102] and **62**[103] and aminoazepinones **63**,[104] **64**,[105] and **65**[106] (Fig. 16). A final example of a potent FXa inhibitor with a unique tricyclic scaffold, compound **66** utilizes a novel substituted *N,S*-spiroacetal scaffold to position a chloronaphthyl P1 and 4-pyridyl to provide a potent inhibitor of FXa with $IC_{50} = 1.2$ nM.[107]

7.16.3.5 Reversal Agents

The anticoagulant effects of the VKAs can be effectively reversed in 12–24 h by oral or intravenous administration of vitamin K, or more rapidly by intravenous administration of vitamin K-dependent clotting factors in the form of prothrombin complex concentrate to prevent bleeding in the event of trauma, a need for immediate surgery or overdose.[108] With the introduction of new highly potent anticoagulants came concerns over the lack of effective reversal agents for this class of drugs. Consequently, a focused effort was quickly undertaken to identify both general and specific reversal agents for these new anticoagulants.[109] Currently, two potential solutions for reversal of FXa inhibitors have been evaluated in clinical trials.[110,111] Andexanet alfa is a recombinant protein with similar structure to FXa but lacking the γ-carboxyglutamic acid terminal amino acid and incorporating a serine to alanine mutation at the active site, thus rendering it enzymatically inactive, and therefore unable to convert prothrombin to thrombin.[112] This protein effectively binds to FXa inhibitors with a greater affinity than natural FXa, leading to rapid inactivation of the inhibitors. In animal models, the protein effectively reversed the effect of both direct and indirect FXa inhibitors. Phase III clinical trials have demonstrated reversal of the anticoagulant effects of both rivaroxaban and apixaban by adexanet alfa.[113]

Aripazine (PER977, **67**, Fig. 17), a small water-soluble, cationic molecule, was originally developed as a reversal agent for heparin and fondaparinux and works by binding to these anionic drugs through noncovalent H-bonds and charge–charge interactions to inactivate them.[114] Recent studies suggest that this compound may also be effective as a reversal agent for the currently

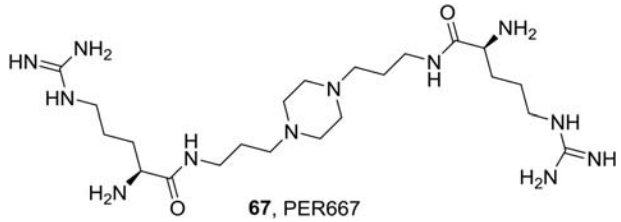

Fig. 17 Structure of PER667.

marketed FXa and thrombin inhibitors. In healthy volunteers pretreated with 60 mg of edoxaban, an i.v. bolus dose of 300 mg of PER977 was shown to return clotting times to normal within 10–30 min.[115]

7.16.3.6 Dual Thrombin/FXa Inhibitors

A number of research groups have proposed dual inhibitors of thrombin and FXa as potentially more effective anticoagulants compared with DTIs or FXa inhibitors alone. A recent publication comparing a thrombin and FXa inhibitor alone or in combination, along with a dual thrombin/FXa inhibitor, RWJ-445167 (**68**, FXa Ki = 230 nM, thrombin Ki = 4 nM, Fig. 18), reported a cooperative antithrombotic effect in vivo in a rat ECAT model when both enzymes were inhibited simultaneously.[116] Based on favorable data in animal models, **68** was studied in Phase I clinical trials; however, oral bioavailability in humans was insufficient for further advancement.[117] A variety of prodrugs were evaluated in rats, but no suitable candidates were identified.

The results of a Phase I clinical trial of another dual thrombin/FXa inhibitor, tanogitran (**69**; thrombin Ki = 2.7 nM, FXa Ki = 26 nM, Fig. 18), in an i.v. model of endotoxin-induced coagulation were published.[118] Plasma aPTT values were prolonged and in vivo thrombin generation (TG) was reduced in a dose-dependent manner. The compound was reported to be safe and well tolerated. No further clinical development has been reported.

The addition of a methyl group to the double bond in vinyl sulfone compound **70** (Fig. 18) converted a 100-fold selective Xa inhibitor into a dual FXa/thrombin inhibitor with 2 nM affinity for both enzymes.[119] This compound had two- to fourfold improved functional potency in plasma-based assays and was orally bioavailable in both dogs and rats. Similarly, using rivaroxaban as a starting point, replacement of the morpholinone P4 group with 2-ethoxycarbonylpiperidine resulted in conversion from a highly potent, selective inhibitor of FXa to a dual FXa/thrombin inhibitor **71**[120] with modest potency for both enzymes, that is, FXa Ki = 62 nM and thrombin Ki = 353 nM. Using docking experiments, the authors proposed that extension of the ethoxycarbonyl group into the S2 pocket of thrombin is responsible for the restoration of thrombin activity. By optimization of a proline analog of another selective FXa inhibitor, the dual thrombin/FXa inhibitor **72**[121] was obtained with FXa Ki = 1.5 nM and thrombin Ki = 3.5 nM. Both this compound and its ethyl ester prodrug had low oral bioavailability and short half-lives in rats that precluded further development.

SAR107375 (**73**, Fig. 18)[122] is a dual inhibitor with FXa Ki = 1 nM and thrombin Ki = 8 nM that was identified from optimization of a thrombin inhibitor with weak FXa affinity. Compound **73** was potent in models of venous and arterial thrombosis in rats and showed reduced bleeding liability compared to either rivaroxaban or dabigatran etexilate. It is orally bioavailable in both dogs and rats (47% and 21%, respectively), and is reportedly in preclinical development.

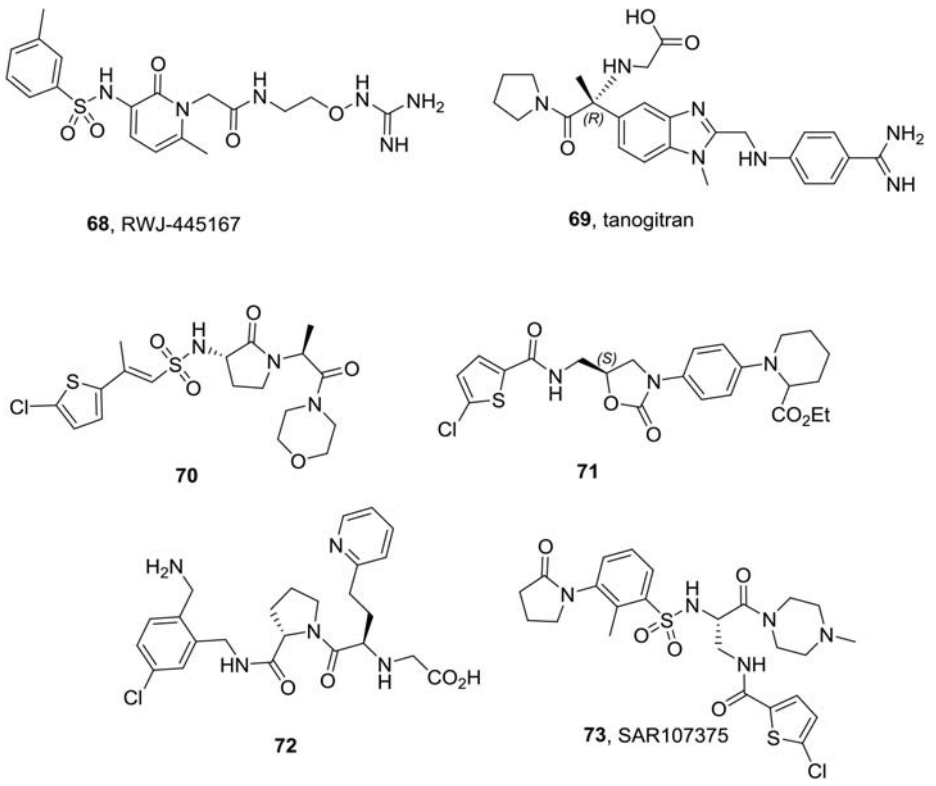

Fig. 18 Dual inhibitors of FXa and thrombin.

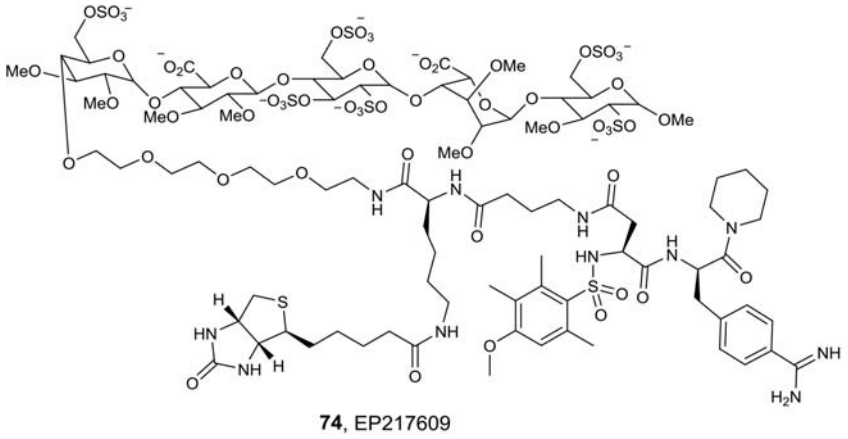

Fig. 19 Structure of parenteral dual inhibitor of FXa and thrombin, EP217609.

EP217609 (**74**, **Fig. 19**),[123] a dual-action parenteral anticoagulant currently in Phase II clinical trials, combines a fondaparinux analog with a peptidomimetic DTI in a single molecule and also incorporates a biotin tag to allow neutralization with avidin. The compound displayed a long half-life with predictable PK, along with the ability to reverse the effects, that cannot be replicated by coadministration of the individual components. It may offer an attractive alternative for use in cardiopulmonary bypass surgery compared to the standard of care.

7.16.4 Factor VIIa Inhibitors

Comparisons of antithrombotic mechanisms have identified the TF–FVIIa complex as a biological target that offers strong antithrombotic efficacy and low bleeding liability in preclinical models.[124–126] Similar to the other serine proteases of the coagulation cascade, a major challenge in the development of drugs inhibiting TF/FVIIa is attaining oral bioavailability. Many TF/FVIIa inhibitors bear a highly basic benzamidine P1 moiety (pKa ~12), a mimetic of the guanidine side-chain of Arg in the natural substrates. Benzamidine-based inhibitors are potent, but due to low permeability of the basic group require administration as a prodrug or replacement with a nonbasic or less-basic moiety to attain orally bioavailability. Replacement of the amidine moiety, which contributes greatly to ligand-binding affinity, requires introduction of compensatory interactions. Neither strategy has yet successfully yielded an orally bioavailable TF/FVIIa clinical compound. TF/FVIIa compounds that have advanced to the clinic thus far have been biological agents[127,128] and a parenterally administered, small-molecule inhibitor.[129]

7.16.4.1 Target Validation and Proof of Concept

Initial evidence for antithrombotic activity for the TF/FVIIa pathway comes from biological agents targeting the complex or its individual components. The anti-TF antibody, AP-1, blocked thrombus formation in a rabbit thrombosis model[130] with reduced bleeding at elevated levels when compared to the DTI napsagatran and heparin.[131] Similarly, inactive mutants of TF showed efficacy in in vivo thrombosis models with decreased bleeding relative to other agents.[132,133] These TF mutants bind FVIIa, but form an enzymatically inactive complex. Active site inactivated FVIIa (FVIIai) showed antithrombotic efficacy in a baboon angioplasty model[134] and a rabbit model of carotid artery thrombosis.[135] These biological agents established a promising efficacy/safety profile for targeting the TF/FVIIa complex.

Following up on initial success of biological agents, many small-molecule inhibitors of TF/FVIIa were advanced into in vivo animal models of thrombosis. In some of the earliest studies of small-molecule TF/FVIIa inhibitors, antithrombotic efficacy in monkeys was reported.[124,125] Addition of a TF/FVIIa inhibitor on top of aspirin increased efficacy in venous thrombosis model without increasing bleeding relative to aspirin alone.[124] In comparisons to other antithrombotic mechanisms, the FVIIa inhibitors showed a superior bleeding profile at equi-efficacious doses or higher multiples.[124–126] Additional in vivo studies of small-molecule inhibitors provide further evidence for TF/FVIIa inhibitors of potent antithrombotic efficacy and minimal bleeding liability, especially when compared to other antithrombotic mechanisms.[136–141]

7.16.4.2 Agents Advanced to Clinical Development

Recombinant nematode anticoagulant protein c2 (rNAPc2) is an 85-amino acid peptide originally isolated from the hookworm, which binds FX and inhibits TF/FVIIa via the formation of a ternary complex.[142] In a Phase II study of patients undergoing total knee replacement surgery, an optimal dose was identified, which balanced antithrombotic efficacy and major bleeding.[127] In a Phase

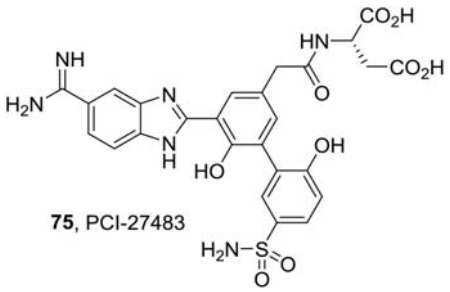

Fig. 20 Structure of parenterally administered TF/FVIIa inhibitor PCI-27483.

II study, rNAPc2 on top of standard therapy in patients undergoing coronary angioplasty suppressed biomarkers of TG and increased minor bleeding only at the highest dose to 27% (vs. 6.7% for placebo).[143] In a Phase II study in patients with non-ST-segment elevation acute coronary syndrome, rNAPc2-suppressed TG, and reduced rates of ischemia by >50%, although the study was not powered to evaluate clinical outcomes.[144] Elevated major bleeding was observed at the highest dose of rNAPc2. No further development as an anticoagulant has been reported.

ALT-836 (also referred to as TNX-832 and Sunol CH36) is an antibody to TF that binds specifically to TF at the FX-binding site, preventing formation of the TF/FVIIa–FX complex, and thus blocks the activation of FX and FIX.[145] In a Phase I study in subjects with stable coronary artery disease, ALT-836 showed dose-dependent anticoagulant effects.[128] Dose-related bleeding was observed, but was limited to minor bleeding events. Preclinically, ALT-836 reduced sepsis-induced respiratory and renal injury in a baboon model.[146] Based upon these results, ALT-836 was subsequently advanced into clinical trials for acute lung injury and acute respiratory distress syndrome (ARDS).[147] A Phase II study to evaluate safety and efficacy in this population is complete and data are pending.[148] A Phase I study of ALT-836 in combination with gemcitabine in patients with locally advanced or metastatic solid tumors is underway.[149]

PCI-27483 (**75**, Fig. 20) is a parenterally administered, small-molecule inhibitor of TF/FVIIa advanced into clinical trials for the treatment of pancreatic cancer. TF is upregulated in cancers and levels correlate with disease progression, making the protein a potential anticancer target.[150] Inhibitors of TF/FVIIa have the potential to prevent cancer-related thromboembolic events and treat cancer by blocking nonhemostatic signaling pathways.[129] In a Phase II study, **75** was dosed parenterally in combination with gemcitabine in patients with advanced pancreatic cancer.[151] Targeted inhibition of coagulation was achieved, but was accompanied by a higher incidence of low-grade bleeding relative to placebo. Clinical endpoints in pancreatic cancer of overall survival versus gemcitabine alone were not achieved.

7.16.4.3 Preclinical Compounds

7.16.4.3.1 Amidine-based inhibitors and prodrugs

Early small-molecule TF/FVIIa inhibitors, like early thrombin and FXa inhibitors, contained an amidine-based P1 moiety (see Fig. 21). A phenylglycine-based TF/FVIIa inhibitor chemotype[137] shows potent inhibitory activity and promising bioavailability upon oral dosing of a prodrug. Compound **76** (TF/FVIIa Ki = 81 nM) showed dose-dependent antithrombotic efficacy upon i.v. infusion in a guinea pig model with little prolongation of bleeding. Oral dosing of the double prodrug **77** showed a similar profile albeit at high doses. In rats, **77** resulted in oral bioavailability of 20%.

A series of amidinobenzimidazole[152,153] and amidinoindole-based[154] inhibitors were disclosed (Fig. 21). Compound **78**[138] potently inhibits TF/FVIIa (Ki = 2 nM) with 3600-fold and >100,000-fold selectivity against FXa and thrombin, respectively. Under i.v. dosing in a baboon thrombosis model, **78** showed potent efficacy, with $EC_{50} = 0.17$ μM. At elevated concentrations, nearly complete inhibition of platelet deposition was reached, accompanied by less than a doubling of bleeding time. Alkoxy and carbamate prodrugs of a related amidinobenzimidazole (**79**)[154] provided low bioavailability (≤2%) of the parent species due to limited cleavage of the highly bioavailable prodrug species. Similarly, oral dosing of amidoxime prodrug **81** in rats gave 11% oral bioavailability of the prodrug, but negligible bioavailability of the parent amidine **80**.[155]

Biaryl acid inhibitor BCX-3607 (**82**, Fig. 21) inhibits TF/FVIIa with an IC_{50} of 4 nM and showed in vivo efficacy in a rat venous thrombosis model.[139] BCX-3607 decreased IL-6 response to LPS (Lipopolysaccharide) in a mouse model of endotoxemia and decreased FVIIa-mediated generation of IL-6 and IL-8 in cells. The combined antithrombotic and antiinflammatory activities of a TF/FVIIa inhibitor may be an attractive profile in treatment of coronary artery disease.[156]

Amidinotetrahydroquinoline-based FVIIa inhibitor BMS-593214 (**83**, Fig. 21) was reported to have a TF/FVIIa Ki = 1.3 nM and >150-fold selectivity versus a panel of 12 serine proteases.[157] In animal studies, **83** showed potent in vivo activities in models of both arterial and venous thrombus formation.[140] Notably, at fully efficacious concentrations, **83** increased bleeding time by only 15%, a favorable efficacy versus bleeding profile.

Prodrug studies of the benzamidine-based TF/FVIIa inhibitor AS1924269 (**84**, Fig. 21) have been reported.[158,159] The carbamate/ester double prodrug **85** resulted in 36% oral bioavailability of the parent species, versus 0.3% for direct dosing of **84**.

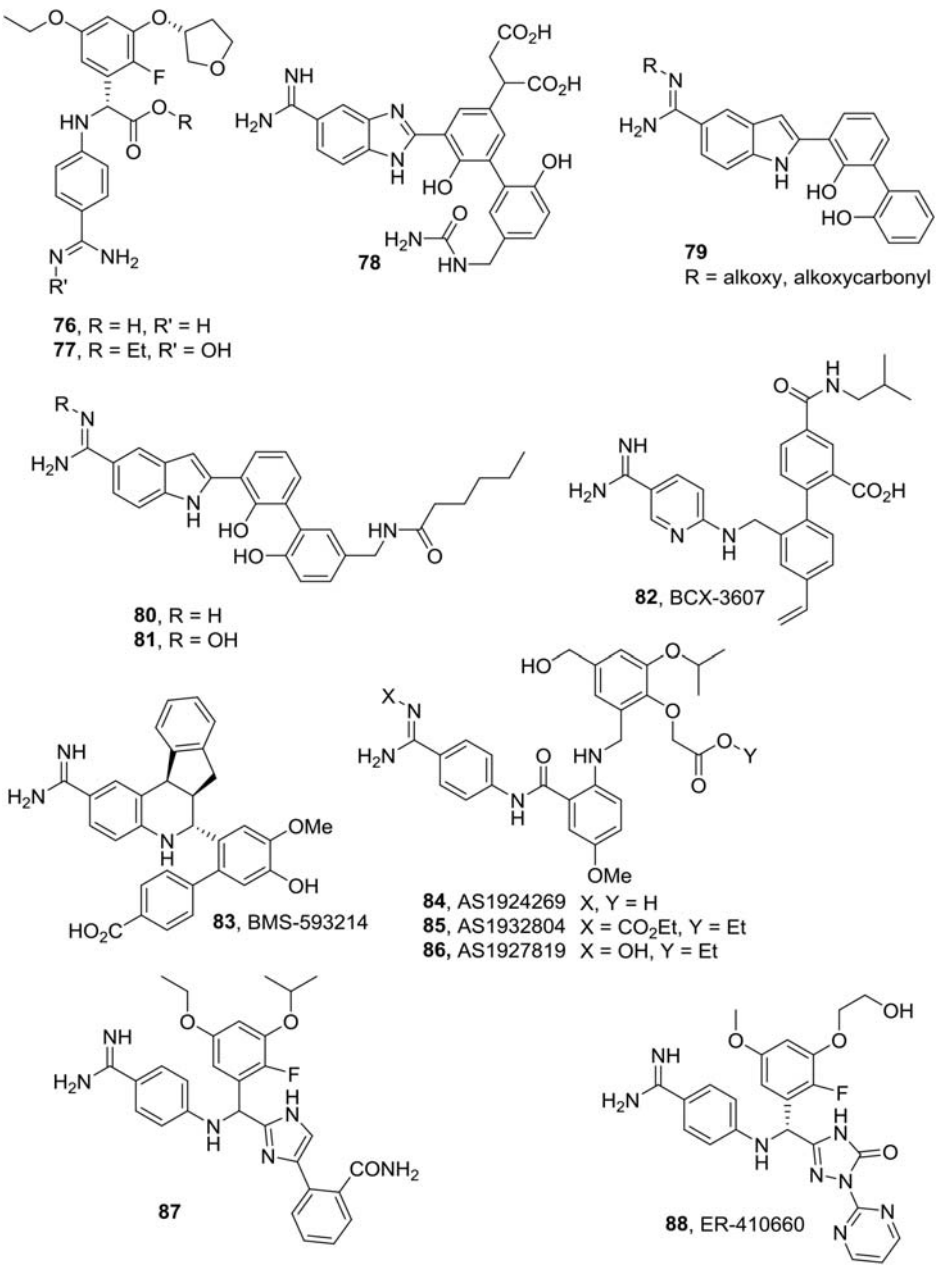

Fig. 21 Structures of amidine-based TF/FVIIa inhibitors.

Alternatively, amidoxime prodrug **86** increased permeability of the intermediate ester-cleaved species, but only 11% of the amidoxime moiety converted to the amidine parent **84**. The high parent oral bioavailability attained with **85** stands out relative to the limited success reported for prodrugs of amidine-based TF/FVIIa inhibitors.

Heterocyclic subunits were incorporated into a phenylglycine chemotype to afford potent FVIIa inhibitors.[160] Compounds were designed to mimic interactions of the carboxylic moiety of compounds such as **76** to the catalytic triad of FVIIa while making additional interactions with the S'_1 pocket. A survey of heterocycles led to the discovery of the optimized phenylimidazole inhibitor **87** (Fig. 21), which was shown by X-ray crystallography to form a key lipophilic interaction with the Cys42–Cys58 disulfide bond of FVIIa.

ER-410660 (**88**, Fig. 21), a structurally similar pyrimidinyltriazolone, along with its prodrug E5539 (structure undisclosed), were studied in vivo.[141] Compound **88** is a potent, selective TF/FVIIa inhibitor with a Ki of 4.9 nM. ER-410660 showed in vivo efficacy in rhesus monkey and rat thrombosis models upon i.v. dosing with reduced bleeding versus both dabigatran and rivaroxaban. The prodrug showed efficacy in a rhesus monkey TF-induced thrombin model after oral dosing, but exposure levels for the parent species **88** were not reported.

7.16.4.3.2 Nonamidine inhibitors

Replacement of the amidinoindole of compound **89** (Fig. 22) with 5-aminopyrrolo[3,2-*b*]pyridine resulted in a 75-fold loss in potency in compound **90** (Ki = 300 nM), but reduced the pKa of the P1 group significantly from ~12 to 8.8.[161] Introduction of additional substitution in **91** (Ki = 20 nM, Fig. 22) recovered much of the lost potency. A related 5-azaindole inhibitor afforded similar potency (**92**, Ki = 62 nM).[162] Incorporation of a 4-amino-5-azaindole P1 group led after further optimization to a potent inhibitor, **93** (Ki = 2.6 nM, Fig. 22).[163] Although the impact of these changes on oral exposure was not reported, these benzamidine replacements may find utility in future serine protease inhibitor design.

Neutral and less-basic benzamidine replacements were also explored in a biaryl chemotype, which led to the discovery of a benzamide P1 group (**95**, Fig. 23), albeit with a 200-fold loss in potency versus benzamidine **94**.[164] Incorporation of an aminomethyl

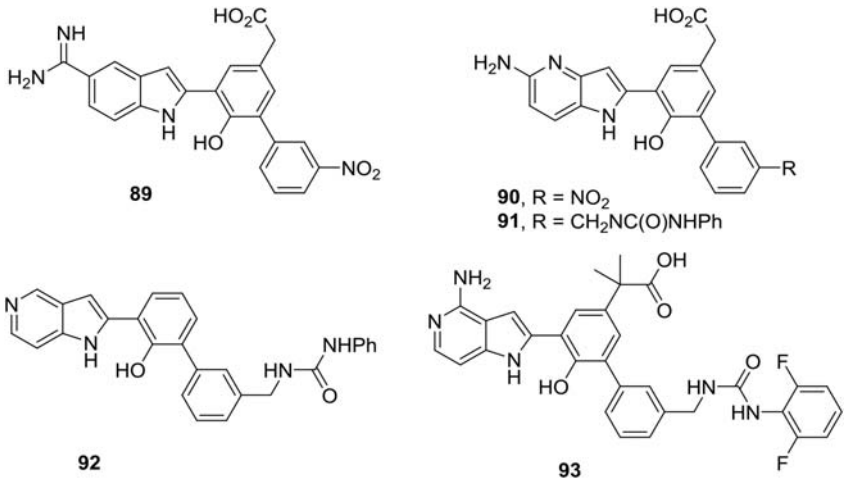

Fig. 22 Nonamidine replacements for amidinoindole and amidinobenzimidazole P1 groups.

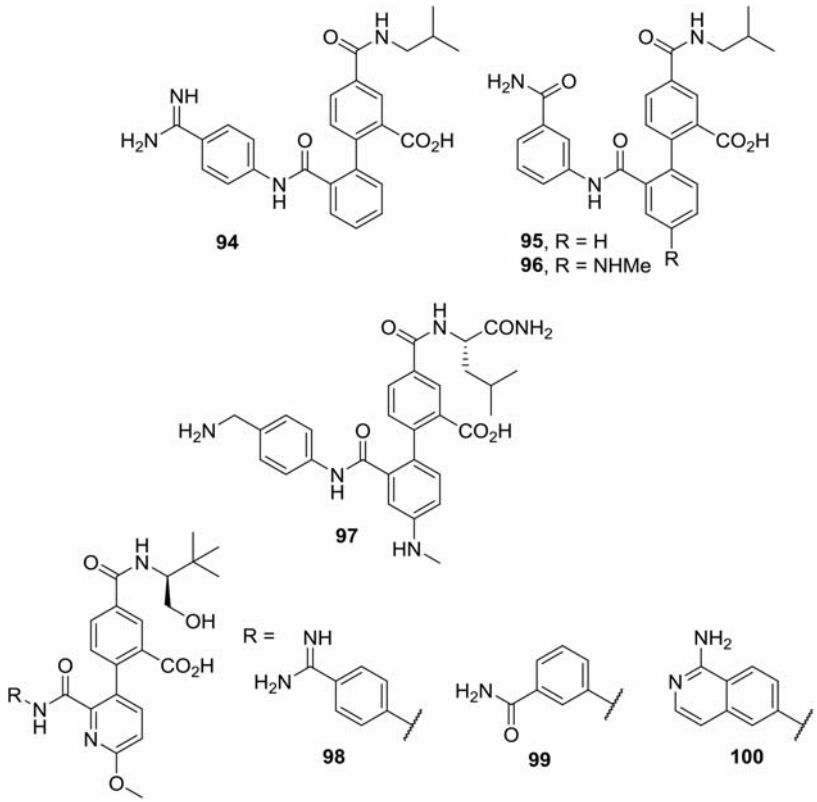

Fig. 23 Nonbenzamidine P1 groups in a biaryl acid chemotype.

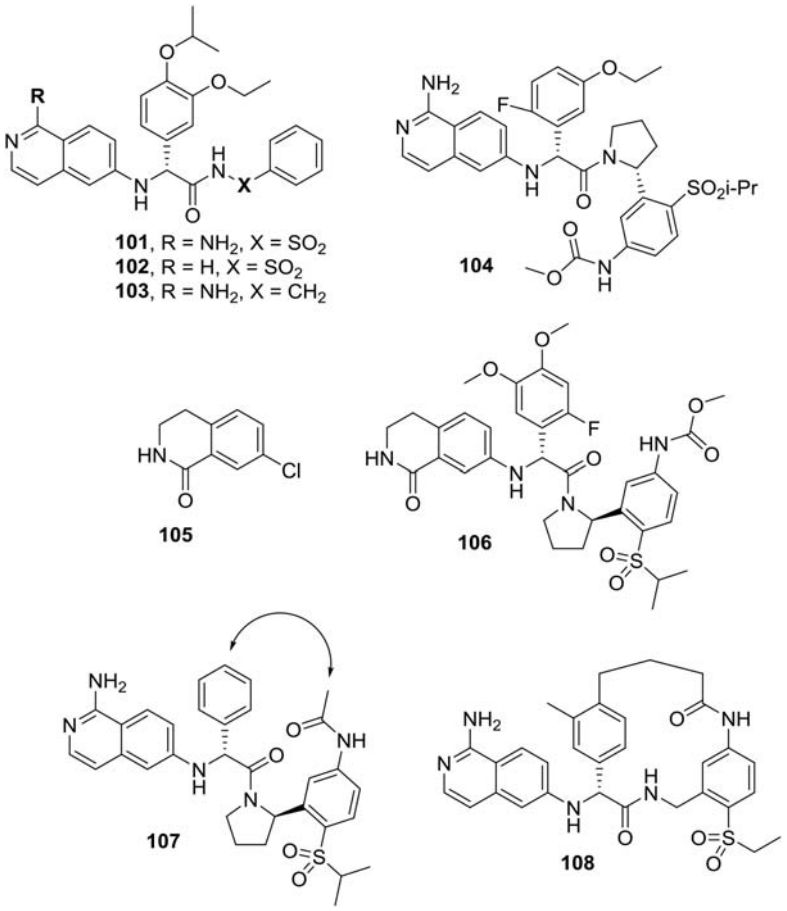

Fig. 24 Nonbenzamidine P1 groups in a phenylglycine chemotype.

group in compound **96** improved potency 30-fold to an IC_{50} of 690 nM. Benzylamine **97** (Fig. 23) showed similar potency (IC_{50} = 590 nM) and reached 2.9 μg mL^{-1} exposure at 1 h after 100 mpk oral dosing, ~10-fold higher than **94**.[165] The same neutral *m*-benzamide P1 group was also identified as a viable benzamidine replacement in a related biaryl acid core example **99** with a 35-fold loss in potency relative to benzamidine **98**.[166] Incorporation of a weakly basic aminoisoquinoline P1 group resulted in a potent inhibitor of TF/FVIIa (**100**, IC_{50} = 7 nM), equipotent with **98**.

Incorporation of the aminoisoquinoline P1 group into a zwitterionic phenylglycine acylsulfonamide core gave another potent inhibitor (**101**, Ki = 10 nM, Fig. 24) with a weakly basic P1 (pKa = 8.9).[167] The compound had low oral bioavailability in dog (F % = 4). The isoquinoline analog (**102**, Ki = 44 nM, Fig. 24) is less basic (pKa = 7.8) and shows improved oral bioavailability in dog of 36%. In a subsequent disclosure, the acidic acylsulfonamide moiety of **102** was replaced with a neutral benzylamide (**103**, Fig. 24).[168] Improved oral bioavailability in dog (45%) and rat (31%) was observed for **103** relative to **102**, but at the expense of potency. Potency was improved while maintaining oral bioavailability by the introduction of a pyrrolidine conformational constraint (**104**, Ki = 1.9 nM, Fig. 24) that maintains good oral bioavailability in dog (45%), but modest bioavailability in rat (8%).

A fragment screen to identify novel, neutral P1 groups was recently described.[169] Fragments were selected computationally using protein ensemble docking in FVIIa. Top-ranked fragments were evaluated in biological and NMR-binding assays yielding a diverse collection of neutral P1 groups. X-ray crystallography of the fragments provided confirmation of binding in the S1 pocket and guided incorporation into inhibitor molecules. Fragment **105** (TF/FVIIa Ki = 8.9 mM, Fig. 24) was grafted onto a phenylglycine amide core to give **106** (Fig. 24) with good potency (TF/FVIIa Ki = 130 nM) and greatly improved parallel artificial membrane permeability assay (PAMPA) permeability when compared to an aminoisoquinoline analog (160 vs. 2 nm s^{-1}).

Novel macrocyclic FVIIa inhibitors have also been reported.[170] A crystal structure of phenylpyrrolidine amide FVIIa inhibitor **107** (Fig. 24) showed close proximity between the P2 phenyl and the P1′ acetanilide and suggested the possibility of macrocyclization. Upon cyclization, the 16-membered macrocycle was 60-fold more potent than the linear counterpart. Further optimization afforded macrocycle **101** (Fig. 24), which is a potent inhibitor of FVIIa (Ki = 1.6 nM) with good selectivity. Macrocyclization provided a potent, structurally well-defined scaffold for FVIIa inhibitor design.

In vivo studies of agents targeting the TF/FVIIa complex show a promising antithrombotic efficacy/bleeding liability profile. Small-molecule inhibitors have made significant advances with regards to oral bioavailability and potency. Promising exposure

levels have been attained with prodrugs of amidine-based inhibitors, and nonamidine compounds have been discovered that combine potency and oral bioavailability. Despite these successes and the advancement of both biological agents and a small-molecule TF/FVIIa inhibitor into clinical trials, a compound targeting this mechanism has yet to reach the market.

7.16.5 Factor IXa Inhibitors

Due to its location in the intrinsic pathway of the coagulation cascade, where it plays a pivotal role in TF-mediated TG, FIXa is also another attractive target for anticoagulant drug development.[171] In a study comparing a humanized anti-FIXa monoclonal antibody, SB249417, to the LMWH, enoxaparin, a superior antithrombotic profile was obtained with SB249217 in a rat model of arterial thrombosis.[172] RB006, an RNA aptamer, a reversible inhibitor with high affinity and specificity for FIXa was evaluated in a Phase II clinical trial in patients undergoing PCI.[173] Dose-dependent aPTT prolongation was achieved with no major bleeding. The effects of RB006 can be reversed by administration of a complementary oligonucleotide antidote, RB007. A Phase III trial comparing the combination of RB006 and RB007 (REG-1) to bivalirudin in patients undergoing PCI has been terminated.[174] Another FIXa inhibitor, TTP889 of undisclosed structure, was evaluated in clinical trials. Phase II clinical trial results for extended prevention of VTE in patients undergoing hip surgery were disappointing. TTP889 was ineffective in reducing biomarkers for TG or the incidence of VTE compared with placebo.[171,175] No further evaluation has been reported.

Early efforts to identify selective, small-molecule FIXa inhibitors by modification of leads obtained from screening of FXa compound collections had limited success, although some potent dual inhibitors were reported.[176–178] Similarly, hydroxy pyrazole based FIXa inhibitor **109** (Fig. 25) was reported to have a FIXa Ki of 50 nM with moderate selectivity over thrombin, FVIIa, FXa, and trypsin.[179] SBDD was employed utilizing a 2-amidinobenzothiphene template to design a series of inhibitors with groups to interact in the S1β and S2–S4 pockets of FIXa.[180,181] Compound **110** was reported to have a FIXa Ki of 8 nM with >200-fold selectivity over FXa and was also shown to be bioavailable in rats.

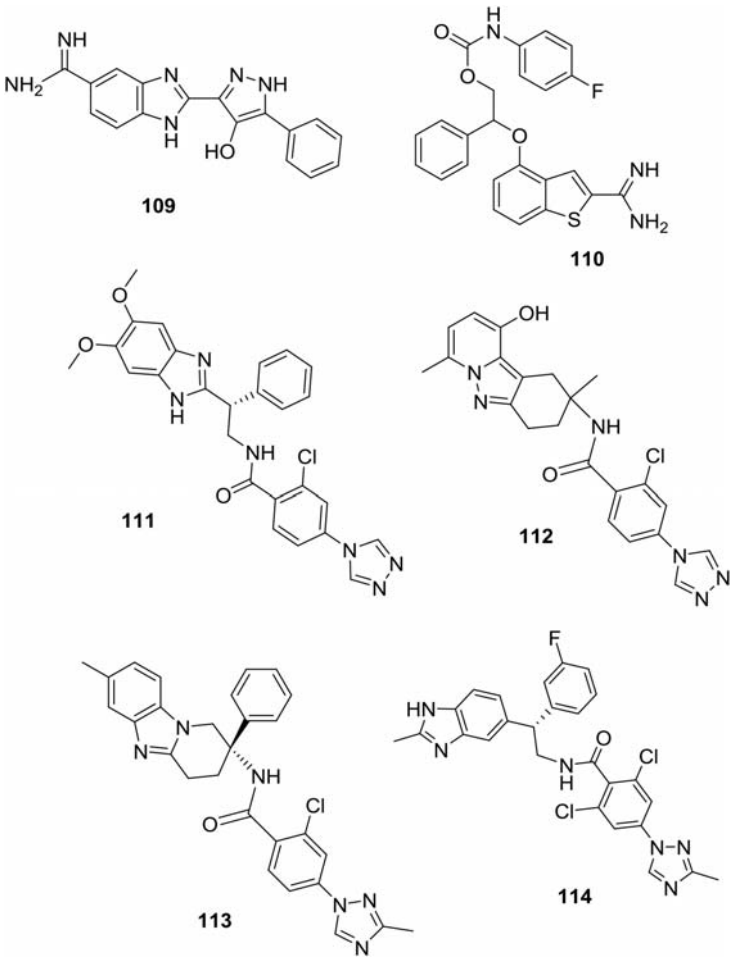

Fig. 25 Factor IXa inhibitors.

Using two screening leads with micromolar potency for FIXa and some selectivity over FXa as a starting point, nanomolar inhibitors of FIXa were identified.[182] Benzimidazole **111** (FIXa Ki = 16 nM, Fig. 25) was 20-fold selective over FXa, and tricyclic compound **112** (FIXa Ki = 90 nM) was > 120-fold selective. Further optimization of both series has been reported. Numerous novel tricyclic scaffolds were explored and compound **113**[183] was identified with improved FIXa affinity (Ki of 5.9 nM), 350-selectivity over FXa, and good oral bioavailability in rat and dog. In a rat A-V shunt model, **113** was as efficacious as apixaban, with little effect on bleeding in a rat cuticle bleeding model. An SAR study beginning with benzamide **111** led to a regioisomeric benzamide analog **114**, with similar potency and selectivity to **113** but lower oral bioavailability in rat.[184] High levels of selectivity versus other coagulation serine proteases were also reported. Both compounds showed aPTT results and a TG profile consistent with inhibition of the intrinsic pathway.

7.16.6 Factor XIa Inhibitors

7.16.6.1 Target Validation and Proof of Concept

FXIa is located upstream in the intrinsic pathway of the coagulation cascade. It plays a major role in the amplification and the propagation of thrombin production. Inhibiting FXIa could disrupt the intrinsic coagulation pathway without affecting either the extrinsic or the common pathways. This approach could provide a reduction in thrombin sufficient to impede occlusive thrombosis, yet allow enough TG to support hemostasis. Therefore, FXIa inhibitors may have the potential to be a promising antithrombotic therapy with a wider therapeutic index.[185,186] Genetic evidence supports this hypothesis. Humans lacking FXI (hemophilia C) have relatively mild bleeding tendencies compared with a deficiency in either FVIII (hemophilia A) or FIX (hemophilia B). Bleeding in individuals with hemophilia C is rarely spontaneous. In addition, clinical studies have shown individuals with a severe FXI deficiency have a lower risk for ischemic stroke and DVT.[187] Similarly, individuals with elevated levels of FXI experience a higher incidence of acute myocardial infarction and DVT.[188,189]

The phenotype observed in FXI-deficient individuals was recapitulated in FXI-deficient mice. Deficiency of mouse FXI provides protection in multiple thrombosis models, and did not show prolonged tail bleeding time when compared with aspirin-treated FXI null and wild-type mice.[190,191] Therefore, studies with FXI null mice are consistent with the tolerable hemostatic defect of human hemophilia C.

Pharmacological studies with FXI-neutralizing antibodies and antisense oligonucleotides (ASOs) in animal models also support the efficacy and safety of the FXI target.[192,193] Antibody 14E11 binds FXI and interferes with the activation of FXI by FXIIa in vitro.[194] Comparable efficacy to total FXI deficiency was obtained with 14E11 in a $FeCl_3$ arterial thrombosis model in mice and reduced thrombus growth was observed in a baboon A-V shunt model. An ASO (ISIS 416858), which blocks the expression of FXI, is the most advanced agent in clinical trials.[195] In a phase II study in arthroplasty, ISIS 416858 reduced the incidence of DVT and showed fewer bleeding events as compared to subcutaneously administered enoxaparin, providing the first PoC in humans.

Pharmacological PoC studies in animal models with small molecules were conducted with irreversible FXIa inhibitors using ketothiazole **115** (FXIa $IC_{50} = 12$ nM)[196,197] and a 4-carboxy-2-azetidinone mechanism-based inhibitor, BMS-262084 (**116**, FXIa $IC_{50} = 2.8$ nM, Fig. 26).[198,199] Ketothiazole **115** was efficacious against $FeCl_2$-induced thrombosis in both the vena cava and carotid artery, and did not alter bleeding time in a rat mesenteric bleeding model.[196] Compound **116** produced dose-dependent antithrombotic effects in rats[198] and rabbits[199] in multiple thrombosis models and did not affect cuticle bleeding time.

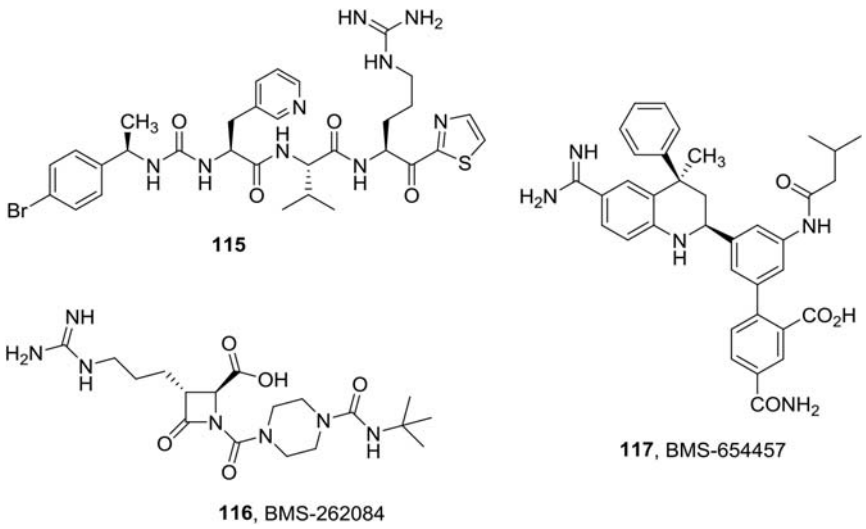

Fig. 26 Small-molecule FXIa Inhibitors used for PoC.

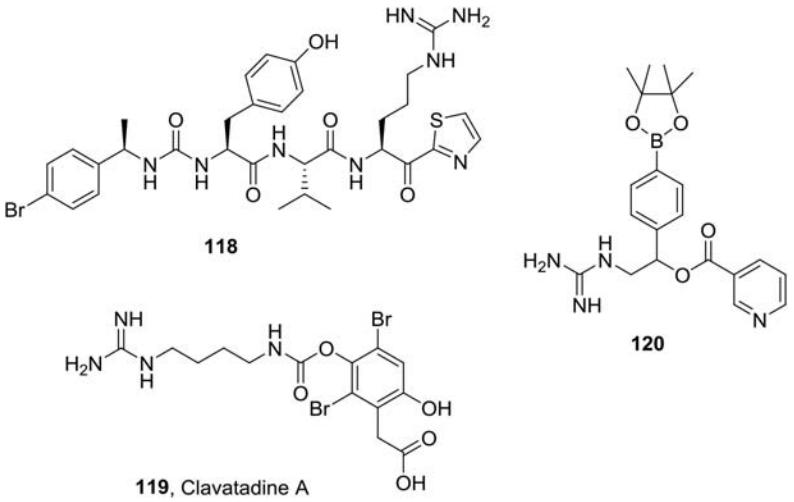

Fig. 27 Irreversible small-molecule FXIa inhibitors.

Proof of concept studies with reversible small-molecule FXIa inhibitors were first reported with BMS-654457 (**117**, Fig. 26),[200,201] a potent FXIa inhibitor (FXIa Ki = 0.20 nM) with >1000-fold selectivity over most of the relevant serine proteases. A dose-dependent antithrombotic effect with an EC_{50} about 300 nM was obtained with **117** in the rabbit ECAT model. A minimal increase in bleeding time was observed for **117** at the dose that gives 80% of thrombosis inhibition. This compares favorably with thrombin inhibitor melagatran, where a significant increase in the bleeding time was observed at the same level of thrombosis inhibition.[201]

7.16.6.2 Preclinical Small-Molecule FXIa Inhibitors

7.16.6.2.1 Irreversible FXIa inhibitors

Keto-arginine-based peptidomimetic FXIa inhibitor 118 (Fig. 27) was reported to have an FXIa IC_{50} of 6 nM with good selectivity over FVIIa, FXa, and thrombin.[196] This series of FXIa inhibitors forms a covalent bond via the keto moiety to the catalytic serine of FXIa. Intravenous infusion of **118** was efficacious in a rat model of venous thrombosis with antithrombotic activity comparable to that of heparin. Modifications to reduce the peptidic character and molecular weight of these inhibitors led to compounds with reduced FXIa affinity.[197] Clavatadine A (**119**), a natural product isolated from a marine sponge, was also reported to be an irreversible inhibitor of FXIa with an IC_{50} of 1300 nM.[202] This compound had no effect on FIXa at a 170-fold greater concentration. A racemic boronate (**120**) was reported to have an FXIa IC_{50} of 1400 nM with 30-fold and eightfold selectivity over FXa and thrombin, respectively.[203]

7.16.6.2.2 Reversible FXIa inhibitors

Several series of reversible small-molecule FXIa inhibitors have been reported (Fig. 28). With the X-ray structure of **117**, SBDD was employed to design and optimize a series of imidazole-based inhibitors. Compound **121** (BMS-724296) was identified as a potent and selective FXIa inhibitor (FXIa Ki = 0.3 nM) that was efficacious in the rabbit AV shunt[204] and ECAT[205] models. The EC_{50} of **121** in the rabbit ECAT model of thrombosis was similar to melagatran. The bleeding time determined at 80% efficacy was fivefold less than melagatran.[205] These results confirm the wider therapeutic index observed with earlier tool compound **117**. Efforts to reduce the basicity of the P1 moiety and polar surface area led to compound **122**. Although the FXIa potency was reduced (FXIa Ki = 6.7 nM), moderate oral exposure was observed in dogs.[206] Further modifications of the P2 and P2′ moieties led to compound **123**, a potent parenteral agent with FXIa Ki of 0.04 nM and dose-dependent efficacy in the rabbit ECAT model with minimal bleeding time prolongation.[207] The imidazole core was replaced with various six-membered ring heterocycles, including pyridine, which showed promising affinity (ie, compound **124**).[208]

A series of diamide FXIa inhibitors was reported (Fig. 29). Compound **125**,[209] derived from fragment screening and SBDD, showed an FXIa Ki of 1.0 nM. Compound **126**,[210] with a different diamide scaffold, was a potent inhibitor with FXIa Ki of 2.0 nM, and efficacy in the rabbit ECAT model.

In addition to the above FXIa inhibitors, data for several additional compounds have been reported, but no structures were disclosed. ONO-8610539[211] is a selective, injectable small-molecule FXIa inhibitor with an FXIa Ki of 1.9 nM. It significantly inhibited thrombus formation in rabbits and monkeys, and did not affect blood loss volume at 33-fold higher than the dose showing the maximum antithrombotic effect compared with enoxaparin. ONO-7750512[211,212] was reported as an orally bioavailable (F = 22% in rats) FXIa inhibitor with an FXIa Ki of 3.8 nM. It has potent antithrombotic efficacy in the $FeCl_3$-induced rabbit venous and the AV-shunt monkey thrombosis models. In the rabbit ear bleeding model, ONO-7750512 had a significantly lower bleeding

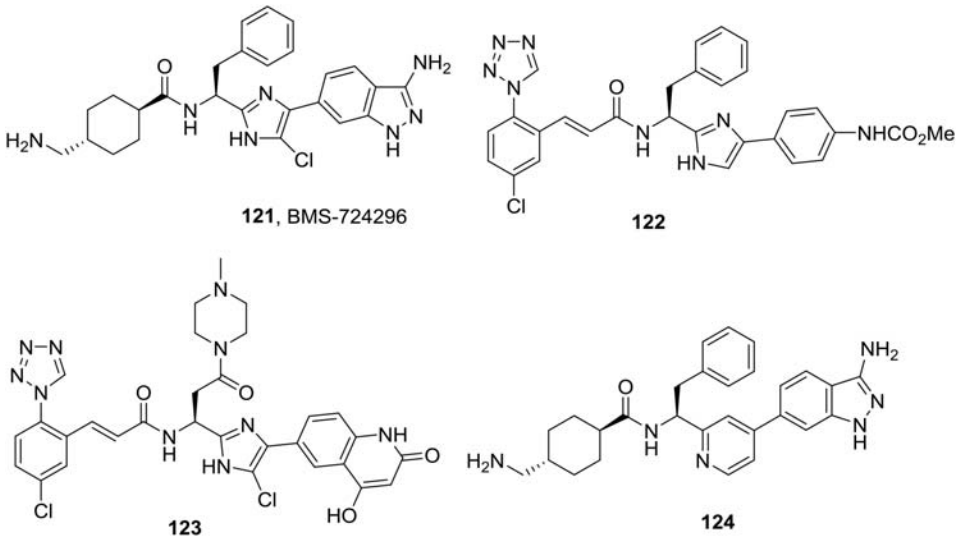

Fig. 28 Reversible small-molecule FXIa inhibitors.

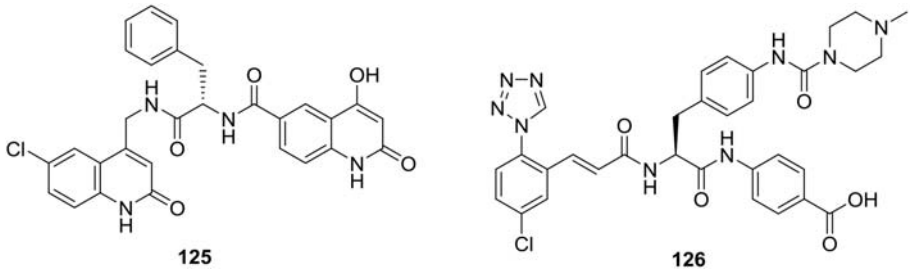

Fig. 29 Diamide FXIa inhibitors.

risk compared with rivaroxaban.[212] DSR-130787 was reported as an orally active prodrug FXIa inhibitor with $IC_{50} < 10$ nM.[213] Intravenous administration of DSR-130787 active form to rabbits produced an antithrombotic effect comparable to that of dabigatran or rivaroxaban with much lower risk of bleeding.

7.16.6.2.3 Allosteric FXIa inhibitors

The FXIa inhibitors described so far all bind to the FXIa active site. A series of allosteric FXIa inhibitors has been published (Fig. 30). Sulfated pentagalloylglucopyranoside **127** was reported to have an IC_{50} of 550 nM with 200-fold selectivity over other relevant

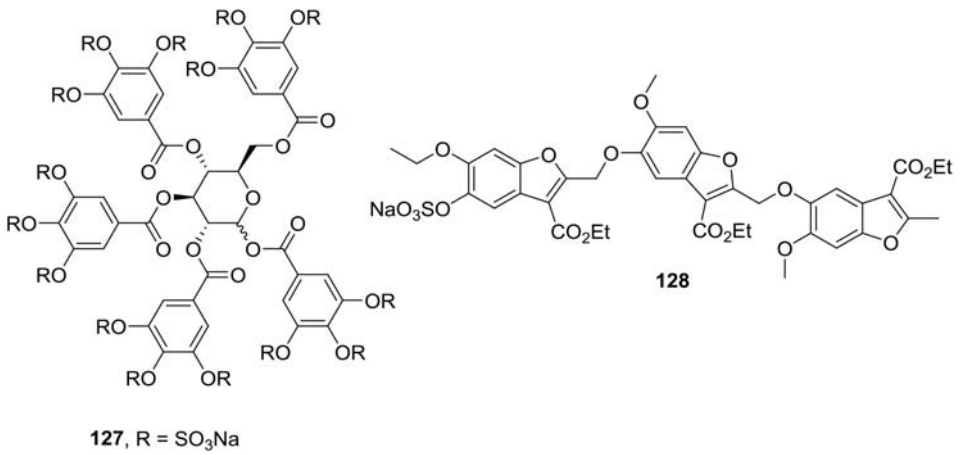

Fig. 30 Allosteric FXIa inhibitors.

enzymes.[214] Competitive binding studies showed that **127** binds in the heparin-binding site of FXIa. A series of allosteric monosulfated benzofuran dimer and trimer FXIa inhibitors that are not competitive with heparin were reported. Compound **128** was the most potent inhibitor with an IC_{50} of 820 nM.[215] Molecular modeling was used to propose a binding site for **128** on the A3 domain of FXIa. As yet these allosteric inhibitors do not have the potent affinity for FXIa demonstrated with active site inhibitors, but they offer an interesting avenue for continued research.

With an FXIa ASO in clinical trials, and reversible, small-molecule inhibitors and an FXI antibody entering clinical trials, the FXIa mechanism may be poised to deliver the next major advance in new anticoagulants since the development of the current class of potent and selective FXa inhibitors.

7.16.7 Conclusion

Through the perseverance of researchers over many years at institutions around the world, patients can now benefit from new oral anticoagulants approved to prevent and treat thromboembolic disorders more effectively, with better overall safety and in particular a lower rate of intracranial hemorrhage, and without the inconvenience of the routine monitoring or dietary restrictions that are associated with VKAs. Direct thrombin and FXa inhibitors have a rapid onset and fixed dosing, thus alleviating the need for initial treatment with a parenteral anticoagulant. Despite these advances in treatment options, however, an increased risk of bleeding still persists to varying degrees with the new thrombin and FXa inhibitors,[216] and an unmet medical need remains for new anticoagulants with even less tendency for bleeding. Preclinical data with FXIa inhibitors and Phase II clinical data with an FXIa ASO suggest that FXIa inhibitors have the potential to provide this added advantage. As the first FXIa inhibitors progress into human clinical trials, further interest in developing novel inhibitors of FXIa and other targets in the intrinsic cascade continues, and the quest for the perfect anticoagulant goes on. Antithrombotic roles for FXIIa[217,218] and plasma kallikrein[219] have been proposed, and may provide new targets for future investigations. For the present, direct thrombin and FXa inhibitors represent major achievements in the identification of safer, more efficacious agents for the treatment of thromboembolic diseases. Their long-term use in patients, along with continued clinical evaluation of inhibitors of other coagulation proteases, will ultimately determine which mechanism offers the optimal benefit/risk profile for specific patient populations.

Glossary

AI, AII Angiotensin I and angiotensin II.

ACE Angiotensin converting enzyme. The enzyme that converts angiotensin I into the pressor and profibrotic ligand, angiotensin II.

ADHF Acute decompensated heart failure (ADHF). A sudden worsening of the signs and symptoms of heart failure, which typically includes difficulty breathing, swelling of the legs or feet, and fatigue.

AHF Acute heart failure. Heart failure requiring immediate medical attention, which can be either of new onset or from worsening of previously recognized heart failure.

ANP Atrial natriuretic peptide. A peptide agonist that is normally secreted by the atrium in response to volume overload (stretch). This peptide is also secreted by the failing ventricle.

BNP Brain natriuretic peptide. A peptide agonist that is normally secreted from the ventricle in response to stretch.

CNP C-type natriuretic peptide. A peptide agonist synthesized in vascular endothelium in response to shear stress and in response to circulating ANP or BNP. CNP is produced in renal glomerular and tubular cells as well.

Cardiac index Cardiac output divided by the body surface area of the individual, thus relating the pump function of the heart to the size of the individual; a measure of pump function.

Cardiac output The volume of blood ejected or pumped by the heart every minute; cardiac output is the product of two measures, stroke volume, and heart rate; a measure of whole body blood flow that depends on many factors including cardiac function, filling pressures, and vascular resistance.

Chronotropic Pertaining to heart rate.

CCD Cortical collecting duct. A specific segment of nephrons in the kidney.

Diastolic dysfunction Abnormal relaxation of the ventricle after each heartbeat. This can be caused by either increase in passive stiffness of the heart or delay in the relaxation of the contractile apparatus within cardiac myocytes.

Diuresis Renal excretion of water.

Duty ratio The proportion of myosin heads forming strong force-generating interactions or crossbridges with actin during the cardiac actin–myosin ATPase cycle.

Dysguesia An unpleasant taste sensation in the absence of any substance to evoke that taste sensation.

Dyspnea Difficulty in breathing.

É An echocardiography metric from the tissue Doppler approach that evaluates the speed of ventricular relaxation.

E-wave/E-wave deceleration An echocardiography metric determined using Doppler imaging to measure the movement of blood across the mitral valve. The E-wave is the early passive flow of blood from the left atrium to the left ventricle as the left ventricle relaxes. Impaired relaxation is associated with shorter values for E-wave deceleration.

Ejection fraction The fraction of blood volume that is pumped out of the left ventricle during contraction of the heart (systole).

End-diastolic elastance A measure of the relationship between a change in pressure and the change in volume at the end of diastole. A higher value reflects a stiffer ventricle and manifests as a greater change in pressure per unit change of volume.

End-systolic elastance A measure of the relationship between a change in pressure and the change in volume at the end of systole. This metric is used as a load-independent measurement of contractile function.

ECM Extracellular matrix. An extracellular protein scaffold that both signals to and provides a supporting anchor for the parenchymal cells of an organ.

HFpEF Heart failure with preserved ejection fraction in which the major deficit is abnormal relaxation of the heart.

HFrEF Heart failure with reduced ejection fraction in which there is contractile dysfunction and abnormal relaxation.

Inotropic Pertaining to the force of cardiac contractions.

L-type calcium channels An integral membrane protein that selectively allows calcium entry into cells in response to depolarization of the cell membrane. These channels are the primary source for calcium entry in cardiac and vascular smooth muscle.

Left ventricular end-diastolic pressure (LVEDP) Pressure measured in the left ventricle at the end of the cardiac relaxation (diastole), which is prior to the contraction (systole). LVEDP is a primary determinant of preload, the load applied by the volume of blood in the left ventricle that results in the stretching of the left ventricle before the initiation of the next contraction.

Lusitropic Pertaining to relaxation of the heart.

Kaliuresis Renal excretion of potassium.

MI Myocardial infarction.

Orthopnea Positional difficulty in breathing, particularly when lying down.

MRA Mineralocorticoid receptor antagonists. Examples include spironolactone and eplerenone.

Natriuresis Renal excretion of sodium.

NEP Neutral endopeptidase (also known as neprilysin, EC3.4.24.11): enzyme that catabolizes ANP and BNP along with other peptide ligands including bradykinin and angiotensin II.

NP Natriuretic peptide (see NPS).

NPS Natriuretic peptide system (includes ANP, BNP, and CNP). A hormonal system that induces vasodilation and excretion of salt and water through the activation of NPRA and NPRB receptors.

NTproBNP The inactive N-terminal fragment that is released when proBNP is cleaved to release BNP.

PCI Percutaneous coronary intervention. A procedure using a catheter and an intravascular approach to unblock coronary arteries.

Phospholamban A protein in the sarcoplasmic reticulum that modulates the activity of the SR calcium pump, SERCA. Nonphosphorylated phospholamban associates with SERCA and inhibits the ability of SERCA to pump calcium back into the SR. Phosphorylation of phospholamban by protein kinase A causes disinhibition and increases SERCA activity.

Pi/Pi release Pi (inorganic phosphate) release is the rate-limiting step in the cardiac actin–myosin ATPase cycle. Selective enhancement of this step is proposed to increase the percentage of high affinity actin–myosin interactions, thereby increasing the proportion of myosin heads forming strong force-generating interactions or crossbridges with actin and thereby increasing force generation and contractility.

Preload Ventricular filling, resulting in the initial stretching of the left ventricle prior to contraction (systole); the load applied by the volume of blood in the left ventricle that results in the stretching of the left ventricle before the initiation of the next contraction. Preload/ventricular filling is elevated in HFrEF due to ventricular dilation and/or increased blood volume.

Pulmonary capillary wedge pressure (PCWP) PCWP is measured by inserting a balloon-tipped catheter into a peripheral vein and advancing the catheter through the right atrium, right ventricle, pulmonary artery, and into a branch of the pulmonary artery. When the catheter balloon is inflated, a branch of the pulmonary artery is occluded. When this occurs, the pressure measured by the catheter distal to the balloon falls and reaches a value that reflects left atrial pressure. As such PCWP provides an indirect estimate of left atrial pressure and therefore by inference an indirect measure of left ventricular end-diastolic pressure (LVEDP). A reduction in PCWP reflects a reduction in pathologically elevated left atrial pressure, which occurs in heart failure patients as a consequence of elevated left ventricular end-diastolic pressure.

RAAS Renin–angiotensin–aldosterone system. A neurohormonal system with important roles in the regulation of blood pressure, blood volume, and maintenance of appropriate levels of sodium and potassium in serum.

Rales An abnormal crackling sound heard when listening to the lungs with a stethoscope.

Respiratory exchange ratio The ratio between oxygen taken up versus carbon dioxide produced that can be used as an indirect measure of whether glucose or fatty acids are being used as the primary energy source for ATP production. Values close to 1 are consistent with the use of glucose while values close to 0.7 are attributed to fatty acid utilization.

Ryanodine receptors A calcium release channel found in the sarcoplasmic reticulum or endoplasmic reticulum. In striated muscle it is the major cite for release in calcium from the sarcoplasmic reticulum. The channel was named based on the modulation of calcium release by the compound ryanodine.

Sarcolemma The surface or plasma membrane of striated muscle cells.

Sarcoplasmic reticulum An intracellular organelle that is the major site for the intracellular calcium stores used to induce muscle contractions. It is the endoplasmic reticulum of striated muscle cells and also functions in protein translation, processing, and transport.

Schwann cells Cells associated with peripheral nerves that myelinate certain large diameter neurons.

SERCA A calcium pump found in the sarcoplasmic reticulum and endoplasmic reticulum membrane that utilizes the energy from ATP hydrolysis to pump calcium into the SR/ER.

Sodium–calcium exchanger A plasma membrane transport protein that exchanges three sodium ions on one side of the membrane for one calcium ion on the other side of the membrane. This protein generally functions as a mechanism for calcium efflux but can function in the reverse mode if the electrochemical driving force favors calcium influx.

Splanchnic Visceral.

STEMI A relatively severe myocardial infarction with elevation of the ST segment of the electrocardiogram.

Systolic dysfunction Abnormal contraction of the heart resulting in less forceful contractions and less efficient ejection of blood with each beat.

Stroke volume The volume of blood that is ejected or pumped out of the heart with every beat; a measure of pump function.

T-Tubules Tube-like membrane invaginations that are found in striated muscle cells and allow for close approximation of surface membrane calcium channels (L-type calcium channels) and the calcium release channels in the sarcoplasmic reticulum (ryanodine receptors).

TAC Transaortic constriction model of heart failure. A pressure overload model in which the aortic arch is constricted with a clip or a ligature to increase the afterload on the left ventricle.

TALH Thick ascending loop of Henle, a specific segment of nephrons in the kidney.

UCNs Urocortins. The urocortins 1, 2, and 3 (UCN1,2,3) are small (38–40 amino acids) endogenous peptide hormones that belong to the corticotropin-releasing hormone family of hormones that are secreted in response to stress.

7.17.1 Preface

The purpose of this article is to review current and evolving pharmacological therapies used in the treatment of patients with acute and chronic heart failure. To this end, the introduction provides a brief overview of heart failure pathology and epidemiology with the goal of enabling an understanding of currently established and emerging pharmacological therapies for heart failure as well as the unmet medical needs. For more in-depth background information, the interested reader is directed to the most recent Heart Failure Guideline Documents from the American College of Cardiology Foundation/American Heart Association,[1] and the European Society of Cardiology[2] as well as recent review articles and texts.[3–7]

7.17.2 Introduction

7.17.2.1 Clinical Description

Heart failure is not a discrete disease and there is no universally accepted definition. It is a complex syndrome in which the intrinsic function of the heart is compromised such that it is unable to pump blood at a sufficient rate to meet the needs of end organs throughout the body. This deficit in blood pumping can result from impaired ventricular filling, impaired ejection of blood, or a combination of both.[1,2] There are many pathophysiological conditions that can lead to the development of heart failure, including myocardial infarction, cardiac ischemia, hypertension, valvular insufficiency, cardiac toxicity of certain cancer chemotherapies, diabetes, metabolic disorders, and viral myocarditis. Although there may be common symptoms in heart failure of different etiologies, the underlying pathology can vary substantially from patient to patient.

There is agreement with regard to many of the signs and symptoms of heart failure. However, there is no universally utilized set of criteria for diagnosing heart failure and no stand-alone tests that can be used for an unambiguous diagnosis.[1,2,4] Signs and symptoms include fatigue, dyspnea, orthopnea, rales, wheezing, pulmonary edema, splanchnic congestion, peripheral edema, the presence of a third heart sound, and cardiac hypertrophy.[1–4] Many of these signs and symptoms can be attributed to sodium and volume overload and are partially relieved by treatment with diuretics. Common comorbid conditions include hypertension, coronary artery disease, obesity, type 2 diabetes, chronic renal disease, chronic obstructive pulmonary disease, and atrial fibrillation.[1–4]

7.17.2.2 Classifications of Chronic Heart Failure

Chronic heart failure has been classified based on symptom severity (New York Heart Association, NYHA), disease stage (American College of Cardiology Foundation/American Heart Association, ACCF/AHA), and whether or not ejection fraction is compromised. These different approaches to segmenting heart failure patients are discussed in the subsequent sections.

7.17.2.2.1 Classification based on disease severity

NYHA functional classification is based on a patient's symptoms and how well exercise is tolerated. Physical activity is not limited in Class I patients. Class II patients tend to be asymptomatic at rest but heart failure symptoms emerge during physical activity. Class III indicates that patients are comfortable at rest but experience symptoms with even modest physical activity. Class IV patients are either symptomatic at rest or symptomatic with any physical activity.[1]

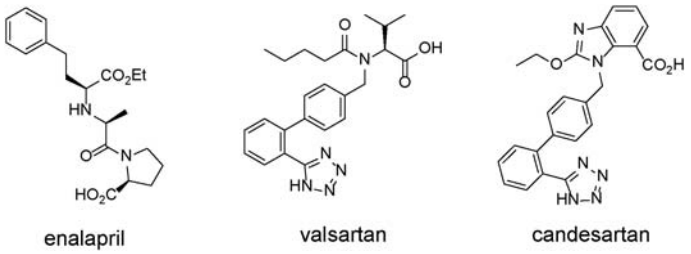
The following stages are defined by the ACCF/AHA classification system. Unlike the NYHA functional classification system where an individual can improve in class over time, patients do not regress from one ACCF/AHA stage to a less severe stage. Stage A indicates an individual at high risk but without evidence of disease. Stage B patients have structural heart disease but do not exhibit signs or symptoms of heart failure. Once symptoms develop, patients are categorized as Stage C. Refractory disease requiring advanced interventions is classified as Stage D.[1]

7.17.2.2.2 Classification based on cardiac ejection fraction

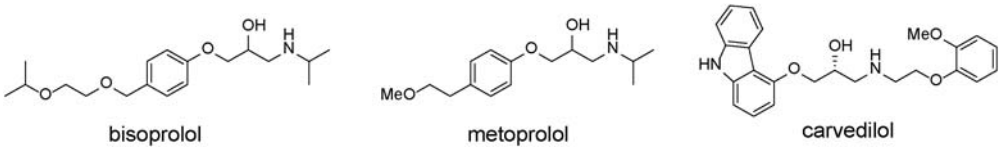
In many patients, cardiac imaging can document a large reduction in cardiac ejection fraction compared to individuals with healthy hearts. These patients are considered to have heart failure with reduced ejection fraction (HFrEF). Patients with HFrEF typically have dilated ventricles with an increase in left ventricular volumes. A common trigger for the development of HFrEF is myocardial infarction.[8] Typically, HFrEF patients exhibit systolic and diastolic dysfunction.

In approximately half of patients with heart failure, the ejection fraction is either normal or only slightly reduced.[4] These patients are classified as having heart failure with preserved ejection fraction (HFpEF). Women and elderly patients constitute the majority of individuals with HFpEF. In general, HFpEF results from conditions that increase afterload such as hypertension or aortic stenosis.[8] Diastolic dysfunction and left ventricular wall thickening are key features of HFpEF.

Several classes of drugs have shown outcome benefits and/or are approved for the treatment of HFrEF patients. An angiotensin converting enzyme inhibitor (ACEi) is recommended for most HFrEF patients.[1,2] ACE inhibitors, exemplified by enalapril (the ethyl ester prodrug of enalaprilat), have been shown to reduce the risk of death and reduce hospitalization in HFrEF patients with mild, moderate, or severe symptoms of heart failure.[9–11] Clinical data suggest that there are no differences among available ACE inhibitors in their effects on survival or symptoms.[12] In patients who cannot tolerate an ACEi, an angiotensin II (AII) receptor blocker (ARB) is indicated.[1,2] The ARBs valsartan and candesartan have demonstrated benefit by reducing mortality (candesartan) and hospitalization (valsartan and candesartan) in HFrEF patients.[13,14]



β-Adrenoceptor blockers are also indicated for most HFrEF patients in combination with ACEi or ARBs.[1,2] Three β-adrenoceptor blockers have been shown to reduce death and hospitalization in HFrEF patients: bisoprolol[15] and sustained-release metoprolol[16] which selectively block the β_1-adrenergic receptor, and carvedilol[17,18] which blocks β_1-, β_2-, and α_1-adrenergic receptors. Positive findings with these three agents should not be considered a β-blocker class effect, as other β-adrenoceptor blocking compounds have demonstrated lesser to no significant effects on heart failure outcomes.[1,2] Mineralocorticoid receptor antagonists (MRAs) (vide infra Section **Antiadrenergics and anti-RAAS**) are also recommended for HFrEF patients in whom there are no contraindications.[1,2] The main concerns with MRA include hyperkalemia and renal insufficiency. In a subset of HFrEF patients, particularly those of African American decent, a combination of isosorbide dinitrate and hydralazine can also reduce mortality when added on top of other guideline-directed therapies.[1,2] There are currently no therapies approved for patients with HFpEF.



7.17.2.3 Acute Heart Failure

The term acute heart failure (AHF) is used to describe an acute onset or deterioration of the signs and symptoms of heart failure. That is to say that AHF can occur due to worsening of previously existing chronic heart failure (either HFrEF or HFpEF) or it can arise de novo.[2,6,19] AHF is a life-threatening condition requiring immediate medical attention. Most AHF patients present with acute dyspnea, a symptom that is not unique to heart failure.[2,6,19] Measurement of plasma natriuretic peptide levels can be used to support clinical judgment and, if not elevated, to rule out heart failure as the cause of dyspnea.[1,2,6,19] There are multiple triggers and phenotypes encompassed by the term AHF and identification of the trigger can guide the course of care (eg, arrhythmias, acute coronary syndrome, sepsis, noncompliance with recommended drug treatments, volume overload, acute elevation of blood pressure, cardiogenic shock, and acute pulmonary embolism).

Current guideline-directed therapy for the treatment of AHF includes loop diuretics, possibly in combination with other diuretic classes, as the cornerstone of pharmacologic therapy.[1,2] Vasodilators (nitroglycerin, nitrates, and the natriuretic peptides BNP (nesiritide; United States and EU) and ANP (carperitide; Japan)) may be added in hypertensive patients but are generally avoided in patients with low blood pressure.[1,2] In patients with low cardiac output at risk for under-perfusion of vital organs, positive inotropes such as dobutamine or milrinone may be indicated.[1,2] US guidelines state that V2 vasopressin antagonists may be indicated in patients with hyponatremia and cognitive symptoms.[1]

7.17.2.4 Epidemiology

Estimates of the prevalence of heart failure vary widely from 1% to 12% due to differences in methodologies and criteria used to identify patients with this syndrome.[4] Recent statistics from the American Heart Association indicate that there are 5.7 million people in the United States with heart failure, and this number is projected to grow to more than 8 million people by 2030.[5] Worldwide prevalence of heart failure has been estimated at 23 million.[4] The prevalence of heart failure increases with age and is $>10\%$ for individuals ≥ 80 years old.[5,20] The lifetime risk for developing heart failure is estimated as one in five from age 40 and beyond.[5] There are 870,000 new heart failure cases annually in the United States.[5] Estimated annual cost for treating heart failure in the United States in 2014 range from $37 billion to as much as $115 billion.[21] There are reasons to believe that the low end of this range significantly underestimates the true cost of treating heart failure.[21]

7.17.2.5 Prognosis

Survival estimates for patients with heart failure are lower than for patients with most types of cancer.[3] Despite treatment with current standards of care, the 5-year survival for patients with heart failure is $\sim 50\%$ and 10-year survival is $\sim 10\%$.[4] Although there

is a significant noncardiovascular contribution to all-cause mortality, the main causes of death for heart failure patients are pump failure and cardiac arrhythmias.[22–24]

7.17.2.6 Pathophysiology

Patients with heart failure exhibit many changes in cardiac structure and function as well as neurohormonal changes that either correspond with and/or contribute to disease progression. These include neurohormonal changes, hypertrophy at both the cellular and organ levels, fibrosis, altered calcium handling, changes in metabolism, altered mitochondrial structure/function, and increased myocyte apoptosis.[3,8,25–30]

7.17.2.6.1 Neurohomonal

Neurohormonal changes that occur in heart failure include an increase in the activity of the renin/angiotensin/aldosterone system (RAAS), an increase in the activity of the sympathetic nervous system, increase in vasopressin and urocortin (UCN) release, and an elevation of plasma levels of natriuretic peptides.[1–3,31] Each of these neurohormonal systems has served as the basis for pharmacological treatments for heart failure patients and the majority of approved drugs that have been shown to improve outcomes target neurohormonal aspects of heart failure.

The first of the neurohormonal changes to be recognized was activation of the sympathetic nervous system.[28] In response to the development of heart failure, there is an increase in sympathetic tone and cardiac sympathetic nerve activity. The level of sympathetic activation correlates with mortality.[32,33] Excessive neuronally released norepinephrine acts on β_1-adrenoceptors in the heart and renal juxtaglomerular cells and α-adrenoceptors in vascular smooth muscle and renal tubules. Activation of adrenoceptors promotes changes in heart rate, cardiac force of contraction, renin secretion, sodium reabsorption, and vascular resistance.[34] These changes initially serve a compensatory role to help preserve organ perfusion but ultimately contribute to disease progression. Although β-adrenoceptor antagonists (β-blockers) were at one time considered to be contraindicated in heart failure due to the potential to induce an acute decrease of contractility, they have become an established standard of care for the treatment of heart failure.[1,2]

Recognition of the role of the RAAS in heart failure evolved after the development of ACEi.[35] RAAS plays an important role in the control of peripheral vascular resistance as well as sodium and water balance; all of which are dysregulated in heart failure patients. In addition to modulating fluid balance and vascular resistance, AII and aldosterone can also promote cardiac hypertrophy, fibrosis, and activation of the sympathetic nervous system.[35–38] Although the beneficial effects of ACEi in heart failure patients were initially believed to be attributable to vasodilation, there is a more complex role for RAAS activation in heart failure pathophysiology and the benefits of RAAS inhibition are greater than can be observed through vasodilation alone.[31,35,36] Renin activity is elevated in the plasma and hearts of dilated cardiomyopathy patients, particularly those with decompensation.[36,39] However, plasma renin activity may be normal in patients who are not decompensated.[31] A role for nonsystemic, local cardiac RAAS activation has also been proposed. In support of this idea, AII formation in human heart tissue has been shown to increase with heart failure progression.[35,36,40]

The natriuretic peptide system (NPS) is a cardiovascular endocrine system comprised mainly of the following peptides possessing vasodilator, natriuretic, diuretic, antiproliferative, antihypertrophic, and antifibrotic actions: atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP).[41–43] ANP is synthesized in atrial cardiac myocytes and released in response to atrial distension. BNP is synthesized primarily in ventricular cardiac myocytes in response to ventricular pressure and volume stress. CNP is synthesized in vascular endothelium in response to shear stress and in response to circulating ANP or BNP. Additionally, CNP is produced in renal glomerular and tubular cells.

The natriuretic peptides elicit cellular responses through activation of at least two cell surface natriuretic peptide receptors (NPRs). NPRA (also known as NPR1, GC-A) binds ANP and BNP, whereas NPRB (also known as NPR2, GC-B) binds CNP. NPRA and NPRB contain cytoplasmic guanylate cyclase domains, which catalyze the formation of cyclic guanosine monophosphate (cGMP) upon ligand binding. Subsequently, cGMP activation of cGMP-dependent protein kinase I (PKG) is responsible for the cellular response to the natriuretic peptides. A third natriuretic peptide receptor NPRC (also known as NPR3) binds all three natriuretic peptides (see **Fig. 4**). NPRC internalizes and is responsible for clearance of about half of the circulating natriuretic peptides, with the remainder degraded enzymatically by neutral endopeptidase (NEP; neprilysin). NEP is the rate-limiting enzyme in the inactivation of the natriuretic peptides, and accordingly has been pursued as an approach to modulate NPS peptide levels to enhance their salutary effects.

The NPS and RAAS act as counter-regulators in cardiovascular and renal homeostasis. At a physiologic level, the vasodilator, natriuretic, diuretic, antiproliferative/antihypertrophic, and antisympathetic effects of the NPS functionally oppose the vasoconstrictor, cell proliferative and hypertrophic effects, and enhancement of sympathetic tone produced by AII. At a mechanistic level, the NPS and RAAS have complex points of interaction including cross-regulation of synthesis and release.

Vasopressin is a posterior pituitary hormone that is released in response to decreases in plasma osmolarity or blood pressure. Cardiovascular and renal effects of vasopressin are mediated by V_2 receptors in the kidney and V_{1a} receptors in vascular smooth muscle. V_2 activation in the renal collecting ducts increases the reabsorption of free water through elevation of cAMP and increased apical membrane insertion of aquaporin. V_{1a} activation in vascular smooth muscle induces vasoconstriction.[44] Although the mechanism is not understood, plasma vasopressin levels are increased in patients with heart failure.[31,44]

The UCNs are peptide hormones belonging to the corticotrophin-releasing hormone family, and are secreted centrally and peripherally in response to stress. UCN plasma and tissue levels are elevated in experimental and clinical heart failure, and the exogenous administrations of UCNs have been shown to affect cardiac and vascular function.[45]

7.17.2.6.2 Calcium homeostasis

Precise spacial and temporal regulation of cardiac intracellular calcium concentrations is critical for controlling the contraction and relaxation that occurs with each heartbeat.[25] Calcium binds to troponin C on thin myofilaments to permit the progressive "walking" of myosin heads along actin filaments, which leads to muscle contraction and ejection of blood. As calcium levels fall, the myofilaments slide back into their resting position to permit refilling of the cardiac chambers. In heart failure, calcium transients are abnormal with elevated resting calcium levels, a reduced peak, and a slower return to baseline.[46] The suppressed peak calcium contributes to systolic dysfunction in heart failure. The slow return to baseline is one of many pathological changes that contributes to diastolic dysfunction in heart failure patients.

An important subcellular structural component for calcium homeostasis is regions where there is close proximity between L-type calcium channels in the T-tubules and ryanodine receptors in the sarcoplasmic reticulum (SR) to form a "calcium release unit" (Fig. 1).[25,47] The transient elevation of intracellular calcium that drives contractions is attributable to three factors. There is a trigger, a release of calcium from intracellular stores (contained in the SR), and removal of calcium from the cytosol. The trigger comes from action potentials which induce the opening of L-type calcium channels on the sarcolemma, particularly in the T-tubules. Influx of

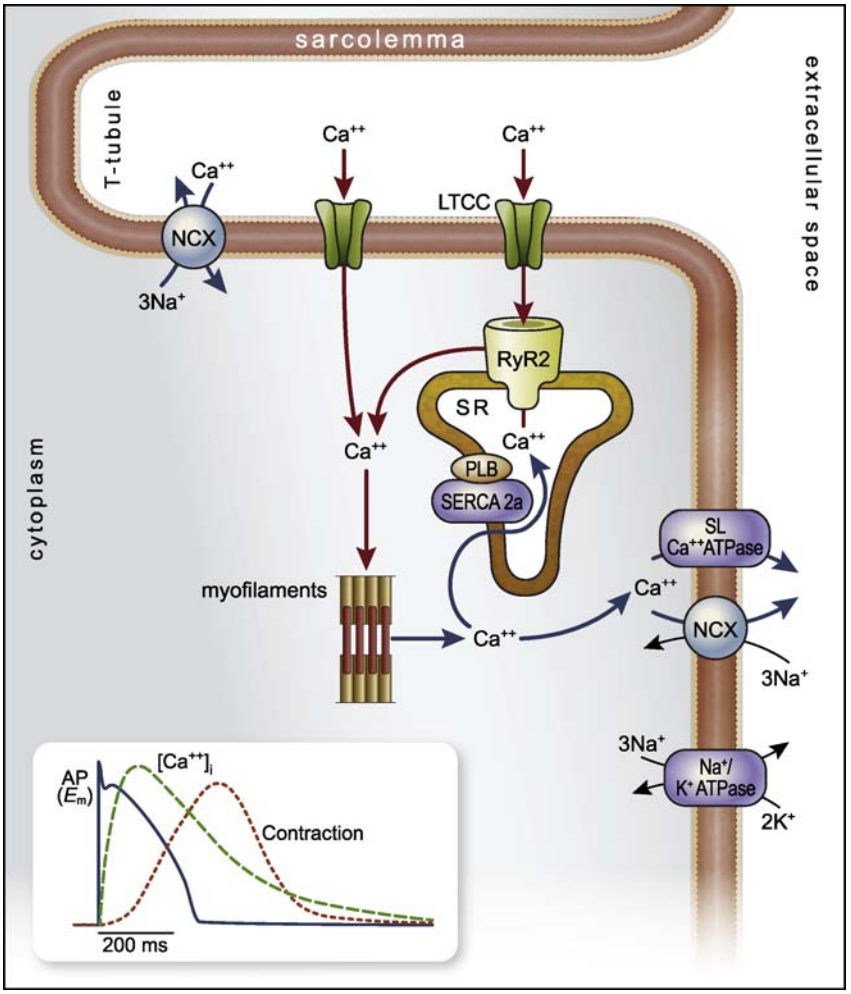


Fig. 1 Schematic representation of key entities involved in intracellular calcium homeostasis in the mammalian ventricle. Action potential propagation into T-tubules induces the opening of voltage gated L-type calcium channels. Close proximity between L-type calcium channels (*LTCC*) and the cardiac ryanodine receptor (*RyR2*) is important for calcium-induced calcium release from the sarcoplasmic reticulum (*SR*), which provides the majority of calcium needed for activation of the cardiac contractile apparatus (myofilaments). Cytoplasmic calcium is then either resequestered into the SR by the sarco/endoplasmic reticulum calcium ATPase (SERCA2a in the heart) or extruded from the cell by either the sarcolemmal sodium-calcium exchanger (*NCX*) or the sarcolemmal calcium ATPase (SL Ca^{++} ATPase). Sodium that enters the cell via the NCX can be extruded by the sodium–potassium ATPase.

calcium across the cell membrane results in a restricted zone of elevated calcium near cardiac ryanodine receptors. Cardiac ryanodine receptors then open by a process referred to as calcium-induced calcium release and allow the efflux of calcium from the SR. Removal of calcium from the cytosol is mediated primarily through the action of an ATP consuming calcium pump on the SR, SERCA2a, but there is also a contribution from the sarcolemmal sodium–calcium exchanger with approximately 70% of cytosolic calcium being resequestered by SERCA2a in large mammals including humans.[25] Two other transporters make minor contributions ($\leq$1% of total each) to the decay of intracellular calcium transients under physiological conditions, the sarcolemmal calcium ATPase, and the mitochondrial calcium uniporter.[25] The function of SERCA2a and the cardiac ryanodine receptor can be modulated by posttranslational modification, notably phosphorylation by protein kinase A (PKA) (to remove phospholamban dependent inhibition of SERCA2a) and calmodulin-activated protein kinase IIδ (CaMKIIδ).

Pathological alterations of calcium handling in the setting of heart failure are caused by changes in cardiac structure, protein expression levels, and posttranslational modifications. First there is a decrease in the expression of SERCA2a, in both animal models and in patients with heart failure.[48] Loss of SERCA2a results in reduced stores of intracellular calcium (weaker contractions) and a slower rate of calcium removal from the cytosol during the relaxation phase (slower relaxation).[48] In addition, there is an increase in the expression of sarcolemmal sodium–calcium exchanger resulting in a larger contribution of this transporter to the decay of calcium transients.[25] Second, phosphorylation of ryanodine receptors by CaMKIIδ or oxidation increases the leakage of calcium from the SR during diastole.[49,50] Somewhat more controversial is a proposed role for PKA-dependent hyperphosphorylation of the ryanodine receptor as an underlying cause of leaky ryanodine receptors.[51–53] The consequences of this increased leak include a further reduction in SR calcium stores and the potential to cause calcium-dependent cardiac arrhythmias. Finally, the close proximity between L-type calcium channels in the T-tubules and ryanodine receptors in the SR can be disrupted in heart failure. One potential reason is a decrease in the density of T-tubules in heart failure.[54] The increased distance between L-type calcium channels and the SR ryanodine receptor can lead to less efficient coupling between trigger calcium from the L-type calcium channel and the calcium-induced opening of the ryanodine receptor resulting in smaller calcium transients and the contractions they induce.[47]

7.17.2.6.3 Extracellular matrix

All forms of heart failure are associated with cardiac remodeling that includes changes in the cardiac extracellular matrix (ECM).[8] In heart failure, there is an increase in the deposition of ECM protein, increased expression of matrix metalloproteinases, altered expression of tissue inhibitors of metalloproteinases, and altered cross-linking of ECM proteins.[8] The increase in ECM contributes to an increase in passive stiffness of the heart. The ECM-dependent increase in passive stiffness, along with the slowing of active relaxation at the level of the myofilaments (primarily via altered kinetics of the intracellular calcium transient), contributes to diastolic dysfunction.[8,29] TGFβ-induced differentiation of fibroblasts into myofibroblasts is an important precursor to ECM remodeling in heart failure.[8] The details of ECM remodeling differ for HFrEF and HFpEF with a more unstable ECM in HFrEF.[8]

7.17.2.6.4 Mitochondria and metabolism

Healthy myocardium utilizes free fatty acids as the preferred source for generating ATP. The heart generally does not produce excess ATP, instead ATP production is finely tuned to match energy demands.[30] In nondiabetic heart failure, there is a decrease in the ability to utilize fatty acids and an increase in glucose metabolism.[26,30] In addition, there is a decrease in the density of mitochondria and alterations of the structure of mitochondria.[30,55] The sum of these phenotypic changes leads to the failing heart persisting in an energy compromised state.[26,30] Although there are no currently approved drugs that target the mitochondria, data from animal models suggests that mitochondrial protection has the potential to be beneficial for heart failure patients.[30]

7.17.3 Approved and Future Pharmacological Therapies for Heart Failure

7.17.3.1 Antiadrenergics and Anti-RAAS

Antisympathetic β-adrenergic receptor antagonists, the anti-RAAS ACE inhibitors, and steroidal MR antagonists have demonstrated significant mortality benefits in large clinical trials and comprise the cornerstones of chronic heart failure therapy in HFrEF patients. While ACE inhibitors are considered first-line therapy, ARBs are also used in HFrEF patients as alternatives when ACE inhibitors are not tolerated.[35,56,57] Consistent with their central roles in heart failure therapy, multiple efforts are investigating alternate means or strategies to elicit and improve upon antiadrenergic and anti-RAAS efficacy.

While the beneficial effects of approved β-adrenergic receptor antagonists in chronic heart failure are attributed primarily to blockade of the β_1-adrenergic receptor, the β_2-adrenergic receptor also plays a significant role in modulating cardiovascular function. In contrast, the β_3-adrenergic receptor is considered to have limited distribution in cardiac tissue at least in normal conditions.[58] Experimental studies have reported that selective β_2-adrenoceptor agonists, exemplified by clenbuterol and fenoterol and administered either alone or in combination with selective β_1-adrenoceptor antagonists, produce beneficial effects potentially relevant to heart failure. In the case of fenoterol, these improvements include increases in cardiac contractile function and remodeling in a rat model of myocardial infarction.[59,60] It also has been reported that β_3-adrenoceptor expression is increased in human heart failure and that the administration of selective β_3-adrenoceptor agonists, exemplified by CGP12177A (β_1, β_2 antagonist, β_3 partial agonist), structurally similar compounds BRL37344, SR58611A, and CL316243, as well as the β_1-adrenoceptor antagonist nebivolol that displays β_3-agonist activity, produce beneficial vasodilator and cardioprotective effects in multiple animal species models of cardiac injury and heart failure.[59,61,62] The observation that the nonselective β_1- and β_2-adrenoceptor antagonist

carvedilol, which has shown mortality benefit in clinical HFrEF trials, induces a change in GPCR conformation leading to β-arrestin-mediated ERK activation has led to the exploration of additional β-adrenergic receptor antagonists with β-arrestin-biased signaling profiles.[59,63–66] β-adrenergic receptor kinase 2 (βARK2) is upregulated in several forms of heart disease and stimulated by excessive catecholamines. This kinase is responsible in part for the desensitization and functional uncoupling of β-adrenoceptors in heart failure and is a potential target for modulating β-adrenoceptor signaling.[67] βARK2ct is a small peptide fragment of the C-terminus of βARK2 that can inhibit βARK2.[68] Delivery of βARK2ct via a recombinant adeno-associated viral vector reversed cardiac contractile dysfunction and normalized β-adrenergic signaling in a rat model of post-MI chronic HF.[69]

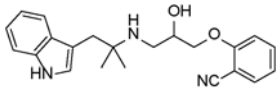
Also of note, an ongoing Phase II study is comparing the efficacies of metoprolol (vida supra Section **Classification based on cardiac ejection fraction**), a selective β_1-adrenoceptor antagonist, and bucindolol, a nonselective β_1- and β_2-adrenoceptor antagonist with weak vasodilator activity, in a genotype-defined population with heart failure and/or reduced ejection fraction at high risk for atrial fibrillation (NCT01970501). For perspective, the previous Phase III BEST trial of bucindolol in HFrEF patients failed to demonstrate significant survival benefit.[70] However, a 1040-patient substudy of the BEST trial identified specific genetic variants of the β_1- and α_{2c}-adrenoceptors that were associated with significant bucindolol benefits on mortality and hospitalization.[71] The ongoing Phase II trial with bucindolol is being conducted in heart failure patients with the specific β_1-adrenoceptor genetic variant to prospectively assess therapeutic efficacy in this patient group.



bucindolol

While the beneficial effects of ACE and ARB inhibition are attributed primarily to reduced activation of the ATR1 receptor, experimental studies have assessed other RAAS pathway members that may contribute to or enhance the efficacies of existing anti-RAAS treatments or constitute novel targets (see **Fig. 2**). Stimulation of the ATR2 receptor either as a consequence of AII tone in the setting of ATR1 blockade or by virtue of a selective ATR2 agonist such as compound 21[72] is postulated to mediate cardioprotective and antihypertrophic effects.[59,67] Overall, the "protective arm of RAAS" including ATR2 but also ACE2, angiotensin 1–7, and the Mas receptor are proposed to counteract the actions of AII on ATR1 and elicit antihypertrophic effects. Similarly, the kallikrein–kinin system, which is stimulated by AT2R activation, is thought to counteract the actions of ATR1 stimulation through the actions of bradykinin.[59,73] TRV027 is an 8-amino acid peptide (Sar-Arg-Val-Tyr-Ile-His-Pro-D-Ala-OH) β-arrestin-biased ligand of the ATR1, which blocks AII-stimulated G-protein signaling but stimulates β-arrestin-coupled signaling.[74] In a canine rapid cardiac pacing-induced heart failure model, TRV027 elicited beneficial hemodynamic and renal effects.[57,75] TRV027 currently is in Phase II clinical trial in patients with acute decompensated heart failure (ADHF) (NCT01966601). Upstream of ACE, the direct inhibition of renin to prevent generation of AI and AII is a long-recognized and explored target.[57,76] The Phase III ASTRONAUT trial of aliskiren, one of the first nonpeptide orally bioavailable direct renin inhibitors,[77] in recently hospitalized AHF patients, reported no benefit on cardiovascular death or hospitalization at 6 or 12 months after discharge (NCT00894387).[78] The ongoing ATMOSPHERE Phase III trial is comparing the effects of aliskiren, enalapril, or dual aliskiren plus enalapril treatment in HFrEF patients (NCT00853658). One additional novel RAAS pathway-related approach to heart failure therapy is the development of the combination NEP inhibition plus ARB treatment LCZ696, reviewed in Section **Natriuretic Peptide System-Related Approaches**.

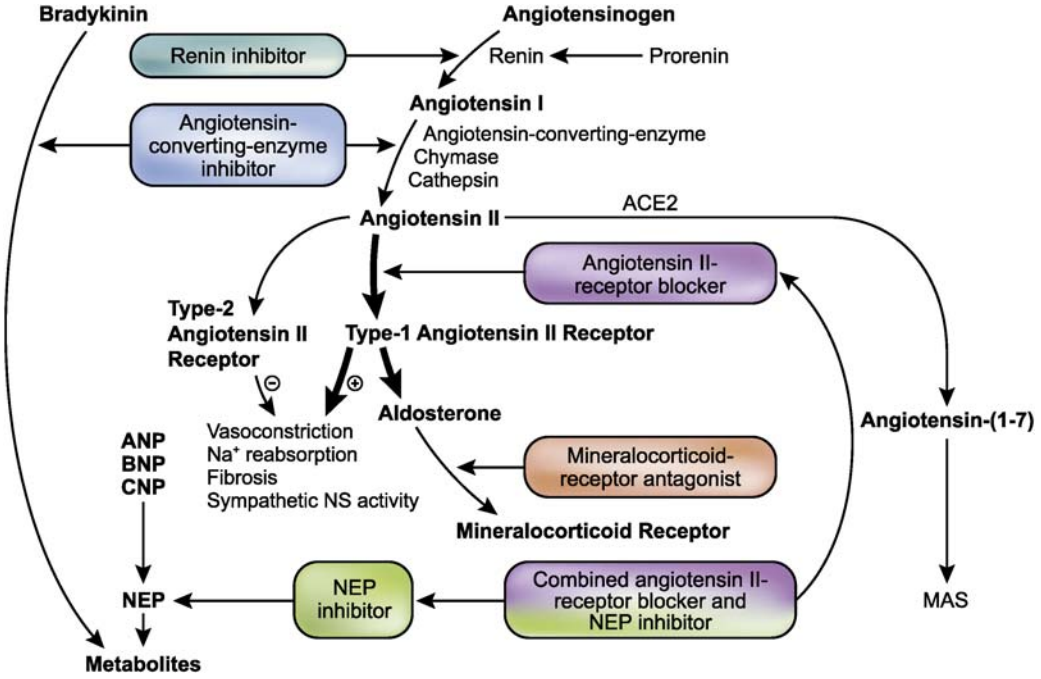


Fig. 2 Schematic of the renin–angiotensin–aldosterone system (*RAAS*) and the natriuretic peptide system. Angiotensinogen is converted to angiotensin II by the sequential action of renin and angiotensin converting enzyme (major). Chymase and cathepsin can also convert angiotensin I to angiotensin II (minor). The main effects of angiotensin II are mediated by the type-1 angiotensin II receptor. In addition, angiotensin II can induce the release of aldosterone, which evokes sodium reabsorption, increased plasma volume and potassium excretion via renal mineralocorticoid receptors. Excessive aldosterone can also promote fibrosis and contribute to the progression of heart failure through tissue remodeling effects. Effects of angiotensin II on type-2 receptors and effects of angiotensin (1–7) on the MAS receptor partially antagonize the pressor and profibrotic effects of angiotensin II. Natriuretic peptides induce vasodilation and sodium excretion through effects on NPRA and NPRB receptors (see **Fig. 4**).

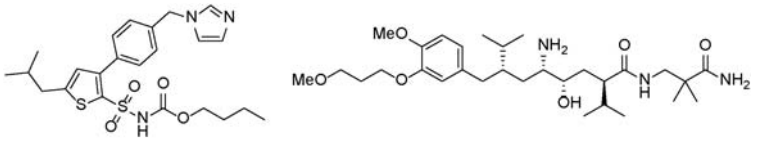
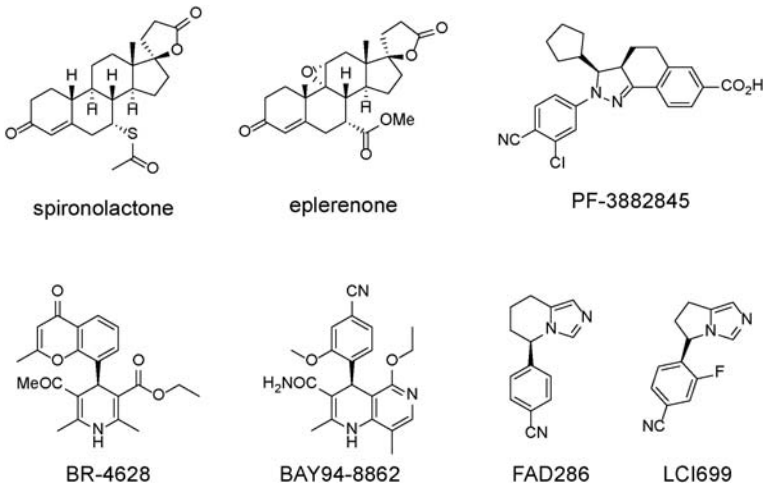


Although short-term treatments with ACE inhibitors and ARBs lower circulating levels of aldosterone, the suppression of aldosterone levels may not be sustained during long-term treatment.[79] Accordingly, MRAs are indicated for use in heart failure patients in order to block aldosterone receptor activation and thereby inhibit the unwanted effects of aldosterone, which include sodium retention, potassium and magnesium loss, sympathetic activation, parasympathetic inhibition, fibrosis, and vascular injury.[80] The Phase III RALES trial demonstrated that the administration of the steroidal MR antagonist spironolactone in HFrEF patients treated with ACE inhibitors reduced the risk of death, reduced the frequency of hospitalization for worsening heart failure, and improved symptoms of heart failure.[80] The Phase III EPHESUS trial assessed the administration of the steroidal MR antagonist eplerenone in patients with myocardial infarction and HFrEF treated with β-blockers, ACE inhibitors, or ARBs. In EPHESUS, eplerenone reduced all-cause mortality as well as cardiovascular death and hospitalization for cardiovascular events.[81] Eplerenone also reduced the risk of death and hospitalization in the Phase III EMPHASIS-HF trial in HFrEF patients with mild symptoms (NYHA Class II) treated with β-blockers, ACE inhibitors, or ARBs (NCT00232180).[82]

A limitation in the use of spironolactone and eplerenone is hyperkalemia due to inhibition of potassium excretion and worsening renal function.[1,2] Accordingly, a number of strategies have been explored to improve upon these steroidal MR antagonists. Novel nonsteroidal MRAs, exemplified by PF-3882845,[83] BR-4628,[84] and BAY94-8862,[85] have been assessed for tissue-selective and renal-sparing actions.[86] PF-3882845 has completed a Phase I safety and tolerability study (NCT00971802). BAY94-8862 (finerenone) has completed a Phase II dose-finding trial in patients with chronic heart failure and mild or moderate kidney disease, with decreases in BNP, NTproBNP, and albuminuria (reflecting reduced ventricular stress and improved renal function) but with significantly smaller elevations in serum potassium compared to spironolactone reported (NCT01345656).[87] BAY94-8862 currently is being studied in a Phase II trial in patients with worsening chronic heart failure and left ventricular systolic dysfunction and either type 2 diabetes mellitus with or without chronic kidney disease or chronic kidney disease alone (NCT01807221).[88] Three Phase III

trials with BAY94-8862 have been announced as soon-to-initiate: the FINESSE-HF study comparing BAY94-8862 to eplerenone in HFrEF patients with type 2 diabetes and/or chronic kidney disease, and FIGARO-DKD (NCT02545049) and FIDELIO-DKD (NCT02540993) assessing BAY94-8862 in diabetic kidney disease patients with moderate and marked albuminuria, respectively.

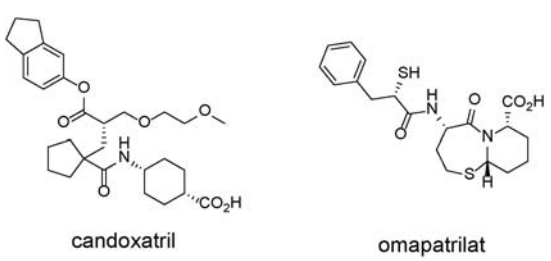
Aldosterone synthase inhibition constitutes an alternate and/or complementary approach to mineralocorticoid receptor antagonism for attenuating aldosterone activity in disease states, potentially including heart failure.[76] In a rat model of myocardial infarction, the aldosterone synthase inhibitor FAD286 has been reported to elicit beneficial effects on left ventricular function and remodeling.[89] FAD286 is the *R*-(+)-enantiomer of the racemic CYP19 (aromatase) inhibitor CGS016949A (fadrozole).[90] Although its antipode is an aromatase inhibitor, FAD286 potently inhibits human aldosterone synthase in vitro.[91] In a Phase II study in patients with essential hypertension, (NCT00758524) LCI699, a purportedly selective aldosterone synthase inhibitor, was effective in lowering diastolic blood pressure.[92]



7.17.3.2 Natriuretic Peptide System-Related Approaches

7.17.3.2.1 LCZ696

As noted in the Introduction, the NPS and RAAS act as counter-regulators in cardiovascular and renal homeostasis.[43] Presently, the only approved treatments exploiting the potential benefits of activating the NPS are the short-term intravenous infusions of recombinant BNP (nesiritide; United States and EU) and ANP (carperitide, Japan) for the treatment of ADHF. There has been long-standing interest and effort directed toward longer duration enhancement of NPS tone for the treatment of chronic heart failure. One approach has been that of inhibiting the catabolizing enzyme NEP.[93] Breakdown by NEP constitutes one of two main elimination mechanisms for endogenous NPs, the other being binding to and clearance by the NP receptor NPRC. Clinical studies primarily in patients with hypertension with selective NEP inhibitors demonstrated a lack of sustained efficacy, which was attributed to the promiscuous role of NEP in breaking down multiple vasoactive peptides including bradykinin and AII. Accordingly, patients administered selective NEP inhibitors, exemplified by candoxatril, displayed increases in plasma AII levels, which presumably offset the beneficial actions of increased NP levels.[94–96] Given the latter observation and the known counter-regulatory relationships of the RAAS and NPS, combination NEP plus ACE inhibition in single molecules termed vasopeptidase inhibitors, exemplified by omapatrilat, were pursued in chronic heart failure and hypertension patients. While encouraging clinical efficacy was observed with combined vasopeptidase inhibition,[97,98] the development of vasopeptidase inhibitors was terminated due to the observation of increased rates of angioedema attributed to an excessive accumulation of bradykinin resulting from concomitant inhibition of two catabolizing enzymes for this kinin, ACE, and NEP, as well as inhibition of the catabolizing enzyme aminopeptidase-P in the case of omapatrilat.[93]



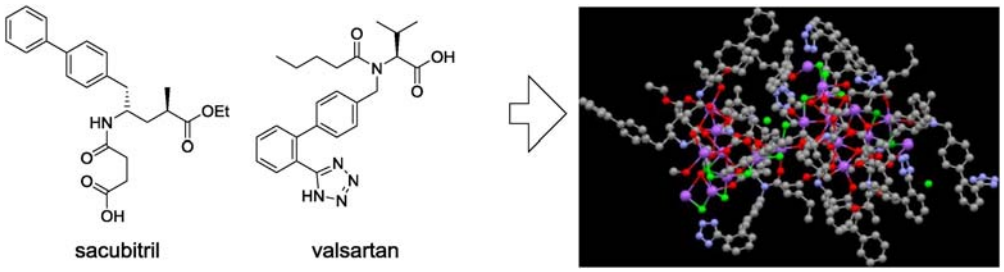


Fig. 3 LCZ696 is a crystalline structure comprising 6 NEP inhibitor prodrug (sacubitril) and 6 ARB (valsartan) molecules in addition to 18 sodium ions and 15 water molecules. Reproduced from Feng, L.; Karpinski, P. H.; Sutton, P.; Liu, Y.; Hook, D. F.; Hu, B.; Blacklock, T. J.; Fanwick, P. E.; Prashad, M.; Godtfredsen, S.; Ziltener, C. LCZ696: A Dual-Acting Sodium Supramolecular Complex. *Tetrahedron Lett.* **2012**, *53*, 275–276.

To circumvent the risk of angioedema, a combination of NEP inhibition plus ARB treatment (LCZ696, cocrystal formulation of the NEP inhibitor prodrug sacubitril (AHU377) plus the ARB valsartan) has been developed in chronic heart failure and hypertension patients. LCZ696 is a unique supramolecular complex consisting of six NEP inhibitor prodrug (AHU377) and six ARB (valsartan) molecules (Fig. 3).[99] Upon oral administration of LCZ696 to healthy volunteers, rapid NEP inhibition and angiotensin receptor blockade is observed with significant elevation of plasma cGMP levels and RAAS biomarkers (renin, PRA, and AII).[100] Importantly, the maximum pharmacodynamic effect (elevated cGMP and RAAS biomarkers) occurred at the same time; 4 h after administration of LCZ696. This is in contrast to omapatrilat where maximum ACE inhibition was observed at 2 h and cGMP elevation was observed at 4 h.[101] The simultaneous effects of the NEP inhibitor and ARB may be responsible for the clinical efficacy of LCZ696.

LCZ696 recently was reported superior to enalapril in reducing the risks of death and of hospitalization in patients with HFrEF in the PARADIGM-HF trial (NCT01035255).[102] LCZ696 was approved for the treatment of patients with HFrEF in the United States, Canada, and the EU in 2015 with approvals in other markets pending. The Phase II clinical trial PARAMOUNT in HFpEF patients has reported encouraging effects of LCZ696 compared to valsartan on the plasma HF biomarker NTproBNP, left atrial dimensions, and NYHA class (NCT00887588),[103] leading to the engagement of the ongoing Phase III PARAGON-HF trial of LCZ696 for the treatment of HFpEF (NCT01920711). ESC guidelines released in May of 2016 recommend that LCZ696 replace ACEi's in ambulatory patients who are symptomatic despite optimal therapy and meet the inclusion/exclusion criteria of the PARADIGM-HF trial.[2]

7.17.3.2.2 Natriuretic peptide analogs

Multiple efforts have been directed toward improving the therapeutic profiles of the natriuretic peptides BNP (nesiritide) and ANP (carperitide) through the synthesis of either modified or chimeric peptides as well as peptide derivatives. These approaches are exemplified by ularitide, cenderitide, PL-3994, and ANX-042.[57,104–107] Ularitide is a synthetically produced form of urodilantin, an endogenous modified version of proANP, which is secreted from the distal tubules of the kidney and regulates renal sodium absorption and water homeostasis through binding to the NPRA receptor. It has been postulated that ularitide/urodilantin possesses greater renal effects with less pronounced peripheral vasodilation compared to BNP and ANP. Two Phase II trials in patients with decompensated heart failure reported that 24 h ularitide IV infusions resulted in reductions in pulmonary capillary wedge pressure (reflecting a reduction in pathologically elevated left atrial pressure that occurs in heart failure patients as a consequence of elevated left ventricular end-diastolic pressure), systemic vascular resistance, and dyspnea.[108,109] The TRUE-AHF Phase III trial assessing the efficacy of ularitide in patients with AHF is ongoing (NCT01661634). Cenderitide (CD-NP) is a chimeric natriuretic peptide that combines CNP and Dendroaspis NP (DNP) and which binds to both the NPRA and NPRB receptors. CNP is a potent venodilator. DNP is a natriuretic peptide family member, which is detected in human circulation and atria by immunoreactivity, activates NPRA, and is a potent natriuretic with additional diuretic and aldosterone-inhibiting activities. It is postulated that this chimeric molecule will display the beneficial effects of predominantly venous vasodilation and natriuresis with reduced risk of hypotension compared to BNP and ANP. A Phase II trial with IV cenderitide in patients with stabilized AHF reported significant reductions in pulmonary capillary wedge pressure and trends toward decreasing right atrial pressure and increasing cardiac output (reflecting more blood being circulated per unit time) (NCT00699712).[110] A Phase II trial with SC cenderitide in chronic HFrEF patients is ongoing (NCT02359227). PL-3994 is a synthetic NPRA receptor agonist with reduced affinity for the NPRC clearance receptor and resistance to degradation by NEP, resulting in an extended in vivo half-life.[104] ANX-042 is a shortened peptide based on an alternative spliced transcript for BNP and is reported to be a renal-selective, nonhypotensive NP.[57] Phase I safety and tolerability studies with PL-3994 (NCT00686803) and ANX-042 (NCT01638104) have been conducted.

7.17.3.2.3 Corin modulation of natriuretic peptide formation

The mature natriuretic peptides ANP, BNP, and CNP are synthesized as preprohormones, with cleavage of the N-terminal signal sequences resulting in the formation of the precursor prohormones proANP, proBNP, and proCNP.[43] The transmembrane serine protease corin is thought to play an important role in the posttranslational cleavage of proANP and proBNP into fully active

ANP and BNP.[111–113] Corin has been shown to be present in human heart, kidney, and circulating in blood, the latter believed to result from the release or shedding of corin from cells.[114,115] In human heart failure, levels of the less active prohormone forms of ANP and BNP have been reported to increase and predominate over the mature forms,[116] whereas circulating levels of corin have been reported to decrease in proportion to increasing heart failure severity.[114] These clinical observations suggest that corin deficiency may contribute to the pathogenesis of heart failure through dysregulation of mature ANP and BNP formation.[114] Preclinically, the potential for corin to impact heart failure development has been assessed in a genetic mouse model of dilated cardiomyopathy (transgenic mice expressing a dominant-negative phosphorylation-resistant cAMP response element-binding protein in the heart). Cardiac-targeted overexpression of corin in this heart failure model reduced the development of fibrosis, increased fractional shortening and ejection fraction (reflecting increased volume of blood ejected per heart beat), and reduced lung water and alveolar congestion.[117] Very recently, in vitro studies have identified proprotein convertase subtilisin/kexin-6 (PCSK6) as the protease responsible for the cleavage of the inactive corin zymogen to active corin.[118] Taken together, these clinical and preclinical findings suggest that PCSK6/corin regulation of ANP and BNP prohormone processing may represent an additional natriuretic peptide-based approach to attenuate heart failure severity.

7.17.3.3 Phosphodiesterase Inhibition, Activation of Soluble Guanylate Cyclase, HNO Donors

Alternate mechanisms to increase myocardial cGMP levels and afford cardioprotective benefit are being explored either as an alternative to, or potentially in combination with, activation of the NPS. One approach being explored is that of inhibiting myocardial phosphodiesterase (PDE) activity to inhibit cGMP degradation (see **Fig. 4**). Inhibition of PDE5A by sildenafil was shown to be effective in preventing cardiac dysfunction and hypertrophy in a mouse pressure overload model of LV hypertrophy and heart failure.[119] However, the administration of sildenafil to HFpEF patients in the Phase III RELAX Trial did not result in significant improvement in exercise capacity or clinical status (NCT00763867).[120] A Phase III study assessing the tolerance, safety, and efficacy of sildenafil in patients with HFrEF and secondary pulmonary hypertension is ongoing (NCT01616381). It has been proposed that cardiac PDE5A primarily regulates nitric oxide (NO)-stimulated, soluble guanylate cyclase-generated cGMP and that NO signaling is often depressed in heart failure.[121,122]

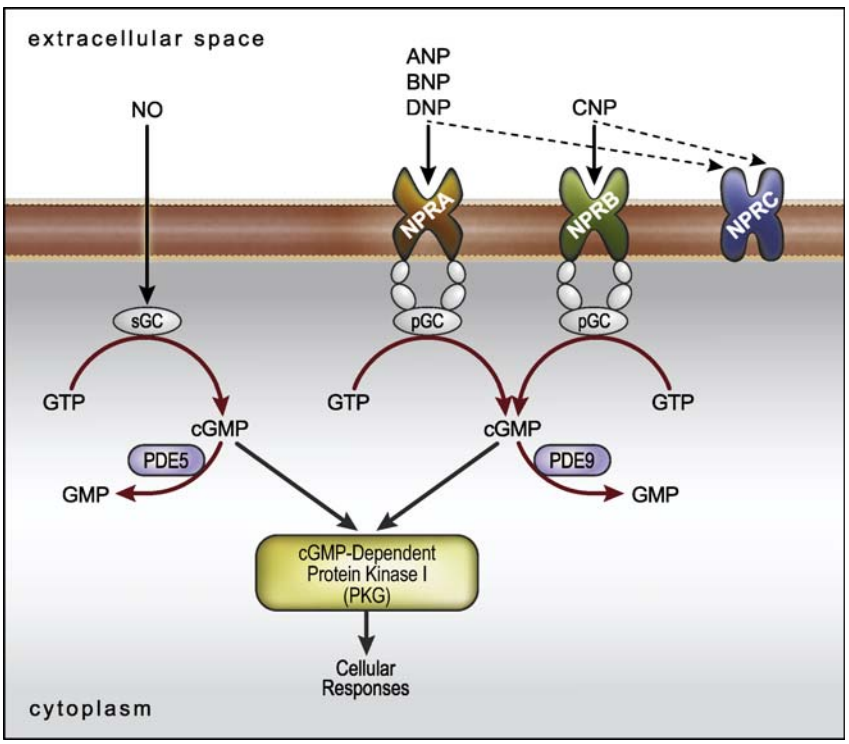

Fig. 4 Overview of the role of cGMP in cardiovascular signaling. Atrial natriuretic peptide (*ANP*), B-type natriuretic peptide (*BNP*), and Dendroaspis natriuretic peptide (*DNP*) activate the NPRA receptor (also termed NPR1, GC-A), which is coupled to particulate guanylate cyclase (*pGC*), thereby stimulating the formation of cGMP. C-type natriuretic peptide (*CNP*) stimulates the generation of cGMP through pGC by activating the NPRB receptor (also termed NPR2, GC-B). Binding of the natriuretic peptides to the NPRC receptor (also termed NPR3) results in receptor internalization and clearance of the natriuretic peptides. Nitric oxide stimulates the formation of cGMP through the activity of soluble guanylate cyclase (*sGC*). The physiologic effects of intracellular cGMP are mediated in great part by activation of cGMP-dependent protein kinase I (*PKG*). It is proposed that PDE9 preferentially regulates the breakdown of natriuretic peptide-generated cGMP, whereas PDE5 regulates the breakdown of NO-generated cGMP.[122]

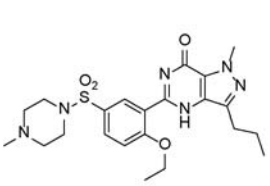
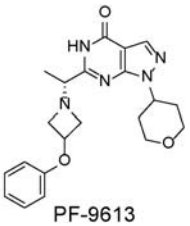


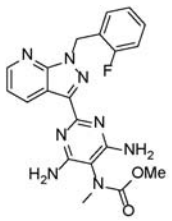
sildenafil



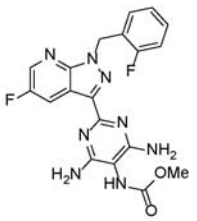
PF-9613

A recent study has suggested that PDE9A, which regulates natriuretic peptide-stimulated and NPRA-associated particulate guanylate cyclase-generated cGMP could be an important target for the treatment of heart failure.[122] PDE9A is expressed in mammalian heart (including human) and is upregulated in human myocardium from patients with HFpEF and patients with left ventricular hypertrophy due to aortic stenosis (pressure overload).[122] A comparison of PDE5A inhibition with sildenafil versus PDE9A inhibition with PF-9613,[123] in the mouse pressure overload heart failure model demonstrated that efficacy in preventing cardiac dysfunction and hypertrophy required active NO synthase activity for sildenafil, whereas comparable efficacy was elicited with PF-9613 independent of NO synthase status.[122] The NO-independence and the upregulation of PDE9A in the setting of heart failure suggest that PDE9A is the preferred PDE isoform (over PDE5A) to target for the treatment of heart failure.

A second approach being explored to enhance myocardial cGMP levels in the setting of heart failure is direct activation of soluble guanylate cyclase.[124] This approach will activate soluble guanylate cyclase in many tissues throughout the body, including vascular smooth muscle. The pulmonary vascular effects of soluble guanylate cyclase activation are responsible for the efficacy of riociguat in the treatment of pulmonary hypertension.[125–127] A Phase II dose-finding study of the soluble guanylate cyclase activator BAY-1021189 (vericiguat) in HFrEF patients with worsening heart failure has been completed (SOCRATES-REDUCED, NCT01951625) and a comparable study in HFpEF patients is ongoing (SOCRATES-PRESERVED, NCT10951638). The primary endpoint of change from the baseline NTproBNP level was not significantly affected when placebo was compared to pooled dosing groups in SOCRATES-REDUCED. However, exploratory analysis indicated that there was a dose-responsiveness with greater reductions in NTproBNP as the dose was increased.[128]

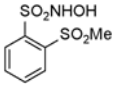


riociguat



vericiguat

Nitroxyl (HNO) donors exemplified by CXL-1020 and CXL-1427 are being developed to produce beneficial cardiac and vascular effects purportedly via multiple mechanisms. HNO elicits combined venous and arterial dilation attributed at least in part to soluble guanylate cyclase activation, but also has been reported to elicit cAMP- and cGMP-independent positive inotropic and lusitropic effects in cardiac muscle. In a canine model of heart failure induced by coronary microembolization, CXL-1020 reduced left ventricular end-diastolic pressure (reflecting a reduction in elevated ventricular filling/preload) and myocardial oxygen consumption while increasing ejection fraction (reflecting more blood being circulated per beat). In a canine model of heart failure induced by rapid cardiac pacing, CXL-1020 increased contractility as assessed by end-systolic elastance (a load-independent metric reflecting contractile function) and evoked venoarterial dilation.[129] In a Phase II trial in HFrEF patients (NCT01096043), the IV administration of CXL-1020 reduced left and right heart filling pressures and systemic vascular resistance while increasing cardiac index and stroke volume index (reflecting increased circulation of blood). However, the development of this compound was suspended due to the occurrence of inflammatory irritation at the intravenous insertion site.[129] A Phase II study in HFrEF patients is ongoing with CXL-1427, a second generation HNO donor (NCT02157506).

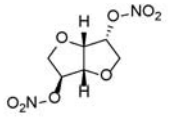


CXL-1020

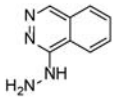
7.17.3.4 Isosorbide Dinitrate–Hydralazine Combination

The combination of two vasodilator compounds, isosorbide dinitrate and hydralazine, is recommended for African-Americans with symptomatic HFrEF who are being treated optimally with ACE inhibitors and β-adrenergic receptor blockers.[1] Guidelines

also suggest that this combination can be considered in all patients, regardless of race, who cannot tolerate an ACE inhibitor or an ARB.[1,2] Isosorbide dinitrate is an NO donor that can be used on its own to prevent angina. A common issue with isosorbide dinitrate and other nitrates is the development of tolerance. In contrast, the mechanism of action of hydralazine is not completely understood. It has direct relaxing effects on vascular smooth muscles with a preferential action on arterioles. The addition of hydralazine to isosorbide dinitrate can prevent or reverse nitrate intolerance and support sustained NO-mediated vasodilation.[130,131]



isosorbide dinitrate

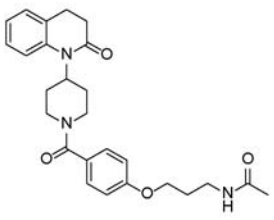


hydralazine

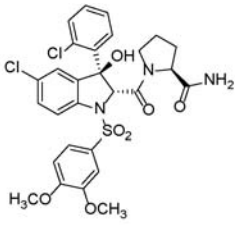
Clinical data supporting the use of isosorbide dinitrate and hydralazine in heart failure comes from three clinical trials; V-HeFT I,[132] V-HeFT II,[10] and A-HeFT.[133–135] V-HeFT I demonstrated that isosorbide dinitrate and hydralazine increased left ventricular ejection fraction in 642 men with impaired cardiac function and reduced exercise tolerance.[132] There was a trend for improvement in survival that was described as being of borderline statistical significance. V-HeFT II compared isosorbide dinitrate–hydralazine to enalapril.[10] Although the mortality benefit was superior with enalapril, isosorbide dinitrate–hydralazine induced greater improvements in ejection fraction and exercise tolerance.[10] The lack of a placebo arm in this study did not permit evaluation of whether there was a mortality benefit with isosorbide dinitrate–hydralazine. However, mortality rates for the isosorbide dinitrate–hydralazine arms were similar in V-HeFT I and V-HeFT II. Retrospective analysis of data from V-HeFT I and II revealed a racial disparity in the response to isosorbide dinitrate–hydralazine. In V-HeFT I African-Americans treated with isosorbide dinitrate had improved survival in comparison to placebo treatment.[136] In contrast, there was no survival benefit in white patients. In V-HeFT II, mortality was not different for African-Americans treated with enalapril versus isosorbide dinitrate.[136] A-HeFT enrolled self-identified black patients with evidence of left ventricular dysfunction that were on optimal therapy. Isosorbide dinitrate–hydralazine improved a composite endpoint of death, heart failure hospitalization, and quality of life as well as each component of the score.[133]

7.17.3.5 Vasopressin Antagonists

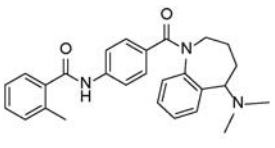
Vasopressin, a 9-amino acid neuropeptide hormone, is synthesized in the hypothalamus and secreted by the anterior pituitary. Vasopressin concentrations are elevated in heart failure and contribute to myocardial fibrosis, hypertrophy, vasoconstriction (mediated by vasopressin V_{1a} receptor activation) and water retention and hyponatremia (mediated by vasopressin V_2 receptor activation).[137] Initial work toward vasopressin receptor antagonists focused on small peptides.[138] However, the low bioavailability of the peptides led to the development of small molecule vasopressin receptor antagonists; the first V_{1a} selective antagonist OPC-21268,[139] and the structurally distinct V_{1a} antagonist relcovaptan.[140] Additionally, a class of structurally related V_2 and V_{1a}/V_2 receptor antagonists have been disclosed: mozavaptan (V_2 antagonist),[141] tolvaptan (V_2 antagonist),[142] and conivaptan (V_{1a}/V_2 antagonist).[143] Tolvaptan and conivaptan have been approved for the condition of hyponatremia including hyponatremia-associated heart failure.[144] However, conivapatan is a potent CYP3A4 inhibitor and this has limited its use.[145]



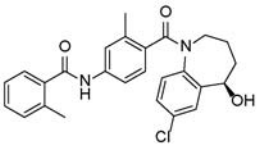
OPC-21268



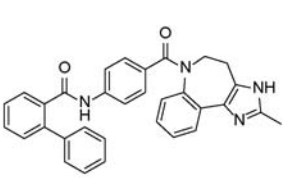
relcovaptan



mozavaptan



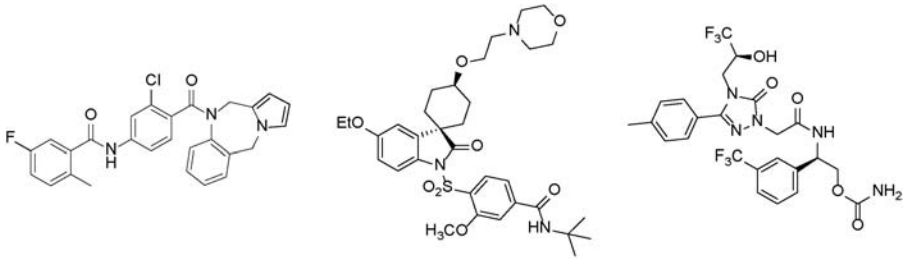
tolvaptan



conivaptan

In a Phase III EVEREST trial in HFrEF patients hospitalized for heart failure, tolvaptan displayed improvement in body weight reduction, dyspnea, and edema within the initial 7 days of treatment but had no effect on short-term global clinical status,[146] and no effect observed on long-term mortality or heart failure-related morbidity (NCT00071331).[147] In a Phase II trial in HFrEF patients, the single dose oral administration of tolvaptan reduced pulmonary capillary wedge pressure, right atrial pressure, pulmonary artery pressure, and increased urine output (NCT00132886).[148] A Phase III trial assessing tolvaptan administered intravenously plus the loop diuretic furosemide in patients with ADHF is ongoing (NCT01644331). In a Phase II trial in patients hospitalized for worsening heart failure, the 12 h IV treatment with conivaptan reduced pulmonary capillary wedge pressure and right atrial pressure, and increased urine output (NCT00057356).[149] In a more recent dose-ranging pilot study conducted in patients hospitalized for worsening heart failure, IV conivaptan administered for 48 h increased urine output and decreased body weight, but had no effect on patient or clinical assessments of global and respiratory status at 48 h of treatment.[150]

Efforts to develop novel vasopressin antagonists include the highly selective V_2 antagonists VPA-985 (lixivaptan)[151] and satavaptan.[151–153] Additionally, Bayer has reported the balanced V_{1a}/V_2 antagonist Bay 86-8050 (ribuvaptan). The 8-week oral administration of lixivaptan was assessed in a Phase II trial in patients with heart failure and volume overload, with reductions in body weight and improvements in dyspnea and orthopnea reported (NCT01055912).[154] The Phase III BALANCE trial of lixivaptan in heart failure patients with hyponatremia and volume overload reported significant increases in serum sodium, no significant effect on mortality, but with a numerical increase in mortality in the lixivaptan group (NCT00578695).[155]



7.17.3.6 Urocortins

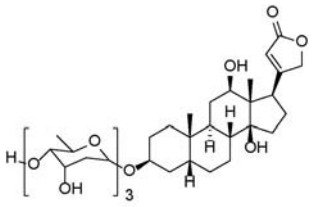
The urocortins 1, 2, and 3 (UCN1,2,3) and corticotropin-releasing hormone (CRH) are small (38–40 amino acids) endogenous peptide hormones that belong to the corticotropin-releasing family of hormones that are secreted in response to stress.[45,156] The UCNs signal through the G-protein coupled receptors CRH-R1 and CRH-R2, which are mainly located in the central nervous system and peripheral tissues, respectively. UCN1 binds to both receptors with similar affinities, whereas UCN2 and UCN3 are selective to CRH-R2. An extensive preclinical literature has explored the cardiovascular effects of the UCNs, and has reported these peptides to elicit peripheral vasodilation, positive inotropic effects, and cardioprotection in multiple animal species and models of cardiac injury and heart failure. Plasma and cardiac tissue UCN concentrations also have been reported to be elevated in heart failure.[45,156] Given the preceding observations, several clinical studies have explored the potential therapeutic benefit of exogenous UCN administration in human heart failure. In a small study of subjects with stable HFrEF, the 1 h IV infusion of UCN1 demonstrated increased adrenocorticotropic hormone (ACTH) and cortisol levels, but no effects on cardiovascular or renal parameters.[157] In a similar study of subjects with stable HFrEF, the 1 h IV infusion of UCN2 increased cardiac output and ejection fraction and heart rate while reducing mean arterial pressure and systemic vascular resistance. In this study, UCN2 increased ACTH and NTproBNP plasma concentrations, while other neurohumoral markers including cortisol, AII, aldosterone, and vasopressin were unchanged, and no renal effects were observed.[158] In the Phase II UNICORN trial, the 4 h IV infusion of UCN2 to patients with ADHF significantly reduced diastolic and systolic blood pressure with no effect on heart rate, decreased total peripheral resistance, and increased cardiac output (ACTRN12609000508279).[159] In a Phase II study in patients with stable HFrEF, three sequential rising dose IV infusions of JNJ-39588146 (stresscopin, homologous with UCN3) increased cardiac index and reduced diastolic blood pressure and systemic vascular resistance, with no significant effects on systolic blood pressure, heart rate, or pulmonary capillary wedge pressure observed (NCT01120210).[160]

7.17.3.7 Positive Inotropic Agents and Sarcomere Targets

7.17.3.7.1 Digoxin

Digoxin, the prototypical cardiac glycoside, is a longstanding positive inotropic agent approved for the treatment of HFrEF.[1,2] Cardiac glycosides inhibit sarcolemmal Na^+/K^+ ATPase resulting in a net accumulation of intracellular sodium which, in turn, inhibits the activity of the sarcolemmal Na^+/Ca^{++} exchanger (NCX) resulting in an increase in intracellular calcium concentration which increases contractility (see **Fig. 1**). Several clinical studies have reported that treatment with digoxin improves symptoms, quality of life, and exercise tolerance in patients with mild-to-moderate heart failure.[1,2] In the Phase III DIG trial, the administration

of digoxin to HFrEF patients treated with ACE inhibitors had no effect on all-cause or cardiovascular mortality, but tended to reduce mortality attributable to worsening heart failure. In the DIG trial, digoxin modestly reduced the rate of hospitalization both overall and for worsening heart failure, and modestly reduced the combination endpoint of death and hospitalization.[161] Post-hoc analysis of the DIG trial demonstrated that the subgroup of patients with serum digoxin concentrations of 0.5–0.9 ng mL^{-1} had less mortality and hospitalizations compared to placebo treated patients regardless of baseline ejection fraction or gender.[162]

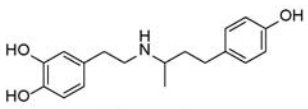


digoxin

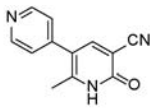
7.17.3.7.2 cAMP elevating agents

7.17.3.7.2.1 β-adrenergic receptor agonists and PDE3 inhibitors

β-Adrenergic receptor agonists exemplified by the β_1 selective agonist, dobutamine, and PDE3 inhibitors such as milrinone are positive inotropic agents approved to increase cardiac contractility only in short-term parenteral use in select ADHF patients who are refractory to other therapies and are suffering consequences from end-organ hypoperfusion. β-Adrenergic receptor agonists and PDE3 inhibitors increase cardiac contractility by increasing myocardial cAMP levels, resulting in cAMP-mediated activation of PKA. PKA-dependent enhancement of L-type calcium currents and SERCA2a activity (via phosphorylation of phospholamban and consequent removal of inhibition of SERCA2a) contribute to increases in SR stores of calcium, peak intracellular calcium during contractions, and the rate of calcium resequestration into the SR. In addition, elevation of cAMP in the SA node results in heart rate increases. Although effective in improving cardiac output, β-adrenergic receptor agonists and PDE3 inhibitors are associated with significant adverse effects attributed to increases in intracellular cAMP and calcium concentration, including decreased myocardial efficiency, increased oxygen expenditure, myocardial ischemia, and tachyarrhythmias.[76,163] Consequently, while the acute short-term use of inotropic therapy with β-adrenergic receptor agonists and PDE3 inhibitors can be beneficial in select ADHF patients, their chronic use is generally associated with increased morbidity and mortality.[76]



dobutamine



milrinone

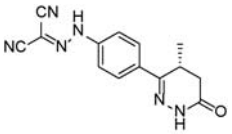
7.17.3.7.2.2 Adenylate cyclase gene therapy

In preclinical models and heart failure patients, the expression of adenylate cyclase 6 is reduced.[164] Adenylate cyclase 6 catalyzes the formation of cAMP from ATP in response to G-protein coupled receptors that signal via Gsα. In animal models of heart failure or cardiac dysfunction, enhancing the expression of adenylate cyclase 6 improved cardiac function without affecting basal cAMP levels or heart rate.[164] It has been proposed that this lack of effect on basal cAMP levels could provide a therapeutic advantage over small molecules that induce persistent elevation of cAMP levels (vida supra, Section β-adrenergic receptor agonists and PDE3 inhibitors). RT-100 is a gene therapy vector comprised of a replication-defective adenovirus (serotype 5) that encodes for human adenylate cyclase type 6. Although peer-reviewed data are presently not available, the sponsor has reported that RT-100 safely reduced heart failure hospitalization compared to placebo treated patients in a small Phase 2 clinical trial.[165]

7.17.3.7.3 Modulators of sarcomeric proteins

A different approach to enhance myocardial contractility is the targeting of myocardial sarcomeric proteins. There has been significant effort devoted to the development of "calcium sensitizers," which most generally are characterized as binding to and increasing the sensitivity of troponin C to calcium such that greater contractility is elicited at a given concentration of intracellular calcium. In practice, reported calcium sensitizers have complex and likely multiple mechanisms of action, including many such agents inhibiting PDE3 and/or activating ATP-sensitive potassium channels.[163] Levosimendan presently is the only approved calcium sensitizer (EU, some South American countries) and is used parenterally in ADHF patients.[166] The Phase III SURVIVE trial compared intravenous infusions (minimum of 24 h) of levosimendan versus dobutamine in ADHF patients requiring inotropic support. The levosimendan group displayed greater decreases in plasma BNP levels compared to dobutamine within the first 5 days of treatment, but there were no significant differences between treatment groups in all-cause mortality at 31 days, number of days alive and out of hospital, patient global assessment, patient assessment of dyspnea at 24 h, and cardiovascular mortality at 180 days. Levosimendan

administration in SURVIVE was associated with a higher incidence of atrial fibrillation and ventricular arrhythmia (NCT00348504).[167] In the Phase III REVIVE I and II trials that compared intravenous infusion of levosimendan to placebo in ADHF patients, levosimendan displayed decreases in plasma BNP levels and improvements in composite clinical symptoms related to heart failure within the first 5 days of treatment, but was associated with more frequent hypotension and cardiac arrhythmias during infusion, and a numerically higher risk of mortality (NCT00048425).[168] Several Phase III and IV trials are ongoing assessing the intermittent administration of levosimendan in advanced chronic HFrEF (NCT01290146, NCT0098806, NCT01536132).[163]



levosimendan

More recently, the targeting of the actin–myosin ATPase cycle has been explored as a means to more directly modulate cardiac contractility through altering the duty ratio, the proportion of myosin heads forming strong force-generating interactions or cross-bridges with actin.[163] Omecamtiv mecarbil (OM) has been described as a cardiac myosin activator that binds to myosin and selectively accelerates the rate-limiting step in the actin–myosin ATPase cycle, Pi release (**Fig. 5**). This results in an increase in the fraction of high affinity myosin–actin interactions (duty ratio), and an increase in contractility in the absence of effects on intracellular calcium levels.[169–171] A potential liability for this mechanism is that the contractions are prolonged resulting in shorter periods of relaxation within each cardiac cycle. As blood flow in the heart is reduced during systole, excessive increases in the duration of contraction could result in ischemia. In an early clinical trial, evidence of ischemia was observed in patients with OM plasma levels ≥ 1350 ng mL^{-1}.[172] Recently, an additional class of flavonoid compounds exemplified by chrysosplenol C have been reported to possess similar activity to OM.[173]

A study with OM in conscious dogs with post myocardial infarction systolic heart failure had indicated that, unlike available inotropes, the effects of OM appeared to be oxygen sparing in the heart.[174] However, a subsequent report studying the effects of OM in pigs with left ventricular dysfunction, ex vivo mouse hearts, and isolated mitochondria indicated that OM significantly increased oxygen wastage in both the contractile and noncontractile (resting) states due to continuous myosin ATPase activation.[175] A clinical study (NCT00748579) to examine this issue was terminated early due to challenges in study design and enrollment. Regardless, in the Phase II ATOMIC-AHF trial (NCT01300013), the 48 h IV administration of OM to patients with ADHF improved symptoms of dyspnea at the highest dose tested, and there was a trend for decreased worsening of HF across all dose groups at 7 days

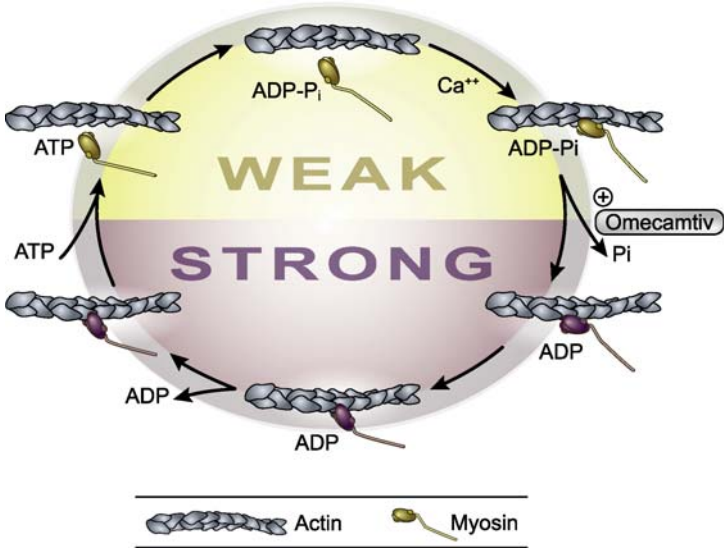


Fig. 5 The actomyosin ATPase cycle. For cardiac myosin the majority of the myosin heads interact weakly with actin, especially in the absence of calcium. Elevation of intracellular calcium removes inhibition of myosin–ADP–Pi interaction with actin by the troponin–tropomyosin complex and promotes the generation of strong crossbridges between myosin heads and actin. The release of inorganic phosphate (Pi) is the rate-limiting step of the cycle and enables the formation of a strong interaction between myosin heads and actin. Subsequently there is a force producing step (power stroke) in which myosin filaments are pulled along the thin filaments. The dissociation of ADP from the myosin heads then enables the binding of an ATP molecule, a weakening of the interaction between actin and myosin and dissociation. The development candidate omecamtiv mecarbil, enhances the release of Pi from actin–myosin–ADP–Pi and in doing so increases the fraction of myosin heads engaged in strong interactions with actin filaments.

after treatment initiation. The Phase II COSMIC-HF trial (NCT01786512) has assessed oral therapy with OM in chronic HFrEF patients.[163] Results of the COSMIC-HF trial were presented at the 2015 American Heart Association Scientific Sessions. Beneficial effects on left ventricular ejection fraction, ventricular size, and NTproBNP were reported at doses that did not raise any major safety concens.[176]

In an analogous approach to targeting the actin–myosin ATPase cycle, albeit to negatively modulate duty ratio and force generation, a preliminary report describes MYK0000461 as stabilizing the detached state of myosin prior to Pi release, thereby inhibiting Pi release and slowing the rate-limiting step in the actin–myosin ATPase cycle.[177] This mechanism potentially would decrease the duration of high affinity myosin–actin interaction, and thereby decrease the duty ratio and decrease contractility. Such a mechanism might be useful in treating hypercontractile disorders such as hypertrophic cardiomyopathy. Multiple Phase I safety and tolerability studies are ongoing with MKY0000461 (NCT02329184, NCT02356289, NCT02480296). These novel approaches targeting of the actin–myosin ATPase cycle to positively or negatively modulate contractility await clinical validation.

7.17.3.8 Correction of Calcium Homeostasis

7.17.3.8.1 Mydicar (AAV-1/SERCA2a)

Correction of altered intracellular calcium handling in heart failure has been a goal for treatments since the abnormal calcium homeostasis in heart failure was first described.[46] One of the more consistent findings during profiling of either human myocardium or ventricular muscle from animal models of heart failure is a reduction in the expression levels of the SR calcium pump, SERCA2a, which is responsible for calcium reuptake after muscle contraction.[25,48,178] The impact of reduced SERCA2a activity includes a reduction in intracellular stores of calcium and a slower removal of calcium from the cytoplasm after it is released. These changes contribute to systolic and diastolic dysfunction, respectively, and make restoration of normal SERCA2a function an attractive goal for treating heart failure patients.

Mydicar is an adenovirus-associated virus 1 construct in which the cytomegalovirus immediate early promotor drives the expression of human SERCA2a.[179] The aim for this viral construct is to restore normal levels of SERCA2a and correct abnormal calcium homeostasis. SERCA2a encoding viral vectors have been delivered by coronary perfusion in animal models of heart failure and in human clinical trials.[180–185] Due to the nature of the intervention, effects develop over weeks to months. Beneficial effects reported after SERCA2a gene therapy in animal models of heart failure include enhanced survival,[181] increased left ventricular pressure development, increased fractional shortening, a reduction in left ventricular end-systolic volume, enhanced relaxation, improvements in the phosphocreatine/ATP ratio, and a reduction in plasma BNP levels.[180,181,184,185]

Initial clinical results with Mydicar in the CUPID trial appeared promising (NCT00454818).[186] Six months after virus administration to patients in NYHA Class III or IV heart failure with an ejection fraction of 0.35 or less, there was stabilization or improvement of 6 min walk distance, end-systolic volume, and end-diastolic volume in the group receiving the highest dose of virus.[186] In addition, a 3-year follow up of patients in the CUPID trial showed that there was a reduction in cardiovascular events in the high dose group.[187] No safety concerns were identified in the CUPID trial. A limitation of the CUPID trial was the small number of patients (39 in total).[186] A subsequent 250 patient Phase II trial (CUPID 2, NCT01643330) did not meet the prespecified primary endpoint (time-to-recurrent HF-related hospitalizations in the presence of terminal events; all-cause death, heart transplant, LVAD implantation).[182,188] As a consequence of the negative results in CUPID 2, the sponsor has placed all further development for Mydicar on hold.[189]

An issue for gene therapy using adeno-associated virus 1 constructs is the prevalence of neutralizing antibodies in the patient population. For the CUPID 2 trial, 60% of potential subjects were excluded based on the existence of detectable titers of neutralizing antibodies.[179]

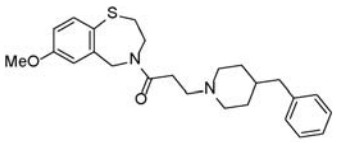
There are a number of potential causes of the negative results of the CUPID 2 trial. Although it is clear that viral delivery of a SERCA2a construct can increase myocardial expression of SERCA2a, it is not known if the protein was expressed at a sufficient level or in all the correct locations to correct the calcium mishandling that occurs in heart failure. Because of the caveats of lack of verification of sufficient SERCA2a expression, and/or tissue/cellular/subcellular localization of Mydicar, one cannot exclude the potential benefit of SERCA2a activity augmentation in heart failure, and more exploration of this mechanism is required.

7.17.3.8.2 Aladorian

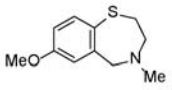
A second source of calcium mishandling in heart failure is the increased release of calcium from the SR during diastole.[27,190] Potential consequences of diastolic calcium leak include systolic and diastolic dysfunction due to effects on the content of SR calcium stores and the ability of the SR to resequester calcium in the face of an abnormal leak.[190] An additional concern is the potential to initiate calcium-dependent ventricular arrhythmias.[27,190]

The cardiac ryanodine receptor complex contains many proteins including the ryanodine receptor 2 (RyR2), FK binding protein 12/12.6 (FKBP 12/12.6), calmodulin, PKA, calmodulin-dependent protein kinase II δ (CaMKIIδ), and phosphatases.[190] Hyperphosphorylated RyR2 is found in heart failure and is thought to contribute to the enhanced diastolic calcium release.[190] There is controversy in the literature as to whether PKA, CaMKIIδ, or both are responsible for the hyperphosphorylation of ryanodine receptors.[51,190] However, the weight of available evidence appears to favor the notion that CaMKIIδ activity is primarily responsible for calcium leak from the SR in heart failure.[52,53,190] Unfortunately, the development of CaMKIIδ inhibitors appears to be limited by the difficulty in achieving kinase selectivity for the δ isoform, which is the predominant form of CaMKII in the heart, because no highly selective inhibitors have been reported.

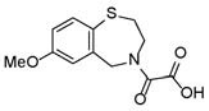
A benzothiazepine class of compounds, JTV519 and S107, can function as stabilizers of RyR1–FKBP complexes in vitro. These compounds were developed based on the hypothesis that phosphorylation of RyR2 in heart failure was dependent on PKA, which prevented a stabilizing effect of FKBP 12/12.6 on RyR2 gating. In vitro, S107 was also shown to inhibit *S*-nitrosylation-mediated FKBP12 dissociation from RyR1.[191] A next generation benzothiazepine aladorian (ARM036) has been identified. Preclinically, aladorian has shown favorable effects in a mouse cardiac ischemia reperfusion model.[192] The compound is listed as being in Phase II clinical trials for ventricular arrhythmias in heart failure patients (ISRCTN14227980) and catecholaminergic polymorphic ventricular tachycardia (2011-000579-15).



JTV519



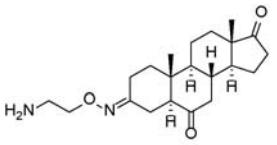
S107



aladorian

7.17.3.8.3 Istaroxime

Istaroxime was identified from efforts to find a less toxic version of the cardiac glycoside, digoxin,[193] which causes cardiac arrhythmias at only two to three times the therapeutically useful doses. Two biochemical mechanisms have been reported for istaroxime and both appear to contribute to the inotropic effects: inhibition of sarcolemmal sodium–potassium ATPase activity and activation of SERCA2a.[194–197] The activation of SERCA2a activity has been attributed to relief of the inhibitory effect of phospholamban (by preventing the interaction between phospholamban and SERCA2a).[198] The addition of SERCA2a activation seems to be beneficial in comparison to the selective inhibition of sodium–potassium ATPase by digoxin. In vitro studies on isolated myocytes and in vivo studies show that istaroxime induces a positive inotropic effect that is comparable to that of digoxin but with a greater therapeutic index.[193,194,199] An important aspect of the effects of istaroxime on contractions is the induction of a positive lusitropic effect. Acute hemodynamic and imaging studies in a canine microembolus model of heart failure demonstrated beneficial effects of istaroxime on left ventricular end-diastolic pressure, chamber volumes (end-diastolic and end-systolic), and ejection fraction without increasing myocardial oxygen consumption or altering heart rate.[200,201] In this model, istaroxime also increased deceleration time of early mitral inflow velocity and diastolic wall stress, effects consistent with improved relaxation of the left ventricle.[201] Additional potential benefits for istaroxime in comparison to digoxin come from its pharmacokinetic properties, which result in a more rapid onset and offset of action.[194]



istaroxime

The Horizon HF trial (NCT00616161) evaluated the effects of a 6 h intravenous infusion of istaroxime in hospitalized heart failure patients with AHF, an ejection fraction $<35\%$, and a pulmonary capillary wedge pressure >20 mmHg.[202,203] One hundred twenty patients were normalized to either placebo, 0.5, 1.0, or 1.5 $\mu g\ kg^{-1}\ min^{-1}$ of istaroxime for 6 h. All patients were subjected to pulmonary artery catheterization and echocardiography (two-dimensional Doppler and tissue Doppler) to gather hemodynamic and imaging data at baseline and during treatment. A reduction in pulmonary capillary wedge pressure was observed in all dose groups. Although ejection fraction was not changed, there was a reduction in left ventricular volumes (end-systolic in the 1.0 $\mu g\ kg^{-1}\ min^{-1}$ group and end-diastolic in the 1.5 $\mu g\ kg^{-1}\ min^{-1}$ group).[202] Evidence for reduced diastolic stiffness included an increase in É (reflecting an increase in ventricular relaxation), an increase in E-wave deceleration time, and a decrease in end-diastolic elastance.[203] Side effects of istaroxime included a dose-dependent decrease in the rate-corrected QT interval, vomiting, pain at the infusion site, dysgeusia, and gastrointestinal symptoms.[202]

The Horizon HF study involved a cohort of AHF patients with milder symptoms than would normally be treated with inotropes based on current guidelines. In fact, patients requiring inotropic support were excluded so effects in the target patient population are

unclear. Istaroxime is presently listed as undergoing additional clinical testing in Italy (Phase II) and China (Phase I) CTR20150354; SN-YQ-2015006. The sponsor for istaroxime has also reported data for novel analogs and claim that some have an even greater therapeutic index.[204]

7.17.3.9 Relaxin

Relaxin is a 53-amino acid peptide that is a heterodimer of two peptide chains (24 and 29 amino acids) that are linked together via two disulfide bonds. The secondary structure of relaxin is very similar to insulin, despite the fact that the amino acid sequences between the two have very little similarity. Relaxin was discovered based its ability to relax the pubic ligament of gophers and guinea pigs.[205,206] This peptide has been shown to contribute to renal and cardiovascular adaptations to pregnancy including increased cardiac output, vasodilation resulting in a decreased vascular resistance, and an increase in glomerular filtration rate.[75,207] Molecular biological techniques have revealed that relaxins are a family of seven different insulin-like peptides that bind to and activate a family of four different G-protein coupled receptors.[205] The ligand/receptor pair that has been shown to induce beneficial effects in AHF patients, namely human relaxin-2 and relaxin family peptide receptor 1 (RXFP1), are discussed here.

RXFP1 is expressed in a wide range of reproductive tissues, including ovary, uterus, mammary gland, testis, and prostate. The receptor is also found in kidney, heart, lung, liver, bone, the vasculature, and brain.[205] Signal transduction via RXFP1 activation is complex and involves at least three distinct G-proteins ($G\alpha_s$, $G\alpha_{oB}$, and $G\alpha_{i3}$) to induce changes in cAMP production, activation of ERK 1/2, and production of NO.[205,207]

In animal models, relaxin has pronounced effects on the vasculature including decreases in vascular resistance and increases in arterial compliance.[206,207] There appears to be a species dependence for cardiac inotropic and chronotropic effects with positive effects in rodents and rabbits, whereas there was no effect in sheep and human heart.[207,208] In addition, renal blood flow and sodium excretion are increased in animal models.[209] Preclinical data show that relaxin protects the heart in multiple disease models through vasodilation, angiogenesis, antifibrotic, and antiinflammatory actions.[206,207,210] The renal and vascular effects of relaxin suggested the potential for benefit in the treatment of AHF.

Serelaxin is a recombinant form of human relaxin-2 that is administered by infusion. In the Phase III RELAX-AHF trial (NCT00520806), 1161 patients with a systolic blood pressure >125 mmHg were randomized to 48 h of infusion with 30 $\mu g\ kg^{-1}$ per day of serelaxin or a comparable volume of vehicle within 16 h of presentation. In this study, serelaxin improved one primary endpoint related to dyspnea, the area under the curve of a visual analog score.[211] However, there was not a statistically significant effect on the other primary endpoint related to dyspnea, the Likert score.[211] Surprisingly, a trend toward decreased mortality was observed at 180 days post serelaxin infusion,[211] but not at 60 days. No mechanism has been identified to account for the 6-month survival benefit after 2 days of infusion. Serelaxin is presently approved for use in Russia; however, the US and European regulatory authorities have asked for additional clinical data to support approvals. An ongoing large ($n=6375$ patients) outcomes trial (RELAX-AHF-2, NCT01870778, estimated completion Aug. 2016) is attempting to reproduce the mortality benefit that was found in RELAX-AHF.[75,212]

7.17.3.10 Neuregulin-1

Neuregulin-1 (Nrg-1) is the name used for a group of alternatively spliced protein ligands that belong to the epidermal growth factor (EGF) family. A single Nrg-1 gene encodes for multiple splice variants (≥ 15) of Nrg-1 that contain a common EGF domain. The EGF domain is responsible for ligand binding to its cognate receptors.[213] Nrg-1s are critical for cardiac development and maintenance of a mature working myocardium. They also play important roles in neural development, nerve myelination, and the maintenance of neuromuscular junctions.[214] Receptors for Nrg-1s are expressed in a tissue dependent manner and include the receptor tyrosine kinases, ErbB3 and ErbB4. Adult cardiac muscle expresses and signals primarily through ErbB4 receptors.[214] Most target tissues have a combination of ErbB3 and ErbB4 receptors. However, in contrast to heart, some cell types, such as Schwann cells, signal primarily through ErbB3 receptors.[215] The active form of ErbB receptors is either a homodimer or heterodimer. When heterodimers are induced, the complex frequently includes ErbB2, which has kinase activity but no ligand recognition domain and is structurally poised to dimerize with other ErbB receptors with bound agonist. ErbB3 receptors lack kinase activity and signal exclusively via heterodimers with ErbB2.[216]

The role of Nrg-1s in the heart became apparent from knockout mice and from clinical experience with the anti-ErbB2 antibody, trastuzumab.[214,216] ErbB4 knockout mice, ErbB2 knockout mice, and disruption of the Nrg-1 gene result in a common cardiac phenotype (defects in ventricular trabeculation) and embryonic lethality.[217] Although cardiac myocyte specific deletion of ErbB2 or ErbB4 permits survival of mice beyond birth, in each case a dilated cardiomyopathy develops.[218–220] Treatment of breast cancer patients with anthracyclines plus anti-ErbB2 antibody results in an increased incidence of cardiomyopathy.[221]

Nrg-1s are protective in both in vitro and in vivo animal models of cardiac damage or heart failure including doxorubicin treatment in vitro and in mice, post MI rats, dog tachypacing, and swine post MI models.[214,222,223] Although the mechanistic details remain to be determined, Nrg-1s induce multiple beneficial actions, including improvements in mitochondrial structure and function, improvement of glucose uptake, enhanced expression of sarcomeric proteins, and enhanced contractile function.[214] Biochemical events that are coupled to activation of Erb4 receptors in cardiac myocytes include activation of Akt and MAPK,[214] but it is not clear whether or how these pathways contribute to the beneficial effects of Nrg-1s in damaged myocardium.

Two different Nrg-1 proteins are currently undergoing clinical evaluation in chronic stable heart failure patients. Neucardin is the EGF domain of human Nrg-1 β2a. This 61-amino acid peptide has a short half-life and has been administered via 10 h of infusion on 11 consecutive days. Neucardin treatment of patients with chronic stable heart failure has been reported to induce an increase in ejection fraction, which persists up to 3 months after treatment[224] as well as favorable acute effects on hemodynamics and neurohormones including an increase in cardiac output, a decrease in PCWP, a decrease in systemic vascular resistance, and decreases in plasma norepinephrine and aldosterone.[225] However, there was a steep biphasic dose response observed with Neucardin; at high doses very little improvement in cardiac function was observed. In vitro studies have demonstrated that Nrg-1 can antagonize the enhancement of rabbit papillary muscle contractions by isoproterenol.[226] Whether this effect contributes to the biphasic dose response relationship in clinical trials with Neucardin is not known.

Improvements in ejection fraction in chronic stable heart failure patients have also been reported with a second Nrg-1 isoform, GGF2 (cimaglermin alfa), which can be administered as a single 15 min infusion.[227] This protein is a recombinant version of a longer and naturally occurring Nrg-1 isoform containing domains that could enhance the tissue half-life through binding to the ECM.[228] GGF2 did not exhibit a biphasic dose response in clinical trials but dose limiting liver toxicity was observed.[229] It is not clear if this toxicity was mechanism based. GGF2 is currently undergoing a Phase I pharmacokinetic study to evaluate potential drug–drug interactions with the CNS depressant benzodiazepine, midazolam (NCT01944683), as the observed liver toxicity could impact the elimination kinetics of midazolam. Neucardin is currently undergoing larger clinical trials in China and Australia.[214] A US Phase II trial with Neucardin is listed as being completed in clinicaltrials.gov but no results have been reported (NCT01251406).[230] Despite promising preclinical data and encouraging efficacy readouts in small clinical trials, it remains to be determined whether an acceptable benefit/risk profile can be demonstrated in clinical trials with Nrg-1s.

7.17.3.11 Ion Channel and Ion Transport Modulators

7.17.3.11.1 Diuretics for decongestion in heart failure

Guideline-directed therapy for AHF patients includes the intravenous administration of loop diuretics, such as furosemide (Lasix), bumetanide, and torsemide, in fluid overloaded patients.[1,2] Although the benefit of treating such patients with loop diuretics is well accepted, the level of evidence from controlled clinical trials to support these recommendations is from limited populations and the impact of loop diuretics on outcomes for AHF patients has not been well studied.[1,2,231] In addition, there is some uncertainty regarding optimal dosing regimens.[231]

Loop diuretics work through inhibition of the sodium/potassium/chloride cotransporter, NKCC2, in the thick ascending loop of Henle.[231,232] Preventing the reabsorbtion of sodium and chloride from the renal tubular lumen into the blood results in increased urine volume and increased sodium excretion (Fig. 6). Because loop diuretics have limited permeability across the epithelium of the thick ascending loop of Henle, they must be filtered across the glomerulus in order to reach their site of action on the luminal side of the tubular epithelial cells.[231] Therefore conditions that decrease glomerular filtration can limit the effectiveness of loop diuretics. There is also the potential to evoke undesirable effects with loop diuretics such as reducing glomerular

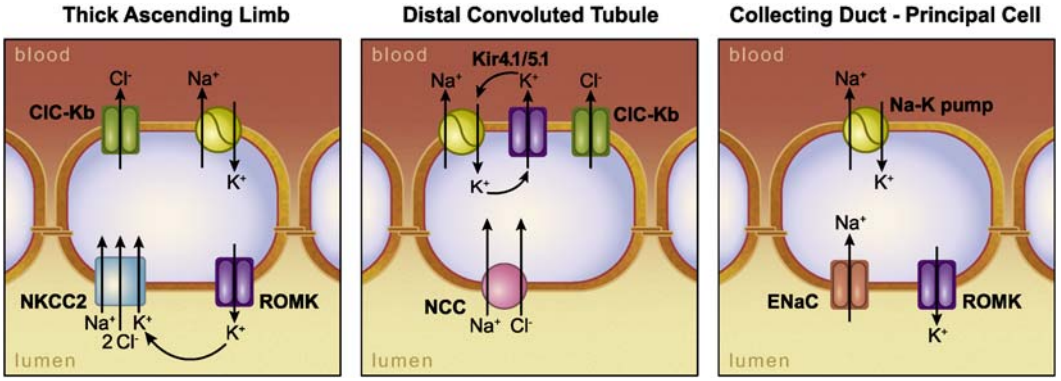


Fig. 6 Ion channels and ion transporters that contribute to transepithelial fluid and electrolyte fluxes within segments of the renal tubule that are targeted by existing diuretics.

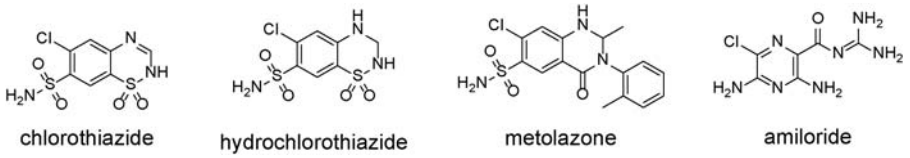
filtration rate, activation of counter-regulatory neurohormonal responses, electrolyte disturbances (particularly hypokalemia), and arrhythmias.[231]

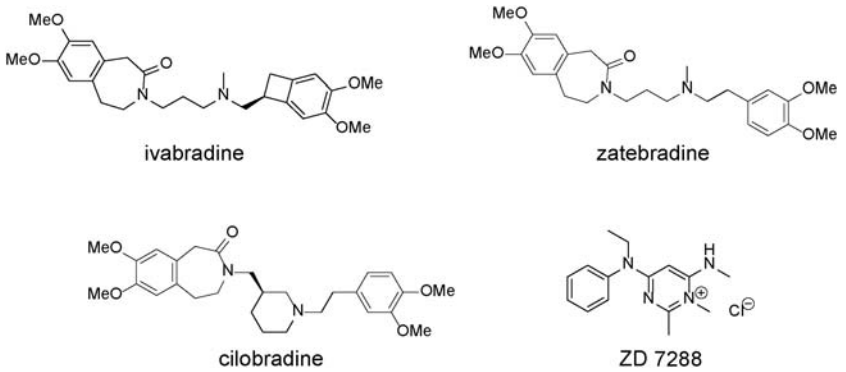
Diuretic resistance is a problem in a subset of AHF patients.[232] One approach for overcoming resistance to loop diuretics is to utilize combination therapy with a thiazide, such as chlorothiazide, hydrochlorothiazide, or metolazone.[231,232] Thiazides inhibit the sodium chloride cotransporter, NCC, in the distal convoluted tubule and prevent reabsorbtion of sodium and chloride which results in diuresis and enhanced urinary excretion of sodium (Fig. 6). The addition of a thiazide in a loop diuretic resistant patient can dramatically increase diuresis. However, potential risks of combining a thiazide with a loop diuretic include hypokalemia, hyponatremia, hypotension, and worsening renal function.[232]

Loop diuretics are also recommended for chronic heart failure patients for relief of dyspnea and edema when there is evidence of fluid retention.[1,2] In patients who are hypertensive, oral thiazides may also be considered because they induce a more sustained blood pressure response. Although there are no trials evaluating the effect of diuretics on outcomes in patients with chronic heart failure, controlled trials have demonstrated increases in sodium excretion, relief of fluid retention, and improvements in exercise tolerance.[233–235] Doses of oral diuretics are typically titrated up until the desired effect on body weight is obtained and need to be carefully adjusted to avoid adverse effects such as hypokalemia, hypomagnesemia, hypotension, and renal dysfunction. Hypokalemia risk can be mitigated in some cases through the use of potassium sparing diuretics such as spironolactone (vide supra MR Antagonists) or amiloride which reduces sodium reabsorption by the epithelial sodium channel, ENaC (Fig. 6). Amiloride is a direct inhibitor of this channel. In contrast spironolactone prevents aldosterone-induced stabilization of ENaC channels in the collecting duct.[236]



7.17.3.11.2 Inhibition of the cardiac sino-atrial (SA) node pacemaker current (I_f)

The SA node functions as the natural pacemaker of the heart due to the intrinsic ability of its cells to depolarize during diastole, resulting in spontaneous generation of action potentials in this structure, which then propagate throughout the heart. The diastolic depolarization of SA node cells is mediated in large part by the activity of the so-called "funny" current (I_f), which is activated by hyperpolarization and is nonselective for monovalent cations.[237] Ivabradine is a selective inhibitor of I_f, and as such functions as a selective bradycardic, that is heart rate reducing agent.[238] Other compounds have been reported to selectively inhibit I_f including zatebradine, cilobradine (both structurally similar to ivabradine), and ZD 7288; however, these agents have not been advanced beyond preclinical studies.[239,240] Ivabradine has no direct effect on inotropy, blood pressure, or vascular resistance.[241] The ability of ivabradine to selectively lower heart rate without affecting other aspects of cardiac function is in contrast to other heart rate reducing agents, such as β-blockers and cardiac glycosides (digoxin).



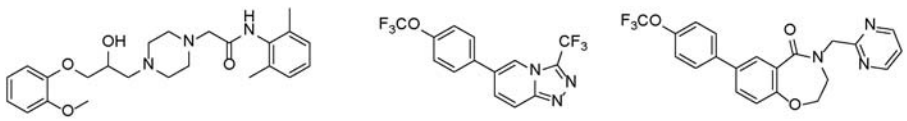
As heart rate is a determinant of myocardial contractile function, coronary blood flow, and myocardial oxygen demand, the therapeutic utility of heart rate reduction with ivabradine has been explored in cardiovascular disease states, such as myocardial ischemia/angina and heart failure.[238,241] The Phase III BEAUTIFUL trial assessed the effect of ivabradine in HFrEF patients with stable coronary artery disease and baseline heart rate $\geq$60 bpm. This trial reported no effect on the primary composite endpoint of cardiovascular death, admission to hospital for acute myocardial infarction, and admission to hospital for new onset or worsening heart failure, whereas a subgroup analysis of patients with baseline heart rate $\geq$70 bpm found that ivabradine reduced admission to hospital for fatal and nonfatal myocardial infarction and coronary revascularization (NCT00143507).[242] A substudy of the BEAUTIFUL trial reported that ivabradine treatment was effective in increasing LV

ejection fraction and decreasing LV end-systolic volume index, reflecting a beneficial effect on remodeling.[243] The subsequent Phase III SHIFT trial assessed the effect of ivabradine in HFrEF patients with baseline heart rate ≥ 70 bpm and reported a reduction in the primary composite endpoint of cardiovascular death or hospital admission for worsening heart failure (NCT02441218).[244] A subanalysis of SHIFT reported that the risk of the primary composite endpoint increased with increasing heart rate, and that the reduction in the primary composite endpoint with ivabradine was accounted for by heart rate reduction.[245] Ivabradine received EU approval in 2012 for the treatment of HFrEF patients in sinus rhythm with a heart rate ≥ 75 bpm and either treated with β-adrenoceptor blockade or for whom β-blockade is not tolerated or contraindicated. Ivabradine received US approval in 2015 for the treatment of HFrEF patients in sinus rhythm with a heart rate ≥ 70 bpm and treated with maximally tolerated β-adrenoceptor blockade or for whom β-blockade is contraindicated. Of note, a small Phase III/IV study in HFpEF patients with baseline sinus heart rate ≥ 60 bpm reported that 7 days administration of ivabradine resulted in improved exercise capacity and peak oxygen uptake associated with an improved left ventricular filling pressure response to exercise.[246] An additional small study in HFpEF patients with baseline sinus heart rate ≥ 75 bpm also has reported that 12 months administration of ivabradine resulted in improved exercise duration, peak oxygen uptake, and NYHA class along with improvements in LV diastolic function.[247] An ongoing Phase II trial is assessing the effect of ivabradine in patients with decompensated heart failure (NCT02236247).

7.17.3.11.3 Inhibition of the cardiac late sodium current ($I_{Na,late}$)

When cardiac myocytes are activated, sarcolemmal sodium channels mainly open transiently and quickly inactivate thereby carrying the peak sodium current (I_{Na} or $I_{Na,peak}$), which underlies cardiac cell depolarization and the upstroke of the cardiac action potential. A small component of sodium current termed late sodium current ($I_{Na,late}$) results from a proportion of sodium channels that remain open, inactivate slowly, or reopen.[248] $I_{Na,late}$ has been reported to be elevated under several cardiac pathological conditions including multiple inherited or acquired arrhythmia syndromes and structural heart disease, including myocardial ischemic injury and heart failure.[249,250] Elevated $I_{Na,late}$ is thought to result in prolongations of and/or dispersions in action potential or QT interval duration that promote arrhythmia.[248,249] Elevated $I_{Na,late}$ also is thought to facilitate intracellular calcium overload through increased NCX activity, which results in diastolic and systolic dysfunction.[248,250] Ranolazine, which is approved worldwide for the treatment of angina, is an inhibitor of $I_{Na,late}$ and has been used to explore the utility of targeting this current in preclinical cardiovascular disease models as well as clinically. In a canine model of coronary microembolization-induced HFrEF, ranolazine was reported to improve left ventricular function when administered acutely, and with chronic treatment prevent progressive LV dysfunction and remodeling when administered alone or in combination with metoprolol or enalapril.[251,252] In the Phase II RALI-DHF proof-of-concept study in HFpEF patients, IV infusion of ranolazine acutely decreased LV end-diastolic pressure and pulmonary capillary wedge pressure, slightly decreased cardiac output but had no effect on LV relaxation parameters.[253] In the same HFpEF study, after 14 days of oral ranolazine treatment, there were no significant changes in echocardiographic or cardiopulmonary exercise test parameters (NCT01163734).[253] Two ongoing Phase II studies are further assessing ranolazine treatment on exercise capacity in HFpEF patients (NCT01505179) as well as in patients with dilated cardiomyopathy (NCT02133911).

Beyond ranolazine, more selective inhibitors of $I_{Na,late}$ have been investigated. In addition to its effects on $I_{Na,late}$, ranolazine inhibits a potassium current that is important for termination of the cardiac action potential, I_{Kr}.[254] Ranolazine also blocks both α- and β-adrenergic receptors,[255] and in one study,[256] but not in another,[257] it was reported to regulate SR calcium release. This lack of selectivity could hinder the interpretation of the mechanism(s) responsible for the beneficial effects of ranolazine. More selective $I_{Na,late}$ inhibitors include GS-967, which has been shown to suppress arrhythmia in preclinical models,[258] and eleclazine (GS-6615), which is being assessed in a Phase II/III study in patients with symptomatic hypertrophic cardiomyopathy (NCT02291237).

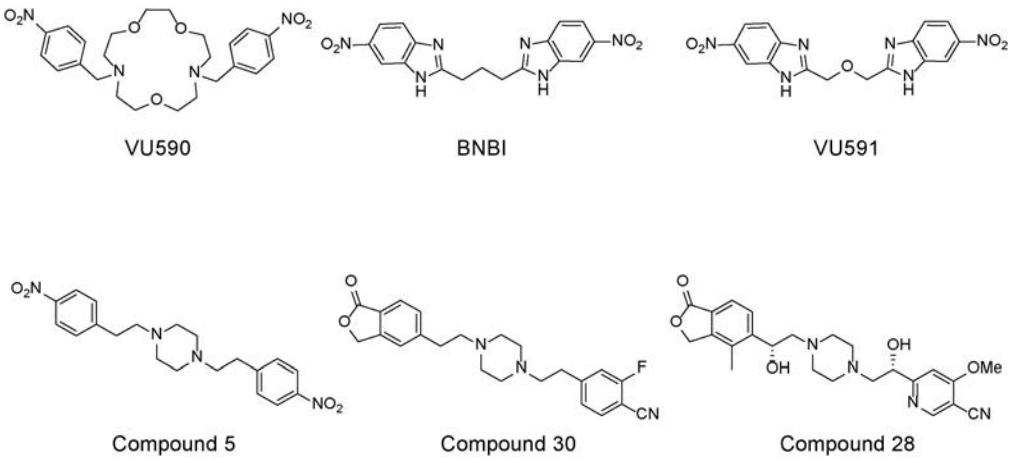


ranolazine GS-967 GS-6615

7.17.3.11.4 Inhibition of the renal outer medullary potassium (ROMK) channel

Currently approved diuretics, which work by reducing sodium and osmotically driven water reabsorption in the nephron, are used extensively in the treatment of heart failure and hypertension. Loop diuretics, exemplified by furosemide (vide supra Diuretics), potentially in combination with other diuretic classes such as the thiazides, exemplified by hydrochlorothiazide (vide supra Diuretics), are first-line treatment of AHF. Hypokalemia is a recognized limitation in the use of loop and thiazide diuretics. Based on human and rodent genetic data, it has been postulated that the selective inhibition of the renal outer medullary potassium (ROMK) channel represents a novel diuretic approach with potential efficacy and safety advantages over existing diuretics. ROMK (designated $K_{ir}1.1$) is a member of the K_{ir} inwardly rectifying family of potassium channels, and is expressed at the apical surface of epithelial cells in two parts of the nephron: the thick ascending loop of Henle (TALH) and the cortical collecting duct

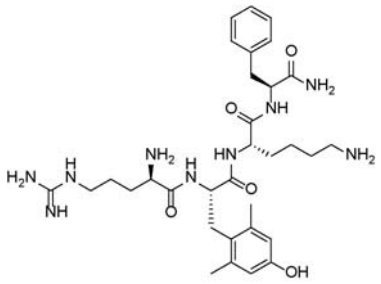
(CCD) (Fig. 6).[259,260] In the TALH, ROMK-dependent efflux of potassium into the lumen is required to maintain luminal potassium at a level that supports $Na^+/K^+/2\ Cl^-$ dependent sodium and chloride reabsorption into the plasma via NKCC2. In the CCD, ROMK is the channel utilized for aldosterone-dependent potassium excretion into the urine and maintaining a cellular resting potential that supports reabsorption of sodium through the epithelial sodium channel, ENaC.[259] It is proposed that by inhibiting sodium reabsorption in the TALH and CCD and blocking potassium secretion in the collecting distal tubules, ROMK inhibitors may induce natriuresis and diuresis but limit the urinary loss of potassium observed with available loop and thiazide diuretics. Furthermore, since ROMK modulates sodium reabsorption in multiple nephron segments, it is possible that ROMK inhibitors may induce natriuresis and diuresis more effectively than available loop and thiazide diuretics which target transport pathways present in single nephron segments (TALH and distal convoluted tubule, respectively). Early screening efforts to identify ROMK inhibitors led to the identification of cryptan VU590 as the first small molecule ROMK inhibitor ($IC_{50}=290$ nM), although selectivity against $K_{ir}7.1$ (also present in the collecting duct) limits this class of compounds.[261] The search for more selective tool compounds (versus $K_{ir}7.1$) led to the discovery of BNBI and VU591.[262] All three compounds share a key nitrophenyl moiety. BNBI possessed modest selectivity versus $K_{ir}7.1$ (at least 10×). Interestingly, the addition of a single oxygen in the tether, generated ROMK inhibitor VU591 and resulted in a 30-fold increase in potency over BNBI due to proposed polar interactions with the ROMK channel.[262] VU591 was also selective (at least 100×) against a large panel of ion channels. VU590 and VU591 were shown to inhibit potassium excretion in vitro in rat isolated collecting duct preparations consistent with ROMK inhibition. More potent and selective inhibitors of ROMK, like Compound 5, were subsequently identified through a high throughput screen.[263] It is interesting to note that compound 5 possesses the same di-nitrophenyl moiety as the previously disclosed inhibitors, although it was actually more potent for hERG (5 nM) than ROMK (52 nM). The metabolic liabilities of the nitro groups could be removed resulting in compound 30 which had good oral bioavailability (64%). Compound 30 was a potent ROMK inhibitor (49 nM) but was still more potent on hERG (17 nM). This series of compounds was evolved to a selective ROMK inhibitor (531-fold versus hERG) resulting in compound 28.[264] Compound 28 was reported to produce dose-dependent natriuretic and diuretic responses with no effect on kaliuresis in vivo in rats and dogs.[264] Further advancement of ROMK inhibition as a novel diuretic target awaits human proof-of-concept studies.



7.17.3.12 Compounds affecting metabolism

7.17.3.12.1 Elamipretide

Elamipretide (aka Bendavia, MPT-131, and SS31) is a tetrapeptide with a cationic 3+ charge at physiological pH that is currently in clinical development for numerous conditions associated with mitochondrial dysfunction, including heart failure.[265–267] This development candidate has unexpected properties for a small highly charged peptide in that it readily permeates cell membranes and crosses the blood brain barrier. A possible mechanism for the observed permeability is the active transport of the peptide through the basolateral peptide transporter.[268] The peptide is also able to be rapidly effluxed from cells despite not being a substrate for P-glycoprotein.[268] The mechanism responsible for cellular efflux is unclear. Elamipretide is concentrated in the inner mitochondrial membrane by >1000-fold relative to plasma and distributes preferentially into the kidney, liver, lung, and heart.[267,268] The proposed mechanism of action is binding to cardiolipin,[269] a phospholipid found exclusively in the inner mitochondrial membrane. The binding to cardiolipin is thought to result in a disruption of interactions between cardiolipin and cytochrome C and consequently reduces oxidative inactivation of cardiolipin by cytochrome C.[265] Cardiolipin plays a role in the formation of mitochondrial cristae, helping to colocalize electron transport complexes in order to promote efficient oxidative phosphorylation, enhance ATP production, and reduce leak of reactive oxygen species.[266]



elamipretide

Preclinically, elamipretide protects against hypertrophy and fibrosis in an AII infusion model and a transaortic constriction (TAC) model. Elamipretide also reduces diastolic dysfunction in the AII infusion model.[270,271] In the mouse TAC model, the expression of a large number of mitochondrial proteins was altered and treatment with elamipretide corrected the expression level of many of these proteins.[270] Beneficial effects were also observed in ischemia–reperfusion models with approximately 50% reduction in infarct size but only if the peptide was administered prior to reperfusion.[272] In the dog microembolus model of heart failure, 3 months of subcutaneous treatment with elamipretide (0.5 mg kg^{-1} per day) decreased left ventricular volumes (end-systolic and end-diastolic), decreased end-diastolic pressure while increasing ejection fraction, peak left ventricular rate of pressure development and ATP synthesis.[272]

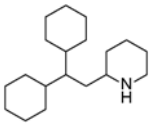
Phase I clinical data reported at the 2015 Europe Society of Cardiology were encouraging and showed that intravenous elamipretide (for up to 2 h) improved secondary endpoints of end-systolic and end-diastolic volume (NCT02388464, PREVIEW, 36 patients).[273–275] An improvement in left ventricular ejection fraction and cardiac output was also reported.[274] Other clinical trials of interest for elamipretide include the EMBRACE trial (NCT01572909)[275] with intravenous injection of elamipretide in patients with anterior wall STEMI scheduled to undergo primary PCI and stenting and a 7-day Phase I study of an oral formulation (NCT01786915).[276] Besides cardiovascular indications, elamipretide is also being developed for diabetic retinopathy, acute kidney injury, and neuroprotection.[266]

7.17.3.12.2 Perhexiline

Under fasted conditions, the heart normally derives the majority of its ATP production from fatty acids.[277] Carnitine palmitoyl transferase 1 (CPT1), an enzyme located within the mitochondrial outer membrane, is a rate-limiting enzyme for providing substrate for mitochondrial β-oxidation of fatty acids. The use of glucose as a substrate results in greater ATP production per unit of oxygen consumed and is therefore a more energy efficient process.

In nondiabetic heart failure and hypertrophic cardiomyopathy, the heart switches from using primarily fatty acids toward a greater dependence on glucose for generation of ATP. CPT1 inhibitors would be expected to cause a further shift toward glucose utilization and in doing so improve energy efficiency. A potential downside is a reduction in metabolic flexibility and the ability to switch between β-oxidation of fatty acids and glucose as the fuel for ATP production.

Perhexiline is a CPT1 inhibitor that is currently undergoing clinical trials for heart failure and hypertrophic cardiomyopathy. This drug has been used to relieve angina since its initial development in the 1970s.[278] Limitations include metabolism by CYP2D6, which leads to poor metabolism in individuals with polymorphisms of this enzyme, which can predispose these individuals to neurotoxicity and hepatotoxicity upon accumulation of perhexiline.[278] Additionally, in some clinical trials, adverse events (headache, nausea, and dizziness) have been observed in almost 60% of patients.[279] Despite these limitations, initial studies in heart failure patients were encouraging. Eight weeks of treatment with perhexiline increased peak oxygen consumption in chronic stable heart failure patients without any significant side effects.[280] This increase in peak oxygen consumption was superior to that achieved by an ACEi (enalapril), which had been previously shown to induce beneficial effects on this read out.[281,282] Peak oxygen consumption was also increased in patients with nonobstructive hypertrophic cardiomyopathy after 3–6 months of treatment with perhexiline.[283] An additional clinical trial using 1 month of treatment in dilated cardiomyopathy patients has shown improvements in the phosphocreatine/ATP ratio, and improvement in NYHA functional class (NCT00841139).[284,285] Surprisingly, there was no change in respiratory exchange ratio, which reflects the relative use of glucose versus free fatty acids as the fuel used to produce ATP.[285] Pending trials for perhexiline include a Phase II trial in patients with diastolic heart failure (NCT00839228) and a Phase III trial in 350 subjects with hypertrophic cardiomyopathy (NCT02431221).



perhexiline

7.17.3.13 MGN-9103 (Antagomir Versus miR-208a/miR499)

Remodeling during heart failure is associated with reactivation of a subset of fetal genes. Downregulation of myosin 6 (Myh6; α-myosin heavy chain) and upregulation of myosin 7 (Myh7; β-myosin heavy chain) occur in heart failure and can affect contractile performance.[286] Micro RNAs (miRs) are small noncoding RNAs that can bind to multiple coding RNA strands and affect their translation. miR-208a is a cardiac specific miR that is encoded by an intron within the Myh6 gene.[287] Related intronic miRs in Myh7 and Myh7b (miR208b and miR-499, respectively) constitute additional members of a family of MyomiRs that control muscle myosin content and muscle performance.[287] Overexpression of miR-208a can induce cardiac hypertrophy in mice and miR208a is upregulated in rodent models of hypertrophy and heart disease.[288] Conversely parenteral treatment of Dahl salt sensitive rats with a locked nucleic acid antisense oligonucleotide (LNA) inhibitor (antagomir) of miR-208a delays mortality in animals placed on high salt, inhibits myosin switching, and improves diastolic function.[289] Co-dosing with an antagomir versus miR-499 accelerates the reduction of Myh7 expression in this model.[289] Additional effects of knocking down the expression of miR-208 in mice have been reported and include resistance to high fat diet and improved insulin sensitivity.[290] The metabolic effects are reportedly dependent on the upregulation of cardiac MED13.[290] Based on these data from animal models MGN-9103, an antagomir versus miR-208a and miR-499 is currently in preclinical development for the treatment of cardiac failure.

7.17.4 Summary

There have been great advances over the past 50 years that have been incorporated into guideline-directed therapies for the treatment of heart failure. However, heart failure remains a therapeutic indication with a high unmet medical need even after the recent approvals for ivabradine and LCZ696. Although current standards of care and newer medications improve long-term outcomes and/or reduce hospitalization, morbidity, and mortality for this syndrome is still disappointingly high, particularly for patients with end-stage disease and those with a recent history of hospitalization for AHF.

Significant research effort remains committed to increasing the efficacy and/or safety of established therapeutic pathways including target subtype-selective or directed biased signaling antiadrenergic and anti-RAAS approaches, as well as alternate or complementary combination approaches to enhance NPS activity and myocardial cGMP generation. While these approaches have the benefit of leveraging validated therapeutic pathways, they face the hurdle of demonstrating significant, greater-than-incremental clinical efficacy over established standard-of-care treatments within the same mechanistic pathway. Alternately, more novel mechanism of action approaches being explored includes the targeting of derangements in intracellular calcium homeostasis, sarcomere targets including modulation of the cardiac actin–myosin ATPase cycle, and interventions aimed at modulating myocardial metabolism and the remodeling process. Recent research also is exploring different modalities for treatment, including gene therapy and microRNA antagomirs. These latter novel approaches await clinical validation.

Although one can never exclude the possibility for identification of new drugs that will benefit all patients with heart failure, recognition of the divergent etiologies that can lead to the development of this syndrome and consequent patient segmentation may be one key for future therapeutic success. HFpEF continues to be problematic, as there are no drugs that have been approved for this indication. Even within this subdivision of heart failure patients further segmentation of the patient population and understanding that there are multiple causes of this condition could be important for delivering the right future drugs to the most responsive patients (eg, pressure overload versus diabetic cardiomyopathy). It is intriguing to speculate whether some of the novel research efforts exploring the modulation of intracellular handling, sarcomere function, and/or remodeling may be relevant to and efficacious in treating diastolic dysfunction in appropriate HFpEF segments.

Our understanding of cardiac biology and integrated cardiovascular biology has also progressed at an incredible pace over the last half century. Despite this, there are still large gaps in our understanding of the physiology and pathophysiology of heart failure. Not discounting the role of serendipity in drug discovery, truly transformational changes in the treatment of heart failure are likely to result from continued attempts to refine our understanding of the molecular triggers for heart failure and the molecular basis for the phenotypic changes that lead down the path to heart failure. The current levels of basic science research, engagement from the pharmaceutical industry, and interest from clinicians suggest that the medical community as a whole will continue to make progress in the treatment of heart failure in the near term and subsequent decades.

7.18.1 Introduction

Atherosclerosis is a chronic inflammatory disease of the arterial walls, characterized by a progressive accumulation of lipids. One of the earliest events in the formation of the atherosclerotic lesion is represented by the infiltration of low-density lipoprotein (LDL) within the artery wall. Here, LDL is oxidized by various mechanisms and subsequently greatly internalized by macrophages, which become foam cells.[1] This process, in turn, induces further deposition of lipids and activates a cascade of inflammatory processes that lead to the formation of atherosclerotic plaque. A large number of studies have recognized low-density lipoprotein cholesterol (LDL-C) level as a relevant risk factor for cardiovascular (CV) disease and established the strong and direct relationship between high LDL-C levels and coronary heart disease (CHD), suggesting that decreasing LDL-C levels significantly reduce the CV risk.

From a biological point of view, the "normal" concentrations of LDL-C are much lower than those observed in modern societies. This suggestion derives from the old observation that optimal plasma concentration of LDL-C should be about 25 mg dL^{-1}, since above this value the low-density lipoprotein receptor (LDLR) is constantly saturated.[2] This hypothesis is supported by the observation that individuals with genetically determined low levels of LDL-C are healthy and exhibit very low incidence of CV events.[3,4]

Several clinical trials have shown that reducing LDL-C decreases the incidence of CV events. A meta-analysis of data from trials of statins showed in fact that, during a mean of 5 years, a 12% reduction in all-cause mortality per mmol L^{-1} reduction in LDL-C, a 19% reduction in coronary mortality, and a 17% reduction in any vascular cause of mortality were observed.[5] These effects were independent of the initial lipid profile or other presenting characteristics, and the proportional reductions were similar in all subgroups of patients examined.[5] In addition, the comparison between more intensive and less intensive statin therapy showed that additional reduction in LDL-C levels achieved with more intensive therapy further reduces the incidence of major vascular events (−13% coronary death or nonfatal myocardial infarction (MI), −19% coronary revascularization, and −16% ischemic stroke).[6] These meta-analyses suggest that the higher the degree of reduction of LDL-C levels, the greater the benefit in terms of reduction of CV risk. This means that patients at high CV risk may benefit from achieving the largest LDL-C reduction. Current therapeutic guidelines suggest that in patients at very high CV risk (such as patients with established cardiovascular disease (CVD), diabetes, moderate to severe coronary kidney disease, and familial hypercholesterolemia (FH)), optimal LDL-C is <70 mg dL^{-1} (<1.8 mmol L^{-1}), in those at high CV risk <100 mg dL^{-1} (<2.6 mmol L^{-1}) and in subjects at moderate risk <115 mg dL^{-1} (<3.0 mmol L^{-1}).[7,8] Moreover, the therapeutic goals of LDL-C should be not only achieved but also maintained over time to obtain the clinical benefit; treatments need to be modulated based on the overall CV risk of the individual patient and according to the objectives to be achieved. This means the choice of the drug with the right effectiveness, a dose selection according to the objectives, and eventually the use of additional drugs with complementary mechanisms of action to increase the efficacy of the therapy.

Despite the evidence confirming the beneficial effect of a significant LDL-C level reduction in patients at very high CV risk, many of these patients often do not reach their LDL-C goal with the starting therapy. When a reduction higher than 50% is required, it is necessary to use a high dose of high-potency statins (atorvastatin and rosuvastatin) (**Fig. 1**) or, alternatively, combined lipid-lowering therapies. The choice of the most appropriate therapeutic approach can be done taking into account either the LDL-C target or distance of LDL-C from the target. The achievement of the therapeutic target implies the choice of pharmacological strategies specific to each subject, according to the goal to be achieved; thus, a high distance from the target requires the administration of a high-potency statin or, alternatively, a combination of cholesterol-lowering drugs with different mechanisms of action.

Familial hypercholesterolemia. Among patients with high CV risk, those with FH present a high risk of premature CHD, due to lifelong exposure to high plasma LDL-C levels.[8] FH is caused by mutations in genes encoding proteins involved in the metabolism of LDL, such as LDLR, apolipoprotein B (apoB), proprotein convertase subtilisin/kexin type 9 (PCSK9), and LDLR adaptor protein; mutations in LDLR gene account for the vast majority of FH cases.[8]

Heterozygous familial hypercholesterolemia (HeFH) patients present a residual LDLR activity (up to 50%) and are characterized by two- to threefold elevation in plasma cholesterol levels and development of early coronary atherosclerosis (usually before 50 years); homozygous familial hypercholesterolemia (HoFH) patients may be receptor-defective, with a significantly reduced LDLR pathway (2–10% activity), or receptor-negative, characterized by an LDLR activity $<2\%$. The HoFH presents more severe CV conditions compared with subjects with receptor deficiency.[9] The lack of LDLR in receptor-negative HoFH determines the exposure to very high cholesterol levels (>500 mg dL^{-1} and >12.8 mmol L^{-1}) from childhood, the occurrence of cutaneous xanthomas prior to 4 years of age, childhood CHD, and even death from MI prior to 20 years of age if untreated.[9,10] Lifestyle interventions (low saturated fat, low cholesterol diet, physical activity, and not smoking) are strongly encouraged, but aggressive and adequate lipid-lowering treatments are crucial to lower LDL-C levels drastically. Despite the fact that statins are the first-choice drug for the treatment of hypercholesterolemia,[8,11] their efficacy is strictly related to the presence of a functional LDLR and thus may be effective in HeFH or in receptor-defective HoFH.[8,9] In LDLR-negative HoFH patients, statins, although inducing a modest reduction of LDL-C ($\sim$20%, probably due to alternative mechanism of action independent of LDLR), do not allow the achievement of the recommended LDL-C level target.[12] In addition, some subjects may exhibit intolerance to statins, leading to therapy discontinuation. All these observations suggest the need of new therapeutic options to decrease LDL-C levels in these very high-risk patients, by using combined lipid-lowering therapies (often in addition to apheresis treatment), with drugs having different mechanisms of action as described in the succeeding text, possibly independent of LDLR that may guarantee a higher reduction of LDL-C levels.

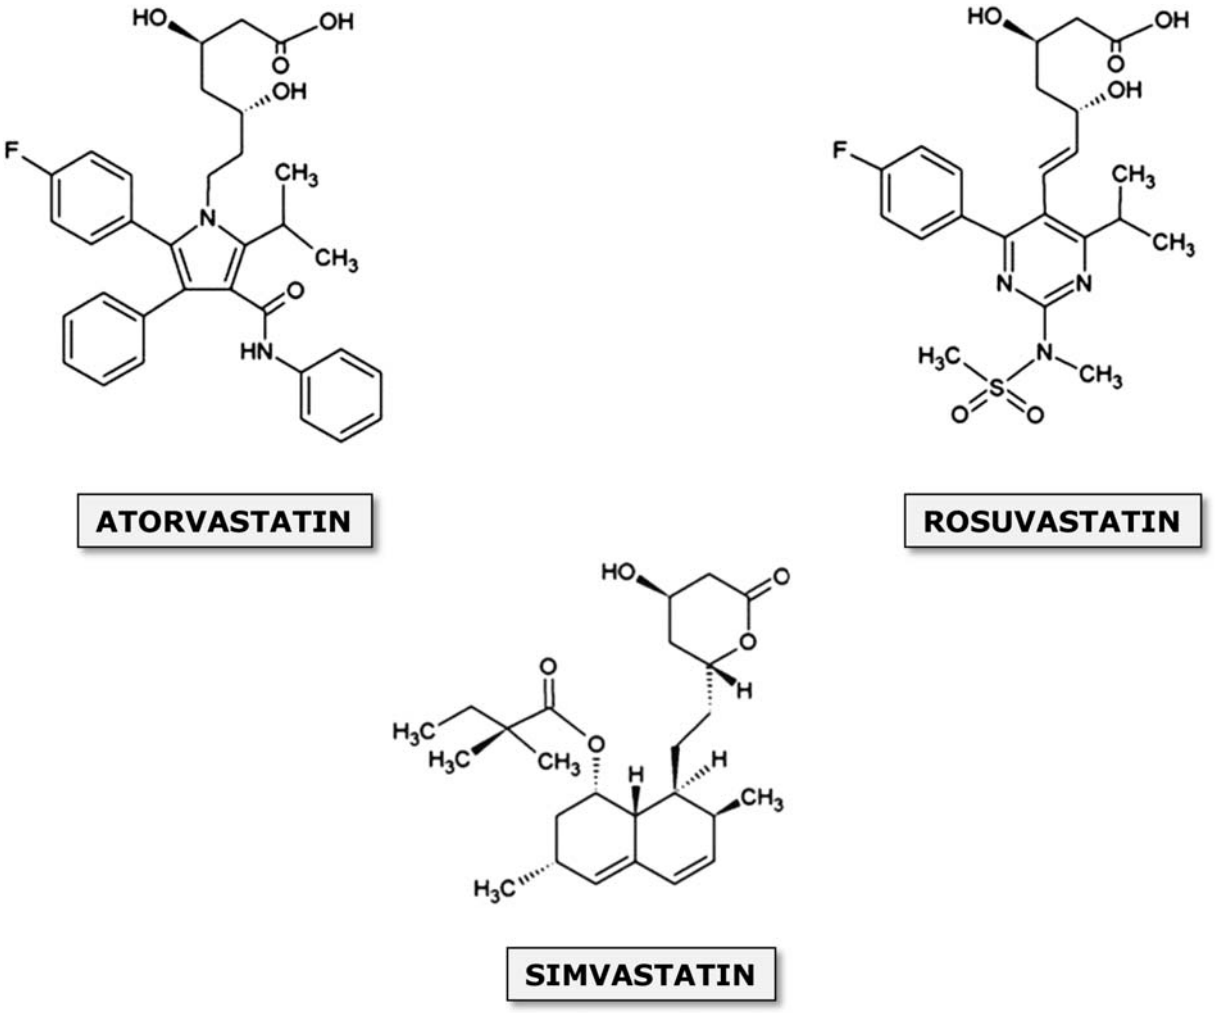

Fig. 1 Structure of atorvastatin, rosuvastatin, and simvastatin.

7.18.2 Statins in the Prevention of CV Disease

Several clinical trials have established the efficacy of statins in reducing CV morbidity and mortality in both primary and secondary prevention.[6,13–18] Statins reduce LDL-C levels by inhibiting 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, thus inhibiting the endogenous synthesis of cholesterol. This, in turn, results in the upregulation of LDLR and in the subsequent reduction of circulating LDL particles. A meta-analysis of 14 randomized clinical trials with 90,056 participants showed an overall safety and benefit of statin therapy [5]: during a mean of 5 years, there was a 12% proportional reduction in all-cause mortality per mmol L^{-1} reduction in LDL-C, with significant reduction in coronary mortality (-19%, $P<0.0001$), MI or coronary death (-23%, $P<0.0001$), and fatal or nonfatal stroke (-17%, $P<0.0001$).[5] An overall $\sim$20% reduction in the incidence of CV events per mmol L^{-1} LDL reduction was reported.[5] When trials of more intensive versus less intensive statin therapy were analyzed, more intensive regimens produced an additional 15% ($P<0.0001$) reduction in major vascular events,[6] suggesting that further reducing LDL-C levels safely translates into a further clinical benefit.

However, despite the significant reduction of CV events in statin-treated patients, certain patients continue to experience CV events, referred to as "residual risk," even in the presence of well-controlled LDL-C levels.[19] The evidence suggests that atherogenic dyslipidemia, that is, alterations in other lipids (such as high triglycerides (TG) and low high-density lipoprotein cholesterol (HDL-C)), may account for this effect.[20] In addition, an increasing number of subjects are treated with statins, often in combination with other drugs, thus increasing the probability of drug–drug interactions and the occurrence of adverse side effects.[21] Finally, the adherence to statin therapy is not always optimal, as many patients discontinue statin therapy due to adverse events.

The most common adverse events reported with statin are skeletal muscle-related disorders (generally referred to as myopathy). Despite randomized clinical trials reported a 1.5–5% incidence of statin-induced myopathy,[22,23] in clinical practice the frequency appears to be higher.[24] This difference can be partly attributed to the patient inclusion criteria adopted in the clinical trials, which tend to exclude subjects with comorbidities, older subjects, or patients with a history of muscle disorders.[24,25] In addition, increased

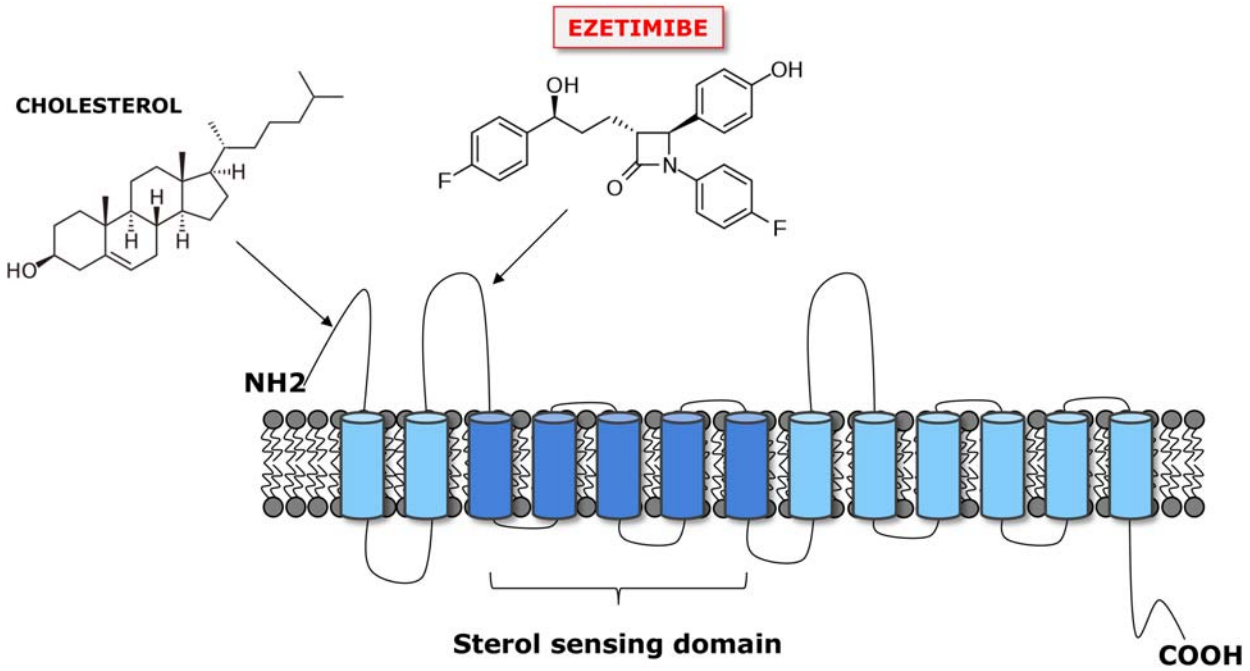

Fig. 2 Structure of human NPC1L1. NPC1L1 contains 13 transmembrane domains, including sterol-sensing domain formed by membrane-spanning helices with short intervening loops. The extracellular N-terminal domain of NPC1L1 directly binds cholesterol; ezetimibe binds to the loop C.

levels of creatine kinase (CK) are used as a marker for statin-induced myopathy, but myopathy occurrence not always associates with these alterations. Finally, less significant signs of myopathy (including fatigability or weakness) are often not considered as relevant.[25] Altogether, these observations may account for the underestimation of muscle-related side effects in statin-treated patients in the clinical trials.

Statin-related myopathy occurs particularly with high-dosage statin regimens, and thus, its incidence is higher in high CV risk patients who need more aggressive lipid-lowering therapies or in patients with comorbidities, due to metabolic interactions with other drugs.[26,27] They include less severe manifestations (asymptomatic moderate serum CK elevation or muscle pain in the absence of CK elevation)[28] up to the most severe and rare rhabdomyolysis.[28,29] Several risk factors may increase the probability of myotoxicity related to statin therapy: chemicophysical properties of statins (lipophilic statins seem to induce myotoxicity more than hydrophilic statins), administration of concomitant drugs that can interact with statins, and patient-related risk factors (age, female gender, and genetic factors).[29] Discontinuation of statin therapy is common among patients experiencing muscle-related adverse effects, but several pharmacological approaches may be adopted to treat patients intolerant to statins. First, a statin rechallenge may be tolerated by patients; the rechallenge may be done by reintroducing the same statin at a lower dose or by introducing a different statin (such as a more potent statin at a low dose) or by using the noneveryday statin administration (this is possible with potent statins with longer half-life, such as rosuvastatin and atorvastatin).[29] Alternatively, the lowest dose of statin tolerated may be combined with nonstatin lipid-lowering drugs.[29] Several nonstatin drugs have been approved for the treatment of dyslipidemia, but, despite an improvement of the lipid profile, results from clinical trials could not support their use as monotherapy or in combination with statins, with the exception of ezetimibe (**Fig. 2**).[30,31] In fact, the addition of niacin to statin therapy did not show any further clinical benefit, compared with statin therapy [32,33]; similarly, clinical trials on fenofibrate showed a benefit only in particular subgroups of patients (i.e., those with high TG and low HDL-C levels).[34,35] In addition, the difficult-to-manage high CV risk patients such as those with FH raised the need of new lipid-lowering drugs that could add significant clinical benefit beyond statin treatment.

7.18.3 Novel Therapeutic Approaches in the Management of Dyslipidemia

In recent years, several therapeutic approaches have been investigated for reducing plasma cholesterol and/or TG levels through different mechanisms of action. Specific therapies were explored not only for the treatment of monogenic homozygous forms of dyslipidemia including familial hypercholesterolemia or chylomicronemia syndrome but also for statin-intolerant patients.

7.18.3.1 Targeting Plasma Cholesterol Levels

7.18.3.1.1 Ezetimibe

Niemann–Pick C1-like 1 (NPC1L1) protein plays a central role in the intestinal absorption of cholesterol and the regulation of cholesterol plasma levels.[36,37] Its expression and localization are strictly regulated by the cellular content of cholesterol: when cells

are enriched in cholesterol, NPC1L1 is localized in the endocytic recycling compartment, but in cells depleted of cholesterol, NPC1L1 translocates to the cell surface to bind extracellular cholesterol[38,39] (Fig. 2). In humans, NPC1L1 is expressed also in the liver, where it prevents excessive loss of biliary cholesterol.[40]

The evidence of the involvement of NPC1L1 in the process of cholesterol absorption derives from observations in animal studies. NPC1L1-deficient mice have a significantly reduced cholesterol absorption (−69%) compared with wild-type mice.[41] In apoE knockout mice, the deficiency of NPC1L1 largely decreased cholesterol absorption, protected them from diet-induced hypercholesterolemia, and prevented atherosclerotic lesion formation.[42,43] On the other hand, NPC1L1 overexpression in cultured cells increased cholesterol uptake in cells,[44] and cholesterol feeding of NPC1L1$^{-/-}$/LDLR$^{-/-}$ knockout mice transgenically expressing human NPC1L1 resulted in significantly increased cholesterol absorption and cholesterol levels compared with the double knockout mice.[45] In humans, carriers of NPC1L1 inactivating mutations exhibit lower LDL-C levels compared with noncarriers and exhibited a relative reduction of 53% in the risk of CHD.[46] These observations suggest that pharmacological inhibition of NPC1L1 can be a therapeutic approach for the treatment of hypercholesterolemia in humans.

Ezetimibe is a selective inhibitor of cholesterol absorption that reduces the cholesterol uptake in enterocytes by inhibiting NPC1L1[47] (Fig. 2). Ezetimibe is rapidly absorbed from the gastrointestinal tract and transformed into its glucuronides. The phenolic glucuronide is the main metabolite detectable in human plasma and accounts for about 90% of the total ezetimibe; it localizes more avidly in the intestine compared with ezetimibe and has similar or even higher cholesterol-lowering activity compared with the parent compound.[48,49]

Statins and ezetimibe have different and complementary mechanisms of action, and thus, the combination statin + ezetimibe may represent a successful approach for the prevention of CV disease and allow the treatment of subjects that manifest intolerance to high-dose statins. In addition, the statin-induced inhibition of cholesterol synthesis results in an increase of absorption markers, and, on the contrary, the reduced cholesterol absorption induced by ezetimibe results in the increase of cholesterol synthesis [50]; this would reduce the efficiency of the single drugs, while the combination decreases both cholesterol synthesis and absorption.[50]

Several clinical trials have shown that adding ezetimibe to statin therapy determines an additional 20% reduction of LDL-C levels[51–54] (Table 1). A pooled analysis of over 21,000 subjects from 27 clinical trials showed that combining ezetimibe with a statin induces a greater lipid-lowering effect than statin monotherapy.[55] Similarly, LDL-C lowering was significantly higher in patients with CHD or CHD equivalent treated with ezetimibe added to current statin therapy compared with patients who titrated the statin doses.[56]

Also, diabetic patients seem to benefit from the combination ezetimibe + statin: the *RESEARCH* (*Recognized Effect of Statin and Ezetimibe Therapy for Achieving LDL-C Goal*) trial reported that the ezetimibe + statin induced a higher LDL-C reduction compared with doubling the statin dose (−24.6% vs. −10.9%, $P<0.0001$)[57]; in addition, more subjects reached their LDL-C goals in the group treated with ezetimibe + statin versus the group treated with a doubled statin dose (89.3% vs. 51%, $P<0.0001$).[57] The combination therapy also improved the atherogenic lipid profile characteristic of diabetes more effectively than statin therapy; this effect can be attributed to a higher reduction of small dense LDL (−20.5% vs. −3.7%) and remnant-like particle cholesterol (RLP-C) (−19.7% vs. +5.5%).[57] Diabetic patients seem to benefit from the combination therapy ezetimibe + statin more than nondiabetic subjects, as they achieve significantly higher reductions in LDL-C and non-high-density lipoprotein cholesterol (non-HDL-C); it has been hypothesized that diabetic patients might have a higher expression of NPC1L1, but a defined explanation is still lacking.[58]

Contrasting results have been reported on the ability of ezetimibe to reduce the carotid intima-media thickness (IMT), a marker of subclinical atherosclerosis. In the *ENHANCE* (*Ezetimibe and Simvastatin in Hypercholesterolemia Enhances Atherosclerosis Regression*, NCT00552097) trial, which compared the effect of ezetimibe + simvastatin (10 + 80 mg) or simvastatin (Fig. 1) alone on the progression of atherosclerosis in HeFH patients, changes in the carotid IMT did not differ in the groups, despite lower LDL-C levels observed in patients treated with the combination therapy (−55.6% vs. −39.1% with statin monotherapy, $P<0.01$)[59] (Table 1). The *ARBITER 6-HALTS* (Arterial Biology for the Investigation of the Treatment Effects of Reducing Cholesterol 6-HDL and LDL Treatment Strategies in Atherosclerosis, NCT00397657) trial, performed in patients with CHD or CHD equivalent to evaluate the effect of ezetimibe or extended-release niacin added to a chronic statin therapy, reported a lack of effect of ezetimibe that instead resulted in carotid IMT progression[60] (Table 1). Lack of effect of ezetimibe added to statin therapy on IMT has been reported also in other studies.[61,62] On the contrary, the *SANDS* (*Stop Atherosclerosis in Native Diabetics Study*, NCT00047424) trial showed that, compared with standard lipid-lowering therapies, aggressive lipid-lowering treatments induced a regression of carotid IMT in type 2 diabetic patients[63] (Table 1). Among subjects treated with aggressive lipid-lowering treatments, those receiving ezetimibe exhibited a greater reduction despite similar LDL-C reductions[64] (Table 1). One possible explanation for these discrepancies is the baseline carotid status: if the patients have IMT values within the normal range, the chance that a cholesterol-lowering therapy may be effective on this parameter is lower than in subjects with significant IMT values.

Two studies have reported a beneficial effect of ezetimibe + statin on coronary atherosclerosis: besides a greater reduction in the plaque volume,[65] a higher increase of the fibrous cap thickness was observed, suggesting a possible role for ezetimibe in the stabilization of atherosclerotic plaque[66] (Table 1).

Ezetimibe in the prevention of cardiovascular disease. Several studies have established the LDL-C-lowering ability of ezetimibe, showing a further reduction of 23% when added to a statin therapy [55,67]; however, few clinical trials have evaluated the clinical benefit of the addition of ezetimibe to statin therapy. The *SHARP* (Study of Heart and Renal Protection, NCT00125593) trial, performed in patients with moderate to severe kidney disease, evaluated the effect of ezetimibe + simvastatin or placebo

FH, familial hypercholesterolemia; *CHD*, coronary heart disease; *T2DM*, type 2 diabetes mellitus; *CAD*, coronary artery disease; *CKD*, chronic kidney disease; *ACS*, acute coronary syndrome; *Eze*, ezetimibe; *Stat*, statin; *Simva*, simvastatin; *Fluva*, fluvastatin; *Rosuva*, rosuvastatin; *LLT*, lipid-lowering therapy.

administration for 4.9 years [68]; the combination therapy reduced LDL-C levels by 33 mg dL^{-1} (0.84 mmol L^{-1}) and decreased the incidence of major atherosclerotic events (including nonfatal MI, coronary death, nonhemorrhagic stroke, and arterial revascularization) by 17%[68] (**Table 1**). When considering chronic kidney disease (CKD) patients with LDL-C not at target despite statin therapy (>120 mg dL^{-1} and >3.1 mmol L^{-1}), the combination therapy was more safe than doubling the dose of statins, as the incidence of adverse events was significantly lower.[69] These observations suggest that ezetimibe is a helpful and safe add-on to statin therapy to treat high CV risk patients such as those with CKD.

The *IMPROVE-IT* (*Improved Reduction of Outcomes: Vytorin Efficacy International Trial*, NCT00202878) compared the effect of a 6-year administration of ezetimibe + simvastatin (10/40 mg) or simvastatin (40 mg) alone in patients with a recent acute coronary syndrome and LDL-C levels at target.[31] At the end of the study, the LDL-C level was significantly lower in the group treated with ezetimibe + simvastatin compared with those treated with simvastatin alone (53.7 mg dL^{-1} vs. 69.5 mg dL^{-1}, $P<0.001$) (**Table 1**); furthermore, more patients treated with the combination therapy reached LDL-C levels <70 mg dL^{-1} (<1.8 mmol L^{-1}).[31] This effect on LDL-C level translated into a higher reduction of the primary end point (a composite of CV death, nonfatal MI, unstable angina requiring hospitalization, coronary revascularization, and nonfatal stroke) in the group treated with ezetimibe + simvastatin group (32.7% vs. 34.7% with simvastatin alone, $P=0.016$)[31] (**Table 1**). Secondary analyses of this study have shown the clinical benefit of adding ezetimibe to statin in subgroups of patients; as an example, women receiving the combination therapy exhibited a 12% reduction of the relative risk of the primary end point, compared with a 5% reduction in men [70]; older patients (≥75 years) showed a greater benefit from the combination therapy compared with younger patients (<65 years HR 0.98, ≥65 years HR 0.89, and ≥75 years HR 0.80). Moreover, type 2 diabetic patients seem to benefit more than nondiabetics from the combination therapy (14% reduction of the relative CV risk vs. 2% in nondiabetics).[71] Combined therapy was also superior to simvastatin alone in reducing the incidence of nonhemorrhagic stroke (HR 0.78, $P=0.008$).[72] All these analyses showed that adverse events did not differ among the various subgroups.[72]

Ezetimibe in the treatment of FH. In FH patients treated with the combination ezetimibe + statin, the levels of total cholesterol (TC) and LDL-C were lower than in those treated with statin alone.[59,73,74] However, no difference was observed in the reduction of carotid IMT [59]; this is likely due to the fact that the vast majority of FH patients enrolled in that study were on statin therapy long before entering the trial, resulting in the attenuation of IMT progression, and thus, a further LDL-C reduction was not able to further reduce the carotid IMT. Other studies with statin-naive patients have shown a regression.[75] Despite these considerations, contrasting results have been reported on the effect of the combination ezetimibe + simvastatin, which, in other studies, was reported to decrease significantly the carotid IMT in two groups of HeFH patients, one with a history of acute MI and the other with carotid lesions but no history of CV events.[76]

7.18.3.1.2 PCSK9 inhibitors

PCSK9 is a proteinase that inhibits the recycling of LDLRs by causing their lysosomal degradation, mainly synthesized and secreted by the liver. PCSK9 activity results in reduced expression of hepatic LDLR and increased circulating LDL-C levels (**Fig. 3**). In addition, statins increase PCSK9 expression,[77] which would translate in a reduced efficacy of statin therapy. Thus, inhibiting PCSK9 expression/activity represents a therapeutic approach that can result in the reduction of LDL-C levels. PCSK9 inhibition is obtained by the means of specific monoclonal antibodies (mAbs). Several clinical studies have shown that anti-PCSK9 monoclonal antibody monotherapies significantly decreased TC and LDL-C, with an overall incidence of adverse effects similar between the treatment and placebo groups.[78] Moreover, since statins induce PCSK9 expression, the addition of a PCSK9 mAb to a statin may result in an increased therapeutic effect.[79,80]

Evolocumab, alirocumab and bococizumab are human mAbs against PCSK9 leading to increased hepatic LDLR expression and LDL clearance. Two recent meta-analyses have evaluated the efficacy and safety of PCSK9 antibodies in randomized controlled clinical trials.[81,82] Li et al.[82] analyzed 20 RCTs including 6464 hypercholesterolemic patients and 3416 controls; participants of 16 studies were hypercholesterolemic and included also HeFH patients; three studies were performed only in HeFH and one in HoFH.[82] Most of these trials had a duration of 8–24 weeks. In some studies (10), the PCSK9 mAb was administered as a monotherapy; in the others, the antibodies were administered in addition to other lipid-lowering therapies. The analysis of these trials showed that treatment with PCSK9 mAbs significantly reduces LDL-C levels, with a weighted mean change

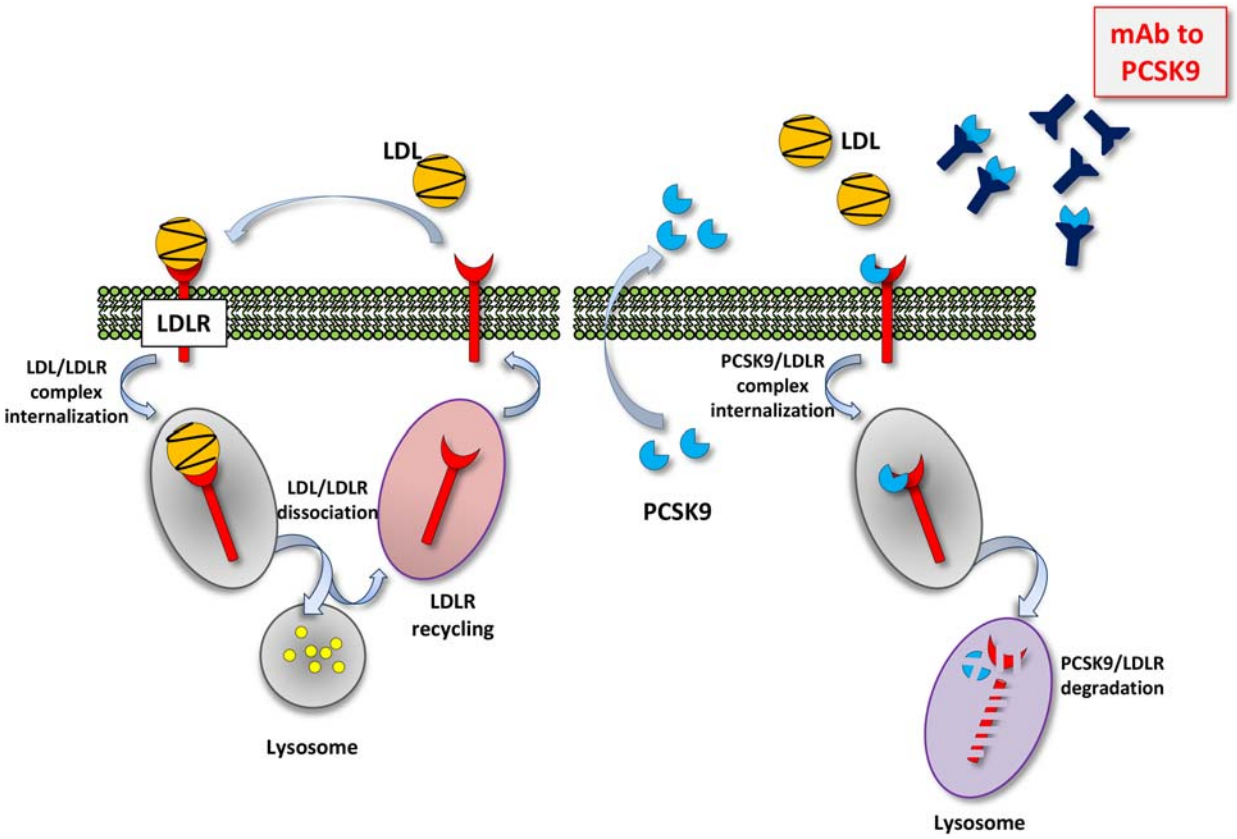

Fig. 3 Mode of action of PCSK9 inhibitors. In the absence of PCSK9, LDL binds to LDLR. After internalization, the LDL-LDLR complex dissociates, LDL undergoes lysosomal degradation, and LDLR is recycled to the cell surface. In the presence of PCSK9, LDLR is degraded within the cells, leading to increased levels of circulating LDL-C. Monoclonal antibodies neutralize secreted PCSK9, rendering it unable to bind to the LDLR. *LDL-C*, LDL cholesterol; *LDLR*, LDL receptor; *PCSK9*, proprotein convertase subtilisin/kexin type 9.

of −65.29 mg dL^{-1}; also, other lipids and apoproteins significantly changed (TC, −60.04 mg dL^{-1}; TG, −12.21 mg dL^{-1}; apoB, −41.01 mg dL^{-1}; HDL-C, +3.40 mg dL^{-1}; and apolipoprotein A-I (apoA-I), +6.75 mg dL^{-1}); lipoprotein (a) (Lp(a)) was significantly reduced following treatment with PCSK9 mAbs (standardized mean difference: −0.94).[82] Despite the reduction of LDL-C levels was greater in patients treated with anti-PCSK9 monotherapy than in those who had received combined therapy (−69.84 mg dL^{-1} vs. −60.16 mg dL^{-1}), the difference was not significant. Patients with HeFH showed a higher LDL-C level reduction compared with patients with non-FH (−79.02 mg dL^{-1} vs. −62.38 mg dL^{-1}). Interestingly, trials with a duration ≤12 weeks obtained greater reductions of LDL-C levels compared with longer trials (−70.89 mg dL^{-1} vs. −55.0 mg dL^{-1}). Mild-to-moderate adverse events as well as serious adverse events did not differ between patients receiving PCSK9 and patients receiving placebo or statin monotherapy. Navarese et al. analyzed 24 RCTs (8 phase 2 and 16 phase 3 trials) including 10,159 patients (6187 receiving anti-PCSK9 and 3972 controls).[81] LDL-C levels were reduced by almost 50% in patients treated with PCSK9 mAb; the reduction was greater when compared with placebo than when compared with ezetimibe (−58.77% vs. −36.17%, $P<0.001$). Also TC and Lp(a) levels were significantly reduced following the treatment with anti-PCSK9 (−31% and −25%, respectively), while HDL-C levels were increased by 6.30% ($P<0.001$). All-cause mortality was significantly reduced in the group of patients receiving anti-PCSK9 (mortality rates: 0.31% vs. 0.53%, $P=0.015$), whereas a nonsignificant reduction of CV mortality was observed (CV mortality rates: 0.19% vs. 0.33%, $P=0.084$) [81]; the rates of unstable angina were similar in the two groups (0.04% vs. 0.08%, $P=0.34$). Treatment with PCSK9 mAb significantly reduced the percentage of patients experiencing an increase in the levels of CK (1.96% vs. 2.31%, $P=0.026$).[81] The overall incidence of serious adverse effects was similar in patients treated with anti-PCSK9 and in patients not receiving the antibodies (9.26% vs. 7.73%, $P=0.879$).[81] Thus, from these two meta-analyses, it appears that anti-PCSK9 antibody treatment effectively corrects lipid abnormalities and reduces the CV mortality in hypercholesterolemic patients.

Evolocumab. A large number of clinical trials have assessed the efficacy and safety of evolocumab in different groups of patients. Most of these studies were 12-week phase 2 and phase 3 trials that reported significant reductions of LDL-C levels compared with either placebo or ezetimibe.[83,84] Tested as monotherapy in *MENDEL* (*Monoclonal Antibody against PCSK9 to Reduce Elevated LDL-C in Subjects Currently Not Receiving Drug Therapy for Easing Lipid Levels*, NCT01375777) and *MENDEL-2* (NCT01763827) trials, the administration of evolocumab for 12 weeks significantly reduced LDL-C levels; similar reductions were observed with 140 mg every 2 weeks (Q2W) or 420 mg every 4 weeks (Q4W) (−50.9% and −48.0% from baseline in MENDEL and −57.0% and −56.1% from baseline in MENDEL-2)[85,86] (**Table 2**). Comparable reductions were reported by other phase 2 trials in different groups of hypercholesterolemic patients.[84]

In *LAPLACE-TIMI 57* (*Low-Density Lipoprotein Cholesterol Assessment with PCSK9 Monoclonal Antibody Inhibition Combined with Statin Therapy*, NCT01380730), hypercholesterolemic patients with LDL-C >85 mg dL^{-1} (>2.2 mmol L^{-1}) despite lipid-lowering therapy (statin with or without ezetimibe), the administration of evolocumab at different doses (70, 105, or 140 mg Q2W or 280, 350, or 420 mg Q4W) for 12 weeks produced a dose-dependent LDL-C reduction[87] (**Table 2**); reductions were comparable in all patient subgroups. Of note, 94% of patients taking evolocumab 140 mg Q2W achieved an LDL-C level <70 mg dL^{-1} (<1.8 mmol L^{-1}), with a mean LDL-C value of 43 mg dL^{-1} (1.1 mmol L^{-1}).[87] In phase 3 *LAPLACE-2* (NCT01763866), patients taking moderate-intensity (atorvastatin 10 mg, simvastatin 40 mg, or rosuvastatin 5 mg) or high-intensity (atorvastatin 80 mg or rosuvastatin 40 mg) therapy were administered with evolocumab (140 mg Q2W or 420 mg Q4W) or placebo or ezetimibe (only in atorvastatin-taking patients).[88] At the mean of weeks 10 and 12, percent reductions were similar across the statin groups and the two evolocumab administration regimens (66–75% with Q2W dosing and 63–75% for Q4W dosing vs. placebo)[88] (**Table 2**). In patients treated with atorvastatin, the addition of evolocumab was significantly more efficacious in reducing LDL-C levels compared with ezetimibe, and greater proportions of patients reached the LDL-C target <70 mg dL^{-1} (<1.8 mmol L^{-1}) with evolocumab than with ezetimibe.[88] When added to a background lipid-lowering therapy for 52 weeks in hypercholesterolemic patients in the *DESCARTES* (*Durable Effect of PCSK9 Antibody Compared with Placebo Study*, NCT01516879) trial, evolocumab significantly reduced LDL-C levels (−57%) either in addition to diet alone or with low-dose (10 mg) or high-dose (80 mg) atorvastatin with or without ezetimibe, and the treatment was well tolerated[89] (**Table 2**). The ongoing *GLAGOV* (*Global Assessment of Plaque Regression with a PCSK9 Antibody as Measured by Intravascular Ultrasound*, NCT01813422) trial will establish whether LDL-C lowering with evolocumab will reduce the percent atheroma volume compared with placebo in subjects with CAD receiving lipid-lowering therapy; the treatment will end after 78 weeks and the trial has an estimated primary completion date in July 2016.

Evolocumab was evaluated in a population of hypercholesterolemic statin-intolerant patients in the phase 2 *GAUSS* (*Goal Achievement after Utilizing an Anti-PCSK9 Antibody in Statin Intolerant Subjects*, NCT01375764) study.[90] Evolocumab was given alone (280, 350, and 420 mg Q4W) or in combination with ezetimibe (420/10 mg) and compared with ezetimibe (10 mg) alone; after 12 weeks, patients who received evolocumab had a dose-dependent reduction of LDL-C levels (−40.8 to −50.7% from baseline), and the association with ezetimibe resulted in a higher decrease compared with ezetimibe alone (−63% vs. −14.8%) (**Table 2**); the maximal reduction was obtained within 2 weeks after starting the treatment.[90] In the group of evolocumab alone, a higher proportion of patients reached the LDL-C targets <100 mg $dL-^{1}$ (<2.6 mmol L^{-1}) or <70 mg dL^{-1} (<1.8 mmol L^{-1}) (54% and 18%) compared with ezetimibe alone (7% and 0%); the combination evolocumab + ezetimibe greatly increased the proportion of patients at target (90% and 62%, respectively).[90] Also TC, non-HDL-C, apoB, and Lp(a) were significantly reduced following evolocumab administration either alone or in combination with ezetimibe; HDL-C and apoA-I increased, although statistically significant differences were observed only with high-dose evolocumab.[90] Overall, the administration of evolocumab was well tolerated, with similar percentages of patients reporting adverse effects in the group of evolocumab and in the group of ezetimibe; myalgia was the most common side effect occurring in 7.4% taking evolocumab alone, in 20% taking evolocumab + ezetimibe, and

Table 2 Results from clinical trials on evolocumab—cont'd

Clinical trial (ClinicalTrials.gov identification number)	*Subjects*	*Duration*	*Background LLT*	*Intervention*	*LDL-C (percent change from baseline)*	*Primary end point for ongoing trials*
RUTHERFORD-2, NCT01763918[93]	HeFH; fasting LDL-C $\geq$100 mg dL^{-1}	12 weeks	Statin $\pm$ ezetimibe	140 mg Q2W 420 mg 04 W	−59.2% versus placebo −61.3% versus placebo	
TESLA part A, NCT01588496[94]	HOFH; LDL-C $\geq$130 mg dL^{-1}	36 weeks	Stable LLT for at least 4 weeks	420 mg Q4W for 24 weeks + 420 mg Q2W for 12 weeks	Q4W: −16.5% Q2W: −13.9%	
TESLA part B, NCT01588496[95]	HoFH; LDL-C $\geq$130 mg dL^{-1}	12 weeks	Stable LLT for at least 4 weeks	420 mg Q4W	−30.9% versus placebo	
TAUSSIG, NCT01624142	Severe FH	5 years	Stable LLT	Evo Q2W or Q4W	Ongoing (2020)	Subject incidence of treatment-emergent adverse events
OSLER-1, NCT01439880[96]	Subjects from phase 2 evolocumab trials	1 year		420 mg Q4W + standard therapy	−58.4% at week 48 versus standard therapy	Subject incidence of treatment-emergent adverse events
OSLER-2, NCT01854918[97]	Subjects from phase 3 evolocumab trials	1 year			Ongoing (2018)	

FH, familial hypercholesterolemia; *HeFH*, heterozygous familial hypercholesterolemia; *HoFH*, homozygous familial hypercholesterolemia; *LLT*, lipid-lowering therapy; *Q2W*, every 2 weeks; *Q4W*, every 4 weeks; *Eze*, ezetimibe.

in 3.1% taking ezetimibe.[90] In the phase 3 *GAUSS-2* study (NCT01763905), effects of evolocumab 140 mg Q2W or 420 mg Q4W compared with ezetimibe daily were evaluated in hypercholesterolemic patients intolerant to statins and with LDL-C above the recommended target.[91] After a 12-week treatment, evolocumab significantly reduced LDL-C levels compared with ezetimibe (−56.1% with evolocumab 140 mg Q2W and −52.6% with evolocumab 420 mg Q4W, compared with −18.1/−15.1% with ezetimibe), with no difference between the two different evolocumab regimens.[91] Similar results were obtained when considering other biochemical parameters, including non-HDL-C, apoB, and Lp(a).[91] More patients treated with evolocumab reached the LDL-C target goals compared with ezetimibe.[91] Myalgia occurred in 8% of evolocumab patients and 18% of ezetimibe patients.[91] The benefit of evolocumab on CV outcomes is currently under investigation in the GAUSS-3 and the FOURIER (*Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk*) studies. The *GAUSS-3* trial (NCT01984424) will include a placebo-controlled reexposure to statin (atorvastatin) before a 24-week double-blind comparison of evolocumab and ezetimibe, followed by 2-year open-label evolocumab extension (**Table 2**). The *FOURIER* study (NCT01764633) will evaluate the effect of evolocumab added to other treatments for dyslipidemia on the risk of CV death, MI, hospitalization for unstable angina, stroke, or coronary revascularization (**Table 2**).

Despite currently used drugs improving the management of HeFH patients, they often do not achieve their LDL-C level target; thus, the *RUTHERFORD* (*Reduction of LDL-C with PCSK9 Inhibition in Heterozygous Familial Hypercholesterolemia Disorder*, NCT01375751) trial evaluated whether evolocumab 350 or 420 mg Q4W was effective in HeFH patients who were unable to achieve LDL-C <100 mg dL^{-1} (<2.6 mmol L^{-1}) despite statin therapy with or without ezetimibe.[92] Percentage reductions of LDL-C were −43.8% and −56.4% versus placebo, respectively[92] (**Table 2**); when compared with patients on ezetimibe or statin alone, similar reductions versus placebo were observed.[92] At week 12, 70% and 89% of patients treated with 350 and 420 mg evolocumab reached LDL-C levels <100 mg dL^{-1} (<2.6 mmol L^{-1}) and 44% and 65% reached LDL-C <70 mg dL^{-1} (<1.8 mmol L^{-1}).[92] Overall, lipid profile was significantly improved, with TC, non-HDL-C, apoB, and Lp(a) significantly reduced.[92] The last finding has a special relevance for FH patients, who commonly exhibit elevated Lp(a) levels. Adverse events were similar in evolocumab-treated patients and in placebo group.[92] The phase 3 *RUTHERFORD-2* (NCT01763918) trial showed that administration of evolocumab 140 mg Q2W or 420 mg Q4W results in similar reductions of LDL-C levels after a 12-week treatment (−59.2% and −61.3% vs. placebo, respectively)[93] (**Table 2**). Reductions were not related to sex, age, body mass index, or type of therapy (intensity of statin therapy or concomitant use of ezetimibe).[93] Among the patients who participated in this study, seven were found to be HoFH or compound heterozygous following the genetic analysis, although they were initially classified as HeFH.[93] They exhibited higher baseline LDL-C levels compared with HeFH, but LDL-C reductions were 68% with 140 mg Q2W and 48% with 420 mg Q4W,[93] which is a much greater response than those reported in trials with selected patients with HoFH. In the pilot study *TESLA* (*Trial Evaluating PCSK9 Antibody in Subjects with LDL Receptor Abnormalities*, NCT01588496) *part A*, eight patients with HoFH (six LDLR-defective and two LDLR-negative) were treated with evolocumab 420 mg Q4W for 24 weeks, followed by 420 mg Q2W for an additional 12 weeks.[94] The treatment resulted in a mean reduction of LDL-C of 17%, with four patients experiencing reductions above 15% and three experiencing reductions above 30%[94] (**Table 2**); the two LDLR-negative patients did not show a reduction of LDL-C levels.[94] In the *TESLA part B*, patients with HoFH not receiving apheresis were administered evolocumab 420 mg or placebo

(33 and 16, respectively) Q4W for 12 weeks in addition to their current lipid-lowering therapy.[95] Evolocumab administration resulted in a reduction versus placebo of 30.9%; one LDLR-negative patient and one patient with autosomal recessive hypercholesterolemia did not respond to the treatment.[95] Among the patients homozygous for the same LDLR mutation, LDL-C reductions were highly heterogeneous and varied from −7.1% to −56%.[95] Overall, the response to evolocumab was related to the genetic defect determining HoFH and ranged from 0% in LDLR-negative patients to 40.8% in more than half of the patients carrying one or two defective LDLR mutations. Patients who completed this study were included in the one-arm open-label extension *TAUSSIG* (*Trial Assessing Long-Term Use of PCSK9 Inhibition in Subjects with Genetic LDL Disorders*, NCT01624142). This study will evaluate the long-term (5 years) efficacy and safety of evolocumab 420 mg Q4W or Q2W in a large cohort (100) of patients with HoFH and has a completion date in March 2020 (**Table 2**). Preliminary data (http://www.athero.org/isa2015/ClinicalBreak/Raal.pdf) show that the reduction of LDL-C persisted up to week 48 and that the administration Q2W results in an incremental 6% reduction compared with evolocumab Q4W in patients not receiving apheresis.

OSLER-1 and *OSLER-2* (*Open-Label Study of Long-Term Evaluation against LDL-C*, NCT01439880 and NCT01854918) are open-label extension trials involving heterogeneous groups of patients that participated in one or more phase 2 or phase 3 studies, respectively, on evolocumab.[96] After 11.1 months, evolocumab reduced LDL-C levels by 61% (**Table 2**).[96] The OSLER-1 study showed that a major part of patients who received evolocumab achieved LDL-C levels below those recommended by current guidelines, with a high percentage of subjects reaching LDL-C levels <50 mg dL^{-1} (1.3 mmol L^{-1}), especially when evolocumab was coadministered with statins.[97] Adverse events, as well as serious adverse events, were similar in placebo- and evolocumab-treated patients.[96,97]

Alirocumab. Alirocumab has a half-life of 6–8 days and is administered subcutaneously every 2 or 4 weeks. In healthy volunteers, alirocumab significantly reduced LDL-C ($>65\%$) and was well tolerated.[98] Three phase 2 trials have evaluated the effects of alirocumab in subjects with hypercholesterolemia. In hypercholesterolemic subjects on stable atorvastatin therapy (*Efficacy and Safety Evaluation of Alirocumab (SAR236553/REGN727) in Patients with Hypercholesterolemia on Stable Atorvastatin Therapy*, NCT01288443), alirocumab when administered for 12 weeks induced a further dose-dependent reduction of LDL-C levels, and the higher efficacy was observed with the Q2W administration compared with higher doses given Q4W[99] (**Table 3**); patients who were not at LDL-C target under atorvastatin therapy achieved this goal after alirocumab treatment.[99] TC, non-HDL-C, and apoB were also significantly reduced.[99] Adverse effects did not differ among groups.[99] Similar results were observed when alirocumab was added to low-dose (10 mg) or high-dose (80 mg) atorvastatin for 8 weeks (*Efficacy and Safety Evaluation of Alirocumab (SAR236553/REGN727) when Coadministered with Atorvastatin in Patients with Primary Hypercholesterolemia*, NCT01288469): a considerable decrease of LDL-C was observed following alirocumab administration compared with atorvastatin alone (−66.2%, −73.2%, and −17.3%, respectively) (**Table 3**), and a greater percentage of patients receiving alirocumab + atorvastatin 80 mg reached the LDL-C target level of <100 mg dL^{-1} (<2.6 mmol L^{-1}) or <70 mg dL^{-1} (<1.8 mmol L^{-1}), without specific safety issues.[100] When tested in a population of HeFH on statin with or without ezetimibe (*Study on the Safety and Efficacy of REGN727/SAR236553 in Patients with HeFH Hypercholesterolemia*, NCT01266876), alirocumab 150 mg Q2W (12-week treatment) reduced LDL-C by 67.9% compared with 10.65% of placebo[101] (**Table 3**).

The *ODYSSEY* program includes 14 phase 3 trials on alirocumab, among a large number of patients ($>23{,}500$) aimed at evaluating the efficacy and safety of alirocumab alone or when combined with other lipid-lowering therapies in several groups of hypercholesterolemic patients. Most of these trials use a dosage of 75 mg Q2W, which is uptitrated to 150 Q2W if the LDL-C target is not reached after 8 weeks. The *ODYSSEY COMBO* studies (I and II) evaluated the efficacy and safety of alirocumab as add-on therapy to stable, maximal tolerated dose of statin, with/without other lipid-lowering drugs in hypercholesterolemic patients of high CV risk. The *COMBO I* trial (*Efficacy and Safety of Alirocumab (SAR236553/REGN727) versus Placebo on Top of Lipid-Modifying Therapy in Patients with High Cardiovascular Risk and Hypercholesterolemia*, NCT01644175) showed that after 24 weeks, LDL-C decreased from baseline by −48.2% with alirocumab and by −2.3% with placebo, and the achieved LDL-C levels were comparable at weeks 24, 36, and 52[102] (**Table 3**); 75% of patients on alirocumab achieved the LDL-C target <70 mg dL^{-1} (<1.8 mmol L^{-1}), compared with 9% of placebo.[102] The incidence of adverse effects was comparable in the two groups.[102] The *COMBO II* trial (*Efficacy and Safety of Alirocumab (SAR236553/REGN727) versus Ezetimibe on Top of Statin in High Cardiovascular Risk Patients with Hypercholesterolemia*, NCT01644188) compared the effect of alirocumab and ezetimibe in a 104-week treatment period in patients with high CV risk and high LDL-C levels despite maximal dose of statin.[103] Mean LDL-C levels decreased rapidly in the first 4 weeks; at week 24, percent change from baseline in LDL-C was −50.6% with alirocumab and −20.7% with ezetimibe (difference between groups: −29.8%) (**Table 3**); these values were maintained up to 52 weeks.[103] Similar incidences of adverse events were observed in the two groups.[103]

In *ODYSSEY FH* studies (FH I, FH II, and HIGH FH), alirocumab was evaluated in the HeFH population.[104] *ODYSSEY FH I* (performed in North America, Europe, and South Africa, NCT01623115) and *FH II* (performed in Europe, NCT01709500) studies, in which patients received alirocumab 75 mg Q2W uptitrated to 150 mg when LDL-C was ≥ 70 mg dL^{-1} (≥ 1.8 mmol L^{-1}) at week 8, showed that HeFH patients with LDL-C levels above the recommended target despite maximal tolerated dose of statin may greatly benefit from alirocumab treatment. In fact, at week 24, LDL-C levels were reduced by 57.9% (FH I) and 51.4% (FH II) versus placebo, respectively (**Table 3**), and these reductions were maintained through week 78.[105] The *ODYSSEY HIGH FH* (NCT01617655) was performed in patients with HeFH with LDL-C ≥ 160 mg dL^{-1} (≥ 4.1 mmol L^{-1}) and treated with alirocumab 150 mg Q2W or placebo for 78 weeks.[104] At week 24, in patients treated with alirocumab, LDL-C levels were reduced by 39% compared with placebo (**Table 3**).

ODYSSEY OPTIONS (I and II) studies were designed to evaluate the efficacy and safety of alirocumab with various therapeutic choices in patients at high CV risk with LDL-C levels not adequately controlled with atorvastatin 20 or 40 mg daily (OPTIONS I) or

Clinical trial (ClinicalTrials.gov)	*Subjects*	*Duration*	*Background LLT*	*Treatments*	*LDL-C (percent change from baseline)*	*Primary end point for ongoing trial·*
ODYSSEY OLE, NCT01954394	HeFH who have completed one of the four parent studies	176 weeks			Ongoing (2017)	Assessment of safety parameters
ODYSSEY OUTCOMES, NCT01663402[112]	Recent ACS (4–52 weeks prior to randomization), LDL-C $\geq$70 mg dL^{-1}	64 months	Atorva 40–80 mg or Rosuva 20–40 or the max tolerated dose	75 mg Q2W 150 mg Q2W	Ongoing (2017)	Time from randomization to first occurrence of CHD death, nonfatal MI, stroke, or UA requiring hospitalization

FH, familial hypercholesterolemia; *HeFH*, heterozygous familial hypercholesterolemia; *HoFH*, homozygous familial hypercholesterolemia; *CHD*, coronary heart disease; *CVD*, cardiovascular disease; *ACS*, acute coronary syndrome; *LLT*, lipid-lowering therapy; *Q2W*, every 2 weeks; *Q4W*, every 4 weeks; *Atorva*, atorvastatin; *Rosuva*, rosuvastatin; *Eze*, ezetimibe.

rosuvastatin 10 or 20 mg daily (OPTIONS II).[106] The *ODYSSEY OPTIONS I* (NCT01730040) trial was performed in patients with very high CVD risk and LDL-C $\geq$70 mg dL^{-1} ($\geq$1.8 mmol L^{-1}) or high CVD risk and LDL-C $\geq$100 mg dL^{-1} ($\geq$2.6 mmol L^{-1}) and compared the efficacy and safety of alirocumab 75 mg Q2W (switched to 150 mg Q2W if LDL-C target was not achieved after 12 weeks) added to atorvastatin 20 or 40 mg with several alternative approaches including adding ezetimibe, doubling atorvastatin dose, or switching from atorvastatin 40 mg to rosuvastatin 40 mg.[107] The addition of alirocumab resulted in the greatest reduction of LDL-C, being reduced by 44.1% and 54.0% with baseline atorvastatin 20 or 40 mg, respectively, by 20.5% and 22.6% after addition of ezetimibe, by 5.0% and 4.8% with doubled atorvastatin dose, and by 21.4% when switching from atorvastatin to rosuvastatin[107] (**Table 3**). A significantly higher proportion of patients receiving alirocumab achieved their LDL-C goals compared with the other treatments[107]; in addition, alirocumab induced a higher reduction of apoB, non-HDL-C, and Lp(a) levels compared with other treatments.[107] Treatment-emergent adverse events were comparable among groups.[107] The *ODYSSEY OPTIONS II* (NCT01730053) evaluated the addition of alirocumab on a background of rosuvastatin 10 or 20 mg in the same type of patients and showed a higher reduction of LDL-C levels with alirocumab ($-$50.6% and $-$36.3%, respectively) compared with the addition of ezetimibe ($-$14.4% and $-$11.0%) or doubling rosuvastatin dose ($-$16.3% and $-$15.9%) after 24 weeks[108] (**Table 3**). Again, similar percentages of treatment-emergent adverse events in the various treatment groups were observed.[108] These trials demonstrated that the addition of PCSK9 antibody achieves LDL-C goals in patients at high/very high CVD risk and not optimally controlled with conventional lipid-lowering treatments.

Statin-intolerant patients with moderate to very high CVD risk with LDL-C $\geq$190 mg dL^{-1} ($\geq$4.9 mmol L^{-1}) were treated with alirocumab 75 mg Q2W (with potential uptitration to 150 mg Q2W) or ezetimibe 10 mg day^{-1} or atorvastatin 20 mg day^{-1} (statin rechallenge; included only as control to define the appropriate patient population) for 24 weeks to evaluate percent change from baseline in LDL-C in the *ODYSSEY ALTERNATIVE* trial (NCT01709513). Alirocumab was superior to ezetimibe in reducing LDL-C levels throughout the study ($-$54.8% and $-$20.1% from baseline, respectively, at week 24, $P<0.0001$) (**Table 3**); a greater proportion of patients receiving alirocumab achieved the LDL-C goals relative to their CV risk compared with those receiving ezetimibe (41.9% vs. 4.4%).[109] TC, non-HDL-C, apoB, and Lp(a) were more significantly reduced with alirocumab than with ezetimibe.[109] Myalgia was the most common adverse event in all groups, but in the alirocumab group, the rate of muscle-related adverse events was significantly lower than in the atorvastatin group (hazard ratio: 0.61, $P=0.042$) with a similar result also compared with the ezetimibe group (HR 0.71, $P=0.096$).[109] Similar results were obtained in the *ODYSSEY MONO* trial (NCT01644474), conducted in hypercholesterolemic patients on no lipid-lowering therapy, with reductions of LDL-C levels of 47.2% with alirocumab and 15.6% with ezetimibe at week 24[110] (**Table 3**).

Two trials have been designed to evaluate the safety of long-term administration of alirocumab. The *ODYSSEY LONG TERM* (NCT01507831) was conducted in high CV risk patients with hypercholesterolemia not adequately controlled by the current lipid-lowering therapy and treated with alirocumab or placebo for up to 86 weeks. The mean percent change in calculated LDL-C was $-$61% with alirocumab and +0.8% with placebo at week 24[111] (**Table 3**) and was similar in HeFH and non-HeFH patients; a consistent reduction of LDL-C levels was obtained after a 4-week treatment and maintained up to 78 weeks.[111] Adverse events occurred similarly in the two groups, but myalgia occurred at a higher frequency in the alirocumab group (5.4% vs. 2.9% in placebo, $P=0.006$).[111] A post hoc analysis suggests a lower rate of major CV events in patients treated with alirocumab than in the placebo group (1.7% vs. 3.3%, HR 0.52, nominal $P=0.02$), with cumulative probability of event curves tending to diverge over time.[111] The ongoing *ODYSSEY OLE* (Open Label Study of Long-Term Safety Evaluation of Alirocumab) (NCT01954394) has as

current primary outcome the assessment of safety parameters (adverse events, laboratory data, and vital signs) following a treatment with alirocumab up to 176 weeks in patients with HeFH. Secondary outcomes are the effects on lipid parameters; the estimated completion date is June 2017.

Finally, the *ODYSSEY OUTCOMES* (NCT01663402) is recruiting patients with a recent acute coronary syndrome to evaluate the effect of adding alirocumab versus placebo to their current therapy on the occurrence of CV events, including CHD death, MI, fatal and nonfatal ischemic stroke, and unstable angina requiring hospitalization.[112]

Bococizumab. Four phase 2 trials on bococizumab have been performed (NCT01342211, NCT01592240, NCT01350141, and NCT02055976); to date, only results from one of these studies have been published. Ballantyne et al. showed that bococizumab (NCT01592240) significantly reduced LDL-C levels across all doses in patients with hypercholesterolemia on stable statin therapy and with fasting LDL-C $\geq$80 mg dL^{-1} ($\geq$2.1 mmol L^{-1})[113] (**Table 4**); however, despite similar reductions with low doses (100 and 150 mg) Q2W or high doses (200 and 300 mg) Q4W, patients who received bococizumab Q2W maintained the LDL-C reductions between dose administration, whereas those who received bococizumab Q4W did not.[113] The frequency of adverse events was similar in all groups.[113] The *SPIRE* (Studies on PCSK9 Inhibition and the Reduction of Vascular Events) program includes eight phase 3 trials (**Table 4**); among these, six are designed to assess the LDL-C-lowering efficiency of bococizumab in several hypercholesterolemic populations (SPIRE-AI, NCT02458287; SPIRE-SI, NCT02135029; SPIRE-FH, NCT01968980; SPIRE-LL, NCT02100514; SPIRE-HR, NCT01968954; and SPIRE-LDL, NCT01968967), whereas the other two will evaluate the effect of long-term bococizumab administration on the occurrence of major CV events in high-risk patients with LDL-C levels 70–100 mg dL^{-1} (1.8-2.6 mmol L^{-1}) (SPIRE-1: NCT01975376) or with LDL-C levels $\geq$100 mg dL^{-1} ($\geq$2.6 mmol L^{-1}) despite high-dose statin (SPIRE-2: NCT01975389).

7.18.3.1.3 Mipomersen

Despite the fact that statins are the most used LDL-C-lowering drug class, certain patients with FH may not benefit from the use of statins or PCSK9 mAbs because their mechanism of action requires the presence of at least partially functional LDLR.[8,9] Thus, HoFH with *ldlr* mutations leading to the absence of LDLR will not benefit from statin- or anti-PCSK9 mAb-based therapies and thus need

Table 4 Results from one clinical trial on bococizumab and list of the ongoing trials

Clinical trial (ClinicalTrials.gov identification number)	*Subjects*	*Duration*	*Background LLT*	*Treatments*	*LDL-C (percent change from baseline)*	*Primary end point for ongoing trials*
NCT01592240[113]	Fasting LDL-C $\geq$80 TG $\leq$400 mg dL^{-1}	24 weeks	Stable statin therapy	Q2W: 50, 100, 150 mg Q4W: 200, 300 mg	Q2W: −35.4%, −52.3%, −54.2% Q4W: −21.3%, −38.3%

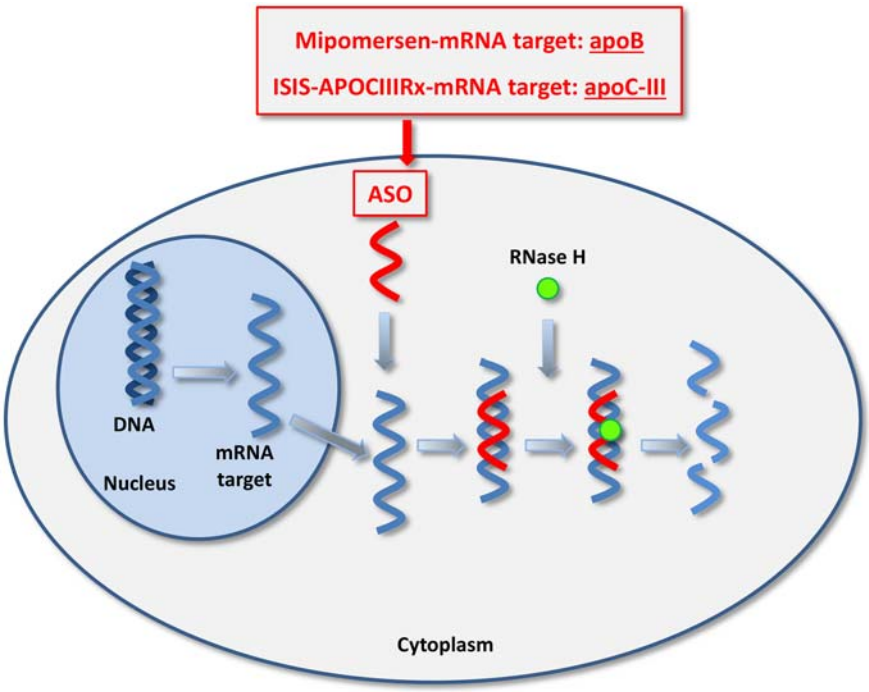

Fig. 4 Mechanism of action of antisense oligonucleotides. Mipomersen and ISIS-APOCIIIRx are second-generation antisense oligonucleotides (ASOs) that inhibit the synthesis of apoB and apolipoprotein C-III, respectively. They bind to the cognate mRNA forming a substrate for ribonuclease H (RNase H), a ubiquitously expressed nuclease, thus resulting in mRNA degradation and reduced production of the encoded protein.

alternative lipid-lowering drugs with mechanisms of action independent of LDLR expression as add-on to the maximal potent statin dose[8] and may include ezetimibe and the most recently approved mipomersen and lomitapide.[9]

High levels of apoB, the main apoprotein of atherogenic lipoproteins [LDL, very-low-density lipoprotein (VLDL), and chylomicrons], represent an established risk factor in atherosclerosis, and the discovery of truncating apoB mutations resulting in low levels of LDL-C indicated it as potential pharmacological target for the treatment of hypercholesterolemia.[114] Mipomersen is a second-generation antisense oligonucleotide (ASO) against the coding region of human apoB mRNA and thus acts as an inhibitor of apoB synthesis[115] (**Fig. 4**). When administered by injection, it is rapidly absorbed, with the liver being one of the organs that accumulate the highest concentrations of this drug,[115] and in humans, it has an elimination half-life of about 30 days.[115] Its administration leads to a dose-dependent reduction of apoB and TC [116]; several studies have shown the lipid-lowering efficacy of mipomersen either as monotherapy or as add-on to current lipid-lowering therapies.[117–124] Mipomersen is not metabolized by the CYP450 system, it does not inhibit major CYP isoenzymes, and it does not show clinically relevant interaction with simvastatin or ezetimibe.[125] The most common adverse reaction associated with mipomersen is the injection site reaction following subcutaneous administration. Due to its characteristics, mipomersen represents an effective approach as lipid-lowering agent in the management of FH but can also be considered in statin-intolerant patients.

Two meta-analyses of randomized clinical trials have reported significant decrease of LDL-C levels induced by mipomersen treatments, as well as beneficial effects on other lipid parameters.[126,127] Both meta-analyses reported as major adverse events associated with mipomersen treatment the risk of injection site reactions, elevated alanine aminotransferase (ALT) $>3\times$ the upper limit of normal (ULN), and hepatic steatosis and flu-like symptoms;[126,127] the most relevant side effect of mipomersen seems to be an increased content of TG in the liver, but though short-term studies revealed an increased steatosis (whose clinical relevance was considered low) in mipomersen-treated subjects, long-term (up to 104 weeks) clinical trials observed a return to normal of hepatic TG level.[128,129] The analysis of liver biopsies of some hypercholesterolemic patients after mipomersen treatment showed a histopathological feature of simple steatosis without signs of inflammation or fibrosis.[130]

In the *ASSIST* (Safety and Efficacy Study of ISIS 301012 (Mipomersen) Administration in High Risk Subjects NCT00707746) trial, mipomersen (200 mg $week^{-1}$) significantly decreased apoB100 and LDL-C levels and reduced small dense proatherogenic LDL, but did not affect high-density lipoprotein (HDL) or apoA-I levels in statin-intolerant hypercholesterolemic patients[124] (**Table 5**); overall, mipomersen was well tolerated.[124] In patients with mild to moderately elevated LDL-C (*Safety and Tolerability of Varying Load and Dose of ISIS 301012 in People with Elevated LDL-C Levels*, NCT00216463) (130 mg dL^{-1} and 3.3 mmol L^{-1}) who did not receive any lipid-lowering therapy in the past month, mipomersen at doses ranging from 50 to 400 mg $week^{-1}$ dose-dependently reduced LDL-C levels (from -8% to -70.6%)[123] (**Table 5**). In hypercholesterolemic patients at high CV risk (*Safety and Efficacy of Mipomersen (ISIS 301012) as Add-on Therapy in High Risk Hypercholesterolemic Patients*, NCT00770146), mipomersen 200 mg significantly reduced LDL-C levels (**Table 5**); after treatment completion, LDL-C levels increased and reached

baseline levels after 24 weeks.[131] The effect appeared to be greater in women and in patients aged >59 years.[131] Other lipid parameters, including Lp(a), were significantly reduced by mipomersen treatment.[131] All patients treated with mipomersen experienced an injection site reaction, while 23% had an ALT elevation >3× ULN.[123] In a phase 2 study (NCT00477594), 44 patients with HeFH were randomized to mipomersen 50, 100, 200, or 300 mg $week^{-1}$ or placebo for 6 weeks in a background of conventional lipid-lowering therapy, including high-dose statins. Mipomersen reduced apoB and LDL-C by 23% and 21%, respectively, at 200 mg $week^{-1}$ and by 33% and 34%, respectively, at 300 mg $week^{-1}$[118] (**Table 5**). The most common adverse effect with mipomersen was injection site erythema (97%); four patients treated with mipomersen (three of which in the highest dose group) experienced transaminase elevations >3× ULN with signs of hepatic steatosis; no clinically relevant interactions with currently used drugs were observed.[118] LDL-C levels remained lower than baseline levels for 2–3 months after the last injection in the two groups with the highest doses (200 and 300 mg $week^{-1}$), likely due to the long mipomersen half-life.[118] In HeFH patients with CAD (*RADICHOL II*: *Efficacy and Safety Study of ISIS 301012 (Mipomersen) as Add-on in Familial Hypercholesterolemic Patients with Coronary Artery Disease*, NCT00706849), mipomersen treatment induced a −28% reduction from baseline in LDL-C (vs. +5.2% placebo, $P<0.001$) (**Table 5**); the reduction was independent of baseline LDL-C levels and age, but the response was greater in women than in men.[122] ApoB, non-HDL-C, TC, and Lp(a) were significantly reduced in the mipomersen group.[122]

Effective LDL-C reduction with mipomersen (200 mg $week^{-1}$ for 26 weeks) was observed also in 51 patients with HoFH already treated with maximal conventional lipid-lowering therapy (*RADICHOL 1*: *Study to Assess the Safety and Efficacy of ISIS 301012 (Mipomersen) in Homozygous Familial Hypercholesterolemia*, NCT00607373): the mean percent change in LDL-C from baseline was −24.7% (vs. −3.3% with placebo), independently of baseline LDL-C levels.[121] Significant reductions in apoB (−24.2%), non-HDL-C (−21.6%), and Lp(a) (−23.2%) were also reported.[121] Again, the most common adverse event was injection site reactions (76% of mipomersen patients and 24% of placebo patients).[121] ALT elevations ≥3 times ULN occurred in four mipomersen patients, including 1 who had significantly increased hepatic fat.[121] A recent report of 2-year interim results of an ongoing open-label study (conducted in patients with FH or severe hypercholesterolemia on lipid-lowering therapy who had completed one of the described studies, NCT00694109) (**Table 5**) showed that, in HoFH and HeFH patients, mipomersen in

combination with the maximally tolerated dose of lipid-lowering therapy showed that favorable effects on lipid profile were maintained throughout the study and that safety issues were similar to those reported for a 26-week treatment.[132] Data from the 4-year time point will further clarify this finding.

Besides its effect on LDL-C levels, mipomersen has been also evaluated on Lp(a) levels. Lp(a) is a causal, independent genetic risk factor for MI, stroke, and peripheral artery disease.[133–135] Its levels are particularly elevated in patients with FH and are related to severity of hypercholesterolemia,[136] and commonly used lipid-lowering drugs are not effective in reducing Lp(a). Lp(a) has a structure similar to that of LDL, from which it differs in the presence of the glycoprotein apolipoprotein (a) covalently bound to apoB.[137] As mipomersen acts by specifically inhibiting apoB production, it may also affect the formation of Lp(a). In four phase 3 trials, mipomersen significantly reduced Lp(a) levels in various hypercholesterolemic populations[138]; the highest effects were reported in HoFH and in patients with severe hypercholesterolemia at week 26 (−31.8% and −39.1%, respectively).[138] In the pooled analysis of all patients, including HeFH with CAD and hypercholesterolemic patients at high risk for CAD, LDL-C levels were reduced by 26.4%,[138] thus suggesting that mipomersen can efficiently reduce both LDL-C and Lp(a) levels. Whether this can translate into a further clinical benefit remains to be addressed, as the commonly used lipid-lowering drugs do not lower Lp(a).[139]

The ongoing *FOCUS FH* (*A Study of the Safety and Efficacy of Two Different Regimens of Mipomersen in Patients with Familial Hypercholesterolemia and Inadequately Controlled Low-Density Lipoprotein Cholesterol*, NCT01475825) study will determine whether administration of mipomersen for 60 weeks at two different dosing regimens (70 mg thrice weekly or 200 mg once weekly) can significantly reduce LDL-C levels in patients with severe HeFH, thus providing further information on the efficacy and safety of this drug.

7.18.3.1.4 Lomitapide

MTP (microsomal triglyceride transport protein) is a lipid transfer protein crucial for the assembly and secretion of apolipoprotein B-containing lipoproteins, including VLDL and chylomicrons (Fig. 5).[140] MTP localizes in the endoplasmic reticulum (ER) of hepatocytes and enterocytes and acts by transferring TG and cholesteryl esters from the ER membrane to the nascent apoB.[140] Since subjects carrying mutations of the gene encoding for MTP (*MTTP*) exhibit significantly reduced synthesis of VLDL and chylomicrons and increased apoB degradation, thus resulting in reduced circulating VLDL and LDL,[141] it has been hypothesized that inhibition of MTP might be a valuable approach to treat hypercholesterolemia in FH patients. MTP inhibition results in the reduction of both cholesterol and TG plasma levels, due to the inhibition of production of apoB-containing lipoproteins in both the liver (VLDL) and intestine (chylomicrons). Studies in animal models of HoFH have in fact showed that MTP inhibition normalized the levels of atherogenic lipoproteins by greatly reducing the secretion rate of VLDL.[142–144]

Lomitapide is an MTP inhibitor that, by binding MTP, inhibits MTP-mediated synthesis of VLDL and chylomicrons, thus resulting in a significant reduction of LDL-C levels (Fig. 5). Due to the high difficulty to efficiently treat HoFH patients, lomitapide

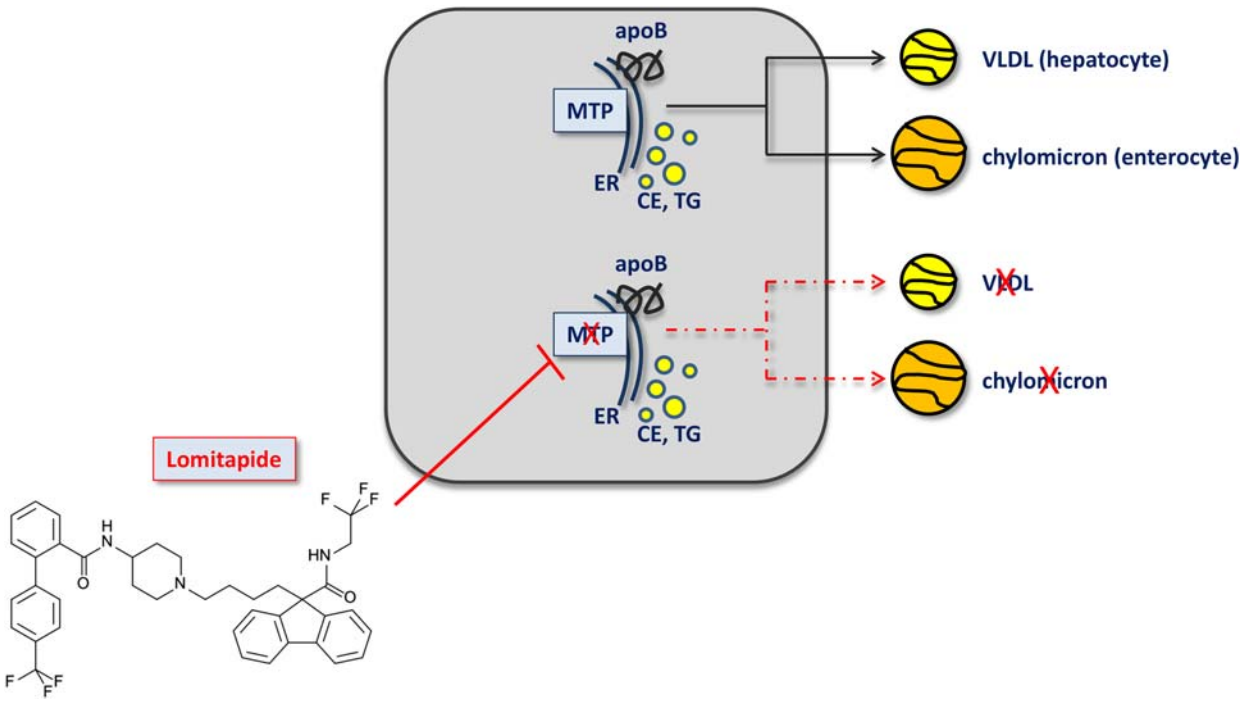

Fig. 5 Mode of action of lomitapide. MTP mediates the transfer of lipid droplet to apoB-100 in the liver and apoB-48 in the intestine, thus resulting in the secretion of VLDL and chylomicrons, respectively. Lomitapide inhibits the activity of MTP in both the liver and intestine.

was considered as a possible approach to reduce LDL-C levels in these patients; to test this possibility, six patients with HoFH (five LDLR-negative and one LDLR-defective) were enrolled in a study in which all lipid-lowering treatments were suspended at least 4 weeks before the baseline visit, and lomitapide was administered at four increasing doses (0.03, 0.1, 0.3, and 1.0 mg kg^{-1} body weight), each for 4 weeks.[145] The mean LDL-C level was reduced by 24.7% after 0.3 mg kg^{-1} for 4 weeks and by 50.9% after 1.0 mg kg^{-1} for 4 weeks[145] (**Table 5**); similarly, TC was reduced by 29.8% and 58.4% from the baseline level, respectively.[145] Both TG and apoB were significantly reduced (TG, −34.1% and −65.2%, and apoB, −14.7% and −55.6%, respectively).[145] The drug was well tolerated and the most serious adverse events were elevations in liver aminotransferase levels and hepatic fat accumulation.[145] Thus, lomitapide was highly effective in reducing LDL-C levels, but the accumulation of fat in the liver requires further investigations to evaluate the long-term safety.

To answer this question, lomitapide was given to 29 HoFH patients in single-arm, open-label, phase 3 study in addition to their lipid-lowering therapy (*A Safety and Efficacy Study of AEGR-733 to Treat Homozygous Familial Hypercholesterolemia*, NCT00730236).[146] This study consisted of a 26-week efficacy study during which lomitapide was initiated at a starting dose of 5 mg day^{-1} for the first 2 weeks and then escalated to 10, 20, 40, and 60 mg day^{-1} at 4-week intervals or until the maximal dose was identified for each subject on the basis of safety and tolerability, and a 52-week safety study that allowed the investigators to modify the concomitant lipid-lowering therapy based on lomitapide effect.[146] Mean LDL-C levels were significantly reduced by 50% at the end of efficacy phase, leading to the discontinuation of LDL apheresis or to the increased interval times between two apheresis processes.[146] At the end of the study (week 78), LDL-C was still significantly reduced, but the reduction was attenuated (−38%) compared with the values at the end of the efficacy study (**Table 5**); this could be due to changes in the concomitant lipid-lowering therapies as well as to the reduction of lomitapide doses in patients experiencing adverse effects.[146] Very-low-density lipoprotein cholesterol (VLDL-C), non-HDL-C, and TG levels were significantly decreased at the end of the efficacy phase (−45%, −50%, and −45%, respectively), and at the end of the study, such reductions resulted attenuated (−31%, −39%, and −31%, respectively), in line with the results obtained for LDL-C levels (**Table 4**).[146] HDL-C and apoA-I levels were significantly reduced at week 26 (−12% and −14%), but returned to levels similar to baseline at the end of the study.[146] During the first period (0–26 weeks), 15 patients reached the LDL-C level target <100 mg dL^{-1} (2.6 mmol L^{-1}), and 8 had LDL-C <70 mg dL^{-1} (<1.8 mmol L^{-1}).[146] The effect of lomitapide on LDL-C level was independent of apheresis treatment, as comparable reductions of LDL-C levels were achieved in patients undergoing apheresis and in those not undergoing apheresis (55.1% vs. 48%).[147] Most patients had mild to moderate gastrointestinal adverse effects during the treatment with lomitapide. Some patients exhibited increased levels of ALT, aspartate aminotransferase (AST), or both, but these changes were transient, were resolved when lomitapide doses were reduced, and were not related to changes of liver function.[146] Mean hepatic fat increased during the efficacy phase but did not further increase (8.6% at week 26 and 8.3% at week 78).[146] The clinical relevance of this rise in liver fat is still unclear and, since lomitapide might be administered lifelong, requires further investigation to assess whether it can progress to hepatic fibrosis or cirrhosis. Comparable results were reported in an Italian subgroup of HoFH patients participating in the described study.[148] These findings, together with the recent data obtained in a HoFH patient treated with lomitapide in addition to other lipid-lowering therapies for 5 years,[149] suggest that lomitapide may be a valuable pharmacological approach for the treatment of these very high-risk patients.

Recently, the use of lomitapide in four HoFH patients (two compound heterozygotes and two homozygotes) in the clinical practice setting has been reported.[150] In all patients, LDL-C levels were significantly reduced (35–73%)[150] (**Table 5**). One compound heterozygous patient having two different severe mutations in the *LDLR* gene, one in each allele, who had LDL-C levels ranging from 290 to 688 mg dL^{-1} (7.4–17.6 mmol L^{-1}) despite atorvastatin + colesevelam therapy, was treated with lomitapide. Lomitapide was started at 5 mg and then escalated to 30 mg day^{-1}; LDL-C levels decreased drastically, reaching very low levels (93 mg dL^{-1} and 2.4 mmol L^{-1}), with a reduction of 83% over 8 months.[150] The second compound heterozygote who had an LDL-C level of about 260 mg dL^{-1} (6.7 mmol L^{-1}) when lomitapide was added to the maximal background LLT (rosuvastatin 40 mg, ezetimibe 10 mg, and colesevelam 2.5 g) had LDL-C reduced by 35%.[150] In one HoFH LDLR-negative patient, who underwent apheresis and was on simvastatin + ezetimibe therapy, lomitapide therapy resulted in LDL-C and TC reductions of 73% and 62%, respectively.[150] The other homozygous patient who had a history of CV disease started lomitapide 5 mg and had a significant decrease of LDL-C within 1 month of treatment.[150] However, when escalated to 10 mg daily, levels of AST and ALT increased by more than 5 × ULN, which resulted in the discontinuation of the drug. Resumption of lomitapide after 4 weeks at 5 mg also increased ALT by three times; thus, the drug was stopped permanently.[150] Altogether, these data indicate that, although lomitapide added to aggressive lipid-lowering therapies may be useful to further reduce LDL-C in HoFH, each patient must be individually monitored to avoid hepatic impairment. Longer follow-ups are required to establish whether lomitapide treatment may effectively prevent CV events.

To date, there are few data on the long-term efficacy and safety of lomitapide. A single case report has been published regarding a patient with a homozygosity for *LPL* gene resulting in the production of noncatalytically active enzyme associated with severe hypertriglyceridemia (HTG) and recurrent pancreatitis.[151] In 1999, lomitapide was given to this patient after stopping all other lipid-lowering treatments; fasting TG levels were significantly reduced, and in the course of 13 years, she had three hospitalizations for pancreatitis during discontinuation of lomitapide or high dietary fat intake.[151] Plasma levels of ALT and AST were within the reference range during the initial 6–7 years and then increased; the fatty liver that was already present before starting lomitapide progressed to hepatitis and fibrosis.[152] It is possible that inhibition of MTP may have reduced the main route by which hepatocytes reduce their fat content. In addition, MTP inhibition increases liver transaminases, and these two different aspects may have interacted and worsened the liver condition.[152]

An ongoing study is evaluating the effect of lomitapide treatment on carotid and aortic atherosclerosis in HoFH patients (NCT02399852) and will measure the percent change from baseline in carotid vessel wall area at the 2-year evaluation as well as the percent change from baseline in carotid aortic vessel wall area and thickness at 1- and 5-year intervals (Table 5).

Lomitapide is a weak inhibitor of CYP3A4 and increases the exposure of statin[153]; thus, caution should be used when administered in combination by monitoring the well-known adverse effects associated with statin therapy.

7.18.3.1.5 CETP inhibitors

Cholesteryl ester transfer protein (CETP) is an enzyme mainly involved in the transfer of cholesteryl esters from HDL to LDL and VLDL; this process results in a reduction and remodeling of HDL particles and in an increase of LDL and VLDL levels (Fig. 6). Under pathological conditions, such as atherosclerosis, CETP activity is increased, while CETP deficiency results in increased HDL-C levels. These observations lead to the hypothesis that CETP inhibition might be a powerful tool to increase HDL cholesterol, decrease LDL and VLDL cholesterol, and reduce the development of atherosclerosis.[154]

The first CETP inhibitor (CETPi) developed, torcetrapib (Fig. 7), although very effective in increasing HDL-C levels (+72%), was withdrawn due to the results of the ILLUMINATE trial that reported an increased risk of CV events and death from any cause.[155] This effect was attributed to an off-target effect of torcetrapib independent of CETP inhibition.[155,156]

The Dalcetrapib HDL Evaluation, Atherosclerosis and Reverse Cholesterol Transport program included three surrogate end point trials, dal-VESSEL, dal-PLAQUE, and dal-PLAQUE 2, and the large phase 3 dal-OUTCOMES trial that evaluated the effects of dalcetrapib (Fig. 7) 600 mg daily added to standard statin therapy on mortality and morbidity in more than 15,000 high-risk CHD patients. In May 2012, however, the development of dalcetrapib was stopped based on the interim analysis of the *dal-OUTCOMES* (NCT00658515) trial that reported lack of efficacy in reducing CV events.[157] One possible explanation for this finding may be the moderate effect of dalcetrapib on HDL-C (+20%) and the lack of effect on LDL-C levels.[157]

Three further CETPi's, anacetrapib, evacetrapib (Fig. 7), and TA-8995, have been developed, and the results of the clinical trials are discussed in the succeeding text.

Anacetrapib. Anacetrapib was initially tested (100 mg daily) in patients with CHD or equivalent conditions (peripheral artery disease, cerebrovascular disease, diabetes, or a 10-year Framingham risk score >20%) resulting in the increase of HDL-C levels and in the decrease of LDL-C and apoB levels either as monotherapy or in combination with a statin.[158–160] The effect of LDL-C reduction is due to an increased rate of apoB fractional clearance.[161] The *DEFINE* (*Determining the Efficacy and Tolerability of CETP Inhibition with Anacetrapib*, NCT00685776) trial showed that in patients at high risk of CHD, anacetrapib increased HDL-C by 138.1% and reduced LDL-C by 39.8% compared with placebo[160] (Table 6), although a subsequent reevaluation of lipid parameters using different methods established an LDL-C level reduction closer to 25–35%.[162] Adverse events were comparable between the two groups.[160] The 2-year extension of the DEFINE study showed that treatment with anacetrapib was well tolerated and determined a 39.9% reduction of LDL-C and 153.3% increase of HDL-C compared with placebo.[163] When analyzed in patient subgroups, defined by age, gender, race, or baseline lipid levels or other conditions such as diabetes status or use of other lipid-modifying therapies, these changes in LDL-C and HDL-C levels were comparable across groups.[164] Only age, gender, and race seem to have a slight effect on anacetrapib-mediated effect, with patients <65 years more responsive than those ≥65 years, men more responsive than women, and whites more responsive than blacks.[164] The *REVEAL* (*Randomized Evaluation of the Effects of Anacetrapib through Lipid-modification*, NCT01252953) trial will determine the occurrence of major coronary events

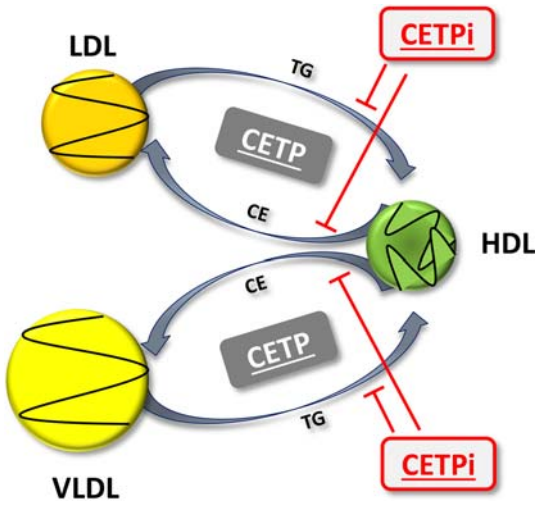

Fig. 6 CETP inhibition. CETP mediates the transfer of cholesteryl ester (CE) from HDL to larger lipoproteins, such as VLDL and LDL, in exchange for triglycerides (TG). This results in the generation of CE-enriched LDL and VLDL and TG-enriched HDL and in the reduction of circulating HDL-C. CETP inhibitors (CETPi's) inhibit the transfer of CE and result in the increase of HDL-C and reduction of LDL-C.

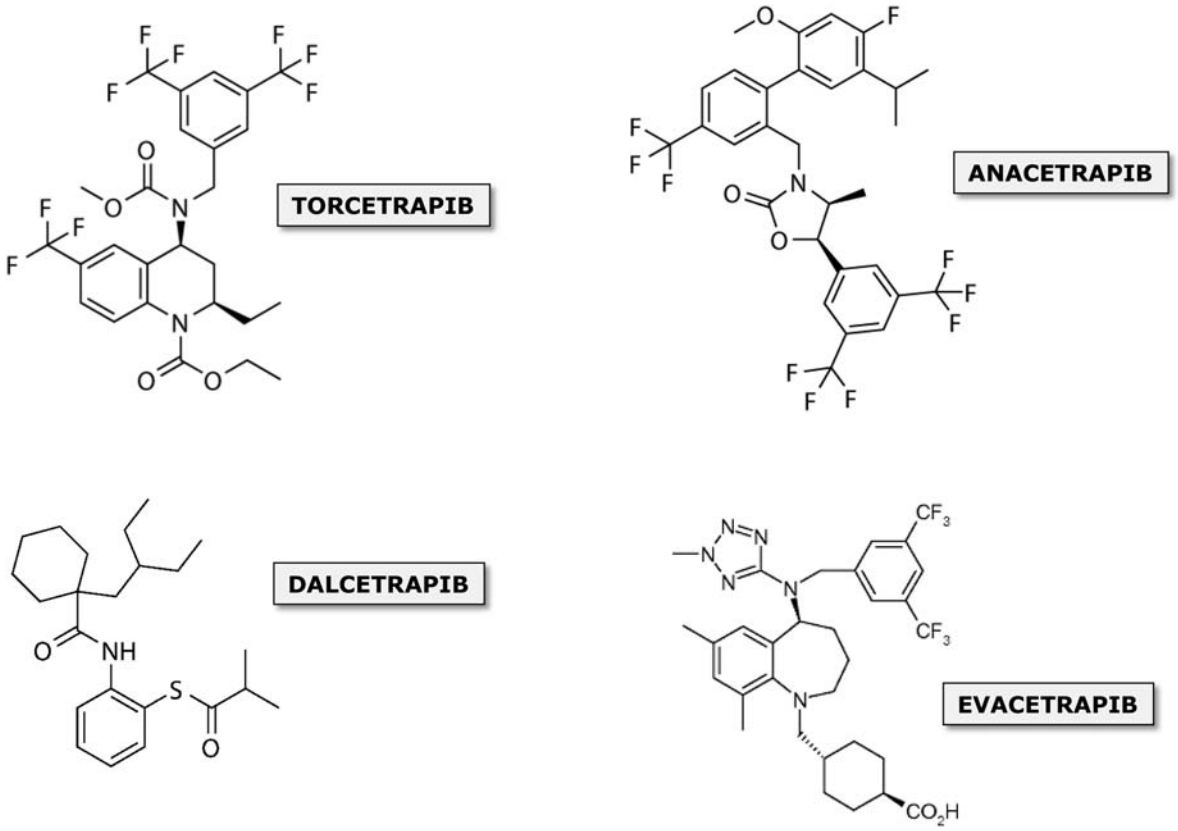

Fig. 7 Structure of CETP inhibitors.

(coronary death, MI, and coronary revascularization procedures) in 30,000 patients with CHD, cerebrovascular atherosclerotic disease, or peripheral artery disease and is estimated to end in 2017.

Anacetrapib has also been tested in patients with HeFH in the phase 3 *REALIZE* study (NCT01524289) that was designed to evaluate the tolerability and efficacy of anacetrapib added to current statin therapy for 52 weeks. This study reported a −39.7% reduction in percent change from baseline in LDL-C versus placebo and a significant increase of HDL-C levels (+105.8% vs. +3.7% with placebo)[165] (Table 6).

Evacetrapib. In a phase 2 study, evacetrapib was effective in reducing LDL-C and increasing HDL-C either as monotherapy (−13.6% to −35.9% and +53.6% to +128.8% from baseline, respectively, vs. +3.9% with placebo) or in combination with statins (Table 6).[166] The *ACCELERATE* (*A Study of Evacetrapib in High-Risk Vascular Disease*, NCT01687998) trial, which enrolled a large population (estimated: 12,000) of patients with diagnosis of high risk of vascular disease to evaluate the time to first occurrence of the composite end point of CV death, MI, stroke, coronary revascularization, or hospitalization for unstable angina in patients administered with evacetrapib or placebo, was stopped early because of futility; in fact, evacetrapib failed to reduce major CV events in these patients when compared with placebo, despite a 130% increase in HDL-C and a 37% decrease in LDL-C.[167]

TA-8995. TA-8995 is a new potent CETPi that demonstrated an almost complete inhibition of CETP, resulting in 96–140% increase of HDL-C and 40–53% reduction of LDL-C in healthy subjects, with no evidence of any off-target effects.[168] The *TULIP* (*TA-8995: Its Use in Patients with Mild Dyslipidemia*, NCT01970215) study evaluated the safety and efficacy of TA-8995 alone or in combination with a statin for 12 weeks.[169] In this trial, TA-8995 reduced LDL-C levels by 45.3% and increased HDL-C by up to 179.1%[169]; when given in combination with a statin, LDL-C levels further decreased (39.8–50.2%)[169] (Table 6). Altogether, we cannot draw a firm conclusion and the results from the REVEAL study will provide a definitive answer.

7.18.3.1.6 ETC-1002

ETC-1002 is a dicarboxylic acid derivative (Fig. 8) that inhibits hepatic adenosine triphosphate citrate lyase (ACL) and activates adenosine monophosphate-activated protein kinase (AMPK), two complementary enzymes involved in the metabolism of lipids and carbohydrates.[170] While ETC-1002-free acid activates liver AMPK, hepatocytes also readily convert the parent compound into ETC-1002-CoA thioester, which has been shown to directly inhibit ACL.[170] The inhibition of ACL results in reduced acetyl coenzyme A (CoA) levels, thus inhibiting both fatty acid and cholesterol synthesis; the activation of AMPK results in the inhibitory phosphorylation of HMG-CoA reductase and acetyl-CoA carboxylase as well as in reduced levels of PEPCK and G6Pase.[170]

Table 6 Effect of new CETP inhibitors

CETP inhibitors	*Subjects*	*Duration*	*LDL-C (percent change from baseline)*	*HDL-C (percent change from baseline)*	*Primary end point for ongoing trials*
Anacetrapib					
DEFINE (NCT00685776)[160]	CHD or CHD risk equivalent Well-controlled LDL-C	76 weeks	−39.8% versus placebo	+138.1% versus placebo	
REVEAL (NCT01252953)	History of MI, cerebrovascular disease, PAD, T2DM with CHD	4 years			Occurrence of major coronary events (coronary death, MI, or coronary revascularization procedure) (completion date: 2017)

Nicholls et al.[166]	Low HDL-C or high LDL-C	12 weeks	Monotherapy: −17.6% (30 mg) to −39 8% (500 mg) versus placebo Statin combination: Eva+ Atorva 20, −13.9% versus Atorva 20; Eva+ Simva 40, −11.2% versus Simva 40; Eva+ Rosuva 10, −13.5% versus Rosuva 10	Monotherapy: +56.7% (30 mg) to +131.9% (500 mg) versus placebo Statin combination: Eva+ Atorva 20, +78.5% versus Atorva 20; Eva+ Simva 40, +79.3% versus Simva 40; Eva+ Rosuva 10, +89.5% versus Rosuva 10	
ACCELERATE (NCT01687998)	History of ACS, cerebrovascular disease, PAD, T2DM with stable CAD	4 years			Time to first occurrence of major CV events (CV death, MI, stroke, coronary revascularization, or hospitalization for UA) (completion date: 2016)
TA-8995					
TULIP (NCT01970215)[169]	Mild dyslipidemia	12 weeks	−27.4% to −45.3% (1-10 mg)	+75.8% to +179.0% (1-10 mg)	

CHD, coronary heart disease; *MI*, myocardial infarction; *PAD*, peripheral artery disease; *T2DM*, type 2 diabetes mellitus; *HeFH*, heterozygous familial hypercholesterolemia; *CAD*, coronary artery disease; *ACS*, acute coronary syndrome; *Atorva*, atorvastatin; *Simva*, simvastatin; *Rosuva*, rosuvastatin; Eva, evacetrapib.

ETC-1002 treatment thus results in the reduction of LDL-C and glucose levels. In addition, ETC-1002 possesses anti-inflammatory properties, attenuates leukocyte homing at inflammatory sites, and inhibits adipose tissue inflammation[171] (Fig. 8).

ETC-1002 has been tested in three doses (40, 80, and 120 mg) in 133 subjects with hypercholesterolemia (LDL-C 130–220 mg dL^{-1} and 3.3–5.6 mmol L^{-1}) stratified by baseline normal or elevated TG levels (A Study to Assess the Efficacy and Safety of ETC-1002 in Subjects with Elevated Blood Cholesterol and Either Normal or Elevated Triglycerides, NCT01262638).[172] After 12 weeks of treatment, ETC-1002 significantly reduced LDL-C levels compared with placebo (from −17.9% to −26.6%), independently of baseline TG levels; reduced non-HDL-C, apoB, and LDL particle number in a dose-dependent manner; and was generally safe and well tolerated.[172] A trend in the reduction of high-sensitivity C-reactive protein (hs-CRP) was observed particularly in subjects with higher baseline hs-CRP values.[172] Similar effects were also observed in subjects with type 2 diabetes mellitus and hypercholesterolemia (NCT01607294): ETC-1002 lowered LDL-C levels by 43% and reduced hs-CRP.[173] ETC-1002 has also been tested in hypercholesterolemic patients with a history of statin intolerance (NCT01751984), showing that TC, LDL-C, non-HDL-C, and apoB were significantly decreased by 8-week ETC-1002 treatment compared with placebo (difference from placebo: −18.4%, −28.7%, −20.9%, and −15.3%, respectively).[174] Among the patients in the ETC-1002 treatment arm who were not at LDL-C target 62% reached their goal at the end of the study, while no patients in the placebo arm reached the LDL-C target.[174] Patients treated with ETC-1002 experienced muscle-related adverse events in a percentage similar to those treated with placebo,[174] suggesting that ETC-1002 might be a valuable alternative to statins

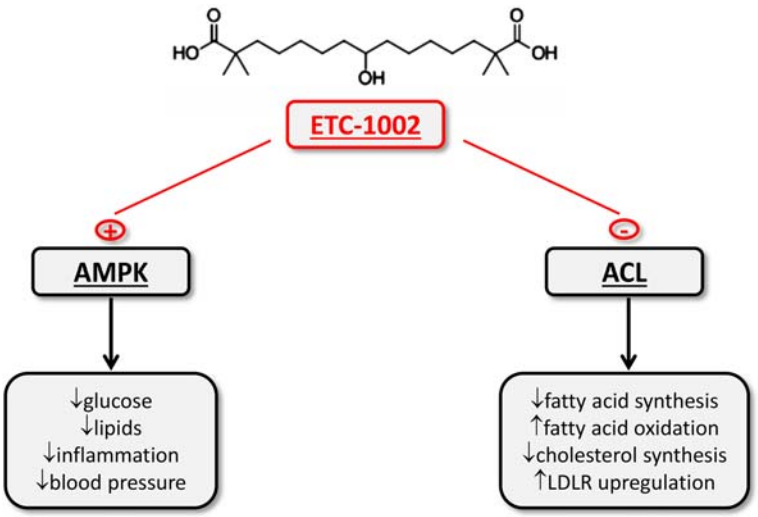

Fig. 8 Dual mechanism of action of ETC-1002. ETC-1002 activates AMP-activated protein kinase (AMPK), thus favorably impacting several metabolic processes, including glucose and lipid metabolism, as well as inflammation. On the other hand, ETC-1002 inhibits ATP citrate lyase (ACL), resulting in the decrease of cholesterol biosynthesis and upregulation of LDLR.

in patients with statin intolerance or as add-on therapy in patients unable to reach LDL-C target despite statin treatment. Future large trials are warranted to confirm these findings.

7.18.3.2 Targeting Plasma TG Levels

High levels of plasma TG are an independent risk factor for atherosclerosis and related CV diseases [175–177]; increased TG levels are usually associated with low HDL-C levels and increased small dense LDL,[178] referred to as atherogenic dyslipidemia.[179] In addition, severe HTG (TG levels $\geq$500 mg dL^{-1} and $\geq$5.65 mmol L^{-1}) significantly increases the risk of acute pancreatitis.[180,181] Thus, several drugs have been developed for the management of HTG, including fibrates, nicotinic acid, and omega-3 polyunsaturated fatty acids. However, new approaches for the management of HTG are now under evaluation.

7.18.3.2.1 Omega-3 free fatty acids

Among the available drugs for the treatment of HTG, there are omega-3 polyunsaturated fatty acids, usually a mixture of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) or EPA alone in their ethyl ester forms. However, to be absorbed in the intestine, the ethyl ester omega-3 polyunsaturated fatty acids need be converted into free acid by pancreatic lipase enzymes.[182] The most recent free fatty acid formulation (Epanova, containing 55% EPA and 20% DHA) is not dependent on pancreatic enzyme activity and is more readily absorbed, even in the condition of a very low fat diet.[182]

The pharmacokinetic parameters of a single dose of omega-3 free fatty acid formulation have been evaluated in comparison with the omega-3 ethyl esters in the *ECLIPSE* (*Epanova® Compared to Lovaza® in a Pharmacokinetic Single-Dose Evaluation*, NCT01208961) study in overweight adults.[183] Under a low fat diet, both EPA and DHA in the free fatty acid form had a higher bioavailability compared with the ethyl ester (ninefold and twofold, respectively).[183] Higher plasma levels of EPA and DHA were found in subjects taking the free fatty acid forms for 14 days compared with subjects taking the ethyl ester form (*ECLIPSE II*), and TG levels were reduced to a greater extent with the free fatty acid form (−21% and −8%, respectively, $P=0.013$),[184] suggesting that omega-3 free fatty acids provide more EPA and DHA under low fat diet conditions, thus resulting in a greater effect on plasma TG levels.

In subjects with severe HTG (TG: $\geq$500 and $\leq$2000 mg dL^{-1}; $\geq$5.65 and $\leq$22.60 mmol L^{-1}) treated with three dosages of 2, 3, and 4 g day^{-1} for 12 weeks in the double-blind, randomized *EVOLVE* (*Epanova for Lowering Very High Triglycerides*, NCT01242527) trial,[185] fasting TG levels were significantly reduced with all doses compared with controls (−25.9%, −25.5%, and −30.9% with 2, 3, and 4 g day^{-1}, respectively, vs. −4.3% of olive oil 4 g day^{-1})[185] (**Table 7**). Despite significant lowering of TC and non-HDL cholesterol, a significant increase of LDL-C was observed (+19.2%, +14.3%, and +19.4% vs. +3.0%) without a concomitant increase of apoB levels,[185] suggesting that the treatment did not increase the number of circulating atherogenic particles. VLDL-C and RLP-C were also significantly reduced in all treatment groups[185] according to the results obtained in studies with the omega-3 ethyl ester formulation[186,187]; also, apolipoprotein C-III (apoC-III) was significantly reduced (−11%, −12%, and −14%, respectively, vs. +1.6%).[185] The analysis of subgroups revealed that high-risk patients with diabetes or baseline TG $\geq$750 mg dL^{-1} ($\geq$8.47 mmol L^{-1}) or the highest tertile of apoC-III or RLP-C may particularly benefit from the treatment with the omega-3 free fatty acid formulation as they reported the most significant reductions in TG and non-HDL-C levels.[188]

The efficacy of free fatty acid formulation of omega-3 as an adjunct to statin therapy and low diet was proved also in high CV risk patients treated with statin and with persistent HTG ($\geq$200 and $<$500 mg dL^{-1}; $\geq$2.26 and $\leq$5.65 mmol L^{-1}) in the *ESPRIT*

Table 7 New TG-lowering drugs

	Subjects	*Duration*	*TG (percent change from baseline)*	*apoC-III (percent change from baseline)*	*Primary end point for ongoing clinical trials*
Omega-3 FFA					
EVOLVE, NCT01242527[185]	HTG	12 weeks	−25.9% (2 g) to −30.9% (4 g)	−10.9% (2 g) to −14.4% (4 g)	
ESPRIT, NCT01408303[189]	Statin-treated patients with residual HTG	6 weeks	−14.6% (2 g) to −20.6% (4 g)		
STRENGTH, NCT02104817[190]	High CVD risk	5 years			Time to the first occurrence of major adverse CV events (completion date: 2019)
ISIS-APOCIIIRx					
Gaudet et al.[200]	FCS	13 weeks	−56% to −86%	−71% to −90%	
NCT01529424[201]	Severe or uncontrolled HTG	13 weeks	Monotherapy: −31.3% (100 mg) to −70.9% (300 mg) Add-on to fibrate: −51% (200 mg) to −64% (300 mg)	Monotherapy: −40.0% (100 mg) to −79.6% (300 mg) Add-on to fibrate: −60.2% (200 mg) to −70.9% (300 mg)

COMPASS (NCT02300233)	HTG	26 weeks			Percent change in fasting TG from baseline (completion date: 2016)
Pradigastat					
NCT01146522[207]	Hyperlipidemia type I or type V	3 weeks	Fasting TG: −41% (20 mg) to −70% (40 mg) Peak postprandial TG: −38% (20 mg) to −31% (40 mg)		
NCT01514461	FCS	12 weeks	−28.8% (20 mg) −40.9% (40 mg)		

HTG, hypertriglyceridemia; *CVD*, cardiovascular disease; *FCS*, familial chylomicronemia syndrome.

(*Epanova Combined with a Statin in Patients with Hypertriglyceridemia to Reduce Non-HDL Cholesterol*, NCT01408303) trial.[189] TG levels were significantly decreased (−14.6% and −20.6% with 2 and 4 g day^{-1}, respectively) compared with controls (−5.9%, statin + olive oil 4 g day^{-1}) (Table 7); other lipid parameters, including TC, non-HDL-C, and VLDL-C, were significantly improved.[189] Such reductions were higher in patients taking high-potency statins.[189]

The ongoing STRENGTH (*A Long-Term Outcomes Study to Assess Statin Residual Risk Reduction with Epanova in High Cardiovascular Risk Patients with Hypertriglyceridemia*, NCT02104817) trial will evaluate the efficacy of omega-3 free fatty acid formulation in addition to statin therapy in high-risk subjects in the prevention and reduction of major CV events[190] and has as primary outcome the time to the first occurrence of CV death, nonfatal MI, nonfatal stroke, coronary revascularization, or hospitalization for unstable angina (Table 7). The eligible patients that will be in the study for up to 5 years have controlled LDL-C levels ($\leq$100 mg dL^{-1}) but with residual atherogenic dyslipidemia (TG: $\geq$200 and $\leq$500 mg dL^{-1}; HDL-C <40 mg dL^{-1} for men and <45 mg dL^{-1} for women).

Overall, the free fatty acid formulation of EPA and DHA is well tolerated, and the most common adverse effects are mild to moderate gastrointestinal disorders[183–185,189]; in addition, its higher bioavailability may allow treatment with lower doses, thus likely increasing the drug compliance. Whether the lipid-lowering effect of free fatty acid EPA and DHA can translate into a CV benefit remains to be addressed.

7.18.3.2.2 Alipogene tiparvovec

Lipoprotein lipase deficiency (LPLD) is a rare autosomal recessive disease caused by loss-of-function mutations of *LPL* gene and is characterized by hyperchylomicronemia, severe HTG, and high risk of diabetes mellitus and recurrent, acute pancreatitis.[191] Alipogene tiparvovec is the first adeno-associated virus-mediated gene therapy approved for the treatment of LPLD[192]; in fact, the intramuscular administration of alipogene tiparvovec delivers a natural gain-of-function variant of LPL that results in a significant improvement of TG-rich lipoprotein characteristics and relevant reduction in the incidence of pancreatitis.[191] In the initial 12-week study performed in LPLD patients with baseline TG levels >14 mmol L^{-1}, the injection of a single alipogene tiparvovec dose induced local LPL expression and significant but transient reduction of TG levels (27–41%).[193] In an open-label clinical trial,

intramuscular administration of alipogene tiparvovec resulted in a significant improvement of postprandial chylomicron metabolism in LPLD patients, without changes in postprandial nonesterified fatty acids.[194] Overall, there was a reduction in the risk of pancreatitis after up to 6 years follow-up after gene therapy.[191] Alipogene tiparvovec was well tolerated; however, LPLD being a rare disease, it is very difficult to undertake clinical trials to define the safety and efficacy of this therapeutic approach.

7.18.3.2.3 ISIS-APOCIIIRx

apoC-III is a glycoprotein mainly associated with VLDL and chylomicron and, to a lesser extent, with HDL; it plays a critical role in the metabolism of TG-rich lipoproteins as it acts as potent inhibitor of lipoprotein lipase (and, when present at high concentrations, of hepatic lipase) but is also involved in the hepatic VLDL assembly and secretion.[195] apoC-III plasma levels are independently associated with the progression of CV disease[195]; loss-of-function variants of *APOC3* gene are associated with low TG levels and reduced risk of ischemic CV disease.[196,197] Several drugs used for the treatment of HTG also reduce apoC-III levels, including fibrates, peroxisome proliferator-activated receptor agonists, and omega-3 polyunsaturated fatty acids.[195] However, these drugs may decrease apoC-III levels by only 10–30%, while larger apoC-III reductions seem to be required to observe a clinical benefit similar to that reported in subjects carrying genetic mutations in *APOC3*.[196,197]

ISIS-APOCIIIRx is a second-generation 2′-*O*-(2-methoxyethyl)-modified ASO that inhibits the hepatic synthesis of apoC-III (Fig. 4). In healthy human volunteers without HTG, ISIS-APOCIIIRx induced a dose-dependent and prolonged reduction of apoC-III and TG levels.[198] In the multiple-dose phase, healthy subjects were treated for 22 days with six total doses of 50, 100, 200, or 400 mg ISIS-APOCIIIRx, showing median percentage reductions of apoC-III levels from baseline to 19.7%, 17.3%, 70.5%, and >77%, respectively, associated with dose-dependent reductions of TG levels (from −19.5% to 43.8%).[198]

ISIS-APOCIIIRx was also tested in three patients with familial chylomicronemia syndrome (FCS), a rare autosomal recessive disease caused by mutations in the gene encoding LPL or genes encoding proteins involved in LPL function, and characterized by high levels of plasma chylomicrons and severe HTG, with a high risk of recurrent acute pancreatitis.[199] After a 13-week treatment, ISIS-APOCIIIRx significantly reduced apoC-III (71–90%) and TG levels (56–86%)[200] (Table 7). Reductions of TG levels in chylomicrons, apoB-48 levels, and non-HDL-C were also reported; the reduction of non-HDL-C was due to the reduction of chylomicron/VLDL cholesterol, while LDL-C levels that were extremely low at baseline (13–17 mg dL^{-1}) resulted unchanged or increased (up to 35.5 mg dL^{-1}).[200]

In the phase 2 randomized trial, ISIS-APOCIIIRx was given once weekly for 13 weeks to patients with severe or uncontrolled HTG, having fasting TG between 350 and 2000 mg dL^{-1} (4.0–22.6 mmol L^{-1}), and to patients on stable fibrate therapy having fasting TG levels between 225 and 2000 mg dL^{-1} (2.5–22.6 mmol L^{-1}) (NCT01529424). Both groups showed significant reductions of plasma apoC-III and TG levels either when the drug was administered as monotherapy or when it was administered as add-on to stable fibrate therapy[201] (Table 7). The large decrease of TG resulted in a dose-dependent increase of LDL-C levels following the treatment with ISIS-APOCIIIRx, associated with increases in apoB levels and LDL particle size[201]; despite this, non-HDL-C was unchanged.[201] This effect on LDL-C levels may be due to the increased conversion of VLDL to LDL determined by the increased activity of LPL, but other mechanisms may contribute as well. The clinical significance of this increase requires further investigation.

Two ongoing phase 3 trials, the *APPROACH* (*The APPROACH Study: A Study of ISIS-APOCIIIRx in Patients with Familial Chylomicronemia Syndrome*, NCT02211209) and *COMPASS* (*The COMPASS Study: A Study of ISIS-APOCIIIRx in Patients with Hypertriglyceridemia*, NCT02300233) trials, will evaluate the efficacy and safety of ISIS-APOCIIIRx. The APPROACH trial will recruit patients with a history of chylomicronemia and a diagnosis of FCS and fasting TG levels ≥750 mg dL^{-1} (8.4 mmol L^{-1}) who will be treated with 300 mg ISIS-APOCIIIRx administered subcutaneously once weekly for 52 weeks versus placebo. The COMPASS trial will recruit HTG patients with fasting TG ≥500 mg dL^{-1} (≥5.7 mmol L^{-1}) who will be administered 300 mg ISIS-APOCIIIRx versus placebo subcutaneously once weekly for 26 weeks. Both trials have as primary outcome the percent change in fasting TG from baseline.

7.18.3.2.4 Diacylglycerol O-acyltransferase inhibitors

TGs are synthesized in enterocytes and hepatocytes and then assembled into lipoproteins and secreted to transport dietary and endogenous fatty acids. TGs are essential for several functions, among which energy storage and membrane composition represent the most important. However, excess TGs are associated with obesity, insulin resistance, nonalcoholic steatohepatitis, and CV disease.[202]

Diacylglycerol *O*-acyltransferase (DGAT) enzymes catalyze the formation of an ester linkage between a fatty acyl-CoA and diacylglycerol. The two enzymes DGAT1 and DGAT2, encoded by two different genes not sharing significant sequence homology, have a different subcellular localization and are differently regulated, suggesting that they likely participate in different pathways of TG synthesis and thus have distinct physiological functions.[202] DGAT2 seems thus to be involved in the incorporation of endogenously synthesized monounsaturated fatty acids into TG, while DGAT1 appears to be involved in the esterification of exogenous fatty acids taken up by cells.[202]

Mice lacking DGAT1, although capable of synthesizing TG (indicating the existence of alternative mechanisms for TG synthesis), have reduced body TG content and are resistant to diet-induced obesity,[203] while mice lacking DGAT2 have severe lipopenia and die soon after birth [204]; this suggests that DGAT1 and DGAT2 play different roles and that DGAT2 plays an essential role in the synthesis of TG in mammals and is required for survival, while DGAT1 is not. Based on these observations, it has been hypothesized that the pharmacological inhibition of DGAT1 could be an attractive way to control HTG. Several preclinical models have shown that treatment with DGAT1 inhibitors inhibits postprandial plasma TG excursion after a lipid challenge and, when administered chronically, metabolic parameters are improved.[205]

Pradigastat in healthy volunteers suppressed postprandial TG in a dose-dependent manner and reduced postprandial chylomicron numbers (as determined by the apoB-48 reduced levels).[206] The DGAT1 inhibitor pradigastat has been tested in six patients with FCS (NCT01146522), who underwent three consecutive 3-week treatment periods (20, 40, and 10 mg, respectively) separated by 4-week washout periods.[207] Pradigastat 20 and 40 mg reduced plasma TG by 41% and 70%, respectively, in FCS patients, while the lowest dose was ineffective (**Table 7**). More specifically, it mainly reduced the size and TG content of secreted chylomicrons[207] that in FCS transport almost all plasma TG (contrarily to healthy subjects that present their fasting TG almost completely in VLDL, while postprandial TG are equally shared between VLDL and chylomicrons). In a phase 3 study (NCT01514461), a −28.8% with 20 mg and −40.9% with 40 mg pradigastat versus placebo was reported after a 12-week treatment in FCS patients (**Table 7**). When tested in obese patients with type 2 diabetes mellitus in a 2–20 mg dose range (NCT00901979), pradigastat had beneficial effects on several metabolic parameters, including TG, LDL-C, TC, and body weight.[208]

7.18.3.3 Conclusions

Several novel therapeutic approaches have been investigated in the last few years with the aim of reducing plasma cholesterol and TG levels. For cholesterol, with the most potent statins, we have reached a highly effective inhibition of cholesterol biosynthesis in the liver; therefore, from a pharmacological perspective, the development of novel strategies has been focused on different mechanisms of action, including the inhibition of cholesterol absorption in the intestine (ezetimibe), the inhibition of lipoprotein synthesis (lomitapide and mipomersen), and the improvement of lipoprotein catabolism (PCSK9 inhibitors). In FH patients, clinical trials of these new compounds were proved to be successful in decreasing plasma cholesterol levels and reducing the burden of CV diseases.

7.19.1 General Overview

End-stage organ damage is typically associated with fibrosis. The fibrotic event leads to disruption of the normal architecture of a wide variety of tissues, which ultimately leads to organ dysfunction and failure. Fibrotic diseases pose one of the most serious health problems in current medicine and represent a series of economic burden to the health system. It has been estimated that as much as 45% of the mortality worldwide are attributed to fibrosis.[1] Multiple studies examining pathways and targets have grown over the years. However translation of these findings to clinical studies has remained a challenge in the area of pharmaceutical research. In this review we will provide an overview of the events leading to the fibrotic state in multiple tissues and end-stage organ damage. Several examples will be outlined in this article including fibrosis of the lung as in idiopathic pulmonary fibrosis (IPF); fibrosis of the liver as in nonalcoholic steatohepatitis (NASH) and liver cirrhosis; and fibrosis of the kidney characteristic of chronic kidney disease (CKD). Furthermore we will describe the underlying molecular pathways associated with these events as well as the multiple pharmacological agents identified for these targets currently at various stages of clinical development.

Although the etiology of fibrosis varies from organ to organ, similar pathology is observed across multiple tissues. As illustrated (Fig. 1), the cellular events that lead to the hallmark characterization of a fibrotic tissue are relatively well understood.[2] Fibrotic disorders are characterized by common, persistent, and chronic inflammation which is initiated by injury to the epithelium and the endothelium. Dysregulation of metabolic pathways including endoplasmic reticulum (ER) and cellular stress, and overproduction of reactive oxygen species (ROS) are some of the common causes of epithelium/endothelium injury. Regardless of the cause, persistent injury eventually leads to activation and migration of inflammatory cells such as T-cells, macrophages, and granulocytes to the site of injury. Production of cytokines and chemokines in turn further activates the macrophages and fibroblasts. The fibrotic event is characterized by increased and persistent production of extracellular matrix (ECM). The primary cells responsible for ECM productions are the alpha smooth muscle actin (α-SMA)-expressing myofibroblasts which are derived from local fibroblasts or from mesenchymal cells. Other cells that contribute to the formation of ECM include fibrocytes which are cells derived from bone marrow[3] as well as epithelial cells, which may undergo epithelial–mesenchymal transition (EMT).[4] The amount of collagen deposition is regulated by the rate of collagen synthesis and breakdown. The kinetics of collagen production is controlled by metalloproteases MMPs and MMP inhibitors (TIMPs). During a fibrotic event, the synthesis of new collagen by fibroblasts exceeds the rate at which it is degraded leading to increased collagen accumulation.[5] The most abundant collagen subtypes are collagen type I and collagen type III, although there are other subtypes which are involved in the process. The secreted collagen gets cross-linked by a family of enzymes called lysyl oxidases such as lysyl oxidase-like 2 (LOXL2) to form abnormal ECM. Deposition of ECM will lead to remodeling, disruption of the normal architecture, and eventually organ failure. This process of uncontrolled fibrosis is different from controlled repair occurring during normal wound healing.[6]

In the last couple of decades the pharmaceutical and biotech industries become increasingly interested in targeting key components in the fibrotic core pathways. One area of focus has been targeting the transforming growth factor beta (TGF-β), which is considered to be the main cytokine in all fibrotic events. Various approaches have been taken to target TGF-β either directly or

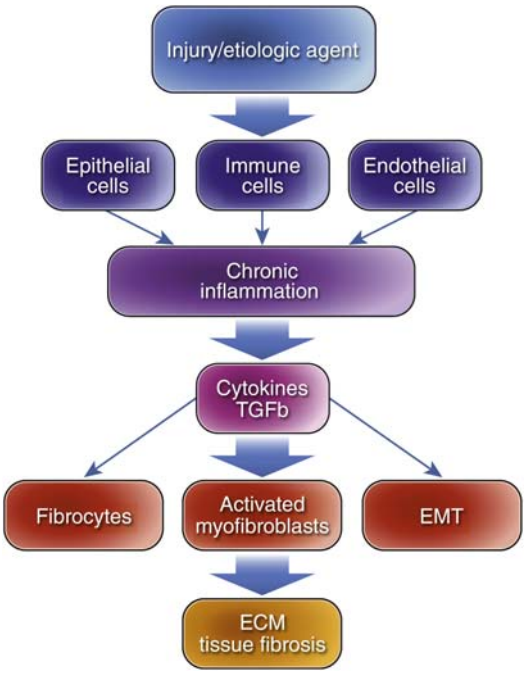

Fig. 1 Disease progression of tissue fibrosis.

indirectly by targeting pathways associated with its activation and regulation. TGF-βs are secreted cytokines, which are synthesized as part of a large molecule, the pro-TGF-β containing the latency-associated proteins. The release of TGF-β from the pro-TGF-β complex can be achieved through several processes.[7] The main process by which TGF-β is activated is thought to be through the RGD-containing integrins.[8] Other mechanisms include proteolytic activity by plasmin, matrix-metalloproteinases, treatment with mild acids,[9] or through the action of thrombospondin.[10] Once TGF-β is activated it can bind to its receptor TGF-β R2 and ALK5 (TGF-β receptor-1).[11] These are the type I and type II Ser/Thr kinase receptors which form a heterodimer upon ligand binding. Once the complex is formed, it propagates signaling by phosphorylating SMAD3 which then forms a complex with SMAD4. Upon dimerization, the complex translocates to the nucleus where it binds to key DNA response elements to transcriptionally control target genes involved in fibrogenesis.[11]

Although our understanding of the process and the mechanisms by which fibrosis is formed has grown, most chronic fibrotic diseases remain poorly treated. The very first approval of antifibrotic drugs pirfenidone and nintedanib in 2014 provided insight into clinical development path for IPF. Other pharmacological and biological agents discussed in this article are in various stages of preclinical and clinical development for multiple indications related to IPF and other fibrotic diseases. It is well accepted that diseases like IPF, NASH, CKD, etc. share common molecular pathways. This concept led to the speculation that IPF could serve as a clinical proof of concept (POC) and an entry point for other indications. The concept of targeting key core fibrotic pathways is reasonable; however, it has yet to be demonstrated that the same mechanisms have similar effect across tissues independent of the underlying injury. Furthermore, the notion that those pharmacological blockages of fibrosis pathways will be efficacious in preventing or slowing down end-stage organ failure remains to be proven in the clinic. In the next several years the field is anticipated to continue growing. Increased efforts in preclinical model development, pathway mining, and basic mechanistic work around cellular signaling will provide insight into the underlying biology of the fibrotic diseases. In addition, the outcome of multiple clinical development programs that are ongoing will shed light into some of these questions.

7.19.2 Idiopathic Pulmonary Fibrosis

7.19.2.1 Introduction

IPF is a life-threatening and devastating disease, and there is no cure available. The median survival is 3–5 years from the time of diagnosis.[12] IPF is the most severe form of interstitial lung disease (ILD) and occurs in 20–30% ILD patients,[13–15] predominantly in adults who are 50–85 years old. IPF patients universally develop dyspnea from progressive ventilatory restriction and hypoxia, and respiratory failure is the most common cause of death (~60%).[16,17] The disease course of IPF is unpredictable, and up to 20% IPF patients experience acute exacerbation, which results in a hospital mortality of at least 50%.[18,19]

7.19.2.2 Epidemiology

In the United States, the prevalence of IPF is 14.0–27.9 cases per 100,000 people, and the annual incidence is estimated to be 6.8–8.8 cases per 100,000 people. In Europe, the prevalence is 1.25–23.4 cases per 100,000 people, and the annual incidence is estimated to be 0.22–7.4 cases per 100,000 people. In Asia the prevalence is 1.7–4.9 cases per 100,000 people, and the annual incidence is 0.9–2.23 cases per 100,000 people.[13,19–31] Distribution of IPF across two genders is uneven, and more men than women are affected and the ratio is estimated to be 1.5:1.[32] Overall, evidences suggest that the prevalence and annual incidence of IPF are increasing, particularly among the elderly (>65 years old), with the estimation that 1 in 1000 will develop IPF.

Among all the IPF patients, 1–4% of IPF patients have a family history of IPF and the symptoms seem to present at younger ages.[33–36] Recent studies suggested that genetic factors, such as polymorphisms around the genes MUC5B, SPA, SPC, SPPL2C, TERT, and TOLLIP, are associated with IPF.[37–45] Environmental risk factors for IPF include cigarette smoking, exposure to organic and inorganic dusts, pharmacologic therapies, and microbial agents such as Epstein–Barr virus. Despite those reported genetic and nongenetic associations, the specific roles of those risk factors and how they interact with each other in the course of the disease are still largely unknown.

7.19.2.3 Pathophysiology

The exact cause of IPF is not completely understood. It was initially believed that inflammation was the leading cause of IPF, but with the failure of multiple trials involving immunosuppressive agents, particularly the PANTHER-IPF trial (prednisolone, azathioprine, and *N*-acetylcysteine combo therapy for IPF),[46] the focus has been shifted to fibrosis.

Histologically, IPF lungs show marked fibrosis with architectural distortion and honeycombing distributed along the inferior portions of the lobes with subpleural accentuation. Unlike other lung diseases, inflammation is very limited in IPF lungs. Epithelial damage is now thought to be the initiator of fibrogenesis in IPF. In a normal setting, alveolar type 2 lung epithelial cells come into injured site to repair lung epithelium once there is damage. However, if there is a recurrent or persistent damage to lung epithelial cells, these cells will initiate proliferation, migration, and activation of fibroblast cells or other fibrosis progenitor cells such as fibrocytes to the damage site.[47] Epithelial cells can also undergo a process called EMT and acquire a fibroblast-like phenotype, becoming mobile and expressing mesenchymal proteins and type I collagen while losing epithelial markers such as E-cadherin.[48] However, it still remains to be determined how much the EMT process contributes to the fibrotic process.[49] Activated

fibroblast cells or myofibroblast cells are responsible for excessive deposition of collagen and formation of fibrotic foci, a hallmark feature of IPF histology. Stiffening of lung tissue caused by accumulation/cross-linking of collagen and other ECM components will ultimately damage the delicate structure of the alveolar spaces and result in poor gas exchange and difficulty in breathing and death.[50]

At the molecular level, genetic mutations or exposure to environmental risk factors induce ER stress in lung epithelial cells, which triggers release of profibrotic factors, such as TGF-β1,[51,52] platelet-derived growth factor (PDGF),[53,54] connective tissue growth factor (CTGF),[55] and cytokines including interleukin-4 (IL-4) and interleukin-13 (IL-13).[56,57] TGF-β1 is thought to be the master regulator of fibrosis. Direct activation of fibroblast cells by TGF-β1 causes overexpression of ECM proteins as well as TGF-β1 itself. TGF-β1 can also induce EMT of epithelial cells, which serves as a feed-forward mechanism to activate more surrounding fibroblast cells. In contrast, secretion of PDGF by epithelial cells induces proliferation but not activation of fibroblast cells. In addition to these two major players, many other secreted factors, such as Wnt proteins,[58–60] have potential roles in IPF. It is currently well appreciated that IPF is caused by a cascade of events involving the crosstalk between epithelial cells and fibroblast cells through secreted factors. Other than the cell-secreted growth factors, chemokines, and cytokines, ECM components also contribute to fibrosis by modulating fibrotic signaling. It has been demonstrated that fibroblast cells are subject to regulation by mechanical cues. Stiffening of ECM due to excessive collagen deposition and cross-linking induces reorganization of cytoskeleton network in fibroblast cells through integrins, which then provides cues to transdifferentiate fibroblast cells into myofibroblast cells through mechanotransducers such as YAP and TAZ.[61] Other ECM components such as lumican, hyaluronan, or even endostatin, a breakdown product of collagen XVIII, are also implicated in modulation of fibroblast activation.[62] Overall, IPF is a result of complex interplay between multiple cell types engaging both intracellular and extracellular mechanisms.

7.19.2.4 Experimental Animal Models

The common animal models used for the study of IPF include chemically induced models, such as asbestos, bleomycin, silica, or fluorescein isothiocyanate-induced lung fibrosis models; irradiation-induced lung fibrosis model; age-dependent fibrosis models, genetically modified mouse lung fibrosis models; and humanized mouse models.

Among all the models, the bleomycin model has been the most commonly applied model over the past few decades, and intratracheal delivery of bleomycin is the most common delivery route. In this model, fibrosis happens in a short period of time (2–4 weeks). Disease progression in the bleomycin model can be separated into two phases, the inflammation phase and the fibrosis phase. In the inflammation phase, a bleomycin insult creates DNA damage, generates free radicals, and induces oxidative stress, which causes cell necrosis and apoptosis and ultimately tissue edema and inflammation, with elevation of cytokines such as tumor necrosis factor alpha (TNF-α) and interleukin 1 beta. After the first week, inflammation subsides and fibrosis starts its course, and by approximately day 14, the expression of TGF-β1 peaks and collagen deposits resembling IPF fibrosis becomes prominent.[63–65] Despite its popularity, bleomycin model using a single dose is not fully consistent with human IPF histologically due to the obvious lack of fibroblastic loci and epithelium hyperplasia. It was suggested that repetitive dosing of bleomycin induces histopathologic changes reminiscent of those seen in IPF patients. Nevertheless, efficacy of the FDA approved drugs pirfenidone (Esbriet) and nintedanib (Ofev) in rodent bleomycin models (mouse, rat, and hamster) has been successfully translated into clinic.

Each animal lung fibrosis model has its own advantages and disadvantages. When evaluating outcomes of any of the models, one must ensure that collagen deposition truly reflects fibrosis. Some appropriate assays include biochemical quantification of collagen using Sircol collagen assay, hydroxyproline assay, or Western blotting of fibrosis markers such as collagen and α-SMA, and histologic evaluation of total collagen or collagen subtypes and other markers such as α-SMA. Alternatively, isotope-guided analysis of newly synthesized ECM proteins can be applied to gain a closer look at the dynamics of fibrosis. To complement the biochemical and histologic measurement, lung mechanics can be measured, such as lung compliance values derived from pressure-volume loops. Nevertheless, with the successful translation from rodents to human for the two approved drugs pirfenidone and nintedanib, bleomycin-induced lung fibrosis model will remain as an anchor model for IPF drug development.

7.19.2.5 Current Treatment

Pirfenidone (Esbriet) and nintedanib (Ofev) (**Fig. 2**) are the first agents approved by FDA and other regulatory agencies for treatment of IPF.

Pirfenidone (5-methyl-1-phenyl-2-[1H]-pyridone) is developed as an oral drug. The exact antifibrotic molecular mechanisms of pirfenidone are not well understood. Preclinically, this molecule demonstrated both anti-inflammatory and anti-fibrotic activities in both in vitro and in vivo studies. In vitro, it inhibits the release of pro-inflammatory and pro-fibrotic cytokines and growth factors, as well as inhibiting the proliferation of fibroblasts and synthesis of ECM proteins from fibroblast cells in response to fibrotic growth factors such as PDGF and TGF-β. In vivo, it showed efficacy in multiple bleomycin lung fibrosis models, including mouse, rat, and hamster models.[66–68] Clinically, pirfenidone is indicated for mild and moderate IPF, and the treatment effect of Pirfenidone appears to begin immediately and persist through the course of therapy measured by vital capacity. More importantly, the use of pirfenidone is correlated with improved mortality in IPF patients.[69] The common side effects of pirfenidone include liver enzyme elevation, high photosensitivity, gastrointestinal disorders, nausea, and rash, with some patients having to discontinue treatment in the clinical trials due to severe side effects.

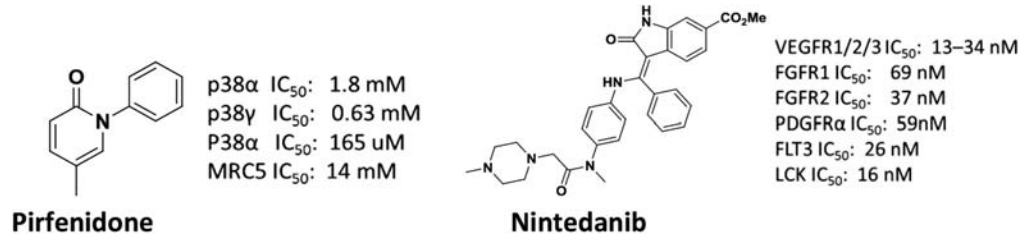

Fig. 2 Pirfenidone and nintedanib: structures and inhibitory activities.

Nintedanib (methyl (3*Z*)-3-{[(4-{methyl[(4-methylpiperazin-1-yl) acetyl]amino}phenyl) amino] (phenyl)methylidene}-2-oxo-2,3-dihydro-1*H*-indole-6-carboxylate) is a small molecule tyrosine kinase inhibitor that is administered orally. It was initially developed as an anticancer drug to treat nonsmall cell lung cancer due to its anti-angiogenesis activity. Nintedanib has inhibitory effect on multiple kinases, including VEGFR, PDGFR, FGFR, Flt-3, Lck, Lyn, and SRC by binding to their ATP binding pocket, and its efficacy on the first 3 kinases is believed to play a role in IPF. It was also shown to inhibit tyrosine phosphorylation of TGF-β receptor type II. Preclinically, nintedanib was able to decrease fibrosis scores, and expression of procollagen and TGF-β1 in both mouse and rat bleomycin lung fibrosis models.[70] Similar findings were reproduced in a silica-induced mouse lung fibrosis model.[70] Due to the broad activity against tyrosine kinases, it is not surprising that nintedanib has a spectrum of adverse effects such as elevation of liver enzymes, gastrointestinal disorders, headache, and weight loss. For nintedanib, there is no evidence to show reduced mortality in IPF patients.[30]

7.19.2.6 Ongoing Clinical Trials

Although pirfenidone and nintedanib have been approved for IPF, the goal of these two therapies is not to cure the disease, but rather stabilize the disease progression. IPF still remains a significant unmet medical need and there is obvious room to improve with respect to drug efficacy and side effects over the long-term treatment. Because of this many companies are spearheading clinical trials with new agents of different mechanisms. Those mechanisms are summarized in **Table 1**.

Other mechanisms being tested in clinical trials are antioxidants, stem cell therapy, immunoglobulin therapy, and others that are unspecified.

7.19.2.7 Emerging Biology and Therapeutic Treatment

Significant advances have been made in our understanding of the pathogenesis of IPF and fundamental biology in tissue fibrosis in the past decade. With this emerging biology, the number of potential targets for IPF has dramatically increased. Other than those

Table 1 Agents on clinical trials for IPF

Modality	*Drug*	*Target*	*Development status*	*Company*
Small molecules	BMS-986020	Lysophosphatidic acid receptor 1 (LPA1R)	Phase II	Bristol-Myers Squibb
	GSK2126458	PI3K–AKT pathway	Phase I	GlaxoSmithKline
	Riociguat	Soluble guanidine cyclase (sGC)	Phase II	Bayer
	TD139	Galectin-3	Phase I/II	Galecto/Bristol-Myers Squibb
Biologics	CNTO 888	CC-chemokine ligand 2 (CCL 2)	Phase II	Centocor
	FG-3019	CTGF	Phase II	FibroGen/Bristol-Myers Squibb
	IW001	Purified collagen V	Phase I	Immuneworks
	Lebrikizumab	Interleukin-13 (IL-13)	Phase II	Roche/Chugai
	Lecithinized superoxide dismutase	Lecithinized superoxide dismutase	Phase II	LTT Biopharma
	PRM-151	Fibrocytes	Phase I	Promedior
	SAR156597	Interleukin-4 (IL-4) and IL-13	Phase I/II	Sanofi
	Simtuzumab	Collagen and lysyl oxidase-like 2 (LOXL2)	Phase II	Gilead
	STX-100	αVβ6 integrin	Phase II	Biogen Idec
	Tralokinumab	IL-13	Phase II	AstraZeneca
Combo	Combined PEX, rituximab and steroids	Combined plasma exchange (PEX), rituximab, and conventional corticosteroid	Phase I/II	University of Pennsylvania

Table 2 Preclinical agents for IPF

Mechanism	*Compound*	*Preclinical validation*
FAK[71]	PF-562271	Bleomycin model
αVβ6[72]	CWHM 12	Bleomycin/CCl_4 model

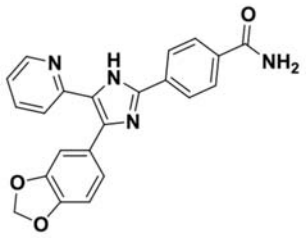
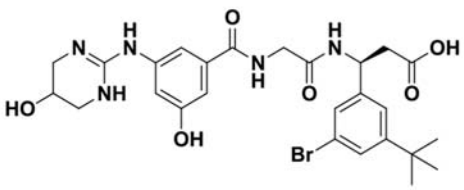
Rho kinase[90]	Y-27632	Bleomycin model

that have already been tested in clinical trials, many more are being explored preclinically (Table 2), many of which can be put into the following categories:

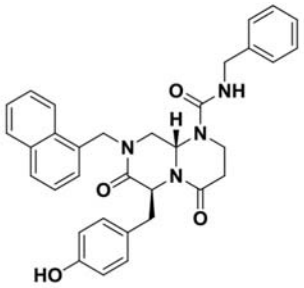
1. TGF-β1 and fibrosis core pathways: TGF-β1 receptor/ALK5 inhibitor, αVβ6 integrin inhibitor, αVβ1 integrin inhibitor, and WNT/β-catenin signaling modulators.



SB-431541 (ALK5 IC_{50}: 94 nM)

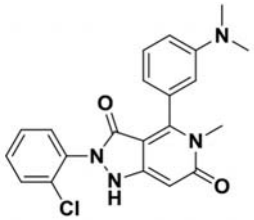


CWHM12 (αvβ6 IC_{50}: 1.5 nM)



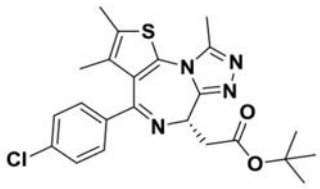
ICG-001 (β-catenin IC_{50}: 3.0 uM)

2. ROS pathway: NOX4 inhibitor and other antioxidants.



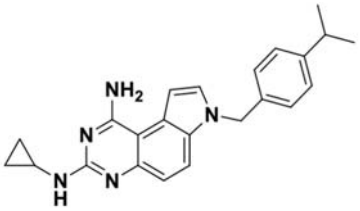
GKT - 137831 (NOX1/4 Ki: 100-150 nM)

3. Epigenetic regulation: miR-21, miR-31, other microRNAs, and BET inhibitor.



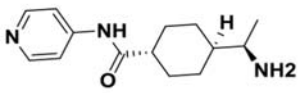
(+) JQ-1 (BRD4 IC_{50}: 33-77 nM)

4. Coagulation pathway: PAR-1 inhibitor and factor Xa inhibitor.

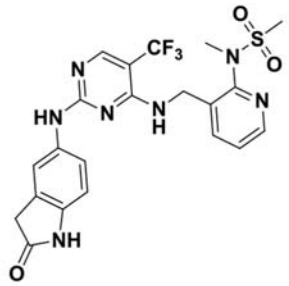


SCH 79797 (PAR1 IC_{50}: 70 nM)

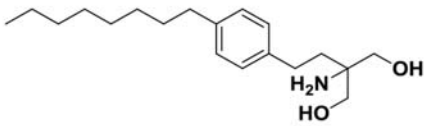
5. Fibroblast/myofibroblast differentiation and migration: Rho kinase inhibitor, FAK inhibitor, TRPV4 inhibitor, Sonic-hedgehog pathway inhibitor, sphingosine kinase inhibitors, and sphingosine-1-phosphate receptor antagonist.



Y-27632 (ROCK1/2 Ki: 0.22/0.3 uM)

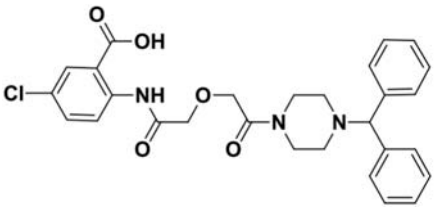


PF-562271 (FAK IC_{50}: 1.5 nM)



Fingolimod (S1PR1/3/4/5 EC_{50} ~ 7-8 nM)

6. Inflammation pathways: NLRP3 inhibitor, PAI1, prostaglandin E2 and EP2 receptor agonist.



TM5275 (PAI1 IC_{50}: 6.95 uM)

7.19.2.8 Concluding Remarks

IPF remains a severe disease with poorer prognosis than most cancers, and no cure is currently available. However, failures of numerous trials focusing on immunosuppression and success of pirfenidone and nintedanib anchoring on antifibrosis have provided guidance for future development of IPF medicine. To date, more than a dozen IPF trials are being actively ongoing and many more novel mechanisms are being tested preclinically. It is to be hoped that in coming years the increased effort around IPF will lead to more choices for patients and physicians who are taking care of them.

7.19.3 Chronic Kidney Disease

7.19.3.1 Introduction

CKD is a major burden on healthcare systems world-wide and represents one of the most prevalent conditions where fibrotic processes are thought to play a pathophysiological role. Renal function is typically defined by glomerular filtration rate (GFR) which is usually estimated from serum concentrations of the freely filtered metabolite creatinine. Albuminuria is a commonly used secondary marker of renal dysfunction. Early stages of CKD (stages 1 and 2) are characterized by mild changes in GFR with attendant albuminuria, whereas later stages of CKD (stages 3 and 4) are associated with more severe decreases in GFR with or without albuminuria. Progression of CKD is typically slow in early stages, due to abundant renal reserve, and is more rapid in later stages. Key accelerants of CKD include diabetes, hypertension, and age, each of which contributes substantially to the risk of developing CKD and progression to end-stage renal disease (ESRD), where dialysis or transplant are required.

7.19.3.2 Epidemiology

In the United States, the overall prevalence of CKD of any stage is 15% of the general population, with 8% of the population at stage 3 or above (CDC website). The incidence rate of CKD stage 3 or above in the United States is estimated to be 10.38 per 1000 person years. Diabetes is the major risk factor for CKD and ESRD in the United States. Around 40% of all diabetics have CKD and diabetes is a contributor to ~40% of all cases of ESRD in the US population.[91] Hypertension was noted as a primary contributor to ~27% of ESRD cases and primary glomerular disease contributed to ~12% of ESRD cases (USRDS). CKD is a major risk factor for cardiovascular disease and patients with low GFR and albuminuria are at 3.2 fold greater risk of cardiovascular events compared to patients with normal renal function.[92] CKD is also a major burden on the healthcare systems, largely due to the high cost of dialysis or kidney transplants once patients progress to end-stage disease. CKD is estimated to cost the US ~$55 billion, and treatment costs for ESRD contribute to 7% of the entire Medicare budget (USRDS). Limited therapeutic options exist for CKD, with ACE inhibitor or angiotensin receptor blocker (ARB) therapy, the only proven treatments to slow the progression of diabetic or hypertensive CKD. Steroids and other immunosuppressive regimens are the primary modalities used to treat primary glomerular diseases such as nephrotic syndrome or focal segmental glomerular sclerosis (FSGS).

7.19.3.3 Pathophysiology

7.19.3.3.1 Features of renal fibrosis (anatomy, histology)

Renal fibrosis is the hallmark and the final common pathway of CKD, regardless of underlying etiology. The pathological finding of renal fibrosis is characterized by progressive tissue scarring including glomerulosclerosis, tubulointerstitial fibrosis, and loss of renal parenchyma (including tubular atrophy, loss of capillaries, and podocytes).[93] Indeed, diphtheria toxin-induced podocyte depletion in rats expressing human diphtheria toxin receptor causes glomerulosclerosis and is linked to progression of glomerular diseases.[94] Imbalance of ECM synthesis over degradation results in excessive accumulation of ECM proteins and fibrosis. Renal fibrogenesis is a dynamic and progressive process mediated by augmented injurious signals, such as profibrotic and proinflammatory pathways, as well as impairment of endogenous protective mechanisms in the kidney. TGF-β is a master regulator of fibrosis and is increased in fibrotic diseases. Cross talk among TGF-β, integrins, and the ECM is implicated in the development and progression of renal fibrosis.[8,95] Interestingly, intersection of profibrotic and metabolic pathways during the progress of renal fibrosis was suggested in a recent intriguing preclinical study, which demonstrated a role for TGF-β in the inhibition of fatty acid oxidation in renal tubular epithelial cells. Correction of defective fatty acid oxidation in tubular epithelial cells may lead to the development of novel therapeutic agents combating kidney fibrosis.[96]

7.19.3.3.2 Evidence for role of fibrosis in CKD progression

Progressive renal fibrosis ultimately leads to ESRD, a devastating disorder that demands new therapies. Preclinically, treatment with low doses of a pan-TGF-β mAb in puromycin aminonucleoside (PAN)-induced CKD model in rats improved renal fibrosis and renal function.[97] Whether antifibrotic mechanisms lead to improvement of renal function in the clinic is still in question. In a study in patients with lupus nephritis (313 patients, follow-up of 61.5 ± 34.9 months), tubulointerstitial fibrosis was found to be a significant independent risk factor predicting renal outcome (free of end-stage kidney disease or serum creatinine doubling).[98] Diabetic kidney disease was traditionally considered primarily a glomerular disease, but it is now accepted that the rate of renal function decline correlates best with the degree of renal tubulointerstitial fibrosis.[99,100] Surprisingly, Lilly's clinical trial testing a TGF-β1 specific antibody (LY2382770, ClinicalTrials.gov Identifier NCT01113801) in patients with diabetic kidney disease failed to show improvement of renal function, which may relate to a narrow therapeutic window or because only the TGF-β1 isoform was targeted (ASN annual meeting, 2014). Pirfenidone, which targets multiple pathways including TGF-β and TNF-α, was recently shown to improve renal function in a small cohort of patients with diabetic kidney disease, suggesting that targeting multiple pathophysiological pathways might increase the probability of clinical success in this patient population.[101]

7.19.3.4 Animal Models of Fibrotic Renal Disease

The common animal models used for the study of renal fibrosis include surgically induced models, such as unilateral ureteral obstruction (UUO) and 5/6th nephrectomy, chemically induced models such as PAN and the aristolochic acid model (AA), as well as genetic models of fibrotic renal disease such as the Col4a1/Alport disease model.

7.19.3.4.1 Unilateral ureteral obstruction

The model of UUO in the rodent produces progressive tubulointerstitial fibrosis, and is useful to examine mechanisms of tubulointerstitial fibrosis in vivo.[102] Complete UUO (by complete ligation of the urethra) initiates a series of pathophysiologic events in the obstructed kidney, resulting in marked renal hemodynamic change, interstitial inflammation (peak at 2–3 days), followed by tubular dilation, tubular atrophy, and progressive tubulointerstitial fibrosis within 2 weeks.[102] The advantages of this model include the following: (1) it can be induced in either rats or mice and shows no specific strain dependence; (2) it is highly reproducible; and (3) the contralateral kidney serves as a control. However, the UUO model in general is a very aggressive renal fibrosis model with the inability to measure changes in renal function. Despite these issues, many putative antifibrotic mechanisms have shown therapeutic potential in the UUO model. For example, deficiency of integrin β6, which locally activates TGF-β in injured tubular epithelial cells, markedly inhibited tubulointerstitial fibrosis in a UUO model.[103]

7.19.3.4.2 5/6th nephrectomy (5/6th Nx)

5/6th nephrectomy mimics the progressive renal failure after loss of renal mass in humans. Two different experimental approaches are used: uninephrectomy followed by either surgical excision of approximately half of the remaining tissue, or ligation of polar branches of the renal artery.[102] In mice, a combination of ligation and ablation model was used due to limited renal artery branching.[104] The 5/6th Nx model presents with proteinuria, glomerulosclerosis, tubulointerstitial fibrosis, and decline of renal function with time. The 5/6th Nx model induced by ligation is also associated with severe hypertension.[102,104] For compounds targeting antifibrotic mechanisms without hemodynamic effects, adequate BP control is required in this model. 5/6th Nx model in mice model is highly strain dependent. Mice on 129/Sv and Swiss-Webster background are among the few mouse strains susceptible to development of glomerulosclerosis after 5/6th Nx.[104] Treatment with high dose of ARBs or mineralocorticoid receptor antagonists not only slows down the progression of kidney injury but also induces regression of glomerulosclerosis in the 5/6th Nx model.[105,106]

7.19.3.4.3 Puromycin aminonucleoside

Single intravenous injection of PAN in rats induces podocyte injury and acute PAN nephrosis.[107] The peak of proteinuria and decline of renal function measured by serum creatinine usually occur between day 7 and 10 after PAN injection.[108] Expression of Nephrin A podocyte specific marker, was changed and showed a remarkable redistribution from the filtration slits to the podocyte plasma membrane.[108] Peroxisome proliferator-activated receptor gamma (PPARγ) agonists, when given at the time or after puromycin injection, reduced proteinuria and restored synaptopodin in the podocyte.[109] Multiple intraperitoneal injections of PAN plus uninephrectomy in rats induce chronic FSGS.[97] The chronic PAN model in rats has been used to evaluate antifibrotic mechanisms as well as mitochondrial dysfunction.[97,110]

7.19.3.4.4 AA injury

Tubulointerstitial fibrosis can be induced by multiple intraperitoneal injections of AA in mice or subcutaneous injections of AA in rats. The AA model is associated with an inflammatory infiltrate, tubulointerstitial fibrosis, and renal function decline.[111] The translational ability of this model is high since clinically AA induces Chinese herb nephropathy and Balkan endemic nephropathy.

7.19.3.4.5 Alport syndrome

Alport syndrome, caused by mutations in the genes encoding α3, α4, or α5 chains of type IV collagen (*COL4A3*, *COL4A4*, and *COL4A5*), is a genetic disorder characterized by progressive glomerulosclerosis associated with hearing loss and lens abnormalities.[112] A mouse model of Alport nephropathy was produced by introducing a null mutation of the α3 chain of collagen IV (Col4a3 −/−) in the 129X1/SvJ background. This model develops proteinuria with mild hematuria by 5 weeks after birth, severe glomerulosclerosis with subsequent tubulointerstitial fibrosis about 10 weeks of age, and progressive renal function decline and kidney failure by ∼11–14 weeks of age.[102] It was reported recently that anti-microRNA-21 oligonucleotides prevented Alport nephropathy progression by modulating metabolic pathways in this mouse model.[113]

7.19.3.5 Current Treatment

There are limited treatment options for patients with CKD. Blockers of the renin–angiotensin system (RAS) including ACE inhibitors and ARBs have been shown to slow the progression of CKD. This has been shown in diabetic kidney disease (IDNT, RENAAL) and in nondiabetic CKD (AASK).[114–116] Risk reduction in the composite renal/mortality endpoint in all these trials was around 20%.

RAS blockers are vasodilatory agents that act on the renal vasculature and induce a preferential dilation of the efferent arteriole. This results in a decrease in intraglomerular pressure and reduces hyperfiltration and stretch-induced glomerular injury.

Importantly, the renal hemodynamic effects of RAS blockers also acutely decrease renal blood flow and GFR, an effect that is clinically relevant.[116] Dual blockade of the RAS system has been shown in multiple clinical trials to increase the risk of acute kidney injury, an effect partially attributed to the hemodynamic effects of RAS blockade, and is currently contraindicated.[117] RAS blockers are also thought to have direct antifibrotic effects. The angiotensin II type 1 receptor (AT1R) receptor signals through ERK to activate noncanonical SMAD signaling and AngII is extremely profibrotic in multiple preclinical models. AngII levels are elevated in multiple tissues including the kidney in response to chronic tissue injury, and RAS blockade directly antagonizes the profibrotic effects of AngII in vitro and in multiple animal models.

In nephrotic syndrome, steroids are first-line treatment options with efficacy attributed to their anti-inflammatory effects, but they are not suitable for chronic management of disease due to multiple systemic side effects. Patients that do not respond to steroid therapy are often treated with other immuno-suppressive agents including calcineurin inhibitors and other disease-modifying antirheumatic drugs. RAS blockade is also part of the standard treatment paradigm for FSGS, a glomerular disease characterized by extensive glomerular scarring, though few trials have rigorously tested the efficacy of these agents in that disease.[118]

7.19.3.6 Ongoing Clinical Trials

A number of therapies with a primarily antifibrotic mechanism of action have recently been tested in various forms of CKD. Pirfenidone, an antifibrotic/antiinflammatory drug with a poorly understood mechanism of action, was tested in a small phase IIa trial in diabetic nephropathy in 2011.[101] Though there was no change in albuminuria, renal function as measured by GFR declined less precipitously in the low dose arm of that study, suggestive of potential benefit. However, there are no reported ongoing trials of pirfenidone for CKD though it was recently approved for the treatment of IPF (Roche/Intermune). Eli Lilly tested an anti-TGF-β1 specific antibody (LY2382770; ClinicalTrials.gov Identifier: NCT01113801) in a larger phase II trial in diabetic kidney disease. Multiple doses were tested, but no efficacy was observed on either urinary albumin or creatinine-based eGFR. A second anti-TGF-β antibody (fresolimumab, Genzyme/Sanofi) with broader specificity has recently been tested in 36 patients with FSGS. Overall efficacy on proteinuria was modest and not dose-dependent, but there was evidence of durable response in seven patients (ASN meeting, 2015). A Nox1/4 inhibitor from Genkyotex, GKT137831, also recently did not meet its primary endpoints in a phase IIa trial in diabetic nephropathy based on a statement posted on the company's website. There are thus mixed data on the effect of a variety of antifibrotic therapies in CKD.

Despite the equivocal results for antifibrotic therapies in renal disease, a number of other antifibrotic agents are currently in early clinical testing for CKD (listed in **Table 3**). FT-011, a derivative of the antiinflammatory/antifibrotic agent tranilast, is in clinical trials for diabetic nephropathy (**Fig. 3**). This agent has shown robust efficacy in numerous preclinical models of fibrotic disease and it will be interesting to see how these effects translate.[119,120] Of potential concern is the fact that the parental compound, tranilast, showed evidence of liver toxicity in a large phase III trial for the prevention of restenosis after percutaneous coronary intervention.[121]

ASK1 is a serine/threonine kinase, belonging to the MAP kinase-kinase-kinase family. Activation of ASK1 leads to activation of c-Jun N-terminal kinases and p38 MAPKs, inducing apoptosis of cells, inflammation, and fibrosis.[122] ASK1 plays important roles in many stress-related disease states, including renal fibrosis and diabetic nephropathy (**Fig. 4**).[123,124] Though this mechanism is less studied than others, ASK1 is thought to play a key role in integrating tissue injury signals such as ER stress and ROS with the fibrotic response. Gilead is the only company with an ASK1 inhibitor in clinical trials (GS-4997) for CKD, and they are pursuing this mechanism in combination with LOXL2 inhibitors for NASH.[125]

MiR-21 is a pro-fibrotic miRNA that has been implicated in liver and renal fibrosis. A recent preclinical study highlighted the therapeutic potential of blockade of miR-21 in both the mouse Alport syndrome model and the UUO model.[113] Based on the strength Regulus is currently contemplating initiating a trial with their miR-21 RG-012 inhibitor in Alport syndrome patients in early 2016.

La Jolla Therapeutics announced preliminary positive data in diabetic nephropathy with an anti-Galectin-3 preparation, but recently discontinued further work on this target to focus on other assets in their portfolio. Other antifibrotic mechanisms with recent clinical activity in CKD include CTGF antibodies (FG-3019, Fibrogen) and a small molecule antifibrotic PM-4050 (Prometic) with a poorly understood mechanism.

Table 3 Agents on clinical trials for kidney fibrosis

Compound	*Route of administration*	*Molecular target*
GKT-137831	Oral	NOX1/4 inhibitor

7.19.3.7 Emerging Biology and Therapeutic Treatment

There has been some debate in the past decade over the role of EMT in renal fibrosis.[126–128] Much of this controversy has centered on whether epithelial cells contribute to the myofibroblast pool in fibrotic kidneys. Fate-mapping studies suggest this is not the case, though it is clear that injured renal epithelia play a critical role in the progressive injury response.[129] Recent proof of concept studies in transgenic rodent models provide strong support that interactions between injured tubular epithelial cells and interstitial fibroblasts are important in driving renal fibrosis.[130] Reactivation or deletion of Snail1 (encoding snail family zinc finger 1, known as Snail1) in mouse renal epithelial cells promoted or improved renal fibrosis.[131,132]

Emerging data support the concept that integrins in the kidney modulate not only podocytes adhesion to the glomerular basement membrane (GBM) and filtration barrier functions but also TGF-β activation and ECM balance.[95] Multiple RGD-binding integrins (αvβ1, αvβ3, αvβ5, αvβ6, and αvβ8) are implicated in fibrosis.[72,133] Integrin αvβ6 is preferentially expressed at sites of injured tubular epithelial cells, binding and activating latent precursor TGF-β locally.[134] Integrin αvβ6 is an attractive target for lung and kidney fibrosis. Robust preclinical validation has been performed using genetic integrin β6 KO mice and pharmacological neutralizing αvβ6 monoclonal antibodies in fibrosis models in lung and kidney as well as in Alport CKD model.[103,135,136] A humanized monoclonal antibody against αvβ6 integrin, STX-100, is currently under evaluation in a randomized, placebo-controlled phase II IPF trial (NCT01371305). In contrast to αvβ6, integrin αvβ1 is thought to be expressed specifically in the fibroblasts. Upregulation of integrin αv and β1 was reported in renal biopsy samples from human diabetic kidney disease.[137] A small molecule αvβ1 inhibitor was shown recently to reduce fibrosis in multiple rodent fibrosis models.[73]

Bone morphogenetic protein 7 (BMP7), which counteracts TGF-β signaling, protects against renal fibrosis.[126,138,139] Gremlin (Grem1), an endogenous antagonist of BMP, is involved in fibrotic process in the kidney.[140,141] Expression of Gremlin 1 is increased in several models of fibrosis and human diabetic kidney disease.[142] Gremlin aggravates hyperglycemia-induced podocyte injury by a TGF-β/Smad-dependent signaling pathway.[140] Overexpression of human Gremlin in proximal tubular epithelial cells in transgenic mice aggravates diabetic kidney injury.[141] Inhibition of Gremlin in Grem1 heterozygous mice attenuated diabetes-induced glomerular basement membrane thickening and microalbuminuria compared to wild type (WT) diabetic mice.[143] Gremlin may also exert BMP-independent responses, including the regulation of cell migration, angiogenesis in endothelial cells, and the activation of Smad signaling and related profibrotic effects in tubular epithelial cells.[144]

Facilitating ECM degradation may prove to be an attractive antifibrotic mechanism.[145,146] The human epididymis protein 4 (HE4) gene, which encodes a putative serine protease inhibitor, is highly expressed in kidney of patients with diabetic nephropathy, human and mouse fibrotic kidneys, and is elevated in the serum of patients with kidney fibrosis.[147] The profibrotic mechanism of HE4 may be related to its ability to suppress the activity of multiple proteases, including serine proteases and matrix metalloproteinases, resulting in a reduced capacity to degrade type I collagen. Treatment with an HE4-neutralizing antibody reduced renal fibrosis in multiple mouse models.[147] Whether inhibition of HE4 improves renal fibrosis and functions warrants further investigation.

In the last few years, a direct link between metabolic dysregulation in renal epithelial cells and fibrosis has begun to emerge. It has long been known that a variety of metabolic interventions such as adiponectin and PPARγ agonists ameliorate renal dysfunction in diabetic animal models, but the basis for these protective effects was often attributed to modulating the effects of gluco- or lipotoxicity. However, the beneficial effects of PPAR agonists and 5′ adenosine monophosphate-activated protein kinase (AMPK) activators in nondiabetic models of CKD hinted at a more pleiotropic mode of action for these agents.[148,149] These observations have been bolstered by recent data that have linked mitochondrial dysfunction and defects in fatty acid oxidation to kidney disease in both diabetic and nondiabetic kidney disease, based on perturbations in urinary tricarboxylic acid cycle (TCA) cycle metabolite

levels and changes transcriptional profiles from biopsies of diseased kidneys.[96,150,151] Further evidence of a primary role in mitochondrial dysfunction in fibrotic kidney disease comes from transcriptional profiles in the mouse model of Alport syndrome which is characterized by extensive renal fibrosis, in which deficits in oxidative phosphorylation and mitochondrial dysfunction pathways were seen.[113] Finally, inherited deficiencies in CoQ10 biosynthesis have been shown to cause rare forms of steroid-resistant nephrotic syndrome, highlighting a critical role for mitochondrial function in human glomerular dysfunction and scarring.[152]

The link between mitochondrial function and renal fibrosis appears to be direct. TGF-β acutely suppresses mitochondrial function in renal epithelial cells in vitro, and the profibrotic effects of TGF-β on pro-fibrotic gene expression can be reversed by PPARα agonists such as fenofibrate.[96] The pro-fibrotic miRNA miR-21 appears to act in part by suppressing genes involved in mitochondrial function, and anti-miR21 is effective in suppressing renal disease in both the Alport and UUO mouse models.[113] The effect in the UUO is PPARα dependent, again highlighting a link between fibrosis and metabolism. Finally, other high-level regulators of mitochondrial function such as AMPK activators and PPAR agonists have been reported to be effective in numerous models of renal dysfunction.[148,151,153]

As yet, a unifying hypothesis linking these observations is lacking, though it has long been known that fatty acids and glutamine are the main source of energy for renal epithelia. When mitochondrial function is impaired, renal epithelial cells could lack the metabolic flexibility to shift to other energy sources and then initiate an injury program that can be ameliorated by restoring the ability to utilize these carbon sources. This would imply that master regulators of fatty acid oxidation and mitochondrial function such as AMPK activators or PPAR agonists might be interesting targets that could directly impact renal fibrosis. Anti-miR-21 is currently being tested in Alport syndrome and this will provide an interesting POC for targeting metabolic regulators in renal disease.

Epigenetic regulators have prominent antifibrotic effects, though much of these data have been elaborated in nonrenal models.[154] Most interesting in this group of targets are miRNAs which are emerging as a class of targets that have pleiotropic—yet restricted effects. The potential role of miR-21 in fibrosis has already been discussed, but a number of other miRs such as miR-29 and miR-200 are also associated with fibrotic renal disease and might represent interesting targets. An interesting aspect of miRNA biology is their potential to act in an endocrine manner, by release from cells in exosomes.[155] A further understanding in this field has the potential to open up a number of novel pathways for intervention.

A number of nonspecific histone deacetylase (HDAC) inhibitors including vorinostat, valproic acid, and sodium butyrate ameliorate renal disease in diabetic and fibrotic models. Their effects have been attributed to modulation of the NO pathway as well as direct effects on fibrotic pathways through BMP7. Finally, knockouts in the histone methyltransferase EZH2 have recently been shown to be renoprotective in diabetic nephropathy models, which was attributed to modulation of endogenous antioxidant defenses through TxnIP induction.

7.19.3.8 Conclusions and Perspectives

There is abundant evidence that fibrosis is a key pathophysiological pathway in the progression of renal disease. Despite some recent clinical setbacks, fibrotic pathways still represent an attractive area for the development of disease-modifying therapies in an area with limited therapeutic options. Exciting advances in the understanding of key pathways driving fibrosis in the kidney, in particular around the link between metabolism and fibrosis and the emerging role of miRNAs as master regulators of fibrosis, hold promise for the next generation of antifibrotic therapies for kidney disease.

7.19.4 Liver Fibrosis

7.19.4.1 Introduction

Acute liver injury induces a transient process of wound healing. Upon chronic injuries such as viral hepatitis, metabolic imbalance, or alcohol consumption, fibrosis arises as an excess deposit of ECM. The accumulation of scar tissue leads to cirrhosis with changes in the relative abundance of hepatic cell types and the organ's vasculature. Ultimately these modifications—that can progress over decades—lead to portal hypertension, liver failure and death. Liver cancer also usually appears in the presence of cirrhosis. Recent therapies for hepatitis B and C proved that cirrhosis and fibrosis can be reversed, encouraging the search for new therapies.

7.19.4.2 Epidemiology

Chronic liver disease and cirrhosis are associated with 36,000 annual deaths in the United States.[156] Nonalcoholic fatty liver disease (NAFLD) is the most common liver disease and affects 70–80% of obese and diabetics.[157] NAFLD is characterized by a continuum of histological abnormalities, ranging from steatosis to NASH with fibrosis and may ultimately evolve into cirrhosis and end-stage liver disease.[158] Cirrhosis moved from the 18th to the 13th rank in all cause of death in the world from 1990 to 2013.[156] The disease progresses over decades and patients usually die in their 50's or 60's from complications such as portal hypertension. Liver cancer often occurs in the presence of cirrhosis and is responsible for 10,000 deaths per year.

7.19.4.3 Pathophysiology

Liver cirrhosis is defined histologically as an accumulation of scar tissue due to fibrosis and abnormal architecture of the vasculature.[159,160] The liver's parenchyma contains epithelial cells (hepatocytes) and endothelial cells that form fenestrated sinusoids (Fig. 5). Hepatic stellate cells (HSCs) and Kupffer cells reside in the space of Disse that separates the blood flow of the sinusoids from the hepatocytes. Fibrosis corresponds to the accumulation and modification of the ECM in the space of Disse that overcomes fibrolysis by collagen-degrading enzymes such a metalloproteinases. Fibril-forming collagen types I, II, and V, and basement membrane collagens (types IV, VI) together with the glycoconjugates such as fibronectin induce the loss of hepatocytes microvilli and the loss of fenestration in the sinusoids (capillarization). Development of a fibrous septa linking the central and portal veins shunts the parenchyma and the bidirectional plasma flow between hepatocytes and the sinusoids lumen and impairs the liver's function (Fig. 5). Alteration in the architecture of the vasculature ultimately leads to portal hypertension.

In the space of Disse, myofibroblasts are the source of ECM during fibrosis. Myofibroblasts are characterized by the expression of alpha smooth muscle cell actin and a contractile phenotype. They also produce cytokines that further enhance inflammation, proliferation, and propagation of fibrosis. Myofibroblasts are mainly derived from HSC. Quiescent, vitamin A storing HSC are activated upon initial injury, depleted of vitamin A and lead the way to fibrosis by becoming myofibroblasts if not eliminated by apoptosis during the normal wound healing process. Other cell types contribute to the pool of myofibroblasts such as portal fibroblasts, circulating fibrocytes, bone marrow derived cells, and epithelial cells through epithelial to mesenchymal transition.[161]

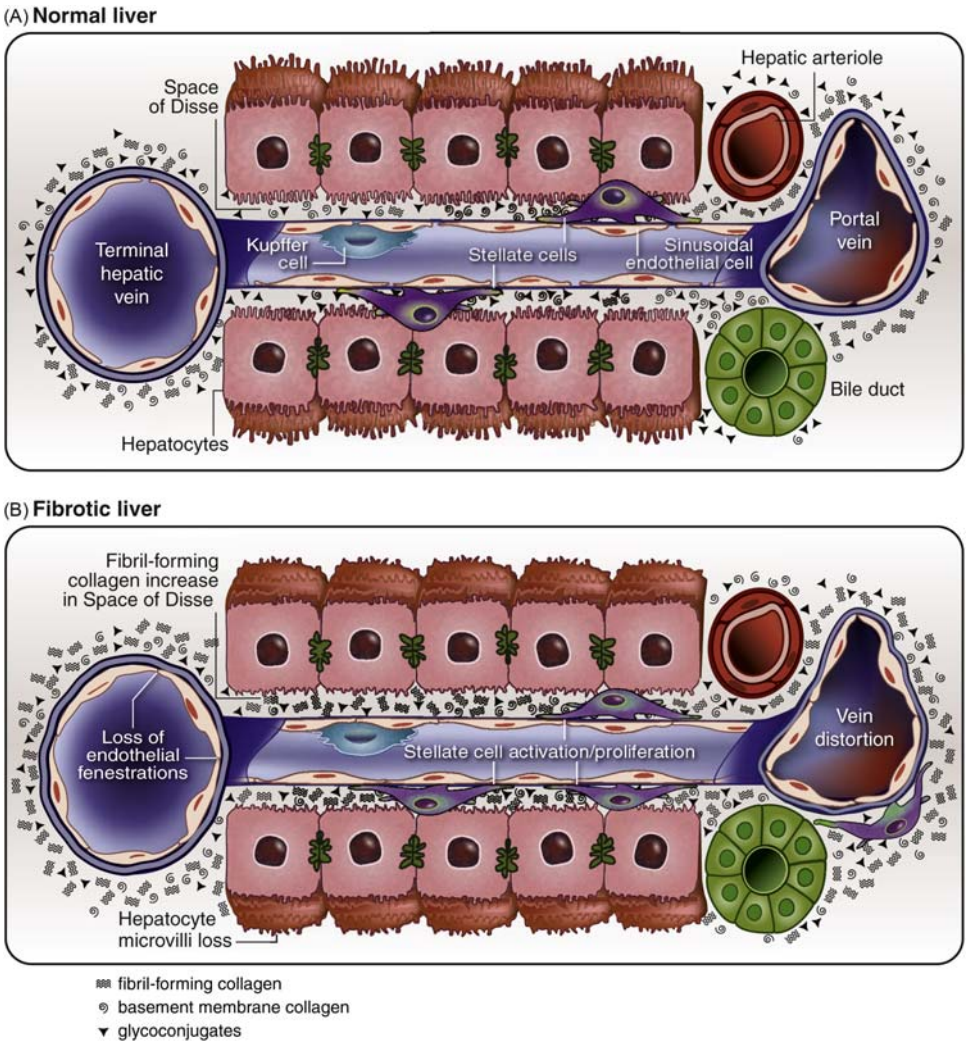

Fig. 5 Normal versus fibrotic liver. Reproduced from Hernandez-Gea, V.; Friedman, S. L. Pathogenesis of Liver Fibrosis. *Annu. Rev. Pathol.* **2011**, *6*, 425–456.

7.19.4.4 Experimental Animal Models

Rodents are the most commonly used species as models of liver injury.[162,163] These models can be classified according to the type of injury used: chemicals, cholestasis, autoimmune, and diet.[162] We will focus here on the models induced by carbon tetrachloride (CCl_4) or bile duct ligation, which are commonly used. CCl_4 is metabolized into the CCl_3 radical by cytochrome p450 2E1 present in perivenular hepatocytes. Necrosis in the centro-lobular area triggers wound healing and localized scar tissue. Repeated injuries prevent resolution of the wound healing and allows for progression into fibrosis. The model offers a window on the various steps of the disease with fibrosis at 2–4 weeks to severe bridging fibrosis at 5–7 weeks and cirrhosis at 8–9 weeks. Longer treatments induce micronodular cirrhosis, portal hypertension, and ascites. Note that compounds tested in this model can interfere with the extent of the disease if they modulate cyp2E1 expression and CCl_4 metabolism. Bile duct ligation is mostly performed in rats because they lack a gall bladder, contrary to mice.[163] This prevents some issues such as the risk of perforation of the gallbladder and death. After laparotomy, the bile duct is ligated above the pancreatic duct and below the junction of hepatic ducts and the segment in between both ligations is resected. The interruption of bile flow induces proliferation of the bile duct epithelial cells, portal inflammation. Portal fibrosis appears within weeks. Although portal hypertension and shunting of the portal to systemic circulation has been described within 6–8 weeks, the architectural defects typical of cirrhosis are usually not observed.

7.19.4.5 Drugs Evaluated in Preclinical and Clinical Trials

There is no current treatment approved for reducing fibrosis in the liver. Still, the regenerative nature of this organ makes it a good candidate for antifibrosis and even anti-cirrhosis therapy, as seen with treatments of chronic hepatitis B[164] and hepatitis C.[165]

Data from preclinical models suggest that multiple pathways could be targeted successfully.[166] We will mention four examples. First, by inhibiting TGFβ1 signaling pathway through impairment of TGF-β activation or its sensing by the cell, inhibitors of integrin improved hepatic fibrosis. Inhibitor of αVβ1 and αVβ6 integrins C8 and CWHM12 attenuated fibrosis in the CCl_4 mouse model (Fig. 6).[72,73]

Second, inhibitors of collagen accumulation also proved efficacious. HOE077 is an inhibitor of prolyl hydroxylase (proline is a major constituent of collagen) that prevents HSC activation and prevented pig serum-induced liver fibrosis in rats (Fig. 7).[167] Third, inhibitors of the RAS such as losartan were proven efficacious in preclinical models such as rat CCl_4.[168] Fourth, bile acid receptor activation improved fibrosis in farnesoid X receptor ligand obeticholic acid reduced fibrosis in CCl_4 or in bile duct ligation mice.[169,170] Thus there might be a broad spectrum of targets and pathways that are opportunities for new therapeutics.

Translation of these findings to humans remains a challenge. In fact, antifibrotic agents have largely failed at reducing liver fibrosis in the clinic. One example are the agonists of PPARγ that are antiinflammatory and reduce stellate cell activation, the antioxidant vitamin E, or colchicine that inhibit collagen secretion.[171] Still, there is a path forward as illustrated by the outcome of some recent clinical trials. Besides the anti-hepatitis C treatments that showed protective effects obeticholic acid improved fibrosis

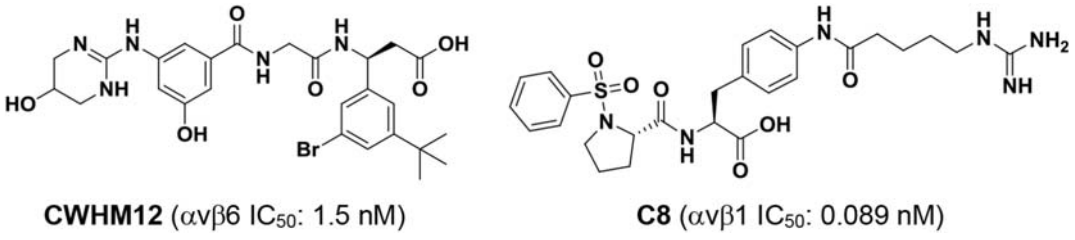

Fig. 6 Structure of CWHM12 and C8.

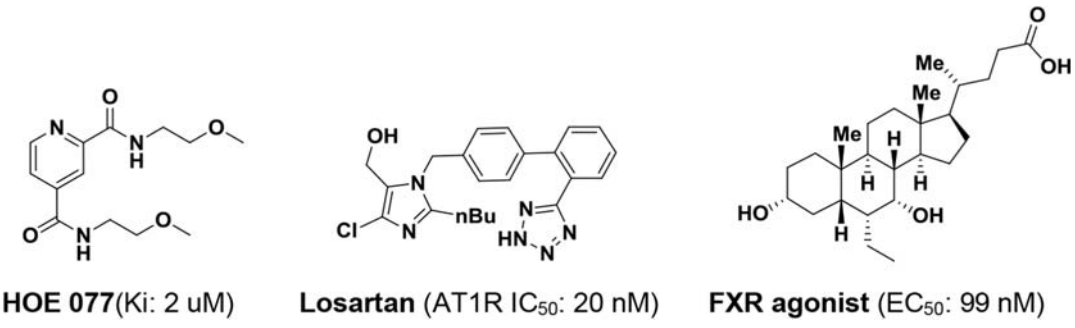

Fig. 7 Structure of HOE 077, losartan, obeticholic acid (INT-747).

in some patients with noncirrhotic, NASH (Fig. 7).[172] Candesartan, an AT1R blocking agent (ARB), aimed at reducing portal hypertension, did improve fibrosis in patients with alcoholic liver disease (Fig. 7).[173]

Table 4 lists small molecules in clinical trials for fibrosis. Biologics are also being evaluated. As an example, Simtuzumab is a monoclonal antibody raised against LOXL2 in phase II in HIV and/or hepatitis C-infected patients with hepatic fibrosis (clinical trial NCT01707472).

7.19.4.6 Emerging Biology

One major development in the field of hepatic fibrosis has been the identification of the main cell types contributing to the disease. The initial injury leading to hepatic fibrosis affects hepatocytes and biliary cells by enrolling multiple effector cells.[171] Dissecting the relative contribution of each cell type has been the subject of numerous studies but HSCs emerge as the main source of ECM after their transformation into myofibroblasts. By tracing cell expressing collagen 1A1 in CCl_4 and bile duct ligation mice models, Iwaisako et al. were able to show that HSCs represent >87% of myofibroblasts in the CCl_4 model.[184] Similar findings were made in the BDL model at day 14 and 20, although portal fibroblasts represented the majority of myofibroblasts in the early stage of fibrosis. Molecular profiling of these cell types instead of the whole tissue gives an unprecedented insight into the biology at play.[184] New targets specific to stellate cell activation could be identified.

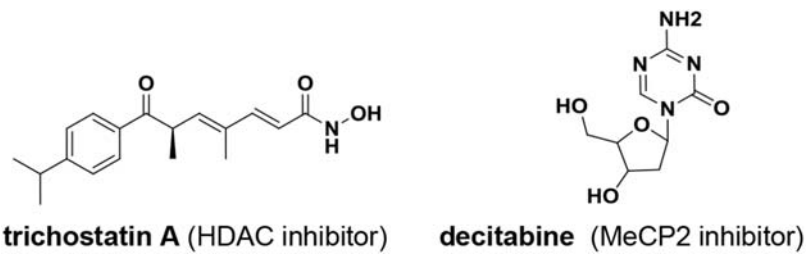
Activation of HSCs by transcription factors-mediated modulation of gene expression has been well documented.[159] Epigenetic regulations are also at play, exemplified by DNA methylation, histone modification, or silencing by noncoding RNAs.[159] Histone deacetylation and acetylation modify the structure of chromatin by making it respectively more or less condensed. Trichostatin A is an inhibitor of class I, II, and IV HDAC and blocked the activation of rat HSC in vitro, including the upregulation of aSMA (Fig. 8).[185] Genome-wide analysis of DNA methylation revealed changes in quiescent versus activated HSCs.[186] Decitabine, an inhibitor of methyl-CpG-binding protein MeCP2 that accumulates in myofibroblasts, blocked transdifferentiation of HSC.[187] Noncoding RNA also alters gene expression in HSC (Fig. 8).[188] Overexpression of miRNA-150 and miRNA-194 inhibited SMA expression and collagen-I secretion in LX2 cells.[189] Future studies of how epigenetic affects liver fibrosis will deepen our understanding of the pathology and might identify new therapeutic targets.

Adaptative and immune systems do play a role in fibrosis. An interesting research area concerns the role of intestinal bacteria in liver disease. Much attention has been recently focused on the interaction between the gut's microbiome and metabolic diseases, including NASH. Changes in intestinal bacteria have been identified in models of liver disease.[190] Recent findings might explain how toll-like receptor 4 is a bridge between gut microbiome and fibrosis, since it is present on stellate cells, activated by bacterial lipopolysaccharides, and associated with portal inflammation in patients with fatty liver disease.[191]

Table 5 presents a list of small molecules that have been evaluated for their antifibrotic properties in liver. Elucidating the nature of the injury and the biological pathways that are responsible for stellate cell activation should lead to more therapeutics.

Table 4 Small molecules in clinical trials for liver fibrosis[120,174–183]

Compound	*Route of administration*	*Molecular target*
GKT-137831	Oral	NOX1/4 inhibitor
Bardoxolone	Oral	NRF2-KEAP1
Sirolimus	Oral	Allosteric mTOR inhibitor
Baricitinib	Oral	Dual JAK1/2 inhibitor
Beraprost	Oral	Prostacyclin mimetic
Bindarit	Oral	CCL2/7/8 inhibitor
FT-011	Oral	Unknown MOA



trichostatin A (HDAC inhibitor) **decitabine** (MeCP2 inhibitor)

Fig. 8 Structure of trichostatin A and decitabine.

Table 5 Emerging biology in treating liver fibrosis

Mechanism	*Compound*	*Preclinical validation*
C–C chemokine receptor type 5	Maraviroc	NAFLD model
Integrin αVβ6	CWHM 12	Bleomycin/CCL_4 model
Integrin αVβ1	C8	Bleomycin/CCL_4 model
Prolyl hydroxylase	HOE 077	Liver fibrosis model
Glutamyl-prolyl-tRNA synthetase (EPRS)	Halofuginone	Thioacetamide model
Pregnane X receptor (PXR)	Pregnenolone 16α carbonitrile	CCL_4 model
T-type Ca channel	Efonidipone	CCL_4 model
Protein kinase C δ (PKCδ)	Rottlerlin	NASH model
5-Hydroxytryptamine 2A/2B receptors 5-$HT_{2A/2B}$	Sarpogrelate	Cirrhosis model
Lopoxin A4 (LXA_4)	BML-111	CCL_4 model
Nuclear receptor subfamily 4 group A member 1 NR4A1	Cytosporone B	Interstitial fibrosis model
Galectin 3	GM-CT-01 and GR-MD-02	Streptozotocin + high fat diet

Small molecules validated in fibrosis preclinical models.[72,73,78,89,167,192–201]

7.19.4.7 Concluding Remarks

Liver fibrosis is a major health issue that can lead to cirrhosis and death. Much progress has been done in our understanding of the pathology. Although there is no specific treatment yet, the reversible nature of cirrhosis and fibrosis has been demonstrated with treatments of hepatitis. Identification of the relative contribution of effector cells and careful delineation of the pathways activated or repressed in these cells should lead to new targets and more specific treatments.

β_3-ARs beta-3 adrenergic receptors; beta-3 adrenoceptors

7.20.1 Overactive Bladder

7.20.1.1 Prevalence, Etiology, and Impact

Overactive bladder (OAB) is a chronic and frequently debilitating syndrome resulting from lower urinary tract dysfunction that negatively impacts the quality of life (QoL) of 11–19% of the worldwide population.[1–5] Prevalence increases with age, and for those over the age of 65, the estimated prevalence is 30%.[5,6] With an increasingly aging world population, the overall prevalence of OAB is therefore expected to continue to increase in the coming years.

The International Continence Society (ICS) defines OAB as a group of lower urinary tract symptoms (LUTS) including "urgency, with or without urge incontinence, usually with increased frequency and nocturia."[7] The etiology of OAB has been linked to multiple factors including anatomical and tissue changes associated with aging, lifestyle choices, various comorbidities, and personal characteristics.[8–13] In addition to significantly impacting QoL, OAB has also been associated with a decline in overall health.[14,15] Symptoms such as urgency, urge incontinence, and incontinence episodes cause the most significant reduction in QoL, and consequently, these symptoms are frequently included as end points in clinical trials studying efficacy of pharmacotherapies aimed at treating OAB. Nocturia (multiple nighttime voiding episodes) has been associated with depression due to the interruption of sleep as well as an increase in bone fractures and subsequent mortality in elderly populations.[16,17] Although OAB is not life-threatening, patients who suffer from it experience a significant drop in their health-related QoL, their physical functioning, and their psychological well-being.[18] Moreover, OAB confers a substantial economic impact worldwide with an estimated cost of over $12 billion per year in the United States alone.[19,20]

7.20.1.2 Treatment of OAB: An Unmet Medical Need

OAB often goes undiagnosed due to the belief by patients that their symptoms are a normal part of aging or due to embarrassment to discuss their condition with physicians.[21] For similar reasons, a high percentage of patients that are diagnosed also go untreated.[22] Treatment options for patients suffering from OAB include behavior therapy, pharmacotherapy, and finally surgical therapy when the previous two options fail.[23] Behavioral approaches include bladder training, pelvic exercises, and education and application of lifestyle changes to mitigate the risk of some of the more detrimental symptoms of OAB.[6,24] When behavioral approaches fail, however, patients are often treated with the first-line pharmacotherapy of antimuscarinic agents (also known as anticholinergic agents).

Antimuscarinic (AM) agents are antagonists at the M_2 and/or M_3 muscarinic receptors, which are important for signaling contraction of the detrusor muscle that surrounds the urinary bladder.[25–28] AM agents have been the standard-of-care pharmacotherapy of OAB for more than 40 years, and improvements in urgency, frequency of micturition, and urge incontinence have been demonstrated with these drugs. Although efficacious, this drug class suffers from a number of undesirable effects that limit both patient and physician satisfaction. Muscarinic receptors exist in the brain where they play an important role in cognitive function. AM agents that penetrate the brain have been linked to cognitive impairment in elderly patients, and therefore, the selection of an AM agent with reduced potential for CNS penetration is recommended.[29] Additionally, nonselective blockade of the M_2/M_3 muscarinic receptors can lead to adverse effects such as dry mouth and constipation due to the presence of this receptor in salivary glands and the gastrointestinal tract, respectively.[28] Much attention has been focused on mitigating these side effects with some degree of success by using a strategy to reduce maximal plasma drug concentrations (C_{max}) using extended-release formulations. Additionally, alternate routes of administration and modification of the muscarinic receptor antagonist subtype selectivity are other strategies that have been pursued to reduce these tolerability concerns.[26,30] Nevertheless, more than 70% of patients discontinue therapy with AM agents because they are unsatisfied with the balance between efficacy and tolerability.[25,28–32] With this high discontinuation rate of the current first-line pharmacotherapy for OAB, it is clear that there is an unmet medical need for treatments with improved adherence that will translate to improved outcomes for patients that suffer from OAB.

7.20.2 History of β_3-Adrenergic Receptors

7.20.2.1 Discovery and Description of β_3-Adrenergic Receptors (Adrenoceptors)

The adrenergic receptors (ARs or adrenoceptors) are a class of G protein-coupled receptors (GPCRs) that have been known for decades as a rich source of pharmacology. Modulation of ARs by either activation or antagonism has resulted in many druggable targets for pharmaceutical intervention. Endogenous agonists of the ARs include naturally occurring catecholamines such as epinephrine (adrenaline, **1**) and norepinephrine (noradrenaline, **2**; Fig. 1). Distinct patterns of agonist and antagonist affinities are the basis for the further categorization of these ARs into α_1-, α_2-, β_1-, β_2-, and β_3-ARs.[33,34] At a high level, activation of the β-ARs at the cell surface catalyzes a cascade of events that results in stimulation of adenylyl cyclase and subsequent intracellular conversion of ATP to cAMP (Fig. 2), which in turn causes a broad range of physiological responses. Isoproterenol (isoprenaline, **3**) is an example of an agonist that is more selective for the β-ARs compared with the α-ARs, although it is not selective among the three β-receptor subtypes. Although the β_1- and β_2-ARs have been studied as early as the 1940s,[35] the existence of a third β_3-AR, sometimes called an "atypical β-adrenoceptor," was only confirmed in 1989 when it was first cloned and characterized.[36,37]

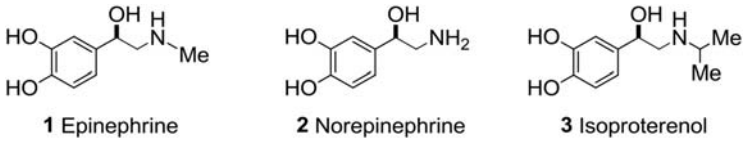

Fig. 1 Some nonselective β-AR agonists. Epinephrine and norepinephrine are endogenous ligands, and isoproterenol is a more stable nonselective agonist of β-AR receptors.

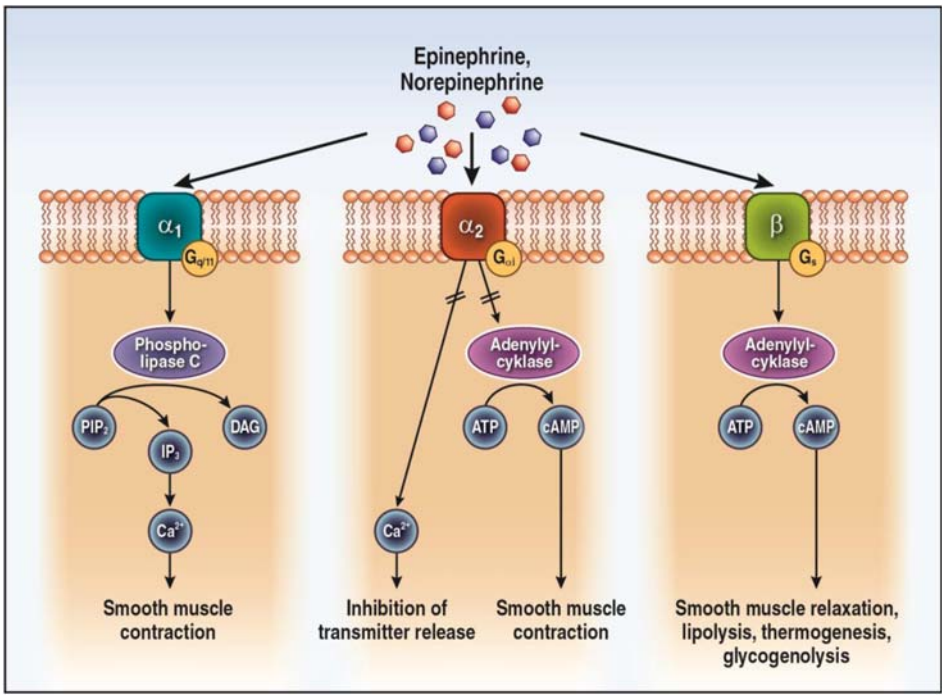

Fig. 2 Adrenergic receptor signaling pathways.

At that time, the β_3-AR was found to be present in rat adipose tissue where it was responsible for mediating metabolic effects such as thermogenesis and the lipolysis of triglycerides (TGs) into glycerol and free fatty acids (FFAs).

The structure of β_3-ARs consists of seven transmembrane (TM) amino acid domains composed of 22–28 amino acids each. Site-directed mutagenesis studies suggest that at least four of these TM domains are responsible for ligand binding, and this topic has been recently reviewed.[38] The gene for the β_3-AR is polymorphic, and extensive research has been applied to attempt to better understand the functional consequences of these polymorphisms, particularly with respect to potential genetic links to hypertension, diabetes, and obesity.[39–41] Sequence homology of β_3 across multiple species (mouse, rat, dog, cow, monkey, and human) is between 79 and 90% with higher homology between monkeys and humans than between rodents and humans.[42] These species disconnects contribute to potency disconnects between rodents and primates in many of the β_3-AR agonists reported in the 1980s and early 1990s.[42] Indeed, many early agonists such as BRL 37344 (**4**),[43] CGP 12177A (**5**),[44] and CL 316,243 (**6**)[45] that were discovered to be potent and selective rodent β_3-AR agonists are either less potent or less selective for human β_3-ARs (Fig. 3).[39] Across subtypes, the human β_3-AR possesses only ~50–70% sequence homology to β_1- and β_2-ARs, suggesting that installing selectivity for β_3-AR agonists is achievable provided that optimization is done with receptors expressed from the appropriate species.[39,46,47]

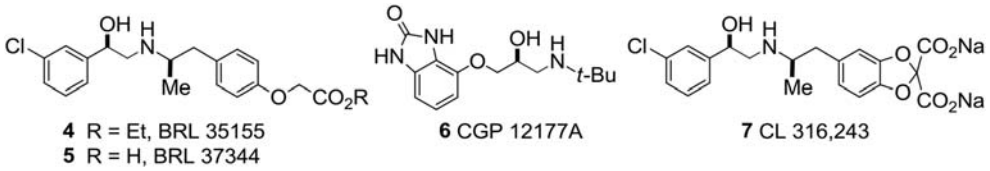

Fig. 3 Early rodent selective β_3-AR agonists frequently used in rodent pharmacology studies.

7.20.2.2 Pharmacology of β_3-AR Agonists

7.20.2.2.1 Metabolic effects of β_3-ARs

Although originally identified in white and brown adipose tissue, the β_3-AR receptor has now also been found in multiple tissue beds including the detrusor muscle that surrounds the urinary bladder, the urothelium, the gallbladder, the large and small intestines, the human heart, the brain, the colon, and the near-term myometrium.[38,48] Activation of β_3-ARs in adipocytes leads to thermogenesis (in brown adipose tissue or BAT) and/or lipolysis (in both BAT and white adipose tissue or WAT) through coupling with the Gs and Gi proteins followed by a cascade of signaling pathways triggered by increases in intracellular cAMP (through Gs)[49] and ERK1/2 (through Gi),[50] respectively (Fig. 4).

In BAT, activation of β_3-ARs triggers increased expression of uncoupling protein 1 (UCP1), which goes on to induce thermogenesis. Meanwhile, in WAT, activation of β_3-ARs induces hydrolysis of TGs and consequently an increase in circulating concentrations of FFAs. The FFAs released in WAT then undergo fatty acid oxidation in BAT through the increased expression of UCP1 in BAT. β_3-AR agonists therefore mobilize fat stores in preclinical species by inducing lipolysis in WAT, while the FFAs then further act as fuel for FFA oxidation and thermogenesis in BAT.[51] Taken together, this cascade of events translates into decreased body weight without food intake reduction, increased energy expenditure, and reduced body fat in preclinical models.[38] These actions of selective β_3-AR agonists have led to decades of investigations for the use of these compounds as a treatment of obesity.[51–55]

β_3-AR agonists have also been investigated for the treatment of diabetes.[51,56] Chronic treatment of the rat β_3-AR agonists **4** and **6** in various rodent diabetes models, for example, results in improved oral glucose tolerance, decreased plasma insulin levels, and/or improved insulin sensitization.[57–59] Although more needs to be understood about the mechanism of these effects, it has been proposed that β_3-AR agonists increase glucose utilization in skeletal muscle.[60] Another recent hypothesis is that some of these antidiabetic and antiobesity effects may be related to the browning of white adipose and/or the maintenance of BAT upon β_3-AR activation in these tissue beds.[56]

7.20.2.2.2 Cardiovascular effects of β_3-ARs

β_3-ARs in cardiomyocytes are linked to the Gi protein and their activation by agonists invokes a negative inotropic effect (Fig. 4). At a receptor expression level, β_3-ARs have been found in both normal and diseased hearts; however, their expression is upregulated

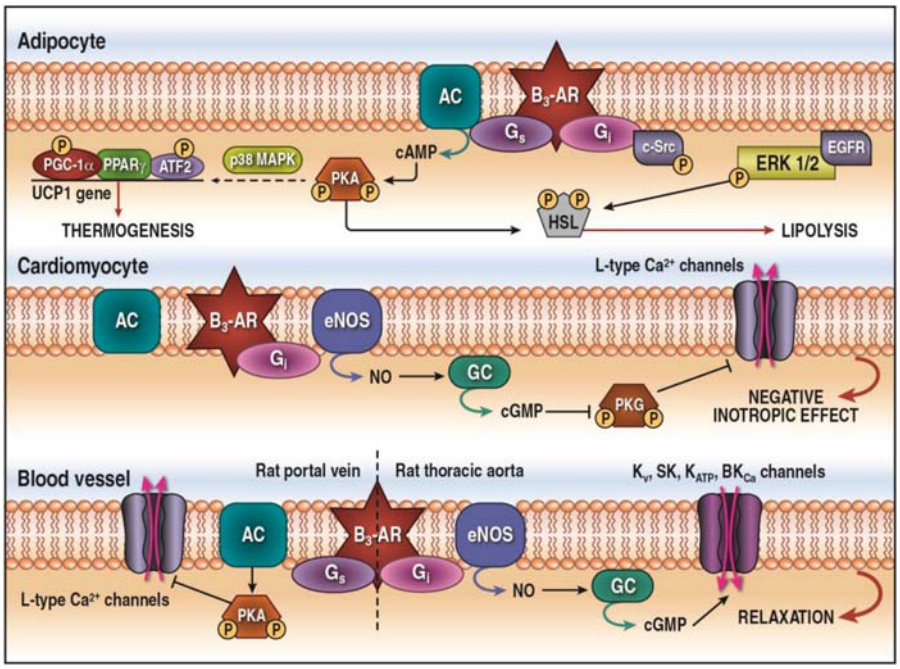

Fig. 4 Cardiometabolic tissue signaling pathways relevant to activation of the β_3-AR. (A) In adipocytes, the β_3-AR is coupled to the Gs protein that activates adenylyl cyclase (AC), which subsequently converts ATP to cAMP leading to activation of protein kinase A (PKA). Upon activation, protein kinase A (PKA) phosphorylates p38 MAP kinase, which then leads to thermogenesis through the action of the uncoupling protein 1 (UCP1) gene. PKA also phosphorylates hormone-sensitive lipase (HSL) leading to lipolysis of triglycerides to glycerol and free fatty acids. Alternatively, lipolysis can be induced through the Gi pathway via the action of ERK1/2 and subsequent phosphorylation of HSL. (B) In cardiomyocytes, the β_3-AR signals through the Gi pathway to activate endothelial nitric oxide synthase (eNOS), which then releases nitric oxide (NO). The increased intracellular NO then activates soluble guanylyl cyclase (GC) releasing cGMP, which then activates protein kinase G (PKG) leading to a negative inotropic effect through calcium ion efflux. (C) In the vasculature, the β_3-AR acts through the Gs signaling pathway to induce calcium efflux through L-type Ca^{2+} channels. In the rat aorta, β_3-ARs can act through the Gi signaling cascade to induce relaxation of blood vessels.

during ischemic and dilated cardiomyopathies in humans.[61] Consequently, it has been postulated that β_3-ARs may play a role in the treatment of heart failure, which has prompted recent investigations into the effects of β_3-AR agonists on cardiovascular pathophysiology. The specific role of β_3-AR agonists in heart failure has yet to be determined, however, and research continues in this potentially exciting area.[61–67]

In vasculature, the β_3-ARs are again coupled with either Gs or Gi proteins and activation of these receptors can lead to vasodilation and subsequent hypotension through two separate biochemical cascades (Fig. 4). Selective and potent rodent and dog β_3-AR agonists **4**, **5**, and **6** induce hypotension and peripheral vasodilation in mice, rats, and dogs but not in monkeys—likely due to their reduced potency at the monkey β_3-AR receptor.[68–72] In anesthetized rhesus monkeys, potent and selective rhesus β_3-AR agonists were shown to evoke peripheral vasodilation, facial flushing, and reflex tachycardia consistent with the effects reported in nonprimates.[73]

The profound vascular effects observed in dogs and monkeys were not observed, however, in humans. Early compounds taken into the clinic as β_3-AR agonists were generally nonselective over either the β_1- or β_2-ARs, which often translated into adverse cardiovascular effects consistent with these off-target activities.[51,74,75] Although some of the early β_3-AR agonists studied in humans induced tachycardia, more recent potent and selective human agonists studied in the clinic have exhibited acceptable cardiovascular safety profiles in humans. For example, no changes in systolic or diastolic blood pressure were observed in a 28-day clinical study upon treatment with a potent and selective human β_3-AR agonist.[76] Furthermore, a recent review of clinical data for mirabegron, a potent and selective human β_3-AR agonist, concluded that this compound possesses a good overall cardiovascular safety profile.[74]

7.20.2.2.3 The role of β_3-ARs in overactive bladder

β-AR activation has long been known to be an important contributor to relaxation of the detrusor muscle, thus enabling bladder compliance during the filling phase of the micturition cycle.[77] It wasn't until the latter half of the 1990s, however, that a series of studies using β_3-AR agonists such as **4**, **5**, and **6** revealed that the β_3-AR is a major functional contributor to β-AR-mediated bladder relaxation in multiple species (Fig. 5).[78–83] Since these early discoveries, a series of *ex vivo* studies demonstrated that potent and selective β_3-AR agonists from a broad range of structure classes can relax precontracted bladder muscle strips in a variety of species including humans.[84,85] In the detrusor muscle, the β_3-ARs are coupled with Gs proteins and their activation increases cAMP through the action of adenylyl cyclase. Subsequent signaling from cAMP then leads to bladder smooth muscle relaxation. In addition to this cAMP-dependent pathway to bladder relaxation, there is a potential contribution from a cAMP-independent pathway, but most studies suggest that the cAMP-dependent pathways play the more significant role in this process.[86] Finally, β_3-ARs were also found to play a functional role for urine storage in the urothelium tissue, which was once believed to serve only as an impenetrable barrier to protect blood and tissue from substances in urine.[87,88]

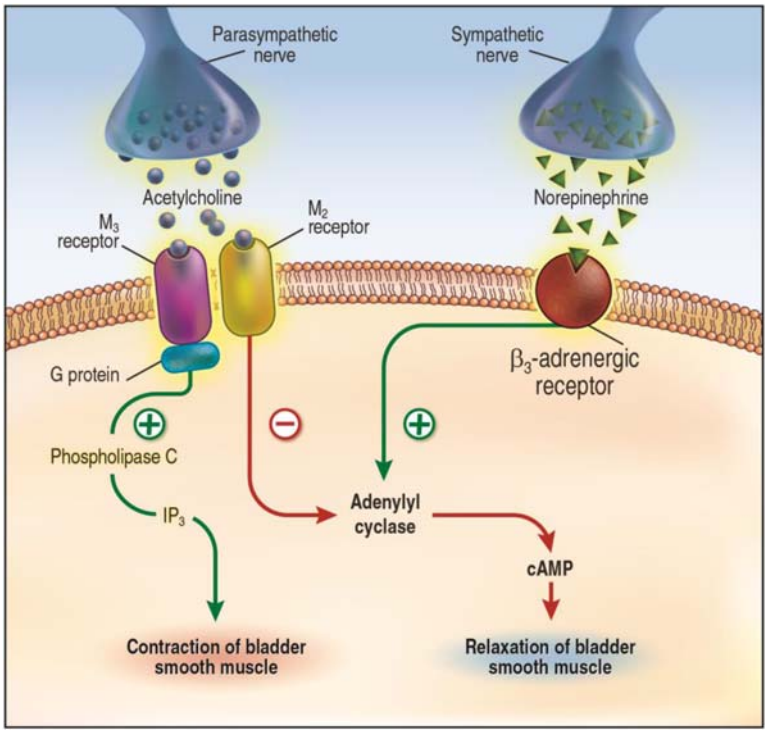

Fig. 5 Signaling pathways in the human detrusor muscle.

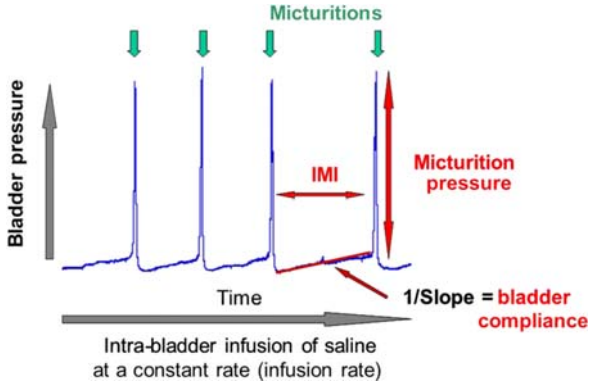

Fig. 6 Representative cystometrogram (CMG) from a preclinical cystometry study. Cystometry is a diagnostic procedure, often performed on anesthetized animals, that is used to evaluate urinary bladder function. A solution, typically saline, is infused into the bladder at a constant rate through a catheter. Pressure builds inside the bladder as it fills with fluid, and eventually, the bladder muscle contracts resulting in expulsion of the liquid in a micturition event denoted by green arrows. This event completes the micturition cycle and the bladder again fills with fluid to repeat the cycle. The measured time between two micturition events is defined as the intramicturition interval (IMI). Bladder capacity (maximum volume of fluid in the bladder) can be measured by multiplying the fluid infusion rate by the IMI. Micturition pressure is the difference in pressure between the highest pressure and the pressure trough after a micturition event. Bladder compliance is the inverse slope of the bladder pressure during the filling phase of the micturition cycle.

In multiple species, cystometry-based models have been used to measure the effects of β_3-AR agonists on bladder compliance and bladder function (Fig. 6).[89] In rat bladder hyperactivity models, for example, selective β_3-AR agonists such as compounds **4** and **6** increase bladder contraction (intramicturition) intervals while reducing contraction amplitude (force) and baseline pressure.[90,91] Mechanistic cystometry studies have also helped shed light into effects of β_3-AR agonists beyond detrusor muscle relaxation. For example, studies with compound **6** suggest a potential contribution of β_3-AR agonists to facilitate urine storage in rats by inhibiting bladder afferent neurotransduction.[92,93] Finally, a recent study demonstrated that intravesicular administration of selective rat β_3-AR agonists resulted in a decrease in micturition frequency as well as a decrease in contraction force in anesthetized rats, suggesting an active role for the urothelium in the effects of β_3-AR agonists.[94] These findings further suggest β_3-AR agonists may improve bladder function through multiple physiological pathways in addition to direct effects arising from detrusor muscle relaxation.[89] Overall, evidence from *in vitro* and *in vivo* studies suggests that β_3-AR agonists act on multiple cell types to regulate bladder function. Results from some of the more advanced mechanistic studies performed in rats with potent and selective rat β_3-AR agonists still need to be confirmed in humans, but the overwhelming evidence to date supports the use of β_3-AR agonists to treat symptoms related to OAB through multiple actions.[95,96]

Muscarinic receptors in the urinary bladder are known to increase smooth muscle tone, and β_3-AR activation has been shown to induce relaxation of smooth muscle as well as oppose muscarinic-mediated muscle contraction (Fig. 5). Each of these two receptor types is therefore important in the regulation of the micturition cycle, and their opposing actions suggest that combination therapies of AM agents with β_3-AR agonists may offer additional opportunities to improve symptoms of patients with OAB.[97] *In vitro* studies on human detrusor muscle demonstrated that the combination of an AM agent with a β_3-AR agonist results in further relaxation of bladder smooth muscle beyond that of either agent alone.[98] Furthermore, a recent rat cystometry study that evaluated the effects of an AM agent and a β_3-AR agonist on bladder capacity in a bladder hyperactivity model revealed that the combination of these two drugs results in a greater increase in bladder capacity compared with either agent alone.[99] Although the earlier rat studies demonstrate potentially additive effects between AMs and β_3-AR agonists on bladder function in rats, it nevertheless remains to be demonstrated in humans whether these combinations will translate into improved efficacy and/or tolerability. Moreover, the balance of antagonism between M_2 and M_3 may also affect the outcome of combination therapy with β_3-AR agonists due to differences between the biochemical effects of the M_2 and M_3 receptors in the detrusor muscle and other tissues involved in modulation of the micturition cycle such as afferent neurons and the urothelium. Clearly much remains to be learned but the future appears to be promising for the use of combination therapies with β_3-AR agonists in patients who suffer from OAB.[100–104]

7.20.3 β_3-AR Agonists in Discovery and Development

7.20.3.1 Overview of β_3-AR Agonists in the Literature

After the first publication of the cloning and expression of the human β_3-AR in 1989[36] and the subsequent reports that β_3-AR agonists evoke lipolysis and thermogenesis in rodents,[37] research publications describing biology, pharmacology, and ligands for the β_3-AR increased dramatically (Fig. 7). Indeed, the rich pharmacology associated with β_3-ARs has produced a steady stream of publications that continues to this day. Early reports of potent and selective *rodent* β_3-AR agonists gave way to reports of potent

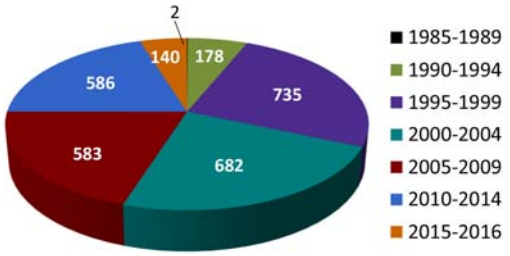

Fig. 7 A total of 2906 peer-reviewed scientific publications containing the text "beta-3 adrenergic" or "beta-3 adrenoceptor" were found between 1985 and 2016 using the Ex Libris Primo literature search tool.[105]

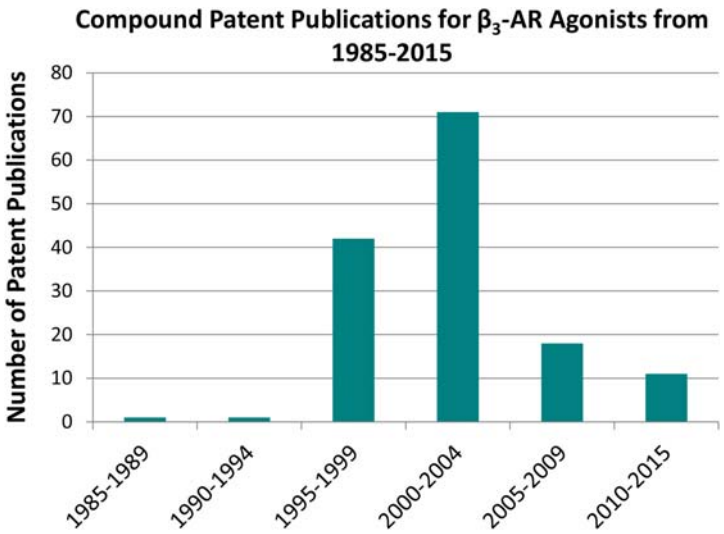

Fig. 8 A summary of β_3-AR modulator compound patent publications from 1985–2015 sorted by first publication date. A total of 144 patent publications were identified from a patent search using Thomson Reuters Cortellis software package from the search query terms "adrenoceptor" and "beta-3" to afford a comprehensive list of patent publications. Other synonymous search terms (eg, "adrenergic receptor" and "beta-3") yielded fewer results and were included in the former query. Three hundred seventy-one initial hits were further filtered by including product patents to afford 147 hits. Each patent publication was then evaluated, and three compound patents not covering β_3-AR receptor modulators were removed.

and selective *human* β_3-AR agonists. Scientists intent on optimization of these ligands developed newer and more sophisticated *in vitro* and *in vivo* models to evaluate novel β_3-AR-mediated pharmacology while also developing more advanced models to inform on selectivity over β_1- and β_2-AR-mediated pharmacology.

Patents describing ligands at the β_3-AR peaked in the decade between 1995 and 2005 (Fig. 8). Early patent publications described potent and selective ligands at the rodent β_3-AR, however, as the research field advanced agonists were later optimized for potency and selectivity at the human β_3-AR. General structural features for the majority of β_3-AR agonists are similar, with an ethanolamine moiety playing a central role as the minimum pharmacophore (Fig. 9).[46] The left-hand side (LHS) of β_3-AR agonists is frequently a minimally substituted aromatic ring designed to mimic catechols **1**–**3**. Typically, this is a phenyl or pyridyl ring attached to the alcohol-bearing carbon of the ethanolamine moiety either directly (X = nothing) or through a methanol ether linker (X = $-OCH_2-$). Aside from relatively simple substituents, the central ethanolamine region is largely conserved for all potent

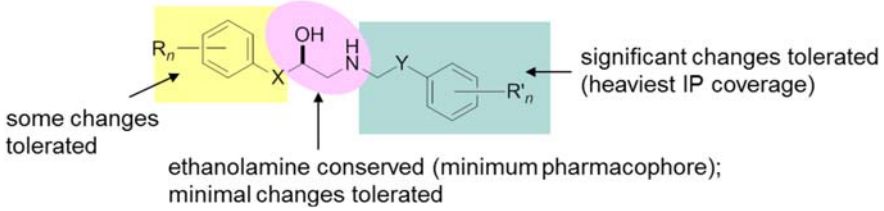

Fig. 9 General pharmacophore and SAR overview of β_3-AR agonists.

β_3-AR agonists, and elaborate changes to this region are not well tolerated. The right-hand side (RHS) of the ethanolamine tolerates the broadest structural variety, though there is usually an aromatic ring that is 2–3 linker atoms away from the secondary amine.

The first series of β_3-AR agonists contained a carboxylic acid moiety attached to the RHS aromatic ring through a short linker at R′ (Fig. 9). The acid was found to be important for both potency at β_3-AR and selectivity over β_1- and β_2-ARs; however, it also reduced permeability in these early ligands, and consequently, teams struggled to achieve oral bioavailability. As medicinal chemistry strategies matured, researchers succeeded at improving oral bioavailability either through a prodrug strategy (eg, esters) or through the use of acid bioisosteres. The large number of patent publications that describe β_3-AR agonists stemming from a single ethanolamine pharmacophore is testament to the creativity and perseverance of scientists working in the field. Several β_3-AR agonists progressed into human clinical trials, and the SAR and optimization strategies that were used to identify these clinical candidates are described in the following sections.

7.20.3.2 Potent Rat β_3-AR Agonists in Early Human Clinical Trials

The earliest generation of β_3-AR agonists was unsuccessful in the clinic as potential drugs for the treatment of obesity and/or diabetes.[106] Active metabolites of BRL 35155 (**4**) and BRL 26830 (**7**) were optimized as selective agonists using assays with rat β_1-, β_2-, and β_3-ARs, and these showed promising profiles in rodent models for obesity and diabetes (Fig. 8).[57,58,107] The reduced species homology between rat and human receptors, however, afforded either divergent potencies of these compounds between the rat and human β_3-ARs or modest selectivities over human β_1- and β_2-ARs or both.[39] Consequently, prodrugs such as **4** and **8** (Fig. 10) had little/no effect on thermogenesis or metabolism in humans,[108,109] although compound **8** was reported to increase insulin-simulated glucose uptake in humans in a glucose clamp study.[110] Additionally, compound **8** was able to induce thermogenesis and weight loss in calorie-restricted subjects; however, it was unclear whether these effects were due to activation of both β_2- and β_3-AR or to β_3-AR alone.[111] Moreover, adverse effects such as tremors and tachycardia were observed in humans with compound **8,** which were attributed to off-target effects at the β_1- or β_2-ARs.[101,112]

Modest effects in the clinic were also observed upon administration of CL 316,243 (**7**) including improvements on insulin action, increased fatty acid oxidation, and increased lipolysis of triglycerides to FFAs and glycerol.[113,114] No changes in energy expenditure or body weight were observed in humans and **7** did not induce tremors or cardiovascular changes.[113] This compound possesses poor oral bioavailability, however, and in humans, it only exhibits modest selectivity over the human β_2-AR.[39,51] Finally, ICI D7114 (**10**), a prodrug for its active metabolite compound **11**, and ZD 2079 both elicit profound metabolic effects and activation of BAT in preclinical species,[114,115] but neither compound demonstrated thermogenesis in humans (Fig. 10).[116,117]

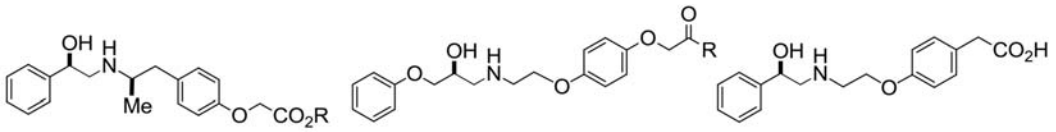
7.20.3.3 Medicinal Chemistry of Human β_3-AR Agonists

By the mid-1990s, the failure of the first generation of potent rat β_3-AR agonists to achieve success in the clinic together with advances in cloning and expressing the human β_3-AR opened the door to a new era of agonists optimized for potency at human β_3-AR and selectivity over human β_1- and β_2-ARs. These medicinal chemistry advances coincided with additional advances in β_3-AR biology and the discovery of new potential therapeutic indications for these compounds.

In the meantime, the next generation of potent and selective human β_3-AR agonists was assessed as potential drugs to treat obesity/diabetes, but clinical data for these indications were again disappointing. Consequently, further efforts to pursue β_3-AR agonists for diabetes and/or obesity ended.[38,42] On the other hand, the second generation of potent and selective human β_3-AR agonists proved safer in humans than earlier agonists and were eventually repurposed for a variety of new potential indications including, but not limited to, OAB.

7.20.3.3.1 Discovery of BMS-196085 and related analogs

Medicinal chemistry reports from Bristol-Myers Squibb (BMS) focused on the progression of β_3-AR agonists for the treatment of obesity and/or diabetes. Replacement of the RHS phenyl ring of the standard β_3-AR agonist pharmacophore with heteroaromatics such as thiazole BMS-187257 (**13**; Fig. 11) was done in an effort to match or exceed the human β_3-AR potency and selectivity of **4**. Although **13** was similar to **4** in terms of potency, the selectivity over β_1- and β_2-ARs was not significantly improved. Moreover, the potent β_3-AR agonist activity of the thiazole heterocycle moiety did not transfer to the truncated series in which the phenoxy



8 R = Me, BRL 26830 (racemate)
9 R = H, active drug

10 R = -NHCH$_2$CH$_2$OMe, ICI D7114
11 R = OH, active drug

12 ZD 2079

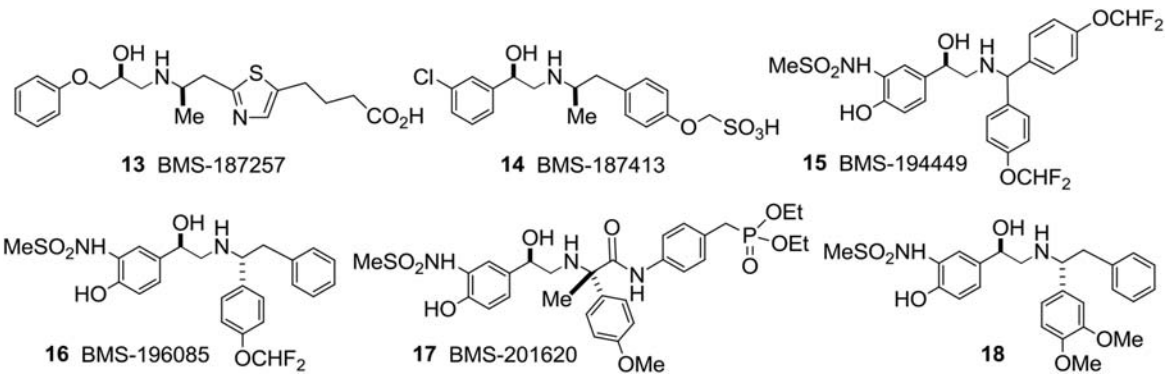

Fig. 11 Medicinal chemistry leading to the discovery of BMS-196085 (**16**) and beyond.

LHS was replaced by a directly connected phenyl group.[118] A new focus to modify the carboxylic acid group of **4** afforded sulfonic acid BMS-187413 (**14**), which was similar in potency and selectivity to **4** but with a distinct RHS acid moiety.[119]

A screening hit from the BMS sample collection identified a series of full β_3-AR agonists, which possessed 4-hydroxy-3-methanesulfonylanilides as bioisosteres for the LHS catechol moiety found in nonselective β-AR agonists. This series of agonists was also potent at the β_2-AR, however, and further optimization of the RHS yielded promising clinical candidates BMS-194449 (**15**)[120] and BMS-196085 (**16**)[121] as compounds with improved *in vitro* selectivity over β_1- and β_2-ARs. Both compounds exhibited poor oral bioavailability in preclinical species due to rapid glucuronidation of the alcohol moieties during first-pass metabolism. The *in vivo* selectivity of these compounds was evaluated in African green monkeys during dose–response studies where β_3-AR-mediated lipolysis (as measured by FFA increases) was compared with off-target effects mediated by β_1-AR (tachycardia) and β_2-AR (hypokalemia). Compounds **15** and **16** exhibited sufficient *in vivo* margins in monkeys to progress into development and subsequently the clinic where they were evaluated after i.v. dosing for their PD effects in humans. Despite promising *in vivo* selectivity in monkeys, **15** evoked lipolysis in a small group of healthy humans at a similar dose/exposure that caused QT prolongation, which was attributed to β_2-AR activation.[120] Compound **16**, on the other hand, evoked increases in FFAs in humans after an i.v. dose that did not effect any β_1- or β_2-AR-mediated side effects, thus supporting progression to multiple-day studies. Unfortunately, a 2-week continuous i.v. dose study with **16** in humans failed to produce any significant increases in metabolic rate up to doses that induced tachycardia, and consequently, further development of this compound was halted.[121]

Further improvements in selectivity over β_1- and β_2-ARs were realized with additional modification of the RHS region of this lead class resulting in the discovery of phosphate ester BMS-201620 (**17**).[122] Although its oral bioavailability in preclinical species was still poor, **17** was nevertheless progressed into humans based on its improved safety margin over off-target effects in the African green monkey models described in the preceding text. Once again, however, there was no difference between the onset of lipolysis resulting from i.v. administered **17** and QT prolongation in healthy volunteers, and so further clinical studies with **17** were terminated.[122] Although additional analogs with modified RHS regions (eg, compound **18**) were identified with improved overall PK profiles and similar *in vivo* margins for β_3-AR-mediated lipolysis compared with off-target effects mediated by β_1 and β_2, further progression of these compounds as potential clinical candidates ceased when compound **16** failed to demonstrate sustained increases in metabolic rate in humans after multiple days of dosing.[123]

7.20.3.3.2 Discovery of LY-377604 and related compounds

Lilly reported a series of highly selective human β_3-AR agonists more elaborated on the LHS region of the general β_3-AR pharmacophore. Urea LY-362884 (**19**) was reported as an early analog in this series that showed excellent *in vitro* β_3-AR potency and selectivity (Fig. 12). This compound also differentiated from earlier agonists by its reduced propensity to induce atrial tachycardia in rats, a PD effect believed to be mediated by a low-affinity state of the β_1-AR.[124,125] Although **19** increased energy expenditure in diet-induced obese rats, its poor oral bioavailability prompted additional optimization in this series. Further SAR demonstrated that excellent selectivity over rat atrial tachycardia was maintained with deletion of one of the urea H-bond donating groups to afford

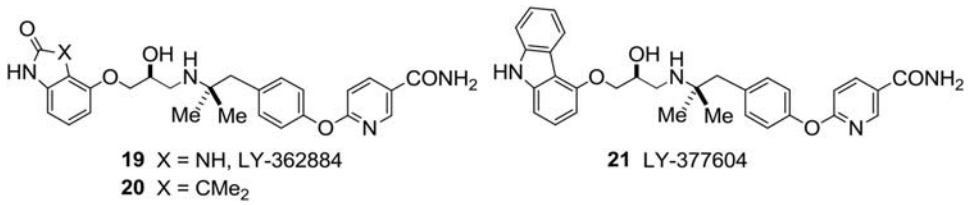

Fig. 12 A series of selective β_3-AR agonists more fully elaborated in the LHS region.

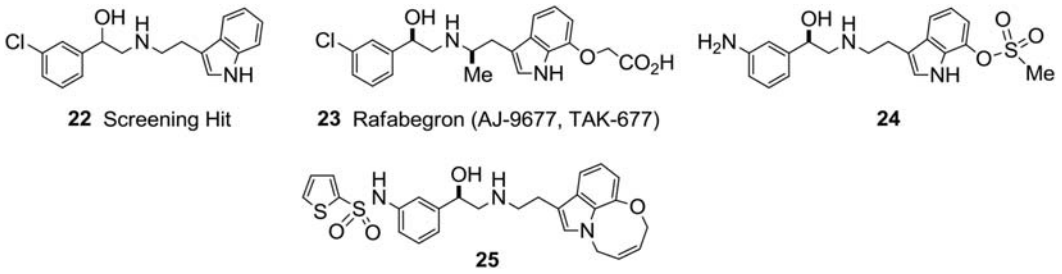

Fig. 13 Medicinal chemistry leading to the discovery of rafabegron (**23**) and beyond.

20, which also increased energy expenditure in rats. Only minimal improvement in rat oral bioavailability was observed with **20** (F = 10%),[126] however, and further elaboration of the LHS moiety afforded carboline LY-377604 (**21**), which was reported to have improved preclinical oral bioavailabilities.[127]

7.20.3.3.3 Discovery of rafabegron and related analogs

A screening hit (**22**) discovered at Dainippon in the early 1990s revealed that the phenyl ring typically present in the RHS portion of β_3-AR agonists can be replaced by an indole moiety (Fig. 13).[128,129] In *ex vivo* studies, **22** demonstrated an ability to inhibit rat colonic contraction while having minimal effect on the rat uterus and the guinea pig trachea indicating potential β_3-AR selective pharmacology.[128] Introduction of an acetic acid substituent to the indole ring and a chiral methyl group at the methylene carbon adjacent to the secondary amine together with resolution of the racemic alcohol resulted in significant improvements at both potency and selectivity for β_3-AR activation. The resulting optimized analog rafabegron (**23**, AJ-9677) demonstrated efficacy in diabetic and obese mouse and rat models.[129–131] Further SAR in this series was focused on (a) removing the chiral methyl group in **23** to facilitate synthesis and reduce the cost of API production and (b) replacement of the acid moiety to improve permeability. Compound **24**[132] was discovered to be a promising analog from this series, and further elaboration of the methyl sulfonate substituent on the RHS side to a cyclic derivative resulted in a series of non-acid-bearing β_3-AR agonists such as compound **25** with improved permeability and selectivity over β_1- and β_2-ARs.[133] Unfortunately, administration of rafabegron (**23**) in obese patients did not afford any significant changes in energy expenditure, body weight, fasting plasma glucose levels, FFA levels, or insulin levels leading to the discontinuation of this compound for further clinical studies.[134]

7.20.3.3.4 Discovery of an oxazole ring as an acid bioisostere

An early search for potent and selective human β_3-AR agonists at Pfizer led to the discovery of indole CP-331,679 (**26**), with a RHS carboxylic acid moiety that confers excellent selectivity (>100-fold) over β_1- and β_2-ARs (Fig. 14).[135] Not surprisingly, however, **26** as well as its ester prodrugs exhibited poor (<10%) oral bioavailability in rats. A renewed focus on improving physicochemical properties to increase oral absorption while maintaining potency and selectivity afforded sulfonylurea **27**. When dosed orally in rats at 30 mg/kg, compound **27** increases oxygen consumption (a surrogate for increased metabolic rate) at a similar magnitude as an intraperitoneal dose of 10 mg/kg, suggesting improved oral absorption of **27** relative to the previous compound **26**.[136] Importantly, compound **27** demonstrated that improved oral bioavailability may be achieved by deletion of the carboxylic acid moiety typically present in the RHS region. Further efforts to improve properties by reducing molecular weight and improving drug-like physicochemical properties resulted in identification of a series of heteroaryl acid bioisosteres in the RHS region culminating in the phenyloxazole **28**. Not only does **28** possess excellent β_3-AR potency and selectivity, but also it possesses high oral bioavailabilities in rats and dogs (F = 66 and 59%, respectively). Compound **28** demonstrated dose-dependent increases in oxygen consumption in rats with a minimal effect on heart rate increase, further proving its promise as an orally active β_3-AR agonist.[137]

7.20.3.3.5 Discovery of amibegron and other cyclic β_3-AR agonists

The crowded competitive environment around the key central pharmacophore of β_3-AR agonists has inspired innovative ways to maintain critical components of the pharmacophore while extending into new intellectual property (IP) space. Cyclization of the linker between the secondary amine and the RHS phenyl group afforded cyclohexane derivative GS-332 (**29**), which was

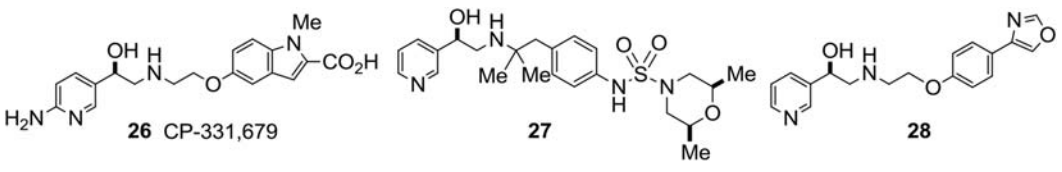

Fig. 14 Medicinal chemistry of β_3-AR agonists from Pfizer.

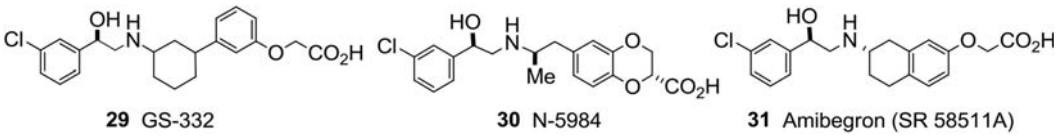

Fig. 15 Structure of novel cyclized pharmacophores and amibegron (**31**).

evaluated in a rat cystometry study where it evoked an increase in the bladder capacity relative to vehicle-treated rats (Fig. 15).[138] Chemists at Nisshin generated a novel cyclic RHS structure class by fusing a dioxane ring to the RHS phenyl moiety leading to the potent and selective β_3-AR agonist N-5984 (**30**).[139]

One of the earliest reported cyclic agonists to exhibit pharmacological differentiation from the first-generation rat β_3-AR agonists was Sanofi's amibegron (**31**) (Fig. 9). Amibegron possesses a novel phenylethanolaminotetraline (PEAT) RHS moiety that helps impart excellent β_3-AR selectivity. In a rat colon motility assay believed to be specific for β_3-AR pharmacology, amibegron inhibited motility in the rat colon without relaxing guinea pig trachea (a β_2-AR-mediated effect) or increasing atrial frequency (a β_1-AR-mediated effect).[140] Amibegron's potency at rat colon motility inhibition was similar to that of the nonselective β-AR agonist isoproterenol (**3**) but without the undesirable effects on trachea and atrial tissues that were attributed to a lack of selectivity over β_1- and β_2-AR agonism. Amibegron never progressed beyond early-phase clinical trials for the treatment of metabolic disorders,[38] however, as it was repurposed for the treatment of depression based on its antidepressant and antianxiolytic activities in rats together with reports that β_3-ARs are present in the brain.[141,142] More recently, however, research has appeared that suggests that the antidepressant activity of amibegron may be attributed to its blockade of serotonin reuptake at the serotonin receptors.[143,144] This compound has recently been shown to be in phase 3 clinical trials for the treatment of major depressive disorder.[38]

7.20.3.3.6 Discovery of solabegron and related analogs

Early research at SmithKline Beecham to identify potent human β_3-AR agonists focused on the introduction of various acidic moieties at the RHS side to improve selectivity over human β_1- and β_2-ARs. Phosphinic acid analog **32**, for example, was reported as a key discovery in this early SAR effort to dial out activity at the other β-AR subtypes (Fig. 16).[145] Parallel to this work, a team at Glaxo discovered an aniline linker between the secondary amine and the RHS phenyl ring that afforded potent human β_3-AR agonists with a chlorophenyl ring on the LHS side such as compound **33**. Improvements in selectivity over β_1- and β_2-ARs were achieved with the installment of a series of acid bioisosteres to afford selective β_3-AR agonists such as acylsulfonamide **34**.[146] To improve the dog pharmacokinetic (PK) profiles of analogs such as **34**, the team then screened a series of biaryl acid derivatives that were simplified by removal of the chiral methyl moiety to eventually identify the biaryl acid solabegron (**35**) as a promising analog with good overall half-lives and oral bioavailabilities in rats, dogs, and monkeys ($T_{1/2s}$ = 2.1, 3.3, and 4.5 h; F = 30, 43, and 46%, respectively).[147] Further optimization of this biaryl series led to the discovery of the structurally related analog **36,** which demonstrated even better potency and selectivity for the human β_3-AR with further improvements in its overall dog PK profile ($T_{1/2}$ = 6.1 h; F = 60%).

Solabegron was initially studied in db/db mice for its antidiabetic and thermogenesis properties,[148] but as attention shifted away from obesity/diabetes as indications for β_3-AR agonists, the compound was repositioned as a potential treatment for irritable bowel syndrome (IBS) and OAB. In addition to adipose tissue, cardiovascular tissue, and bladder smooth muscle, β_3-ARs are expressed in the human gastrointestinal tract.[149,150] In normal mice, rodent β_3-AR agonists have been shown to delay GI transit, while no effect was observed in β_3-AR-deficient mice.[151] In another study demonstrating the function of β_3-AR agonists in rodents, the selective rodent β_3-AR agonist **6** decreased fecal weight in a rat diarrhea model.[152] Finally, multiple teams have reported that β_3-AR agonists inhibit spontaneous human colon contractions in *ex vivo* studies using isolated human colon samples.[153–156] Solabegron was able to inhibit cholinergic contractions in isolated human colon samples; however, when it was tested in healthy human volunteers, there was no overall change in gastric, small bowel, or colonic transit after 7 days at 50 or 200 mg twice-daily doses.[157] In this study, solabegron was reported to be rapidly absorbed with a T_{max} that ranged from 1 to 3 h and a mean half-life ranging from 1.6 to 2.3 h.

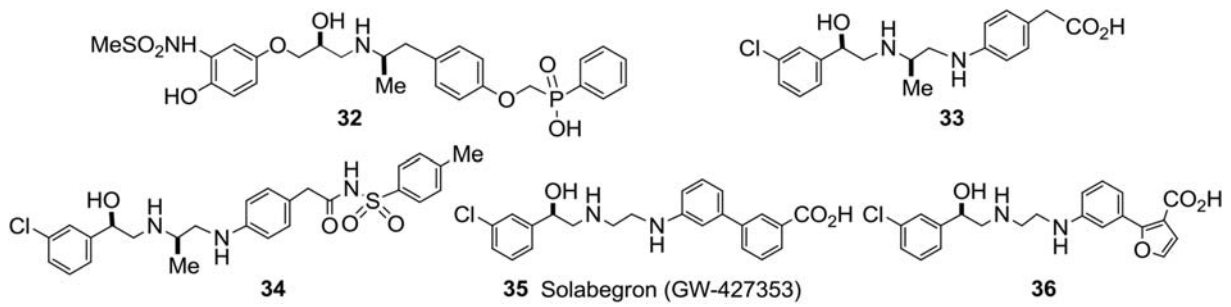

Fig. 16 Medicinal chemistry leading to the discovery of solabegron (**35**) and beyond.

Furthermore, the compound had no effect on bowel function during this study. Consequently, solabegron was not an effective treatment for IBS as it has no overall effect on gastrointestinal transit or bowel function.[157]

Solabegron was more successful as a treatment for OAB.[158] This compound demonstrated bladder smooth muscle relaxation in dog bladder strips as well as increased bladder capacity in a dog cystometry model.[159] Additionally, solabegron induced relaxation of precontracted isolated human bladder strips in an *ex vivo* study.[160] In a phase 2, double-blind placebo-controlled study in female OAB patients, solabegron reduced the number of incontinence episodes from baseline compared with placebo after 8 weeks of treatment at doses of 50 and 125 mg twice daily (BID).[161] Additionally, solabegron reduced the number of micturitions over 24 h from baseline compared with placebo at week 4 and week 8 as well as the number of urgency episodes over 24 h. A dose-dependent increase in voided volume in the same study suggests that solabegron also dose-dependently increases bladder capacity. With regard to tolerability, there was no difference between placebo group and drug treatment group in the incidence of dry mouth or constipation, two of the key tolerability issues that lead to discontinuation of AM therapies. On the other hand, a few patients receiving the 50 and 125 mg BID doses exhibited hypertension. Follow-up on cardiovascular parameters with 24 h blood pressure monitoring demonstrated no significant mean changes from baseline out to week 8 for ambulatory systolic or diastolic blood pressure, mean arterial pressure, or heart rate for each dose of solabegron tested.[161] Overall, the phase 2 study of solabegron in female OAB patients was promising; however, longer term phase 3 studies in a broader patient population would be needed to better inform on the potential of this drug to treat patients suffering from OAB.[158]

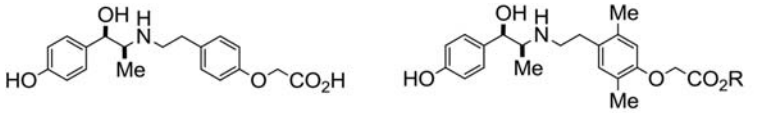
7.20.3.3.7 Discovery of ritobegron and related analogs

Early work from Kissei revealed that phenol derivatives such as ritodrine (**37**) possess potent β_2-AR and β_3-AR agonist activity (Fig. 17).[162] In an early report, they describe the use of a ferret detrusor muscle relaxation assay to help steer SAR toward potent β_3-AR agonists while maintaining high selectivity over β_1- and β_2-AR pharmacology using rat atria and rat uteri.[163] Further modifications of the LHS portion of this lead class afforded compounds that exhibited further improvements in β_3-AR agonism at the human receptor. The dimethylphenyl analog KUC 7322 (**39**) was selected for further development as its ethyl ester prodrug ritobegron (**38**) that improved oral exposures in rats by about an order of magnitude.[164] The active drug **39** is a potent and selective rat β_3-AR agonist and was shown to relax precontracted rat bladder muscle at a potency and efficacy comparable with rat β_3-AR agonists **3**, **4**, and **6**.[165] *In vivo*, the prodrug **38** dose-dependently decreases intravesicular pressure (IVP) in the rat bladder. In contrast to the nonselective β-AR agonist **3**, however, compound **39** showed much higher selectivity in rats for its effects on atrial rate and myometrial contraction, thus demonstrating improved selectivity with respect to *in vivo* PD effects.[165]

To demonstrate the effects of this drug in a primate, compounds **38** and **39** were evaluated in a series of cynomolgus monkey studies.[166] The acid **39** reduced resting tension in isolated cynomolgus bladder tissue at a potency and efficacy similar to **3** and **6**. In contrast to **3**, however, compound **39** was significantly more selective for its bladder effects compared with its effects on atrial rate (β_1-AR-mediated effect) and tracheal relaxation (β_2-AR-mediated effect). In anesthetized cynomolgus monkeys, intraduodenally administered **38** dose-dependently decreased intravesicular bladder pressure without having any effects on blood pressure or heart rate even at the highest dose tested (10 mg/kg). Moreover, the drug concentrations that induce bladder relaxation in the *in vitro* study correlated well with the efficacious plasma concentrations from the *in vivo* study, suggesting a potential *in vitro*/*in vivo* correlation that may help guide human PK targets. Ritobegron progressed into phase 3 clinical trials for the treatment of OAB; however, these trials were halted, and although the results have not been published, a press release from Kissei reported that the efficacy end points from this study were not achieved.[101]

7.20.3.3.8 Discovery of MK-0634, vibegron, and related analogs

A screening hit from Merck's sample collection (**40**) afforded a good starting point for a discovery program aimed at identifying selective human β_3-AR agonists (Fig. 18).[167] Instead of using animal tissue assays to identify selective human β_3-AR agonists, the cloned human β_3-AR *in vitro* assay was used to guide human β_3-AR agonist potency, and binding to β_1- and β_2-AR was used to guide selectivity over these subtypes.[167–169] The binding assay was critical because the active enantiomer of **40** showed potent binding to β_1- and β_2-ARs but very little functional agonist activity at these antitargets. A significant improvement in human β_3-AR selectivity was achieved by shortening the linker chain between the amine and the RHS phenyl group, removal of the chiral methyl substituent, and replacement of the methoxy substituent with a sulfonamide moiety such as **41**.[170] Further elaboration of the RHS bromide to a series of ureas culminated in the discovery of the potent human and rhesus β_3-AR agonist L-755,507 (**42**), which was more than 440-fold selective over binding to human β_1- and β_2-ARs.[170] When administered intravenously to rhesus monkeys, compound **42** increases lipolysis and metabolic rate dose-dependently, thus demonstrating β_3-AR-mediated PD effects



37 Ritodrine (KUL-7211)

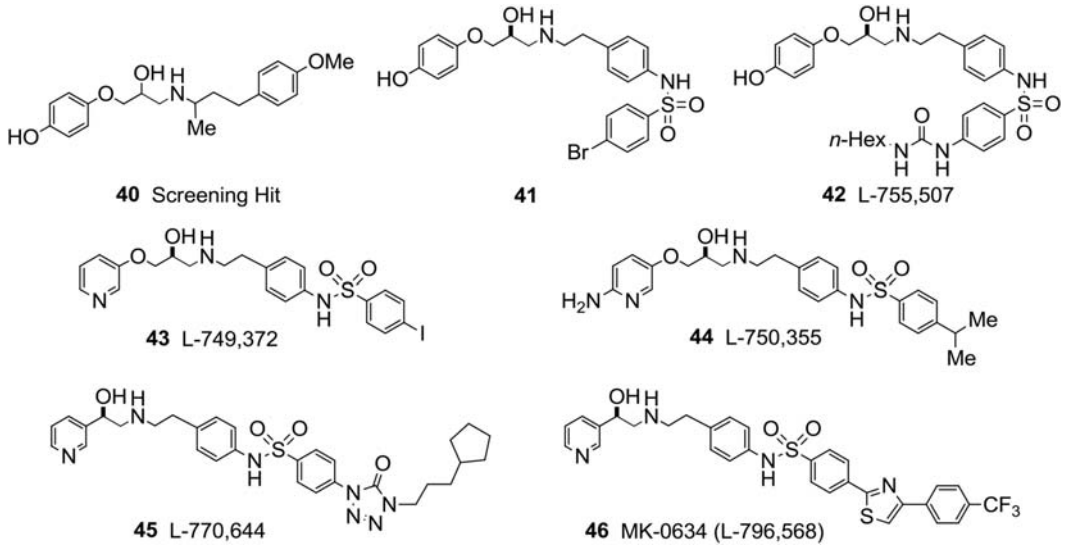

Fig. 18 Medicinal chemistry leading to the discovery of MK-0634 (**46**).

in a primate. Furthermore, only minimal increases in heart rate were observed, which further confirmed a high *in vivo* selectivity over β_1-AR.[171]

The promising PD effects of **42** in rhesus monkeys together with the poor oral PK profile of this compound in preclinical species prompted further investigation to improve the overall PK profile of this sulfonamide series. Further investigation in this series suggested that absorption could be achieved by replacement of the RHS urea, but oral bioavailability was still poor due to rapid glucuronidation of the LHS phenol moiety. Replacement of the phenol with either a pyridine ring or an aminopyridine ring helped address the first-pass metabolism liability, while replacement of the urea with more hydrophobic substituents such as iodine L-749,372 (**43**) and isopropyl L-750,355 (**44**) improved absorption. Although oral bioavailabilities for **43** and **44** were still somewhat low in rats (4% and 13%, respectively), they were significantly improved in dogs (41% and 47%, respectively). In the human β_3-AR *in vitro* assay, both of these compounds appeared to be partial agonists, although both demonstrated full lipolytic effects when administered to rhesus monkeys.[172] Further efforts to improve these compounds were focused on improving the overall PK properties while also improving *in vitro* selectivity over human β_1- and β_2-AR binding. Introduction of the arylethanolamine moiety instead of the aryloxy group on the LHS side[173] accompanied by further modification of the urea moiety of **42**[174,175] ultimately led to the discovery of L-770,664 (**45**), a potent and highly selective human β_3-AR agonist with moderate oral bioavailability in both rats and dogs (27% for both).[176] Compound **45** was investigated extensively in rhesus monkeys where in increased metabolic rate, lipolysis induces facial flushing and also tachycardia that was attributed to the vasodilation effects of β_3-AR agonism.[73,176]

To further improve the oral bioavailability of **45**, extensive investigation was performed to identify replacements of the aliphatic RHS "tail," which culminated in the discovery of MK-0634 (**46**). A wide range of fused heterocycles[177] and substituted biaryl groups[178–181] were tolerated in the RHS region; however, few demonstrated improved oral bioavailability or selectivity compared with **45**. A breakthrough was realized with the discovery and optimization of a thiazole benzenesulfonamide substituent that showed improvements in potency, selectivity, and oral bioavailability compared with previous analogs.[182–184] The compound with the best combination of potency, selectivity, and overall PK properties was the trifluoromethylphenyl-substituted benzene thiazole MK-0634 (**46**), which was selected for further *in vivo* evaluation.[183] Compound **46** evoked hyperglycerolemia (lipolysis) in dogs after oral dosing and dose-dependently in monkeys in sequential rising dose i.v. infusion studies. The ED_{50} for the expected β_3-AR-mediated lipolysis in monkeys (0.26 mg/kg) was substantially lower than the dose observed to modestly increase the heart rate with this compound ($ED_{15HR} = 10$ mg/kg).[183] Further development of compound **46** supported its advancement into human clinical trials. After a single-dose administration of **46** in obese men, this compound increased both metabolic rate and lipolysis as measured by increases in circulating plasma FFAs and glycerol.[185] Although the acute lipolysis and metabolic rate increases observed with **46** suggested β_3-AR target engagement was achieved in adipose tissue at the exposures studied, a 28-day study with **46** in obese men at matching drug exposures revealed that the lipolysis and metabolic rate increases were not sustained, and further study of this compound for obesity was discontinued.[70] Compound **46** was later repurposed for the treatment of OAB where it demonstrated reductions in the number of daily micturitions, total incontinence, urge incontinence, and strong urge after 8 weeks of dosing in OAB patients.[186] The efficacy of **46** from this study was comparable with similar reports using the AM agent Detrol LA at 12 weeks of treatment, but in contrast to Detrol LA, compound **46** showed a low rate of prevalence of dry mouth or constipation.[186,187] Unfortunately, further development of **46** for the treatment of OAB was stopped due to structure-based toxicity observed in preclinical safety studies. Moreover, compound **46** possessed additional structure-specific liabilities such as victim drug–drug interactions, phospholipidosis in preclinical species, and the formation of metabolites that circulate at high levels in preclinical species and

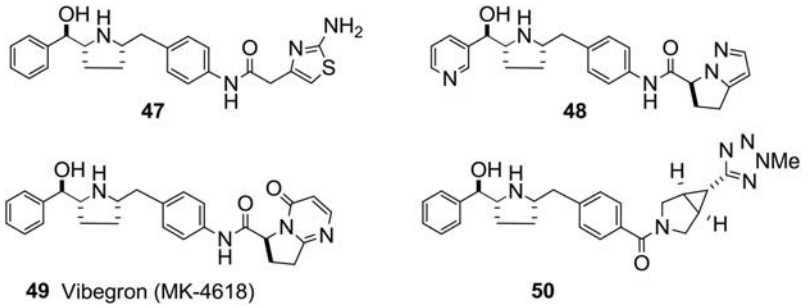

Fig. 19 Medicinal chemistry leading to the discovery of vibegron (**49**) and beyond.

humans.[186] Consequently, a new effort was initiated to identify a backup compound more suitable for long-term clinical development for the treatment of OAB.

One of the liabilities of **46** is related to oxidative metabolism that occurs around the secondary amine moiety and results in cleavage of the chain to form metabolites that accumulate in preclinical species and humans.[188,189] To reduce the risk of oxidative metabolism and the linker cleavage concern, a pyrrolidine ring was incorporated into the ethanolamine pharmacophore, thus introducing a second generation of β_3-AR agonists such as compound **47** (Fig. 19).[189] The aminothiazole **47** possessed poor oral bioavailability, however, which prompted evaluation of additional RHS groups. Some early SAR from a related anilide series revealed that the right balance between the LHS aromatic ring and the RHS anilide heterocycles could afford compounds with improved overall PK properties,[190] and application of these early discoveries to the pyrrolidine scaffold led to the discovery of compound **48**, which possessed modest to excellent oral bioavailabilities in rats, dogs, and monkeys (35%, 100%, and 11%, respectively) and excellent selectivity over β_1- and β_2-ARs.[191] Additionally, **48** decreases micturition pressure in a rat bladder hyperactivity model, thus confirming its PD effects in the tissue of interest. On the other hand, more extensive off-target screening demonstrated that **48** inhibited serotonin transport (SERT) and hERG, and the acetamide moiety underwent rapid hydrolysis in human plasma to afford the aniline. Although the resulting aniline was negative in an *in vitro* mutagenicity assay, this nevertheless suggested a risk for human-specific metabolites that would not be formed in preclinical species. Consequently, an improved overall profile was sought.

By changing the pyrazole of **48** to a pyrimidone and the LHS pyridine ring to a phenyl, the issues encountered with compounds **46**–**48** were solved. Vibegron (**49**) was selective over hERG, SERT, $\beta_{1/2}$-ARs, and a large panel of off-target assays. Additionally, the overall cross-species PK properties for **49** are excellent with oral bioavailabilities between 20 and 46% across three species and preclinical $T_{1/2s}$ ranging from 7 to 14 h. In contrast to **48**, compound **49** was stable in human plasma incubations, thus indicating a reduced risk for formation of human-specific metabolites.[186] Furthermore, the overall profile of **48** suggests a low risk for this compound to be a victim or a perpetrator of any drug–drug interactions. In rats, **49** dose-dependently decreased micturition pressure, increased functional bladder capacity, and increased lipolysis, thus demonstrating the effects of activation *in vivo*. Importantly, compound **49** demonstrated a reduced risk for phospholipidosis *in vitro*[192] as well as *in vivo*, and the overall preclinical safety profile of this compound supports long-duration phase 3 clinical trials. Vibegron (**49**) is currently in phase 3 clinical trials for the treatment of OAB.

More recently, the same team reported a benzamide series in the RHS region such as compound **50**.[193] This "reverse amide" series demonstrates that potent and selective β_3-AR agonists can be identified that lack the hydrogen-bond donor that is often present in this region. Although good oral bioavailabilities were achieved in rats and dogs (56% and 51%, respectively), the half-lives in these species were suboptimal, and further work in this series is needed to identify a compound with improved potential for QD dosing in humans.

7.20.3.3.9 Discovery of mirabegron and a series of biphenyl acid β_3-AR agonists

Inspired by the cyclic PEAT derivative **13**, a team at Fujisawa fused a cycloheptane ring to the RHS phenyl ring of the standard β_3-AR agonist pharmacophore to generate a new class of agonists. By hybridizing the fused seven-membered ring analog with early rat β_3-AR agonists **6** and **4**, novel analogs FR-165914 (**51**)[194] and FK-175 (**52**)[195] were generated (Fig. 20). Upon oral dosing in rodent models, FR-149175 demonstrates antiobesity and antidiabetic effects.[195,196] In obese Zucker fatty rats, compound **52** increased lipolysis and oxygen consumption (energy expenditure) dose-dependently in a rising single-dose study. Additionally, increased oxygen consumption was sustained during twice-daily oral dosing after two weeks of treatment with **52** in these rats demonstrating that the thermogenic pharmacodynamic effect is not attenuated upon multiple-day dosing.[195] In phase 1 clinical trials, compound **52** was well absorbed, but its human half-life and potency were insufficient to support once-daily dosing for OAB, and thus, the compound was discontinued.[197]

Further SAR in the PEAT class of β_3-AR agonists led to identification of tetralin **53** as a promising potent and highly selective β_3-AR agonist in this fused-ring class. In rats, dogs, and monkeys, **53** exhibited impressive oral bioavailabilities ($F > 60\%$) and half-lives (14, 14, and 8 h, respectively).[197] In a dog cystometry model that used carbachol to increase IVP in the bladder, i.v. administration of compound **53** resulted in a reduction of IVP similar to that observed for compound **52**, thus supporting its use as a potential therapeutic for the treatment of OAB. In a structurally related series of ring-opened derivatives, optimization around

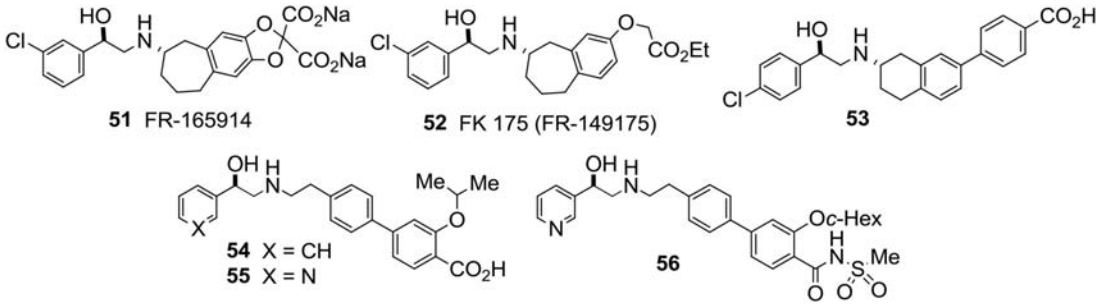

Fig. 20 Medicinal chemistry leading to the discovery of a series of biaryl acid-derived β_3-AR agonists and their acylsulfonamide bioisosteres.

the biaryl benzoic acid moiety led to identification of compound **54**, which exhibits excellent human β_3-AR potency and selectivity over human β_1- and β_2-ARs.[198] Further SAR on the LHS led to the identification of the related pyridine derivative **55**, which also possessed excellent potency and selectivity.[199] Both **54** and **55** showed good oral bioavailabilities in preclinical species ($F > 60\%$ and 25%, respectively), but the phenyl analog **54** had longer half-lives in rats, dogs, and monkeys ($T_{1/2} = 9.5$, 14.5, and 22 h, respectively) compared with pyridine **55** ($T_{1/2} = 3.5$, 9.9, and 2.2 h, respectively). Upon intraduodenal (i.d.) administration of these compounds into dogs, both **54** and **55** demonstrated excellent efficacy in the carbachol-induced IVP model, although the pyridine analogs generally outperformed the phenyl analogs.[198,199] The overall balance of potency, selectivity, and PK profile led the team to select compound **54** as a clinical candidate.[199]

In vitro metabolite identification studies with compounds such as **54** and **55** in hepatocytes revealed the presence of metabolites resulting from oxidative metabolism and cleavage at the carbon–nitrogen bond to the left of the secondary amine and acyl glucuronidation of the carboxylic acid moiety.[200] In order to reduce the risk of formation of potentially toxic metabolites, the team sought to replace the carboxylic acid moiety with acylsulfonamide acid bioisosteres such as compound **56**. Despite elimination of the carboxylic acid moiety, compound **56** maintains excellent β_3-AR potency and selectivity over β_1- and β_2-ARs. Moreover, compound **56** maintained good overall oral bioavailabilities in preclinical species ($F \geq 25\%$) but relatively short half-lives in rats, dogs, and monkeys ($T_{1/2} = 3.0$, 5.5, and 4.7 h, respectively).[200] In the dog carbachol cystometry model, a reduction in IVP was observed with a series of acylsulfonamides, although their IVP reduction was less than their acid counterparts likely due to the higher lipophilicity and therefore higher plasma protein binding of this series.

Inspired by the early sulfonamides such as **41** that were reported to be potent and selective human β_3-AR agonists,[167] a team of scientists at Astellas designed a series of RHS acetanilide-derived β_3-AR agonists to mimic the orientation of the two RHS aromatic groups of the sulfonamide series. 2-Pyridylacetanilide derivative **57** was identified as an early lead toward discovery of a selective β_3-AR agonist with roughly a 10-fold selectivity over β_1-AR agonism (**Fig. 21**).[201] A significant improvement in selectivity over β_1-AR was eventually achieved by introduction of a methyl group to the anilide nitrogen. Potency at β_3-AR was retained with removal of the phenol moiety and modification of the RHS to the benzyl-substituted imidazole **58**.[202] High selectivity over human β_1- and β_2-AR activation could also be achieved without methylation of the anilide by replacement of the imidazole ring with aminothiazoles such as compound **78**. Once-daily oral administration of compounds **58** and **59** for 4 days to diabetic KK mice resulted in a reduction in plasma glucose levels at doses of 30 and 3 mg/kg/day, respectively.[202,203] Next, replacement of the LHS phenoxymethylene group with a simple phenyl ring and removal of the phenyl ring from the aminothiazole afforded **60**, the most potent and selective β_3-AR agonist reported in the series.[204] Finally, removal of the methyl substituent on the thiazole ring afforded mirabegron (**61**, YM-178).[205,206]

Mirabegron is well characterized in various *in vitro* and *in vivo* models of bladder muscle relaxation and bladder dysfunction. *In vitro*, mirabegron induces concentration-dependent relaxation of isolated precontracted bladder strips from both normal rats and rats with partial bladder outflow obstruction (BOO).[206–208] Similarly, mirabegron relaxes precontracted bladder strips from healthy humans as well as patients with BOO due to benign prostate hyperplasia (BPH) both with and without detrusor overactivity (DO).[206,209] In anesthetized rats, the actions of mirabegron and oxybutynin, an AM agent, differ from each other. Both compounds

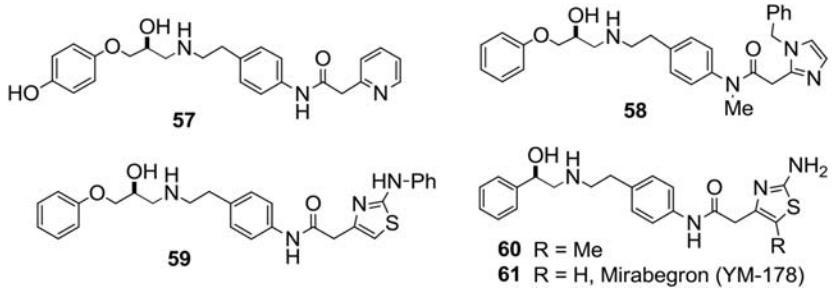

Fig. 21 Medicinal chemistry leading to the discovery of mirabegron (**61**).

are able to dose-dependently reduce the frequency of bladder contractions to improve urine storage, but only mirabegron was able to do so without affecting the contraction amplitude.[206] Additionally, mirabegron was able to reduce resting IVP in anesthetized rats, while AMs such as oxybutynin and tolterodine had no effect on IVP.[210] Finally, one recent cystometry study in rats demonstrated that mirabegron can inhibit mechanosensitive bladder afferent activity and that this is a potential mode of action for its effects on the reduction of bladder microcontractions.[211] In contrast, oxybutynin had no effect on the number bladder microcontractions in the same study.[211] Atherosclerosis can contribute to the symptoms of OAB when accompanied by bladder ischemia and subsequent DO. In a conscious rat model of chronic bladder ischemia, mirabegron increased bladder capacity, voiding volume, and micturition intervals, thus suggesting that the compound may have a protective effect on bladder function in patients with DO due to bladder ischemia.[212] In conscious cynomolgus monkeys, oral administration of mirabegron dose-dependently decreased micturition frequency and increased voiding volume per micturition.[213] Moreover, mirabegron also evoked concentration-dependent relaxation of precontracted monkey bladder strips.[213]

Results from preclinical safety assessment studies with mirabegron in rats and dogs have been summarized, and only effects consistent with β_3-AR activation in preclinical species were present near clinically relevant doses/exposures.[205] These effects typically include elevated heart rate in rats and dogs and a decrease in blood pressure in dogs consistent with the vasodilatory effects of β_3-AR agonists in this species.[69–72] At high exposure multiples, hepatotoxicity, neurotoxicity, cardiovascular toxicity, and reproductive effects were noted, although many of these effects were reversible and monitorable.[205] Mirabegron was neither genotoxic nor carcinogenic in the standard set of genotoxicity assays and from the 2-year rodent carcinogenicity studies, thus mitigating any concerns around the aniline substructure or the aminothiazole moiety.[205]

Mirabegron is formulated using an oral controlled absorption system (OCAS)[214] that serves to facilitate once-daily dosing in humans as well as to reduce the C_{max}. In humans, the oral bioavailability of mirabegron is about 24–53% and the terminal half-life from the extended-release formulation is around 50 h.[215] The compound is eliminated mostly as intact parent in both urine and feces, although metabolites were also detected in urine as well as in circulation. Circulating metabolites are inactive and possess shorter half-lives than parent; therefore, they all exhibit formation rate-limited kinetics. Major circulating metabolites are due to amide hydrolysis followed by glucuronidation followed by dealkylation around the secondary amine.[216] In renally impaired patients, mirabegron plasma concentrations are increased; therefore, a lower dose is recommended for this patient population.[217] Mirabegron is metabolized by both CYP3A and CYP2D6,[218] and it shows only a modest increase in drug levels in patients who are poor CYP2D6 metabolizers compared with patients who are extensive CYP2D6 metabolizers.[219] This compound is also a CYP2D6 inhibitor, and when co-dosed with drugs metabolized by CYP2D6, an increase in their systemic exposure was observed.[220] Consequently, care must be taken not to co-dose mirabegron with a drug metabolized by CYP2D6 that possesses a narrow therapeutic index.

The clinical safety of mirabegron has been reviewed extensively, and in general, the compound is safe and well tolerated at clinically relevant exposures.[205,221–223] An analysis of clinical data comparing patients treated with mirabegron with patients treated with AM agents revealed that mirabegron appears to be better tolerated with respect to gastrointestinal adverse events such as dry mouth, constipation, dyspepsia, and nausea.[222] The long history of cardiovascular effects associated with earlier, less selective β_3-AR agonists has led to careful evaluation of the cardiovascular effects of mirabegron in patients with OAB. At the clinically used dose of 50 mg QD, mirabegron causes small increases in blood pressure ($\leq$1 mm Hg) and pulse rate (1 bpm) compared with placebo.[223] Larger increases in pulse rate (5–6 bpm) were noted in the proof-of-concept study in OAB patients who were dosed with immediate-release mirabegron twice daily.[224] These small changes in pulse rate and/or blood pressure were not associated with any clinically significant increases in cardiovascular AEs. At therapeutic doses, mirabegron does not cause any increase in QTc or ventricular arrhythmia; however, at a supertherapeutic dose of 200 mg, a prolongation of the QTc interval was observed in women.[225] As a result of clinical trial exclusion criteria, mirabegron has not yet been studied in some high-risk populations such as patients with arrhythmia, uncontrolled hypertension, or heart failure.[223]

Multiple clinical trials have demonstrated the benefits of mirabegron in patients suffering from OAB syndrome, and the results of these studies have been summarized recently.[205,226,227] With regard to efficacy at treating symptoms of patients with OAB, mirabegron is as efficacious as most AMs including the market leader tolterodine ER. Compared with placebo, reductions in daily micturitions, voiding volume, daily episodes of urinary incontinence, and daily episodes of urge urinary incontinence were observed with daily treatment of mirabegron. Mirabegron also demonstrated improvement on subjective secondary end points compared with placebo as measured by quality-of-life questionnaires for patients with OAB. The overall tolerability profile of mirabegron is similar to placebo, whereas the rates of adverse effects are increased with AM agents relative to placebo. Although both 50 mg and 100 mg daily doses were studied in phase 3 clinical trials, it was determined that the higher dose does not offer any additional benefit to OAB patients, and thus, the current recommended dose is 50 mg for most patients and 25 mg for patients with severe renal insufficiencies or moderate hepatic failure. Importantly, mirabegron was efficacious in patients who discontinued AM therapy due to either lack of efficacy or poor tolerability.[228] In summary, mirabegron is the first-in-class β_3-AR agonist approved drug that is currently used for the treatment of patients who suffer from OAB. It is efficacious, safe, and well tolerated and is recommended as a treatment option for patients who either have discontinued AM therapy or are contraindicated for AM agents.

7.20.4 Summary

Valuable lessons that apply to the broader field of drug discovery can be gleaned from reviewing the history of β_3-AR agonists. For example, the disconnect between ligand SAR at rodent β_1-, β_2-, and β_3-ARs and the corresponding human receptors led to some early

clinical failures with β3-AR agonists due to either lack of efficacy, adverse effects, or both. Moreover, species differences in early ligand profiles made it difficult to discern whether the corresponding clinical failures were due to differences in β3-AR biology (ie, mechanism-based) or to the progression of suboptimal agonists into humans (ie, compound-based).[42,48] As greater biochemical and pharmacological rigor was applied to optimize potent and selective human β3-AR agonists, an improved understanding of both the preclinical and clinical pharmacology of selective β_3-AR agonists emerged.

After potency and selectivity were addressed, significant hurdles remained to identify safe and orally bioavailable β_3-AR agonists. The polar nature of the conserved ethanolamine pharmacophore limited passive permeability of early agonists, and this hurdle was overcome through the use of prodrugs, acid bioisosteres, and/or novel ways to present the acid moieties. Once oral bioavailability was achieved, however, there are reports of new safety challenges that emerged due to metabolites arising from the resulting compounds. Consequently, teams focused on removing the metabolic hot spots that may have contributed to safety concerns while also seeking to maintain acceptable oral bioavailability. Finally, more recent optimization efforts describe the importance of managing physicochemical properties to reduce toxicity risks.[229]

IP coverage around β_3-AR agonist chemical structures has largely focused around a single conserved ethanolamine pharmacophore derived from the receptors' endogenous ligands. As a result of this crowded competitive space, scientists working in the area were increasingly challenged to create novel structure classes through a variety of different strategies. For example, heteroatom incorporation into linkers or incorporation of heteroaromatic rings in the place of phenyls was frequently leveraged as a means to generate novel IP space. Likewise, innovative incorporation of saturated rings into the extended pharmacophore region often served as a launching point for novel IP while simultaneously improving selectivity of the resulting scaffolds. Finally, the need to improve oral bioavailability often led to the incorporation of SAR that also afforded novel IP space, thus underscoring the proverb that necessity is the mother of invention. Importantly, each successful new scaffold discovery required reoptimization of the remaining substituents to achieve adequate potency, selectivity, and physicochemical and ADMET properties for further development. Once optimized, the final clinical candidates possessed unique profiles with respect to advantages and liabilities, thus demonstrating that a common pharmacophore can ultimately yield optimized compounds with distinct profiles. Regardless of the impetus behind the discovery of these multiple novel scaffolds, it is a testimony to the creativity of the medicinal chemists working in this area that well over 100 patent publications have appeared around a single conserved pharmacophore.

The switch of therapeutic indication for β_3-AR agonists away from obesity and diabetes to OAB illustrates some of the opportunities and challenges that can be encountered when repurposing therapeutics. It is clear from early animal models used to characterize compounds that most organizations initiated β_3-AR agonist programs with the goal to develop a drug to treat either obesity or diabetes. As disappointing clinical data began to emerge, however, the search for new indications for these potent and selective β_3-AR agonists became apparent. Indeed, β_3-AR is expressed in multiple tissues, and agonists induce a broad range of measurable pharmacologies in preclinical species. Ultimately, the weight of evidence in favor of using β_3-AR agonists to treat symptoms of OAB gave way to reports of success in the clinic in OAB patients. Clearly, the availability of potent and selective β_3-AR agonists accelerated investigations into the new indication by facilitating the acquisition of supportive preclinical data in OAB animal models. Nevertheless, some of the challenges encountered in repurposing these agonists as new animal models were incorporated to guide optimization efforts.[96] Care must be exercised in bridging pharmacodynamic data from different tissues, however, as the effects of β_3-AR agonists in the bladder may not reflect their effects in adipose tissue, and translational PK/PD strategies needed to be further developed.[230,231] Evidence continues to accumulate for the use of β_3-AR agonists to treat a variety of additional disorders[38] such as heart failure[62–67] and preterm labor,[232–234] and some of the lessons learned from the transition between obesity and OAB may be applied for these new efforts.

β_3-AR agonists are emerging as one of the most promising new therapeutic options for the treatment of OAB.[235,236] A comparative cross analysis of published OAB efficacy and safety data comparing mirabegron data with data from six different AM agents revealed that the β_3-AR agonist exhibited similar efficacy but with an improved tolerability profile compared with the AM agents, especially with respect to dry mouth.[237] Additionally, a recent evaluation of patient and physician preferences for oral OAB medications revealed a patient preference for drugs exhibiting a profile that more closely resembles β_3-AR agonists than AM agents.[238] Further clinical comparisons are needed, however, to better inform on the risks and benefits of these two classes of medications. One promising direction for the future of OAB pharmacotherapy is the use of combinations of existing AM agents with β_3-AR agonists.[91–93,239] The two mechanisms may complement each other and offer even better options for patients who suffer from OAB.

In conclusion, research on β_3-AR agonists has provided not only a promising new therapeutic option for the treatment of OAB but also a valuable insight into the broader field of drug discovery. Early challenges to characterize the biological profile of β_3-AR agonists were solved but new challenges to optimize chemical matter arose. As the chemistry challenges were solved, focus shifted once again back to the biology of β_3-AR agonists and the search for an appropriate therapeutic indication. Ultimately, the successful discovery of the application of β_3-AR agonist to treat OAB is a testimony to the perseverance and innovation of the hundreds of scientists who have worked in this field throughout the past 27 years.

PREFACE

Previous editions of *Comprehensive Medicinal Chemistry*, published in 1990 and 2006, provided an integrated reference source that encompassed all major aspects of drug discovery research. The third edition follows this tradition and considerably expands its scope and content.

The trailblazing scientific discoveries of the 21st century have brought new opportunities for drug discovery research. The discipline of medicinal chemistry continues to evolve as it adapts to these new opportunities and strives to solve new challenges. Covered in the new edition are not only the breakthrough therapies of the past decade in cancer, hepatitis C, heart failure, dyslipidemia, cystic fibrosis, multiple sclerosis, HIV, etc., but also extensive discussion of new business models in drug discovery research, shifting industry demographics, emerging technologies, *in silico* drug discovery tools, experimental ADME and toxicology, and biologics medicine. The tone of this edition is prospective in which contributors identify outstanding issues and paths forward in their area of expertise. The aim is to provide drug discovery scientists in industry, government, academia, and research organizations with a contemporary global perspective on the field that includes a look ahead in selected areas.

The eight individual volumes fulfill these objectives and include extensive discussion of biomolecular therapeutics, drug targeting and delivery, development of chemical biology tools, data collection and analysis, *in silico* models as predictors for biological properties, identification/validation of new targets, approaches to quantify target engagement, new methods for synthesis of drug candidates such as green chemistry, development of novel scaffolds for drug discovery, and the role of regulatory agencies in drug discovery.

The individual volume editors have done an outstanding job to identify topics and contributors to meet these goals and we thank them for their hardwork and diligence. In volume 1, Ana Martinez and Carmen Gil recruited an international group of contributors who provide chapters on the emerging role of organizations other than traditional pharmaceutical companies in drug discovery, the evolving science of chemical biology, and new organic chemistry contributions to the discipline. In volume 2, Helmut Buschmann, Norbert Handler, and Andrea Wolkerstorfer have accomplished a seemingly impossible task and attracted world-leading experts across the wide field of drug discovery enabling technologies, covering contemporary thinking in a wide range of key disciplines that enable modern medicinal chemistry and drug discovery and development. The computational enabling technologies are the focus of volume 3, in which Andy Davis and Colin Edge have assembled chapters covering both ligand-based and protein structure–based advances as well as exciting new methodologies and case studies exploiting these. Alan Wilson identified experts in the fields of pharmacokinetics and toxicology who describe a wide range of contemporary advances in prediction and analysis of pharmaceutical properties and drug safety in volume 4. In volume 5, Ian Collins, Louis Lombardo, and Will Watkins have assembled leading experts to discuss high impact drug discovery accomplishments over the past decade in cancer chemotherapeutics, immunology and inflammation, and infectious diseases therapeutic areas. Ved Srivastava edited volume 6 on biologic medicines, a significant and rapidly evolving area where medicinal chemistry plays an important role. The chapters in this volume provide timely information on not only protein-based drugs, such as monoclonal antibodies and therapeutic proteins, but also peptides and nucleic acid–based therapeutics. Volume 7, edited by Adrian Hall, Santhosh Neelamkavil, and Rob Jones, presents a detailed account of the major advances in CNS, metabolic, and cardiovascular fields over the past decade and the promising new opportunities. Joerg Holenz edited volume 8 that presents case histories of successful drug discovery and strategic differentiation that have resulted in commercialized drugs and candidates in advanced clinical trials.

We are truly grateful to the publishing team at Elsevier that includes Gemma Tomalin, Rachel Gerlis, Marise Willis, and Sean Simms for their assistance and support throughout the process. With their expertise, this project became what we believe is a noteworthy and valuable resource for the discipline of medicinal chemistry. We look forward to the response and feedback of our colleagues who will use this information in their own work.

Samuel Chackalamannil, David P. Rotella, and Simon E. Ward

EDITORS-IN-CHIEF: BIOGRAPHIES

Dr. Samuel Chackalamannil

Dr. Chackalamannil obtained his PhD in chemistry from Yale University in 1984 and subsequently worked in drug discovery research at Schering-Plough Corporation and Merck Research Laboratories, where he was a distinguished fellow when he left in 2011. Since then, he has been teaching at Ernest Mario School of Pharmacy, Rutgers University, New Jersey.

Dr. Chackalamannil has significant accomplishments in the discovery of new medicines. He led the discovery of vorapaxar (Zontivity®), an FDA-approved antiplatelet drug for the prevention of heart attack and stroke. His group also discovered a PDE-5 inhibitor clinical candidate dasantafil and an adenosine A2a antagonist clinical candidate for the treatment of Parkinson's disease. Altogether, he was responsible for the discovery of nine development candidates in cardiovascular, central nervous system, and metabolic disease areas.

Dr. Chackalamannil is a coinventor of 62 allowed US patents and numerous patent applications worldwide. He has published 81 peer-reviewed articles and has coauthored a book. He has also given numerous lectures at international meetings and academic institutions.

Dr. Chackalamannil is a two-time recipient of the Thomas Alva Edison Award for Emerging Technology Patent and a two-time recipient of the Presidential Award for Discovery at Schering-Plough Research Institute. He has chaired several sessions at American Chemical Society national meetings and Gordon Research Conference on Medicinal Chemistry and was an organizer for Chemistry as a Life Science Symposium.

Dr. David Rotella

Dr. Rotella earned a PhD in medicinal chemistry from The Ohio State University and carried out postdoctoral research in organic chemistry at Penn State University. He joined the faculty at Montclair State University in July 2011 as the Margaret and Herman Sokol Professor of medicinal chemistry after a successful career in the pharmaceutical industry. He is an expert in the discovery and optimization of small molecule drug candidates for use in metabolic, cardiovascular, cancer, and central nervous system diseases. His current research is focused on discovering new lead compounds for use in parasitic and central nervous system diseases. He has coedited the seventh edition of *Burger's Medicinal Chemistry* and is a senior editor for the Royal Society of Chemistry's Drug Discovery book series. He has authored over 40 peer-reviewed articles, is an inventor on 8 issued US patents, and has contributed 10 book chapters.

Simon E. Ward

Simon Ward has an MA in natural sciences and PhD in synthetic organic chemistry from Cambridge University, UK. He has a wide-ranging experience of drug discovery in both large and small companies (GlaxoSmithKline, Knoll Pharmaceuticals, Vernalis, Chiroscience, BioCrea) and specialist experience of discovering and developing drugs for central nervous system indications. He has led multidisciplinary project teams and medicinal chemistry groups from target identification through to early clinical studies, delivering multiple clinical development candidates across indications. He is a fellow of the Royal Society of Chemistry. He is currently a professor of medicinal chemistry at the University of Sussex, UK, and the director of the Sussex Drug Discovery Centre, which he established within the University of Sussex in 2010.

CONTENTS OF VOLUME 8

Preface *v*

Editors-in-Chief: Biographies *vii*

Contributors to Volume 8 *ix*

Editorial Board *xiii*

Introduction *xv*

8.01 Medicinal Chemistry Case History: Osimertinib (AZD9291) 1
R A Ward and M R V Finlay

8.02 Trametinib 33
H Kawasaki and T Yamaguchi

8.03 Discovery of the Hypoxia-Activated Prodrug SN30000 58
M P Hay, K O Hicks, and W R Wilson

8.04 The Discovery of First-in-Class Inhibitors of the Nedd8-Activating Enzyme (NAE) and the Ubiquitin-Activating Enzyme (UAE) 95
J Ciavarri and S Langston

8.05 The Discovery of p97 Inhibitors 113
D J Wustrow, D J Anderson, M Rolfe, and H-J Zhou

8.06 Discovery of AMG 337: Using Structure Guided Scaffold Hybridization to Optimize Physicochemical Properties and Target Coverage of a MET Kinase Inhibitor 138
A A Boezio, E A Peterson, and J-C Harmange

8.07 Discovery of AZD0156: The First Potent and Selective Inhibitor of ATM Kinase for Clinical Evaluation 161
K G Pike

8.08 Tepotinib 178
O Schadt and A Blaukat

8.09 Verubecestat 204
A W Stamford, J N Cumming, J D Scott, and C O Strickland

8.10 The Discovery of Macitentan—A Standard Medicinal Chemistry Program? 252
M H Bolli, C Boss, J Gatfield, M Iglarz, and A Treiber

8.11 Case Histories: Anacetrapib 284
A Ali and J Duffy

8.12 Discovery of ROMK Inhibitor MK-7145: A Novel Mechanism Diuretic 308
Alexander Pasternak

8.13 Fragment-Based Discovery of AZD2716: A Novel, Potent Secreted Phospholipase A_2 ($sPLA_2$) Inhibitor for the Treatment of Coronary Artery Disease 339
F Giordanetto and D Pettersen

8.14 Canagliflozin 349
S Nomura

8.15 The Discovery and Development of *Seletalisib*: A Potent and Selective PI3Kδ Inhibitor for Inflammatory Diseases 366
D C Brookings

8.16 Medicinal Chemistry Case History: Structure-Based Drug Design of Oral and Inhaled p38 MAP Kinase Inhibitors as Clinical Candidates 408
L Xing and J Mathias

8.17 Are Two Better Than One in Rheumatoid Arthritis? Development of Dual p38α MAPK/PDE-4 Inhibitors for Treatment of TNFα-Driven Diseases 431
W Albrecht, S M Bauer, and S A Laufer

8.18 The Discovery of Potent and Selective Nonsteroidal Glucocorticoid Receptor Modulators AZD5423 and AZD7594, for the Inhaled Treatment of Respiratory Diseases 450
P Sjö, T Hansson, and K Edman

8.19 The Discovery of the MCH-1 Receptor Antagonist NGD-4715 for the Potential Treatment of Obesity 488
J Tarrant, K J Hodgetts, B L Chenard, J E Krause, and D Doller

8.20 Case History: AN5568 (SCYX-7158) 516
Y-K Zhang, Y R Freund, and R T Jacobs

8.21 KAE609 (Cipargamin): Discovery of Spiroindolone Antimalarials 529
B K S Yeung

8.22 Medicinal Chemistry Case History: Discovery of the Dihydroorate Dehydrogenase Inhibitor DSM265 as an Antimalarial Drug Candidate 544
M A Phillips, P K Rathod, T Rueckle, D Matthews, J N Burrows, and S A Charman

8.23 Harvoni: A Combination Therapy for Curing HCV 558
M J Sofia and J O Link

8.24 Discovery of Boceprevir and Narlaprevir: Ketoamide-Derived HCV NS3 Serine Protease Inhibitors for the Treatment of Chronic Hepatitis C 583
S Venkatraman

INTRODUCTION

For Claudia

Challenged by the decrease in productivity mainly due to high clinical attrition rates, pharmaceutical research, and development has fundamentally changed within the recent years. Disease understanding and target validation based on genetic evidence have significantly improved and lay the ground for testing selective modulation of relevant pathological pathways in stratified patient populations in the clinic. To name a few examples, advances in biology such as the ready availability of inducible pluripotent stem cells (iPSCs) along with gene editing (CRISPR-CAS9) have revolutionized phenotypic high content screening, and Chemical Biology has emerged as an important discipline for generating novel target hypotheses to selectively modulate disease relevant phenotypes.

These major drug discovery paradigm changes, but also the increased advances in the field of biological drugs (vaccines, antibodies, or cell-and-gene therapy), have put enormous pressure on Medicinal Chemistry to innovate itself and respond by demonstrating not only that chemical entities can be successfully developed for demanding targets but also that those drugs offer significant advantages in areas of high unmet medical need.

In this volume, I am very proud to present 24 powerful "answers" of distinguished Medicinal Chemists to the challenge of how to tackle the increasing demands for candidate drugs with respect to quality, disease relevance, and translatability successfully. Case histories have always represented a fascinating opportunity for the reader to learn: from "tips and tricks" how to solve a specific problem to best Medicinal Chemistry practices and strategies. At all major conferences, Medicinal Chemistry success stories are among the keynote lectures to attract and inspire audiences and to jointly celebrate learnings. I have been very fortunate to work with such an outstanding team of authors from academia, biotech, and big pharma to deliver what I believe is a very substantial, comprehensive, and up-to-date reference for successful applied Medicinal Chemistry.

Special thanks go to my series editor Samuel Chackalamannil, David P. Rotella, and the entire Elsevier team for their continuous support and their trust in my concept.

8.01.1 The Role of Epidermal Growth Factor Receptor (EGFR) Biology in Nonsmall Cell Lung Cancer (NSCLC)

Ligand induced activation of receptor tyrosine kinases such as the EGFR promotes activation of downstream pathways, driving proproliferative and survival cellular signals.[1] In a subset of NSCLC, the tumor is characterized by EGFR activating mutations (AMs) such as an exon-19 deletion (eg, E746-A750) or an L858R single point mutation, which largely renders the receptor constitutively activated even in the absence of ligand binding.[2] This results in sustained hyper-activation of signaling pathways downstream of EGFR such as protein kinase B and extracellular signal-regulated kinase, and promotes oncogenic dependency of the cell on these proproliferative and survival drives from the mutated EGFR. Therefore, abrogation of activated EGFR signaling using small molecule inhibitors results in a pronounced tumor cell apoptosis and inhibition of tumor growth through the prevention of signaling and therefore reduced oncogenic drive.

"First-generation" EGFR tyrosine kinase inhibitors (TKIs), such as gefitinib and erlotinib, are now National Comprehensive Cancer Network recommended therapies in NSCLC patients with AMs in EGFR.[3,4] Approximately 70% of patients respond to these drugs with significant tumor shrinkage but eventually develop resistance within 10–16 months. In up to two-thirds of these patients, disease progression appears to be driven by the emergence of a secondary acquired mutation T790M (ie, threonine changed to a methionine), in exon-20 of EGFR gene (typically referred to as the "gatekeeper mutation"), and in combination with an activating sensitizing mutation in the same protein.[5] This TKI-resistant form of mutant EGFR is therefore commonly referred to as the "double mutant" (DM) form.

The mechanism by which these AMs of EGFR exert their effect is not proven but in vitro studies on the L858R mutation have shown there to be a decreased affinity to Adenosine triphosphate (ATP) (**Fig. 1**),[7] thereby increasing the potency of compounds such as gefitinib (**1**)[8] and erlotinib (**2**).[9] It has been proposed that the AMs may bias the equilibrium toward active conformation of the kinase to which a number of inhibitors may bind (**Fig. 2**).[9,10] Further reports suggest additional mechanisms, including the differential ability of the mutants to sample the active and inactive conformations[11,12] and impact on release of ADP. However, the acquired mutation T790M has been shown to increase the affinity of the kinase for ATP,[7,13] substantially reducing the cellular activity of ATP-competitive inhibitors such as gefitinib and erlotinib toward EGFR T790M. T790 is known as the "gatekeeper residue" and it is positioned at the entrance of what is typically referred to as the "back pocket"[14] of the kinase, the nature of this residue impacts on which compounds are tolerated in this region of the protein. It is also likely that there is a steric component to the resistance mechanism against early EGFR inhibitors, which have a preference for threonine gatekeeper as this is the target to which they were initially identified.

A number of additional EGFR-TKIs were subsequently developed based on the anilinoquinazoline template of gefitinib/erlotinib, often referred to as second-generation inhibitors. Unlike gefitinib and erlotinib, these inhibitors contain an acrylamide functionality that covalently bonds to C797 (ie, cysteine at position 797).[15,16] Such compounds reported include afatinib, **3**;[17]

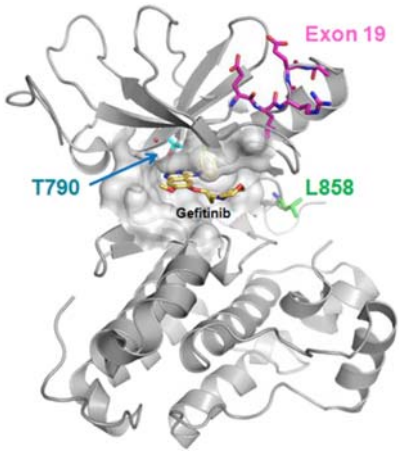

Fig. 1 EGFR crystal structure highlighting location of activating (L858R and Exon 19 deletion) and acquired mutation (T790M) in the kinase domain of EGFR (pdb code 2ITY[6]). canertinib, **4**;[18] and dacomitinib, **5**[19] shown in **Fig. 2**. The formation of this covalent bond apparently makes these inhibitors irreversible and thus able to overcome the increase in ATP affinity of the DM resulting in increased activity in cellular models compared to their reversible counterparts. C797, however, is present in all these forms of EGFR; therefore not only do these second-generation compounds have increased activity against the activating and resistant mutations but also against the wild-type (WT) enzyme. Inhibition of WT EGFR is not thought to significantly contribute to clinical efficacy in patients with EGFR mutation-positive advanced NSCLC but is thought to be responsible for the most commonly observed clinical side effects such as skin rash and diarrhea.[20] As these side effects are typically dose limiting in patients, it appears the WT activity of these inhibitors limits achievable activity against the T790M mutation in a clinical setting. Afatinib was approved by the Food and Drug Administration (FDA) for use in patients with activating EGFR mutations, and in addition, the reversible EGFR inhibitor icotinib **6** has been approved in NSCLC by the China Food and Drug Administration (CFDA) in China.

8.01.2 The Discovery of Osimertinib (AZD9291)

The discovery of osimertinib is described in three sections. The first section describes the specific activity profile, we aimed for, with a novel small molecule, which would be required to show clinical efficacy against the emerging T790M mutation. The second section reports our lead generation strategy, which rapidly identified the lead series using focused compound biochemical testing and structure-based design. We then report our lead optimization work to overcome some key challenges around the template, which ultimately resulted in the discovery of osimertinib.

8.01.2.1 EGFR Mutant-Selective Hypothesis

Our hypothesis behind the initiation of this work was that to successfully target the acquired T790M mutation in a clinical setting an inhibitor needed to be able to not only show potent cellular activity against the T790M form but that a "mutant-selective" profile was required where an optimal compound had reduced activity against the WT form of EGFR.[21] Ideally, an appropriate inhibitor would also show potent cellular activity against the AMs of EGFR (**Table 1**). First-generation inhibitors such as gefitinib and erlotinib had been demonstrated to be ineffective due to limited activity against the L858R/T790M and Exon19-del/T790M DM forms in vitro, in vivo, and in a clinical setting. Although compounds such as afatinib are reported to show in vitro activity against the T790M DMs it was not clear they had an appropriate profile due to their potent activity against WT EGFR. Central to our design hypothesis was the direct exploitation of T790M mutation to leverage selectivity against the WT form of EGFR. When we initiated this work at AstraZeneca, there were no examples of small molecule inhibitors with such a profile reported in the literature (**Fig. 3**).

To confirm our understanding of first- and second-generation inhibitor cellular profiles, we measured the cellular activity of a number of known inhibitors against the different forms of EGFR (**Table 2**) using assays detecting phosphorylation endpoints. These included the WT enzyme with a human LoVo cell line and the Exon-19del activating mutant (AM) using a PC9 cell line. Activity against the L858R/T790M DM enzyme was measured in a NCI-H1975 cell line. Although much of this dataset had been published by a number of different groups, we believed it was useful to measure compound activities in consistent assays to allow an accurate comparison of their biological profile.

Gefitinib and erlotinib were confirmed to be active against WT EGFR, with greater activity against the AM and significantly reduced cellular activity against DM EGFR (3.3 and 7.6 μM respectively). Afatinib (**3**) and dacomitinib (**5**) had increased activity

against WT and AM EGFR, along with increased activity against the DM compared to gefitinib and erlotinib. Importantly, the potency of these compounds against the DM is lower than the potency against WT EGFR (ie, DM to WT margin of <1). These data confirmed our rationale for the clinical opportunity for a novel T790M mutant-selective inhibitor series.

8.01.2.2 Identification of a Mutant-Selective Lead Series

The rationale we followed was to identify a DM selective template, through exploitation of differences in properties of the threonine and methionine gatekeeper residues. We hypothesized that exploiting the hydrophobic nature of the methionine gatekeeper residue to leverage increased potency might lead to a profile in which the compounds are active against the DM enzyme, but with reduced activity against WT EGFR. Ideally, compounds would also show greater activity toward the activating EGFR mutations than WT, but this was not specifically considered at this stage as part of our design hypothesis.

Subsequently, a set of 40 compounds was tested in EGFR WT and DM biochemical enzyme assays at an external contract research organization,[22] Fig. 4, to inform our hypothesis around exploitation of the gatekeeper residue. This set included reversible EGFR inhibitors from our corporate compound collection (red) and a selection of published irreversible EGFR inhibitors (yellow). Additional compounds from our collection were added that had shown activity against kinases with methionine gatekeepers during historic internal drug discovery projects (blue). The reversible EGFR inhibitors showed higher activity against the WT form compared to the DM. The irreversible anilinoquinazoline-based EGFR inhibitors (including **3**, **4**, and **5**) showed significant activity in both assays, consistent with an increase in activity from the formation of the covalent bond. However, it is difficult to accurately compare the relative potencies of the reversible versus irreversible compounds in these assays due to their different mechanism of action, irreversible inhibitors often demonstrating time-dependent inhibition.[23,24] This aside, the subset of compounds that was of particular relevance for our efforts to target EGFR T790M were the aforementioned examples from internal AstraZeneca projects.

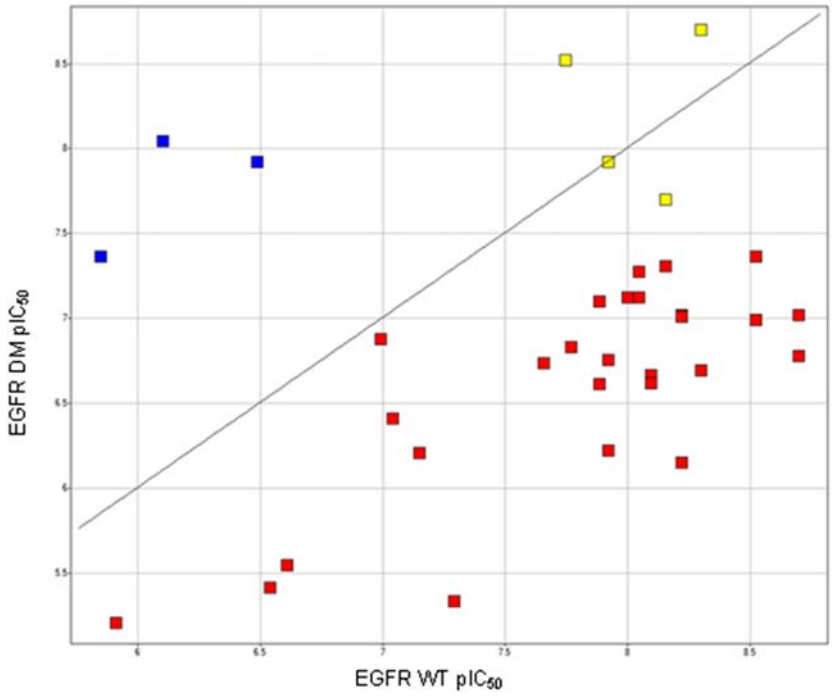

Fig. 4 EGFR wild-type (*WT*) and T790M/L858R (*DM*) biochemical assay data on a subset of compounds. *Red points* are reversible EGFR inhibitors, *yellow points* are covalent EGFR inhibitors, *blue points* are selected compounds from internal AstraZeneca projects. Importantly, these compounds showed promising activity against DM EGFR with selectivity over WT. Example **7** (Table 3) contains an indole "head-group" on a mono-anilino-pyrimdine (MAP) core with IC_{50} 0.009 μM against the DM enzyme and 88-fold selectivity over WT. Although compound **7** was active in this biochemical DM assay, a large enzyme to cell drop-off of around 90-fold was observed when tested in our H1975 DM cellular assay (IC_{50} 0.77 μM). This drop-off is likely driven by the high ATP affinity of this enzyme and the high ATP concentration present in the cellular environment.[25] We then directed our efforts to convert **7** into an (irreversible) covalent inhibitor to lessen the impact of the increased affinity of ATP for the mutant kinase, while maintaining selectivity over the WT EGFR.

A modeled binding mode of compound **7** was generated using protein–ligand docking software[26] and a public domain crystal structure of the EGFR-T790M mutation (PDB code 2JIT[7]).

Our hypothesis from the molecular modeling (MM) was that a hydrogen bond acceptor on the pyrimidine core formed a hydrogen bond to the kinase hinge, specifically to the backbone hydrogen bond donor of Met-793 (Fig. 5). A key feature of this binding mode is that the chlorine substituent is directed toward the methionine gatekeeper, supporting our rationale to target this region of the pocket through lipophilic interactions compared to the more hydrophilic WT threonine. The indole group is

positioned adjacent to the region of the kinase referred to as the "back pocket." The anilino group of the inhibitor is oriented toward solvent and was also predicted to provide a hydrogen bond donor to interact with the hinge region. We subsequently attempted to design compounds with a reactive substituent positioned in a manner that would enable targeting C797 via the formation of a covalent bond based on this binding mode. The *meta*-position of the aniline appeared to be the most suitable location and such examples were prioritized. A range of potential substituents were modeled and from this work we decided to incorporate an acrylamide-based side chain. A particular example of interest from our synthesis efforts was compound **8**, which showed improved cellular activity in the DM cell assays with selectivity over WT (**Table 4**). Also of great interest was that this compound also showed promising (and surprising) activity in our PC9 (Exon19-del) AM cell assay.

Additional examples were then synthesized, including an example with an *ortho*-methoxy group at R_1 (compound **9**), which showed increased activity and improved broader kinase selectivity. Further examples were synthesized with the acrylamide attached to different regions of the molecule. Interestingly, moving the acrylamide to the *para*-position, which is also likely to be positioned near Cys-797, appears not to result in covalent inhibition. This compound showed only moderate activity in the DM biochemical assay (0.3 μM) and minimal activity in cellular assays.

To gain confidence that these compounds were able to form the desired covalent bond, **9** was prioritized for crystallization in an EGFR WT structural system.[27] The binding mode of compound **9** was subsequently solved (PDB code 4LI5), shown in **Fig. 6**, showing covalent bond formation to Cys-797. In this case, the binding mode of this template in the EGFR receptor was consistent with the binding mode found in our earlier modeling work.

One of the key issues with these early compounds was high lipophilicity ($LogD_{7.4} > 4.3$). Excessive lipophilicity can often translate into both poor physicochemical properties and pharmacokinetics (PK) and may hinder subsequent development of a series.[28,29] A primary aim of the evolution of this series was to reduce the overall lipophilicity, indicated in subsequent tables by experimental $LogD_{7.4}$ measurements, while retaining (ideally further increasing) EGFR potency and the favorable WT selectivity profile. The primary activity and WT selectivity of subsequent compounds were measured using in-house cellular assays as we felt that the additional data from biochemical assays would have limited impact.

In an attempt to improve the physical properties of compounds, we decided to modify the indole group, or what we referred to as the "head-group." In addition, we assessed the effect of the addition of a basic functionality to the acrylamide (Table 5). The pyrazolopyridine (compound **10**) was an interesting head-group that we had previously utilized in our IGF1R project, maintaining satisfactory potency in our double and single mutant cell assays (IC_{50} 0.033 and 0.15 μM) with an improved margin to WT EGFR (390-fold). Furthermore, the basic acrylamide-based side chains of template B (examples **11** and **12**) showed a small decrease in activity of two- to threefold compared to the neutral equivalents, but with a marked reduction in $LogD_{7.4}$. Based on the overall potency, selectivity and physical property profile of **12** this compound was selected as a key in vivo probe compound for this template. These compounds also began to populate a more favorable area of physicochemical property space, with a ligand lipophilicity efficiency (LLE) of 3.4 for example **12** using the DM cell assay and experimental $LogD_{7.4}$.

Our modeling work predicted that the 5-position of our template would be located adjacent to the "gatekeeper residue"; we therefore surmised that varying this position may have some interesting effects on the primary potency and WT selectivity of compounds. Our initial compound contained a chlorine atom at this position, which is relatively lipophilic and therefore changes here offered the potential for compound lipophilicity to be reduced.[30] A range of 5-substituted compounds were subsequently synthesized and assessed across our in-house cellular assays (Table 6).

The range of substituents investigated varied in both size and lipophilicity. Interestingly, although compound potency varied in the DM cell assay, the LLE (using the DM cell data) remained constant at around 3.4-3.5 except for R_1=H where it was increased to 4. This was an interesting result as removing the chlorine of compound **12** (giving compound **13**) reduced $LogD_{7.4}$ by an order of magnitude (3.6 compared to 2.6) and might enable physicochemical properties of this series to be improved. Although the DM activity was reduced for compound **13**, compared to **12** (0.25 vs. 0.096 μM), the activity against the AM was broadly unchanged (0.39 vs. 0.40 μM). The DM selectivity of **13** was reduced to 80-fold, from 237-fold for compound **12**, rationalized by chlorine interacting more effectively with the methionine gatekeeper residue. Our collective data across these compounds suggested that it might be possible to achieve reasonable potency in the EGFR double and AMs, while leveraging selectivity over WT, without a chlorine in the 5-position to enable improved compound properties.

The potency of covalent inhibitors is impacted by both reversible binding properties to the protein (K_i) and their ability to covalently bind to the active site (k_{inact}). It is therefore important to aim for compounds of sufficient chemical reactivity toward an active site residue (in this example cysteine), while balancing against off-target binding, which could lead to idiosyncratic toxicity.[31] One method of optimizing covalent compounds in this way is through the measurement of k_{inact}/K_i values. This approach, however, proved technically challenging using our assays so we were unable to exploit it for driving structure–activity relationships (SAR) routinely,[23] although progress has been made more recently in this area.[32] The alternative approach we used was to establish a suitable "reactivity window" for our compounds and to develop an understanding of how to synthesize compounds that were likely to fall within the intended range. As a measure of thiol reactivity we have used an assay based on determining the second order rate constant (k_{GSH}) for the reaction of our compounds with glutathione (GSH).[33–35]

In an attempt to determine the structural and electronic features that influenced the chemical reactivity of our compounds, a set of 6-membered aromatic ring acrylamide-containing "models" were investigated in the GSH assay (Table 7). These "model" acrylamides have relatively good aqueous solubility and thus avoided any complication of reaction kinetics that might have arisen due to compound precipitation. All compounds were stable in phosphate buffer alone at pH 7.4. In the presence of GSH a simple addition reaction (Scheme 1) was observed, generating the more polar GSH adduct, seen by liquid chromatography–mass spectrometry (LC-MS) as a mass increase of 307 units.

The Hammett plots in Fig. 7 enabled a quantitative understanding of the relationship between the electronic effects exerted through the R_1 position of the acrylamide, expressed as sigma values, and reactivity. This knowledge was then applied to design elaborated compounds, which sit in the desired reactivity window, using appropriate R_1 sigma values. From our results set, the rate of the reaction appeared to be dependent upon the electron withdrawing ability of groups in the R_1 position (Fig. 7) of the

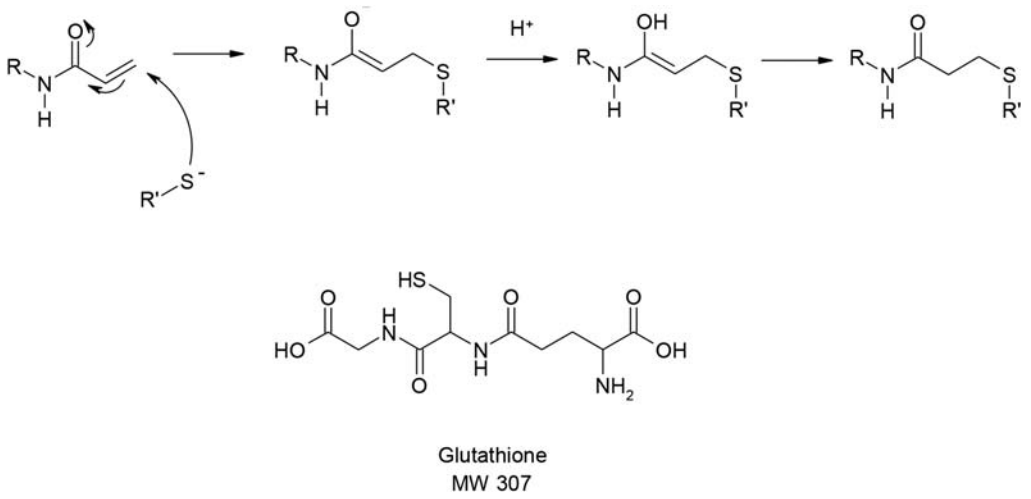

Scheme 1 Addition reaction of model compounds with glutathione.

acrylamide. In particular, the inductive effect of the R_1 group (represented either as σ_{meta} or σ_{ind}) was seen to determine thiol reactivity with ρ values of 5.56 and 9.23, respectively. The addition of further electronic descriptors such as σ_{para} or σ_{meso} to the Hammett equations and in Fig. 7 did not appear to be significant. Such inductive electron withdrawal at the R_1 position would be consistent with enhanced polarization of the alkene bond via carbonyl conjugation and also serve to stabilize the enolic transition state. The introduction of methyl groups on to either the α or β carbon of the "model" acrylamides (R_3 and R_4) resulted in no reaction being observed with GSH, removing these substituents as options on elaborated compounds. A similar decrease in thiol reactivity following methylation at the α and β carbon has been observed by other workers in their investigations with α,β-unsaturated

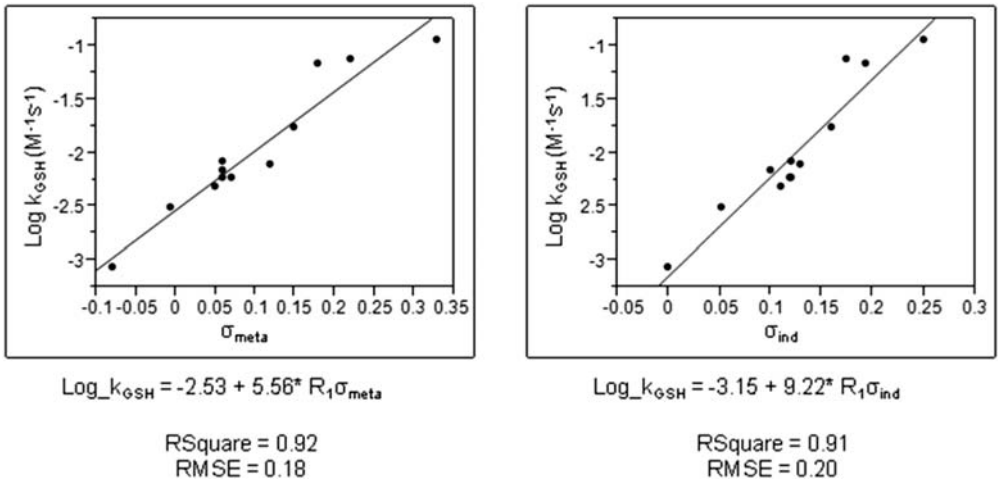

Fig. 7 Hammett plot of σ_{meta} and σ_{ind} properties versus compound reactivity (Log k_{GSH}) across the "model" compound set. Reprinted (adapted) with permission from Ward et al., *J. Med. Chem.* **2013**, *56* (17), 7025–7048. Copyright (2013) American Chemical Society.

aldehydes, ketones, esters, acids, and amides.[36–39] Engels et al. calculated via quantum mechanical/MM an increased energy barrier to methyl thiolate attack on α,β-unsaturated phenyl ketones with an elevated energy of the enolate intermediate upon methylation at the α and β positions, suggesting steric effects as a possible reason for such a reactivity change.[38] While other workers have similarly suggested steric effects as an explanation for decreased reactivity for α and β-methylation,[36] Kerske et al. argue that reactant stabilization by hyperconjugation of α and β methyls and not steric hindrance is the reason for the lowered reactivity.[39]

This SAR and the equations based on these Hammett plots more generally were used to try and predict compound reactivity of more elaborated compounds through further optimization of the series. In seeking to define a suitable "reactivity window," elaborated project compounds studied for GSH reactivity were also tested in the DM cell assay. **Fig. 8** reveals the relationship between cellular potency and GSH reactivity for a subset of compounds. As hoped, there is not a strong correlation since initial target noncovalent binding (K_i) will play a key part in defining potency (R^2 0.52 and RMSE 0.53). Noncovalent contribution to the binding is essential for driving the selectivity of these compounds over other proteins with potentially accessible cysteine residues. There is, however, a general trend toward more reactive compounds showing increased activity and compounds with pIC_{50} values >7 for the most part tend to have GSH half lives <400 min. As such we took a GSH half-life of 400 min as a guide for a suitable lower limit of reactivity. Afatinib (**3**) is now an FDA approved clinical agent and reported clinical side effects of the compound appear to be linked to the inhibition of WT EGFR rather than off-target effects due to covalent binding. For this reason, this seemed an appropriate compound to benchmark in our GSH assay generating a half-life of 25 min. We therefore used a half-life of 25 min as the higher limit to the window of reactivity we aimed to work within.

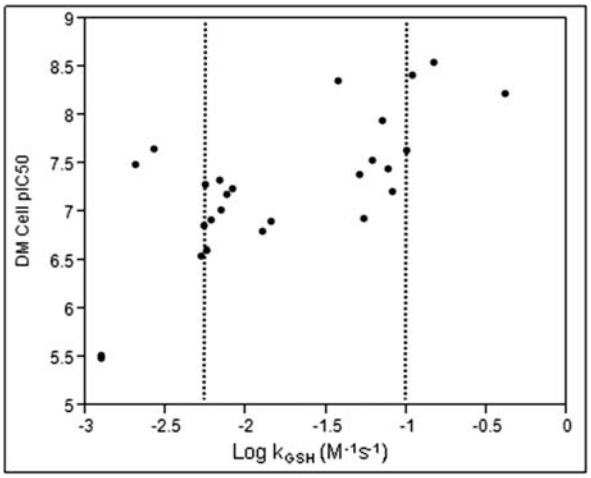

Fig. 8 Compound reactivity measured by Log k_{GSH} ($M^{-1}s^{-1}$) plotted against EGFR double mutant (DM) cellular pIC_{50} for the elaborated compounds reported in this article. *Dashed lines* indicate the "reactivity window" in which the design of novel compounds was subsequently focused. Compound **12** was identified as a suitable in vivo proof of concept (POC) compound from our early lead generation work (Table 8). To build further confidence in the covalent mechanism of action, the equivalent nonreactive propionamide was synthesized, which showed significantly reduced cellular activity (2.3 μM). Although not the most potent (or WT selective) example synthesized, the overall balance of properties identified **12** as having an acceptable combination of activity and PK properties (Table 12). In addition, **12** demonstrated encouraging antiproliferative activity when tested in our H1975 (DM), PC9 (AM), and Calu3 (WT) cell lines with an EC_{50} of 0.099, 0.14, and 1.78 μM, respectively. This profile is consistent with the described cellular activity using phosphorylation endpoints showing significant activity in the double and single mutants with selectivity over the EGFR WT. **12** was orally dosed in an in vivo efficacy study using an H1975 DM xenograft model in immune-compromised mice. Tumor growth was measured from start of treatment and assessed by comparison of the mean change in tumor volume for the control and treated groups, and represented as tumor growth inhibition (where >100% total growth inhibition, TGI is a regression from start size). Compound **12** showed significant efficacy of 105% TGI of the tumors after 7 days at an oral dose of 60 mg kg^{-1} day^{-1} (formulated as the mesylate salt to improve solubility and PK properties).

Compound **12** was also administered in an efficacy study in a PC9 AM cell line and a WT A431 cell line in immunocompromised mice. The activity against the PC9 xenograft model at the same dose (134% TGI, resulting in tumor regression) was encouraging and compound **12** showed reduced activity against the A431 xenograft model (46% TGI), as compared to the PC9 and H1975 studies, reflecting the WT margin demonstrated from the in vitro cellular profile (Table 9).

In comparison, an oral dose of gefitinib of 6.25 mg kg^{-1} day^{-1} (representative of the clinically relevant human dose) showed 142% TGI in the PC9 xenograft model and 79% TGI in the A431 xenograft model after 7 days (Table 13). Gefitinib showed little activity in the H1975 xenograft model, as an oral dose of 100 mg $kg^{-1}day^{-1}$ resulted in 8% TGI after 7 days.

To assess the broader kinase selectivity of our series, we routinely submitted key compounds to a panel of >70 diverse kinases at the University of Dundee,[40] testing at a concentration of 1 μM in biochemical assays. Compound **12** showed >75% inhibition in 10 kinases, which were IGF1R, insulin receptor (IR), CAMKKbeta, CHK2, PBK, FLT1, MAP3K11, smMLCK, BTK, and MELK. However, out of these kinases only BTK has a cysteine in the same position as EGFR so the mode of inhibition is likely to be via a reversible mechanism in the majority of these targets. Consequently, we believed that such covalent inhibitors such as compound **12** would have increased selectivity versus those off-targets in a cellular setting.

8.01.2.3 Lead Optimization to the Discovery of Osimertinib

Our aim was to further increase the potency of our series by exploiting additional interactions with the protein, along with the learning from our exploration of compound reactivity.[41] As part of this, we synthesized a set of compounds with a piperazine substituent on the *para*-position of the aniline, which we hoped would be tolerated from compounds such as **7** (Table 10). We expected that the addition of the piperazine adjacent to the acrylamide would impact the conformation and geometry of both substituents so we were keen to assess whether this combination was compatible with good potency on our template. We combined this change with 5-position SAR described in the previous section, using both our indole and pyrazolopyridine "head-groups."

The emerging data suggested a general improvement in potency with the addition of the piperazine substituent (**Table 11**). Compound **33** is more potent than **12** in both primary cell assays (0.14 vs. 0.4 μM in the single mutant and 0.019 vs. 0.096 μM in the DM assays), while maintaining good selectivity for the DM over WT. There is a small increase in reactivity against GSH for compound **33** ($t_{1/2}$ 188 min) compared to 352 min for compound **12,** which is consistent with the small increase in electron withdrawing ability of the group attached to the acrylamide nitrogen (σ_{meta} 0.09 compared to sig σ_{meta} 0.07). A number of factors could influence this increase in compound activity including the preference for a basic group in this region of the protein, the increased compound reactivity along with the effect on acrylamide geometry. The LLE of these compounds is improved with **33** showing an increased LLE of 4.1, compared to 3.4 for **12**. Removal of the chlorine (compound **34**) showed a reduction in DM cellular activity, 0.071 μM compared to 0.019 μM, but minimal impact on single mutant activity as observed previously. The transferring of this learning back to the indole "head-group" identified compounds that were significantly more potent against the single and DM. Example **35** is a particularly potent compound, with an LLE = 4.6. The data on these compounds is consistent with the early data on this head-group with the indole-containing compounds showing a reduced margin with WT EGFR (140-fold and 19-fold for **35** and **36,** respectively), albeit with greater absolute DM activity. These more recent compounds were then profiled more broadly to assess the impact of the piperazine group on nonefficacy properties.

At this stage, we began to monitor IGF1R actively more routinely, driven by the knowledge that our initial lead compound was synthesized within our internal IGF1R drug discovery program. While compound **36** showed broadly similar DM potency to **12**, it had reduced IGF1R activity and increased AM activity with no increase in lipophilicity, which was of significant interest, albeit with a slightly reduced WT margin. Broader kinase selectivity for these inhibitors, as judged by profiling in a kinase selectivity screen,[10] also appeared to be good. Compound **33** appeared to offer superior selectivity for the mutant forms of the receptor, although **36**, as mentioned above, did carry significantly less activity against IGF1R, which also has a methionine gatekeeper. Although a lipophilic group at the pyrimidine 5-position appeared to offer a favorable interaction with the methionine in both IGF1R and the EGFR DM we speculated that covalent binding to EGFR would help drive selectivity over IGF1R, where the binding was noncovalent. While IGF1R inhibitors have been employed in a clinical setting, their lack of selectivity with respect to inhibition of IR signaling has in some instances led to dose limiting toxicity and monitoring these effects can complicate study designs[11] and more recently such effects have been observed with CO-1686 (rociletinib) from an active metabolite.[42] However, **33** in contrast to **36** did offer modest exposure when dosed orally at 50 mg kg^{-1} in SCID mice so we focused further work around this compound.

One early avenue we explored as part of this work was around a piperazine-amide subset of compounds (Fig. 9). While a number of these compounds offered reasonable profiles, we stopped working on such compounds due to the moderate cellular potency and greater progress of other avenues. A number of other carbon and oxygen linked basic side chains were also examined, but they offered little advantage in terms of potency, physical properties, or oral exposure when compared to the nitrogen linked systems described earlier.

One area of most interest to us was around compounds where the piperazine group had been replaced with particular basic side chains, producing a number of examples with exquisite cellular potency and three key examples are shown here (Table 12). Of additional interest was that this increase in potency did not come with the addition of further lipophilicity (as also noted for **33** and **36**), in contrast to some of our earlier SAR in regions of the molecule such as the 5-position of the pyrimidine. Encouraged by these data, we further made and tested a range of compounds from this subseries. The compounds showed excellent cellular potency against both mutants in phosphorylation (and phenotypic antiproliferation assays) with selectivity over WT EGFR. Compound LogD was around 3 along with modest aqueous solubility in pH 7.4 buffer being evident. In addition, they also showed good overall kinase selectivity, apparently improved from earlier compounds and the GSH reactivity also fitted into our understanding of a suitable "reactivity window." However, these compounds showed moderate affinity for the hERG channel and potent IGF1R activity in a similar fashion to earlier examples. The in vitro intrinsic clearance of the compounds was relatively high but, encouraged by the overall profile of the series, we elected to investigate the exposure of the compounds when dosed orally in the SCID mouse. Compounds were prioritized for in vivo work based on cell potency, free fraction, and aqueous solubility.

Compound **37** was well tolerated at a 50 mg kg^{-1} once daily oral dose and excellent exposure was observed. Plasma levels achieved were substantial and well in excess of the concentrations needed to achieve free cover over the cellular IC_{50} values. As a consequence, for subsequent compounds in the series, we reduced to 10 mg kg^{-1} as an initial dose. At this lower dose, multiples of free cover were still achieved for compounds **38** and **39** and these inhibitors were selected for evaluation in a pharmacodynamic (PD) study. A single dose of compounds **37**, **38**, and **39** were administered orally in SCID mice at 10 mg kg^{-1}, and the percentage knockdown of EGFR phosphorylation in H1975 (DM) and PC9 (AM) xenografts was measured compared to control (Tables 13 and 14 and Figs. 10 and 11). These compounds showed a profound effect on the PD biomarker. In the PC9 tumor cell line, **39** and **38**

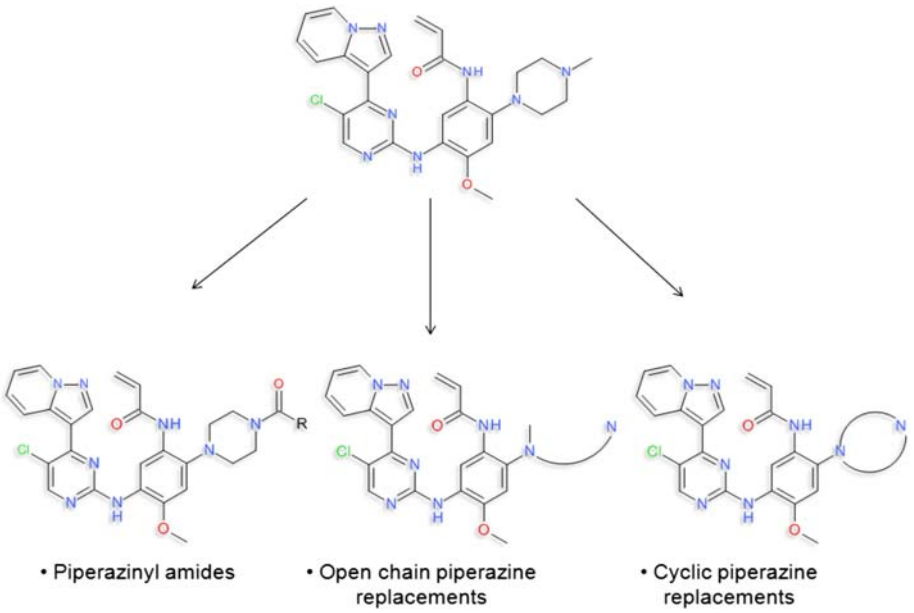

Fig. 9 Summary of modifications to the piperazine region.

showed broadly similar effects with maximal inhibition (85% and 83%, respectively) at the 6 h time point. Compound **37** showed slightly less biomarker modulation at 6 h but in contrast to the other two compounds continued to show sustained inhibition at the 24 h time point. In contrast, in the H1975 PD study, all three compounds showed sustained biomarker inhibition out to 24 h, although **38** now showed the most marked effect. By the 30 h time point, **39** inhibitory effects seemed to have been reduced whereas **38** still displayed a significant level of biomarker modulation. Given these data, the three compounds were selected for further evaluation in antitumor efficacy studies.

As with our earlier efficacy study on compound **12**, in vivo xenograft models representing the drug-resistant, DM (H1975), AM (PC9), and WT (A431) were selected. Compounds were dosed orally once a day for 7 days (Fig. 12).

At 10 mg $kg^{-1}day^{-1}$, all three compounds showed pronounced tumor growth inhibition in the two mutant models (Fig. 12), with regression being achieved in each case, while having relatively little impact on the A431 WT model. With this encouraging data, we elected to more fully characterize the PK properties of these compounds in rat and dog, where good cross-species PK was observed.

As the incorporation of the basic side chains described earlier in **37**, **38**, and **39** had brought significant benefits relative to the early lead compound **12**, we elected to further explore the indole head-group using this learning. Although we had previously moved away from the indole head-group due to its more modest oral PK properties and lower WT margin,[7] the enhanced potency available from this novel basic side chain SAR prompted us to reexamine this subseries. Thus we decided to explore a matrix of compounds where we would incorporate favored groups at the 5-position of the pyrimidine core, along with the indole head-group with the basic side chain SAR. Leading examples from this work are shown in Table 15.

It can be seen that incorporation of the newly identified basic side chain delivered high cellular potency across all the examples shown (Table 15). However, the presence (or indeed absence) of a substituent at the 5-position of the pyrimidine ring also had a differential effect on DM potency (and therefore EGFR WT selectivity), IGF1R potency, and hERG binding. From the data generated, it reinforced the earlier observation that a 5-substituent had a beneficial impact on EGFR DM cell potency, possibly driven by interaction with the methionine gatekeeper residue although in the case of the more polar cyano 5-substituent, the conformational effect on the indole group may be important. A similar pattern is observed for IGF1R activity, although it should be noted that the potency increase imparted by the 5-Cl was generally of a greater magnitude for IGF1R than any of the EGFR mutants or WT receptor. The presence or absence of a methyl group on the indole 1-position nitrogen also had an impact on IGF1R activity. Analysis of the broader data suggested that the removal of the methyl group generally results in increased cell potency against all three Epidermal growth factor (EGF) forms, with human Ether-à-go-go Related Gene (hERG) potency having no discernible trend. However, the NH indole analogs showed increased IGF1R potency. The SAR for WT selectivity is also interesting, with DM selectivity over WT showing a trend to be greater for the N-methylated compounds. When profiled in the Millipore kinase selectivity panel,[10] it became evident that for the two 5-H compounds tested, in addition to reducing IGF1R and INSR activity, we had also maintained the high broader kinase selectivity of our above-described inhibitors. In summary the 5-Cl group appeared to bring benefits to DM cellular potency and WT selectivity, but issues around IGF1R and hERG activity. The 5-H equivalents showed reduced potency and WT selectivity, but reduced IGF1R and hERG activity. However, the cellular activity of the 5-H equivalents could be recovered to some extent by the inclusion of the indole head-group with indole alkylation allowing increased WT selectivity.

Examining the data for this matrix of compounds in more detail, the profile of most of the compounds was broadly similar to our earlier examples described above. However, Compound **44** demonstrated improved rat PK, reduced hERG affinity, and improved IGF1R margins relative to the previously described compounds and was selected for further investigation. Compound **44** also offered an additional degree of broader chemical and profile diversity when compared to the previously described lead compounds. Upon dosing **44** in our three efficacy models, we observed comparable efficacy at relatively low doses (10 mg $kg^{-1}day^{-1}$, Fig. 13). Intriguingly, excellent efficacy was also observed when **44** was dosed at 5 mg $kg^{-1}day^{-1}$ and this unprecedented level of activity combined with its previously mentioned attractive attributes added to our interest in this compound, despite the slightly lower WT selectivity. Given the significant free cover of earlier compounds, it seems difficult to explain how this level of efficacy could be achieved with the relatively modest exposure achieved with **44** (free $C_{max} = 13$ nM, 0.9-fold free cover over DM cell IC_{50}), but further understanding did become apparent with additional studies.

Our focus subsequently turned to the investigation of the in vivo toxicological profile of our preferred compounds. With our observation around the IGF1R activity of some compounds, we designed bespoke rat toxicology studies to explore whether reversible inhibition of IGF1R/INSR would lead to hyperglycemia or impaired insulin signaling in vivo. Rats received a single oral dose of 200 mg kg^{-1} of each compound with assessment of blood glucose and insulin concentrations over a 24 h period. While all compounds were broadly tolerated well, a single oral dose of **38** and **37** led to marked hyperglycemia and hyperinsulinemia

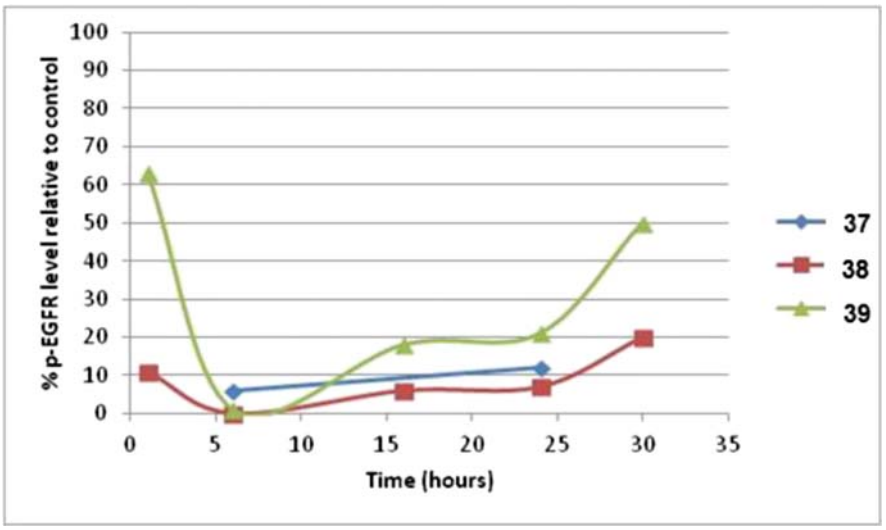

Fig. 11 p-EGFR inhibition time course profile in H1975 (double mutant) xenograft bearing mice following 10 mg kg^{-1} oral dose of compounds **37**, **38**, and **39**. (Figs. 14 and 15), whereas at the same dose, **39** did not cause significant changes in blood glucose levels, but insulin levels were clearly increased, consistent with insulin being a more sensitive marker for perturbation of the glucose/insulin axis. Compound **44**, however, did not impact measured levels of glucose or insulin. This is consistent with the observation that **44** did not inhibit IGF1R or INSR with significant potency. For compound **44**, pharmacological cover over the INSR IC_{50} and perturbation of the insulin-glucose axis was therefore considered extremely unlikely.

Although IGF1R inhibitors have been studied clinically in an oncology setting, hyperglycemia can be dose limiting.[11] Inhibition of IGF1R and INSR signaling and its associated pharmacology had the potential to limit maximal tolerated doses in the NSCLC EGFR sensitive patient setting. Furthermore, it could affect patient exclusion criteria and require additional monitoring during

clinical trials. In light of these findings it was decided to focus remaining efforts on **44** and **39,** which had no or minimal effects on the IGF1R-INSR axis, respectively.

We subsequently performed a preliminary cardiovascular safety evaluation on compounds **44** and **39**. The compounds were assessed in an in vivo guinea pig model[15] to explore the effect of the compounds on hemodynamic, ECG, and contractility parameters. Comparison of the cardiovascular profile revealed a major difference in the compounds with respect to QT prolongation. In contrast to **44**, **39** was associated with a pronounced QT prolongation at free C_{max} concentrations <30-fold predicted human free C_{max}. These data were consistent with the in vitro data for both compounds with **39** having a greater affinity for the hERG ion channel than **44** (Ionworks hERG IC_{50} for **39** and **44** is 4.3 and 16.2 μM, respectively). In view of the data package, as a whole, **44** was considered to have a desirable profile and ultimately selected as clinical candidate AZD9291,[43] subsequently given the generic name osimertinib.

In addition to the relatively short 7-day antitumor models previously described, longer term studies were subsequently carried out with compound **44** resulting in long-term sustainable efficacy[43] at a dose of 5 mg $kg^{-1}day^{-1}$ in the H1975 DM model (**Fig. 16**). At the same dose in the AM PC9 model compound **44** showed increased efficacy when compared to a 6.25 mg $kg^{-1}day^{-1}$ dose of gefitinib, matching clinical exposure as previously with our compound **12** study (**Table 9**).

The selectivity profile of **44** as determined in the Millipore kinase panel[16] of 270 kinases is shown in **Fig. 17**, and it can be seen that the compound displays an excellent overall profile with the majority of more active hits being other tyrosine kinases.

Although we had not been able to generate an X-ray crystal structure of **44** bound to an EGFR T790M mutant, we were able to utilize a published structure (pdb code 3IKA)[8] to model the binding mode, as shown in **Fig. 13**. Notable features include the covalent bond formed to C797, the hinge interaction at M793, and the orientation of the indole. This binding mode was also consistent with the binding mode of the earlier compounds, which we crystallized in WT EGFR (**Fig. 18**).

Fig. 19 summarizes in detail the key differences between the binding mode of **44** into EGFR T790M and first-generation inhibitors such as gefitinib or erlotinib. As discussed previously, a key difference is the scaffold of the inhibitor, osimertinib containing a monoanilinopyrimidine core as opposed to an anilinoquinazoline core. This monoanilinopyrimidine scaffold enables osimertinib to interact with the T790M gatekeeper mutation more favorably than gefitinib or erlotinib, reflected in the T790M

mutant-selective profile of osimertinib. Osimertinib is also a covalent inhibitor through the formation of a covalent bond to C797S, which enables the compound to inhibit the T790M protein in cellular concentrations of ATP.

Our subsequent focus was to further understand the metabolic fate of compound **44** in vivo. Previously, when investigating in vivo metabolism in rat bile samples, minimal metabolism had been evident apart from GSH conjugation to the acrylamide portion of the molecule. In contrast, when in vivo plasma samples from rat and mouse were assessed in more detail, it became evident that loss of the indole *N*-methyl group occurred, leading to small quantities of compound **45** (AZ5104), Fig. 20. In addition, dealkylation was also seen to occur to a small extent in the *N,N,N′*-trimethylethylenediamine side chain of **8**, yielding **46**. A small amount of the side chain *N*-oxide was also evident at low levels.

Highlighted in Fig. 15 are the total levels for **44**, **45**, and **46** over a 12 h period following a 25 mg kg^{-1} oral dose in the nude mouse. Compound **46** appeared to offer a broadly similar potency and selectivity profile to the parent compound. In contrast, we had previously prepared and profiled **45** (see Table 15), but despite its impressive double and AM potency, we had not progressed the compound further, partly due to its slightly reduced in vitro WT margin. In addition, oral dosing of **44** in the mouse led to only modest levels of exposure and low levels of free cover over the cellular IC_{50} values (Fig. 21).

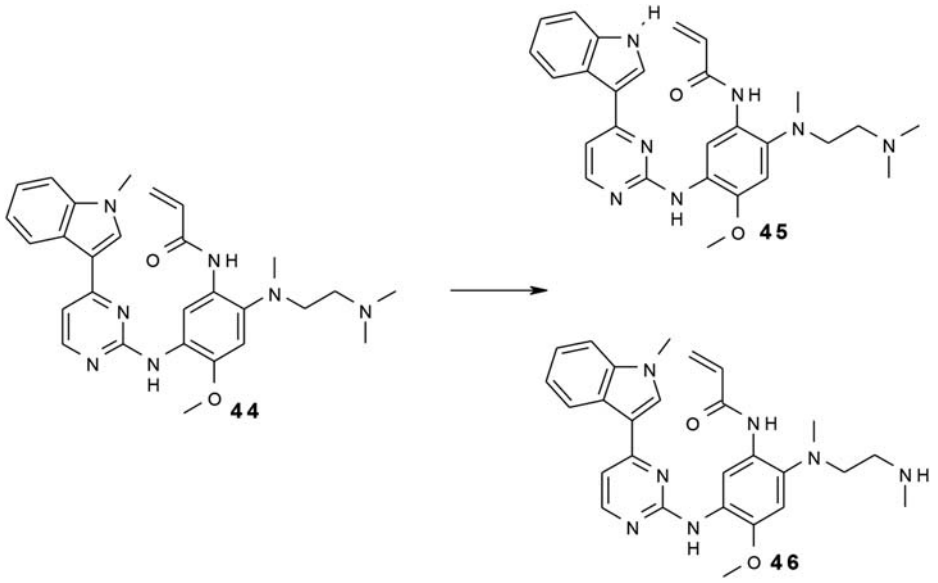

Fig. 20 Compound **44** and identified circulating metabolites **45** and **46**.

Nevertheless, there was an intriguing prospect that a degree of the observed efficacy in vivo for 44 was enhanced by the generation of metabolite 45. While 45 is present at lower concentrations in vivo than 44, the higher cellular potency and lower protein binding equate to broadly similar free cover in vivo. A number of experiments were undertaken to try and establish the in vivo efficacy of 44 in the absence of 45. These included codosing mice with 44 and the pan cytochrome P-450 inhibitor benzotriazol-1-amine[17,18] in an attempt to reduce oxidative metabolism of the indole *N*-methyl group to give 45. In addition, we undertook the preparation of an isotopically labeled version of 44, where the indole *N*-methyl group was replaced by the $^{13}CD_3$ equivalent. Our hypothesis here was that the kinetic isotope effect[19] might slow the deuterium atom extraction process relative to the corresponding hydrogen atom reaction and thus suppress formation of 45, but neither of these measures were able to completely prevent the in vivo formation of 45.

To understand the implications of the presence of the metabolite 45 in vivo, we elected to dose 45 in the previously described antitumor models. These studies (Fig. 22) suggested that while substantial double and AM efficacy is apparent, the level of WT efficacy was also significant, reflecting the narrower in vitro margin as predicted from the in vitro cellular potency. It is also noteworthy

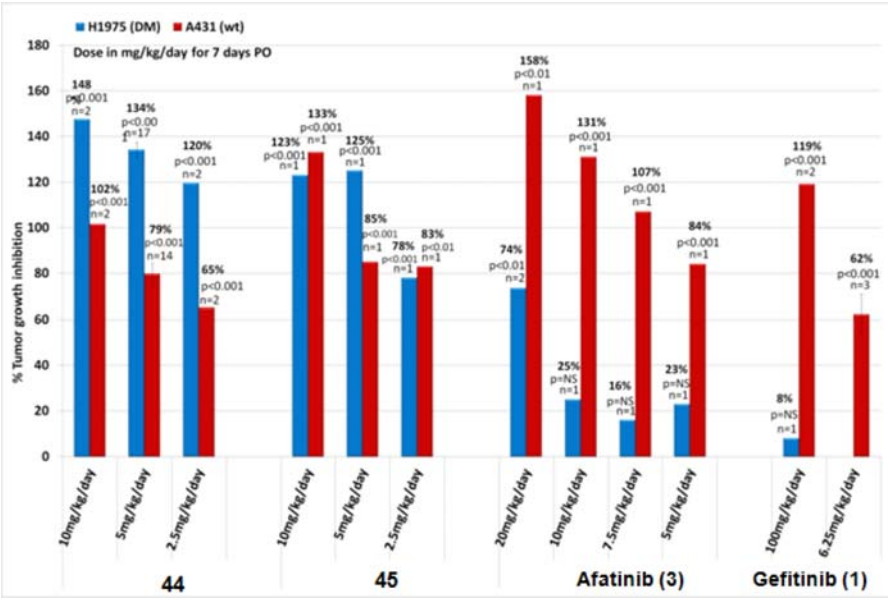

Fig. 22 In vivo efficacy profiles (% tumor growth inhibition) of **44**, **45**, afatinib (**3**), and gefitinib (**1**). Reprinted (adapted) with permission from Finlay et al., *J. Med. Chem.* **2014**, *57* (20), 8249–8267. Copyright (2014) American Chemical Society.

that in the case of **45**, only very modest cover over the free cell IC_{50} is needed to achieve significant efficacy. This is also apparent for **44**, but the presence of **45** in vivo perhaps makes this observation simpler to rationalize.

Comparison of the efficacy profiles between the two compounds revealed significant differences, and while it is likely that **45** contributes to the observed in vivo efficacy of **44**, the parent compound has a large influence. It is apparent from Fig. 16 that the efficacy profiles of **44** and **45** are quite different from both the reversible inhibitor gefitinib (**1**), and the irreversible EGFR inhibitor afatinib (**4**) and that mutant-selective inhibitors **44** and **45** offer a superior efficacy profile than these earlier agents. Clearly, the extent of formation of **45** in human patients would be a pivotal piece of information, as while its absence could potentially reduce the efficacy of the agent, more substantial levels could potentially lead to diminished margins to EGFR driven WT toxicity. Upon dosing patients in a clinical setting, however, this risk appeared reduced, vide infra. Predicting an efficacious dose in patients for this agent therefore presented challenges as estimating the levels of metabolite exposure in humans would be important along with the irreversible mode of action also needing consideration. The full details of these studies have been reported elsewhere, but basing human PK estimations on a metabolite **45** formation rate of 25% of parent (formation of **46** could not be quantified in vitro), the predicted efficacious dose in patients based on data from the H1975 DM model was approximately 10 mg, with a 20 mg predicted dose based on the PC9 AM model.

In silico modeling of human absorption[20] showed that **44** should not be solubility limited at clinically relevant doses with Fabs $>50\%$ up to 330 mg. Although the free base properties of **44** were considered to offer a low biopharmaceutical risk, the mesylate salt was selected for further work due to manufacturing risks around the physical form of the free base. In vivo studies established that the PK of **44**-mesylate were largely comparable to those of the free base.

We have described herein the rapid evolution of a chemical series from lead selection through to candidate nomination and the emerging clinical findings with this novel agent. From start of the project in early 2009, we were able to deliver clinical candidate AZD9291 in Mar. 2012 (first synthesized 9 Jun. 2011), for first time in man, studies commencing in Mar. 2013. During the course of this work, a number of key challenges were addressed including off-target kinase selectivity and cardiovascular safety. AZD9291 offered a number of advantages over earlier EGFR TKI agents including high cellular potency, superior efficacy in relevant disease models, and selectivity over the WT form of the receptor. To date, reproducible drug exposure has been achieved in humans, and of particular significance was the early evidence of tumor responses in patients who had previously progressed on earlier treatments, accompanied by good tolerability. Full synthetic procedures for all the highlighted EGFR inhibitors from our drug discovery program can be found in our two J. Med. Chem publications from 2013[21] and 2014.[41]

8.01.3 Emerging Clinical Data of Osimertinib

The mesylate salt of **44** was first dosed in Mar. 2013 to patients with EGFRm + advanced NSCLC, who had disease progression following treatment with an EGFR TKI (including **1** or **2**). Based on our preclinical data, the initial dose selected for oral administration to patients was 20 mg, once a day. Initial PK data from this cohort of six patients is shown further.[21] It can be seen that after a single dose, 7-day washout and then 8 days of once daily dosing, exposure to **44**, **45**, and **46** was observed. It is also evident that

the formation rate of the **45** metabolite is largely consistent with the predicted levels, and that inter patient variability is low (Fig. 23). Clearly these data discharge to some extent the aforementioned potential risks around the presence or absence of **45**.

Clinical testing with osimertinib showed encouraging efficacy in NSCLC patients from the first patient dosed. Specific data from two patients have been reported[21,22] from the AURA Phase I study and are presented here (NCT01802632). Serial computerised tomography (CT) scans from two patients who received **44** at a 20 mg once daily dose are shown (Figs. 24 and 25). Prior to commencing dosing, both patients' tumors were known to exhibit T790M mutations as well as EGFR sensitizing mutations. The first patient was a 57-year-old East Asian female from South Korea, diagnosed with stage IV EGFR mutant (Exon 19 deletion) NSCLC in May 2011. Tumor shrinkage on treatment with **44** was 39.7% at RECIST 1.1 (response evaluation criteria in solid tumors)[23] scan 1, 48.3% by scan 2 (Fig. 18), remained at 48.3% at both scan 3 and scan 4, and was 51.7% at scan 5 (data not shown).

The second subject[21] was a 57-year-old white female from the United Kingdom, diagnosed with Stage IV lung adenocarcinoma in Dec. 2010. At the cycle 1 day 15 assessments on **44**, the patient reported full resolution of preexisting persistent nocturnal cough. Tumor shrinkage was 38% at RECIST 1.1 scan 1, 39.3% by scan 2, 56.7% by scan 3 (Fig. 19), 62% by scan 4, and 59.3% by scan 5 (data not shown). By Cycle 7 day 1, the patient reported significant improvement in preexisting hair and eyelash abnormalities, which had developed during the immediately prior gefitinib therapy. Both patients had a duration of response of approximately 9 months and were progression-free on 20 mg day^{-1} of compound **44** mesylate salt for approximately 11 months until disease progression by RECIST 1.1. No significant aberration of blood glucose levels were noted in either patient during the study.

Osimertinib was approved by the US FDA on 13 Nov. 2015, with a recent disclosure showing an overall response rate of 66.1% in T790M positive patients (Fig. 26).[44] This approval was based on data from the preplanned analysis of both AURA (NCT01802632) and AURA2 (NCT02094261) clinical trials at the 80 mg QD dose.

Further disclosures from this analysis demonstrated a median progression-free survival of 9.7 months (maturity 39%). Additional emerging data of osimertinib in first-line treatment of advanced EGFRm NSCLC treatment from the Phase 1 AURA study have also been very positive, showing that 72% of patients were alive and progression-free at 12 months, with an overall confirmed response rate of 75%.[44] In addition, osimertinib has also demonstrated clinical activity in cases of EGFR-mutant NSCLC with brain metastases and leptomeningeal disease.[45] In support of this, positron emission tomography imaging demonstrated that osimertinib is highly distributed into cynomolgus monkey brain. In all patients treated with osimertinib at all doses, diarrhea and rash were the most reported adverse events; these were however primarily low grade as hoped from the mutant-selective profile. Along with the rapid discovery phase this has been one of the fastest development journeys for a drug in history. From the dosing of the first patient to approval of osimertinib by the US FDA, the process took only 2 years and 8 months.

8.01.4 Current Progress of EGFR-Mutant Inhibitors

Since we initiated our efforts to identify compounds with this preferred selectivity profile, other compounds have been reported exploiting similar principles (Table 16). An early example published was from the Dana-Farber Cancer Institute (WZ-4002, **47**),[54]

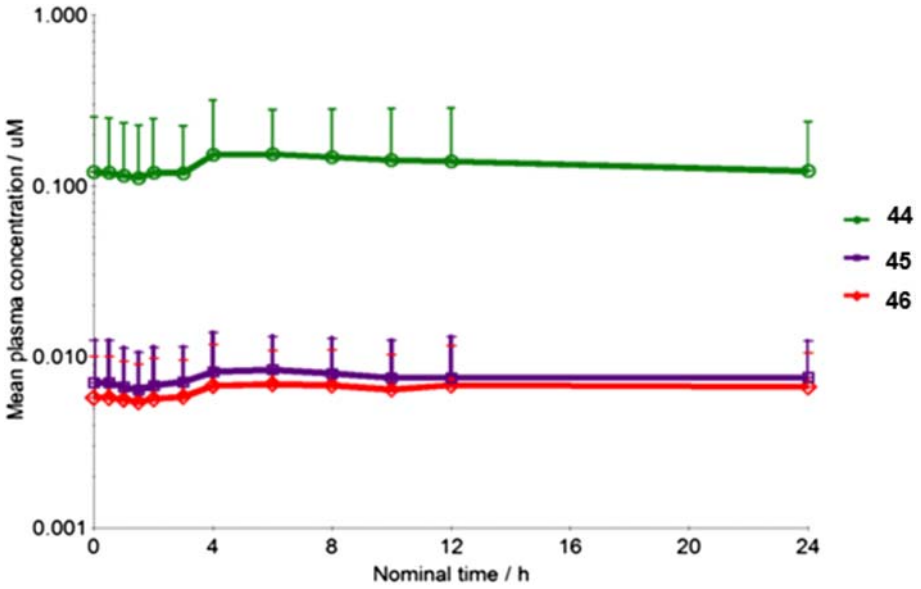

Fig. 23 Preliminary plasma concentration versus time plots (mean + SD) of **44**, **45**, and **46** after 8 days of once daily 20 mg oral doses of **44** to patients with advanced EGFRm + NSCLC in AURA Phase 1 study (NCT01802632) ($n = 6$). based on a pyrimidine template along with additional covalent inhibitors from Clovis Oncology (CO-1686/rociletinib, **48**), and Hanmi Pharmaceuticals (HM61713) have been reported to be in clinical studies. More recently, reports have emerged of additional covalent inhibitors targeting EGFR T790M include ASP8273 (Astellas), EGF-816 **49** (Novartis), AC0010 (ACEA Biosciences), TAS-121 (Taiho), and PF-06747775 **50** (Pfizer). Also reported is the reversible anaplastic lymphoma kinase inhibitor (AP26113/brigatinib) from Ariad, with reported activity against the T790M DM form of EGFR.

Although clinical data from a number of the more recent inhibitors has been disclosed at meetings such as the American Association for Cancer Research and American Society of Clinical Oncology, clear comparisons of their clinical efficacy and side-effect

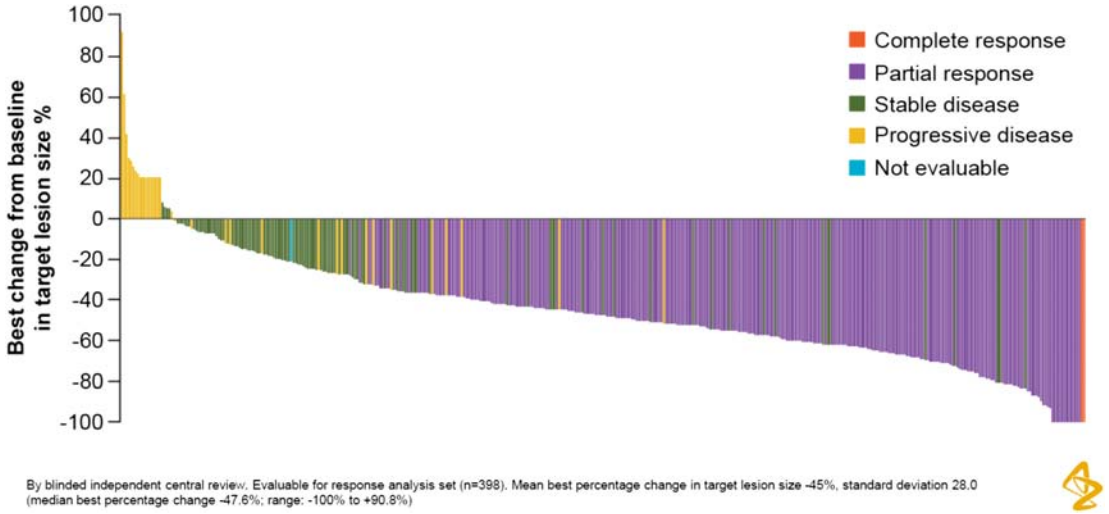

Fig. 26 AZD9291 in pretreated patients with T790M positive advanced nonsmall cell lung cancer (NSCLC): pooled analysis. By blinded independent central review. Evaluable for response analysis set ($n=398$). Mean best percentage change in target lesion size -45%, standard deviation 28.0 (median best percentage change -47.6%; range: -100% to $+90.8\%$).[44] Adapted from a presentation by Goss G.D. ECC 2015 European Cancer Congress.

profiles are challenging due to limited data. A significant number of preclinical compounds have been disclosed including covalent and noncovalent inhibitors.[55–57] It is beyond the scope of this article to attempt to summarize all of these, but the area continues to attract significant interest from the pharmaceutical industry and academia.

8.01.5 Learnings, Future Challenges, and Opportunities

As clinical data emerges on patients treated with osimertinib, and the subsequent approval by the US FDA in Nov. 2015 and positive Commission for Health Improvement (CHIMP) recommendation in Dec. 2015, it is perhaps timely to reflect on the potential learning's from our drug discovery program and also a chance to look forward to additional opportunities and challenges. A number of publications highlight the significant ongoing challenges pharmaceutical companies face in delivering new drugs to the market, in response to this a recent AstraZeneca publication sought to identify key attributes of drug discovery projects, which appeared important to successful delivery.[58] These factors were summarized in a "5Rs framework," which considers the right target, right tissue, right safety, right patients, and right commercial potential of a drug discovery program (Fig. 27). Although this framework was not developed when the drug discovery project that delivered osimertinib was initiated, many of the strengths of the drug discovery program are reflected in these areas. In terms of "right target" EGFR biology is relatively well understood with a clear idea of the primary target (EGFR DM) being a key driver of tumor growth. An additional benefit to the project was that suitable in vitro and in vivo models (with clear disease linkage) could be rapidly deployed in-house to enable novel compounds to be tested against disease-relevant models. In particular the availability of the DM resistant H1975 and PC9 AM cell lines enabled early access to relevant cellular assays and in vivo models. For "right tissue," in addition to have compounds with good PK properties, it was important to have access to reliable PK/PD models to ensure accurate dose predictions, especially important with the impact of active metabolites. In terms of "right safety" a number of potential off-targets were suspected upfront and therefore closely monitored, such as EGFR WT in particular, which was a key part of the compound profile. Activity against IGF1R/INSR and hERG was also monitored as possible risks with suitable in vivo models available to assess this. The "right patient" aspect was also strong with this drug discovery program as the initial focus would be on patients, who have failed on current TKIs and therefore readily identifiable, in addition to progress being made to detect the presence of the T790M mutation from patient samples. The "right commercial potential" of such an agent was perhaps more difficult to estimate with confidence at such an early stage of the project. However, it was felt that if a compound with the specific "mutant-selective" profile could be identified, it would show significant clinical benefit to a number of NSCLC patients with limited treatment options.

Other publications have also assessed emerging targets for drug discovery projects. A publication from Pfizer summarized "The four pillars of cell-based target validation." The aim of their work was by applying the four principles to new projects one could be more confident between the link between target perturbation and disease-relevant pharmacological modulation. The pillars highlight the importance of cellular penetration, target engagement, and selectivity along with the expression of functional pharmacology and relevant phenotype. Again, these themes could be considered as being particular strengths of our internal drug discovery program for identifying mutant-selective EGFR inhibitors.

Table 16 Selection of EGFR T790M targeting inhibitors which have been tested in human clinical trials

Compound	*Structure*	*Company*	*Clinical phase*
Osimertinib (44) (AZD9291)		AstraZeneca	Approved by FDA (Nov. 2015)
WZ-4002 (47)		Dana-Farber Cancer Institute/Gatekeeper Pharmaceuticals, Inc	–

PF-06747775[53] **(50)**		Pfizer	Phase I

With respect to the medicinal chemistry optimization strategy there are also some reflections that are useful to consider. The broad timelines for the key stages of the project are captured in Fig. 28 and show rapid progress of the drug discovery and clinical phase.

One early decision within our drug discovery program was to fully commit to a covalent strategy to overcome the issues with the significant enzyme cell drop-off due to high ATP affinity of the EGFR T790M DM. Although covalent inhibitors are currently being reported relatively frequently, in the early phase of our drug discovery there were relatively few specifically designed covalent inhibitors and prosecuting such a strategy faced some resistance. This focus on a covalent strategy enabled internal work to de-risk covalent compounds using in vitro approaches such as our GSH reactivity assay. A second important decision was to use compound **12** as an early in vivo probe to benchmark against gefitinib as an important POC of the approach. Although this compound had some issues and was therefore not likely to be a clinical candidate (moderate potency, poor properties, and hERG activity) the data generated was invaluable as it enabled understanding of what levels of potency and PK cover might be required for a clinical candidate. This was especially important due to the lack of previous experiences in-house with testing covalent inhibitors in vitro and in vivo. Finally, another important decision to the drug discovery program was made when short-list compounds **37**, **38**, and **39** had been evaluated. These compounds appeared of high quality and one option was to stop chemistry at that stage and ultimately select one of these as a clinical candidate. However, internal AstraZeneca chemistry continued to target compounds of reduced IGF1R and hERG activity, which we had flagged as potential risks with these early compounds. This continued chemistry, in combination with targeted prenomination toxicity work to look at effects on glucose/insulin and hERG resulted in **37**, **38**, and **39** being discontinued and **44** (osimertinib) being identified as a replacement to those compounds with minimal delay in the final selection of a clinical candidate. Therefore, one reflection here might be that chemistry should continue until enough confidence is generated in the potential clinical candidate that no further chemistry is required as once chemistry has stopped, there can be significant delay in restarting and reestablishing a suitable compound testing cascade.

Right target/ efficacy	▪ Strong link between target and disease ▪ Differentiating efficacy ▪ Available and predictive biomarkers
Right tissue/ right exposure	▪ Adequate bioavailability and tissue exposure ▪ Human PK / PD prediction, PD biomarkers ▪ Drug-drug interaction
Right safety	▪ Differentiating safety ▪ Predicted margin – secondary pharmacology ▪ Reactive metabolites, Gentox, drug-drug interactions ▪ Target liability
Right patients	▪ Scientific evidence in lead indication ▪ Risk / benefit stratification of patient population
Right commercial	▪ Differentiated value proposition vs. future standard of care ▪ Invest to win/priority areas – DTPP / CDTP ▪ Market access/payor/provider focus ▪ PHC strategy including diagnostic/biomarkers

Fig. 27 The 5Rs framework developed for project assessment.

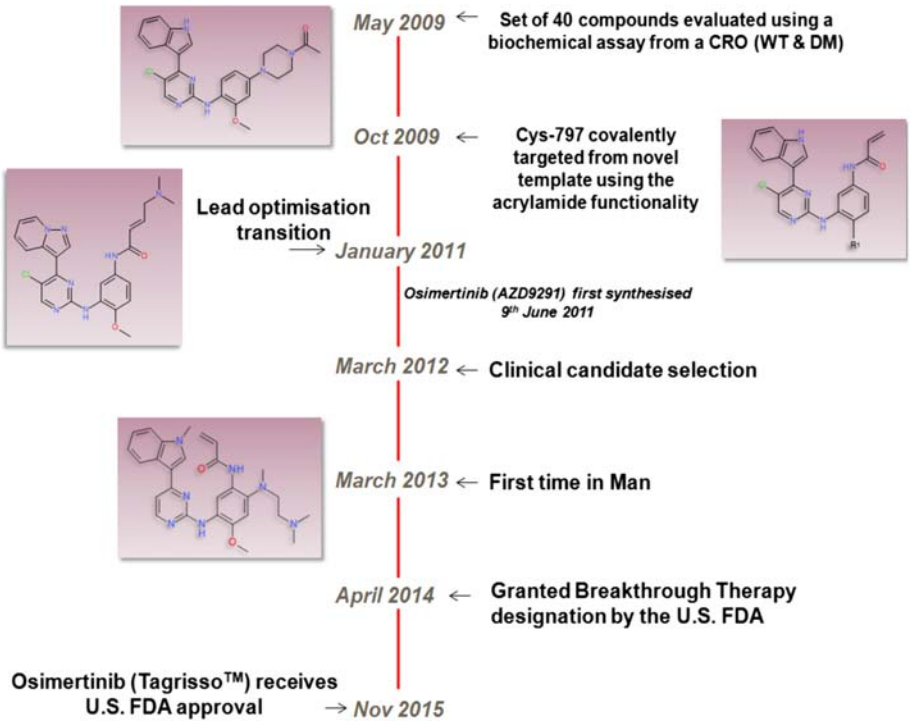

Fig. 28 Drug discovery and clinical phases of the osimertinib drug discovery project.

The recently emerging clinical data from osimertinib also reinforces the challenges and potential limitations with small molecule kinase inhibitors around issues with emerging resistance mechanism. In the same way as the T790M mutation emerges when patients are dosed with gefitinib or erlotinib, early data suggests a subset of patients become resistant to osimertinib via a C797S mutation.[59] In previous work at AstraZeneca, this mutation had been speculated as a potential mechanism of resistance to covalent EGFR inhibitors more broadly, as this amino acid is the residue to which osimertinib (and compounds such as CL-1033 and afatinib) covalently binds to.[60] Emerging mechanisms of resistance have also recently been disclosed for CO-1686 (rociletinib),[61] which includes emergence of EGFR T790 WT clones in vivo and additional point mutations in vitro.[62] There is therefore likely to be an ongoing requirement for additional therapies that circumvent various mechanisms of resistance as they emerge in the clinical setting. As inhibitors are developed targeting other kinases within the kinome, a similar story may develop against a number of these, therefore learning from these experiences with EGFR could have great benefit in oncology more broadly than EGFR and NSCLC. A significant challenge moving forward in kinase drug discovery appears to be how these acquired mutations

and resistance mechanisms are addressed. An aspect of this is how such mutations will inevitably lead to smaller, more fragmented patient populations, leading to challenges in identifying mutation status using next generation sequencing approaches. Although as these patient populations become fragmented thought has to be given to the feasibility of targeting each emerging mutation with additional novel, mutant-specific compounds. In future being able to reliably predict such emerging resistance mechanisms preclinically, ideally in vitro, would be of great benefit to direct such ongoing drug discovery efforts.

In addition to the monotherapy clinical studies for the various T790M directed inhibitors in the clinic, a number of combinations of clinical trials are also underway for osimertinib, rociletinib, and EGF-816, among others. This includes combination studies with MEK and MET small molecule kinase inhibitors and anti-PD-L1 antibodies.[63,64] Such combination approaches may also be an effective way to target potential emerging resistance mechanisms. It is likely that combination strategies with approved and novel agents will be extremely important to find the most effective therapeutic options for NSCLC patients.

Acknowledgments

We would like to thank all of our colleagues who were involved in this work, of which there are many, in what was an interdisciplinary team. We would also like to take this opportunity to thank all of our collaborators who have worked with us through the discovery, development, and clinical phases. Most of all we would like to thank all the patients who have taken part in a clinical trial of osimertinib to which we are extremely grateful.

8.02.1 Introduction

Trametinib (**1**) is an orally available MEK1/MEK2 inhibitor with high potency and high selectivity possibly due to its allosteric binding mode to MEK protein.[1–3] This compound was originally discovered by our group in 2004, and then its clinical trials were conducted by a GlaxoSmithKline group.[4,5] MEK1, MEK2 are protein kinases that play a central role in the MAPK pathway, which is comprised of ras, c-Raf/B-Raf, MEK1/MEK2, and ERK1/ERK2. In human malignant tumors, the Raf–MEK–ERK pathway is often hyperactivated through aberrant activation of the receptor tyrosine-kinases or gain-of-function mutations in the Ras or B-Raf gene.[6] Therefore, in the last two decades, manipulation of this pathway has been of much interest as a molecular targeting antitumor therapy. However, despite the promise of the preclinical evidence, previous MEK inhibitors have proven to be less efficacious for patients.[7,8] In 2013, an open-label international Phase III study demonstrated a statistically significant increase in progression free survival (PFS) in the trametinib treatment group compared with the chemotherapy group in unresectable or metastatic melanoma patients with BRAF V600E or V600K mutation.[4] From this result, trametinib, as the first MEK1/MEK2 inhibitor, has been approved as a single-agent oral treatment for unresectable or metastatic melanoma in adult patients with BRAF V600E or V600K mutations by the US Food and Drug Administration (FDA) in 2013. In addition to this, a combination therapy of trametinib with the BRAF inhibitor dabrafenib has been evaluated in clinical trials, comparing this dual drug strategy with single-agent therapy of another BRAF inhibitor vemurafenib[9] or with single-agent therapy with dabrafenib.[10] Each of these studies demonstrated a significant increase in PFS in patients treated with trametinib as compared to active comparators. Particularly in the study comparing trametinib with vemurafenib, the overall survival rate, a primary endpoint, was increased in combination therapy group with statistical significance. Also in the study compared with single-agent treatment of dabrafenib, the combination of trametinib with dabrafenib tends to yield a statistically significant increase in overall survival rate. It should be noted that this combination therapy showed much benefit for the patients by reducing the incidence of new cutaneous squamous-cell carcinoma that is often observed as an adverse effect in dabrafenib-treated patients. From these results, the combination treatment of trametinib with dabrafenib has been approved in the United States in 2014,[11] and the EU in 2015.[12] In Japan, the submission documents for an approval of trametinib and dabrafenib has been completed and approved in 2016 (**Fig. 1**).[13]

In the present chapter, the development story of trametinib, a unique compound that opened a new horizon in melanoma treatment, will be reviewed with a focus on its lead identification and subsequent medicinal chemistry campaign. Interestingly, this compound was not discovered from pursuing MEK inhibitory activities. Instead, the lead compound was identified by a phenotypic cellular high-throughput screening (HTS) assay. The HTS campaign, leading to the lead identification of trametinib, was designed as a screening of a compound with the ability to induce the expression level of $p15^{INK4b}$, an endogenous cyclin-dependent kinase (CDK) inhibitor protein. This methodology resulted in the discovery of compound **2** as a lead compound.[1,14] Extensive medicinal chemistry efforts were undertaken for this lead structure (**2**), by improving the antiproliferative effect on cancer cells as well as various drug-like properties, and trametinib was selected as a clinical candidate. Although the molecular target of trametinib was unknown until the time that trametinib was synthesized, a chemical biological technique revealed that MEK1/MEK2 were the binding proteins of trametinib. Possibly due to this unique development process, trametinib has a distinct core structure compared with other MEK inhibitors. This core structure may provide the ADME profile with low Cmax/trough ratio, which is ideal for antitumor agents with a narrow therapeutic window. The most stable crystal form of trametinib identified through

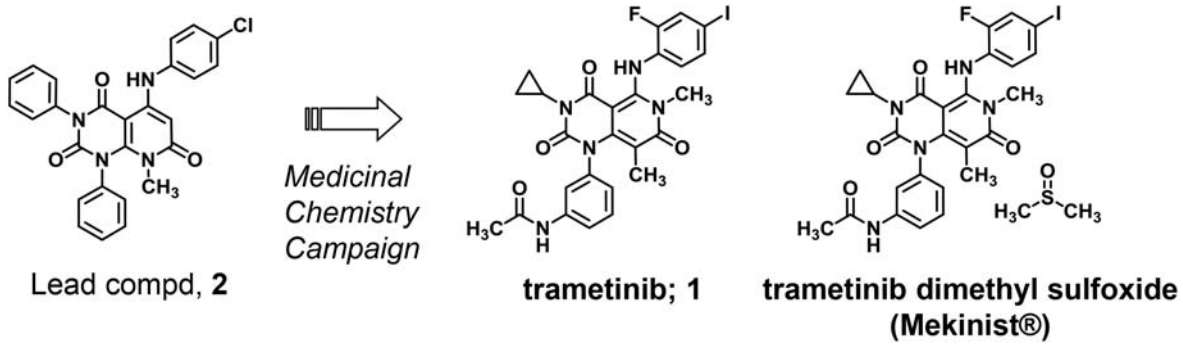

Fig. 1 Trametinib developed from lead compound **2**.

polymorphism study lost its oral exposure. This issue was solved by searching for a stable solvate instead of salts. Thus, we found trametinib DMSO, the first FDA approved drug of this solvate. The practical synthetic route to trametinib featuring its unusual rearrangement reaction is highly efficient and suitable for large scale production.

8.02.2 Concept

The lead compound (**2**) was identified by a phenotypic screening for its ability to induce the expression of a cell cycle regulatory protein, $p15^{INK4b}$, which inhibits CDK4 and CDK6, important proteins for the progression of the cell cycle from G1 phase to S phase.[1,14] Subsequently, trametinib was discovered by extensive medicinal chemistry efforts and its binding proteins were found and proven to be MEK1 and MEK2.[15] Disruption of cell cycle control, reported in numerous tumor cells, is thought to be one of the primary causes of malignant transformation.[16] CDK are key regulators that function in a phase-specific manner during cell cycle progression (Fig. 2). Cyclin D–CDK4/CDK6 and cyclin E–CDK2 play important roles in the G1 to S phase transition of the cell cycle by phosphorylating the tumor suppressor retinoblastoma protein (pRb), which forms a complex with E2F. The phosphorylation of pRb by CDKs causes release and activation of E2F, allowing transcription of genes necessary for the progression to S phase (Fig. 2).[16,17]

The loss of G1/S transition control in tumor cells often arises from aberrant activation of cell-proliferative signaling pathways or inactivation of cell cycle-regulating proteins. Of these pathways, the Ras–MAPK pathway has been investigated extensively. The classical MAPK cascade, comprising c-Raf or B-Raf, MEK1/MEK2, and ERK1/ERK2, is constitutively activated in various malignant tumors, often through gain-of-function mutation of Ras and Raf family members. These activating mutations cause increased expression level of cyclin D, leading to CDK activation and aberrant cell proliferation.[18,19] The cell cycle progression through cyclin–CDK activation is negatively regulated by CDK inhibitors (CKIs). Two families of CKI have been identified in mammalian cells: One includes $p21^{WAF1}$ and $p27^{KIP1}$, each of which inhibits cyclin E/A–CDK2 complexes. The other family, referred to as the INK4 family, is comprised of $p16^{INK4a}$, $p15^{INK4b}$, $p18^{INK4c}$, and $p19^{INK4d}$, which inhibit cyclin D–CDK4/6. $p16^{INK4a}$ is known to function as a tumor suppressor (Fig. 2). Mutation or inactivation of $p16^{INK4a}$ has been detected in many human malignant tumors,[20] and mice deficient in $p16^{INK4a}$ are highly susceptible to malignant tumors.[21,22] $p15^{INK4b}$ has similar functions to $p16^{INK4a}$ with regard to the suppression of CDK4/CDK6, leading to cell cycle arrest at the G1 phase. TGFβ inhibits cell proliferation at the G1 phase and induces the expression of $p15^{INK4b}$ ~30-fold in human keratinocyte HaCaT cells, suggesting that $p15^{INK4b}$ may act as an effector of TGFβ-mediated cell cycle arrest.[23] It has also been demonstrated that the overexpression of $p15^{INK4b}$ in cancer

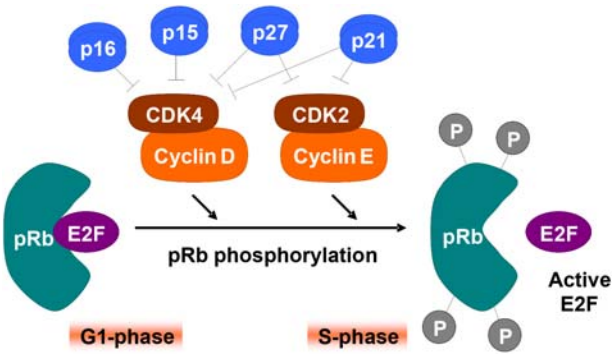

Fig. 2 Cell cycle regulation.

cells induced cell cycle arrest at the G1 phase.[24,25] These observations imply that $p15^{INK4b}$ may function as a replacement for $p16^{INK4a}$, and that agents with the ability to induce $p15^{INK4b}$ may provide new strategies for the prevention or therapy of malignancies, especially against tumors that lack $p16^{INK4a}$ function.[26] Therefore, we conducted a HTS campaign with our chemical library to find a compound that had the ability to increase the expression level of $p15^{INK4b}$. This screening assay was designed as a phenotypic type of screening,[14] and the lead compound was successfully identified in this assay. The first MEK1/MEK2 inhibitor, trametinib, was discovered from this lead structure by subsequent extensive medicinal chemistry efforts.

8.02.3 Lead Compound Identification

A phenotypic type of screening assay was employed for the HTS assay and its primary index was set as the ability of the compound to increase the expression level of $p15^{INK4b}$. To establish a robust screening assay, several cell lines, including mainly melanoma cell lines, were evaluated by whether $p15^{INK4b}$ was constitutively expressed and its expression was induced upon TGFβ stimulation as a potential positive control for the screening assay. However, among these cell lines, none of them demonstrated upregulation of $p15^{INK4b}$ by TGFβ stimulation. Therefore, we decided to use HaCaT cells, which are immortalized human keratinocytes. These cells have been reported to upregulate $p15^{INK4b}$ expression when the cells are stimulated by TGFβ.[23] Three readouts, $p15^{INK4b}$ mRNA quantification, $p15^{INK4b}$ protein quantification, or reporter gene assay using $p15^{INK4b}$ promoter region, were investigated and compared. The quantification of mRNA by q-PCR and the quantification of protein by Western blot method had a problem of low throughput, whereas mRNA quantification of the branched-DNA method and the reporter gene assay did not have such problems. Finally, we employed $p15^{INK4b}$ mRNA quantification by the branched-DNA method for our HTS phenotypic screening assay, since this method gave us a robust window of signal/noise ratio and reproducible results.[14]

By applying this HTS phenotypic screening assay for our chemical library, hit compounds were selected if $p15^{INK4b}$ mRNA was upregulated more than 50% from the basal level by treatment with a single dose of a compound at 10 μM. Then, 22 compounds were selected from those hit compounds after reproducibility assay and the dose-dependency study (Fig. 3, data only shown for the three lead candidates).

The 22 compounds were categorized into seven groups by similarity of core structure, and seven representative compounds were further investigated to determine if the compound had an ability to induce $p15^{INK4b}$ protein in cancer cells since HaCaT cells were not tumor cells. A part of the NCI60 cell lines were screened and 16 cell lines were selected by the following criteria: the expression of $p15^{INK4b}$ was detected by mRNA level and protein level and the promoter of $p15^{INK4b}$ was not inactivated by the methylation. Using those 16 cell lines, $p15^{INK4b}$ induction was evaluated after the treatment of those seven lead candidate compounds. A human renal cancer cell line, ACHN, exhibited relatively high sensitivity to the lead candidates; some compounds induced the expression of $p15^{INK4b}$ in the ACHN cells. Among them, compounds **2**, **3**, and **4**, which showed robust and reproducible $p15^{INK4b}$ induction (Fig. 4), were further confirmed as the cell cycle was arrested after the compound treatment. Compounds **3** and **4** share the adenine-like core structure employed in various tyrosine kinase inhibitors. Since gefitinib (**15**) was a representative compound among these inhibitors around that time, the phosphorylation of EGFR upon EGF stimulation was investigated in ACHN cells after the treatment of compounds **3** and **4**. Compound **4** clearly inhibited EGFR phosphorylation. In addition, we found that gefitinib also had the ability to induce $p15^{INK4b}$ expression and to arrest the cell cycle at G1 phase in our assay system (Fig. 4).[27]

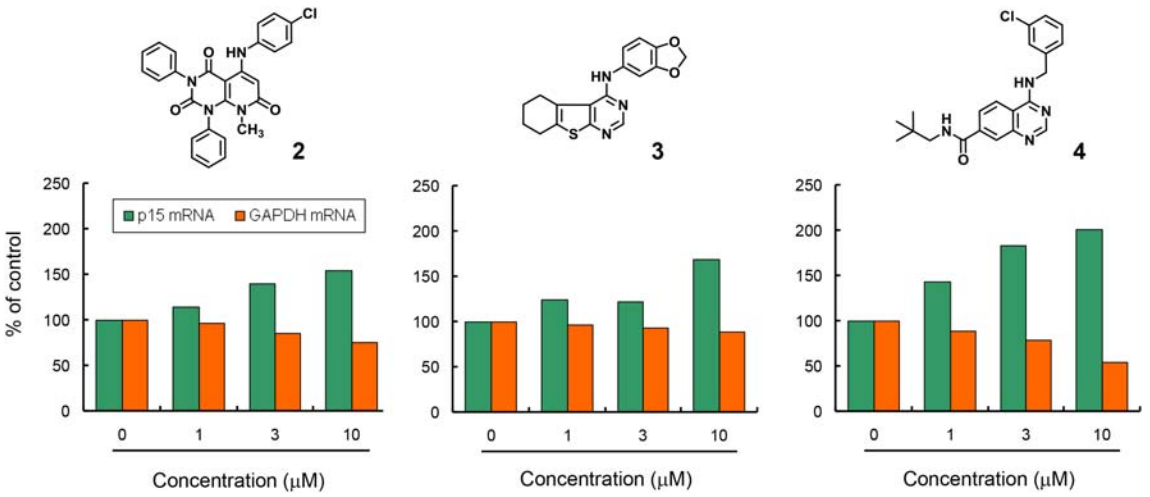

Fig. 3 $p15^{INK4b}$ induction by lead candidates. HaCaT cells were treated with 1, 3, 10 μM of compound **2**, **3**, and **4** for 24 h, then the expression level of $p15^{INK4b}$ mRNA was determined by branched-DNA methods. The housekeeping gene GAPDH mRNA was also measured. The values are indicated as % of control (ratio with respect to mRNA levels in vehicle (DMSO) treated cells).

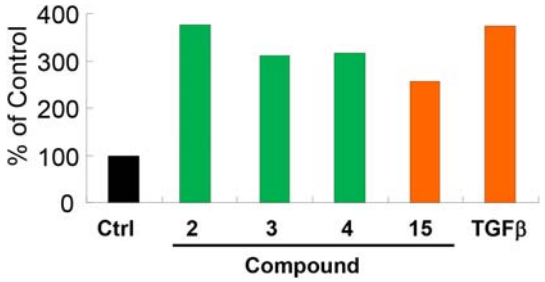

Fig. 4 p15^{INK4b} protein expression in ACHN cells treated with lead candidates. Cells from a renal cancer cell line, ACHN cells were treated with 10 μM of compound **2**, **3**, **4**, gefitinib (**15**) or TGFβ for 24 h, then the expression level of p15^{INK4b} protein was determined by Western blotting. The values are indicated as % of control (ratio to vehicle (DMSO) treated cells).

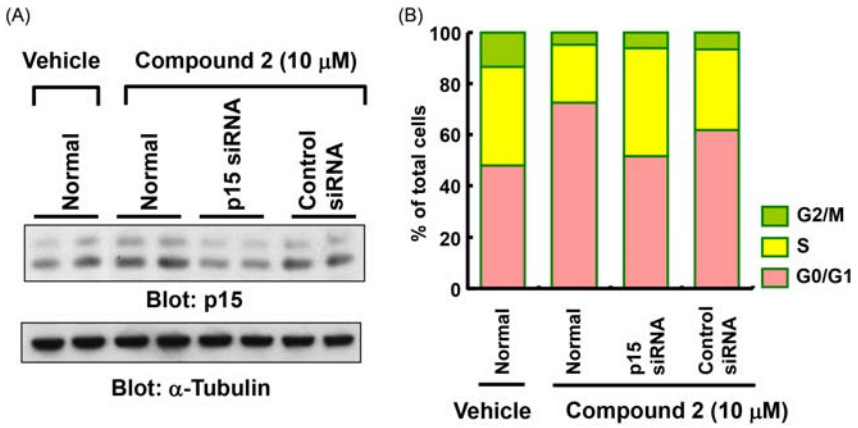

Fig. 5 p15^{INK4b} expression and cell cycle analysis in p15^{INK4b}-siRNA treated cells. Effect of p15^{INK4b} siRNA on cell cycle arrest by compound **2** in human renal carcinoma cell line ACHN. The expression levels of p15^{INK4b} were determined by Western blot (A). Cell cycle analysis was performed in compound **2**-treated ACHN cells after p15^{INK4b} siRNA transfection (B). The representative data was shown from 2 to 3 independent experiments.

Further confirmation studies were conducted with compounds **2**, **3**, and **4** to evaluate if p15^{INK4b} induction was involved in the cell cycle arrest effect, using p15^{INK4b} knockdown cells by the siRNA method. As a result, the G1-cell cycle arrest by the compounds was attenuated in p15^{INK4b} siRNA treated cells (Fig. 5, results only shown about compound **2**), suggesting that p15^{INK4b} at least contributes to the growth arrest effect of the lead candidate compounds. To clarify compound effects on the growth of normal cells, a colony formation assay was carried out using normal human bone marrow cells. All of the lead candidates (**2**, **3**, **4**) and gefitinib (**15**) had no effect on colony formation up to 10 μM, suggesting that p15^{INK4b} inducer compounds have minimal effect on the cell growth of normal cells (Fig. 6).

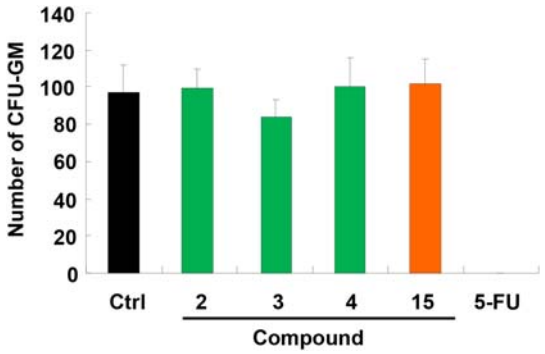

Fig. 6 Colony formation assay using human bone marrow cells. Normal human bone marrow cells were treated with 10 μM of compound **2**, **3**, **4**, **15** or 5-fluorouracil (5-FU), and cultured in the presence of several cytokines. The number of granulocyte/macrophage colonies (CFU-GM) was counted 7 days after the start of treatment.

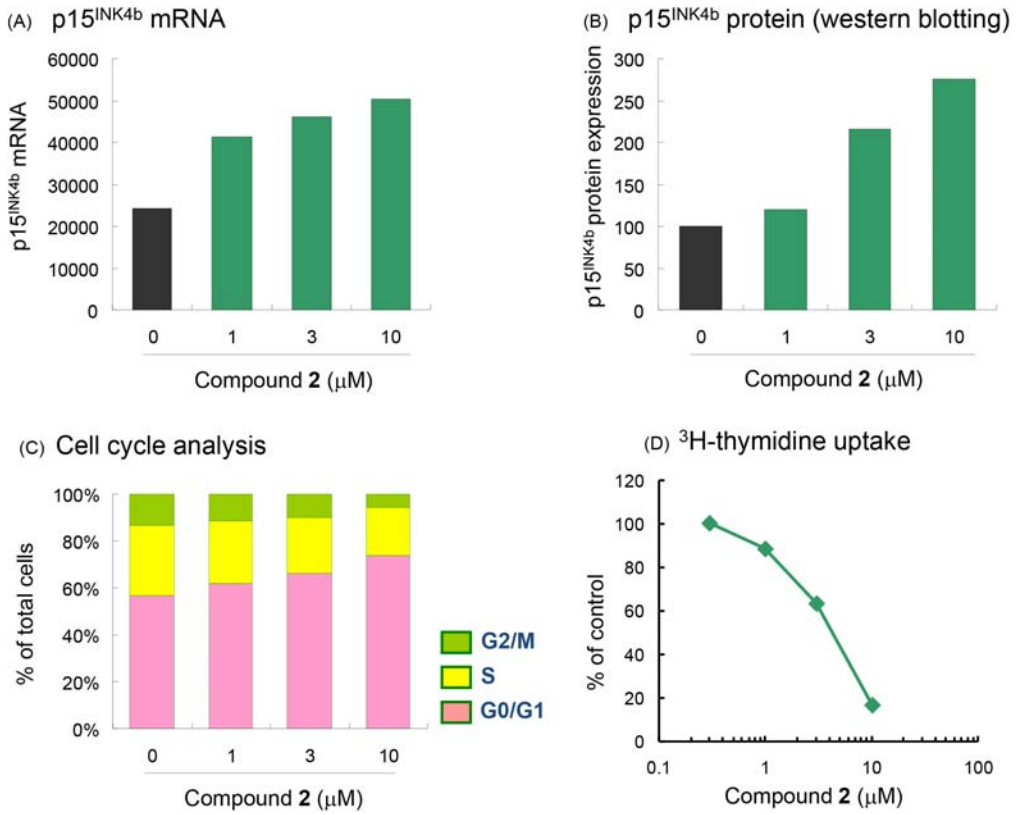

Fig. 7 p15^{INK4b} induction, G1-arrest, cell growth inhibition by compound **2**. ACHN cells were treated with 1, 3, 10 μM of compound **2** for 24 h, then the expression level of p15^{INK4b} mRNA and protein were determined by q-PCR (A), and Western blotting (B), respectively. The cell cycle arrest was examined by the cell cycle analysis with flow cytometry (C) and the cell growth activity was determined by ^{3}H-thymidine uptake study (D).

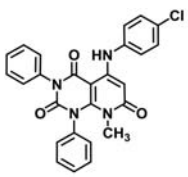
The lead candidates, compounds **2**, **3**, and **4**, were nominated as described above. At that time of 2002–03, investigators in this field considered the discovery of a highly selective kinase inhibitor still to be a great scientific challenge. Indeed, our lead candidate, compound **4**, exhibited suppression activity of EGFR phosphorylation in the cells after stimulation by EGF, for example. Since unfavorable adverse effects due to low selectivity of the compound should be circumvented in this project as well, we selected compound **2** with distinct structural features as an antitumor drug, but not compounds **3** and **4**, which have substructures that could potentially interact with the hinge region of protein kinases. As shown in Fig. 7, lead compound **2** induced the expression of p15^{INK4b} mRNA and protein in ACHN cells in a concentration dependent manner, resulting in cell cycle arrest at G1 phase and growth inhibition over the same concentration range. The IC_{50} values of this compound (**2**) for growth inhibitory activity were determined as 4800 nM in ACHN cells (a human renal cancer cell line) and 990 nM in HT-29 cells (a human colon cancer cell line) (Fig. 8). The medicinal chemistry effort of lead optimization was initiated for this compound **2**, looking at cell growth inhibition activity as the index of SAR.



Lead compd, **2**

- p15 protein inductive ability
  - 2-3 fold (at 10000 nM)
- Cancer Cell Lines Growth Inhibition (IC_{50})
  - ACHN 4800 nM (renal adenocarcinoma)
  - HT-29 990 nM (colorectal adenocarcinoma)
- Physical Property
  - ClogP 6.3
  - Solubility: very low

8.02.4 SAR Study-1

Variations in the substituents at the 1- and 3-positions of the pyridopyrimidine core were first examined. As indicated by the increase in the IC_{50} values (Table 1), these modifications (**5a–5g**) were not well tolerated.

Next we explored substitution on the aniline ring. Chloro-substitution was tolerated at all positions, but 2- and 3-homologs were twofold less active than **2** (Table 2). Accordingly, we investigated substitution at the 4-position as shown in Table 3. The simple phenyl analog (**7a**) was less active than **2**, as were other alkyl analogs (**7b–7d**). Methyl (**7b**) and ethyl (**7c**) (one carbon extension) equally showed weak potency. However, substitution with a halogen atom was more sensitive. Replacement of the chlorine with the bromine atom (**7f**) improved potency by twofold.

Compounds synthesized thus far had three aromatic rings on the pyrimidine core and their hydrophobicity was very high (ClogP > 6). In addition, they formed very stable crystals and thus had low solubility. We often had difficulties in measuring their NMR spectra even in DMSO-d_6. These features made them unattractive starting points for further optimization. In an effort to reduce hydrophobicity, we next systematically replaced each of the three benzene rings with less lipophilic small alkyl groups.

Replacement of the 1-phenyl substituent (**8a–8c**) or the phenyl group of the 5-aniline moiety with alkyl groups (**9b**, **9c**) resulted in a decrease in potency as shown in Tables 4 and 5.

We modified the remaining phenyl ring at the 3-position (Table 6). Compounds (**10a–10d**), which contain simple alkyl chains, were found to be less active. Cyclic alkyl groups such as cyclopentyl (**10f**) and cyclohexyl (**10g**) also gave no improvement. However, the compound **10e**, possessing a cyclopropyl group, showed similar potency to **2**.

We also examined the same modification in the bromo-series (Table 7). We were delighted to find that **11b**, which contained the cyclopropyl group at the 3-position and the *para* bromo substituent at the aniline ring, improved potency by twofold. Moreover the hydrophobicity of **11b** was reduced as expected (ClogP 5). Interestingly, compound **11c** with the cyclobutyl group showed weak potency. Only the cyclopropyl group among other cycloalkyls gave a modest improvement in potency. Compound **11b** displayed a poor pharmacokinetic (PK) profile (low %*F* of 11%, mouse). Still, we tested this compound in an HT-29 human tumor xenograft model. Encouragingly, **11b** showed the first sign of antitumor effect in this model, although high dosing of **11b** was needed (30 mg/kg, bid, p.o., 43% tumor growth inhibition). It took seven months for us to obtain this compound. One might think that this small improvement was not significant, but this finding fueled further exploration by keeping our morale high.

We next introduced a small substituent (e.g., methyl, halogen, methoxy, etc.) at the 2- or 3-position on the aniline ring. Alkyl analogs (**12a**, **12b**) and oxygen-containing substituent (**12e**, **12f**) attenuated potency (Table 8). Introduction of a halogen atom at the 2-position (**12c**, **12d**) resulted in an increase in potency. Compound **12c** with a fluorine atom showed a fourfold improvement compared to **11b**. However, 3-substitution (**13a**, **13b**) was not well tolerated (Table 9). These results indicated that analogs with the 2,4-disubstituted pattern were promising inhibitors.

Having an improved compound (**12c**), we revisited exploration of the substitution at the 4-position on the aniline ring. Representative examples are shown in Table 10. We found that as the size of the substituent increased from hydrogen (**14a**) to ethyl (**14c**), the compounds became more potent. However, lengthening the carbon chain to 3 in the propyl derivative (**14d**) resulted in

a slight loss in activity. However, cyclopropyl (**14e**) restored potency to the level of **14c**. This outcome indicated the existence of a small pocket on the target protein that recognizes the *para*-substituents. Introduction of a halogen substituent improved potency as the size of the substituent increased from fluoro (**14f**) to bromo (**12c**). In the end, compound **12c** with a bromo substituent was the most potent, and no additional improvement on potency was noted.

Having come to an impasse, we decided to consult structures of anticancer agents from other companies. In those days, gefitinib (**15**) and erlotinib (**16**) were lionized as promising molecularly targeted drugs in many articles (Fig. 9). However, we realized that we could not apply other substitution pattern on the aniline ring of gefitinib because compounds **6a** (3-Cl) and **14f** (4-F) were not potent. Erlotinib with an ethynyl group on its aniline ring attracted our attention. Although the position of the ethynyl was 3- instead of 4- in erlotinib, we tried it anyway. We synthesized compound **14i** with the ethynyl substituent by Sonogashira reaction of synthetic intermediate **14l** having an iodo substituent. Capable medicinal chemists usually avoid synthesizing compounds with iodo substituent as drug candidates. However, I noticed one of my colleagues put both **14i** and **14l** into a list of compounds for biological assays. I thought "poverty dulls the wit," but I didn't bother to cross iodo-compound **14l** off the list with weary sigh. The next week, we were astonished to hear the news. Biologists rushed into our room and told us both compounds were the most potent synthesized to date and IC_{50} values for HT-29 were less than 30 nM with complete growth inhibition at this dose! The IC_{50} values turned out to be 5.9 nM for ethynyl (**14i**), and most excitingly, 1.5 nM for iodo (**14l**). This iodo-compound was 500-fold more potent than lead compound **2**.

Compounds **14h** and **14i**, which bear unsaturated carbon substituents, were more potent than the saturated ethyl (**14c**). However, lengthening the carbon chain to three (**14j**) again reduced potency. Interestingly, the cyano variant (**14k**), of almost the same size as the ethynyl, only showed weak potency.

Caco2 permeabilities for compounds **14c** and **14h** were relatively high (Caco2 permeability (cm/s 10^{-6}): **14c**, 30.3; **14h**, 19.5), however, highly potent compounds such as **14i**, **12c**, and **14l** exhibited very low permeability of less than 0.1. These compounds also showed very low aqueous solubility and high hydrophobicity (ClogP **14l**, 5.5). We set out to investigate introduction of hydrophilic groups on the 1-phenyl ring of **12c** and **14l** as a means to improve physicochemical properties. We also expected some increase in potency. Early results of the incorporation of a methoxy group into the phenyl ring at the 1-position revealed that substitution was tolerated at the *meta*-position of the phenyl in terms of potency (data not shown). Representative results of *meta*-substitution on the phenyl are summarized in Table 11. We first examined the incorporation of amine or carboxyl group, which are suitable for salt formation, into compound **12c**. Amino group analogs (**17a**, **17b**) retained potency, while carboxylic groups (**17c**, **17d**) attenuated their activity dramatically. We were delighted to observe that some of the neutral hydrophilic groups gave satisfactory results. An acetamide analog (**17f**) and a sulfonamide (**17i**) gave two to threefold improvement in potency. Sulfamide (**17j**) exhibited further improvement in potency, but this compound was labile to metabolism (in vitro). The same modification to iodo-compound **14l** afforded highly potent compounds (**18a**, **18b**). Compound **18b** exhibited IC_{50} values of 3.9 and 0.37 nM for ACHN and HT-29, respectively. These two compounds reduced their hydrophobicity (ClogP **18a**, 4.5; **18b**, 4.3) and exhibited improved permeability (Caco2 permeability (cm/s 10^{-6}) **18a**, 28.4; **18b**, 18.1). With all these promising data, we believed we had succeeded in obtaining a candidate compound for development. However, unexpected experimental results forced us to give up all the compounds synthesized so far. (Details will be discussed in "SAR Study-2" section.)

The general syntheses of the compounds discussed thus far are outlined in Fig. 10. Treatment of **22** with methyl amine afforded key intermediate **23** in 96% yield. Chlorination of **21** proceeded with poor regioselectivity and needed to be improved. The introduction of different aryl groups at the 5-position in the final step was accomplished by thermal reaction of the tosylate **25** with appropriate aromatic amines and afforded good yields of the target compounds **26**. However, compounds bearing the

iodo substituent in the aniline ring (e.g., **18b**) were prepared in only c.30% yield due to the deiodination of iodo-aniline caused by employing a high temperature reaction condition. We addressed these issues rigorously in the synthesis stated above. We will discuss these in "Synthetic Studies" section.

8.02.5 SAR Study-2

We succeeded in obtaining a very potent compound (**18b**) starting from lead compound **2**. Analogs (**2**–**18b**) detailed in the previous section possessed the pyrido[2,3-*d*]pyrimidine core. But, unfortunately, the compounds with this pyrido[2,3-*d*]pyrimidine core proved to be unstable under weakly basic conditions as shown in Fig. 11. In the basic desilylation step of the precursor of **14i**, one of my associates noticed the formation of a side-product having the same MW as the target molecule **14i**. The side-product was assigned as compound **27** having the pyrido[4,3-*d*]pyrimidine core. After a few weeks, we determined the structure of **27** by careful analyses by two-dimensional NMR. We assumed that this new core was generated through the opening of the pyrimidinedione ring by the attack of a nucleophile (in this case methanol) at the C-2 carbonyl and subsequent ring-closure reaction gave another pyrimidinedione by the attack of the neighboring nitrogen atom of the other aniline.

Although compound **18b** exhibited a promising activity profile, we decided not to pursue **18b** and its analogs as suitable candidate for development due to their chemical instability. On the other hand, the newly formed pyrido[4,3-*d*]core was chemically stable. Compound **11b** provided the rearranged product **28** under basic conditions in the same way as illustrated in Fig. 11. And this rearranged **28** was very weak in potency (Fig. 12). However, we noticed compounds **11b** and **28** shared very similar chemical motifs, the spatial arrangement of two benzene and cyclopropane rings and three carbonyls on two heterocyclic cores was almost identical and only the positions of the nitrogen were swapped. We hypothesized that placement of appropriate substituents on the rearranged scaffold might afford chemically stable and highly potent compounds.

First, we transposed the bromine atom from the lower left position of **28** to the upper right position to afford **29**. But the potency was not restored. Next, we introduced a methyl substituent at the 8-position of **29**. Compound **30** had activity comparable to the parent **11b**. We reasoned that this was due to a potential effect of the methyl substituent on the orientation of the neighboring phenyl ring. Finally, introduction of the 2-F,4-I aniline moiety to give **31a** provided the substantial boost in potency that we sought. Compound **31a** exhibited the highly potent activity similar to **14l**.

Caco2 permeability for compound **31a** was good (Caco2 permeability (cm/s 10^{-6}) was 14), however, this compound was highly hydrophobic (ClogP 5.96). Although we asked our PK-specialists to measure the in vivo PK on **31a**, they politely turned it down due to the poor physicochemical profile of this compound. So, we set out to investigate introduction of hydrophilic groups on the 1-phenyl ring, the lower left, as a means to enhance hydrophilicity and hopefully improve the antiproliferative activity (the same strategy as mentioned before applied for the conversion from compound **14l** to **18a**,**b**).

Among the various functional groups that we examined, amides and sulfonamides were the preferred substituents in terms of potency (Table 12). Especially, compounds **31b** and **31d** substituted at the 3-position improved potency by threefold. On the other hand, a compound substituted at the 4-position such as **31c** resulted in an attenuation in potency by 10-fold. Compounds **31b** and

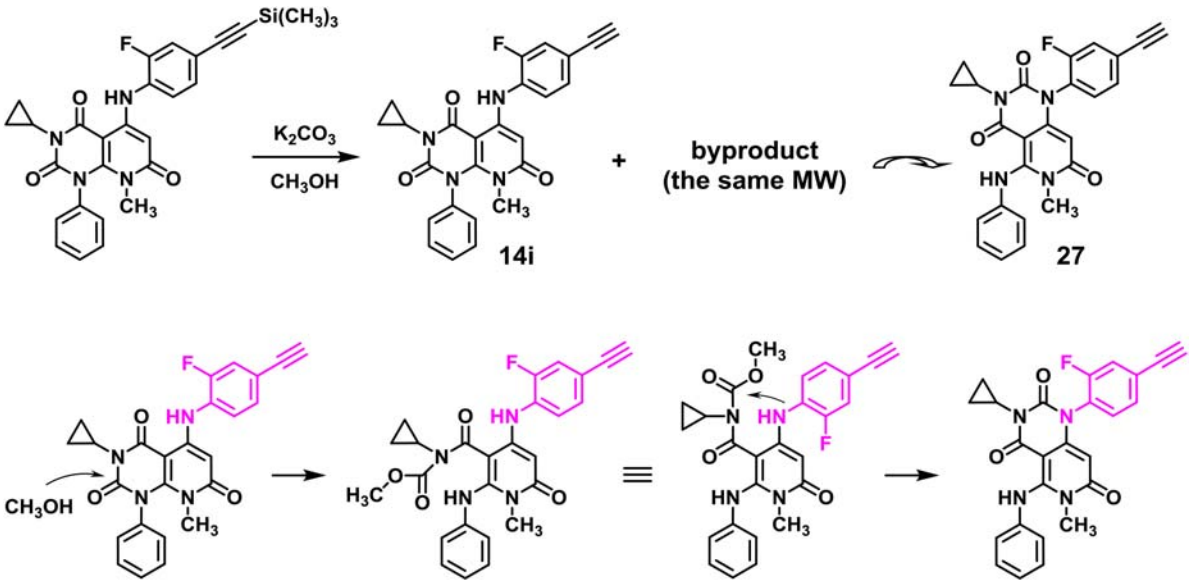

Fig. 11 Lability of pyrido[2,3-*d*]pyrimidine core.

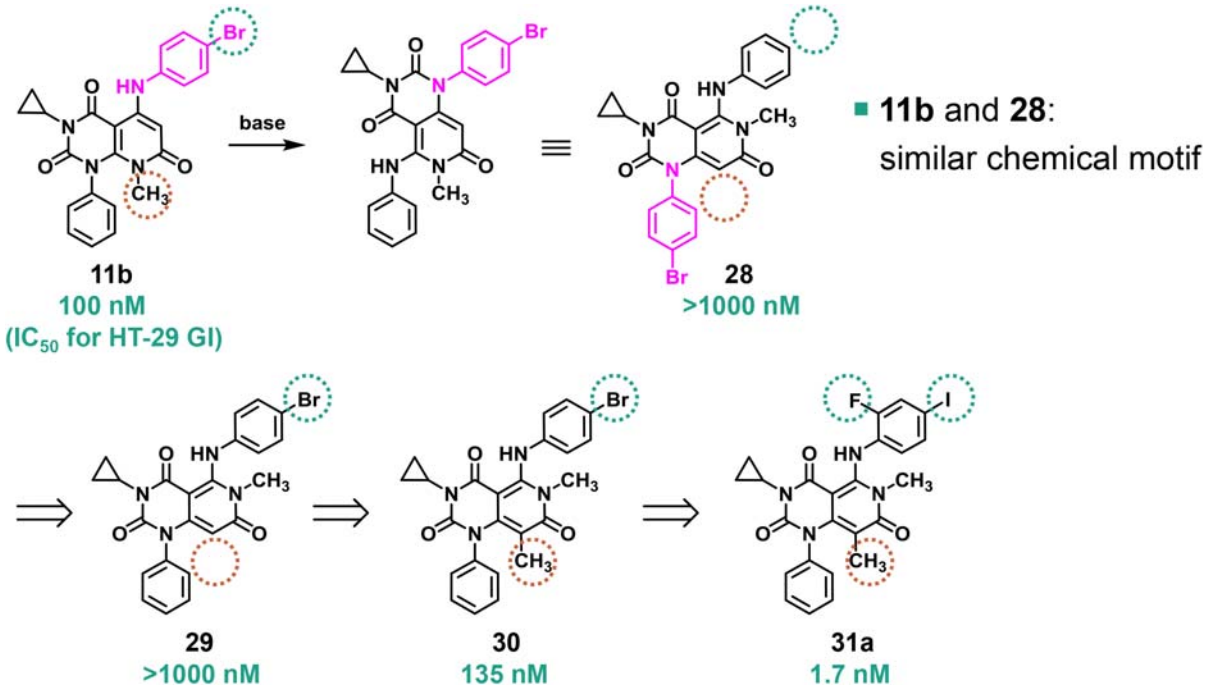

Fig. 12 Optimization of newly found core.

31d reduced their hydrophobicity (ClogP **31b**, 4.99; **31d**, 4.77) and retained good permeability (Caco2 permeability (cm/s 10^{-6}) **31b**, 17; **31d**, 26) (Table 13). Moreover, this modification resulted in a reasonable improvement in solubility. These compounds had an acceptable oral bioavailability of 30–60%.

To confirm the in vivo efficacy of compounds **31b** and **31d**, we evaluated the antitumor effect in the nude mouse xenograft model. HT-29 cells were inoculated subcutaneously into the right flank of nude mice, and compound **31b** or **31d** was administered orally once daily for 14 days starting from 5 days after the inoculation. Both 0.3 mg/kg and 1 mg/kg of compound **31b** were effective in inhibiting the HT-29 xenograft growth, and 1 mg/kg of compound **31b** blocked the tumor increase almost completely (Fig. 13).[2] In contrast, the antitumor effect of compound **31d** was ~10-fold weaker than that of compound **31b** on a dose-dependency basis. No significant changes in body weight of nude mice were observed after treatment of compounds **31b** or **31d**, suggesting that both compounds had sufficient efficacy of antitumor effect with lower dose range than the maximum tolerance doses. (The maximum tolerance dose was determined later as 3 mg/kg for compound **31b** and 30 mg/kg for compound **31d**.) We

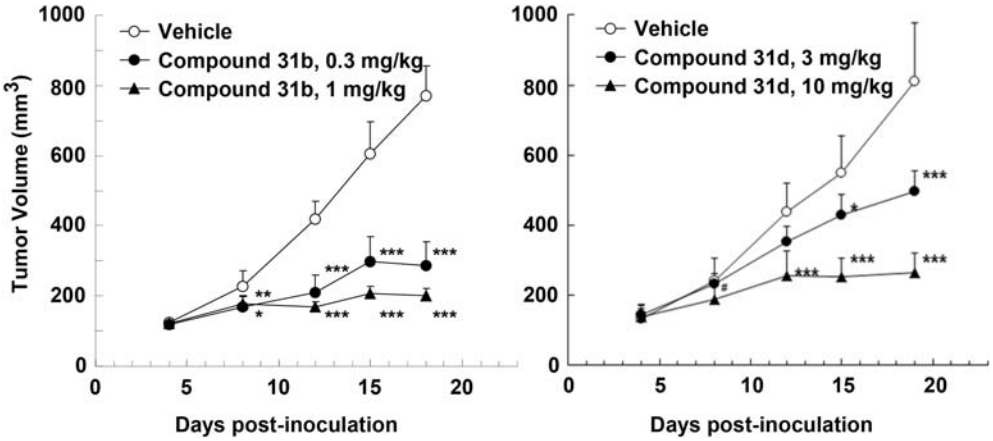

Fig. 13 Antitumor effect of **31b** and **31d** in nude mice bearing HT-29 xenografts. HT-29 cells were inoculated subcutaneously into the right flank of nude mice, and compound **31b**, **31d**, or vehicle (10% PEG400, 10% cremophor EL) was administered orally once daily for 14 days starting from 5 days after the inoculation. Tumor volumes were measured twice a week. The results are expressed as mean ± SD ($n=6$). $^{*}P<.05$, $^{**}P<.01$, $^{***}P<.001$ versus vehicle (Dunnett's test).

also evaluated PD0325901 (**34**, Fig. 19) in this model, and found that 30 mg/kg of PD0325901 (**34**) showed comparable efficacy of 1 mg/kg for compound **31b**.

The pharmacokinetic profiles in mouse for **31b** and **31d** are presented in Fig. 14. The compounds were administered intravenously to mice at 1 mg/kg. Compound **31b** showed longer mean residence time (MRT) and higher blood concentrations than **31d**. These features of **31b** might contribute to the superior in vivo activity of this compound (Fig. 13). The PK profile of **31b** was studied in three preclinical species (mouse, rat, and dog) as shown in Fig. 15. The compound showed low blood clearance and a long half-life, especially in dog. These features might translate into sustained plasma drug concentrations and narrow "peak/trough" ratio in human studies.

We selected compound **31b** (JTP-74057, GSK1120212, trametinib) as a candidate for further development based on the results of these in vivo xenograft model and PK studies.

8.02.6 Mechanism of Action and Pharmacological Characterization

8.02.6.1 Target Identification of Trametinib

During the discovery process of trametinib, we carried out the HTS screening campaign with the index of $p15^{INK4b}$ induction. Lead optimization was performed with the index of antiproliferative activity in ACHN and HT-29 cells, in vivo PK profile, and in vivo efficacy in the mouse xenograft model.[1,14] However, the molecular target of trametinib was still unknown at the time of discovery of this compound. Therefore, we undertook a search for the binding partner of trametinib by precise pharmacological and biological profiling. The $p15^{INK4b}$ upregulation was considered to be still involved in the antiproliferative effect of trametinib, since the relationship was found to be very reasonable between $p15^{INK4b}$ protein expression and antiproliferative activity during the course of lead optimization to trametinib (Table 14).

To clarify the mechanism of $p15^{INK4b}$ induction by trametinib, we examined the direct effect of trametinib on the $p15^{INK4b}$ promoter and the effect on degradation of $p15^{INK4b}$ mRNA, but these studies did not afford significant insights, leaving the mechanism of action of trametinib an enigma. On the other hand, an analysis of the expression levels of cell cycle related proteins revealed that trametinib can increase the expression of $p27^{KIP1}$ and decrease the expression of cyclin A and cyclin D1 while also affecting the $p15^{INK4b}$ induction activities (Fig. 16). In addition to this, the decrease in the phosphorylation of pRb can be seen in trametinib treated cells, indicating that those changes are related to the G1 cell cycle arrest effect of trametinib

(Fig. 16).[14] c-Myc was found to be the earliest gene that is affected by trametinib treatment (data not shown here).[14] The expression of c-Myc rapidly decreased within 2 h after starting the trametinib treatment. This rapid effect led us to speculate that the molecular target of trametinib might exist in the growth signaling pathway(s).

The drug-affinity chromatography technique using chemical probes was utilized for the molecular target exploration of trametinb.[15] As a starting point, we selected and synthesized compounds for the chemical probe. We had successfully incorporated a hydrophilic moiety into the 1-position in the benzene ring of **31a** during the SAR process, so we considered that the linker moiety to the resin (Sepharose) could be incorporated into this region. Compound **32** was prepared as a most potent probe and **33** was

ACHN or HT-29 cells were treated with test compounds for 24 h, then cell growth activity was determined by ^{3}H-thymidine uptake assay. The results were shown as IC_{50} values. In addition, the expression level of $p15^{INK4b}$ protein in ACHN cells was examined by Western blotting after the treatment with various concentrations of test article for 24 h. (−); no induction, (+); weak induction, (++); strong induction of $p15^{INK4b}$ protein.

prepared as a less potent probe. Compounds **32** and **33** themselves showed very weak antiproliferative activity, but its pentanoyl derivative on the primary amine, which demonstrated the Sepharose-immobilized chemical probe status, exhibited the IC_{50} values of 2.1 and 840 nM for **32** and **33** in the HT-29 cell growth assay, respectively (**Fig. 17**).[15]

Taken together, compounds **32** and **33** were considered to be useful for the chemical probes in the drug-affinity chromatography. To identify specific binding targets, we prepared three chemical affinity resins. The first was unconjugated and used as a negative control, the second was conjugated with compound **33**, and the third was conjugated with the most potent compound **32**, which shared most of the structure to trametinib. HT-29 cell lysates were incubated with the individual resins and the bound proteins were extracted by pull-down assays. Specific binding proteins, including a dominant 46 kDa protein, accumulated in the compound-conjugated resins (**Fig. 18**).
