More recently, Bajusz et al. have established that the Tanimoto index, Dice index, Cosine coefficient, and Soergel distance were identified to be the best and in some sense equivalent measures for similarity calculations (in combination with the path-based Chemaxon Chemical Fingerprint), whereas the similarity metrics derived from the Euclidean and Manhattan distances are not recommended on their own, although their variability and diversity from other similarity metrics might be advantageous in certain cases. The behavior of these similarity coefficients was very similar for fragment-sized, lead-like, and drug-like compounds. Analysis of variance (ANOVA) showed that the choice of the data preprocessing method (such as interval scaling, standardization, and rank transformation) does not affect the results significantly.[279]

Haws et al. have described an easy way to unfold symmetric diagonal matrices into vectors (so that they can be compared with, e.g., the similarity metrics included in **Table 6**).[285] Their first figure uses the example of a dissimilarity map, but it can also be used for correlation matrices as well (see **Fig. 14**).

Schuffenhauer and Brown have approached the problem from the opposite direction[286]: "diversity selection can be … only of value if used with dissimilarity cut-offs in ranges where the similar property principle is at least partially valid." Mean pairwise intermolecular dissimilarity has been calculated for a rapid selection of external datasets.[287]

Sheridan and Kearsley put the various approaches to define similarity into the context of receptors and bioactivities: "There is clearly a lot of 'art' involved in defining similarity, and different definitions are useful for different purposes … Different methods select different subsets of actives for the same biological activity and the same method might work better on some activities than others in a way that is difficult to predict beforehand. In retrospect, this makes sense because receptors are diverse, and chemical groups that appear equivalent to one descriptor might not be equivalent to another."[288] Novel types of plots for the comparison of binary similarity coefficients have been elaborated by Salim et al. These plots clearly show the differences between coefficients in size, and the size bias of similarity coefficients is revealed.[289]

There is no doubt that the Tanimoto coefficient is the most frequently applied similarity measure for bit strings. It can be advantageously applied in many cases, but it is not the best (and can even be deficient) in other cases. Below we summarize some (contradictory) findings concerning the Tanimoto coefficient. If a compound has a Tanimoto similarity coefficient (based on "Unity" fingerprints) larger than 0.85 to an active compound, then the compound has an 80% chance of itself being active in the same assay.[290] Martin et al. have shown that similar biological activity might be expected from structurally similar compounds: "as the structural similarity is increased, so is the biological similarity." The enrichment in active compounds is higher than the same of docking to proteins of known 3D structures. If setting the limit for Tanimoto coefficients higher than 0.85 in the case of Daylight fingerprints only 30% of compounds proved to be active.[269] Cosine and Tanimoto coefficients were compared. If the Cosine coefficient is used for the calculation of the intermolecular (dis)similarities, a set of dissimilar molecules is selected faster than earlier algorithms. The algorithm is applicable to any type of representation that characterizes a molecule by a set of attribute values and to any procedure that involves calculating a sum of intermolecular similarities.[291] The Tanimoto coefficient is not a perfect similarity measure, it also has some limitations. The distribution of Tanimoto coefficients for a comparison of 54-bit strings is peculiar: it is a multimodal skewed distribution.[292] "The Jaccard coefficient, also known as the Tanimoto coefficient is the most widely used in practice." "There cannot be one similarity measure and one descriptor that correlates with every molecular property at the same time. In different 'similarities,' different features emerge as being important (and in our case, different

Table 6 Formulas for frequently used similarity and distance measures

Similarity/distance measure	*Definition/Formula for numerical variables*[a]	*Formula for dichotomous variables*[b]
Hamming (Manhattan) distance	$D_{A,B} = \sum_{j=1}^{n} \lvert x_{j,A} - x_{j,B} \rvert$	$D_{A,B} = a + b - 2c$
Euclidean distance	$D_{A,B} = \sqrt{\sum_{j=1}^{n} (x_{j,A} - x_{j,B})^2}$	$D_{A,B} = \sqrt{a + b - 2c}$
Soergel distance	$D_{A,B} = \frac{\sum_{j=1}^{n} \lvert x_{j,A} - x_{j,B} \rvert}{\sum_{j=1}^{n} max(x_{j,A}, x_{j,B})}$	$D_{A,B} = 1 - \frac{c}{a+b-c}$
Pearson correlation (r) distance (PCD)	$PCD_{A,B} = 1 - abs(r)$. For centered x variables r is identical with cosine coefficient, otherwise: $r = \frac{\sum_{j=1}^{n} (x_{j,A} - \bar{x}_j)(x_{j,B} - \bar{x}_j)}{\sqrt{\sum_{j=1}^{n} (x_{j,A} - \bar{x}_j)^2 \sum_{j=1}^{n} (x_{j,B} - \bar{x}_j)^2}}$	$PCD_{A,B} = 1 - \frac{c}{\sqrt{ab}}$
Spearman rank correlation (ρ) distance	$SRCSD_{A,B} = 1 - abs(\rho)$ $\rho = \frac{\sum_{j=1}^{n} R(x_{j,A}) R(x_{j,B}) - n\left(\frac{n+1}{2}\right)^2}{\sqrt{\left(\sum_{j=1}^{n} R(x_{j,A})^2 - n\left(\frac{n+1}{2}\right)^2\right)\left(\sum_{j=1}^{n} R(x_{j,B})^2 - n\left(\frac{n+1}{2}\right)^2\right)}}$	Not defined
Pearson correlation squared distance	$PCSD_{A,B} = 1 - r^2$	$PCSD_{A,B} = 1 - \frac{c^2}{ab}$
Spearman rank correlation squared distance	$SRCD_{A,B} = 1 - \rho^2$	Not defined
Minkowski distance	$D_{A,B} = \left(\sum_{j=1}^{n} \lvert x_{j,A} - x_{j,B} \rvert^p\right)^{1/q}$ Where p and $q > 0$ and generally $p = q$	Not defined
Chebishev distance	$D_{A,B} = \lim_{n \to \infty} \left(\sum_{j=1}^{n} \lvert x_{j,A} - x_{j,B} \rvert^p\right)^{1/q}$	Not defined
Correlation coefficient	Pearson: $r = \frac{\sum_{j=1}^{n} (x_{j,A} - \bar{x}_j)(x_{j,B} - \bar{x}_j)}{\sqrt{\sum_{j=1}^{n} (x_{j,A} - \bar{x}_j)^2 \sum_{j=1}^{n} (x_{j,B} - \bar{x}_j)^2}}$	Matthews: $S_{A,B} = \frac{cd - (a-c)(b-c)}{\sqrt{ab(a-c+d)(b-c+d)}}$
Ochiai/Cosine coefficient	$S_{A,B} = \frac{\sum_{j=1}^{n} x_{j,A} x_{j,B}}{\sqrt{\sum_{j=1}^{n} (x_{j,A})^2 \sum_{j=1}^{n} (x_{j,B})^2}}$	$S_{A,B} = \frac{c}{\sqrt{ab}}$
Dice coefficient	$S_{A,B} = 2\frac{\sum_{j=1}^{n} x_{j,A} x_{j,B}}{\sum_{j=1}^{n} (x_{j,A})^2 + \sum_{j=1}^{n} (x_{j,B})^2}$	$S_{A,B} = \frac{2c}{a+b}$
Tanimoto coefficient	$S_{A,B} = \left[\frac{\sum_{j=1}^{n} x_{j,A} x_{j,B}}{\sum_{j=1}^{n} (x_{j,A})^2 + \sum_{j=1}^{n} (x_{j,B})^2 - \sum_{j=1}^{n} x_{j,A} x_{j,B}}\right]$	$S_{A,B} = \frac{c}{a+b-c}$
Russell-Rao coefficient	Not defined	$S_{A,B} = \frac{c}{n}$
Forbes coefficient	Not defined	$S_{A,B} = \frac{cn}{(a+c)(b+c)}$
Simpson coefficient	Not defined	$S_{A,B} = \frac{c}{min(a,b)}$
Simple matching coefficient	Not defined	$S_{A,B} = \frac{c+d}{n}$
Tversky coefficient	Not defined	$S_{A,B} = \frac{c}{\alpha(a-c) + \beta(b-c) + c}$

[a]In the definitions for continuous variables (such as physicochemical properties or biological activities), $x_{j,A}$ and $x_{j,B}$ are the values of feature j for molecules A and B, respectively; $\bar{x}_j$ is the average value of feature j; $R(x_{j,A})$ is the rank number of feature j of molecule A; and n is the number of features.
[b]In the definitions for binary variables (such as fingerprints), a is the number of *on* bits in molecule A, b is number of *on* bits in molecule B, c is the number of bits that are *on* in both molecules, d is the number of common *off* bits, and n is the bit length (total number of bits) of the fingerprint: $n = a + b - c + d$.

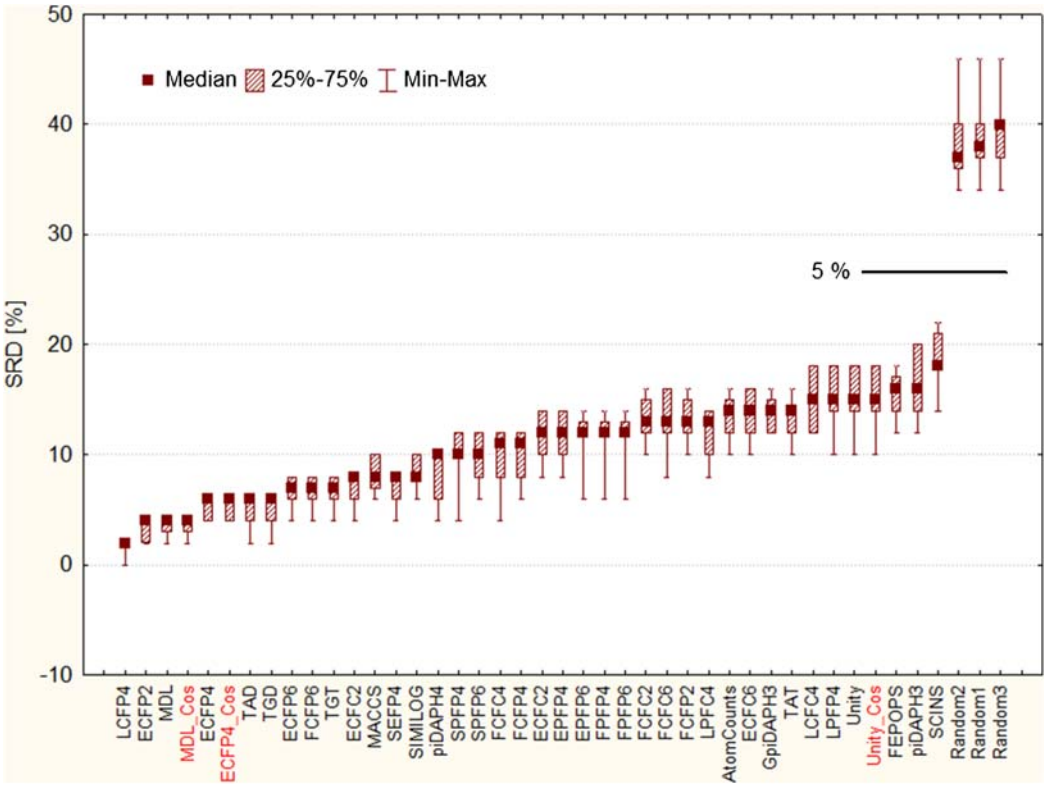

Fig. 13 Leave-one-out cross-validated SRD (sum of ranking differences) values for the fingerprint methods compared by Bender et al.[90] As SRD values measure a method's distance from the consensus (in terms of ranking the observations—here, molecules), the smaller SRD values are better. Here, LCFP4 proved to be the best (most consistent) fingerprint for these 11 activity classes. The ranking has passed the randomization test, 5% level of random ranking is shown in the figure. It can also be concluded that the similarity metrics (Tanimoto or Cosine, the latter is marked with red) do not affect the ranking behavior significantly.

bioactivities invariably require different descriptors)."[271] Even the efficiency of the well-known Tanimoto coefficient can be increased using a single, bioactive reference compound (or using several reference structures) with data fusion (see later) and machine-learning techniques.[293]

"It was also found that different coefficients perform better in certain ranges of molecular size (or bit density). The Russell–Rao coefficient was found to perform better in the case of large queries, while the Forbes coefficient performed better on small queries. The Tanimoto coefficient was outperformed in many cases, but not consistently. The good performance of Russell–Rao and the weak performance of Forbes were also observed in an application using the Dictionary of Natural Products database (DNP), where the Tanimoto coefficient was often outperformed by a factor of two."[294] "Certain coefficients whether single or in combination, appear repeatedly as best performers. One would definitely include the Russell/Rao, Forbes, and Simple Match in this pool and would probably add the Tanimoto, Cosine and others."[289] It was revealed that the size-bias and asymmetries that are inherent in most similarity coefficients lead to a bias in the selection of active compounds (altogether 14 coefficients were examined, including the Tanimoto coefficient).[295] Considering the large number of studies about the inconsistent and unsatisfactory behavior of the Tanimoto coefficient, it is somewhat surprising that it is still the "default" similarity metric. On the other hand, recent investigations show that Tanimoto index, Dice index, Cosine coefficient, and Soergel distance are the best ones, and they are in some sense equivalent metrics.[279]

Association coefficients may be more suitable for 2D fragment-based similarity searching than distance values. Atom sequences seem to perform best among the studied descriptors. Combination of atom sequences and the set theoretic Tanimoto coefficient is strongly recommended in similarity searching.[296] Fingerprint-based iterative similarity search with multiple active compounds as references performs better than 2D fingerprint similarity searching in a large-scale comparative analysis carried out on 208 well-defined compound activity classes.[297]

In the work of Reisen et al., six types of similarity measure were tested for their use in High-Content Screening (HCS)[298]: (i) distance measures (Euclidean, Manhattan, and Mahalanobis distances), (ii) linear correlation measures (Pearson correlation coefficient, Cosine similarity), (iii) nonlinear correlation measures on a ratio scale (Maximum information coefficient, Distance correlation), (iv) nonlinear correlation measures on an ordinal scale (Kendall's τ, Spearman's ρ), (v) comparison of up- and down-regulated features using a threshold (Tanimoto index, Dice coefficient), and (vi) CMAP-like similarity measures (see **Fig. 15**).

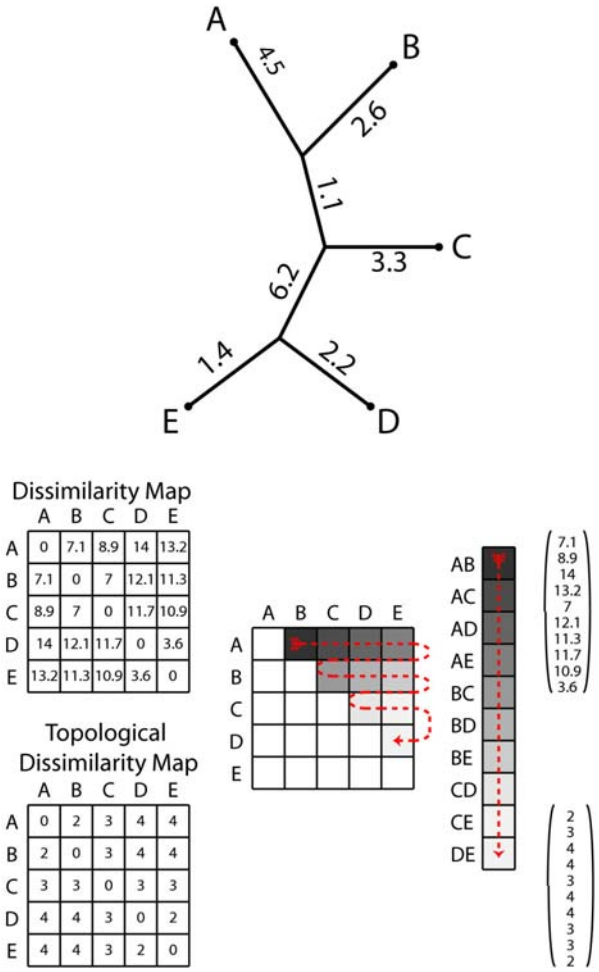

Fig. 14 A process to "unfold" diagonal dissimilarity maps into vectors according to Haws et al.[285] The dissimilarity map contains distances, whereas the topological dissimilarity map is calculated with path counts. While the original work revolves around phylogenetic trees, the concept presented can be easily translated to be applicable to distance, similarity, or correlation matrices, as well as topological distance matrices (as presented in subsection "**Topological descriptors**").

Receiver operating characteristic (ROC) curves are used to evaluate the performance of the similarity functions using the area under the curve (AUC). Data preprocessing greatly influences the results. The right choice of a similarity measure is a prerequisite for high-quality, high-content screening fingerprints. The nonlinear rank-based correlation methods (Kendall's τ and Spearman's ρ) seem to be suitable for identifying similarities and dissimilarities among the high-dimensional high-content screening readouts.

Scaffold hopping has played an increasing role in the last decade. Sufficient degree of diversity should be preserved not to overlook promising drug candidates or classes. A set of methods is presented that are designed to find compounds that are structurally different to a certain query compound while retaining its bioactivity properties (scaffold hops). These methods utilize various indirect ways of measuring the similarity between the query and a compound that take into account additional information beyond their structure-based similarities.[299] Stiefl et al. have defined scaffold hops based on whether the Extended reduced Graph approach (ErG) is able to switch among different chemotypes (and if yes, to what extent).[300] Group fusion is suitable for scaffold-hopping applications as well. Scaffold similarity searches were introduced by Ertl.[301] Classical similarity search and scaffold keys similarity search were compared, and the superiority of the latter has been proven. He also stated that the successful Tanimoto similarity measure unfortunately did not work well for scaffolds.

Structural unit analysis identifies the molecular substructures or fragments that distinguish compounds with high activity from those with average activity. The method is suitable to scaffold hopping, as well. A set of techniques were elaborated using the nearest-neighbor graph-based similarity.[302] Maggiora, in his editorial, discussed the reasons why QSAR modeling often fails and mentioned the idea of activity cliffs: "identifying and removing outliers may not necessarily always be a statistical problem as some outliers may only be *apparent* and may, in fact, arise from activity cliffs in the data."[303] Maggiora et al. outlined the various similarity concepts in an easily perceivable way.[304] Chemical, molecular, biological, global, and local similarity all have different meanings. They reformulated the definition of the Tanimoto coefficient in a more intuitive way to interpret it "as the ratio of the number of features shared by A and B molecules to the number of their unique features."

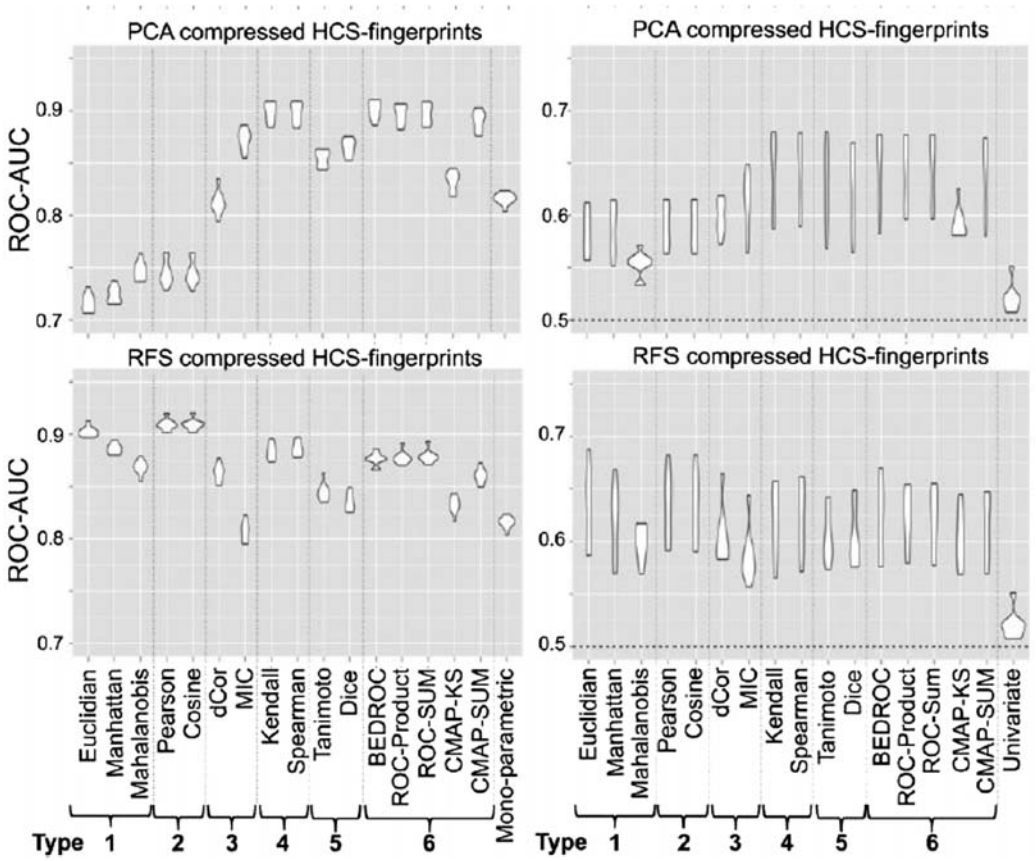

Fig. 15 Comparison of similarity metrics for high-content screening (HCS) fingerprints in the work of Reisen et al.[298] *Left* column: similarity analysis among replicates; *right* column: correlation between chemical and HCS fingerprints. Violin plots show the performance distribution over the 10 separate evaluation sets. © 2013 Society for Laboratory Automation and Screening.

Interestingly Muchmore et al. utilize a different terminology in their work, where they interpret fingerprints as similarity measures. A novel probabilistic framework was used for their interpretation. Tanimoto coefficients were calculated for 10 different similarity methods (MACCS keys, Daylight fingerprints, Maximum Common Subgraphs, Rapid Overlay of Chemical Structures (ROCS) shape similarity, and six connectivity-based fingerprints) combined with a database of more than 150,000 compounds and activity data against 23 protein targets. Different similarity measures were compared with Receiver Operating Characteristic curves (ROC) and the Boltzmann-Enhanced Discrimination of Receiver operating Characteristics (BEDROC). Decision theory helped in the data fusion, and the probability that any two molecules will exhibit similar biological activity is calculated.[305]

Density in chemical space is one of the limitations when using similarity methods. Insufficient density causes heavy computational time consumption and can lead to sometimes inaccurate results.[95] Todeschini et al. compared the largest pool of binary similarity coefficients.[280] Five pairs and a triplet of coefficients were found to yield identical similarity values, i.e., the same coefficients were rediscovered and bear different names. The similarity coefficients were grouped differently: symmetric, asymmetric, intermediate, and correlation-based binary coefficients (their shapes were plotted for the simulated data sets). Other partitioning options include metric–nonmetric, and—based on the shape behavior—increasing exponential, quasilinear, logarithmic, and sigmoidal. The best-ranked coefficient was CT4 (Consonni-Todeschini coefficient, fourth version),[306] which is basically the logarithmic transformation of the (shifted) Tanimoto index used for similarity analysis. Nonetheless, the Harris–Lahey, Tanimoto, Gower–Legendre, Sokal–Sneath and Jaccard (2012) coefficients are ranked similarly well on two real data sets (MDDR and WOMBAT).

3.14.6.2 Similarity Fusion, Fusion Rules, Consensus Scoring

In analytical chemistry data fusion usually means uniting data of vastly different origins and scales, for example, the fusion of NMR and mass spectrometry data[307] or the combination of "fluorescence with the biomarkers … and traditional metabolomics measurements in the form of ^{1}H NMR spectroscopy," as reported in the work of Bro et al.[308]

In chemoinformatics and medicinal chemistry, data fusion usually means "merging" different, eventually seriously conflicting rankings. The basic idea is far-reaching: multicriteria optimization, method comparison, feature ranking can all be considered as data fusion techniques.

Selection of structurally diverse subsets of chemical structures is a valuable aim. Several different algorithms have been compared, and all of them have been suggested for dissimilarity-based compound selection, provided that they are sufficiently rapid in execution for use with large files of compounds. MaxMin is the best algorithm currently available for nonfocused, dissimilarity-based compound selection based on a comparison of the number of activity classes identified using the MaxMin and other algorithms.[309]

Virtual screening based on fingerprints is rarely used as a standalone method. Methods such as group fusion, data fusion, or voting have been introduced to combine similarities calculated from multiple fingerprint methods.[95] Binary similarity coefficients (22) were compared using Unity fingerprints (2D fragment bit-strings), the coefficients were clustered, and a consensus scoring was calculated.[276] Two, three, and four binary similarity coefficients were merged in the work of Salim et al., who have established that the best fusions were better than the best single coefficients for 12 data sets out of 15. Consensus scoring has been shown to improve the hit rates in virtual library screening.[289] There are different possibilities to combine information from several scoring algorithms to provide a single prediction. Using several data sets, Ginn et al. used MIN, MAX, and SUM rules, defining the combined prediction by the lowest, highest, and average prediction of the individual methods. Both SUM and MAX are, overall, to be preferred to the individual results. The most effective for similarity fusion is generally the usage of the SUM rule with rank data. It was also found that consensus scoring performed better (and significant at $p < 0.05$) in 28 out of 30 runs if the SUM rule is used. In practice, one can use this information to determine how to deal with multiple known active structures: in particular it was shown that adding up individual scores of each pair of query and library compound improves the overall results.[310]

As so many similarity methods have been defined, it became a valid research goal to provide guidance on which similarity measure is the most suitable for solving a special task. Sheridan and Kearsley provided some justification to use a large number of molecular similarity methods.[288]

As some of the available similarity coefficients quantify different types of structural resemblance, it seems to be advantageous to use them in combination. Willett distinguishes between *similarity fusion* (combining the results of database searches that use a common reference structure but use different similarity coefficients) and *group fusion* (when several, structurally diverse reference structures are available, the reference molecule is allowed to vary and the similarity measure is kept constant).[91,311,312] *Consensus scoring* (combination of the results of different search algorithms and/or scoring functions) is a similar data fusion technique for structure-based approaches, such as docking.

Later, Willett extended the three accepted fusion rules (MIN, MAX, and SUM) to include the average, median, geometric and harmonic means, Euclidian norm, and some other rules concentrating on the top ranks only. Fusion rules are to be used for similarity scores or the ranks alike. Supervised fusion rules are also interpreted in the Bayesian framework when biological activity is also considered in the search.[312] Willett devoted a chapter to answer the question: why does data fusion work? He has established that "the SUM rule is likely to out-perform the MAX rule in similarity fusion; that the converse applies in group fusion; and that group fusion is generally far superior to similarity fusion." A further fusion rule is emphasized in Willett's work: the Reciprocal Rank Fusion (RRF) rule, which is applicable only to rank data and which derives from the fact that virtual screening often involves applying a cut-off on the similarity scores (such as the top-1%) so that only a small fraction of the database is considered further in a project.[91] Let p ($p \leq n$) be the number of times that an individual database structure dy occurs above the chosen cut-off. Then the RRF rule involves summing the reciprocal ranks for those p occurrences to give a fused score:

$$\sum_{x=1}^{p} \frac{1}{\mathrm{RANK}_x(dy)} \tag{35}$$

The reciprocal rank fusion rule outperformed all of the other rules that Chen et al. considered in their comparative study of 15 different fusion rules.[313] Group fusion is most effective when: (i) as many reference structures as possible are used, (ii) only a small proportion (1–5%) of each ranked similarity list is submitted to the final fusion rule, and (iii) when the reciprocal rank rule is used to combine the individual search outputs. The Pareto data fusion approach has been elaborated by Cross et al.[314] The Pareto approach counts for each molecule the number of times other molecules achieve a better rank in all of the lists, thus the best molecules will receive a Pareto score of 0. (The ties are managed by successive interactive ranking.)

Independently from virtual screening and similarity coefficients, data fusion is extensively used for method and model comparison.[284,315,316] Sum of Ranking Differences (SRD) are supported with theoretical considerations[317,318]: in particular, the average of ranks (or scores) is a better option than any of the individual ranks (or scores), as derived from the maximum likelihood principle. The SRD procedure involves two kinds of validation: a randomization test and a leave-one-out or leave-many-out cross-validation. Maximum for correct classification rates or minimum for error rates is the natural data fusion choice.[317]

The performance of ranking methods in the context of virtual screening cannot be evaluated without accepted, consensual metrics. Area under the Receiver Operating characteristic curve is not suitable to the "early recognition" problem. Performance indicators such as enrichment factors, robust initial enhancement, Boltzmann enhanced discrimination of receiver operating characteristic, area under the accumulation curve corresponding to an empirical cumulative density function, and their weighted variants were analyzed theoretically in detail.[319]

3.14.6.3 Clustering Algorithms

Clustering is the collective name for a group of methods, where the molecules (samples, objects, etc.) are arranged in groups (or "clusters") based on their distances from (in other words their similarities to) each other. Since clustering is not the main focus

of this chapter, we refer the reader to recent, well-written reviews on clustering methods and applications from the fields of chemometrics[278] and cheminformatics[320] and collect only a small set of diverse developments and applications in this subsection. (Also, it would be virtually impossible to enumerate all clustering algorithms that were provided by the machine-learning community.)

The following sentences are typical of the current literature and state: "Using various stopping rules the grouping of similarity coefficients resulted in three, 11 or 13 clusters."[289]

"The average clustering coefficient similarity threshold function can be characterized by the presence of a peak that covers a range of similarity threshold values. This peak is preceded by a steep decline in the number of edges of the similarity network. The maximum of this peak is well aligned with the best clustering outcome. If no reference set is available, choosing the similarity threshold associated with this peak would be a near-ideal setting for the subsequent network cluster analysis."[321]

"Despite the long tradition of pattern recognition research, there is no technique that yields the best classification in all scenarios. Therefore, as many techniques as possible should be considered in high accuracy applications. Typical related works either focus on the performance of a given algorithm or compare various classification methods." Amancio et al. compared the performance of nine well-known classifiers and found that the *k*-nearest-neighbor method frequently allowed the best accuracy.[322]

Large margin nearest-neighbors approach and its multimetric extensions have recently been elaborated by Kireeva et al.[323] Their algorithms cluster the compounds in the training set with the same property label together, while the compounds from different classes are separated by a large margin. In most of the cases the metric learning algorithm leads to better classification; the performance dependence from the data density has been discussed. The *k*-medoids clustering method was favored by Jaskowiak et al.[324] Saeh et al. generated robust models while combining 3D pharmacophore fingerprints and the support vector machine classification algorithm. Lead-hopping was also simulated: an entire class of compounds was excluded from the training set. Still, the model trained on the remaining compounds was able to recall 75% of the actives from the "new" lead series and correctly classifying >99% of the 5000 inactive compounds included in the validation set.[325]

The Generalized Metric Swarm Learning (GMSL) algorithm has been developed by Zhang and Zhang, where a sample pair is represented as a similarity vector *via* the well-learned metric swarm. The sample pairs are transformed into a vectorized similarity space (metric swarm space) *via* an established joint similarity function, whereas SVM-like classification can be easily implemented.[326] They have presented the efficiency of their approach on the example of face recognition, but it should have great potential in medicinal chemistry, as well. Gaussian Ensemble Screening (GES) was developed by Perez-Nueno et al.[327] "GES is a new and fast way to predict polypharmacological relationships between drug classes; it quantitatively provides an efficient way to measure the similarity between clusters of arbitrary numbers of members."

3.14.6.4 Similarity Measures for Special Tasks

3.14.6.4.1 Symmetric field-based similarity indices

The first quantum chemical similarity index was defined by the analogy of correlation coefficients in 1980:

$$r_{AB} = \frac{\int \rho_A \rho_B \mathrm{d}V}{\sqrt{\int \rho_A^2 \mathrm{d}V \sqrt{\int \rho_B^2 \mathrm{d}V}}} \tag{36}$$

where ρ_A and ρ_B are the first-order density functions for molecules A and B.[328] This is the most frequently used field-based similarity index. Similar ones are defined by Hodgkin and Richards[329] and Petke.[330] A comparative analysis of quantum chemical similarity and dissimilarity indices has been carried out not long ago.[331]

Standard Quantum-Based (SQB) similarity methods were compared with Tanimoto-based similarity, and it was established that "the use of a complex number format for molecular representation proved to be superior compared to real representation and benchmark Tanimoto method (TAN), where the complex SQB method outperformed TAN in nine cases."[332]

3.14.6.4.2 Similarities of 1D structures

Gene expression data analysis requires special similarity measures. The Jackknife correlation coefficient (successively removing the outlying features) provided the best results, showing better enrichments than other distance measures, whereas the second-ranked measure is the Kendall tau. Good results were also shown by Manhattan distance, popular distance measures in the gene expression clustering literature, namely, Euclidean distance, Spearman, and Pearson coefficients displayed inferior results to at least five other distances under evaluation.[324]

In another example, Dixon and Merz, Jr. have introduced a truly 1D representation of chemical structure. A 3D molecular model or a 2D chemical graph is projected onto a single coordinate of atomic positions. A novel measure of overall structural similarity has been defined after the alignment of 1D representations to match identical atom types:

$$\mathrm{Sim}_{A,B} = \frac{S_{A,B}^{\max}}{\sqrt{S_{A,A}^{\max} S_{B,B}^{\max}}} \tag{37}$$

1D similarity has been defined in such a way: molecule B is aligned at various offsets with respect to molecule A, and the total overlap area S_{AB} between rectangular regions of the same type is computed. The largest overlap area that can be achieved, $S_{A,B}^{\max}$, is

combined with normalization factors from aligning each molecule with itself. The constraint is valid: $0 < \mathrm{Sim}_{A,B} < +1$. These 1D similarities have been reported to consistently outperform both Daylight 2D fingerprints and Cerius2 pharmacophore fingerprints.[186]

Similarities of drug chemical structures, drug protein targets, and drug side-effect profiles (Tanimoto similarities and protein sequence similarities) were calculated and fused into an overall prediction score using the *k*-nearest-neighbor algorithm.[333]

A web-interfaced target identification program (called TargetHunter) with a built-in powerful data-mining algorithm (TAMOSIC) has been elaborated for predicting potential biological targets of query compounds. Its performance has been compared with the multiple-category models (MCM) for predicting protein targets and therapeutic activities.[334]

A revised algorithm based on Shannon's information theory, and the Neumann entropy characterizes each individual protein residue position with the number of significantly correlated pairs by computing the corresponding mutual information matrix.[335] Chemogenomics aspects were summarized by Bender et al. focusing on target prediction of small molecules with molecular descriptor-based models.[164] Semantic links between compounds and proteins, including *similarity neighboring links*, and interaction links were utilized to predict drug target interactions.[336] Features are structured according to prior knowledge into groups based on similarity in gene expression.[337] Pearson correlation similarity was calculated, and heatmaps were plotted.

3.14.6.4.3 Graph (tree)-based similarities

Direct similarity between two feature trees has been defined by Rarey and Dixon.[338] The similarity value of the feature trees is computed by a weighted average over the similarity values of the matches. The weight factor for each match is the sum of the subtree sizes size(m) of the match. The total weight is the sum of the sizes of the matched subtrees plus a scaling factor u times the total size of the unmatched subtrees:

$$S_M(A,B) = \frac{\sum_{x\in M} \mathrm{size}(m)\mathrm{sim}(m)}{u(\mathrm{size}(A)+\mathrm{size}(B)) + (1-u)\sum_{x\in M} \mathrm{size}(m)} \tag{38}$$

There is a notable research gap on comparing different approaches retrieving those models in the repository that most closely resemble a given process model or fragment thereof.[339] Business process graphs use various notations and customs. Three types of parameterized similarity metrics between business process models have been elaborated: (i) node matching similarity metrics based on properties of business process model elements (such as their labels and their other attributes), (ii) structural similarity metrics based on the relations between these elements, and (iii) behavior similarity metrics based on the intended behavior of process models.

A detailed, comprehensive survey on techniques to define and calculate business similarity measures has been carried out. Nine properties of distance measures were enumerated, and 21 business similarity measures have been compared in the work of Becker et al.[340] Sum of ranking differences using the average as reference provides the ordering presented in Fig. 16.

There is no doubt that similarity based on traces (Sbt) is the best, most consistent one according to the SRD methodology. Some similarity metrics (Edbrm, Lsged, Pcan, Lms, Fbas, Nlbs, Ged2, and Lsged2) are comparable with random ranking (the analysis was based on Table 26 in Ref. 340).

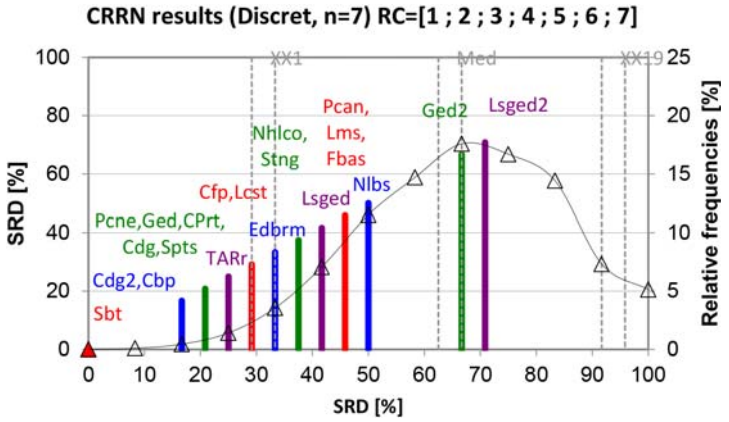

Fig. 16 Ordering of business similarity measures by sum of ranking differences (SRD). XX1 band corresponds to 5% first kind error, i.e., many of the similarity measures are indistinguishable from random ranking (black distorted Gaussian like curve and right *y* axis). Notations (in the order of appearance): Similarity based on traces (Sbt), Comparing dependency graphs (Cdg and Cdg2), Causal behavioral profiles (Cbp), Percentage of common nodes and edges (Pcne), Graph edit distance (Ged and Ged2), Comparing PMs represented as trees (CPrt), Similarity based on principal transition sequences (Spts), TAR-relationship (TARr), Causal foot prints (Cfp), Longest common subsequence of traces (Lcst), Edit distance between reduced models (Edbrm), Number of high-level change operations (Nhlco), Sets of traces as n-grams (Stng), Label similarity and graph edit distance (Lsged and Lsged2), Percentage of common activity names (Pcan), Label matching similarity (Lms), Feature-based activity similarity (Fbas), and Node- and link-based similarity (Nlbs).

In a ligand-based virtual screening experiment, the similarity between every library molecule and a query molecule is measured by some similarity function. An extension of the optimal assignment method for chemical graphs was produced that uses evolutionary algorithms to optimize edge weights. A variety of similarity functions can be improved by optimizing the edge weights.[341] The similarity between two chemical graphs can be evaluated by means of the Maximum Common Subgraph approach.[342] Ralaivola et al. reviewed graph kernels and developed new graph kernels (Tanimoto, MinMax, and Hybrid kernel) for molecules. These kernels measure the similarity between feature vectors, or molecular fingerprints, consisting of binary vectors or vectors of counts.[343]

3.14.6.4.4 Semantic similarity measures

Semantic similarity was defined by Resnik based on information content:[344]

$$\mathrm{sim}(c_1c_2) = \underset{c\in S(c_1c_2)}{max}\left[-\log p(c)\right] \tag{39}$$

where $\mathrm{sim}(c_1c_2)\in[0;+\infty]$ and $-\log p(c)$ is the negative log likelihood, or the *information content* of a concept c (not to be confused with the partition coefficient log*P*!).

A similar definition is given by Lin.[345] Lin defines the similarity between two terms as the ratio of the commonality of the terms, and the information needed to fully describe the two terms:

$$\mathrm{sim}(c_1c_2) = \underset{c\in S(c_1c_2)}{max}\left[\frac{2\log p(c)}{\log p(c_1)+\log p(c_2)}\right] \tag{40}$$

where $\mathrm{sim}(c_1c_2)\in[0;+\infty]$.

Schlicker et al. have combined Lin's and Resnik's similarities into relevance similarity:[346]

$$\mathrm{sim}(c_1c_2) = \underset{c\in S(c_1c_2)}{max}\left[\frac{2\log p(c)}{\log p(c_1)+\log p(c_2)}(1-p(c))\right] \tag{41}$$

Their approach enables the comparison of the underlying molecular biology of different taxonomic groups and provides a new comparative genomics tool identifying functionally related gene products.

A novel similarity measure for ligand-based virtual screening has been created from a text-processing similarity measure called Adapted Similarity Measure of Text Processing (ASMTP).[347] ASMTP was reported to outperform the Tanimoto coefficient-based virtual screening.

Kendall's τ has been the most widely used measure of similarity between two orderings, R^* and R^F; a novel similarity function is defined as:

$$\tau\left(R^*,R^F\right) = \frac{P}{P+Q} = \frac{Q}{\binom{|D|}{2}} \tag{42}$$

where P is the number of concordant pairs and Q is the number of discordant pairs on a data set D.[348] An optimal method has been derived based on rank support vector machine that selects the most ambiguous objects for ranking so that the ordering on the set maximizes the degree of learning.

In a linguistics application, Mandera et al. calculated the cosine distances between the cue word and all the other words in semantic spaces.[349] The similarity score for each associate was normalized by dividing it with the sum of all the similarity values for the cue. Next, an additive smoothing was applied to each distribution, and the relative entropy between probability distributions was computed. Finally, the relative entropies were averaged across all cue words, and the average relative entropy was used as the final score of a given semantic space. Semantic vectors for English and Dutch were provided for a range of models of psycholinguistic theories together with a convenient interface that can be used to extract a great number of semantic similarity measures.

3.14.6.4.5 Supervised similarity measures

Ligand similarity measures, such as shape similarity, are defined such a way: each atom of a molecule is mapped to a five-dimensional space, where the first three coordinates are determined by the 3D conformation of the molecule. The two remaining dimensions encode the atomic partial charges and the atomic lipophilicity (A log *P*).[350,351] Multiple logistic regression was applied to combine different similarity values.

One popular measure of the roughness of a structure–activity landscape is the structure–activity landscape index, SALI[352]:

$$\mathrm{SALI}_{A,B} = \frac{|A_A - A_B|}{1-\mathrm{Sim}_{A,B}}, \tag{43}$$

where A_A and A_B are the affinities/activities of compounds A and B, while $\mathrm{Sim}_{A,B}$ is their similarity. Basic characteristics of molecular similarity and dissimilarity *networks* are reviewed by Sukumar et al.[353] "The choice of descriptors affects the computed similarity—for instance, two molecules might be constructed from the same molecular scaffold and thus be very similar in size and shape, but have very different properties because of the different chemical natures of the functional groups or substituent atoms. Conversely, molecules with very different molecular scaffolds might look similar for binding to a protein."

Cuissart et al. have constituted two more similarity indices in the biodegradability context:[354]

$$\mathrm{Sim}_1(\mathrm{QS}, IS) = \frac{|\mathrm{MCS}|}{|\mathrm{QS}|} \tag{44}$$

and

$$\mathrm{Sim}_2(\mathrm{QS}, IS) = \frac{|\mathrm{MCS}|}{|\mathrm{QS}|} \times \frac{|\mathrm{MCS}|}{|\mathrm{IS}|} \tag{45}$$

where $|S|$ equals the number of nonhydrogen atoms within molecule S, and MCS is the maximum common substructure between two molecules. "IS" means "Instance Structure", whose biodegradability value is used to compute the prediction model, whereas QS means "Query Structure", whose biodegradability is predicted by this model. Both similarity indices are discriminant to a group of compounds of similar activity. The index Sim_2 operates more in conformity with the SAR principles than Sim_1.

Dropout training of artificial neural networks (ANNs) outperforms conventional ANNs when using two types of fingerprints and two similarity metrics (Tanimoto and Buser).[355] Dropout means randomly omitting a large portion of the nodes from an artificial neural network.

Naderi et al. have predicted drug-likeness for molecular synthesis. Each active compound in the DUD-E library was decomposed into fragments, and a molecular synthesis was simulated. A search space was constructed from small molecules, followed by the stochastic exploration of the chemical space by constructing multifragment molecules. Tanimoto coefficient was used to reveal the chemical similarity. Parent compounds are compared to those constructed with the eSynth computational package using molecular fingerprint matching.[356]

Sixteen different feature ranking methods were compared by Jankowski and Usowicz in combination of six weighting schemes, and the counts of winnings, defeats, and draws were presented.[357]

3.14.6.4.6 Chemometric/Spectral similarity

An adaptive similarity measure (sample similarity) was proposed to construct highly accurate locally weighted partial least squares (LW-PLS) calibration models. The method is based on the weighted Euclidean distance and was used for weighting in regression.[358]

Common mathematical methods to express similarity in NIR (near-infrared) spectroscopy are correlation coefficients and distances.[359] The authors of a recent work have successfully transformed differences in spectra into Bayesian hypothesis testing.[360] Logarithm values of the posterior odds ratios for the spectra are able to detect subtle differences, e.g., changes in the analytical process.

A novel spectral similarity measure was introduced by Bodis et al.[361] De Gelder and colleagues have shown that "various similarity and dissimilarity criteria previously described in literature can be written as special cases of a general expression." They have introduced a new similarity criterion, based on this generalized expression.[362]

The spectral-contrast-angle method introduced by Wan et al. is based on the vector representation of mass spectra and has been shown to perform better than the similarity index method for spectral comparison.[363] The spectral contrast angle is defined as the angle between two mass spectrum vectors.

The correlation and congruence coefficients (i.e., similarity values) of all total ion chromatograms relative to the reference chromatogram were calculated with median or averaged data. Principal component analysis and cluster analysis can successfully discriminate between mountain origins of green teas and therefore can be further applied to identify and authenticate Pu-Erh green teas.[364]

Three mass spectral similarity measures (NIST composite measure, the real part of Discrete Fourier Transform, and the detail of Discrete Wavelet Transform) were compared and integrated with retention indices. As a consequence compound identification was enhanced by 1.7–3.5%.[365]

Similarity of infrared spectra was characterized by: correlation coefficient of mean centered absorbance (i.e., cosine measure), mean of the absolute absorbance differences, mean of the squared absorbance differences, dot product of the absorbance vectors, each normalized to unit length, whereas Tanimoto index has provided the chemical structure similarity. The definitions were given in vector notations and scaled properly. The first hits corresponding to the most similar spectra yield the highest structural similarity with the query compound. Among the four investigated spectral similarity measures the correlation coefficient of mean-centered absorbances performed best.[366]

3.14.6.4.7 Fuzzy similarity measures

Enormous progress took place in the development of fuzzy similarity measures. Fuzzy sets are sets whose elements have degrees of membership. Thus, instead of 0 (not a member) and 1 (is a member), the membership of an element in a fuzzy set can be any real number between 0 and 1. Fuzzy similarity measures are defined for the comparison of such fuzzy sets. A small but characteristic selection can be found below.

Three new equations were suggested to calculate the distance between intuitionistic fuzzy sets (IFSs) on the basis of the Hausdorff distance. The proposed similarity measure is much simpler than the existing methods and is well suited to use with linguistic variables.[367]

Existing similarity measures can provide unreasonable results in some special cases. Therefore, several new similarity measures were proposed to differentiate different IFSs. The proposed similarity measures can deal with problems more effectively and reasonably than some of the existing methods.[368]

The degree of similarity between Intuitionistic Fuzzy Sets A and B (B^c is the complement of B) is defined as:

$$\dot{s}(A,B) = \sum_{j=1}^{n} \dot{s}(\alpha_j, \beta_j) = \frac{1}{n} \sum_{j=1}^{n} \frac{d\left(\alpha_j, \beta_j^c\right)}{d(\alpha_j, \beta_j) + d\left(\alpha_j, \beta_j^c\right)} \tag{46}$$

where α_j and β_j are the jth intuitionistic fuzzy values of A and B, respectively, and $d(\alpha_j, \beta_j)$ is the normalized Hamming distance. The analogous formula has been used for interval-valued Intuitionistic Fuzzy Sets, as well. Then, the developed similarity measure was applied for consensus analysis in group decision-making based on intuitionistic fuzzy preference relations, and it was extended to the interval-valued intuitionistic fuzzy sets.[369]

"Reasonable" measures to calculate the degree of similarity between Intuitionistic Fuzzy Sets were proposed based on the L_p metric.[370] A new similarity measure for IFSs was suggested and its usefulness in medical diagnostic reasoning was proven.[371]

An axiomatic definition of a similarity measure between dual hesitant fuzzy sets was proposed, and the shortcomings in existing similarity measures were enumerated.[372]

Some new distance measures between Intuitionistic Fuzzy Sets (IFSs) were suggested. Maximum degree of similarity between IFSs was applied for pattern recognition.[373]

Some similarity measures were introduced between two triangular fuzzy numbers based on the vector similarity measures in vector space (which can be used to aggregate the decision information). A methodology for multiple criteria group decision-making (MCGDM) problems with triangular fuzzy information is proposed; the criteria values take the form of linguistic values. The weighted similarity measures between each alternative and ideal alternative can be used to rank alternatives and select the most desirable alternative.[374]

Dual hesitant fuzzy sets include fuzzy sets, intuitionistic fuzzy sets, and hesitant fuzzy sets as its special cases. Some distance and similarity measures based on the Hamming distance, Euclidean distance, and Hausdorff distance were derived for usage in decision-making, pattern recognition, etc. Two examples illustrate these distance and similarity measures and their applications in pattern recognition.[375]

Novel discrete and continuous hesitant fuzzy distance measures and hesitant fuzzy-ordered distance measures between hesitant fuzzy sets were elaborated. A hesitant fuzzy clustering algorithm based on novel similarity measures was also created.[376]

3.14.6.4.8 Other similarity measures

The most detailed collection of dissimilarity measures and their comparison can be found in the work of Todeschini et al.[377] Methods of data preprocessing (transformation) and the next classification of dissimilarity measures can also be found there: distances for real-valued data, distances for ranked data, distances for frequency data, binary similarity measures, and mixed-type distances.

A novel asymmetric hybrid similarity function (metric) was recently introduced using Maximum Common Substructures (MCSs). The hybrid metric was designed molecules to detect structurally similar compounds of increasing size while using small reference compounds. This Tversky metric could detect similarity relationships between small and large compounds much better than other similarity measures.[378]

In other areas, an object is often described by sets of features instead of geometric points in a metric space. A new measure of remoteness between sets of nominal values is proposed instead of considering the distance between two sets: a new measure of perturbation type 1 of one set by another was introduced. The consideration is based on set-theoretic operations, and the proposed measure describes changes of the second set after adding the first set to it, or *vice versa*. The measure of the sets' perturbation returns a value in the range [0, 1], and this measure is not symmetric in general.[379]

According to a scientometric study by Hamers et al. the Cosine formula often yields a similarity measure in citation studies that is twice the number of that obtained by the Jaccard index.[380]

Most online shopping sites and many other applications now use collaborative recommender systems. The measurement of similarity plays a fundamental role in such systems. The accuracy of the most well-known similarity measures (Pearson's correlation coefficient, cosine similarity, and mean squared differences) decreases due to data sparsity. Therefore, a user–user potential matrix is calculated; potential similarities between users from this matrix are computed; the potential similarities are modified based on the users' preliminary neighborhoods; and k users with the highest modified similarity values are selected.[381] A novel similarity measure introduced by Cha can cope with the sparsity problem often encountered in the case of Pearson and cosine coefficients and mean squared differences. Cha enumerated and categorized a large variety of distance/similarity measures for comparing nominal type histograms. The grouping has concentrated upon three aspects: syntactic similarity, implementation caveats, and semantics.[382]

3.14.7 Online Web Resources

Since the pool of cheminformatics and molecular modeling software is quickly and constantly renewed, we refrain from providing a detailed overview of them: a current and prominent selection was presented recently by Cereto-Massagué et al.,[88] and we have

already referred to several of them throughout this chapter. However, online resources such as molecular databases are more permanent over time, thus we provide a short overview of top-level databases to provide some guidelines to anyone who wishes to apply them. These databases implement diverse ways of submitting search queries: besides recognizing chemical names and SMILES strings, many of them have an integrated sketching interface and support similarity searches (based on the entered queries). Most of these databases offer some possibilities for batch downloading and query automation as well, through a Graphical User Interface (GUI), an application programming interface (API), or other mechanisms.

- Chemical Abstracts Service (CAS) Registry: The CAS Registry (operated by the American Chemical Society) is the largest molecular database to date.[3,4] It is constantly updated and stores every reported chemical structure (c.111 million at the time these lines are written) with a uniquely assigned identifier, the CAS Registry number. In addition to the database itself, the CAS Registry powers the two major chemical information services of CAS: Scifinder (for querying chemical structures and reactions, primarily in the literature)[5] and STN (a search engine that provides access to patent content).[6] While these are paid services, a freely available website covering a subset of high interest of the CAS Registry entries—titled Common Chemistry—is also operated by CAS.[383]
- Pubchem: An open chemistry database operated by the National Center for Biotechnology Information.[109,384] The database covers a diverse set of information about the stored compounds, from chemical names, 2D and 3D structures, and line notations (InChI, InChIKey, SMILES) to calculated properties and even vendor and patent information. Pubchem operates separate (overlapping) databases for substances (i.e., depositor-supplied molecules) and compounds (i.e., unique chemical structures, including stereoisomers and even tautomers). In addition, the Pubchem Bioassay database is a rich source of deposited biochemical screening data.[385]
- ChemSpider: An open chemistry database operated by the Royal Society of Chemistry.[386] In addition to 2D and 3D representations and chemical names, ChemSpider also stores experimentally determined properties and NMR spectra, as well as links to literature articles and reference works.
- ChEMBL: Operated by the European Bioinformatics Institute (EMBL-EBI), ChEMBL is today's probably largest database of experimental bioactivity data.[387–389] In addition to bioactivity data, line notations, links to external databases and drug-related information (availability type, route of administration, etc.) are also stored. ChEMBL integrates bioactivity data from various sources, including full-matrix datasets such as DrugMatrix or the GSK Published Kinase Inhibitor Set, as well as screening results contributed by pharma companies. Lately, ChEMBL has integrated the full bioactivity content of PubChem BioAssays, which currently accounts for more than half of the data points in the ChEMBL database. EMBL-EBI also operates an open, searchable patent database called SureChEMBL.[390]
- Protein Data Bank (PDB): The Protein Data Bank is without question the largest and most commonly used repository for experimentally determined protein structures, hence it is one of the most important data sources for medicinal chemical and modeling work.[41] The database is thoroughly linked and annotated and offers a detailed and highly configurable "Advanced search" mechanism for exploring and analyzing not only the protein–ligand complexes but also the ligands themselves.
- ZINC (ZINC Is Not Commercial): Probably the largest molecular database focusing on commercially available compounds (storing approx. 35 million compounds the time these lines are written).[391,392] In addition to storing the molecules with calculated properties and links to vendor databases, ZINC also offers a plethora of subsets for downloading, categorized based on various attributes, such as physicochemical properties, targets, vendors, or availability. Thus, it is a flexible and customizable source of information for virtual screening. Other comprehensive vendor databases include eMolecules[393] and Mcule,[394] with the latter offering a wide set of online virtual screening tools as well.

  GDB databases: Besides commercially available compounds and experimentally determined data, databases of virtual compounds are also available, the most prominent of which are probably the GDB databases based on the work of the research group of Reymond.[151] GDB databases are generated with a systematic enumeration of all possible combinations of a predefined number of common heavy atoms (C, N, O, S, and halogens). For example, the latest database, GDB-17 enumerates molecules of up to 17 heavy atoms: a total of 166 billion molecules![395] Such approaches serve not only as a basis for analytical work but also define the future directions in synthetic medicinal chemistry by providing an abundance of ideas for new scaffolds. In addition to downloadable subsets, the same group has implemented online browsers based on various fingerprints, as well as molecular quantum numbers (MQN)[113] for the efficient exploration of the chemical universe.

3.14.8 Case Studies

In this section, we briefly summarize a few illustrative case studies that apply some of the methods discussed in this chapter: (i) fingerprints (Protein–Ligand Interaction Fingerprints, as well as hashed topological fingerprints), (ii) QSAR modeling using calculated molecular descriptors, and (iii) similarity measures in an application to support decision-making.

(i) As a case study for the use of fingerprints in drug discovery, we briefly summarize the work of de Graaf et al., who have applied docking in combination with Protein–Ligand Interaction Fingerprints for the virtual screening of fragment-like human histamine H_1 receptor (hH_1R) ligands.[396] The H_1 receptor is of key importance in allergic responses and the target of so-called antihistamines: a class of drugs used to relieve the symptoms of allergic rhinitis. The 2–3 years preceding the cited study[396] (2011) have seen several breakthroughs in GPCR crystallography, including the publication of the first crystal structure of the H_1

receptor, bound to a fragment-like ligand (doxepin). Based on this structure, the authors have developed a customized virtual screening protocol for the identification of novel H_1R fragments.

The protocol involved the use of PLANTS—a docking program based on ant colony optimization—and Interaction Fingerprints (IFPs, as defined by Marcou and Rognan[168]) as two orthogonal scoring methods for predicting ligand binding. (Quite literally, as the authors have compiled 2D plots of PLANTS and IFP scores to select a region retrospectively with a favorable enrichment of known H_1R ligands versus decoy molecules.) The IFPs contained seven bits per residue to encode hydrophobic, aromatic (face-to-face and edge-to-face), H-bond (donor and acceptor), and ionic (positive and negative) interactions, and IFP scores were defined as the Tanimoto similarities to the experimentally supported binding mode (IFP) of doxepin. The authors have confirmed that the use of the two orthogonal scoring methods greatly surpassed—in terms of the retrospective enrichment of known actives—the performance of PLANTS scores, as well as IFP scores, on their own. In addition to interaction fingerprints, ECFP_4 fingerprints were applied as a measure of ligand novelty: any ligand with a Tanimoto similarity of more than 0.4 to any known H_1R ligand was rejected. (Hence this work also exemplifies the popularity of the combination of ECFP_4 fingerprints and Tanimoto similarities to quantify molecular similarity.)

Prospectively, the screening protocol was applied to ultimately select 26 virtual hits from a set of 108,790 fragment-like compounds (282 before visual inspection). Upon experimental testing for their binding affinity to H_1R, 19 of them have been confirmed. Overall, the work of de Graaf et al. can be considered a proof-of-concept for crystal structure-based virtual screening for fragment-like GPCR ligands and has resulted in the identification of 19 diverse fragment-like H_1R ligands with a hit rate of 73%, which is exceptionally high in the area of drug discovery.

(ii) For a case study on the use of descriptors for QSAR model building, we refer to the work of Keserű on the prediction of hERG potassium channel affinities.[397] The hERG potassium ion channel is best-known for its regulatory role in the electrical activity of the heart that coordinates the heart's beating. Its inhibition can result in a potentially fatal disorder called long QT syndrome and create a risk of sudden death as a side effect. Thus, it is a very important off-target in drug discovery whose inhibition should always be avoided. The cited study employs traditional and hologram QSAR methods for the quick computational prediction of hERG affinities. Because of the multiple binding sites of hERG K^+ channels, a functional assays format is preferred for affinity evaluations. However, these techniques have limited capacity, thus a fast method for the *in silico* prediction of hERG affinity is needed.

The number of used compounds was 68, which was split into training and test sets: 55 compounds were applied for training and 13 for test set predictions. After the calculation of the 99 potentially relevant molecular descriptors, multiple linear regression was applied in stepwise mode for the training. In the next step, the model was validated with the 13 test set compounds and with an additional (external) test set of 82 compounds, as well. For the appropriate model building five descriptors were chosen, namely, Clog*P*, molar refractivity (CMR), Partial Negative Surface Area (PNSA1), and two VolSurf descriptors (W2—polarizability and D3—hydrophobicity). The created model had good quality parameters for the training ($R^2 = 0.97$) and test sets ($Q^2 = 0.75$) too.

Based on the chosen descriptors a concept of the interaction with the hERG channel was proposed: the compounds have to be larger, lipophilic and highly polarizable with a basic character. Because of the differences between the averages values of active and inactive molecules regarding the five used descriptors, discriminant analysis was also used for classification with correct classification rates of 83% for actives and 87% for inactives.

Since the generation of 3D VolSurf descriptors is time-consuming, hologram QSAR (HQSAR) was also applied. This methodology avoids the descriptor calculations, selection of conformers, and the structural alignment that makes the use of 3D QSAR nontrivial. The final model was also very good, and it was validated with the same dataset as in the previous case, but here a much lower correct classification rate was obtained for the inactive molecules (18 %). Thus, the work of Keserű also highlights the importance of the 3D aspects of QSAR modeling, in addition to providing a fine example of the use of molecular descriptors for affinity prediction for an important off-target.

(iii) An interesting example for a practical application of similarity measures can be found in Kwak et al.'s work on the detection of cancer in prostate tissue samples.[398] If a new tissue is evaluated, the closest matches and their clinical information are retrieved from a tissue database. Then, a pathologist makes a diagnosis and the database is updated, if necessary. Consistent and reliable diagnoses can be achieved via the automatic selection of similar tissues. Nine morphologic criteria were defined (they describe the architectural properties of a tissue): (1) Gland crowding, (2) Gland roundness, (3) Stromal reaction, (4) Nuclear grade, (5) Clefts, (6) Lumen/gland ratio, (7) Gland continuity, (8) Cell separation, and (9) Gleason score. Tissue morphologic similarity $\mathrm{TMS}(d_1, d_2)$ between two tissue samples d_1 and d_2 was defined as:

$$\mathrm{TMS}(d_1, d_2) = \sum_{i=1}^{9} \mathrm{TMS}^i(d_1, d_2) \tag{47}$$

where $\mathrm{TMS}^i(d_1, d_2)$ is the morphologic tissue similarity for ith criteria. It is calculated as follows:

$$\mathrm{TMS}^i(d_1, d_2) = 1 - \frac{\sum_{s=s^i_{d_1+1}}^{s=s^i_{d_2-1}} h^i(s) + \frac{1}{2}\left(h^i\left(s^i_{d_1}\right) + h^i\left(s^i_{d_2}\right)\right)}{Z} \tag{48}$$

where s_d^i is the ith morphologic criterion score of a tissue sample d, $h^i(s)$ is the number of samples having ith morphologic criterion score s, and Z is a normalization factor ensuring that as $1 \leq i \leq 9$, TMS(d_1,d_2) ranges between 0 and 9. TMS scores represent the true tissue similarity and served as the gold standard of tissue retrieval.

In summary, an efficient and effective tissue management and decision-support system was developed.[397]

3.14.9 Outlook

Cheminformatics—and by extension, computational medicinal chemistry—is a field that has the potential to change very quickly. Novel file formats and fingerprints, based on original ideas, continue to emerge, providing an always renewing toolbox for the researchers of these fields. However, applications seem to lag behind these technological advances. If we want to look for the reasons behind that, we might consider factors such as publication delays, customs, and personal preferences (i.e., if I have learned to apply one method that seems to work, I might not be open to learning a new one), or a sort of "canonization" (the process of a scholarly community accepting some works as the most important—not to be confused with canonicalization!) similar to that in literature. For example, if ECFP4 fingerprints are widely accepted for quantifying the 2D similarities of molecules, one might feel a motivation to prefer them over, e.g., topological torsion fingerprints, when the latter might be in fact more suited for the given application. Similarly, the MDL *mol* (and *sdf*) formats continue to be the most prevalent chemical file formats despite their flaws and limitations. Since we maintain that true progress requires the thorough and independent testing, validation, and application of the new computational tools, we expect a steady increase in the number of application-related works in this field. (Nonetheless, we hope to have provided useful guidance for that with this chapter.)

In terms of descriptors, the question is always open: "Do we need more and more molecular descriptors?" This question has been raised already in 2001 by Randic and Basak.[205] On the other hand, a distinguished publication of Cherkasov et al. paraphrases Mark Twain about QSAR (and thus molecular descriptors): "reports of [QSAR] death are an exaggeration."[399]

After carefully rereading many publications in the field of molecular descriptors, we can infer the following: although there are some novel descriptors in the recent literature, most of the widespread ones were developed in the second part of the last century. In the near future we expect more application-related articles and somewhat fewer works about the development of new descriptors and fingerprints. However, it is also clear based on the aforementioned works and our previous experience that we want to have as diverse of a toolbox as possible, to cover the various possible descriptions of molecules as fully as possible. (It is worth noting that this is true for other fields of science as well, in fact it is an essential part of making progress in science.)

Like molecular descriptors, similarity measures are abundantly developed recently. The machine-learning community provides a plethora of novel algorithms, whose limitations, usefulness, and applicability have been only scarcely studied as of yet. More and more specific applications are taken into account, e.g., the early recognition problem or the need for diverse data sets. Unfortunately, a lot of novel measures and algorithms require an elaborate computational and mathematical skill set and expertise from the user to understand and implement them. In addition, some factors (weighting, desirability) are too subjective to let the measures and algorithms spread widely and unambiguously.

Consensus modeling (the usage of the average for more similarity measures) becomes more and more popular, and multicriteria optimization seems to be unavoidable nowadays. Multicriteria Decision-Making (MCDM) and Multiresponse Optimization (MRO) intend to find compromising (optimal, consensus) solutions to unsolved problems. Recently the equivalency of MCDM with sum of ranking differences (SRD) has been proven.[400] SRD is a general, nonparametric procedure to compare alternative methods/models/etc. that provides optimal solutions without the above-mentioned subjectivity, and its propagation can be predicted without much risk. Like molecular representations, various similarity measures and algorithms can be used for solving different types of problems; a complex interplay of the mentioned methods should be considered and are expected as a future trend.

Novel similarity measures are to be expected from diverse disciplines (graph theoretical-, business similarity-, fuzzy measures, etc., are transferrable to pharmaceutical applications) with great probability. Such measures will be tested and filtered by the drug design community—possibly slowly but definitely.

While there are well-established methods and algorithms in cheminformatics, new problems and new approaches arise abundantly and the pharma industry needs economic and effective techniques. As the amount of the generated data increases, cheminformatics and rational drug design approach the domain of big data. Nevertheless, extensions of the current data analysis methodologies are already being developed and successfully applied in related fields. Machine-learning algorithms can operate with extremely complex models (e.g., neural networks with many thousands or even millions of nodes, ant colony, support vector machines, random forest, etc.) and may solve problems that scientists only dreamed of—even just several years ago. However, the validation practices are developing slowly and more emphasis should be placed on developing suitable validation techniques.

Finally, we refer to some recent reviews showing the present state of arts and some future trends in the cheminformatics field.[273–275]

3.15.1 Quantitative Structure–Activity Relationships in Drug Design SAR

Quantitative Structure–Activity Relationships (QSARs) are statistical empirical models that relate a quantitative description of chemical structure features of a series of molecules to the responses those molecules show in an experimental system. QSARs are empirical models as they are based on observed trends and correlations between the chemical descriptors and response variables, rather than on an a priori physics-based model. Although empirical in nature, a robust QSAR model can be used to propose a physical hypothesis that underlies an observed relationship. Medicinal chemistry structure–activity relationships are based on serial pairwise comparisons of structural changes with activity changes. QSAR takes a complementary approach and tries to identify how structural changes across a series of molecules are related to their activity.

3.15.2 History of QSAR

The first QSAR model is reputed to have come from the work of Alexander Crum-Brown and Thomas Frazer, which was read before the Royal Society of Edinburgh on Jan. 6, 1868.[1] They were studying the muscle paralyzing activities of quaternized alkaloid "poisons" and focused on differences in activity and chemical structure. As the constitution of the substances was not known, they hypothesized "there is more hope of arriving at some definite conclusion by studying the changes produced in the action of physiologically active substances, by performing on them certain well defined chemical operations which introduce known changes to their composition": They treated natural alkaloids from strychnia, brucia, thebaia, codeia, morphia, and nicotia with methyl iodide and studied their effects in rabbits and dogs. In the paper, they expressed the relationship between structural changes (Δ and changes activity as a mathematical equation, Eq. (1)

$$\Delta(\text{physiological activity}) = f(\Delta\ \text{constitution}) \tag{1}$$

QSAR still follows this formalism, where chemical descriptors are used to numerically quantify chemical constitution, and the mathematical tool, sometimes called a machine-learning algorithm, is used to define the function "*f*" that relates structure to activity.

In 1869, Richardson[2] showed that the narcotic effects of primary alcohols were inversely related to their molecular weights. In 1893, Richet[3] showed that the toxicities of simple ethers, alcohols, and ketones were inversely related to their solubility in water. A major step was taken toward QSAR as we know it when in 1899, Hans Horst Meyer[4] first proposed and demonstrated that anesthetic potency was related to lipid solubility. Two years later, a similar proposal was made by Charles Overton.[5] They showed the narcotic effect on tadpoles was proportional to the partition coefficient of the compounds from water into olive oil, as a model for the partition of the narcotics into the biological membrane. Further, their correlation prompted them to hypothesize that it was the compounds partitioning into nerve cells that led to the narcosis. Today, we still use partition coefficients as a measure of a compound's hydrophobicity, although *n*-octanol has superseded olive oil as a hydrophobic receptor phase.

In the 1930s, quantitative structure-property relationships (QSPRs) defined the field of physical organic chemistry through the work of Hammett,[6] Brönsted, Pederson, and others.[7]

Hammett proposed that the effect of substituents attached to the benzene ring, *meta* or *para* to a reaction center, upon the reaction rate or position of a chemical equilibrium in which the reaction center participates, is a property of the electronic effect substituent alone. Different reactions may have different sensitivities to the effect of this substituent. Hammett defined an experimentally based descriptor σ, to quantify the electronic effect of a substituent. The σ scale used the ionization of benzoic acids as the calibrating reaction, and σ_m or σ_p represented the difference in pK_a between the different m- or p-substituted benzoic acids and benzoic acid itself. The sensitivity of a particular reaction to the electronic effect of a substituent was described by ρ, the slope of the correlation between the logarithm of the equilibrium (K) or rate constant (k) for that reaction and the sigma values, Eq. (2)

$$log k = \rho\sigma + \text{constant} \tag{2}$$

In Hammett's initial publication, he tabulated σ values for 31 substituents, and linear energy correlations for 39 reactions. While Hammett's observations were empirical, he recognized that they may indicate a common underlying physics-based explanation relating to electron attraction or repulsion by inductive and resonance effects.

In the 1950s, Taft extended Hammett's work to define a sigma scale for aliphatic systems.[8] Taft used the acid- and base-catalyzed hydrolysis of esters as the calibrating reaction. He proposed that as the acid- and base-catalyzed hydrolysis of esters proceed through a very similar tetrahedral transition state structure, and under identical conditions, both reactions would experience similar steric influences. As the base-catalyzed reaction went from a neutral ground state to a negatively charged transition state, it would be more sensitive to electronic effects of substituents than the acid-catalyzed hydrolysis reaction which moves from a positively charged ground state (rapid preprotonation of the ester carbonyl) to a similarly positively charged transition state. Therefore the acid-catalyzed hydrolysis of esters would be less sensitive to the electronic effect of substituents, while remaining sensitive to their size. On the other hand, base-catalyzed hydrolysis would be sensitive to both size and electronic effects. Taft was therefore able to also define a new steric substituent constant scale, termed Es. Taft gave the symbol σ^* to the electronic effect of the aliphatic substituent. The sensitivity of a particular reaction to the electronic and steric effects of a substituent was described by ρ^* and d, respectively, the regression coefficients from the correlation between the logarithm of the equilibrium (K) or rate constant (k) for a given reaction and the σ^* and Es values of the substituents, Eq. (3).

$$log(k - R/k - \text{Me}) = \rho^*\sigma^* + d \times \text{Es} + \text{constant} \tag{3}$$

Modern QSAR began with the work of Corwin Hansch and Toshio Fujita.[9,10] They were studying the effect of auxins as growth regulators. Their hypothesis was that auxin mode of action was more chemical in nature, covalently modifying their molecular target. But attempts to apply a Hammett equation to describe biological activity failed and led them to reevaluate their hypothesis. Their new hypothesis was that transport through biological membranes to the site of activity in fact may be the rate-determining step. To describe the partitioning step, they defined a new substituent scale π. The π parameter was defined as the difference in logarithm of the partition coefficient between *n*-octanol and water of the aromatic-substituted compound to the logarithm of the partition coefficient of the unsubstituted aromatic compound, in an analogous fashion to Hammett's sigma scale. They modified the Hammett equation to incorporate both the linear and nonlinear dependence upon this new substituent constant π, incorporating both the π and π^2 terms. They took a multivariate approach to describe biological activity and used multiple linear regression (MLR) to fit the relationship between a set of descriptors and biological activity: they were successful in building a model based on their new hypothesis and their new approach to QSAR modeling. The work was extended in a follow-up paper to show the general application in a number of other systems.[11]

Also during the 1960s, Free and Wilson developed their own QSAR formalism to optimize substituent selection in a design-make-test cycle. One can consider the Free and Wilson analysis[12] as a limiting case of QSAR analysis, which directly correlates biological activity with the presence or absence of a substituent at a particular position. The presence of absence of the substituent in the Free–Wilson method is represented as a numerical "indicator" descriptor, where 1 = presence of a substituent and 0 = absence of a particular substituent. The Free–Wilson analysis has inspired the recently introduced molecular-matched pair analysis.

3.15.3 QSAR Today

QSAR remains a popular technique, and is now a fully embedded tool within drug discovery. But QSAR model derivation and use is fraught with pitfalls and complexity. Many literature QSAR models with apparently appealing statistics can in reality encode no more than chance relationships.

The statistical algorithms applied are very powerful tools to find correlation patterns in datasets, and the model builder may not know if these are true underlying relationships or statistical flukes that fail to predict forward in time, that is in real life usage.[13,14] For example, in Stouch and colleagues' paper "In silico ADME/Tox: why models fail," the authors highlight Bristol-Myers Squibb's own experience in trying to validate vendor built QSAR models for hERG inhibition, Caco-2 permeability, cytochrome P450 2D6 inhibition, and an aqueous solublility.[13] The authors concluded that even in the best case models, builders and users may have different criteria for success, and a lack of appreciation of the model quality and scope. In the worst cases the models were of no value. For example in the hERG model, they identified using validation compounds measured in both assays, that the assay used for the training's set hERG data gave results quite unlike the same compounds tested in their internal hERG assay. In the Caco-2 model, which was not predictive, (**Fig. 1**) they identified that the internal test set compounds, were quite unlike the literature training set compounds (based on 2-dimensional similarity). Nils Bohr was certainly right, when he said, "Prediction is very

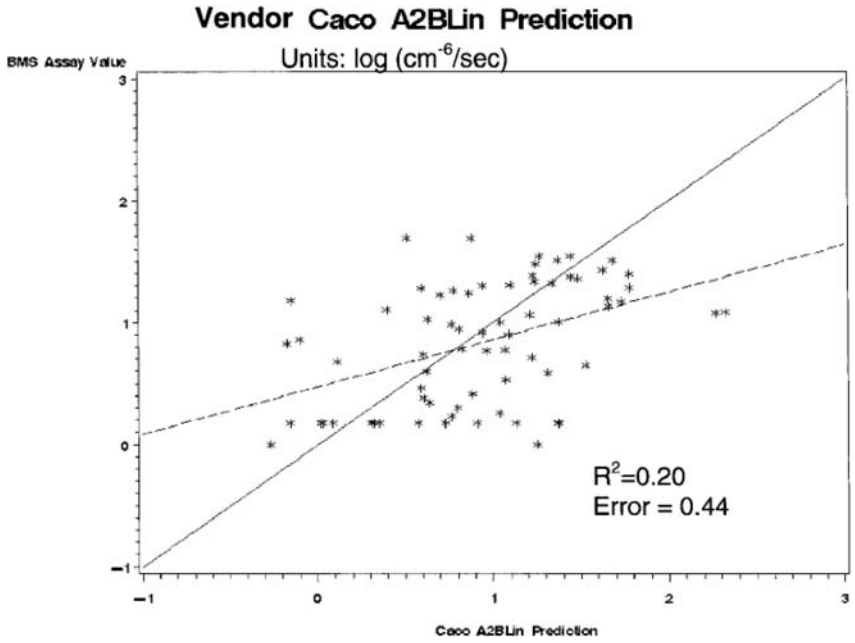

Fig. 1 Caco-2 A2B permeability predictions from a vendor QSAR model versus measured Caco-2 A2B permeability from Bristol-Myers Squibb validation. (Reproduced with permission from Stouch, T. R.; Kenyon, J. R.; Johnson, S. R.; Chen, X-Q.; Doweyko, A.; Li, Y. In Silico ADME/Tox: Why Models Fail. J. *Comput. Aided Mol. Des.* **2003**, *17* (2–4), 83–92.)

difficult, especially about the future". However, a carefully built and validated QSAR model can be a powerful tool to guide drug design. For example in AstraZeneca, hERG QSAR models[15] have contributed to the reduction in synthesized "red-flag" compounds (hERG potency <1 μM), from 25.8% of all compounds tested in 2003 to only 6% in 2010.

As an example of the impact of QSAR models, the European Community in its Registration Evaluation Authorisation and Restriction of Chemicals (REACH) now accept validated QSARs as part of the required complete dossier on the physicochemical, biological, and technological properties for every chemical circulating in Europe.[16] Because of this, and the complexity in building robust models, the Organisation for Economic Co-operation and Development (OECD) has defined good practice in the validation of QSAR models, with the aim of increasing regulatory body acceptance of QSAR models for toxicity and environmental assessment.[17] They have also published a "QSAR toolbox" for use by regulatory authorities and companies to allow look-up, near neighbor analysis, and robust prediction of toxicity and environmental properties of new compounds based on its database of structures and responses. The OECD guidelines, although focused on environmental toxicology, are recommended reading for any scientist involved in the derivation of QSAR models. The guidelines state that, to facilitate consideration of a QSAR model for regulatory purposes, the model should be associated with:

1. an unambiguous endpoint;
2. an unambiguous algorithm;
3. a defined domain of applicability;
4. appropriate measures of goodness-of-fit, robustness, and predictivity;
5. a mechanistic interpretation, if possible.

Peer-reviewed journals now require all data and molecular structures used to carry out a QSAR/QSPR study to be reported in the publication. This enables the reader to reproduce the analysis in the paper and to validate the quality of the published work.[18]

3.15.4 QSAR Model Building

Many tools for building QSAR models are freely available on the Internet. Integrated QSAR toolkits exist in commercial computational chemistry software packages and free integrated tools include Bioclipse[19] and KNIME.[20,21] Bioclipse can be freely downloaded, will run under Windows, Linux, and Macintosh operating systems, and contains a fully integrated QSAR toolkit that can be used for datasets of up to 2000 compounds.

Online systems are available for the automatic QSAR building, for example, OCHEM[22] and OECD QSAR toolbox.[23] Submitting datasets to online public QSAR engines may compromise an institution's requirements regarding confidentiality of structures, therefore local implementations are often preferable.

For computational chemists who prefer more flexibility, many machine-learning libraries exist for the R statistics suite,[24] and many descriptor calculators are available on the Internet.[25] Computational chemistry software suites contain useful QSAR implementations with descriptor calculation and machine-learning tools, but freely available integrated QSAR toolkits are less common.

The CDK toolkit is an open-source cheminformatics package, developed by more than 50 researchers worldwide, and widely used to provide chemical descriptors for QSAR modeling.[26] A number of other cheminformatics toolkits also exist, including RDkit and OpenBabel.[27] CINFONY is an open-source application program interface to a number of cheminformatics toolkits, including CDK, RDkit,[28] and OpenBabel. The previously mentioned BIOCLPSE system contains a choice of descriptor sets including Signature descriptors, which are a type of fingerprint descriptor, and which allows the results of the QSAR analysis to be mapped back onto the training set structure, highlighting areas of the molecule most significantly contributing to the response.

Where three-dimensional (3-D) structural information is known, whether from experimental X-ray structures, NMR, or computational models, descriptors can be calculated directly from the observed drug–receptor interactions (CoMFA,[29] GRID-GOLPE,[30,31] and VALIDATE[32]). Some of the scoring functions inside docking programs use methods based on QSAR equations to rank the affinity of molecules from the observed drug–receptor interactions (e.g., LUDI[33]).

3.15.4.1 Calculating Descriptors

How you describe changes in molecular structure across a series of molecules within a vector of numbers is one of the critical steps in setting up a QSAR model. Very many descriptors are available, representing molecular size, volume, lipophilicity, hydrogen bonding counts, shape, and electronic distribution. Representing 3-D shape within a single number vector is challenging, although many shape descriptors have been suggested. Some descriptors like H-bond donor counts are understandable by medicinal chemists. Other descriptors, in an attempt to encode complex properties such as shape, molecular connectivity, or charge distribution, although mathematically accurate, can be difficult for the medicinal chemist to deconvolute. There are whole books just devoted to descriptors for QSAR. The DRAGON descriptor suite contains 4885 molecular descriptors for use in QSAR.[34] Many of the mathematical tools used to define QSAR equations are very sensitive to the number of descriptors included in the analysis. Including more descriptors increases the probability of finding correlations just by chance, particularly when there are more descriptors than the number of molecules with biological activity being modeled. If this is the case, some regression tools such as partial least squares (PLS) analysis, which extract summary variables from a larger descriptor matrix, and uses "cross-validation" to assess the significant contribution of variables added to the model, are less sensitive to finding spurious correlations in what are called "over-square" matrices (more descriptor columns than compound rows).

Comparative molecular field analysis (CoMFA) and related 3-D QSAR methods attempt to describe both the 3-D shape and charge distribution of molecules by recording the interaction between the target molecules and a small probe molecule placed over a 3-D grid surrounding the molecules in the training set. The molecules have to be overlaid in 3-D space, so common molecular features occupy common volumes in space. The overlay can be thought of as a putative pharmacophore. The result of the QSAR analysis is the importance of the interactions the probe felt at each point in space to describing the response variable. These coefficients can be mapped back onto their respective points in 3-D space, to form a 3-D regression map. These can be interpreted by the medicinal chemist. For CoMFA, the probe is usually a positively charged methyl group, which perceives electrostatics and volume. The maps tell the medicinal chemists where in 3D space to place or remove charge and molecular volume to increase or decrease potency.[29]

As we have already mentioned a number of descriptor calculators are available on the Internet.[25] ACD physical property suite calculates log P, log $D_{7.4}$, and ionization constants. ACDLabs also makes available iLab, a pay for service web-based system for calculated physical properties.[35] The CDK toolkit, RDKit, OpenBabel, CINFONY BIOCLIPSE and KNIME are excellent sources of descriptors.

Whatever the dataset, descriptors being used, and machine-learning algorithm applied, the following steps are normally taken in deriving QSAR models.

3.15.4.2 Preparation of the Dataset

Some machine-learning methods are sensitive to the numerical range of the data in each descriptor. PLS regression is one example. Descriptors that have a larger range because of the units chosen can unduly influence the fitting of the descriptors to the y-response data using your chosen statistical learning method. Therefore the dataset is often "normalized," or "unit scaled" by subtracting the mean value of each descriptor vector from each descriptor value, and dividing by the standard deviation of the descriptor column. Hence each descriptor will have a mean of zero and standard deviation = 1.0. In those methods sensitive to scale, this process gives each descriptor an equal weight to contribute to the model.

3.15.4.3 Generating a Training and Test Set

Next the dataset is split into a training set and a test set. The training set is used to define the mathematical relationship, or correlation, between the y-response and x-descriptors, using the chosen machine-learning method. The test set is used to assess the quality of the QSAR model by its ability to predict a set of molecules that were not part of the training phase. Because many of the machine-learning methods used to define QSAR models are very good at fitting the x-descriptors to the y-response data, the

quality of the model is usually best assessed on how well it predicts an independent test set, rather than the fit to the training set compounds. Some methods require a training set, a tuning set, and a test set/validation set, where the tuning set is used for internal model validation and the test set for external validation. In this case, the tuning set is used to stop the model training phase, or to select between different models, while the validation set is an independent test of model performance. The disadvantage of this approach is that it limits the number of compounds available to train the machine-learning algorithm.

The test set/validation set can be selected from the original dataset in a number of ways, including random selection, by clustering and selecting representative examples from the original dataset, or in a way that would satisfy Nils Bohr, by selecting in time order, so the latest compounds make the test set. When the model is to be used in a design-make-test environment, a time-ordered test set most closely reflects how the model will be used, to predict future compounds. The size of the test set selected often depends on the amount of compounds on which you have activity data. The compounds selected for the test set limit the amount of information you make available to the machine-learning method to build a model from. A common approach is to select 20–30% of your dataset as a test set. If a QSAR has been used in a design-make-test environment, week on week, and confidence has been built in its predictivity, a much smaller test set could be used at later rebuilds, to maximize its ability to predict tomorrows compound.

3.15.4.4 Exploring the Dataset

A critical step in an QSAR analysis is getting to know your dataset. One can examine plots of response versus variables, as it may inform your choice of statistical tool, and it may allow you to refine your dataset. Projection methods such as principal component analysis may also help one identify clusters or outliers that may bias an analysis. This may affect how the training set for the model is selected. Often such visual explorations of the dataset are enough to understand important underlying QSAR relationships. There are a number of commercial tools for data exploration, and even powerful freely available tools such as DataWarrior.[36] A lot of information can be extracted by such a simple exploration, and this approach is very complementary to the traditional medicinal chemist pairwise approach to exploring SAR. During an analysis of the duration of action of dual acting β_2 adrenoceptor, dopamine D_2 receptor agonists, a simple visual analysis of such plots provided the catalyst for building a very predictive QSAR model.[37,38]

The next step is the choice of machine-learning algorithm. This can be informed by the data exploration step previously described, the descriptors to y-data point ratio, and by the modeler's experience and background. The choice can have a critical impact on the quality of the model derived. If the algorithm is very sensitive to parameterization, this again leads to a lack of confidence in the derived model. Investigations to automate QSAR model building have explored the effects of model and algorithm parameterization and found methods such as PLS and random forests are robust to changes in model parameterization.[39]

There are a number of statistical methods widely used in the QSAR analysis, and many that have been explored. They can be divided into two categories, unsupervised and supervised methods. Unsupervised methods are used to explore the distribution of the compounds through property space, and do not use the response variable to choose or weight variables. Supervised methods attempt to find correlations between the responses and descriptors. Here, we briefly describe four characteristic machine-learning tools, which have spawned many derivative methods. Still, other methods exist and are being explored and are not cited here. The reader is referred to SciFinder and we wish you good luck if you choose to work at the "bleeding edge" of the machine-learning space. The following methods are tried and tested.

Hansch used MLR, and this is still a common method today. It is limited to datasets where there are many more compounds than descriptors, as it is particularly sensitive to chance correlations where many descriptors are available. The principle on which MLR was built assumes all variables are relevant in the model. But MLR algorithms allow "forward and backward stepping," where descriptor variables are sequentially added or excluded from the models, facilitating QSAR scientists to pick and choose from a larger array of descriptors, those relevant to the model to find a good model. While this may be a useful data exploration method, it has a significant probability of leading to chance models. The statistics which govern the selection were not designed to allow such choice, and due to the combinatorial nature of selection a few relevant descriptors from a matrix of many more, MLR is particularly susceptible to chance correlations.[40] But MLR does produce simpler to interpret models, that is, if the descriptors are meaningful to a medicinal chemist.

MLR assumes all variables are uncorrelated with each other, but this is rarely the case. Where variables are correlated, then the coefficients of the regression equation become dependent upon each other, and so their size and even sign cannot be used independently of all the other descriptors in the model to deduce that variable's unique contribution.

PLS analysis, introduced by H Wold and his son S Wold, was developed in response to a request by the Swedish government for an objective method of handicapping state-run horse races,[41] it is a linear correlation method, that is less sensitive to chance correlations in datasets where there are more descriptors than compounds. It uses the intercorrelation structure of the descriptor set to form new underlying summary descriptors (components), as weighted linear combinations of the original variables. PLS forms these summary variables to maximize the correlation with the response variable. As the method uses the intercorrelation structure of the descriptor set, it makes it less sensitive to a chance correlation in any one variable. The method principal components analysis (PCA) is similar in that it forms summary variables as weighted linear combinations of the original variables. But in PCA, no response variable is defined to supervise the extraction of components. In PCA, each component is chosen in decreasing order of its ability to summarize the information on the x-descriptor set. Hence one can see that PLS is a development from PCA.

The influence of the original variables on the derivation of these new summary descriptors is described by the loadings or weightings of the variables on the new summary descriptor, and the summary descriptor's numerical values are the scores. Because all the

original variables contribute more or less to forming each summary variable, it is harder to interpret the underlying physical meaning of PLS and other multivariate models.

Neural networks as a group have a structure of a set of layered nodes interconnected to each other, which prompts the analogy to the structure of the human brain. They often consist of an input layer, one node per descriptor, one or more hidden layers, on which the input descriptor nodes are projected, and an output layer. There are nonlinear "transfer functions" that operate between the nodes of the input layer and the hidden layers, and mathematically transform the original data as it is combined onto the "hidden layer" which allows the neutral network to model nonlinear data. They usually run in an iterative fashion where either a random or a distribution (Bayesian approach) of weighting parameters are starting points for linking the input nodes to the hidden and output nodes. These weights are iteratively optimized, to drive a correlation between descriptors and response. The fitting routines together with the nonlinear transfer functions in neural networks are very powerful, and if unchecked, will fit both signal and noise in the training set. So neural networks often maintain a calibration set/tuning set, the prediction of which is used to stop the training phase. Neutral networks can generate a single QSAR equation, or in the case of Bayesian approaches, an ensemble of models.

Regression Trees and Random Forests are a form of classification method. In regression trees, the method attempts to classify the response into "bins" that represent ranges of activity. The method attempts to find critical values of x-variables which result in an improvement in the purity of y-bins with correctly classified compounds. Random Forests is an extension, where instead of one tree, an ensemble of trees are formed, with each tree built on a subset of the original dataset by sampling rows and columns. Each tree in the "forest" is a decision tree. When a prediction is made, all models participate in the prediction and the predicted value is an average from across the forest of trees. The dispersion of predictions from across the ensemble of models can give an indication of the confidence in the prediction. Like PLS, Random Forests appear less sensitive to the size of the descriptor matrix, as spurious models influence becomes averaged out across the ensemble of models. Because the prediction is made from across the forest of trees, it is more difficult to interpret which are the truly important underlying descriptors, although the method provides diagnostics to indicate important underlying variables.

3.15.4.5 Appropriate Measures of Goodness-of-Fit—Model Diagnostics

The coefficient of variation in fit to training set r^2, the fraction of the variation in response described by the model, and residual root mean square error (RMSE)—the variation in the response variable unexplained by the model is often reported. But the fit to the training set is not a good indication of a model's ability to generalize. Spurious models can have very appealing fit statistics, but with no ability to predict. Rather, most analyses focus on the performance of the model in prediction of a chosen test set. Similar quality of fit statistics to r^2 can be defined in this prediction mode, but to indicate that the assessment is based on prediction rather than fit, the r^2 diagnostic is replaced with Q^2 and RMSE with root mean square error in prediction (RMSE/RMSEP). Unlike r^2, which is bounded between 0 and 1, Q^2 can take values less than zero, meaning the model predicts the test set worse than if one had used the mean of the model as the prediction for every compound.

r^2 for the fitted model can be written as Eq. (4)

$$r^2 = 1 - \frac{\Sigma(y_{\text{obs}} - y_{\text{fitted}})^2}{\Sigma(y_{\text{obsd}} - y_{\text{mean}})^2} \tag{4}$$

Q^2, the r^2 in prediction, can be defined in a similar way, Eq. (5)

$$Q^2 = 1 - \frac{\Sigma(y_{\text{obs}} - y_{\text{predicted}})^2}{\Sigma(y_{\text{obsd}} - y_{\text{mean train set}})^2} \tag{5}$$

The root mean square error in prediction (RMSEP) value is particularly useful as it is in the same units as the experiment, and can be directly compared to the experimental error of the response variable. The RMSE of the test set gives the medicinal chemist an indication of the likely error associated with a prediction, Eq. (6).

$$\text{RMSE} = \frac{\Sigma(y_{\text{predicted}} - y_{\text{obs}})^2}{n - 1} \tag{6}$$

The average error in prediction tells you if there is any systematic bias in the predictions, Eq. (7).

$$\text{Mean absolute error/bias} = \frac{\Sigma_{i=1}^{n_{\text{ext}}}(y_{\text{obs}} - y_{\text{predicted}})}{n} \tag{7}$$

An external set of compounds may be predicted with a systematic bias, which would inflate RMSE, and decrease Q^2. A nonzero mean absolute error indicates that the predictions may not be accurate, but may still be useful in ranking compounds. It also may indicate a structural or substructural feature present in the test set but not encoded in the training set or its description.

Assessment of performance based on a test set only using Q^2 or even RMSE can still be problematic. An ambiguity occurs with the Q^2 statistic when the test set data is not evenly distributed over the range of the training set. As the variance of the external test set approaches the RMSE of the fitted model, the Q^2 measure would approach zero—even though it would appear the predictions are in accord with the model. Consonni defined a new Q^2 statistic that expresses the mean predicted error sum of squared deviations

between the observed and predicted values for the test set over the mean training set sum of squared deviations from the mean value, Eq. (8)

$$Q^2 = 1 - \frac{\left[\sum_{i=1}^{n_{ext}} (\hat{y}_i - y_i)^2\right]/n_{ext}}{\left[\sum_{i=1}^{n_{TR}} (y_i - \bar{y}_{TR})^2\right]/n_{TR}} = 1 - \frac{\mathrm{PRESS}/n_{ext}}{\mathrm{TSS}/n_{TR}} \tag{8}$$

where n_{ext} is the number of compounds in external set, $\hat{y}_i$ is the prediction estimate of y, y_i is the observed value, n_{TR} is the number of compound in the training set, $\bar{y}_{TR}$ is the mean of the training set observed values, PRESS is predicted error sum of squares deviations between the observed and measured y values, and TSS is the training set sum of squared deviations from the mean.

Consonni demonstrated this formulation of Q^2 is stable with test sets of different variances.[42]

The use of a test set in the model evaluation process protects you from using a spurious QSAR model, as it is less likely that a model that randomly fits the training set would also randomly predict a test set. The use of a test set in the model-building process excludes valuable chemical information from the model-building process, and so some methods attempt to utilize all the data, and perform an internal validation procedure known as cross-validation. In cross-validation, a number of cases from the training set are left out during the model fitting process and then predicted from the resulting model. Multiple models are built with a fraction of the compounds excluded at each build. Enough models are built so that each compound is predicted from a model from which it was excluded. The sub-models is then used to predict the excluded compounds. A prediction statistic can be defined as in Eq. 5. To differentiate this cross-validated measure of predictivity from a measure of predictivity calculated from an external test set, a lowercase q^2 symbol is often used to delineate a cross-validated statistic. A $q^2 > 0.3$ is often taken as a rule of thumb for a potentially useful model.

Leave-one-out cross-validation is the simplest and least challenging validation method, and has been widely criticized,[43] as being too easy a test of the model. Leaving out compounds in multiple groups is a tougher test for the model. The archetypal PLS program, SIMCA,[44] uses seven subsets as default, so at each rebuild 1/7th of the training set is left out at each model build.

Cross-validation can only give an unbiased estimate of future predictive ability if future compounds come from the same population as those in the cross-validation sample. This is not a safe assumption as the nature of drug design is that compounds evolve with time.

The assessment of the significance of the model can also be explored by performing a y-randomization experiment. The y-randomization procedure compares the performance of models built for a randomly shuffled y-response. When repeated multiple times, the distribution of r^2 values obtained is an assessment of the significance of the original model, without assuming the data follow a particular statistical distribution (nonparametric). Y-randomization has been referred to as probably the most powerful validation procedure,[45] although only if the full model generation procedure is repeated including variable selection, rather than just permuting the y-variables of the final model.[46]

Tropsha has recommended a set of criteria to be evaluated before one can claim a QSAR model is predictive.[47,48] Using the correlation coefficient R^2 between the predicted and observed activities; coefficients of determination (predicted vs. observed activities R_0^2 and observed vs. predicted activities R'^2_0); slopes k and k' of the regression lines through the origin, and considers a QSAR model predictive if the following conditions are satisfied:

$$q^2 > 0.5$$
$$R^2 > 0.6$$
$$\left(R^2 - R_0^2\right)/R^2 < 0.1 \quad \text{or} \quad \left(R^2 - R'^2_0\right)/R^2 < 0.1$$

$$0.85 \le 1.15 \quad \text{or} \quad 0.85 \le k' \le 1.15$$

Following the REACH recommendations, one of the most highly cited reviews on QSAR model validation was published by Gramatica.[49] In this review, Gramatica discussed whether Principle 4 of the OECD recommendations "appropriate measures of goodness-of-fit, robustness and predictivity" should have been split into two principles, reflecting internal validation and external validation. Originally they were separate principles, but were merged into the single Principal 4. Experts held different views, on the one hand splitting internal and external validation highlighted the importance of external validation, while having them merged was more appropriate to allow flexibility in regulatory acceptance. In the review, particular attention is paid to the differences between internal and external validation—strongly recommending that only models that have been validated externally, after their internal validation, can be considered reliable and applicable for external prediction and regulatory purposes. As an example, validation statistics for a 30 genetic algorithm population-models for mutagenic potential of 48 nitrated polycyclic aromatic hydrocarbon (PAH) compounds (31 in training and 17 in prediction set) was shown in fitting cross-validation (q^2_{LOO} and q^2_{boot}) and external validation (Q^2_{ext}).The example clearly shows that some models (in bold) appear stable and predictive by internal validation, but less predictive or indeed not predictive when applied to external compounds that were not presented to the genetic algorithm on model building (**Table 1**).

3.15.4.6 A Defined Domain of Applicability

The chemical space encompassed by the model is termed the domain of applicability. The hope is that molecules being predicted that are "near" the applicability domain of the training set compounds will be predicted with lower error and therefore with more confidence than compounds further away.

Table 1 Internal validation versus external validation shown on a set of 48 nitro-PAH compounds tested for mutagenic potential on TA100 cells

For a description of the QSAR model building, descriptor sets, and data, see the original reference 50.

Confidence in the model can be gained by examining the error in prediction of compounds in the test set most similar to your compounds.

Definition of domain of applicability of the QSAR model, and "distance" of a compound being predicted to the defined domain, is an intense area of research in QSAR. The OECD QSAR Guideline 3 states one should have a defined domain of applicability. The principles are easy to grasp, although the mathematics associated with some of the methods can be quite complex.

A suitable distance to model measure should show a dependence of the distance upon the error in prediction of the test set compounds. By knowing the distance of the compound being predicted to the model space, the confidence in the prediction can be inferred, based on the error in prediction of the test set compounds similarly distance from the model space. Unfortunately, many of the distance measures only produce a weak relationship to error in prediction, which limits the confidence that can be extracted from the statistic.

The relationship between of distance to model on prediction precision was clearly shown by Bruneau in an assessment of models built using a Bayesian neural network on an internal AstraZeneca (AZ) solubility dataset and on a public domain solubility data.[51] Bruneau found that when using the internal AZ model to predict internal AZ compounds, or the model built on the public domain data to predict the public domain test set, the models gave comparable prediction statistics, with similar root mean square errors in prediction. But when used to cross-predict each other's test set, the predictions were worse. Interestingly, while the solubility model built on external data did a worse job at predicting the AZ compound test set than its own test set, the predictions were not as bad as the AZ model predicting the public domain test set. When Bruneau examined how the prediction error depended on distance to model, the results became understandable. The AZ compounds were more distant from the public domain compounds than their own training set, which corresponded to an increase in the prediction error. But their error in prediction was similar to public domain compounds at a similar distance to the public domain training set compounds.

Different numerical approaches are taken to defining the domain of applicability, and the distance of compounds being predicted from it (distance to model). Euclidian distance (geometric distance) assumes that the model space is spherically distributed. Alternatively, one can use a Mahalanobis distance (probability distance) which takes note of the intercorrelation structure of the dataset and hence the shape of the model space to be nonspherical and more "ellipsoid." Distances can also be measured in structure space using molecular fingerprints, among many others.[52]

So far it appears there is no single measure that performs better than another across many datasets, although one should be used. A measure that correlates with error in prediction of the test set would be a useful and validated method for any particular dataset. Suffice to mention here that medicinal chemists should request information on the distance to the model space of the compound being predicted, and this distance can be calibrated based on the relationship of the error in prediction to distance to the model of the test set compounds.

While statistics can guide you, there are other ways a medicinal chemist can gain confidence in a QSAR model. Firstly work closely with your QSAR scientist when assessing the model's utility to your compounds. Medicinal chemists who do commit to synthesis based on the predictions from a model will get real-time feedback on the quality of the model, once their compounds are tested. Maybe this is a more useful confidence build for the practicing medicinal chemist than any QSAR diagnostic.

Interpretation of the QSAR model can also build confidence in the model itself. A predictive QSAR model must identify some of the underlying controlling physical features of the response variable being modeled, although in the case of multivariate models, it can be difficult to untangle the primary controlling properties when many variables contribute to the overall model. The case studies described so far led to mechanistic interpretations which guided further insights, from Overton and Meyer's theory of narcosis, Hammett's hypothesis for electronic induction and resonance, and Hansch's "random walk" of drugs to their receptors. The QSAR expert can work with the medicinal chemist in interpreting the model, to explore if it makes some kind of logical sense. If an interpretation can be made, then the model can be used to rationally design the next compound. Otherwise the QSAR model can only be used as a black box filter. Particularly with complex multivariate models, trying to interpret the controlling properties so new compounds can be rationally designed, the so-called inverse QSAR, can be challenging. So there has been a renewed interest in Free–Wilson type analyses. These methods do not use derived descriptors, but rather correlate the change in response to the structural change itself and this inspired the recently introduced method of matched molecular pairs

3.15.5 Examples of Influential QSAR Models

Many marketed drugs have depended, at least in part, on classical QSAR approaches in their discovery, including drugs as diverse as norfloxacin, lomerazine, flobufen,[53] and cimetidine, among many others.

QSAR has found a particular niche in predicting physicochemical and ADMET properties. This is because QSAR models attempt to find patterns across a series of molecules in a dataset, and ADMET endpoints are more bulk property-controlled than structurally dependent. Drug–receptor interactions inherent to primary potency endpoints are often fraught with "activity cliffs"—where activity falls away very rapidly with small structural variations. These are harder for QSAR models to identify without the knowledge of the nature of the drug–receptor interactions, as can be gained from X-ray crystallography and docking studies. This is the subject of a highly cited editorial by Maggiora. "On Outliers and Activity Cliffs—Why QSAR Often Disappoints."[54] The structure–activity relationships for activity landscapes as Maggiora describes them, tend to look more like "rugged landscapes of Utah's Bryce Canyon" than the "gently rolling hills of the Kansas Prairie." 3-D QSAR methods have found a particular niche here, but can still suffer from the steep SAR dependence of potency endpoints in prediction. The literature is replete with examples of QSAR models being applied in drug design. Nevertheless, QSAR models are often sought for primary potency endpoints, as they are easy to look for, and can at least help the medicinal chemist explore the SAR within a dataset, even if they are not refined enough to be used for accurate prediction.

The false negative prediction rate of potentially genotoxic impurities by in silico models was recently surveyed across eight companies. The methods for prediction were given and the approaches across the companies were very similar. The true negative prediction rate was found to be 94%, and when expert evaluation of the results was included in the decision this increased to 99%.[52] The results of this analysis are currently being written into an ICH guideline M7 on genotoxic impurities.

While the CLOG P algorithm from Pomona College was manually constructed as a fragmental-based system from a combination of first principles and empirical observations, a number of the most widely used clog P and clog D algorithms are QSAR based including Alog *P*,[55] Xlog *P*,[56] and Mlog *P*.[57] Many pharmaceutical companies have derived their own log *P* and log *D* calculators using QSAR approaches, which outperform the standard CLOG P method.[58] An implementation of Alog *P* has even been made available on a tablet computer within the RSC Medicinal Chemistry Toolkit IPAD app.[59]

The scoring functions used inside many structure-based design docking programs are QSAR derived. The archetypal scoring function in LUDI was derived from regression analysis of a set of predetermined physics-based descriptors calculated from the 82 protein-ligand X-ray crystal structures together with the reported ligand affinity.[60] The initial dataset defining scoring function SCORE1 of 45 complexes, Eq. (9) was extended to 82 complexes, and was named SCORE2, Eq. (10). The SCORE 2 function has a lower residual standard deviation of 8.8 kJ/mol (relative to 9.5 kJ/mol for SCORE1), suggesting SCORE2 fits the experimental data for $\Delta G_{binding}$ better than SCORE1. The prediction of an independent test set of 12 complexes showed a root mean square error in predicting RMSE = 8.8 kJ/mol, in good agreement with the unexplained error in fitting the training set data. It is interesting that the magnitude of some of the coefficient change significantly, which is probably due to the changing intercorrelation structure of the descriptors within the larger dataset. As mentioned earlier in the multiple linear regression section, the regression equation can be used to predict affinity, but the magnitude of the coefficients may not be quantitatively independently interpreted, as the intercorrelation of the descriptor set makes them dependent upon each other

$$\text{SCORE1}\ \Delta G\ \text{binding} = 5.4\,G_0 - 4.7\,G_{HB} - 8.3\,\text{Gionic} - 0.17\,\text{Gapolar} + 1.4\,\text{Grot kJ/mol}$$
$$N = 45, R = 0.835, s = 9.5 \quad (9)$$

$$\text{SCORE2}\ \Delta G\ \text{binding} = -1.4\,G_0 - 3.1\,G_{HB} - 6.6\,\text{Gionic} - 0.15\,\text{Gapolar} + 1.0\,\text{Grot kJ/mol}$$
$$N = 85, R = 0.841, s = 8.8 \quad (10)$$

LUDI scoring function has inspired many other docking scoring functions.

Large datasets are now available, not just for proprietary model building, but also for open-source initiatives, and research groups are eager to utilize them to learn from the past to guide the design of the future compounds. For example, GlaxoSmithKline have described simple interpretable QSAR models built on between 10,000 and 50,000 data-points across many assays.[61] Global initiatives from the likes of the NIH and EMBL have made available huge datasources to public model building such as PubChem and CHEMBL from which many QSAR models have grown.

3.15.6 The Future of QSAR

Subjectivity has been a big problem in the field of QSAR model building, from the subjective choice of training set and test set to the descriptor set choice of algorithm and its parameterization to the method of validation. QSAR models are empirical by nature and as such, as the prediction set gets further from the training set, the quality of predictions can become worse. For these reasons, a number of groups have explored the concept of auto-building and auto-updating QSAR models.[62–64] Where the choice of machine-learning method of descriptors is unclear, the use of consensus prediction has been adopted in a number of these systems.

Discovery Bus stakes the competition one step further, in that the choice of descriptor set is combined with a set of statistical methods to find the combination that predicts best at that point in time. The name Discovery Bus is derived from the "computer bus" which allows peripherals to be plugged or unplugged and be easily integrated into the signal flow. In the case of Discovery Bus, new machine-learning agents, datasets, or descriptors can be plugged in and be available for model building and model comparison within "a competitive workflow"—where Discovery Bus tries to find areas of data/descriptors/modeling methods where good models exist, and compare their performance to previous models built in older versions of the datasets. In this manner, good models can be found and kept up-to-date. The comparisons across models do increase the risk of chance correlations, due to the multiple testing, but the continuous feedback of measurements from predicted compounds builds confidence in the success of these approaches.

Rodgers and colleagues have explored the decay of a number of QSAR models in time-ordered datasets, where a model was build to predict increasingly later synthesized compounds.[65,66] They also explored the temporal dependence of a number of common QSAR machine-learning algorithms. They found that models built different machine-learning algorithms aged differently with time. PLS models appeared to be conservative and inferior to a Bayesian neural network model in predicting test sets near in time to the training set model, but maintained their predictivity better over the long term. In their study they also found that regression trees outperformed both methods. The "best" model may change depending on when you make your measure and how you use the model. The learnings were embodied into the AstraZeneca AutoQSAR system for building and maintaining a portfolio of QSAR models for projects. AutoQSAR includes comparison of chemical series versus project series versus global modeling—to find the best model for the next new compound.

Discovery Bus and AutoQSAR apply good modeling and validation practice, to maximize the robustness of models built and selected for use. Developments such as Discovery Bus and AutoQSAR help to minimize a number of major problems associated with QSAR modeling. They apply QSAR modeling in a consistent fashion using objective decision-making criteria. They allow for the updating of QSAR models with the most recent data, which, in active drug discovery programs, ensures the distance between the compound predicted and the domain of applicability of the QSAR model is minimised. Finally they apply the best model, whether it be a local chemical series model or the global cross-project model, based using temporal predictions to make the decision. A weakness in the competitive workflow approach is that, as multiple comparisons are being made, this increases the chance that a spurious model could be selected. AstraZeneca's experience shows that in practice, more accurate and precise predictions are made routinely across projects, so the benefit clearly outweighs the risk, and improved models are available to project teams.[67] In a 2-year temporal validation across 10 active projects, AstraZeneca demonstrated that the hierarchical and updating modeling method of AutoQSAR outperformed updating global models, which outperform static global models (**Fig. 2**, **Table 2**). Discovery Bus has inspired the machine-learning engine, Optiplex, one of the key technologies driving the drug discovery company, Molplex.[68]

The interest in auto-updating QSAR models is growing. The benefit of building local models over global models is a continuing debate. Sheridan compared local versus global mode building and concluded that local models may not have a benefit over global models, depending upon a descriptor set being able to discriminate between local series, and the machine-learning algorithm being able to utilize the descriptor distinction.[69] If such a descriptor exists, then the global model may predict just as well as any project or project series model. Carlsson and colleagues came to a similar conclusion using simulated data, that with suitable descriptors a local modeling strategy may be redundant.[70] They used simulated data to rigorously explore the benefit or deficit of local modeling over global modeling, as the underlying relationship could be better controlled than in real world data, where the underlying relationship is unknown. They defined local by clustering using Tanimoto distance-based DAYLIGHT fingerprints. They also validated their findings on an AMES dataset of 4253 examples, hERG dataset (6020), and a solubility dataset (1186 cases). They did

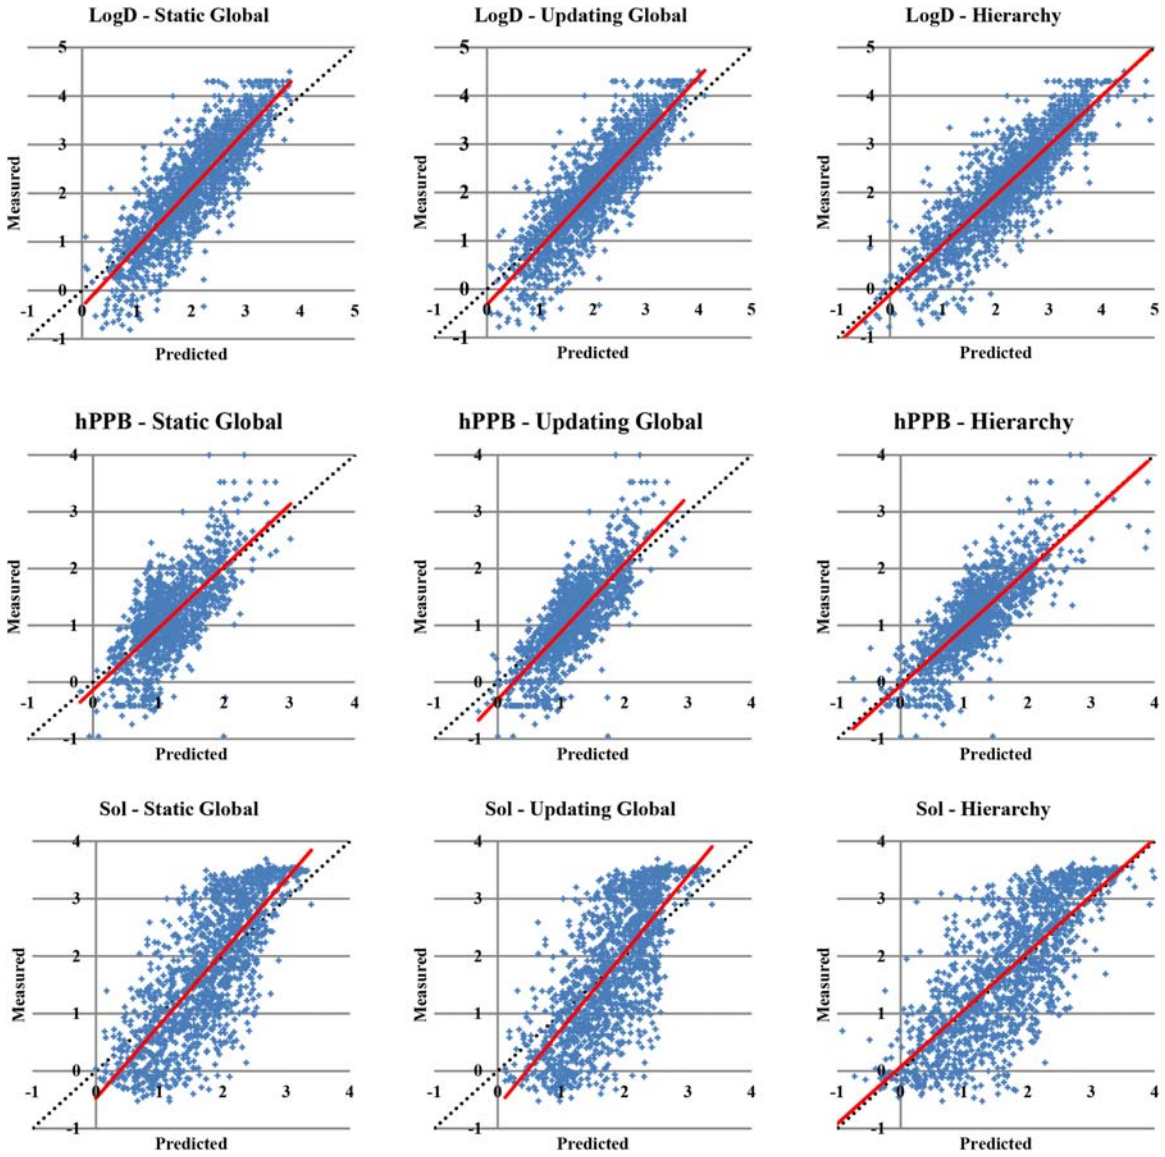

Fig. 2 Forward prediction time simulation of 10 active AZ Projects using the AutoQSAR method over 2 years—each month the AutoQSAR hierarchy selects the best model from chemical series, project or global updating model over the static global model, and uses the best model to predict next-month compounds. This hierarchy model is compared to using an updated global model (using data from all 10 projects each month), or a static global model. The accumulated next-month future predictions made on models from last month's data are shown here over the 2-year period. The figure shows predicted versus observed values for all "future" predictions from the three prediction strategies over the three endpoints. The *broken black line* shows the line of unity and the *solid red line* shows the fitted correlation between the observed and predicted values.

Table 2 Statistics on the full "future" prediction sets

Endpoint	*N*	*Mean*	*SD*	*Strategy*	*RMSE*	R^2	R_0^2
Log D7.4	1763	2.18	1.05	Static	0.58	0.73	0.69
				Updating	0.54	0.76	0.74
				Hierarchy	0.51	0.76	0.76
Human ppb	1291	1.13	0.73	Static	0.53	0.49	0.48
				Updating	0.47	0.62	0.60
Plasma protein binding				Hierarchy	0.43	0.65	0.65
Solubility	1401	1.77	1.13	Static	0.79	0.54	0.50
				Updating	0.73	0.61	0.58
pH 7.4 buffer				Hierarchy	0.72	0.60	0.60

N, the number of test compounds; *Mean*, the mean measured value of the test compounds; *SD*, the standard deviation of the measured values for the test compounds.

find some examples where local modeling gave an improvement over the global models, and these were where the local neighborhood could be well defined, but often this was not the case using the Tanimoto clustering, and then the global model was preferred. In the 10-project AZ case study described earlier, local was defined by project code (the manual definition of project membership recorded by the chemist at the time of first registration), a more robust definition of "local" then could be perceived by cheminformatic clustering. Overall the message is clear, updating QSAR models are better than static QSAR models, objective automated workflows can build predictive models and remove subjectivity from the QSAR model-building process and apply good practice. It seems updating global models can perform well, and with appropriate descriptors, may negate the need for extensive local modeling strategy, but if local can be well defined, then a local modeling strategy may be worth the extra computational effort. With automated workflows and easy availability of computational power, there is no reason why all levels of the hierarchy (global, project, and chemical series) cannot be continually evaluated.

When it comes to choice of machine-learning tool, is there a clear best method independent of dataset and parameterization? In a temporal test, a static QSAR model built with three machine-learning tools, predicting ever-growing temporal test set of compounds, Rodgers and colleagues found that random forests outperformed BNN and PLS methods.[66] Rodgers also found that random forest predictivity was quite stable to parameterization, and therefore a suitable tool for use in an AutoQSAR procedure. Norinder also found random forest to be an accurate method. But the dataset may dictate the most appropriate machine-learning tool, and many automated workflows, such as Discovery Bus and AstraZeneca's AutoQSAR, include choice of the machine-learning method within a competitive workflow.

GSK have described their QSAR Workbench, which provides a consistent set of routines for data preparation and chemical normalization that are also applied for predictions. The Workbench provides a large degree of automation with the ability to publish preconfigured model-building workflows for a variety of problem domains, while providing experienced users full access to the underlying parameterization if required. Methods are provided to allow for publication of selected models as web services, thus providing integration with the chemist's desktop. Green and coworkers demonstrated its utility on two large public datasets.[71] The QSAR workbench is now deployed within the Biovia's Discovery Studio.[72]

Recently Schrodinger has built an implementation of an auto-updating QSAR workflow, also called AutoQSAR, within the Schrodinger suite of software.[73]

3.15.7 Using QSAR Models

Many medicinal chemists will want to use QSAR models, rather than build their own. Many QSAR models for ADMET endpoints are available in the public domain, either as freeware or in commercial packages. These are based on literature datasets, and in the absence of any data from their own chemistry, or expertise to build their own QSAR models, these are the only models many medicinal chemists may have access to. How confident one can be in the predictions from such models requires careful thought. If the compounds you are predicting are unlike the compounds within the training set of the model, one may be concerned in the quality of the prediction. One should remember the OECD guidelines when assessing the utility of these models for your intended use. Before you use the model to prioritize your synthetic targets and commit valuable resources to synthesizing your chosen targets, consider the hints and tips given here as guidance.

For a medicinal chemist using a QSAR model, the following steps are recommended:

- Look at the distribution of compounds in the training set and test set over the range of responses. Are the data evenly distributed or is there a region of activity or property space that contains better coverage—indicating where better predictions are likely to be made?
- Examine the Q^2 and RMSE of the test set used to validate the model. Does the model have the resolution you require to solve your project problem. A high r^2 or q^2/Q^2 looks impressive, but if the range of the training set or test set is very large, the unexplained residual error in model can still be large. So examine the RMSE of the model. For example, if the RMSE of predictions of the test set is 0.7 log units and you only wish to move your property by 0.3 log units, it is likely you are within the noise of the model.
- Examine the error in prediction of compounds in the test set that are "closest" to the compound you are predicting (based on distance to model measures). You may find this gives you more or less confidence in the model. You may find that within the test set, compounds that are more similar to the training set are predicted better than the average across the test set. If these compounds are similar to your target compound, this will give you more confidence in the models ability to predict your compound.
- The QSAR model can be used as a filter for a virtual library, or interpreted to influence the compound design. Examine the controlling features of the QSAR model, this may give you an indication how you can rationally change your molecules to improve the property you are trying to optimize.
- Examine the QSAR model visually. Plot the important controlling variables against the response variable, this may allow you to see patterns in the dataset that can guide further design.
- Are the important variables similar as new compounds are added to the model, or if compounds are removed from the model, or if submodels are built during cross-validation? Instability in selected variables can point to a poor, spurious or unstable QSAR model.

- Are new compounds well predicted by your model? This is the ultimate test of any model.
- As new compounds are synthesized and measured in your assay, ask your computational chemist to update the QSAR model to minimize the distance the compounds are you will design will be from the domain of applicability of the QSAR model. Keep monitoring your predictions as compounds synthesized are subsequently measured in the assay your QSAR model is supposed to predict. This may give you increased confidence in the model, or highlight new features in your molecules not identified in the model (e.g., if it is surprisingly badly predicted where previous compounds had been well predicted). QSAR models may be automatically updated, ensuring your model always contains your latest compounds (AutoQSAR).

3.15.8 Conclusions

QSAR is a mature technique and a core part of the computational chemist's predictive armory. It is an empirical technique, identifying patterns from yesterday's compounds to predict tomorrow's. At worst, a QSAR model can be used like a black box, but if a model has true predictive power, it is highly likely it is identifying some of the underlying physics controlling the response variable being measured, whether that is activity, stability, or a physical property. The choices involved in the dataset, its partition and preparation, the choice of descriptors, and the machine-learning method, and validation can be subjective, leading to the risk of over fitted or even spurious models. The past 10 years have seen even this mature discipline taking its next steps, with the increasing need to mine ever-growing data sources to guide the design of tomorrow's compounds. Researchers have been increasingly focused on removing the subjectivity, and even automating QSAR model building to provide up-to-date and updating QSAR models. While the intellectual focus of the computational discipline has been on physics-based models over the past 10 years, these two powerful disciplines of physics and empirical modeling could become even closer together as we seek to choose which compound to make next.

3.16.1 Introduction

3.16.1.1 Why We Need to Predict Physical–Chemical Properties?

Attempts to predict physical–chemical properties began very shortly after the first few measurements were made. This happened for a variety of reasons. In some cases an estimate of the likely value of the property is a useful aid to measurement. Octanol/water partition coefficients determined by the shake-flask method are a good example of this since judicious selection of volumes is required in order to achieve an accurate measurement.[1,2] For other properties, the measurement may be expensive or difficult and thus prediction is desirable. When a property is being used to construct models aimed at the design of new and better materials, some method of prediction is essential. Examples of this most notably include "drug design" as discussed at length in the book, although of course this is equally well required in the development of other products such as agrochemicals, fragrances, paints, adhesives, and dyestuffs. Indeed, anywhere where a material involving one or more chemicals has some practical application.

Whatever the reason, different methods have evolved involving different levels of theoretical treatment ranging from purely empirical to totally theoretical. This article will examine the more important physical–chemical properties and their prediction showing how the techniques work, discussing the theoretical basis of the methods and highlighting their strengths and weaknesses including an examination of the likely errors.

3.16.1.2 Physical–Chemical Properties in Drug Design

To elicit its pharmacological and therapeutic effects, a drug has to cross various barriers (Fig. 1). Orally administrated drugs need to be dissolved at the site of absorption in the gastrointestinal tract (GIT), be chemically stable at the low pH of stomach media, be metabolized appropriately and traverse several membrane barriers before achieving high free concentrations at the target site. The behavior of a drug molecule in each of these environments is the direct result of the drug's physical–chemical properties that are determined by its chemical structure.

3.16.1.3 A Brief Historical Overview

Octanol/water partition coefficients ($\log P$) formed the basis of the first systematic application of a mathematical modeling approach to attempt to link the biological properties of molecules to their chemical structure, the so-called Hansch approach.[3] Hansch, being a chemist, applied the principles of physical organic chemistry to biological activity prediction using Hammett σ constants to describe electronic effects and his own chosen system of octanol/water to describe transport and/or hydrophobic effects in the biosystem. This was not the first application of partitioning in the explanation of biological properties as Meyer[4] and Overton[5] at the turn of the 19th century independently described the potency of local anesthetics in terms of olive oil/water partition

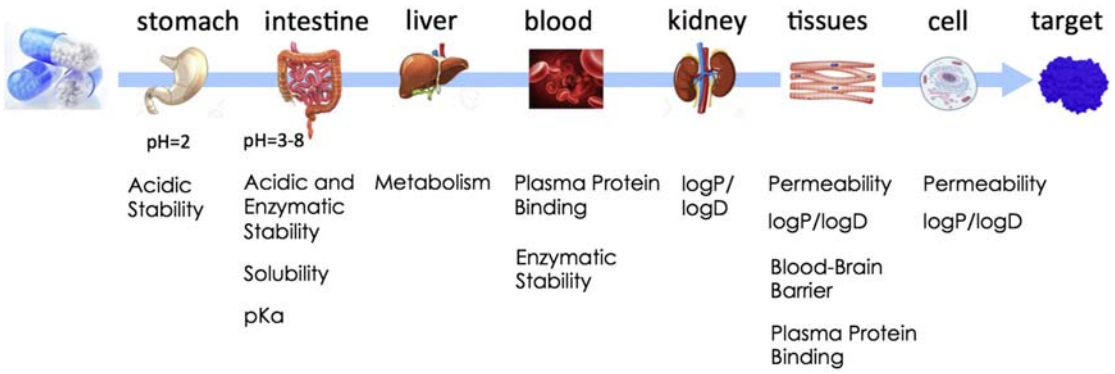

Fig. 1 Physiological and physical–chemical barriers affecting a drug bioavailability. Adapted from Kerns, E. H.; Di, L. Pharmaceutical Profiling in Drug Discovery. *Drug Discov. Today* **2003**, *8*, 316–323. Copyright (2003), with permission from Elsevier.

coefficients. Initially, Hansch employed a substituent constant approach, again in keeping with physical organic chemistry practice, and defined a substituent constant, π, thus:

$$\pi_x = \log P_x - \log P_H, \tag{1}$$

where the subscripts x and H refer to an x-substituted compound and the H-substituted (parent). Early measurements of $\log P$ showed that, broadly speaking, π values were additive but measurements became necessary for different parent systems such as phenols and anilines since there were systematic differences between them due principally to electronic effects.[6] The disadvantage of a substituent constant approach is that any models constructed using the constants are limited in terms of applicability to derivatives of the parent.

As a result of this, and because of the demonstrated importance of hydrophobic effects, focus began to be turned increasingly to the use of whole-molecule $\log P$ values. The use of whole molecule $\log P$ values prompted the development of predictive systems. The earliest of these, based on a statistical analysis of a large number of partition coefficient values, was reported in 1973.[7] This was a "reductionist" approach since it broke compounds down into a number of predefined structural fragments, which were combined with a single correction factor. Another system, based on an opposite "constructionist" approach, was published by Hansch and Leo toward the end of the 1970s[8] and this formed the basis of the first computer system for $\log P$ prediction and, indeed, one of the earliest physical–chemical property prediction programs. These early modeling approaches to drug discovery made use of measured physical–chemical properties and essentially empirical methods of prediction.

At about the same time as these studies reports began to emerge of the use of theoretical descriptors such as the correlation of antibacterial potency with superdelocalisability[9] and hallucinogenic activity with the energy of the highest occupied molecular orbital (E_{homo}).[10] The general scarcity of adequate computing resources, their low performance, and the lack of easily operated software combined to restrict the widespread use of theoretical descriptors until the 1980s.[11–13]

There was, however, one other form of theoretical descriptor, which saw widespread use from the middle of the 1970s and this was a topological descriptor known as the Randic index.[14] Topological descriptors are based solely on the standard 2D representation of a chemical structure and in their simplest form are calculated from the hydrogen-suppressed skeleton of the compound by the assignment of a degree of connectivity to each atom based on the number of atoms attached to it. The Randic index is computed by summation of the product of the degrees of connectivity of atoms over all edges of the hydrogen-suppressed molecular graph. Higher order indices may be generated by the consideration of longer paths in a molecule and other refinements have been considered, such as valence connectivity values, path, cluster, and chain connectivities.[15]

Although connectivity descriptors have been applied to compound design, they found most ready application in the area of environmental research. One of the principal reasons for this, at least in the early years of this type of research, is that the datasets tend to consist of quite diverse collections of molecules. Since topological descriptors just depend on the 2D structure with no reference to a parent, they were ideally suited for this purpose. A major problem with such parameters, though, is their physical and/or chemical interpretation and attempts were made to justify their significance.[16] This resulted in a dialog,[17,18] reminiscent of a debate, which took place between physical organic chemists over the F and R parameters (components of Hammett σ constants) of Swain and Lupton.[19] Whatever the truth or otherwise of these arguments, the debate was really about the wrong thing. If the models, which are being constructed with any type of descriptor, are intended for chemical understanding then it only makes sense to use parameters, which may be interpreted. If, on the other hand, models are being constructed solely from the point of view of prediction then the interpretability or otherwise of the descriptors used is unimportant. Since topological parameters are based on 2D structure they can be calculated very quickly, which is a great advantage when dealing with large collections of compounds such as libraries. They are also unambiguous, unlike properties derived from a 3D structure, since that structure must be generated in some way and there are debates about this and, indeed, which of the generated 3D structures is relevant. Topological descriptors have been shown to correlate with a number of different physical–chemical properties such as cavity surface area and molecular polarizability,[20] water solubility,[21] and partition coefficient[22], so there is little doubt that they do contain some chemical information. A principal component analysis of 108 molecular connectivity descriptors for a set of n-alkanes and polychlorinated biphenyls showed[23] that three principal components accounted for 98% of the variance in the dataset. These three principal components were associated with degree of branching, molecular size or bulk, and structural flexibility.

This has been a very brief and incomplete account of the development of computer-aided drug design intended to give the reader a flavor of how the field developed. A fairly comprehensive review of the description of molecules using physical–chemical properties was published at the turn of this century,[24] and to give some indication of the complexity of the field a handbook of descriptors lists over 3100 different parameters.[25]

3.16.1.4 Main Questions in the Field

An early reference work, which was subtitled "Environmental Behavior of Organic Compounds," was published by the American Chemical Society in 1990.[26] The origins of this handbook date to late 1978 when, to quote from the introduction to the book, "… with support from the US Army Medical Bioengineering Research and Development Laboratory (Fort Detrick, Frederick, MD) Arthur D. Little, Inc., undertook a preliminary problem definition study to answer the following questions:

(1) What are the important properties of organic chemicals with regard to their transport and fate in the environment?
(2) What methods are available for the estimation of these properties?

(3) What limitations and/or uncertainties are associated with these methods?
(4) Can a comprehensive user's manual incorporating the basic elements of these methods be prepared so they become not only easy to comprehend and use, but hard to misuse?"

These are excellent questions with a great deal of relevance today. The first one, despite more than 25 years of research, still remains to be answered completely although we do have many useful theories and models. The second one was partly answered in the referenced handbook and continues to be a topic of interest[27–29] including the subject of the present article. The third is important and often neglected when estimations are made, particularly when one or more estimated properties are used to calculate some further property from a model. Models, however, well developed, tested, and characterized are always dependent on the quality of the data subsequently used in them. The final question is an ongoing project with various attempts to provide this being made by different research groups.

3.16.2 Background Information on Physical–Chemical Properties

3.16.2.1 Polymorphism

A great majority of drug products marketed worldwide are formulated in oral solid dosage forms.[30] The pharmaceutical solid state may be characterized by a degree of a long-range order of molecular arrangement—in all three directions (crystalline), in one or two directions (liquid crystals), or only close-range order (amorphous). Typically, new drug candidates enter the pharmaceutical development process in molecular crystal forms, which makes it possible to ensure more desirable properties: superior stability, purity, and manufacturability relative to amorphous and liquid form formulations.

Different crystalline structures of one substance are named *polymorphs*.[31] Polymorphism, which exists as a result of different crystal packing of rigid molecules, is a *packing polymorphism*. *Conformational polymorphism* results from crystallization of different conformers of the same molecule(s), which is a more common phenomenon for typically flexible drug-like molecules. Based on an industrial solid form screening statistics, at least 50% of pharmaceutical molecules display a polymorphic behavior.[32] At any given set of environmental conditions (temperature, humidity, pressure, etc.) only one polymorph (and a corresponding solid form) is thermodynamically stable, having the lowest free energy and therefore the highest physical stability. All other forms are considered to be metastable.

Polymorphism can have impact on the performance of a drug in terms of solubility and bioavailability, chemical and physical stability, and mechanical properties.[33] Therefore, in the pharmaceutical industry, drug polymorphism can be a critical problem and is the subject of various regulatory considerations.[34,35] There are many reported cases when appearance of previously unknown more stable polymorphs significantly affected drug performance, typically causing a recall of the products from the market.[31] One of the most famous examples of polymorph-induced impact on drug performance is related to the marketed drug Norvir (ritonavir). Abbott Laboratories had to stop sales of Norvir in 1998 due to a failure in a dissolution test, which was caused by the precipitation of a more stable (and less soluble) form II of the compound.[36]

Therefore, in the pharmaceutical industry there is a strong interest in the prediction of crystalline solid-state structure and related properties of a molecule in question (ideally, with only the chemical structure known), allowing identification of potential polymorphic forms of a compound prior to synthesis in drug discovery. In addition, such calculations complement polymorph screening at early stages of drug development by facilitating an assessment of the likelihood of a missed stable form.[37]

The basic parameter to characterize a crystalline solid state and its polymorphic landscape is *lattice energy*. It corresponds to an internal energy of the crystal formation from infinitely separated molecules (in a vacuum). The lattice energy can be deduced from experimental sublimation enthalpy, $\triangle H_{sub}$,[38,39] according to the following relationship:[40]

$$E_{latt}(T) = -\Delta H_{sub}(T) + RT, \tag{2}$$

where T is the experimental temperature and R is the gas constant. The RT term is necessary to change enthalpy into an internal energy.

Since theoretical predictions of the lattice energies are typically performed at $T = 0$ K, an additional correction is needed to allow comparison with the experimental sublimation enthalpies. An approximate correction on the molecular motion contribution due to temperature differences leads to the following simple relationship:[40]

$$E_{latt}(0\,\mathrm{K}) = -\Delta H_{sub}(T) - 2RT \tag{3}$$

A significant limitation of the lattice energy property (as well as sublimation enthalpy) is that it lacks an entropic contribution and cannot accurately account for a phase transition phenomenon—such as crystal solubility or solid form conversion induced by a relative physical stability. Therefore, the most fundamental physical property of the crystalline state is a *lattice (crystal) free energy*, which is related to an experimental Gibbs (free) energy of sublimation, $\Delta G_{sub}(T)$.[41] Unfortunately, there is a very limited $\Delta G_{sub}(T)$ data available for the drug-like molecules.[38]

There are two contributions toward the lattice and sublimation energy properties—a long-range order and a short-range order, where the latter is the stronger one. Therefore, in some cases for computational considerations, a crystalline solid form may be approximated by an amorphous (or a supercooled liquid) state. In that case, energy ranking of the forms may be performed based on dominant contribution(s) into the short-range interactions. For drug-like molecules, such contribution is typically presented by intermolecular hydrogen bonding (H-bonding). The corresponding molecular property describes strength (or propensity) of the H-bonding.[42,43]

3.16.2.2 Melting (Fusion) of Crystals

The temperature at which a compound changes its state from solid to liquid at atmospheric pressure is called the *melting point* (MP). It is sensitive to the 3D structure of molecules and their packing in a crystal, which is determined by complex interactions including electrostatic, van der Waals, hydrogen bond formation (both internal and between molecules), and aromatic stacking as well as the flexibility and symmetry of molecules.[44] Therefore, MP is widely used as a criterion for compound purity and polymorph detection.

The recent increase in interest in MP prediction is connected with the development of ionic liquids (ILs).[45] By definition, ILs are a group of salts that have MP below 373.15 K, which clearly indicates that MP is a key parameter of this group of compounds. ILs have attracted great attention due to their green and tunable properties. Firstly, their negligible vapor pressures allow their use as an alternative to volatile organic solvents. Secondly, different cation/anion combinations permit fabrication of ILs with physical–chemical properties well fitted to a specific problem. Apart from the above factors influencing MP, ILs have a few specific problems: certain types of IL melt from eutectic mixtures of several crystalline polymorphs,[46] whose melting temperature is considerably lower than that of individual polymorphs. Moreover, ILs may form glasses instead of crystalline phases.[47] In this case, MP represents the glass transition temperature, which is rather different from MP of the corresponding crystalline state.

The MP can be also characterized by the free energy of fusion property, $\Delta G_{fus}(T)$ which can be presented as follows:

$$\Delta G_{fus} \approx \Delta H_{fus}\left(1 - \frac{T}{T_m}\right), \tag{4}$$

$$\Delta G_{fus} \approx \Delta H_{fus}(T_m - T)\frac{T}{T_m^2}, \tag{5}$$

$$\Delta G_{fus} \approx \Delta H_{fus}\frac{T}{T_m}\ln\frac{T_m}{T}, \tag{6}$$

where ΔG_{fus} and ΔH_{fus} are the free energy and enthalpy of fusion, respectively, T_m is the MP, and T is the temperature. Eqs. (4)–(6) are approximations based on various assumptions related to a difference in heat capacity between liquid and solid states of the compound. It was demonstrated that for drug-like molecules, approximation (5) (Hoffmann approximation) significantly outperforms approximation (4), while approximation (6) demonstrates an intermediate performance.[48]

3.16.2.3 From Condensed-Phase to Gaseous Phase

Volatility of compounds is described in terms of the *vapor pressure* (VP). It is reached when the condensed phase is in equilibrium with its own vapor (in the case of crystals, the rate of a solid's sublimation matches the rate of its vapor phase deposition).

Apart from pharmaceutical research, VP has widespread applications in environmental science since it is one of the key parameters determining the global fate of pollutants.[49] Thus, pesticides with high vapor pressures may become environmental problems because they can volatilize and disperse over a large area. Chemicals with a low vapor pressure do not move into atmosphere but they can accumulate into water, soil, and biota with respect to hydrophilic/hydrophobic properties. Volatility of pesticides is usually described with a flux (corresponding to the amount of chemical that flows from a unit of water/soil/biota surface into the atmosphere) or half-life (the time that is required for volatilization of half the chemical dose). In the case of the flux across air/water surfaces (Fig. 2) vapor pressure is required to calculate Henry's Law constant:

$$K_H = \lim_{x \to 0}\frac{p}{x} \tag{7}$$

where p is the vapor pressure of liquid and x is the molar fraction.

Due to the fact that drug-like compounds have extremely low vapor pressure, they are usually characterized in terms of sublimation thermodynamic parameters:

$$\Delta G^0_{sub} = -RT\ln\frac{p}{p^0}, \tag{8}$$

where ΔG^0_{sub} is the sublimation free energy (the free energy change that accompanies a molecule transfer from crystal to gaseous phase), p is the vapor pressure, p^0 is the atmospheric pressure (1 atm, 1.013×10^5 Pa), R is the ideal gas constant, and T is the temperature.

3.16.2.4 Dissolution and Solubility of Pharmaceuticals

3.16.2.4.1 Dissolution

Dissolution from the dosage form to the gastrointestinal (GI) fluids is the first property that has to be considered before any absorption (the movement of a drug into the bloodstream) can take place at all.[50] The Noyes–Whitney equation identifies key factors influencing the kinetics of drug dissolution:

$$DR = \frac{dm}{dt} = \frac{A \cdot D}{h}(C_s - C_b), \tag{9}$$

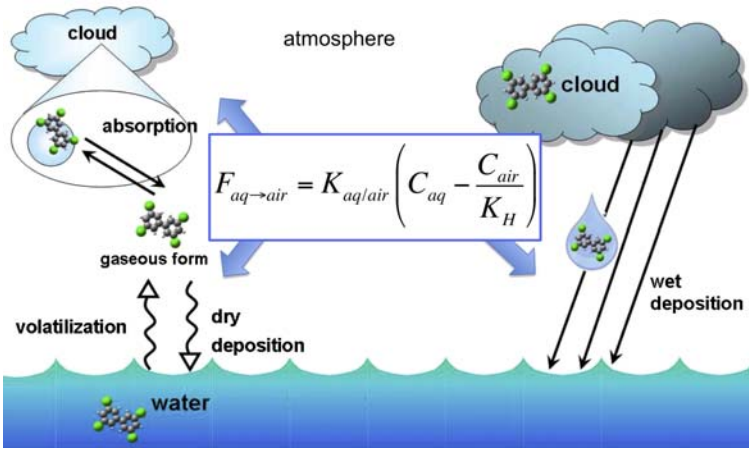

Fig. 2 Flux of a compound from aqueous media to atmosphere ($F_{aq \rightarrow air}$), where $K_{aq/air}$ is the kinetic parameter represented by the mass transfer coefficient on the molecule; C_{aq} and C_{air} are molecular concentrations of the compound in aqueous media and atmosphere, respectively. Combination of RISM and Cheminformatics for Efficient Predictions of Hydration Free Energy of Polyfragment Molecules: Application to a Set of Organic Pollutants. *J. Chem. Theor. Comp.* **2011**, *7*(5), 1450–1457. Copyright (2011) American Chemical Society.

where *DR* is the dissolution rate, *m* is the mass of the dosage form, *t* is the time, *D* is the diffusion coefficient of the drug, *A* is the surface area of the solid wetted by the luminal fluids, *h* is the thickness of the boundary layer of the solvent at the surface, C_s and C_b are mass concentrations of the drug on the surface and in the bulk of the solvent, accordingly. The last parameter corresponds to the solubility of a drug in the GI contents, which is determined by such factors as crystalline form and pK_a.

Dissolution rate of immediate release (IR) solid oral dosage forms, such as tablets and capsules, depends on the specific formulation of the drug product (particle size, solid form, etc.). An IR product is considered rapidly dissolving when at least 85% of the labeled amount of the drug substance dissolves within 30 min using standard dissolution apparatus in the following media: 0.1 M HCl or simulated gastric fluid, pH 4.5 buffer and pH 6.8 buffer or simulated intestinal fluid.[51] An IR product is considered *very rapidly dissolving* when 85% or more of the labeled amount of the drug substance dissolves within 15 min using the abovementioned conditions. Rapid or very rapid in vitro dissolutions of IR solid oral dosage forms are required in combination with some other criteria (high solubility, etc.) to justify requests for biowaivers. http://www.fda.gov/downloads/Drugs/.../Guidances/ucm070246.pdf

3.16.2.4.2 Aqueous solubility

According to IUPAC,[52] aqueous solubility can be defined as the analytical composition of a saturated aqueous solution expressed in terms of the proportion of a solute in the solvent (concentration, molar fraction, molality, density, etc.). The definition is rather too general and may comprise different solubilities of the same compound. One can distinguish the following definitions of aqueous solubility:

Equilibrium aqueous solubility is the concentration of compound in a saturated solution when excess solid is present, and solution and solid are at equilibrium (two simultaneous opposite processes: dissolution and phase joining, e.g., precipitation of solids, proceed at constant rate). Under certain conditions equilibrium solubility may be exceeded to give metastable supersaturated solution, which will carry on precipitating until the system reaches equilibrium.

Intrinsic aqueous solubility (S_0) corresponds to the equilibrium solubility of neutral form of the compound (in the case of an ionizable compound this corresponds to the apparent aqueous solubility (see below) at pH where it is fully unionized).

Apparent aqueous solubility (S_{pH}) is defined for ionizable compounds in pH-buffered solutions. If the pK_a value of a drug is known, the apparent solubility can be calculated from the intrinsic solubility using the Henderson–Hasselbalch equation:

$$S_{pH} = S_0\left(1 + 10^{\pm(pH - pK_a)}\right), \tag{10}$$

A set of Eq. (10) should be considered for compounds with multiple ionizable centers.

Kinetic aqueous solubility is the solubility at the time when an induced precipitate first appears in a solution. It can be measured much faster than equilibrium solubility, but obtained values are often much higher. The kinetic aqueous solubility is employed for high-throughput screening (HTS) at early stage drug design. In this case, compounds are not isolated in the crystal form but stored as DMSO solutions.

Thermodynamic cycles: Solubility is a function not only of chemical structure but also of crystal form.[53] To estimate the significance of the solid state one can consider a thermodynamic cycle representing dissolution at equilibrium as a sum of two processes: sublimation/fusion, which allows estimation of the effect of crystal packing, and solvation/mixing—to analyze a molecular or liquid property (Fig. 3).

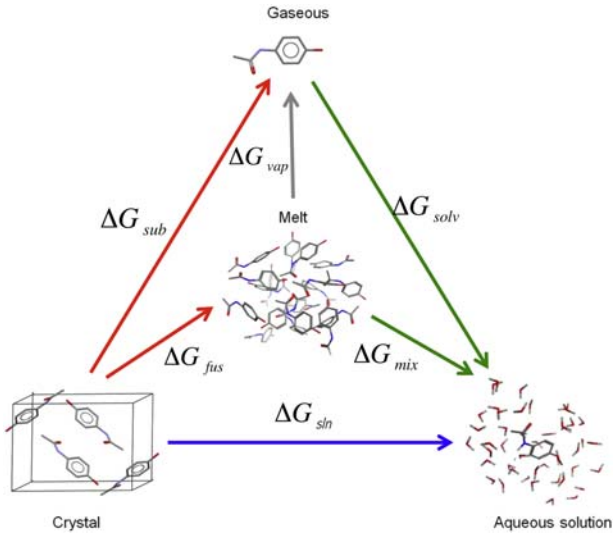

Fig. 3 Fusion and sublimation thermodynamic cycles describing aqueous solubility of crystalline compounds. Adapted with permission from Abramov, Y. A. Major Source of Error in QSPR Prediction of Intrinsic Thermodynamic Solubility of Drugs: Solid vs Nonsolid State Contributions? *Mol. Pharmacol.* **2015**, *12*(6), 2126–2141. Copyright (2015) American Chemical Society.

In this case, intrinsic aqueous solubility (referred to molar fractions) is connected to Gibbs free energy changes of the corresponding processes as follows:

$$\log S_0 = -\frac{\Delta G_{sub} + \Delta G_{solv}}{RT\ln(10)} = -\frac{\Delta G_{fus} + \Delta G_{mix}}{RT\ln(10)}. \tag{11}$$

BCS classification: Due to many cases of solubility-limited absorption, analysis of aqueous solubility is included in the early-stage drug design. Fig. 4 exhibits the minimal acceptable solubility that is required for compounds with low, medium, or high permeability values at a particular clinical dose.[54] With respect to their solubility and intestinal membrane permeability, drugs have been classified into four categories according to the Biopharmaceutics Classification System (BCS): class I, high solubility and high permeability; class II, low solubility and high permeability; class III, high solubility and low permeability; class IV, low solubility and low permeability.[55]

High aqueous solubility governs the possibility of oral administration of a drug, which is the most frequently used because of its convenience (high degree of drug stability and accurate dosage) and cost-effectiveness. However, oral drugs do not have such a high level of bioavailability (the proportion of a drug that reaches the systemic circulation) as that of drugs given parenterally. Therefore, in case absorption is not limited by intestinal permeability, the higher solubility an oral drug has, the higher bioavailability it should exhibit. Clearly, one of the key goals in pharmaceutics is solving the problem of poor drug aqueous solubility. Analysis of up-to-date databases of drug compounds shows that compounds with high biological activity (high affinity to the receptors) typically are poorly soluble in aqueous solutions.[56]

3.16.2.5 Drugs Properties in a Solution

3.16.2.5.1 Ionization constants

Many drug molecules are ionizable in aqueous media. Gaining and/or losing a proton they can form positively charged, negatively charged, or zwitterionic particles. The charge state of a drug molecule can be estimated from its ionization constant, pK_a, and pH of the medium in which the molecule is dissolved:

$$pK_a = pH - \log_{10}\left(\frac{[A^-]}{[HA]}\right), \tag{12}$$

where A^- is a conjugate base of the acid HA.

Eq. (12) corresponds to the Henderson–Hasselbalch approximation, which does not consider a proton transfer. Accounting for the process leads to the following expression:

$$pK_a = -\log_{10}\left(\frac{\left[A^-_{(aq)}\right]\left[H_3O^+_{(aq)}\right]}{\left[HA_{(aq)}\right]\left[H_2O_{(aq)}\right]}\right). \tag{13}$$

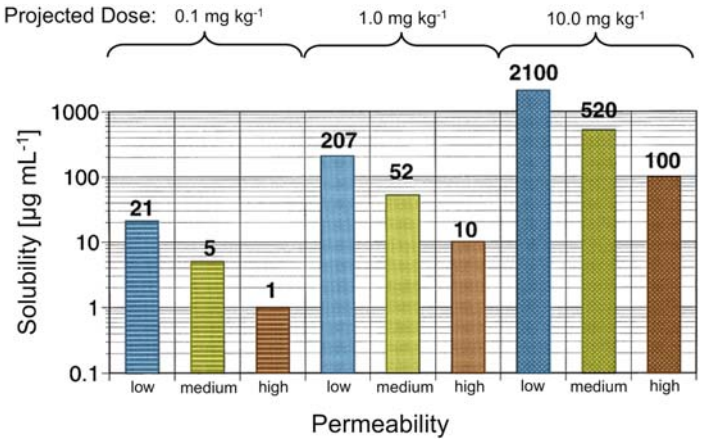

Fig. 4 Minimum thermodynamic aqueous solubility (at pH 6.5 or 7.0) that is required for low, medium, and high permeability values at a particular clinical dose. Reprinted from Lipinski, C. A. Drug-Like Properties and the Causes of Poor Solubility and Poor Permeability. *J. Pharmacol. Toxicol. Meth.* **2000**, *44*, 235–249. Copyright (2000), with permission from Elsevier.

pK_a plays a crucial role in pharmacokinetics of drugs since it significantly affects their ADME properties: absorption in GI tract, distribution in various organs, their metabolic transformation along the way, and, finally, excretion from the body (**Fig. 5**).[57]

Tautomerism: Some drug compounds can be represented by several structures (tautomers) that are related by an intramolecular movement of hydrogen from one atom to another, which is accompanied by changes of H-donor/acceptor properties of particular atoms, the rearrangement of double bonds, or ring opening/closing. Due to the fact that tautomers of a molecule have different structure, they usually have different pK_a values.[58] Therefore, even small changes in solvent environment can dramatically change the ratio of tautomers. If we consider a simplified case with two tautomers of the deprotonated state (A^-), total pK_a of the compound can be calculated as following:

$$\mathrm{p}K_a = \mathrm{p}K_a^{(1)} + \log\frac{[A_1^-]}{[A_1^-]+[A_2^-]} = \mathrm{p}K_a^{(2)} + \log\frac{[A_2^-]}{[A_1^-]+[A_2^-]}, \tag{14}$$

where $[A_i^-]$ is the equilibrium concentration of ith deprotonated tautomer of the molecule.

3.16.2.5.2 Solution stability

To reconcile slow solubility reactions to the HTS needs of drug discovery research, candidate compounds are not isolated in the crystalline form but are stored in DMSO solutions under various physical conditions.[57] The choice of the solvent is quite

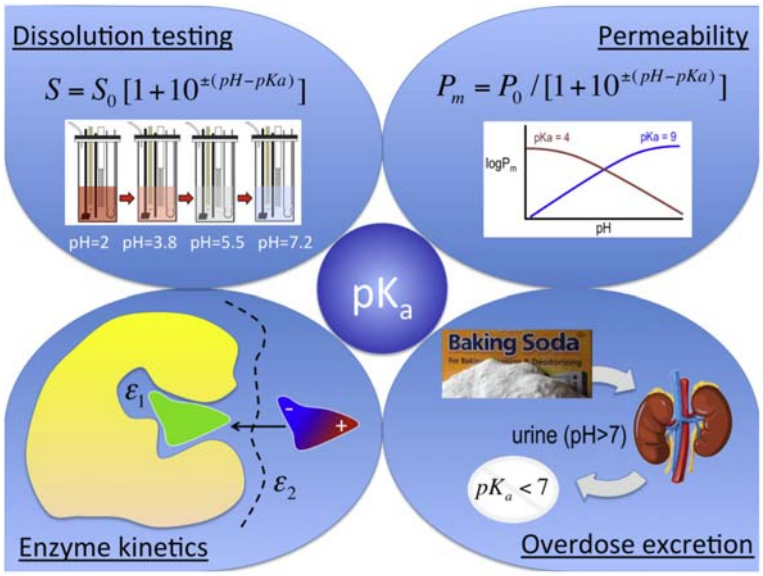

Fig. 5 Examples of pK_a application in pharmaceutical industry.

Copyright (2010).

understandable; around 90% of the compounds that end up in a library will dissolve in DMSO (in chloroform or acetone, the figure is only 70%).[59] However, it is not an inert solvent. In addition to its mild reactivity, DMSO adsorbs a considerable amount of water. This causes the problem that part of that liquid stored can decompose over time (e.g., due to oxidation and hydrolysis). Degradation in stock solutions may occur also due to oxygen that gets absorbed from the air, light, heat, and trace materials (e.g., HCl, TFA, OH^-, and metals).[60] Degradation products of drugs in solution might have increased or decreased activity or toxicity than the parent compound, which can lead to either false positive or false negative conclusions in bioassays, and confuse structure–activity relationships.

3.16.2.6 Passive Transport of Drugs

Permeability is a measure of how fast a compound passes through a lipid membrane. Permeability of a drug through physiological barriers such as membranes of intestinal epithelium and blood–brain barrier is one of the key determinants of drug bioavailability. Generally, drugs can penetrate across a membrane passively or/and actively (Fig. 6).[61] In the case of macromolecules, compounds are very large and must be transported across membranes in vesicles (endocytosis/exocytosis).

Passive diffusion is considered as the primary route of membrane permeation for the majority of drugs in many cell types (e.g., in intestinal membrane permeation). The driving force of the process is the concentration gradient of a drug; a membrane does not actively participate in it. Passive diffusion can take place either through lipid structures of a membrane—*transcellular diffusion*, or through its aqueous pores and/or tight junctions—*paracellular transport*. In turn, active transport is assumed to coexist with passive diffusion for such cases as brain and liver distribution, and in renal excretion.[62]

It has being a long-term challenge to rationalize membrane permeability with physical–chemical properties.[63] Logarithm of *partition coefficient* ($\log P$) of a compound in equilibrium between two immiscible media (water and organic phases) is the most widely used parameter for this purpose:

$$\log P_{orq/wat} = \log \frac{[HA]_{org}}{[HA]_{wat}}, \tag{15}$$

where $[HA]_i$ is the equilibrium concentration of a compound in the compartment i. However, $\log P$ is applicable only for unionized drugs since it does not reflect the pH of media and acidity/basicity of a compound. The drawback can be overcome with the logarithm of distribution coefficient ($\log D$), which accounts for ionizable particles:

$$\log D_{org/wat} = \log \frac{[HA]_{org}}{[HA]_{wat} + [A^-]_{wat}}, \tag{16}$$

If $\log P$ and acid/base behavior of a drug are known, the $\log D$ can be calculated as following:

$$\log D_{org/wat} = \log P_{org/wat} - \log\left(1 + 10^{\pm(\mathrm{pH}-\mathrm{p}K_a)}\right), \tag{17}$$

It is a common practice to measure $\log D$ at pH 7.4, store these values in databases, and use them for QSAR/QSPR predictions. *n*-Octanol is the most widely used solvent to mimic cell membranes, despite the fact that it poorly reproduces the structure of the phospholipid bilayer. Different shapes of permeability—$\log D$ (water/octanol) relationship were reported: linear,[64] hyperbolic,[65] sigmoidal,[66] parabolic,[67] etc. In 1998, Camenisch et al.[68] suggested an aqueous pore model of diffusion, which brought some light to the problem (Fig. 7). The model was analyzed for compounds with various molecular weights (MWs). For low MW compounds they obtained sigmoidal shape of the relationship which corresponds to (i) diffusion through aqueous pores of hydrophilic compounds, and (ii) transcellular transport of lipophilic compounds, which became so rapid that convective diffusion through

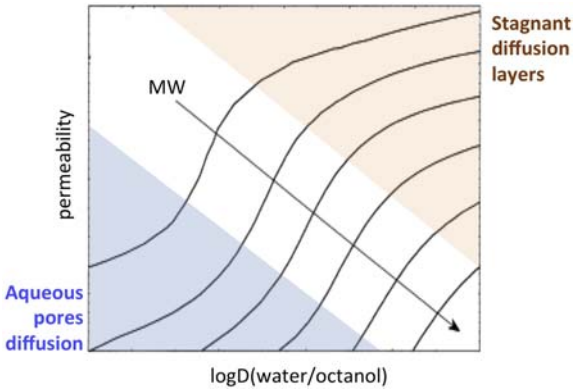

Fig. 7 Model correlation between permeability and log *P*(*oct*/*wat*). Simulation curves as a function of increasing MW. Reprinted with permission from Camenisch, G.; Folkers, G.; van de Waterbeemd, H. Shapes of Membrane Permeability-Lipophilicity Curves: Extension of Theoretical Models With an Aqueous Pore Pathway. *Eur. J. Pharm. Sci.* **1998**, *6*, 321–329. Copyright (1998), with permission from Elsevier.

the stagnant layers is rate limiting. In turn, for higher MW compounds the shape was found to be bilinear/hyperbolic, which can be described with a simple diffusional resistance model of van de Waterbeemd.[69]

Nevertheless, *n*-octanol does not always function as the universal standard for all types of membranes. For example, isopropyl myristate was found to be a better model for skin lipids permeability studies.[70] To cover the variation in biophysical characters of different membrane types, Taylor and coworkers[71] proposed a set of four solvents, the "critical quartet": *n*-octanol (amphitropic), alkane or 1,2-dichloroethane (inert), chloroform (proton donor), and propylene glycol dipelargonate (proton acceptor).

3.16.3 What Methods are Available for the Estimation of These Properties?

3.16.3.1 Physics-Based Methods

A comprehensive description of the main physics-based methods such as QM (quantum mechanics) and MD (molecular dynamics) are out of scope of this publication. Here, we give a short introduction to alternative approaches, which are of great value for physical–chemical properties prediction.

3.16.3.1.1 COSMO-RS

Conductor-like screening model for real solvents (COSMO-RS) is based on the statistical thermodynamics of interacting molecular surface segments. The polar and H-bond interactions are described by the surface screening charge densities, which result from a quantum-chemical continuum solvation calculation (COSMO solvation approach).[72–75] COSMOtherm is the first available and most advanced implementation of COSMO-RS theory.

(i) *COSMO*: Firstly, a gas-phase geometry optimization of a solute should be performed (Fig. 8A). Charge distribution of the solute is estimated. Secondly, a molecular shaped cavity is constructed around the solute molecule (Fig. 8B). The details of the cavity construction differ in various COSMO implementations. In most cases, it is constructed as an assembly of atom-centered spheres with radii approximately 20% larger than the van der Waals radius. For the actual calculation the cavity surface is approximated by a set of surface segments (e.g., hexagons). Thirdly, the solvent is treated as a dielectric continuum with a permittivity $\varepsilon = \infty$ (perfect conductor), surrounding the solute molecules outside of a molecular cavity. The dielectric polarization of the continuum is represented by a set of Coulomb charges $\underline{q}$ placed on the surface segments (Fig. 8C). They are calculated by a linear set of equations:

$$\underline{\underline{A}}\,\underline{q} + \underline{\underline{B}}\,\underline{Q} = 0, \tag{18}$$

where $\underline{Q}$ is the charge distribution of the solute, and $\underline{\underline{A}}$ and $\underline{\underline{B}}$ are linear operators dependent on the boundary conditions. Unlike other continuum solvation models, which employ the exact boundary conditions, COSMO uses scaled-conductor approximation:

$$\underline{\underline{A}} = \underline{\underline{V}} \quad \text{and} \quad \underline{\underline{B}} = \frac{\varepsilon - 1}{\varepsilon + x}\underline{\underline{V}}, \tag{19}$$

where $\underline{\underline{V}}$ is a matrix generating the electrostatic potential on each surface segment caused by polarization charges $\underline{q}$ (the potential is readily available in every QM program), and the value of x is set to 0.5 based on theoretical arguments. Then, the screening charges of surface segments (σ-surface) are resubstituted as external charges. This yields a modified electron density of the solute and requires repetition of the second step. Both sets of charges, $\underline{q}$ and $\underline{Q}$, are self-consistently optimized to find the minimum energy of the system. This can be achieved by different empirical, semi-empirical, or *ab initio* methods. In most cases, DFT methods are employed as these currently represent a good compromise between computational effort and reliability of the result. Finally, histograms of screening charge densities, the so-called σ-profiles, $p(\sigma)$, are constructed (Fig. 8D). They give the relative amount of

surface with polarity σ for the solute molecule. In the case of flexible molecules or components with different tautomeric forms, the calculation needs to be repeated for different conformers and/or tautomers. The resulting geometries, energies, and σ-profiles are calculated only once and stored for later use in the so-called COSMO files.[76]

(ii) *COSMO-RS*: Methodology treats the solvent as an ensemble of pairwise interacting surface segments (**Fig. 8E**). The interaction energies of the surface pairs are defined in terms of screening charge densities σ and σ' of the respective surface segments:

$$\Delta E_{int}(\sigma,\sigma') = \Delta E_{misfit}(\sigma,\sigma') + \Delta E_{HB}(\sigma,\sigma'), \tag{20}$$

where ΔE_{misfit} is the electrostatic energy change corresponding to the difference in two polarities (in the case of perfect fit of the polarities $\sigma = -\sigma'$, e.g., in a perfect conductor, the term would be zero), ΔE_{HB} is an empirical term accounting for hydrogen bonding. In addition, there is van der Waals energy term, $E^X_{vdW}(A^X_\alpha)$, describing energy gain of a molecule X during the transfer from the gas phase to a solvent. Because this *vdW* term is independent of the neighborhood, it is not really an interaction energy, but it is considered as an additional contribution to the energy of the reference state in solution. $E^X_{vdW}(A^X_\alpha)$ is represented as a surface proportional term with element-specific coefficients. A^X_α is the COSMO surface on atom α. If we consider an ensemble of solvent molecules, its energy in comparison to the perfect conductor state can be expressed as the sum over all surface contacts k:

$$\Delta E^S_{tot} = \sum_k \Delta E_{int}\left(\sigma_k, \sigma'_k\right), \tag{21}$$

Instead of calculating all different mutual contacts of the three-dimensional representations of the molecules, a further approximation is introduced. A surface piece with polarity σ is added to the surface of a solvent molecule (**Fig. 8F**). The chemical potential of the process is calculated using the probability $p_S(\sigma')$ to find a certain polarity inside the solvent and the corresponding interaction energy:

$$\mu_S(\sigma) = -kT \ln \int p_S(\sigma') \exp\left\{-\frac{\Delta E_{int}(\sigma,\sigma')}{kT}\right\} d\sigma'. \tag{22}$$

Due to the fact that $\mu_S(\sigma)$ is present on both sides of Eq. (22), it needs to be solved iteratively with the first approximation of $\mu_S(\sigma') = 0$. The final step of COSMO-RS consists in the evaluation of the chemical potential of any solute molecule X in the solvent S as following:

$$\mu^X_S(\sigma) = \int p^X(\sigma)\mu_S(\sigma)d\sigma + kT\ln\left(x\gamma^X_{comb,S}\right). \tag{23}$$

The logarithmic term takes into account the dependence of the chemical potential of solute X on its mole fraction x, and a correction for the relative sizes of solute and solvent molecules.

3.16.3.1.2 UNIFAC

Universal quasichemical functional-group activity coefficients (UNIFAC) is based on combination of a group approach with an activity coefficients model UNIQUAC.[77] In principle, the statistical thermodynamic problem in UNIFAC is analogous to that in COSMO-RS; both approaches consider an ensemble of pairwise interacting species: surface segments in COSMO-RS (characterized by the screening charge density σ), and functional groups in UNIFAC (characterized by *vdW* volume and surface area). Instead of calculations of the corresponding interaction energy as a function of the interaction species parameters (as it was implemented in COSMO-RS), UNIFAC employs empirical pairwise interaction parameters, which are related to the interaction energy. In fact, UNIFAC is focused on the calculation of the activity coefficient of a molecule:

$$\ln \gamma_i = \ln \gamma_i^C + \ln \gamma_i^R, \tag{24}$$

where the combinatorial term (with superscript C) takes geometrical (entropic) effects into account, while the residual part (with superscript R) considers enthalpic interactions. The residual activity term, which is employed in vapor pressure calculations, can be estimated as the following (for a pure compound):

$$\ln \gamma^R = \sum_k \nu_k \ln \Gamma_k = \sum_k \nu_k Q_k \left(1 - \ln\left(\sum_m \Theta_m \Psi_{mk}\right) - \sum_m \frac{\Theta_m \Psi_{km}}{\sum_n \Theta_n \Psi_{nm}}\right), \tag{25}$$

where ν is the number of groups, Γ is the group residual activity coefficient, Q is the group van der Waals surface area, Θ is the surface area function, which is a function of x (the group mole fraction, Eq. (26)), Ψ is the group interaction parameter.

$$\Theta_m = \frac{Q_m x_m}{\sum_n Q_n x_n}. \tag{26}$$

3.16.3.1.3 SAFT

Statistical associating fluid theory (SAFT) is a method comprising theoretically based equations of state, originating in Wertheim's first-order perturbation theory.[78] In the SAFT approach, molecules are described as chains of bonded homonuclear monomer segments interacting via dispersion and associating forces (Fig. 9).

The Helmholtz energy of a fluid (a^{res}) is obtained by summing different contributions that account for (i) the monomer–monomer interactions (a^{seg}), including both reference system (e.g., hard-sphere) and dispersion terms, (ii) chain formation, and (iii) intermolecular association:

$$a^{res} = a^{seg} + a^{chain} + a^{assoc}. \tag{27}$$

If the Helmholtz free energy of a fluid is known, all other properties such as pressure, chemical potential, among others, can be calculated using basic thermodynamic equations.

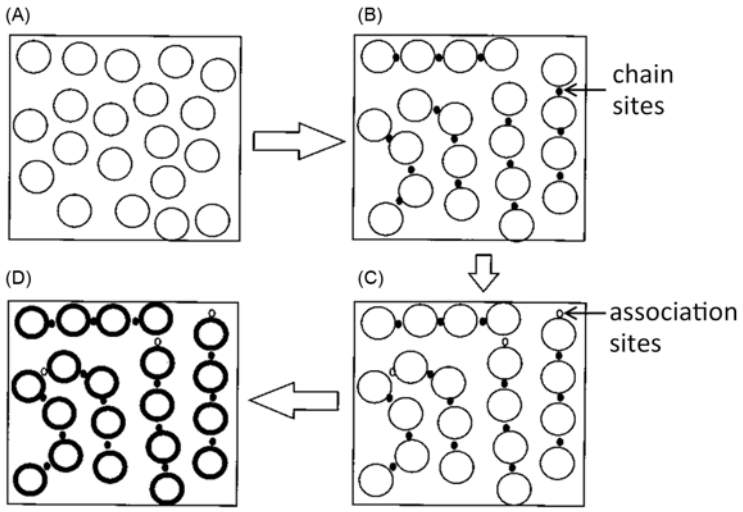

Fig. 9 Schematic representation of the physical basis of the SAFT model: (A) the reference fluid consists of hard spheres (repulsion forces only), (B) the reference fluid forms chains through covalent bonding (chain sites are added), (C) different chains form association complexes (oligomers) through hydrogen bonding between their terminal sites (association sites are added), (D) dispersive potential is added to account for attractive forces. Adapted with permission from Economou, I. G. Statistical Associating Fluid Theory: A Successful Model for the Calculation of Thermodynamic and Phase Equilibrium Properties of Complex Fluid Mixtures. *Ind. Eng. Chem. Res.* **2002**, *41*(5), 953–962. Copyright (2002) American Chemical Society.

During the past two decades, many versions of SAFT equations have been proposed, including original SAFT, Chen-Kreglewski SAFT (CK-SAFT), simplified SAFT, Lennard-Jones SAFT (LJ-SAFT), soft-SAFT, variable-range SAFT (SAFT-VR), perturbed-chain SAFT (PC-SAFT), and simplified PC-SAFT.[79] The principal differences among SAFT versions are in a^{seg} contribution, which requires the choice of reference system and description of repulsive and attractive interactions. Expressions for chain and association terms (a^{chain} and a^{accos}) correspond to Wertheim contributions, which stay unchanged in various versions of SAFT.

SAFT-type models contain a number of parameters for pure compounds. Typically, they contain 3–4 parameters for nonassociating compounds: the segment energy and diameter, the number of segments, polar term; and additionally two parameters: the association volume and energy, for associating compounds. The parameters are estimated from experimental data on vapor pressure and liquid density (optionally, monomer fractions and enthalpies of vaporization can be used).

However, the combination of SAFT equations with group-contribution type schemes (GC-SAFT) allows thermodynamic property (e.g., vapor pressure) predictions based solely on the chemical structure. As in the previous case, functional group parameters are determined by fitting the theory to experimental data but only for the smaller members of the chosen chemical families, whereas phase behavior of larger MW compounds (which were not included in the parameter estimation) is calculated using the obtained data without reparameterization.

3.16.3.1.4 3D RISM

3D reference interaction site model (3D RISM) is a statistical mechanical approach describing thermodynamic properties of molecular liquids.[80,81] It has a special place among implicit solvent methods, since it combines a reasonable level of molecular description of the solvent with low computational costs.[82] Within the approach a system is described in terms of intermolecular, $h_\alpha(\mathbf{r})$ and $c_\alpha(\mathbf{r})$, and intramolecular, $\omega_{\zeta\alpha}(r)$, correlation functions (Fig. 10). The functions are connected via a set of 3D Ornstein–Zernike equations and corresponding closure relations:

$$\begin{cases} h_\alpha(\mathbf{r}) = \sum\limits_{\zeta} \int c_\zeta(\mathbf{r}-\mathbf{r}')\chi_{\zeta\alpha}(|\mathbf{r}'|)d\mathbf{r}' \\ h_\alpha(\mathbf{r}) = \exp\{-\beta u_\alpha(\mathbf{r}) + h_\alpha(\mathbf{r}) - c_\alpha(\mathbf{r}) + B_\alpha(\mathbf{r})\} - 1 \end{cases} . \tag{28}$$

Here $u_\alpha(\mathbf{r})$ is the interaction potential, $B_\alpha(\mathbf{r})$ is the bridge functional, $\chi_{\zeta\alpha}(r)$ is the site–site bulk solvent susceptibility function, which is defined as following:

$$\chi_{\zeta\alpha}(r) = \omega_{\zeta\alpha}(r) + \rho h_{\zeta\alpha}(r). \tag{29}$$

Iterative solution of Eq. (28) yields intermolecular correlation functions of the system at thermodynamic equilibrium, which are further employed to calculate physical–chemical parameters of interest.

3.16.3.2 Statistical Methods

A large number of statistical and machine learning methods are used to predict physical–chemical properties of molecules. Traditionally methods can be separated into two large groups: linear and nonlinear methods. The use of both types of methods is strongly related to their assumptions as well as complexity of the analyzed problems and the used descriptors.

3.16.3.2.1 Linear methods

Linear methods, such as multiple linear regression analysis (MLRA), frequently assume an additivity of the investigated properties from the used descriptors. For some properties, for example, MW, which is calculated as a sum of contribution of individual atoms,

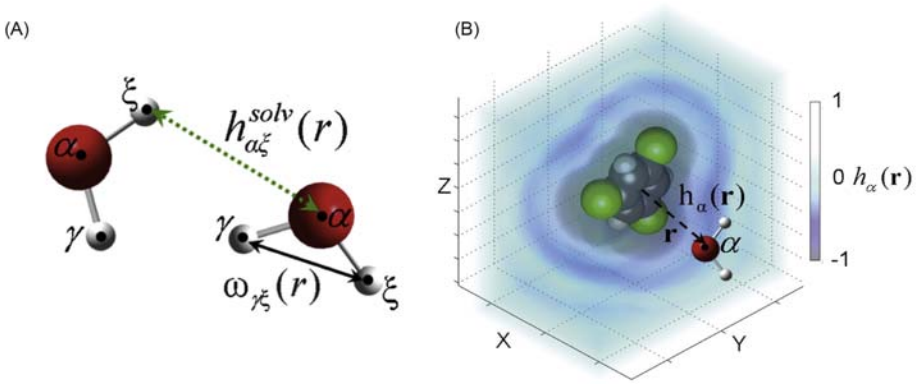

Fig. 10 3D-RISM correlation functions: (A) site–site intramolecular correlation functions ($\omega_{\gamma\xi}(r)$) and intermolecular correlation functions ($h_{\alpha\xi}(r)$) between sites of solvent molecules, (B) intermolecular site–molecule correlation function $h_\alpha(\mathbf{r})$ between α site of solvent and center of mass of solute. Solvation Thermodynamics of Organic Molecules by the Molecular Integral Equation Theory: Approaching Chemical Accuracy. *Chem. Rev.* **2015**, *115*(13), 6312–6356. Copyright (2015) American Chemical Society.

as well as for several other properties such as molecular refraction and parachor, such assumptions work very well. For more complex properties the additivity may not work and in order to account for deviations from linearity the equations start to include correction factors to account for nonlinear interactions. For example, the XLOGP program[83] includes four such factors, that is, number of hydrophobic atoms, indicator of amino acids, intramolecular hydrogen bonds, and halogen–halogen interactions.

In case additivity schemas based on atom contributions do not work very well, it is possible to use a more complex description of molecules, such as functional groups. They divide a molecule into chemically significant substructures, thus capturing interactions among its atoms and allowing the representation of the molecule at a higher level of description. The methods, which use the additivity principle to predict properties based on contribution of nonoverlapping groups, are also known as linear free energy relationships (LFER) methods. These methods actually assume that (for a congeneric series of compounds) an influence of a structural feature on the free energy change of a chemical process is constant. The properties, which depend on the free energy, thus can be approximated as a sum of a property of a basic structure (which can be also just one group) as well as a sum of properties of nonoverlapping predefined fragments. Frequently not only groups but also their interactions are used. For example, UNIFAC (see section "UNIQUAC functional-group activity coefficients") is widely used to predict nonelectrolyte activity in nonideal mixtures by using experimentally measured interaction parameters between the functional groups.

While functional groups in combination with linear methods are useful and easily interpretable, they may provide insufficient accuracy for modeling of some properties and their design can require considerable effort and chemical expertise. Such efforts are currently actively explored in an attempt to identify, for example, frequent hitters for high throughput screening (HTS) data analysis.[84,85] The functional groups, such as "toxicophores," are also used to identify molecules that are toxic, unstable, reactive, or frequent hitters.[86] One can also develop general purpose groups covering, for example, heterocyclic compounds, which could be useful for prediction of various properties.[87]

Instead of using predefined groups one can also generate all possible fragments of a predefined length, as is done in Isida fragmentor.[88] In addition to functional groups, the users can generate multiple descriptors using different software tools. For example, Dragon[25] currently includes 5270 descriptors separated in 30 different blocks. The analysis of such large descriptor sets can be also performed using linear regression methods. However, regression models derived using such sets are more difficult to analyze compared to LFER approach due to intercorrelations and dependencies amid the descriptors.

3.16.3.2.2 Nonlinear (machine learning) methods

Nonlinear methods, such as support vector machines (SVM),[89] neural networks (NN),[90] random forest (RF),[91] or metaheuristic algorithms, such as genetic algorithms (GA) and evolutionary programming (EP),[92] and many others were inspired either by the organization of the brain (NN), and/or natural evolution (GA and EP) or advances in statistical learning theory (SVM) and statistical properties of ensembles of models (RF). One of the most recent developments in this field includes deep learning NN,[93] which can find a lot of applications in the drug discovery field and is becoming an attractive method for the prediction of physical–chemical and biological properties of compounds.[94]

The machine learning methods usually provide better accuracy of predictions in comparison to linear methods, which justifies their application for prediction of different properties as shown in the respective articles below. At the same time models developed using these methods are more difficult to analyze compared to linear models. The interpretation of models using predicted matched molecular pairs (MMPs),[95] or based on descriptors used to generate models[96] represent important approaches to get deep insight into the models.

The model development includes several important steps: data preparation, descriptors selection, model development, and model validation.[97] The model validation performed as the last step is frequently based on prediction of test sets and/or on a cross-validation method. In the cross-validation method part of training set samples (e.g., 20% for fivefold-cross validation) are used as a test set and a new model is developed without them. The developed model is then used to predict the test set compounds. The exclusion of samples is repeated until all training samples are predicted. The predicted values for compounds in the test set are used to estimate the accuracy of models. Thus, this method reuses the whole training set as a test set. However, if validation of models is performed after optimization of parameters of models and, in particular, variable selection, it can be biased.[98] In order to avoid this problem all model development steps should be repeated.

Model development can be implemented manually or be executed on the web using integrated environments, such as the On-Line Chemical Database and Model Environment (OCHEM)[99] or CHEMBENCH.[100] The advantage of the use of the web platforms is that models published by them are publicly available to the research community and can be used by all interested partners on the web without a need to reimplement published models.

3.16.4 Applications and Limitations of the Methods for Physical–Chemical Properties Prediction

3.16.4.1 Polymorphism

There are two major applications of crystalline polymorphism prediction in the pharmaceutical industry. One is related to improving the solubility of crystalline compounds at early stages of drug discovery. This may be achieved by a better description of solid-state contribution to the solubility. Another application is related to an estimation of the likelihood of existence of a new stable form missed during initial experimental polymorph screening.[37]

3.16.4.1.1 Physics-based models

3.16.4.1.1.1 Crystal structure prediction

The most logical and at the same time the most complicated theoretical physical approach to study pharmaceutical crystalline solid form and polymorphism is based on the crystal structure prediction (CSP) approach. Milestones of the CSP method developments and compound complexity progress are reflected in the results of six blind tests,[277] and are covered in recent comprehensive reviews.[101–103] However, in spite of over 20 years of method development, it is only recently that a focus of CSP studies has shifted toward drug-like molecules. In addition, until recently the CSP studies were rarely verified by experimental polymorph screening. Examples of pharmaceutical molecules, for which combined computational and experimental solid form screenings were performed, are presented in **Fig. 11**.

Current CSP techniques describe the possible polymorphism of an organic molecule via lattice energy minimization. Minima of the lattice energy landscape within a certain energy range describe thermodynamically feasible polymorphs of the molecule at $T=0$ K. A schematic representation of CSP steps by global lattice energy minimization is presented in **Fig. 12**.

The resulting lattice energy values (and *in silico* polymorph stability ranking) reflect interplay between molecular (energy penalty relative to a free molecule in the gas phase) and intermolecular (interactions between the molecules in crystal) contributions:

$$E_{latt} = E_{intra} + E_{inter}. \tag{30}$$

The improvement of intrinsic solubility via the application of CSP is based on utilization of the sublimation thermodynamic cycle of solubility (**Fig. 3**). The thermodynamic cycle describes the intrinsic thermodynamic aqueous solubility as an interplay between crystal packing and molecular hydration contributions. There was recently presented a novel method, solid-state perturbation,[104–106] which perturbs both of these contributions by substitution of selected hydrogen atoms of a given molecule by a small group (such as, methyl, fluoro, or chlorine). The method is based on the assumption that the differences in free energy of sublimation within a drug compound series are dominated by enthalpic rather than entropic contributions, and one should expect a simple linear model between the intrinsic solubility and predicted CSP lattice and hydration energies:[104,105]

$$\log S_0 = \ln\left(\frac{p_0}{RT}\right) - \frac{\Delta H_{sub}}{RT} + \frac{\Delta S_{sub}}{R} - \frac{\Delta G_{hydr}}{RT} \approx k_1 + k_2\left(E_{latt} - \Delta G_{hydr}\right). \tag{31}$$

The solid-state perturbation method was validated on the benzodiazepines series (including nordiazepam),[104,105] GPR119 ligands,[106] and benzoylphenylurea (unpublished data of Yu. Abramov), in all studies correctly predicting the trend of the intrinsic solubility, allowing the most significant perturbations to be identified. As an example, the result of application of the solid-state perturbation method to benzodiazepines is presented in **Fig. 13**.

In application to the likelihood of a missed stable form, interpretation of different crystal energy landscape patterns depends on the energy separation of the predicted observed structure from all other real or potential polymorphic forms. An ideal scenario supporting a low likelihood of a missed stable form is described by a pattern in which the observed crystal form is a global minimum in lattice energy separated from all other structures by a considerable energy gap. The proposed energy gap is 6 kJ mol^{-1} or higher depending on the level of theory.[102] The oncology drug crizotinib (Xalcory)[37] and the antibacterial drug candidate sulopenem[107] (**Fig. 14**) are two reported pharmaceutical examples of a true monomorphic behavior in which the observed most stable forms are separated from all other simulated potential structures by an energy gap of ~8 and ~7 kJ mol^{-1}, respectively.

Strictly speaking, due to the limitations discussed below all other lattice energy landscape patterns cannot by themselves testify to a low likelihood of a missed stable form, and in certain cases may suggest that additional polymorph screening is required.

An interpretation of crystal energy landscapes should be performed bearing in mind *the limitations and challenges* of the CSP methodology:[37]

- *Potential energy*. The energy difference between possible structures is typically very small so that virtual polymorph ranking strongly depends on the way the lattice energy is calculated. Different methods may give significant differences, even in prediction of relative stabilities of observed polymorphs.[108,109] The density functional theory with dispersion energy corrections and a model with distributed multipole expansion of electrostatic interaction (DMA) appeared to be the most successful methods of the CSP.[110]
- *Temperature effect*. One of the most important limitations of polymorphism prediction by typical CSP techniques is related to the fact that the free energy landscape of possible crystal structures at ambient temperature is approximated by a static lattice energy landscape at $T=0$ K. It was recently demonstrated for 508 polymorphic organic molecules that though the distribution of vibrational energy differences between polymorphs is rarely exceeding 2 kJ mol^{-1}, these contributions are large enough to cause a reranking of polymorph stability below or at ambient temperature in 9% of the polymorph pairs.[111]
- *Kinetics effect*. Barriers of transformation between minima of the lattice energy landscape, which are important for polymorph kinetics, are typically not considered by the current CSP methods. It is reasonable to assume that kinetic effects may account for a lower number of observed polymorphs relative to the predicted ones.
- *System complexity*. The computational challenges of performing accurate CSP studies quickly increase with the system complexity (molecular size and flexibility, and number of molecules in an asymmetric unit cell).

3.16.4.1.1.2 Hydrogen bonding propensity approach

An alternative simplified approach to the classification of polymorph stability is based on selected dominant interaction analyses. Since H-bonds are the strongest and most specific (directional) interactions, they typically play a dominant role in the crystallization and stability of pharmaceutical solids. Therefore a probabilistic approach to analyses of organic crystal stabilities was recently developed[112] based on statistical analysis of hydrogen bonds in the Cambridge Crystal Structure Database (CSD).[113] This knowledge-based method analyzes potential H-bonding functional groups of a molecule of interest to predict statistically likely pairwise H-bonding interactions in the stable crystalline form. According to this approach, a crystal structure that adopts the highest propensity H-bonds displays a low likelihood of the existence of a more stable form indicating that the polymorph screening was likely to be complete. In contrast, the presence of only low propensity H-bonds indicates a high risk of existence of a more stable form and an additional study is likely to be required. Successful applications of the knowledge-based approach to multiple drug-like systems were reported in the literature for ritonavir,[114] N^2-(indol-3-ylacetyl)-L-asparagine,[112] lamotrigine,[115] crizotinib,[37] axitinib,[37] and sulopenem.[107]

An alternative and complementary approach to the knowledge-based one is based on theoretical prediction of H-bonding strength (propensities). From the diversity of the available theoretical methods of H-bonding analysis two approaches, COSMO-RS σ_{HB} charges and QTAIM (Quantum Theory of Atoms in Molecules), are the most popular in application to evaluation of stability of the crystalline solid form.[43]

There are several important limitations in stability ranking based on H-bonding propensity analysis in addition to the fact that H-bonding is not the only contribution to the stability of drug-like crystals. Similar to the CSP approach, the models based on the propensity of the H-bonding interaction generally cannot account for the temperature-dependent relationship between the polymorphic forms. In addition, an inherent limitation of the H-bonding propensity methods (the knowledge-based and the σ_{HB} charges analysis) is the inability to estimate the stability ranking of the polymorphs, which preserve similar H-bonding interactions.[37]

3.16.4.1.2 Statistical methods

Statistical approaches cannot replace physics-based methods (like CSP) in the prediction of molecule's polymorphic landscape. However difficulties in experimental determination of sublimation energy, along with significant computational complexity of CSP methods, make QSPR models an attractive alternative approach for calculation of representative values of lattice energies of drug-like molecules. Many studies have reported lattice or sublimation energy models of organic compounds based on QSPR/QSAR approaches. The reported QSPR models used a variety of statistical approaches (comparative molecular field analysis (CoMFA),[116] variations of MLR,[117–119] and NN[118,120] approaches, nearest neighbors,[38] RF,[127] and Cubist (https://www.rulequest.com/cubist-info.html)[126,127] and descriptor sets (VolSurf,[122] Dragon,[25] charged partial surface area (CPSA),[124] hydrogen bond thermodynamics (HYBOT),[125] fragment-based or group contribution (GC)). However many of the reported models were focused on a small dataset of homologous (and nondrug-like) series and are therefore of less interest to pharmaceutical applications.

A remarkably simple and relatively accurate ΔH_{sub} QSPR model was reported by Maryam Salahinejad et al.[118] In that study VolSurf and CPSA descriptors were utilized to build a four-parameter linear model based on a dataset of 1302 chemically diverse organic molecules:

$$\Delta H_{sub} = -(23.5 \pm 0.3) + (386.7 \pm 12.8)\mathrm{FPSA3} + (0.385 \pm 0.019)\mathrm{PSA} + (0.114 \pm 0.003)V + (0.0495 \pm 0.0027)W1. \quad (32)$$

Here, $W1$ is the volume of a molecular envelope at the selected energy level, which is accessible to and interacts favorably with water molecules. FPSA3 is the fractional CPSA, V is the water-excluded molecular volume, and PSA is the polar surface area. The model performance for a test set was reasonably good: $R^2_{test} = 0.95$, standard error of estimation (SPE) = 7.88 kJ mol^{-1}.

The same dataset was used for building a nonlinear recursive partition Cubist algorithm[122] utilizing VolSuf descriptor set.[126] The model performance for a test set of 260 compounds ($R^2_{test} = 0.97$, RMSE = 5.8 kJ mol^{-1}) appeared to be quite comparable with that of the MLR model. This observation supports the suggestion that the relationship between the molecular descriptors and the enthalpy of sublimation is predominately linear.[118]

The aforementioned Cubist ΔH_{sub} QSPR model was used to develop an approach describing compound solubility as interplay between molecular solvation features and packing properties.[126] The approach was based on a treatment of the crystal packing contribution to equilibrium solubility based on ΔH_{sub} QSPR calculations and a quantum mechanical treatment of solvation effect via free energy of mixing, ΔG_{mix}, of the supercooled liquid phase of the molecule of interest with water (**Fig. 15**). This model allows evaluating the source of poor solubility (crystal packing vs. molecular solvation) of a drug-like molecule. The model also allows prediction of likely solubility changes associated with molecular modification with no knowledge of the crystal solid state needed. Such an approach is attractive for lead optimization in pharmaceutical discovery where multiple compounds with limited structural experimental information are evaluated.

There are a limited number of studies reporting QSPR models of Gibbs energy of sublimation. Perlovich and Raevsky used 965 experimental observations to build a ΔG_{sub} QSPR model using a nearest neighbor approach based on HYBOT physicochemical descriptors.[38] The model performance for a test set of 279 compounds provided values of $R^2_{test} = 0.768$ and $\mathrm{RMSE}_{test} = 9.35$ kJ mol^{-1}.

Abramov used 1213 experimental observations of Gibbs energy of sublimation (a database provided by Dr. German Perlovich) for building a Cubist regression model based on a combination of Dragon, VolSurf, and SMARTS keys descriptors.[127] The model performance for a test set of 181 compounds provided values of $R^2_{test} = 0.88$ and $\mathrm{RMSE}_{test} = 7.0$ kJ mol^{-1}. An error propagation

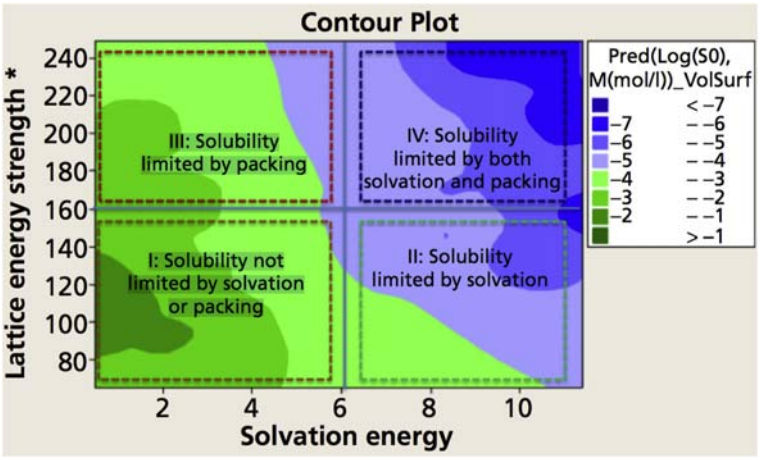

Fig. 15 Solvation packing grids based on free energy of mixing with water (kcal mol^{-1}) and lattice energy strength, as measured by QSPR estimated $\triangle H_{sub}$ energy (kJ mol^{-1}). The solvation energy is in kcal mol^{-1}. (I) Solubility not limited by solvation or packing; (II) solubility limited by solvation; (III) solubility limited by packing; (IV) solubility limited by both solvation and packing. consideration demonstrated that the resulting model accuracy was not good enough for a reasonably accurate (≤ 1 log unit) prediction of absolute values of solubility from a sublimation thermodynamic cycle. Indeed, assuming that sublimation and hydration free energies are independent from each other, one may approximate a standard error of log S prediction as (referred to molar fractions):

$$\sigma(\log S) = \frac{\sqrt{\sigma^2(\Delta G_{sub}) + \sigma^2(\Delta G_{hydr})}}{\ln(10)RT}. \tag{33}$$

Therefore, assuming that RMSEs can be interpreted as standard errors, even neglecting $\sigma^2(\Delta G_{hydr})$ contribution, RMSE(ΔG_{sub}) values should be below 5.7 kJ mol^{-1} in order to provide a standard error of log S prediction below 1 log value.

One of the important factors affecting QSPR/QSAR model building of sublimation and lattice energies is a limited amount of ΔG_{sub} and ΔH_{sub} observations available for the drug-like molecules. In addition, it was recently demonstrated[53] that a major limiting factor of accuracy of QSPR/QSAR models of crystalline state properties (such as solubility, fusion, and sublimation) is the lack of descriptor sets accounting for the long-range order (periodicity) phenomenon. There are also important entropic contributions, which are noticeably more pronounced in absolute value for the sublimation properties and should be appropriately considered for an accurate QSPR modeling of sublimation free energy, ΔG_{sub}.[127]

3.16.4.2 Melting Point

3.16.4.2.1 Physics-based methods

3.16.4.2.1.1 Molecular dynamics and Monte Carlo

The molecular simulation methods for MP prediction can be categorized into two groups: (i) "direct methods" such as the hysteresis method,[128] the voids method,[129] and solid–liquid interface methods[130]; and (ii) "free energy methods" including the single-occupancy cell method,[131] the Einstein crystal method,[132] and λ-integration methods.[133,134] The first group of approaches involve the direct simulation of the melting process in a dynamic manner. They are relatively easy to apply but their accuracy can be limited. In turn, the second group of approaches are more rigorous but are generally more complicated to apply. A comprehensive review of the methods can be found elsewhere.[135] The main problem is that all these methods require an experimental crystal structure as input, which means the calculation is not really predictive as the MP can be measured easily once the crystal structure is known. The first attempt to perform fully *in silico* prediction of MP was recently performed by Zhang and Maginn, where simulations were used to predict both a crystal structure and a MP for two rigid molecules (2-propenal and 4-cyanopyridine N-oxide).[136] The packages MOLPAK[137] and PMIN were employed for CSPs, while melting-point calculations were realized using the pseudosupercritical path[134] method of classical MD. The study was based on the assumption that accurate MP predictions can be made using predicted crystal structures with free energies that are close to that of the experimental structure. Indeed, despite the fact that CSPs failed to reproduce the experimental crystal structures of both molecules, MPs were estimated with an error of 15–25 K. The main problem, which Zhang and Maginn stressed in their work,[136] is inaccurate force fields, which lead to inaccurate MP predictions regardless of the methods applied.

3.16.4.2.2 Statistical methods

The MP has been a target of modeling for a long time. Already in 1881, Mills derived QSPR models for the hydrocarbon chain as following:[138]

$$\text{MP (K)} = \beta x/(1 + gx), \tag{34}$$

where β and g are constants for a given class to achieve accuracy of prediction less than 1 K and x is number of methyl groups. This result indicates that for some specific classes of chemicals a high accuracy of MP prediction can be achieved. Unfortunately, the high precision accuracy of Eq. (34) was a very particular case and, even after 140 years of research, such high precision models for diverse compounds do not exist and actually cannot be developed, as analyzed later.

During the second part of the last century there were a large number of articles devoted to analysis of other chemical series as nicely reviewed by Dearden.[44] Such studies frequently involved few tens and seldom few hundreds of compounds grouped by chemical class, for example, alkanes, hydrocarbons, PAHs (polycyclic aromatic hydrocarbon), alcohols, anilines, etc. The average errors for nonaromatic compounds were ~20 K and increased to ~30 K for aromatics, that is, indicating that prediction of the latter compounds was more difficult. The descriptors used for chemical series frequently included several topological indices or other descriptors (e.g., physical–chemical, quantum-chemical, and structural) while for larger diverse sets having more than a thousand compounds the GC, structural, and frequently correction factors were used too.

The GC methods assume additivity of the modeled property with respect to the groups. Since this assumption does not really hold for MP, the researchers frequently used correction factors to account for nonlinearity. For example, Simamora and Yalkowsky used correction factors accounting for hydrogen bond formation and disruption of planarity of biphenyl by the presence of substituent(s) at the 2,2′, 6, or 6′ positions to achieve STDE = 38 K for $n = 1690$ compounds. Such strategy and development of functional groups targeted for the MP allowed the authors to calculate much higher accuracy compared to the GC method of Joback and Reid,[121] STDE = 69 K. The latter method used the same groups for several properties.

Complex GC, which include three levels of description of molecules, were developed by Maerngo and Gani.[139] The first-order groups covered the whole molecule and did not overlap. The second- and third-order groups were overlapping and covered only specific parts of molecules, thus capturing interactions within larger molecular fragments to better cover complex polyfunctional molecules. De facto, such complex groups play a role of correction factors. This method allowed the authors to calculate STDE = 28 K for $n = 1547$ compounds.

There are only few studies published with large sets of MP data. Karthikeyan et al.[123] analyzed a diverse set with $n = 4173$ using NN and different sets of descriptors. The authors found that models developed with 2D descriptors provided better prediction accuracy (RMSE = 48–50 K) compared to those based on 3D indices (RMSE = 55–56 K). An attempt to improve the model by combination of both sets did not improve the results. The use of 3D descriptors also did not provide an advantage over 2D for analysis of MP of ILs of 717 bromides of nitrogen-containing organic cations.[140] In this study several methods, such as MLRA, partial least squares (PLS), k-nearest neighbors (kNN), NN, and SVM, were analyzed using fragment-based descriptors,[88] E-state indices,[141] and Dragon descriptors.[25] When analyzing the performance of the models for individual sets, the higher errors were calculated for more diverse ones. At the same time the results were dependent on the use of the machine learning methods: nonlinear methods such as NN and SVM provided consistently better prediction abilities.

When developing a model, it is important also to understand which molecular properties are responsible for a decrease/increase in MP. A comprehensive analysis using MMPs was performed for the public set of Karthikeyan as well as in-house data of $n = 746$ compounds by Schultes et al.[142] The authors identified four main factors influencing MP: number of hydrogen bond donors and acceptors as well as number of rotatable bonds and halogen atoms (I, Br, and Cl). In order to exclude intercorrelations, the analysis of MMPs was performed only for pairs of molecules when only one factor was changed. The number of hydrogen bonds had the highest impact, increasing MP for about 50 (30) K for in house (public) set, respectively. The increase in the number of hydrogen acceptors by one contributed an increase in MP by 22 (9) K, while the increase in the number of rotatable bonds leads to a decrease in MP by −17 (−10) K. It is also interesting that the effects were more pronounced for *in house* data, which shows their higher consistency. The addition of one Br atom increased MP by 47 (24) K. The significant increase of MP due to the addition of I (39) and Cl (7) was also observed for public set but no conclusion could be made for in-house data, due to limited number of MMPs.

The two largest models so far to predict MP were published by Tetko et al.[143,144] The first model was based on $n = 47{,}000$ compounds collected from the OCHEM database,[99] chemical compounds provided by Enamine, Bergstrom dataset of MP for drugs,[145] and the "Bradley" dataset[146] containing doubly curated data collected by Open Notebook science community members. The important result of this article was finding that the majority of MP data of pharmaceutical relevance, >90%, have MP in intervals of 50°C (323.15 K)–250°C (523.15 K) (drug-like MP range, **Fig. 16**). Thus, in principle, when developing and testing models to be used in pharma, one can concentrate on their performance for this temperature region. Like in study of Varnek et al.[140] it was demonstrated that MP is a nonlinear property: the use of Associative Neural Networks and SVM calculated significantly lower errors compared to the use of linear methods. This set was extended with $n = 225{,}000$ compounds mined from patents. These compounds also had about 90% of their data within drug-like MP region.

The error of the final consensus model for the patents data closely followed the estimated experimental error of the data. This error was 33 K for the drug-like MP range and perfectly matched STDE = 32 K calculated using experimental data. For MP < 50°C (323.15 K) the same model calculated RMSE = 47 K and RMSE = 28 K for data mined from patents and Bradley set, respectively. Again, the large difference in both errors is due to the higher accuracy of data in the latter set. This result showed that the used approach (consensus modeling) and descriptors were sufficient to predict MP up to the level of experimental data accuracy.

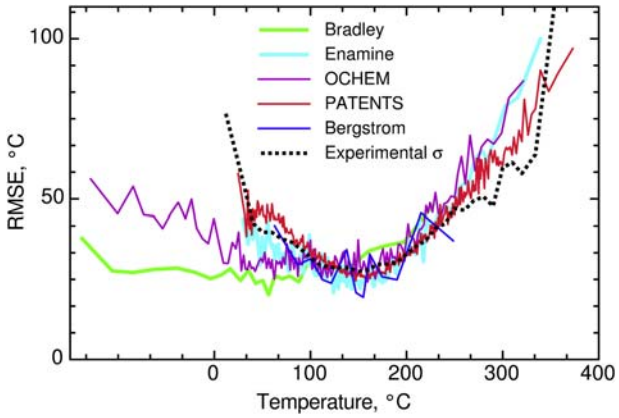

Fig. 16 The experimental and calculated errors of the consensus model as a function of the MP temperature for different subsets. The experimental accuracy line was built based on $N=18{,}058$ differences in the MP temperatures. Reproduced with permission from Tetko, I. V.; Lowe, D.; Williams, A. J. The Development of Models to Predict Melting and Pyrolysis Point Data Associated With Several Hundred Thousand Compounds Mined From PATENTS. *J. Cheminform.* **2016**, *8*, 2. Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/).

Thus it is in contradiction to the conclusion of Hughes et al.,[147] who explained low accuracy of models to predict MP by deficiency of used descriptors.

The experimental error of 33 K looks very high. The majority of experimental measurements in patents were provided as intervals with standard deviation STDE = 3 K between both measurements, which can be used as an estimation of the reported experimental accuracy of measurements for single experiments. There are many more aspects contributing to the variation of MP measurements due to sample preparation of the same compound, which were nicely summarized by Preiss et al.[148] in their analysis of MP of organic salts. The author indicated that factors such as contamination, polymorphism, presence of liquid and plastic crystals, and decomposition could easily contribute variations in ten degrees. For example, the purity of compounds for HTS screening is usually about 85%–90%. The impact of contamination can be calculated as following:[148]

$$\Delta \mathrm{MP} = -\mathrm{MP}\frac{mR}{\Delta S_{fus}}, \tag{35}$$

where R is the Avogadro constant, m is the molar amount of contaminant, and ΔS_{fus} is the melting entropy of the target compound. The equation indicates that contamination has a higher effect not only on compounds with higher MP but also on compounds with higher molecular mass for the same mass% of contaminant. Considering that MP increases with MW of compounds, higher experimental errors (depression of MP) could be expected for high temperature MP values. Moreover, contaminants with lower mass will provide a stronger impact. In this respect the authors noticed that water, which is able to form strong hydrogen bonds and has low MW, could be the worst contaminant. In their example the authors considered the IL 1-*n*-hexyl-3-methylimidazolium bis(trifluoromethylsulfonyl)-imide which would have MP depression of 1 K for 1.85 mass% of moisture.

3.16.4.3 Vapor Pressure

3.16.4.3.1 Physics-based models

3.16.4.3.1.1 Molecular dynamics and Monte Carlo

Vapor pressure predictions with MD methods are based on the estimation of thermodynamic parameters of the corresponding process. First, one can calculate heat of vaporization using potential energies ($E^{potential}$) in the gaseous and liquid (pure compound) phases:

$$\Delta H_{vap}(T) = E_{gas}^{potential}(T) - E_{liquid}^{potential}(T) + RT + C, \tag{36}$$

where C is the correction term, which accounts for the difference in vibration energies calculated quantum mechanically and classically (it is usually neglected). Wang and Hou estimated heats of vaporization and the temperature dependence for a set of 71 small organic compounds covering diverse functional groups.[149] The best performing MD protocol predicted vapor pressure with RMSE = 1.2 kcal mol^{-1} (5.02 kJ mol^{-1}).

Secondly, one can estimate the free energy of vaporization, which can be performed using the free energy perturbation (FEP) method.[150] Unfortunately, FEP simulations for drug molecules in the MW range from 400 to 600 Da, typical of modern drugs, may be so time-consuming that they cannot be used routinely.[151] An alternative methodology was proposed by Lindfors and coworkers.[152] They suggested a relation between the free energy of solvation in the pure melt (opposite to the free energy of vaporization) on the one hand and more readily accessible quantities such as interaction energies and molar volumes on the other hand:

$$-\Delta G_{vap} \cong \Delta G_{cavity} + E_{LJ} + \frac{E_c}{2}, \tag{37}$$

where ΔG_{cavity} is the energy to create cavity in the melt, E_{LJ} is the Lennard-Jones energy, and E_C is the Coulomb energy. In general, the process can be considered as a sum of three following steps: (i) creating a cavity in a melt, (ii) insertion of a solute in the cavity, and (iii) turning on atomic partial charges. The two last steps can be performed with a coupling parameter λ using FEP simulations. The free energies of solvation of a drug in a pure melt were obtained at 400°C (673.15 K) for 46 drug molecules. Further cooling down of a system from 400°C (673.15 K) to 25°C (298.15 K) leads to vapor pressure predictions with accuracy close to that for FEP simulations.[153]

3.16.4.3.1.2 COSMO-RS

One of the widely used physics-based methods for vapor pressure prediction is COSMO-RS. As it was shown above it is a theory about molecules in the liquid phase. However, vapor pressure prediction requires chemical potential in the gas phase as well:

$$p_X^X = \exp\left\{-\frac{\mu_{gas}^X - \mu_X^X}{RT}\right\}. \tag{38}$$

The potential can be calculated using the difference between quantum-chemical total energies of the molecule X in the gas phase and the conductor (COSMO reference state):

$$\mu_{gas}^X = E_{gas}^X - E_{COSMO}^X - E_{vdW}^X + \omega n_{ring}^X + \eta_{gas}, \tag{39}$$

where E_{vdW}^X is the van der Waals energy of the solute (conductor reference state), ωn_{ring}^X is the correction for ring systems, and η_{gas} connects reference states in solution and in the gas phase. One should note that Eq. (39) does not take into account any gas-phase nonidealities such as dimerization of organic acids. They can be added externally starting from the ideal gas reference state. As it was reported by COSMO-RS developers,[154] the typical prediction accuracy of the approach for vapor pressure of neutral liquid compounds is better than 0.5 log units. The results were recently proved on a wide set of multi-functional oxygen-containing organic compounds, with an accuracy of prediction of about 0.5–1.0 log units, overestimating data for self-associating compounds (carboxylic acids and alcohols).[155] Liquid vapor pressure calculation for a set of polychlorinated aromatic compounds also showed a good match of the predicted data with experimental values (0.2–0.8 log units error).[156] Analysis of the method performance for more complicated systems, such as ILs,[154] showed that COSMO-RS underestimated the vapor pressure by roughly 0.5–4.0 log units depending on the composition of the IL.

COSMO-RS calculations are more complicated in the case of vapor pressure prediction for solid compounds since it requires chemical potential for crystalline phase. In general, solid–liquid equilibrium calculations with COSMO-RS employ an experimental estimation for the fusion free energy, which characterizes the melting of the crystal phase:

$$\Delta G_{fus}^X(T) = -\Delta H_{fus}^X\left(1 - \frac{T}{T_{melt}^X}\right) + \Delta Cp_{fus}^X\left(T_{melt}^X - T\right) - \Delta Cp_{fus}^X T \ln\frac{T_{melt}^X}{T}, \tag{40}$$

where T_{melt}^X is the MP, ΔH_{fus}^X is the heat of fusion, and ΔCp_{fus}^X is the heat capacity of fusion. However, experimental data are not always available, for example, for explosives.[157] Therefore, the following QSPR model was proposed for ΔG_{fus}^X estimation[157–159]:

$$\Delta G_{fus}^X(T) = a_1 V_{\mathrm{COSMO}}^X - a_2 N_{ring} + a_3 \mu_{water}^X + a_4 \mu_{gas}^X, \tag{41}$$

where V_{COSMO}^X is the cavity volume of the solute molecule and N_{ring} is the number of aromatic ring atoms. Several versions of the model differ in values of empirical coefficients a_i and presence of the last right-hand side term.

General limitations of the COSMO-RS method are its inapplicability for systems near or beyond the critical point, and low accuracy for systems with polar ions or tertiary amines.

3.16.4.3.1.3 UNIFAC

Among alternative physics-based approaches for vapor pressure predictions one can mention a GC method based on UNIFAC groups, which was developed by Fredenslund and Rasmussen in 1979.[160] The method is based on the Eq. (8), where Gibbs free energy of vaporization/sublimation is represented as following:

$$\Delta G_{vap/sub} = \sum_k v_k \Delta g_k + RT \sum_k v_k \ln \Gamma_k. \tag{42}$$

Here Δg_k is the difference between the molar free energy of group k in the pure state and in the gas at 1 atm (1.013×10^5 Pa), the second term is the UNIFAC "residual" term (Eq. (25)). Generally, UNIFAC is acknowledged to be an accurate predictive method for vapor pressure (deviation about 15% for hydrocarbons).[161] However, the method suffers from a number of inherent limitations:[162]

- Due to assumptions behind the theory, UNIFAC is accurate only for low or moderate pressures;
- It cannot be applied to systems containing ions, salts, polymers, or noncondensable gases;
- UNIFAC fails for mixtures of isomers because it does not account for the effect of surrounding groups on the particular fragment behavior;
- UNIFAC depends critically on the available experimental data and their quality. Existing interaction parameters are limited by 18 functional groups (covering aliphatic and aromatic hydrocarbons and oxygen-containing compounds).

3.16.4.3.1.4 SAFT

A GC approximation was also proposed for the SAFT method (GC-SAFT).[163–165] Elliott and coworkers[166] formulated its generalized methodology as follows: (i) pure component parameters were obtained by matching their boiling points, estimated solubility parameters, and estimated liquid density; (ii) GC were regressed for the shape factor (86 first-order functional groups were found to cover 19 different families of compounds). The method allows for vapor pressure predictions based solely on the chemical structure and very satisfactory results are reported (deviation around 30% of vapor pressure).

3.16.4.3.2 Statistical methods

There are two principal types of approaches to predict vapor pressure using statistical methods. The first one implies the use of other physical–chemical properties, along with additional descriptors that can be computed from chemical structures, to create predictive statistical (machine learning) models. In this way, Kühne et al.[167] have trained an ANN (artificial neural network) on a training set composed of 1200 compounds (hydrocarbons and halogenated hydrocarbons) represented by 23 descriptors computed from chemical structure, system temperature, and MP for solid compounds to create a model that can be used to predict vapor pressure for new compounds. The absolute average error of prediction of this model estimated using an external set of compounds is 0.13 log units. Similarly, Godavarthy et al.[168] have trained an ANN on a diverse dataset of 1100 compounds represented by several structural descriptors and the values of triple and critical points to obtain a model with relative average errors of less than 0.5%. The latter model can predict accurately the vapor pressure of organic chemicals over the entire saturation range from the triple point to the critical point. Nonetheless, in spite of an excellent prediction performance of such models, they are not capable of making predictions for compounds with unknown values of physical–chemical properties included in models. This can be considered a significant limitation of this approach.

The second type of approach is currently much more popular. In this case only descriptors computed from chemical structure are involved in building statistical models in the framework of a QSPR approach. Application of QSPR models to predicting vapor pressure is surveyed in Refs. 169–171. Here we consider several important examples. Chastrette et al.[172] built an MLR model with standard error of 0.1 log units for a set of 186 compounds (alkanes and alcohols) using the components of the autocorrelation vector calculated from Bondi's surface areas as descriptors. Basak et al.[173] used a hierarchical QSAR approach to build an MLR model with standard error 0.29 log units for a set of 476 diverse chemicals using topostructural, topochemical, and geometrical descriptors. Liang and Gallaher[174] developed an MLR model with standard error 0.53 log units for a diverse set of 479 compounds using polarizability and polar functional group count as descriptors. Katritzky et al.[175] built an MLR model with standard error 0.33 log units for a diverse set of 411 diverse compounds using an extensive set of constitutional, topological, electrostatic, geometrical, and quantum-chemical descriptors. Artemenko et al.[176,177] applied a combination of back-propagation neural network and fragmental descriptors to build models for a set of 352 organic compounds (linear, branched, and cyclic alkanes, alkenes, arenes, and halogen derivatives). The RMSE of prediction estimated using external cross-validation procedure of these model are 0.22 and 0.15 log units. The second model with enhanced predictive performance was obtained by the use of ensemble modeling. Cash[178] developed kNN models in a Euclidean space defined by electrotopological descriptors with errors 0.56 and 0.55 log units for a large dataset of 1676 compounds.

Vapor pressure is known to depend highly on temperature, and hence it is desirable to build temperature-dependent models. Chalk et al.[179] developed a temperature-dependent model based on a feed-forward neural net and quantum-chemical descriptors. A set of 7681 measurements at various temperatures performed on 2349 compounds was used for this study. The reported standard error of prediction for this model is 0.33 log units. Yaffe and Cohen[180] also developed a temperature-dependent neural network model using valence connectivity indexes based on a dataset of 274 hydrocarbons. An excellent average prediction error of 0.04 log units was demonstrated. Finally, Gharagheizi et al.[181] developed a temperature-dependent neural network model for an extremely large dataset of approximately 42,000 vapor pressure values belonging to about 1400 chemical compounds. The reported average absolute relative deviation of this model is 6%, while a squared correlation coefficient is 0.994.

In summary, the most popular statistical (machine learning) methods for building models to predict vapor pressure are multiple linear regression (mostly in earlier studies) and ANNs (in more recent studies), while descriptors are usually either fragmental[182] or quantum-chemical. The advantage of fragmental descriptors is the ease of their calculation and handling. The drawback of fragmental descriptors is the problem of "rare fragments," which sharply narrows applicability domain of model. Quantum-chemical descriptors are potentially capable of providing much larger applicability domain, but by the expense of the drastic loss of computational efficiency. Another general limitation of all statistical methods of predicting vapor pressure is related to the fact that this property may be measured only for volatile compounds, which usually have relatively low MW. This should be taken into account in the application of statistical models to predict the vapor pressure of new compounds.

3.16.4.4 Aqueous and Nonaqueous Solubility

3.16.4.4.1 Physics-based models

Physics-based modeling methods for predicting absolute solubility can be roughly classified into several main categories: (i) direct methods based on separate calculations of ΔG_{sub} and ΔG_{solv} terms, (ii) COSMO-RS model[159] and (iii) methods based on the GC approach that use UNIFAC and SAFT theories.[30] In this section we will briefly overview main principles of solubility prediction by the first approach.

The most straightforward approach to model solubility is to calculate it directly through the free energy of solution, ΔG_{sln} in the thermodynamic cycle (Fig. 3) using *ab initio* approaches for multibody molecular systems, like, for example, *ab initio* molecular dynamics[183] and use the fundamental relationship (referred to molar fractions):

$$\log S_0 = -\frac{\Delta G_{sln}}{RT\ln(10)}. \tag{43}$$

However, due to the number of molecules in the system, as well as the maximum simulation time being too small to properly sample the phase space of the system, there is an extremely large computational expense associated with such simulations, even with the use of modern high-performance computing (HPC) systems. Even less expensive molecular mechanics methods, that use classical force-fields, are still difficult to apply to direct modeling of dissolvation process due to the long timescales associated with the process and the overall complexity of the modeling setup due to the multiphase nature of the system (coexistence of the liquid and solid phases). Therefore, in practice, the most popular approaches are based on using the first part of the Eq. (11) and a consequent relationship: (referred to molar fractions)

$$\Delta G_{sln} = \Delta G_{sub} + \Delta G_{solv} \tag{44}$$

and calculating separately the ΔG_{sub} and ΔG_{solv} contributions into ΔG_{sln}. Such an approach has several advantages due to the flexibility of choices for ΔG_{sub} and ΔG_{solv} calculations. Thus, for ΔG_{sub} one can use different CSP methods[103,184] based on either QM of classical mechanics approaches. At the same time, for ΔG_{solv} calculations one can use suitable methods for simulations of liquid systems such as MD/MC,[151,185] molecular theories like 3D RISM,[186] or continuum solvation methods.[187] We would like to emphasize the role of recent series SAMPL blind challenges (http://www.eyesopen.com/sampl and https://drugdesigndata.org/about/sampl) that provoked a wave of interest in ΔG_{solv} predictions using different computational techniques. These works contain several benchmark datasets that can be used for verifying new models. The critical analyses of the performance of different methods in these challenges are insightful and provide interesting information.

However, the use of *different* methods in such an approach may lead to some problems due to the inherent inconsistencies between the theories involved at different steps of the overall modeling setup for calculating solubility as well as the input parameters for modeling ΔG_{sub} and ΔG_{solv}. Indeed, due to the accumulation of errors on different steps of the simulations, the overall accuracy of the predictions of ΔG_{sln} by direct simulation methods is in general within the range of 3–10 kJ mol^{-1}.[187,188] Such calculation errors in estimation of ΔG_{sln} lead to at least 10-fold error in the prediction of the solubility.[147] Overall, developing a consistent procedure for high-accuracy prediction of solubility of wide classes of pharmaceutical compounds based on direct simulation approach represents a challenge for the molecular modeling community.

3.16.4.4.2 Statistical methods

Statistical approaches to predicting aqueous and nonaqueous solubility of organic compounds in solid and liquid states are discussed in detail in the monograph of Yalkowski et al.[189] and several comprehensive review articles.[170,171]

According to Yalkowski and Banerjee,[189] there are three main categories of statistics-based solubility prediction methods: (i) using correlations with other experimentally measured properties such as partition coefficients and MP; (ii) using GC schemes; and (iii) using QSPR models based on descriptors computed only from molecular structure. Consider the most prominent examples for all of these categories.

In 1980 Yalkowski and Valvani[190] developed the general solubility equation for estimating the aqueous solubility of either liquid or crystalline organic nonelectrolytes, which uses three parameters, the octanol–water partition coefficient ($\log P_{oct/wat}$), melting point (MP, °C), and the entropy of fusion (ΔS_{fus}):

$$\log S_{aq} \approx -\log P_{oct/wat} - 1.11\frac{\Delta S_{fus}(\mathrm{MP}-25)}{1364} + 0.54 \tag{45}$$

Two terms in this equation, MP and ΔS_{fus}, reflect the role of crystal structure. Two terms, $\log P_{oct/wat}$ and ΔS_{fus}, could be estimated from chemical structure, while the value of MP should be either known or experimentally determined. For the case of rigid molecules, where the entropy of fusion of the solute could be taken as a constant, this equation takes a very simple form,[191] which depends only on two parameters, $\log P_{oct/wat}$ and MP:

$$\log S_{aq} \approx -0.01\mathrm{MP} - \log P_{oct/wat} + 1.05 \tag{46}$$

Later on Jain and Yalkowski[192] revised the general solubility equation and obtained a more accurate estimation of the aqueous solubility (the average absolute error was estimated as 0.54 log units).[192] This method was further expanded by Meylan et al.[193] to include MW. The main limitation of this category of solubility estimation methods is that they are based on experimental properties (at least, MP) and therefore they can be applied only to compounds for which the measured values of the required parameters are known and, hence, they are not suitable for compounds not yet synthesized.

Unlike the aforementioned methods, GC approaches do not require experimental measurements and therefore can be applied to new compounds. Several methods based on GC were developed to predict the aqueous solubility of organic compounds with rather good predictive performance.[194–196] For example, the average absolute calculation error of 0.5 log units was reported by Klopman.[196] The main limitation of all pure GC approaches is that they can be applied only to compounds composed of the groups well represented in the training set.

Most of the studies aimed at building statistical models for prediction of the solubility of organic compounds are based on the QSPR methodology and involve a large variety of different types of descriptors and machine learning methods. Several dozens of QSPR models built for this purpose are comprehensively surveyed in the review articles[170,171,197,198] covering literature up to 2010, while several recent models are listed by Winkler.[199] Kuhne and coworkers[200] compared the predictive performances of several previously developed GC and QSPR models using a reference set of 1826 compounds, and the standard prediction errors were reported to lie in the range from 0.86 to 1.69 log units. A similarity-based model selection method decreased the standard error to 0.71 log units.[200] In a recent study, Winkler et al.[199] have developed several QSPR models for aqueous solubility based on VolSurf[122] and CPSA[124] descriptors trained using several statistical and machine learning methods (standard multiple linear regression, robust multiple linear regression employing an expectation maximization algorithm, and Bayesian regularized ANN with Laplacian prior) using a dataset of 4558 chemically diverse compounds. The best statistical results with squared correlation coefficients of 0.90 and standard errors of 0.65–0.67 log units were reported.[199] Surprisingly, the inclusion of the descriptors capturing crystal lattice interactions appeared not to improve the models. Cheng et al.[201] have developed a binary classification model of aqueous solubility (showing whether a solute is soluble in water) built using SVM with descriptor selection on the largest known public dataset containing over 46,000 compounds.

Because aqueous solubility is a key physical–chemical property in drug development, much effort has been spent on the development of models with maximum predictive performance with respect to drug-like compounds.[197,202–205] A "solubility challenge" was conducted to assess the prediction accuracy of several aqueous solubility prediction models on a set of 32 drug-like compounds, using a set of 100 drug-like compounds with accurately measured solubility values as a training set.[206] The results of this "challenge" obtained for 99 different models are reported by Hopfinger et al.[207]

QSPR models for prediction of nonaqueous solubility of organic compounds have also been reported in several publications. Katritzky et al. have developed a series of models to predict free energies of solvation in various solvents.[208] A QSPR model for solubility of fullerene C60 in different organic solvents built using multiplicative SMILES-based optimal descriptors was reported by Toropov et al.[209] Kravtsov et al.[210] have developed a universal model for the estimation of solvation free energy of organic molecules in different solvents, which was built using NN and fragment descriptors for representing both solute and solvent structures.

So, various methods for predicting aqueous and nonaqueous solubility of organic compounds have been developed. Most of them are based on QSPR models. The most accurate prediction methods involve ANNs and physical–chemical molecular descriptors. They were built using large datasets of experimentally measured values of solubility. Since the solubility of chemical compound depends very strongly on the experimental conditions of the measurements, such as temperature and pH, there are considerable differences between solubility values measured in different laboratories for the same compound. As a result, the accuracy of the predictions based on statistical models is limited by the accuracy of experimental measurements.

3.16.4.5 pK_a

3.16.4.5.1 Physics-based methods

This group of methods is based on the relation between Gibbs free energy of the dissociation process and its constant:

$$\mathrm{p}K_\mathrm{a} = \Delta G^0_{(aq)} \frac{1}{RT\ln(10)}. \tag{47}$$

Historically, the methods rely on the fact that the Gibbs free energy is a state function. Therefore any convenient thermodynamic cycle that connects the initial reactants and final products provides a way to calculate acidity/basicity of a compound[211,212] (Fig. 17).

In this case, the main source of error in pK_a calculations is the uncertainty in the value of the solvation free energy of a bare proton H^+. At present, the best literature value is believed to be -265.6 ± 1 kcal mol^{-1} (-1111.27 kJ mol^{-1}) for a 1 M standard state.[213]

The gas-phase free energy calculation introduces the lowest source of error in pK_a calculations since quantum-chemical calculations can nowadays be good or even more accurate than experimental measurements of gas dissociation constants.[211] CCSD(T) (coupled cluster with all single and double substitutions along with a quasiperturbative treatment of connected triple excitations) is considered a gold standard method for the calculations.[214] It allows predictions with uncertainty of about 0.5 kcal mol^{-1} (2.0 kJ mol^{-1}) in comparison with experimental data from NIST database.[214] However, the problem here is producing accurate results with less computationally expensive levels of theory. Model chemistry methods (e.g., CBS-QB3, CBS-APNO, and W1) produce reliable predictions of $\Delta G^0_{(g)}$ with slightly lower accuracy, RMSE within 1.1–1.6 kcal mol^{-1} (4.60–6.69 kJ mol^{-1}) from experimental data.[214,215] In turn, DFT offers a more cost-effective approach. Various DFT functionals (PBE1PBE, P3P86, B3LYP, etc.) were tested against experimental data from NIST database and provided results with accuracy 1.6–2.7 kcal mol^{-1} (6.69–11.29 kJ mol^{-1}).[216] One should keep in mind that each particular DFT functional represents its own parameterization method and, therefore, requires benchmarking for the system of interest.

It was found that the detour through gas phase is counterproductive because any gain from improved accuracy in gas-phase calculations is outweighed by errors caused by liquid-phase pK_a calculations, which are much more complicated because of strong solvation effects.[217,218] Therefore, at computational levels that are routinely applicable today, it is preferable to calculate the free energy of the dissociation process directly in aqueous solution avoiding gas-phase calculations. Due to the very high cost of rigorous explicit solvent calculations (for a review, see Ref. 219) solvent effects are often approximated by implicit solvent models. Although

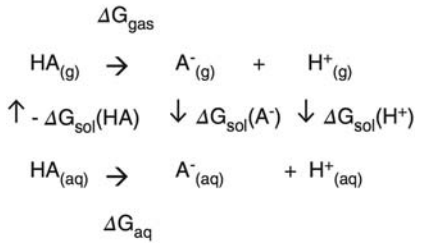

Fig. 17 Proton-based thermodynamic cycle. Reprinted with permission from Seybold, P. G.; Shields, G. C. Computational Estimation of p*K*(a) values. *Wiley Interdiscip. Rev. Comput. Mol. Sci.* **2015**, *5*(3), 290–297. Copyright (2015) John Wiley and Sons, Inc.

the models allow highly accurate solvation free energy predictions for neutral molecules, the corresponding predictions for ions still remain challenging.[211,220] Thus, the widely employed COSMO-RS method was quite successfully applied to the first principle prediction of aqueous acidity[218] and basicity,[221] but it still suffers from several systematic errors: (i) correlation between predicted free energies and experimental pK_a values has a slope that is lower than that expected from thermodynamic theory (Eq. (45)) and (ii) systematic deviations known from other continuum solvation models for aliphatic amine compounds remain for COSMO-RS predictions.[221]

It was found that including explicit water molecules within implicit solvation calculation ("cluster–continuum" or "implicit–explicit solvation" approach) improves overall pK_a predictions.[220,222,223] The discussion about how many explicit water molecules should be used still remains open,[223] although use of variation methods to determine the number of water molecules[223,224] and considering water molecules as clusters[224] were found to be promising.

3.16.4.5.2 Statistical methods

The first book on pK_a prediction using QSAR was published in 1981 by Perrin et al.[225] and covered mostly the use of classical approaches based on LFER, Hammett, and Taft equations. However, all these models can be applied only for very small congeneric series of organic compounds with simple structure and are impractical for large systems, especially for compounds of pharmaceutical interest. In the past 25 years, most of the methods for constructing statistical models for prediction of pK_a were based on QSAR/QSPR methodology.[171] In these studies, several types of descriptors were used to build models for predicting pK_a: quantum-chemical,[226] fragmental[182], etc. Most of the quantum-chemical descriptors used for this purpose describe local properties of atoms or bonds. For example, Citra[227] used partial atomic charges and bond orders as descriptors to predict the pK_a of phenols, carboxylic acids, and alcohols. Tehan et al.[228] used for this purpose semi-empirical quantum mechanical descriptors derived from frontier electron theory. Using these descriptors, the pK_a values of phenols, aromatic and aliphatic carboxyl acid, amines, anilines, oxygen-, and nitrogen-containing heterocyclic compounds were successfully modeled.[228] Chaudry and Popelier[229] applied descriptors from the "atoms in molecules" theory in the framework of the quantum topological molecular similarity approach. Correlations obtained were shown to outperform the use of Hammett and other traditional parameters to predict the pK_a values for simple carboxylic acids, anilines, and phenols. Various types of quantum-chemical descriptors were also used by Gross et al.,[230] Soriano et al.,[231] Habibi-Yangjeh et al.,[232] Baskin et al.[233] and other research groups to predict either the pK_a values or the Hammett constants closely related to them.

Ivanova et al.[234] developed models for predicting the pK_a values for phenols and carboxylic acids and closely related pK_b values for nitrogen-containing compounds using fragmental descriptors with labeled atoms,[235] local quantum-chemical indexes, and their combinations using multiple linear regression and ANNs. It was shown that combining both types of descriptors leads to QSPR models with more accurate prediction of pK_a as compared with models based either on quantum-chemical or fragmental descriptors. Different types of descriptors (constitutional, topological, geometrical, electrostatic, and quantum-chemical) were also mixed by Luan et al.[236] to obtain models for prediction for neutral and basic drugs.

A group of models for predicting pK_a were developed in the framework of 3D-QSAR approach. Gargallo et al.[237] applied the CoMFA to a set of nucleic acid components to obtain very strong correlation between pK_a and AM1 proton affinity values at grid nodes. Although a very small prediction error was reported (standard error 0.23 log units), the use of this method is efficient only for estimating the pK_a values within a congeneric set of compounds because of the necessity to perform spatial alignment of molecules. This imposes severe restrictions on the applicability of the CoMFA method, as well as other alignment-based 3D-QSAR approaches, for predicting the properties of wide heterogeneous sets of drug-like compounds. Milletti et al.[238] developed much more practical computational methods for pK_a prediction of organic compounds using descriptors based on molecular interaction fields precomputed on molecular fragments. External validation demonstrated good predictive performance (root mean square error 0.90 log units). For a validation set of 28 drug-like compounds, the method gave better results than the ACD/pK_a program (root mean square error 1.36 log units).

Several publications deal also with developing models for predicting the pK_a values for organic compounds in nonaqueous solvents. In this way, Jover et al. developed neural-network models to predict the pK_a values for phenols,[239] anilines,[240] carboxylic,[240] and benzoic[240] acids in arbitrary protic and aprotic solvents using a mixture of descriptors for solutes and solvents.

Because of the extreme importance of acidity constants, a number of commercial pK_a prediction tools are available: ACD pK_a/DB (Advanced Chemistry Development, Inc., www.acdlabs.com), ADMET Predictor (Simulations Plus, Inc., www.simulations-plus.com), Epik,[241] and Jaguar[242] (Schrödinger, Inc., www.schrodinger.com), Marvin pK_a (ChemAxon Ltd., www.chemaxon.com), Pallas pKalc (CompuDrug International, Inc., www.compudrug.com), Pipeline Pilot (SciTegic, Inc., accelrys.com), and SPARC[243] (University of Georgia, EPA). The programs ACD pK_a/DB, Epik, and Pallas pKalc are based on classical LFER; SPARC uses a combination of LFER with a perturbed molecular orbital method, whereas ADME Boxes, ADMET Predictor, Marvin, and Pipeline Pilot pK_a predictors are based on the use of QSPR models. Their prediction performances are compared in several publications.[244–247] In particular, the nine aforementioned commercial programs were compared in a benchmarking study[247] by applying them to 197 pharmaceutical substances with 261 carefully determined and highly reliable experimental pK_a values, and it was shown that ADME Boxes 4.9, ACD/pK_a DB 12.0, and SPARC 4.2 provide the most accurate predictions with mean absolute errors of 0.39, 0.48, and 0.65 log units, respectively. On the other hand, the latter LFER-based three programs failed to provide predictions for several sites.

The main limitation of all statistical methods of predicting pK_a values is related to the fact that most of the training compounds with experimentally measured values of pK_a contain a single acidic or basic center, and for this reason various combinations of such centers are poorly represented in training sets. However, organic compounds of pharmaceutical interest usually contain several such centers, and therefore it is necessary to take into account interactions between them. So, further development is needed in this direction.

3.16.4.6 Chemical Stability/Degradation

3.16.4.6.1 Statistical methods

The largest study of compound chemical stability was performed by SPECS.[248] The authors used $N = 12{,}700$ compounds provided by seven companies stored in pure DMSO and 20/80% DMSO/water solution. The study temperatures included 50, 25, 4, and −20°C (323.15, 298.15, 277.15, and 253.15 K), while the duration of experiment was up to 105 days. If a compound was not stable at a higher temperature, its stability was also investigated at a lower temperature until its purity was above 50%, which was used as a threshold to stop measurement for the investigated temperature. Since >60% of compounds were stable even after 105 days at $T = 50$°C (323.15 K), the dataset was biased with respect to stable compounds. Therefore, the authors limited the analysis using only data obtained at the following conditions: $T = 50$°C (323.15 K) and $\tau = 105$ days. The 80% purity was considered as a threshold for the stability of compounds.

The authors developed several local models assuming the reaction mechanism of instability, which were hydrolysis and oxidation. A use of local descriptors describing the reaction sites allowed the authors to model degradation of halides, esters, and amides, for which relatively large sets of compounds ($n \geq 25$) were found.

The accuracy of prediction using fivefold cross-validation was 80%–90% depending on the analyzed class. Unfortunately, due to a high diversity of data no large sets could be compiled for other chemical reactivity classes. An analysis of all data was done using molecular fragments based on Allen's schema, which was developed for prediction of heats of formation of molecules.[249] The use of different machine learning algorithms, such as kNN, RF, and PLS, calculated 10-fold cross-validation accuracy of about 70%–73%. The authors highlighted an importance of understanding of decomposition mechanisms, which can be achieved by analysis of decomposition products.

The same dataset was recently reanalyzed by Liu et al. to develop a naïve Bayesian model.[250] As in the case of previous study, only degradation data at 105 days and $T = 50$°C (323.15 K) were used. The authors used atom center fragments as descriptors. The use of new descriptors as well as a new machine learning method increased the accuracy of models in 10-fold cross-validation to 76% as compared to 73%. Unfortunately, it is not clear whether the improvements came from the use of different descriptors or machine learning method. The developed method uses Bayesian scores of fragments to interpret stability of molecules. The developed models are available as a web server (http://www.rcdd.org.cn/chemstable/) and can be used to predict the stability of new compounds.

The aforementioned studies indicate that prediction of stability of compounds is still in the initial stage of research and new approaches and, more importantly, properly generated data are strongly required to make a progress in this field.

3.16.4.7 Partition Coefficients

3.16.4.7.1 Physics-based models

The most straightforward approach for calculating the partition coefficient for a given compound with physics-based methods is to calculate the difference between the solvation free energies for the solute in the two different compartments as follows:

$$\log P_{oct/wat} = -\frac{\Delta G_{solv(oct)} - \Delta G_{hydr}}{RT\ln(10)}. \quad (48)$$

In the case of charged compounds, one has to estimate log D instead, which takes into account all relevant charged and neutral forms of the solute. If the log P and acid/base behavior of the compound are known, the log D can be calculated with Eq. (17).

Generally, the diverse sets of physics-based methods employed for hydration free energy calculations, including MD, QM, QM/MM, COSMO-RS, RISM, etc. (see section "Physics-based Methods"), can be applied to log *P*/log *D* predictions as well. A very recent SAMPL5 blind challenge[251] was focused on the prediction of cyclohexane–water distribution coefficients log $D_{cyclohex/wat}$ for 53 small molecules (log *D* replaces the previous focus on hydration free energy, see SAMPL0-4 (http://www.eyesopen.com/sampl and https://drugdesigndata.org/about/sampl), due to a lack of ongoing experimental work to generate new data). Organizers of the challenge performed an interesting analysis of the expected performance of computational methods for log *D* from the past hydration free energy calculations. In SAMPL4, the top performing submission achieved an RMSE around 1.5 kcal mol^{-1} (6.3 kJ mol^{-1}), which would correspond to a 1.54 log unit error in log $D_{cyclohex/wat}$ if both solvation free energies have comparable errors. However, in SAMPL5 only five submissions had a RMSE less than 2.5 log units.[251] The best performing submission (2.11 log units) was made by A. Klamt using COSMO-RS.[252] The main reasons for the much worse predictive ability of existing computational approaches are a more complex set of molecules (larger, more flexible, containing multiple functional groups per molecule), the complexity of tautomer enumeration, and the use of cyclohexane as a solvent, which appeared to be not completely immiscible with water. It was shown that the presence of water in the cyclohexane phase can dramatically affect the log *D* of the compound, depending on the affinity of the solute for water.[251]

3.16.4.7.2 Statistical methods

Numerous methods of calculating the log $P_{oct/wat}$ value are comprehensively reviewed in excellent publications.[170,171,253–258] So, we only give a very short overview of the most important approaches. All log $P_{oct/wat}$ prediction methods fall into two major categories: (i) the GC methods and (ii) the whole molecule methods. The GC methods can be either fragment-based or atom-based, in which the log $P_{oct/wat}$ value of a molecule is estimated by summation of the contributions from fragments (substructures) and atoms, respectively. The whole molecule methods are based on molecular properties, such as molecular surface area, electrostatic potential, molecular volume, or nonfragmental molecular descriptors.

The first method for prediction of log $P_{oct/wat}$ was developed in 1964 by Hansch and Fujita.[6] It was based on the summation of empirical π-constants of substituents and hence could be applied only within a congeneric series of compounds with the same framework. The limitations of this approach led Rekker[259] to develop the first fragment-based method, which was followed by the first atom-based method put forward by Broto.[260] The first computerized fragment-based method was developed by Leo and Hansch in 1982 and implemented in computer program CLogP.[255,261] The reported average deviation of this model is 0.31 log units. In 1994 Klopman et al.[262] developed KLogP method based on a multiple linear regression model with fragmental descriptors, which was built using a database of 1663 compounds. The reported average deviation of this model is 0.38 log units. In 1999 Wildman and Crippen[263] developed a purely atom-based model, ALogP, using a dataset of 9920 compounds and reported the average deviation to be 0.68 log units. In 2000 Viswanadhan[264] developed HLogP program based on a PLS regression model built on molecular holograms, a special type of fragmental descriptors. HLogP was shown to have better predictability for drug-like compounds as compared with the afore-mentioned CLogP and ALogP programs. Meylan and Howard[265] developed LOGKOW model based on 150 atoms and fragments with 250 correction factors. The model was derived from a training set of 2473 compounds and applied to an independent validation set of 10,589 compounds. Excellent prediction accuracy (standard deviation of 0.47 log units, and absolute mean error of 0.35 log units) was reported. Commercial program ACD/LogP (Advanced Chemistry Development Inc., www.acdlabs.com) is based on a model including 500 basic fragment descriptors and over 2000 correction factors.[266] In 1997 Wang et al.[83] built XLOGP model based on pure atomic contributions. Its version 2.0 includes 90 atom type descriptors with 10 correction factors, making rather good predictions with standard deviation of 0.35 log units on a dataset of 1853 compounds.[83] The commercial program Pallas ProLogP (CompuDrug International, Inc., www.compudrug.com) is also based on atomic contributions with additional correction terms.

There are also several whole-molecule approaches to predicting the log *P* values. Raevsky et al.[267] developed computer program SLIPPER-2001 based on the use of polarizability and hydrogen-bond descriptors in combination with structural similarity principle. The ALOGPS program developed by Tetko et al.[268,269] is based on a model built using associative neural network (ASNN) trained on 12,908 compounds from PHYSPROP database using 75 E-state indexes. For this model, the root mean square error of prediction is 0.35 log units and an absolute mean error is 0.26 log units. A dozen of other log *P* prediction models based on various physical–chemical, quantum-chemical, and topological descriptors are considered in a comprehensive review article by Katritzky et al.[171] At the same time a reliable prediction of this property remains a significant challenge as it was demonstrated by a benchmarking of commercial and academic algorithms for prediction of *in house* log *P* data.[270] The error of prediction >1 log unit of the best algorithms for $n=96$k compounds measured in Pfizer could be explained by differences in chemical diversity of *in house* and data used to develop the respective approaches. Thus, the majority of predictions were outside of the applicability domains[271] of the respective models, which contributed to their low accuracies of prediction. This conclusion was confirmed in the further study. The extension of the training set of the ALOGPS program[269] with new data allowed to reduce the error to 0.59 log unit for the same set.[272] Importantly, $>60\%$ of the most reliable predictions, as identified by the applicability domain,[271,272] had accuracy similar to that of experimental measurements.

Besides the *n*-octanol/water system, QSPR models for predicting partition coefficients in several other organic solvent–water systems have been developed. Leahy et al.[71,273] used physical–chemical Abraham's descriptors based on the linear solvation energy relationship to model log $P_{org/wat}$ for four solvents composing the "critical quartet": octanol, alkane, chloroform, and propylene glycol dipelargonate. It was argued that the set of solvents could be useful for modeling membrane binding and transport and therefore have particular reference to the rationalization of biological selectivity. Oliferenko et al.[274] used hydrogen bond basicity and

acidity scales to model partition coefficients in several systems: octanol–water, hexadecane–water, chloroform–water, gas–water, gas–octanol, gas–hexadecane, gas–chloroform.

To conclude, the majority of log $P_{oct/wat}$ prediction methods are based on atom- and fragment-based approaches. A serious limitation of these approaches is that reliable prediction can be made for only those compounds in which all atom and fragments types are also present and sufficiently abundant in the training set (the problem of "rare" fragments). Atom-based models can be applied for much larger sets of compounds than fragment-based models, but their predictions within the applicability domain of fragment-based models are less accurate. The problem of "rare" fragments can be partially solved using whole-molecule approaches based on physical–chemical properties or molecular descriptors. The main limitation of all log P prediction models, both atom/fragment-based and whole-molecule approaches, is they cannot be applied to compounds not similar to those in the training set.[98,271,272] One more limitation of almost all existing log P statistical prediction methods is they are not capable of taking into account sufficiently well 3D structures of molecules and the presence of intramolecular interactions.

3.16.5 Conclusions

Computational methods are important for the estimation of physical–chemical properties of chemical compounds for medicinal chemistry. Such methods are invaluable for the analysis and ranking of compounds from virtual libraries before such compounds are synthesized. During this century significant progress in prediction of physical–chemical properties was achieved for the prediction of pK_a. The current models are reported to achieve errors below 0.5 log units.[247] These models have made possible accurate prediction of log D and can also contribute better prediction of pH-dependent solubility. Still, a reliable prediction of properties such as intrinsic aqueous solubility,[207] or even partition coefficients[251,270] remains a significant challenge for complex compounds with many functional groups or those from *in house* libraries.

The development of text mining approaches has allowed automatic extraction of information from literature and, in particular, patents. This has made possible the collection of many MP data and the development of models to predict this property with errors of about 30 K for drug-like molecules.[144] Since the MP data measured in different laboratories have about the same accuracy, it is difficult to expect a further dramatic progress with prediction of this property. However, one may still develop more precise models for some particular classes of compounds, as it was reported in 150-year-old study of hydrocarbons.[138]

The estimation of the physical–chemical properties can be done using statistical or/and physics-based theoretical approaches, both groups of which were reviewed in this article. A limiting factor for the statistical methods is the availability of high-quality experimental data. The data also define the applicability domain of developed models and reliable predictions can be achieved only for similar molecules.[271,272] The further development of this group of methods can be expected with development of new HTS screening approaches allowing measurements of large datasets of experimental values; however, the HTS methods cannot be automatized for all properties. Moreover, costs of experimental measurements can significantly vary, which leads to different amount of data for various properties. In this respect the development of methods, which can explore intercorrelations between properties, for example, deep learning NN,[94], can further contribute to the advance of this field.

The development of physics-based approaches is related to the advance of theoretical methodologies and, actually, the development of HPC. The use of more physically relevant simulations, for example, explicit solvent or explicit–implicit solvent calculations, can result in a more accurate prediction of different physical–chemical properties of compounds. Despite the fact that the cost of rigorous explicit solvent calculations is still high,[219] the fast development of HPC should make the widespread use of such methods possible during the next decade.

Last but not least, the progress in the field strongly depends on public availability and user-friendliness of methods and models. The methods which are available on-line as free[275] or commercial software tools allow benchmarking of different approaches and, thus, significantly contribute to the development of computational and medicinal chemistry.[276]

3.17.1 Introduction

Drug discovery, particularly from an industrial perspective, has been analyzed from many angles. Since the 1980s, R&D innovation and productivity have been stated to be in decline.[1,2] To some extent, fascination with animal models, rather than the study of man, has been considered the culprit,[3] although high-throughput technologies, from chemical synthesis to biological screening,[4] and intellectual property concerns[5] have also been associated with the decline. Diagnoses[6] and solutions[7] have been proposed.

In this article, we discuss the process of drug discovery from an informatics perspective and focus on some of the *in silico* aspects that are pertinent to the practice of medicinal chemistry. In doing so, we address five questions, outlined in the succeeding text, with focus on discrepancies and issues of general concern to the practice of medicinal chemistry.

1. Where do drug targets come from? Can we compute target druggability?
2. Can we compute drug-likeness?
3. Can we use *in silico* methods to evaluate leads?
4. Are computational drug discovery criteria useful?
5. Can *in silico* technologies help medicinal chemists?

3.17.2 Where Do Drug Targets Come From? Can We Compute Target Druggability?

In the most general sense, drug targets are entities with molecular mass that are present in living systems, which can be perturbed upon interacting with therapeutic agents. Here, "living systems" refers to not only humans (or animals, if veterinary medicines are discussed) but also foreign organisms such as viruses, bacteria, and parasites that may be present in the human body. Therapeutic agents ("drugs") are, in the widest sense, substances that are administered to influence the outcome of the disease, whether to cure it, to reduce, or to eliminate some of its symptoms, or simply to improve the quality of life for the patient in question. It is important to recall that the interaction between a drug and its target results in an observable clinical outcome. For drug targets, "mode of action" (MoA), more precisely referred to as "mechanism of action," refers to the manner in which drugs exert their action at the molecular (target) level, resulting in the desired or intended therapeutic outcome, that is, the indication(s) stated on the drug package insert ("drug label"). However, some targets interacting with medicines may be responsible for what are commonly referred to as "side effects," which are often neither related to nor compatible with the indication.

Historically, drugs have been discovered through phenotypic observations,[8] and the exact identification of targets associated with drug mechanisms of action remains an arduous process.[9] Only by means of modern molecular and cellular biology, specifically technologies related to genetic engineering, can we establish a causality relationship between drug–target interactions at the molecular level and phenotypic and clinical outcomes. *To answer the first part of the first question, drug targets emerge from causal inferences that relate molecular events and phenotypic observations.*

Establishing causal inferences, however, requires significant effort. A survey of 67 internal projects at Bayer Healthcare concluded that only 25% of the data published elsewhere were confirmed in-house,[10] whereas two-thirds of the projects were not reproducible. The Hematology–Oncology group at Amgen noted[11] that reproducibility from "landmark studies" over a 10-year period was as low as 11%. As the role of the scientific community is to detect and correct such errors, leading National Institutes of Health (NIH) scientists have announced NIH initiatives to improve reproducibility in preclinical research.[12] Ioannidis concludes that most biomedical research findings are false,[13] and the issue of scientific reproducibility has a dedicated Wikipedia entry.[14] Furthermore, the lack of dissemination of negative clinical trial data is likely to keep competitors and academics focused on targets that may have already

been proved to be inadequate.[15] Some of the corollaries stated by Ioannidis[13] can be applied verbatim to target selection for drug discovery: *"The greater the financial […] interests and prejudices in a scientific field, the less likely the research findings are to be true"* and *"The hotter a scientific field (with more scientific teams involved), the less likely the research findings are to be true."* Since "more scientific teams" may include pharmaceutical companies, one needs to contemplate no further the risks concerning target selection.

Target "druggability" is defined as the ability of a target to be therapeutically modulated by medicines, and by definition, the "druggable genome" is comprised of genes that encode proteins that can be modulated by drugs for therapeutic purposes.[16] Hopkins and Groom restricted their "druggable genome" analysis[16] to those targets that can be modulated by orally formulated drugs, as estimated by the "rule of five" (Ro5, *vide infra*)[17] and concluded that the intersection between disease-modifying genes and the "druggable genome" results in a set of 600–1500 drug targets. Although Kubinyi responded that in vivo, single proteins may combine in ways that could in fact lead to many more drug–target combinations across multiple pathways, that is, a "druggable proteome" (or "targetome"), thus questioning the single-gene view,[18] the concept of "druggable genome" has become quite popular.

To understand target druggability, we need to know how many drug targets exist. A 1997 estimate of 483 targets[19] was revised in 2006 to 218 [20] and 324,[21] respectively. DrugBank,[22] an online resource that indexes 8203 drug entries, including 2198 FDA-approved small-molecule drugs and biologics, linked to 4333 nonredundant proteins.[23] Small-molecule drugs are associated to 1682 unique targets, whereas biologics target 234 proteins.[23]

We conducted our own extensive, independent curation at the European Bioinformatics Institute (EMBL-EBI), at the Institute of Cancer Research (ICR), UK and at the University of New Mexico (UNM). We identified 893 human and pathogenic biomolecules that we annotate, at the molecular level as MoA drug targets for 1578 FDA-approved drugs, and a small number of drugs approved elsewhere in Europe and Japan.[9] The 601 human proteins of the MoA drug targets subset are referred to as *"Tclin,"* in other words, protein targets through which a therapeutic agent is known to bind with potency that is appropriate for leading to the desired therapeutic outcome via the intended mechanism of action.

The discrepancies between the number of drug targets in the *Tclin* subset, comparing DrugBank target statistics, the analyses reported in 1997 and 2006, respectively, and our own study, can only in part be attributed to an increasing amount of evidence regarding the way in which drugs act. Even more relevant is the assignment of a drug target to a certain drug, particularly when linking drug–target interactions to desired therapeutic response, to side effects, to off-label effects (i.e., desired for a different indication), and last but not least, when linking the drug effect to different types of patients (e.g., responders and nonresponders. Serious challenges were encountered when assigning MoA targets for anti-infectives, since pathogens themselves, not molecular targets, are the primary object of study in microbiology.

Predicting target druggability is not trivial. Structural biology, computational chemistry, and medicinal chemistry aim to predict and test whether a protein can bind small, drug-like compounds[24] with high affinity and specificity, with structural biologists and computational scientists focused on *in silico* techniques to assess these interactions.[25] Many in-house programs, both in industry and academia, rely on this type of computational druggability assessment, using, for example, automated detection of protein-binding sites, pocket-feature computations related to their size, shape, and hydrophobicity, in order to rapidly detect "druggable" proteins.[26]

Hopkins and Groom instead focused[16] on specific protein domains from the InterPro database[27] and assign protein "druggability" based on the presence within a protein primary sequence, of specific protein domains known to interact with small-molecule drugs. By manually examining InterPro domains and including genes from the Consensus Chemical Database Service,[28] Russ and Lampel concluded that there may be 2200 druggable genes.[29] Others have expanded the druggable genome either by evaluating side-effect similarity for known drugs[30] or by performing combined chemical and target similarity queries,[31] followed by experimental confirmation of novel drug targets derived from clinical observation[30] or computation.[31] *To answer the second part of the first question, there are many conceptually distinct methods to predict target druggability. However, none of them can perform a rigorous de novo evaluation for proteins for which little knowledge exists.*

The emergence of new knowledge was the focus of a recent bibliometric evaluation, which examined how many of the newly sequenced proteins, for several target families, are the subject of new studies, 10 years after the sequencing of the human genome was completed.[32] This analysis concluded that the process of druggable target selection is conservative and that limited progress has been observed with respect to understanding newly discovered proteins. Choosing the appropriate proteins as drug targets remains a complex process, where scientific elements need to be balanced against commercial ones, for example, company investors and medical insurance companies, societal ones, for example, physicians and patients, and legal aspects, for example, regulators.[33]

To assist with target prioritization and selection, two precompetitive initiatives have emerged. Hosted by EMBL-EBI since 2015, the Open Targets Consortium[34] is developing the Target Validation Platform,[35] which provides robust and comprehensive data integration linking genes and proteins with human disease. At NIH, the "Illuminating the Druggable Genome" (IDG) program was launched in 2014, with the aim to catalyze research around understudied targets.[36] The IDG categorizes proteins based on available data, information, and knowledge from more than 100 sources. Quantification of available data and knowledge from IDG confirms the presence of a bias toward well-described proteins, particularly drug targets, or *Tclin*, bias that is confirmed not only with respect to patents and publications but also with respect to experimental data and molecular probe availability (e.g., antibodies and chemicals). About 37.5% of the human proteome is comprised of understudied proteins (*"Tdark"*). Given the current level of knowledge, *Tdark* proteins are poorly understood, and a knowledge deficit exists concerning experimental data, availability of patents, and scientific literature. Perhaps, scientists engaged in target druggability prediction, and target selection should focus to a higher extent on *Tdark*, where novel research and commercial opportunities in drug discovery may exist.[74]

3.17.3 Can We Compute Drug-Likeness?

Target druggability remains a challenging task, yet an equally important task is prediction of compound druggability. At the outset, we note that "drug" is not an intrinsic quality of chemicals.[37] There is a growing body of scientific literature concerning the computation of drug-likeness, some of which we comparatively discussed previously.[37] Yet, the "drug" attribute is an authorization issued by a regulatory body such as the US Food and Drug Administration to the sponsor, to market that therapeutic agent. In other words, a "drug" is deemed safe based on scientific evidence available at the time of the New Drug Application (NDA). NDAs must be obtained in each country, where committees weigh in all evidence, compare the submission with existing therapies and drugs, and decide to approve, or sometimes withdraw, the "drug" attribute from the therapeutic agent on the basis of efficacy, safety, and cost-benefit. Therefore, "drug" is not an attribute one could compute from molecular structure and is not a natural property of chemicals. At best, compound druggability is time-dependent and remains a heuristic process that is likely to require frequent revisions, as our body of knowledge concerning drugs develops.

Although the property of "drug" remains a societal issue, there remains a stringent need to assess compound quality, particularly given the large numbers of chemicals available. The iResearch Library from ChemNavigator currently has over 60 million unique chemicals from more than 200 chemical vendors.[38] Another chemical procurement service, eMolecules, tracks over 7 million screening compounds.[39] Therefore, there is a critical need to develop abilities to evaluate compounds for purchasing or further downstream after high-throughput screening (HTS) campaigns. Therefore, drug-likeness (or chemical druggability) prediction is not a direct answer to the question "could this molecule be a drug?" but rather an *in silico* estimate of the molecule's probability for becoming a drug. Given the large number of chemicals in need of evaluation, this is regarded as a machine (not human) learning problem, since the ability to distinguish between "drugs" and "nondrugs" is likely to remain limited to those few scientists that are successful "drug hunters."

We reviewed 18 reports on successful "drug-likeness" models elsewhere.[37] The first two models were disclosed[40,41] shortly after the Ro5 publication.[17] Briefly stated, machine learning models start with (at least) two sets of molecules, namely, "drugs" (though given the small sample space of approved drugs, this is often a larger set of chemicals of pharmaceutical interest) and "nondrugs" (typically reagents or compounds available for procurement), for which a set of molecular descriptors, perhaps physicochemical properties, are computed. From these datasets, machine learning models that successfully discriminate (on average, at the 80–90% rate) "drugs" from "nondrugs" are developed. Of the 18 models reported, 9 used "Available Chemicals Directory" (ACD) as the "nondrug" reference set. ACD is a very ill-defined reference set for "nondrugs," since nearly 40% of ACD (after removing all chemical structures of drugs from the ACD catalog) are chemicals with a high content of drug-like fragments, that is, these molecules are likely to be chemically similar to drugs.[42] To make matters more complex, the set of "nondrugs" has been constantly evolving. *In silico* efforts to model drug-likeness use sets of chemicals offered for purchase from a variety of vendors, including Sigma and ACD. Yet, computational chemists are actively working within the chemical vendor companies to match selection criteria imposed by the customers (academic groups and primarily pharmaceutical companies). The net effect of this adaptive process is that, over time, the "nondrugs" reference set is shifting more and more toward "drugs," since chemical vendors are making deliberate efforts to improve their offerings and maintain a competitive offering.

To conclude, machine learning remains the preferred method when analyzing large sets of molecules, such as chemical libraries, and when prioritizing chemicals for procurement and HTS. Thus, the development of models for drug-likeness can provide tangible benefits by saving time and resources allocated to preclinical drug discovery. However, as stated from the outset, the effort to predict "compound druggability" from molecular structure is a poorly defined problem, since "drug" is an attribute decided by regulators. Moreover, the "nondrugs" reference set is increasingly becoming more similar to "drugs." Without proper filters in place, machine learning models are likely to be derived from ill-defined (noisy) data, which in turn leads to overfitting, and diminished performance on external (blind prediction) sets. *To answer the second question, many models have been developed to predict chemical drug-likeness. Their use should be restricted to large chemical libraries. Experienced scientists (experts in "human learning") should be the deciding factor concerning in-depth profiling of individual chemicals.*

3.17.4 Can We Use *In Silico* Methods to Evaluate Leads?

To discuss lead-likeness, we need to examine Ro5 criteria more closely. This was the first study[17] to alert the pharmaceutical industry to the importance of restricting small-molecule synthesis in the property space defined by molecular weight (MW), the calculated octanol/water partition coefficient (ClogP), number of hydrogen-bond donors (HDO), and the sum of nitrogen and oxygen atoms in a molecule, as a surrogate for the number of hydrogen-bond acceptors (N + O). Lipinski et al. started with the analysis of the early (1994) results of HTS and combinatorial chemistry at Pfizer, where most of the hits were large (high MW) and hydrophobic (high ClogP), which in turn increased the difficulty of optimizing them toward oral drugs. Their analysis,[17] based on 2245 compounds from the World Drug Index that had reached phase II clinical trials or higher, looked at the 90th percentile for the distribution of $MW \leq 500$, $CLogP \leq 5$, $HDO \leq 5$, and $N + O \leq 10$. Natural products and actively transported molecules were excluded from this analysis. The authors concluded that if any two of the aforementioned conditions are violated, the molecule is unlikely to be an orally active drug.

We compared oral drugs approved up to 1997 (the year of the Ro5 publication) with those approved in 1998 and later and noted[43] that two or more Ro5 violations were present in 15.7% of the newer drugs (191 small molecules), compared with 5.6%

in the prior set ($N=661$). This indicates that the 90th percentile cutoff values are already shifting, a trend already noted a decade earlier.[44] Leeson and Davis noted that the median values for MW, CLogP, and N + O, as well as other parameters, went up when comparing sets of drugs approved before 1983 and during the 1983–2002 period.[44] Although the discussion focused on median values, we believe that looking at 90th percentile, which was effectively used to define Ro5, makes it more amenable for direct comparisons.

Table 1 shows an extension of the analysis reported earlier, as we examine temporal trends for Ro5 criteria.[43] Here, we extracted all orally formulated drugs approved by the FDA from DrugCentral,[45] a total of 1491 drugs. Of these, 11 lack precisely defined chemical structures (e.g., benzonatate is a mixture of three aliphatic esters) and were thus excluded from the analysis. The remaining set was queried for approval date. A set of 479 drugs lack approval information and were excluded from the comparison; $N=671$ drugs were approved in 1997 or earlier, whereas $N=330$ drugs were approved in 1998 or later. By examining the 10th, the 50th (median), and the 90th percentile, we confirm the trend observed earlier. Oral drugs shown an increase in MW for the newly approved drugs (e.g., MW = 586.39 at 90%), compared with those approved pre-1998 (MW = 469.66 at 90%). The same can be said for CLogP, which shifts from 5.06 to 6.28 at the 90th percentile, and for the hydrogen-bond acceptors (N + O), which shift from 9 to 12. Of equal interest is the number of drugs that are fully compliant with Ro5 criteria: Within the "older" drugs set, 81.7% drugs have Ro5 = 0, 12.46% have Ro5 = 1, and 5.85% have Ro5 ≥ 2. For the "newer" set, 69% drugs have Ro5 = 0, 15.9% have Ro5 = 1, and 15.1% have Ro5 ≥ 2. Confirming what Leeson and Davis noted in 2004, the number of Ro5 compliant drugs is decreasing over time.

The Ro5 cutoff values should not have been a multiple of five after all: After a careful reevaluation[46] of the same set of World Drug Index compounds, the 90th percentile cutoff values for Ro5 parameters were as follows: MW ≤ 427.5, CLogP ≤ 5.3, HDO ≤ 3, and N + O ≤ 8. Differences between these values and those reported in the original Ro5 study were attributed to differences in salt handling, duplicate structure removal, and other details in data processing. The reader will also note discrepancies between these values and those obtained from orally formulated approved drugs shown in **Table 1**.

Highly influential and groundbreaking, the Ro5 work remains one of the most cited papers in medicinal chemistry. This work raised the awareness of the medicinal chemistry community regarding the existence of a property space for oral drugs, forced us to examine the design of combinatorial libraries,[47] what the properties of drugs are,[48] the origin of leads,[49] and sparked interest in lead discovery. Many library design programs, based on combinatorial chemistry or compound acquisition, subsequently included the default Ro5 filters. However, as shown earlier, *Ro5 cutoff values are not likely to stand the test of time*, but are likely to shift toward higher values.

The ability to develop machine learning models that discriminate between "drugs" and "nondrugs" based on chemical fingerprints caused some confusion, as it was by default assumed that Ro5 criteria are also "drug-like." We showed that this was not the case during a comprehensive survey[48] of "drugs" versus "nondrugs." The outcome of many HTS campaigns[47] is usually *micromolar hits*, which when filtered according to the drug-based Ro5, are not easily amenable to medicinal chemistry optimization. We also pointed out[49] that the aim of HTS and combinatorial library design programs is to identify *leads*, not drugs. Therefore, the use of Ro5 filters for lead discovery is not warranted, at least not with respect to small organic compounds.

As we discussed in part 1, from a chemical standpoint, it is not clear what a drug is. By the same extension, a chemical lead, or drug prototype,[50] cannot be discussed in strict chemical terms. *"Lead" is not an intrinsic property of chemicals*, just as "drug" is not. Although the process of approving a drug follows very strict protocols, a significant process involving multidisciplinary evaluations and due diligence is observed when nominating a lead for further optimization.[51] What is a lead? Though a high number of compounds may be HTS hits or potent bioactive chemicals, not all of these are leads. Leads are compounds that are part of a series of analogs with validated biological activity, both in primary and secondary screens, against known targets. Whereas specific criteria for nominating a lead are project-dependent, lead compounds must also allow favorable intellectual property positioning and display good solubility and permeability and overall a promising pharmacokinetics and toxicology profile.

Although there is a general consensus that lead discovery is an essential goal that precludes drug discovery, the only way to analyze the nature of the "lead-like" space has been to examine chemical structures that, historically, were leads. We had to face the question[49] whether these chemical structures could provide an objective link between the chemical space of leads and the chemical space of drugs. Our preliminary survey of 18 lead–drug pairs prompted us to suggest[47] that lead-like libraries should be designed with lower MW(≤300) and lower CLogP (≤3.0) cutoffs, which constituted a significant departure from Ro5 criteria. An extension to 96 lead–drug pairs allowed us to note[49] differences between the median property value of drugs and leads, as

Table 1 Property distributions of the four Ro5 parameters for FDA-approved oral drugs

LogSw	385	−3.25	−5.24	643	−3.47	−5.31	320	−4.17	−5.53

follows: $\Delta MW = 69$, $\Delta N + O = 1$, and $\Delta CLogP = 0.43$ (among other properties). We concluded that lead structures exhibit, on the average, less molecular complexity (less MW and less number of rings and rotatable bonds) and are less hydrophobic (lower CLogP and LogD74) and less drug-like. An independent study reached similar conclusions,[52] starting with 470 lead–drug pairs extracted from Walter Sneader's monograph on drug prototypes.[50]

Criteria for lead-likeness have been subjected to several revisions. For example, a so-called "reduced complexity" lead-like set was assembled[53] at GSK using several computational criteria, for example, average values for $MW < 350$, $HDO \leq 3$, $N + O \leq 8$, $CLogP \leq 2.2$, and number of nonterminal rotatable bonds,[48] $RTB \leq 6$. The most extensive analysis was based on 385 documented leads, 1651 launched drugs, thousands of phase I, II, and III clinical trial drug candidates, and tens of thousands of literature-reported high-activity or inactive molecules.[54] The 90th percentile from the 385 leads were as follows: $MW \leq 436.9$, $CLogP \leq 5.08$, $HDO \leq 3$, $N + O \leq 11$, and $RTB \leq 10$. We also reported 90% values for calculated intrinsic aqueous solubility ($LogSw \geq -5.24$), computed with the ALOGPS software,[55] and for the number of rings ($RNG \leq 4$). For comparative purposes, these values, together with median values, are shown with properties of oral drugs in **Table 2**.

Whereas these data support the general notion that leads are, in fact, smaller compared to oral drugs, there is no definite conclusion regarding CLogP, RNG, and RTB (except for drugs post-1997 that are more hydrophobic, may have more rings and more flexible bonds). A weak trend is observed for LogSw, which is that leads are on average slightly more soluble, but not markedly so. However, without experimental data, it is difficult to draw additional conclusions.

Although based on a smaller statistical sample (below 500) compared to "drugs," the concept of lead-likeness appears to continue to play an important role in drug discovery, perhaps as important as the concept of "drug-likeness." *The answer to the question, can we compute lead-likeness, has a case-dependent answer. Just like "drug," "lead" cannot be computed from molecular structure. Although several paradigms for lead discovery have been proposed, it would be prudent to avoid "one-size-fits-all" criteria for leads, since each project has specific needs, both from a chemical series and from a therapeutic perspective.* For example, leads for a urinary tract anti-infective project would require high solubility and the ability to pass through glomerular filtration; by contrast, leads for an anti-inflammatory project for topical (skin) applications would require lower solubility but high CLogP.

3.17.5 Are Computational Drug Discovery Criteria Useful?

Some of the extensions of the Ro5 concept[17] and the lead-like concept[47] are summarized in **Fig. 1** and discussed in this section. The first Ro5 extension was developed[56] at GSK from rat bioavailability data from a proprietary set of 1117 compounds: Their model stated that using $RTB \leq 10$ and $PSA \leq 140$ Å^2 as cutoff values would capture ~80% of the compounds with oral availability above 20%. Not reproduced on 434 Pharmacia compounds,[57] this model is also not supported by oral drugs, data shown in **Table 3**. While the 90% cutoffs for oral drugs pre-1998 for PSA (127.1 Å^2) and for RTB (9) are well within the range proposed by Veber et al.,[56] these values would capture less than 90% of oral drugs approved after 1997. The 90% distribution moments are 150.8 Å^2 for PSA and 12 for RTB (data in **Tables 2** and **3**). When applied simultaneously, these two criteria capture 259 out of 330 oral drugs; the same criteria for pre-1998-launched drugs capture 575 out of 671 compounds. From the entire dataset ($N = 1480$; see **Table 1**), only 1418 drugs have PSA and RTB calculations; of these, 1228 (or 86.6%) satisfy the Veber criteria. This is a reasonable success rate given that one parameter (RTB) is not represented by Ro5 criteria (note that PSA and hydrogen-bond donors/acceptors correlate), but we should recall that 190 oral drugs (of which, 71 were launched after 1997) are excluded by these criteria. As shown by the increase in 90th percentile values for "newer" drugs, the Veber criteria are not likely to stand the test of time.

Conceptual developments in the rapid evaluation of large chemical libraries, in particular for compound druggability and lead-likeness, paved[58] the way for fragment-based drug discovery,[59] particularly after "rule of three" (Ro3) was formulated.[60] Stated succinctly, Ro3 imposed the following cutoff values for fragments: $MW < 300$, $CLogP \leq 3$, $RTB \leq 3$, $HDO \leq 3$, and $N + O \leq 3$. An additional parameter, polar surface area ($PSA \leq 60$ Å^2) was also considered useful during fragment selection (see **Fig. 1**). Although

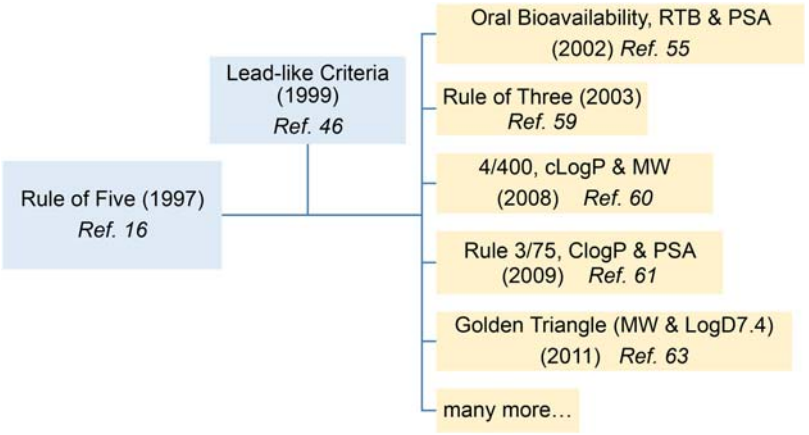

Fig. 1 The evolution of metrics in lead and drug discovery literature. Most of these metrics contain a measure of molecular size (typically MW), hydrophobicity (typically CLogP), and hydrogen-bonding capacity (e.g., PSA), which reflect the Ro5 criteria.

Table 3 Property distribution for additional parameters discussed throughout the text, for FDA-approved oral drugs. See text for details

	All oral drugs				*Oral drugs approved pre-1998*				*Oral drugs approved after 1997*			
Category	*N*	*10%*	*50%*	*90%*	*N*	*10%*	*50%*	*90%*	*N*	*10%*	*50%*	*90%*
PSA	1468	21.3	66.6	134	666	18.1	63.5	127.1	320	330	81.6	150.8
LogD74	1471	−2.18	1.31	3.97	669	−2.43	1.07	3.63	328	−1.14	1.97	5.03
FSP3	1450	0.13	0.40	0.76	656	0.12	0.40	0.78	327	0.13	0.36	0.69
Chiral#	1471	0	1	6	669	0	1	6	328	0	1	5

these parameters are designed for fragments, not drugs, it may be of interest to know how many oral drugs match Ro3 criteria: out of 1418 oral drugs in this set, 134 match the first 5 criteria, with only 119 matching the sixth one, PSA ≤ 60 Å^2. Of these, 21 drugs (16, including PSA) were approved in 1998 or later.

Looking at an information-rich set of ~30,000 internal GSK compounds, Gleeson chose to examine MW and CLogP, as two almost orthogonal dimensions derived from a set of 15 computational descriptors.[61] He then compared the influence of MW and CLogP on a number of pharmacokinetic properties, including solubility, permeability, bioavailability, and blood–brain-barrier penetration, metabolism via cytochrome P450 enzymes, efflux transport via P-glycoprotein, and inhibition of the K+ ion channel, hERG. Based on extensive analyses, he then identified two qualitative filters, namely, MW < 400 and CLogP < 4 (also known as the 4/400 rule), which are likely to lead to molecules having more desirable properties, compared with the molecules having one or both of these parameters above the cutoff values.

We applied the same filters on the 1412 oral drugs discussed throughout this work. Indeed, there appears to be an enrichment of drugs that match the 4/400 rule, as this parameter selects ~60% of the drugs (**Table 4**). However, nearly 40% of the drugs ($N = 577$) lie above this cutoff value, with CLogP having perhaps a slightly stronger influence than MW. We note that, while there are fewer (less than 10%) pre-1998 drugs in the high-MW/high-CLogP quadrant, there is a significant increase in the post-1997 (newer) drugs—more than 25% of the newer drugs have high MW/high CLogP. This is not surprising, as the data match similar trends concerning the Ro5 violations discussed in section "Can We Compute Drug-Likeness?" Although the 4/400 criteria appear to provide an overall enrichment for oral drugs, this filter appears to be less effective for newer drugs, as ~57% of these ($N = 183$) are not 4/400-rule compliant. Thus, the Gleeson criteria are unlikely to stand the test of time.

Table 4 Count of drugs using the 4/400 filters (MW and CLogP), for FDA-approved oral drugs. The second column (shaded) matches the Gleeson 4/400 criteria[61]

Oral drugs (N = 1412)	*MW < 400, CLogP > 4*	*MW < 400, CLogP ≤ 4*	*MW ≥ 400, CLogP ≤ 4*	*MW ≥ 400, CLogP > 4*	*Total*

Total	415	390	438	169	

By examining in vivo toxicology outcomes on 245 preclinical Pfizer compounds, Hughes et al. found an increased incidence of toxicity for low-polarity, high-lipophilicity compounds,[62] as defined by CLogP > 3 and PSA < 75 Å^2. The authors claimed that the promiscuity of highly lipophilic molecules may lead to an increased in vivo toxicity. This is currently referred to as the 3/75 rule. A dramatic illustration that dataset dependence can result in misleading conclusions is provided by Muthas et al., who examined toxicity observed before phase II studies of 150 AstraZeneca development compounds.[63] The exact opposite parameters, CLogP < 3 and PSA > 75 Å^2, provide enrichment for high-toxicity compounds on their internal dataset. They confirmed that this was also the case had they classified the dataset on toxicity observed in the preclinical in vivo studies and thus more closely resemble the Pfizer study.

Hughes et al. wrote[62] that *"high-CLogP/low-PSA compounds are approximately 2.5 times more likely to be toxic as to be clean, representing an odds ratio of greater than 6"* and that *"compounds with low CLogP/high PSA are approximately 2.5 times more likely to be clean as to be toxic."* If these parameters had any relevance for general clinical outcomes, we would have expected to see a skewed distribution of drug counts when examining the 1412 oral drugs discussed earlier. However, this effect is not present, regardless of the time point of the drug launch (**Table 5**), confirming a similar observation[63] made by Muthas et al. We note fewer approved drugs in the high-CLogP/high-PSA quadrant, probably due to the difficulty of making drugs that are highly lipophilic and water-soluble (as reflected by high PSA). Unless the in-house compound collection warrants this type of filtering, one should exercise care when applying the 3/75 rule.

Another proposal built on Ro5 criteria, the "Golden Triangle," is a visualization device that plots MW against LogD7.4, which is the octanol–buffer (pH 7.4) partition coefficient. The Golden Triangle is best explained by the authors: "*(1) As MW decreases, the lipophilicity range affording both permeable and stable compounds increases; (2) within a LogD bin, the relative number of permeable and stable compounds increases as MW declines; (3) Within a LogD range of 1.0–2.0, the opportunity for permeable and metabolically stable compounds increases; (4) all trends combined lead to the observation that the polarity and MW of in vitro permeable and low clearance compounds are concentrated within an area with a base-line from LogD = −2.0 to LogD = 5.0 at MW = 200 and an apex at LogD = 1.0–2.0 and MW = 450. These trends lead to a triangular shaped area known as the Golden Triangle and molecules within this area that are low clearance and permeable are said to obey the Golden Triangle Rule. While LogD positively correlates with permeability at a given molecular mass, LogD is negatively correlated with the in vitro clearance, giving rise to a balanced maximal effect near LogD 1.0–2.0. The strong influence of polarity and MW on permeability and in vitro metabolic stability give rise to the observed improvements in both clearance and absorption inside the Golden Triangle. In the center of the Golden Triangle (LogD = 1.5, MW = 350), 25% of the compounds pass permeability and clearance criteria, although percentages will vary according to limits imposed defining stable and permeable compounds. Compare this 25% "success" rate in the heart of the Golden Triangle with the 3% "success" rate at MW 450 at both LogD 0 and 3.0 and the odds of preparing an in vitro low clearance and permeable compound diminishes by roughly eightfold. Beyond a MW of 450, there is a precipitous lowering of likelihood that in vitro low clearance and permeable compounds exist."*[64] Furthermore, *"the Golden Triangle boundaries shift slightly from series to series."*[65]

It is quite challenging to compare data calculated from 1418 oral drugs with a set of parameters that is not precisely defined. Within this article (e.g., **Table 3**), we use calculated LogD7.4, using software from ChemAxon.[65] Data in **Table 3** shows that a LogD74 baseline between −2 and 5 covers most of the drugs ($N = 1228$ or 86.6%). We note that the calculated range goes from −14.42 (for paromomycin, an older aminoglycoside antibiotic) to +17.16 (for ubidecarenone, commonly known as coenzyme Q10, sold as a dietary supplement). Such extremes are clearly impossible to measure. After restricting our analysis to the range of LogD7.4 from −2 to +5, we were unable to detect a pattern reminiscing of a Golden Triangle, even after filtering MW to a range below 600. **Fig. 2** reproduces the visualization shown[65] in Figure 7. Based on an attempt to digitize an image and absent exact parameter cutoff values, we estimate that these filters remove approximately 500 drugs from the 1228 set. Recalling the 190 drugs eliminated because their LogD7.4 is outside the range from −2 to +5, we can conclude that the MW/LogD7.4 space defined by the Golden Triangle rule eliminates ~50% of the orally approved drugs.

We have shown, earlier, that most of these metrics have questionable values. Kenny and Montanari[66] highlighted that the importance, or strength, of many of the reported relationships, such as the Golden Triangle, is overstated because the approaches used to analyze and visually represent the data exaggerate trends in data. Another parameter covered in **Table 3** highlighted the apparently overlooked importance[67] of the fraction of sp3 carbons, FSP3. In that report,[67] binning FSP3 as a function of LogSw resulted in a high correlation ($r = 0.97$), which suggests a very strong relationship. Since these data were made available as supplementary material, Kenny and Montanari reanalyzed it without data binning, which inflate artificially the correlation for FSP3. They noted that the correlation coefficient between FSP3 and LogSw is only $r = 0.25$. We found no such relationship ($r = 0.06$) when computing the

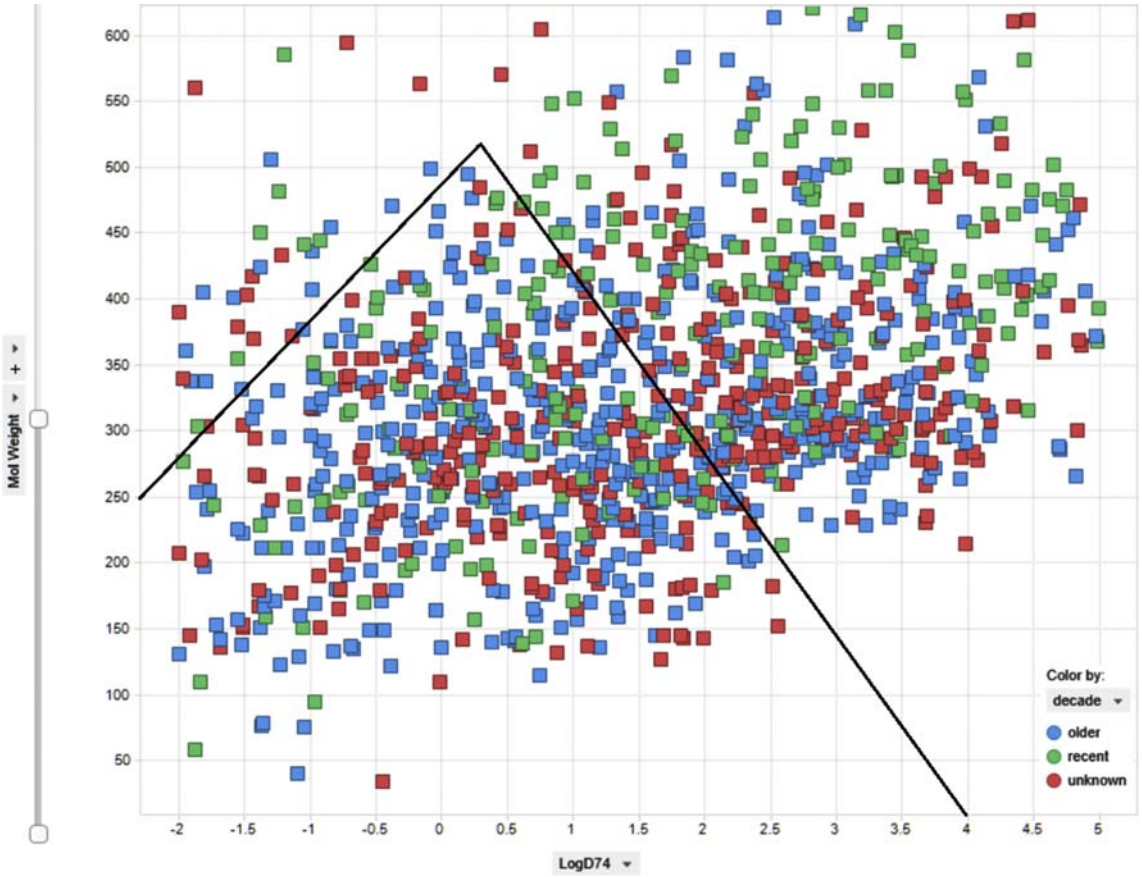

Fig. 2 Calculated LogD7.4 and MW values for oral drugs, using the Golden Triangle scheme. Older drugs refer to drugs approved pre-1998, whereas newer drugs refer to drugs approved post-1997.

relationship between FSP3 and LogSw for the $N = 1418$ drugs used in this article. However, Kenny and Montanari reported that the correlation between MW and LogSw for this study was actually much higher ($r = -0.62$) and questioned why Lovering et al. placed such an importance on FSP3, which only described 6% of the LogSw variance. We confirmed the MW/LogSw relationship ($r = -0.61$) for the 1418 drugs.

Lovering et al. stated[67] that *"as compounds are prepared in the drug discovery setting and transition from discovery through clinical trials to drugs, those that are more highly saturated are more likely to succeed in these transitions. Saturation also increased the likelihood of higher solubility and lower melting points. Compounds are much more likely to succeed as drugs if they have appropriate values for these properties. Another descriptor for complexity, the presence of stereo centers, also increases as we transition from discovery, through clinical trials, to drugs. This held true even after filtering compounds that failed any one of the Ro5, as well as had greater than 10 rotatable bonds."* As shown in **Table 3**, the median and the 90th percentile for FSP3 are slightly shifted, from 0.4 to 0.36 and from 0.78 to 0.69, when examining "older" versus "newer" drugs. Combined with the observation that the 90% number for chiral centers (chiral#) drops from 6 to 5 for the same period, we conclude that the opposite trend occurs. That is, newer drugs are less saturated and have lower complexity, whereas RTB, the number of rotatable bonds, is increasing (*vide supra*).

3.17.6 Can *In Silico* Technologies Help Medicinal Chemists?

> When a measure becomes a target, it ceases to be a good measure
>
> Charles Goodhart[68]

To properly address this question, we first note some of the systemic problems that exist in biomedical research, as they are pertinent to medicinal chemistry as well. The practice of Western (allopathic) medicine through the ages has introduced a separation of diseases by organs and by medical specialties. Whereas this separation is well suited for medical practice, it has translated into a conceptual fallacy with respect to biomedical research. Just as NIH institutes are separated by disease areas, so are medicinal

chemistry and drug discovery units separated by therapeutic areas. And yet, genomics, pharmacology, and molecular biology, to name a few sciences, have no such separation. The same molecular pathways, the same biology, are at work regardless of organ or cell. The consequences of this "mental divide" have yet to be examined, but we believe they hamper progress in the search for new cures.

Another systemic issue is the objectification of disease. As we stated elsewhere,[9] *"Medical care has two goals: to properly diagnose the disease and to select the appropriate therapeutic. As long as (drug-induced) phenotypic alterations are observed under appropriate conditions, it is possible to steer medical care and adjust the therapeutic management for a better outcome. Hence, the key to successful drug discovery and application resides in the seamless integration of pathological mechanisms of disease (that is, molecular and cellular level processes) with diagnoses (clinical embodiments of disease at the organ and/or organism level) and therapeutics (that is, modulating clinical manifestations at the molecular level via therapeutics)."* Somewhat related to overspecializing in a therapeutic area, this has practical implications for basic scientists, particularly in the pharmaceutical industry. It is quite common for clinician scientists, active at university hospitals, to interact with basic scientists on a daily basis. This provides a fertile, common ground, where clinical and fundamental scientific aspects are discussed. Unfortunately, clinicians are rarely accessible for industrial scientists, which may prove to be a detrimental practice, with respect to understanding physical manifestations of disease and practical approaches to therapeutics.

Throughout this article, we questioned most of the guidelines that are currently influencing the practice of medicinal chemistry. Analyses by Kenny and Montanari[66] and by Muthas et al.,[63] as well as our own analyses based on over 1400 oral drugs, highlight some of the issues associated with drug discovery "metrics." Many such metrics, not covered here, study the same space, of oral (or nonoral) drugs, chemical probes, leads and drug prototypes, and targets associated with drugs, while ignoring the basic tenet that "drug" is not a computable property, nor are "lead" or "drug target." To drill this point further, a MoA drug target would cease to be a Tclin target if the only approved drug that is known to act via that target is withdrawn. In other words, "Tclin" targets are a human-given attribute. Moreover, many of the "metric" studies are based on applied statistical analyses, but as Kenny and Montanari have shown,[66] several of these papers have questionable statistical and scientific validity—which reinforces the tenet by Ioannidis[13] even further.

One of the most popular metrics, ligand efficiency[69] (LE) and derivatives such as lipophilic ligand efficiency[70] (LLE) have been criticized at the fundamental level by Kenny et al.[71] They point out that the defining assumptions are made arbitrarily and take no account of the possibility that different activities might respond differently to a risk factor. This arbitrariness was highlighted by comparing LE and LLE. In the common formulation of LE, the scale taken for potency is free energy divided by the number of heavy atoms, whereas the ligand lipophilicity scale uses potency on a pIC50 scale and offset by lipophilicity. The thermodynamic standard states chosen for the metrics are not defined, and the choice has a large effect upon how these metrics perform. Whether logP is the most appropriate measure of hydrophobicity is seldom questioned, as the n-octanol–water scale is itself an arbitrary measure of hydrophobicity, and n-octanol partition "does not sense" hydrogen-bond donors to the same extent as it senses acceptors. As there are many methods to calculate LogP and some use LogD7.4 (also with multiple ways to compute it), the results are not likely to be comparable from one LE/LLE study to another. No consideration is given to the ionization state of the ligand as it binds to the receptor (which should be the most relevant state). Their recommendation is, that if the question is, do these compounds "beat the trend," then this trend should first be defined via a least-square regression to the risk factors. The residual of such a correlation would inform on the extent to which a compound forms the series "beats the trend." The variability of computer models and the dangers of generalization were also noted by Clark[72]: *"First, perhaps obviously to computational scientists, the precise values that are obtained for the number of rotatable bonds in a molecule and its polar surface area depend upon the software that is used to compute these quantities. So, unless it is certain that the software used is the same as in the work used to derive the "rule," then there is always the danger that a compound will be misclassified,"* and *"it is likely to be extremely difficult to obtain a simple and general rule to predict a complex physiological endpoint such as oral bioavailability; that great caution should be exercised when prospectively applying conclusions obtained from one set of data using one particular computational protocol to other data sets using different protocols."*

Some of these metrics cannot even be reproduced,[56,64,73] as we and others have illustrated. These metrics are becoming the target, as stated by Goodhart.[68] We fear that these metrics are invented to mask the lack of productivity and the inability to introduce new drugs in the market and that Ro5 derivative metrics are often used to justify productivity (or lack thereof). In other words, one of the reasons for this "soft science" of metrics is that it provides goals to be met and discussed during annual performance reviews. "How many Ro5 compliant compounds have you made/tested," a performance-review goal introduced at Pfizer in the late 1990s, has evolved into a plethora of rules, most of them derived only from one company's collection and not reproducible by others. In fact, the claim made by Ioannidis[13] that most published research findings are false is likely to apply to most (if not all) drug-space-derived metrics. Just like we are witnessing an increasing number of new drug approvals that are not Ro5 compliant, most of these rules will be rendered false by the emergence of new drugs within the next decade.

There is a growing division among medicinal chemists, those who believe that controlling fundamental properties is important in minimizing compound-related attrition through development and those who believe they are unimportant and/or these quality metrics are invalid. This later camp believes that these metrics unduly limit medicinal chemists, who should strive to break free from the "tyranny of Lipinski" and the Ro5 space. But there is a more nuanced third camp. It was Picasso who once said that it took him 4 years to paint like Raphael but his whole life to learn to paint like a child. Acceptance that certain property space limitations exist for some drug classes, because these properties reflect inherent pharmacokinetic or pharmacodynamic limitations (e.g., what drives low solubility or poor cell permeability) can stimulate creativity and more innovative ways to solve the problem at hand. For example, chemists who work with peptides, a drug class clearly outside the Ro5 space, are trying to work around physicochemical limitations by cyclization, N-methylation, or hydrogen-bond matching or making use of active uptake processes to get the peptides into cells or

via lipidation to increase peptide half-life for example. From this middle-ground perspective, metrics and *in silico* models can be used to adequately sample the chemical space and to limit the actual number of experiments, help interpret results, and guide future work.

Acknowledgments

This work was supported by NIH grants U54 CA189205, P30 CA118100, and UL1 TR001449 (TIO). We would like to thank Dr. Oleg Ursu (UNM) for preparing the DrugCentral database and Dr. John Overington (BenevolentAI), for countless conversations on the topic of druggability.

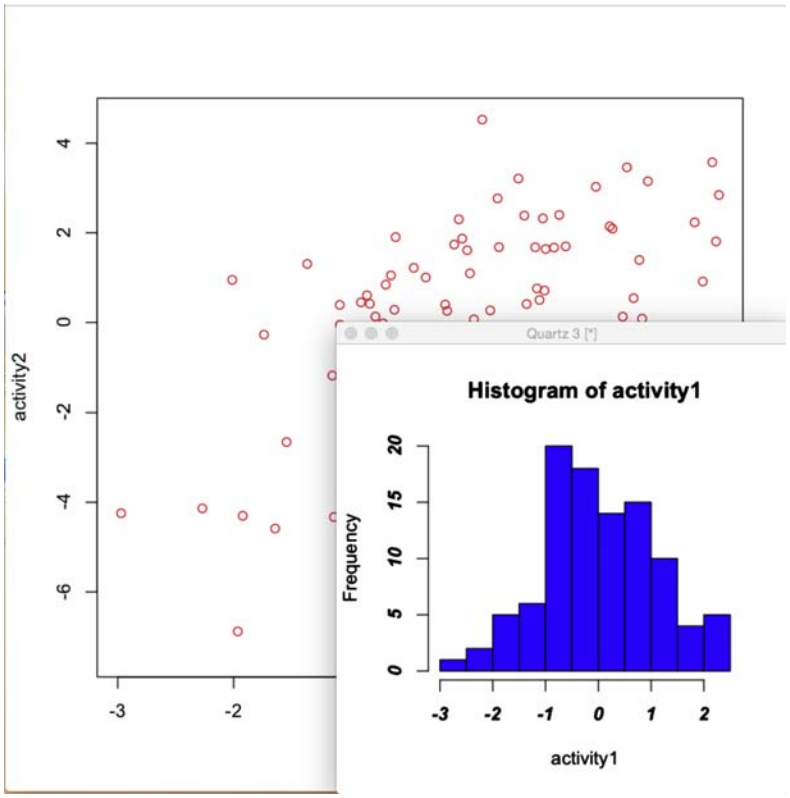
3.18.1 Introduction

All scientists know that every experiment generates data, but collecting data is usually the easy part; indeed, experiments can often generate vast amounts of data ("big data"). The challenge has always been to turn the data into something useful. For this, we use a variety of different tools, and indeed, there is a vast array of tools from which to choose. These can range from open-source libraries or frameworks to sophisticated desktop applications costing many thousands of pounds. Some are command-line driven with a steep learning curve, while others offer a simple graphic user interface; others are components of computational chemistry or molecular modeling packages. The purpose of this article is not to try and detail every option available but to highlight selected tools that might be used in different environments bearing in mind that the audience will likely be scientists and most probably chemists. A number of molecular modeling packages also include data analysis tools, but they are not included in this article since data analysis is not the primary feature of the software. The first part of the article looks at command-line or programming languages, probably initially the preserve of specialists, but with the widespread adoption of Python as the lingua franca of scientific programming, many more scientists are using it for data analysis. The next section deals with desktop tools; this section could easily provide content for an entire book, and thus, this article focuses on those tools that provide cheminformatics support. The remainder of the article is intended to be rather more forward-looking, exploring the emergence of web-based or mobile apps and finally the possible implications of "big data."

3.18.2 Command Line/Programming Tools

R (http://www.r-project.org) is a programming language and statistical computing environment; it is open-source and cross platform, and precompiled versions are available for multiple platforms. In the 17th annual KDnuggets data miners poll in 2016 (http://www.kdnuggets.com/2016/06/r-python-top-analytics-data-mining-data-science-software.html), R was the most popular tool among data miners and scientists. While much of the source code for R is written in C, C++, and Fortran, many of R's main functions are written in R itself.

Perhaps the greatest strength of R is that it is highly extensible through user-submitted packages. Currently, there are 9715 packages listed (http://crantastic.org) (as of Jun. 2016). These packages provide access to a range of specialist statistical techniques; of note are caret (https://cran.r-project.org/package=caret) for machine learning and also randomForest (https://cran.r-project.org/web/packages/randomForest/index.html) and nnet (https://cran.r-project.org/web/packages/nnet/index.html). For plotting ggvis (https://cran.r-project.org/web/packages/ggvis/index.html) and ggplot2 (https://cran.r-project.org/package.ggplot2) support graphing, interactive plotting, and reporting tools.



Example of plotting within R.

Bioconductor (http://www.bioconductor.org/about/) provides access to a fantastic range of statistical and graphic methods for the analysis of genomic data; however, the support for chemistry within R is limited.

ChemmineR (http://www.bioconductor.org/packages/devel/bioc/vignettes/ChemmineR/inst/doc/ChemmineR.html) is a cheminformatics package for analyzing drug-like small-molecule data in R. Its latest version contains functions for efficient processing of large numbers of small molecules, physicochemical/structural property predictions, structural similarity searching, classification, and clustering of compound libraries with a wide spectrum of algorithms. ChemmineOB provides access to some of the cheminformatics functionality available in Open Babel.

The rcdk[1] package provides R users access to CDK,[2] a cheminformatics framework written in Java. Rajarshi Guha has put together an excellent slide deck describing cheminformatics in R (http://www.slideshare.net/rguha/cheminformatics-in-r).

On importing molecules, it is often necessary to "wash" molecules to remove counterions, often done by simply selecting the largest component.

```
> m <- parse.smiles("c1ccccc1")
> is.connected(m)
[1] TRUE
>
> m <- parse.smiles("C1CC(N=C1)C(=O)[O-].[Na+]")
> is.connected(m)
[1] FALSE
>
> largest <- get.largest.component(m)
> length(get.atoms(largest))
[1] 8
```

Chemical structure-based queries are also possible using SMARTS (http://www.daylight.com/dayhtml/doc/theory/theory.smarts.html).

```
mols <- sapply(c("CC(C)(C)C",
                 "c1ccc(Cl)cc1C(=O)O",
                 "CCC(N)(N)CC"), parse.smiles)
query <- "[#6D2]"
hits <- matches(query, mols)

> print(hits)

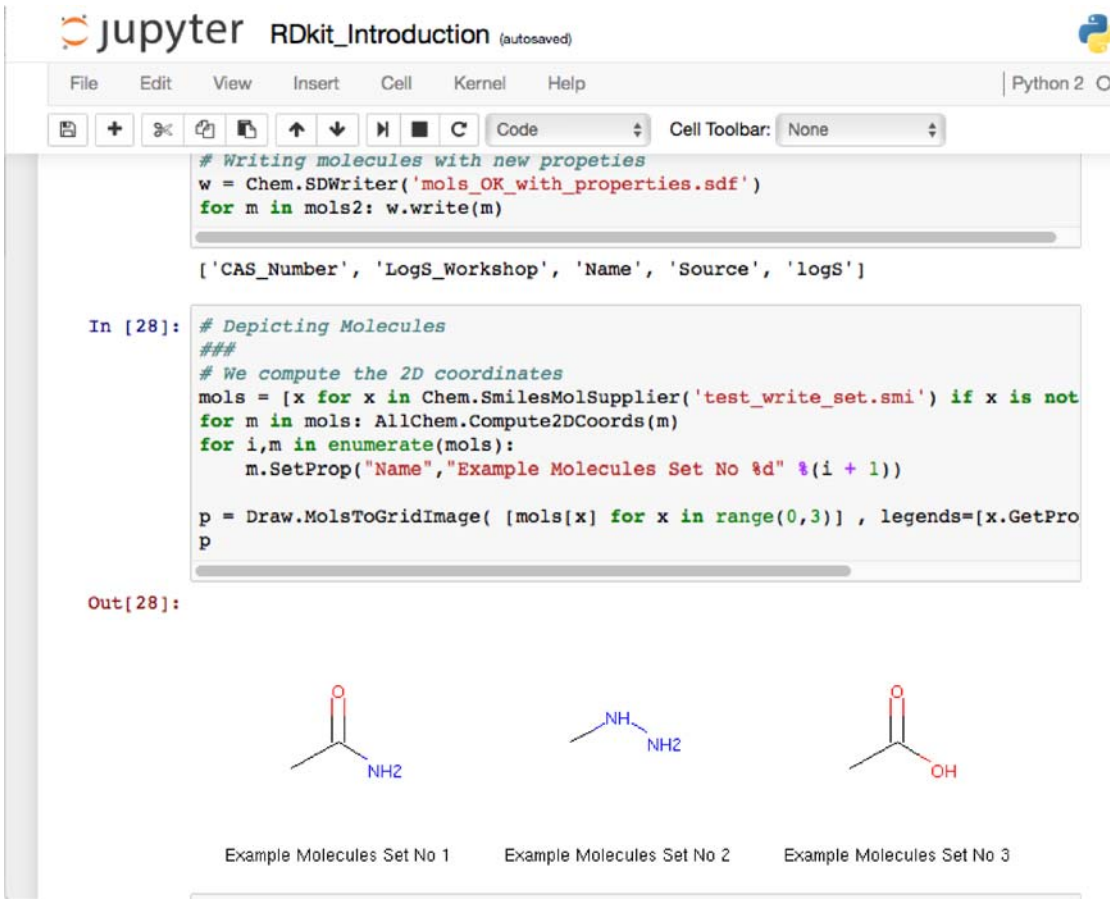
Julia (http://www.julialang.org) is a high-performance programming language designed to approach the performance of C while maintaining a code language format that would be readily accessible to scientists familiar with other mathematical languages. While most users probably use the command line, it is also possible to use the Jupyter Interactive Notebook environment (https://github.com/JuliaLang/IJulia.jl) originally developed for Python. This combination allows you to interact with the Julia language using Jupyter/IPython's graphic notebook, which allows the user to combine code, formatted text, math, and multimedia in a single document. In a similar manner to R, Julia can be extended by installing specific packages; currently, there are 624 packages (as Jul. 2015). It appears there are no packages supporting cheminformatics.

In the 17th annual KDnuggets data miners poll in 2016, Python (https://www.python.org) usage was highlighted as the fastest growing platform and likely to overtake R in 2 or 3 years. Python was also the most popular of the programming languages earning nearly three times the votes of Java, the next most popular.

Python is an open-source, cross platform scripting language; it has a relatively simple syntax and has a reputation for rapid prototyping. Similar to R, there is a very active community of users contributing libraries to support needs in very diverse fields. In addition, there is the IPython notebook, an interactive notebook environment,[3] which allows the user to combine code, formatted text, math, and multimedia in a single document.



Originally developed by Fernando Pérez, a data scientist at the University of California, Berkeley, and computational physicist Brian Granger at California Polytechnic State University in San Luis Obispo, the IPython notebook concept is being expanded to incorporate other languages (http://jupyter.org). The IPython notebook provides an environment for scientists to write and test code but is also ideal for teaching, collaboration, and sharing (http://nbviewer.ipython.org).

The popularity of Python among scientists for data analysis is probably due to the strength of several core libraries matplotlib, NumPy, SciPy, pandas, and IPython notebook. Python is also excellent for acting as scripting language to integrate other programs into a workflow.

pandas (http://pandas.pydata.org) is a library providing a high-performance data framework within Python. NumPy (http://www.numpy.org) adds support for large, multidimensional arrays and matrices, together with a library of high-level mathematical functions. SciPy (http://www.scipy.org) provides modules for optimization, linear algebra, integration, statistics, and interpolation. scikit-learn (http://scikit-learn.org/stable/) is an open-source machine learning library giving access to classification, regression, and clustering algorithms including support vector machines, random forests, gradient boosting, *k*-means, and DBSCAN. matplotlib (http://matplotlib.org) provides publication-quality 2-D plotting and limited 3-D plotting. Rpy2 (http://rpy.sourceforge.net/index.html) provides both a low-level interface to R from Python and a high-level interface, including wrappers to graphic libraries and R-like structures and functions; the aim is to abstract some of the details and provide an intuitive interface to both Python and R programmers.

Cheminformatics is well supported under Python; cinfony[4] is a python library that provides access to a variety of cheminformatics toolkits via a common API, in particular Open Babel, RDKit, CDK, Indigo, JChem, OPSIN, and cheminformatics web services. Many of the toolkits also provide their own Python binding. The Cactvs toolkit is now accessible from Python,[5] and commercial cheminformatics packages such as ChemAxon (https://www.chemaxon.com/webservices/python/) and OpenEye (http://www.eyesopen.com/toolkits) provide python access.

There is a comprehensive listing of Python numeric and scientific here https://wiki.python.org/moin/NumericAndScientific.

George Papadatos, ChEMBL Group, and EMBL-EBI have kindly provided this example of IPython notebook for getting biological target predictions based on the current multicategory Naive Bayesian ChEMBL_20 models for a single-molecule input. The predictions are ranked by the output classifier probability or score (http://nbviewer.ipython.org/gist/madgpap/10457778).

First of all, get the models from the ChEMBL ftp site and import the necessary modules and set up plotting.

```

This IPython notebook nicely illustrates some of the features that make Python such a popular choice, in particular in-line display of plots and chemical structures, the easy integration of web services, and access to machine learning modules. In addition, the completed IPython notebook can act like an application; simply edit the path to an input file and then rerun.

In the recent poll (http://www.kdnuggets.com/2015/05/poll-r-rapidminer-python-big-data-spark.html#pro), Java was behind Python in popularity but still commands a significant number of users. Again, the popularity stems from open-source libraries; Java Data Mining Package (https://jdmp.org) is an open-source Java library for data analysis and machine learning. JDMP facilitates the access to data sources and machine learning algorithms (e.g., clustering, regression, classification, graphic models, and optimization); it also interfaces with Weka,[6] which is a collection of machine learning algorithms for data mining tasks. Weka contains tools for data preprocessing, classification, regression, clustering, association rules, and visualization. Cheminformatics support comes from CDK,[2] *JChem* (https://www.chemaxon.com/), or a wrapper for RDKit (http://www.rdkit.org/).

Bioclipse (http://bioclipse.net) is an open-source scientific workbench based on the popular Java Eclipse platform (http://eclipse.org). Cheminformatics support comes from CDK,[2] and data analysis is provided by integration of R (http://www.r-project.org). Bioclipse has its own scripting language based on Javascript.

MATLAB (http://uk.mathworks.com/products/matlab/) is a popular high-level language and interactive environment; it uses a proprietary programming language developed by MathWorks.

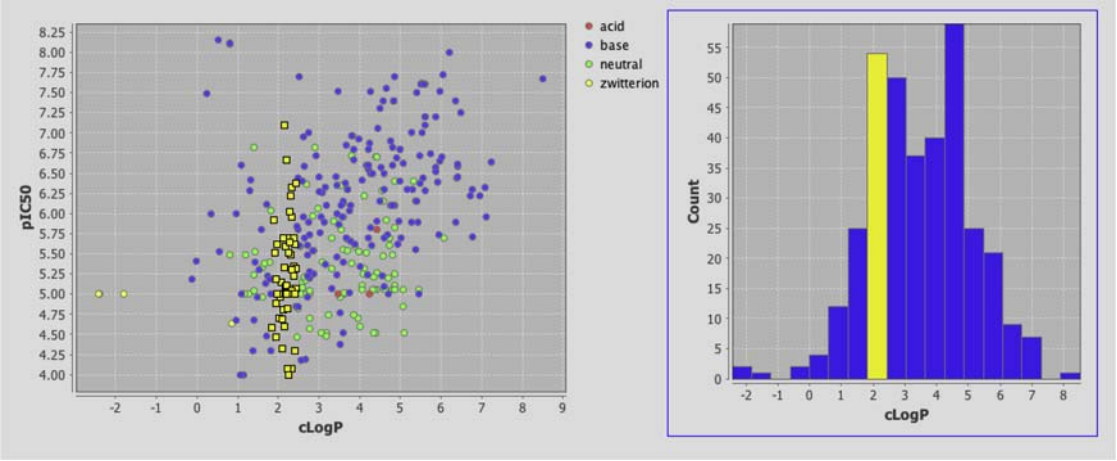
Mathematica (http://www.wolfram.com/mathematica/) is a very powerful software program used in many scientific, engineering, mathematical, and computing fields, based on symbolic mathematics.

GNU Octave (https://www.gnu.org/software/octave/) is a high-level interpreted language, primarily intended for numerical computations via a command-line interface. The Octave language is quite similar to MATLAB so that most programs are easily portable.

3.18.3 Desktop Tools

There is a vast array of desktop tools for data analysis, and it is impractical for this article to describe every package; instead, this article focuses on those tools that have support for chemistry.

Instant JChem (https://www.chemaxon.com/products/instant-jchem-suite/instant-jchem/) is a desktop client that provides database management functionality together with a variety of physicochemical property and molecular descriptor calculations. Instant *JChem* also supports graphic visualization of database content using a variety of plot formats. Any selection in one plot is instantly synchronized with other plots and the form view, allowing direct identification of chemical structures associated with the selected data point.

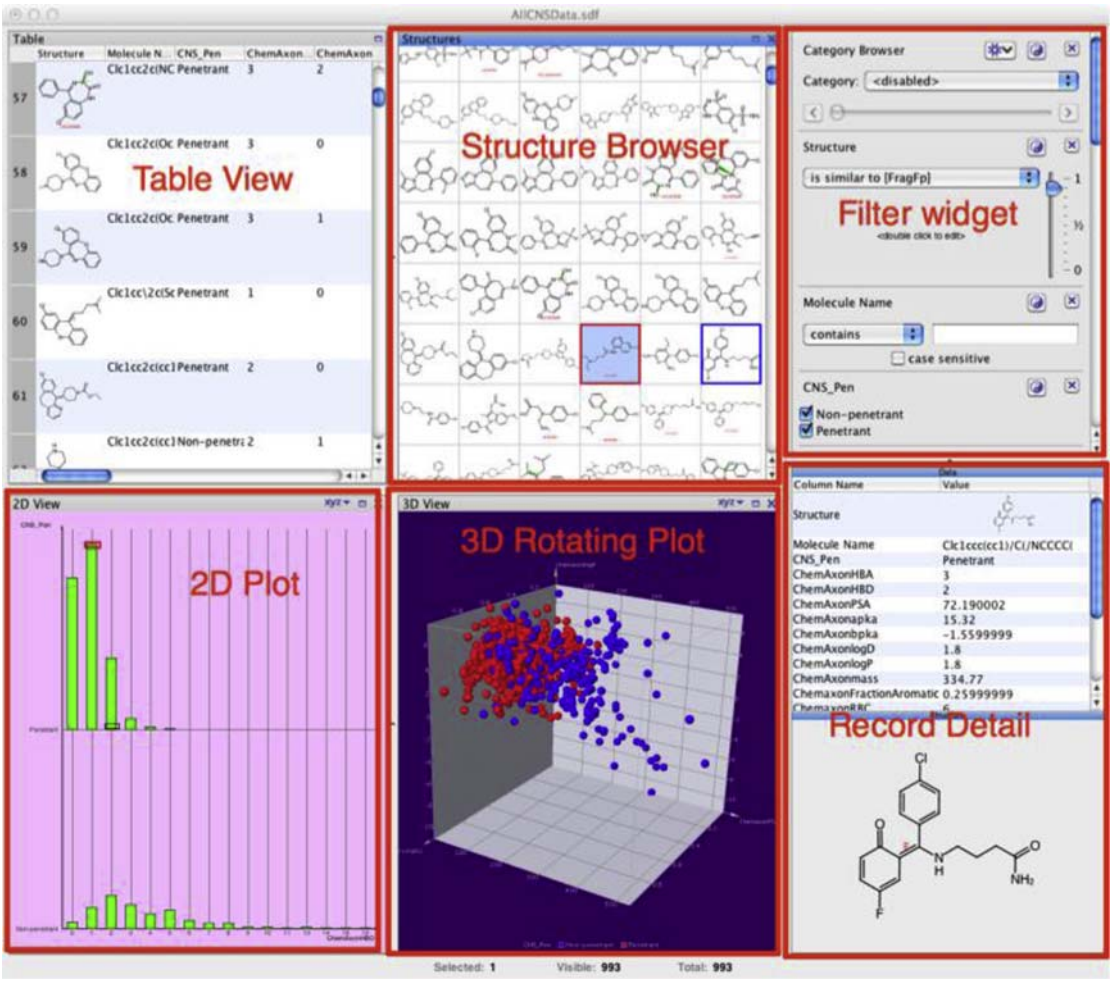


For more extensive data analysis, it can be integrated with KNIME or Spotfire.

DataWarrior (http://www.openmolecules.org/datawarrior/) is an open-source data analysis tool that understands chemistry; it provides an efficient way to search, sort, and analyze structure–activity data. DataWarrior was developed at Actelion; in 2014, it was decided to release DataWarrior as a stand-alone tool to the public available as compiled binaries and source code.

DataWarrior can import text-delimited files and chemical structure files in SDF format, a very widely accepted industry standard for exchanging chemical and associated alphanumeric data. After import, the data appear in the default view shown in the image in the succeeding text. Additional columns of calculated physicochemical properties can be added, and there is support for other calculated criteria such as "drug-like" and "ligand efficiency."

The table view supports data summarization tools such as pivot table and binning numerical data and allows calculating a new column from an expression using data within the table view. There is also support for principal component analysis (PCA), a widely used technique to convert a large number of highly correlated variables into a smaller number of uncorrelated variables.

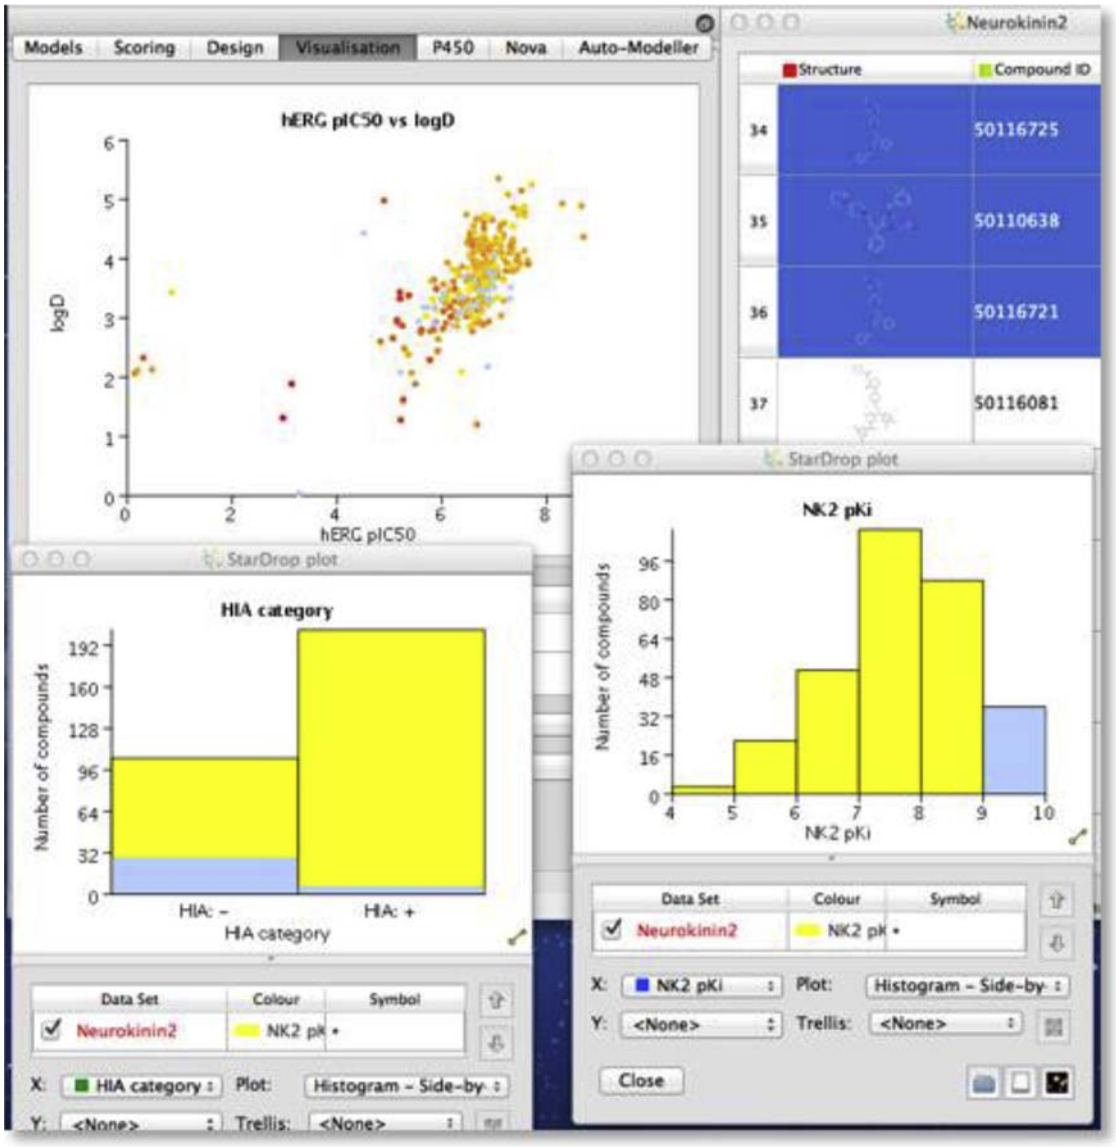


DataWarrior supports substructure and similarity searching, and there is limited support for compound clustering. There is also support for popular structure–activity analysis approaches including R-group analysis, Kohonen maps, and activity cliffs.

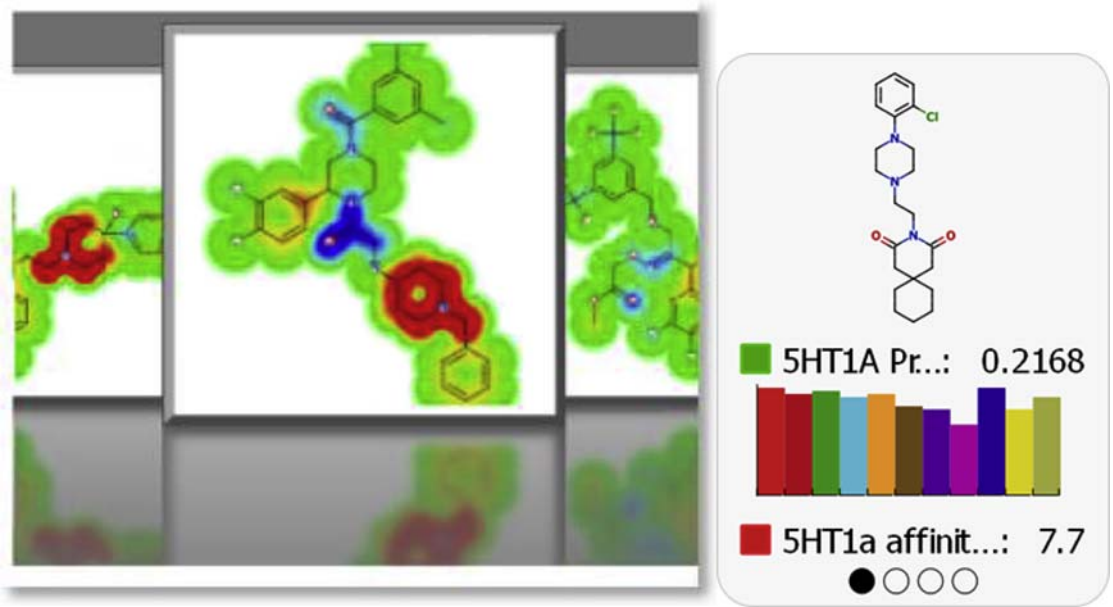
The graphic 2-D- and 3-D-views are potentially the most interesting for exploring data. The xyz button on the view's header area opens a drop-down menu for defining which property is to be assigned to each axis. Columns that do not contain numerical values, date values, category information, or chemical descriptors cannot be assigned to axes and, therefore, do not appear in the column menus. Columns with incomplete data, that is, with some empty cells, appear in red color indicating that some rows of the data may not be shown, if this column is selected. Nonnumerical category columns appear in blue color, while complete numerical or date columns are shown in black. Points selected in one plot are automatically highlighted in the other plots. You can change the chart type by simply right-clicking in the chart area. One nice feature is that if you right-click on a data point, there is the option to use the associated chemical structure as a filter.

DataWarrior can use macros to automatically follow a complicated or long series of tasks. These macros can be generated by recording a sequence of actions or by hand using the inbuilt macro editor.

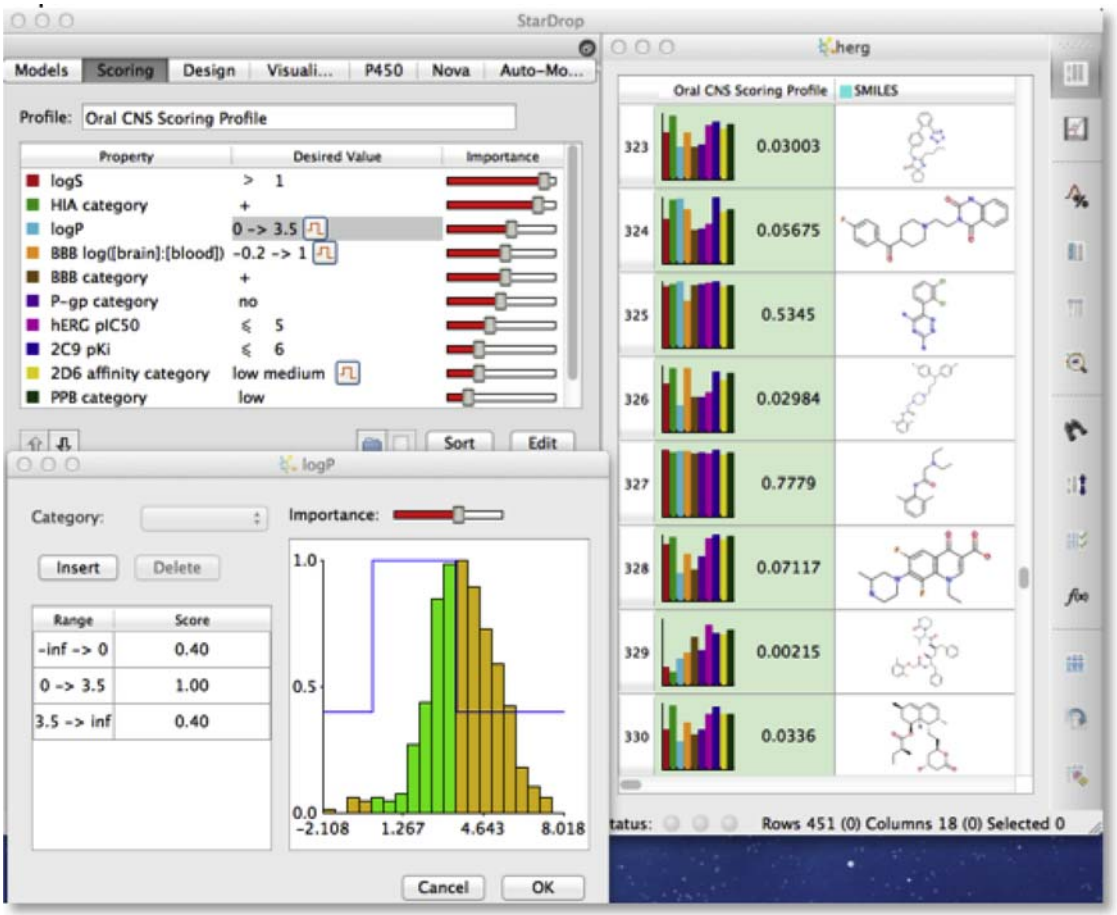
Stardrop (http://www.optibrium.com/stardrop/) is a tool designed to aid data analysis and decision-making for scientists involved in drug discovery. Stardrop provides a wide variety of ways to view data from spreadsheets to scatterplots and histograms all interlinked such that selection of a data point in the scatterplot automatically highlights the relevant data in the other plots and the spreadsheet.



One very nice feature is the "glowing molecules" display; selecting a model results in the molecule display being rendered as a heat map to highlight the molecular features that are responsible for the activity in the model with red indicating structural features that have a positive effect in the model and the cooler blue a negative effect. Alternatively, there is a "card view" in which key data are displayed in a playing card format. These cards can be stacked and linked to aid analysis. This can be a useful way to view the results of clustering.



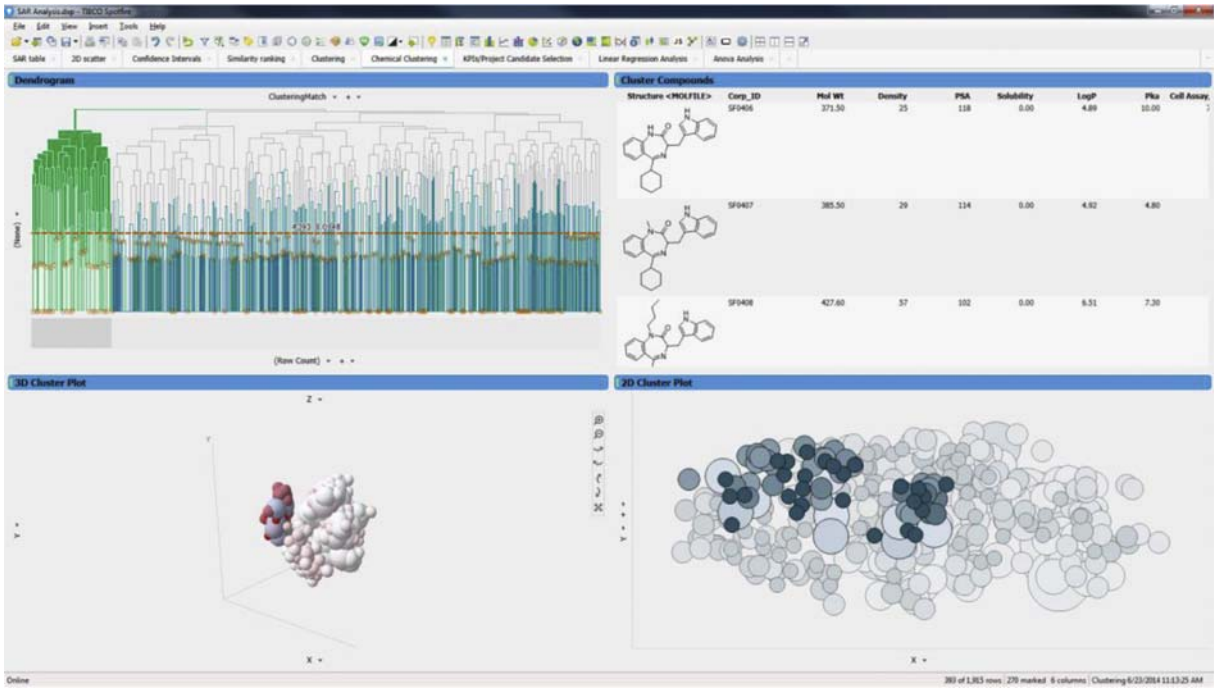
Stardrop has an interesting feature that allows you to set up a desired profile using all the experimental and calculated properties. You can set the desired value or range of values and the relative importance; this is then translated into a scoring profile and displayed in the molecular spreadsheet, together with a histogram of the property values (normalized from 0 to 1). For the low-scoring compounds, it is then very easy to see which properties need to be improved.



All that has been described earlier is part of the "desktop" portion of Stardrop; there is an equally important "server" side that is available on purchase of the appropriate plug-in modules. This includes predictive models and AutoModeller. AutoModeller, as the name suggests, allows expert and nonexpert users to build predictive QSAR models of data. The setup of calculations is controlled by a "wizard" that takes the user through the steps required, selecting the data set and activity, splitting into training, validating and testing sets, and choosing descriptors and type of model. A variety of modeling techniques are available, including Gaussian processes, random forests, radial basis functions, PLS, and decision trees.

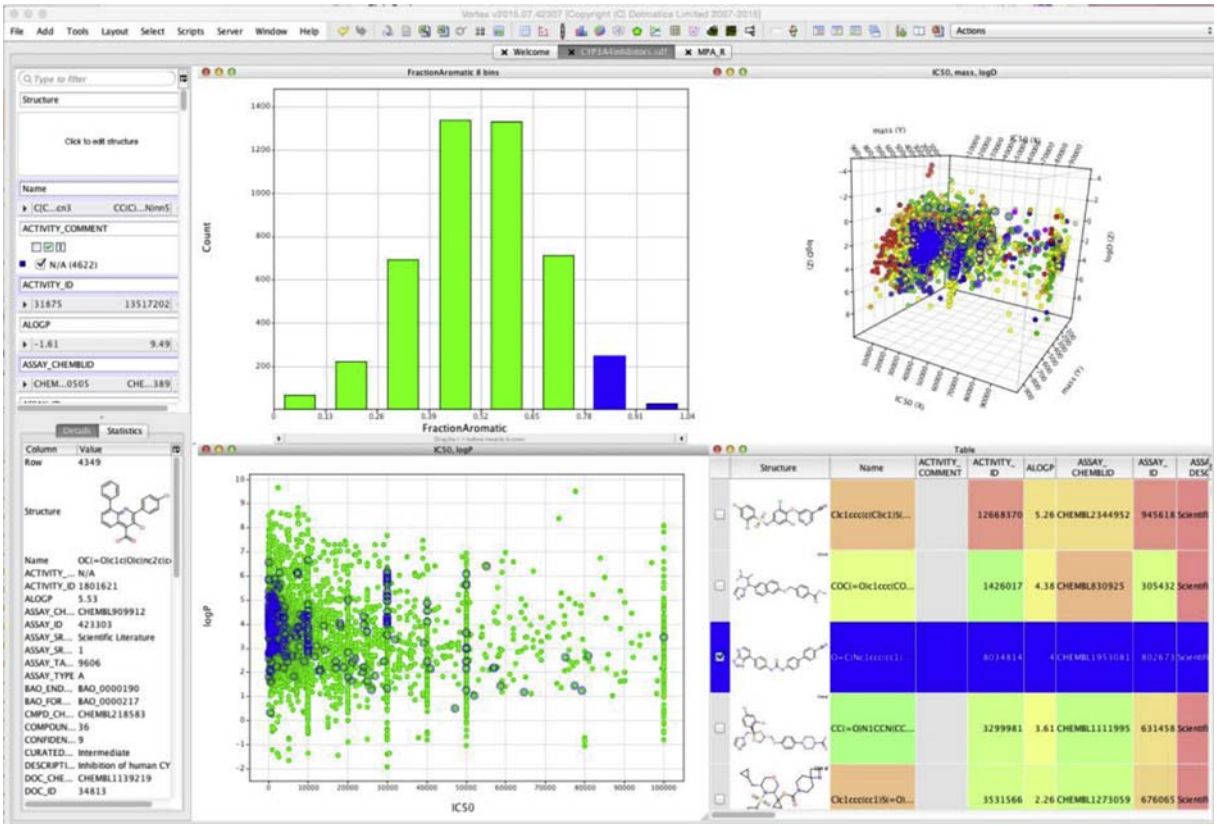
Optional plug-ins provide access to a variety of predictive models covering key ADME and physicochemical properties, quantum mechanical simulation of drug metabolism, and knowledge-based toxicity prediction. There is also a module for the automatic generation and scoring of new compounds using bioisosteric replacements and virtual library enumeration.

Spotfire (http://spotfire.tibco.com) is a general-purpose data analytics platform; support for chemistry is provided by the PerkinElmer (http://www.perkinelmer.com) (better known as CambridgeSoft) tools. This includes ChemDraw for structure drawing and property calculations and fingerprints for searching/filtering/clustering. The API does provide access for other toolkits. Data can be imported as flat files or from an Oracle database.



As the image earlier shows, a wide variety of plot types are supported, and selection of a data point in one plot highlights the corresponding point in other plots. The scatterplots can be coded by color, size, shape, or label allowing the display and exploration of multidimensional data, and sliders allow filtering of the data. It is also possible to provide connections between tables using an identifier such as molecule ID, allowing selections in one table to be flagged in another. The Spotfire server is also accessible via a mobile app.

Vortex (http://www.dotmatics.com/products/vortex/) is a high-performance data visualization platform suitable for many sciences. Vortex is available with full built-in chemical structure intelligence. Vortex can import files in a variety of formats and includes JDBC drivers to interface with Oracle, SQL Server, or MySQL databases. It provides chemical structure depiction and substructure or similarity-based searching, together with physicochemical property calculations tightly integrated with excellent charting and analysis tools.



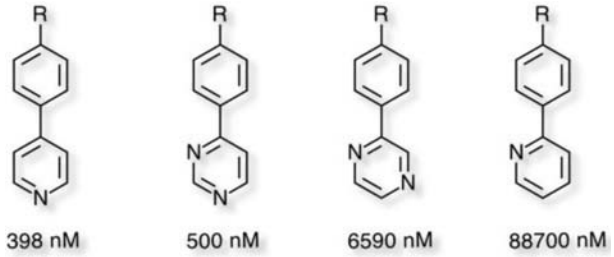
The image earlier contains 2-D and 3-D color-categorized scatterplots, a histogram, and a spreadsheet showing the molecular structure and all the alphanumeric data. The upper left hand panel contains a series of slider bars that allow the user to filter the details of the display, while the lower panel gives details of the highlighted molecule. The real beauty is that each of the displays is interlinked such that selection of a data point in the scatterplot automatically highlights the relevant data in the other plots and the spreadsheet. The spreadsheet also supports data summarization tools such as pivot table.

The tools menu allows the user to quickly add multiple scatterplots or to add extra columns of calculated physicochemical data such as molecular weight, various atom type counts, XlogP, and a variety of PSA measures. These take just a few seconds to calculate and are added to the end of the data table for use in plots, etc. You can rapidly look at the distribution of data within a column by selecting the bin option. The results can be displayed as either a bar chart or a pie chart. And of course if you select a bar, it highlights the corresponding points in the scatterplot. The ability to have multiple interactive plots of the data alongside grids of the highlighted structures is an enormous aid to understanding the data.

Vortex has a high-performance structure-searching engine capable of running at 2.36M matches per second on the PubChem 67 million structure data set (http://macinchem.org/reviews/vortex/tut24/scripting_vortex24.php).

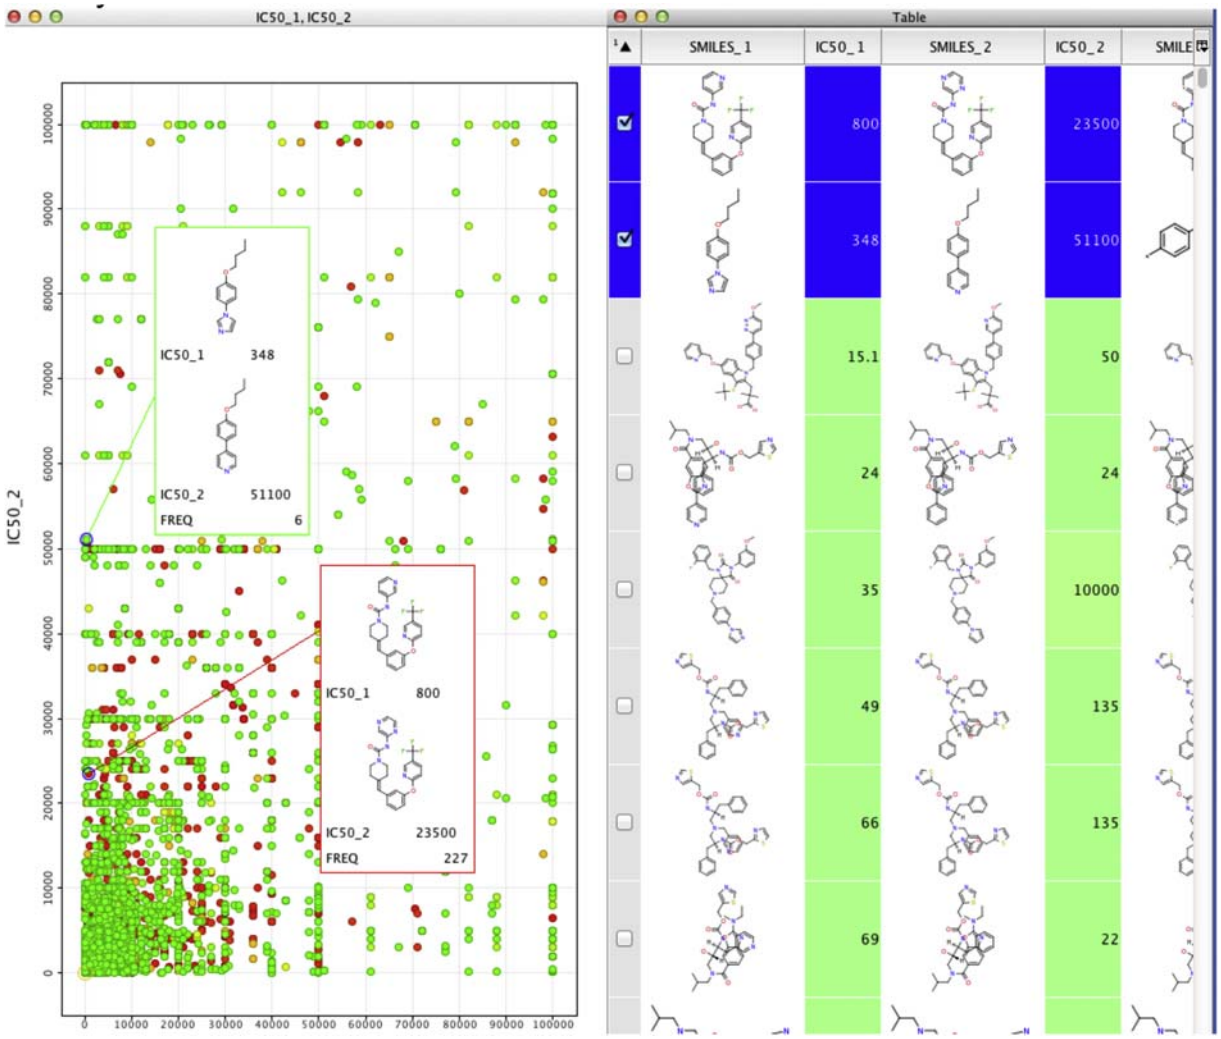
While a useful selection of analysis tools is available including *k*-means clustering, matched-pair analysis, and R-group analysis, it is also possible to access other analytic tools via scripts.

Using Vortex to conduct a matched-pair analysis helps to identify small changes in chemical structure that have a significant influence activity. Using CYP3A4 inhibition data taken from ChEMBL, a matched-pair analysis was undertaken. In the image in the succeeding text, the scatterplot shows the activities of each of the matched pairs color-coded by the frequency in which a particular match occurs. By clicking on a point, we can see the details of the molecular change, the difference in activity, and the frequency with which the molecular change has occurred.



Matched-pair analysis 2D6 inhibition.

The points are also highlighted in the table, which means we can then filter the table by a molecular transformation to see other examples of the same transformation and see if it always has a similar effect on biological activity.



Vortex contains a powerful scripting facility built on Jython, a Java implementation of the Python programming language, and allows access to the key components of Vortex, Python, and Java. Scripting gives users the ability to extend Vortex to give access to web services such as ChEMBL and OCHEM, command-line applications such as Open Babel and SMARTCyp, Perl scripts, statistical packages like R, and linking via SOAP to computational chemistry packages. The increasing popularity of user group-generated scripts/libraries is a notable feature of many of the data analysis tools.

A number of computational chemistry and molecular modeling programs such as MOE (https://www.chemcomp.com/MOE-Molecular_Operating_Environment.htm), SPARTAN (https://www.wavefun.com/products/spartan.html), and SYBYL-X (http://tripos.com/index.php?family=modules,SimplePage&page=SYBYL-X) also combine data analysis tools but are not described in detail here since this is not the main purpose of these applications.

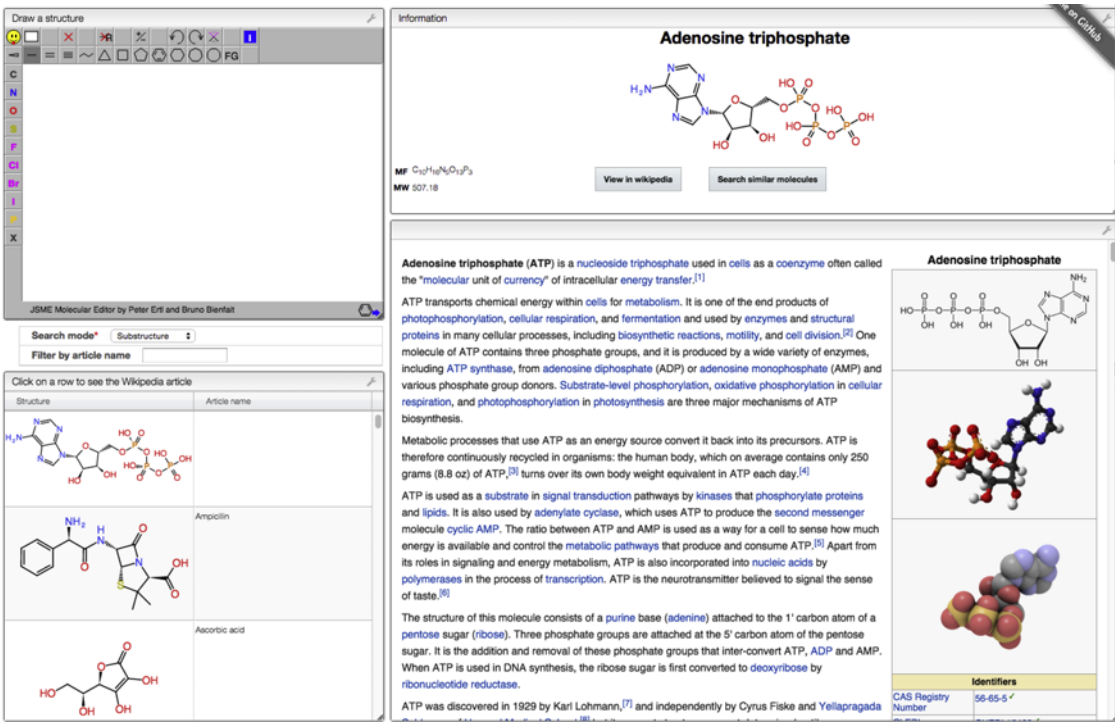
3.18.4 Web-Based Tools

Historically, web-based data analysis tools have relied on Java applets (https://en.wikipedia.org/wiki/Java_applet) or Flash (https://en.wikipedia.org/wiki/Adobe_Flash) to provide interactive content. More recently, with the increased security concerns, many web browsers no longer allow access to Java applets or Flash by default. This has been accentuated by the rapid increase in the use of mobile devices such as tablets and smartphones where neither Java nor Flash is supported. This has led to a movement toward the development of JavaScript-based data analysis tools that are accessible via the web browser on desktop or laptops, but, perhaps more importantly for the future, are also available on mobile devices.

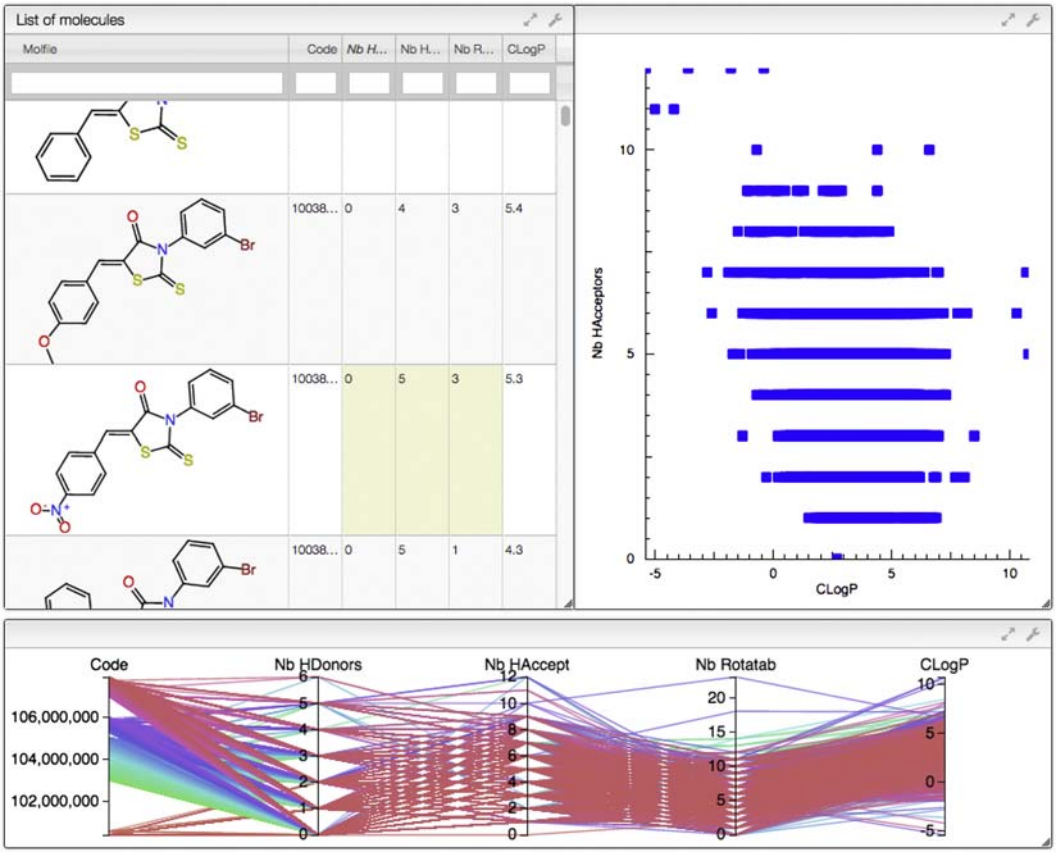
Despite the name, JavaScript is unrelated to Java and is also known as ECMAScript. It is a lightweight scripting language capable of providing interactive content to web browsers without the need for a plug-in. Recent improvements to the compilers have resulted in execution speeds similar to native code.

Many of the web-based tools rely on jQuery (https://jquery.com), a JavaScript library designed to simplify access to document elements, load data, parsing, and handle events. There are many different JavaScript charting frameworks available (https://en.wikipedia.org/wiki/Comparison_of_JavaScript_charting_frameworks) that gives a comparison of 39 different frameworks, but there are many more available.

One of the most impressive demonstrations of the use of JavaScript that supports cheminformatics comes from work supporting http://www.cheminfo.org, first mentioned in a publication describing a web tool for exploring molecules in Wikipedia.[7] The structure-based searching in addition to the data and chemical structure visualization system is all written in JavaScript. The Wikipedia chemical structure explorer is accessible online at http://www.cheminfo.org/wikipedia.



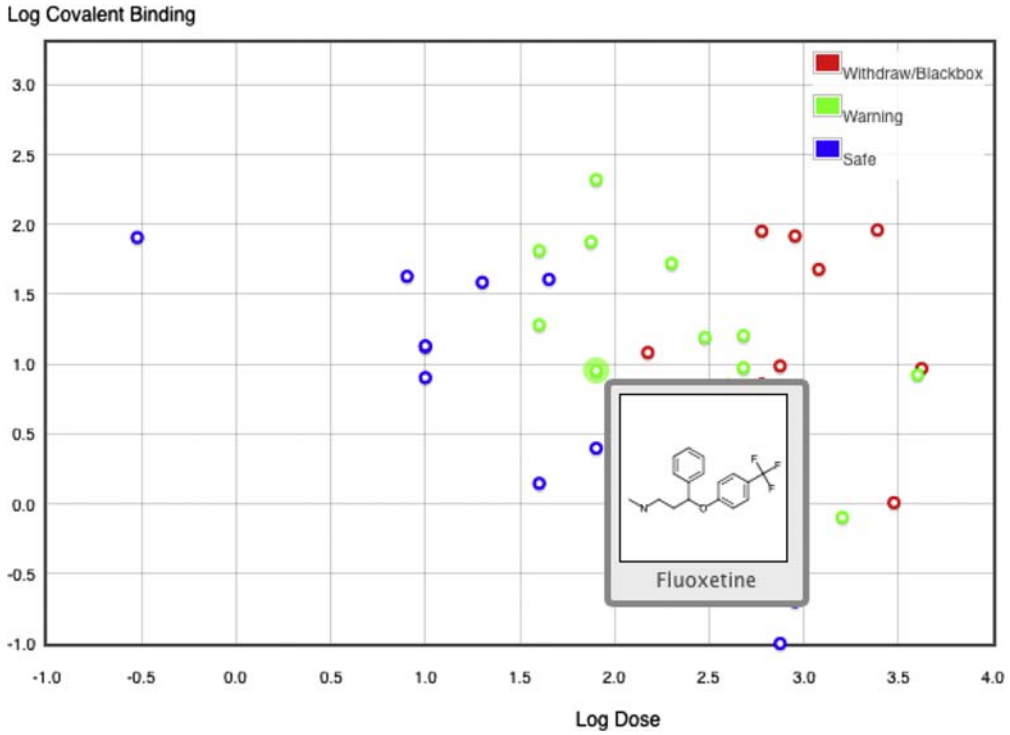
The display allows the user to add further modules; these include 2-D and 3-D scatterplots, pie or radar plot and more sophisticated plots such as self-organizing maps. As in the desktop applications described earlier, selecting a data point in one module highlights the corresponding data point in other modules.



This sort of functionality allows the user to rapidly customize the display.

Flot (http://www.flotcharts.org) is a pure JavaScript plotting library for jQuery, in which it is simple to create attractive interactive plots. It supports all modern web browsers. Flot supports a variety of plot types even within the same plot, and it allows the user to interact with the plots, making selections or interacting with data points. It is also possible to update a chart periodically to get a real-time effect by using a timer to insert the new data in the plot and redraw it.

While many of the JavaScript libraries have little support for chemistry, it is possible to incorporate the ChemDoodle Web Components (http://web.chemdoodle.com), a JavaScript library designed to provide chemical graphics and cheminformatics support. In the plot shown in the succeeding text (http://macinchem.org/reviews/flot2.php), the scatterplot is implemented using the Flot JavaScript library, and the interactive mouseover pop-up displaying the chemical structure is rendered by ChemDoodle Web Components.



While Flot provides access to data visualization, it does not provide any statistical analysis. JStat (https://github.com/jstat/jstat) is a JavaScript statistical library intended for use in the browser. It optionally includes jQuery, jQuery UI, and Flot for creating plots. Science.js (https://github.com/jasondavies/science.js) is a JavaScript library for scientific and statistical computing that contains various implementations of statistical methods similar to those provided by R. Gauss, another JavaScript statistics, analytics library.

One of the most popular JavaScript libraries for data visualization is D3.js (http://d3js.org). This is in some ways similar to jQuery in that it allows the programmer to select specific document objects and manipulate them to create dynamic interactive plots. It handles multiple data formats including XML and CSV, as well as JSON.

While R is very well known for command-line desktop use, there is also a web application framework for R (http://shiny.rstudio.com) that enables users to access R from a simple web browser.

3.18.5 Mobile Applications

Slowly declining desktop/laptop computer growth and an enormous growth in mobile devices have led many to speculate that mobile devices would soon be the major computation platform. While they certainly dominate communication, it remains to be seen what their influence will be in science and data analysis. That being said, there are now a number of data analysis apps designed for mobile applications; in addition, there are now graphing/plotting libraries available for mobile platforms including iOS/chart (http://www.threedgraphics.com/tdg/products/tools/ioschart/) and Vivdget (http://www.vvidget.org/support/).

In addition to mobile client apps, there are a couple of examples where a client/server model has been used to provide analytics to mobile devices.

While there are simple spreadsheet applications such as Numbers (http://www.apple.com/support/ios/numbers/), Calc XLS (https://itunes.apple.com/us/app/calc-xls-free-spreadsheet/id468674805?mt=8), and Excel (https://itunes.apple.com/us/app/microsoft-excel/id586683407?mt=8) available for mobile devices, there are also a variety of other applications that might be of interest.

Chart Maker is a graphing tool for creating printable graphs from small sets of data (https://itunes.apple.com/us/app/chart-maker-lt/id489717377).

DataAnalysis (https://itunes.apple.com/us/app/dataanalysis/id375603883) is a general-purpose iPad app for the plotting and analysis of all types of data that can be formulated as x,y pairs.

Eigen (http://scical.net/eigen.html) is an app that performs PCA.

Graph (http://www.vvidget.org/graph/index.html) is the mobile version of a desktop application. It supports 1-D, 2-D, and 3-D graph types such as bar, column, pie, line, area, scatter, 3-D perspective scatter, trajectory and surface, volumetric, z-sliced cell, maps, linear, semilog, x-log, log–log, polar, and r-log. It also supports touch to allow the user to interact with the plots. Interestingly, full source code has now been made available (https://github.com/VVI). The idea is to provide scientists, engineers, and professional programmers the ability to import their own data and modeling algorithms and perhaps over time commit the work back to the GitHub repository.

StatsMate (http://www.statsmate.com) is a mobile app that comes with a variety of statistical tools including

- 17 Probability Distribution Calculators
- 10 Hypothesis Testing Calculators
- Four p-Value Calculators
- Two Confidence Interval Calculators
- A Basic Data Analysis Calculator with Histogram
- Two ANOVA Calculators
- A Linear Regression Calculator

TouchPlot (https://itunes.apple.com/app/touchplot/id286347960) is a graphing calculator.

Variables (http://variablesapp.com) is a data analysis tool designed specifically for touch devices, descriptive statistics, and supports:

Histograms
Kernel density estimates
Correlations and covariances
Scatterplots

All of the earlier methods are separated by categories of another variable:

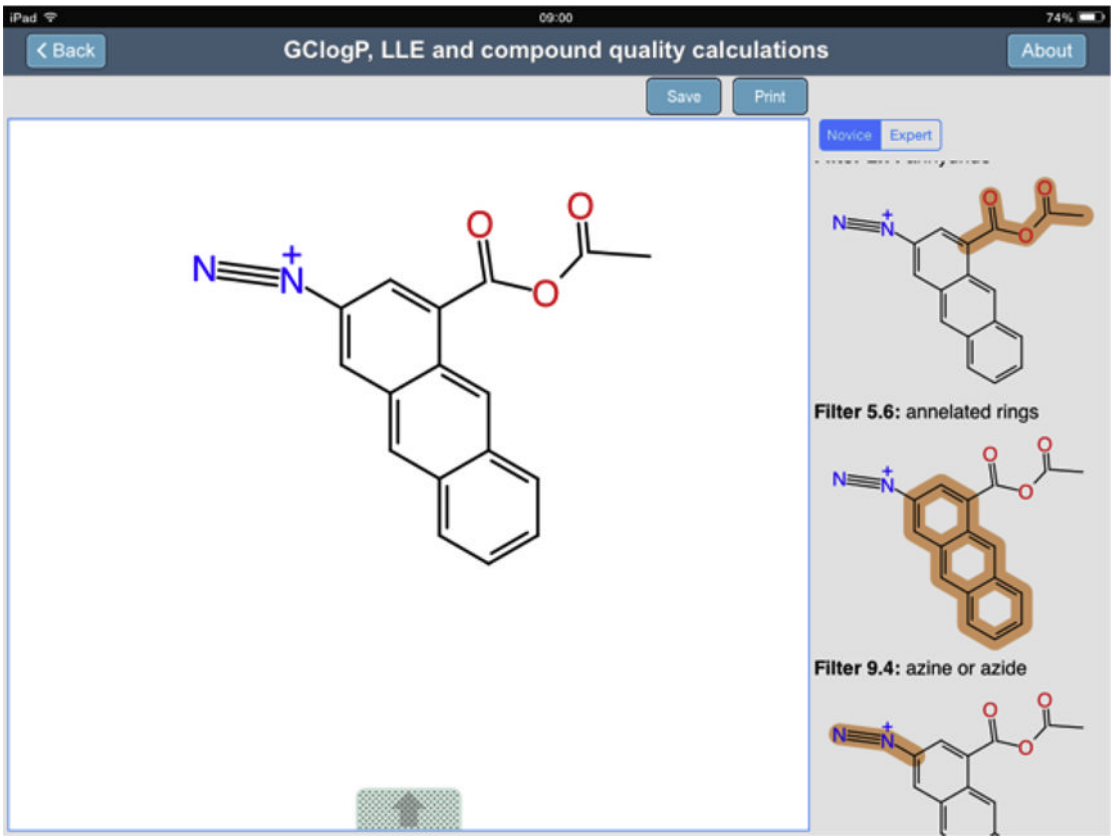
Linear regression
Logistic regression
Poisson regression

Model summaries and per-predictor statistics are the following:

Actual versus fitted plots
Residuals versus fitted plots

Vernier Graphical Analysis (http://www.vernier.com/products/software/ga-app/) allows users to wirelessly collect, analyze, and share sensor data.

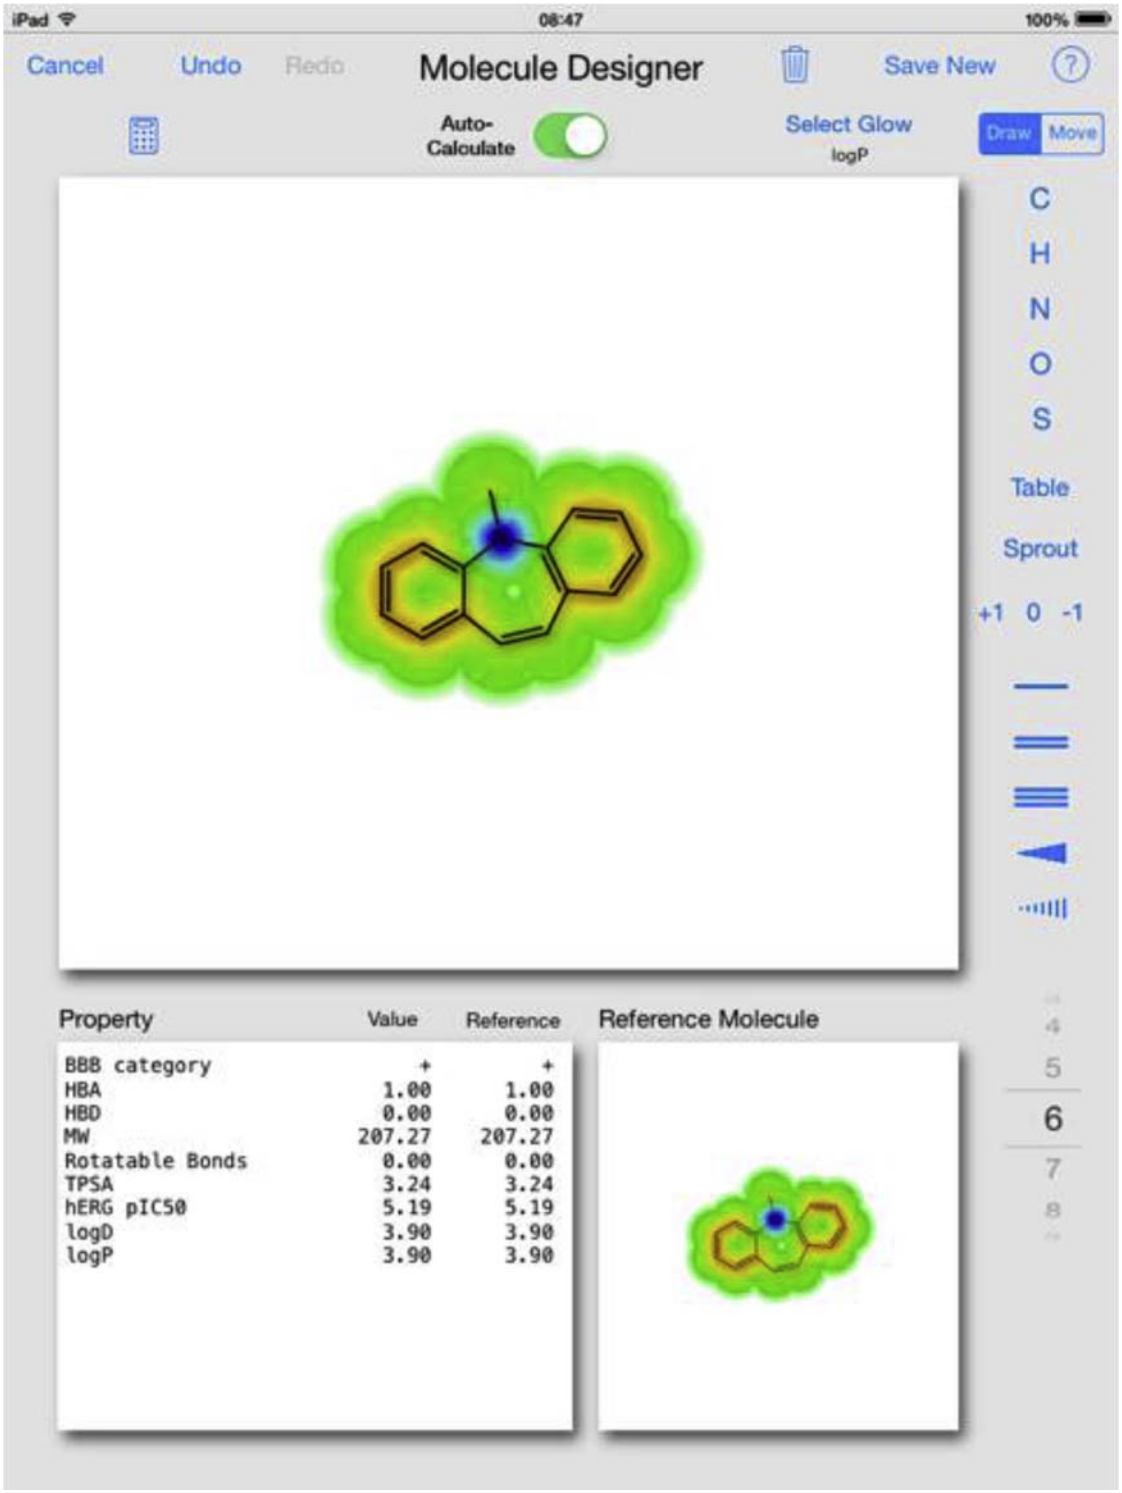
The Medicinal Chemistry Toolkit (https://itunes.apple.com/gb/app/medicinal-chemistry-toolkit/id910073742) illustrates an alternative approach; rather than provide analysis of raw data, it offers access to an increasing variety of predictive models.



Properties are calculated on the device as you sketch in the molecule so you can actually see the contributions of functional groups as you add them. The currently available calculations are chemical formula, MWt, GCLogP, ligand efficiency, ligand lipophilic efficiency, AZfilters, Cheng–Prusoff, and plasma protein binding.

3.18.5.1 Mobile Apps Using a Client–Server Model

Asteris (http://www.asteris-app.com/support) is an iOS app that arose from a collaboration between Optibrium and Integrated Chemistry Design that allows medicinal chemists to design and analyze novel molecules on their iPad and then calculate a range of physiochemical and ADME properties. Once you have drawn the structure, you can calculate properties and use the "glowing molecule" display to highlight a particular property. All properties are calculated on the Asteris cloud server on Amazon Web Services; core properties include LogP/D, molecular weight, TPSA, and HBD/A. The StarDrop ADME properties include predictive models for hERG, PGP, 2C9, and 2D6 activities. In addition, any predictions derived by the user using StarDrop data analysis tool can also be accessed.

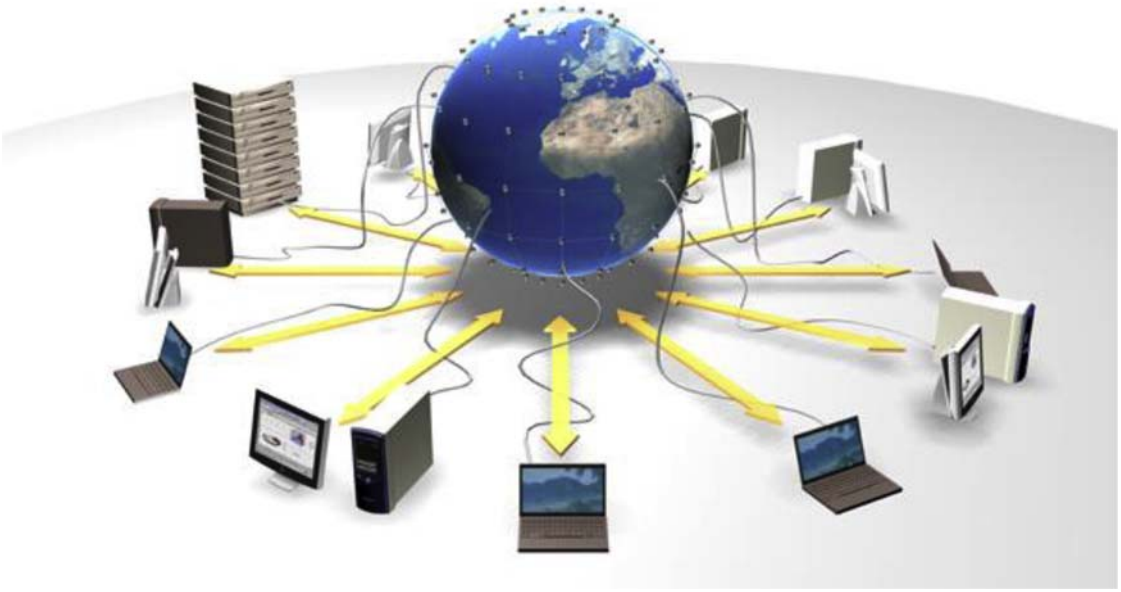


For regular StarDrop users, the results will be very familiar; you can select which calculated property is mapped onto the "glowing molecule"; this is very useful in determining which parts of the molecule contribute most to a particular calculated property or prediction.

Spotfire analytics (http://spotfire.tibco.com) for the iPad requires access to a TIBCO Spotfire Web Player Server to visualize, aggregate, filter, and drill into data sets of virtually any size. This offers the opportunity for institutions that use Spotfire to share data across multiple platforms.

3.18.6 Big Data Analysis

The definition of "big data" probably changes regularly as the improvements in hardware and software allow efficient handling of ever-greater data sets. At CERN, they generate more than 20 petabytes of data from CERN's Large Hadron Collider (LHC) every year. This has led to the construction of the Worldwide LHC Computing Grid (WLCG) (http://wlcg-public.web.cern.ch), a global computing infrastructure whose mission is to provide computing resources to store, distribute, and analyze the data generated by the LHC, making the data equally available to all partners, regardless of their physical location.



http://copyright.web.cern.ch.

The four main components of the WLCG are networking, hardware, middleware, and client software. Networking is via dedicated, private, high-bandwidth optical fiber links working at 10 gigabits per second, spanning oceans and continents. The grid centers and the 12 Tier-1 centers maintain disk and tape servers. Middleware is the software infrastructure that allows clients to access the vast distributed computing resource and the huge amount of data generated; full details of the middleware are available here (http://www.eu-emi.eu/middleware). The persistency framework is a project providing two software packages (CORAL and COOL) that address the data access requirements of the LHC experiments in several different areas.

At CERN, the workhorse for data analysis is ROOT (https://root.cern.ch/drupal/); the ROOT system provides a set of object-orientated frameworks with all the functionality needed to handle and analyze very large amounts of data quickly and efficiently. ROOT includes methods for creating 1-D, 2-D, and 3-D histograms, curve fitting, function evaluation, minimization, graphics, and visualization. It includes a built-in C++ interpreter so the command language; the scripting, or macro, language; and the programming language are all C++. While this helps performance, it results in a very steep learning curve. While this system is not designed for cheminformatics, it does give an indication of the hardware and software strategy that might be needed to handle increasingly larger data sets.

Within chemistry, the large data sources PubChem (68M structures), ChemSpider (34M structures), and ChEMBL (1.7M structures) probably do not count as "big data." These data sets would increase enormously if all the structures described by Markush structures (https://en.wikipedia.org/wiki/Markush_structure) in patents were exemplified or if multiple 3-D conformations were stored.

However, efforts to bring together chemical and physicochemical data, structural data (PDB) with pharmacological/biochemical/imaging, and genomic data such as Open PHACTS (https://www.openphacts.org) will result in large data sets with very complex interrelationships that traditional data processing applications will be inadequate to handle.

Distributed data storage is a critical component of big data analysis, and Hadoop (https://wiki.apache.org/hadoop/FrontPage) is an open-source software framework specifically written for distributed storage and distributed processing of very large data sets. In particular, it supports computer clusters built from commodity hardware rather than expensive custom hardware. It is designed to scale up from a single server to thousands of machines, with very high degree of fault tolerance. Rather than relying on high-end hardware, the resiliency of these clusters comes from the software's ability to detect and handle failures at the application layer. Yahoo has more than 100,000 CPUs in >40,000 computers running Hadoop (https://wiki.apache.org/hadoop/PoweredBy#Y). A key component is MapReduce (http://mapreduce.sandia.gov/index.html), a framework for handling parallelizable problems with huge data sets across large clusters.

An alternative to Hadoop is HPCC (http://hpccsystems.com). Perhaps the most significant difference is the implementation of Enterprise Control Language (ECL), the query and management language specifically designed to support large data sets.

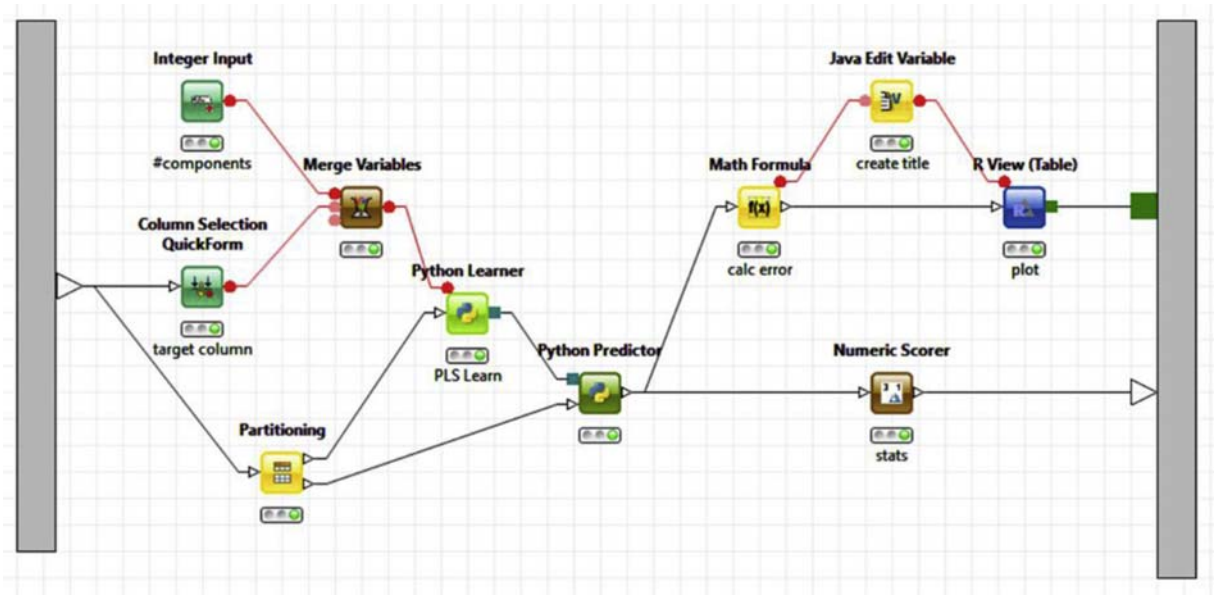
While SQL databases lead the DB-Engine rankings (http://db-engines.com/en/ranking), NoSQL databases are increasingly used in big data applications, and MongoDB (https://www.mongodb.org) is by far the most extensively used. The popularity of MongoDB (and other NoSQL databases) is probably because the document-style data structure allows the capture of many different types of data within a document as key–value pairs. In addition, as the database outgrows a single machine, it can be distributed across multiple servers in a process called sharding (http://docs.mongodb.org/manual/sharding/). Chemistry support is very much in the early days, but several people are exploring chemical searching within MongoDB (http://chembl.blogspot.co.uk/2015/08/lsh-based-similarity-search-in-mongodb.html) and claim performance superior to the RDKit PostgreSQL cartridge (http://www.rdkit.org/docs/Cartridge.html). A recent paper ("Chemical data visualization and analysis with incremental generative topographic mapping: big data challenge") (http://doi.org/10.1021/ci500575y) describes the iGTM algorithm implemented in the ISIDA–GTM program being applied to a database of more than 2 million molecules, encoded either by MOE descriptors or by MACCS keys.

3.18.7 Collaboration Tools

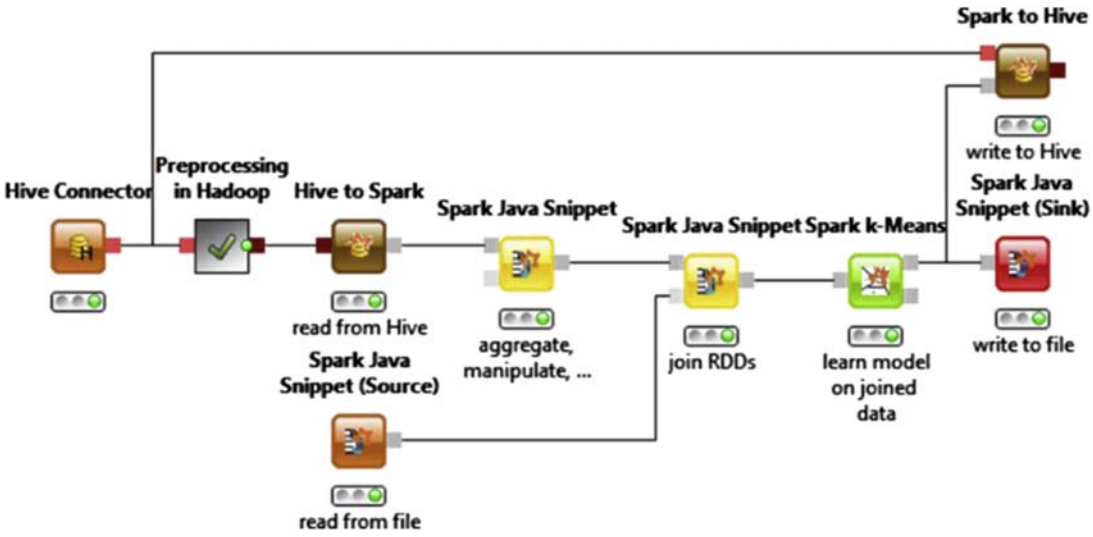
3.18.7.1 Workflow

KNIME (https://www.knime.org) is an open-source data analytics and workflow platform that allows the user to perform sophisticated statistics and data mining on their data. The KNIME Analytics Platform incorporates hundreds of user-created custom processing nodes (https://tech.knime.org/community) for data I/O, preprocessing and data cleaning, modeling, analysis and data mining, and various interactive views, such as scatterplots, parallel coordinate, and histograms. One of the major strengths of KNIME is the ability to integrate best of breed data analysis, model building, and visualization tools and languages.

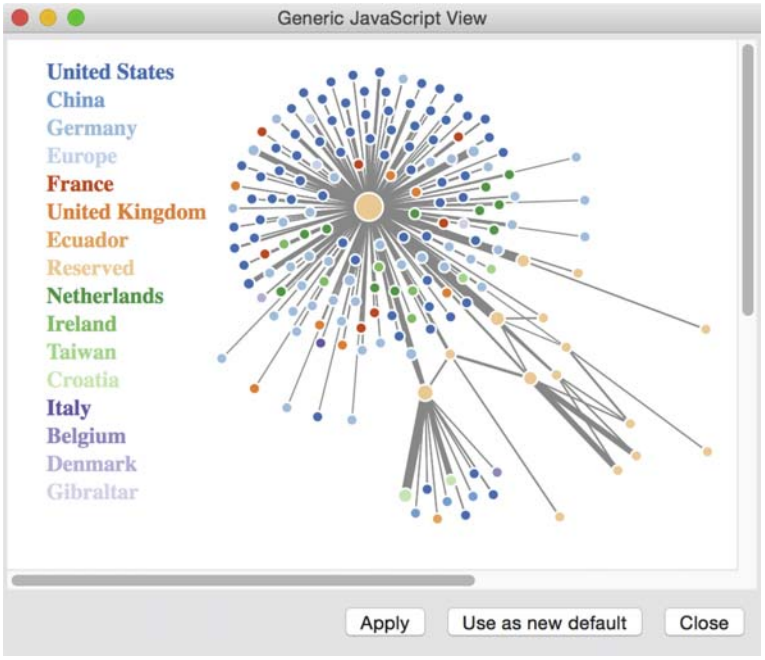
The screenshot in the succeeding text shows how code written in Python and R languages can be integrated in a KNIME analytics workflow. In this example, R is used to create a graphic, and Python is used for the model building.



As mentioned previously, analysis of big data is likely to become more of a challenge, and KNIME Big Data Extension already has nodes giving access to Hadoop and Spark.



KNIME has recently also introduced a JavaScript node that quickly builds new visualizations and exposes them as KNIME nodes; the figure in the succeeding text shows an example of network graphics generated using the previously described D3 library, wrapped into a KNIME node.



Example of the use of JavaScript plotting tool.

Access to many cheminformatics toolkits are available as KNIME nodes (https://tech.knime.org/cheminformatics-extensions) including OCHEM, RDKit, JChem, CDK, Open Babel, Dotmatics, BioSolveIT, Schrodinger, and MOE. In addition, database access for ChEMBL is available via a KNIME node as is ChemSpider and Open PHACTS. There are also contributions from pharma companies such as Vernalis (https://tech.knime.org/book/vernalis-cheminformatics-nodes).

Pipeline Pilot (http://accelrys.com/products/collaborative-science/biovia-pipeline-pilot/) is a graphic scientific workflow authoring application. It has been used in a wide variety of different areas of science. There are now many components that allow integration of many data types into automated workflows. A number of cheminformatics and computational chemistry software companies have developed Pipeline Pilot components to interface with their proprietary technologies such as ChemAxon (https://www.chemaxon.com/download/pipeline-pilot-components/) and BioSolveIT (http://www.biosolveit.de/PipelinePilot/). In addition, there are components that give access to visualization tools like Spotfire.

Taverna (http://www.taverna.org.uk) is an open-source scientific workflow system that provides modules for data access, for example, chemistry web services set (http://www.myexperiment.org/packs/135.html), management, analysis, and visualization tools including R, Bioconductor, and CDK.

3.18.8 Conclusion

In such a rapidly changing field, this article can only ever be an incomplete snapshot. New tools become available regularly, and support for others dwindles. Data analysis is one area of science where the open-source tools compete on an equal standing with commercial tools. Perhaps, the key difference is the level of guaranteed support provided by commercial versions. That said, community support for Python, R, etc. is outstanding and provides a model for successful open-source development. It does seem that the ones that have stood the test of time are perhaps those that offer a scripting interface allowing users to extend and/or integrate other toolkits.

Ever-increasing-size data sets suggest that "big data" will be of more interest in the future and will require a greater consideration of both hardware and software integration strategies.

Mobile devices are an interesting development, while server farms/cloud computing can offer vast compute resources; mobile devices offer the potential to connect to millions of human beings. The challenge is to phrase the data analysis problem in form that is accessible to millions of nonexperts. Perhaps "gamification" of problems offers a possible solution (https://vimeo.com/146537270).

3.19.1 Introduction

This article will present examples of interrogating medicinal chemistry patent sources with the primary objective of digging out structure activity relationships (SAR). Since the details as described later will show this to be more difficult than for papers, it raises the question why bother? The main reasons are that patents not only contain more SAR but also that this published earlier than in the peer-reviewed literature. Statistics in support of both these advantages are difficult to obtain but will be partially addressed here. For discrete SAR values, a conservative estimate of at least twofold more data-mapped structures in patents can be made. If ranged values are included, the difference rises to at least fivefold. In support of this, it was reported in 2011 that Factor IXa (F10, P00742) had 5.8K assayed compounds mapped to it via extracted from papers by ChEMBL, but this had increased to 43K from combined literature and patent extractions by GVKBIO (i.e., papers:patents ~1:6).[1]

The time advantage is more difficult to support with data, but it is well known that pharmaceutical company drug discovery teams typically wait 2–3 years after a patent application before publishing in a journal. In some cases, high-quality project results will be exemplified as substantial SAR sets in patents but may never surface elsewhere.

As an important adjunct to SAR extraction per se, this article will also exemplify ways of exploring connectivity between papers and patents from the same teams. However, both aspects will be done using open databases and tools. Reasons for this restriction are outlined here:

- Commercial sources, even just major ones, now present too broad a spectrum of technical features to review (i.e., no author would have either the multiple licenses or capacity for detailed comparative evaluation).
- There has been a remarkable "big bang" in the availability of automated patent-extracted chemistry just in the last few years, culminating in the secondary deposition of ~19 million patent-derived entries in PubChem and primary extraction of ~17 million of these into SureChEMBL.[2]
- This has led to a democratization of patent mining that has now become more accessible for those without commercial databases or tools.
- Concomitantly, parallel interrogation of open resources has become essential for users of commercial databases anyway, since the inevitable divergence of coverage by different sources precludes any one-stop-shop.
- PubChem precomputes relationships between 2D and 3D chemical structures, patent documents, PubMed IDs (PMIDs), PDB entries, bioassay results, and annotation from many curated submitting sources.[3] This means that the combined PubChem and Entrez functionality now encompasses the majority of bioactive patent chemistry. This thus presents a scale of relationship navigation that closed commercial databases cannot match.

Although aspects of intellectual property (IP) focused searching and/or competitive intelligence analysis will briefly be touched upon, strategically they may be better addressed by commercial databases, depending on what value-added features they offer for these two domains. This may include enhancing the indexing depth and precision of public data in various ways, including manual annotation.

Additional caveats related to the coverage of this article need mentioning. The first is that the techniques exemplified here are small-scale, largely manual and thus more individual-orientated exercises rather than large-scale approaches. The second coverage

restriction is that illustrative examples can only be accompanied by short technical descriptions, although they will be referenced for users to access the details. The third is that the queries describe here we executed in Sep. 2016 and may thus give different results at later dates. The fourth is that, particularly in the patent domain, queries are rarely "clean" in terms of specificity or recall (some of the reasons for this will be discussed). The ones used here are presented in good faith with the expectation of some level of reproducibility. However, they can be disconcertingly noisy and inconsistent in practice. One reason is that patent offices and other sources often do not index document metadata in standardized ways (e.g., conflating applicants with inventors or multiple synonyms for the same applicant institutions). Another is that different interfaces to nominally the same document corpora can give different results (e.g., depending on the filtration options selected and the syntax used for complex queries). The fifth caveat is that while queries executed here have been designed to reflect real-world tasks they are also somewhat contrived for illustrative purposes and thus may not be the most efficient way to get to the explicit results. There are many choices of entry points, tools, query strategies, and technical tricks that may answer particular questions more quickly.

Five final points related to the usability of this article should be mentioned.

1. With the exception of a few novel structures not yet submitted to any public databases, specifically mentioned compounds will be specified either by a PubChem Compound Identifier or a Substance Identifier, or in some cases both.
2. Rather than necessitate the addition of many hyperlinks into the text, each of these can be accessed via two standard URLs. For example, atorvastatin, as CID 60823 can be linked out as https://pubchem.ncbi.nlm.nih.gov/compound/60823. The specific submission from SureChEMBL, SID 226395935, can be analogously linked as https://pubchem.ncbi.nlm.nih.gov/substance/226395935.
3. There are too many patents to be fully referenced so their numbers are specified in the text. These will usually retrieve links to the document in the upper ranks of a Google search result within seconds.
4. SAR retrievals will focus on beta-secretase 1 (BACE1, Swiss-Prot P56817) as an Alzheimer's disease protease.[4] The illustrative advantages of an intensively pursued drug target will become apparent as we track through over a decade of substantial SAR and explore patent-to-patent and patent-to-paper connections.
5. For reasons of space, a basic familiarity with querying databases and patents has to be assumed. In particular, this should include patent office websites (e.g., EPO Espacenet, USPTO, and WIPO), kind codes (A1, B2, etc.), patent classifications, the concept of patent family, and experience with searching in PubChem or other chemistry portals.

3.19.2 Statistics of Extractable SAR

The complex task of extracting chemical and biological entities from patents has been well studied. Some of the different approaches will be referred to here, but the complication is that SAR is defined by relationships between entities. For this reason, questions regarding SAR statistics both inside and outside patents are difficult to get precise answers to, but would be useful for making judgments on what is realistically achievable.

In this context it is useful to review our high-level assumptions. The first is that readers have an interest in bioactive chemistry in the wider sense, with the obvious proviso that very low or inactivity is crucial for SAR and control experiments, but data sets are biased toward activity and potent compounds. The second would be that, regardless of the dominance of medicinal chemistry, IP domains related to tropical diseases, antivirals, antibiotics herbicides, pesticides, toxicology, and chemical biology can be approached for SAR mining in broadly the same ways as described here for human target-centric drug discovery. It is also a reasonable assumption that medicinal chemists have at least some interest in extracted structures that were not designed to have biological effects per se (e.g., novel reactions, dyestuffs, photochemistry, etc.) but where the documented synthetic chemical space lies within the broad property envelope associated with potential bioactivity.

So what do we mean by SAR in the context of this article? The concept of a series of close structural analogs with a range of quantitative bioactivity data that can form the basis for different types of predictive modeling is well understood but also continually developing.[5] For in vitro data they need specific links between the entities of compounds, the protein bioentities whose activities they modulate, and the assays used to measure this. These can be classified as (data supported) compound-to-assay-to-protein relationships.[6] Typically, a document "D" describes a biochemical assay "A" with a quantitative result "R" (e.g., an IC_{50}) for compound "C" (with an explicit structure) defining it as an inhibitor of protein "P" (with a sequence and species-specific identifier). Useful shorthand for these relationships is thus "D–A–R–C–P" (note the substitution of "P" with target "T" can be used to indicate a black-box mechanism of action such as a tumor cell or a tropical disease parasite). This shorthand can be extended to describing a basic SAR series as a multiplexing of R and C, while a specificity cross-screen would be a multiplexing of A, R, and P. Separate patent filings of SAR interest often cover closely related but distinct chemical series. These can be linked as a set of "D" that have A–R–P in common (since they were from the same institution and reasonably close in time) but the different sets of "C" are varied.

Medicinal chemists have traditionally manually extracted the key entities from patents and papers of interest and organized the relationships locally, thereby converting unstructured data from document text, chemical images, result tables, and supplementary data into structured information (e.g., D–A–R–C–P in an Excel sheet). It should also be pointed out that, beyond a sketching tool, access to patent office portals along with a basic familiarity of enzymology, receptor pharmacology, and protein naming, a scientist can curate A–R–C–P sets from a patent on the day of publication within a few hours (i.e., in advance of any commercial extraction service). Notwithstanding, this presupposes that (a) the indexing of the title and abstract allowed the specific retrieval of patents of interest and (b) that these actually contained novel, useful, and extractable SAR.

While the ability to perform bespoke curation and annotation remains a core competence for medicinal chemists, they are increasingly likely to hand-off this activity for two main reasons. The first is that commercial or public databases, as well as internal support from Information Scientists, can provide project teams with partial or complete D–A–R–C–P extractions from various sources. For example, those with SciFinder access can collate the D–C records within days of publication but will still have to fill in A–R–C–P themselves (or from another resource). The second reason is that drug discovery enterprises (academic or commercial) usually have local systems for collating, mining, and modeling SAR originating from their own internal projects. These are now likely to include the use of electronic laboratory notebooks for primary chemical structure registration and data capture. These are then extracted to populate in-house databases that increasingly also integrate external bioactivity data sources. Pioneering examples of these include the AstraZeneca enterprise applications of Chemistry Connect[7] and SAR Connect.[8] What this means is that bespoke extractions are now expected to be format-compatible with internal systems and thus easily subsumed into them for intraorganization sharing rather than languishing in local directories.

An expanding range of curated compilations containing partial or complete D–A–R–C–(P or T) mappings are available as commercial products or deposited in public databases.[9] Depending on scale and update frequencies, these largely obviate the need for individuals to "do-it-yourself" extractions. However, a number of key points need to be made before reviewing some of these in the context of this article. Firstly, the facility with which a medicinal chemist can extract a document is reflected in the resource curation model (commercial or academic) where professional biocurators are hired or contracted for scaling-up essentially the same process. Secondly, D–A–R–C–P extraction with useable specificity has so far defied complete automation. While text mining combined with natural language processing (NLP) is making progress toward this goal, challenges remain. The principle one is the need to semantically link structures, assay descriptions, result tables, and protein identifiers extracted from different sections of a document. Experienced biocurators can cognitively discern these relationships in a matter of minutes, but they increasingly use automated tools for triage and to improve their efficiency of capture. Thirdly, while it actually violates the principle of patenting, some applicants in the medicinal chemistry domain deliberately introduce varying degrees of obfuscation into their documents (examples will be mentioned). In practice this can not only make the elucidation of SAR relationships more difficult but in some cases impossible.

The third point concerns patent coverage. As testimony to the difficulty of managing a patent curation pipeline, compared to processing papers, even now relatively few resources surface complete D–A–R–C–P sets from patents. Some commercial offerings may index a molecular mechanism of action (mmoa), but this is only a partial substitute for a standard protein identifier. The fourth point is that, in many cases, it is necessary to compare sources indexed for bioactivity as a surrogate for SAR per se. Consider for example, a published report on an orphan (i.e., with no analog structural neighbors) complex natural product that potently inhibits malaria in a mouse model. A record of this bioactivity is clearly valuable and worth finding but is not immediately useable for SAR exploration. In contrast, extended data sets either where "T" uses growth inhibition of the parasite in vitro with 100s of IC_{50} values for a designed synthetic library and/or recording K_i's for the identical chemical series against one or even multiple "P"s as purified *Plasmodium* enzyme targets. While filtering database entries between these different bioactivity levels can sometimes be done for papers, this is more difficult for patents.

The content statistics of three databases in **Table 1** are partitioned into D–A–R–C–P metrics. The reasons for selecting these in particular are not only that the relevant numbers are available from the teams concerned but also that, in combination, they sample the global "bioactivity space" and thus provide useful overviews of what could potentially be SAR-mined.

There are caveats associated with **Table 1**. These include that the individual data models give rise to differences in entity counts, redundancy reduction, and relationship definitions. Note also that GOSTAR is a merge of a suite of databases. Nonetheless, **Table 1** provides a useful quantitative overview. We can briefly go through them in sequence. As a commercial database, GOSTAR is the largest manually curated resource of chemical modulators of biological targets (mostly proteins) with associated activity data (mainly inhibition) extracted from papers and patents. Notwithstanding the fact it cannot serve as an example of open patent mining, it nonetheless provides data-supported upper limits of extractable SAR from public documents. A 2013 analysis indicated the journal:patent compound split was approximately 1:2.7 with a document number split of 82K:58K.[10] A recent update from Exelera (**Table 1**) records current counts as 2.2 million structures from the literature, 5.1 million from patents (i.e., a slight shift toward papers since 2013), and an overlap of 0.19 million (i.e., not much change). Other relevant figures from the 2013 publication included that manual extraction yielded, on average, 12 compounds from a paper and 45 from a patent.

The BindingDB figures are derived from an open database, not only in situ but also as a regular submitter to PubChem.[11] In addition, this resource supplies a set of D–A–R–C–P expert manual extractions of US patents (reviewed later). Since 2009 ChEMBL,

Table 1 Document, assay, result, compound, and protein target content counts for Excelra GOSTAR (commercial), BindingDB, and ChEMBL22 as recorded in Sep. 2016

Name	*D (pubs)*	*D (pats)*	*A*	*R*	*C*	*P*
GOSTAR	110,000	69,000	17 million	24 million	7.3 million	9,212
BindingDB	25,000	1,200	0.96 million	1.3 million	0.57 million	6,468
ChEMBL	65,000	1,200	0.9 million	5.6 million	1.2 million	6,888

Numbers for the latter were taken from the release notes except the protein target count was obtained from the UniProt cross-reference. Those from BindingDB were personally communicated by Michael Gilson and the Excelra figures by Anil Kumar and Sreeni Devidas.

also open and a PubChem submitter, is an open source of literature-extracted bioactivity and it also subsumes confirmatory PubChem BioAssays.[12] Full release statistics are available from which the headline numbers in Table 1 were obtained. Between BindingDB and ChEMBL there are similarities, differences, and complementarity in terms of SAR content. Firstly BindingDB subsumes protein-mapped ChEMBL content. Consequently, the former has 78% of compounds in common with the latter (although a proportion of these include identical structures collated by different routes). In addition, BindingDB has extracted 3000 PMIDs not in ChEMBL. The average of 18.5 extracted compounds per paper for ChEMBL22 is slightly higher than for BindingDB at16, but below the current GOSTAR average of 20. Thus, these three independent numbers indicate a reasonably consistent yield of manual compound extraction from the medicinal chemistry literature along with the linked A–R–P data.

So just how much total SAR is extractable from the journal corpus? This question provides context for comparisons with patents, but it is not easy to get a clean answer. On balance, the 2.2 million compounds from papers extracted into GOSTAR indicate a plausible lower boundary, since the spread of journals and curation backfill time span is larger than ChEMBL. However, quantifying how much of this is useful for SAR modeling (e.g., a series of analogs against the same protein as opposed to singletons with just one assay result) is less straightforward (but the distribution could probably be discerned from GOSTAR internal statistics). Upper boundaries remain uncertain but what we can record is that 92K PubMed entries are classified under the MeSH term "Chemistry, Pharmaceutical," and 713K under "Chemistry." While GOSTAR would not be expected to cover all bioactive chemical structures ever published, by their own selection criteria of SAR-density per paper, they have probably captured the major part. Given the PubMed figures earlier, we can thus estimate a conservative upper limit for ~3 million structures as being within the wider frame of SAR interest. Notwithstanding, as will be expanded on, ChEMBL constitutes the largest open resource of literature-extracted SAR against which patent sources and subsets can be intersected.

3.19.3 Statistics of Putative Patent SAR

As we have seen for the literature, precise comparative statistics for document corpora entity content are difficult to come by. Notwithstanding, useful calibrations from automated extractions with a 2015 time point have been provided by SureChEMBL and the Minesoft Chemical Explorer (commercial). The former declare 17 million compounds from 14 million patent documents, while the latter claim 12 million from 10 million. While the gap between these numbers and the 5.1 million selected for SAR linking from the same corpus for GOSTAR is wide, we can reconcile them to a certain extent via other methods of analysis and orthogonal queries to provide broadly plausible cuts. The first filter we need to consider is patent family redundancy. Using the World Intellectual Property Organization (WIPO) PATENTSCOPE database, we can establish that 58 million national documents collapse to 3 million international patent applications (PCTs or WO filings). This indicates an average family size of 19 that, for the purposes of mining, can be considered as having the same chemistry content (despite postexamination claim scope changes). The other advantage of selecting WO is that they are generally the first family members to publically surface (for the record thought, these are technically only published applications since granting is done by the national authorities). Their disadvantage for mining is that, compared to the XML format of USPTO applications from 2001 onward, WOs have poorer text and image quality from suppliers of the electronic transformations. This degrades chemistry extraction, sometimes severely (this topic is addressed later).

The second key filter is to identify relevant chemical content. As a first step toward the latter, we can use the Intentional Patent Classification (IPC, see website listing). This is a hierarchical system where C for "chemistry" accounts for 20% of the WO. However, the combination of C07 for "organic compounds" and A61K "preparations for medical purposes," while not 100% specific, is highly selective for small molecule drug discovery, medicinal chemistry, and therefore potential SAR content. (n.b. not all relevant national filings proceed to a PCT and some not captured in this intersect may be using submission tricks to "hide.") The individual numbers, via PATENTSCOPE, are 217K and 235K, respectively, with a C07/A61K intersect of 85K (for comparison A01N "herbicides and insecticides" has 29K WO with 7.4K of these intersecting with C07). The corresponding C07/A61K count for EPO publications is 371K which drops to 233K for USPTO. Despite the uncertainties on absolute document redundancy (e.g., further collapsing by Kind codes), we can make a plausible estimate that the medicinal chemistry relevant patent subset could be in the range of 100K to 200K. We can then use the average count of 257 unique IUPAC structures per patent from recent exhaustive extraction exercise to make a total chemistry estimate for the C07/A61K set of just over 25 million.

Compared to document counts in the high millions often highlighted by patent indexing and extraction resources, these numbers for the medicinal chemistry intersect seem lower than might be expected. However, it is comparable to the GOSTAR extracted patent count of ~70K in Table 1 which is SAR selective. The yearly WO published output corresponding to C07/A61K can be plotted (Fig. 1). The result clearly mirrors the published rise and fall in the concomitant GOSTAR chemistry extraction indication the amount of patent SAR has actually declined since ~2006.[10]

While commercial operations are triaging this output, it is difficult to get open statistics that could support SAR estimates. For example, the family redundancy between the WO, USPTO, and EPO is unclear (even though some measure might be obtainable from the INPADOC system). Note it is possible to select granted versus nongranted applications in USPTO as a nominal quality filter and redundancy reduction. However, not only does the time lag for examination run into years but also granting is by no means a guarantee of scientifically useful content. What we can attempt is to empirically divide C07/A61K into data-centric utility groups (i.e., not based on IP considerations) with respect to putative SAR content. These can be outlined as follows:

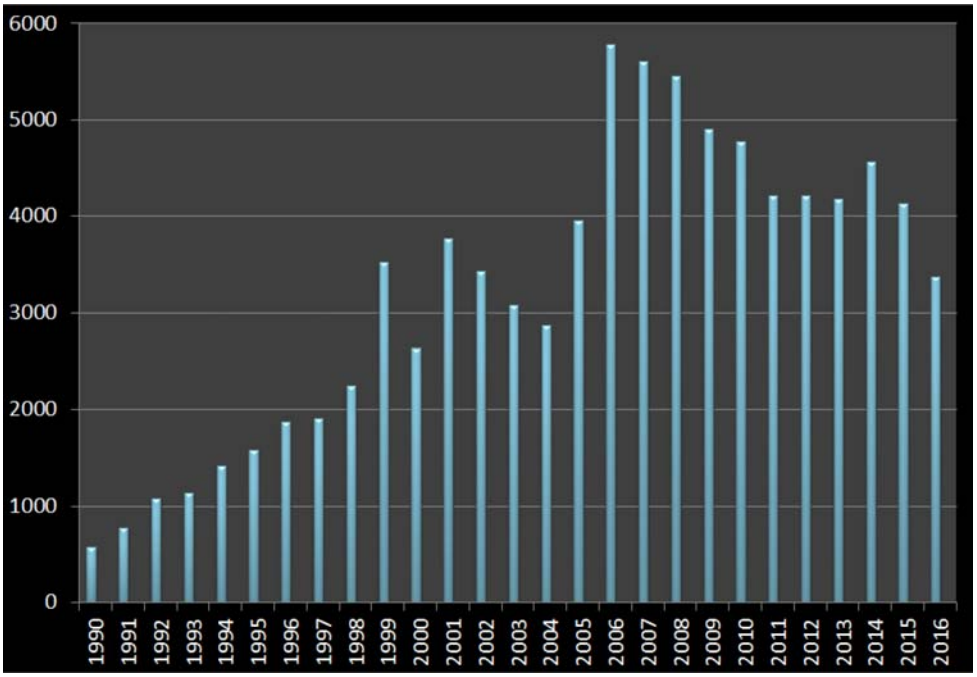

Fig. 1 A plot of the per-year WO patent counts for the intersect between the IPC codes C07 and A61K. The Sep. 2016 total was 85K.

1. An extended chemical series, including synthesis and analytical details with novel composition of matter, described as directed toward a specific target and a set of diseases, possibly including assay descriptions. However, beyond general statements, such as "found to be active," no data can be assigned to individual structures.
2. As above but with a proportion of the examples having aligned bioactivity data, although much less than the number of example structures and/or heavily gapped.
3. Assignments of activity to each exemplified structure but only as ranged values. This can be typically in the form "between 10 and 100 nM or 100 and 500 nM" or using a binning system of one to five stars, ABCDE or suchlike.
4. The document includes a complete set of discrete assay results, typically IC_{50} or K_i, displayed in a data table with anywhere between 5 and 500 rows. These can be aligned with the structures (novel at filing time) and their synthetic descriptions. By definition, this constitutes the most useful SAR patent (particularly if cross-screening data from two or more parologous proteins are included) but note the results may be generated with assay formats that do not use purified proteins (i.e., "T" not "P").
5. Documents similar to 3 and 4, ostensibly including an extensive set of results, but where the degree of obfuscation in the description or layout (e.g., activity and example numbering not being in register) is high enough to preclude unequivocal SAR mapping.
6. A category that encompasses what we can term secondary filings in the sense that structures have been filed previously are not novel and few in number. These can include crystallization or synthetic route descriptions by the erstwhile originators of the lead compounds as well as generic manufacturers jockeying for inventive claims on clinical candidates.
7. Outside the above there are many filings that defy any simple classification. They are still assigned the two codes we deem useful but for various reasons, difficult to discern SAR. Perhaps the most interesting are data-supported authentic new uses for previously claimed structures (i.e., repurposing). Others may cover mixture combinations, often with huge permutated listings. Some include various types of virtual enumeration where potential activities for structures are claimed that have neither been made nor tested.

The informal categories described earlier can be assigned by detailed inspection of patent documents. However, they expose the problem that there are no statistics as to how these are partitioned at scale. Consequently, there are no reliable methods of automated SAR detection. While 2, 3, and 4 are of primary interest, some of the other categories could be useful. For example, in category 1 there are fillings by drug discovery teams with an established reputation but whose project leaders or company management take the strategic decision to file a chemical series without disclosing any activity data. Notwithstanding, these are logically expected to include actives (i.e., a series with cryptic SAR) to justify the IP investment in the first place. They can certainly be used for modeling (e.g., building a pharmacophore) and some structures may be selected as a smaller SAR series and published later in a journal.

3.19.4 Identifying Specific Patents

Retrieval of patents with a view to significantly enriching for categories 2, 3, and 4 is a major subject that cannot be covered in depth here. However, examples will naturally emerge as we explore queries in different resources. In the interim, we can outline the general

challenges but even before this we need to clarify operational imperatives in the context of this article. In searching databases that include patent-extracted chemistry in the context of IP due-diligence, the consequences of false-negatives (e.g., overlooking relevant prior art) for any drug discovery organization can be dire in terms of economic cost and erosion of competitive position. However, the assumption is made here that if an individual happened to miss some patent SAR that was retrospectively found to be relevant, they would not be held to account too severely (although the same oversight from patent attorneys or Information Sciences teams might not be seen in such an equable light). Another real-world consideration is that researchers are likely to be more focused on the SAR of the present rather than the past. This is especially so since the latter is well covered by review articles (e.g., the journal "Expert Opinion on Therapeutic Patents"). This means researches are unlikely to want to pull back SAR from decades ago and are thus more likely to filter for more recent time spans (where the chemotypes, potencies, and properties should, at least implicitly, be improving). Thus, in regard to the strategic dilemma of specificity versus recall, examples used here will be high-specificity queries and recent time scales in order to reduce time spent triaging false-positives for rejection, rather than being overly concerned about missing false-negatives or older filings.

As we know patents can be identified by their metadata such as inventor names, affiliations, and patent classification codes (even though these can have noisy indexing). Filtering or ranking by publication date is of course useful but can be confounded by families, Kind codes, and priority equivalents which can surface identical documents across time spans of 5 years or more. However, examples here will concentrate on target-centric searching that, while certainly prone to false-negatives, has an acceptable specificity. In addition, target searching is the most common first-pass for literature searching so that grappling with protein naming issues becomes more familiar.

3.19.5 Chemistry Extraction

As mentioned, manual curation of SAR from a patent is intuitively obvious to medicinal chemists, many of whom have engaged in generating the data that goes into them and may even have had a hand in drafting applications. However, most sources that have pursued the large-scale manual extraction of chemical structures from patents (with or without A–R–C–P mapping) have been commercial. This means that technical details of their selection and triage are not usually disclosed. However, being proprietary about exactly how databases are populated always leaves users with uncertainties. In particular, it is important to know curation strategies and chemistry business rules that might directly affect how easily and how much SAR can be collated from any particular resource (as we will see in the section later). These include

- How are ambiguous partial stereo centers handled?
- Is the parent added as an extra structure where the document specifies a salt?
- Are obvious applicant-originated chemical errors fixed?
- What activity units do they normalize to?
- Which software do they use to output their sketched structures?
- What primary standardized chemical representations are captured from this output?
- Are activity figures rounded down?
- Do they number structures corresponding to their example numbers in the document (i.e., so the extracted structure can be unequivocally matched to the activity values even if it is exemplified multiple times)?
- Do they have capping rules for very large SAR tables?
- Are all examples extracted or only key structures selected by the curators?
- Do they add the structures of known drugs or clinical compounds even though these may only be specified by a semantic name?

Users who commit a lot of searching time to any particular curated resource may have to work these rules out "backwards" during the course of their analyses. They can also compare between sources (e.g., for the same patent number) but this does become time consuming.

By definition, the manual throughput of chemistry and other entity extractions (e.g., A–R–C–P) from documents factors linearly with the cost of biocurator time. For this reason, the technology with the greatest impact on open chemistry extraction in recent years (and provision of structures that can potentially be SAR-mapped) has been automated chemical named entity recognition (CNER). This approximately scales according to computing power and algorithmic efficiency. In essence, electronically formatted documents go into a pipeline and structures come out. As well as indexing the chemistry, outputs may be tagged with metadata, such as whether they were derived from text and/or images, recognized in the title, abstract, description, or claim sections. In practice, CNER extends beyond just text-to-structure (n2s) to encompass automated image-to-structure (i2s) as well as manually drawn ChemDraw files then automatically converted to molfiles structures. These are generated by the USPTO Complex Work Units (CWUs) process as part of their pipeline for complete electronic processing of patent applications. While researchers mining patents do not need to keep abreast of the details of CNER technology, it is important to understand the associated strength and weaknesses, particularly from the point of view of exploiting resources derived from it. A useful schematic describing SureChEMBL is shown in Fig. 2 (interrogation of this database will be described later).

The basic operations shown in Fig. 2 are n2s and i2s. The first is via conversion of IUPAC systematic names as text strings, but this also encompasses what we can call semantic n2s where names such as "atorvastatin" are converted into explicit structures via

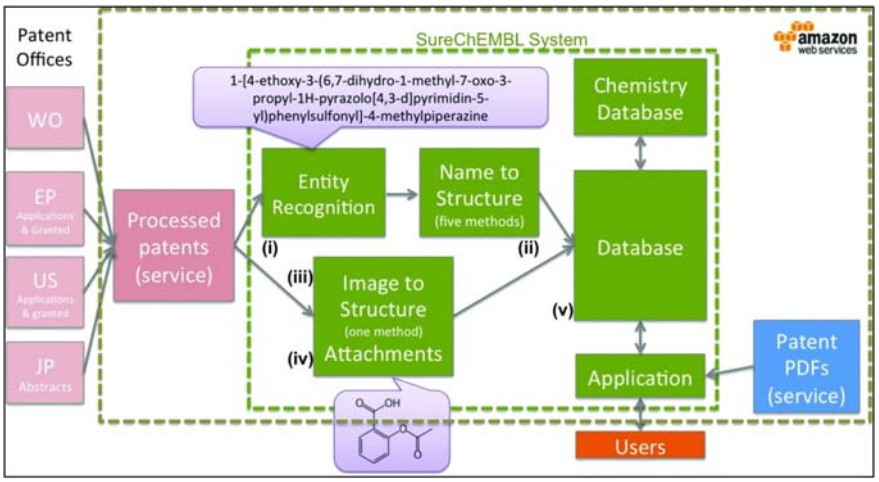

Fig. 2 A diagram of the SureChEMBL CNER pipeline. Adapted from Papadatos, G.; Davies, M; Dedman, N.; Chambers, J.; Gaulton, A.; Siddle, J.; et al. SureChEMBL: A Large-Scale, Chemically Annotated Patent Document Database. *Nucleic Acids Res.* **2016**, *44*, D1220–D1228. http://dx.doi.org/10.1093/nar/gkv1253.

a look-up dictionary. The second is via image processing for i2s that also includes the CWU-derived molfiles. We can now move on to see how the interplay between manual inspection and automated extraction can be exploited for SAR retrieval.

3.19.6 Patent SAR Retrieval From BindingDB

Before moving on to CNER resources, it is instructive to explore one of the few open resources that includes manual patent extraction of complete D–A–R–C–P sets. As of Sep. 2016 BindingDB had curated 1229 US patents with target-directed small molecule binding data. While a relatively small number (now mirrored in ChEMBL22) it has the advantage of being produced by the expert triage of recent USPTO publications selected via the inclusion of K_d, IC_{50}, K_i, or EC_{50} in the abstract. The triage also selects for CWU molfiles that provide complete sets of example structures, thereby enabling the expert manual curation to focus on target identification and activity mapping. There is a pointer to this section from the front page or lower down on the left-hand facets under citation sources. There is also an Advanced Search tools option for focused searches within just the patent data (or other sets). The top-10 patent extraction records by date added are shown in Fig. 3.

These BindingDB true-positives (i.e., most being from category 4) serve not only as a useful introduction of the principles of SAR mining but also to benchmark other resources. A disadvantage is that, as USPTO publications, these can lag some time behind the surfacing of WOs. For example, the most recent in the list, US9199947 published on Dec. 1, 2015, was first published as

Patent: (prefix with "US" like US6078908) Search

Patent	Data	Patent Title	Organization	Deposition
US9199947	140	Biaryl-propionic acid derivatives and their use as pharmaceuticals	Sanofi	09/20/16
US9199927	112	Guanidinobenzoic acid compound	Astellas Pharma Inc.	09/20/16
US9199944	155	N2,N4-bis(4-(piperazine-1-yl)phenyl)pirimidine-2,4-diamine derivative or pharmaceutically acceptable salt thereof, and composition containing same as active ingredient for preventing or treating cancer	KOREA RESEARCH INSTITUTE OF CHEMICAL TECHNOLOGY	09/20/16
US9199949	11	Selective glycosidase inhibitors and uses thereof	Alectos Therapeutics Inc.; Merck Sharp & Dohme Corp.	09/20/16
US9193689	18	3-aryl-5-substituted-isoquinolin-1-one compounds and their therapeutic use	INSTITUTE OF CANCER RESEARCH: ROYAL CANCER HOSPITAL (THE)	09/19/16
US9187487	46	Azaindole derivatives as tyrosine kinase inhibitors	PRINCIPIA BIOPHARMA, INC.	09/19/16
US9192603	67	Heterocyclic sulfone mGluR4 allosteric potentiators, compositions, and methods of treating neurological dysfunction	Vanderbilt University	09/19/16
US9193697	39	Oxazole derivatives useful as modulators of FAAH	MERCK SHARP & DOHME CORP.	09/19/16
US9193736	311	PDE 10a inhibitors for the treatment of type II diabetes	Janssen Pharmaceutica, NV	09/19/16
US9193762	57	Selective inhibitors of prolylcarboxypeptidase	UNIVERSITY OF MISSISSIPPI	09/19/16

Fig. 3 Entries from the BindingDB patent extraction page. The numbers under the "Data" column are measurement counts. Each of these has a PubChem CID derived either from a BindingDB submission (as an SID) or it matches a preexisting CID from another source. The majority are unique within this patent set, but there is some multiplexing for dual values (e.g., K_i and EC_{50}) or multiple target cross-screens.

WO2014154727 on Feb. 2, 2014. However, since it is the availability of the CWU structures that make this pipeline possible in the first place, WO documents cannot be used. As a first look at the set, we can plot the number of compounds per document to display the SAR distribution (Fig. 4).

The most common first-pass strategy is to search by target name. However, as we can see in the list, the use of unambiguous protein names by applicants is patchy and titles such as "Chemical compounds" (US9156831) immediately present the false-negative problem. Notwithstanding, in this case cell proliferative disorders are mentioned in the abstract, the description goes on to specify PI3K-α and PI3K-δ, and BindingDB curation has resolved the activities against PIK3CA, P42336. We can move on to the question "how many BACE1 patents can we find in this list?" Note that the BindingDB has already resolved the targets during their triage (i.e., there are 8030 records linked to BACE1, mostly from papers), but in this case we can use the text query to illustrate general principles of patent retrieval.

The results in Table 2 indicate some of the obstacles to target name resolution. An initial test with "BACE1" gave only four matches. A stemming variation "BACE" gave 17 matches but only to the 14 records in Table 2. It happens that BACE is both a synonym for BACE1 and a common stem for the paralogous pair of BACE1 and BACE2. Importantly for SAR aspects, these two are both targets for Alzheimer's disease and type 2 diabetes, respectively,[4] and are also sometimes used in reciprocal cross-screening (thus expanding the SAR). Hence "BACE" not only conveniently picks up all the BACE1 single-target filings but also US8754075 and US8748418 as "and/or" double-target filings.[14] We also find US8541427 that uses an incorrectly hyphenated BACE-1 as symbol. However, "BACE" misses two false-negatives that, from testing the common synonyms, we can retrieve with "beta-secretase" and "memapsin 1." The latter is a synonym for BACE2 which makes US9096541 nominally the only BACE2 single-target filing in this set, but the data also include BACE1 cross-screening results. With the proviso of needing a registration log-in, BindingDB facilitates the full download of SAR sets. An example is shown in Table 3.

Importantly, these can be related to their positions in the patent document and detailed connectivity information is available in the BindingDB entry (Figs. 5 and 6).

The utility of this "precooked" SAR is clear. However, if significant downstream effort is going to be invested in the data set (e.g., modeling and/or synthesis), it is prudent to cross-check extractions (from any source in fact) against the original document. In this case, US8748418 reveals 28 examples in the patent in Table 1, thus indicating the 53 BindingDB records have both BACE1 and BACE2 assay results as the SAR set. We can now compare this with a CNER source.

3.19.7 Patent Chemistry in SureChEMBL

In a relatively short space of time, SureChEMBL[13] has become the major public source of chemistry from patents since it had accumulated 17.25 million structures by the end of Aug. 2016 (as indexed in UniChem[15]).This not only offers advantages of scale but also speed because in situ (i.e., without the lag time associate with feeding-on to other databases such as UniChem or PubChem) chemistry from an individual patent document is downloadable within days of publication. The main limitation is that the primary relationship capture is only D–C. This means that users have to connect A–R–P data for the collation of SAR.

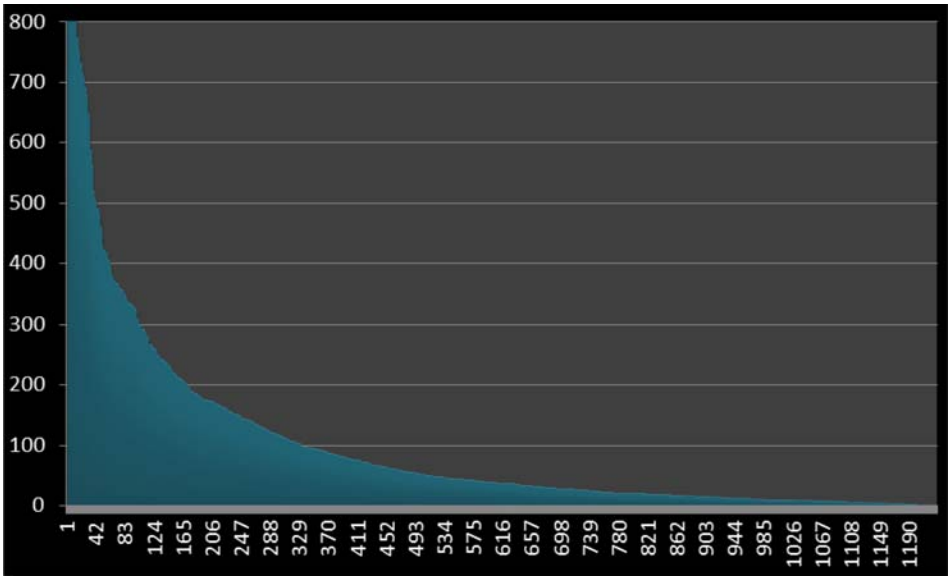

Fig. 4 1218 curated patent documents from BindingDB (horizontal axis) ranked by number of compounds × activities (the 14 with over 800 were truncated out of the vertical axis range). Over 80% have 20 or more SAR records and nearly 30% include at least 100. (Note: the average measurement record per patent of 98 is comparable to the GOSTAR nonredundant count of 65 structures per patent.)

Table 2 Entries from BindingDB patents that can be retrieved by related target names

Patent	*Data*	*Patent title*	*Organization*	*Deposition*
US9181236	290	2-Spiro-substituted iminothiazines and their mono-and dioxides as bace inhibitors, compositions, and their use	Merck Sharp & Dohme Corp.	08/29/2016
US8865911	180	Compounds and their use as BACE inhibitors	Astrazeneca AB	04/06/2015
US8754075	87	1,3-Oxazines as BACE1 and/or BACE2 inhibitors	Hoffmann-La Roche Inc.	11/11/2014
US8748418	53	1,4-Oxazepines as BACE1 and/or BACE2 inhibitors	Hoffmann-La Roche Inc.	11/11/2014
US8541427	45	Phenyl-substituted 2-imino-3-methyl pyrrolo pyrimidinone compounds as BACE-1 inhibitors, compositions, and their use	Merck, Sharp & Dohme, Corp.	11/26/2013
US9000182	41	2*H*-imidazol-4-amine compounds and their use as BACE inhibitors	AstraZeneca AB	10/19/2015
US9145426	38	Pyrrolidine-fused thiadiazine dioxide compounds as BACE inhibitors, compositions, and their use	Merck Sharp & Dohme Corp.	06/13/2016
US9000184	31	Cyclohexane-1,2′-naphthalene-1′,2″-imidazol compounds and their use as BACE inhibitors	AstraZeneca AB	10/19/2015
US9067924	24	1,4-Thiazepines/sulfones as BACE1 and/or BACE2 inhibitors	Hoffmann-La Roche Inc.	02/22/2016
US9000183	21	Cyclohexane-1,2′-indene-1′,2″-imidazol compounds and their use as BACE inhibitors	Astrazeneca AB	10/19/2015

US8703785	9	2-Aminopyrimidin-4-one and 2-aminopyridine derivatives both having BACE1-inhibiting activity	Shionogi & Co., Ltd.	10/14/2014
US9029367	5	BACE inhibitors	Eli Lilly and Company	11/16/2015
Synonym matches				
US9096541	28	Inhibition of memapsin 1 cleavage in the treatment of diabetes	Oklahoma Medical Research Foundation; Purdue Research Foundation	03/28/2016
US8637504	37	Sulfur-containing heterocyclic derivative having beta-secretase inhibitory activity	Shionogi & Co., Ltd.	08/22/2014

The first 14 rows are matches for "BACE," ranked by compound count. The last two rows are matches to "memapsin" and "beta-secretase."

Table 3 Selected structure-to-activity records from US8748418

BindingDB MonomerID	*BindingDB Ligand Name*	*Target Name Assigned by Curator or DataSource*	*IC_{50} (nM)*	*PubChem CID*
123867	US8748418, 12	Beta-secretase 2 (BACE2)	5	68307545
123862	US8748418, 6	Beta-secretase 2 (BACE2)	11	60194542
123857	US8748418, 1	Beta-secretase 2 (BACE2)	24	66547140
123869	US8748418, 14	Beta-secretase 2 (BACE2)	28	66547488
123864	US8748418, 8	Beta-secretase 2 (BACE2)	30	66547317
123862	US8748418, 6	Beta-secretase 1	30	60194542
123858	US8748418, 2	Beta-secretase 2 (BACE2)	35	66547141
123858	US8748418, 2	Beta-secretase 1	40	66547141
123870	US8748418, 15	Beta-secretase 1	40	66547492
123870	US8748418, 15	Beta-secretase 2 (BACE2)	58	66547492
123857	US8748418, 1	Beta-secretase 1	70	66547140

The complete table of 53 rows and a detailed set of columns was edited down to just the columns and rows below and ranked by IC_{50}.

As an example we can compare what SureChEMBL extracted from US8748418 where we have just located the SAR series manually extracted by BindingDB. One of the many routes to query SureChEMBL is shown in **Fig. 7**.

We can download a table of the entire (i.e., unfiltered and redundant counts) chemistry records that SureChEMBL has extracted from US8748418 by a combination of n2s, i2s, and CWU molfiles. This gives 876 rows. Extending this to all the family members increases to 1581. We thus see the main advantage of CNER in presenting what is probably close to total chemistry extraction. The important proviso is that achieving this is dependent on preprocessed patent text and image quality. The problem is that a priori from the download we cannot directly establish which of these have any SAR (i.e., could correspond to the 28 examples that BindingDB has already identified). Notwithstanding, this can be done manually within SureChEMBL by scrolling though the automatic mark-up of **Table 1** in the document (i.e., each of the 28 images in this case). Insights into CNER output can be discerned in **Table 3**.

TABLE 1

IC_{50} values of selected examples

Ex.	Structure	BACE1 IC_{50} [μM]	BACE2 IC_{50} [μM]
1		0.070	0.024
2		0.040	0.035

Fig. 5 Original SAR data from US8748418 aligned with the example images and IC_{50} data from page 32 of the PDF. Example 1 = BindingDB 123857 = US8748418, 1 = CID 66547140. For Example 2 = BindingDB 123858 = US8748418, 2 = CID 66547141.

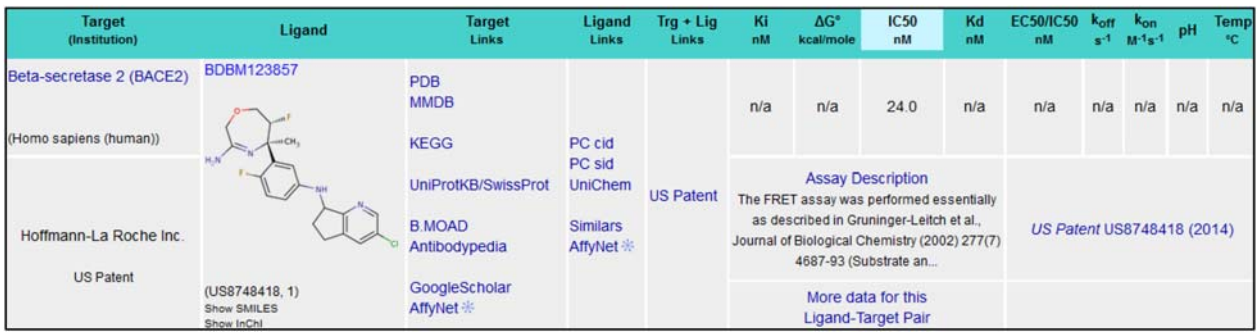

Fig. 6 The database entry for BindingDB 123857. The IC_{50} is specified along with a citation for the assay. In addition, many outlinks are presented such as the protein target in UniProt, the patent document (in Google and the USPTO portal), and the structure in PubChem (PC CID = CID 66547140).

The key points are:

- Multiple extractions of the same structure have been made from the four family members.
- The n2s and i2s are concordant (i.e., alternative extractions produce the same ID).
- For the US application (A1) and grant (B2), the intra-document count was eight, split between two different IUPACs and one image.
- The EP and WO missed one conversion (probably an image).
- The "corpus count" across all of SureChEMBL provides a reassuring inter-document consensus for this particular structure.
- Manual inspection of the documents confirms the statistics of the data download in that Roche have exemplified their active series eight times.
- This seems unusually high but we have no overall statistics to test this.

The useful aspect of this example is that, using foreknowledge of the BindingDB extraction (albeit done at a later date) we can explore multiple ways of discerning the correct SAR series. One of these is via the corpus count shown in Fig. 8.

The corpus count distribution of US8748418 shows the pros and cons of CNER pipelines in general. The problem is that most of the processing effort goes into the continual reextraction of frequently specified compounds (e.g., methanol occurs 7.2 million times across the SureChEMBL corpus and the name match finds 0.9 million documents). This is not to say that the statistics of common chemistry do not have utility for certain applications (e.g., surveying synthetic trends[16]), but these extractions can swamp

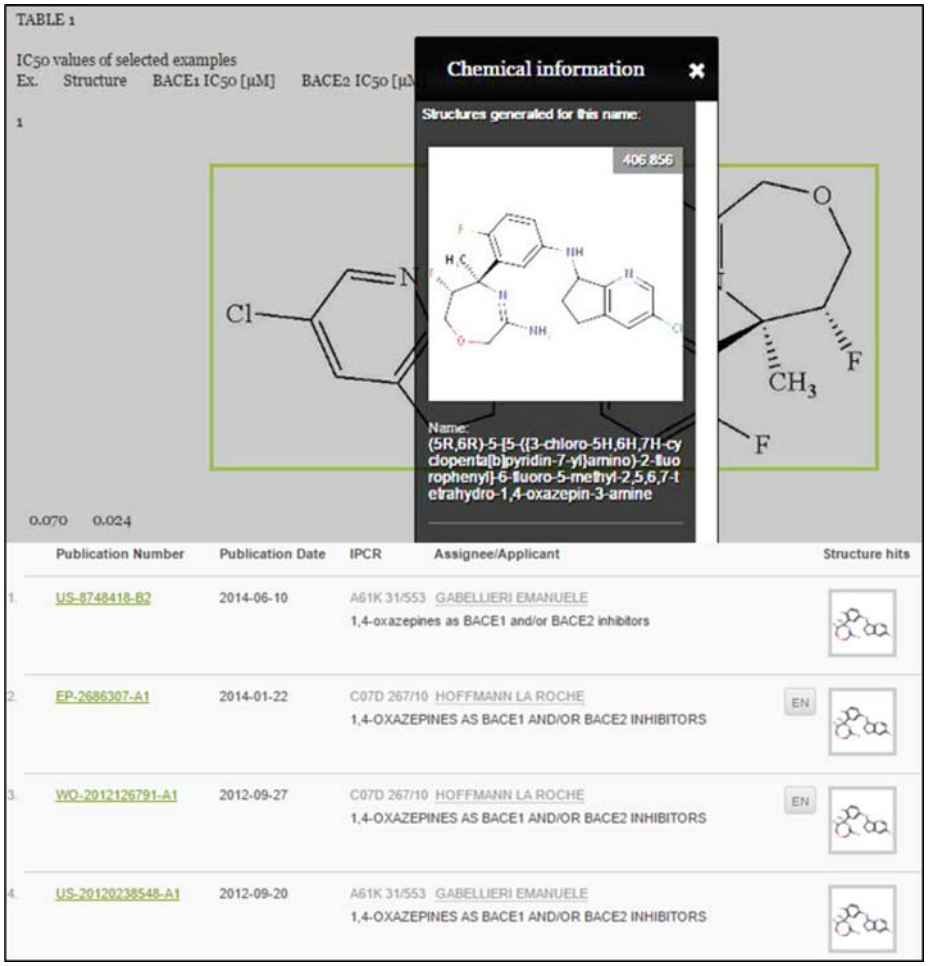

Fig. 7 SureChEMBL queries related to the BindingDB 123857 structure. The *upper panel* shows the result of an exact-match structure search. This gives nine intradocument matches, one of which an image-conversion (corresponding to **Fig. 5**) with the IC_{50} values in the lower left. The *lower panel* shows the interdocument matches across four family members.

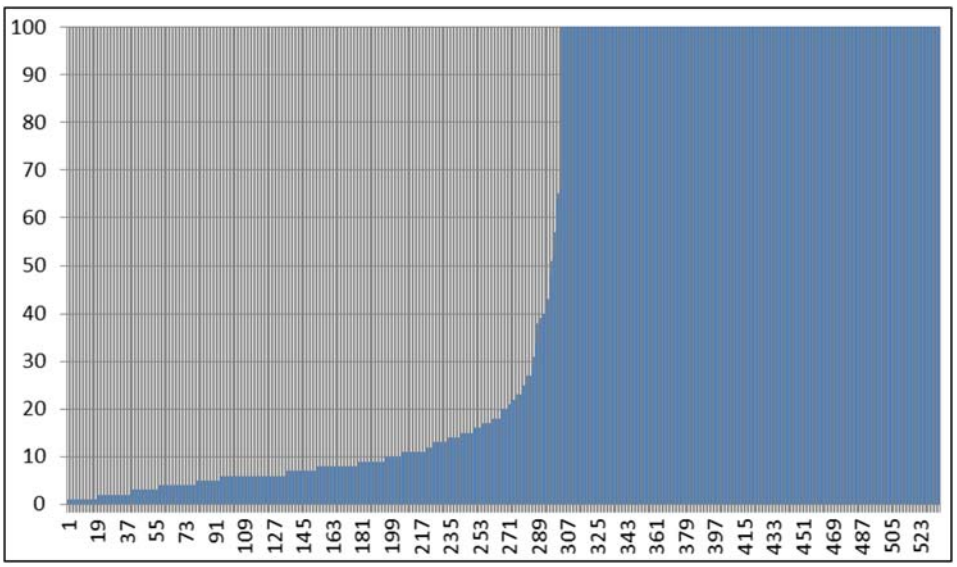

Fig. 8 A plot of the corpus count (the vertical axis, truncated at 100 occurrences) for the nonredundant SureChEMBL chemistry download for US8748418.

out the bioactives. However, the leftmost section of Fig. 8 indicates that lower corpus counts probably represent (a) novel structures and (b) encompass the SAR series. However, while from Table 3 we might expect 17 to be an SAR-specific cut-off, it turns out that the occurrences from 10 to 20 form a continuum of approximately 70 structures rather than a clean set. However, a key feature of SureChEMBL is the ability to filter downloads as shown in Fig. 9.

Toggling these settings can be complemented by further postdownload filtering (e.g., removing SureChEMBL ID duplicates and selecting occurrence ranges in the description section) to enrich for an SAR series. However, even with these options we are still left with 96 structures (i.e., within which should be the 28 we would like to identify). The caveat with Mw filtering is that it may encompass larger intermediates that are still novel structures but for which no bioactivity was reported. Corpus counting has the caveat that low frequencies of one or two (i.e., well below the document family count) may be chemically plausible structures but could represent artifactual extractions.

Regardless of the challenge of isolating an explicit SAR-linkable set, the facility to download patent chemistry extractions in SureChEMBL is powerful. There are, however, complementary ways to approach the isolation problem that can be revealed by manual inspection of context within the document. We have already seen this with the straightforward identification of the image structures and IC_{50} data in Table 1 of the patent. A second useful option is to simply browse the SureChEMBL mark-up and thereby spot sets of structures that look as though they could be matched to activity tables. An example of this is shown in Fig. 10 for US8748418.

The ability to identify such large sections in patent mark-up (either as a *blue*-highlighted IUPAC strings and/or a *green* border around the images) is useful for both assessing the quality of extraction and delineating examples. In this case, the series is not numbered so we cannot reliably link the structures to the data table rows in any automated way. However, example assignments (e.g., Examples 1, 2, 3, etc.) can be found further down in the synthesis descriptions and thus manually collated via the compound displays. This example thus shows both the generic problem for SAR-digging and the solution via manual collation. Additional ways of establishing these structure-to-data links will be shown later.

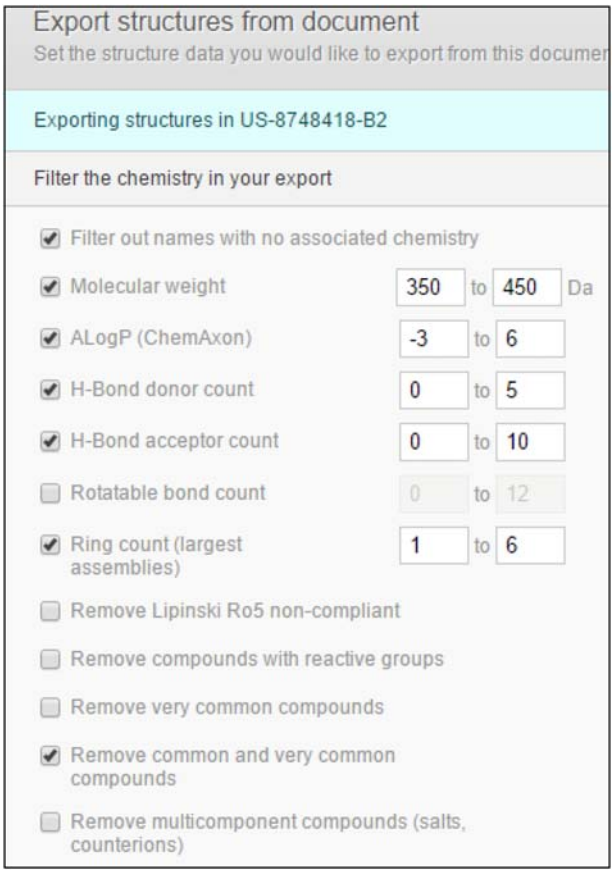

Fig. 9 SureChEMBL chemistry export filters for individual patent documents or whole family extractions. Note the default Mw window is 300–700, but this was narrowed down since we have established that SCHEMBL12273617 (CID 66547140) has an Mw of 407.

One embodiment of the invention is a compound of formula I, selected from the group consisting of

- [3-((5R,6R)-3-Amino-6-fluoro-5-methyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-4-fluoro-phenyl]-(3-chloro-6,7-dihydro-5H-[1]pyrindin-7-yl)-amine,
- (5R,6R)-5-{5-[(4-Chloro-1-difluoromethyl-1H-pyrazol-3-ylmethyl)-amino]-2-fluoro-phenyl}-6-fluoro-5-methyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (5R,6R)-6-Fluoro-5-[2-fluoro-5-(tetrahydro-furan-3-ylamino)-phenyl]-5-methyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (5R,6R)-6-Fluoro-5-[2-fluoro-5-(tetrahydro-pyran-3-ylamino)-phenyl]-5-methyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (5R,6R)-6-Fluoro-5-[2-fluoro-5-(tetrahydro-pyran-4-ylamino)-phenyl]-5-methyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-5-[5-(6-Chloro-2,3-dihydro-benzofuran-3-ylamino)-2-fluoro-phenyl]-6,6-difluoro-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-5-[5-(6-Chloro-pyridin-3-ylamino)-2-fluoro-phenyl]-6,6-difluoro-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-5-{5-[(4-Chloro-1-difluoromethyl-1H-pyrazol-3-ylmethyl)-amino]-2-fluoro-phenyl}-6,6-difluoro-5-methyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-5-{5-[(4-Chloro-1-difluoromethyl-1H-pyrazol-3-ylmethyl)-amino]-2-fluoro-phenyl}-5-ethyl-6,6-difluoro-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-6,6-Difluoro-5-[2-fluoro-5-(1-methyl-1H-pyrazol-3-ylamino)-phenyl]-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-6,6-Difluoro-5-[2-fluoro-5-(4-fluoro-phenylamino)-phenyl]-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-6,6-Difluoro-5-[2-fluoro-5-(5-fluoro-pyridin-3-ylamino)-phenyl]-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-6,6-Difluoro-5-[2-fluoro-5-(5-trifluoromethyl-pyridin-3-ylamino)-phenyl]-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-6,6-Difluoro-5-[2-fluoro-5-(6-methoxy-pyridin-3-ylamino)-phenyl]-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-6,6-Difluoro-5-[2-fluoro-5-(6-methyl-pyridin-3-ylamino)-phenyl]-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-6,6-Difluoro-5-[2-fluoro-5-(pyridin-3-ylamino)-phenyl]-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine,
- (R)-7-[3-((R)-3-Amino-6,6-difluoro-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-4-fluoro-phenylamino]-6,7-dihydro-5H-[1]pyrindine-3-carbonitrile,
- (R)-7-[5-((R)-3-Amino-6,6-difluoro-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-2,4-difluoro-phenylamino]-6,7-dihydro-5H-[1]pyrindine-3-carbonitrile,
- (S)-7-[3-((R)-3-Amino-6,6-difluoro-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-4-fluoro-phenylamino]-6,7-dihydro-5H-[1]pyrindine-3-carbonitrile,
- [3-((R)-3-Amino-6,6-difluoro-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-4-fluoro-phenyl]-(3-chloro-6,7-dihydro-5H-[1]pyrindin-7-yl)-amine,
- [3-((R)-3-Amino-6,6-difluoro-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-4-fluoro-phenyl]-(6-chloro-2,3-dihydro-furo[3,2-b]pyridin-3-yl)-amine,
- [3-((R)-3-Amino-6,6-difluoro-5-methyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-4-fluoro-phenyl]-((S)-3-chloro-6,7-dihydro-5H-[1]pyrindin-7-yl)-amine,
- [3-((R)-3-Amino-6,6-difluoro-5-methyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-4-fluoro-phenyl]-((R)-3-chloro-6,7-dihydro-5H-[1]pyrindin-7-yl)-amine,
- 4-[3-((R)-3-Amino-6,6-difluoro-5-methyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-4-fluoro-phenylamino]-benzonitrile,
- 8-[3-((R)-3-Amino-6,6-difluoro-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-4-fluoro-phenylamino]-5,6,7,8-tetrahydro-quinoline-3-carbonitrile,
- (S)-7-[5-((R)-3-Amino-6,6-difluoro-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-5-yl)-2,4-difluoro-phenylamino]-6,7-dihydro-5H-[1]pyrindine-3-carbonitrile, and
- (R)-6,6-Difluoro-5-{2-fluoro-5-[6-(2,2,2-trifluoro-ethoxy)-pyridin-3-ylamino]-phenyl}-5,7,7-trimethyl-2,5,6,7-tetrahydro-[1,4]oxazepin-3-ylamine, or a pharmaceutical acceptable salt thereof.

Fig. 10 List of IUPAC names from page 11 of the US8748418 PDF. The unbroken *blue* highlighting means that SureChEMBL has made a successful IPUAC conversion to a structure in each of the 27 cases and they would thus be included in the download. In addition, each one has a link to information about the structure (as shown in **Fig. 7**).

3.19.8 Target Searching in SureChEMBL

Having looked at target-specific retrieval in BindingDB, we can compare this to searching the much larger patent set in SureChEMBL. It is also important to understand the major difference between these resources. The latter has indexed the full content of the documents, whereas BindingDB only indexes what has been expert selected (but this includes the target name, UniProt ID, quantitative affinity values, etc.). We can look at a configured query in the SureChEMBL interface (**Fig. 11**).

The filters in **Fig. 11** were selected primarily for specificity rather than recall (i.e., to give a good yield of true-positives). The first filter is the HGNC gene symbol and two common protein synonyms as described for the BindingDB search in **Table 2**. We have used C07D as the second select but we can skip A61K in this case since we are already selecting a biological target. The third select is to search only the title and abstract rather than the entire text that could include false-positives as incidental mentions of the target. The fourth select is for WO as already described. The retrieval results are shown in **Fig. 12**.

Useful circumstantial information on SAR-likelihood can be gleaned from inspecting the retrieved title list even before opening up the individual documents (although less obvious aspects need some experience to be discerned). For example, we can see all three synonyms have been used by applicants and the patent titles appear to be true-positives. (Note: We did not need this for the BindingDB search since they were preselected.) It is also clear that we might have used "inhibitor" as another filter, but this could have an associated false-negative risk. As we could already see from BindingDB, this larger result set confirms that BACE1 is a popular target since no less than five pharmaceutical companies are slugging it out even in just these 2016 publications. Another clue we can pick up is that Merck have a secondary filing as "crystalline forms" which, by implication, should connect the structure back to an earlier novel active series that might include SAR. As an additional context, we can also establish that both Merck and AstraZeneca

have candidate BACE1 inhibitors still in clinical trials with Roche having had RG7129 in Phase 1 but terminated. We can thus infer that these recent filings from these three companies could include SAR from back-up and/or follow-on series for each of those clinical candidates. Roche have assigned identical titles to two different WO numbers that, by definition, should therefore include different chemistry claims (see IC_{50} search below).

Having assessed the titles we can focus on some of these documents to illustrate particular points. The trio of titles from Lundbeck seem worth investigating because, as mentioned in the introduction section, they could be a set of "D"s that have A–R–P in

common and where "C" is an extended series. This turns out to be the case, with the three filings including individual K_i data tables for 41, 14, and 19 structures. We can pick out the following aspects from this set:

- They present a complex set of patent families but further down in the hit list we can find a yet a forth SAR set of 48 structures with K_i results in WO2015124576 from a 2-amino-3,5,5-trifluoro-3,4,5,6-tetrahydropyridine series.
- SureChEMBL did a good job on all four sets. Notably, two had already appeared as US publications (e.g., WO2015124576 as US9353084 and WO2016075063 as US9346797) which, as expected, gave better extraction results.
- It turns out that WO2016075064 has unusual content. Firstly, there is a 3D crystal structure image of what was extracted as CID 121334268. This provides a configuration for the series but had no reported activity data. Secondly, examples 16 and 18 were deuterated. This confounds a standard CNER pipeline both because the i2s did not recognize "D-" and the text OCR missed the "-d3" (although the n2s would have converted it within an IUPAC string). To complete the SAR set, a chemical sketcher could be used to input the two deuterated compounds. (Note: It may also happen that when this filing eventually surfaces at the USPTO the deuterated images will be linked to the document as molfiles via CWU processing.)

3.19.9 Tools for Stand-Alone Extraction

There are several options to collate SAR from US9346797 but this needs the example numbers to be matched to the data table on page 30 of the PDF. Analogs to the conversions of the example list indicated in Fig. 10, the sets are visible in SureChEMBL but in this case the applicants have usefully numbered them to match the K_i values that the document processing has extracted as text. While the SureChEMBL document chemistry export (at default filter settings) produced 114 rows that reduced to 55 unique structures, there was no easy way to isolate the 14 examples in the correct sequence. However, we can exploit the ordering by converting them extrinsically using a stand-alone operation. The resource of choice here was the open ChemAxon chemicalize resource that allows users to run n2s on text from a variety of sources an input formats.[17] In this case, an external webpage was made for batch conversion with just the 14 IUPACs pasted across from the SureChEMBL text. (Note: This may seem redundant since they have already been converted to structures but note that isolating just the selected strings and maintaining the order is important in this case.) The results are shown in Fig. 13.

One of the features of chemicalize is that we can download an SD file from the webpage extractions in which the extraction order is maintained. This can then be easily transformed using commercial packages or open resources such as OpenBabel.[18] Thus,

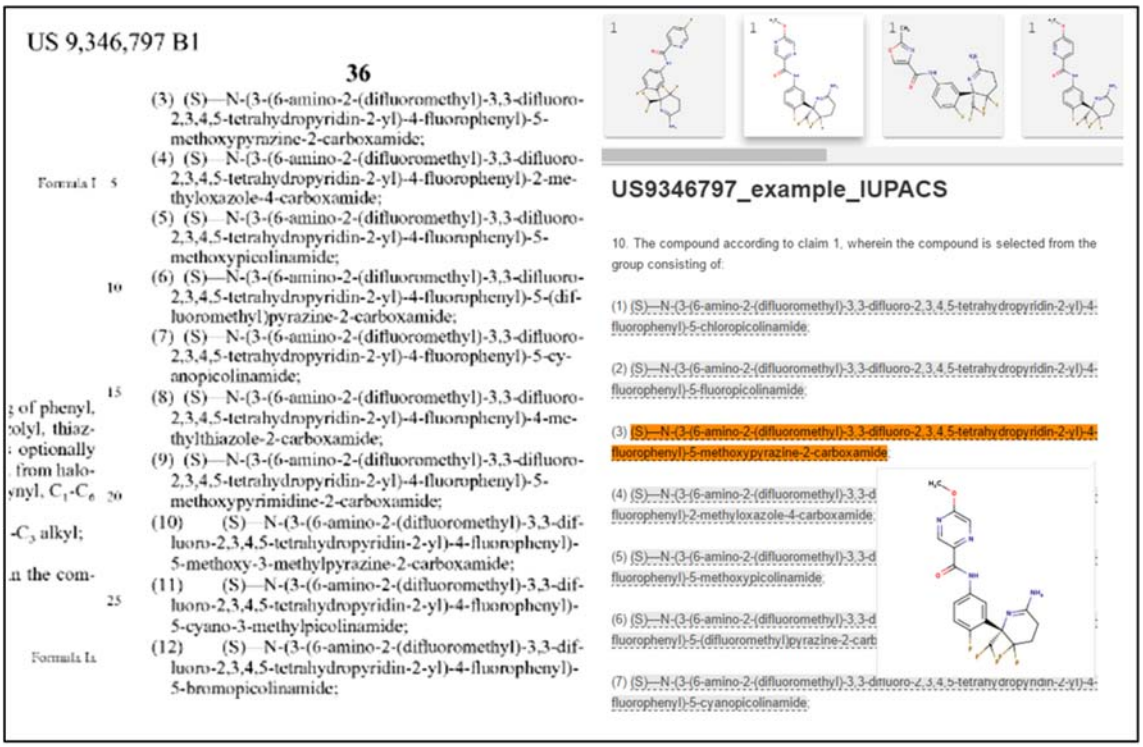

Fig. 13 The SAR series from US9346797 extracted using chemicalize. Page 36 from the patent PDF specifying the structure is shown on the left. On the right are the chemicalize webpage conversions of the same numbered examples pasted over in the same order. The IUPAC for example three is highlighted in *orange* which also displays the ChemAxon structure rendering on mouse-over.

a combination of using SureChEMBL, chemicalize.org together with some manual collation and cross-checking against the original PDFs to tie things together, we can generate a complete K_i SAR set for the 96 tetrahydropyridines.

Cases where SAR extraction presents more of challenge include the most recent in the Fig. 12 set, WO2016096979 from the Janssen team in Spain. We can quickly find SAR in the form of two different assays already log transformed to pIC_{50}s cross-referenced against 33 compound numbers. Here again the OCR does a sufficiently good job on the data table to be copied over to Excel with the rows staying in register and the greater than signs as we can see in Fig. 14 (even though the out-of-range results might be rejected for model building).

However, the failure of many of the ChEMBL chemistry conversions indicated that, compared to what we have looked at so far, it would not be straightforward to resolve compounds to match the numbers in the data table (Fig. 15).

Inspection of the SureChEMBL output establishes that text quality had confounded the n2s algorithms. The extraction problems in this document were compounded by the i2s introducing an artifactual iodine from converting the B7 image (unfortunately now permanently enshrined in CID 121433102). One option would be wait for the US patent to surface with improved conversions. However, we can see the original document contains the necessary information we need for SAR collation but arranged in a somewhat complex way (e.g., example numbers are nested intermediates for the compound numbers that are also depicted in Markush tables). Below is the SureChEMBL text associate with compound 19 from Fig. 16, where the obvious OCR errors are marked in *red*.

N-r3-r(26′,3i?)-5-amino-2-methyl-3-(trifluoromethyl)-3,4-dihvdropyrrol-2-yl1-4-fluoro-phenyl1-5-chloro-pyridine-2-carboxamide.

The tool we can use for stand-alone n2s is the open parser for systematic IUPAC nomenclature (OPSIN).[19] While the web interface is only suitable for small numbers of conversions, it has the advantage over chemicalize of presenting error notifications and also allowing trial-and-error iterative editing of the input text. By this means we can correct the compound 19 string from the incorrect one above to one that converts successfully.

With some editing it now becomes possible to generate compound 15 as the "flat" chloropicolinoamide as well as specifying the resolved enantiomers for 19 and 20 by editing the IUPAC S/R prefixes. To demonstrate another useful open tool set we can corroborate the i2s from the left-hand side of Fig. 15 by using the Optical Structure Recognition Application (OSRA) (Fig. 17).

Example B7

Preparation of **compound 15**: (±)-*N*-[3-[(2*S**,3*R**)-5-amino-2-methyl-3-(trifluoromethyl)-3,4-dihydro-2H-pyrrol-2-yl]-4-fluorophenyl]-5-chloropicolinamide, **compound 19**: *N*-[3-[(2*S*,3*R*)-5-amino-2-methyl-3-(trifluoromethyl)-3,4-dihydropyrrol-2-yl]-4-fluoro-phenyl]-5-chloro-pyridine-2-carboxamide and **compound 20**: *N*-[3-[(2*R*,3*S*)-5-amino-2-methyl-3-(trifluoromethyl)-3,4-dihydropyrrol-2-yl]-4-fluoro-phenyl]-5-chloro-pyridine-2-carboxamide

compound 15: $C_1(RS),C_1(RS)$, single diastereoisomer (cis)
compound 19: $C_1(S),C_1(R)$, single diastereoisomer, pure enantiomer
compound 20: $C_1(R),C_1(S)$, single diastereoisomer, pure enantiomer

Fig. 15 Chemistry for one example in WO2016096979. The compounds associated with example B7 in the original PDF are shown on the left with the corresponding SureChEMBL section on the left. Note the "Highlight additional recognized chemical terms" option was toggled on. The consequent appearance of the *gray* highlighting indicates where the n2s recognized a potential name (i.e., an IUPAC-like text string) but could not generate a structure (in which case the highlighting would have been *blue*).

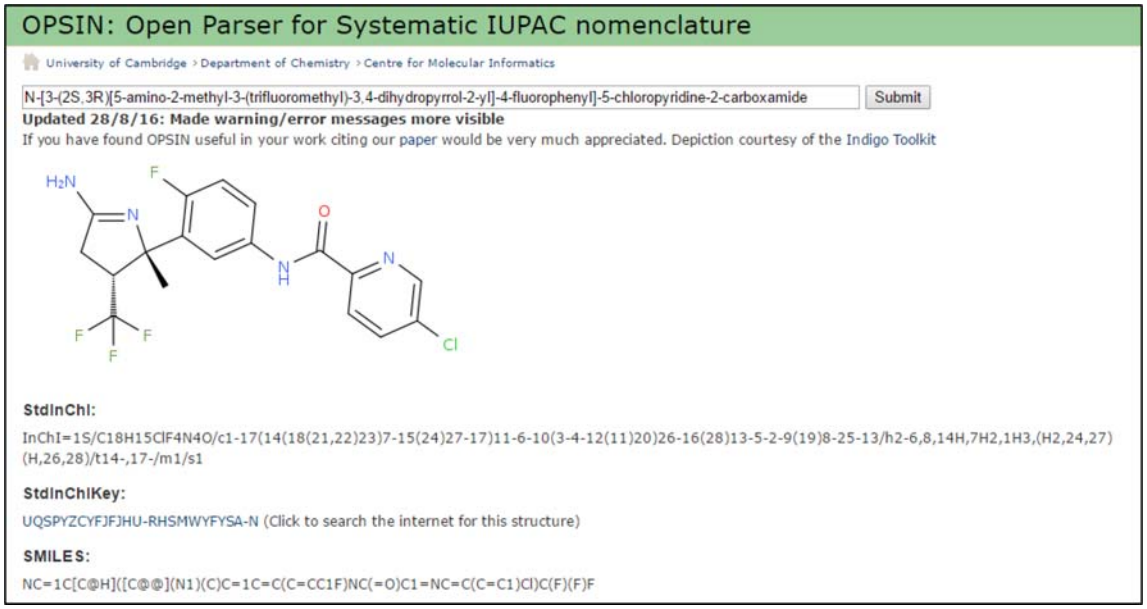

Fig. 16 Conversion of compound 19 from WO2016096979 using the OPSIN interface. The input (after editing corrections) was *N*-[3-(2*S*,3*R*)[5-amino-2-methyl-3-(trifluoromethyl)-3,4-dihydropyrrol-2-yl]-4-fluorophenyl]-5-chloropyridine-2-carboxamide.

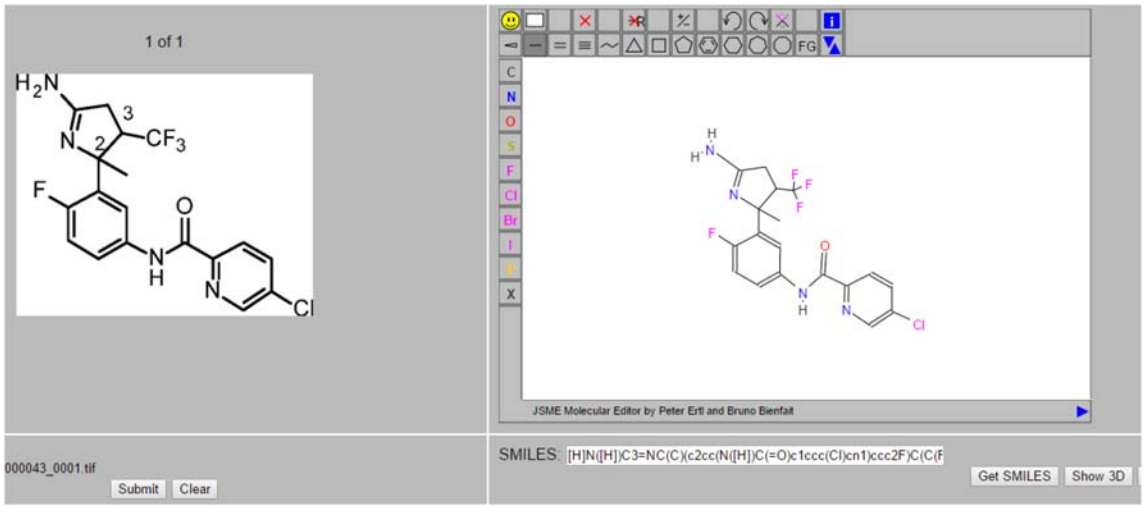

Fig. 17 The OSRA result for conversion of the downloaded image from **Fig. 15**. The SMILES output can be converted to the example 15 IUPAC of *N*-{3-[5-amino-2-methyl-3-(trifluoromethyl)-3,4-dihydro-2*H*-pyrrol-2-yl]-4-fluorophenyl}-5-chloropyridine-2-carboxamide.

This WO2016096979 example shows the synergies of working between the original document, the SureChEMBL output with the addition of the OPSIN and OSRA tools (chemicalize could also have utility here depending on individual preferences). While it has been said that collating the complete SAR set from these 33 examples, including the enantiomeric splits, would require some effort, the combined approach brings many other such "difficult" documents within practical reach of extractability. It is important to note that, due to partial failure of the SureChEMBL conversions, many of these examples will not be in PubChem.

3.19.10 Selecting for SAR

A particular advantage of full text indexing in resources such as SureChEMBL is that, regardless of the expected specificity issues, simple searches such as "IC_{50}" or "inhibitor" actually work (108,115 and 650,147 documents, respectively, with an AND union of 56,870). We can see a practical example in **Fig. 18**.

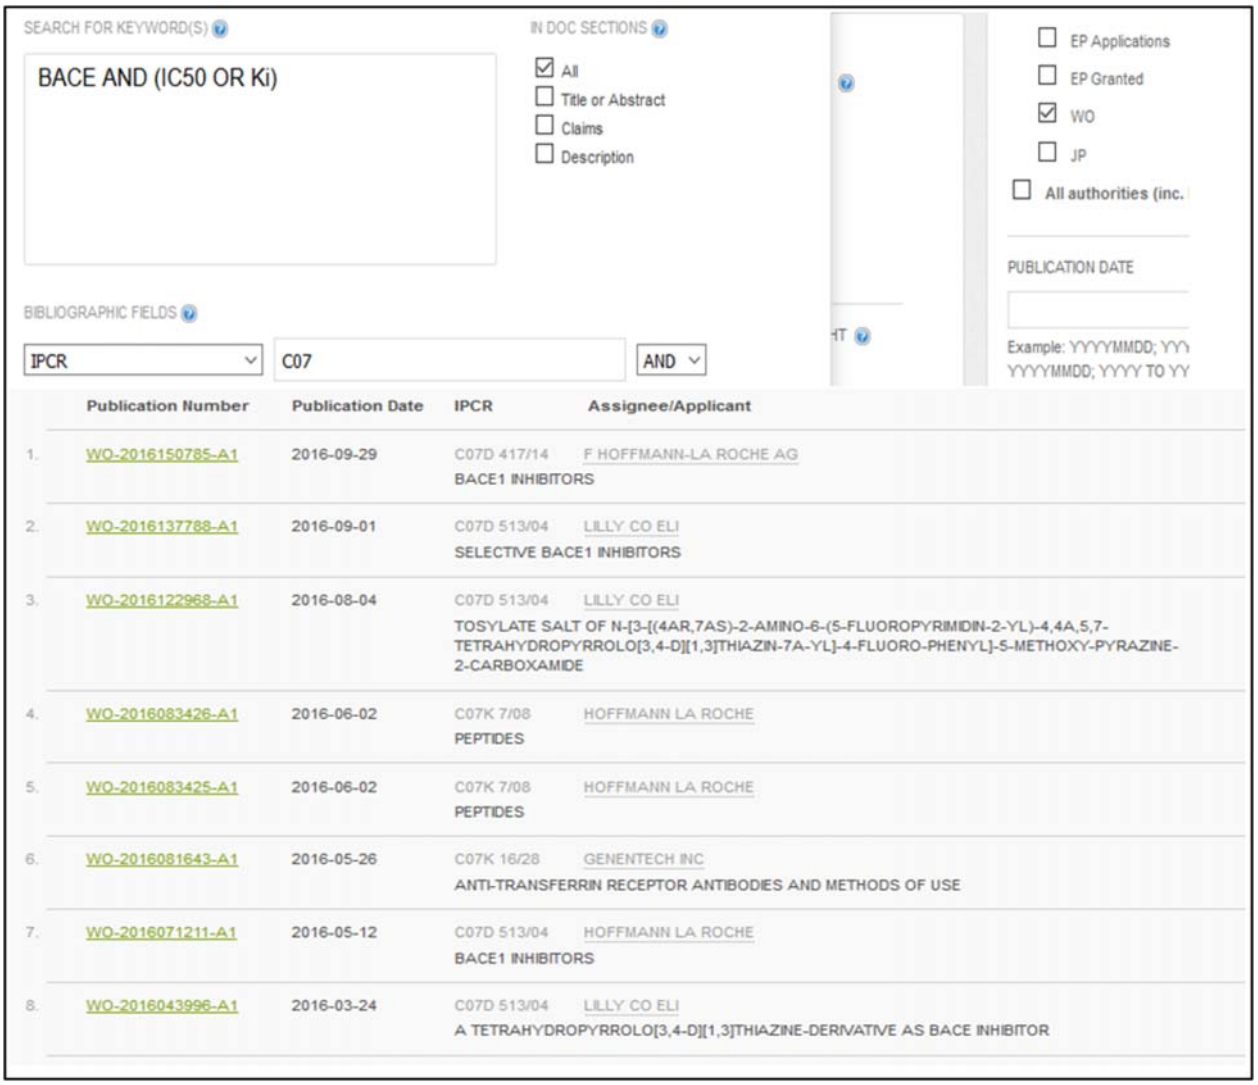

Fig. 18 The most recent matches (from 138 in total) SureChEMBL search with for matches to BACE1 and IC_{50} or K_i and C07 within WO documents.

We can see that Fig. 18 has matches in common with Fig. 12 and spot what seems a likely consecutive series from Roche as WO2016150785 and 4 months earlier WO2016071211 both titled "BACE1 inhibitors." Inspection reveals these to be true-positives with WO2016150785 having seven intradocument IC_{50} matches including "Table 1: IC_{50} values of selected examples." While there are only four intradocument matches in WO2016071211 and the result table is not numbered, we can pick out both tables. This Roche patent appears to be a true-positive for the IC_{50} trawl on the one hand, but may present borderline SAR value on the other. The first issue is data sparsity (compared with what we have seen so far) since in WO2016071211 only 12 of the 25 IC_{50} examples have data and in WO2016150785 its 38 from 44. We can also see signs of probable deliberate obfuscation in the use of confusing nested numbering systems. However, more serious issues we can immediately spot are difficulties for chemistry extraction, because the poor OCR has confounded most of the n2s (including extensive introduction of the notorious 1-to-l conversion errors). While the i2s has fared better in at least getting structures out, the multiple conversions from small images in the tables present a confusing picture. We can look at an example in Fig. 19.

We can follow these structures "back round" in the sense of mapping them back to their locations in the document (via PubChem or inside SureChEMBL). However, we see a peculiar pattern of stereo enumerations and "flat" structures that are matching multiple different example numbers (e.g., two and three are identical). The minimum parsimonious assumption is that these multiple mappings could be due to errors in the document. At the end of the day, this example can be seen as a cautionary tale. Thus, WO2016071211 would seem unreliable for SAR modeling and not worth spending time on with tools to try to sort things out. However, thanks to the SureChEMBL "efforts" we can at least see the series chemotype.

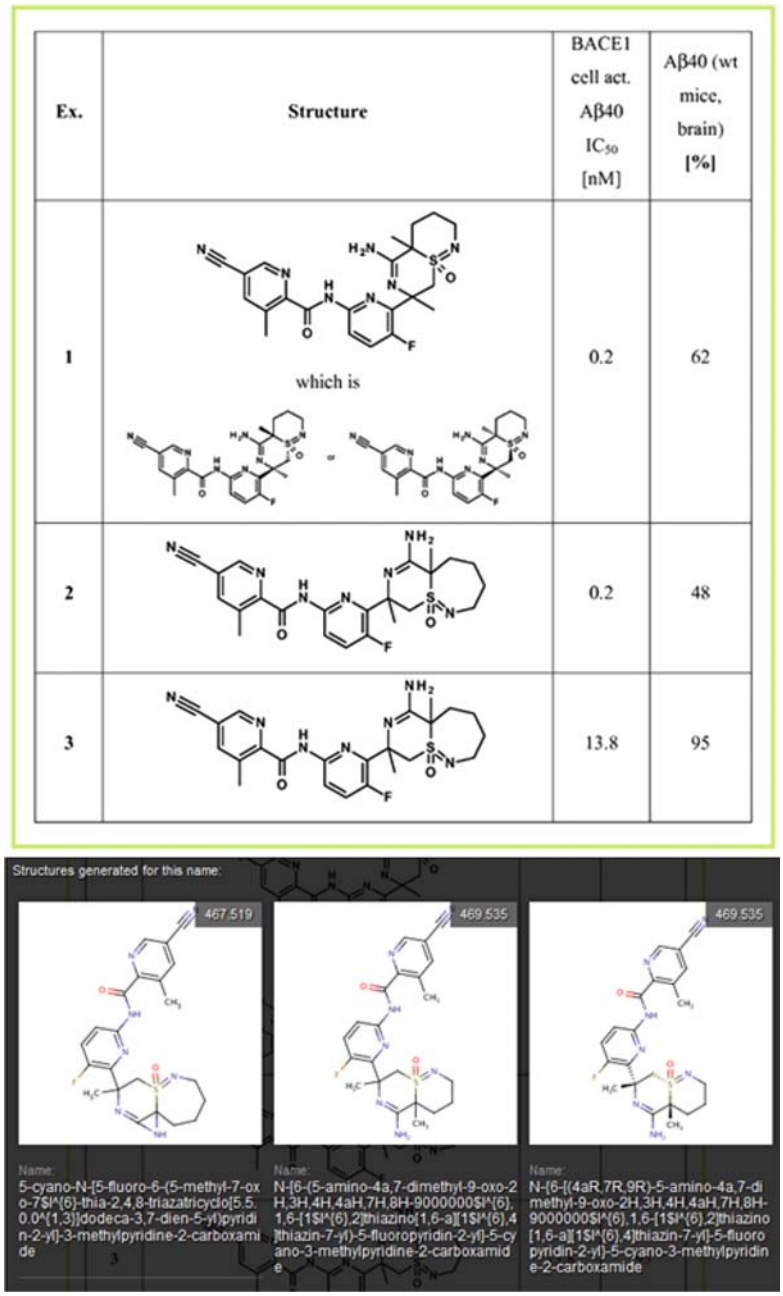

Fig. 19 The first three examples from **Table 1** in WO2016071211 are in the top panel. The SureChEMBL rendering is shown, with the *green* boarder signifying an intradocument search match. The image conversions from this section of the table have spawned the three structures in the lower panel (but not necessarily in order). From left to right in the panel these are in PubChem as CID 121329828, CID 121329766, and CID 121329765.

3.19.11 Connecting Between Patents and Papers via PubChem

Explorations of patent SAR naturally generate a range of questions with respect to the literature. The two basic ones are (Q1) "have any of the bioactive structures in this patent appeared in papers?" The converse question (Q2) is "have any of the bioactive structures in this paper (in particular the lead compound) appeared within a (possibly larger) SAR series in a patent?" These questions thus look forward or backward in time and can both be important. There are technically different ways to approach the questions and with different search stringencies (e.g., an exact match, a connectivity match, a similarity match, or multiple matches across a series). Before looking at some examples it is important to understand the time relationship of what surfaces where when, how much, and who cross-points to whom. Starting with patent chemistry in PubChem first we can establish that it contains 16.3 million substances

from SureChEMBL up to Aug. 6. We can also check that in situ the latest extractions were only 3 days behind the publication date. While the lag time in PubChem is thus about a month, this is more than acceptable for a free resource. There are four other sources of patent chemistry in PubChem that each have more than a million structures (see **Table 1** in ref. [2] for a 2015 snapshot) but three of these are static and are not likely to update. Selecting SureChEMBL, IBM, SCRIPDB, and NextMoveSoftware (all CNER sources) adds up to 19.7 million compounds with 82% coming from SureChEMBL.

PubChem is extensively connected to the literature via different types of CID-to-PubMed connectivity[20] one of which includes ChEMBL via the PubChem BioAssay database. However, there is an associated lag time for when PMIDs are connected to CIDs, because ChEMBL release times are well over 6 months. Nonetheless, there are multiple ways to answer Q1 and Q2. One of these is by following the reciprocal cross pointers between PubChem, SureChEMBL, ChEMBL, and UniChem. This means for any individual structure we can follow inter-database and paper-to-patent connectivity without doing any searches at all (this was already demonstrated for SureChEMBL-to-PubChem). Before we explore search examples we should examine the general question of what is the overall overlap between structures in papers and patents. The commercial GOSTAR figure is that 9% of compounds from papers are found in their patent extractions, indicating a slight rise from 6% in 2009.[6] By contrast 18% of ChEMBL has a SureChEMBL match. There are two possible reasons for the higher number. Firstly, ChEMBL subsumes ~0.5 million compounds from confirmed Molecular Libraries Screening Centers Network (MLSCN) assays so this substantial increase in structures would be expected to increase in turn the number of literature extraction matches. The second is that SureChEMBL extracts approximately three times the number of compounds GOSTAR does, which should also increase the percentage overlap with literature extraction.

We can approach the questions by looking at Q2. A simple PubMed search with "BACE1 inhibitor" brings up a relevant looking paper high in the result list (**Fig. 20**).

This very recent paper (not yet captured by ChEMBL) from Bristol–Myers (BMS) has the hallmarks of a drug discovery team pursuing an orally available, brain penetrant BACE1 inhibitor for which they already have activity in a mouse model. The bonus for our question answering is that they have deposited two PDB structures containing ligands from the paper. Because the NCBI

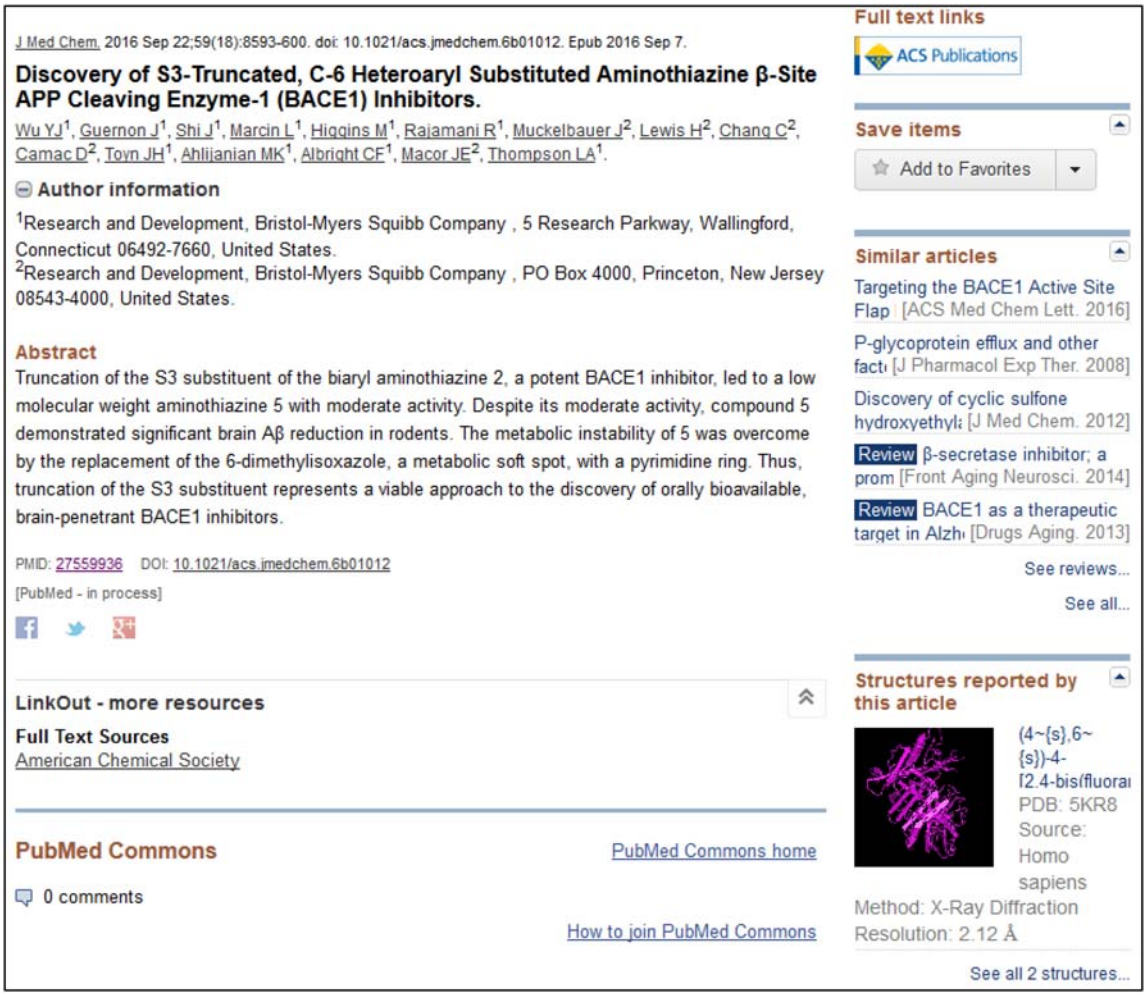

Fig. 20 The fourth ranking match in PubMed with the query "BACE1 inhibitor."

MMDB system assigns a CID-to-PDB ligands where possible, the resulting CID 90253397 connects us right through to the SureChEMBL patents (Fig. 21).

While the BMS paper has good SAR characterization for 18 structures in total,[21] the patent has cell-based IC_{50} data for a series of 62 compounds that, with some manual engagement, can all be identified from the SureChEMBL output. Note also that WO2014098831 was picked up in the Fig. 12 search but was a year further down the list. Of the possible approaches to Q1 perhaps the most effective is to download filtered patent chemistry from SureChEMBL and upload it to PubChem using the Indentifier Exchange Service. The next step is to intersect these CIDs with ChEMBL. Lead-like matches (i.e., not common chemistry) are likely to be from journal extractions at least 2 years or more after the patent date.

3.19.12 Tracking Back to First-Filings

This is a variation on the paper-to-patent Q2, but here the focus is searching backward for the early patents on clinical candidates or recently approved drugs. The special interest here is to possibly access patent SAR around a compound that has reached some level of success, even just in the preclinical stages. One resource that enables making the appropriate connections is the IUPHAR/BPS Guide to Pharmacology (GtoPdb).[22]Inspection of the BACE1 entry indicates the expert curation of 15 lead compound and clinical candidates as ligand entries. For some of these, patents have been curated into the reference where these were found to contain useful SAR. A section from this panel is shown in Fig. 22 and the SureChEMBL page shown in Fig. 23.

Given the verubecestat compound from Merck is now in Phase III, it is somewhat unusual in not having any journal publications. In this case, the curation of a patent link into GtoPdb is particularly useful. Although the discrete SAR in US8940748 is minimal there are BACE1 and BACE2 K_i values. Also somewhat unusually there are in the order of 200 analog structures fully described without inhibition data but many with permeability measurements. Using the approaches described earlier most lead compounds and drugs, using GtoPdb or other resources as entry points, can now be tracked back to their first-filings as novel structures, many of which include SAR.

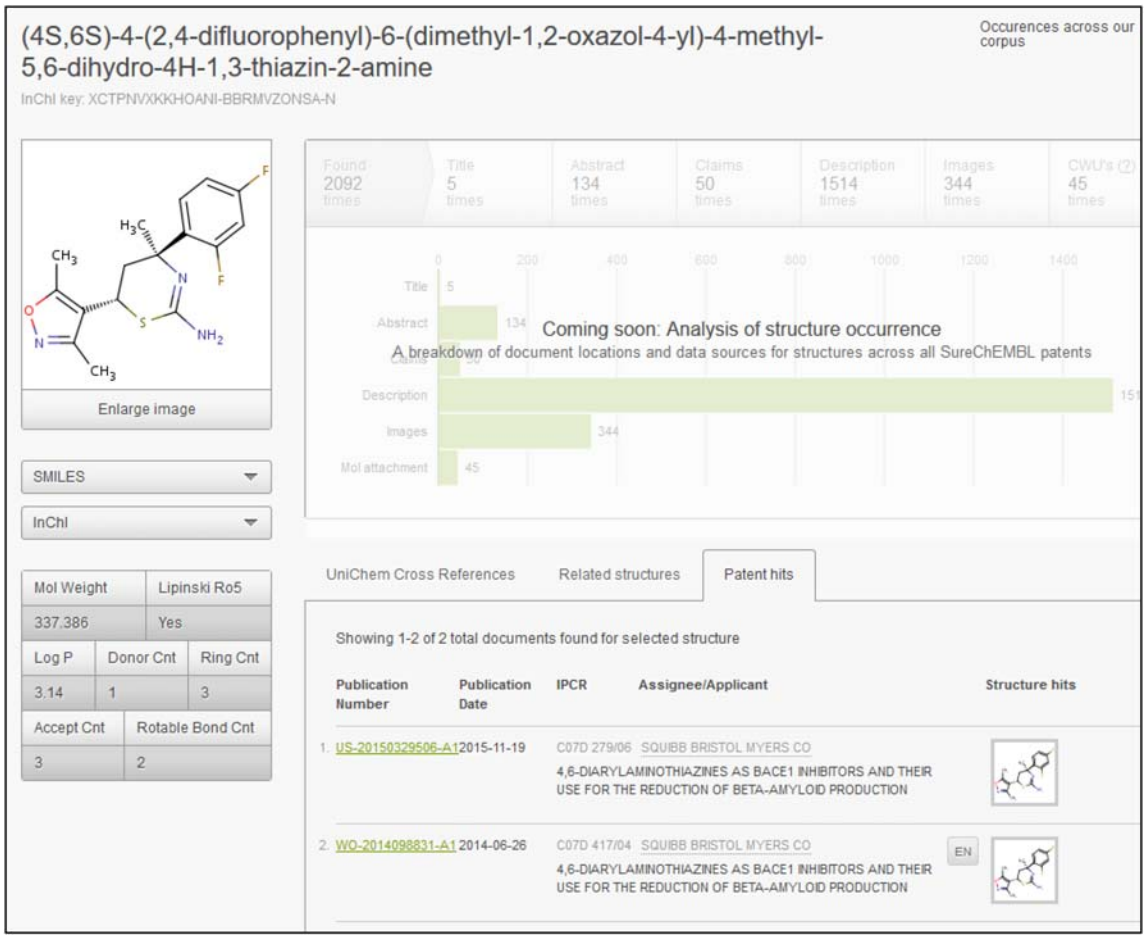

Fig. 21 The connection between the publication PMID 27559936, the PDB entry 5KR8, the CID 90253397, the SureChEMBL SID 240769892, and the two family BMS patents above.

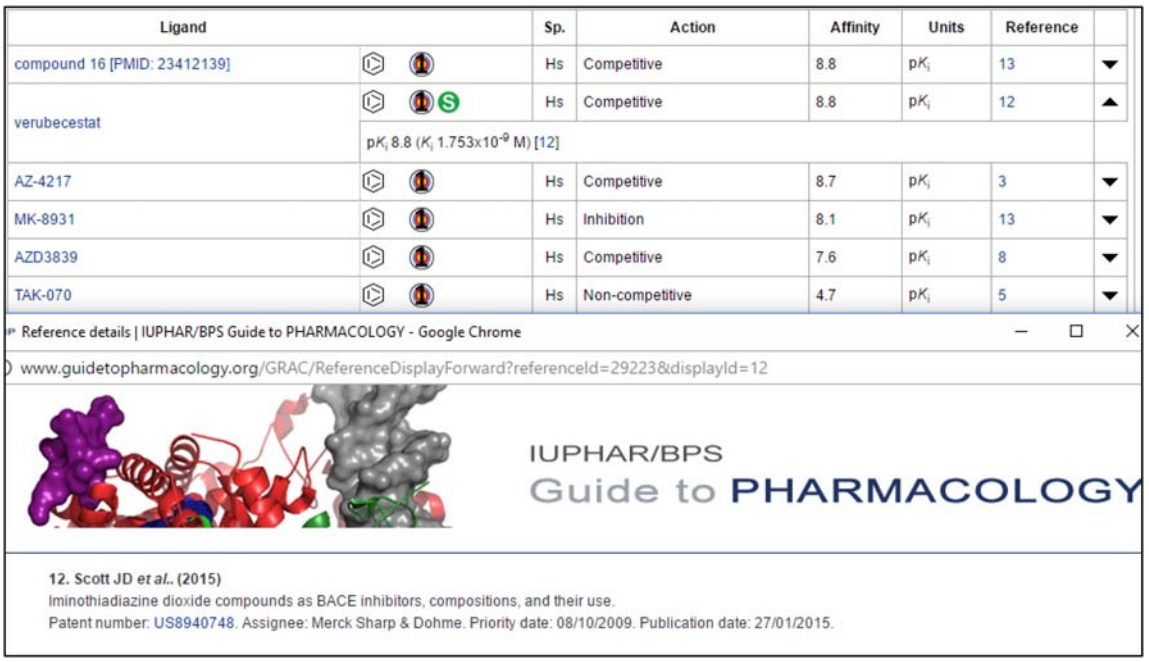

Fig. 22 Snapshot from the GtoPdb page for BACE1 ligands. The record for verubecestat is expanded to show the pK_i, the patent reference in the lower panel, a live link to the SureChEMBL patent document, and identification of the example number as 25.

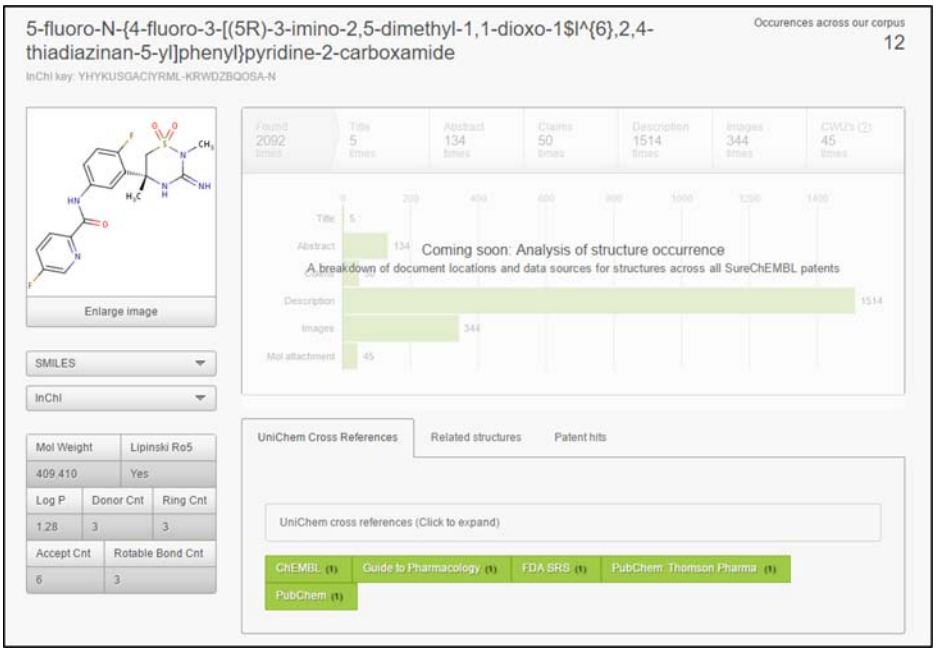

Fig. 23 The SureChEMBL page for verubecestat. The lower set of *green* panels show the cross pointers to other databases mediated via UniChem, including a GtoPdb link to **Fig. 22**. Note also if the 14 patent document hits are opened up we see Merck WO2016053767 for "Novel crystalline forms of a bace inhibitor, compositions, and their use" which was the secondary patent pointed out in **Fig. 12**.

3.19.13 Conclusions and Prospects

It is hoped that the approaches and examples presented here will not only encourage but also enable medicinal chemists to dig SAR out of patents. The recent "big bang" of patent chemistry flowing into public databases, alluded to above, now presents the best of both worlds situation in two senses. The first is that open patent data is becoming more synergistic with the features and content of

commercial resources. The second is that those without access to the latter are no longer constrained for SAR-digging even if it may take a bit more time and effort. So what of the future? It would be useful to see comparative modeling results that might illuminate similarities and differences between data sources (i.e., Could adding patent-only SAR improve models?).

Other developments will include significant optimization of the PubChem patent system in 2017 (Evan Bolton, personal communication). In addition, the development of patent information extraction systems continues (e.g., the 2015 BioCreative V challenge "Chemical and Drug Named Entity Recognition from patent text" CHEMDNER patents[23]). As an extension of these efforts, both the commercial and open sectors are pursuing the holy grail of fully automated D–A–R–C–P extraction using NLP and deep indexing approaches. In conjunction we may also see "big data" scale patent processing initiatives in the public domain. These can exploit Application Programming Interfaces (APIs) web services (WS) and Resource Description Frameworks (RDF). These are already becoming available for SureChEMBL as part of the OpenPHACTS initiative.[24] So might the major patent offices move toward fully electronic patent applications that would include XML full text, direct submission of chemical structures, use of bioassay ontologies, standardized data tables, and bioentity identifiers for C07/A61 applications?

3.19.13.1 *Note added in proof*

As an important new development, in October 2016 the WIPO PATENTSCOPE portal (see website below) released a chemical structure search feature for ~7 million compounds they have already indexed from WO patent documents.

3.20.1 Introduction

At the heart of modern scientific progress is a reductionist belief that biology can be understood by close examination of the individual components of the whole. This idea was first suggested by Rene Descartes (1596–1650). "He formulated the notion that complex situations can be analyzed by reducing them to manageable pieces, examining each in turn, and reassembling the whole from the behavior of the pieces."[1] By contrast, systems biology seeks to comprehensively understand the time-dependent changes in a network of interactions in order to describe the integration of all the molecular or cellular components. As such, systems biology lies at the confluence point of three streams—biology, computer simulation, and high-throughput screening. As a tool of pharmaceutical drug discovery, the goal of systems biology is to find the most efficacious point(s) of intervention to change the pathophysiological state of the biological process (the system) in order to return it to a more healthy condition.

From a practical point of view, in academic and pharmaceutical industry labs, assays are usually created to test the effect of a single property at a time. For example, the concentration of a cytokine is varied and the amount of binding to its receptor is followed. After some calculation, this yields a binding affinity. A new candidate antagonist of that receptor can be tested to determine the strength of inhibition of that cytokine/receptor interaction, and hence provides a simple measure of the potency of a possible therapeutic. If a misguided investigator were to merely dose the same compound to an individual with a disease associated with this cytokine/receptor pair, and to ask whether the potential drug was effective in ameliorating the disease, he would find his questionable ethics and flawed experimental design justifiably criticized. We all "know" that successful drug discovery requires many steps (compound screening, chemical and/or biological refinement of candidates, animal models, safety assessment, dosing evaluation, etc.). And yet, in the modern pharmaceutical industry, at each step of this discovery and development process, different groups of individuals, with different focused skill sets, attempt to provide clear analysis by reducing the complexity of the system to a simple, human-comprehendible and variable-limited output. To be fair, this form of methodological reductionism[2] is usually the result of a sensible approach to the limitations of the human mind. Most people would not be able to understand assays that tested multiple parameters simultaneously. Perception and visualization of trends of multidimensional data can be difficult. However (properly programmed) computers have no difficulty processing high-dimensional data.

The availability of sufficient computing power and specialized modeling software is one of the influences that gave rise to systems biology. In fact, the notion of systems biology arose from the discipline of systems analysis and control theory, where self-monitoring circuits adapt outputs to varied inputs through amplification and feedback loops. The other major driver of the growth of systems biology was an increasing appreciation that a deeper comprehension of systems of metabolic pathways, genomic control, cellular signaling, etc., was available when biological processes were observed at larger scales than single, isolated reactions.

This is the result of the concept of "emergent properties." In the flocking of birds (or the schooling of fish, the coordinated migration of locust, and other complex systems), behavior of the flock is not the property of one leader, the master bird. Instead, all the birds move as if there is a linkage between individuals that supersedes an individual's actions. This linkage is an emergent property of the system. The demonstration that the sum is greater than the parts is the "holy grail" of systems biology. This same type of behavior is recapitulated at many levels in humans and other organisms. Each cell in a multicellular organism is constantly receiving myriad cues from neighboring cells within an organ and more distant organs through signaling molecules, direct contact with circulating sensor cells (e.g., T and B cells), or enervations from nerve cells. The cell processes this information and integrates it with its own current state, metabolic demands and specialized functions, and responds with alterations in transcriptional output and activation of regulatory networks within the cell and, in turn, communicates with the rest of the organism by initiating release of its own signaling molecules. No single cell is the "master switch" for any process in a human, and yet complex, emergent behaviors are observed in the regulation of metabolism, the growth or decline in subpopulations of cells, the maintenance of a beating heart, our immune response to invading infectious agents, and even truly astonishing supracellular things like thought. But the discovery of emergent properties goes beyond the purely observational when it can be practically applied, as it now is, in drug discovery. Understanding the origins of an emergent property, such as a feedback loop in a signaling pathway can lead to a drug that targets a pathway with greater precision than one directed at a single component enzyme.

Historically, one can always point to earlier and earlier harbingers and innovative people that led to the eventual creation of systems biology. It is the nature science to build on the work of others. Alan Hodgkin and Andrew Huxley are often cited as being instrumental in the founding of systems biology, though this discipline was not given that name at the time. Their success in creating a mathematical model of the generation and propagation of nerve impulses gave rise to other new attempts to apply mathematical principals to the description of fundamental physiological processes. By modeling the ion (K^+ and Na^+) conductances from a giant nerve fiber (see **Fig. 1**), they were able to construct a model that well mimicked the previously described, all-or-none action

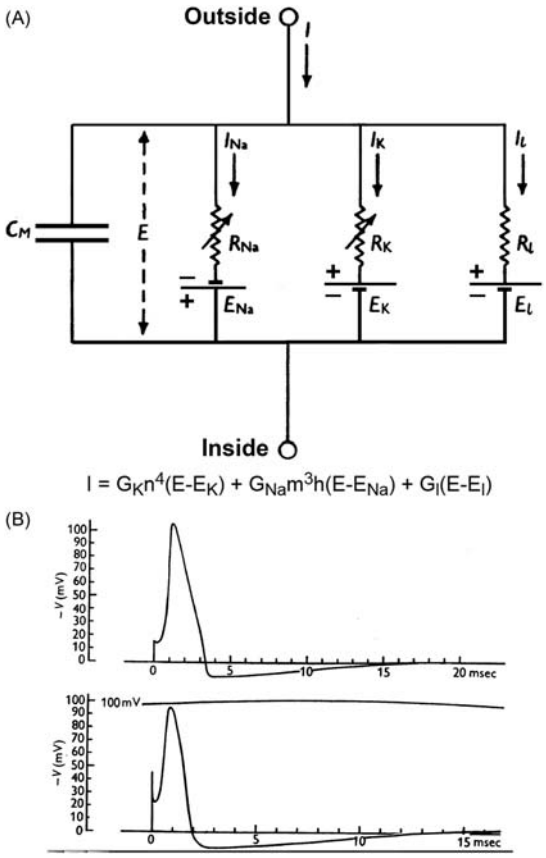

Fig. 1 (A) Hodgkin and Huxley represented the plasma membrane as a number of parallel circuits—one each for the movement of sodium, potassium, and other ions. In the equation shown, the G terms stand for conductances of the ions, E is the resting potential of the membrane, and ENa, EK, and El are the electrical potentials of each ionic circuit. The terms *n* and *m* represent the activation of potassium and sodium ion transport, respectively, while *h* stands for the inhibition of sodium transport. The standard methods of circuit analysis generated the equation shown. (B) The simple model of the conductances allowed for the comparison between the simulated (*upper curve*) and the measured biological response (*lower curve*). The model correctly predicted the magnitude and wave form of the propagation of an action potential, as well as the refractory period that occurs after the firing of the axon.

potential.[3] It should be noted that this mathematical model was formulated before the details of ion channel firing were fully envisioned. This highlights the idea that useful and innovative modeling does not require knowledge of every molecular and physical event in the process—only the important ones. Subsequently, Denis Noble built on the Hodgins–Huxley model to describe the action and pacemaker potential from the Purkinje fibers of the heart.[4] There has been a continuous building on these early works, culminating in the recent mathematical description of heart failure.[5] This paper describes how heart failure is a multiscale process that propagates from the modulation of sarcomere number, giving rise to alteration in muscle cell architecture. At the organ level, these changes then affect ventricular wall thickening and electrical properties of the heart.

Another formative force for systems biology was the rapid evolution of molecular biology. In the 1960s, molecular biology exploded with the basic understanding of the structure of genetic controls. The most thorough of these was the description of the *lac* operon.[6] It was realized, almost immediately, that these genetic processes were akin to the monitor-adapt-output cycles of mathematically approachable electronic circuitry. Labs began to construct reporter gene systems, genetic toggle switches, and simple memory, etc.[7] Hence, they had created biological analogues of many of the components of circuits, which are amenable to modeling.[8] By modularizing these control processes, they made it evident that biology is driven by recurring themes and, in turn, made in silico modeling of these processes tractable.

3.20.2 Definitions

Recently, systems biology has fragmented into many sub disciplines—systems immunology,[9,10] systems genetics,[11] systems oncology,[12,13] systems pharmacology,[14] etc. Even these more focused systems approaches vary widely in methodology. The following is a nonexhaustive explanation of some of the terms and forms of systems biology.

3.20.2.1 Systems Biology

Systems biology is somewhat difficult to define because different people use the term to mean different things. The term "systems biology" was first used in 1968 with a fairly strict mathematical and logic description,[15] but has evolved to encompass virtually any mathematical approach to elucidate biology. All these treatments share an in silico computational component and all are directed at some level of biology, but the methods and focus of this work varies greatly. Systems biology attempts to provide a quantitative and comprehensive view of some biological phenomenon by the use of a collection of connected equations. It has been used to describe biological topics as diverse as predator/prey population dynamics,[16] circadian rhythms,[17] cell cycle regulation,[18] the complement cascade,[19] DNA damage repair by surveillance driven by p53,[20] and many others. Systems biology seeks to find the underlying foundation for emergent properties in the biology under study. Mathematical formalisms will be discussed below, but all methods create a map—a topological organization of all the relevant components. Secondly, they have a linkage among elements that describes a time-dependent strength of interaction. In most cases, this means that rate constants are applied that determine the velocity of conversion of one species into another. Finally, the model ascribes initial concentrations for all species at the start of the simulation. The systems can be complex or simple, abstract or described in great detail, and often are nonlinear. They are dynamical (at each point in time there is a vector with a specified value for each species in the system). The concentration of the species and the relative contribution to the overall output of the model will mostly be changing throughout the simulation. To complete a molecular-level systems model, it is helpful to understand the full list of component parts (proteins, peptides, metabolites, etc.), as well as their concentrations. It is then a natural progression that systems biology has surged in usage with the completion of the human genome project (and the genome of species that are used in animal models) as well as advances in proteomics (e.g., mass spectrometric methods). Once all the pieces are elucidated, it becomes easier to create the network connections that make up a systems biology model. Thus, the definition of systems biology given by Leroy Hood, one of the leading voices in the human genome project as well as systems approaches, is most relevant—"Systems biology studies biological systems by systematically perturbing them (biologically, genetically, or chemically); monitoring the gene, protein, and informational pathway responses; integrating these data; and ultimately, formulating mathematical models that describe the structure of the system and its response to individual perturbations."[21] In the drug discovery area, it is a reasonable question to ask, "What does a pharmaceutical scientist gain by having a systems model of the healthy and diseased states that cannot be found by mass screening of drug candidates versus protein binding assays?" Firstly, it unlikely that binding or inhibition assays for all proteins that underlie the disease could be established in a timely manner (even if all the responsible proteins were known). Secondly, this kind of reductionism would discard all the interaction information in the crosstalk interrelationships of the network. The idea of "one disease–one target" is likely wrong for all but a few, enzyme deficiency disorders. Also, though it is an area of systems modeling that is in its infancy, systems biology does not necessarily uncover a single point of intervention, but often finds that synergistic effects are found by combinations of drugs.[22] A good example of the increased understanding of combination therapies provided by systems modeling is the work of Bown et al.[23] Using the previously described model of the PI3K/PTEN/AKT and RAF/MEK/ERK signaling pathways they simulated the development of drug-induced resistance to a first anticancer agent, followed by treatment with a second drug to correct for the resistance. Another example of modeling combination therapies is in the Nitric Oxide–cGMP pathway.[24] The authors investigated intervention at various points in the pathway as well as in combination. They give a conclusion that optimal therapy, when measured as maximizing cGMP accumulation, would be observed by intervention at three points in the pathway. This was confirmed by experimentation. A good mathematical discussion of how to evaluate synergy of combined treatment has been done.[25]

3.20.2.2 Simulation Versus Prediction

Some models seek to mimic the observed outputs (objective function) of known biology. The previously mentioned mathematical treatment by Hodgkin–Huxley simulates nerve conduction in an axon. All models start with this kind of approach because it allows the modeler to construct (most of) the critical components and links in a way that is verifiable from known data. However, particularly valuable models go beyond simulation to further predict undocumented behavior of the system. Experimental confirmation of nonobvious predictions builds the confidence in the model. These predictive models contribute to scientific progress by allowing the formation of new hypotheses for further understanding of the underlying biology. In the pharmaceutical setting, when models make strong, testable predictions, drug discovery is accelerated.

3.20.2.3 Multiscale Modeling

To some extent, most systems approaches use known information about component parts to find more holistic descriptions of biological processes. Thus, these models cross scales of structure or extend the scale of time predictions. For example, individual kinetic parameters and species concentrations are linked together to produce a simulation of a signaling network. The emergent properties of this linked system might give a picture of the dynamic relationships that occur at a cellular level in terms of signal and response. In turn, the summation of many specialized cells or organelles, for example, Islet cells in the pancreas,[26] mitochondria in the heart,[27] or endothelial cells in intestine[28] might exhibit an organism-level response of growth, correct cardiac rhythm, or ionic homeostasis in the blood. Does this understanding of multiscale processes lead to better drug discovery? To quote from a paper by Sanofi scientist, "… aiming for the discovery of novel targets increasing the glucose-dependent insulin secretion, we have established a mathematical model of the pancreatic beta cell. The 'virtual pancreatic beta-cell' has been generated by capturing all relevant processes in this cell type by combining three published models describing elements in the control of glucose-triggered insulin secretion in the beta-cell (GPCR/cAMP signaling, β-cell electrophysiology and calcium handling, insulin granule exocytosis)… The resulting model contains numerous enzymes, transporters and ion-channels involved in glucose stimulated insulin secretion… The 'virtual pancreatic β-cell' is currently used to predict the best drug targets or target combinations for increasing the glucose-dependent insulin secretion."[29]

3.20.2.4 Metabolic Control Analysis

This is an area of modeling that can see its direct antecedents in the mathematical analysis of single enzyme reactions. This area was pioneered by Westerhoff.[30] It is mostly used for looking at metabolic pathways. Earlier models had focused on synthesis and degradation pathways in which it was suggested that there was a single rate-limiting enzymatic conversion step, which was then studied in detail to understand regulation of the whole pathway. Metabolic Control Analysis seeks to understand the fluxes of metabolites through the whole collection of enzymes, in order to give a more refined view of the enzymatic ensemble. This technique is used for finding inhibitors that exploit metabolic differences as seen in disease-causing microorganisms or cancer cells.[31]

3.20.2.5 Pathway Modeling

One particularly well-worked area of systems biology is pathway modeling. This approach seeks to build mathematical models of cell-signaling networks.[32] The modeling requires setting the concentration and rates of each enzyme in the pathway, as well as the strength of any feedback and feedforward loops. This usually requires a certain amount of parameter optimization, that is, fitting of unknown (or poorly characterized) parameters. This is done by fitting a range of parameter values to a known, experimentally derived, output graph. For example, a fluorescent assay might measure the production of an intermediate of the pathway. The concentration or rate of an enzyme with unknown values is determined by varying the rate constant or protein concentration until a reasonable fit to the data is obtained. This value is then entered into the pathway. In this way, the MAPK[33,34] pathway and its connection to EGFR[35,36] signaling have been modeled extensively. The topology of the pathway had been previously determined and most of the phosphorylations and dephosphorylations had been parameterized and feedback loops had been mapped. This has led to insights about control of the pathway, which in turn, has led to better drug design[37] for this pathway, which is inappropriately regulated in breast cancer and other neoplasms. Many pathways have been modeled in this way, including the Wnt,[38] JAK/STAT,[39] PI3 kinase,[40] NF-κB,[41] Notch,[42] TGF-β,[43,44] and multiple others.

3.20.2.6 Integrative Biology

Integrative biology is every bit as difficult to define as systems biology. It stresses cross-discipline studies to unify a view of biological phenomenon into a cohesive whole.[45] Integrative biology emphasizes biology as information, thus bringing insights from genomic, physics, chemistry, etc., to provide a clearer view of the area of study. Many papers in integrative biology highlight taxonomy and comparative biology. Others stress a hybridization of bioinformatics and -omics that rely heavily on clustering of data and finding statistical means to understand informational content that underlies the organizational connectedness of interacting proteins, genes, etc. It has been suggested that systems biology is a subset of integrative biology since systems biology also gives priority to combining computational and biological disciplines.[46] Systems approaches face a challenge from "big data." The system under

study in a model, might be large, but does not contain influences from all other proteins and isoforms. Therefore, at some point integrative biology demarcates the most influential players in a system and allows systems modelers to draw operational boundaries for their studies. Quickly interrogating huge data files systematically, and incorporating the relevant pieces of them into a systems model has not been achieved (yet).

3.20.2.7 Physiologically Based Pharmacokinetics

PBPK is a specialized systems approach to drug distribution.[47] Each organ in the body is essentially treated as a compartment with physiology-based pharmacokinetics (PBPK) is a specialized systems approach to drug distribution specified input and output of flows, a volume and (sometimes) a measure of drug metabolism, and binding capacity.[48] These models can be quite useful to track the amount of a dosed drug that reaches the tissue in which the pathophysiology is located. They can also aid in understanding the half-life of a pharmaceutical and hence the required dosing regimen to be efficacious. Mostly, PBPK models have been used for molecules of low-molecular weight, though as more information becomes available on the physiological properties of different classes of macromolecules, they are also being studied in PBPK models.[49] In general, macromolecules are dosed intravenously, so absorption from the gut does not need to be addressed in the model. Absorption of orally delivered, small molecule drugs from the gut can be a very complex process,[50] and is idiosyncratic for each drug, but in combination with experimentally derived data, predictions of drug disposition can be helpful. While little information at the molecular level is usually present in these models, they can also have utility in informing more mechanistic models. An example of a physiologically informed simulation, with a significant degree of molecular detail is a model of calcium homeostasis and bone remodeling.[51] In this model, the authors mathematically explain the delicate balance of calcium intake from the gut, kidney reabsorption/excretion of phosphate and calcium mediated by multiple endocrine mechanisms, and the constant bone loss and growth driven by the osteoclasts and osteoblasts. This model allows hypothesis testing in an area of intense pharmaceutical industry interest, due to competition for safe and effective osteoporosis drugs.

3.20.2.8 Quantitative Systems Pharmacology

Quantitative systems pharmacology (QSP; also called systems pharmacology, systems clinical pharmacology, and mechanistic physiological modeling, pharmacologically-orientated systems biology) is an enhancement to the more standard PKPD (pharmacokinetics pharmacodynamics) simulation. PKPD modeling is the traditional modeling found in the pharmaceutical industry and academia. PKPD links the dose of a drug to an observed time-dependent appearance and clearance of the drug (PK) and correlates this with a desired physiological effect (PD) or the appearance of an undesirable side effect (toxicology).[52] While PKPD models are very valuable for aiding in dose prediction, cross species dose calculation, and drug safety assessment, they only rarely are based on understanding the basic biological phenomenon that they describe. To be fair, understanding basic biology is not the goal of PKPD models. Rather, they are mathematical constructs to give vital information that is necessary in registration of drugs with regulatory authorities. The models are descriptive and empirical. But to more firmly attach the PKPD framework to the physical characteristics of the pharmaceutical, it was a natural evolution that empirical PKPD models began to add some kinetic and mechanistic details to produce, what is known by the title, semimechanistic PKPD models. At early times in this migration to semi-mechanistic models, these simulations were standard PKPD models with details about drug/target binding added.[53] However, some of these models have become much more expansive (e.g., see references 54–57). To continue the evolution of this area, the idea of adding "some" mechanistic detail soon gave rise to adding sufficient information to build systems models.[58] However, systems models have now entered the regulatory arena.[59] The FDA advisory board recently used a QSP model to evaluate the dosage for a recombinant human parathyroid hormone, for the long-term treatment of hypoparathyroidism. The FDA committee suggested that, based on the model, dosing needed to be further refined to avoid the safety concern of hypocalciuria. This might be a harbinger of greater QSP modeling involvement in FDA oversight of pharmaceutical safety and efficacy. At this point, it would seem that systems biology and QSP are overlapping in goals and methodology. However, true to its name, QSP, remains focused on drug discovery, while systems biology describes a broader study of any biology, pharmaceutically related or not. Also QSP has found a niche in translational medicine,[60,61] the part of the drug discovery process that moves the new pharmaceutical agent from its research foundations in binding assays and early animal models of efficacy and preliminary toxicology onto the threshold of clinical trials, where human dose prediction and dosing regimen become paramount, that is, the "bench-to-bedside" bridge. One of the most ambitious and enlightening models was an immune response model[62] (**Fig. 2**). This model simulates the reaction to infection. It shows reactions at the protein level (e.g., cytokines) as well as at the cellular level. It predicts the kinetic changes in T and B cell subsets, macrophages, dendritic cells, and the clearance of antigens. This model, when fully validated, will allow for evaluation of drugs that alter the immune response.

Systems pharmacology is many times linked to pathways models. This is because many of the same signaling pathways are reoccurring themes in many disease states.[63] There is an underlying belief that models from one disease can be "recycled" for use in other pathology. The problem with this assumption is that the same pathway is used differently in different cells or that the concentration of reactants varies in different tissues. The network of crosstalk or influence from other pathways is different throughout the organism. This is a source of on target toxicology and is hard to predict.

Systems pharmacology has been suggested to be the future deliverer of personalized medicine.[64] In theory, a general model of a disease process could be parameterized with information from each patient. This hypothetical model would then choose a drug

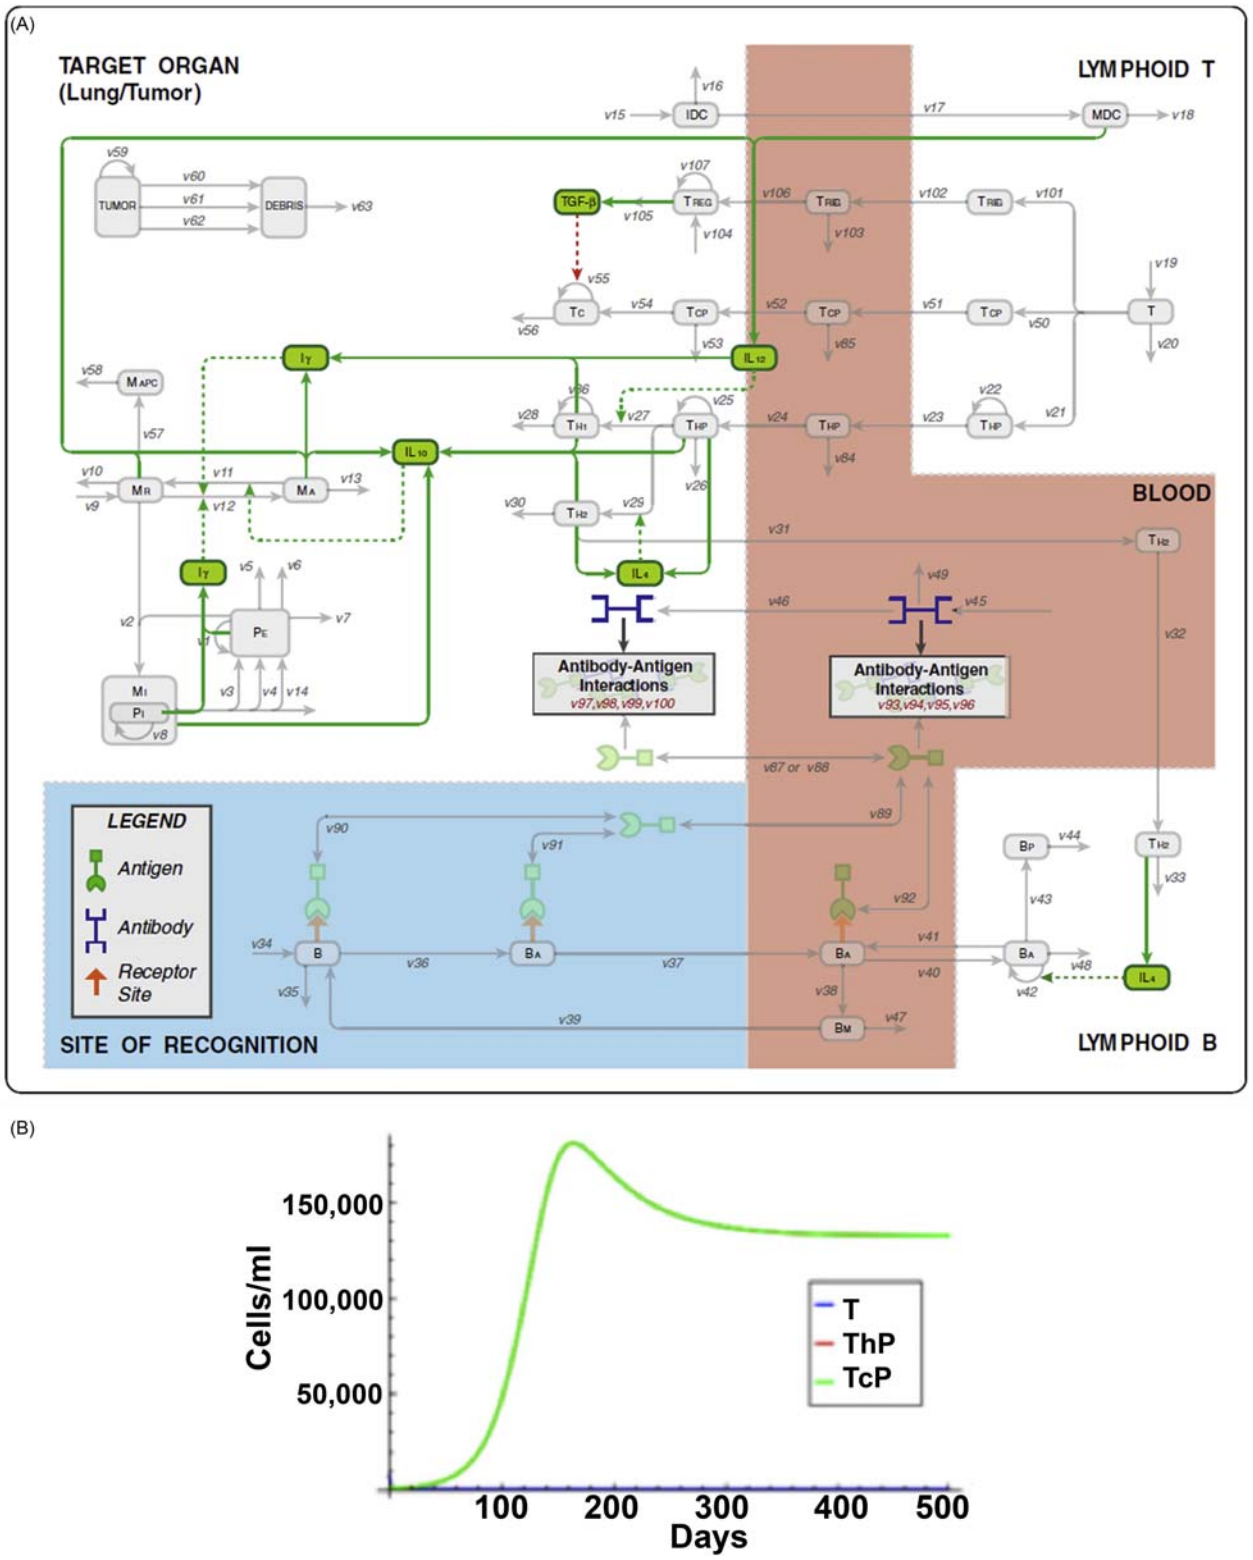

Fig. 2 A fully integrated immune response model. (Adapted from Palsson, S.; Hickling, T. P.; Bradshaw-Pierce, E. L.; Zager, M.; Jooss, K.; O'Brien, P. J.; Spilker, M. E.; Palsson, B. O.; Vicini, P. The Development of a Fully-Integrated Immune Response Model (FIRM) Simulator of the Immune Response Through Integration of Multiple Subset Models. *BMC Syst. Biol.* **2013**, *7*, 95.) The model seeks to show the immune response (in this case the effects on cellular reactions and cytokine production) to tumors, bacterial infections, etc. Abbreviations: *AB*, antibody; B, naïve B-cells; *BA*, activated B-cells; *BM*, memory B-cells; *BP*, plasma B-cells; *DEBRIS*, tumor cell debris; *IDC*, immature dendritic cells; *MA*, activated macrophages; *MAPC*, antigen-presenting macrophages; *MDC*, mature dendritic cells; *MI*, infected macrophages; *MR*, resting macrophages; *PE*, extracellular bacteria; *PI*, intracellular bacteria; *T*, naïve T-cells; *TC*, cytotoxic T-cells; *TCP*, cytotoxic precursor T-cells; *TH2*, T-helper 2 cells; *THP*, helper precursor T-calls; *TH1*, T-helper 1 cells; *Treg*, regulatory T-cells.; *TUMOR*, tumor mass. In panel A is part of the topology for the immune response in the lung/tumor. Panel B represents the model simulation of the time course of subsets of T cells after an intracellular bacterial infection. The model actually computes time courses for all the cells, cytokines, and antigens represented in the model.

(or mixture of drugs), dose, and dosing regimen for that person. But this is (at present) wishful thinking. QSP has considered the heterogeneity in drug action (epigenetic factors, environmental influences, proteomic variability, the individual's reaction to the physicochemical properties of the drug, etc.)[65] and it seems that without a massive computational approach, this will not be possible. However, this is a very complex system made of contributions from many disciplines. After all, even the prediction of an individual's toxicology is still not possible.[66] However, in science, today's impossible is tomorrow's attainable.

3.20.3 Mathematical Formalisms

As discussed above, systems biology seems dissectible into subdisciplines, based on the specific areas of biology addressed (systems toxicology, systems ecology, systems neuroscience, systems medicine, etc.). It can also be partitioned by the form of mathematics used to solve the complex network (rules-based modeling, process algebras, lattice-based cellular automata, Boolean analysis, ordinary differential equation-based models, etc.). The following is a brief description of some of the techniques used. The list is not exhaustive and the explanations are somewhat oversimplified. Additionally, many hybrid approaches exist. There is no single method of modeling that works under all conditions. Rather, the optimal choice of modeling algorithm is dependent on what questions need to be answered and what starting information is available. In the real world, modelers must also consider the audience for their work—some modeling methods are easier to visualize and explain to others with less modeling background. All modeling formalisms have limitations, strengths, and assumptions, and modelers must choose to balance these and other considerations.

3.20.3.1 Boolean Modeling

Boolean modeling[67,68] is, in some ways, the simplest modeling method that is applied to some of the most complex systems. It has been realized that the idea of discrete pathway models is an abstraction that does not match the cellular reality. For example, an MAP kinase pathway is easy to draw, with each enzyme having distinct, digitizable input and output kinetics, reactants, and products. But, at the next level of complexity, this pathway is modulated by signaling contact with other pathways (which are, in turn also regulated). Where do we draw the boundary between pathways in the network? Can this very complex system be parameterized? Many methods, simply practical or bounded by assumptions, try to address this conundrum. One approach is Boolean modeling,[69] which simplifies the problem by limiting the number of states that each component in the system can have. The modeling usually proceeds through two stages (see **Fig. 3A**). The first stage establishes the architecture of system. This is usually completed by information from the literature or pathway data banks. The second step is to train the system from data. Some connections are strengthened while others are eliminated due to low contribution to the measured output. Each molecular entity (DNA, RNA, enzyme, etc.) in the system is set to active or inactive (in some forms of Boolean modeling they have three states—high, medium, or low). It does this by determining the state of the components based on the sum of positive and negative (stimulatory and inhibitory) inputs at each node of the model, at a given time point. No intermediate states are allowed, only on or off. The model is then advanced one time unit and the states of nodes are reassessed. This leads to a time course for each node, for the length of the simulation. Because of the limited number of states for each node in the system, Boolean modeling is considered qualitative or semiquantitative. This type of reduced-complexity model is very useful for finding global steady states (called attractors) of the network, which can be, for instance, the homeostatic state or a disease state. It is obvious that ascribing only a binary status to each species does not mimic the observed behaviors of cells, tissues, or organisms. To address this limitation, a number of approaches have extended Boolean modeling, such as probabilistic approaches,[70] and the use of fuzzy logic.[71,72] Boolean modeling has found application in yeast budding,[73] oncogenic pathway regulation,[74,75] and T cell differentiation.[76] In this last publication, the authors were able to demonstrate that a minimal transcriptional control network composed of the proteins GATA-3, T-BET, Bcl6, FoxP3, and RORyt could explain the cell fate attainment and plasticity of $CD4^+$ T cells including Th0-, Th1-, Th2-, Th17-, Tfh-, Th9-, iTreg-, and Foxp3-independent T regulatory cells. The interconversion of some of these cell types and the lack of interconversion of others would be extraordinarily difficult to model with other types of mathematical formalisms.

3.20.3.2 Petri Nets

Petri nets[77] are graphical and computational representations of biological networks that, in their simplest form, represent species (formally called *places*) and reactions (formally called transitions) that can model multiple, concurrent processes (see **Fig. 3B**). Arcs (directed arrows) represent potential interactions and have specified weights.[78] This gives a visually intuitive picture that is akin to metabolic pathway maps, but with a time-dependent flow. Tokens, added to the model, represent molecules or concentrations. Thus, a given reaction (transition) fires if the concentration (number of tokens) reaches a threshold level and if there is sufficient capacity in the receiving specie. Also, molecule de novo synthesis (gain in token number) and decay (loss of token number) can be represented as transitions without input or output arcs, respectively.[79] Using petri nets, it is possible to get a dynamic picture of the system as it responds to stressors or modulators. This method has been used to model signal transduction induced by the proinflammatory cytokines, IL-1β and TNF-α[80] and the hypoxia response driven by HIF-1α.[81] In this last publication, the authors attempt to unravel the difficult hypoxia tolerance system that is activated in tumor. Petri nets were used to show the core regulatory net for this system. More importantly, they were able to identify the key node that allows for the switch-like behavior of the system.

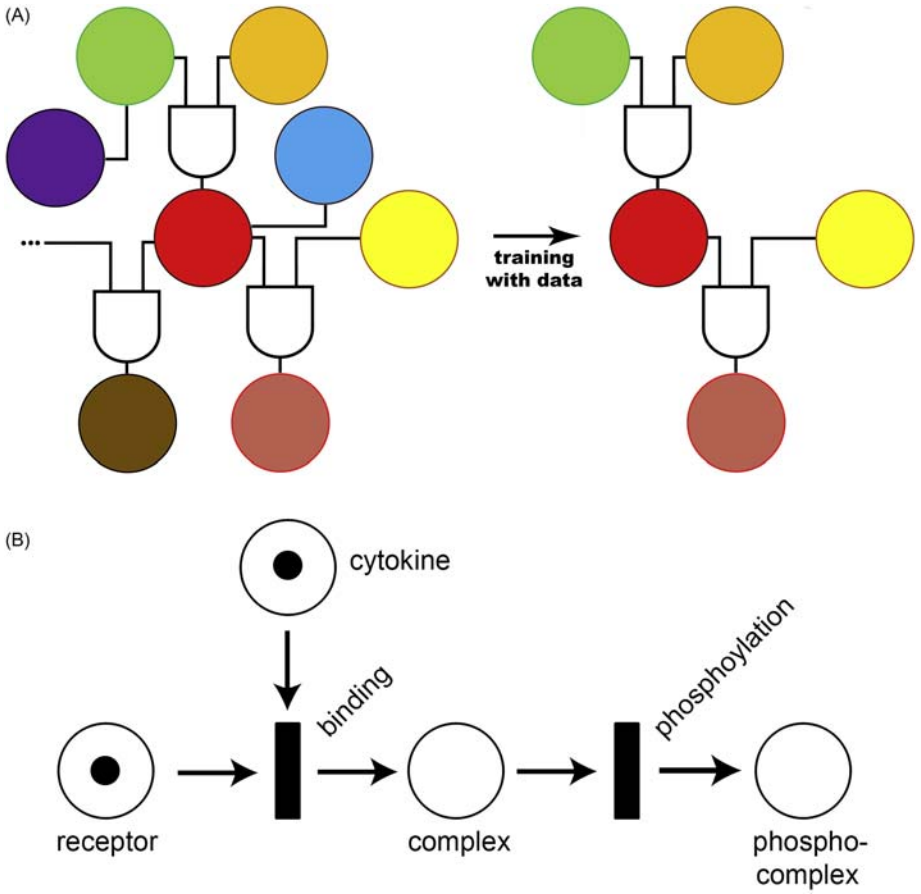

Fig. 3 (A) A simplified Boolean model. In the first step the model structure identifies entities, relationships, and connections. This structure is then trained with the biological data. For example, some stimulus is supplied to the system. The measured experimental time courses for the components (*circles*) are measured. Connections that allow the observed path outputs are given stronger weights and those that do not contribute are eliminated. (B) A simple Petri net for the binding of a cytokine and subsequent phosphorylation of the receptor. *Circles* represent species and boxes represent reactions. The *dark circle* within the circles represents tokens, which are interpreted as units of that species (number of molecules or concentrations).

3.20.3.3 Agent-Based Modeling[82]

In an agent-based model, a grid is created where each box (or cube in three-dimensional models) represents an independent entity. To make this easier to understand, let us assume that this entity is a cell. Within this cell a series of rules are established that create something like a decision tree. The rules can be complex or simple (in fact, in hybrid models the rules can be a mixture of discrete states and continuous variables). All the individual agent cells within the array are given a set of initial conditions and then apply their rules. The individual cell then "decides," based on a preordained, triggering threshold to either wait or create some output (e.g., growth or secretion of substance that is a proliferative stimulus). Within the lattice, each cell only interacts with a limited set of surrounding cells, that is, the output of a cell is not distributed to all agents in the grid, but rather only to those in the limited contact environment of the single cell. The neighboring semiautonomous cells respond to that "secreted stimuli" by applying their own set of (identical) rules. Each agent is integrating the response of their neighbors and reacting by making a state decision. Agent-based models are particularly appealing in oncology because tumor cells expand or undergo apoptosis as a response to cues from their microenvironments (oxygen levels, nutrient availability, proinflammatory cytokines, etc.) and their own internal rule set based on the somatic mutations that cause malignant aberrations (chromosomal rearrangements to place growth signals under the control of active promoters, loss of contact inhibition receptors, loss of apoptotic pathways, upregulation of secreted proteases to allow tissue infiltration, etc.). In this way, the overexpressed EGFR signaling pathway was used as a decision rule set to study neoplasm growth in nonsmall cell lung cancer[83] and brain glioblastoma.[84] Cell death, proliferation, and migration in cancer were modeled by an agent-based algorithm,[85] and the oncogenic cellular responses to DNA damaging compounds were also studied.[86] In this last publication, the authors attempt to understand the processes that underlie how tumor cells respond to chemotherapeutics and radiation therapy. At the level of single cells, the processes of repair of damaging agents are somewhat understood, and yet the tumor acts as if there are emergent properties that are not solely under the control of these mechanisms. Part of this finding is due to the cells of the tumor being asynchronous. This agent-based model used probabilistic methods to predict tumor cell survival curves due

to the population dynamics that result from the underlying DNA damage and repair processes. In other works, the study of cell cycle control in cancer, under the influence of checkpoint inhibitors, has benefited from agent-based models.[87] Agent-based models have also been used to model colonies of microorganisms, such as in the establishment of antibiotic resistant biofilms,[88] and to study Ebola virus epidemiology.[89]

3.20.3.4 Bayesian Network Models[90]

Like Petri Nets, Bayesian network analysis is a graph-based system. Unlike ordinary differential equation (ODE) modeling, which is deterministic, Bayesian network models are probabilistic. In other words, given the same set of initial conditions, ODE models will always give the same results. By contrast, given a data set, Bayesian models yield the likely probability of an ensemble of connections being found. Bayesian network models often start with large data sets, which are prone to noise. Bayesian network models look to uncover the statistical connections between a set of objects. In the case of signaling networks, the objects could be, for an example, phosphorylated proteins, activated enzymes, or genes.[91] The connections that are uncovered can be simple two object physical interactions, for example, protein A binds to protein B, or protein A and B are in a product/precursor relationship. Alternatively, the relationship could be a complex, functional, and previously unknown relationship between many objects (e.g., protein A leads to a downregulation of protein B via a transcriptional suppression mechanism). Bayesian network models not only tolerate large data sets but require sizable collections to detect subtle relationships. The model returns the conditional probability that a particular set of connections explains the data. Therefore, Bayesian network analysis allows the modeler to rank possible network topologies. Often in signaling networks, the connections are already drawn into convenient pathway structures of seemingly fixed architecture of nodes and edges (e.g., the Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway maps[92]). Bayesian network analysis can test the likelihood of the connections that are drawn into this kind of map.[93] This kind of Bayesian network analysis was used to assess the relative strengths of several different regulatory mechanisms for IL-12 in $CD4^+$ T cells.[94] Biomarkers for oral squamous cell carcinoma were identified by use of this technique.[95] Also research based on microarrays was used in a Bayesian network to identify connections between ten receptor tyrosine kinases and two sites from Src kinase.[96]

3.20.3.5 ODE and PDE Models

Ordinary differential equation modeling is, by far, the most common mathematical methodology in systems biology and QSP because this approach is powerful and versatile. Ordinary differential modeling can supply a continuous and quantitative view of the dynamics of a system. In other words, the concentration of every species in the model is tracked over the time course of the simulation. If the topology and parameters are correctly specified, then the results of the model are accurate predictions. However, this is far from easy. To build ODE models, the initial concentrations of every species in the model and the rate constants of every reaction in the model must be known. For all but the simplest of models, the parameters are usually determined by experiments or derived from literature values. The values of literature-derived parameters are often difficult to use in a model. This is because the various parameters are inconsistent with respect to the choice of cells, tissues, animal species, and variations in experimental design. Later, we will discuss how modelers address some of these concerns. When a system shows spatial heterogeneity, that is, concentrations varies in both time and position, partial differential equation models are employed. For example, to model the growth and invasion of tumors, a partial differential equation model is desirable,[97,98] or to understand the contribution of diffusion in cell signaling, PDE modeling is essential.[99]

In the context of modeling, the ordinary differential equations are simply rate expressions that reflect the formation and consumption for each species in the system. Therefore, each species in the system has a differential equation that subtracts the sum of rates that consume the species from those that form it. For example, the equilibrium interconversion of A and B:

$$\mathrm{A} \underset{k_{\mathrm{reverse}}}{\overset{k_{\mathrm{forword}}}{\rightleftharpoons}} \mathrm{B}$$

This would yield two ODE equations (one for each species).

$$\frac{d\mathrm{A}}{dt} = k_{\mathrm{reverse}}\,\mathrm{B} - k_{\mathrm{forward}}\,\mathrm{A}$$

$$\frac{d\mathrm{B}}{dt} = k_{\mathrm{forward}}\,\mathrm{A} - k_{\mathrm{reverse}}\,\mathrm{B}$$

In the case of irreversible reactions, there may be no formation terms (e.g., the first-order decay of a species) or no consumption terms (e.g., the zeroth order synthesis of a species). These equations usually follow the conventions of mass action chemical reactions. However, more complex behavior such as Michaelis–Menten kinetics (hyperbolic reactions that exhibit saturation), Hill equation behavior (sigmoidal concentration dependencies and other more complex behaviors), and inhibition of the various kinds of kinetics, observed in standard enzyme assays can be simply reformulated into mass action formats,[100] though one must be careful that the assumptions of the original equation are understood (e.g., steady-state assumptions or the requirement that substrate concentration greatly exceeds levels of enzymes). Mass action is not the only kind of rate equations that can be incorporated

into models. Since ODE modeling is similar to chemical kinetics, any physical or chemical rate can be used in the model. For example, diffusion rates into tissues and tumors are routinely modeled using Fick's law of diffusion.

When the ODE formalism is applied to multistep reactions, the same methodology is employed that was shown above for a one step "system." The summation of formation and consumption terms for particular specie may grow quite large if that specie is used as a reactant, or produced as a product, in many steps in the network, however, the procedure remains the same. When the reaction scheme is simple, as for example, the binding of a ligand to a receptor or a straightforward enzyme-catalyzed reaction, the ODE equations can be solved analytically by simple (though often tedious) algebraic manipulations. However, for most signaling networks, pathway models, or multiscale models of proteins, tissues and cells, which usually exhibit nonlinear behaviors, this kind of exact solution is not practical or possible. Under these conditions, the numerical solution of the set of ODE or PDE equations is done by discretizing the time component (and space component for PDE models). In other words, initial values for the concentrations of all the species are used to simultaneously recalculate their values at a very small time step away from time zero. The results of that calculation are then used in the next small time interval to generate the next set of concentrations, and the process is repeated. In this manner, a seemingly continuous trajectory is produced for each system species. Many ODE solvers are available to do this type of calculation. MatLab has several ODE solvers available (ode15s, ode45, etc.) and open source solvers are available on the Internet at https://sourceforge.net.

As mentioned above, as the complexity of the ODE model increases, more care must be applied to parameterizing the model. Poor estimates of initial values can cascade through the model to produce spurious outputs. However, it is likely that some uncertainty will creep into most models that are large enough to have value. This uncertainty is further exacerbated if the model contains novel proteins, for which little information has been derived. One solution to the parameterization dilemma is "big data." In theory, the measurement of the concentration of "protein X" in a wide range of settings (e.g., measuring the same protein in the same cell type in many healthy people and the same protein in the same cell type in a disease state) could produce a relevant range of values to apply to the model. Unfortunately, most big data databases are not organized in this way or use RNA expression data, which does not correlate with protein levels under many conditions.[101] High-throughput proteomics by mass spectrometry is getting much closer to being able to deliver this kind of critical data. But even that approach can be hampered by biological heterogeneity (e.g., tumor cells exhibit great heterogeneity both between patients and within a single person[102–104]). Also, this approach only focuses on the concentration of reactants, not the rate constants. A second option is to do a sensitivity analysis on the model. All values are held constant except one, which is varied over a small range and the effect on the model is calculated. The same procedure is repeated for all parameters in the system. In this way, a modeler can determine which parameters in the model are uniquely sensitive to change, and whose exact values can cause large variation in modeling outputs. Those parameters with the most influence might need further experimental verification. This method also has flaws. If parameters synergize or are not mutually orthogonal, the "vary one at a time" method may not work. Also sensitivity analysis is notoriously sensitive to initial conditions, so being grossly incorrect about some important parameter in the model, might give erroneous sensitivity analysis results. There are global sensitivity analysis approaches that sample the huge parameter space and that bypass the problems of most single parameter methods.[105,106] Validated and easy to use global sensitivity analysis will be a boon to modelers but are not generally available. Often, when a sensitivity analysis is done, a particular parameter that was hard to uncover from the literature, proves to be not sensitive. The model output may not be sensitive to this parameter and hence the precision with which it is known (within a reasonable range) does not change the results of the model. The last method to address a truly unknown value within the model is use parameter optimization. This requires an experimentally verified objective function for the system. To choose a very simple example, assume that the system under examination is the same protein A to protein B interconversion that was used above. Assume the time courses of A conversion to B and B to A are independently known. Further assume the initial concentrations of A and B are available and the forward rate constant is known, but the reverse rate constant is uncertain. Given this highly simplified example, the computer modeling software can be asked to vary the unknown rate constant until the time courses are fit. In this way, the fit rate constant can then be used in the model. In more complicated (more realistic) cases, unknown or uncertain parameters can be established by this method, but if the number of these unknowns is too high, the reliability of the model is questionable. In practice, modelers often face the problem of unknown parameters and use parameters from closely related species or protein family members to get a rough approximation for the unknown values as a starting point for further refinement.

In addition to the pathway models mentioned in the "**Definitions**" section of this paper, ODE models have shown success in many systems. To name only a few, ODE models have been used to understand gene regulatory networks,[107,108] to explore the development of autoimmunity through regulation of T_{reg} cells,[109] to unravel the complex dynamics of the immune system's response to tumors,[110] and to investigate the progression of Type 1 diabetes during β cell death.[111]

3.20.4 A Detailed Discussion of a Systems Biology and Quantitative Systems Model

In this section, the goal is to look at an example of a computational model in more detail, in order to give the reader a better understanding of the capabilities and limitations of modeling. The example is an ODE-based antibody drug conjugate (ADC) model. An ADC is a combination of an antibody, a drug payload, and a chemical linker that attaches the two other parts and has unique properties to release the toxin only when inside a cell.[112–115] ADC molecules are, currently, highly effectively employed in cancer therapy.[116–118] However not all ADC molecules are successful.[119] To aid in the design of safe and effective ADC drugs, an ordinary differential equation model of the underlying biology of these drugs, was created.[120] Probably this model best fits under the heading

of a QSP model, as it was created to predict pharmacometric parameters. No model, no matter how detailed, can hope to get right all the details of any therapeutic. The human "system" is just too complex. However, from a practical standpoint, getting a validated model to correctly predict enough detail to design more successful drugs has been achieved with this model. To be an efficacious drug, an ADC must complete a series of rather stringent steps. ADC molecules are administered as an intravenous infusion into the blood. Therefore the potential drug must first traverse the capillary wall. With most reagents of the molecular weight and shape of an antibody, crossing the endothelial cell layer that makes up the blood vessels is tissue dependent. With some notable exceptions (such as brain and eye, for example), the concentration of an antibody-based drug in the tissue is about 5–15% of the blood concentration.[121] Tumors are thought to be somewhat more leaky than normal tissue due to tortuous capillary architecture in the neoplasms.[122] Hence tumor penetration by ADC drugs should be somewhat higher than normal tissue. Aberrant growth also produces lymphatic vessels that are not correctly connected. Hence there is little or no lymphatic drainage from tumors. This results in higher retention of ADC drugs, compared to that seen in normal tissues. The model must account for these differences. After leaving the blood vessels, the ADC is in the interstitial space of the tumor, where it encounters tumor cells, which express the target of the antibody moiety of the ADC. All tissues are arranged so that no cell is more than about three cells away from a blood vessel. This is due to the need for efficient transfer of nutrients and oxygen from the blood. Tumor cells can resist hypoxia due to the upregulation of the HIF-1α system, which results in some tumor cells being more distant from the capillary wall. This biology provides a radial symmetry to the cells of the tumor that allows the model to treat the capillary as if it is a long cylinder with cells projecting out from the center. This allowed simplification of the model, and is based on previous work.[123] It also means that cells proximal to the capillary see the highest concentration of ADC, while cells distal to the capillary see less drug (see below). The ADC then binds to the tumor cell. In some cases, the ADC might be designed as an agonist of the receptor target and then it internalizes relatively rapidly. However, even in the case where the ADC does not trigger internalization, receptors on the surface of cells spontaneously internalize with a slower rate. This internalization carries the ADC reagent (and the receptor target) into a lipid bilayer enclosed endosome. The endosome is acidified by proton pumps. Depending on the composition of the chemical linker, some payloads are released during this step. In other chemical linkers, the intact ADC moves to the lysosome. In the lysosome, a number of proteases release the payload by proteolytic degradation of the antibody and linker. The payload has one of three fates if it is a mitotic toxin. It can accumulate if the cell is not in mitosis, or it can move to the nuclear machinery if the cell is in mitosis, or it can leave the cell either by diffusion or through the action of drug pumps. If the cell is in mitosis the payload binds tubulin and prevents its polymerization, which halts the synthesis of the mitotic spindles that are necessary for transit through mitosis. Freezing the cell in mitosis causes the cell to initiate a program of cell death, apoptosis. All of the preceding steps are necessary to make an effective drug, and the model was created to give a picture of the best blend of properties to achieve this goal.

The model can be thought of as being divided into a number of modules (see **Fig. 3**). One component of the model computes the diffusion of the ADC reagent out of the capillary and across the tumor cells. It determines how much of the administered dose gets to the desired tissue (the tumor), and follows the fate of the payload (either delivery of the toxin to the tumor cells or the payload that is released from the tumor back into the interstitial space) (see **Fig. 4A**). This section also keeps track of how far the ADC must penetrate the tumor since different tumors are vascularized to different extents. Another section of equations explores the parameters for binding of the antibody moiety to its target receptor, the internalization kinetics of the ADC/receptor complex, rates of processing in the endosome or lysosome, and release of the payload by cleavage of the chemical linker (**Fig. 4B**). The third module of the model follows tumor dynamics (see **Fig. 2C**). Since the payload of the ADC (in the current state of the field) is usually a mitotic toxin. The payload will only act to kill the tumor if a neoplasm cell is in mitosis, and if the internal concentration of the payload exceeds a threshold level (the maximum tolerated dose, MTD). Thus the model must also track the proportion of cells that are in mitosis at any time point and decide if the internal cellular concentration is in excess of the MTD. The model then eliminates those cells that meet these criteria. Finally, this module of the model follows the tumor doubling rate, since the drug is only effective if the tumor is killed faster than it grows.

A number of the predictions of the model have been verified by experimental results. For example, the model predicts that, if the affinity of the antibody portion of the molecule for its target is too high, the drug will be trapped by the first cell of the tumor that is proximal to the tumor capillaries (especially if the tumor target is expressed at high levels), and will hence not diffuse effectively and will not markedly reduce the tumor mass. However, too weak of an interaction between ADC and target also limits utility. This has been verified by experiments.[124] Antibody moiety affinity is an important ADC consideration. Many ADC candidates are created by taking a preexisting antibody and coupling it to the payload. Preexisting antibodies are often those that have shown efficacy as drugs by themselves. These antibodies often exhibit high affinities. From the discussion above, it should be clear that high-affinity antibodies (especially those directed against high abundance targets) may not be optimal. The model predicts an optimal affinity for the antibody or suggests ways in which the drug can be adapted to compensate for binding that is too tight. The model shows that there is a delicate balance between several design properties of ADC reagents in addition to affinity. For example, molecular weight (and shape) of the reagent must be large enough to avoid rapid clearance by the kidneys, but not be so large that penetration of the capillary wall and tumor diffusion is unlikely. Antibody-based reagents have long half-lives because there is FcRn recycling, which is mediated by the Fc region of the immunoglobin. Molecules of less than about 50,000 Da molecular weight are cleared by the kidney (if they do not bind to larger molecules). Therefore, making hybrids of small and large molecules gives superior PK compared to small molecule drugs, but making ADC based on smaller parts of the IgG molecule can have some advantages.[125] There are further balances between tumor properties and ADC characteristics addressed by the model. Lower tumor intercapillary distances leads to rapid transport of the ADC, however, highly vascularized tumors (e.g., head and neck squamous cell carcinomas) tend to double at an accelerated rate versus tumors with poor vascularization (e.g., pancreatic ductal cancers). Another critical balance derives from

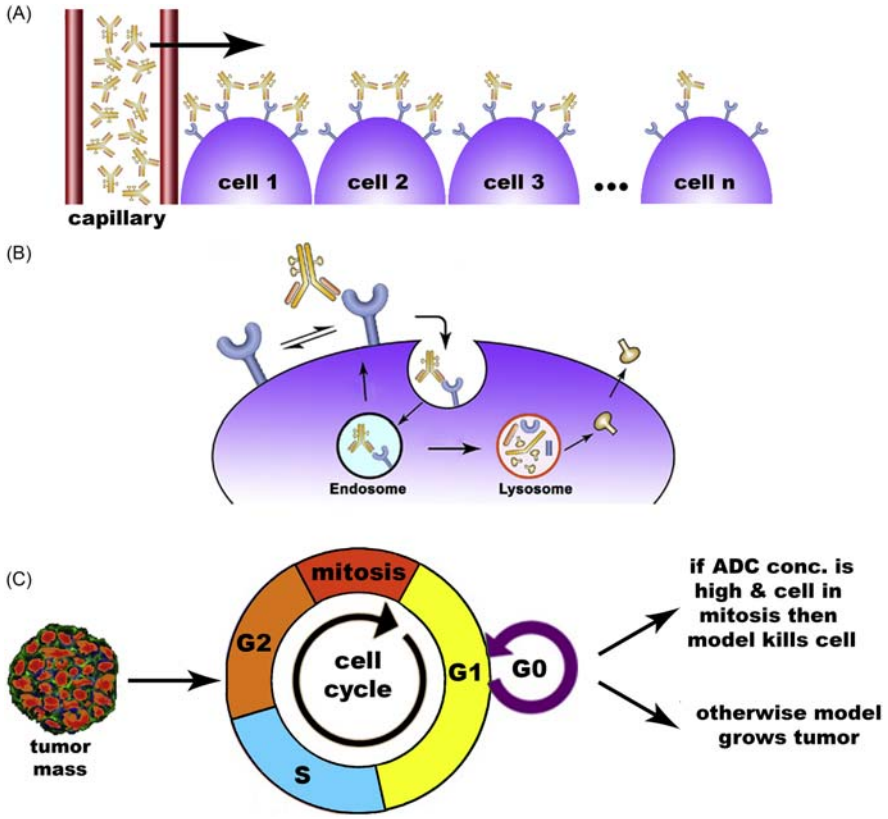

Fig. 4 A representation of the three conceptual modules in the antibody drug conjugate example. (A) The distribution of the ADC from the blood into the tumor. Because of the sink caused by the most capillary-proximal cells, a gradient of concentration is generated. (B) The kinetics of ADC binding, internalization, release of payload, and distribution of the toxin. (C) The module that keeps track of tumor dynamics, killing, and/or growth.

the loss of cleaved payload from the cell. On the one hand, this lowers the effective internal concentration of the drug, but it also promotes "bystander killing"[126] and increased tumor penetration. In theory, the model can be parameterized with tumor variables and, separately, with healthy tissue characteristics. This, in principle, allows for the generation of an in silico therapeutic index, though this avenue has not yet been extensively explored. Properly applied, this model allows the pharmaceutical drug designer a way to objectively choose ADC properties that best match with the tumor characteristics. The model can reduce the number of design/test/redesign cycles that are necessary to create an ADC candidate. Hopefully, this example demonstrates that ODE modeling can easily accommodate most kinds of problems that occur in deterministic models. Instead of only handling sequential steps associated with pathway modeling, this model allows the incorporation of the treatment of many biological processes—diffusion, cell cycle monitoring, and tumor dynamics, as well as binding and internalization kinetics.

3.20.5 Summary

This article has given the reader a beginner's guide to understanding systems approaches to biology and pharmaceutical discovery. Systems biology or QSP (or any of the other, myriad names this work is called) is at an important point in its development. The concomitant evolution of mass sequencing and even more massive biological data collection set out to give a complete components list of human biology, but has often left scientists to drown in vast information overload. Reductionism has been left behind for the very practical reason that there is just too much to study "one at a time." There seem to be more contradictions than grand unifiers of biological knowledge. This is where systems biology will play a crucial role. The need to quickly examine new hypotheses about the nature of biological processes and to suggest the most impactful experiments to test them is fertile ground for the growth of systems biology. The closely related field of QSP applies the same toolbox to finding new drugs and describing the optimal properties of those drugs to achieve the best chance for successful amelioration of disease. Systems biology or QSP are an amalgam of biology, chemistry, physics, and computer sciences. The English biochemist Fredrick Gowland Hopkins said "…where sciences meet, there growth occurs." The adoption of systems approaches in the pharmaceuticals industry is slow. Drug discoverers have been very successful without systems biology and systems pharmacology. Why change? The main driver of the growth in systems approaches

is the realization that biology is complex—patients vary in response to drugs; the same pathways giving rise to one output in one cell type gives a completely different outcome in another; arrangements of signaling networks are subverted by disease; and heterogeneity in toxicology is difficult to understand. Aristotle wrote, "The chief forms of beauty are order and symmetry and definiteness which the mathematical sciences demonstrate in a special degree." But maybe Aristotle was not a systems thinker because biology is messy and systems studies thrive on complexity.

PREFACE

Previous editions of *Comprehensive Medicinal Chemistry*, published in 1990 and 2006, provided an integrated reference source that encompassed all major aspects of drug discovery research. The third edition follows this tradition and considerably expands its scope and content.

The trailblazing scientific discoveries of the 21st century have brought new opportunities for drug discovery research. The discipline of medicinal chemistry continues to evolve as it adapts to these new opportunities and strives to solve new challenges. Covered in the new edition are not only the breakthrough therapies of the past decade in cancer, hepatitis C, heart failure, dyslipidemia, cystic fibrosis, multiple sclerosis, HIV, etc., but also extensive discussion of new business models in drug discovery research, shifting industry demographics, emerging technologies, *in silico* drug discovery tools, experimental ADME and toxicology, and biologics medicine. The tone of this edition is prospective in which contributors identify outstanding issues and paths forward in their area of expertise. The aim is to provide drug discovery scientists in industry, government, academia, and research organizations with a contemporary global perspective on the field that includes a look ahead in selected areas.

The eight individual volumes fulfill these objectives and include extensive discussion of biomolecular therapeutics, drug targeting and delivery, development of chemical biology tools, data collection and analysis, *in silico* models as predictors for biological properties, identification/validation of new targets, approaches to quantify target engagement, new methods for synthesis of drug candidates such as green chemistry, development of novel scaffolds for drug discovery, and the role of regulatory agencies in drug discovery.

The individual volume editors have done an outstanding job to identify topics and contributors to meet these goals and we thank them for their hardwork and diligence. In volume 1, Ana Martinez and Carmen Gil recruited an international group of contributors who provide chapters on the emerging role of organizations other than traditional pharmaceutical companies in drug discovery, the evolving science of chemical biology, and new organic chemistry contributions to the discipline. In volume 2, Helmut Buschmann, Norbert Handler, and Andrea Wolkerstorfer have accomplished a seemingly impossible task and attracted world-leading experts across the wide field of drug discovery enabling technologies, covering contemporary thinking in a wide range of key disciplines that enable modern medicinal chemistry and drug discovery and development. The computational enabling technologies are the focus of volume 3, in which Andy Davis and Colin Edge have assembled chapters covering both ligand-based and protein structure–based advances as well as exciting new methodologies and case studies exploiting these. Alan Wilson identified experts in the fields of pharmacokinetics and toxicology who describe a wide range of contemporary advances in prediction and analysis of pharmaceutical properties and drug safety in volume 4. In volume 5, Ian Collins, Louis Lombardo, and Will Watkins have assembled leading experts to discuss high impact drug discovery accomplishments over the past decade in cancer chemotherapeutics, immunology and inflammation, and infectious diseases therapeutic areas. Ved Srivastava edited volume 6 on biologic medicines, a significant and rapidly evolving area where medicinal chemistry plays an important role. The chapters in this volume provide timely information on not only protein-based drugs, such as monoclonal antibodies and therapeutic proteins, but also peptides and nucleic acid–based therapeutics. Volume 7, edited by Adrian Hall, Santhosh Neelamkavil, and Rob Jones, presents a detailed account of the major advances in CNS, metabolic, and cardiovascular fields over the past decade and the promising new opportunities. Joerg Holenz edited volume 8 that presents case histories of successful drug discovery and strategic differentiation that have resulted in commercialized drugs and candidates in advanced clinical trials.

We are truly grateful to the publishing team at Elsevier that includes Gemma Tomalin, Rachel Gerlis, Marise Willis, and Sean Simms for their assistance and support throughout the process. With their expertise, this project became what we believe is a noteworthy and valuable resource for the discipline of medicinal chemistry. We look forward to the response and feedback of our colleagues who will use this information in their own work.

Samuel Chackalamannil, David P. Rotella, and Simon E. Ward

EDITORS-IN-CHIEF: BIOGRAPHIES

Dr. Samuel Chackalamannil

Dr. Chackalamannil obtained his PhD in chemistry from Yale University in 1984 and subsequently worked in drug discovery research at Schering-Plough Corporation and Merck Research Laboratories, where he was a distinguished fellow when he left in 2011. Since then, he has been teaching at Ernest Mario School of Pharmacy, Rutgers University, New Jersey.

Dr. Chackalamannil has significant accomplishments in the discovery of new medicines. He led the discovery of vorapaxar (Zontivity®), an FDA-approved antiplatelet drug for the prevention of heart attack and stroke. His group also discovered a PDE-5 inhibitor clinical candidate dasantafil and an adenosine A2a antagonist clinical candidate for the treatment of Parkinson's disease. Altogether, he was responsible for the discovery of nine development candidates in cardiovascular, central nervous system, and metabolic disease areas.

Dr. Chackalamannil is a coinventor of 62 allowed US patents and numerous patent applications worldwide. He has published 81 peer-reviewed articles and has coauthored a book. He has also given numerous lectures at international meetings and academic institutions.

Dr. Chackalamannil is a two-time recipient of the Thomas Alva Edison Award for Emerging Technology Patent and a two-time recipient of the Presidential Award for Discovery at Schering-Plough Research Institute. He has chaired several sessions at American Chemical Society national meetings and Gordon Research Conference on Medicinal Chemistry and was an organizer for Chemistry as a Life Science Symposium.

Dr. David Rotella

Dr. Rotella earned a PhD in medicinal chemistry from The Ohio State University and carried out postdoctoral research in organic chemistry at Penn State University. He joined the faculty at Montclair State University in July 2011 as the Margaret and Herman Sokol Professor of medicinal chemistry after a successful career in the pharmaceutical industry. He is an expert in the discovery and optimization of small molecule drug candidates for use in metabolic, cardiovascular, cancer, and central nervous system diseases. His current research is focused on discovering new lead compounds for use in parasitic and central nervous system diseases. He has coedited the seventh edition of *Burger's Medicinal Chemistry* and is a senior editor for the Royal Society of Chemistry's Drug Discovery book series. He has authored over 40 peer-reviewed articles, is an inventor on 8 issued US patents, and has contributed 10 book chapters.

Simon E. Ward

Simon Ward has an MA in natural sciences and PhD in synthetic organic chemistry from Cambridge University, UK. He has a wide-ranging experience of drug discovery in both large and small companies (GlaxoSmithKline, Knoll Pharmaceuticals, Vernalis, Chiroscience, BioCrea) and specialist experience of discovering and developing drugs for central nervous system indications. He has led multidisciplinary project teams and medicinal chemistry groups from target identification through to early clinical studies, delivering multiple clinical development candidates across indications. He is a fellow of the Royal Society of Chemistry. He is currently a professor of medicinal chemistry at the University of Sussex, UK, and the director of the Sussex Drug Discovery Centre, which he established within the University of Sussex in 2010.

4.01.1 Introduction

4.01.1.1 The Meaning of ADME/PK

It is well understood by now that for a clinical drug to produce the desired therapeutic benefit, the agent must be bioavailable by a suitable dosing route, distribute to the proper physiological compartment at concentrations sufficient to interact with the target receptor, maintain these concentrations long enough to modulate the target biological pathway, operate within an adequate safety margin, and be eliminated within a period short enough that unexpected adverse effects do not persist for a long time. Each of these

criteria is partially or fully controlled by the ADME/PK (absorption, distribution, metabolism, and excretion and pharmacokinetic) properties of the drug. To be sure, a successful drug must also have suitable properties of other sorts, such as solubility, chemical stability, receptor potency and selectivity, and synthetic accessibility. However, this article will focus on ADME/PK. Let us briefly elaborate the ways in which ADME/PK properties underlie these five aspects of the clinical performance of a drug candidate.

4.01.1.2 Bioavailability

This term refers to the efficiency of the intended dosing route (e.g., oral, intravenous, subcutaneous, and topical) to deliver into the body an external dose of the drug sufficient to have good clinical effect. It is typically measured as the ratio of the amount of drug reaching the systemic circulation to the administered amount, expressed as a percentage. Since the body presents various types of barriers to actively resist uptake of xenobiotic chemicals, especially by the oral route, bioavailability can range from 0% to 100%. Obviously, very low bioavailability will necessitate a very large, possibly unfeasible, administered dose to achieve an adequate absorbed dose. In addition, even if low bioavailability can be overcome by administration of a massive dose, one still has issues of large body burden of drug-related material (absorbed and unabsorbed parent drug and metabolites) and high cost of goods entailed by the requirement to administer an excessive dose in order to deliver only a small fraction of that dose. Thus, an important goal of a discovery and development program is to design a molecule that achieves acceptable bioavailability.

4.01.1.3 Distribution

Drugs enter the blood either by direct infusion by intravascular administration or by passive or active diffusion through membrane barriers, for instance, the membrane of the gut luminal wall, lung alveoli for an inhaled drug, or skin for a topical drug. Once in the blood, drug molecules circulate around the body and have the opportunity to diffuse from the blood into all organs. This is a good thing for the majority of drugs whose biological targets are outside of the blood compartment. However, distribution also allows the drug to enter compartments that are not relevant to the indicated disease condition, so that those tissues are exposed to the drug without the possibility of local therapeutic but with the possibility of off-target toxicity. Thus, it is desirable that a drug be preferentially distributed to target organs such as the brain for central nervous system (CNS) drugs and tumor for cancer drugs at concentrations sufficient to interact with the target receptor while distributed as little as possible to other compartments. In human subjects, extravascular distribution is only measurable by invasive techniques such as biopsy or, in some cases, by scanning techniques such as magnetic resonance imaging (MRI) and positron emission tomography (PET). Thus, most information about distribution of a drug is derived from animal studies.

4.01.1.4 Persistence

Just as mechanisms exist to limit the introduction of xenobiotics into the body, related mechanisms exist to eliminate those molecules that successfully enter. This elimination process is called clearance, and this term encompasses all mechanisms by which the drug can be eliminated from the blood, including metabolism and direct biliary and renal excretion. Therapeutic effect depends on concentrations in the local target compartment persisting long enough to modulate the target biological pathway. With most drugs, we strive to reach a PK steady state in which the local concentrations at the target receptor stay above the minimum therapeutic concentration for an entire dosing cycle but below the corresponding minimum toxic concentration. This steady state represents a balance between the rate at which molecules are cleared from the blood and the rate at which new molecules are introduced into the blood by successive doses. Up to a point, it is beneficial for a molecule to have low clearance (i.e., long persistence), so that dosing frequency can be made convenient, such as once per day. However, a drug whose clearance is too low may persist too long. A physician who encounters a patient exhibiting an adverse reaction to a drug desires to be able to stop dosing and expect the patient to improve in a day or so. Consequently, a desirable clinical characteristic in a drug is that once dosing stops, blood levels of the drug will drop significantly in a reasonable time. Thus, a good clinical drug has persistence that is not too short and not too long, although there are numerous exceptions to this rule depending on the nature of the therapeutic indication. Persistence is measured by serial sampling of blood followed by specific assay for the drug and reconstruction of the blood concentration–time curve. Persistence is usually quantified by the PK parameters' half-life and mean residence time (*MRT*).

4.01.1.5 Excretion

This term refers to the complete elimination of the mass of the drug and/or its metabolites from the body. It is distinguished from the term clearance, which specifically describes the process of elimination of the parent drug from tissues and blood. However, this clearance process may have merely converted the parent drug to a metabolite sharing many structural, pharmacological, and toxicological features with the parent. Only when the parent and the metabolites have been totally removed from the body has the possibility of continued pharmacological and/or toxicological effect been abolished. Excretion occurs when the drug mass (parent drug and metabolites) has been delivered to the urine and/or feces. The chemical form in which the mass is found in the excreta provides information about the clearance pathway. For instance, recovery of most of the dose as unchanged drug in urine (as happens with a number of antibiotics) informs us that renal elimination (by glomerular filtration and active transport from renal tubules) is the major route of clearance. Conversely, recovery of most of the mass of the dose as metabolites in excreta informs us

that one or more processes of metabolism of the parent drug were the major routes of clearance. Measurement of the rate of excretion may alert us that a long-lived metabolite is still in the body even though PK clearance of the parent drug from the blood is complete.

4.01.1.6 Safety Margin

Drug candidates invariably have some level of toxicity at a high enough dose, and their safety profile must be determined from a series of preclinical safety studies in animals followed by rising-dose safety and tolerance studies in humans. Although an occasional drug candidate has such a low level of toxicity that it is essentially not clinically relevant, the majority of drugs have a threshold for some type of adverse event that is at least *accessible* by clinically deliverable doses. Thus, in most cases, we can define an optimal range of blood concentrations that extend from the lowest concentration that gives clinically meaningful efficacy to the highest concentration that does not produce a dose-limiting toxicity. This concentration range would be considered the safety margin, which is usually expressed as the ratio of the corresponding administered doses (e.g., a 10-fold safety margin between the minimally effective dose and the lowest toxic dose). Most safety issues probably arise from the parent drug itself, but because the subject of this article is ADME/PK, we will only discuss issues resulting from toxic metabolites or metabolism-based drug–drug interactions (DDIs) resulting in magnified toxicity of either the drug candidate or a coadministered drug.

4.01.1.7 The Goal of the Medicinal Chemist

The medicinal chemist, in addition to designing molecules that strongly and selectively engage the target receptor, must also engineer a clinical candidate to have these ADME/PK and safety properties. How can the chemist determine that the effort has succeeded in the selected new drug candidate? This question encompasses the two main roles of ADME in drug discovery and development, and the organization of this article will separately examine each. Because the involvement of the medicinal chemist is mainly in the discovery phase of new drug candidates, the majority of attention in this article will be devoted to that phase. For the same reason, we will only discuss the ADME/PK properties of small-molecule drugs, although protein drugs have a corresponding set of ADME/PK properties to be studied.[1]

4.01.2 The Importance of ADME/PK in Drug Discovery

4.01.2.1 The Continuing Need for ADME/PK During Drug Discovery

Despite decades of intense effort, the attrition of drug candidates entering clinical trials remains high. The analyses of Kola and Landis,[2] Hay et al.[3] 10 years later, and Waring et al.[4] 11 years later show that the overall success rate of phase 1 entries to New Drug Application (NDA) approvals stubbornly remains at only about 1 in 10. The leading causes of failure are safety (51%, including both preclinical and clinical), efficacy (9%), and business reasons (21%).[4] In fairness to the industry, it must be noted that the bar for success has been steadily rising. Regulatory requirements continually increase, especially in the area of safety, and marketed drugs continually get better, making clinical trials based on superiority or even noninferiority of efficacy ever more difficult for next-generation candidates that must be compared with current "standard of care." Nonetheless, safety is clearly where the most progress is required.

On the other hand, the failure rate attributable to "bioavailability and pharmacokinetics" remains low at about 4–5%.[4] ADME/PK-related failures dropped from about 40% in 1991 to 10% by 2000,[2] reflective of the effort most drug discovery research institutions applied in the decade of the 1990s to detect and design out ADME/PK deficiencies. A further reduction from 10% to 5% occurred from 2000 to 2005, and the failure rate had plateaued at 4% by 2010,[4] a rate so low that further reduction of the rate of failure due to ADME/PK would probably not be meaningful.

Does the low rate of ADME/PK-related failure mean that the issue no longer requires the attention of the medicinal chemists in designing their drug candidates? No. The specter of poor ADME/PK has not gone away, and chemists who ignore ADME/PK will quickly find problems popping up again in this area. Chemists must continue to be vigilant in building in desirable characteristics from the beginning. However, the good news is that the continued success of efforts to produce clinical drug candidates with "drug-like" ADME/PK properties constitutes validation of the methods by which these properties are measured and extrapolated from preclinical in vitro and animal studies to humans. However, this statement does not mean that improvement of the process of ADME/PK support of discovery is impossible. One author has drawn attention to the need for better in vitro systems for testing drug candidates,[5] especially in the area of liver surrogates, a point where progress is already being made (see section "**Addressing high first-pass clearance**").

Another point worth noting is that just as with potency and efficacy, the average ADME/PK performance of new drugs continues to improve. The fact that drugs seldom fail for ADME/PK reasons merely means that the ADME/PK properties of new drug candidates are good enough not to be the cause of failure. Most new drug candidates have at least one, and often more than one, ADME/PK property that could be better. In fact, ADME/PK can be the source of major improvements in the clinical effectiveness of new drugs compared with predecessors that had "adequate" ADME/PK properties. One thinks of second-generation compounds with greater oral bioavailability so that lower doses are needed or with longer half-lives so that dosing frequency is reduced from three times a day (TID) to once a day (QD). But achieving these improvements requires more than

merely adhering to "rules" based on physical properties that describe "drug-like" compounds.[6] A fundamental understanding is necessary of the physiological processes with which drug candidates interact to exhibit their drug-like behavior. Imparting this understanding is a goal of this article.

4.01.2.2 What Happens During Drug Discovery?

To provide context for discussing the role of ADME/PK in drug discovery, let us consider the totality of what must be accomplished to nominate a new chemical entity for clinical development. A number of biological, chemical, and physical considerations are involved in the design, testing, and selection of clinical drug candidates.

4.01.2.2.1 Biology

4.01.2.2.1.1 Pharmacology

Innovations in therapy typically involve the discovery of new physiological targets, such as new enzymes or receptors, or the recognition of a regulatory relationship between biochemical pathways. The possibilities for modulation of these targets to affect a pathological condition are considered, and a specific molecular target is chosen for further investigation. Initial experiments often involve biological rather than chemical modulation, such as gene knockout or upregulation, to observe the effect in a disease model such as a cell line or a mouse. If the biological modulation gives positive results, then the decision is made to see if the target is "druggable" by finding a small-molecule ligand for the molecular target, often by high-throughput screening of libraries or collections of compounds. A chemical compound that shows a nontrivial level of binding to the receptor (e.g., $IC_{50} < 10\ \mu M$) would be considered a "hit" and would justify the dedication of medicinal chemistry resources to attempt to find novel synthetic analogs of the "hit" that show much tighter binding.

As the "hit-to-lead" phase of the discovery program proceeds, chemists will explore a variety of compound types corresponding to the most active of the "hits" that came out of screening, while pharmacologists will develop more holistic in vitro and in vivo disease models to enable the therapeutic concept to be tested with the "actives" coming out of the chemistry program. Eventually, a successful program will find compounds with binding activity sufficient to be classified as a "lead," and the program will focus on the most active of these to initiate a full exploration of the structure–activity relationship (SAR) for these chemotypes (i.e., "lead optimization"). Pharmacology has the task of creating even more sophisticated models to continue to investigate the biological events attending the modulation of the molecular target to understand whether the cell biology is actually responding in the way envisioned in the original pharmacological intervention concept.

4.01.2.2.1.2 Toxicology

The term "toxicology" will be used in a broad sense to indicate undesirable biological effects of the chemical compounds being tested as therapeutic agents, whether in the early-phase discovery period or full clinical development. In early discovery, candidates with levels of pharmacological activity exceeding a certain threshold will be tested in follow-up assays for binding to related enzymes or receptors, which often exist in multimembered families of closely related gene products. These are relatively easy to test with in vitro assays similar to those used for the target receptor. Ideally, the program will produce a compound that binds tightly to the exact target receptor and not at all to closely related receptors of the same family, which, however, control different physiological events.

At some point in the "lead optimization" process, the program will need to start investigating binding to receptors *not* closely related to the target receptor by submitting the most active candidate to a broad receptor-binding panel. This will reveal unanticipated "activities" that do not contribute to the desired therapeutic action but have the potential to produce adverse actions, if not outright toxicity. Ideally, no binding to unrelated receptors is discovered and the compound is "clean." More likely, however, some level of binding to an unrelated receptor is seen, and this binding must be monitored in subsequent analogs and possibly actively designed out. Another way to investigate "off-target" activities of a lead series is the use of in vitro cell-based toxicology screens, which have the advantage of looking at a living biological system without assumptions about which receptors may be engaged by the candidates. As with receptor-binding panels, detection of adverse activities with this approach requires monitoring and possibly active remediation.

4.01.2.2.2 Chemistry

4.01.2.2.2.1 Exploration of chemical space

During the hit-to-lead phase of discovery, chemists are often aware of the general ADME/PK properties of their early compounds, but these do not figure prominently in their design campaign. Once several chemical series are identified as leads, the lead optimization phase begins. The primary objective during lead optimization is to improve potency and receptor selectivity, but monitoring the ADME/PK profiles of the chemical series that they seek to optimize becomes a secondary goal. Although modeling strategies may be employed to guide the search for activity within the chemical space afforded by the chosen leads, the major approach is almost always the synthesis of many analogs of the lead series for direct assay of activity toward the target and off-target receptors.

Contemporary synthetic methods are so powerful that medicinal chemists seldom have to omit potential compounds from their list of design candidates simply because they are synthetically inaccessible. On the other hand, it is true that features such as short, convergent synthetic pathways; suitability to apply well-behaved, high-yield synthetic reactions; lack of complicating structural features such as stereoisomers; and probable ease of scalability from gram level to kilogram level to metric ton level enhance the

attractiveness of some compound series. But as a general rule during lead optimization, experienced medicinal chemists typically can freely pursue the exploration of whatever properties they seek to improve (e.g., activity, selectivity, solubility, and ADME/PK) without crippling synthetic limitations. In fact, we can say that this ready accessibility of a large number of active compounds *enables* the optimization of ADME/PK and pharmaceutical properties. As a practical matter, then, medicinal chemists are frequently able to define a certain core pharmacophore that can be modified in pharmacologically tolerant noncore parts of the molecular series to achieve a single molecule with an excellent balance of activity, selectivity, pharmaceutics, and ADME/PK.

4.01.2.2.2.2 Optimization of ADME/PK

ADME/PK depends almost completely on the chemical and physical properties of single molecules. This is because the biological systems with which drug molecules interact, such as drug-metabolizing cytochrome P450 (CYP) enzymes or membrane drug transporters, work on one molecule at a time. In fact, then, ADME/PK properties are often attributable to chemical features of the molecule that chemists intuitively understand. Of course, the interaction is not entirely a matter of the chemistry of the small molecule, since in almost all cases there is a large biological structure (i.e., a protein, polynucleotide, or membrane) that constitutes the second partner in the interaction. Thus, the interaction, while still chemical in nature, is complex and usually only approximately understood. Consequently, consideration of the chemical properties alone of the molecule (e.g., functional groups, chemical reactivities, and polarity) is insufficient to completely predict the interaction, and empirical methods are still necessary to assess these interactions. For example, one can look at the structure of a drug candidate and make note of the susceptibility of various portions of the molecule to biotransformation by oxidation, conjugation, or hydrolytic enzymes, but one cannot tell in a reliable way which pathway will be predominant or what absolute rate of metabolism will be observed. Thus, since the science is not yet advanced enough to provide fully dependable values of ADME/PK properties based on molecular properties alone, we still need to experimentally interrogate various in vitro and in vivo systems with the molecule of interest to get a trustworthy answer that can be used for selection decisions. Case histories have been published illustrating application of ADME/PK optimization to discovery and preclinical development.[7,8]

4.01.2.2.2.3 Optimization of pharmaceutics

In contrast to ADME/PK, pharmaceutics depends largely on bulk properties of the chemical compound. Examples of such biopharmaceutical properties are solubility, membrane permeability, wettability, rate of dissolution, hygroscopicity, storage stability, crystallinity, and crystal morphology. In practice, chemists don't worry too much about the pharmaceutics. With the exception of permeability, pharmaceutical properties tend not to be extremely critical to the ultimate success of a candidate molecule, and less-than-optimal characteristics can often be remedied with salt forms, amorphous preparations, and formulation excipients. Thus, for example, while chemists are aware of the desirability of good solubility, it is unusual to see an otherwise promising clinical candidate be discarded because solubility is poor. However, solubility can become a differentiating feature when multiple good compounds exist.

4.01.2.3 Major ADME/PK Characteristics to Optimize

4.01.2.3.1 "Right Box" analysis

Discovery lead optimization is the only chance that medicinal chemists have to build in desirable ADME/PK characteristics. During this phase, the structure is continually altered to optimize and balance activity, selectivity, toxicity, ADME/PK, and pharmaceutics. However, once a clinical candidate is nominated, all freedom of structural modification is frozen out. In particular, the ADME/PK properties are fixed. Therefore, it is important to be able to reasonably project the range into which each important PK parameter (e.g., oral bioavailability, half-life, and brain penetration) will fall in humans, well before there is any clinical experience with the compound, and only in vitro and animal in vivo data are available. It is usually not necessary to be able to predict the human value of each parameter exactly; it is only necessary to be able to say with confidence that the parameter will fall into the acceptable range. For instance, one can say that a successful oral drug should be at least 20% bioavailable. Therefore, it doesn't matter strongly if we predict 80% bioavailability, whereas the true value in the clinic turns out to be 40%. The drug would still be acceptable for oral use, although we obviously would prefer to have 80% compared with 40%. This tolerance of moderate error is true for essentially all ADME/PK properties and allows us to use "Right Box" analysis.[9] We have only to successfully project the compound's ADME/PK properties into the "right" box: poor, moderate, or good. With these considerations in mind, let us discuss the various ADME/PK properties that are necessary for a successful clinical drug and how we estimate them.

4.01.2.3.2 Oral absorption and bioavailability

4.01.2.3.2.1 In vivo determination of oral bioavailability

It is common practice at the beginning of a discovery program to characterize the pharmacokinetics of one or more of the "hit" compounds. This is merely to establish the general characteristics of the compound to help define the ADME/PK properties that present the biggest need for improvement. Mice or rats are used for a full intravascular (IV)/ per oral (PO) PK study, which reveals the fundamental PK parameters, such as oral bioavailability, systemic clearance, *MRT*, and terminal elimination half-life. Oral bioavailability (F) may be defined as the fraction of an orally administered dose that reaches the systemic blood circulation, where it becomes available (bioavailable) to the organs and tissues. Experimentally, oral bioavailability is determined from the ratio of the

area under curve (*AUC*) for the plasma concentration versus time curve for the PO and IV doses as shown in Eq. (1) (adjusted for the ratio of PO and IV doses):

$$F(\%) = \frac{AUC_{\text{PO}}}{AUC_{\text{IV}}} \times \frac{Dose_{\text{IV}}}{Dose_{\text{PO}}} \times 100\% \tag{1}$$

The discovered PK deficiencies, if any, define the types of in vitro ADME/PK assays that are incorporated into the screening funnel for the "hit-to-lead" process. When a certain predefined level of potency against the target receptor is achieved, the program identifies one or more lead series to advance to the "lead optimization" phase, and a full IV/PO study in mice or rats is conducted on each of these to establish again the PK baseline of each series. It is common for the screening funnel to change in lead optimization from the sequence of assays that were used in the hit-to-lead phase. At various points in the lead optimization process, full IV/PO PK is done yet again to provide unambiguous information about the in vivo performance of the compounds. And, as before, the PK deficiencies inform the team about which in vitro screens are to be retained or added in the screening funnel.

We occasionally need to conduct in vivo PK because in vitro assays have a level of uncertainty of interpretation and prediction that limits how precisely the assay results can be used to screen out bad compounds.[10,11] It is necessary to do some checking from time to time that apparent progress made in improving the in vitro PK parameters actually has translated to real in vivo performance. However, it is obvious that conventional full IV/PO PK studies take too long to be useful for screening compounds in a fast-moving lead optimization campaign. These studies take days to mount and carry out, because, among other reasons, one cannot determine that a drug candidate has a 12-h half-life in only an hour. In addition, a full IV/PO study requires a nontrivial amount of compound for dosing, an amount that typically exceeds the few milligrams that may have been prepared in the initial synthesis. The dilemma is that the in vitro assays give data on lots of compounds fast, but the data are not easy to interpret, while in vivo PK studies give full and easy-to-interpret data on a very few compounds, with significant compound and time requirements. For this reason, a number of discovery organizations have introduced various intermediate PK approaches to bridge the gap between purely in vitro surrogate PK assays and full in vivo PK.[11]

Cassette dosing (CD) involves dosing a number of compounds to a single animal to minimize the average time for results to be available and the number of animals to be used. Blood samples are taken at the appropriate times after PO or IV dosing and simultaneously analyzed for all dosed compounds, taking advantage of the capability of mass spectrometers to monitor the unique molecular weights (MWs) associated with each compound in a complex mixture. White and Manitpisitkul[9,12] provided a theoretical PK analysis of CD that prescribed the conditions under which the data would be relatively free of the inevitable DDIs that accompany dosing with multiple compounds at the same time. The rapid rat assay[13] was introduced as a compromise approach featuring single-compound dosing but other compensating accelerations to provide very rapid in vivo PK data, and rapid rat has been very successful.[14] A closely related method, snapshot PK, similarly provides a very quick but useful picture of the in vivo PK.[11] A third variation, the rapid PK approach, provides more PK information than rapid rat or snapshot PK, but results still come faster than with conventional full PK.[11] The combination of all these methods makes possible frequent "reality checks" on what the in vitro ADME/PK assays indicate, and most organizations use some combination of these in vitro and in vivo PK methods to drive the PK optimization in a time frame compatible with the rate of production of pharmacologically interesting analogs.

Once the PK deficiencies of the best lead compounds have been identified, chemists seek to improve these properties by making intelligent structural modifications to the chemotypes while maintaining (and even improving) the pharmacological properties of potency and selectivity according to the SAR, which has been discerned in the lead optimization process. First, let us examine the case in which in vivo testing has revealed that oral bioavailability is poor and needs to be brought at least into the acceptable range in order to nominate a clinical candidate. Let us consider how the chemist can approach the problem of low bioavailability in a systematic way. In subsequent sections, we will look at the corresponding problems of half-life and distribution.

4.01.2.3.2.2 Determinants of bioavailability

Good oral bioavailability depends on a compound being able to solubilize in the GI tract (or remain soluble if dosed as a solution), survive degradative enzymes in the intestinal lumen, diffuse through the intestinal wall, survive metabolism by enzymes in the intestinal wall, not be excreted into bile, and survive metabolism by hepatic enzymes during passage through the liver on its way to the systemic blood. We can summarize this concept symbolically with the simple equation in the succeeding text:

$$\text{Fraction of oral bioavailability } (F) = (1 - f_{\text{ld}}) \times f_{\text{a}} \times (1 - f_{\text{im}}) \times (1 - f_{\text{hm}}) \times (1 - f_{\text{eb}}) \tag{2}$$

where f_{ld} is the fraction degraded by the enzymes of the intestinal lumen, f_{a} is the fraction absorbed through the intestinal wall, f_{im} is the fraction metabolized by the drug-metabolizing enzymes of the intestinal wall, f_{hm} is the fraction metabolized by hepatic drug-metabolizing enzymes, and f_{eb} is the fraction excreted into the bile.

As with a multistep chemical synthetic sequence, even a 90% yield at each step still can produce a disappointing overall return. For example, a hypothetical drug that was 10% degraded by digestive enzymes during intestinal transit ($f_{\text{ld}} = 0.1$), 90% absorbed through the intestinal wall ($f_{\text{a}} = 0.9$), 10% metabolized by enzymes in the intestinal wall ($f_{\text{im}} = 0.1$), 10% metabolized by liver enzymes ($f_{\text{hm}} = 0.1$), and 10% excreted into the bile during the first pass ($f_{\text{eb}} = 0.1$) would have $F = 0.9 \times 0.9 \times 0.9 \times 0.9 \times 0.9 = 0.59\%$ or 59% oral bioavailability. Since each f factor can range from 0 to 1, one can easily see multiple ways that oral bioavailability could be severely limited, since if any of the f factors reached 0.9, bioavailability would be automatically reduced to 10% or less, no matter how good the other factors are. As an example, F is only 2% for the osteoporosis drug raloxifene, which is subject to extensive first-pass glucuronidation.[15] The chemist must get all five f factors into the good range.

It is easy to see why bioavailability is sometimes very low. In fact, it is somewhat surprising that high bioavailability, approaching 100%, is *ever* found, yet a number of drugs are nearly completely orally bioavailable (e.g., *F* for indomethacin is 98% and for rosiglitazone 99%).[15]

So what properties does the chemist have to build into the molecule during lead optimization to get good bioavailability? One approach to this question is to design molecules to have physicochemical properties in the range that favors good oral bioavailability. This approach requires the use of physicochemical descriptors that are readily calculable from the structure, and examples are MW, extent of ionization, lipophilicity, polar surface area, number of rotatable bonds, number of hydrogen bond donors and acceptors, and solubility.[16] However, another approach is to dissect the reasons that certain chemotypes fail to easily generate good bioavailability.

4.01.2.3.2.3 Absorption through the intestinal wall

Solubility and resistance to intestinal degradative enzymes such as proteases, esterases, amidases, and lipases are relatively easy for the chemist to circumvent. Although solubility is an intrinsic molecular property reflecting MW, degree of solvation, lipophilicity, and ionization state of the molecule at the pH of the biological medium, it can often be improved by the use of standard formulation excipients such as polyethylene glycol, surfactants, and cyclodextrins. The digestive enzymes usually (but not always) don't recognize nonbiological molecules well. Membrane permeability, on the other hand, is a more difficult property to build in, yet is essential for an orally deliverable drug, since it must diffuse through both the luminal and basolateral membranes of the gut wall to enter the blood. A few exceptions exist to the need for passive membrane permeability, for instance, the recognition of certain drugs by uptake transporters in the gut wall, such as the antiviral drug valacyclovir, which incorporates the amino acid L-valine as an ester of acyclovir, allowing it to be recognized by the intestinal peptide uptake transporter Pept1.[17,18] In most cases, however, the chemist must design the proper combination of solubility, membrane permeability, and lack of recognition by the intestinal efflux transporter P-glycoprotein (P-gp, also called MDR1).[19] The standard method for measurement of both intrinsic membrane permeability and P-gp recognition is measurement of bidirectional membrane transport across cell monolayers, such as Caco-2 or MDCK-MDR1 cells.[20] These systems have sufficient throughput that they can easily be placed into a screening paradigm for initial assessment of newly synthesized analogs during lead optimization. The result of these permeability assays is to characterize a compound into one of four categories: high permeability/non-P-gp substrate, high permeability/P-gp substrate, low permeability/non-P-gp substrate, and low permeability/P-gp substrate. This categorization can be used to screen out compounds likely to have poor intestinal absorption and is also helpful when seeking to diagnose poor bioavailability.

4.01.2.3.2.4 First-pass metabolism in the intestinal wall

As molecules pass through the luminal membrane into the interior of the enterocyte, the first of the barriers comprising the so-called first-pass elimination is encountered. Drug-metabolizing enzymes, especially CYP, sulfotransferase (SULT), and UDP-glucuronosyltransferase (UGT), are present in the enterocytes, with the role of providing a metabolic barrier to the entrance of nonnutritional molecules that were ingested from the diet or from therapeutic intervention (i.e., xenobiotics).[21] These enzymes are nonspecific as an important part of their function, ready to metabolize any small molecules that present themselves. In the case of molecules synthesized as part of lead optimization, this represents the first time in the history of Earth that these enzymes have encountered these molecules. The drug-metabolizing enzymes obviously did not evolve as specific catalysts for these particular drug molecules, yet the compounds nonetheless are often recognized and metabolized. Only the fact that the metabolism requires a finite time to occur prevents the metabolism from being complete, since the molecules are only transiently exposed to metabolism as they rapidly diffuse down the concentration gradient from the gut lumen to the bloodstream. Thus, some molecules with metabolic "hot spots" suffer a large fraction of gut metabolism and consequently have low bioavailability, while others that happen to be more resistant to metabolism can survive long enough to pass through the gauntlet.

4.01.2.3.2.5 First-pass metabolism in the liver

However, the danger is not over, for all the blood coming from the intestine is collected from the mesenteric circulation into a single vessel called the portal vein, which feeds directly into the liver. In cases of universal low bioavailability in a series, an in vivo diagnostic procedure such as portal vein cannulation[22] can help the discovery team decide if the principal first-pass barrier is the intestine or liver. The enzyme-rich liver acts as a second metabolic barrier, in which the same types of enzymes, and others such as aldo-keto reductase (AKR), alcohol dehydrogenase, glutathione *S*-transferase (GST), and carboxylesterase (CES),[23] have a chance to metabolize the drug candidate molecules. Only molecules with exceptional resistance to metabolism can survive the double metabolic barriers of the intestine and liver to finally reach the systemic bloodstream. Virtually, all drug candidate molecules contain functional groups or molecular features potentially susceptible to metabolism by at least one of these metabolic reactions. Given long enough exposure to hepatic enzymes, almost every possible small organic compound would be extensively metabolized. But, just as with the intestinal drug-metabolizing enzymes, time is the key. Different compounds display a wide range of kinetics for these metabolic reactions, so the challenge for the chemist that wants to improve bioavailability among a series of analogs that suffer a large first-pass metabolism effect is to slow down the rate of metabolism by making modifications that render the analogs less susceptible to metabolism. But how is that to be done?

4.01.2.3.2.6 Common metabolic reactions

To understand the problem better, we should first note that, by far, the most common metabolic reactions are those catalyzed by the CYP enzymes, with the UGTs being a distant second.[24] The reason that the CYPs dominate metabolism is simple: they catalyze a variety of oxidative reactions on groups, such as methyl, methylene, and aromatic rings, that are present in almost every drug candidate. All other drug-metabolizing enzymes carry out reactions that are specific to certain functional groups, such as hydroxyl groups, carboxylic acids, amides, esters, ketones, and alkyl halides, that are present only in some drugs. **Table 1** summarizes the frequency of various types of metabolic reactions and the enzymes that catalyze them. The typical reaction shown for CYP, methyl hydroxylation, is a specific example of the addition of an oxygen atom at many potentially oxidizable sites on drug molecules, including aliphatic and aromatic C–H bonds, double and triple bonds, and nitrogen and sulfur atoms. In contrast, other enzymes can only catalyze a specific reaction type on a specific functional group in the drug molecule, as shown.

Because of the central importance of the CYP enzymes in several ADME/PK phenomena, including metabolic clearance, drug interactions, and individual PK variability,[25] it is worthwhile to provide some additional helpful information to medicinal chemists about these enzymes. Although the human genome contains 57 CYP genes,[26] only about a dozen of these genes code for CYP enzymes that have a role in the metabolism of drugs (see **Table 2**). These enzymes are sometimes erroneously referred to as "isozymes," but the strict definition of that term refers to different proteins that catalyze the exact same reaction from the exact same substrate. **Table 2** clearly shows that although CYP enzymes catalyze similar oxidative reactions, the exact substrates and reactions vary widely among the different enzymes. Seven of the enzymes shown in **Table 2** (1A2, 2B6, 2C8, 2C9, 2C19, 2D6, and 3A4) are important in the metabolism of enough drugs to warrant the attention of regulatory agencies, especially in regard to drug interactions.[28,29]

The CYP enzymes are hemeproteins that, unlike the cytochromes of the mitochondrial respiratory chain or hemoglobin, contain a unique combination of thiolate ligand to the heme iron, a binding site for molecular oxygen on the iron, and a large open pocket above the plane of the heme that serves as a binding site for drug molecules. This arrangement allows for the simultaneous binding of molecular oxygen and an oxidizable drug molecule, allowing the characteristic CYP hydroxylation reaction:

$$R-H + O_2 + NADPH + H^+ \rightarrow R-OH + H_2O + NADP^+$$

The function of the cofactor NADPH is to provide reducing electrons to convert the iron-bound O_2 molecule to a highly reactive iron-oxo intermediate capable of oxidizing many different types of functional groups on drugs, including aliphatic C–H bonds, olefinic and aromatic double bonds, and the heteroatoms N, O, and S.[30] The oxidation reaction is a two-step process proceeding through a carbon radical intermediate, shown in simplified form in the succeeding text:

$$R-CH_2-H + Fe^{5+}=O \rightarrow R-CH_2^{\bullet} + Fe^{4+}-OH \rightarrow R-CH_2-OH + Fe^{3+}$$

As implied by the data in **Table 2**, the size, shape, and polarity of the binding site account for the selectivity of the various CYP enzymes for different types of drug substrates. The exact orientation and proximity of the drug molecule with respect to the iron-oxo unit determines which point on the drug molecule undergoes oxidation. The fact that so many drugs are metabolized by one or more CYP enzymes, then, is because most drug molecules will bind to at least one of the various CYP active sites. Once bound,

Table 1 Most important human drug-metabolizing enzymes

Enzyme[a]	*Subcellular localization*[b]	*Metabolic reaction*	*Percentage of all metabolism*[c]	*Diagnostic metabolite MW*[d]	*Example drug*
CYP	SER	R-CH_3 → R-CH_2-OH	40	*P*+16	Methyl hydroxylation of celecoxib
UGT	SER	ROH → RO-Gluc	14	*P*+176	Phenolic glucuronidation of ezetimibe
DH	CYT	R_2-CH-OH → R_2-C=O	8	*P*−2	Secondary alcohol dehydrogenation to ketone of ezetimibe
HYD	SER	RCOOR′ → RCOOH	7	*P*−R+1	Ethyl ester hydrolysis of prodrug enalapril
GST	CYT	R-X → R-SG	5	*P*+307-HX	Displacement of Cl on chlorambucil by glutathione
SULT	CYT	ROH → RO-SO_3H	5	*P*+80	Phenolic sulfonation of raloxifene
AKR	CYT	R_2C=O → R_2CH-OH	4	*P*+2	Reduction of keto group of warfarin
NAT	CYT	$ArNH_2$ → ArNH-$COCH_3$	2	*P*+42	*N*-Acetylation of sulfadiazine
Other	CYT, CYT, MIT, MIT, SER	Methylation, phosphorylation, monoamine oxidase, taurine conjugation, nitro reduction, etc.	15	*P*+14, *P*+80, *P*−1, *P*+107, *P*−30	

[a]*CYP*, cytochrome P450; *UGT*, UDP-glucuronosyltransferase; *DH*, dehydrogenase; *HYD*, hydrolase; *GST*, glutathione *S*-transferase; *SULT*, sulfotransferase; *AKR*, aldo-keto reductase; *NAT*, *N*-acetyl transferase.
[b]*CYT*, cytosol; *MIT*, mitochondria; *SER*, smooth endoplasmic reticulum (microsomes).
[c]Percentages as compiled by Testa et al.[24]
[d]MW is molecular weight of metabolite; *P* is molecular weight of parent drug.

Table 2 Properties of the most important human cytochrome P450 (CYP) enzymes involved in drug metabolism

CYP	*Active site volume*[a] ($Å^3$)	*Characteristic substrate drugs*	*Functional polymorphism*	*Inducible*	*Clinical inhibitor*
1A1	ND	Polycyclic aromatic hydrocarbons (benzo [*a*]pyrene)	No	Yes (cigarette smoke)	None
1A2	406	Heteroaromatic amines (theophylline, ondansetron)	No	Yes (heterocyclic amines; cigarette smoke)	Furafylline
1B1	398	Polycyclic aromatic hydrocarbons (benzo [*a*]pyrene)	Yes	Yes (cigarette smoke)	Resveratrol
2A6	230	Small lipophilic (nicotine, coumarin)	Yes	Yes (rifampicin)	Tranylcypromine
2B6	279	Small lipophilic (cyclophosphamide, bupropion)	No	Yes (barbiturates)	Orphenadrine
2C8	1536	Large lipophilic (paclitaxel, cerivastatin)	Yes	Yes (rifampicin)	None
2C9	1457	Large aromatic amides/esters (warfarin, tolbutamide)	Yes	Yes (rifampicin)	Sulfaphenazole
2C19	ND	Large lipophilic heteroaromatics (mephenytoin, diazepam)	Yes	Yes (rifampicin)	None
2D6	797	Lipophilic amines (dextromethorphan, fluoxetine)	Yes	No	Quinidine
2E1	190	Small hydrophilic (ethanol, acetaminophen)	No	Yes (ethanol)	Disulfiram
3A4	1508	Large lipophilic (midazolam, nifedipine)	No	Yes (rifampicin)	Ketoconazole, ritonavir

[a]Active site volume data taken from Dong et al.[27]

the molecule encounters a rich oxidative chemistry that can usually find an acceptable oxidative target somewhere on the drug molecule.

4.01.2.3.2.7 Addressing high first-pass clearance

If the in vitro membrane permeability assay (e.g., Caco-2) indicates that intestinal absorption is not the reason for low bioavailability, and we believe from the structure of the drug molecule that degradation by digestive enzymes in the stomach and intestinal lumen is unlikely (this can actually be tested, but usually simple inspection of the structure of the molecule is enough), then most likely, high first-pass clearance is the reason. First-pass clearance is the result of both first-pass metabolism and first-pass biliary excretion. The extent of biliary excretion of intact parent drug may be investigated in vivo with bile duct-cannulated (BDC) animals or in vitro with hepatocytes.[31] However, most commonly, the metabolic component of first-pass clearance is the greater of the two, so let us devote considerable discussion to this process.

We can investigate the rate of metabolism by in vitro methods, most notably liver *S*9 fraction, microsomes, and hepatocytes. One or another of these is commonly an in vitro assay in the screening funnel, so the information may be already at hand. Liver microsomes and *S*9 fractions are formed by homogenization of liver cells. Differential ultracentrifugation produces fractions containing various subcellular organelles and, therefore, various metabolic enzyme sources. Whole liver homogenate contains all components, including plasma membrane, smooth and rough endoplasmic reticulum (SER and RER), mitochondria, nuclei, and cytosol. Whole homogenate, which contains all metabolic enzymes and cofactors, is used when one is certain that the liver is a major metabolic organ, but the type of metabolism may be uncertain. To further distinguish the location of the metabolic process, subcellular fractions are isolated and tested for metabolic activity. Relatively slow-speed centrifugation at $9000 \times g$ precipitates the heavier components of unbroken cells, plasma membrane, RER, mitochondria, and nuclei, leaving behind the cytosol and the SER (combination referred to as *S*9, the supernatant from $9000 \times g$ centrifugation). Determining that the metabolic activity remains in *S*9 fraction demonstrates that the major metabolic process occurs in the SER or cytosol. If the activity is not found in *S*9, then the metabolic activity must have been associated with one of other subcellular organelles, such as the mitochondria. Assuming that activity is found in *S*9, then further ultracentrifugation of *S*9 at $105{,}000 \times g$ separates the microsomes (resulting from the SER being broken apart by homogenization and reforming as spherical bodies) and cytoplasm. Thus, testing metabolic stability (MetStab) in microsomes differentiates the enzyme type into membrane-bound enzymes, such as CYPs, and soluble enzymes, such as AKR (see **Table 1**). Because of the prominence of CYP enzymes in drug metabolism, *S*9 or microsomes are often used for MetStab screening. These two systems are easy to prepare, easy to use, and available from common laboratory species as well as humans. To have full metabolic competency, both systems must be supplemented with appropriate cofactors, such as NADPH for CYP-catalyzed oxidations, UDPGA for UGT-catalyzed glucuronidations, and glutathione for GST-catalyzed glutathionylations. Thus, results from these systems have to be interpreted carefully in terms of recognizing that the experimental question asked depends on which cofactors and in what ratios were supplied. Cytosolic and microsomal hydrolytic enzymes such as CES do not require a cofactor.

An alternative in vitro system for MetStab screening is hepatocytes. These have an advantage over *S*9 and microsomes in that they are a complete living system. All liver metabolic processes are present simultaneously in their normal in vivo proportions,

and hepatocytes do not require supplementation with cofactors. Thus, it is felt that hepatocytes provide a more complete and accurate assessment of metabolism of drug candidates without prior knowledge of the pertinent metabolic pathways. On the other hand, they are more difficult to prepare and require cell-culture methods to maintain, so they are correspondingly more expensive and difficult to use than *S*9 and microsomes. Since hepatocytes are a cell-based system, usually less protein can be applied in an assay, and absolute enzymatic rates are slower than for *S*9 and microsomes. However, the sensitivity of mass spectrometry (MS) as the analytic instrument of choice for ADME/PK work allows accurate measurements with even low concentrations of drug candidates.

Recent innovations in the preparation and use of hepatocytes have resulted in the availability of enhanced hepatocyte systems that will eventually replace the conventional systems that presently dominate ADME/PK work. Conventional hepatocytes only survive in an active metabolism experiment with an experimental drug for a few hours before dying. Because the absolute enzymatic rate in a typical hepatocyte experiment is already low, if the experimental drug is one with very low clearance, then the hepatocytes don't have enough catalytic capacity to appreciably metabolize the test article drug in the relatively short time before the cells die.

Admittedly, this sounds like an odd problem to discuss in the context of a discovery program seeking to slow down high clearance, but this problem actually has discovery-level ramifications as well. When we cannot detect a rate of metabolism of the parent drug because it is very low, then the most we can say is that the rate is less than a certain threshold number. Unfortunately, this low unmeasurable rate may not distinguish a rate corresponding to a 24-h clinical half-life (which might be very desirable) from a low unmeasurable rate corresponding to a 10-day clinical half-life (which we probably would not want to nominate as a clinical candidate). Thus, there is a need to magnify the rates below the threshold to measurable rates that can be used to distinguish compounds that would be problematic from those that would be acceptable.

The enhanced systems fall into three fundamentally different categories. First is the so-called relay method for extending the period over which a hepatocyte experiment can be run.[32] In the relay method, the culture medium, which contains the metabolizable drug substrate and the formed metabolites, is transferred to a fresh batch of cells every 4 h, allowing an unlimited period of time for a slow rate to be measured. Eventually, even a very slow rate will have depleted the drug enough that a useful estimate of the rate of metabolism could be derived. In practice, the total incubation times of 20 h were demonstrated to be feasible, greatly expanding the range of low rates that could be measured.

Other approaches use various biological approaches, including modifications to the hepatocytes themselves or the generation of hepatocyte-like cell lines, all of which survive much longer in culture during active metabolism experiments. One of these uses human pluripotent stem cell-derived hepatocytes as surrogates for conventional hepatocytes.[33] These cells seem to have all the function of true hepatocytes and last at least 2 weeks in culture. However, they have not yet been applied to MetStab assays. Another surrogate hepatocyte system is the human hepatoma cell line, HepaRG.[34,35]

Three long-lived true hepatocyte systems are available and in use. One is the HepatoPac micropatterned hepatocyte–fibroblast coculture system that can be used for continuous incubations of up to 7 days.[36–38] Validation experiments with a variety of low-clearance drugs established that these cells gave useful estimates of the absolute values of clearance, sufficient to serve as a screening assay. Another is the upcyte system of extended lifetime human hepatocytes.[39,40] The third is the HμREL hepatocyte coculture system,[41,42] which has been shown to maintain viability and fidelity of metabolism for at least 2 weeks. Each of these systems has advantages and disadvantages,[42] although the HμREL system is reported to show slightly superior overall assay performance.[41] Straightforward methods exist for converting these quantitative in vitro rate measurements into useful estimates of the in vivo first-pass clearance in order to judge the importance of metabolism in limiting bioavailability.[21,42–44]

In addition to their ability to measure low metabolic rates, these enhanced hepatocyte systems have applications to toxicity testing (see section Early Toxicity Assessment) and to determining routes of metabolism. All three uses reflect the facts that at least some of these systems retain fidelity to the metabolic processes existing in the liver of living human beings, as opposed to conventional hepatocytes, which have a tendency to lose their identity and dedifferentiate. One example illustrates this phenomenon. The marketed antihistamine desloratadine has long been known to be hydroxylated in the 3-position as the major human metabolic process,[45] although the enzyme responsible for the transformation could never be identified due to the inability of in vitro systems, including conventional hepatocytes, to produce the 3-hydroxy metabolite. But then, for the first time, the high-fidelity HμREL hepatocyte coculture system was applied to the problem and shown to produce this metabolite, even though in side-by-side experiments conventional hepatocytes did not.[46] Once it had been shown that an enhanced hepatocyte system could make the correct metabolite, Kazmi et al.[47] took a fresh look at the previous failures of conventional hepatocytes and discovered the unusual features of the metabolic process that had confounded prior attempts. The important lesson was that high-fidelity hepatocyte systems are likely to produce the correct answer the first time, without prior knowledge of what the correct answer is. This valuable characteristic will, in the opinion of this author, eventually result in broad use of such systems in pharmaceutical discovery and development and the requirement that they be used for hepatocyte-based assays submitted in regulatory filings.

It often happens that merely knowing that the rate of metabolism is high is enough to suggest to the medicinal chemist possible modifications to reduce the rate by chemical intuition and experience. Analogs with "fixes" to the proposed problems are easy to make and test in vitro. However, this cognitive approach is usually not enough and actual experimental data on sites of metabolism are needed, as elaborated in the succeeding text.

MS has seen tremendous improvement in the last few years, and new applications to the problem of metabolite detection and identification have emerged as a result. This applicability entirely rests on the capabilities of new high-resolution MS instruments, as well as inventive new algorithms, to detect metabolites in in vitro incubation mixtures and even ex vivo biofluids such as plasma, urine, and bile.[48–51] Several techniques are now widely available to afford rapid detection of metabolites without the use of

radiolabel. Furthermore, in almost all cases, partial structure identification is possible in the absence of authentic standards, with many instances of *full* identification possible.

First, let us discuss how metabolites can be reliably found without the use of radiolabel. The most intuitive and easily understood technique is baseline subtraction of control incubations or biofluid samples in which no metabolism occurred. Excellent concordance of the revealed metabolite peaks to those of corresponding incubations with radiolabeled drugs demonstrated the reliability of this enhanced baseline subtraction with noise-reduction algorithm to find metabolites without prior knowledge of their structures or presence in the sample.[52] One can also use the "list" technique in which one creates a table of common metabolic transformations of the parent compound, as illustrated in **Table 1**. The MS software marks peaks as likely metabolites when their nominal mass matches one in the list. Of course, unusual metabolites whose masses are not in the list would be missed, so that the list technique alone may not produce a complete answer. Another technique called isotope pattern filtering (IPF)[53] is applicable to drugs that contain a chlorine or bromine atom in the molecule, since all metabolites containing one of these halogens will show the characteristic isotope pattern (i.e., 35/37 in the ratio 3:1 for chlorine and 79/81 in the ratio 1:1 for bromine). The MS data-collection software is programmed to mark peaks with molecular ions showing a doublet in the proper proportions. Of course, this technique will not be applicable for nonhalogenated chemotypes, and furthermore, it assumes that the halogen has not been lost from the metabolite. But for chlorine/bromine-containing analogs, IPF is simple and unambiguous. Two additional techniques for finding metabolites rely on commonality of certain fragmentation patterns between parent and metabolite, namely, product ion filtering and neutral loss filtering.[48]

Finally, a technique called mass defect filtering (MDF) is much less intuitive than the others but very powerful with much less reliance on assumptions about the metabolites.[54] MDF is based on the fact that atomic weights are not exact integers. The difference between the nominal atomic weight and the actual atomic weight is called the mass deficit. Summing the deficits of the atoms composing the parent drug molecule allows one to define a characteristic molecular mass deficit. For example, the nominal molecular mass (MH^+ positive ion electrospray) of the antidepressant nefazodone ($C_{25}H_{32}ClN_5O_2$) is 470 (^{35}Cl isotope), but the actual measured MH^+ as determined in a high-resolution MS instrument is 470.2323.[48] Thus, the mass deficit for nefazodone is 0.2323 Da. Somewhat counterintuitively, the same mass deficit (within a window of ± 0.05 Da) is observed for metabolites of nefazodone that retain most of the full structure of the parent drug (e.g., the hydroxylated and deethylated metabolites). Extensive validation has established that the mass deficit of the parent carries through to the metabolites, so that the high-resolution MS software determines the mass deficit of each peak in the LC-MS chromatogram and marks those peaks whose deficit falls within the window established by the parent drug.

After application of some combination of the techniques in the preceding text, we can create with good confidence a set of discovered metabolites in the form of marked chromatographic peaks. But this information is almost useless by itself. We also need to quickly determine the chemical structure of each metabolite (metabolite identification (MetID)). The nominal mass of the molecular ion of the discovered metabolite encodes the nature of the metabolic modification. For example, as seen in **Table 1**, a metabolite with MW 16 Da higher than that of the parent drug (i.e., P + 16) is almost certainly a product of CYP oxidation of the parent drug. Similarly, a glucuronide will show an MW at P + 176. There are many such numerical combinations that automatically define the nature of the metabolic reaction, and often, this information alone is sufficient to exactly define the point of metabolism on the drug molecule. For example, a metabolite of MW at P-14 from a drug containing a dimethyl amine functional group must be the *N*-desmethyl metabolite, while a metabolite showing MW at P + 176 from a drug than contains a single hydroxyl group is surely the glucuronide attached through that hydroxyl, and a metabolite of an ethyl ester with MW of P-28 can confidently be identified as the corresponding carboxylic acid.

For a metabolite whose MW alone does not completely define the structure, fragmentation by standard MS/MS methodology provides very good information about the position of the metabolic modification. This is often important for hydroxylated metabolites, in which the parent drug usually contains multiple potentially oxidizable C–H bonds, and thus, the metabolites have many structures consistent with MW P + 16. The major fragmentation pathways are often similar between parent drug and metabolite, so that a change in the mass of one fragmentation daughter ion while other fragmentation daughters are constant signals the position of the hydroxylation. An MS-based method even exists now for distinguishing the position (e.g., *ortho*, *meta*, or *para*) of a metabolic modification on an aromatic ring, a useful additional MetID tool, since positional isomers can vary greatly in pharmacological and/or toxicological activity.[55] The techniques in the preceding text can be used singly or together in parallel to provide unambiguous detection of and structures for the major metabolites of drug candidates.[56] All major vendors of high-resolution mass spectrometers provide powerful auxiliary software to largely automate and facilitate the rapid discovery and structural elucidation of metabolites.

The advantage of this capability to chemists cannot be overstated. Before the advent of rapid MetID during lead optimization, the use of in vitro metabolic systems such as liver microsomes or hepatocytes was limited to measurement of the rate at which the in vitro system metabolized the drug analog. For example, a series of 10 analogs subjected to a MetStab screening assay might show that most of the analogs had very short in vitro half-lives and should be discarded. One or two, however, might have had half-lives approaching 1 h and would be retained as potentially good candidates. This would be a completely one-dimensional empirical process, with no fundamental chemical understanding of what was bad about the discarded compounds or good about the retained ones. However, as long as some good analogs *did* come out of the screening process, it didn't matter very much if the reason for success was fully understood by the chemists. But it is often the case that most, if not all, of the analogs have high rates of metabolism and few, if any, have suitable MetStab kinetics. The chemists don't want to keep throwing away compounds that had other desirable properties, especially potency and selectivity. Instead of relying on the empirical, trial-and-error approach, they want to rationally design out the metabolic liability.

Now imagine that the same in vitro incubates used for the rate determination were split, and the second sample was submitted for MetID. If the MetID data were available in the same time frame as the quantitative rate data, then an illuminating second dimension would be added to help the chemist fix the problem. With respect to timing of the availability of this valuable chemical information, it is enlightening to remember that liquid chromatography (LC)-MS/MS is almost invariably used for the quantitation of the rate of metabolism of the parent drug. The metabolites are present in the same samples as the parent drug and consequently also elute from the LC along with the parent drug (usually at an earlier retention time due to greater polarity). However, in the old one-dimensional approach, we only quantitate the parent drug, and the metabolites go straight through the mass spectrometer without detection, since we "close our eyes" as they elute. Such a waste!

The second dimension, being structurally based, is well understood by chemists and can be directly translated to structure evolution during lead optimization. In the past, chemists, who are typically not strong in pharmacokinetics, have been content to allow the pharmacokinetic scientists decide on what data to deliver. Conversely, the pharmacokineticists are typically not strong in chemistry and have not appreciated how valuable the MetID structural information would be to the medicinal chemists. The capability of obtaining at least partial structures of these metabolites currently exists in any bioanalytical group that supports MetStab, but chemists may have to insist on getting these structures, not just the rates. With a two-dimensional array of information about how and how fast analogs are metabolized, the problem of slowing down metabolism becomes a straightforward exercise in the SAR, something that medicinal chemists do as easily as breathing. And once the SAR is recognized, effective measures to slow down or even eliminate certain modes of metabolism are soon evident. It should be noted that these powerful MS metabolite recognition methods have already been in routine use for years in clinical phase 1 searches for circulating metabolites before the standard ^{14}C-ADME study has been accomplished (see section "**Circulating human metabolites**").

4.01.2.3.3 Distribution

4.01.2.3.3.1 Distribution to the target organ

Although we frequently measure the suitability of the PK of a drug candidate in terms of the blood concentrations achieved, the presence in the blood is not sufficient for most drug candidates to express their potential pharmacological activity. The compound must also distribute from the blood to the target organ (e.g., brain for CNS drugs, liver for hepatitis drugs, and tumor for cancer drugs). By the use of dosed animals, it is possible to determine drug levels in the target organ by excision of the organ, homogenization, organic solvent extraction, and LC-MS/MS assay for drug concentrations. Radiolabel is not required for this determination and in fact is potentially misleading if the method does not distinguish radiolabeled parent drug from radiolabeled metabolites. Tissue uptake is usually expressed as the tissue/plasma ratio to give the absolute concentration a context for interpretation.

The most common distribution issue encountered in drug discovery is restriction of net uptake of drug into the brain by the blood–brain barrier (BBB). The BBB is a set of three biological structures that inhibit diffusion of small organic molecules from the blood to brain tissue. The first is the plasma membrane of the cerebral vascular endothelial cells, which is poorly permeable by very polar or permanently ionic compounds (e.g., quaternary amines). The second barrier is the tight junctions between the cells, which prevent flow of drug molecules around the cells, bypassing the membranes. Third is the presence in the endothelial membrane of efflux transporters, such as P-gp[57] and BCRP,[58] which use ATP energy to actively pump some drugs from the interior of the brain back to the blood. There is nothing the medicinal chemist can do to defeat the tight junction barrier, but the other two barriers are surprisingly manageable.

The solution is found in the same membrane permeability assays that are used for assessing the intestinal absorption potential (i.e., bidirectional transport across monolayers of Caco-2 or MDCK-MDR1).[59] The bidirectional transport assay provides information about both the intrinsic permeability, as measured by the absolute rate that the compound can diffuse from one side to the other, and the substrate recognition by P-gp, as measured by the "efflux ratio" (ER) of transport in the basolateral-to-apical direction and the apical-to-basolateral direction.[59] Drugs that show a high ER (three or higher) are likely good substrates for P-gp, whereas those that show an ER about unity are not. Therefore, it is quite feasible to establish an SAR for BBB penetration based on measurable molecular properties that are modifiable by the chemist.

Measurement of BBB penetration is accomplished in lead optimization in mice and/or rats, often in concert with a full IV/PO PK study. This is considered sufficient to indicate whether human BBB penetration will be problematic, as this property is qualitatively, even if not exactly quantitatively, constant across species. CD (see section "**In vivo determination of oral bioavailability**") has also been used successfully to address problems of brain penetration, where the potential for error in PK determination due to DDIs is much less than in systemic PK studies.[60] One can also measure levels of drug in cerebrospinal fluid, although this is much more difficult and not applicable to rapid screening.[61] Although computational approaches to predicting BBB penetration have been used,[62] more recent recognition of the important role of efflux transporters in the process makes this more complicated than was originally believed. The astute medicinal chemist will notice that molecule features that give a molecule good intestinal absorption are the same as those that promote good BBB penetration, for the simple reason that both the BBB and the intestinal absorption barrier use the same biological exclusion strategy. Note that for non-CNS drugs, for which we may wish to *limit* brain exposure, the problem is turned on its head, but the properties that determine the susceptibility of a compound to be blocked by the BBB apply in both cases.[63]

4.01.2.3.3.2 Plasma protein binding

Blood plasma contains proteins that have binding sites for transporting small organic molecules such as fatty acids around the body. The principal binding protein, by mass, is serum albumin, but a number of other proteins are present as well, including α_1-acid

glycoprotein and various lipoproteins. Drug molecules bind to these proteins with various affinities, some poorly (such as amikacin, 4%[15]) and some extensively (such as diclofenac, >99.5%[15]). In addition to this binding being considered a type of distribution itself, it also tends to hold drugs in the plasma, thereby buffering their distribution into organs and tissues. This binding appears tight when expressed in the usual manner as "% bound drug in plasma." For instance, indomethacin is 90% plasma protein-bound,[15] which sounds as if only 10% of the drug is available to interact with target receptors. This, however, is misleading, and an excellent discussion on the misconceptions of applying in vitro estimations of the extent of plasma protein binding to in vivo pharmacology warns against the use of protein binding as a single-dimensional screening criterion.[64]

An important reason that a drug could be 90% bound is the pure mass action effect of the high concentration of protein in plasma. For instance, the normal concentration of human serum albumin is 42 mg mL^{-1} (~650 μM),[65] and each molecule has two or more drug binding sites.[66] However, the binding affinity itself is almost always rather loose. In the case of a typical drug 90% bound by albumin, one can back-calculate that the corresponding K_d for the protein–drug interaction is about 70 μM. This is very loose binding compared with the typical K_d for a target receptor of single-digit nanomolar. Obviously, then, molecules of a drug "only" 90% bound will easily be able to dissociate from albumin and bind to the thermodynamic sink represented by the receptor, and albumin binding will not effectively compete with receptor binding. However, even in the case of diclofenac binding of >99.5%, the usual dose is not high (50 mg), demonstrating that the drug is not seriously restricted from binding to its receptor, the COX-1/2 enzyme. On the other hand, drug binding to plasma proteins *can* be so tight that it actually *is* restrictive. The antiarrhythmic drug amiodarone has plasma protein binding of 99.98%,[15] corresponding to a K_d value of about 100 nM. In such a case, the assumption of no serious competition with receptor binding may not be true, and one would want to proceed with caution. Therefore, most discovery programs avoid compounds showing plasma protein binding higher than 99.9% if possible. But it is worth pointing out that some successful marketed drugs do display extremely high plasma protein binding, for instance, zamifenacin, which is 99.98% plasma protein-bound.[64]

Experimental measurement of plasma protein binding is accomplished by equilibrating drug with plasma in either a dialysis or ultrafiltration apparatus that segregates the unbound drug so that it's concentration can be independently measured, usually by LC-MS/MS. Simple arithmetic converts this unbound concentration into percent binding. This technique is too slow for high-throughput screening, but fast enough for a second-tier screen. Computational predictive approaches have been published,[67] but these have not had the accuracy to allow the chemists to compute their way out of unacceptable protein-binding problems.

4.01.2.3.3.3 Red blood cell uptake

Another type of distribution is uptake of the drug into blood cells. Although this can happen with any type of blood cell, only the red blood cells (RBCs) are numerous enough to actually sequester an appreciable fraction of the total drug contained in blood. Thus, one PK parameter that should be checked in a nomination candidate is the blood/plasma ratio. If this is higher than unity, then it means that the RBCs are sequestering the drug. This is not a problem per se, but it can lead to misinterpretation of PK results, particularly clearance values that are based on plasma concentrations (as they usually are). The result is that ultrahigh apparent clearance values may be calculated from the plasma PK measurements, leading the chemist to think that there is an issue, when in fact it is a distribution phenomenon. Thus, for instance, if calculated systemic clearance values were much higher than physiologically reasonable (e.g., three times hepatic blood flow), then one would want to measure the blood/plasma ratio as part of the diagnostic process. High RBC uptake can happen when a dibasic amine, such as some heteroaromatic compounds like chloroquine, get trapped in a low-pH compartment of cells, such as lysosomes. The trapping phenomenon is not limited to RBCs,[68] but its effect on the blood/plasma ratio makes it easily visible in RBCs.

4.01.2.3.3.4 Volume of distribution

Full IV/PO PK studies deliver as a derived parameter the so-called "apparent volume of distribution at steady state" (V_{ss}). This is an operationally defined parameter that can be applied to vaguely describe the physiological distribution of the drug candidate. The usual units of V_{ss} are liters per kg of body mass (i.e., L kg^{-1}), and it can be treated as the volume of blood (i.e., the sampled biological compartment) in which the drug *appears* to be dissolved. A more intuitive and useful way to think of V_{ss} is as the volume of total body water (TBW), reduced by factors such as plasma protein binding that tend to restrict it to plasma and increased by factors such as Log *P* and tissue binding that tend to pull it out of plasma. Let us now illustrate this intuitive approach.

A drug that is confined to the plasma compartment (perhaps by extremely strong plasma protein binding) would show a V_{ss} about 0.04 L kg^{-1}, because there is about 40 mL of plasma for every kg of body mass. One might think that such a low V_{ss} might be ideal for a drug whose target receptor is in the blood, since the entire dose of the drug would be in the blood, with essentially no distribution into other nontarget organs. However, a drug that has such strong plasma protein binding might not be able to effectively dissociate from plasma protein and bind to target receptors, even though they are in the blood (see section "**Plasma protein binding**"). Thus, a candidate with very high plasma levels due to very low V_{ss} may look promising, but one has to examine the magnitude of the pharmacological effect to avoid being misled.

A second value for V_{ss} that has an approximate physiological correlate is 0.21 L kg^{-1} (extracellular fluid). Amoxicillin, which is highly water-soluble, is poorly bound to plasma proteins, and does not permeate membranes well, has a V_{ss} of 0.21 L kg^{-1}. A third definable physiological compartment, TBW, has the value of 0.6 L kg^{-1} (i.e., our bodies are about 60% water). The water-soluble, poorly protein-bound, membrane-permeable drug theophylline has a V_{ss} of 0.5 L kg^{-1}, similar to TBW, and ethanol, which distributes uniformly everywhere in the body, has a V_{ss} of 0.7 L kg^{-1}.

A drug with V_{ss} significantly higher than 0.6 L kg^{-1} (of which there are many) *appears* to be dissolved in a volume higher than the total amount of water in the body. For instance, the calcium channel blocker diltiazem has a V_{ss} of 3.3 L kg^{-1}. Since this is a physiologically impossible volume, the only way for this to happen is that most of diltiazem is sequestered in some compartment such as the liver or adipose tissue. We often say that a drug with a high V_{ss} is well distributed into tissues, but this is misleading, because V_{ss} reflects the weighted average of distribution into all tissue compartments. There is no requirement that the distribution be uniform. Thus, we cannot say from the value of V_{ss} alone how much drug is distributed into what extravascular compartment, and it is possible, for example, that most of the drug is in one type of tissue such as adipose or liver, with very little in the brain.

4.01.2.3.4 Persistence

4.01.2.3.4.1 *Half-life and* MRT

Three of the ADME/PK characteristics that we have considered up to this point for optimization (i.e., plasma protein binding, RBC uptake, and V_{ss}) are important in determining the magnitude of dose to be administered and the target plasma concentration range. However, they seldom are the reason for a drug to fail in clinical trials, and the chemist operates with broad latitude in deciding that any of them are acceptable for a particular drug candidate. On the other hand, oral bioavailability must be above a threshold level of 10% for a drug to be considered a reasonable clinical candidate, at least for a drug intended for oral delivery. Just as important as bioavailability is the length of time that effective plasma levels are maintained by a drug candidate (i.e., its persistence). There are several ways that persistence is expressed, including terminal elimination half-life ($t_{1/2}$), accumulation half-life, operational multiple-dosing half-life,[69] *MRT*, and dosing interval. A variant is time above minimum inhibitory concentration (MIC), which is often used in the field of anti-infectives, but which we will not discuss further here.

The most common way to express persistence is $t_{1/2}$. This intuitive parameter nominally refers to the time for plasma levels to fall by half and is most often favored by chemists. Since an ideal drug follows simple first-order kinetics, then a $t_{1/2}$ value of 12 h means that from a given point, such as C_{max}, we can expect plasma concentrations to decline to 50% in the first 12 h and then 25% in the next 12-h period, 12.5% in the third period, etc. This simple relationship makes it easy to see that a drug with a clinical $t_{1/2}$ of 12 h would be easy to formulate as a once-a-day regimen, ideal for patient compliance. The plasma concentration–time curve is usually plotted as Log [drug] versus time (i.e., semilog plot), which for an ideal first-order drug will be a straight line. The value of $t_{1/2}$ is calculated from the slope of that line. However, the vast majority of drugs are not perfectly ideal, and consequently, the semilog plot is curved at early times. At some later time, the plot becomes a straight line, and this straight terminal phase is used for half-life calculation. The half-life is then called the terminal elimination half-life ($t_{1/2\beta}$).

A problem arises for the many drugs and drug candidates that show complex nonideal kinetics that do not break into a straight line in the semilog plot until the only last few percent of the concentration declines. In these cases, most of the molecules were apparently eliminated from plasma much faster than was indicated by $t_{1/2\beta}$. The question arises whether $t_{1/2\beta}$ is the "true" half-life and the earlier curved portion of the semilog plot merely reflected a slowly eq distribution process or is the half-life of only a small fraction of the drug contained in some slowly equilibrating compartment, such as adipose tissue or bone. In the latter case, $t_{1/2\beta}$ is unrealistic as an indicator of how long the plasma levels will stay in the effective range. One way to distinguish the two possibilities is to do multiple dosing to "steady state," operationally defined as a period in which the trough level between subsequent doses is constant. Without going into detail, one can calculate the average plasma that will be observed at steady state, assuming either that the early phase of the semilog plot is the true half-life or that $t_{1/2\beta}$ is the true half-life. Obviously, such an experiment takes a long time and a lot of the precious supply of drug candidate and is not suitable for a fast-moving lead optimization campaign.

Another measure of the realistic persistence of a drug candidate is *MRT*, and this is easily determined in the same single-dose experiment from which $t_{1/2\beta}$ derived. *MRT* is less familiar to most chemists than $t_{1/2\beta}$. It is a fundamental parameter of "noncompartmental kinetics," which uses the statistical theory of moments to treat the entire plasma concentration–time curve as a population of molecules that can be described by parameters that make no assumptions about the exact mechanisms of absorption, distribution, and clearance. As the name indicates, *MRT* is the average time that a molecule of the drug candidate stays in the plasma before elimination. For the ideal first-order drug we were considering in the preceding text, *MRT* has the value, derived from calculus, of $1.44 \times t_{1/2}$. To give *MRT* a clearer, more intuitive, meaning, we can simplistically estimate *MRT* in terms of half-life by a simple "back-of-the-envelope" calculation of the weighted average of the time that drug molecules stay in the plasma before being cleared. Half of the molecules last for one half-life, a quarter more last for two half-lives, an eighth last for three half-lives, etc. Thus,

$$MRT \approx 0.5 \times t_{1/2} + 0.25 \times 2\,t_{1/2} + 0.125 \times 3\,t_{1/2} + \cdots \approx 1.5 \times t_{1/2} \quad (3)$$

This equation should not be thought of as rigorously correct but as a way to estimate an "effective half-life" that applies to the entire ensemble of molecules, not just the final 1%.

MRT is valuable for a drug discovery program because it allows rapid diagnosis of whether $t_{1/2\beta}$ from an in vivo PK study of a drug candidate is realistic. If *MRT* is approximately the same or somewhat longer than $t_{1/2\beta}$, then $t_{1/2\beta}$ is representative of most of the molecules. On the other hand, if *MRT* is much shorter than $t_{1/2\beta}$, then $t_{1/2\beta}$ is misleading because it is representative of only a small fraction of the molecules. In the latter case, *MRT* would be a much better way than $t_{1/2\beta}$ to gauge the real persistence of the candidate. It is probably obvious that one can avoid the question of the relevance of the half-life by just always using *MRT* to

describe persistence, but the old practice of referring to half-life remains popular. For those who prefer to think in terms of half-life rather than *MRT*, then one can use Eq. (3) to calculate effective half-life from the value of *MRT* printed in the PK report.

Accordingly, to readily detect unrepresentative half-life values, chemists should always insist that the list of calculated PK parameters accompanying the preclinical PK study report includes *MRT*. One can even ask the question: why even bother with $t_{1/2\beta}$ when a more reliable parameter is easily available? Always use *MRT* when comparing drug candidates to make decisions about which ones to advance, since the terminal half-life may be inconsistently in error from compound to compound, whereas *MRT* is much more reliable and interpretable.

In addition to the reality check on the terminal elimination half-life, *MRT* provides a very useful insight into how fast the drug candidate is absorbed, because *MRT* is calculable for both the IV and PO doses. Making the very reasonable assumption that once a molecule has reached the bloodstream, its PK is the same regardless of the dosing route followed to get there, we can calculate the average time a molecule requires to be absorbed following oral dosing (mean absorption time (*MAT*)) by simple subtraction:

$$MAT = MRT_{PO} - MRT_{IV} \tag{4}$$

MAT is much easier to visualize and understand than the absorption rate constant (k_a), which is sometimes reported as a measure of the speed of absorption. Although T_{max} is most commonly used as a measure of speed of absorption, it can be very misleading, since it merely denotes the time when the rate of absorption happens to equal the rate of elimination, and therefore, plasma concentrations stop rising (i.e., C_{max}). T_{max} definitely does not indicate the end of the absorption process.

4.01.2.3.4.2 Clearance

While the PK parameter clearance (*CL*) is frequently used as a simple word for removal of drug from the plasma, it actually has a rigorous mathematical definition. *CL* is the volume of blood that is completely cleared of drug in unit time, and it is expressed in units of mL $min^{-1} kg^{-1}$ of body mass (or L $h^{-1} kg^{-1}$). While this definition is not very useful to a chemist as stated, it has great conceptual power when combined with volume of distribution. Returning to our consideration of an ideal first-order drug, an equation relating clearance and volume of distribution is

$$t_{1/2} = \frac{0.693 V_d}{CL} \tag{5}$$

Translating this equation into noncompartmental kinetic terms, we can write

$$MRT = \frac{V_{ss}}{CL} \tag{6}$$

Eq. (6) is normally used to calculate V_{ss}, but in this form, it is a very helpful way to think about clearance. We may consider Eq. (6) to state that a given clearance takes a characteristic amount of time to eliminate the drug from a given volume. For a given volume, the higher the clearance, the shorter the *MRT*, and the lower the clearance, the longer the *MRT*. Conversely, for a given value of clearance, the higher the V_{ss}, the longer the *MRT*, and the lower the V_{ss}, the shorter the *MRT*. This simple inverse relationship immediately explains why two drug candidates may have the same value of *CL*, determined either directly from an in vivo PK study or by calculation from in vitro MetStab data, yet much different in vivo half-lives. Because of the multifactorial origin of V_{ss}, it is difficult for chemists to try to target a certain range in designing their molecules. Therefore, we target a certain half-life range by adjusting *CL* and let V_{ss} fall where it may. Experimentally, clearance is calculated from another simple relationship between the easily measured quantity dose and *AUC* for the IV dose (Eq. 7). Eq. (7) shows us that for a given dose, high clearance gives low *AUC*, and vice versa:

$$CL = \frac{Dose}{AUC_{IV}} \tag{7}$$

What do we consider high clearance and low clearance? Because the liver is so often the principal clearing organ, we often express high and low clearance in terms of the fraction of liver blood flow (Q_H), remembering that *CL* and clearance and organ blood flow have the same units of mL $min^{-1} kg^{-1}$. For renally cleared drugs, we would compare *CL* and renal blood flow (Q_R). **Table 3** shows values of hepatic and renal blood flows for various laboratory species and humans. The value of *CL* reported in the table of PK parameters from a typical conventional IV/PO PK study can be directly compared with the values of blood flows for the species of interest to characterize the drug candidate as high or low clearance in that species. For instance, a measured clearance of

Table 3 Organ blood flows for common laboratory species and humans[a]

Blood flow (mL $min^{-1} kg^{-1}$)						
Organ	*Mouse*	*Rat*	*Rabbit*	*Dog*	*Monkey*	*Human*
Liver	90	55	71	31	44	21
Kidney	65	37	32	22	28	18

[a]Calculated from data published by Davies and Morris.[65]

5 mL $min^{-1}kg^{-1}$ for a drug candidate in rats would be considered low, while 50 mL $min^{-1}kg^{-1}$ would be high, because hepatic blood flow in rats is 55 mL $min^{-1}kg^{-1}$. In any species, clearance cannot exceed the value of blood flow for the clearing organ for the simple mass transport reason that an organ cannot clear a drug faster than the drug is delivered to the organ by blood flow. However, if clearance is not restricted to a particular clearance organ, for example, a drug that is subject to a high rate of metabolism in blood or that is cleared by both the liver and kidney, clearance can exceed liver blood flow.

Yet another useful way to think about clearance is in terms of the hepatic extraction ratio (E_H), the fraction of drug in the plasma that is removed by the liver during a single passage:

$$E_H = \frac{CL_H}{Q_H} \tag{8}$$

The fraction of drug escaping hepatic clearance on each passage is $1 - E_H$. We can similarly define a renal extraction ratio (E_R) for renally cleared drugs.

Suppose we have a drug whose clearance in an IV/PO PK study in rats is 52 mL $min^{-1}kg^{-1}$, and we believe that all clearance is due to metabolism in the liver (perhaps from in vitro data or experience with analogs). Substituting the values of rat hepatic blood flow from **Table 3** and measured clearance into Eq. (8), we estimate that oral bioavailability will be 5% or less, even if intestinal absorption was 100%. Since the PK study included both IV and PO doses, we have an experimental value of F to compare the estimate with, and if there is general agreement between the two, then we have learned something about the in vivo disposition of the drug. We can see that when chemists want to think about how long a drug candidate will stay in the body, they will apply Eq. (6), and for thinking about bioavailability, they will apply Eq. (8).

4.01.2.3.4.3 Mechanisms of clearance

A chemist facing short *MRT* values caused by high clearance in a series of compounds needs to do something to the series of molecules to reduce the clearance. There are three general mechanisms by which a compound is cleared from the body: metabolism, biliary excretion, and renal excretion. Transporters also have a role in clearance: uptake transporters expose a drug to metabolic clearance in the liver, and efflux transporters are fundamentally involved in biliary and urinary excretory clearance.

Metabolism was discussed in section "**Determinants of bioavailability**" in the context of oral bioavailability, and the same major clearance organ (liver) and metabolic enzymes are responsible for systemic clearance as well. A set of energy-linked active uptake transporters, including OATP1B1 and OCT1 to name but two of many, often supplement simple permeation of drug molecules from blood into liver cells, thereby increasing their rate of metabolism.[19,70–72] In addition to metabolism, some drug molecules are subject to excretion in bile and/or urine. Almost all excretion into bile is mediated by active transport from liver cells into bile by efflux transporters, including P-gp, breast cancer resistance protein (BCRP), and bile salt export pump (BSEP).[19] Similarly, many drugs require active transport from kidney cells into urine by efflux transporters, including but not limited to multidrug and toxic compound extrusion protein 1 (MATE1), multidrug resistance-associated protein 2 (MRP2), and P-gp,[19] although some soluble compounds with low plasma protein binding such as antibiotics can be excreted into urine by the glomerular filtration process.

Recognition by these metabolic enzymes and transporters of a drug candidate as a substrate is a principal determinant of the magnitude of clearance and, therefore, the macromolecular component of the SAR of clearance for drug candidates. Since these macromolecules can be studied in various in vitro systems, they represent an important way for chemists to adjust clearance in a data-driven fashion to solve problems of either too short or too long *MRT*. In other words, fast metabolism leading to short *MRT* can be studied in vitro with liver microsomes or hepatocytes to design metabolism-resistant analogs whose in vivo PK can then be tested in animals, perhaps first in one of the rapid PK methods described in section In vivo determination of oral bioavailability and then in full conventional PK studies for final confirmation that the metabolic "fix" has worked. However, so far, there is little use of in vitro transporter systems to design molecules that don't get transported into liver cells in the first place.

4.01.2.3.5 Excretion

Excretion is not a property that chemists seek to optimize when designing a drug candidate, except to the extent that it is reflective of clearance of the parent drug, as discussed in the preceding text. However, excretion is an important property of the clinical action of a drug, as this process prevents the accumulation of parent drug and metabolites in the body during the chronic dosing that is typical of most drugs. Consequently, during lead optimization, a drug discovery program does not monitor the excretion of drug-related materials during the ADME/PK testing of the list of potential drug candidates sequentially examined, except occasionally as part of a high-clearance problem-solving exercise. But as part of the final selection of a clinical candidate, the discovery team does want to eliminate the possibility that incomplete excretion will present an unwelcome surprise if discovered halfway through clinical development when the clinical ^{14}C-ADME studied is conducted (see section "**Clinical ^{14}C-ADME study**"). Thus, a BDC rat study is often part of the characterization package of a nominated drug candidate. The BDC rat study collects bile and urine quantitatively typically over a 12- or 24-h period to estimate the "mass balance" of the drug. Plasma samples are also collected at selected time points to validate against known concentrations of the drug from the IV/PO PK study, as well as investigate the presence of circulating metabolites. Sometimes, the BDC study is done with radiolabeled drug candidate, but with the powerful MS methods available today, mass balance can be determined with reasonable confidence without the use of radiolabeled drug.

4.01.2.3.6 Computational approaches to ADME/PK problems

In the context of modulating rates of metabolism, we note that an even more elegant approach than simply synthesizing and then testing metabolism-resistant analogs would be to use in silico methods to predict metabolism before any wet synthetic chemistry is ever done. The feat of qualitative and quantitative prediction of metabolism has been studied extensively for almost three decades, and there is no doubt that progress has been made.[73] Some approaches use knowledge-based algorithms, based on similarity to the metabolism of other compounds reported in the literature, and others rule-based. Some approaches are much more focused, such as prediction of sites of metabolism by specific enzymes such as CYP 2C9,[74] CYP 2D6,[75] CYP 3A4,[76] other CYPs,[77,78] and SULTs[67] with the use of computational molecular docking. A closely related activity is to predict which CYP will recognize a new drug candidate as a substrate.[27] Because direct inhibition of CYPs leading to DDIs is such a ubiquitous problem, much energy has been invested in developing software for docking CYPs[67] and computational approaches.[79] All three of these CYP-related processes are possible because considerable effort has been expended toward determination of the three-dimensional crystal structures of various CYP enzymes.[80,81]

However, both aspects of metabolism prediction, qualitative and quantitative, must be reasonably accurate to be useful to the chemist designing molecules. It is not sufficient to predict the approximate point of hydroxylation of a molecule, because the chemist needs to modulate the exact point of attack. Similarly, it is not acceptable to misidentify the major metabolic pathway that is to be slowed down. Yet the difference in rate might be only a small factor that is hard to predict by molecular docking methods. For instance, a difference in rate of only three would result in reducing the percent of total metabolism represented by a particular pathway from 100% to 30%, yet this rate difference amounts to less than a single kcal mol^{-1} of activation energy in the metabolic reaction. In other words, a small amount of error in estimating the difficulty of a chemical reaction is magnified in the absolute rate. This effect produces big uncertainty in predicting which of several potential qualitative pathways (e.g., *N*-demethylation vs. benzylic hydroxylation vs. aromatic hydroxylation) will *actually* be the one that need to be modified, and the prediction becomes useless to the synthetic chemist. As a practical matter, then, there is much skepticism among the community of chemists about the value of in silico prediction of sites and rates of metabolism, and, so far, there has been limited uptake of such methods as a driver of lead optimization. Still, in silico prediction *can* be useful in planning chemical scaffolds to be pursued in optimization of a selected lead series.

Cumming et al.[82] have provided a useful explanation of compound quality and overview of various modeling approaches to improving the absorption, distribution, metabolism, excretion and toxicity (ADMET) quality of clinical candidates. An interesting alternative way of using computational approaches to solving ADME issues is the graphic representation of physicochemical parameters and various desirable ADME properties, allowing the medicinal chemist to visually inspect a data set and see what properties need to be adjusted to achieve the goal.[83] The problem of knowing the mechanism of clearance as the first step in solving problems of high clearance has been addressed by a process designated as the Extended Clearance Classification System[84] in which the chemist can examine a variety of physicochemical and other features of drug candidates to determine the most likely means by which they are eliminated.

However, not all computational approaches to predicting ADME/PK properties work well. A quantitative structure–PK relationship was developed to predict the biliary clearance and percentage of dose eliminated in bile in humans based on simple physicochemical descriptors. However, extensive evaluation of compounds beyond the training set showed poor predictive capability except within a series of structurally related compounds,[85] a result that is not surprising given that biliary secretion depends mainly on transporter recognition, not simple physical processes such as membrane permeability and solubility. On the other hand, modulation of renal clearance can be reasonably successful for various chemotypes by recognition of the physicochemical determinants of the process, much as we do with processes such as absorption and first-pass metabolism. Not surprisingly, the most important determinants are MW, lipophilicity, polar surface area, number of rotatable bonds, and number of hydrogen bond donors and acceptors.[86]

4.01.2.3.7 Screening for DDI potential

4.01.2.3.7.1 Occurrence of DDIs

Virtually, every marketed drug will, at least with some patients, be coadministered with other xenobiotics, including prescription drugs, over-the-counter drugs, herbal medicines, and nutritional supplements. The prescribing physician often is not aware of everything else that a patient is taking. Anytime that two xenobiotics are in the body simultaneously, there is a potential for the two to interact with one another at the levels of therapeutic efficacy, toxicity, and PK phenomena. PK DDIs are particularly common because many of the physiological systems responsible for drug metabolism and disposition are nonspecific, leading to the probability of competition of the two xenobiotics for the same enzymes and transporters. These interactions can result in bioavailability of one or both of the drugs to be increased or reduced, plasma levels to be elevated or diminished, *MRT* to be increased or reduced, metabolic profiles to be altered, tissue distribution to be affected, etc. It is the responsibility of the medicinal chemist to design drug candidates that do not produce such interactions and are themselves insensitive to the presence of other drugs. There are two main strategies by which this is accomplished. First, the chemist wants to build drugs that are highly potent and specific for the target receptors, so that the drug candidate has a wide therapeutic margin between plasma levels that produce efficacy and those that produce adverse effects, in case PK DDIs do occur. Second, the chemist wants to build drugs that are unlikely to interfere with the disposition of other drugs (i.e., be a perpetrator drug) or have its own disposition strongly affected by other drugs (i.e., be a victim drug).

4.01.2.3.7.2 Screening assays for PK DDIs

Coadministered drugs may affect each other's pharmaceutical, pharmacological, toxicological, and dispositional behavior. For the purposes of this article, we will discuss only the last of these, the PK DDIs. The three most important ways that drugs interact at the PK level are the following:

- Inhibition of an important metabolic pathway, thereby slowing clearance and increasing bioavailability and/or *MRT*
- Induction of an important metabolic pathway, thereby increasing clearance and decreasing bioavailability and/or *MRT*
- Inhibition or induction of a transporter involved in direct excretion or exposure of the drug to metabolism

The first of these, inhibition of metabolic clearance, is the most common and potentially most serious and therefore receives the most attention. Furthermore, among the metabolic enzymes, the CYP family is definitely the most inhibition-prone, for which there are two reasons. First, the CYP enzymes are able to interact with almost every type of drug molecule (see section "**Common metabolic reactions**" and **Table 1**), resulting in a much greater statistical chance for two drugs to share an enzyme. Second, the CYP enzymes tend to have much lower enzymatic K_M values than other metabolic enzymes, often in the same single-digit micromolar range in which drug plasma levels occur. Thus, the resulting "$[I]/K_i$" ratio can easily be of sufficient magnitude to cause significant competitive inhibition.

The second main cause of PK DDIs (induction) occurs when the presence of one drug causes elevation of the net expressed levels of an enzyme capable of metabolizing other drugs. Most commonly, this induction occurs at the gene expression level through xenobiotic-sensing nuclear receptors,[87] although other mechanisms also exist. Obviously, if the levels of a particular drug-metabolizing enzyme are elevated, then clearance of drugs that are metabolized by that enzyme will increase, and plasma levels will decrease. Several members of the CYP family (e.g., 1A2, 2B6, and 3A4) are highly inducible and, for the same statistical reason as in the preceding text, commonly lead to DDIs.

The third type of DDI, involving transporters, is much less common and usually of smaller magnitude than the other two when it does occur. Consequently, when a discovery program has to make hard choices about where to put scarce screening resources, assaying for transporter inhibition/induction is seldom chosen. However, investigation of transporter inhibition, induction, and substrate recognition will be discussed in section "**Definitive characterization of DDIs**" covering ADME/PK as an objective of phase 1 clinical studies in which we have a single compound that must be thoroughly characterized.

From the earlier considerations, it is easy to see why discovery-level screening assays for DDIs almost exclusively focus on CYP enzymes. What types of assays are needed for this purpose? Let us first discuss assays for CYP inhibitors, which fall into two distinct categories: direct and time-dependent.

Direct inhibitors are those that bind to the substrate-binding site of one or more of the CYP family enzymes, usually in a simple competitive fashion, directly preventing metabolism of other drugs by that CYP enzyme. These type inhibitors exert their effect immediately, and, because the binding is reversible, the inhibition is lifted when the inhibitor is removed from the environment of the enzyme, as, for instance, by dialysis of an in vitro incubation mixture or by clearance of the inhibitor in vivo. Direct inhibition is the type most commonly encountered during lead optimization and also the easiest to detect. We measure the strength of the inhibition by the operational parameter IC_{50}[88] for each of several CYP enzymes that are most likely to metabolize drugs (typically 1A2, 2B6, 2C9, 2C19, 2D6, 2E1, and 3A4 or a subset of these).[89,90] The actual assay is an in vitro incubation of the test article with a metabolism-competent system such as cDNA-expressed single human CYP enzymes or human liver microsomes with enzyme-specific substrates. In most cases, assay of the metabolic reaction is accomplished with LC-MS/MS,[88] but systems using substrates that produce a fluorescent metabolite are also popular.[91]

For discovery lead optimization screening purposes, the assay is usually based on human liver microsomes, and CYP specificity is achieved by the use of a series of substrates that are metabolized by only one of the CYP enzymes. The degree of inhibition of the selected CYP is measured at several concentrations of the test article spanning the concentration range of interest for the plasma levels expected to be pharmacologically relevant in the clinic, for example, 0.03–30 μM. From the data so generated, the IC_{50} value may be calculated and the corresponding competitive inhibition constant (K_i) derived.[88] The chemist may use the K_i data in a cutoff fashion to screen out drug candidates that are likely to cause clinical CYP-based DDIs. For instance, a common paradigm is to designate ranges such as $K_i < 1$ μM (likely to cause drug interactions), K_i 1–10 μM (may cause drug interactions), and $K_i > 10$ μM (unlikely to cause drug interactions). Obviously, the ranges and interpretations given will depend on the expected clinically relevant plasma concentrations of the drug candidate.

DDIs resulting from competitive inhibition of a metabolic enzyme such as a CYP are governed by Eq. (9):

$$CL_{int} = \frac{V_{max}}{K_M\left(1 + \frac{[I]}{K_i}\right) + [S]} \tag{9}$$

where CL_{int} is the intrinsic clearance of that CYP enzyme to metabolize a victim drug, K_M is the Michaelis constant for the victim drug, $[I]$ is the concentration of the inhibitor drug, K_i is the competitive inhibition constant of the inhibitor drug for the CYP in question, and $[S]$ is the concentration of the victim drug. Related equations may be written for other types of enzyme inhibition, such as uncompetitive and noncompetitive. To make this equation a little simpler, further suppose that the victim drug, which is a substrate for CYP 3A4, is present at a concentration well below its K_M for CYP 3A4 (i.e., $[S] \ll K_M$), yielding Eq. (10):

$$CL_{int} = \frac{V_{max}}{K_M\left(1 + \frac{[I]}{K_i}\right)} \tag{10}$$

To illustrate the utility of this equation in the context of DDIs, suppose a drug candidate has a K_i of 1 μM for inhibition of CYP 3A4 and the expected clinical C_{max} is 10 μM. Note that in the following derivation, we are using the total plasma concentration as a surrogate for the intracellular concentration experienced by the drug-metabolizing enzymes. Although this assumption is not rigorously correct, it often gives a reasonable estimate of the net inhibitory effect of plasma drug concentrations on drug-metabolizing enzymes. In any event, this assumption is used in regulatory guidances for estimating the inhibitory potential for drug candidates[28,29] and is thus useful for discovery screening for eliminating candidates highly likely to cause DDIs. Turning our attention back to Eq. (10) and taking the ratio of the CL_{int} values in the presence and absence of the inhibitor drug, we can write the observed reduction of clearance of the victim drug as Eq. (11):

$$\frac{CL^*_{int}}{CL_{int}} = \frac{1}{1 + \frac{[I]}{K_i}} \tag{11}$$

where CL_{int}* is the reduced clearance of the victim drug in the presence of the inhibitor drug. In this example, clearance of the victim drug will be reduced to only 9% of its value in the absence of the inhibitor. One can readily see that the ratio $[I]/K_i$ is crucially important in determining the magnitude of a drug interaction caused by competition of two drugs for the same CYP enzyme. Simple inspection shows that even when the inhibitor drug is merely present at its K_i value, a reduction of clearance of the victim drug of 50% will occur. Thus, we see that if we expect the clinical C_{max} of a new drug candidate to be 10 μM, we will want its K_i value to be well above 10 μM to avoid clinically significant DDIs. Conversely, a drug candidate with expected C_{max} of 0.1 μM would be free of DDIs even with a K_i value of 1 μM.

Time-dependent inhibitors are those that do not exert their full inhibitory effect immediately, but may require minutes or even hours to reach maximal inhibition. The proximal inhibitory species is not the parent drug candidate per se, but rather a reactive intermediate formed by the action of the enzyme during the process of metabolism of the candidate. Typically, the reactive intermediate is an electrophile that reacts with a nucleophile from the enzyme resulting in covalent binding of a drug residue to the enzyme. With a large drug fragment covalently attached at or near the active site of the enzyme, additional drug molecules are sterically denied access to the active site, and that particular enzyme molecule has been permanently inactivated, even if the parent drug is subsequently cleared from the system. New drug-metabolizing activity is only restored by de novo protein synthesis of the enzyme molecule. The time dependency represents the amount of time required for the metabolic and subsequent covalent binding events to occur. Time-dependent inhibitors are often also called mechanism-based or metabolism-based inhibitors.

Detection of time-dependent inhibition is based on measuring enzyme inhibition as a function of time. For the purposes of rapid screening of a set of candidate compounds during lead optimization, the so-called shift assay is utilized. In this assay, the enzymatic assay toward a probe substrate for the enzyme of interest (e.g., midazolam for CYP 3A4) is tested after a preincubation period (usually 30 min) of the enzyme with several concentrations of the test article. From these data, an apparent K_i value for the test article is calculated. This apparent K_i is then compared with the K_i observed when the test article and probe substrate are added simultaneously. A significant difference in these two values of K_i (i.e., a shift) indicates that the inhibitory effect of the test article on the enzyme has changed over the period of 30 min. The K_i value can (1) decrease, indicating that the test article has apparently become more inhibitory with time, (2) be unaffected (within experimental error), or (3) increase, probably indicating that the concentration of the test article had been significantly depleted during the preincubation period by metabolism. In case (1), where a compound shows time-dependent inhibition, the compound may have been metabolized to a reactive electrophilic metabolite that inhibits the enzyme, as discussed in the preceding text. Note that it is theoretically possible that the compound was converted to a nonreactive metabolite that happens to be a much more potent direct inhibitor, but this is rarely observed.

Assuming that the time-dependent inhibition is due to covalent inactivation of the enzyme, then one must interpret the data in order to decide whether to eliminate the compound from further consideration as a candidate. This decision obviously has a measure of judgment involved in it, but a good rule of thumb is that if the K_i shift is 10× or more and the resulting shifted K_i is in a "danger" region for DDIs, then the compound probably should be eliminated. For example, a compound whose K_i shifted from 30 to 1 μM by a 30-min preincubation period is likely a true time-dependent inhibitor that will cause important clinical DDIs, and it should be discontinued in the lead optimization process. The usual procedure is to place the CYP inhibition "shift assay" in a second- or third-tier position in the screening paradigm (see section "**Triage of ADME/PK screening assays**") because it is more resource-intensive than the simple direct inhibition assay. Another question involves which CYP enzymes should be screened for time-dependent inhibition during lead optimization. Although it is possible to test all CYP enzymes that were tested for direct inhibition, as a practical matter, only two of the CYPs (1A2 and 3A4) have an appreciable likelihood of suffering time-dependent inhibition and represent a good use of discovery resources.

To illustrate time-dependent inhibition, we can consider bergamottin, a natural product found in grapefruit juice, that is a potent time-dependent inhibitor of CYP 3A4. Oxidation of bergamottin generates an arene oxide on the benzofuran group, which ring-opens to a γ-ketoenal Michael acceptor that reacts with the amide nitrogen of residue glutamine-273 in the 3A4 primary structure (a simplified representation of this process is shown in **Fig. 1**).[92] Covalent attachment of the bergamottin residue interferes with proper folding of the protein backbone and disrupts the structure of the active site, effectively quenching catalytic activity of the 3A4 enzyme. Another 3A4 time-dependent inhibitor, raloxifene, has been shown to be oxidized to an extended quinone structure that is captured by cysteine-239, blocking the substrate access channel.[93] Many other examples of time-dependent inhibition of CYPs are known, and a rich variety of electrophilic chemistries are displayed,[94,95] making the job of predicting these events by

4.01.3 The Importance of ADME/PK in Safety Assessment

4.01.3.1 Early Toxicity Assessment

Often, the drug discovery program incorporates one or more assays to assess the toxicity potential of representative members of the most important chemotype series during lead optimization or perhaps as part of the final selection process between several possible nomination candidates. Most often, the assay is cell-based, investigating simple cytotoxicity or the more complicated hepatotoxicity.[99] As with ADME/PK, a number of computational approaches to predictive drug toxicity have been reported.[100,101] Hornberg et al. have proposed a comprehensive and integrated approach to early toxicity assessment that even includes exploratory in vivo rodent toxicity studies.[102,103] While these approaches should certainly be utilized to some extent during the drug discovery process, the medicinal chemist should not conclude that a series or an individual compound is "clean" based on favorable assay results, since in vitro and in silico are fundamentally limited in their abilities to predict toxicity (or lack thereof). However, a strongly positive indication of toxicity in an in vitro or in silico assay system should probably be taken at face value and that compound discontinued. If a structurally distinct analog from the same series shows similar toxicity, then the entire chemotype is brought into question. In vivo animal exploratory safety studies offer a much better chance of picking up toxicities and providing a level of comfort in their absence. However, the obvious limitations of compound mass requirement and time required to conduct the study mitigate against frequent use of this type of assay except for one or two compounds at the end of the discovery program.

4.01.3.2 Reactive Metabolites

Toxicities due to metabolites, not the parent drug, are well documented in the literature. For instance, efavirenz produces a nephrotoxic glutathione-adducted metabolite. Extensive cross-species comparison studies showed that this particular metabolite was produced only in rats, clearing a way to the clinic for this important HIV drug. Mechanistic work established that a reactive metabolite of the disubstituted acetylenic bond was the key step in production of the ultimate toxin.[104] This was an early example of what has become recognized as a frequent occurrence during drug metabolism, namely, the formation of reactive electrophiles that are capable of capturing various cellular nucleophiles, especially protein-derived nucleophiles such as lysine amino groups, cysteine thiols, and serine hydroxyls, leading to intracellular damage and possible cytotoxic and immunogenic effects.[105,106]

It is now common for drug discovery programs to incorporate various strategies for the detection of reactive metabolites and provide structural feedback to medicinal chemists on how to remediate the problematic functional group.[107] Many functional groups and molecular features have now been reported to be capable of electrophilic activation, most often by CYP-mediated oxidation. Because of the rich oxidative chemistry of the CYP iron-oxo intermediate (see section "**Common metabolic reactions**"), these events are often nonintuitive and difficult to anticipate, requiring an empirical approach to detect them.

In addition to the well-known example of furan-containing drugs generating reactive metabolites,[108] many other types of molecular configurations are also known to generate reactive metabolites, in not obvious ways, for instance, imidazothiazoles,[109] and vanilloid rings.[110] Lenz et al.[107] discovered that a homomorpholine ring, which most chemists would surely regard as innocuous, was metabolically activated to an unstable thiazolidine. The cannabinoid receptor antagonist rimonabant was oxidized to a cytotoxic iminium ion.[111] There are even cases when the CYP-mediated oxidative formation of a reactive intermediate produces the actual pharmacologically active molecular species. The tetrahydrothienopyridine antithrombotic drugs (ticlopidine, clopidogrel, and prasugrel) are metabolized to electrophilic thiolactone sulfoxides as precursors of the proximal antagonists of the platelet receptor P2Y12.[112]

There are also examples of reactive metabolites formed by non-CYP enzymes, such as SULTs, which can create an excellent sulfate leaving group on aliphatic hydroxyl groups as a precursor to an electrophilic intermediate.[113] Another example of non-CYP-produced electrophilic reactive metabolites is the acyl glucuronides, which are glucuronosyl esters of carboxylic acid drugs, that can react either by direct acylation of cellular nucleophiles or by rearrangement to form an aldehyde capable of reacting with amine groups of proteins to form covalent imine bonds.[114,115] Acyl glucuronides vary widely in their ability to covalently modify proteins, and it is possible to assess their potential of this potentially toxic reaction.[116]

The only chance in the development of a clinical candidate to avoid reactive metabolites is during discovery lead optimization and final candidate selection. Once the clinical candidate is chosen, one must live with whatever safety liabilities are carried by that molecule. Thus, it is important to assess the potentiality for reactive metabolites during discovery while there is still a chance to change the selection.[117–119]

4.01.3.3 In Vivo Toxicology Assessment

Having selected a single compound for clinical development, it is now necessary for a development sponsor to determine with definitive studies what ADME/PK profile has actually been achieved. A subset of these studies is conducted to enable the preclinical safety program. Because of the focus of this article on ADME/PK, we will only discuss safety of the parent drug itself to a limited extent, but will draw attention to the phenomenon of toxicity related to the production of various metabolites that may have safety profiles quite different from those of the parent drug. However, to understand the context in which metabolites are important in safety, it is necessary to briefly introduce the general outline of the preclinical safety program that is required to support the regulatory application for an investigative new drug.

The preclinical safety program investigates the limits of safe exposure of animal species to the clinical candidate that has been delivered from the discovery program. The core of the safety program is a series of increasingly long chronic dosing studies at several dose levels in at least one rodent and one large animal species (typically dog or monkey). During the "in-life" phase, blood samples are taken at appropriate intervals and analyzed for concentrations of the clinical candidate to estimate simple PK measures of exposure, such as C_{max}, C_{min}, and *AUC*. At the end of the in-life phase of an animal safety study, toxicologists and pathologists examine the animals in various ways for evidence of toxic effects of the clinical candidate. These examinations include clinical chemistries, morbidity, mortality, and dissection with both macroscopic examination of organs and microscopic inspection of many types of tissues.

The final report from a completed study will, ideally, identify the major toxicities and most affected organs (if any) of the candidate. From a comparison of the PK exposure data with the observed occurrences of toxicities, the report will also assess whether a "safe" exposure was observed, usually expressed as a dose labeled "no observed adverse effect level" (NOAEL). A related observation is the "maximum tolerated dose," which is the daily dose that the animals can tolerate for long intervals, though not necessarily without some minor degree of morbidity. And most importantly, the study should assess what dose constitutes an "effect level" and what specific toxicities are associated with that dose. This information establishes the limits of exposure to the candidate that may be accessed in phase 1 clinical trials. As a general rule, but with some exceptions, the phase 1 clinical PK exposures should not exceed the NOAEL established for the more sensitive one of the two preclinical safety species. The ratio of these two exposures (NOAEL/clinical dose) is called the "exposure multiple." Going forward, the preclinical safety program leads the clinical program, investigating longer exposures that allow longer studies in later stages of clinical

development. Thus, a goal of the discovery program is to produce a drug sufficiently potent that the efficacious clinical exposure is much less than that from the NOAEL.

One of the preliminary activities is a dose range-finding study to determine the low and high doses that will actually be used in the preclinical GLP safety studies. Part of dose range-finding is to determine the relation between administered dose and systemic exposure of the animal to parent drug. The highest dose used for dose range-finding will typically be one for which the plasma levels of drug as a function of dose either reach a maximum plateau or, conversely, tend to increase unpredictably. The first effect is due to saturation of absorption, while the second is due to saturation of clearance and excretion. This dose–exposure relationship usually has no fundamental importance for the clinical behavior of the drug because the toxicological doses are much higher than the clinical efficacious doses. Thus, these saturation phenomena serve merely as operational parameters relating to the feasibility of conducting a preclinical safety investigation beyond a certain top dose.[120]

4.01.3.4 Metabolites in Safety Testing

Both the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA) require that safety assessment be conducted with major circulating plasma metabolites in addition to the parent drug.[121,122] The basic requirement is to establish that at the NOAEL dose in at least one of the preclinical safety species each major metabolite is present at an exposure level equal to or greater than its corresponding exposure in the pharmacologically relevant clinical dose. A major human metabolite is operationally defined as one that comprises more than 10% of the total exposure to drug-related material in the plasma. Exposure is measured as *AUC* at PK steady state. In most cases, the so-called "Metabolites in Safety Testing (MIST)" requirement is met by demonstrating that these metabolites were present at adequate levels in animal safety studies. Large-scale clinical trials, understood to refer to clinical phase 3, cannot proceed until safe exposures are delineated for major metabolites.

Therefore, to avoid a delay in the start of phase 3, a sponsor must identify major metabolites early in phase 1, so that there is adequate time to determine whether there is a problem and take remediation steps if necessary. The power of contemporary LC-MS methods to discover metabolites of the parent drug without resort to radiolabeling is of great utility in this regard (see section "**Addressing high first-pass clearance**"), allowing clinical plasma samples from phase 1 single- and multiple-ascending dose (SAD and MAD) studies to be directly scanned for the presence of metabolites. A problem of quantitation of metabolite concentrations in plasma results when, as is often the case, authentic standards of the major metabolites do not yet exist. However, clever methods have been published to use ratios of either metabolite/parent or metabolite/internal standard derived from animal and human plasma to estimate the relative exposure of the metabolite in animals and humans.[123–125] Useful examples of checking for "MIST" metabolites in early clinical development have been published.[126–128]

When exposures to a major metabolite in animals are substantially lower than the corresponding exposures in humans, then the safety of the metabolite has not been established by the standard animal safety study, and it must be considered that human beings are being exposed to a chemical compound of unknown toxic potential. In that case, a different approach must be used to assess safety of the metabolite in question. The two available methods are (1) identification of another animal species that *does* display adequate plasma levels of the metabolite and conduct a safety study of the clinical candidate in that species and (2) synthesis of the metabolite followed by direct study of its safety in one or more animal species. Option (1) is unattractive because it involves running additional unplanned safety studies, assuming that a suitable alternative species can even be found. Option (2) is also unattractive, since the metabolite must be prepared in kilogram quantities with GLP methods before a separate study of its safety can be conducted. Obviously, both options (1) and (2) will considerably add to the development timeline. Thus, it is advisable for the discovery program to compare the metabolites formed in human and animal hepatocytes as part of the ADME/PK characterization package during clinical candidate nomination. A clear absence in the animal hepatocytes of a major metabolic pathway in human hepatocytes should raise a caution flag. While in vitro metabolic profiles do not definitively predict in vivo metabolic profiles, they can at least somewhat derisk the clinical candidate. Ma and Chowdhury have provided an overview of the regulatory aspects of metabolites in drug development.[129]

4.01.4 The Importance of ADME/PK in Clinical Development

4.01.4.1 IND-Enabling ADME/PK Studies

4.01.4.1.1 Purpose of IND-enabling ADME/PK studies

As pointed out in section "Right-Box" analysis, once a single compound has been selected for clinical development, no additional chemical modifications can be made, and the role of the medicinal chemist ends, at least for that compound. Of course, process chemistry comes to the forefront, but that activity does not have an ADME/PK component and will not be discussed here. In this section, we will discuss the ADME/PK-related activities that occur in the IND-enabling period and the clinical development program. Because the main purpose of this article is to discuss the role of ADME/PK in the discovery and development of new drugs from the perspective of the medicinal chemist, the discussion of the ADME/PK activities will not be as detailed as those given for the discovery section. Mainly, we will focus on what is done and why it is important for the understanding and registration of a new chemical entity (NCE). This information will illuminate why it was important to optimize ADME/PK in discovery, when it was still possible to do so.

Having selected a single compound for clinical development, it is now necessary to determine with definitive studies what ADME/PK profile has actually been achieved. This profile includes the large and small species selected for GLP safety studies as well as other animal species that may be useful in characterizing the in vivo profile for purposes of understanding ADME/PK, pharmacology, off-target pharmacological effects, and adverse events. Most importantly, the sponsor will need to characterize the human in vivo ADME/PK profile, which up to this point relied on in vitro studies and extrapolation from animals for assessment.

As part of the Investigational New Drug (IND) application, we need to show regulatory authorities evidence that the drug candidate can likely be systemically delivered to clinical subjects, that it will likely persist in the body long enough to give a therapeutic benefit within a practical dosing regimen, that the potential for DDIs is at least partially understood, that significant active metabolites in the pharmacological model species have been detected and can be monitored in early clinical studies, and that preclinical safety studies likely exposed animals to the same major metabolites as humans. A sponsor is expected to make a good faith effort to provide a reasonable level of such prospective ADME/PK information before putting an NCE into human beings. However, in the real world, it is not feasible for an IND application to contain full information on all of these topics, and regulatory authorities recognize this reality. But an application that contained no information on any of these topics would be judged inadequate, and approval might well be delayed until basic ADME/PK information was provided.

4.01.4.1.2 Animal PK and bioavailability

The full IV/PO pharmacokinetics of the drug candidate should be presented in the IND application, providing a comprehensive determination of the PK parameters in several species. If this information is not already available from discovery, appropriate studies should be conducted in the IND-enabling period. The species studied should be both the rodent and large animal species used for pre-IND safety studies, plus one or two others, including the pharmacological animal model if applicable. This provides an evidential basis for the claim in the IND that the compound is expected to be orally bioavailable in humans. It also provides the PK parameters such as CL and V_{ss} that are used for human PK prediction. In addition, if PK in the pharmacological animal model was determined at a pharmacologically efficacious dose, the C_{max} and AUC data from that study are very useful in predicting the human efficacious dose. Eventually, a definitive GLP study of animal PK will be conducted as part of the animal ^{14}C-ADME study (see section "**Clinical ^{14}C-ADME study**"), but often, a scientifically valid non-GLP study conducted during candidate characterization in the last stage of discovery leading to nomination is adequate to be used for these purposes in the IND application.

4.01.4.1.3 Major routes of clearance in animals

As with animal pharmacokinetics, regulatory approval of a new drug requires full characterization of the routes of clearance and excretion of the drug and its metabolites in appropriate animal species, normally the rodent and large animal species used in animal safety studies. These studies are usually run in a GLP mode and are based on ^{14}C-radiolabeled drug. As such, there is no time to conduct two fully definitive animal ADME studies (or even one) during the IND-enabling period, and they are instead planned to begin after phase 1 SAD and MAD studies (see section "**Clinical pharmacokinetics**") have been completed, when it is more clear whether the NCE is a viable clinical candidate. To meet the requirement for animal ADME data in the IND application, then, it is desirable to collect animal metabolism and excretion data in non-GLP but scientifically valid studies during the discovery stage as part of clinical candidate nomination process.

Animal ADME studies have the triple goals of establishing the so-called mass balance, defining the mechanisms of clearance, and identifying plasma circulating metabolites (see section "**Active circulating metabolites in animals**"). "Mass balance" refers to quantitative excretion of the drug in a reasonable amount of time, either as unchanged parent drug or as metabolites. This is established by exhaustive collection of urine and feces and determining the total amount of drug-related material in these excreta, ideally with the use of ^{14}C-radiolabel as a means of detection. In some special cases, depending on the metabolic pathways present and the location of the ^{14}C-radiolabel in the molecule, expired $^{14}CO_2$ may need to be collected in special sealed environment chambers. The mechanisms of clearance are established by assessing the relative amounts of parent drug to metabolites in the excreta. Drugs that are cleared mainly by direct renal excretion of unchanged parent drug, for example, some antibiotics, will show almost the entire excreted dose in the urine. Conversely, a drug that shows little parent drug but almost entirely metabolites in either urine or bile must have been cleared mainly by initial metabolism of the parent drug. Identification of the chemical structures of the metabolites reveals which drug-metabolizing enzymes were involved. For example, if the predominant metabolite was formed by hydroxylation of an aromatic ring, then the CYP enzyme family was mainly responsible for clearance (see **Table 1**).

In recent years, some important leaders in the ADME/PK discipline have suggested that these animal ^{14}C-studies provide little benefit and should be discontinued,[130] but some others have felt uncomfortable about administering an NCE to a large number of humans without knowing as much as possible about its disposition in animals first.[131] Thus, at least until such time as regulatory authorities advise otherwise, sponsors continue to provide animal ADME data in the IND and NDA.

4.01.4.1.4 Active circulating metabolites in animals

As mentioned in the previous section, an important goal of animal ADME studies is to discover and identify metabolites circulating in the plasma. Since these metabolites are in the blood, they potentially can partition into all tissues, although some organs such as the brain have barriers between the tissue and plasma that may limit exposure. A special situation arises when one or more of these metabolites have significant pharmacological activity, since they may actually make a significant contribution to the expressed therapeutic benefit. Determination of whether circulating active metabolites are present is important in the interpretation of the expressed efficacy of the drug in the animal pharmacological model. Consequently, if circulating active metabolites are discovered

in animal plasma, the search for these metabolites in human plasma becomes a high priority in early clinical trials (this topic will be further discussed in section "Circulating human metabolites").

4.01.4.1.5 Projection of human PK

Planning for the conduct of clinical trials for a drug candidate requires some estimation of the range of human doses that will be explored, since we want to be sure that the corresponding exposures were covered in the GLP preclinical safety studies. Equally importantly, we need to estimate the number of milligrams of drug that will need to be combined with excipients in the solid dosage formulation to be used, and we have to plan a process chemistry campaign sufficient to provide the needed number of kilograms of active pharmaceutical ingredient (API) to support the planned clinical program. These needs require a preclinical method to estimate the efficacious dose, and the usual method is through allometric scaling.[132,133] In this procedure, the known PK parameters of three, or preferably four, animal species are used to project the corresponding parameters in humans. A parameter such as *CL* or V_{ss} is plotted against standard physiological parameters such as body mass and body surface area[65] in a double-log fashion to achieve a straight line. Extrapolation of the line to the corresponding physiological value for humans provides an estimate of the PK parameter in humans. Next, the *AUC* determined from an efficacious dose in the animal pharmacological model can be, with several assumptions, adjusted up or down based on the relative K_i values of the drug toward the target receptor to derive the *AUC* expected to be associated with efficacy in humans. With estimates of human *AUC* and *CL*, one can project the dose to be expected in humans by use of Eq. (7). Similarly, with estimates of *CL* and V_{ss}, the human *MRT* can be estimated by use of Eq. (6). These human projections are subject to several sources of uncertainty and error, so they must be conducted with experienced pharmacokineticists. Even so, the estimates of dose and *MRT* must be treated as only approximations useful for planning purposes. Thus, one can see the practical value of good animal PK studies prior to the initiation of phase 1 clinical trials.

4.01.4.1.6 Initial in vitro assessment of clinical DDI potential

In recent years, regulatory agencies have become more concerned about the safety of drugs due to DDIs. They are especially wary of DDIs in early clinical trials, when even the safety of the new drug candidate itself as a single agent is not yet fully understood. Consequently, a sponsor is expected to take measures to minimize the chance for DDIs by either investigating them in early clinical studies or severely limiting recruitment of subjects by imposing strict exclusion criteria based on comedications that the subjects may be taking. Since both of these options have the effect of slowing down early clinical development, regulatory agencies have provided a written guidance on how to test for DDIs with preclinical in vitro DDI studies.[28,29]

These documents provide a means for the sponsor to assess the potential for serious DDIs and in some cases avoid both the need to conduct some clinical DDI studies and the need to impose restrictive exclusion criteria. In vitro studies of the potential for the drug to inhibit, induce, or be a substrate for certain biochemical systems important in drug metabolism are delineated for the CYP and UGT families of enzymes, as well as a number of drug transporters. If the sponsor can show that the NCE interacts only insignificantly with any of these systems at expected clinical plasma concentration, then the sponsor may be able to proceed with phase 1/2 studies without having to first conduct clinical DDI studies with the drug-metabolizing systems that were "clean."

It is recognized that even doing in vitro studies rather than full clinical DDI studies is a substantial burden if they must all be accomplished prior to submission of the IND application. Therefore, the usual approach is for a sponsor to provide scientifically valid study results on the enzyme systems that most frequently cause clinical DDIs and then exclude a much smaller set of comedications that are of concern for a DDI. Thus, it is recommended that during the last stage of discovery and candidate nomination, a sponsor conduct (a) valid in vitro studies on inhibition and induction of CYP enzymes and (b) a study of substrate recognition by the efflux transporter P-gp. This subset of the guidance-required studies can be included in the IND application. The full list of recommended in vitro DDI studies can then be completed while phase 1 proceeds (this topic will be further discussed in section "Definitive characterization of DDIs").

4.01.4.2 Clinical ADME/PK Studies

4.01.4.2.1 Clinical pharmacokinetics

Up to this point in the discovery and development program, all information about human PK derived from use of in vitro human systems, such as hepatocytes, and extrapolations from animal in vivo studies. Now, in phase 1, the sponsor will determine in clinical dosing studies the true human ADME/PK properties of the drug candidate, including basic PK parameters, PK DDIs, presence and biological activities of circulating metabolites, relationship between plasma levels and therapeutic efficacy (pharmacokinetics/pharmacodynamics or PK/PD), and the interindividual variation of PK parameters in the patient population (population PK). Ideally, the results of the preclinical in vitro human and in vivo animal ADME/PK studies have been adequately predictive of the actual human ADME/PK profile of the candidate so that no big surprises are encountered. However, the science of in vitro-to-in vivo and animal-to-human extrapolation is not mature yet, and discrepancies between preclinical estimates and clinical reality are not uncommon.

Phase 1 clinical trials establish the safety, tolerability, and PK properties of a drug candidate in human beings. The subjects of phase 1 are normal healthy volunteers, although patients may be the subjects in cases where there is a known risk associated with the drug candidate, such as with cytotoxic cancer drugs. PK is determined in two foundational studies, the SAD and MAD studies. The route of dosing depends on the intended route of administration for the ultimate marketed product, typically oral, but possibly intravenous, intramuscular, or subcutaneous instead.

SAD involves giving each subject a single dose of the drug, with separate cohorts being singly dosed at escalating levels. MAD involves giving each subject several doses at a single dose level. Usually, doses are given once a day for 1 or 2 weeks. As with SAD, separate cohorts are dosed at escalating levels. Blood samples are collected from subjects at preselected time points based on the expected PK profile from animal studies and human PK prediction. Plasma concentrations are measured by LC-MS/MS in almost all cases of small-molecule drugs. The following PK parameters are then calculated: C_{max}, T_{max}, *AUC*, apparent volume of distribution (V_{ss}/F), apparent systemic clearance (CL/F), *MRT*, and terminal elimination half-life. An additional goal of the MAD study is to determine the time to reach PK steady state (usually defined as a state in which sequential predose trough levels of the drug are constant) and to define the average plasma level achieved at steady state. A plasma concentration versus time profile at steady state that deviates significantly from that predicted from simulations based on SAD data suggests that the PK of the drug changes with chronic dosing, possibly indicating a decrease in clearance due to a toxicity or an increase in clearance due to an autoinduction phenomenon. It is recommended for oral drugs that a separate single intravenous dose be given at an appropriate pharmacologically relevant dose level, allowing calculation of oral bioavailability (F) and the true values of V_{ss} and CL. Other PK-related phase 1 studies are usually conducted to determine the effects of food on oral bioavailability and of renal and liver impairment on clearance. Additionally, studies of PK as a function of age, gender, and pediatric applications may be required.

In phase 2, the subjects are patients with the disease or condition to be treated. These studies determine if the drug is actually therapeutically effective, and they tend to use one or two dose levels near the top of the tolerated dose range so that the drug candidate has the best possible chance to work. If the drug is intended for a new biological target, this may well be the first human in vivo test that modulation of the targeted receptor can actually provide a benefit, and so, phase 2 is sometimes called "proof of concept." PK is very important in phase 2 for two reasons. First, we must know if the PK is altered in patients compared with healthy volunteers. Second, if the drug failed to demonstrate POC, we can determine if the plasma levels expected to show efficacy were achieved and held long enough. Conversely, if POC was achieved, then we have the beginnings of a PK/PD relationship, which will be an expected part of the regulatory end-of-phase 2 (EOP2) meeting to justify the proposed doses for phase 3.

In phase 3, the need to collect PK information from the patients continues. Phase 3 is normally the first investigation of the drug in a large number of patients, unlike phases 1 and 2 in which much smaller numbers were examined. It therefore offers the opportunity to get statistically meaningful correlations of plasma levels and therapeutic effect, allowing the construction of the full PK/PD relationship. Regulatory authorities expect a sponsor to at least identify a nonefficacious dose, a minimally effective dose, a dose giving nearly full efficacy (perhaps 80%), and a dose that gives even higher efficacy, but at the cost of increasing adverse event issues, possibly to unacceptable levels. This understanding of the balance of safety and efficacy will be essential to select, in concert with regulatory authorities, the exact doses to be marketed. In addition, the large data set in phase 3 allows a population PK relationship to be created. In "Pop PK," statistical methods are used to create a generic PK profile for the drug that is then fine-tuned by identifying "covariates" drawn from readily obtainable demographic, physiological, or genetic characteristics such as age, gender, body weight, body mass index, race, ethnicity, and CYP genotype. The resulting Pop PK relationship can be useful in selecting the proper dose for a particular individual. The FDA encourages the sponsor to combine all of the available PK date to construct a physiologically based mathematical model of the PK of the new drug to demonstrate a complete understanding of its disposition in the human body.[134,135]

4.01.4.2.2 Definitive characterization of DDIs

Agency guidances (FDA and EMA) on clinically significant DDIs cover those resulting from competition between two drugs for metabolic enzymes (CYPs and UGTs), competition for clearance-related transporters, and induction of enzymes (CYPs) and transporters. The guidances encompass DDIs arising from the NCE as both a perpetrator and a victim. Thus, all NCEs must be investigated as both an inhibitor and inducer of CYPs, UGTs, and transporters (i.e., NCE is a perpetrator). In addition, if an NCE is a substrate of one of these systems, then a second drug has the potential to inhibit or induce its clearance (i.e., NCE is a victim). Thus, substrate phenotyping of the particular enzyme in the families of CYPs, UGTs, and/or transporters may also be required. Although these are the recommended systems to be studied because they are involved in the vast majority of known DDIs, in some cases, other enzyme systems not in these lists may still require investigation. In addition, major metabolites must be investigated for in vitro DDIs through the same guidance process, since there are a number of documented cases of major circulating metabolites being the cause of DDIs.[136–141] An extensive analysis of the situation of metabolites being CYP inhibitors has been provided by Callegari et al.[142] The process outlined in agency guidances for in vitro investigation of DDIs is structured as follows:

Metabolism-based DDIs
Drug candidate as a perpetrator of DDIs
 Inhibitor of DM enzymes
  CYP enzymes
   Direct inhibition (1A2, 2B6, 2C8, 2C9, 2C19, 2D6, 3A4)
   Time-dependent inhibition (1A2, 2B6, 2C8, 2C9, 2C19, 2D6, 3A4)
  UGT enzymes (1A1, 1A3, 1A4, 1A6, 1A9, 2B7, 2B15)
 Inducer of DM enzymes
  CYP enzymes (1A2, 2B6, 3A4)
  UGT enzymes (1A1, 1A4, 1A6, 1A9, 2B4 2B7)

(Continued)

Drug candidate as a victim of DDIs
Metabolic enzyme substrate phenotyping
CYP enzymes (1A1, 1A2, 1B1, 2A6, 2B6, 2C8, 2C9, 2C18, 2C19, 2D6, 2E1, 2F1, 2J2, 3A4, 3A5, 4F2)
UGT enzymes (1A1, 1A3, 1A4, 1A6, 1A9, 2B7, 2B15)
Transporter-based DDIs
Drug candidate as a perpetrator of DDIs
Inhibitor of drug transporters (P-gp, BCRP, OATP1B1, OATP1B3, OAT1, OAT3, OCT2)
Inducer of drug transporters (CAR and PXR nuclear receptors may induce transporters)
Drug candidate as a victim of DDIs
Transporter substrate phenotyping (P-gp, BCRP, OATP1B1, OATP1B3, OAT1, OAT3, OCT2)

The long experimental process entailed by the outline of regulatory DDI requirements in the preceding text means that typically only part of the work has been completed by the initiation of phase 1. It is generally understood that the agencies expect this work to be completed by the time of the EOP2 meeting. However, most sponsors lag behind this expectation and often have a comment by the agencies in their report of the EOP2 meeting that the remaining unfulfilled studies must be completed before phase 3 can proceed. In cases where only a discovery-level assessment of some of the in vitro DDI phenomena has occurred, the sponsor will be required to bring the quality of the studies up to full scientific rigor. For instance, if MBI was investigated previously with only the shift assay (see section Screening assays for pharmacokinetic drug-drug interactions), then the full MBI assay should be pursued in which the fundamental inhibition parameters K_i and k_{inact} are determined. These parameters can be used to provide much more accurate predictions of the risk of serious clinical DDIs due to MBI.[143] Similarly, if only the discovery-level assessment of induction based on activation of nuclear receptors was used for the IND, then a study with the "gold standard" human hepatocytes should be completed. Usually, there is little or no information on either the UGT enzymes or transporters[144–146] at the beginning of clinical phase 1, and these in vitro studies should be conducted during phase 1/2.

Finally, there is the question of substrate phenotyping for CYPs, UGTs, and transporters. Although it is possible to investigate all three of these with human in vitro systems, the information may not be relevant since in vitro metabolites are not guaranteed to be the important circulating in vivo metabolites. Therefore, the best procedure is to determine which metabolites are actually circulating in initial phase 1 studies (see section "**Circulating human metabolites**") and then conduct the phenotyping studies. The general procedure for enzyme phenotyping is to use an in vitro system such as human hepatocytes or microsomes that produces the metabolite seen in human plasma. This system is then challenged with known specific inhibitors of the various CYP and UGT enzymes to see which one knocks out the activity, thus revealing the identity of the enzyme responsible. Sometimes, more than one enzyme, for example, CYPs 2D6 and 3A4, produces the metabolite in question. Once the inhibition studies indicate the identity of the enzyme, then the results are confirmed by the use of single cDNA-expressed enzymes to provide a definitive conclusion. For transporters, the best procedure is to use a bank of single cDNA-expressed transporters to determine which, if any, are responsible for transport of the drug across membranes.

One can appreciate that these guidances represent a significant investment in time and resources for a sponsor, and for that reason, the process is triaged so that the most likely and most serious DDIs are evaluated first, preferably before the initiation of phase 1. For NCEs that show no significant interaction with these in vitro DM systems, the clinical DDI program may be dramatically simplified. However, any in vitro result that indicates a significant interaction will probably warrant a follow-up clinical DDI study between the NCE and a representative drug metabolized by the system giving the positive in vitro result. Agency guidances direct how these clinical DDI studies should be conducted.[28,29] The University of Washington has provided two useful tools that a sponsor may consult when interpreting clinical DDI data to evaluate such questions as how strong may a particular DDI be, which drugs are likely to interact with the NCE, and what is the DDI profile of related drugs in a therapeutic class.[147,148]

4.01.4.2.3 Circulating human metabolites

When one administers a small-molecule therapeutic agent, the patient is usually exposed to the biological activity of more than one chemical compound: the parent drug and any metabolites. We are particularly concerned with metabolites found in the plasma, as these circulate with the blood, and hence, all organ systems are exposed to their activity. It is the responsibility of the sponsor to find these metabolites, identify the chemical structures of the major ones, estimate their concentrations in plasma, and characterize their biological activities.

The four classifications of biological activity of metabolites are pharmacologically active, modulators of ADME systems, toxic, and innocuous. Pharmacologically active metabolites are not uncommon, and in some cases, they may account for a significant fraction, even the majority, of the expressed therapeutic effect. Obach has compiled an extensive list of such drugs.[149] A sponsor must be able to explain the observed PK/PD when conducting clinical trials, and sometimes, this means taking into account the activity contributed by the metabolite adding to that of the parent. For example, the angiotensin II antagonist losartan produces a long-lasting carboxylic acid metabolite that is responsible for approximately 14 times the activity of the parent drug.[149] Recognition of cases where an active metabolite is principally responsible for the in vivo pharmacology is important because DDIs or CYP polymorphisms that prevent the metabolism of the drug will also render it therapeutically ineffective. Note that we distinguish active metabolite-producing drugs from prodrugs, the difference being that a prodrug typically does not have activity itself and is only activated by metabolism.

As another example of biological activity, some metabolites are modulators (i.e., inhibitors and/or inducers) of drug-metabolizing enzymes or drug transporters. It is for this reason that regulatory agencies have included characterization of metabolites as an objective in the in vitro testing of drugs for DDIs in their guidances. Metabolites can also be toxic, which we can define as showing significant binding to off-target receptors. This could be manifest as a simple loss of selectivity compared with the parent drug among related receptors or binding to a completely different type of receptor with undesirable pharmacological effects. In a few cases, the metabolite may be frankly toxic, as, for instance, cyanide released during metabolism of the industrial chemicals acetonitrile and acrylonitrile[150,151] or the nephrotoxin thioformamide formed from thiabendazole.[152] A special case of circulating metabolites is the production of the opposite stereoisomer by chiral inversion, which has the effect of making a metabolite with similar dispositional properties to the parent drug but usually with loss of pharmacological activity but retention of toxicity.[153] Fortunately, despite the comments in the preceding text, most metabolites are innocuous, although perhaps this is not so surprising when one considers the chance that a random chemical modification to the structure of a drug molecule carefully crafted by the medicinal chemist to fit the binding pocket of a target receptor will result in retention of that fit.

It is worth noting that we are interested only in the major circulating metabolites, which are not necessarily inclusive of all the metabolites that are actually produced. The observed circulating concentration relative to the parent drug is the net result of the processes of formation, distribution, and clearance of the metabolites and is not reliably predictable from inspection of the structure alone.[154] Thus, we must rely on empirical means to become aware of them, and because of their potential clinical importance as outlined in the previous paragraph, it is necessary to initiate in vivo human exploration of the presence of circulating metabolites in phase 1. In this regard, we must depend on the new techniques of "cold" detection and structural identification of metabolites outlined in section "**Addressing high first-pass clearance**." However, once an apparent major circulating metabolite is found, it is almost always necessary to have a quantity of the metabolite synthesized, allowing it to be tested for pharmacological activity as well as providing a standard for LC-MS bioanalysis. However, it is often the case that a metabolite cannot be easily chemically synthesized. In such cases, the metabolite can usually be biosynthesized in quantities adequate for testing by using a human in vitro system such as liver microsomes or an enhanced hepatocyte system (see section "**Addressing high first-pass clearance**").[155,156]

4.01.4.2.4 Clinical ^{14}C-ADME study

The final part of the process of characterization of the human ADME/PK process is the clinical ^{14}C-ADME study. This study is commonly done with healthy volunteers and therefore classified as a phase 1 study, but it may not be started until phase 2 or even phase 3. Given that the sponsor has established the human circulating metabolite profile using "cold" methodology, there is not an urgent need to do the ^{14}C-ADME study until the results of phase 1/2 show that the new drug is safe and effective and likely to advance to phase 3. It is often called a "mass balance" study, but this is the least important of its objectives. The main objectives are to establish primary and secondary routes of clearance and excretion, provide definitive information on human circulating and excreted metabolites, and compare plasma PK of parent drug with PK of radioactivity.[157] Although FDA rules indicate that the PK and disposition of an NCE must be characterized in humans, they do not require these to be based on ^{14}C-radiolabeled drug.[158] However, a practical alternative methodology that avoids the use of radiolabel while maintaining the certainty of radiolabel is not yet available, although there is considerable interest in extending the capabilities of LC-MS to the human mass balance study in addition to its present utility to find and identify circulating metabolites.[52,53]

The study consists of administration of a single dose of a radiolabeled analog of the NCE with specific activity diluted down to a suitable level with nonradiolabeled drug to allow convenient administration of about 100 μCi of radiolabel at a total dose in the relevant pharmacological range. The use of a very low radioactive dose (~100 nCi) combined with quantitation by accelerator MS rather than conventional scintillation counting has also been demonstrated to be practical.[159] The radionuclide of choice for these studies is ^{14}C, which is generally easy to incorporate into the structure. Prior metabolism studies establish which positions in the molecule are likely to be stable toward release of small ^{14}C-containing fragments such as $^{14}CO_2$, which would be lost by expiration in the breath. Before humans can be exposed to a radiolabeled NCE, the sponsor must conduct a dosimetry study in rats to assess organ distribution and elimination kinetics of the radiolabel to determine the maximum exposure of various organs to ^{14}C-emitted beta radiation. These data establish the maximum dose of ^{14}C that can be dosed to humans. Achievement of mass balance requires total collection of urine and feces for typically 2 weeks after dosing, and thus, these studies are normally done in specialized "resident–subject" clinical sites. However, the collection period may need to be extended for long half-life drugs. The goal is to recover at least 90% of the radioactive dose.

The results of the mass balance study are important in several ways. Although the circulating metabolite profile was investigated by "cold" methodology in the SAD and MAD trials, those data are considered preliminary for registration purposes. The profile obtained from the ^{14}C-ADME study is the "gold standard," and only when we have the definitive human metabolite do we have a definitive assessment of the adequacy of the animal safety studies (i.e., MIST). It must be mentioned in the MIST context that the agency guidances stipulate that the human metabolite exposures that must be covered in the animal safety studies are to be measured at PK steady state to allow for possible accumulation of the metabolites after multiple dosing. But, of course, plasma metabolite concentrations in the ^{14}C-ADME study are measured after a single dose, since it is not feasible to multiply dose radiolabeled drug. However, Prakash et al. have demonstrated a method for meeting the MIST requirement by estimating the steady-state concentrations through standard PK simulations to steady state from single-dose data.[160] Another important objective of the mass balance study, central to the task of characterizing the ADME/PK of the new drug, is determining the main routes of clearance, since these are the determinants of clinically important phenomena such as susceptibility to DDIs, possibility of polymorphic PK, and changes in PK due to disease states. And let us not forget that, although the mass balance

component of the "mass balance" study is not the most important aspect, it is nonetheless necessary to establish the time required for a therapeutically relevant dose of the drug to be completely cleared from the body, including parent drug, metabolites, and possible strongly retained drug residues. A recent example of a well-executed mass balance study illustrates how much may be learned.[161] With the completion of the clinical ^{14}C-ADME study, one can consider that the human ADME/PK profile has been defined for the new drug candidate. In the absence of special metabolism issues, the ADME/PK package has been finished and is ready for inclusion in the NDA.

4.01.5 Summary

ADME/PK becomes a core activity of the drug discovery and development process very early. In fact, most discovery teams start to at least investigate ADME/PK properties shortly after the initiation of the hit-to-lead phase. During lead optimization, ADME/PK screening becomes as important as improving target receptor binding. Usually, the strategy is for the medicinal chemists to learn how to make potent and selective ligands to the target receptor, followed by optimization of ADME/PK while maintaining potency and selectivity. Many times, this is accomplished by modifications to the lead molecular series in pharmacologically tolerant portions of the molecule to adjust properties such as solubility, permeability, and polarity. On the other hand, for modulating metabolism, chemists must modify the molecule at the site where the metabolism occurs, whether or not the region is pharmacologically tolerant. But it is typically possible to build in MetStab while maintaining activity. The ADME/PK goals in discovery lead optimization are to design a molecule with acceptable bioavailability (for oral drugs), *MRT* consistent with once-a-day dosing, good target organ penetration, and little potential to cause DDIs.

Once a clinical candidate is nominated, all aspects of the molecular structure are locked in, with the exception of salt-form selection, and it is necessary to conduct a series of more rigorous in vitro tests with human systems and in vivo studies of ADME/PK in animals to define what profile has actually been achieved. Preclinical animal safety studies become the most important activity on the path to phase 1 clinical trials, but ADME/PK retains a role in defining exposures and metabolism/disposition of the clinical candidate in support of the safety program. In addition, in the preclinical period, projection of the ADME/PK profile in humans begins in order to help design the early clinical program. In vitro tests to investigate the potential for DDIs should also begin in the IND-enabling phase.

Finally, with the initiation of clinical phase 1, the sponsor at last has the opportunity to characterize the true human ADME/PK profile, including PK, drug interactions, metabolism, major routes of clearance, and excretion. These properties must be known to allow proper planning of phases 2 and 3. The ^{14}C-human ADME study becomes the final activity in definitive characterization of the human ADME/PK profile to accompany the new drug application. The three roles of ADME/PK are seen to be distinct but closely related and interlocking: discovery leads to safety assessment that leads to clinical development. And this is the reason that it is incumbent on the medicinal chemist to design the most ADME/PK-optimized structure possible.

4.02.1 Introduction

The application of pharmacokinetic (PK) principles in drug discovery and development is now widespread due to the recognition of the role of drug concentrations as a surrogate for measuring pharmacological effects. A basic tenet of pharmacology is that the magnitude of a pharmacological response is a function of the drug concentration at the site of action. Thus, the objective of therapy may be achieved by maintaining sufficient concentration of drug at the site of action for the necessary duration, yet not so high as to elicit a deleterious effect. The concentration of drug is typically measured in blood or plasma as direct measurement at the site of action is challenging.

PK is defined as the study of change of drug concentration over time and describes a systematic approach to relating dose to amount of drug in the body and is typically separated into the distinct physiological processes of absorption, distribution, metabolism, and excretion (ADME). The pharmaceutical industry is currently increasing the diversity of approaches to therapeutic intervention, including several different large molecule concepts. These are at various stages from hypothesis to clinical testing and pose interesting challenges to ADME scientists. However, this article restricts its focus on the more established ADME concepts for "traditional" small-molecule new chemical entities in drug discovery for oral therapies.

It is now recognized in the pharmaceutical industry that acceptable human PK parameters and minimized drug–drug interaction potential increase the probability of a promising candidate becoming a successful therapy. Moreover, the role of DMPK scientists in drug discovery is not to merely provide project teams with measurements and data from the plethora of DMPK related assays and models that have been developed and implemented in screening cascades over the past 10–20 years, but to develop a mechanistic understanding of the disposition of the candidate drugs toward the optimization and confident prediction of key properties associated with *human* drug absorption, clearance (CL), distribution, and elimination. This is achievable from a consideration of physicochemical properties and data from in vitro assays with human-derived material and from in vivo animal studies. This article is targeted at medicinal chemists and drug design teams and provides general definitions of fundamental PK parameters together with characterization, prediction, and optimization strategies employed at AstraZeneca.

4.02.1.1 Absorption

The route of administration for potential therapies is an important consideration in drug discovery. The oral route is most common and favored because of convenience and patient preference and is the focus of this article. Oral absorption can be defined as the irreversible transfer of a drug from the gut lumen across the mucosal membranes of the gastrointestinal tract. This is just one step in a multifaceted process, which transfers a drug from the site of administration (ie, mouth) to the systemic circulation. The active pharmaceutical ingredient (API), typically administered through the mouth using tablets or capsules, needs to get dissolved in the gastric fluids where prior to the absorptive step it may be degraded by the acidic pH of the gastric fluid and the enzymatic activity of the gut flora. The small intestine is the primary site of absorption due to its high surface area, drug permeability properties, and high blood flow. Additionally, drug movement through the gastrointestinal membranes is dependent on the physicochemical properties of the drug molecule. Drugs may be transported passively, via the transcellular route, that is, through the cell, passing through both apical and basolateral membranes, or the paracellular route, that is, between the cells. The majority of drugs are absorbed transcellularly since paracellular permeability through water-filled tight junctions between cells decreases significantly

with increasing molecular size (> 250 Mwt) and lipophilicity (logP > 0).[1] Absorption may also be facilitated or hindered by uptake and efflux transporter proteins.

It is important for the medicinal chemist to be able to differentiate the definitions of absorption versus oral bioavailability (F), which is the fraction of the dose of administered drug that reaches, in an unchanged form, the systemic circulation and is a measure of a compounds' ability to avoid all the processes that protect the body from exposure to xenobiotics. These processes include the physical barrier of the gut wall, active transport into the gut lumen, metabolism in the gut, metabolism in the liver, and biliary elimination. Thus, F is a product of the fraction of dose that is absorbed through the gut and the fraction of drug that escapes elimination by the intestinal tract and liver, the so-called "first-pass" elimination. High extraction drugs that are rapidly metabolized will have low systemic exposure following an oral dose and low F, whereas low extraction drugs that are relatively stable to metabolism, assuming they are absorbed across the gut wall, will have high systemic exposure following an oral dose and high F. Bioavailability is estimated from $F = AUC_{oral}/AUC_{IV}$, for an equivalent dose. Thus there exists interplay between the physiology of gastrointestinal tract and compounds' biopharmaceutical, physicochemical, and structure–activity properties with drug metabolizing enzymes (DMEs) and transporters, which are required to be understood to facilitate optimization of new chemical entities to enable acceptable oral absorption and bioavailability.

4.02.1.2 Distribution

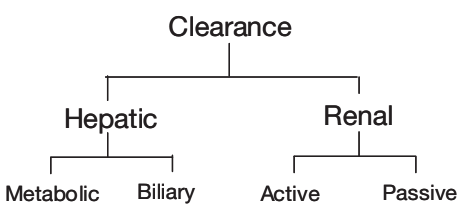
Drug distribution describes the reversible transfer of drug from one location to another. For an orally administered drug, distribution occurs from the bloodstream into the interstitial and intercellular fluids. Volume of distribution (V_d) is the theoretical volume that would have been available for the drug to disperse everywhere in the body were it at the same concentration as in blood and can be derived following intravenous (IV) administration. A measured dose is administered and drug levels in plasma are determined over time. Early concentrations are back-extrapolated to estimate the concentration at $t = 0$, and simple mass balance considerations allow estimation of the volume that the dose would have to be distributed in to yield that concentration. This is the initial volume of distribution (with units of L or L kg^{-1}). If there is a mono exponential decline in plasma concentrations, this is the V_d. V_d is most usefully thought of as a measure of the relative affinity of the compound for tissues over the sampled blood or plasma, and hence the ratio of the total amount of drug in the body to the concentration in the blood. The volume term that most accurately describes this measure, for multiexponential profiles, is the volume of distribution at steady state (V_{ss}), since this is an estimate of drug distribution independent of elimination processes (steady state referring to the pseudo-equilibrium achieved between drug entering the tissues from the systemic blood and drug being eliminated from the body).

4.02.1.3 Metabolism

Xenobiotic metabolism can be defined as chemical transformation by a biological system usually via DMEs, which typically converts relatively lipophilic compounds into more readily excreted hydrophilic metabolites. Drug metabolites may be pharmacologically active, weakly active, inactive, or indeed reactive with endogenous macromolecules. The liver is the principal site of drug metabolism; moreover, hepatic metabolic CL is the predominant elimination route for oral marketed drugs.[2] The most important drug metabolism enzyme family is cytochrome P-450, a superfamily of membrane-bound isoenzymes that catalyses the oxidation of many drugs. In addition to oxidation, reduction and hydrolysis are common xenobiotic metabolism pathways and conjugation with endogenous polar substrates such as glucuronic acid and glutathione may occur directly to the parent molecule or subsequent to an initial transformation.

CL is the parameter that best describes the efficiency of the eliminating process. The area under the plasma concentration-time profile (AUC) for a given dose is a measure of how efficiently a compound is removed from the body. Compounds yielding low AUCs are eliminated by efficient processes. This ratio (Dose/AUC) is used to derive the CL of a compound and has units of flow (mL $min^{-1}kg^{-1}$). CL relates the rate of elimination (ng min^{-1}) to the substrate concentration (ng mL^{-1}), that is, CL = Rate of elimination/[Substrate]. CL has units of flow, and can be related to physiological parameters such as organ blood flows. A CL to hepatic blood flow ratio of 1:2 means 50% of drug is extracted in a passage through the liver.

4.02.1.4 Excretion



Metabolism together with renal and biliary excretion are the major drug elimination routes in humans and preclinical species. CLs are additive, if the processes are parallel. As human glomerular filtration rate (GFR) is only ~ 1.7 mL min^{-1} kg^{-1} and as the majority of drugs are, to various extents, bound to plasma proteins, CL via renal elimination is typically low whereas biliary excretion can be an important route of elimination and remains challenging to predict to man.

An important PK parameter obtained from a simple fit of IV data is the half-life ($T_{1/2}$). Of course multiexponential plasma drug concentration-time profiles have half-lives associated with each exponential phase of the decline (where the $T_{1/2}$ is ln(2)/exponential rate constant). The simplest case is often a profile that has an initial drug distribution phase (where the drug is subject to elimination but the major process is distribution from the central systemic circulation into the tissues) and an elimination phase (in which the majority of the drug in the body is eliminated). It is this latter phase that accounts for the largest proportion of the AUC (since the drug is being eliminated) and approximates to $\ln(2) \times V_{ss}/CL$. This is only the terminal $T_{1/2}$ if there is no later phase observed in the dose interval. Further phases of the plasma profile can occur beyond the elimination phase when, for example, the drug distributes into tissues or body compartments that release the drug with a rate lower than the elimination rate. This is typically true for lipophilic or basic drugs that have good distribution properties, but not for acidic drugs that do not distribute extensively beyond the plasma. The most important $T_{1/2}$ depends on the key phase of the profile for maintaining the drug concentration above the level required for efficacy. Generally the elimination $T_{1/2}$ is the most important, as it describes the decrease in plasma concentration associated with the largest proportion of the AUC and therefore largest drop in plasma (or blood) concentration of drug. This $T_{1/2}$ is consequently often the most influential in maintaining the drug concentration above the required minimum effective concentration. $T_{1/2}$ does not describe the efficiency of eliminating processes (this is CL) but is related to CL by the equation $T_{1/2} = \ln(2)V_d/CL$. As there is only one value for CL, each $T_{1/2}$ is associated with a different distribution volume (eg, initial, V_0; steady state, V_{ss}; terminal, V_z) and can be modulated accordingly by changing the V_d or CL.

After identification of a relevant druggable target, maximizing the likelihood of a chemical series yielding a candidate drug that subsequently becomes a marketed therapy can be achieved by optimizing potency and selectivity for the target protein together with a strategy that achieves an adequate PK profile in patients with minimal drug–drug interaction potential. A drug discovery approach of optimizing key properties in parallel while not guaranteeing, undoubtedly maximizes the probability of success. What can assist in this difficult, and at times seemingly insurmountable, challenge is that the key PK parameters of drugs are often strongly associated with their inherent physicochemical properties. Understanding these relationships is a key element of drug design. The most important physicochemical properties, in this context, are molecular size, hydrophobicity, aqueous solubility, and ionization state at physiological pH. These properties, to a greater or lesser extent, effect dissolution in the gastrointestinal tract and membrane permeability (and therefore oral absorption), susceptibility to DMEs and other elimination processes.

The sections below outline the authors' view of current best practice for optimizing and predicting the key ADME parameters in man. It is intended to be a practical guide directing both optimization strategies and mechanistic understanding for ADME properties in drug discovery and development. There are many literature sources that provide more fundamental information. The authors can strongly advocate *Metabolism, Pharmacokinetics and Toxicity of Functional Groups* edited by Dennis Smith[3] and for a comprehensive analysis of PKs and full derivation of equations the authoritative reference *Clinical Pharmacokinetics* by Rowland and Tozer[4] is recommended.

4.02.2 Optimization and Prediction of Key Human Pharmacokinetic Parameters in Drug Discovery

Both human PK and clinically efficacious dose may be estimated from in vitro experiments utilizing human-derived material and by in vivo animal studies. Prediction of clinical dose is a useful parameter in the optimization of compounds as a holistic measure of "quality" that relies on both human PK estimates and of the anticipated therapeutic concentration.[5] The prediction and refinement of therapeutic concentrations in relevant patient populations is vital. It is built on the foundation of a quantitative understanding between target engagement and relevant biomarkers, from an integrated assessment, in which the pharmacology and the role of the biological target in the pathophysiology of the disease are considered to establish an exposure profile most likely to deliver clinical efficacy. Thus pharmacokinetic–pharmacodynamic relationships should be derived from clinical precedents, preclinical PD, or disease models and mechanistic studies of the drug target interaction, and refined throughout the life of a project. The optimization and prediction of human PK and likely efficacious clinical dose are essential elements of drug discovery projects.[5]

In addition to potency and selectivity against the target, the focus for drug design teams with respect to PK optimization strategies should be on the influential parameters, F_{abs}, CL, and V_{ss}. Establishing a set of quantitative criteria for these parameters upfront in programs facilitates optimization toward, and discovery of, a promising candidate drug as rapidly and efficiently as possible. A PK property that remains challenging to determine is the free concentration of drug at the site of pharmacological action, which is dependent on the involvement of drug transporters, a rapidly developing yet still immature area of ADME science. The next sections outline the authors' experience and view of current best practice for predicting the key PK parameters for man.

4.02.2.1 Oral Absorption

Interpatient variability in drug exposure is inversely related to bioavailability,[6] and therefore absolute bioavailability in man of greater than 30% is an appropriate target for acceptable intersubject variability, and effect on dose size. As F is a product of the

fraction of absorbed drug, the fraction escaping intestinal metabolism and liver extraction as it passes from the portal vein to the systemic circulation ($F = F_{abs} \times F_g \times F_h$) targeting a human absorption of >50% is appropriate.

It is important to understand the relevance of the contribution of first-pass hepatic and intestinal metabolism, and of intestinal permeability and not just determine F in preclinical species. As animal in vivo PK may poorly predict human kinetics, good PK properties in animals per se are not necessarily a sign of quality in molecules, likewise a low animal bioavailability value and/or suboptimal PK profile is not necessarily an indicator of poor human PK. The real value of animal PK data is to validate, or otherwise, the approaches that are used to predict PK in man. Fundamentally, low bioavailability in animals may impact in limiting exposure in preclinical PD, efficacy, and safety testing.

An assessment of the role of intestinal drug extraction is a component of the human F prediction. Intestinal DMEs are well characterized with CYP3A, CYP2C9, and Uridine 5′-diphospho-glucuronosyltransferase (UGT) predominating.[7–12] Mathematical modeling can enable in vitro data to be used in the prediction of F_g[13] and extraction by the intestine can be similar to, or exceed, hepatic extraction, despite much less intestinal compared to hepatic cytochrome P450 (CYP).[13–17] Intestinal extraction is typically associated with metabolically unstable drugs. Efficient location of DMEs including CYP3A4 and p-glycoprotein efflux transporter (which also share substrate specificity), in the villus tip of enterocytes, facilitates cycling of drugs prolonging exposure and, therefore, intestinal metabolism.[13,14,18,19] Drug properties associated with limited permeability and being substrates for efflux transporters and DMEs are required to be efficiently extracted by the intestine. If optimization strategies early in the drug discovery process are efficient at mitigating these properties, intestinal metabolism should rarely be a significant issue for candidate drugs.

Optimizing toward compounds with appropriate physicochemical properties that ensure sufficient solubility of crystalline API and transmembrane permeability should maximize oral absorptive potential of candidate drugs. The apparent permeability measure (P_{app}) is typically obtained from assessment of drug flux across a monolayer of cells intended to mimic the intestinal barrier, most commonly determined using Madin–Darby canine kidney or Caco-2 cell lines.[13,20] P_{app} values are transformed into effective permeability (P_{eff}) values, describing intestinal permeability per unit surface area, as a prerequisite to develop relationships between in vitro permeability and human absorption.[13,21]

It is now widely accepted that efflux by p-glycoprotein or other intestinal drug transporters is unlikely in most cases to limit absorption of drugs with good permeability and solubility.[22,23] However, in vitro p-glycoprotein dependent efflux can be clinically relevant if the K_m between substrate-p-glycoprotein is high (>10s of μM) and/or the dose is low (<1 mg kg^{-1}).[24] The intestinal drug concentration range sufficient for interacting with p-glycoprotein may be estimated from the maximum dose taken per 250 mL (intestinal fluid volume) or alternatively, via an estimation of the maximum concentration in the enterocyte ($F_{abs} \times k_a \times \text{Dose}/Q_{ent}$) where Q_{ent} is enterocyte blood flow.[13,19]

In our laboratory, a solubility–permeability heat map has been generated and is used as a visual and simple tool, which demonstrates for a 1 mg kg^{-1} dose, a fraction absorbed in man of >50% requires a crystalline solubility of 100 μM and a Caco-2 P_{app} of 5×10^{-6} cm/s.[25] Especially for compounds that have borderline physicochemical properties, supplementary dynamic simulations incorporating measured in vitro permeability and dissolution rate measures, such as commercial software as Gastroplus® or SimCYP®, validated with known clinical data, are valuable at providing additional information for decision making.[24,26,27] Indeed more generally, physiologically based pharmacokinetic modeling approaches have great utility in the prediction and simulation of PK profiles, including the potential for assessing likely variability in man.

In oral drug discovery programs, an estimate of rat oral bioavailability is likely important for determining if safety or PD/efficacy studies can be adequately performed, yet poor oral absorption in the rat should not per se preclude progression of compounds. In our experience rat oral absorption is, generally, not a good predictor of human absorption.[5] This is most likely explained, at least in part, by the fact that once normalized for body surface area, the rat small intestine has a four-times lower surface area compared to human.[28] Predicting human absorption from preclinical in vivo data is more successful using dog as a model, since the dog to human absorption correlation appears strong for high molecular weight (>325) compounds, when absorption is not by the paracellular oral route (**Fig. 1**, adapted from McGinnity et al.[5]). In our experience, for drugs absorbed by the transcellular route, not only does dog PK data indicate a systematically greater absorption than in rat but also that dog absorption, using crystalline API and an appropriate formulation, is more akin to human. Good oral drug-like physicochemical properties providing sufficient aqueous solubility of the crystalline form and passive transcellular permeability can support a confident and acceptable human absorption prediction of >50%, which can be further strengthened by good in vivo absorption in the dog.

4.02.2.2 Volume of Distribution

V_d is a measure of the relative affinity of a drug for tissues and plasma, thus correlating with the relative affinity of compound for tissues. This is expressed by the equation $V_d = [fu_p/fu_T] \times V_T + V_P$, with units of L kg^{-1}, where fu_p is the unbound drug fraction in the plasma; fu_T is the unbound drug fraction in the tissue; V_T is the volume of the tissue (~1 L kg^{-1}); and V_P is the volume of the plasma (0.03 L kg^{-1}). As $V_T \gg V_P$, changes in fu_p will directly affect V_d.[4] Moreover, Oie and Tozer's approach defines the key driver of interspecies differences in V_d to be differences in ppb on the assumption that interspecies differences in tissue binding are minimal.[29] Using preclinical in vivo PK data and correcting for species ppb differences, V_d or V_{ss} as the most predictable of PK parameters: if unbound volumes are consistent across species, human volume can be predicted from animal data, by estimating V_u (**Fig. 2**). Based on our experience unbound V_{ss} is usually conserved within twofold across species.

In general bulk physicochemical properties rather than specific pharmacophores determine V_d values, albeit transporters can modulate distribution into and out of tissues. Typically, for drug-like molecules, acids have low (<1 L kg^{-1}), neutrals and

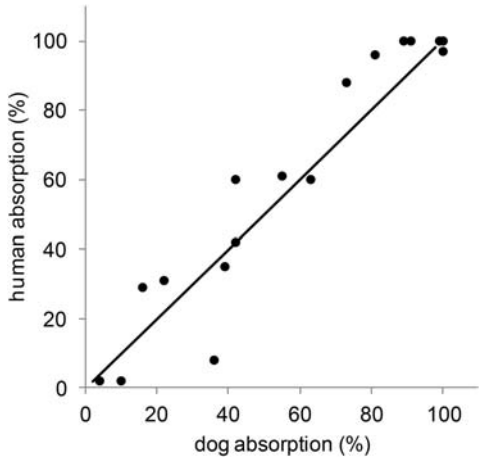


Fig. 1 Relationship showing correlation between human absorption and dog absorption for compounds with Mwt >325. Shown is the line of unity. Figure adapted with permission from McGinnity, D.F., Collington, J., Austin, R., Riley, R. Evaluation of Human Pharmacokinetics, Therapeutic Dose and Exposure Predictions Using Marketed Oral Drugs. *Curr. Drug Metab.* **2007**, *8*, 463.

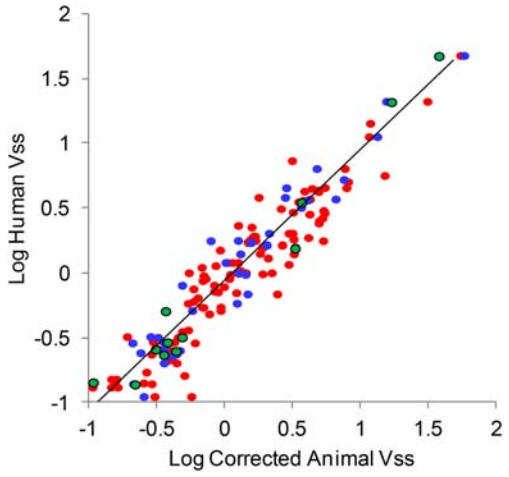

Fig. 2 Using preclinical species to predict human V_{ss}.[5] Relationship between human V_{ss} values and preclinical animal V_{ss} values corrected for human/animal differences in ppb as detailed in McGinnity et al., 2007.[5] The dataset includes both data generated in this laboratory and literature data from rat (red circles), dog (blue circles), and mouse (green circles) and compared to clinical V_{ss}. Line of regression shown with the equation $\log y = 1.\log x + 0.06$, $r^2 = 0.93$, $p = 4.6 \times 10^{-101}$, afe = 1.36. Thus human V_{ss} can be predicted from preclinical animals using Eq. (1). Figure adapted with permission from McGinnity, D.F., Collington, J., Austin, R., Riley, R. Evaluation of Human Pharmacokinetics, Therapeutic Dose and Exposure Predictions Using Marketed Oral Drugs. *Curr. Drug Metab.* **2007**, *8*, 463.

zwitterions moderate (1–3 L kg^{-1}), and bases high (>3 L kg^{-1}) steady state V_d values (Fig. 3). Basic drugs tend to have similar ppb to neutral drugs, in contrast to acids that show higher binding even for a given $\log D_{7.4}$.[30] The overriding influence on the distribution of acidic drugs is that of extensive binding to albumin in plasma. Apparent distribution volumes thus approach that of albumin, approximately 0.1 L kg^{-1} and do not typically exceed 0.3 L kg^{-1} unless active hepatic uptake or entero-hepatic recirculation is a factor. Recirculation of parent drug after elimination in bile (of parent or glucuronide that can be hydrolyzed to parent in the gastrointestinal tract) can lead to an extended PK profile and a larger apparent V_{ss}. Moreover, this can yield incorrect predictions if extrapolating to a species where recirculation does not occur to same extent. The V_d for neutral drugs is governed by hydrophobic interactions with plasma proteins and tissue membranes. Increasing lipophilicity raises tissue affinity but also has the counter effect of restricting tissue distribution due to an increase in ppb. Being positively charged at physiological pH, bases have favorable interactions with anionic phospholipid head groups leading to higher tissue affinity and therefore for the same ppb as a neutral compound, a base will tend to have a higher tissue distribution.[31] Ion trapping in lysosomes, subcellular acidic organelles abundant in liver and lung, also contribute.[32] V_d is not by itself a parameter that should be optimized in drug discovery, rather estimates of the boundaries of V_d for a given chemical series can be transformed into a strategy for obtaining the necessary human elimination $T_{1/2}$ via optimizing the elimination processes toward a target CL value.

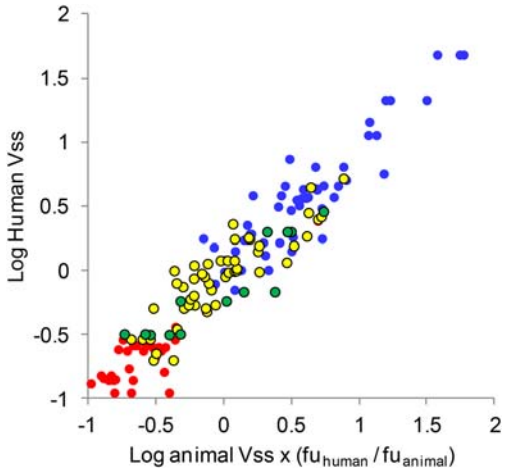

Fig. 3 Using preclinical species to predict human V_{ss} for compounds with a range of physicochemical properties. Relationship between human V_{ss} values and preclinical animal V_{ss} values corrected for human/animal differences in ppb. *Red circles* are acids, *green*–zwitterions, *yellow*–neutrals, and *blue*–bases. Same data included in **Fig. 2** and McGinnity et al., 2007.[5]

V_{ss} is reasonably predictable from physicochemical properties, in silico approaches[33,34] and in vitro data.[35–37] However the Oie and Tozer method from preclinical species PK appears superior for making human predictions, as demonstrated by several laboratories.[38–40] via Eq. (1). Also as determination of PK profiles is required for several reasons in at least two species before clinical candidate selection, this is the preferred predictive methodology in our laboratory for candidate drugs.

$$log\left(V_{ss_{human}}\right) = log\left(V_{ss_{animal}}\frac{fu_{human}}{fu_{animal}} + 0.1\left(1 - \frac{fu_{human}}{fu_{animal}}\right)\right) - 0.06 \quad (1)$$

4.02.2.3 Human Clearance

Identification of the elimination route and rate in preclinical species and optimization of human CL are major challenges and goals of most drug discovery projects. The major drug CL routes in humans and preclinical species are metabolic, biliary, and renal and as there is currently no reliable way to predict human elimination from purely in silico or in vitro methods, a combination of determining CL routes in preclinical species and use of in vitro human tools is required to predict human CL.

Liver is the major xenobiotic metabolizing organ and it is now widely accepted that in vitro–in vivo extrapolation (IVIVE) can be used to estimate hepatic metabolic CL in human and animals, via in vitro determination of rates of turnover and a mathematical liver model.[41–45] The model describes hepatic metabolic CL (CL_H), via terms for liver blood flow (Q_h), hepatic intrinsic clearance (CL_{int}), and blood binding (fu_b). Hepatocytes are the optimal in vitro system for predicting in vivo metabolic hepatic CL, as they contain the full complement of DMEs and transporters. However, data from subcellular liver fractions such as microsomes that define the oxidative metabolic component, and that have a larger dynamic range than hepatocytes, can add value by increasing the mechanistic understanding of the primary metabolic pathways for chemical series and key compounds. Both hepatic microsomes and hepatocytes are used routinely for this purpose in our laboratory. A panel of recombinant heterologously expressed CYPs can also be used to predict metabolic CL and to determine the individual CYPs responsible for the metabolism of key compounds. This information is important to understand likely variability of CL in the population associated with metabolism via polymorphic CYPs, potential intestinal CL contributions (eg, if via CYP3A and 2C9), and to determine the risk of drug–drug interactions as victims of coadministered inhibitors of the CYPs involved. There is less drug–drug interaction risk associated with compounds that are cleared via multiple CYPs and other elimination routes. For this latter reason alone, it is important to attempt to quantify all elimination pathways as far as possible.

Predicting in vivo hepatic metabolic CL involves initially building in vivo–in vitro CL_{int} models for each species using a training set of compounds with estimated in vivo hepatic metabolic CL values, via subtracting nonhepatic metabolic CL from total CL values. Hepatocyte CL_{int} is measured and fraction unbound in the incubation (fu_{inc}) incorporated to calculate unbound in vitro CL_{int}, which is scaled up to a whole liver unbound CL_{int}.[46] To establish prediction accuracy, the unbound in vivo CL_{int} of the test compound is calculated from in vivo hepatic metabolic CL adjusted for in vivo blood binding. The derived unbound in vitro and in vivo CL_{int} values form a line of correlation from which estimations of unbound in vivo CL_{int} values for test compounds can be made after determination of in vitro CL_{int}.[41,42,44,47] Evaluation of the predictive accuracy for the test compound is made against the linear relationship of unbound in vitro versus in vivo CL_{int}, not CL.

Fig. 4 and the regression equation in the legend demonstrate the approach, using all the in vitro measured terms on the X-axis and predicting in vivo CL_{int} from the Y-axis. This in vivo CL_{int} is put back through the Well Stirred Model equation ($CL_H = CL_{int} \cdot Q / CL_{int} + Q$) to predict human CL_H. As can be observed from **Fig. 4**, this approach yields a systematic under prediction of in vivo CL_{int}

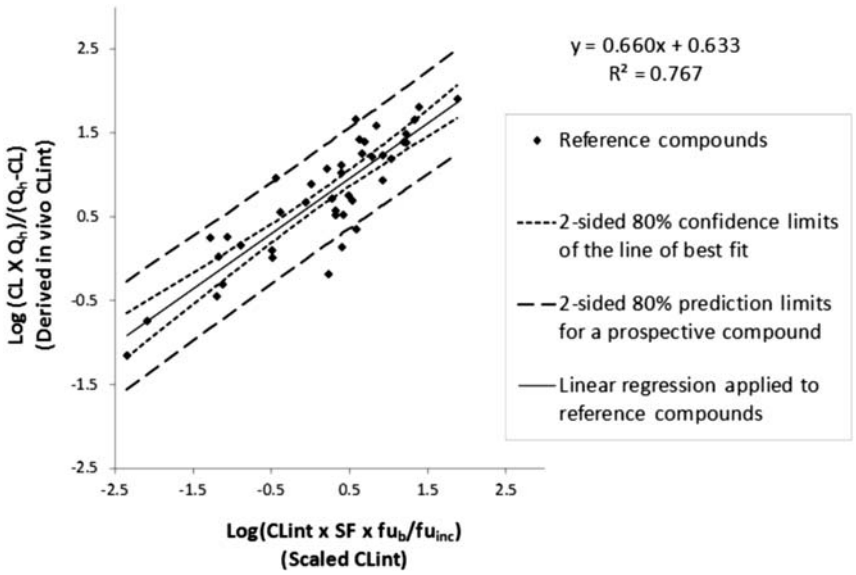

Fig. 4 Human hepatocyte regression line comparing in vitro CL_{int} with in vivo CL_{int} with all in vitro variables grouped together on *x*-axis. Figure adapted with permission from Sohlenius-Sternbeck, A.K., Jones, C., Ferguson, D., Middleton, B.J., Projean, D., Floby, E., Bylund, J., Afzelius, L. Practical Use of the Regression Offset Approach for the Prediction of in vivo Intrinsic Clearance From Hepatocytes. *Xenobiotica* **2012**, *42*, 841.

for reasons not yet mechanistically understood, although several rational explanations have been proposed. However, it is important to realize that this under prediction factor, corrected via use of the regression line, is associated with the assay not the compounds and is observed across several laboratories and species and using both hepatic microsomes and hepatocytes.

If the unbound in vivo CL_{int} has been accurately predicted in animals, typically rat and dog, the approach can be used in human with confidence that a similar relationship may apply. Moreover, if rat and dog hepatic metabolic in vivo CL_{int} cannot be predicted from in vitro data there should be little confidence that a similar approach will predict human CL_{int}. Importantly for candidate drugs, a quantitative mechanistic understanding of rates and routes of elimination pathways in human-derived in vitro milieu and preclinical species is critical to increase the likelihood of successful prediction of rates and routes in human.

In our laboratory the instances of "lack of scaling" of in vitro to in vivo CL_{int} in chemical series or key compounds are relatively frequent and require a systematic approach to investigate the possible causes of such disconnects. It is advisable that the first step should always be a close examination of existing in vitro CL_{int} and in vivo PK data as several experimental and/or biological phenomena may have led to an under or over estimation of in vitro or in vivo CL_{int}. An understanding of the known rates, and metabolic and excretion routes, from structurally related compounds may then provide mechanistic clues and a systematic in cerebro and experimental investigation of the key in vitro measured terms CL_{int}, *B*:*P*, ppb, and fu_{inc} can follow. Often discovering the cause of poor CL predictions adds to the mechanistic understanding of the compounds disposition, which may increase, or indeed decrease, the confidence in an accurate human CL prediction.

Consideration of significant extra-hepatic metabolic CL may include experimental identification of the enzymes responsible for metabolism. These may include amidases, esterases, amine oxidases, and transferases, for example, and experiments using hepatic and nonhepatic subcellular fractions and blood or plasma can be useful. Plasma hydrolysis of drugs can be scaled to whole body CL from in vitro data by multiplying the measured in vitro elimination rate constant ($\ln(2)/T_{1/2}$) by the volume of plasma. Unless the rate is rapid, hydrolysis solely in plasma is unlikely to be a major CL pathway but hydrolysis can occur at a number of sites throughout the body and the cumulative CL can thus be both high and challenging to estimate. Indeed for compounds cleared via DMEs other than the CYPs or UGTs on which the IVIVE approaches have been predominantly validated may require additional experimentation and refined methodologies can be applied as appropriate.

A common misconception is that high ppb is to be avoided or designed away from and decreasing ppb will result in a lower efficacious dose through the generation of higher circulating free drug concentrations available to the pharmacological target. However, this neglects the fact that decreasing ppb also results in higher CL. Thus for most drugs, decreasing ppb has no effect on the in vivo unbound drug concentration. The $T_{1/2}$ is, in most cases, also largely unaffected, since CL and V_d are impacted similarly by ppb changes. The only notable exception to this is when ppb is so high that drug distribution volume is restricted to that of plasma proteins. At this lower limiting value for V_d, increasing ppb further does indeed lower CL but with V_d unaffected, $T_{1/2}$ increases. These concepts are elegantly and comprehensively outlined in Smith DA et al.,[31] which provides guidance on the use of ppb in drug discovery. Therefore the focus should be on physiochemical parameters such as logP, pKa, and PSA or structural modifications based on knowledge of the metabolically liable functional groups to affect a change in CL, to optimize free drug concentration.

Renal excretion of untransformed compounds can be complex and may involve both passive and active components. The high pressure and relatively large pores in the glomerulus result in free drug in blood entering the proximal tubule. The filtration rate, as a CL, is the product of the compound's fraction unbound in blood and GFR (approximately 1.7 mL $min^{-1} kg^{-1}$ in human), and thus can be readily estimated. As the majority of drugs are highly bound to blood proteins, passive renal CL is low in particular relative to hepatic CL. Furthermore, only compounds with negative $logD_{7.4}$ values are passively renally cleared to any extent as the kidney tubules passively reabsorbs molecules of sufficient lipophilicity back into the blood.[48] Uptake transporter proteins may recover compounds if sufficient structural similarities exist to their physiological endogenous substrates. Active renal secretion consists of uptake across the basolateral membrane of the proximal tubule then egress across the apical membrane via combinations of different transporters polarized to the apical or basolateral membrane. In man, the principal transporters in the basolateral membrane are organic anion transporters OAT1 and OAT3 and organic cation transporter OCT2 are whilst the apical transporters include P-glycoprotein, breast cancer resistance protein (BCRP), multidrug resistance protein (MRP2, MRP4), organic anion transporters OAT4 and URAT1, and organic cation transporters OCTN1, OCTN2, and MATE-1.[49] Intuitively, transporter dependent renal CL is likely to be less predictable across species than when flow dependent passive processes predominate. However, in our laboratory, a reasonable prediction using dog renal CL corrected for ppb and kidney blood flow species differences emerged for a diverse set of 36 actively secreted drugs, forming the basis of our approach to predicting renal CL in human for candidate drugs (**Fig. 5**).[50] Male rat renal CL correlated less well with human possibly due to poor species crossover for OAT substrates or sex differences for rat organic anion transporting polypeptide (oatp) substrates.[50–52] The continued development of human-derived in vitro models for the prediction of active human renal CL and kidney transporter mediated drug–drug interactions is an area of ongoing research in our laboratory and others.

Biliary excretion is an important elimination route but in part due to the lack of high quality definitive clinical data there remains no consensus on the best practice strategy to predict human biliary CL and human-derived in vitro models are still in active development.[43,53,54] As for renal elimination, biliary excretion of drugs can be a two-step process involving the hepatic uptake transporters OATP, OAT, and OCT and bile canalicular efflux transporters P-gp, BCRP, MRP1, and MRP2.[55–58] High biliary CL is most often observed with acids, likely due to synergy between OATP and MRP transporters. In the authors' laboratory, rat, dog, and human biliary CL data from drugs of different chemotypes and therapeutic classes were compared (**Fig. 6**).[59] For the majority of the compounds studied, rat unbound biliary CL values, when corrected for body weight and ppb differences, were >10-fold higher than the human value with some >100-fold. Interestingly, these compounds appeared to be substrates for hepatic uptake OATP transporters. This is in line with the observation that rat uptake transporters are typically more efficient than the human and dog counterparts.[60,61] Albeit based on relatively few compounds, dog biliary CL when corrected for body weight and ppb differences appears to be more comparable to human than rat. However, for drugs that seemingly have no significant active hepatic uptake component, rat, dog, and human biliary CL were similar.

In the literature, several interspecies allometric scaling methodologies for biliary CL have been evaluated,[54,62,63] but a consensus is not apparent, likely due to the relatively few compounds analyzed, the fact that some used total drug related material rather than parent and that allometry underpredicts human biliary CL for some compounds but not others.[64,65] Simple allometry using unbound CL and an exponent of 0.66 gave the best predictions of 18 drugs between rat and human.[66] Human predictions were within threefold of observed values for 12 of the compounds, yet for others human CL was overestimated by one to two orders

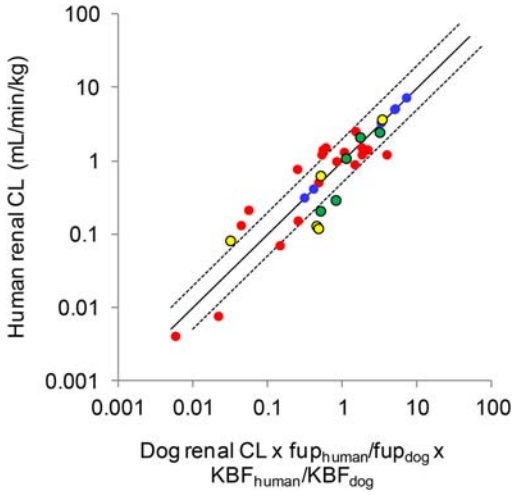

Fig. 5 Relationship between human renal clearance and dog renal clearance corrected for human/dog differences in ppb and kidney blood flow. *Red circles* are acids, *blue*–bases, *yellow*–neutrals, and *green*–zwitterions. of magnitude. Compared to rat alone, multiple species allometry using biliary CL data corrected for ppb yielded improved predictions.[66]

Intuitively, because CL predictions require several input parameters (hepatocyte CL_{int}, extra-hepatic CL_{int}, renal and biliary CL, ppb, in vitro incubational binding, and B:P), human estimates are more uncertain than for oral absorption or V_{ss}. In summary, human CL can be predicted as follows: Human hepatic metabolic CL from human hepatocyte CL_{int}, human renal CL from dog renal CL, and human biliary CL tentatively estimated from the dog or rat biliary CL for non-OATP substrates. Both prediction of renal and biliary CL remain important challenges from human-derived in vitro tools. Publications from Pfizer, J&J, and GSK[67,68,40]confirm the authors' view that allometric scaling approaches offer fairly poor predictivity of human CL, in particular for metabolic CL where there may be clear species differences in metabolic rates and routes. However, for a key candidate drug an allometric prediction in agreement with the more mechanistic and validated approaches presented here may increase the confidence in that human CL prediction, thus adding value to decision making.

4.02.3 Summary

AstraZeneca drug project teams use a five-dimensional framework to maximize the probability of project success and pipeline quality, described as the five 'R's: the right target, right patient, right tissue and exposure, right safety, and right commercial potential.[69] Under this overarching framework, the focus of AstraZeneca drug design teams, with respect to clinical PK optimization, are on the key parameters that support PK profiles CL, V_{ss}, and F_{abs}, underpinned by an understanding of the candidate drug's exposure–effect relationship.[70] Other parameters such as those related to mitigating against drug–drug interactions are incorporated as necessary.

As outlined above, PK parameters have strong interdependencies with the physicochemical properties of compounds, and thus optimizing these fundamental properties may be a focus for project teams. However, a recent and extensive analysis of the relationship between physicochemical properties and drug attrition concluded further refinement of physicochemical properties within the oral drug-like space is unlikely to have a significant effect on attrition rates for small-molecule drug candidates.[71] Moreover, it is critical, in the authors' view, to develop as full a mechanistic understanding of the ADME disposition properties of key candidate drug(s) during drug discovery via detailed experimentation and thorough investigations to optimize toward a candidate drug with acceptable human PK profile and attain a sufficient degree of confidence in the predicted clinical PK parameters to make informed investment decisions. PK is complex and all predictions are fraught with uncertainty and somewhat paradoxically the establishment, in the last two decades, of a plethora of in silico methods, in vitro screens, and in vivo models could lead to a box-ticking checklist approach to drug discovery, generating in our opinion only a superficial understanding of the compounds disposition properties. Excellent ADME science contribution to drug design teams requires additional in cerebro and experimental application by experienced and expert scientists. Furthermore, the limitation of predictive accuracy should be appreciated. It is commonly and subjectively accepted within the DMPK community that a prediction within twofold of the measured value is a success. However, a successful prediction of individual parameters may not equate to a successful prediction of clinical dose and exposure due to the cumulative impact of twofold errors in CL and V_{ss} predictions on $T_{1/2}$, exposure, and dose.[5] This understanding of uncertainty and risk explains, for example, why for once daily dosing of a candidate drug, a human $T_{1/2}$ prediction of approximately 16 h is desirable, if drug effect is related to trough concentration, since being twofold out in

either direction elevates the dose and C_{max} by only twofold for a 8 h $T_{1/2}$ or results in only a fourfold accumulation from single dose to steady state for a 32 h $T_{1/2}$.

Based on a robust understanding of the interdependencies between physicochemical properties and key PK parameters and with targeted experimentation using well validated assays and models as a foundation, together with bespoke experiments designed to test specific hypotheses, an ADME optimization strategy toward clinical candidates with an acceptable clinical PK profile is achievable. DMPK scientists working in partnership with medicinal chemists and drug design teams can maximize the probability of success via building predictions, knowledge, and developing a thorough mechanistic understanding of the ADME disposition properties of the relevant chemical series and candidate drug.

4.03.1 Introduction

Accounting for species differences in drug metabolism and disposition between animals and humans is an important issue in the field of preclinical research. Before conducting a human microdosing study as the first-in-human administration of a potential new drug, a traditional distribution study of the radiolabeled compound in pigmented rats is often carried out to estimate the internal exposure in humans. To address the species differences, the levels of radioactivity per gram in animal organs need to be converted to the amount of injected activity in a whole organism, and this value is scaled up by the human body weight/animal body weight ratio.[1]

The human cytochrome *P450* gene superfamily is made up of 57 functional genes and 58 pseudogenes.[2] The corresponding P450 (P450 or CYP) enzymes are involved in the oxidative metabolism of a variety of drugs, toxic chemicals, and endogenous compounds. In the course of new drug development, rodents are often used as animal models, but it is well established that species differences exist in terms of drug metabolism mediated mainly by rodent P450 enzymes and human P450 isoforms. The relevance and limitations of all animal models used in nonclinical safety assessments of investigational products should be carefully considered.

Because of their genetic similarity to humans, nonhuman primates are often used in preclinical studies to predict the toxicity and pharmacokinetics of new drugs. Old World monkeys, such as cynomolgus monkeys (*Macaca fascicularis*), are most commonly used among the nonhuman primates. In addition, the common marmoset (*Callithrix jacchus*), a New World monkey, is beneficial in various research fields such as neuroscience, stem cell research, drug metabolism, toxicology, and immune and autoimmune diseases[3,4] because of their small size, availability, high reproductive efficiency, and early sexual maturity.[5] Although information on P450 enzymes in cynomolgus monkeys (hereafter, "monkey" means the cynomolgus monkey) is increasingly available, the characterization of marmoset P450 enzymes is currently limited. Chimeric mice with humanized liver or human *P450* genes are commonly used as animal models to investigate the human metabolites of new and known drug candidates.[6] In vivo models using chimeric mice with human hepatocytes also have potential for use in drug interaction studies and the investigation of human reactive metabolites.

Many drug-induced toxicity events are associated with immune-mediated hypersensitivity reactions, which are idiosyncratic in nature and therefore difficult to predict. In the United States, more than 50% of acute liver failure cases in adults are caused by drugs.[7] It is, therefore, not surprising that many drug regulatory authorities require evaluation of the potential for metabolic activation prior to market approval and during the post-marketing period. Both in vitro and in vivo studies play roles in the safe development and effective use of medicines. In this section, taking into account the aforementioned discussion, drug-metabolizing activities are compared among human, monkey, and marmoset P450 enzymes. The effects of age-related changes and genetic polymorphisms on P450 enzymes are seen in monkeys and in humans. Consequently, it is important to take into account species differences when evaluating the roles of human P450 enzymes in the metabolism of a variety of drugs.

4.03.2 In Vivo Pharmacokinetics of Human P450 Probes in Experimental Animals

Human cytochrome P450 enzymes have been well characterized with respect to drug metabolism. Research has also elucidated the P450 isoform contents in liver microsomes,[8] the relatively broad but selective P450 substrate specificities,[9,10] P450 induction and inhibition,[11] P450-mediated drug interactions,[12] and genetic polymorphisms of P450 enzymes. In addition, a nomenclature system for polymorphic human P450 alleles (http://www.cypalleles.ki.se/) has been established. Research has mainly focused on the P450s involved in the oxidation of compounds associated with pharmacological and/or toxicological actions.

A study of the pharmacokinetics in humans of caffeine (1,3,7-trimethylxanthine), *S*-warfarin, omeprazole, metoprolol, and midazolam in combination as probe substrates of P450 1A2, 2C9, 2C19, 2D6, and 3A, respectively, has been reported.[13] A different

human P450 probe cocktail using losartan and dextromethorphan with caffeine, omeprazole, and midazolam has also been reported.[14] In addition, studies have investigated the pharmacokinetics of the human P450 probes caffeine, warfarin, omeprazole, metoprolol, and midazolam in minipigs, marmosets, monkeys, and humans at doses of 1.0 mg kg^{-1} to clarify the similarities and occasional species differences.[15–17] Among these probe substrates, pharmacokinetic assessments of caffeine and metoprolol in dogs, minipigs, marmosets, monkeys,[15–17] and humans[13] are summarized in Fig. 1. The data show similar slowly decreasing plasma concentrations for caffeine in these animals; however, for metoprolol, the maximum concentration and the rate of decrease varied greatly among these animals. Plasma concentrations of metoprolol in orally treated minipigs and monkeys were at the level of the quantitative detection limits at doses of 1.0 mg kg^{-1} (Fig. 1). Metoprolol, a human P450 2D probe, was extensively metabolized by monkey P450 enzymes.[16] In addition, it has been reported that the typical human P450 3A4/5 probe midazolam is cleared more rapidly in monkeys than in humans.[18]

Caffeine is a standard phenotyping substrate for human P450 1A2. Although the caffeine disappearance rates were similar for minipigs, marmosets, monkeys, and humans (Fig. 1), the primary oxidative metabolites of caffeine were different among these species. The predominant reaction in caffeine metabolism in humans is reportedly the 3-demethylation of caffeine to generate 1,7-dimethylxanthine.[19–21] In humans, the 3-*N*-demethylation of caffeine is the major metabolic pathway (81% of total dimethylxanthines); in monkeys, however, 7-*N*-demethylation to form pharmacologically active theophylline is reportedly predominant (89%).[22] Interspecies differences regarding caffeine oxidation exist, but the predominant 8-hydroxylations of caffeine in mice, rabbits, and rats have been shown to be broadly similar.[22] In an analytic approach to investigate species differences in P450 activities, rat P450 1A2 (75% homologous with human 1A2) was aligned with the crystal structure of human P450 1A2 (PDB 2HI4) to model the three-dimensional structure. A docking simulation was able to explain the typical species differences in caffeine metabolism by these two orthologous enzyme forms with possibly different substrate pockets. An additional example of such species differences is the predominant caffeine 7-demethylation mediated by monkey P450 2C9 in contrast to the predominant caffeine 3-demethylation mediated by human P450 1A2.[23]

The well-established and clinically important anticoagulant drug *S*-warfarin is a typical human P450 2C9 substrate.[24] Monkey P450 2C19 reportedly has high activity toward *R*-warfarin 7-hydroxylation,[25] whereas in humans, *R*-warfarin 7-hydroxylation is much slower than *S*-warfarin 7-hydroxylation. The activities of orthologous P450 enzymes from humans and monkeys (Table 1) are generally similar, but some differences were recently recognized, such as those for warfarin hydroxylation described earlier. Marmoset liver microsomes efficiently catalyzed the 7-hydroxylation of *S*-warfarin, but not of *R*-warfarin; this finding was similar to that of humans but not to that of monkeys.[28] Among marmoset P450 2C enzymes,[27] P450 2C19 efficiently catalyzes the 7-hydroxylation of *S*-warfarin, but not of *R*-warfarin, which is similar to the findings for human P450 2C9.[28] The similar stereoselectivity for warfarin 7-hydroxylation between marmosets and humans indicates that the drug-metabolizing properties of marmoset P450 2C19 are similar to those of P450 2C9 in humans. Additionally, plasma concentrations of *S*-warfarin in marmosets after intravenous administration of warfarin decreased faster than those of *R*-warfarin, suggesting that *S*-warfarin was stereoselectively metabolized in marmoset livers in a similar way to that in human livers.[17] However, the metabolic clearances of *S*-warfarin in marmosets exhibited larger interindividual variations than those of *R*-warfarin, suggesting the possible genetic polymorphism of marmoset P450 2C19.[28] Other reported examples of polymorphic enzymes involved in drug oxidations include monkey P450 2C and 2D enzymes.[29–31] Clinical impacts of neonatal opioid toxicity should be noted following maternal use of codeine associated with highly polymorphic human P450 2D6.[32]

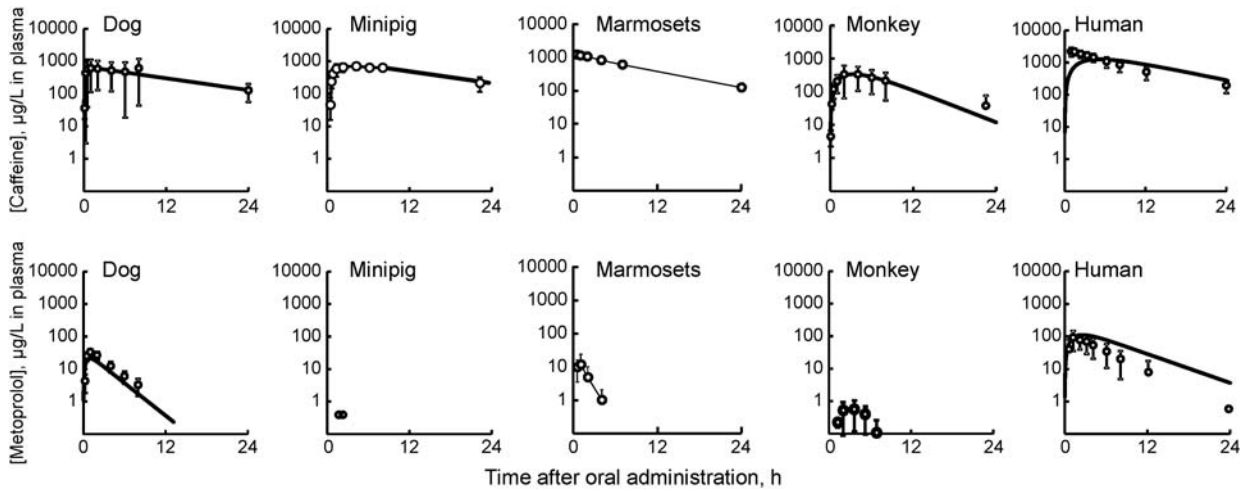

Fig. 1 Pharmacokinetic assessment of caffeine and metoprolol at doses of 1.0 mg kg^{-1} (oral administration) in dogs, minipigs, marmosets, monkeys, and humans. Data are means and standard deviations (SDs) (*circles and bars*, $n=4–6$). *Lines* represent results by PBPK simulations.

Human P450s whose sequences are highly similar to P450s identified in monkeys or marmosets are listed. Rendic and Guengerich,[9,10] Uno et al.,[26] and Shimizu et al.[27] and updated. For P450s that have been renamed, the original names are indicated in parentheses. Human genes in brackets indicate nonactive ones.

4.03.3 Age-Related and Polymorphic Pharmacokinetic Changes of Human P450 Probes in Monkeys

Age-related changes in pharmacokinetics can alter drug responses (pharmacodynamics) and may cause adverse drug reactions. During drug development, it is important to predict how the pharmacokinetics of drug candidates will change in older patients to reduce such risks. There is currently more awareness of the need for modeling and simulation of special conditions as part of drug development. Early in vivo studies in a preclinical species such as the monkey or dog may be helpful. Monkey liver microsomal P450 contents were established in 2011 by immunochemical determinations.[33] Against this background, the pharmacokinetics of the human P450 probes caffeine, racemic warfarin, omeprazole, metoprolol, and midazolam in combination were recently investigated after single intravenous and oral administrations at doses of 0.20 and 1.0 mg kg^{-1}, respectively, to three young (3-year-old) and three aged (16-year-old) monkeys.[16] The mean maximum concentrations of *R*- and *S*-warfarin (4.6 and 3.7 μg mL^{-1}, respectively) in aged monkeys after oral administration were significantly higher than those in young monkeys (3.3 and 2.7 μg mL^{-1}).[16] The mean clearance value of midazolam in aged monkeys (9.5 mL $min^{-1}kg^{-1}$) was significantly lower than that in young monkeys (13 mL $min^{-1}kg^{-1}$).[16] These findings suggest that aged monkeys could be a good model for aging in humans, especially with particular characteristics of reduced clearances for some human P450 substrates in aged monkeys.[16]

In addition, hepatic blood flow rates, but not albumin concentrations, were found to decrease with age in monkeys and in humans.[34] The effects of aging on the pharmacokinetics of acetaminophen (a marker of gastric emptying), antipyrine (a marker of hepatic metabolic activity and total body water), diazepam (lipophilic and highly distributed), diphenhydramine (hepatic blood flow-limited and alpha-1 acid glycoprotein-bound), and ofloxacin (renally eliminated) have been found in monkeys; such changes likely resulted from increased concentrations of alpha-1 acid glycoprotein and total body fat and decreased hepatic blood flow, hepatic and renal clearance, and body water as a result of aging.[34] Consequently, intrinsic clearances, factors unbound in plasma fractions, and hepatic blood flow rates are important parameters for the determination of in vivo clearance values in models of aging.

Resequencing of the monkey *P450 2C19* gene identified three variants p.[(Phe100Asn; Ala103Val; Ile112Leu)] that showed substantially reduced activity compared with wild type *P450 2C19* in terms of *R*-/*S*-warfarin 7-hydroxylation.[30] Because such defective or impaired alleles of human *P450* genes must be considered in drug metabolism studies during drug development, the role of monkey *P450* genes, especially polymorphic monkey P450 2C19, was elucidated in vivo. It was found that interanimal variations of *R*-warfarin clearance in monkeys were associated with monkey *P450 2C19* genetic variants p.[(Phe100Asn; Ala103Val; Ile112-Leu)].[29] Because some interindividual variability of P450 2C-dependent drug metabolism in monkeys, as in humans, is accounted for by polymorphic *P450 2C19* variants, genotyping of drug metabolism enzymes should be considered before and after P450-dependent drug metabolism testing and evaluations in monkeys.

A widely used antiplatelet agent clopidogrel is a prodrug that is metabolized by two main metabolic pathways in humans:[35,36] an esterase-dependent pathway leading to hydrolysis into an inactive carboxylic acid derivative and a P450-dependent two-step oxidative process leading to its active metabolite.[36] Although contributions of human P450 1A2, 2B6, 2C19, and 3A4 on the activation pathway have been reported,[36] genetic polymorphisms of human *P450 2C19* could be one of the key clinical considerations in interindividual variability in clopidogrel pharmacokinetic and pharmacodynamic responsiveness[35,37] when clopidogrel treatment is initiated. It should be noted that recombinant monkey P450 2C9, 2C19, and 2C76 extensively metabolized clopidogrel to a similar extent in substrate deletion assays.[38–40]

4.03.4 Using Chimeric Mice With Humanized Liver to Investigate Drug-Induced Toxicity

Considerable discussion has centered on the importance of drug metabolites as potential determinants of drug safety.[41] This debate led to a guidance note for the drug development industry issued in 2008 by the US Food and Drug Administration, namely, "guidance for industry safety testing of drug metabolites," and ultimately culminated in recommendations from the International Conference on Harmonization M3(R2) in 2010. These guidance documents laid out criteria establishing when human metabolites need to be measured in laboratory animal species and defined the circumstances under which direct testing of a metabolite in animal toxicology studies is needed to provide a reliable risk assessment. Recent developments in bioanalytical methodology have yielded several strategies to provide robust data that can inform critical decisions related to metabolite quantification and monitoring in plasma.

The National Institutes of Health LiverTox database (http://livertox.nih.gov/) was developed by the Liver Disease Research Branch of the National Institute of Diabetes and Digestive and Kidney Diseases and the National Library of Medicine to promote basic and clinical research on drug-induced liver toxicity. This is a free online source of textual documents on liver injury caused by prescription and nonprescription drugs, herbal medicines, and dietary supplements collected from various databases, the scientific literature, and the interpretations of the curators.[42] Recently, systematic research into metabolic drug activation has become more comprehensive and more complex.[43] Drug-induced toxicity may be caused by active intermediates formed by human cytochrome P450 enzymes. To understand the roles of human P450 enzymes in drug metabolism, safety assessment of drug metabolites is proposed by potential application of engineered mouse models. Human drug-metabolizing P450 3A enzymes have been found to undergo thalidomide activation.[44] In in vivo models with chimeric mice with humanized liver, high midazolam clearance and a higher area under the plasma concentration–time curve of the metabolite 1′-hydroxymidazolam were obtained following coadministration of thalidomide, indicating that heterotropic cooperativity of human P450 3A4/5 by thalidomide occurs in vivo.[45] Thalidomide and its human disproportionate metabolite 5-hydroxythalidomide were oxidized by autoinduced human P450 3A enzymes[46] to reactive intermediates (with reactive sites on the aromatic ring) that were trapped as glutathione conjugates.[47,48]

As an example of species differences in metabolic drug activation, human liver P450 1A2 exhibited different functionality from rat P450 1A2 in bioactivation of the primary metabolite of 5-*n*-butyl-7-(3,4,5-trimethoxybenzoylamino)pyrazolo[1,5-*a*]pyrimidine (an amide moiety-bearing pyrazolopyrimidine derivative with potential analgesic effects).[49] A primary metabolite was metabolized by human P450 1A2 to form a proximate metabolite, which was conjugated with a peptide to form an adduct.[50] In rats, the same P450 1A2 enzyme formed some proximate metabolites but predominantly mediated the formation of another metabolite that exhibited no toxicity.[51] These metabolic differences highlight some of the perils of animal testing of drug candidates for metabolite toxicity. A zone analysis using electrophoresis with accelerator mass spectrometry revealed that in vivo bioactivated radiolabeled troglitazone and flutamide (both known to be hepatotoxic in humans) bound nonspecifically to a variety of microsomal and/or cytosolic proteins present in liver from chimeric mice with humanized liver.[52] In contrast with those of radiolabeled diazepam (rarely hepatotoxic) and 5-*n*-butyl-pyrazolo[1,5-*a*]pyrimidine (limited hepatotoxicity), some of the proteins binding troglitazone and flutamide were located high in a zone analysis of specific covalent binding contents and target protein concentrations.[52] Drug metabolism mediated by humanized livers in chimeric mice (leading to binding in vivo) may be a good tool for evaluating the relationship between nonspecific protein binding tendencies of medicines and their metabolites and potential hepatotoxicity in humans. These findings indicate the usefulness of using transplanted human liver cells in humanized mice to give accurate preclinical predictions of human drug metabolism.

Many results have also been reported on the in vitro–in vivo extrapolations of hepatic clearance, on the volume of distribution, and on the estimated unbound microsomal fraction for a wide variety of drugs.[53] Simplified human physiologically based pharmacokinetic (PBPK) models for acephate,[54] chlorpyrifos,[54] bisphenol A,[55] and di(2-ethylhexyl)phthalate[56] were recently developed based on the pharmacokinetics in humanized mice; these models successfully estimated the human pharmacokinetics. Glucuronide metabolites of bisphenol A[55] and mono(2-ethylhexyl)phthalate[56] were excreted in the urine of chimeric mice with humanized liver, in contrast with the results of experiments on rodents without humanized liver. Simplified PBPK models are able to estimate human plasma and urine concentrations of drugs after ingestion and are capable of both forward and reverse dosimetry. This simple system was also successful in estimating human plasma concentrations of various P450 probes based on monkey plasma data.[57]

4.03.5 Epilogue

The success of research into drug-metabolizing enzymes and its application in drug discovery and development has been remarkable. The combination of pharmacokinetic data with a simple PBPK model has great potential for assisting evaluations of the

pharmacological/toxicological potential of new drug substances and for estimating human radiation exposures from radiolabeled drugs when planning human studies.[58] The applications of P450 research continue to expand and develop. Interest should also focus on another monooxygenase, flavin-containing monooxygenase 3 (FMO3), because it is responsible for the *N*- or *S*-oxygenations of various drugs; moreover, genetic polymorphism in the human *FMO3* gene may result in changes of catalytic efficiency and lead to drug interactions.[59] Pharmacokinetics and safety assessments of drug metabolites should be done with marmosets/monkeys and mouse models with humanized liver to achieve a good understanding of the effects of drug-metabolizing enzymes on potential new drug candidates.

Biological systems are a complex mix of heterogeneous phases. Drug molecules usually traverse many of these phases to get from the site of administration to the eventual site of action. Along this random-walk process, they may perturb many other cellular components such as organelles, lipids, proteins, and so forth. These interactions are complex and vastly different from organic reactions in test tubes, even though the eventual interaction with a receptor is chemical or physicochemical in nature. Thus, depending on the biological system involved—isolated receptor, cell, or whole animal—one expects the response to be multifactorial and complex. The overall process, whether in vitro or in vivo, involves a mix of equilibrium and rate processes, a situation that defies easy separation and delineation.[1]

4.04.1 Predicting Human Pharmacokinetics and the Future of In Silico-Based Research and Development

4.04.1.1 Prologue

In his fascinating book, *The Vital Question. Why is life the way it is?*, Nick Lane puts forth his hypothesis on the origin of the electrochemical processes that led to the energy production essential for life on earth.[2] These early chemical processes from eons ago reverberate in the complex processes and supportive cellular structures resident in all eukaryotic cells today. Many of these processes have been extensively explored in cleverly designed experiments that led to theories that can explain many of the complex intricacies of drug absorption, distribution, metabolism, and excretion (ADME).

In silico tools are now available that encompass an amalgamation of reductionist-based theories and experimental results. The availability of software tools and complementary sources of input parameters, such as in silico predictions of drug properties from molecular structure and in vitro and in vivo experimentation, has led to an increasing use of physiologically based pharmacokinetic (PBPK) modeling and simulation in a wide variety of applications across the entire research and development (R&D) lifecycle.

PBPK modeling and simulation tools, such as GastroPlus™,[3] provide a framework for specifying species-specific physiological parameters and drug-specific physicochemical properties to predict and explain the pharmacokinetic (PK) behavior of drug molecules as they "traverse" the body.

The goal of this article is to explore some of the key concepts, theories, and practices involved in successfully using PBPK modeling and simulation to predict pharmacokinetics in preclinical and clinical settings. This includes the use of molecular–structure-based in silico predictions of physicochemical properties and the performance of in vitro to in vivo extrapolations (IVIVEs).

An overview of PBPK model development is provided, along with selected examples of applications of PBPK modeling and simulation. Future implications and applications of these approaches are also explored. The focus will be on small molecules, but it should be noted that PBPK modeling and simulations are being directed toward large molecules, such as proteins, antibodies, and antibody–drug conjugates.[4]

4.04.1.2 Introduction

Pharmaceutical R&D scientists continue to seek new knowledge and insights that can lead to innovative medicines. This search for safe and effective medicines is remarkably expensive and prone to failure. The productivity crisis engendered by past failures has led to a variety of new technologies and various attempts at innovation aimed at reducing the costs and improving the chances of successfully bringing new medicines to market.

Labor-intensive one-by-one synthesis has given way to combinatorial chemistry techniques that can quickly create unprecedentedly large libraries of new compounds. Tissue-culture-based, high-throughput phenotypic screening has replaced phenotypic screening in intact organisms as the preferred way to assess activity against selected targets that might lead to a clinically useful and commercially viable new medicine. This new generation of tools has produced notable successes and failures, albeit at an unsustainable expenditure in resources. One of the reasons for the productivity crisis is that compounds with limited potential are erroneously progressed through the R&D lifecycle. The costs of preclinical and clinical testing accumulate until further testing is made futile by unmistakably clear signs of a failure to meet minimal program objectives.[5] Every drug that fails was a failure as soon as the molecular structure was drawn for the first time, but determining that it was a failure in the traditional manner sometimes costs years of development time and hundreds of millions of dollars of wasted resources. Recognizing these failures as early as possible in discovery or very early development would save billions of dollars in pharmaceutical R&D expenses.

An analysis of failures in clinical development performed by Kola and Landis[6] demonstrated that the causes of attrition over a 10-year period from 1991 to 2000 changed substantially during that period of time. In 1991, adverse PK and bioavailability results were a significant cause of attrition, and accounted for approximately 40% of all attrition. By 2000, adverse PK and bioavailability

results had been dramatically reduced as a cause of attrition, but this was accompanied by a shift toward failures due to efficacy and safety issues, and overall attrition rates remain high to this day.[7] One explanation for the changing reasons for attrition was the recognition that most orally administered drugs are relatively small and moderately lipophilic molecules. Lipinski's Rule of 5 (Ro5)[8] was developed as a heuristic to predict whether a chemical was likely to be absorbed orally. The rule raised awareness of the importance of physicochemical properties, and not just in vitro potency, in predicting the likelihood of clinical success.[9]

The concern about attrition and the rising costs of R&D has inspired much debate among scientists and prompted a search for strategies to improve efficiencies and enhance the success rates for new medicines. The efforts to improve productivity have focused on ways to identify compounds likely to fail in later stages of development where failure is most expensive, or, alternatively, to find ways to optimize the R&D program for compounds with an acceptable level of promise in order to improve the chances for success.

The emergence of in silico tools, such as PBPK modeling, to predict human pharmacokinetics for new compounds now provides significant opportunities to anticipate the advantages and liabilities associated with compounds under consideration in discovery. Physiologically based PK modeling is being used in diverse applications including simulation of preclinical, Phase 1 healthy volunteer, and special population pharmacokinetics; modeling of absorption, impact of formulation differences, and food effects; and predicting the magnitude of drug–drug interactions (DDIs). These applications have had significant impact throughout the stages of drug discovery and development to increase efficiency, reduce the need for animal studies, and increase PK understanding in order to anticipate problems and optimize development programs.

The use of PBPK modeling and simulation methodology has increased considerably in the last few years, driven by a number of factors. First, there are now commercially available software tools, such as GastroPlus, that effectively deal with the complexity of the series of differential equations required to describe the transit of drug through the body. Second, enhancements in the design and utility of in vitro systems provide quantitative information on the relevant PK properties of a drug. Third, there have been enhancements to the in silico tools used to build models of quantitative structure–activity relationships (QSAR) that can accurately predict physiochemical properties from molecular structure. In combination, the in silico and in vitro systems enable a representation of in vivo processes that have proven to be valuable in the prediction of drug pharmacokinetics across a wide range of compounds and decision-making scenarios.[10] Lastly, regulatory agencies have been at the forefront of encouraging these applications of PBPK modeling and their inclusion in regulatory submissions. For example, the United States Food and Drug Administration (FDA),[11] the European Medicines Agency (EMA),[12,13] and the Ministry of Health, Labor, and Welfare (MHLW) of Japan[14] suggest the use of PBPK modeling in their latest guidance documents on DDI assessment and hepatic impairment studies.

Given the diversity of PBPK applications and the requirements for input data from multiple departments, there is a critical need for effective interdisciplinary collaboration in model development and interpretation. The knowledge and expertise of preclinical scientists, formulation scientists, pharmacometricians, clinical pharmacologists, clinicians, and statisticians are important for a number of reasons. First, the science and the theories behind in silico tools continue to advance and improve the accuracy of predictions. Second, scientists continue to find new and creative ways to apply in silico tools and the simulations are becoming central in decision-making at all levels of R&D. Third, science-based R&D enterprises, such as the pharmaceutical, biotechnology, and agrochemical industries, will continue to be shaped by emerging applications of in silico tools. The availability of in silico tools as a basis for decision-making will require new approaches to the management of the R&D enterprise in order to foster interdisciplinary collaboration and provide innovative training and career development strategies for scientists and managers alike.[15]

4.04.2 Overview of Pharmacokinetics and Pharmacodynamics

4.04.2.1 Pharmacokinetics

The term "pharmacokinetics" was first introduced in 1953 by F.H. Dost,[16] yet the concepts and ideology have been at the heart of medicine for over a century as outlined in Wagner's seminal article, "The History of Pharmacokinetics."[17] Pharmacokinetics is broadly known as the study of the time course of what the body does to the drug, characterized by the key ADME components.[18] The rate and extent of ADME mechanisms, particularly clearance, volume of distribution, and absorption, are of central importance in PBPK models and are described in the sections here.

4.04.2.1.1 Clearance

Organ clearance is defined as the volume of fluid presented to an eliminating organ that is completely cleared of drug per unit time. Clearance (CL) has units of volume per time, for example, L/h, and is mathematically described by Eq. (1).

$$\mathrm{CL} = Q \times E \tag{1}$$

where Q is the flow rate to the eliminating organ and E is the extraction ratio of the drug.

The total clearance of a drug represents the sum of all clearance mechanisms in all eliminating organs and tissues in the body including the gastrointestinal (GI) tract, liver, heart, lung, kidney, and so forth.[19] Clearance of a drug in the GI tract is important as it pertains to first-pass extraction of a drug before the drug even enters the systemic circulation. Once in the systemic circulation, the most important eliminating organs are generally the liver and the kidney.

Hepatic clearance is determined by hepatic blood flow, free fraction of unbound drug, and intrinsic clearance. Intrinsic clearance is the rate at which the liver is able to metabolize a drug when it has unrestricted access to it. Hepatic clearance of drugs is often classified according to the drug's hepatic extraction ratio. This ratio is the rate at which the liver clears drug divided by the rate

at which the liver is presented with the drug. For high extraction drugs, hepatic clearance is limited by blood flow, whereas for low extraction drugs, hepatic clearance is contingent upon fraction unbound and intrinsic clearance.[20]

Renal clearance is defined by the processes a drug is subjected to as it transits through the kidney. Renal filtration and renal secretion into the renal tubules positively contribute to renal clearance, whereas reabsorption from the renal tubules decreases renal clearance. Renal filtration is governed by molecular size and protein binding alone, while renal secretion is dependent on renal transporters—which can be inhibited or saturated—as well as on protein binding. Renal reabsorption can be active or passive, with passive resorption dependent on lipophilicity, the pH of the urine, the pK_a of the drug, and urine flow rate.

In addition to hepatic and renal clearance mechanisms described earlier, drugs can also be eliminated via biliary secretion and can undergo enterohepatic circulation. Enterohepatic circulation refers to the process whereby a drug or a metastable metabolite thereof in the liver is secreted into the bile, stored in the gall bladder, and subsequently released into the small intestine, where the drug can be reabsorbed back into circulation and subsequently returned to the liver. Enterohepatic circulation is clinically significant when the prolonged presence of the drug in the systemic circulation results in an increase in the duration or magnitude of the drug's pharmacologic effect.

4.04.2.1.2 Volume of distribution

The concentration of a drug in plasma after drug administration is a function of dose, the extent of distribution of drug into tissues, and the amount of drug eliminated during the distribution process.

There are two types of volume of distribution of interest. The apparent volume of distribution (V_d) is estimated during the terminal phase of elimination and is influenced by the relative speeds of distribution and elimination of the drug. The steady-state volume of distribution (V_{ss}) represents the volume required to explain the steady-state plasma concentration of a drug after all distribution-related phenomena have equilibrated. In either case, drugs distribute into various tissues and fluids of the body and binding to tissue components may be so great that the volume of distribution can exceed the physical volume of plasma in an individual.[20]

Drug concentrations are generally determined in plasma so that V_{ss} is the theoretical volume of plasma at a given drug concentration that would be required to account for the entire amount of drug in the body.

The volume of distribution of a specific drug is shaped by its unique characteristics, including the extent of binding in tissue and blood, mechanisms and rate of drug transport, physical volumes of distributing tissues, and rate and extent of metabolism and elimination. Volume of distribution is useful in estimating the dose required to achieve a given plasma concentration or, conversely, to estimate the amount of drug in the body when the plasma concentration is known.[20]

4.04.2.1.3 Half-life

The elimination half-life ($t½$) is the time it takes for the drug concentration to decrease by one-half. The half-life is a function of the V_d and the total CL of a drug as shown in Eq. (2).

$$t½ = (V_d \times log_e 2)/CL \tag{2}$$

This relationship is such that the larger the total clearance, the shorter the half-life and, conversely, the larger the V_d, the longer the half-life.[19,20]

Half-life is used to determine the optimal frequency of drug administration for chronically administered medicines. Often, drugs are administered every half-life in order to minimize the difference between peak and trough drug concentrations over the dosing interval.

"Steady state" is achieved when the rate of drug input is equal to the rate of drug output, and is generally recognized to be achieved after a drug has been repeatedly administered for approximately four to five "half-lives." Steady-state concentrations are considered therapeutically relevant, especially for chronically administered drugs, where these concentrations are associated with the desirable and undesirable clinical outcomes of drug therapy.

4.04.2.1.4 Absorption

An orally administered drug must clear several barriers in order to reach the systemic circulation. Accordingly, the overall systemic bioavailability, F, when a drug is administered orally, is computed by Eq. (3)

$$F = F_a \times F_g \times F_h \tag{3}$$

where F_a is the fraction of drug absorbed into enterocytes, F_g is the fraction of drug that escapes gut metabolism, and F_h is the fraction that escapes first-pass extraction by the liver. Bioavailability can be based on comparison of an intravenous dose with any extravascular (e.g., oral, dermal, nasal, pulmonary) dosage form (absolute bioavailability), or comparison of any two routes of extravascular administration (relative bioavailability).

PBPK modeling allows the scientist to mechanistically investigate the absorption of a compound and account for the various processes that can impact systemic bioavailability. Orally administered solid dosage forms must disintegrate and the drug molecules must enter into solution. In order to be absorbed systemically, drug in solution must then pass through the enterocytes lining the intestinal wall and enter into the portal vein, which then carries the drug molecules to the liver and into the systemic circulation. Moreover, some drug may not get absorbed and is lost in the feces or via decomposition in the lumen. All of these processes,

including incomplete disintegration or dissolution, slow penetration of the enterocyte membranes, decomposition in the gut lumen, and metabolism of the drug as it passes through the gut wall and the liver, can reduce the systemic availability of the drug.

The physicochemical properties of a drug play an important role in determining the rate and extent of absorption of a drug. The properties that can lead to poor absorption include low solubility and low permeability. The properties of a compound or a formulation might be altered or modulated to improve absorption; the solubility of a compound could be increased by physical, chemical, or other modifications. Formulation of a drug as a salt, for example, can favor ionization and dissolution in the GI tract thereby increasing absorption. Physical modifications including particle technologies, such as micronization, are used to increase surface area and allow an increased dissolution rate.[21] Alternatively, solubilizing agents can be added to the formulation.

Addition of an ionizable group that gets cleaved off after absorption—that is, generation of a prodrug—offers a unique way to address solubility or permeability problems. Such "promoieties" include a wide range of functional groups with well-established chemistry and safety. Besides being more soluble, such conjugates can act as substrates for influx transporters, all of which can improve absorption.[22]

4.04.2.2 Pharmacodynamics

Pharmacodynamics is the study of what the drug does to the body and describes the relationship between drug concentrations at its sites of action and the pharmacologic responses, either therapeutic or adverse. The time course and intensity of a drug's effect is a function of its concentration at receptor sites and is dependent on the pharmacokinetics of the drug. The target concentration range is the range of plasma drug concentrations defined by the minimum effective concentration and the maximum therapeutic concentration. Dosing regimens that deliver concentrations below the minimum effective concentration may not provide an adequate therapeutic response. Conversely, regimens that deliver concentrations above the maximum therapeutic concentration may result in adverse events.

The Hill equation shown in Eq. (4) defines the relationship between drug concentrations and pharmacologic effect.[23]

$$E = \frac{E_{max} \cdot C^{\gamma}}{EC_{50}{}^{\gamma} + C^{\gamma}} \tag{4}$$

where E_{max} is the maximum achievable effect, EC_{50} is the concentration eliciting half the maximal effect, and C represents the drug concentration at the site of action. The gamma superscript (γ)[24,25] is a coefficient used in the Hill equation as a mathematical adjustment which can account for a variety of pharmacologic processes, such as receptor cooperative binding, that cause deviation from a classic binding isotherm where $\gamma = 1$.

A variety of pharmacodynamic (PD) models that relate drug concentrations to pharmacologic effect have been introduced in the literature. These models include simple direct effects, biophase, indirect response, signal transduction, irreversible effects, and more complex models including tolerance, cell kill, receptor binding dynamics, and so forth.[23,26]

Fig. 1 shows an illustration of the drug concentration-time profile and the influence that drug dose and pharmacokinetic behavior can have on therapeutic response.

In the figure, the lag time of absorption is related to the time required for drug disintegration, dissolution, and passage to the systemic circulation. Time to peak effect is related to the rate of absorption, the volume of distribution, drug dose, and bioavailability. The duration of effect is related to the time the drug concentrations are within the therapeutic range, which in turn is related

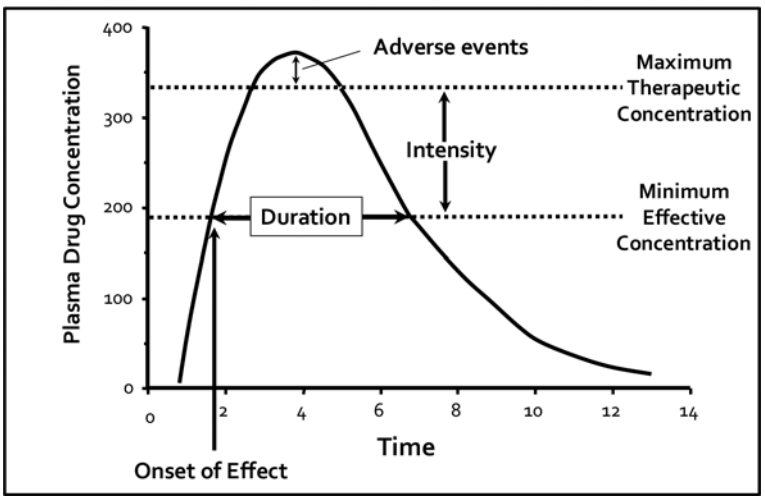

Fig. 1 The plasma concentration-time profile for a hypothetical drug after oral administration overlaid with the therapeutic range of the drug.

to the rate of absorption and the half-life of elimination. The magnitude of the dose and the frequency of administration are selected to achieve steady-state concentrations in the targeted therapeutic range which are correlated with the desired effects.

4.04.3 The Relationship Between Physicochemical Properties and Pharmacokinetics

The pharmacokinetic properties of a drug play an important role in determining the fate of drug molecules as they move through the body. These properties, in turn, reflect the drug's physicochemical characteristics. Much of the medicinal chemistry work done on a given series of compounds involves making relatively small modifications—that is, tweaking—the structure of a lead compound to address pharmacokinetic and/or toxicological issues discovered during lead optimization. Because it would be inefficient to assess every conceivable structural variation, the models employed by computational chemists are used to provide valuable guidance as to which part(s) of the problematic molecule to focus on when determining where to tweak the structure and what substitutions to try first. Indeed, much of the computational work performed in the early phases of drug development goes into collaborative brainstorming to determine which modifications or elaborations are most likely to address the issue(s) at hand without themselves creating new problems.

4.04.3.1 Molecular Size

The size of molecules that have a typical drug-like shape is commonly given as the molecular weight (MW), defined as the mass of one mole of a compound. MW is typically given in grams per mole or the more standard unit of daltons. MW of an active ingredient can have an impact on its ability to be effectively transported or to permeate cells. For example, drugs with a high MW often have poor bioavailability unless they are absorbed via a mechanism other than passive diffusion, such as active transport.

Historically, drugs with MWs below 600 Da were considered desirable due to the correlation between MW and absorption profile, that is, higher MW is associated with lower oral bioavailability. As a result, drugs with a low MW have been seen as more likely to make it through clinical trials.[27] The association between higher bioavailability and lower MW is not a result of MW per se, but MW may be a surrogate for other properties often associated with it.[28] Such correlated properties include molecular flexibility (rotatable bonds) and/or hydrophobicity, which may affect permeation or absorption across physiological membranes and therefore affect oral bioavailability in the absence of active transport.[28] The relationship between MW and properties such as hydrophobicity is complex in that up to certain values of hydrophobicity/lipophilicity, absorption may increase, and as the values continue to increase, compounds may have difficulty leaving biological membranes and may demonstrate reduced absorption. At the other end of the extreme, highly hydrophilic molecules will have trouble entering biological membranes in the first place.

4.04.3.2 Hydrophobicity

A *hydrophobic* molecule is "water fearing" in that it will prefer to be dissolved in a relatively nonpolar solvent over being dissolved in water. It is expressed in terms of the log of the partition coefficient P between 1-octanol and water,[29] which is a key physicochemical parameter for determining membrane permeability. The hydrophobicity of a molecule is often correlated with its absorption, distribution, and route of elimination.[29]

Biological membranes are comprised of a bilayer of phospholipids and other lipids as well as cholesterol. Each membrane is distinguished by a characteristic lipid composition as well as by a specific complement of embedded proteins. The lipids are amphiphilic, that is, each molecule has one hydrophobic end (typically derived from a fatty acid) and another *hydrophilic* ("water loving") end. The hydrophilic parts are localized at the inner and outer bilayer surfaces, whereas the hydrophobic portions make up the central region of the membrane. This composition makes it easy for nonpolar molecules to diffuse into the central region readily; however, a molecule which is too hydrophobic ($\log p > 5$) has trouble diffusing out into aqueous solution on the other side. This phenomenon underlies the use of the alternative term *lipophilic* ("lipid loving") to describe such molecules.

The inability of highly lipophilic molecules to traverse membranes leads to poor oral bioavailability. The absorption penalty for being too lipophilic is associated with high MW because it is relatively easy to synthesize large lipophilic compounds but relatively difficult to synthesize large hydrophilic ones. There are, however, many large commercial drug molecules, but they are generally derived from relatively hydrophilic natural products. To paraphrase Lipinski et al., there are large drugs and there are greasy drugs but large greasy drugs are a rarity in the therapeutic armamentarium.[9]

Highly lipophilic compounds also tend to bind to plasma proteins.[29] When drugs are bound to plasma proteins, there is less free drug in solution available to exert its effect at the sites of action. Lipophilic drugs can be filtered and excreted in the urine, or be reabsorbed and further metabolized. Passive reabsorption that occurs in the kidneys is governed by the molecule's lipophilicity, that is, the more lipophilic a molecule is, the more passive reabsorption occurs, and therefore the renal clearance of the molecule decreases. When a drug is reabsorbed, it might be subject to metabolism to a more polar metabolite and may then be filtered in the kidneys and renally excreted.

As described earlier, lipophilicity is often expressed as a partition coefficient (P), or $\log P$, and is defined in terms of the partitioning of neutral molecular species. Many drugs can ionize under physiological pH, however, and ions are much more hydrophilic than their neutral counterparts. A more appropriate measure of drug partitioning in the body is the distribution coefficient D at a specified pH (generally expressed as $\log D$).[29] In the experimental determination of $\log D$, an aqueous buffer at pH 7.4 is used to mimic blood, whereas an aqueous buffer at pH 6.5 is used to mimic intestinal conditions.

4.04.3.3 Solubility

Solubility of a drug in GI fluids is important and its determination is required by the FDA for new drug applications and bioequivalence testing. When a drug is orally administered in a solid dosage form, the first steps in the absorption process include the disintegration of the tablet or capsule followed by the dissolution of the active drug. Drug must be in solution before it can be absorbed; consequently, solubility and dissolution rate can limit absorption if they are low, as can premature precipitation. In general, compounds with low MW, low lipophilicity, and high polarity dissolve more readily. Conversely, compounds with high MW, high lipophilicity, and low polarity are less soluble. The solubility of a compound will be pH-dependent if it is ionized at the physiologic pH conditions encountered in the stomach and GI tract. A drug is considered highly soluble if the highest dose strength is soluble in ≤ 250 mL of water over the pH range of 1.0–7.5.[30] For drugs with low solubility, in vivo solubility can be enhanced by micellar solubilization due to bile salts.

4.04.3.4 pK_a

Most drugs are acidic or basic; many are both. In solution, they exist in equilibrium between unionized and ionized forms. The ratio of ionized and unionized forms is controlled by both the pH of the solution and the pK_a(s) of the drug according to the Henderson–Hasselbalch equation (Eqs. 5 and 6).

For acids that have a single ionizable center (i.e., monoprotic acids),

$$log_{10}(\text{ionized concentration}/\text{unionized concentration}) = \text{pH} - \text{p}K_a \tag{5}$$

and for monoprotic bases,

$$log_{10}(\text{unionized concentration}/\text{ionized concentration}) = \text{pH} - \text{p}K_a \tag{6}$$

Given that log10 (1) = 0, the pK_a of such compounds is the pH at which half of the molecules are ionized. If the pH of the environment is less than the pK_a of the molecule, then more molecules are protonated than are deprotonated: for bases this means the drug is mostly ionized and for acids this means the drug is mostly unionized.

The pH values observed in the body typically range from 1.0 to 7.5 in the GI tract and the renal tubule. For drugs that have a pK_a in the range of 3.0–7.5, the fraction unionized can change dramatically as the drug travels down the GI tract or is excreted in the urine. These changes in pH can have marked effects on permeability and diffusion across membranes. For instance, considering renally excreted drugs, ionized molecules are less likely to be passively reabsorbed and more likely to be eliminated in the urine. When the pH of the urine increases or decreases, the ionization and renal clearance of that drug can change. Therefore, renal excretion of a weak base is increased when the urine is acidified, whereas for a weak acid, increasing the pH of the urine increases renal excretion.

4.04.3.5 Hydrogen Bonding

The hydrogen-bonding capacity of a drug solute is an important determinant of permeability. In order to cross a membrane, a drug molecule needs to break hydrogen bonds with its aqueous environment. The more potential hydrogen bonds a molecule can make, the more energy this bond-breaking costs. Consequently, high hydrogen-bonding potential is an unfavorable property in that it reduces lipophilicity[31] and results in low permeability and poor absorption.

Hydrogen bonds are inherently important because too many hydrogen bond interactions with solvent and with the polar head groups of membrane lipids will impair membrane penetration. Water can serve as either a hydrogen bond donor or an acceptor, so having too many acceptors or donors on a drug molecule will usually reduce permeability. Hydrogen bond donors can be assessed by summing the number of hydrogens in NH and OH groups (i.e., NH_2 counts as two). Similarly, hydrogen bond acceptors in a drug molecule can be estimated by summing the number of nitrogen and oxygen atoms. This is not a precise measure, since it ignores the effects of protonation and deprotonation, but it works well as a rule of thumb when consistently applied.

4.04.3.6 Permeability

The permeability of a drug represents the cumulative effects of pK_a, lipophilicity, hydrogen bonding, and MW, which markedly affect the compound's ability to traverse the physiological barriers and reach the systemic circulation. Drugs that are lipophilic, have a low MW, and have significant unionized fraction at physiological pH generally exhibit good permeability. When a drug has poor permeability, it can lead to poor bioavailability, and alternative routes of administration, such as intravenous or intramuscular injection, may be required to achieve desired systemic concentrations.

4.04.3.7 Implications of Physicochemical Properties

Solubility and permeability are critical factors that affect the bioavailability of orally administered drugs. The importance of solubility and permeability emerged from research conducted in the 1990s by Amidon et al.[32] and separately by Lipinski[9] into the factors associated with good oral bioavailability. This research has had significant implications regarding management decisions

about advancing lead compounds during discovery, as well as regulatory decisions regarding the need for bioavailability and bioequivalence studies for immediate-release solid oral dosage forms.[30]

4.04.3.7.1 Biopharmaceutics Classification System

The Biopharmaceutics Classification System (BCS) is a scientific framework for classifying drug substances based on their aqueous solubility and intestinal permeability. A BCS was implemented by the FDA in 1995[33] after Amidon's seminal article established the influence of fundamental parameters of drug solubility and permeability on rate and extent of drug absorption.[32]

These parameters, combined with the dissolution rate of an oral formulation, address three major factors that govern the rate and extent of drug absorption from immediate-release solid dosage forms. The BCS approach to classifying compounds provided the FDA with a legally acceptable guideline for justifying waivers of in vivo bioavailability and/or bioequivalence studies for rapidly absorbed, immediate-release solid oral dosage forms of high solubility and high permeability (class 1) compounds.[30] The BCS also provides a basis for making inferences about the absorption rate behaviors of compounds in other classes. For example, class 2 compounds (low solubility–high permeability) are predicted to be well-absorbed, and the rate of absorption will be controlled by the dissolution rate of the formulation. Class 3 compounds (high solubility–low permeability) are predicted to have limited oral absorption. Lastly, class 4 compounds with low solubility and low permeability are likely to be poorly absorbed when administered orally.

4.04.3.7.2 Lipinski Rule of 5

Based on an analysis of the characteristics of orally administered drugs, Lipinski determined that, in general, a successful orally active drug has no more than one violation of the following criteria: no more than five hydrogen bond donors (N—H and O—H bonds), no more than 10 hydrogen bond acceptors (all nitrogen or oxygen atoms), a molecular mass less than 500 Da, and an octanol–water partition coefficient (log *P*) not greater than five. The Ro5 gained its name because its four criteria involve multiples of five.[9]

The Ro5 was proposed as a heuristic to guide the selection of small molecules that were likely to have favorable oral bioavailability during lead drug modification. The Ro5 was innovative and useful because, at the time it was introduced, there was not a guide to predict if a molecule produced from combinatorial chemistry would be likely to succeed.

Once it began to be applied, it became clear that much of the combinatorial chemistry then being done produced compounds that were unlikely to succeed as orally dosed drugs in vivo. Moreover, the hydrophobicity and size that limited their bioavailability tended to confer exaggerated potency in high-throughput in vitro screens. The collection of physicochemical properties included in the Ro5 gave interdisciplinary teams a basis, beyond just potency, for challenging the quality of compound candidates as put forth by discovery scientists.

The widespread application of the rule had a significant impact on the reasons for attrition and demonstrated that the R&D enterprise could be positively affected by what was essentially a simple model to predict absorption using data from molecular structure, including MW and polarity, and the computationally estimated (or, occasionally, measured) octanol–water partition coefficient (log *P*). The Ro5 demonstrated that physicochemical information was useful in moving toward a more productive drug discovery process.[34]

The success of the Ro5, its subsequent refinements,[28,35] and the implications of BCS have called attention to the importance of an early consideration of physicochemical properties in advancing compounds from discovery.

4.04.4 In Silico Predictions of Physicochemical Properties

The utility of PBPK modeling to support drug discovery and early development has previously been limited by the resource-intensive experiments required to generate the physiologically relevant ADME data used as input into the models. Large amounts of in vivo animal tissue concentration data were required[36,37] and PBPK models were mainly used to predict tissue exposure in toxicological, safety, and risk assessment studies.[38,39]

The large chemical libraries and capacity for high-throughput screening of biological activity has fed the need for early information on absorption, distribution, metabolism, excretion, and toxicity (ADMET) properties of compounds. Various in vitro ADMET screens are now in use, but many of these represent surrogate endpoints, that is, they are themselves models. There remains a need for tools capable of reliably estimating ADMET properties from a compound's structure alone at the earliest stages of discovery when only very small amounts of material are available or before a compound has even been synthesized.[40–42]

Oftentimes, direct measurements of drug-like properties, such as hydrophobicity, log *P*, and polarity, are not available in early discovery. This lack of information can delay a proper assessment of compound potential before the information about potency drives decision-making. This need for early information on physicochemical properties has led to interest in predicting physicochemical properties solely from compound structure. These predictions have proven useful in optimizing the screening and testing process by focusing on the most promising compounds with the goal of reducing the need for expensive in vitro and preclinical in vivo testing.[29]

4.04.4.1 Brief Descriptions of QSAR Methodologies

QSAR are based on the assumption that the geometric, steric, and electronic properties of a molecule are responsible for its physical, chemical, and biological properties and that these properties can be adequately represented by one or more numerical descriptors.[43] By developing QSAR models, many properties of a new or untested compound can be inferred from the molecular structure of compounds whose properties have already been determined.[44–48]

The model-building process makes use of three components, including: (1) a data set that provides experimental measures of activity or properties for a group of chemicals; (2) the molecular structure and/or descriptors for the chemicals, and (3) statistical tools for delineating the relationship between these two data sets.

The limiting factor in the development of predictive QSAR is typically the availability of high-quality experimental data. Ideally, the data set should address a well-defined endpoint and include enough molecules to provide adequate statistical representation of the chemical space of interest. For regression models, a wide range of response values is required, whereas an adequate number of representatives of each class are required for classification models. The response data must be accurate and precise and the corresponding compounds need to be sufficiently structurally diverse if the model built from them is going to be applicable to structures of future interest.

Data curation is an often underestimated task in helping to ensure the validity of models. The curation process includes correcting any errors in reported structures that can adversely affect the accuracy of the descriptors, addressing incomplete or inaccurate descriptors and verifying doubtful values, removal of duplicates, curation of tautomeric forms, removal of data that cannot be appropriately handled by conventional cheminformatics techniques such as inorganic and organometallic compounds, consideration of the removal of outliers if warranted, and so forth.[49]

In model-building efforts intended to provide a validated model for future predictive purposes, the curated data set is split into a training pool and a test set.

The training pool is used to generate several candidate models. Ideally, it has a high degree of molecular diversity and includes enough compounds to cover a large range of endpoint values or (classification models) to provide a reasonable balance between positive and negative examples.

The goal of the model-building process is to fit the information in the data but to avoid fitting the noise that is also inevitably present. This is done by splitting the training pool into a training set and a verification set; the former is used to build a candidate model and the latter is used to assess its performance. Performance on the verification set may be used to tune model parameters or to stop an iterative optimization process before it starts fitting the noise. This provides a measure of how well each model is likely to perform when applied to *new* compounds.

Using it to select among candidate models biases the validation set's performance statistics because doing so involves it in the overall model-building process. The following thought experiment may shed light on why this is so. Suppose two or more candidate models are equally predictive in terms of all possible compounds to which the model might be applied. Nonetheless, one model will perform better just by chance on this particular validation set and the corresponding statistics will look better than they would be for a different validation set. The effect gets worse as the data set gets more diverse.

The ("external") test set is not biased in that way, so the selected, final model's performance statistics when applied to *it* provide estimates for how well it is likely to perform in future applications. The data for the compounds in the external test set were not used to fit the models nor to select among them, so performance in predicting their endpoints is a reasonable surrogate for predicting endpoints for compounds altogether outside the data set.

The most straightforward way to split a data set into training, validation, and test subsets is by random selection. The training set is typically largest to provide as much information as possible into the model. The smaller the validation and test sets are, however, the more likely they are to not be representative of the whole. Unfortunately, the high-quality data sets available for many endpoints of interest are likely to be too small for random sampling to find a good trade-off. In such cases, some form of stratified sampling may be used.[50]

Guidelines assembled by the Organization for Economic Cooperation and Development provide a list of four things that a QSAR model should have if it is to be satisfactory from a regulatory standpoint. These characteristics include a defined endpoint; an unambiguous model-building algorithm; a defined domain of applicability; and appropriate measures of goodness-of-fit, robustness, and predictivity. Being mechanistically interpretable is desirable where possible but is not essential. Note that these are minimal criteria; satisfying them does not guarantee that a particular QSAR model is of practical use for a given endpoint. The model-building tools available today are powerful enough to extract signals from most data sets, so the usefulness of a model is now usually limited by the amount of *relevant* data available and how well that data has been curated.

A bewilderingly broad array of descriptors is available for building models. These include chemical descriptors such as log *P*; quantum chemical descriptors related to charge and energy values of individual atoms or the molecule as a whole; the presence or absence of characteristic substructures; and topological indices derived from graph theory as applied to the 2D structure. Other available descriptors include molecular volume; molecular properties based on electron distribution or spatial disposition of component atoms (conformation, geometry, shape, etc.); and physicochemical properties that quantify the hydrophobic, electronic, and steric attributes of a molecule.

Most QSAR models are constructed for the purpose of predicting endpoints for compounds which were not included in the data set used to build, select, and evaluate the performance of the model. In the context of drug development, the predictions that are of the greatest interest are those which are novel in terms of chemical structure or biological properties or both, which makes them

likely to fall "outside" the original data set to some degree. A QSAR model can only be claimed to be "predictive" if it successfully predicts the modeled endpoint for compounds in an external test set.

The applicability domain of a model describes the structure and property space covered by the compounds in the training set. It provides a basis for determining how similar a new compound structure must be to the compounds in the curated data set to be reasonably confident that the model's prediction for that compound will be reliable. Exactly how the domain should be defined is an active area of research, but the general goal is to avoid extrapolation. In some cases the degree of similarity is used, while in others the domain is defined by the range of values of the descriptors used in the model. Regardless, predictions for compounds falling outside the applicability domain are suspect. Such predictions may still be correct, but one cannot be confident that they are.

4.04.4.2 Case Study: Improving In Silico Predictions of pK_a

A drug candidate's predominant charge state at a given pH can be a major determinant of pharmacologic activity, aqueous solubility, permeability, plasma protein binding, metabolism, and so forth. The importance of pK_a is reflected in the commercial availability of automated instruments for high-throughput measurements of ionization constants and the use of in silico methods for predicting pK_a from molecular structure in virtual libraries. However, it is generally acknowledged that these in silico models do not perform very well when the data used for developing the models do not adequately cover the chemical space of interest to specific researchers.

Fraczkiewicz and his colleagues described a collaborative effort with Bayer to extend the pK_a model in Simulations Plus' ADMET Predictor™ program to include compounds from Bayer's chemical space.[51] The earlier version of the in silico model for pK_a had been trained on approximately 11,000 compounds collected from the scientific literature, herein referred to as the Public data set. Over the years this publically available data has been heavily curated at Simulations Plus to remove duplicates, correct erroneous chemical structures, verify doubtful values against original sources, and so forth. These data were supplemented by approximately 16,000 compounds from Bayer drug discovery programs with their experimentally determined pK_a values, herein referred to as the Industrial data set, and additional curation of the data was performed.

The model-building approach for both the Public data set and the combined Public and Industrial data was based on the use of artificial neural network ensembles (ANNE), microstates analysis, and the respective curated data. Model validation was performed with several test sets consisting of a total of approximately 31,000 new pK_a values measured at Bayer.

For the largest and most difficult test set with $>16{,}000$ pK_a values that were not used for training, the original model based on the Public data set achieved a mean absolute error (MAE) of 0.72, root-mean-square error (RMSE) of 0.94, and squared correlation coefficient (R^2) of 0.87. The new model based on the combined data achieved significantly improved prediction statistics, with MAE = 0.50, RMSE = 0.67, and $R^2 = 0.93$.

Interestingly, there were significant differences in the types of compounds included in publically available data versus the chemical space of current interest to Bayer drug discovery programs. In general, the Bayer compounds were significantly larger, more lipophilic, and possessed more basic ionizable groups than the compounds from the open literature. The distribution of pK_a values in the Public data set had a balanced bimodal distribution with peaks at $\sim$4 and $\sim$9, whereas the Bayer data pK_a values were significantly skewed toward 4. Taken together with the differential distribution of the number of basic groups, this clustering of pK_a values around 4 reflects the prevalence of weak bases (aromatic nitrogen) rather than carboxylic acids in this set.[51]

Note that many of the compounds in the Industrial data set violate the Ro5 criteria for MW and log *P*. A similar observation was made by Mannhold et al. when comparing the public literature's chemical space with that of Pfizer and Nycomed drug-like research compounds.[52] They cited this discrepancy as the main factor responsible for unsatisfactory performance of log *P* predictors trained on public data.

Taken together, these results suggest that the improvements in the predictive performance of the new model stem from a combination of factors, including the greater experimental consistency of the Bayer data than that seen for models built on data extracted from hundreds of published articles over the last few decades, the application of rigorous microstates analysis, the use of high-performance ANNE modeling tools, inclusion of the large amounts of data representing the chemical space of current interest to discovery scientists, and careful curation of the data.

The latest version of the in silico model for pK_a was included beginning in Version 7.2 of the ADMET Predictor™ software.[41]

4.04.5 Physiologically Based Pharmacokinetic Modeling and Simulation Methodology

4.04.5.1 Brief Description of a Physiologically Based Pharmacokinetic Model

Traditionally, PK data were analyzed using empirical compartmental models, as illustrated in Fig. 2. These models encompassed one or more mathematical compartments including a central compartment and peripheral compartments that served as reservoirs with different volumes and different rates of exchange of drug with the central compartment. The observed concentration-time profile data for a drug defined the number of compartments and the rates of exchange between the compartments rather than the physiology of the study subject. Consequently, compartmental models are used to describe the data rather than to provide mechanistic insights into the relationships between physiology, physiochemical properties, and the pharmacokinetics of the compound.

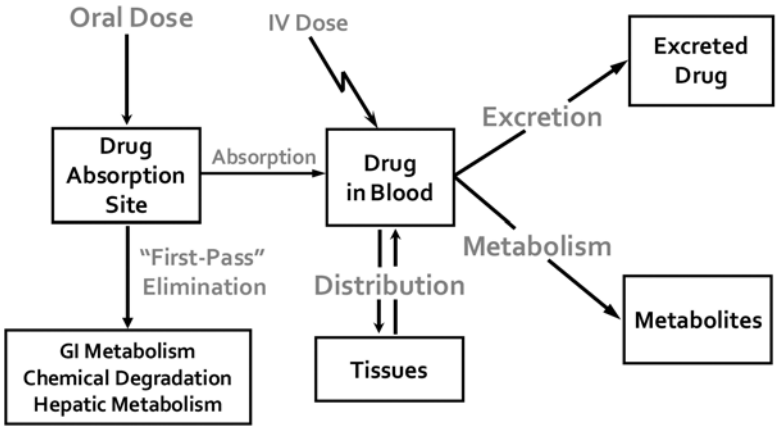

Fig. 2 Empirical compartmental model used to describe the concentration-time profile for a drug.

In contrast, PBPK models divide the body into anatomically and physiologically meaningful compartments. These compartments correspond to different tissues of the body, such as liver, kidney, and brain or tissue groups such as fat and muscle, all connected by the circulating blood system. Each tissue compartment is defined by a tissue volume or mass, a number of tissue-specific characteristic parameters (e.g., volume fraction of neutral lipids, volume fraction of phospholipids, volume fraction of water, and expression levels of enzymes and transporters), blood perfusion rate, and partition coefficients (K_p) dependent on the physicochemical properties of the drug and tissue composition.

Physiologically based PK models integrate system-specific properties together with drug-specific information in order to describe the ADME characteristics of a compound. A series of differential equations based upon mass balance considerations are constructed and solved numerically to simulate the plasma and tissue concentration versus time profiles of a compound in the animal or human system.[53–59] The goal is to predict the overall PK profile of a compound in the species of interest (e.g., rat, dog, or human), after various routes of administration (e.g., intravenous or oral administration). The concentration-time profile may be predicted for either plasma or site-specific tissue compartments.

4.04.5.2 Representing a Physiologically Based Pharmacokinetic Model in GastroPlus

Building a PBPK model requires the careful definition of the species-specific characteristics of a series of compartments. Each compartment represents a tissue, with a specified volume, a number of tissue-specific characteristic parameters, blood perfusion rate, and K_p supplied for each tissue. There are three types of compartments: blood, perfusion-limited tissue, and permeability-limited tissue. Tissues can have intrinsic clearance as a result of the presence of enzymes that may metabolize drug and can also harbor transporters that facilitate movement of drug into and/or out of the tissue.

Fig. 3 represents the GastroPlus schema for the compartments included in a typical PBPK model. Note each compartment is represented in an anatomically correct relationship, including species-specific tissue volumes, characteristic parameters, blood flows, and enzyme and transporter expression levels.

4.04.5.2.1 The absorption model

The rate and extent of absorption following oral administration is determined by the complex interaction of a variety of factors. Yu and Amidon[60] described a mechanistic absorption model that integrates all these factors. This model was further developed by Agoram et al.[61] into the Advanced Compartmental Absorption Transit™ (ACAT™) model and incorporated into the GastroPlus program. The model relies on a variety of in vitro and/or in silico input data such as solubility, permeability, particle size, lipophilicity, pK_a, interactions with intestinal transporters and enzymes, and dose to predict the kinetics associated with dissolution, precipitation, passive and carrier-mediated absorption, and intestinal first-pass elimination of a compound as it transits through the different segments of the GI tract.[56,62]

Fig. 4 illustrates the components of the ACAT model in GastroPlus.

Fig. 5 illustrates the various physical and physiological phenomena that must be represented to accurately describe drug movement from the lumen through the enterocytes lining the intestinal tract and on into the blood system. When formulated with long chain triglyceride lipids, a fraction of highly lipophilic compounds can be absorbed into the lymphatic system within the gut wall, bypassing the mesentery and portal vein delivery to the liver, thereby avoiding first-pass extraction in the liver.[63]

After a drug dissolves in the fluids of the GI tract, the molecules must traverse the enterocytes that line the GI tract and serve as a barrier to systemic entry. Entry can occur through several mechanisms. Paracellular and transcellular transfer are the routes by which a drug molecule can travel from the gut lumen to the blood.[64] Paracellular transport is dependent on the drug's physicochemical properties (molecular radius and geometry, pK_a, and diffusion coefficient) as well as physiological parameters (pore radius,

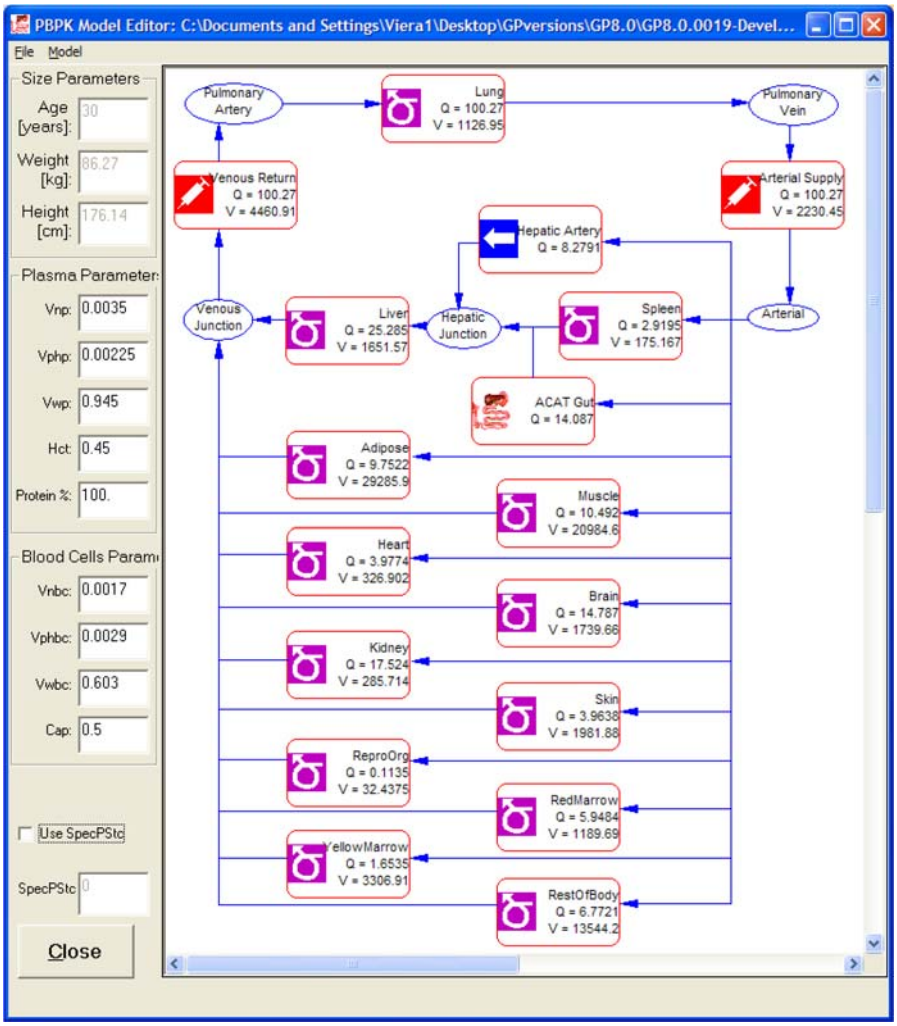

Fig. 3 Schematic from GastroPlus. Figure reproduced, with permission, from the GastroPlus™ product manual (Version 9.0).

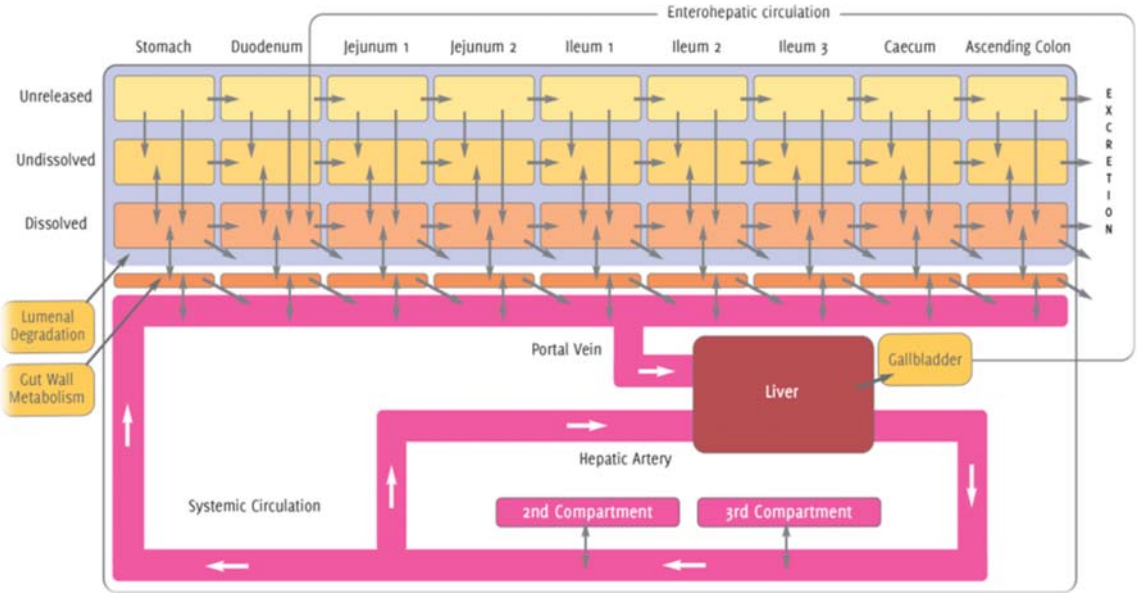

Fig. 4 Advanced compartmental absorption and transit model (ACAT™). Figure reproduced, with permission, from the GastroPlus™ product manual (Version 9.0).

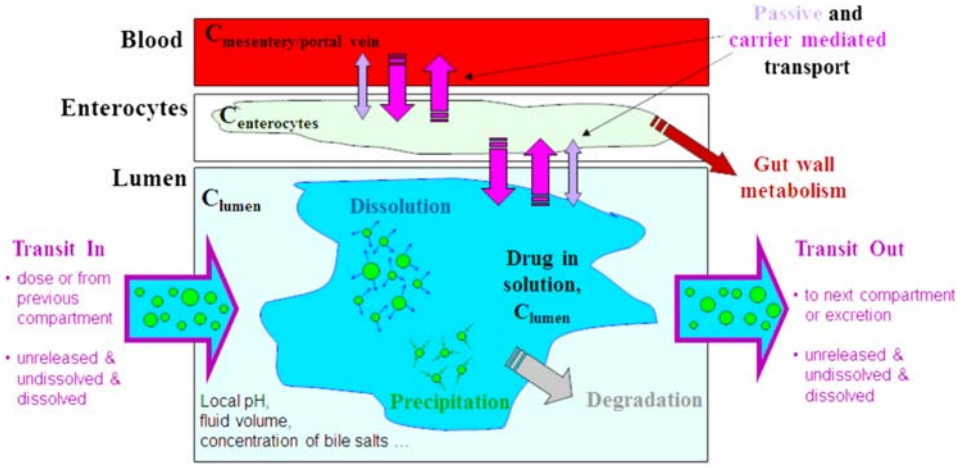

Fig. 5 A close-up view of processes involved in drug absorption through enterocytes. Figure reproduced, with permission, from the GastroPlus™ product manual (Version 9.0).

pore density, and electrical potential gradient across the GI tract). Interestingly, the paracellular permeability of a molecule is likely to change as it moves through the GI tract considering that the size and density of pores and the extent of ionization will change en route. There are also important differences in paracellular transport between species that reflect differences in the characteristics and distribution of pores along the respective animal's GI tract.

Transcellular absorption refers to transport through the cell, and includes passive diffusion as well as carrier-mediated influx and efflux due to transporters. Passive diffusion is not saturable and cannot be inhibited; this type of transport is dependent on lipophilicity and charge as the diffusion must occur without any energy expenditure. Carrier-mediated transport is saturable and inhibitable, and has structural specificity, stereospecificity, and cell specificity.

Paracellular transport occurs between the cells through the tight junctions that hold the cells together. It is important to account for paracellular in addition to transcellular absorption because, in the case of drugs that are substrates of intestinal enzymes or efflux transporters, paracellular absorption does not expose the drug to the enzymes or transporters, unlike transcellular mechanisms.

4.04.5.2.2 Tissue distribution model

Each tissue is described as either perfusion or permeability rate-limited. For perfusion-limited tissues, the rate of drug accumulation in the tissue is limited by the tissue blood flow rate (perfusion rate). Partitioning is assumed to be instantaneous and the tissue-specific partition coefficient, K_p, is used to calculate the drug partitioning between plasma and whole tissue at each time step. Consequently, the concentration of drug in the tissue is the product of the K_p for that tissue multiplied by the instantaneous concentration of drug in the plasma over the relevant time period. Perfusion-limited kinetics are generally observed for small lipophilic molecules where the blood flow to the tissue is the limiting process for drug transfer into the tissue. In some cases, a PBPK model can be developed using a mix of perfusion-limited and permeability-limited tissues to account for slower distribution into poorly perfused tissues like skin and bone marrow.[65]

For permeability-limited tissues, the rate of drug accumulation in the tissue is limited by the rate of drug transfer between extracellular and intracellular space. The tissue-specific K_p is used to calculate the drug partitioning between plasma and the extracellular space at each time step. The rate and direction of passive drug transfer between extracellular and intracellular space is calculated by the product of the permeability, the surface area of the tissue exposed to the plasma, and the gradient between the unbound drug concentrations in extracellular and intracellular space. If influx and/or efflux transporters are present, the intracellular tissue concentration will also be affected by carrier-mediated drug transfer across the cellular membrane.

4.04.5.3 Predicting In Vivo Pharmacokinetic Parameters

In the past, empirical methods, for example, allometric scaling, have been widely used to predict PK parameters in humans. The allometric approaches are descriptive only and provide little mechanistic information on the underlying processes of drug distribution, metabolism, and excretion. This approach uses in vivo data collected from preclinical animal experiments to obtain information about PK parameters, such as clearance and volume of distribution, and then scales the parameters by various measures of body size to account for differences with humans.

Allometric scaling is based on the principle that land mammals have similar physiology, biochemistry, and cellular structure, thus justifying an empirical relationship based on body size for interspecies scaling as illustrated for clearance in Eq. (7):

$$\mathrm{CL} = aW^b \tag{7}$$

where CL is the clearance of a drug, *a* and *b* are the coefficient (*a*) and exponent (*b*), respectively, for the equation. The value of the exponent for whole body metabolic rate is typically taken to be 0.75.[66] However, exponents in the range 0.6–0.8 have been reported for metabolic rate.[67] A value of 0.75 means that the whole body metabolic rate increases as body weight increases, but to a lesser extent than would be expected of a simple proportional relationship.[68]

This allometry equation has evolved from a simple transformation based upon body weight or surface area to more complex versions which can account for unbound clearance, renal and biliary excretion, or liver blood flow. The kidneys filter blood via the nephron, which scales reasonably well; however, when drugs are extensively actively secreted and require transporters, allometric predictions may not be accurate. Hepatic clearance can also be scaled by a simple ratio of hepatic blood flow between humans and animals. A more comprehensive review of different scaling methods can be found in a review paper by Zou et al.[69]

Attempts have been made to improve the prediction accuracy of these allometric scaling methods by applying corrections for protein binding, brain weight, maximum life span potential, and in vitro intrinsic metabolic clearance. These approaches have had varying degrees of success depending on compound properties.[70–74]

While allometric scaling of PK parameters is common, the literature is lacking for information on how to properly scale PD parameters. The Hill equation's parameters of capacity and sensitivity are unlikely to scale as well as biochemical or physiological variables using allometric principles.[75,76] Similar to allometric scaling of PK parameters, PD parameters also often require corrections based on physiological variations between species, such as the correction of half-maximal inhibitory concentration (IC_{50}) values for protein binding. Notably, allometric scaling has been combined with PBPK modeling in efforts to create more accurate predictions.[77]

Distinct from the purely descriptive allometric approaches, IVIVE methodologies generate inputs for PBPK modeling that are physiologically based and can provide mechanistic insights into the underlying processes responsible for the pharmacokinetic behavior of drugs. Using IVIVE, the results of in vitro experiments are scaled according to physiologically appropriate factors that effectively translate in vitro results into likely in vivo values. For example, liver microsomes, recombinantly expressed enzymes, and hepatocyte systems can be used to assess the intrinsic clearance and enzyme kinetic constants of a drug. These estimates can then be scaled with various correction factors, such as protein binding and hepatic blood flow, to obtain an estimate of in vivo hepatic clearance.[78]

Prior to the interest in PBPK modeling, data from in vivo and in vitro experimental systems were treated in a straightforward manner and static values of measurements of interest were reported. The input of these results into PBPK models has enabled the value of these data in providing dynamic, mechanistic insights into drug behavior to be realized.

Over time, a kind of symbiotic relationship has developed between experimental scientists and PBPK modelers. The in vivo and in vitro experimental protocols have undergone continued refinement and improvement as the data requirements of PBPK models were better appreciated. This has led to the design of more complex and informative experiments which allow the PBPK input parameters to be defined more precisely. This iterative relationship between the experimental models and the computational models has improved our understanding of the true complexity of experimental data and consequently improved the predictive performance of PBPK models and our understanding of the dynamic behavior of drug molecules in the body.[56]

4.04.5.3.1 Predicting intestinal and hepatic clearance

In vitro drug metabolism studies have traditionally focused on qualitative assessments of identifying metabolites, establishing the enzymes involved, and investigating the mechanism of reaction. This began to change in the 1990s as advances in in vitro methodologies along with improvements in the sensitivity of analytical chemistry techniques combined to permit the use of quantitative information from in vitro drug metabolism systems to predict in vivo drug behavior.[78] The marked species differences in the enzymology associated with common clearance processes necessitate the use of species-specific in vitro systems for the prediction of clearance in animals and man.[59]

The prediction of drug clearance from in vitro systems has been described in detail by Houston and Carlile.[78] The predictive performance of this approach has been evaluated in a variety of preclinical and clinical applications.[79–83]

When human in vitro and preclinical PK data suggest that a compound is eliminated via hepatic metabolic pathways, the in vivo prediction of hepatic clearance is based on IVIVE. The liver is arguably the most important organ for metabolism as it contains the highest number of drug metabolizing enzymes to which the drug is exposed prior to reaching the systemic circulation. However, even though intestinal epithelial cells have a much lower mass of cytochrome P450 enzyme (CYP) (10 to 100-fold less on a mg enzyme/whole tissue basis), each molecule that is absorbed by the transcellular pathway is exposed to those enzymes. Consequently, the magnitude of first-pass extraction for substrates of CYP3A4, 2C9, 2C19, and 2D6 can make a significant impact on bioavailability.[84] Notably, drugs which are inhibitors of enzymes located in the gut can, therefore, have a marked effect on resultant systemic concentrations of coadministered drugs which are substrates (e.g., furanocoumarins in grapefruit juice and their effect on simvastatin).

Even more significant is the potential for enzyme saturation in the gut by therapeutic doses of drugs due to the higher intraenterocyte concentrations compared to much lower free plasma concentrations. This saturation can result in nonlinear dose dependence as seen for substrates like midazolam and UK-343,664.[61,85]

Typically, a four-step process is required to perform IVIVE and predict in vivo drug behavior.[78] First, the metabolite formation of a particular drug is measured in vitro at relatively low concentrations across a range of microsomal protein concentrations or cell density and is used to obtain an estimate of intrinsic clearance (CL_{int}). Low concentrations are vital to ensure linear kinetics. The CL_{int} of a compound acts as a proportionality constant to describe the relationship between the rate of metabolism and low

concentrations of substrate. It is a measure of enzyme activity toward the drug that is independent of blood flow. The rate of metabolism at low concentration (v_0) is given by Eq. (8).

$$v_0 = \mathrm{CL_{int}} \times C_e \tag{8}$$

where C_e is the unbound concentration of drug within the metabolizing tissue, which is assumed to be the concentration available to the enzymes. The various CYP contributions to the overall $\mathrm{CL_{int}}$ are additive, so the overall value can be measured in human or murine microsomes. Typically, liver microsomes or hepatocytes are used, but the microsomes or cells from other tissues may be used to characterize the metabolism in other tissues. In many cases, the intrinsic clearance determined from liver microsomes can be used to parameterize the contribution of gut metabolism if the regional gut CYP distribution and level of expression compared to the liver is known.

The particular CYP isoforms responsible for metabolism can be identified by looking at the effects of isoform-specific inhibitors on microsomal or hepatocyte metabolism or by assaying recombinant CYPs (rCYPs) in microsomes from cell lines transfected with individual CYPs and cytochrome P450 reductase. Insect cell lines transformed with baculovirus are particularly useful for this purpose.[86]

The relationship between C_e and the rate of metabolism becomes nonlinear at higher substrate concentrations because CYPs, like most enzymes, are saturable—that is, their rate of catalysis approaches a limiting value (V_{max}) as substrate concentration increases. The susceptibility to saturation is different for each CYP/substrate combination, and the differences in affinity are not additive. As a result, kinetic parameters are best determined by fitting data from rCYP assays for contributing isoforms to:

$$v = V_{max} \times C_e/(K_m + C_e) \tag{9}$$

where v is the rate of metabolism at drug concentration C_e, and V_{max} is the maximal rate of metabolism. K_m is the Michaelis constant, which characterizes the affinity of the enzyme for its substrate. Note that when $C_e >> K_m$, the term $C_e/(K_m + C_e) \sim 1$, and $v \sim V_{max}$. Under linear conditions, when the free substrate concentration (C_e) is low relative to K_m, v approaches v_0 and Eq. (9) reduces to Eq. (8).

From which it is evident that:

$$\mathrm{CL_{int}} = \text{Rate of metabolism}/C_e = V_{max}/K_m$$

Several in vitro systems have been used to estimate intrinsic clearance. These systems range in structural integrity from liver slices, to freshly isolated hepatocytes, to subcellular fractions such as microsomes. The units used to report activity vary, but typically are $\mu L\ min^{-1}$ mg microsomal protein, $mL\ min^{-1}\ g^{-1}$ liver, or $mL\ h^{-1}\ kg^{-1}$ body weight. Hepatocyte $\mathrm{CL_{ints}}$ are reported in units of pL/min/10^6 cells.

Comparative experience with these systems suggests that hepatocyte preparations provide more accurate predictions of in vivo clearance estimates. Liver slices are poorly predictive, in part, because of delayed accessibility of substrate to cells with the core of the slice. Hepatic microsomes are the most inconsistent predictor of $\mathrm{CL_{int}}$. However, this system can provide acceptable predictions for many compounds and there is a need to fully define where its limitations occur. Hepatocytes have the virtue of incorporating transporter and Phase 2 metabolism effects such as glucuronidation and sulfation. This caveat is of particular relevance to the use of human tissue, as hepatic microsomes will continue to be the dominant system employed in vitro, while there is limited availability of suitable fresh human tissue for hepatocyte preparation.[78]

In the second step, the estimate of $\mathrm{CL_{int}}$ is scaled to quantify the full activity in the liver as measured in vitro. The choice of scaling factor relates to the type of in vitro system used for measuring $\mathrm{CL_{int}}$. For example, in the case of a hepatocyte preparation, the scaling factor is simply the number of hepatocytes found in an intact liver. The scaling factor for microsomal preparations is more complicated because the preparation of microsomes by differential centrifugation is incomplete and the scaling factor must represent this inefficiency.[87] In this case, the scaling factor is typically the microsomal protein ratio, which represents the amount of microsomal protein isolated per liver slice.[78] While recombinant enzyme systems provide useful information regarding enzyme kinetics, neither enzyme prevalence nor enzymatic activity is considered due to the innate simplicity and specificity of the preparation. Due to this lack of incorporation of the variable expression observed in human populations, different approaches exist to encompass these factors in an effort to create a more realistic metabolic clearance prediction. The relative activity factor and the relative abundance method are the two most commonly used approaches.[88] The details of how to apply these scaling procedures within PBPK models have been described elsewhere.[53]

In the third step, a model of liver metabolism is used to convert the estimated $\mathrm{CL_{int}}$ into the predicted hepatic clearance ($\mathrm{CL_h}$). The liver model uses information on species-specific hepatic blood flow and binding of drug in the blood to convert $\mathrm{CL_{int}}$ to an expression of hepatic clearance in terms of the circulating blood drug concentration rather than drug concentration within the liver. In the commonly used venous equilibration liver model, the distribution of drug within the liver is assumed to occur instantaneously with no concentration gradient. Consequently, the liver acts like a single, well-stirred compartment. This model enables hepatic clearance to be calculated as follows[78]:

$$\mathrm{CL_H} = \frac{Q_H \cdot \mathrm{CL_{int}} \cdot \mathrm{fub}}{Q_H + \mathrm{CL_{int}} \cdot \mathrm{fub}}$$

where Q_H is the hepatic blood flow and fub is the unbound concentration of drug in the blood for the species of interest. Other liver models, such as the parallel-tube model and dispersion model, may be utilized; it is important to consider the assumptions associated with the chosen model.

For compounds that are primarily metabolized by CYPs, detailed enzyme kinetic data based on metabolite formation are preferred over intrinsic clearance estimated from substrate depletion studies since the kinetic data capture the saturation effects that lead to dose-dependent metabolic clearance. Moreover, care must be taken to ensure that drug loss equates with enzyme-mediated metabolism and not some other process such as physical adsorption, incorporation into cellular components, or nonenzymatic degradation. As the time period for monitoring drug loss is likely to be substantial, the stability of the particular enzyme preparation becomes of prime concern.[78]

For cases in which Phase 2 conjugation or other non-CYP metabolism contributes significantly to the hepatic clearance, for example, based on the metabolite profile, the human hepatocyte intrinsic clearance is preferred over that from human liver microsomes.[79] This is due, in part, to the location of the majority of Phase 2 enzymes in the cytosol (those involved in methylation, acetylation, sulfation), which would not be detected in microsomal preparations. While some Phase 2 enzymes are microsomal, such as the glucuronosyl transferases, the lack of most enzymes and the need to add cofactors hinder the use of microsomal preparations. In contrast to the situation for CYP enzymes in the gut, where intrinsic clearance in the liver can be used to estimate gut first-pass extraction, many of the Phase 2 enzymes have very different expression in gut, liver, and kidney.[89]

Consequently, the application of IVIVE for Phase 2 enzymes is more complex.

Houston and Carlile[78] introduced criteria to determine whether a prediction of hepatic clearance is acceptable or not. They used the ratio of the predicted CL_{int} to the observed CL_{int} and an arbitrary precision limit of $\pm$ twofold of the in vivo prediction, that is, between a 50% underprediction and a 100% overprediction. The logarithm of the ratio is employed to achieve a symmetrical distribution. Hence, a twofold precision limit for this ratio corresponds to ± 0.3 log units. Perfect predictions would appear as zero values, underpredictions and overpredictions are represented as negative and positive values, respectively.

In the final step, nonhepatic routes of elimination, such as renal excretion of unchanged drug or extrahepatic metabolism, are incorporated into the prediction. The utility of IVIVE for hepatic metabolic clearance has been well established in the literature[90–92] and is developing to improve poor predictions by incorporating hepatic uptake and/or biliary excretion.[79,93,94]

4.04.5.3.2 Predicting volume of distribution

The use of PBPK models to simulate drug concentration-time profiles requires information on the distribution of drug into each organ and tissue compartment represented in the model. Previously, the determination of tissue-to-plasma partition coefficients (K_{ps}) required costly animal studies and limited the use of PBPK models in early drug research and development. The development of mechanistic tissue composition-based equations enabled the calculation of drug-specific K_{ps} in different tissues and organs based on physicochemical properties. These K_p values, in conjunction with tissue-specific volumes, are used to estimate the species-specific V_{ss} of a compound as the sum of the individual tissue (including blood) distribution volumes. These mechanism-based formulas have enabled the routine application of PBPK methods in early drug discovery by reducing the reliance on data from in vivo experiments.[79]

Experimental methods for determining V_{ss} require an intravenous drug administration followed by compartmental or statistical moment analysis of the resultant plasma concentration-time data. Since this information is generally not available in early discovery, the development of a PBPK model requires an alternative approach. Previously, the prediction of V_{ss} required a determination of drug affinities for various tissues and organs of the body along with measures of associated tissue and plasma volumes. The considerable time, resources, and costs associated with experimentally determining tissue affinities has lead to various attempts to predict V_{ss} based on information about the underlying distribution mechanisms, physiologic considerations, and physiochemical properties of the compound.

The mechanism-based equations to predict V_{ss} have evolved over time, and research has revealed more about the determinants of drug distribution into different tissues. Poulin and Theil were among the first to investigate these mechanistic approaches for drug molecules, and by expanding on the earlier work of Poulin and Krishan,[95] they demonstrated the ability to predict the affinity of small molecules for various tissues and organs.[96] In this method, homogeneous drug distribution into each tissue is assumed to occur by a process of passive diffusion. Tissue and plasma are assumed to be a combination of water, lipids, and proteins at pH = 7.4. The tissue composition method of calculating K_p derives from an assumption that drugs partition into tissues by virtue of nonspecific binding with neutral lipids and phospholipids in the tissues and these interactions may be further impeded or enhanced by specific binding to plasma or tissue proteins. Berezhkovskiy subsequently published a correction to the Poulin equation for calculating the tissue–plasma partition coefficients.[97]

In subsequent applications of these approaches, it was recognized that although the equations reliably predicted K_p values for neutral molecules, many drug substances that are cationic at physiologic pH were observed to have higher volumes of distribution compared to neutral and acidic molecules of similar lipophilicity. Consequently, adjustments were necessary to incorporate the extent of drug ionization in predicting tissue-to-plasma water partition coefficients (K_p).

Rodgers et al. developed equations to predict tissue distribution coefficients (K_p) for moderate to strong bases[98] and separately for acids, very weak bases, neutrals, and zwitterions.[99] These equations are based on the assumption that all drugs will dissolve in intra- and extracellular tissue water and partition into the neutral lipids and phospholipids located within tissue cells.[100] For compounds with at least one basic $pK_a \geq 7$, the corresponding equation accounted for electrostatic interactions with tissue acidic phospholipids. For compounds that bind with extracellular proteins, the affinity and extent of binding must also be considered. Acids and weakly basic compounds are assumed to bind primarily to albumin and neutral drugs to lipoproteins.

The major distributional processes that must be incorporated into these mechanistic equations to predict K_p include dissolution into tissue water, lipid partitioning, electrostatic interactions with acidic phospholipids, and extracellular protein binding.

The Rodgers et al. K_p calculations[98–100] are based on a distinction between strong bases and other compounds with an arbitrary cut-off at base $pK_a = 7$. This puts significant weight on an accurate measurement or prediction of base pK_a values, especially for those drugs with values around seven. Small errors in measurement or prediction of pK_a around seven can result in the selection of the wrong equation and subsequently significant errors in the estimated K_p values.

In order to address the dichotomy arising from the two Rodgers and Rowland equations, Lukacova and colleagues[101] derived a modified form that combines the two equations into one. This equation provides a continuous shift from neutrals and acids binding almost exclusively to albumin toward strong bases binding almost exclusively to acidic phospholipids. Moderate bases (base pK_a in the range of 6–8) will have neutral as well as cationic species present in plasma and in tissues at physiological pH values. It is assumed that these compounds could bind to both albumin (via their neutral forms) and acidic phospholipids (via their ionized cationic forms). As expected, in comparing the two approaches, the calculated K_{ps} will be similar to the original Rodgers approach for acids, neutrals, very weak bases, and very strong bases, where the fraction of molecules with positive charge will be either insignificant or nearly 100%. Differences in K_p values will be seen for moderate bases (with pK_as in the range of 6–8), where significant contributions from both types of binding can be expected.

Several situations arise that can result in over- or underpredictions of K_p and subsequently affect the accuracy of the predictions of V_{ss}. These situations arise when active transport processes, nonlinear pharmacokinetics, or binding to tissue constituents are not accounted for by the mechanistic equations. For example, doxorubicin extensively interacts with tissue DNA and the mechanistic equations result in significant underprediction of V_{ss}.[102,103] Another example is provided by chlorthalidone, a basic compound with a high affinity for human carbonic anhydrase, an enzyme primarily located in the cytosolic fraction of red blood cells.[104] This enzyme affinity results in a high blood-to-plasma concentration ratio and subsequent overprediction of V_{ss}.

It is important to recognize that uncertainty in parameters, for example, arising from the compilation of data from rats of different ages, strains, weights, and gender, can influence the accuracy of K_p predictions generated from these equations. Experimental difficulties can also be encountered for compounds that are extensively protein bound and/or highly lipophilic. Finally, the inherent variability in the measurements of the variables required for selected equations can also impact the accuracy of the predictions.[100]

4.04.5.3.3 Case study—impact of lysosomal trapping

Azithromycin (AZM) is a semisynthetic macrolide antibiotic with a broad range of activity against Gram-positive bacteria and some community-acquired Gram-negative pathogens. The drug has a large distribution volume of approximately 23 L kg^{-1} of body weight and a long half-life of 68–79 h.[105] These PK characteristics often allow for a convenient once-daily dosing regimen and a short overall duration of treatment, as brief as 3–5 days for some indications.[106]

Although the large distribution volume suggests extensive tissue distribution, the majority of the drug is confined to intracellular compartments and thus is unavailable for extracellular antimicrobial activity. This is due to the fact that AZM is a diprotic base (pK_a 1, 8.1; pK_a 2, 8.8).[107] Once it enters the acidic subcellular compartments, such as the lysosomes, the drug becomes protonated and is subsequently trapped there. This mechanism, known as lysosomal trapping, is responsible for the long elimination half-life and the retention of AZM within the tissue long after the administration of the last dose.[105,106,108]

In a clinical PK study, Matzneller et al.[106] determined the free concentrations of AZM in the interstitial fluid (ISF) of muscle and subcutaneous adipose tissue and total concentrations in polymorphonuclear leukocytes in six healthy male volunteers receiving 500 mg once-daily AZM for 3 days. This data was subsequently used by Zheng and colleagues[109] to develop a tissue distribution model for AZM that allowed the simultaneous characterization of free drug concentrations in the ISF of muscle and subcutaneous adipose tissue, taking into consideration the effects of protein binding and the differences in ionization state at physiological pH values in the different tissue sites.

This work demonstrated that AZM concentrations during and after treatment were the highest in white blood cells due to intracellular accumulation, whereas the total concentrations in plasma and the free concentrations in the ISF of muscle and subcutaneous adipose tissue were markedly lower. While the long terminal half-life of AZM helps to maintain drug concentrations above the minimum inhibitory concentration of the infecting pathogen in certain compartments, the persistent low drug concentrations in other tissue sites may potentially lead to an increased risk of the emergence of resistance.

4.04.5.3.4 Predicting transporter effects

Our understanding of the importance of endogenous influx and efflux transporters on drug absorption, distribution, and clearance has increased greatly since 2008. In fact, Kell and colleagues have suggested that carrier-mediated membrane transport greatly outweighs passive membrane permeability mechanisms.[110,111]

This view has not met with wide acceptance, but has invigorated strong debate and visibility of the importance of drug transporters.[112]

In many cases, nonlinear dose dependence for therapeutically relevant doses of drug molecules can be explained by saturation of intestinal influx and efflux transporters. Bolger and colleagues used transporter K_m values determined in vitro for substrates of intestinal influx transporters and in silico PBPK modeling to explain the nonlinear dose dependence for gabapentin, a substrate for organic cation transport-1 (OCTN1) and L-type amino acid transporter (LAT2), and for valacyclovir, a substrate for oligopeptide transporters (PepT1 and HPT1).[113]

In contrast to PBPK modeling for substrates of influx transporters, experimentally determined values of apparent K_m for efflux transporters do not reflect the intraenterocyte unbound concentration of drug molecules and must be corrected to accurately explain nonlinear dose dependence in vivo.[114,115]

These principles are reflected in PBPK modeling for the nonlinear dose dependence of talinolol, a substrate of P-glycoprotein (P-gp) and UK-343,664, a substrate for both CYP3A4 and P-gp.[85,113,116]

A general purpose cellular simulation program (MembranePlus™, Simulations Plus, Inc.) is available to facilitate the determination of intracellular unbound K_m values for substrates of efflux transporters by fitting in vitro permeability assay data. This program was used to estimate the K_m for interaction of digoxin with P-gp and GastroPlus was used for PBPK modeling of digoxin in vivo intravenous and oral Cp-versus-time data.[117]

Prior to the adoption of quantitative targeted absolute proteomics (QTAP) for the determination of absolute transporter expression in human tissues,[118] two approaches for performing IVIVE of transporter effects were published over the past few years.[119,120] The general consensus between these approaches is that the extrapolation requires an additional empirical scaling factor. Two types of scaling factors were proposed, system-specific and compound-specific. With system-specific scaling factors,[119] the same scaling factor would be used to extrapolate the transporter parameters from a specific in vitro assay setup to in vivo conditions for a wide range of compounds. With compound-specific scaling factors,[120] a compound-specific scaling factor is derived for extrapolation from in vitro assay to in vivo animal predictions and the same scaling factor is used for extrapolation from in vitro assay to in vivo human predictions. A common feature of the published approaches is the focus on low passive permeability and the importance of transporter effects in the gut, liver, and kidney. These approaches do not consider the effect of low passive permeability on the distribution of drug to other tissues with subsequent effects on plasma concentration.

Consideration of low passive permeability requires specification of the permeability-surface area product (PStc) value. Without knowledge of the total cell surface areas in different tissues, the model would typically require fitting the tissue-specific PStc values against in vivo data, which may be difficult with only available plasma concentration profiles. Lukacova et al.[121] suggested an alternative approach to obtaining the tissue-specific PStc values by introducing the "*Specific PStc*" parameter (*PStc* per mL of cell volume), which makes this extrapolation easy and straightforward. By accounting for low passive permeability in all tissues, more accurate IVIVE was obtained without the need for empirical scaling factors.

4.04.5.3.5 Predicting permeability

The permeability of a compound is a critical determinant of its potential to be absorbed from the GI tract and reach the systemic circulation. Consequently, in vitro assays to measure permeability have been developed to help predict a drug's permeability in humans.

Several experimental approaches to evaluate intestinal permeability are commonly used during drug development and the choice of assay is dependent upon the circumstance. The parallel artificial membrane permeability assay (PAMPA) measures passive transcellular transport and is good for high-throughput screening, having low cost compared to other methodologies. PAMPA is designed to mimic the lipid composition of enterocytes, but only assesses passive permeability in the intestine and does not account for transporter expression. More expensive assays which can provide additional information regarding transporter expression are also available, including human colorectal adenocarcinoma cells (Caco-2) as well as Madin–Darby canine kidney (MDCK) cells. These cells can be used in confluent monolayers as surrogates for the intestinal epithelium. They include the effects of some carrier-mediated transport, providing answers to questions regularly posed in transporter studies such as those listed by Brouwer and colleagues, investigating the influence of active uptake or apical efflux on intestinal absorption.[122]

Because these permeability assays are cell cultures, inherent variability exists between and even within laboratories as expression levels of transporters can differ. This is especially true for Caco-2, which come from a heterogeneous cell line. For this reason, MDCK cells transfected with specific transporters are often preferred. In both cases, varying expression of endogenous transporters should be considered while studying transport.[123] The results of these cellular studies can vary substantially even for drugs that are not substrates for transporters. This is because the results depend on many factors such as how long the cells were cultured, the pH on each side of the membrane, solvents used, amount of protein on receiver side, concentration of drug on donor side, nonspecific binding to plastic ware, among other variables. However, in vitro assays remain a reasonable foundation for predicting permeability of compounds.

4.04.6 Applications of Physiologically Based Pharmacokinetic Methodology

PBPK models are routinely applied in early discovery where limited in vivo data exists and in silico prediction of parameters or extrapolations from in vitro assay results are required to generate drug-related input parameters for model building. These applications have been bolstered of late by improved in silico and in vitro systems capable of acting as surrogates for in vivo absorption, distribution, metabolism, and excretion (ADME) processes and the advancement of strategies for the IVIVE of these data.[10]

The applications of PBPK in the preclinical space include predicting animal or human PK, and the use of PBPK models to inform the design and predict the outcomes of formulation, toxicokinetic, PK, and pharmacologic studies. These applications, which have aided in the reduction of animal use in research, play an important role in guiding R&D plans and focusing efforts on critical questions that can impact the future direction of development programs. In the preclinical setting, the questions focus on optimization

of the preclinical testing program and gaining an early understanding of critical factors that can affect the success of the clinical development program. These questions include,

- What is the expected PK profile in humans and what is our level of confidence in the PBPK model?
- Is there likely to be a food effect? Can we mitigate a food effect with an appropriate formulation strategy?
- Do we expect clinically relevant DDIs or pharmacogenetic effects in human populations? How should we best study these effects in clinical trials?

From the beginning of clinical development and into the post-approval period, PBPK models have been used to predict PK in various subpopulations, including pediatrics and patients with various disease states, in addition to oral absorption and DDI modeling. In this setting, the questions focus on improved understanding of the determinants of safety and efficacy outcomes, including:

- What is the expected plasma or tissue exposure in various subpopulations? How can we use this information to anticipate exposure-response relationships?
- What clinical dosing regimens are required to achieve therapeutically effective concentrations?
- How do we balance risk versus benefit? Would a modified release formulation improve the safety or efficacy profile and improve marketability of a compound?

A comprehensive listing of the various applications of PBPK modeling and simulation over the lifecycle of R&D is beyond the scope of this article. Publications are available that can shed additional light on the full scope of applications.[57,124]

4.04.6.1 Lessons Learned From the Early Applications of Physiologically Based Pharmacokinetic Modeling and Simulation

4.04.6.1.1 Reducing the use of animals in toxicology testing

Once a lead chemical series is identified, an early toxicology study (ETS) is typically performed in a rodent and nonrodent species prior to lead development to screen out toxic compounds. An ETS normally requires daily dosing over a 7- or 14-day period using a range of doses. To help set the dose, a preliminary single dose toxicokinetics study would be performed at three dose levels. In this scenario,[56] experience has shown that PBPK modeling can be used to reduce the need for the preliminary dose-setting study, thus reducing requirements for compound, improving process efficiency, and reducing animal usage. The same report showed that PBPK modeling can be used to predict saturation in absorption and formulation issues to ensure appropriate dose selection for toxicology studies. In a retrospective analysis using a cohort of 39 compounds to assess PK prediction accuracy, PBPK methods were shown to more accurately predict area under the curve (AUC) and C_{max} observed with high dose PK data than an approach assuming linearity from low dose studies.[56]

4.04.6.1.2 Assessing the feasibility and performance of physiologically based pharmacokinetic predictions of human pharmacokinetics

A series of publications in the early 2000s sought to evaluate the feasibility and performance of PBPK models for the prediction of human PK.[57–59,125–127]

Parrott et al. compared empirical and physiologically based approaches for the prediction of human pharmacokinetics using 19 diverse compounds taken from Roche clinical development projects.[59] Predicted values of PK parameters and plasma concentrations were compared to observed values in order to assess the accuracy of the prediction methods. Overall, the physiologically based approach gave more realistic predictions than the other methods with a greater proportion of the predicted parameters (e.g., C_{max}, AUC, $t½$) within twofold error of the observed values. For example, 76% versus 42% of compounds had a predicted AUC within twofold error of the observed value using physiologically based models versus an allometric approach, respectively.

Importantly, the authors recognized that poor predictions from the physiologically based models were often the result of processes that were not incorporated into the model due to uncertainty in the scaling between species (e.g., biliary clearance, enterohepatic recirculation). In this context, 70% of compounds were judged as being good candidates for a reliable extrapolation since such processes were not needed for good simulations in animals. Of these compounds, 92% had predicted AUC within twofold of the observed value.

De Buck and colleagues evaluated different PBPK modeling approaches for the prediction of human PK parameters.[125] GastroPlus was used to construct an absorption–disposition PBPK model and provided accurate predictions of area under the plasma concentration-time profile, oral apparent volume of distribution, and maximum plasma concentration after oral dosing, with 74%, 70%, and 65% of the predictions within a twofold error, respectively. However, the methods used to compute the model input parameters affected the results and better predictions were obtained when in silico predictions of V_{ss} were refined using rat experimental data and when binding was properly accounted for in computing estimates of clearance from in vitro measurements.

Jones and colleagues at Pfizer recognized that early predictions of human pharmacokinetics can reduce failures in clinic related to poor pharmacokinetics by enabling the early selection of the best candidates for development and rejection of those compounds with a low chance of success.[58] They compared the accuracy of a simple one-compartment approach using allometric scaling to obtain estimates of clearance and V_{ss} to a PBPK approach using tissue composition models to estimate K_p and, hence V_{ss}, and IVIVE methods to estimate clearance. The simulation results obtained from PBPK models were able to accurately predict

passive distribution and absorption processes and these predictions were superior to the one-compartment model previously employed for this purpose. Some issues and limitations were noted with respect to the prediction of clearance and active transport processes.

More recently, the Innovative Medicines Initiative (IMI) in the European Union funded a 5-year grant involving many academic and industrial collaborators in basic research to improve oral biopharmaceutical tools (OrBiTo). This collaboration will provide additional results for blinded prospective PBPK modeling of pharmaceutical active pharmaceutical ingredients that both failed and succeeded in regulatory approval.[128,129]

4.04.6.1.3 First-in-human prediction and trial design

Using a set of 19 compounds from F. Hoffmann la Roche, Jones et al.[57] proposed and validated a strategy for the use of PBPK for human PK simulations. Initially, the PBPK simulation is performed using animal PBPK models, animal in vitro data, and compound-specific physicochemical data. The animal simulation is compared with the in vivo data; if this simulation in animals is reasonable, then the human simulation is performed using a human PBPK model, human in vitro data, and compound-specific physicochemical data. If the simulation in animals is inaccurate, this would indicate a violation of one or more of the model assumptions; in this case, further experiments may be performed to understand the mismatch. For those compounds where good predictions of animal PK were achieved, 92%, 67%, and 100% of compounds had prediction accuracy within twofold in humans for AUC, C_{max}, and T_{max}, respectively. The prediction accuracy was reduced (76%, 47%, and 94% for AUC, C_{max}, and T_{max}, respectively) when the compounds that were judged as having poor predictions in animals were included in the human analysis, emphasizing the need for good understanding in animals prior to the simulation in human.

4.04.7 Generalized Approach to Building and Validating a Physiologically Based Pharmacokinetic Model

The development and validation of a PBPK model requires a step-wise approach to the assembly of the required system- and drug-specific information and its input into a well-constructed PBPK software product. The goal is to utilize all available in vitro and in vivo data as they become available during the R&D lifecycle to determine the most appropriate assumptions regarding model specification.[79] The completeness of a PBPK model can depend on the timing of model development with respect to the extant knowledge base for a drug. For example, early-stage PBPK models may utilize predicted physicochemical properties of the drugs of interest and simplifying assumptions about the nature of drug metabolism and elimination. These simplifying assumptions can then be updated as additional information becomes available about the compound.

It is important to note that the quality and certainty of predictions from the PBPK model can improve over time as in vitro data, preclinical in vivo data, and finally in vivo data in humans become available. A key aspect of this progression is that estimates from each stage can provide a valuable reality check for subsequent stages, for example, predictions sometimes disagree with experimental measurements because mistakes were made in carrying out the measurements.

Although the critical parameters for a specific compound will vary depending on the ADME properties of the compound, it is possible to define a generalized scheme for developing PBPK models and performing simulations.[130] The scheme outlined below illustrates the need to understand, as much as possible, the relevant properties of a drug (or related compounds) that might inform on likely characteristics and then to proceed in an iterative process of assessing the performance of the model against observed data. The importance of understanding the compound properties, the quality of data used as model inputs, and the nature of the interactions of the compound with human physiology are paramount in developing confidence in the model and accuracy of the predictions in humans.

Step 1: Identify the drug's ADME pathways and quantify the rate and extent of relevant parameters.
Step 2: Incorporate drug-specific parameters into the PBPK model.
Step 3: Compare the predicted concentration-time profiles with those obtained from available in vivo preclinical and/or human studies.
Step 4: Refine the model on the basis of the results from Step 3.
Step 5: Use the refined PBPK model for predicting PK profiles under various scenarios of interest that have not been studied experimentally.
Step 6: Incorporate information about the mean and upper/lower boundaries for relevant parameters in order to reflect interindividual variability or uncertainty in the parameter estimates in the simulations.[130]

In general, model building should begin as early as possible in the discovery stage in order to provide input for consideration in lead selection. Scientists must recognize that the database for use with the PBPK model will continue to evolve as the drug moves through different R&D stages and different issues are encountered. An interdisciplinary process for model building, evaluation, and adjudication should be established.

At each stage, the model must have a champion to manage the testing of model assumptions and performance. A system for alerting champions to changes in data or knowledge is critical to enabling the model to keep pace with changes in the knowledge base. It is important to keep good notes on model evolution so that subsequent champions can quickly pick up and continue model development. Given the complexity of interpretation of data and model assumptions, there is an important role for experienced

mentor(s) during model building in order to monitor the acceptability of model assumptions and data interpretations. It is important to establish a standard format for data retrieval and storage, along with a process for change control, naming conventions, and data archiving.

As experience with PBPK modeling and simulation has increased, so has an appreciation of the nuances involved in building PBPK models and the emergence of ideas for best practices in many aspects of the effort. Recent publications[10,131–137] have explored the various aspects of model building, parameter optimization, reporting, and model qualification with an eye toward improving the quality and confidence in relying on models to support corporate and regulatory decision-making. Aspects of PBPK modeling and simulation that warrant special consideration are described below.

4.04.7.1 Model Building and Input Data

The in vitro methodology used to determine input values for PBPK models, such as intrinsic clearance or permeability, can vary across companies and sometimes within companies as a compound moves through the R&D lifecycle. This can create sources of uncertainty that must be kept in mind as the knowledge base for a compound evolves over time.

Best practices in the use of in vitro and in vivo ADME data to provide drug-specific input parameters are emerging and the value of a quantitative mass balance diagram for a compound has been proposed.[132] When feasible, pharmacokinetic information obtained after both orally and intravenously administered dosing is valuable in the quantitative mechanistic understanding of drug disposition. Data to support this understanding should include answers to the following questions: (1) What are the clearance pathways and their quantitative contributions? (2) What is the extent of absorption of the drug and is parent drug in feces a result of lack of absorption (F_a) or biliary/intestinal excretion? (3) When oral bioavailability is low, what are the contributions of intestinal and hepatic first-pass loss? (4) What is the rate-limiting step in hepatic drug clearance (basolateral uptake, metabolism, or biliary secretion)?[132]

In building a PBPK model, tissue weights, tissue perfusion rates, tissue densities, and tissue-specific partition coefficients for the compound of interest are required. In GastroPlus, the initial estimates for these physiologic parameters are obtained from the Population Estimates for Age-Related Physiology™ (PEAR™ Physiology)[138–141] module within the software.

GastroPlus also has the ability to represent infant physiologies for infants less than 1 year of age who were born at term or up to 16 weeks premature.[142] Other sources of system-dependent parameters (e.g., tissue volume, blood flow) for human and preclinical species are available in the literature[139,143] and have recently been compiled.[144,145]

4.04.7.2 Model Optimization

The process of model optimization using sensitivity analysis and parameter optimization relative to observed data is integral to the development of robust PBPK models. The optimization process must explicitly recognize information gaps and the consequences with respect to specific applications of the model. The optimization process may lead to a more predictive model; however, the process should be transparent and consider available in vitro data, clinical DDI information, urinary excretion data, human mass balance data, and plasma PK data. The optimization process should be purpose-driven and the plausibility of the resultant model should be considered. For example, scaling factors used in IVIVE vary in plausibility; some being physiologically based, but others more empirical, and they may vary between analyses.

Sensitivity testing of model predictions to changes in model parameters is essential, and the range of sensitivity analyses performed should be defined depending on the physiochemical properties of the drug and/or the experimental systems under consideration. A reasonable range for sensitivity analysis should be provided and justified. Model parameters with known certainty can be prespecified, allowing more informed determination of candidate parameters for sensitivity analysis. Often optimization of several independent factors may lead to a model with superior predictive performance. When possible, the hypotheses that lead to the optimized parameters should be tested with experimental data.[131,132]

4.04.7.3 Reporting

There has been considerable discussion about the critical elements required for inclusion in PBPK reports submitted for regulatory consideration. Shepard et al.[132] pointed out that reports should clearly address the regulatory question, the clinical context, and whether the simulations will lead to changes in dose recommendations. The inclusion of background information, for example, clinical pharmacology, purpose of the modeling effort, history of PBPK model development, and so forth, is helpful and the level of detail should be adequate to support the desired application of the model. It is vital that the clinical pharmacology information be integrated across studies and that the adequacy of the model be assessed in conjunction with the known therapeutic index of the drug. Uncertainty, sensitivity analysis, and plausibility of the assumptions should always be presented and discussed. Reports of simulations used in support of a waiver of an in vivo study (such as a DDI study) require particular care to integrate the simulations with the rest of the clinical data, including a discussion of the implications for drug dosing.[132]

4.04.8 Case Studies

4.04.8.1 Predicting Bioavailability

Oral bioavailability (F) can determine the fate of a compound in clinical trials. Predicting F directly from the 2D structure of the molecule prior to first-in-human dosing is highly desirable. Lawless and colleagues[146] created a database of 62 drugs, primarily metabolized by CYP enzymes, that included the observed bioavailability (F) and the recommended dose. The reported %F values, defined as F times 100%, varied from 3% (fluphenazine) to 99% (diazepam, galantamine, glimepiride, indomethacin, and tamsulosin), with an average of 60%. For the 43 drugs with more than one reported value of %F, the average experimental CV% was 29%.

ANNE models based on 2D molecular structures were used to predict physicochemical properties and CYP pharmacokinetic parameters required as input into a PBPK model for each drug. These models were then used to predict the bioavailability solely from structure for each compound.[146]

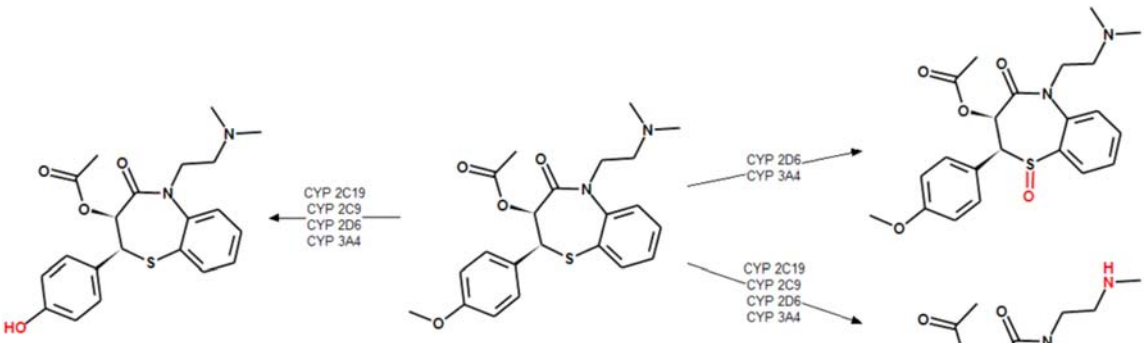
The in silico predicted parameters included aqueous and biorelevant solubility, pK_a, log D, GI permeability, fraction unbound in human plasma, and blood-to-plasma concentration ratio. A hierarchical set of ANNE models was used to determine CYP metabolism. First, classification models predicted whether each compound was a substrate for each of five major CYP isoforms (1A2, 2C9, 2C19, 2D6, and 3A4). These predictions included confidence estimates that provide a measure of the confidence in the prediction that the compound is actually metabolized by a particular CYP isoform.[147] Next, sites of metabolism were predicted for those compounds that were projected to be substrates. Finally, K_m and V_{max} predictions were made for each predicted site of metabolism. These predictions were used as inputs for PBPK models implemented within GastroPlus. A 35-year-old American male physiology was used for all PBPK simulations.

Diltiazem provides a good example of how this sort of analysis is applied, in that it is metabolized by several CYP enzymes to yield several different metabolites in unequal amounts. The compound is predicted to be attacked by four of the major CYP isoforms, that is, 2C9, 2C19, 2D6, and 3A4 (Fig. 6).[146] The methoxy and dimethylamino groups are attacked by all four isoforms, whereas oxidation of the sulfur is only predicted for CYP isoforms 2D6 and 3A4. Examining the corresponding CL_{ints}, however, indicates that CYP3A4 will be responsible for the majority (86%) of the metabolism and that *N*-demethyldiltiazem will be the major (58%) metabolite.

Based on the modeling results, all of the drugs were predicted to be well-absorbed. All molecules were correctly predicted to be substrates of the CYPs associated with their major clearance pathways. Furthermore, these pathways had the highest predicted CYP intrinsic clearance in 42 of the 62 molecules. Overall, 58% of the molecules were predicted within 1.5-fold of their reported %F.

Fig. 7 shows the observed versus predicted %F for the 62 compounds in the database. The dashed line is the line of unity. The dotted lines represent 1.5-fold errors. On the right-hand graph, V_{max} was scaled by the confidence estimate from the CYP substrate model (i.e., multiplied $V_{max} \times$ Confidence%/100). This had the effect of reducing severe underpredictions of %F in order to avoid early rejection of good candidates.

Fig. 8 shows a graph of cumulative fraction and fold error. %F was predicted to be within 1.5-fold of the reported value for 58% of the compounds. For 46 compounds, the reported %F either spanned a range (e.g., 80–90%) or included a standard deviation (e.g., 80 + 15%). The area of the bubble is proportional to the expected measurement uncertainty. The %F of lovastatin is difficult to simulate due to opening and closing of the lactone ring. Tamsolusin has the highest fold error. Note that PBPK simulations using



CYP Isoform	2C9 (54%)	2C19 (78%)	2D6 (81%)	3A4
Predicted CL_{int} [µl/min/mg MP]	1.2	4.6	3.1	54.3
fm%	2%	7%	5%	86%

Fig. 6 Metabolite predictions for diltiazem. Lawless M., DiBella J., Bolger M.B., Clark R.D., Huehn E., Waldman M., Zhang J., and Lukacova V. Poster Presented at International Society for the Study of Xenobiotics (ISSX): Prediction of Oral Bioavailability In Silico, 2015.

Poster Presented at International Society for the Study of Xenobiotics (ISSX): Prediction of Oral Bioavailability In Silico, 2015.

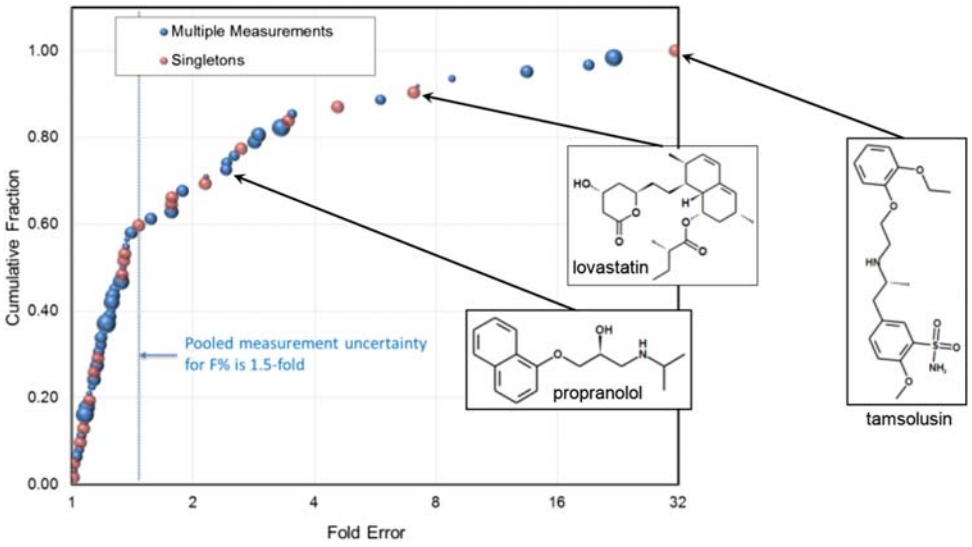


Fig. 8 Graph of cumulative fraction and fold error. Lawless M., DiBella J., Bolger M.B., Clark R.D., Huehn E., Waldman M., Zhang J., and Lukacova V. Poster Presented at International Society for the Study of Xenobiotics (ISSX): Prediction of Oral Bioavailability In Silico, 2015.

in vitro microsomal K_m and V_{max} values also resulted in large differences between reported and predicted %F. Propranolol was incorrectly predicted to be metabolized by 1A2; only including metabolism by 2D6 gives a correct %F prediction.

In silico tools predicting %F from 2D molecular structures can play an important role in anticipating challenges prior to initiating clinical development. Refining ANNE models based on the chemical space of interest is one strategy for improving prediction of %F. It is also important to note that PBPK simulations using in vitro microsomal K_m and V_{max} values also resulted in large differences between reported and predicted %F for some compounds. This reflects uncertainties in the bioavailability measurements themselves as well simplifying assumptions in the model details, for example, that the CYPs involved follow simple Michaelis–Menten kinetics across the entire concentration range, which is often not the case.[148]

4.04.8.2 Halofantrine Concentration-Related QTc Prolongation

Halofantrine hydrochloride is useful for the treatment of uncomplicated malaria and is effective when used against both chloroquine-sensitive and chloroquine-resistant *Plasmodium falciparum* infections. Halofantrine is orally administered as a racemic mixture and undergoes *N*-debutylation in the liver by CYP3A4 to its major metabolite *N*-desbutylhalofantrine. This metabolite is found in serum soon after administration of halofantrine, usually at lower concentrations. Both compounds are thought to contribute to the antimalarial activity.

Halofantrine is associated with lengthening of the QT interval and there have been reports of palpitations, syncope, and fatal or near-fatal arrhythmias in patients.[149–151] Electrophysiological studies on wild-type human ether-a-go-go gene (hERG)

demonstrated that both halofantrine and *N*-desbutylhalofantrine blocked hERG K^+ channels in a concentration-dependent manner with an IC_{50} of 21.6 and 71.7 nM, respectively.[152]

Proper interpretation of these results must take into consideration differences in the ADME characteristics of the parent and metabolite compounds. The reported elimination half-life of halofantrine is quite variable, ranging from 1.8 to 15.8 days. *N*-desbutylhalofantrine has been shown to have slower elimination kinetics and can achieve higher steady-state plasma concentrations than the parent compound.[153–155]

A PBPK model was developed for halofantrine and its metabolite using a combination of predicted and measured drug-related properties (see **Table 1**).

Fig. 9 shows the model-predicted plasma concentration-time profiles for halofantrine and *N*-desbutylhalofantrine and the respective observed concentrations for a 500-mg single oral dose given to a typical 28-year-old, 68 kg male subject. The considerably longer elimination half-life observed for *N*-desbutylhalofantrine results in considerable accumulation upon repeated dosing.

An important advantage of developing a whole body PBPK model and specifying the physiological characteristics of the various tissues in the body is the ability to predict tissue concentrations of drugs of interest. These tissue concentrations can be input into an appropriate PD model to obtain more clinically relevant predictions of drug effects beyond what can be obtained with plasma concentrations, particularly when the site of action of the drug resides outside the plasma compartment. In the example of halofantrine and *N*-desbutylhalofantrine, the PBPK model was used to predict tissue concentrations in the heart and these tissue concentrations were then input into an E_{max} model, similar to the one presented in Eq. (4) in the pharmacodynamic section.

The recommended dose for halofantrine in patients with no previous exposure or minimal exposure to malaria is 500 mg (2×250 mg tablets) of halofantrine hydrochloride every 6 hours for three doses. This course of therapy should be repeated 7 days after the first course. **Fig. 10** shows a population simulation for healthy adult males using the above dosing regimen, predicted tissue concentrations in the heart for halofantrine and *N*-desbutylhalofantrine, and the expected QTc interval (ms) impact for each moiety. This latter prediction is based on the observed IC_{50} for parent and metabolite in the hERG experiment.

Although *N*-desbutylhalofantrine has been suggested to be a safer antimalarial agent compared to halofantrine, these results suggest that the gain in safety margin for QT interval prolongation-related cardiotoxicity is minimal. In fact, with chronic dosing the higher concentrations of *N*-desbutylhalofantrine are likely to be associated with concentrations considerably higher than the IC_{50} for the hERG blockade. Consequently, the metabolite can play a substantial role in the cardiotoxicity of halofantrine.

4.04.9 Regulatory Implications

The cumulative academic, industry, and regulatory experience with PBPK modeling and simulation has led to the confidence in the value of PBPK predictions in various applications and an appreciation of the need for additional experience and validation efforts in

Table 1 Physicochemical, metabolism, and toxicity properties of halofantrine

Physicochemical properties	*Value*	*Reference*
Log *P* (octanol/water)[a]	7.58	ADMET Predictor[b]
Aqueous solubility at pH 5.5 ($\mu g\ mL^{-1}$)	1.3	Humberstone et al.[156]
FaSSIF ($\mu g\ mL^{-1}$)	2.1	
FeSSIF ($\mu g\ mL^{-1}$)	264	
pK_a base	9.2	ADMET Predictor[b]
Percent unbound in plasma (%)[c]—human	0.7	
Percent unbound in plasma (%)—rat	0.038	Brocks[157]
Blood/plasma concentration ratio	1.5	Klein et al.[158]
Metabolism		
In vitro CYP3A4 K_m halofantrine (μM)[d]	48	Baune et al.[159]
In vitro CYP3A4 V_{max} halofantrine (pmol $min^{-1}\ mg^{-1}$ protein)[d]	215	
In vitro CYP3A4 K_m *N*-desbutylhalofantrine (μM)	71.7	ADMET Predictor[b]
In vitro CYP3A4 V_{max} *N*-desbutylhalofantrine (pmol $min^{-1}\ mg^{-1}$ protein)	1410	ADMET Predictor[b]
Toxicity		
hERG IC_{50} halofantrine (nM)	21.6	Mbai et al.[152]
hERG IC_{50} *N*-desbutylhalofantrine (nM)	71.7	
Hill coefficient halofantrine	0.62	
Hill coefficient *N*-desbutylhalofantrine	1.36	

FaSSIF, fasted state simulated intestinal fluid; *FeSSIF*, fed-state simulated intestinal fluid; IC_{50}, concentration resulting in 50% of the maximum inhibition; K_m, concentration at 1/2 maximum metabolic velocity; Log *P*, octanol water partition coefficient; V_{max}, maximum metabolic velocity.

[a]Experimental log *P* not determined due to low aqueous solubility.

[c]Assumed fraction unbound in enterocytes to be 1% to account for lysosomal trapping.

[d]In vivo V_{max} and K_m calculated using the Halifax Fu calculation method and GastroPlus default values for CYP3A4 microsomal content and molecular weight.

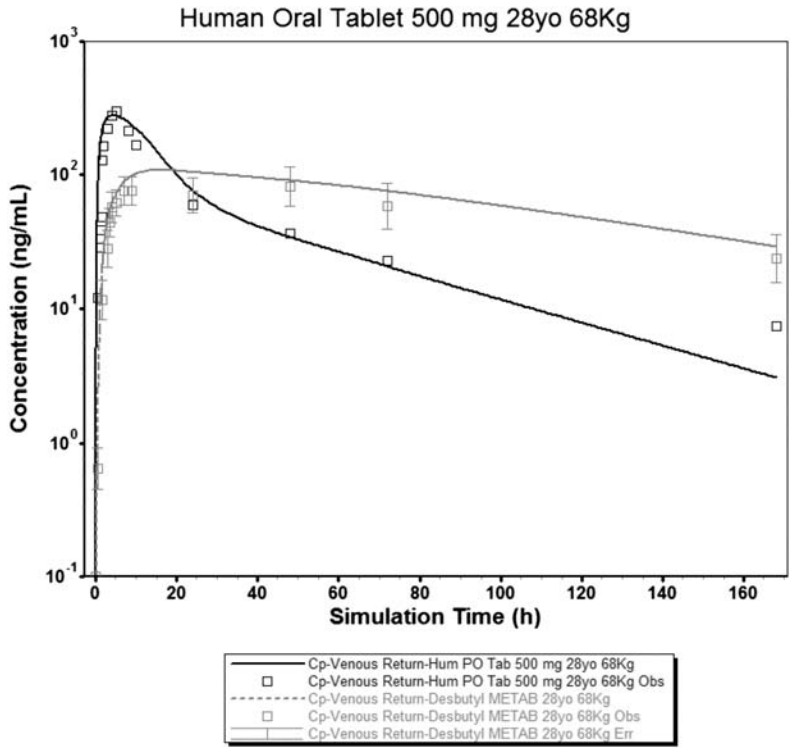

Fig. 9 Plasma concentration-time profiles for parent and metabolite following a 500-mg single oral dose. From GastroPlus.

others. In general, confidence is generally higher for BCS class 1 and 2 molecules that are also predominately eliminated by cytochrome P450 oxidation. Confidence is generally lower in cases where elimination is via non-CYP pathways or for interactions with transporters and enzymes. Similarly, there is a paucity of data and systematic experience in predicting the effects of disease states, such as hepatic and renal insufficiency.[10,131,132]

Regulatory agencies have recognized the value of PBPK modeling and simulations and have begun working to encourage their use in drug development. Workshops sponsored by the FDA and the EMA have been held to better define what constitutes a credible physiologically based simulation system and what evidentiary standards must be met to use such a system in various aspects of regulatory decision-making.[131,132]

In general, PBPK modeling is viewed as having great potential value to support benefit–risk assessments, providing a mechanistic basis for extrapolation beyond the clinical trial population, reducing uncertainty by understanding the sources of interindividual variability in the outcomes observed in clinical trials, enabling better labeling around DDIs, developing recommendations for dosing in specific populations (e.g., elderly, pediatric), and even predicting drug exposure in clinically untested treatment scenarios.[132]

Based on regulatory research and review experiences, predictive performance is considered well established for evaluating the DDI potential of an investigational drug as a substrate of metabolizing enzymes, specifically those metabolized by CYP3A isoforms and 2D6. In other areas of drug development, the predictive performances of PBPK are not as well established and there is an important need to establish methodological best practices and evidentiary standards.

A systematic understanding of the utility and validity of these model applications requires insight into the performance characteristics and properties of both the drug and the prediction tool. This understanding is a vital prerequisite for achieving reliable predictions and for developing general principles about the robustness, predictability, and reliability of the model, rather than looking at each case individually.

The FDA's views on the predictive performance of PBPK in different application areas have been summarized and considerations in demonstrating the validity and robustness of a PBPK model in various circumstances have been defined by Wagner:[131]

- Predictive performance should be reflected by the ability of a model to reasonably describe all available data.
- Biological plausibility of the model components should be demonstrated.
- Predictive performance of a system component should be demonstrated through modeling of multiple, relevant drugs.
- The predictability of a PBPK model should be seen in the context of its intended use and should not be over-interpreted, e.g., a PBPK model deemed adequate to predict drug interaction potential may not be sufficient to predict the effect of other patient factors such as organ impairment.

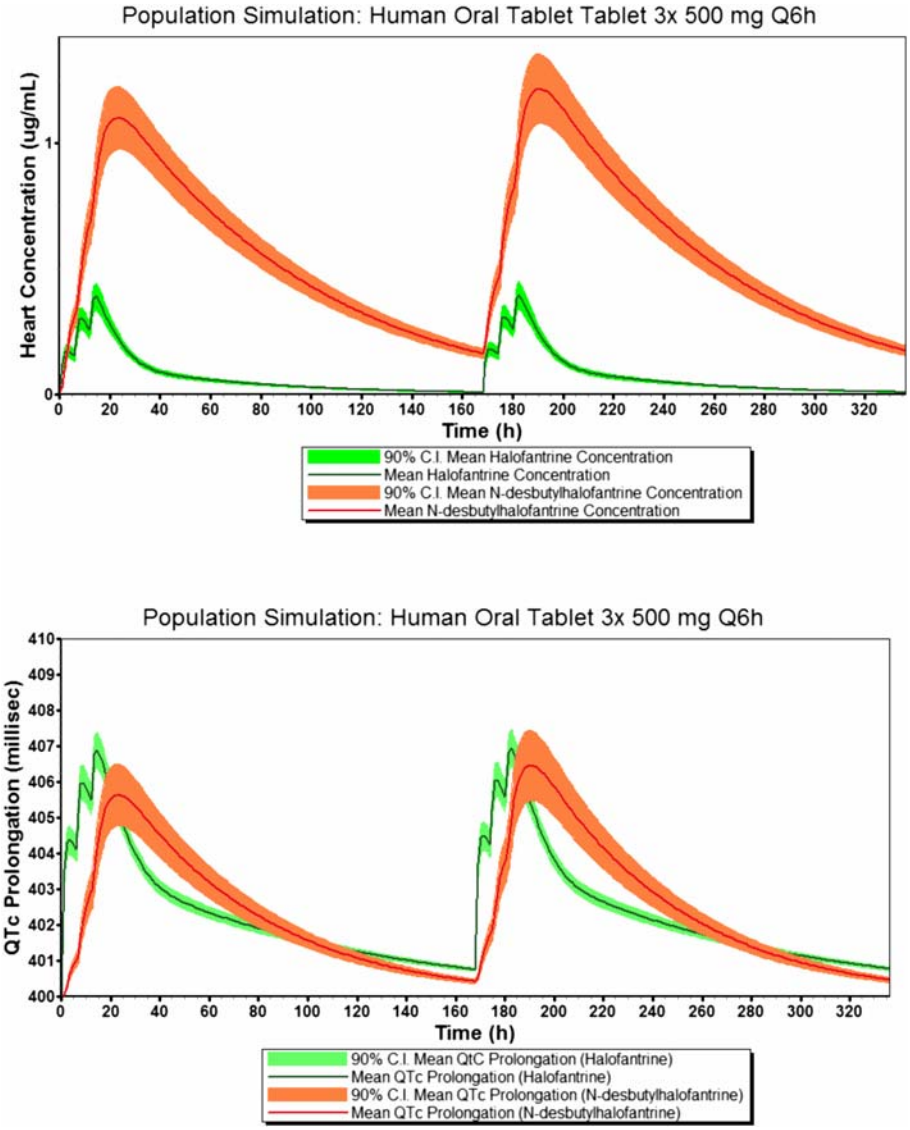

Fig. 10 Heart concentrations and effects on QTc interval from population simulation using recommended dosing regimen for treatment of malaria. From GastroPlus.

Regulatory agencies recognize the need for a full understanding and description of methodology to measure input parameters, preferably with adoption of common reference standards across companies, and a need for greater clarification and justification of empirical scaling factors.

4.04.10 Future Directions

4.04.10.1 Scientific Challenges

The mechanistic understanding of the myriad interactions between drug and system is the crucial factor enabling predictions for different scenarios in which in vivo or clinical studies have either not yet been performed or that are not technically or ethically feasible. As our knowledge of drug pharmacology and systems physiology continues to evolve, and we find innovative applications of PBPK that open new areas of research, we will continue to require additional information to address gaps in knowledge. For example, major challenges remain in the prediction of transporter effects and non-CYP related elimination; however, the introduction of QTAP for the determination of absolute transporter expression in human tissues[118] has opened the door for more accurate parameterization of IVIVE and PBPK modeling for substrates of influx and efflux transporters.[133–135]

As we move into predicting PK in the youngest pediatric patients, new information about the ontogeny of enzymes and transporter proteins are required.[136]

Further, understanding of the influence of disease on changes in enzyme or transporter abundance and distribution becomes necessary.

4.04.10.2 Cultural Challenges

Just as important as these scientific challenges are the cultural changes that loom large as modeling and simulation activities become more prominent in support of internal R&D and external regulatory decision-making. Applications of PBPK require input from many different disciplines over the lifecycle of R&D. This can create new challenges in terms of the collaborative environment required for success and the need to update drug- and system-specific input data as new knowledge emerges from preclinical and clinical studies. Given that PBPK modeling is an iterative learning process in which the PBPK model for a compound evolves with time, new strategies in terms of project and program management are required in order to ensure that the data required to achieve an acceptable level of confidence in the model are available when required for decision-making. This will require changes in scientist and management roles and responsibilities. Just as experimental models have evolved alongside the computational models in the PBPK software, so will management responsibilities change to improve the value and predictive performance of PBPK modeling and simulation.

The following questions are representative of the issues that will need to be addressed as PBPK models play a more prominent role in decision-making.

1. Goals for the modeling effort
   - What questions does the model need to address? What are the expectations of the model? What is the relationship between the available data and the required level of confidence to support decision-making in different phases of development?
2. Sources and completeness of input data
   - What data are required? Does some needed data already exist? Who has it? How do I identify inadequate or missing data? How do I to keep track of new or revised data? Are there data standards in place across projects that would enable the use of data from one program to be applied in other projects?
3. Interdisciplinary cooperation
   - What are considered reasonable parameter values or model assumptions from each discipline? What is the adjudication process when there is disagreement across disciplines? How much tolerance is there for model uncertainty? How do I best present the model and anticipate questions that will inspire confidence in the model from peers? Is the team willing to make the time commitment needed to understand the model and appropriately interpret the results?
4. Model refinement and validation
   - How do I use new information to make model refinements in order to create the best model for the next stage of drug development?
   - How robust are the predictions? Is the team asking good "what if" questions? What can I do to improve the quality of the predictions? Can I get different experiments performed to fill in the gaps?
5. Administrative aspects of in silico modeling and simulation
   - Who should have access to the model? What are appropriate change control procedures? Do I have adequate staff with appropriate training to develop and apply PBPK models?
6. Strategic application of modeling and simulation results
   - What evidentiary standards are acceptable for different risk levels of decision-making? How do I assess the value of alternative strategies to guide decision-making? How can this model-building process inform future drug development?

4.04.11 Epilogue

Sufficient experience in the use of in silico tools has accrued to clearly demonstrate the value that these tools provide to R&D decision-making. The emergence of in silico tools, such as PBPK modeling, to predict human pharmacokinetics for new compounds provides significant opportunities to anticipate the advantages and liabilities associated with compounds under consideration in discovery. Physiologically based PK modeling is being used in diverse applications and having a significant impact throughout the stages of drug discovery and development by providing mechanistic insights into drug PK and enabling scientists to anticipate problems and optimize development programs.

Given the diversity of PBPK applications and the requirements for input data from multiple departments, there is a critical need for effective interdisciplinary collaboration in model development and interpretation. The combined knowledge and expertise of preclinical scientists, formulation scientists, pharmacometricians, clinical pharmacologists, clinicians, and statisticians are critical to the successful application of PBPK modeling and simulation. We are just beginning to appreciate the need for new approaches to the management of the R&D enterprise in order to foster interdisciplinary collaboration and to provide innovative training and career development strategies for scientists and managers alike.[15]

The value of these interdisciplinary collaborations has been made apparent in the symbiotic relationships that have developed between experimental scientists and PBPK modelers. The in vivo and in vitro experimental protocols have undergone continued refinement and improvement as the data requirements of PBPK models are better appreciated. These improvements have led to the design of more informative experiments which allow the input parameters to be defined more precisely and to improvements in the software that allow for a more accurate representation of the phenomena of interest. This iterative relationship between the experimental models and the computational models has improved our understanding of the true complexity of experimental data and the predictive performance of PBPK models.[56]

It is important to note that the quality and certainty of predictions from the PBPK model can improve over time as in vitro data, preclinical in vivo data, and finally in vivo data in humans become available. A key aspect of this progression is that estimates from each stage can provide a valuable reality check for subsequent stages, for example, predictions sometimes disagree with experimental measurements because mistakes were made in carrying out the measurements. Metcalfe and Thomas have pointed out that much of the difficulty in predicting oral absorption, bioavailability, and clearance is in the experimental quantification of solubility, membrane permeability, plasma protein binding, metabolism, and active transport, rather than in the formulation of in silico models.[40]

As our knowledge of drug pharmacology and systems physiology continues to evolve, and we find innovative applications of PBPK that open new areas of research, we will continue to face new gaps in knowledge. The quote from Selassie[1] succinctly describes the challenges of PBPK modeling and simulation. During the early applications of PBPK modeling, the deficits in the knowledge base and in silico models were recognized and these deficits provided sources of inspiration for improvements. With each new application, the scientific community learns more about the interactions between physiology and pharmacology.

Although the job of learning and adapting to new knowledge will never end, we have amassed enough experience to know that PBPK modeling and simulation will continue to play an ever more vital role in science-based R&D.

4.05.1 Introduction

Humans are capable of disposing foreign compounds, drugs, or xenobiotics, via a myriad of enzymes that reside predominantly in the liver, and in extrahepatic tissues such as the intestine, kidney, brain, lung, skin, and other tissues. Drug metabolism occurs via Phase I reactions by enzymes belonging to the cytochrome P450 family,[1–3] epoxide hydrolases[4], and Phase II enzymes including UDP-glucuronosyltransferases or UGTs, sulfotransferases or SULTs, and glutathione S-transferases or GSTs.[5,6] Phase I metabolites may be further metabolized by Phase II enzymes, which usually transforms metabolites to more polar and easily excretable forms for renal disposal.[7]

There is an increasing need to consider the importance of metabolites in drug development since metabolites exhibit pharmacological active or toxic properties, and may bind to therapeutic targets or interact with nontherapeutic targets to result in undesired side effects.[8–11] Due to our ability to assay extremely low quantities of metabolites, and there was a movement to consider Metabolite In Safety Testing.[12] In Feb. 2008, the US Food and Drug Administration issued guidance to industry that classified metabolites as major ones when the metabolite in the circulation exceeds 10% of drug exposure. Major metabolites can be defined by relative exposure (%exposure) or the area under the curve (AUC) of precursor and its formed metabolite. But typically, major metabolites are defined as those having %exposure exceeding 10% or 25% that of the precursor drug.[12,13] The modification in chemical structure will change the distribution volumes, lipophilicity, and pKa. It may not be meaningful, however, to consider the %AUC since the metabolite is usually of a smaller volume of distribution than for drug due to its higher polarity.[14] On the other hand, the monitoring of metabolites is especially important for metabolites that are unique and formed only in humans and whose levels are disproportionately greater ($>10\%$) when compared to other animal species.[15] It has been suggested that metabolites be synthesized and administered as preformed metabolites directly for testing in preclinical toxicity studies.[12,16–19] Often times, it may not be possible to administer the metabolite intravenously or give it to humans. Moreover, the %exposure might not be the only parameter to define whether metabolites are major or not, especially when the formed metabolite that is monitored in circulation has been formed and sequentially metabolized before reentering the systemic circulation.[20] Alternatively, the preformed metabolite may not be able to reach tissue sites due to the poor permeability, and exposure to the metabolite will differ from that of the formed metabolite. Others resort to defining parameters, for example, fraction of total or hepatic clearance or fraction of dose that forms the metabolite to describe metabolite formation.[21]

The need for a thorough understanding of kinetics of a formed metabolite from a precursor is paramount. Metabolites can undergo immediate removal within the formation organs, a phenomenon known as "sequential first-pass metabolism" of formed metabolites.[22] This aspect is often ignored and the removal extent of formed metabolites can differ from those for the preformed species.[14,23,24] The difference is particularly noticeable when the polar, preformed metabolite exhibits limited entry into the eliminating organ, contrasting the scenario for the formed metabolite, which is formed from a lipophilic precursor that is highly

permeable and enters the organ readily for formation within the organ.[25] Therefore, it is not guaranteed that preformed and formed metabolites behave similarly in vivo when the metabolite encounters a membrane barrier[23,26] or when enzyme zonation exists in the liver for metabolite formation and sequential removal.[27,28] Additionally, it is not easy to synthesize reactive, stable metabolites. Many of these aspects have been discussed.[14,18,24] What is the most proper way to administer preformed metabolites to best mimic the exposure of formed metabolite is uncertain.[20] For instance, direct administration of preformed metabolite could lead to formation of other metabolites which are not formed from parent.[20] Since metabolite kinetics is of great importance in pharmaceutical research and drug development due to toxicity issues, there have been rigorous efforts devoted toward the elucidation of how much of the dose or clearance forms the metabolite, and under which route of drug administration.

In this communication, we revisit descriptors used in metabolite formation and removal in specific organs or whole body.[21] We prefer use of physiologically based pharmacokinetic (PBPK) versus compartmental models, since the PBPK model can describe multiple tissues in metabolite formation, and the compartment model cannot.[22] The PBPK models are able to characterize the kinetics of preformed and formed metabolite simultaneously[14,24,29] in providing richer information for the understanding of metabolite disposition. An inherent advantage of PBPK models is the specification of the tissue (such as liver and intestine) for metabolite formation. The PBPK models can define intestinal removal of drugs given orally or intraluminally than when given intravenously. Moreover, here, we can accommodate the segregated flow model (SFM) that describes a lower, partial intestinal flow perfusing the enterocyte region where the majority of drug transporters and enzymes are located. The SFM distinguishes route-dependent intestinal metabolism,[30–34] that for drugs metabolized by the intestine, there will be a greater extent of intestinal metabolism for oral (PO) versus intravenous (IV) dosing. These methodologies will be useful in drug development in defining active or toxic metabolite formation and removal. PBPK models are readily scaled up from preclinical to clinical data.[35–37] In addition, the (SFM)PBPK model will consider drug/metabolite transporters, protein binding, sequential metabolism of parent and metabolites in metabolite formation, and removal and transmembrane barriers.

4.05.2 Parameters That Identify Metabolite Formation

One of the common terms that describes primary metabolite formation is the formation clearance of metabolite, mi, as a fraction of total body clearance, g_{mi}. This term, when multiplied to the IV dose, should yield the total amount of metabolite formed.[21] However, because the formed metabolite may be sequentially metabolized or excreted, only a fraction of the newly formed metabolite (denoted by $F^{mi,P}$) appears in systemic circulation.[22,38] Hence, the fraction of total body clearance of the precursor (g_{mi}) that forms the metabolite is given by:

$$g_{mi}F^{mi,P}\text{Dose}^{P,IV} = f_{mi}\text{Dose}^{P,IV} = \text{CL}^{mi,P}\text{AUC}^{P,IV}_{mi,P} \quad (1)$$

where $\text{CL}^{mi,P}$ and $\text{AUC}^{P,IV}_{mi,P}$ are the clearance of the metabolite and AUC of the formed metabolite after intravenous dosing ($\text{Dose}^{P,IV}$) of the precursor, *P*.[21] Note that the formation clearance could be expressed in terms of f_{mi}, the product of $g_{mi}F^{mi,P}$, or the fraction of drug clearance that *furnishes* mi to the circulation, after accounting for sequential elimination of the formed metabolite.[21] Alternatively, the metabolite may be expressed in terms of the hepatic clearance that forms mi, since $h_{mi} = (1 - f_e)g_{mi}$:

$$h_{mi}F^{mi,P}\text{Dose}^{P,IV} = (1 - f_e)g_{mi}F^{mi,P}\text{Dose}^{P,IV} = (1 - f_e)\text{CL}^{mi,P}\text{AUC}^{P,IV}_{mi,P} \quad (2)$$

The fraction of hepatic clearance (h_{mi}) that forms the metabolite is $g_{mi}(1 - f_e)$ where f_e is the fraction of the IV dose that is excreted. Detailed equations for g_{mi}, f_{mi}, and d_{mi} (fraction of intravenous dose that forms mi) were described in previous publications.[21,22,39,40] These parameters are useful descriptors for estimation of the fractional contribution of metabolite formation to total or hepatic clearances.[21]

Martin and colleagues and others[41–44] have described metabolite behavior and parameters. Early plots of the drug and metabolite show important parameters such as the total elimination rate constants of the precursor drug (k) and for the metabolite ($k\{mi\}$). Upon plotting the concentration–time profiles of drug and metabolite, two distinct patterns may be found. Both the elimination rate constants of drug and metabolite, k and $k\{mi\}$, are revealed as terminal slopes. Note that the metabolite formation rate constant, k_{mi}, does not appear in the slope but in the intercept. One shows that the decay profile of the metabolite is longer than that of the drug, with the metabolite formation rate constant (k_{mi}) being slower than its elimination rate constant ($k\{mi\}$) (**Fig. 1A**) and the second, with the decay rate constant for the metabolite ($k\{mi\}$) being parallel to that for drug (k), showing that metabolite elimination is formation rate-limited (**Fig. 1B**). Details surrounding the estimation of elimination rate constants of both drug and metabolites can be found.[44–46]

As more is learned about the handling of the metabolite, the compartmental approach described above may no longer be accurate or useful. First, metabolites formed within tissues are prone to sequential elimination and the available fraction ($F^{mi,P}$) differs. Second, metabolites are usually more polar and exhibit permeability barriers, and the fates of nascently formed metabolite and the metabolite that has returned to the circulation and exists in systemic blood can differ. Third, since both the intestine and liver are serially arranged metabolic organs, and it is very likely that intestinally formed metabolites would travel down to the liver and undergo further metabolism, especially if the metabolite is able to traverse the sinusoidal membrane. The notion that drug or metabolite exposure within eliminating organs or target tissues is additive and combined within the central or peripheral compartments as homogeneous compartments is not tenable. Generally, compartmental modeling fails to quantitatively distinguish the

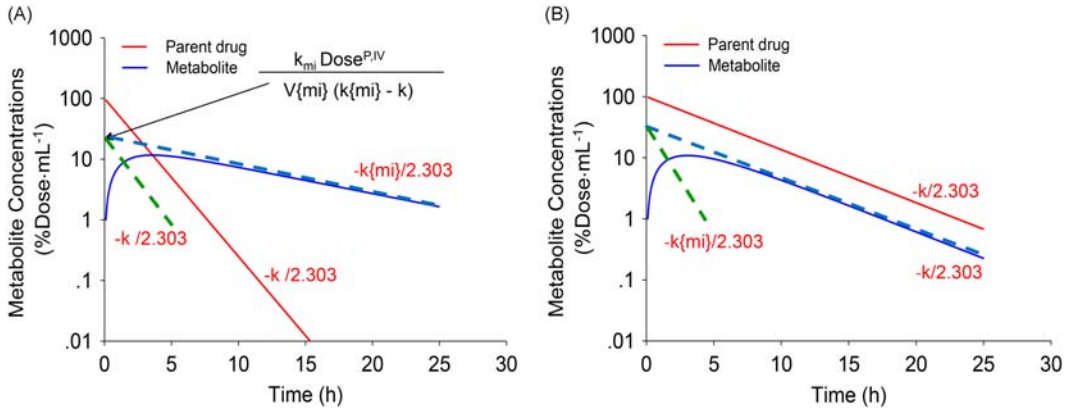

Fig. 1 Log concentrations versus time profiles of parent (*P*) and its formed metabolite (mi). The terminal slopes of parent and metabolite temporal profiles can either be nonparallel (A) or parallel (B), where *k* and *k*{mi} denote the elimination rate constants of *P* and mi, respectively; k_m is the metabolite formation rate; *V*{mi} is the volume of distribution of mi; Dose^{P,IV} is the intravenous dose of *P*. Simulations were performed with $k=0.5\ h^{-1}$, $k\{mi\}=0.1\ h^{-1}$ for (A) and $k=0.1\ h^{-1}$ and $k\{mi\}=0.5\ h^{-1}$ for (B). $k_m=0.1\ h^{-1}$, *V* and *V*{mi} = 1 L using ADAPT5 (BSMR, USC).

location (liver and intestine) of metabolite formation and secretion, characterize induction or inhibition of intestinal but not liver enzyme/transport.[47] For these reasons, compartmental modeling fails to reveal useful information on how much a metabolite is formed or excreted/metabolized in the intestine and liver.[47] Therefore, the PBPK modeling is evoked as the alternative approach to better address these deficiencies.

4.05.3 PBPK Models to Study Metabolite Kinetics

PBPK models provide a physiological approach to examine metabolite disposition when the organ/tissues are anatomically placed. In PBPK modeling of metabolites, it is important to know how many tissues form the metabolite in question from the precursor drug. Sequential metabolism within the same tissue or different tissues as the formation organ will reduce the net appearance of formed metabolite in the systemic circulation.[22] The approach interconnects tissues of discrete volumes by flow, and interrelates physical properties such as transmembrane transport, blood/plasma and tissue binding, and biochemical parameters, such as intrinsic clearances for influx and efflux, and metabolism and secretion in multiple tissues such as the intestine and liver.[47,48] Inherently, these PBPK models allow for consideration of both precursor and formed metabolite and sequential metabolism within the intestine and liver as first-pass organs. For drugs and metabolites of perfusion-limited distribution (no permeability barrier), the tissue-to-plasma/blood partitioning coefficients (K_Ps or K_Bs) that define the steady-state tissue-to-plasma/blood concentration ratio are chosen to simplify rate equations, since the outflow concentration (C) may be expressed as $\frac{C_{tissue}}{K_P \text{ or } K_B}$ when the K_P or $K_B = \frac{C_{tissue}}{C_P \text{ or } C_B}$. The K_P values can be estimated according to equations by Rodgers and Rowland,[49,50] and K_B is related to K_P as $\frac{K_P}{(C_B/C_P)}$. The K_P or K_B is useful to relate the effective volume of distribution of drug in tissue ($K_P \cdot V_{tissue}$, where V_{tissue} is tissue volume). In addition, these PBPK models are equipped to include, within the model, preformed metabolite data for modeling simultaneously.[51] Unlike compartmental models that are unable to separate metabolite formation from individual tissues, PBPK models can align discrete enzymes and transporters in different organ components and characterize the origin of metabolite formation within the organ and account for sequential metabolism.[22,52] The superiority of PBPK modeling over compartmental approach is supported by the fact that PBPK models can better predict human pharmacokinetics based on preclinical data and is more suitable for scale up to man.[35–37]

4.05.3.1 PBPK Modeling of the Intestine

Previously, a simple intestinal model, namely traditional model (TM), has been routinely used for the intestinal tissue where transport, binding, parallel, and sequential metabolism of both drug and metabolite are considered[30]; the intestinal tissue is homogeneous and receives 100% of the intestinal flow (Q_I) (Fig. 2A). In TM, first-order absorption rate constant (k_a), intestinal intrinsic influx ($CL_{in,I}$) and efflux ($CL_{ef,I}$) clearances through basolateral membrane, and intrinsic secretory clearance ($CL_{int,sec,I}$) are used to describe the transport of parent or metabolite through intestinal lumen, intestinal blood, and tissue regions. The intrinsic metabolite formation clearance ($CL_{int,met,I}$) includes formation of major metabolite ($CL_{int,met,I}^{P\rightarrow mi}$) and other metabolites ($CL_{int,met,I}^{P\rightarrow others}$).

However, much data have surfaced to show that the TM model fails to characterize the route-dependent nature of intestinal metabolite formation. This exists when a drug given orally shows extensive intestinal metabolite formation, but the drug produces only little or no intestinal metabolite when given systemically.[30–34] Examples of these that show route-dependent intestinal metabolism[32] include enalapril,[53] acetaminophen,[54] morphine (M),[31] erythromycin,[55] α(−)-6-aminocarbovir,[56] midazolam,[57,58], and

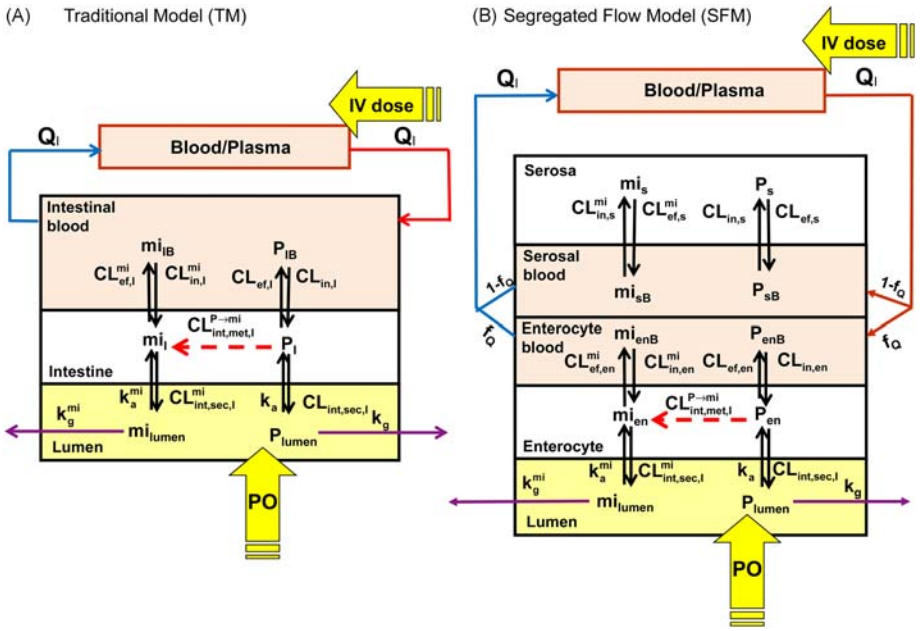

Fig. 2 Schematic representation of TM- (A) and SFM-PBPK (B) models for the intestine which consists of plasma/blood, intestinal blood (IB), and intestinal tissue (I) compartment. In the SFM-PBPK intestinal model (B), the intestinal compartment is subdivided into serosa (s) and enterocyte (en), where f_Q denotes the fraction of intestinal flow (Q) perfusing through enterocyte blood compartment. The intrinsic influx and efflux clearances of precursor (*P*) and formed metabolite (mi) through the intestinal membrane are denoted as $CL_{in,I}$ or $CL^{mi}_{in,I}$ and $CL_{ef,I}$ or $CL^{mi}_{ef,I}$, respectively. The intrinsic metabolite clearance is responsible for metabolite formation ($CL_{int,met,I}$) and intrinsic intestinal secretion for *P* ($CL_{int,sec,I}$) and mi ($CL^{mi}_{int,sec,I}$). The first-order absorption and degradation rate constants are denoted as k_a and k_g for *P*, and k^{mi}_a and k^{mi}_g for mi, respectively, where the fraction of oral dose absorbed, or $F_{abs} = k_a/(k_a + k_g)$. The intravenous (IV) dose is administered into blood/plasma compartment directly whereas oral (or PO) is given into intestinal lumen compartment.

bisphenol.[59] Such route-dependent intestinal metabolism is explained by the pattern that a smaller fraction (5%–30%) of intestinal blood flow perfuses the enzyme/excretory transporter-rich enterocyte region while the majority of blood flow perfuses the inactive, serosal region.[30,32] As the model defines a much lower percent of flow to the enterocyte region, the amount of parent drug in the circulation that enters the enterocyte for metabolism is also less following intravenous administration since most of the drug is shunted away to the serosal region. By contrast, during oral absorption, drug traverses the enterocyte region first before reaching systemic circulation, and all drug becomes available for intestinal metabolism.[32] Thus, there is no difference in intestinal metabolism between the TM and SFM for oral dosing and between IV and PO for TM, the extent of intestinal metabolism after IV dosing according to the SFM is much less than that for the TM. For this reason, a segregated flow intestinal model (SFM) is proposed[30] (**Fig. 2B**). In SFM, the enterocyte blood (enB) and the tissue (en) are perfused by the fractional (f_Q) intestinal blood flow (Q_I), whereas serosal blood (sB) and serosal (s) tissue are perfused by rest of intestinal flow $[(1-f_Q)\cdot Q_I]$. Previous studies have shown that the SFM better describes route-dependent intestinal glucuronidation of M in the rat intestine,[31,47] the kinetics of benzoic acid in perfused recirculating rat intestine[60], and apical excretion of digoxin by P-glycoprotein (P-gp), with and without induction from the pregnane X receptor ligand, pregnenolone-16α-carbonitrile.[61] Recently, PBPK modeling of 1α,25-dihydroxyl vitamin D_3 (an active ligand of vitamin D receptor), developed for consideration of feedback regulation of its synthesis and degradation enzymes, also favors the SFM. Inclusion of segregated, fractional intestinal flow ($f_Q = Q_{en}/Q_I = 10\%$) improves model fitting and prediction of the temporal drug plasma/tissue concentration profiles with escalating (2–120 pmol), repetitive intravenous doses.[62] The fitted value of f_Q is about 2.4%–20% (see **Table 1**).

Consideration of the SFM versus the TM only takes on addition of one extra compartment, namely, the intestine compartment, is not one but now two tissue subcompartments, one for the enterocyte and one for the serosa, with flows of $f_Q Q_I$ and $(1-f_Q)Q_I$, respectively. The impact is large since the SFM encompasses the idea of route-dependent intestinal metabolism and described the greater effects of inducers and inhibitors when given PO, together with the victim drug, also given PO, and less effect or virtually absence of effect when the victim drug is given IV. This was observed for the interaction between digoxin and rifampin in man.[65] Also, a greater inhibition of P-gp activities toward intravenously injected [^{3}H]digoxin by interferon-γ in liver and not intestine in the mouse was observed.[66]

Expression for the availability for the intestine (F_I) exists, and the same equation applies to the TM and SFM.[52] The only difference is in the value of f_Q, which, together with the flow term as $f_Q Q_I$, defines the effective flow to the enterocyte region. For SFM, $f_Q < 0.3$ and for TM, $f_Q = 1$. It is noted in the solution that the drug that is secreted into the gut lumen is subject to reabsorption, by the fraction F_{abs}.

Table 1 Summary of f_Q values for the SFM obtained from fitting

Compound	f_Q *values*	*Details on experiment*	*Intestinal removal*	*Reference*
Morphine	0.024	Recirculating perfused rat small intestine preparation	Morphine 3-glucuronide formed with intraduodenal (oral) but not intravenous dosing of M	30,31
Morphine	0.1	Rat in vivo following intravenous or intraduodenal dosing of M	M glucuronidation, greater with intraduodenal but not intravenous dosing of M; ratio of bile/urine of MG after PO is greater than that after iv	47
[^{3}H]Digoxin	0.2	Recirculating perfused rat small intestine preparation	Cyp3a and P-gp	61
[^{3}H]Digoxin	0.16	Mouse intestine in vivo	P-gp for excretion into gut lumen	63
1α,25-dihydroxyl vitamin D_3	0.11	Mouse in vivo with PBPK modeling	Cyp24a1 forming metabolite 1,24,25-trihydroxyl vitamin D_3	62
Benzoic acid	0.07	Recirculating perfused rat small intestine preparation	Better distribution; no metabolite data to substantiate SFM	60
Codeine	0.l6	Rat in vivo following intravenous or intraduodenal dosing of codeine	Minor intestinal contribution to overall first-pass metabolism	64

$$F_I = \frac{f_Q Q_I CL_{ef,I}}{f_Q Q_I CL_{ef,I} + \left(f_Q Q_I + f_B CL_{in,I}\right)\left[CL^{P\to mi}_{int,met,I} + CL^{P\to others}_{int,met,I} + CL_{int,sec,I}(1 - F_{abs})\right]} \tag{3}$$

where for the TM, $f_Q = 1$ and for SFM, $f_Q < 0.3$.

4.05.3.2 PBPK Modeling of the Liver

The liver is the most modeled tissue, mainly because it is the most important organ for drug metabolism and biliary excretion. A common strategy is to consider the liver as a "well-stirred" compartment where drug in the liver tissue is rapidly equilibrium with that in the emergent hepatic venous blood[67–70]; bulk blood flow exists, and the liver is viewed as a simple, well-mixed reactor.[71] Alternately, the liver may be considered as a series of parallel tubes that are surrounded with evenly distributed hepatic enzymes[72,73] for the "parallel tube" model.[68] Another flow model that considers plug (parallel tube model)[72,73] or dispersive flow (dispersion model)[74–77] is available for the modeling hepatic drug extractions. The properties of these models have been reviewed and differ primarily with the type, flow, and degree of mixing (characterized by the D_N number), which is infinite for the well-stirred model, nonexistent for the parallel tube model, and intermediate for the dispersion model.[77–79]

The "well-stirred" model is the most extensively used among the models to describe drug/metabolite kinetics in eliminating organs such as the liver, with or without diffusional barrier through sinusoidal membrane.[62,80] Generally speaking, the liver-PBPK model consists of plasma/blood and liver (tissue and liver blood) compartments that are interconnected by liver blood flow. The influx and efflux clearances through sinusoidal membrane for unbound precursor and formed metabolites are denoted by $CL^P_{in,L}$ and $CL^P_{ef,L}$ and $CL^{mi}_{in,L}$ and $CL^{mi}_{ef,L}$, respectively. The unbound precursor drug of concentration $f^P_L P_L$ (f^P_L is the unbound fraction of precursor in liver blood and P_L is concentration in liver) is metabolized to form the primary metabolite (mi) with intrinsic metabolite $CL^{P\to mi}_{int,met,L}$ (or $V^{P\to mi}_{max,L}/K^{P\to mi}_{m,L}$ for first-order condition), and mi can be also further metabolized to other secondary metabolites with intrinsic metabolic clearance $CL^{mi}_{int,met,L}$. Precursor and mi are secreted into bile with $CL^P_{int,sec,L}$ and $CL^{mi}_{int,sec,L}$, respectively). A representative model scheme is shown in **Fig. 3**. Binding of precursor and mi in blood (f^P_B and f^{mi}_B) and liver tissue (f^P_L and f^{mi}_L) is considered as well. The AUC for the precursor and metabolite, with the liver as the only eliminating organ for drug, have been solved,[52]

$$AUC^{P,IV}_P = \frac{Dose^{P,IV}}{CL} = \frac{Dose^{P,IV}\left[Q_L CL^P_{ef,L} + CL^P_{int,L}\left(Q_L + f^P_B CL^P_{in,L}\right)\right]}{Q_L f^P_B CL^P_{in,L} CL^P_{int,L}} \tag{4}$$

$$CL = \frac{Dose^{P,IV}}{AUC^{P,IV}_P} = Q_L \frac{f^P_B CL^P_{in,L} CL^P_{int,L}}{Q_L CL^P_{ef} + CL^P_{int,L}\left(Q_L + f^P_B CL^P_{in,L}\right)}$$

$$\text{where} \quad CL^P_{int,L} = CL^P_{int,met,L} + CL^P_{int,sec,L} \tag{5}$$

$$AUC^{P,IV}_{mi,P} = \frac{Dose^{P,IV} CL^{P\to mi}_{int,met,L} CL^{mi}_{ef,L}}{CL^P_{int,L} f^{mi}_B CL^{mi}_{in,L} CL^{mi}_{int,L}} \tag{6}$$

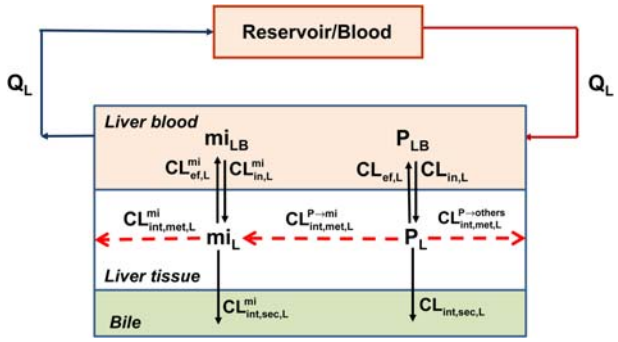

Fig. 3 Schematic representation of liver-PBPK model which consists of blood, liver blood (LB), and liver tissue (L) compartment. The influx and efflux clearances of precursor (*P*) and metabolite (mi) through the sinusoidal membrane are denoted as $CL_{in,L}$ or $CL^{mi}_{in,L}$ and $CL_{ef,L}$ or $CL^{mi}_{ef,L}$, respectively. The intrinsic metabolite clearance is responsible for metabolite formation ($CL_{int,met,L}$) and intrinsic biliary secretion for *P* ($CL_{int,sec,L}$) and mi E($CL^{mi}_{int,sec,L}$). Q_L denotes the hepatic plasma/blood flow.

These equations are applicable only when liver is the only eliminating organ[52] and total body clearance (CL) is hepatic clearance (CL_L). Hepatic availability (F_L) is

$$F_L = \frac{Q_L\left(CL_{ef,L} + CL_{int,sec,L} + CL_{int,met,L}\right)}{Q_L\left(CL_{ef,L} + CL_{int,sec,L} + CL_{int,met,L}\right) + f_B CL_{in,L}\left(CL_{int,sec,L} + CL_{int,met,L}\right)} \tag{7}$$

and may be determined by:

$$\frac{AUC_P^{P,PO}\Big/Dose_P^{P,PO}}{AUC_P^{P,IV}\Big/Dose_P^{P,IV}} \quad \text{or} \quad \frac{AUC_{mi,P}^{P,PO}\Big/Dose_P^{P,PO}}{AUC_{mi,P}^{P,IV}\Big/Dose_P^{P,IV}} \tag{8}$$

In the above relations, $AUC_P^{P,PO}$ and $AUC_P^{P,IV}$ are the AUC of parent drug after PO and IV administration, respectively; $AUC_{mi,P}^{P,PO}$ and $AUC_{mi,P}^{P,IV}$ are the AUC of the formed metabolite after PO and IV drug doses, respectively. Again, these equations are applicable only when the liver is the only eliminating organ.

Based on the above equations (especially, Eq. (5)), effects of the activities of enzyme (denoted by $CL_{int,met,L}$) and transporters (reflected by $CL_{ef,L}$, $CL_{in,L}$, and $CL_{int,sec,L}$) on hepatic availability (F_L) could be appraised with simulations based on increased/decreased values of the parameters of interest. The utility of Eq. (7) has been fully explored.[81] For example, an inhibition of the hepatic intrinsic metabolic pathway $\left(CL^{P\rightarrow mi}_{int,met,L}\right)$ will lead to increased $AUC_P^{P,IV}$ of parent drug and increased metabolic clearance of the alternative pathway but a decreased $AUC_{mi,P}^{P,IV}$ of the formed metabolite.[52] On the other hand, increased $CL_{int,sec,L}$ will increase biliary clearance and total hepatic clearance of parent drug but will decrease the metabolic clearance.[82] The observed transporter/enzyme interplay toward the competition of hepatic canalicular efflux transporter and metabolizing enzyme for the same intracellular substrate for hepatic elimination could be readily assessed.[52,81,83,84] Additionally, both lower $CL_{in,L}$ and higher $CL_{ef,L}$ allow high drug accumulation in systemic circulation (increased $AUC_P^{P,IV}$), and lower hepatic clearance of the drug, and vice and versa.[83,84]

4.05.3.3 PBPK Model of Whole Body

4.05.3.3.1 Intestine-liver: Modeling of first-pass metabolism

Because there are measureable intestinal enzymatic activities and because of the intestine being a gateway tissue to the liver for first-pass drug metabolism, it is paramount to assess the importance of the intestine versus the liver in first-pass removal. The model scheme, depicted in Fig. 4, shows that the intestine and liver are serially arranged tissues that are interconnected by blood flow through portal vein (Q_{PV} or Q_I or intestinal blood/plasma flow), a venous outflow that feeds into the liver as an input. In this circuit, it is crucial to investigate drug/metabolite kinetics in the whole-body setting, with consideration of appropriate physiological parameters for enzyme and transporter activities for drug as well as sequential metabolism. The systemic bioavailability (F_{sys}) is the product of hepatic availability (F_L), intestinal availability (F_I), and fraction absorbed [F_{abs} or $k_a/(k_a+k_g)$ where k_a and k_g are the absorption and luminal degradation rate constants, respectively]. The AUC and *F* of precursor drug and formed metabolite have be solved using matrix inversion based on rate equations derived from PBPK model,[20,52] under four different scenarios with different eliminating organ/metabolites.[52] F_L (Eq. (9)) and F_I (Eq. (10)) are solved[52,85]::

$$F_L = \frac{(Q_I + Q_{HA})\left(CL_{ef,L} + CL_{int,sec,L} + CL^{P\rightarrow mi}_{int,met,L} + CL^{P\rightarrow others}_{int,met,L}\right)}{(Q_I + Q_{HA})\left(CL_{ef,L} + CL_{int,sec,L} + CL^{P\rightarrow mi}_{int,met,L} + CL^{P\rightarrow others}_{int,met,L}\right) + f_B CL_{in,L}\left(CL_{int,sec,L} + CL^{P\rightarrow mi}_{int,met,L} + CL^{P\rightarrow others}_{int,met,L}\right)} \tag{9}$$

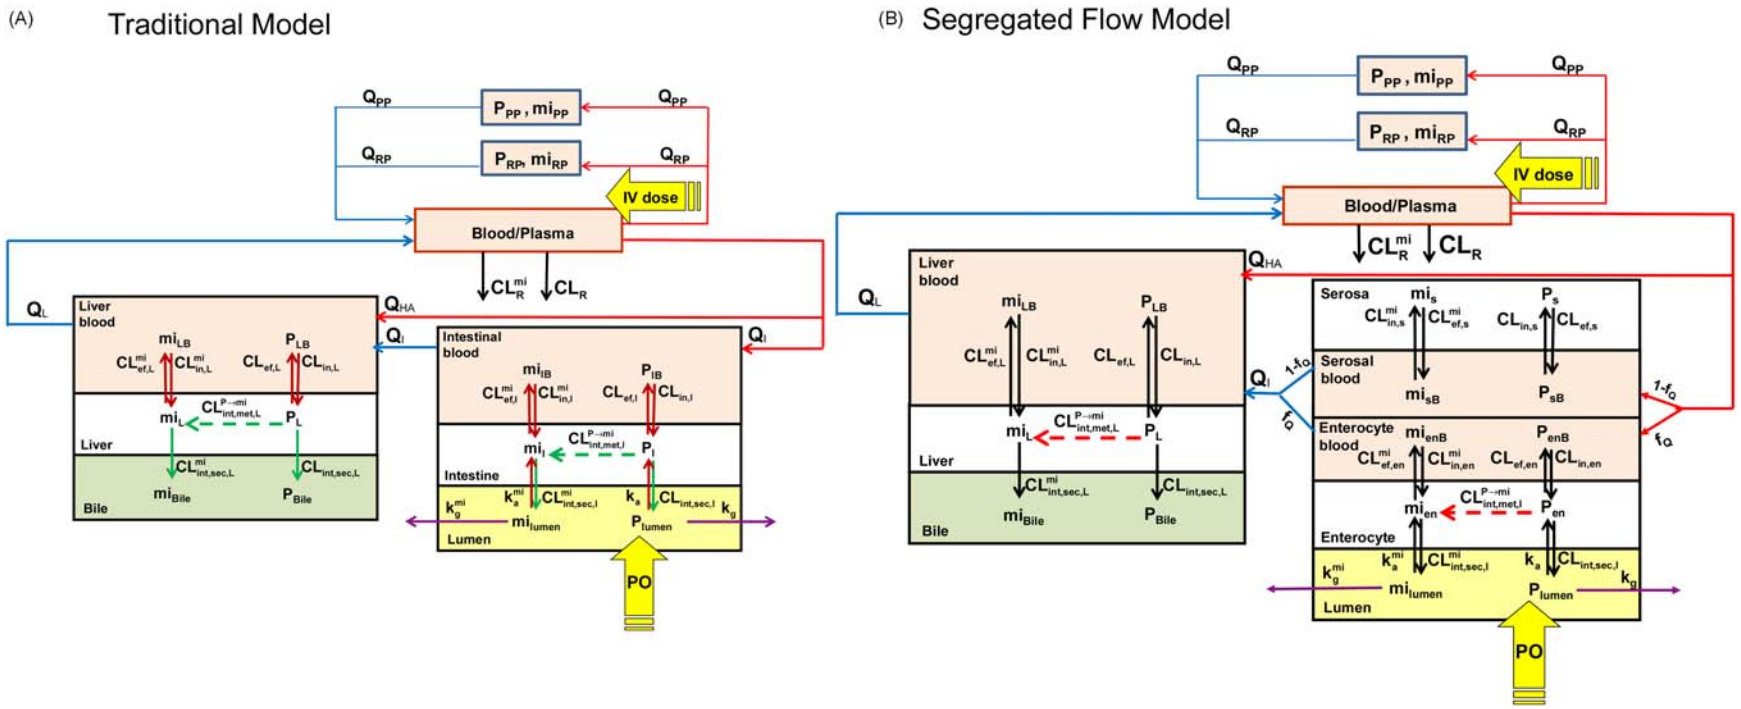

Fig. 4 Schematic representation of full TM- (A) and SFM-PBPK (B) model which consists of plasma/blood, liver (L), intestine (I), RP and PP compartments. The parameter descriptions are the same as those in **Figs. 2** and **3**. The renal clearances for *P* and mi are denoted as CL_R and CL_R^{mi} from blood/plasma compartment. The IV dose is administered into blood/plasma compartment directly whereas the PO dose is given directly into the intestinal lumen compartment.

$$F_I = F_{abs}\frac{f_Q Q_I CL_{ef,I}}{f_Q Q_I CL_{ef,I} + \left(f_Q Q_I + f_B CL_{in,I}\right)\left[CL_{int,met,I}^{P\rightarrow mi} + CL_{int,met,I}^{P\rightarrow others} + CL_{int,sec,I}(1 - F_{abs})\right]} \quad (10)$$

The systemic bioavailability (F_{sys}) is the product of fraction absorbed (F_{abs}), F_I and F_L, given by:

$$F_{sys} = F_{abs}F_I F_L = F_{abs}\frac{f_Q Q_I CL_{ef,I}}{f_Q Q_I CL_{ef,I} + \left(f_Q Q_I + f_B CL_{in,I}\right)\left[CL_{int,met,I}^{P\rightarrow mi} + CL_{int,met,I}^{P\rightarrow others} + CL_{int,sec,I}(1 - F_{abs})\right]} \times \frac{(Q_I + Q_{HA})\left(CL_{ef,L} + CL_{int,sec,L} + CL_{int,met,L}^{P\rightarrow mi} + CL_{int,met,L}^{P\rightarrow others}\right)}{(Q_I + Q_{HA})\left(CL_{ef,L} + CL_{int,sec,L} + CL_{int,met,L}^{P\rightarrow mi} + CL_{int,met,L}^{P\rightarrow others}\right) + f_B CL_{in,L}\left(CL_{int,sec,L} + CL_{int,met,L}^{P\rightarrow mi} + CL_{int,met,L}^{P\rightarrow others}\right)} \quad (11)$$

Note that for Eqs. (10) and (11), F_{abs} accounts for the influence of reabsorption of drug on the net apical secretion of drug; generally, a higher value of F_{abs} infers a lower net apical secretion.

As discussed before, PBPK model is useful in drug/metabolite kinetic testing as it integrates the pharmacokinetic data into a model with physiological, biochemical, and thermodynamic-relevant parameters.[86] However, the whole-body PBPK model has limited use due to its high complexity and dimensionality,[87–89] whereas lumping of organs/tissues with the same model specification and identical position in the system structure greatly simplifies these structural considerations.[86] The above TM- and SFM-PBPK models (Fig. 4) represent full PBPK models that define both intestine and liver as the first-pass metabolite formation organs, and lumped organ/tissue compartments into rapidly perfused (RP; such as heart, brain, lung, kidney) and poorly perfused (PP; such as muscle, fat, and skin) compartments. The primary metabolite (mi) is formed by liver and intestine with metabolite formation intrinsic clearance ($CL_{int,met}^{P\rightarrow mi}$), and the precursor also forms other metabolites ($CL_{int,met}^{P\rightarrow others}$). The formed metabolites can reenter the intestine and liver with influx clearances denoted as CL_{in}^{mi} and efflux back to systemic circulation with clearance that is denoted by CL_{ef}^{mi}. The same or different metabolites can be formed in liver ($CL_{int,met,L}^{P\rightarrow mi}$) and intestine ($CL_{int,met,I}^{P\rightarrow mi}$). Both precursor and metabolite can undergo biliary ($CL_{int,sec,L}^{P}$ and $CL_{int,sec,L}^{mi}$) and intestinal ($CL_{int,sec,I}^{P}$ and $CL_{int,sec,I}^{mi}$) secretion. The reabsorption (k_a^P and k_a^{mi}) and degradation (k_g^P and k_g^{mi}) of drug and metabolites in intestinal lumen are also considered. The renal clearances for precursor (CL_R^P) and metabolite (CL_R^{mi}) can be included, and, for the sake of simplicity, are assigned to the blood/plasma compartment. Similarly, the developed PBPK-SFM model can be used to appreciate the route-dependent pharmacokinetics.

4.05.3.4 Case Studies, Showcasing the Usefulness of SFM-PBPK Modeling on First-Pass Removal

4.05.3.4.1 Case study 1: SFM to detect route-dependent intestinal glucuronidation of morphine

The prevalence of intestinal first-pass metabolism has led to resurgence in PBPK modeling of the intestine and liver, with the newly developed SFM model being considered in parallel to that for the TM. M is avidly glucuronidated by the rat intestine[31] and liver.[90] M is a lipophilic substrate that can freely diffuse across membrane barrier, glucuronidated in liver and intestine,[91] and undergo renal and biliary secretion. Its polar, morphine 3β-glucuronide (MG) enters hepatocyte with a relatively low influx clearance (0.1 mL min^{-1} g^{-1} liver), due to the existence of a diffusional barrier at the sinusoidal membrane.[90] MG formed in liver is secreted via the multidrug resistance-associated protein 2 (Mrp2) into bile or is effluxed into the systemic circulation via the multidrug resistance-associated protein 3, Mrp3. Analogously, intestinally formed MG undergoes luminal secretion via Mrp2 or is effluxed out by Mrp3 back to the circulation[92] (Fig. 5).

The kinetics of MG excretion was studied in the rat in vivo for examination of the relative contributions of intestine and liver to MG formation following the intravenous or intraduodenal (or oral) dosing of M.[47] The extent of MG formed in liver and intestine is reflected by its appearance in urine or bile. As MG is poorly permeable, MG that is excreted into urine originates from both intestine and bile whereas MG secreted into bile is formed mostly from the liver. For this reason, the SFM will likely bring about large changes in the MG recovered in bile versus that in urine for IV versus PO dosing of M.

The substrate is uniquely suited for the discrimination between the SFM versus the TM. The SFM-PBPK model was found to fit the data better than the TM (Fig. 6). The rich data obtained from the perfused rat intestinal and liver preparations and background information from the literature were inputted into PBPK models comprising the intestine and liver in first-pass removal.[47] The SFM successfully describes the systemic delivery of M being shunted away from the enterocyte for metabolism whereas all M delivered intraduodenally/orally must enter the enterocyte first before reaching the recirculation. The MG species found in bile, originating mostly from liver metabolism of M, is higher with IV dosing of M, whereas urinary MG is higher with PO than IV dosing. Therefore SFM successfully predicts the urine/bile ratio of MG with PO dosing being higher than for IV dosing (2.6-fold). The observed ratio for urinary/bile excretion data of MG for PO is 2.6-fold that after IV dosing of M, as predicted by the SFM and not the TM or compartmental model. For the TM and compartmental models, a ratio of one is expected (Table 2).

The data fitting with the SFM-PBPK model is excellent (Fig. 6).[47] Model fitting further provided useful terms, expressed as products of the unbound tissue fraction and the efflux, secretory, or metabolic intrinsic clearances (Table 3). These estimates, expressed as ratios, could, in turn, provide estimates of the tissue distribution ratios ($K_{I,uu}$ and $K_{L,uu}$), intestinal availabilities of drug (F_I^P) and metabolite (F_I^{mi}), as well as those for the liver (F_L^P and F_L^{mi}).

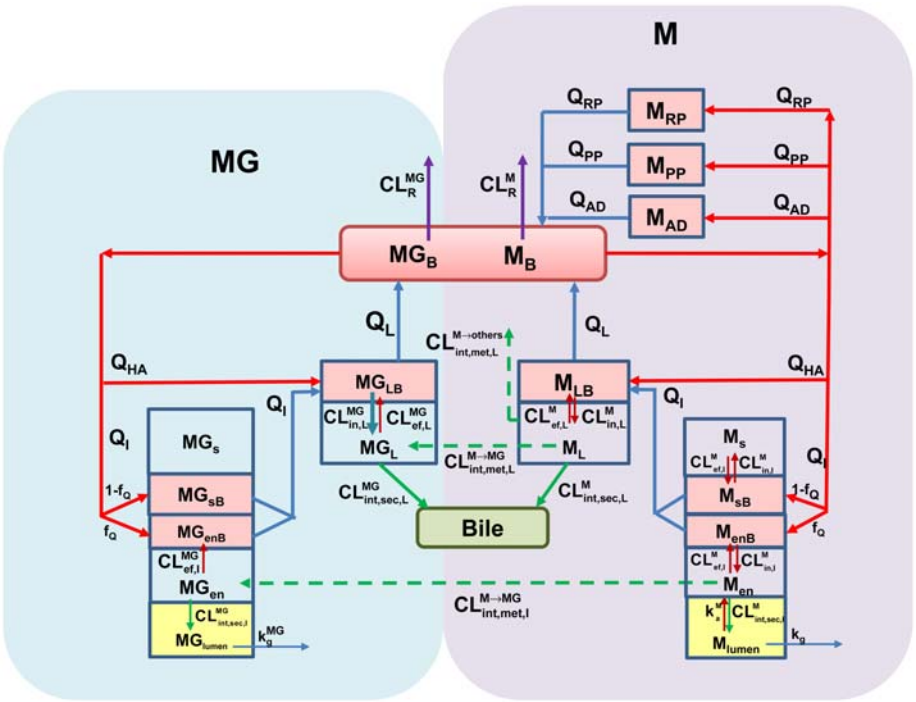

Fig. 5 Schematic representation of TM- (A) and SFM- PBPK (B) models has been used to describe the pharmacokinetics of M and its major metabolite, MG.[47] MG exhibits poor entry into tissues (including the intestine and liver) and is formed within the intestine and liver. The metabolite, mi (or MG) that appears in bile originates primarily from liver metabolism, since the MG in circulation experiences a permeability barrier to enter the liver tissue: $CL_{in,L}^{MG}$ is 1 mL min^{-1} according to Doherty et al.[90] The liver and intestine possess intrinsic metabolite clearances responsible for mi formation in liver $\left(CL_{int,met,L}^{P\rightarrow mi}\right)$ and in intestine $\left(CL_{int,met,I}^{P\rightarrow mi}\right)$, and for forming other metabolites $CL_{int,met,L}^{P\rightarrow others}$ and $CL_{int,met,I}^{P\rightarrow others}$.The intrinsic biliary and intestinal secretion for *P* ($CL_{int,sec,L}$ or $CL_{int,sec,I}$, respectively) and mi ($CL_{int,sec,L}^{mi}$ or $CL_{int,sec,I}^{mi}$, respectively). The first-order absorption and degradation rate constants are denoted as k_a and k_g for the precursor drug, and k_a^{mi} and k_g^{mi} for mi, respectively. The renal clearances for *P* and mi are denoted as CL_R and CL_R^{mi} and for the sake of simplicity, arise from the blood compartment. The IV dose is administered into blood/plasma compartment directly whereas intraduodenal (or PO) doses are injected into the intestinal luminal compartment. Obtained from Yang, Q. J.; Fan, J.; Chen, S.; Liu, L.; Sun, H. and Pang, K. S. Metabolite Kinetics: The Segregated Flow Model for Intestinal and Whole Body Physiologically Based Pharmacokinetic Modeling to Describe Intestinal and Hepatic Glucuronidation of Morphine in Rats In Vivo. *Drug Metab. Dispos.* **2016**, *44*, 1123–1138, with permission.

$$F_I^P = \frac{f_I^P CL_{ef,I}^P}{f_I^P CL_{ef,I}^P + f_I^P CL_{int,sec,I}^P + f_I^P CL_{int,met,I}^P} = \frac{CL_{ef,I}^P}{CL_{ef,I}^P + CL_{int,sec,I}^P + CL_{int,met,I}^P} \tag{12}$$

$$F_I^{mi} = \frac{f_I^{mi} CL_{ef,I}^{mi}}{f_I^{mi} CL_{ef,I}^{mi} + f_I^{mi} CL_{int,sec,I}^{mi} + f_I^{mi} CL_{int,met,I}^{mi}} = \frac{CL_{ef,I}^{mi}}{CL_{ef,I}^{mi} + CL_{int,sec,I}^{mi} + CL_{int,met,I}^{mi}} \tag{13}$$

$$F_L^P = \frac{f_L^P CL_{ef,L}^P}{f_L^P CL_{ef,L}^P + f_L^P CL_{int,sec,L}^P + f_I^P CL_{int,met,L}^P} = \frac{CL_{ef,L}^P}{CL_{ef,L}^P + CL_{int,sec,L}^P + CL_{int,met,L}^P} \tag{14}$$

$$F_L^{mi} = \frac{f_L^{mi} CL_{ef,L}^{mi}}{f_L^{mi} CL_{ef,L}^{mi} + f_L^{mi} CL_{int,sec,L}^{mi} + f_L^{mi} CL_{int,met,L}^{mi}} = \frac{CL_{ef,L}^{mi}}{CL_{ef,L}^{mi} + CL_{int,sec,L}^{mi} + CL_{int,met,L}^{mi}} \tag{15}$$

Another interesting comparison is the fractional contribution of intestine $\left(\frac{v_I}{v_I + v_L}\right)$ or liver $\left(\frac{v_L}{v_I + v_L}\right)$ to the overall intestinal–liver removal for a drug entering the first-pass organs via the circulation.[85] It must be noted that these equations estimate the % contribution of drug entering systemically (after IV dosing). The fractional contributions of intestine and liver to the overall intestinal–liver removal[85] are:

$$\frac{v_I}{v_I + v_L} = \frac{f_Q Q_I (1 - F_I)}{f_Q Q_I (1 - F_I) + E_L \langle Q_I [f_Q F_I + (1 - f_Q)] + Q_{HA} \rangle} \tag{16}$$

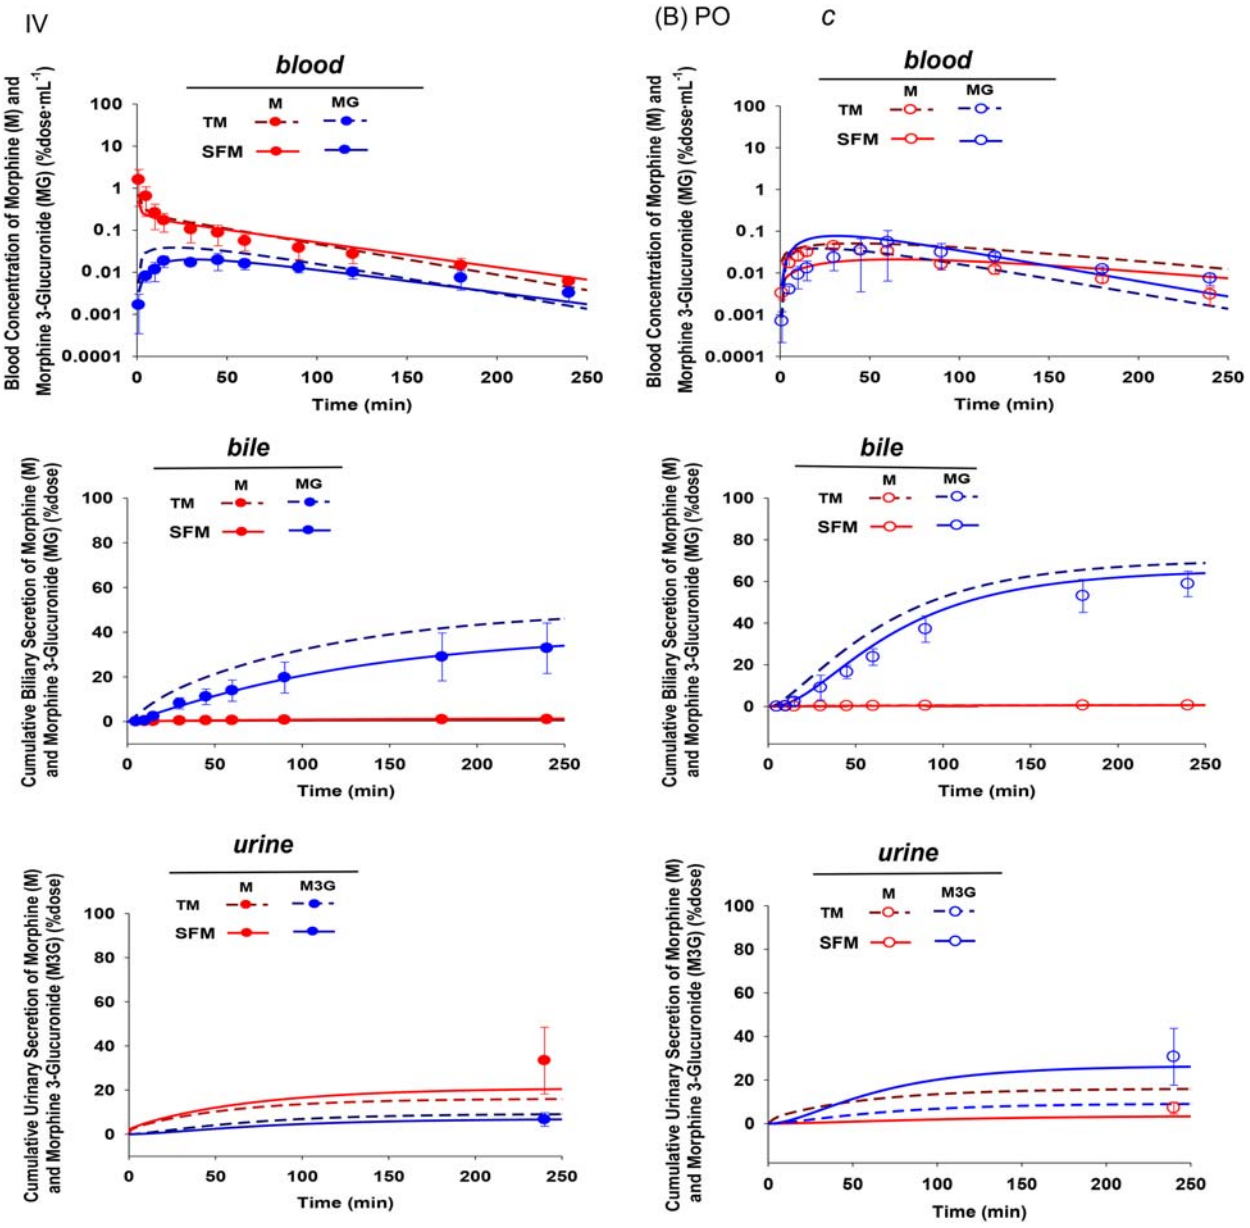

Fig. 6 Observed and fitted blood concentration–time profiles of M and MG as well as the cumulative amounts of M and MG in bile and urine after intravenous (A) intraduodenal or oral (B) administration of M (IV, *solid circles*, $n=4$; PO, *open circles*, $n=3$; M and MG are denoted as *red* and *blue symbols*, respectively). The fits of TM-PBPK are shown with dashed lines and SFM-PBPK is shown with solid lines. Data are presented as means ± SD. Obtained from Yang, Q. J.; Fan, J.; Chen, S.; Liu, L.; Sun, H. and Pang, K. $\frac{v_L}{v_I+v_L}$ [d]	Fractional contribution of liver to intestinal–liver removal	0.540	0.907
		0.430[e]	0.829[e]

[a] Equations from Sun and Pang.[52]
[b] Based on definition of Ref. 21.
[c] Calculated based on equations from Pang and Chow[85]: $\frac{v_I}{v_I+v_L} = \frac{f_Q Q_I(1-F_I)}{f_Q Q_I(1-F_I) + E_L\langle Q_I[f_Q F_I + (1-f_Q)] + Q_{HA}\rangle}$.

[d] Calculated based on equations from Pang and Chow[85]: $\frac{v_L}{v_I+v_L} = \frac{E_L\langle Q_I[f_Q F_I + (1-f_Q)] + Q_{HA}\rangle}{f_Q Q_I(1-F_I) + E_L\langle Q_I[f_Q F_I + (1-f_Q)] + Q_{HA}\rangle}$.

[e] F_I and F_L values, based on equations from Sun and Pang,[52] for method 2.

$$\frac{v_L}{v_I + v_L} = \frac{E_L\langle Q_I[f_Q F_I + (1 - f_Q)] + Q_{HA}\rangle}{f_Q Q_I(1 - F_I) + E_L\langle Q_I[f_Q F_I + (1 - f_Q)] + Q_{HA}\rangle} \quad (17)$$

Here, v_I and v_L define the rates of intestinal and liver secretion/metabolism, respectively, in forming the metabolites; Q_{HA} defines flow rate of hepatic artery; E_L or $(1-F_L)$ denotes the extraction ratio of the liver, where $f_Q = 0.1$ for the SFM and 1 for the TM.

With these equations, the first-pass effect by the intestine and liver could be estimated. For TM, the %contribution for the intestine and liver for PO and IV dosing are expected to be identical, and the %contribution for PO is the same for both TM and SFM, since the entire dose needs to traverse the enterocyte region. However, for SFM, the %intestinal contribution for IV dosing reflects the influence of shunting away from the enterocytes. This results in a greater %liver contribution. Consistent with this line of reasoning, fitted results for M show that 46% of the MG formed originates from the intestine and 53% of MG formed originates from the liver in first-pass metabolism with PO dosing for TM. The same ratio, 46%:53%, should apply for PO dosing of M according to the SFM. However, for IV dosing, the %contribution by the intestine and liver to M glucuronidation are 9.3% and 91%, respectively, according to the SFM.

4.05.3.4.2 Case study 2: SFM to detect lack of codeine demethylation

The above modeling strategy for analyzing intestinal versus liver metabolic activity was also applied to examine the demethylation activity toward codeine in the rat in vivo.[64] The blood, urine, and bile data of codeine (C), M, and MG after PO and IV dosing of codeine was examined under first-order conditions (Fig. 7). However, in this case, both the TM and SFM predicted the drug and metabolite data equally well (Fig. 8). There was little change in the ratio of urinary/bile ratio of M or MG after IV versus PO administration (Table 4). More importantly, the $\%\frac{v_I}{v_I + v_L}$ was low and F_I^C was high for both TM and SFM, and the values were virtually identical (Table 5). This suggests that there is little intestinal demethylation of codeine. By contrast, the $\%\frac{v_L}{v_I + v_L}$ was almost 100%. The ratio of the liver/intestinal intrinsic clearance was about 10-fold, and is consistent with literature data,[64] showing that liver activity greatly exceeds that of the intestine. PBPK modeling again provides detailed and meaningful information on first-pass drug metabolism of codeine.

4.05.4 Other Considerations

4.05.4.1 Intestine Segmental Heterogeneity

Further to the SFM, both the TM and SFM have been extended to describe segmental distributions of transporters and enzymes.[32,93] Much heterogeneity in transporter and enzyme among intestinal segments has been noted (see Refs. [23,34,94–97]). Inclusion of

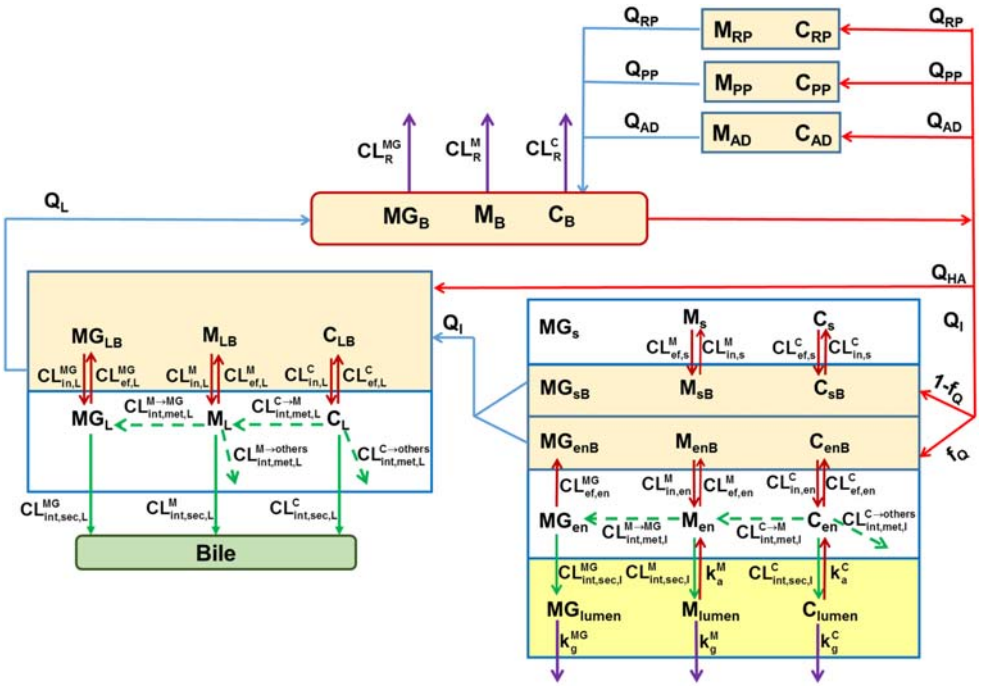

Fig. 7 The TM-nested PBPK (A) and SFM-nested PBPK (B) models were used to describe the pharmacokinetics of codeine (C), which is metabolized to M and MG in the rat (see Noh et al.[64]). The parameters are similar to Fig. 5. Obtained from Noh, K.; Chen, S.; Yang, Q. J. and Pang, K. S. Physiologically Based Pharmacokinetic Modeling Revealed Minimal Codeine Intestinal Metabolism in First-Pass Removal in Rats. *Biopharm. Drug. Dispos.* **2016**, 38(1), 50–74, with permission.

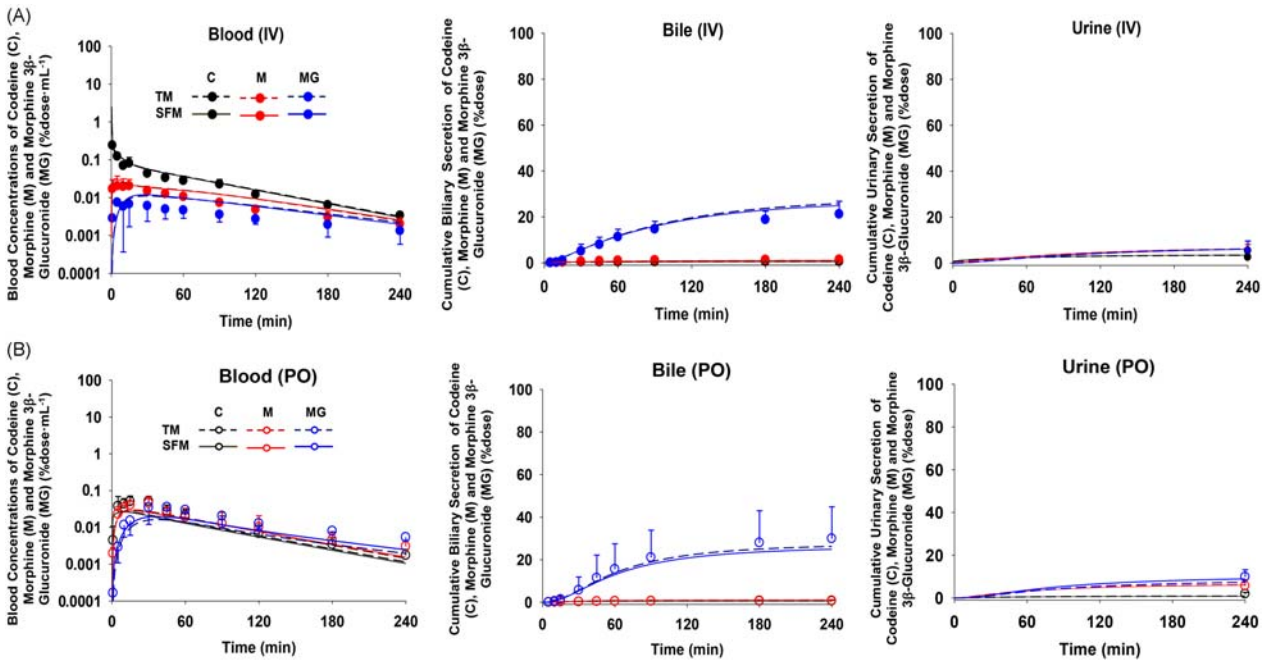

Fig. 8 Observed and fitted blood concentration–time profiles of codeine (C), M and MG and cumulative amounts of C, M, and MG in bile and urine following intravenous, IV (A) intraduodenal or oral (B) administration of C. The parameters are similar to **Fig. 5**. Obtained from Noh, K.; Chen, S.; Yang, Q. J. and Pang, K. S. Physiologically Based Pharmacokinetic Modeling Revealed Minimal Codeine Intestinal Metabolism in First-Pass Removal in Rats. *Biopharm. Drug. Dispos.* **2016**, 38(1), 50–74, with permission.

Table 4 Comparison of the predicted urine/bile ratio of M and MG after C dosing by TM-PBPK and SFM-PBPK models after intraduodenal (or PO) and IV administration of codeine[64]

	Ratio of M in urine/bile						*Ratio of MG in urine/bile*

SFM-PBPK	6.06	6.20	5.98	6.18	1.0	1.0	0.36	0.39	0.24	0.26	1.5	1.5

[a]Values are mean ± SD.

transporters and enzymes among different segments has been shown in recent modeling approaches.[98,99] The heterogeneous distribution of P450 (more proximal to duodenum) and P-gp (distal in ileum) was shown to reduce the intestinal availability of drugs,[100] and alter parent drug and metabolite profiles, especially when there is enterohepatic circulation, as shown for glucuronides.[101]

4.05.4.2 Liver Enzyme and Transporter Zonation

At least three zonal regions exist[102] and enzymes and transporters are not distributed evenly among the zones.[24,32] Enzyme metabolic zonation has long existed in terms of intermediary metabolism such as gluconeogenesis (periportal) and glycolysis (perivenous).[103] Zonal, metabolic zonation is the consequence of the gradients of oxygenation and hormone concentrations.[102] Liver metabolic zonation was revealed by techniques such as retrograde versus prograde perfusion in liver perfusion studies on P450 (Cyp1a2)[104,105] and UGT-mediated reactions (UGT1a toward *p*-nitrophenol[106]; or glucuronidation activity toward harmol[107] in the perivenous zone. Others showed the presence of enzyme heterogeneity with microlight guides for detection of loss of fluorescence of parent drug, or appearance of fluorescent metabolites, placed in periportal versus perivenous regions of the liver[108] or in microdissected tissue or zonally isolated hepatocytes.[105,109–111]

The same comment goes for the localization of transporters in the liver or intestine; some of the rat transporters such as Mrp3,[112] Oct1[113,] and Oatp4[114] are more enriched in perivenous region although many other transporters such as Oatp1a1, Oatp1a4, P-gp[115,116], and Mrp2[105] are found to be evenly distributed. Some laboratories, including our own, have examined the impact of

[e]Calculated based on equation from Pang and Chow[85]: $\frac{v_I}{v_I + v_L} = \frac{f_0 Q_I (1-F_I)}{f_0 Q_I (1-F_I) + E_L \langle Q_I [f_0 F_I + (1-f_0)] + Q_{HA} \rangle}$.

[f]Calculated based on equation from Pang and Chow[85]: $\frac{v_L}{v_I + v_L} = \frac{E_L \langle Q_I [f_0 F_I + (1-f_0)] + Q_{HA} \rangle}{f_0 Q_I (1-F_I) + E_L \langle Q_I [f_0 F_I + (1-f_0)] + Q_{HA} \rangle}$.

[g]F_I and F_L values, based on equations from Sun and Pang,[52] for method 2.

zonal distribution of enzymes and transporters on parent drug and metabolite removal.[104,107,116,117] We have identified that the coupling of formation and metabolic enzymes for the primary metabolite has led to the formation of gentisamide 5-glucuronide after formation of gentisamide from salicylamide, whereas gentisamide forms mainly the 5-sulfate conjugate, a more anterior distributed enzyme.[27,28]

4.05.4.3 Futile Cycling Kinetics

In addition to enzymes, transporters, flow, and binding, hepatic drug clearance is also influenced by futile cycling, namely the interconversion between drug and metabolite. The reaction is particularly prevalent for sulfate and glucuronide conjugates that can undergo deconjugation to form the parent drug again, notably, between estrone and estrone sulfate,[118] as well as estradiol-17β-glucuronide and estradiol-3-sulfate-17β-glucuronide[119] found in the rat liver. These reactions exist between prednisone/prednisolone and their methyl counterparts.[120–122] The presence of interconversion will increase the mean residence times of drug and metabolite in the organ,[120] and the species undergoing interconversion will display parallel decay profiles. However, the presence of uptake sinusoidal transporters or canalicular transporters will further modulate the profiles.[118,119]

In examining the interconversion between estradiol-17β-glucuronide and estradiol-3-sulfate-17β-glucuronide in the rat liver, Sun and colleagues[119] solved for the AUC for the precursor drug (P) and formed metabolite, mi, and have described terms to denote futile cycling. The effective coefficient for metabolite formation, ef''_m, considers the reformation intrinsic clearance of metabolite to the precursor drug, as well as the alternative metabolic and secretory intrinsic clearances of metabolite, $CL_{int,met,L}^{mi\rightarrow other}$ and $CL_{int,sec,L}^{mi}$, respectively.

$$ef''_m = \frac{CL_{int,sec,L}^{mi} + CL_{int,met,L}^{mi\rightarrow others}}{CL_{int,sec,L}^{mi} + CL_{int,met,L}^{mi\rightarrow P} + CL_{int,met,L}^{mi\rightarrow others}} \tag{18}$$

Conversely, the effective recycling coefficient, ef'_m, is

$$ef'_m = \frac{CL_{int,sec,L}^{P} + CL_{int,met,L}^{P\rightarrow others}}{CL_{int,sec,L}^{P} + CL_{int,met,L}^{P\rightarrow mi} + CL_{int,met,L}^{P\rightarrow others}} \tag{19}$$

The net metabolite formation intrinsic clearance of the precursor ef''_m will be reduced by the factor

$$\left(1 - ef''_m\right) \quad \text{or} \quad \frac{CL_{int,met,L}^{mi\rightarrow P}}{CL_{int,sec,L}^{mi} + CL_{int,met,L}^{mi\rightarrow P} + CL_{int,met,L}^{mi\rightarrow others}} \tag{20}$$

4.05.4.4 Membrane Barrier for Metabolite

Most formed metabolites are more polar than their precursors and therefore may have diffusional barrier when entering the organs. One of the drawbacks of compartmental modeling is the failure to consider transmembrane barriers that bar the entry of polar metabolites into the cell, but entrap the formed polar metabolite formed within the cell. For this reason, the extraction ratio and therefore the availability of the formed metabolite differ from that of the preformed species.[14,23,24] In this case, the extraction ratio of the formed metabolite is greater than that of the preformed metabolite, E^{pmi}, as the preformed metabolite cannot enter into the eliminating organ.[26,80,123,124] However, the validity of this assumption is rarely tested. Only when the metabolite is formed rapidly (high formation intrinsic clearance) and displays a high permeability, would the extraction ratio and availability of preformed and formed metabolite are equivalent.[14,125]

4.05.5 Metabolite Data in Bioequivalence

Our understanding of metabolite kinetics is key to drug development, not only for safety issues but also for drug regulation as to whether it is plausible to use metabolite data in bioequivalence study.[126–129] There are several reasons to use metabolite data for bioequivalence, such as (1) the precursor is inactive prodrug; (2) precursor concentrations are too low to be detected; (3) precursor is rapidly metabolized to form an active or toxic compound; (4) both precursor and its formed metabolite are pharmacologically active and metabolite is present in higher concentrations.[126] Previously, researchers investigated the role of metabolite in bioequivalence study by performing modeling and simulations with compartmental modeling,[128–130] and conducted sensitivity analysis of bioequivalence parameter (AUC, C_{max}) of parent and metabolites with two different formulations (test and reference).[131] Based on simulated results, both parent and metabolite were found equally useful when AUC was used as the bioequivalence measure, and, if the absorption phases of test and reference products are similar, metabolite data may further be used for the determination of bioequivalence.[131] However, we view that metabolite kinetics is highly dependent on the tissue location of the metabolite formed, and how it is sequentially metabolized. For this reason, we consider that the AUC of the formed metabolite ($AUC^{mi,P}$) is not useful to define bioavailability measurements. In the case of metabolites undergoing sequential first-pass metabolism, the measured metabolite concentrations from systemic circulation cannot represent the actual metabolite

concentrations since part of metabolites is immediately eliminated within the metabolite-forming organs.[22] If route-dependent intestinal metabolism occurs, as projected by the SFM, it is further inappropriate to compare metabolite concentrations resulted from oral dosing forms to those from intravenous administration. Additionally, multiple factors, including drug physiochemical properties, enzyme zonal distribution, and heterogeneity, are important but these are neglected when analyzing bioequivalence data arising from different formulations when based on compartmental modeling.

4.05.6 Summary Remarks

Metabolite testing is currently gaining more and more attention in drug development. In this communication, we have discussed the use of PBPK modeling as a useful tool for appraising parent drug and metabolite kinetics simultaneously. It is able to consider the physiochemical properties of precursor and metabolite as well as incorporate transporter-mediated process, sequential metabolism, drug binding, enzyme heterogeneity and segregated flow pattern on small intestine into one model. The SFM, in particular, is superior over the TM in description of route-dependent metabolism. Two case studies are given to appreciate the advantages of SFM over TM and compartmental modeling. Furthermore, PBPK model can integrate pharmacokinetic data with pharmacodynamic changes and toxicity data. Lastly, we highlighted several important considerations, such as enzyme/transporter interplay, enzyme zonal distribution, protein binding, and sequential first-pass metabolism in metabolite kinetics analysis. We also discussed that the use of metabolite in bioequivalence study is questionable, given the fact that the kinetics of formed metabolite is dependent on where and how it forms. Undoubtedly, PBPK modeling is an advanced and powerful approach that can be used to decipher metabolite kinetics in drug development.

4.06.1 Introduction

For a drug to be effective, it must become available at the target site. However, target sites are often inaccessible and it is necessary to dose from a convenient location. The drug must therefore be absorbed from a dosing site, often from the gastrointestinal tract since many drugs are orally administered. Subsequently, the drug must distribute throughout the body until some drug reaches the target site. However, because drugs are xenobiotics, the body will attempt to protect itself by eliminating the drug, either by directly excreting it as the parent drug, usually in the urine or the bile, or by metabolizing it to something generally easier to excrete. The combination of these processes is given the acronym ADME and is regarded as drug disposition. Pharmaceutical scientists attempt to optimize each of these processes to ensure that drugs reach their targets safely and efficaciously, yet with few off-target effects, and can be dosed on a convenient schedule. This is affected by physiological factors and chemical properties of drugs. Pharmaceutical scientists have invested a lot of research into understanding these properties in order to predict disposition prior to developing a drug and testing it in humans.

ADME can be assessed with plasma concentrations over time. The area under this curve (AUC) represents drug exposure, which is generally correlated with therapeutic response. However, for some drugs, antibiotics, for example, the maximum concentration (C_{max}) may better predict therapeutic response. In other cases, a relatively immediate response is required, when using sleep-inducing hypnotics, for instance. Drugs of this nature must enter the systemic circulation and be able to access their target quickly, which means that the time to maximum concentration (t_{max}) must be short and that the drug must have properties that allow rapid distribution to the target tissue (e.g., the brain).

The primary goal of pharmacokinetics in therapeutics is to select an appropriate dose. AUC is the clinical output from which clearance, bioavailability, and volume of distribution, the primary pharmacokinetic parameters, can be calculated. Clearance and bioavailability contribute to dose and regimen selection. When conditions are nonnormal, pharmaceutical companies, physicians, or pharmacists must know how to adjust the dose. Changes in clearance and bioavailability are reflected in changes in AUC. By understanding how different factors can impact dispositional factors, we can deduce the mechanism of the observed exposure change and appropriately amend the treatment regimen.

Humans all have unique physiology, which is why some people can drink milk, eat wheat, or even smoke cigarettes for decades without a problem, while milk consumption can cause intestinal distress, wheat consumption can affect nutrient absorption, and cigarette smoke can lead to cancer in other people. Drugs also exhibit marked variability. Consider the chemotherapeutic drug cyclophosphamide, which is used to treat certain forms of leukemia: Some people experience extreme nausea, while others tolerate the treatment with no disturbance in their daily life. The dispositional profile of a drug also varies between people. The same dose can deliver poor systemic concentrations and lack of efficacy in some patients but overdose a second patient and leave them susceptible to toxicity. Pharmaceutical scientists and regulatory agencies recognize factors that increase this risk in variability and spend much time and money understanding the important contributing dispositional factors.

Much of the disposition is regulated by the active impact of metabolizing enzymes and drug transporters. Other factors such as blood flow, membrane permeability, pH, protein binding, and endogenous substances all play a significant role as well. There is marked variation in the expression and activity of metabolizing enzymes and drug transporters in healthy individuals. The impact of this variation is studied in a field called pharmacogenomics. In this article, we will discuss how pharmacists and physicians can garner this knowledge to predict how a drug will respond in an individual with a specific genetic profile. Even when a patient has a normal wild-type genetic variation of metabolizing enzymes and transporters, other drugs, supplements, and even food can alter the activity of metabolizing enzymes and transporters. Eating food also results in transient physiological changes that may impact how a drug is absorbed and disposed compared with when a drug is taken without food.

In renal disease, the ability to eliminate and clear drugs is directly impacted by decreased renal function. However, chronic kidney disease (CKD) can also impact drug disposition by affecting the concentrations of endogenous compounds, which can interact with drugs, or affecting physiological aspects like blood flow or protein binding. In celiac disease, structural and physiological changes and decreased CYP3A expression[1] in patients may potentially alter drug absorption.[2] Other diseases including, but certainly not limited to, diabetes, cystic fibrosis, cancer, and cardiac disease can significantly impact a drug's disposition.

Understanding how physiological systems change with disease and how interindividual differences, either biological or due to external factors such as copharmacy, will impact drug disposition helps pharmaceutical companies develop safer, more efficacious dosing regimens with a clearer understanding of necessary alterations in dosing. In fact, pharmacokinetics was once a leading cause of drug failure during development, but is no longer a significant concern due to our improved understanding of drug disposition.[3,4]

During development, it is advantageous to harness drug disposition predictions using preclinical models, including in silico, in vitro, or in vivo animal studies. Information can be gathered from predictive models more quickly and cheaply than from humans and mitigates unnecessary risk early in development. While evaluating some aspects of drug disposition, including the contribution of metabolizing enzymes or drug transporters, a negative result may obviate the need for additional studies in humans.

4.06.2 Current Issues and Challenges in Pharmacokinetics

Drugs can be administered through a myriad of routes. These include topical, optical, or oral administration or injections (including intramuscular, subcutaneous, or intravenous). Intravenously administered drugs are directly administered to the blood, and

therefore, the entire dose is available for distribution in the body. However, drugs administered by any other route must pass some barriers before entering the blood, in the process called absorption. Naturally, a percentage of the drug cannot pass through the barriers and is lost between the site of absorption and the blood. This loss depends on both the barrier that must be crossed and properties of the drug.

Some membranes are leakier than others, while some are perfused by higher blood flow. Other differences include higher or lower fat content, pH differences, and differences in the expression of transporters and metabolizing enzymes. This impacts how a drug can be administered. For instance, insulin is generally administered subcutaneously, but can also be inhaled because of the relatively high permeability of the alveolar epithelium.[5] Insulin, however, cannot be given orally due to degradation by proteolytic enzymes and an inability to be transported in and through the gastrointestinal tract.[6]

Metabolism dominated the understanding of drug disposition for a very long time. Eventually, scientists began to realize that drug transporters, initially called phase III metabolism, had an equally important role in drug absorption, distribution, and elimination. Hundreds of drug transporters have been identified in humans,[7] but currently, at least seven are considered clinically important in regulating drug disposition. The FDA 2012 guidance on drug interactions[8] recommends determining if a drug is a substrate, inhibitor, or inducer of P-gp and BCRP for all drugs, OATP1B1 and OATP1B3 if a drug is hepatically eliminated, and OAT1, OAT3, and OCT2 when a drug is renally eliminated. However, other transporters such as MATEs are considered clinically relevant by the International Transporter Consortium (ITC), who recommends prospectively studying MATE interactions. The ITC recommends that MRP2 and BSEP be evaluated in retrospective studies depending on clinical and preclinical observations. Other transporters such as OATP2B1, ENTs, and PEPTs are also considered clinically relevant.[7,9] Other drugs, high-fat food or components in food, endogenous substrates, disease, and genetics can alter the function of these and other transporters. Since transporters often highly regulate drug exposure in the systemic circulation and tissues as well as play a role in drug elimination, when their function is altered, the safety and efficacy of a drug can be compromised. We will discuss when transport is relevant to the clinical outcome of a drug, as well as many cases when it is not.

4.06.2.1 Predicting Oral Absorption and Availability

Most drugs are preferably administered by the oral route to increase patient compliance and facilitate delivery and packaging. Before a drug can enter the systemic circulation after oral dosing, it must (a) be absorbed in the gut, where it may be affected by apical uptake and efflux transporters, (b) pass through gut epithelial cells (enterocytes) where it may be metabolized, and then (c) escape from metabolism or biliary elimination in hepatocytes. The combination of these processes determines the bioavailability of the drug or the fraction of the dose that enters systemic circulation.

In humans, bioavailability (F) can be readily measured by comparing exposure from intravenous and oral dosage forms: $F = AUC_{oral}/AUC_{iv}$, correcting for dose if necessary. However, it is very difficult to predict the fraction of the bioavailability due to absorption (F_A) and thus the extent of absorption. Hepatic bioavailability (F_H) can be estimated when an intravenous dose is given and total and renal clearances are measured ($F_H = 1 - CL_H/Q_H$, where hepatic blood clearance (CL_H) equals total blood clearance (CL) minus renal blood clearance (CL_R) and Q_H is the estimate of hepatic blood flow rate). However, then, determining the fraction of the dose that is absorbed requires an estimate of the fraction of the dose that escapes gut metabolism since $F = F_A \times F_G \times F_H$. F_G, the gut bioavailability, requires invasive methods such as sampling from the portal vein. The rate and extent of absorption depend upon the physicochemical properties of the active component in a drug product, the formulation and release of the drug from the product, and physiological traits of the gastrointestinal system.

Additionally, microbiotic metabolism and luminal degradation of drugs can reduce the proportion of the parent drug that is available for absorption. Even after initial absorption, a drug can be effluxed by transporters in the enterocytes back into the gut lumen, effectively reducing absorption.

Drug absorption can be mediated through passive or active permeation across (primarily) enterocytes. Passively absorbed compounds can be transcellularly diffused (through the cell) or paracellularly diffused (between the cells). Active permeation requires the intercession of drug transporters, which can move a drug across either side of a polarized cell membrane. Active transporters are responsible for either bringing the drug into a cell or ejecting it from a cell.

4.06.2.1.1 Physicochemical determinants of absorption

It is generally presumed that lipophilicity correlates with cell permeability, within a reasonable boundary and when considering structurally similar compounds. (Lipophilicity is derived from the Greek "fat-loving." Highly lipophilic molecules are often nonpolar and prefer to partition into nonpolar versus polar phases.) In 1997, Lipinski et al.[10] developed a set of rules that aided in understanding the properties of drugs that are readily absorbed. Poor absorption is more likely when a drug has greater than 5 hydrogen bond donors (OH and NH), a molecular weight >500 Da, cLogPa >5, or greater than 10 hydrogen bond acceptors (oxygens and nitrogens). However, this rule does not apply when transporters mediate drug absorption.

4.06.2.1.1.1 Passive absorption

Passive absorption generally refers to permeation of compounds that have properties that allow them to cross through a cell (transcellular). Drugs can only pass transcellularly if they are small and relatively lipophilic. Compounds that instead pass between cells (paracellular permeation) may be small and hydrophilic.

4.06.2.1.1.2 Active absorption

Most compounds are known or presumed to be substrates of active transporters, even if they can also be passively absorbed. However, highly permeable, highly soluble compounds are not dependent upon active transporters for their absorption even if they are substrates and will not be impacted by disruptions to their function. This will be discussed in great detail in section "Biopharmaceutics Drug Disposition Classification System."

4.06.2.1.2 In vitro predictions

The Biopharmaceutics Classification System (BCS), as we will discuss later, opened the door to predicting absorption with surrogate in vitro systems, such as Caco-2 and Madin–Darby canine kidney (MDCK). The Biopharmaceutics Drug Disposition Classification System (BDDCS) allowed us to do the same with artificial membranes such as parallel artificial membrane permeability assay (PAMPA). Compounds with a high in vitro permeability rate are expected to be well absorbed.

Caco-2, an immortal cell line derived from colorectal adenocarcinoma cells, comes from human enterocytes. They confer the advantage of being human in nature with a microvillus surface. However, these cells take 2–3 weeks to culture and even then do not fully express transporters or metabolizing enzymes. Additionally, tight junctions predominate and resistance is high compared with in vivo morphology.[11] This can lead to significant underprediction of permeability rate and absorption. The in vitro lack of expression of highly expressed transporters in humans can greatly underpredict the extent of absorption.[12]

MDCK cells are immortal cells that come from the kidney of dogs. These cells have a shorter culture time than Caco-2 and have lower resistance than Caco-2 cells, a condition more similar to the human gut. However, these cells are not human in nature and, similar to Caco-2, they poorly express CYP3A.

PAMPA is an artificial membrane that does not express transporters and has no cells to create tight junctions or cellular pores. It is representative of passive permeability through a lipid bilayer.

All in vitro models lack the flow of gut contents and blood on either side of enterocytes. Portal blood flow constantly removes drugs from the basolateral membrane of enterocytes, resulting in "sink conditions," a downhill concentration gradient that facilitates drug absorption in vivo. The fluidity of gut contents means that drugs in the gut lumen will be exposed to the different morphologies and expressions in different segments of the gut in vivo that are not simulated in in vitro cell studies.

While highly permeable compounds are almost all extensively absorbed, in vitro permeability rate predictions often underpredict absorption. This is because many compounds are actively absorbed, but have low passive permeability. Predicting extent of absorption is improved by including active drug transport. Larregieu and Benet[12] showed that when transporter expression is decreased more than 10-fold in Caco-2 cells compared with humans, absorption of compounds that are substrates of highly expressed transporters such as PEPT1, amino acid transporters, and nucleoside transporters is poorly predicted.

Permeability rate as a surrogate for absorption will be extensively discussed in section "Biopharmaceutics Classification System."

4.06.2.2 Predicting Distribution

Drug distribution is determined by cardiac output, tissue blood flow and volume, and capillary permeability, as well as tissue permeability and drug transporters. Following drug dosing, well-perfused tissues such as the liver and kidney initially receive a high drug concentration. This initial distribution phase is apparent when considering the shape of a plasma concentration–time profile. A secondary distribution phase, characterized by slowly decreasing plasma concentrations, reflects drug distribution to the more poorly perfused tissues. Additionally, protein-bound drugs cannot traverse cellular membranes, and therefore, protein binding has an impact on drug distribution. In the plasma, drugs primarily bind to either albumin, if the drug is acidic, or α-1-acid glycoprotein, if the drug is basic. Protein binding can be modified by disease and drug–drug interactions. For instance, patients with cystic fibrosis often have hypoalbuminemia.[13] However, Benet and Hoener[14] have shown that changes in protein binding are only important for high-clearance, narrow therapeutic index drugs that are dosed intravenously, for example, lidocaine.

4.06.2.2.1 Volume of distribution

Distribution can be characterized by the theoretical pharmacokinetic term, the apparent volume of distribution. This term characterizes the apparent space in the body into which a drug distributes. That is, systemic concentration multiplied by the apparent volume of distribution is equal to the amount of drugs in the body. A large volume of distribution indicates that a compound is predominantly located outside of the systemic fluids flowing to the organs of elimination. Volume of distribution depends on the extent of drug binding to receptor sites, plasma proteins, and tissues, as well as the lipophilicity of a drug. Volume of distribution measures can be determined from plasma concentration–time curves. While the volume of distribution can be calculated a few ways, the volume at steady state or V_{ss} is the most useful measure of the apparent space available in the body into which drugs may distribute, since it is not affected by elimination. V_{ss} measures can be determined from plasma concentration–time curves using the following equation:

$$V_{ss} = \mathrm{CL} \times \frac{\mathrm{AUMC}}{\mathrm{AUC}}$$

Here, AUMC is the area under the moment curve or the area under the curve of the product of concentration and time versus time.

Additionally, physiologically based PK models such as GastroPlus™ and Simcyp provide estimates of V. Age, percent of body fat, sex, and disease can all affect the volume of distribution. Accurately predicting volume of distribution is vital in predicting C_{max} and can be important in defining clinically relevant half-life ($t_{1/2}$) measures. Volume of distribution is also predicted in animal models, which include physiological features like blood flow and organ topology. The volume of distribution can be estimated by collecting plasma concentrations over time and using allometric scaling approaches to predict the volume of distribution in humans.

4.06.2.3 Predicting Metabolism and Elimination

Most drugs are eliminated by metabolism, renal elimination of unchanged drug, or biliary elimination of unchanged drug. To ensure safety, pharmacokinetic studies are conducted with mass balance or collection of the entirety of a dose in eliminated equivalents (parent drug or metabolites). Ideally, the entirety of the dose is eliminated in either the urine or the bile. This provides evidence that the compound is not sequestered and accumulating in a peripheral tissue, potentially resulting in unanticipated toxicity, and lends support to the validity of the calculated pharmacokinetic parameters. Incomplete recovery sometimes indicates that a drug is eliminated by another organ (e.g., the lungs). However, mass balance may not be as simple as it sounds. Realistically, the entirety of the dose often cannot be collected. Some drugs have very long half-lives, which makes collections in a clinical setting unrealistically arduous.

Many metabolites and some parent drugs are eliminated in the bile, which is a difficult fluid to accurately obtain and analyze. The bile drains into the lumen of the intestine and its contents are eventually eliminated as part of the feces. Fecal samples could be collected to estimate the fraction of the dose that is eliminated in the bile. However, the feces also contain orally administered material that was never absorbed from the lumen of the intestine. For this reason, it is impossible to differentiate between parent drug that is unabsorbed from an oral administration and parent drug that is eliminated in the bile in fecal samples. This means that, unless a drug was administered non-orally so that all of the drug in the feces must therefore come from biliary excretion, direct bile collection approaches such as collection from T-tubes or nasobiliary tubes are necessary to account for the elimination of unchanged drug in the bile. However, such approaches are rarely conducted and when done are predominantly done during surgeries. The patients often have hepatobiliary disease, so the donor samples do not necessarily represent healthy conditions. Other methods such as the bile string or duodenal collection studies are slightly less invasive and can be conducted with healthy volunteers. Duodenal collection studies are difficult to conduct, however, and are still invasive.

It is much easier to determine the extent of urinary elimination of unchanged drug or the extent of metabolism. Urine samples are almost always collected during pharmacokinetic studies to account for mass balance, and the parent and metabolites can be readily quantified. Parent drug collected in the urine represents absorbed drug only since the drug can only reach the kidneys after entering the systemic circulation. Metabolites can be quantified in the urine and may also be collected in feces. If the drug was not degraded or metabolized by bacteria in the gut, we can assume that the drug was absorbed since most metabolism occurs postabsorption. Degradation and presystemic metabolism can be confirmed with stability studies to be described in section "**Determining permeability in humans**."

Prior to conducting trials in humans, pharmaceutical scientists try to predict what the major route of drug elimination will be. In silico, in vitro, and in vivo models of drug elimination have been developed to predict elimination routes and their potential liabilities. For instance, biliarily eliminated drugs may be subject to enterohepatic recycling, which exposes the drug to the intestine and liver multiple times and may result in several peaks. Metabolism may produce pharmacologically active or toxic metabolites that can alter pharmacodynamics or need to be evaluated for safety. A developer may want to avoid renal elimination if the drug is likely to be dosed to patients with failing kidneys. Alternatively, an eliminating organ may be the desired site of action and a developer may attempt to target that route.

Recently, there have been many efforts to associate the chemical properties of drugs with their major elimination routes. Certain trends have been noted for a long time, with properties such as lipophilicity, molecular weight, protein binding, and ionization state proposed as harbingers of elimination route. However, these relationships are sometimes considered too simple or were applied to small data sets of compounds that are often structurally similar. With the advent of "big-data" methodologies, more complicated and/or thorough analyses are possible.

4.06.2.3.1 Characteristics of metabolism

Most drugs are designed to be sufficiently lipophilic to cross biological membranes during absorption or distribution and to achieve biochemical potency by encouraging protein binding to a target site through hydrophobic interactions. Coincidentally, most drugs are metabolized, and indeed, lipophilicity is historically considered a prerequisite for drug metabolism.

There are at least a couple of reasons why lipophilicity and metabolism are associated with each other. The first is that relatively lipophilic drugs may be able to be passively reabsorbed across membrane barriers surrounding excretory fluids including the aqueous bile and urine.[15] Metabolic enzymes generally convert a lipophilic substance into a more hydrophilic substance, which aids in accumulation in and thus elimination from the aqueous bile or urine. Secondly, lipophilicity is correlated with protein binding[15] and may aid in binding to enzymatic proteins through hydrophobic interactions,[15] which will convert a drug to a more hydrophilic molecule.

Many very lipophilic molecules are indeed metabolized, and in fact, we are unaware of any marketed poorly metabolized drugs with a measured or calculated LogP > 5.[16] As always, it is important to note that these are trends and not rules. Despite the common assumption that metabolized compounds are lipophilic and vice versa, metabolized compounds cover a vast physicochemical

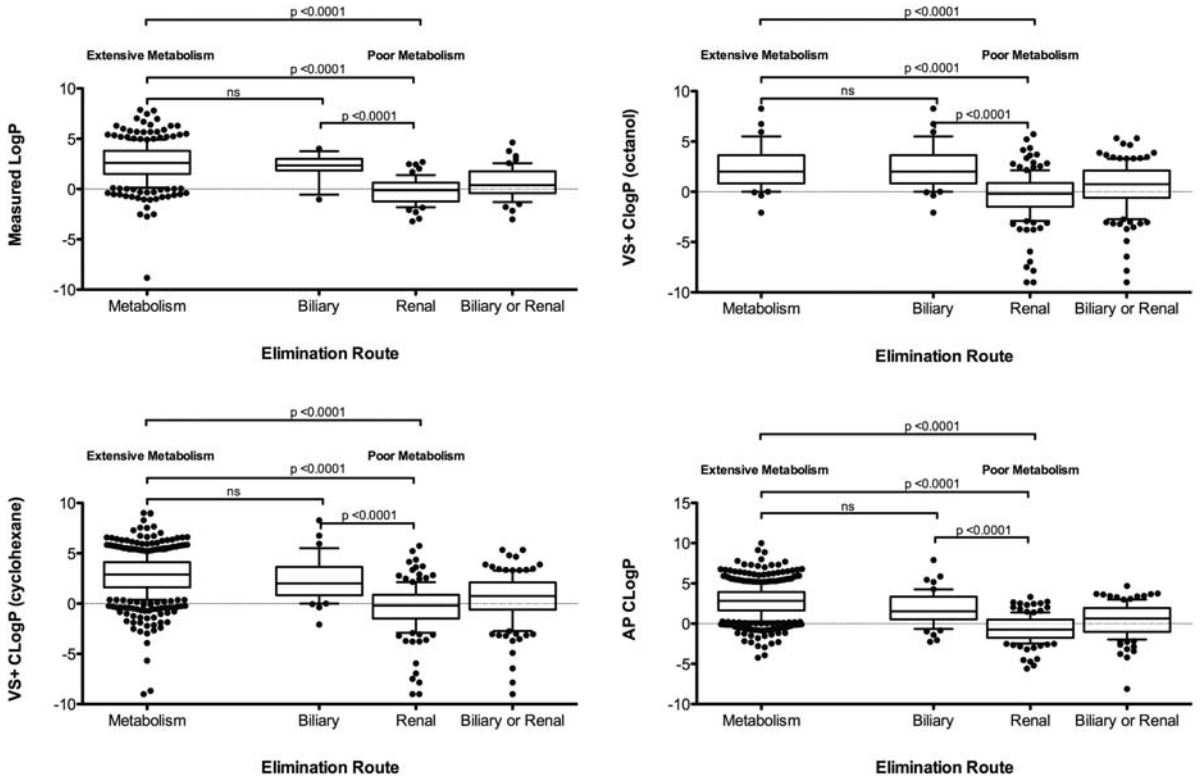

Fig. 1 Measured and calculated partition coefficients segregated by major route of elimination. Reprinted with permission from Hosey, C. M.; Benet, L. Z. Predicting the Extent of Metabolism Using In Vitro Permeability Rate Measurements and In Silico Permeability Rate Predictions. *Mol. Pharm.* **2015**, *12*, 1456–1466. Copyright (2015) American Chemical Society.

space, and not all lipophilic compounds are metabolized. In particular, drugs that are eliminated unchanged in the bile also exhibit relatively high LogP values, with no significant difference in this parameter from metabolized compounds as determined by the *t*-test (Fig. 1) and no rank-ordered differentiability as indicated by receiver operating characteristic curves. (The receiver operating characteristic is a plot that illustrates how well a continuous feature (e.g., LogP) classifies a binary outcome (e.g., biliary vs. metabolic elimination.) When the area under the ROC curve is greater than 0.8, the continuous feature is expected to differentiate between the classes well.) Furthermore, a large proportion of metabolized drugs have a low LogP. This may be because drugs eliminated unchanged in the bile require uptake and efflux transporters in the hepatocyte and therefore must be sufficiently lipophilic to bind to these transporters. Alternatively, almost all compounds eliminated as unchanged drug in the urine have a low LogP and are poorly bound to proteins.

However, given the somewhat ambiguous predictability of LogP, it is necessary to predict which compounds will be metabolized by other methods. Metabolism can be assessed using in vitro, in vivo, or in silico methodologies.

4.06.2.3.2 In vitro predictions

The extent, rate, and mechanisms of metabolism are often initially evaluated in vitro. Ideally, human hepatic and enterocytic tissues can be utilized to evaluate metabolism. However, these merely serve as predictive tools and are fraught with errors.

Microsomes are a subcellular fraction containing the contents of the endoplasmic reticulum including CYPs and UGTs. CYP metabolism accounts for about 70% of the metabolism of extensively metabolized drugs of the top 200 drugs,[17] while UGT metabolism accounts for about 14% of the metabolism of the top 200 drugs prescribed in the United States.[18]

In vitro microsomal experiments can determine the rate of microsomal metabolism, called the intrinsic clearance (CLint), representing the capacity of metabolizing enzymes to eliminate a compound in the absence of other factors like blood flow, membrane permeability, protein binding, and competing elimination mechanisms.

Intrinsic clearance can be expected to correlate with clinical clearance in humans, particularly for drugs that are primarily metabolized by CYP enzymes in the liver. Prior to the recognition of the contribution of transporters to drug disposition, human clearance was estimated from intrinsic clearance in microsomes generally using the well-stirred model. However, in the late 1990s, Miyauchi et al. proposed an extended clearance concept to include the effect of transporters on hepatic clearance.[19]

Microsomes can provide a reliable estimate of metabolic kinetics (clearance). However, microsomes have been used to predict the extent of metabolism by measuring the percent of dosed drug that is unmetabolized after a set period of time. This may be an unreliable predictor of the extent of metabolism[20–22] since presumably most drugs will be metabolized if they are left to incubate in

the presence of a variety of enzymes without interference. As we will discuss in detail later, in vitro permeability rate can predict the extent of metabolism in humans.

Supersomes, expressing only one enzyme, may be used to predict the metabolic intrinsic clearance by a single enzyme and to identify metabolites formed by a specific enzyme.

A major concern of predicting the extent and/or rate of metabolism in vitro, perhaps especially in microsomes, is that metabolism is assessed in isolation of competing processes. In vivo, transport-limited clearance into the bile or passive or transport-limited clearance into the urine may prevail. However, microsomal incubations cannot tell a researcher what is the major route of elimination, and metabolic clearance does not necessarily relate to extent of metabolism. Isolated or sandwich-cultured hepatocytes are more complex tools that incorporate transporters and may be used to predict metabolic or hepatic clearance.

4.06.2.3.3 In vivo predictions

In vivo approaches confer the advantage of including factors such as blood flow, sequestration due to transport, and membrane permeability. In vivo approaches include humanized animals and allometric predictions. Humanized animals, like supersomes, can help assess the impact of a single enzyme or transporter.

Allometry applies scaling factors based on body size to pharmacokinetics across species. Simple allometry from a single species is commonly used early in drug development, requiring only clearance data from preclinical species. Modifications of simple allometry have been proposed to improve the predictability of these models.[23]

These predictions require sampling plasma concentrations over time in preclinical animal models and may incorporate other physiological parameters such as plasma protein binding and the blood to plasma ratio. They can be supplemented with physicochemical drug properties such as molecular weight or LogP.

The most obvious disadvantage to using preclinical animal models is physiological differences. While allometry attempts to correct for differences in body weight, protein binding, blood flow, etc., animals often have different patterns of metabolizing enzyme and transporter expression and substrate specificity. While pharmacokinetics are frequently similar between species, marked differences can be seen in a variety of substrates. Consider, for instance, digoxin or zidovudine. Digoxin is extensively metabolized in rats,[24] but is primarily eliminated as unchanged drug in humans.[25] Zidovudine is extensively metabolized in humans,[26] but is primarily eliminated unchanged in rats.[27]

4.06.2.3.4 In silico predictions

Several in silico methods predict aspects of metabolism, including understanding the affinity for a particular enzyme[28] and the site of metabolism on the molecule,[28] predicting metabolic clearance,[29] identifying metabolites,[30] and predicting metabolic stability.[31] Unfortunately, many of the published methods rely on proprietary descriptors or are derived from small or structurally similar data sets.[32] Since many compounds are metabolized by several enzymes and/or are sequentially metabolized, it is crucial to integrate many predictive models. Several reviews discuss the challenges and applications of in silico predictions of drug metabolism in depth and discuss available predictive software.[28,30,32]

Second to metabolism, renal elimination of unchanged drug is responsible for the elimination of most drugs.

4.06.2.3.4.1 Renal elimination of parent drug

Renal elimination of drugs is dependent upon three renal processes: glomerular filtration, renal secretion, and renal reabsorption. Glomerular filtration is a passive process where free (unbound) small-molecule compounds are drained from the blood in the afferent arteriole and collected in the filtrate. Large molecules, including drugs bound to proteins, cannot sieve through the glomerulus and they remain in circulation. While glomerular filtration rate = 120 mL min^{-1}, urine is only formed at 1 mL min^{-1}, so 119 mL of water is reabsorbed from the kidney tubules every minute. For this reason, many compounds, especially metabolized compounds, are passively reabsorbed from the filtrate as water is actively retained in the body. Several compounds are actively secreted into the filtrate directly from the blood via drug transporters expressed on the proximal tubule.

Renal clearance tends to decrease with increasing lipophilicity.[33] This is intuitive, since highly lipophilic compounds are often susceptible to reabsorption. Additionally, lipophilic compounds are more likely to be protein-bound.[15] Unsurprisingly, compounds that are primarily eliminated as unchanged drug in the urine are expected to be small and polar, having low protein binding. However, Hosey et al. demonstrated that while this holds true for orally dosed compounds, many non-orally dosed (generally intravenously administered) compounds could be renally eliminated even if the molecular weight is high. Alternatively, protein binding of compounds primarily eliminated in the urine was low for both orally and non-orally administered medications.[22] This is likely because all small molecules ($<10{,}000$ Da)[34] can be filtered through the glomerulus, but compounds bound to proteins are not. Therefore, highly protein-bound drugs must be eliminated by other routes and protein binding is a determinant of renal elimination.

While charge does not determine if renal elimination is the primary route of elimination,[22] it does trend with renal clearance. Anions and cations are primarily secreted, whereas neutral compounds are primarily reabsorbed. Additionally, renal clearance tends to decrease with increasing compound lipophilicity, while renal secretion increases with polar descriptors.[33]

Table 1 Molecular weight distribution of orally and non-orally administered drugs by major elimination route[22]

	Molecular weight (Da)			
Major elimination route	*> 380*	*< 380*	*> 475*	*< 475*
Oral administration				
Biliary	22	5	13	14
Renal	13	65	0	78
Metabolism	153	345	53	445
Non-oral administration				
Biliary	11	1	7	5
Renal	42	21	21	42
Metabolism	42	50	29	63

4.06.2.3.4.2 Biliary elimination of parent drug

Biliary elimination of unchanged drug is the third major route of parent drug elimination. Biliary elimination is an active process requiring both uptake transporters on the hepatic basolateral membrane facing blood in the portal vein and efflux transporters on the hepatic apical membrane facing the bile canaliculi.

Historically, it was hypothesized that high-molecular-weight (>500 Da) anions would preferentially be eliminated in the bile and that biliary excretion was selective for these properties. This was likely derived by considering the weight and molecular species of the primary endogenous substrates: bile salts. Millburn et al.[35] suggested that drugs with a molecular weight $<500–600$ g mol^{-1} were less susceptible to biliary elimination. More recently, Yang et al.[36] predicted that when anions have molecular weights >475 Da, 10% or more of the dose is likely to be eliminated in the bile. Hosey et al. demonstrated that drugs whose major route of elimination is unchanged drug in the bile were poorly permeable and had a high polarizability, which is highly correlated with molecular weight, and a low predicted metabolic stability.[16,22] That study also points out that high molecular weight is descriptive of biliarily eliminated drugs, but that high molecular weight does not qualify biliary elimination. In other words, almost all drugs that are predominantly eliminated as unchanged drug in the bile are heavy, but the primary route of elimination is not biliary excretion for the majority of high-molecular-weight drugs (**Table 1**).

Other properties associated with biliary elimination have been less clearly defined and in some cases have contesting associations between studies. Greater hydrogen bond interactions have been associated with increased biliary excretion.[36,37] Some studies indicate that biliarily eliminated compounds are primarily anions,[36,37] while some indicate that cations are also eliminated in the bile,[38] and yet, others suggest that ionization is not an important characteristic.[22] Greater dipole moments,[36,38] the presence of a carboxylic acid group,[36,38,39] and more rotatable bonds[37,39] have also been associated with increased biliary excretion. Lipophilicity has varying indications between studies, with some indicating that biliarily eliminated drugs are hydrophilic,[37,38] some indicating they are lipophilic[16,40] and others discussing both lipophilic and polar regions, and some studies finding no relationship between lipophilicity and extent of biliary elimination.[36,41] While the bile is a hydrophilic medium, compounds likely require a degree of lipophilicity to bind to and be transported by drug transporters such as P-gp. This may be especially true as the most widely accepted mechanism of P-gp transport relies on an initial partition into the membrane.[42] These relationships likely depend on how "major" biliary elimination was defined and which drugs were included in the study.

As we mentioned earlier, biliary elimination data are difficult to gather and quantify in humans. However, in vitro, in vivo, and in silico approaches may provide a reasonable quantitative or qualitative understanding of biliary elimination.

Perhaps the most widely accepted in vitro approach to predict biliary clearance is the use of sandwich-cultured hepatocytes, isolated from humans or rats, which maintain the polarity of cell membranes, a crucial condition to determine canalicular efflux. These hepatocytes are plated on a collagen platform and maintained in the presence of calcium. After several days, transporter expression is optimized for vectorial transport. After introducing the test drug, the tight junctions are ruptured by removal of calcium, and differences in accumulated intracellular concentrations can be measured.[43]

In vivo, one of the most common approaches to estimate the contribution of biliary elimination is with bile duct cannulation in an isolated perfused rat liver. Unfortunately, rats have a higher bile flow (relative to body weight),[44] greater efflux transporter expression,[45] and increased rate of efflux[46] compared with humans, so more compounds are eliminated in the bile at greater concentrations and rats are not altogether reliable models.

Ghibellini et al.[47] have published a comprehensive review of methods of evaluating biliary excretion in humans.

4.06.3 Biopharmaceutics Classification System

Small changes in drug product composition may alter pharmacokinetics, potentially resulting in toxicity or lack of efficacy. For this reason, a drug must be evaluated for pharmacokinetic differences any time a company uses a new manufacturing site, new synthesis, or a new formulation. A drug product that demonstrates very similar pharmacokinetics to the original product is said to be bioequivalent. A bioequivalence study generally consists of a crossover study of a single dose of the highest dose strength of the

drug.[48] For a drug to be considered bioequivalent, the 90% confidence interval of C_{max}, $AUC_{0\rightarrow\infty}$, and $AUC_{0\rightarrow tlast}$ must be between 80% and 125% of the reference product.

While many non-orally administered compounds and compounds administered as oral solutions that meet certain requirements (minimally including dosage as an aqueous solution with the same concentration of active drug as the reference product and the same or similar excipients at comparable concentrations as the reference product) are exempt from bioequivalence testing,[48] the complexity of oral absorption requires bioequivalence testing for products administered orally outside of solutions. This is a large burden since the majority of compounds are administered orally and not in solution.

To determine bioequivalence in a clinical study, a drug is given to volunteers with 250 mL of water (about 8 oz.) on an empty stomach. Per the FDA, for a drug to be considered highly soluble, the highest dosage strength of the drug must be able to completely dissolve in this volume of water or less. The drug also needs to remain soluble over the entire pH range of the stomach and small intestine. The FDA recommends that solubility be tested at pH 1, pH 6.8, and a variety of pH in between, specifically at the pK_a of the compound and above and below the pK_a by one unit.[49] This pH range represents the range of pH from the stomach to the jejunum under fasting conditions.[50] Highly soluble drugs are defined by a dose number (D_o) ≤ 1, which can be calculated from the minimum solubility of a drug over the pH range 1–6.8, at body temperature, 37°C:

$$\text{Dose number} = \frac{\text{Highest dose strength (mg)}}{250\,\text{mL} \times \text{minimum solubility}\left(\text{mg mL}^{-1}\right)}$$

In 1995, Amidon et al. developed the BCS on the basis of a good correlation between human jejunal permeability in single-pass perfusion studies and the fraction of the dose absorbed across the gut wall.[51] They concluded that highly "permeable," highly soluble compounds were well absorbed and not susceptible to minor changes in the drug product.[51] If 85% or more of the drug is dissolved within 30 min, it is considered rapidly dissolved, and if 85% or more is dissolved in 15 min, it is very rapidly dissolved. The goal of this system is to use in vitro dissolution methodology to predict in vivo behavior.

The rate and extent of absorption for an immediate-release dosage form depend upon effective permeability, solubility, dissolution rate, and gastrointestinal transit time.[52] In order for a compound to be absorbed, it must be in solution. Therefore, the compound must be completely in solution prior to reaching the absorption site, most commonly the intestine. This is dictated by a dissolution rate. The compound must also remain in solution at the pH of the absorption site, which is ensured by measuring the minimum solubility throughout the pH range of the absorbable regions.

The BCS classifies drugs on the basis of solubility and permeability (Fig. 2). The BCS predicts that highly permeable, highly soluble class 1 drugs are well absorbed and rate-limited by gastric emptying if the compound dissolves rapidly. If the compound is contained in an immediate-release dosage form and rapidly dissolved, bioequivalence can be ensured. Class 2 drugs are well absorbed, but absorption is rate-limited by dissolution, and there may be variability in absorption due to the drug formulation or in vivo factors. Class 3 and 4 drugs are limited by permeability.

This system provides a major advantage to pharmaceutical companies because in vitro methodology may qualify drugs for a waiver of in vivo bioequivalence studies. The principles of the BCS were adopted by the FDA, EMA, and WHO in terms of biowaivers. Biowaivers grant regulatory approval based on dissolution studies to certain immediate-release drug products for drugs already on the market, but are being manufactured differently or by a different company (generics), or having formulation changes, without requiring clinical evaluation of bioequivalence. Prior to the development of this system, drug products undergoing any production changes (e.g., manufacturing location or equipment) required additional clinical bioequivalence trials to be proved

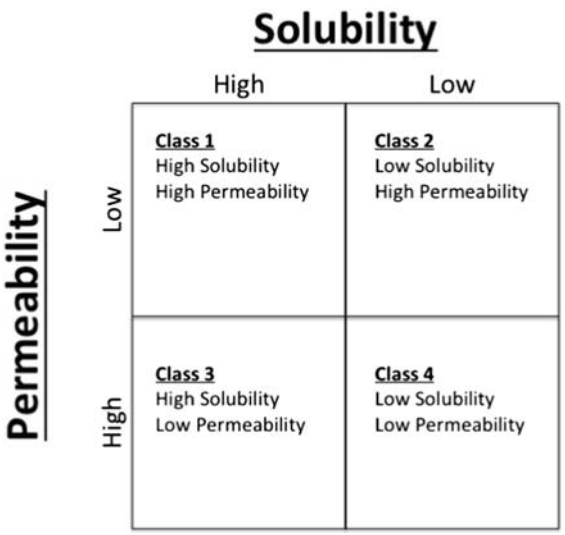

Fig. 2 Biopharmaceutics Classification System.

safe and efficacious. However, there are small differences in the regulations for biowaiver approval. As indicated in the 2015 draft guidance for biowaivers, the FDA now allows biowaivers for certain immediate-release, orally administered BCS class 1 and BCS class 3 drugs that have an acceptable therapeutic index, as well as some BDDCS class 1 drugs, which will be discussed in section "Biopharmaceutics Drug Disposition Classification System."[49] Biowaivers are not available to narrow therapeutic index drugs or drugs absorbed in the oral cavity.

The EMA now requires a stricter definition of solubility, using the highest dose administered in a single setting,[53,54] as opposed to the highest dose strength.[49] This impacts only a few drugs, but does shift the classification in some instances. For example, the highest formulated dosage strength of verapamil is 120 mg, but two tablets are often given in one setting, so the highest dose administered in a single setting is 240 mg. By the FDA definition, verapamil is considered a class 1 drug and is eligible for a biowaiver, but is ineligible for a biowaiver under the new EMA guidance.[55]

4.06.3.1 Biowaivers Granted by the US Food and Drug Administration

4.06.3.1.1 BCS class 1

These highly permeable, highly soluble compounds may be issued biowaivers if the compound is

- dosed as an immediate-release product,
- rapidly dissolved,
- an excipient in the formulation that does not interfere with the rate or extent of absorption,
- stable in the gastrointestinal tract.

Immediate-release products can be partially or completely dissolved in the stomach. These drugs are often rapidly absorbed, while extended-release products dissolve slowly in the small intestine by design. Using a highly soluble drug that is also rapidly dissolved ensures that solubility is not the rate-limiting step of absorption. Gastric emptying time is about 30 min to 1 h on a fasted stomach. Therefore, when 85% or more of a drug is dissolved within 30 min, the compound is likely to be dissolved prior to entering the intestine and is considered rapidly dissolving. In other words, the drug is ready to be absorbed once it reaches the small intestine. Additionally, the high permeability rate of class 1 drugs predicts little absorptive barrier. These BCS class 1 compounds do not have permeability barriers that would prevent the drug from being absorbed during the limited transit time through the gastrointestinal tract. Excipients that have been FDA-approved for immediate-release products will generally not interfere with drug absorption.[49]

4.06.3.1.2 BCS class 3

These highly soluble but poorly permeable compounds may be issued biowaivers if the compound is

- dosed as an immediate-release product,
- very rapidly dissolved,
- composed of the same ingredients, in similar quantities, as the reference compound.

Class 3 drugs have slightly stricter requirements than class 1 drugs, being limited by permeability rate. Additionally, since the absorption of class 3 drugs can be site-dependent, gastrointestinal transit time is a limiting factor in its absorption. Some excipients alter gastrointestinal transit time and membrane permeability[50]; therefore, there must be no alterations in the formulation including excipients. Class 3 drugs are required to be very rapidly dissolved (85% within 15 min).

4.06.3.1.3 BCS class 2a

In addition, the WHO also recommends that an additional category of BCS class 2 drugs,[56] "2a," be granted biowaivers. This subset is composed of weakly acidic class 2 drugs. They must be rapidly dissolving and highly soluble at pH 6.8. These drugs have a low solubility at the low pH in the stomach, but are well absorbed due to high solubility in the more basic intestine.

4.06.3.2 Determining Permeability

Per the FDA, compounds are considered highly permeable for the application of biowaivers when the extent of absorption is $\geq 85\%$ of the dose. The FDA permits a variety of methods of determining if a compound is highly permeable. Permeability can be assessed in humans, in vivo, or in vitro. When a pharmaceutical company intends to use a permeability-determining method for bioequivalence purposes, it should be validated by comparing permeability values generated in the assay with extents of absorption and confirming that they share a rank order.

4.06.3.2.1 Determining permeability in humans

Evaluating permeability rate by direct intestinal perfusion in humans is the most preferable method. However, acquiring such measurements is difficult and invasive. Alternative methods that are routinely assessed include evaluating the mass balance of a drug or evaluating its bioavailability.

- Mass balance: If 85% or more of the parent drug or its metabolites are eliminated in the urine, presumably, at least 85% of the drug must have been absorbed and is indicative of nearly complete absorption, and the compound meets the criteria for a high permeability compound. However, when the parent drug alone does not account for >85% of the dose, stability studies must be conducted to ensure that the metabolized compounds were not degradation products formed in the gut prior to absorption.

  Stability studies can be carried out in simulated fluids for the expected duration of drug contact with these fluids or about 1 h in simulated gastric fluid and about 3 h in simulated intestinal fluids. If <5% of the drug is degraded, it is likely stable in the stomach and intestinal lumen and the drug can be classified as extensively absorbed (BCS class 1 or 2).[49]
- Absolute bioavailability: If more than 85% of a compound is bioavailable, as compared with intravenous administration, at least 85% of the compound is absorbed and is therefore qualified as highly permeable.
- Intestinal perfusion (direct rate of mass transfer across the intestine): Drugs can be directly infused into jejunal segments of humans, and the mass that is lost between the two segments, which are sequestered by inflatable balloons, is assumed to be absorbed[57] if stability studies confirm that drugs were not metabolized or degraded in the lumen. Water absorption and secretion are corrected for with a nonabsorbable marker such as mannitol. Correlating intestinal perfusion studies to absorption extent in humans initially requires six drugs. After the protocol has been well established, the test drug must be compared with a high permeability and a low permeability standard. This study is not commonly used to quantify permeability due to its invasive nature.

If a compound is a passively diffused drug, pharmaceutical companies may employ in vitro or in vivo methodology to determine permeability. The FDA defines a passively permeable drug as one with an efflux ratio <2,[49] when linear pharmacokinetics exist between dose changes and bioavailability, and when in vivo or in vitro permeability does not depend upon the initial concentration. This specification exists because many animals or cell lines have low or nonexistent efflux compared with a well-expressed and active homolog in humans. An animal or cell line with negligible efflux can artificially boost permeability and overpredict human permeability. (An efflux ratio is defined as the basal to apical intestinal permeability divided by the apical to basal intestinal permeability).

4.06.3.2.2 Determining permeability in vivo or in situ

Animal models provide physiological conditions analogous, but not necessarily similar, to humans, including gastric and enteric dissolution, blood flow on the basolateral membrane of enterocytes, and the presence of endogenous components such as bile salts, which can impact drug solubility and absorption. Animal models may be advantageous because experiments in animals are less expensive and less time-consuming than clinical experiments in humans. In an acceptable animal model such as a rat, intestinal perfusion studies can be carried out to determine the rate and extent of drug absorption. Keep in mind, however, that while animal studies provide a physiological model, animal physiology significantly differs from humans.[44] Animal models have different expressions, activities, and substrate specificity of transporters and metabolizing enzymes as well as different blood flows, membrane permeabilities, and compositions of endogenous fluids (e.g., stomach acid and bile).

Single-pass intestinal perfusion studies examine the continuous perfusion of drug from the duodenum to the ileum of anesthetized animals, generally rats. Drugs containing fluid are introduced and removed from cannulas at either end. These models tend to correlate better with human effective permeability and human absorption than cell-based models like Caco-2.[58,59]

4.06.3.2.3 Determining permeability in vitro

Epithelial cell monolayers such as colorectal adenocarcinoma cells (Caco-2) or MDCK cells can be used to evaluate the permeability of the compound in question. The permeability of test drugs is assessed and compared with an acceptable standard compound to determine if the test compound has a relatively high or low permeability. As opposed to a quantitative value, a reference compound is an important control because permeability measurements are extremely variable between laboratories[60] and are very sensitive to experimental conditions.

Excised intestinal tissues can also be used. Excised intestinal segments from animals (most commonly rats) or humans can be mounted on an Ussing chamber, and effective permeability can be calculated. Rat tissues are more commonly used than human tissues because human tissues are scarce. This approach is beneficial because it incorporates flow as well as an intact membrane and maintains transport polarity.[61] The effective permeability rates calculated from rat tissues correlate very well with human jejunal permeability values.[52] It is, however, a laborious approach.

When the BCS was first introduced, cellular permeability of a test drug was compared with that of metoprolol.[62] As experiments progressed, however, it became readily apparent that metoprolol is an extremely permeable compound, and its usage resulted in many false negatives. The FDA now includes a list of potential model drugs representing high absorption, though pharmaceutical companies may select other drugs provided the mechanism of absorption is passive permeability and reliable human absorption data are available. To confirm the reliability of an in vitro permeability method, the sponsor should demonstrate a rank order between the permeability rate values determined via the method and human absorption values using high-, intermediate-, low-, and zero-permeability/absorption model drugs. A full list is provided in the FDA guidance.[49]

4.06.3.3 Approval of BCS Class 1 Classification

The FDA Center for Drug Evaluation and Research (CDER) has created a BCS committee that approves submissions for drugs to be officially given a class 1 assignment. Solubility criteria are well standardized, but permeability can be confirmed in a variety of manners, as listed in the preceding text. The most commonly submitted permeability evidence comes from mass balance studies, followed by Caco-2, absolute bioavailability, RLD label, and then rat intestinal perfusion.[63]

The BCS was developed and is successfully used to provide biowaivers for some highly soluble compounds. Since its development, similar classification systems have been created to predict aspects of drug disposition (BDDCS) and clearance (ECCS,[64] ECCCS,[65] and CPathPred[66]).

4.06.4 Biopharmaceutics Drug Disposition Classification System

The BDDCS was initially proposed when Wu and Benet[67] recognized that compounds with a high passive intestinal permeability rate in the BCS were extensively metabolized, while drugs eliminated in an unchanged form in the urine or bile were primarily poorly permeable in the BCS. In this seminal publication, they suggested that extent of metabolism might serve as an appropriate surrogate for absorption and/or intestinal permeability when those data are unavailable, since the extent of metabolism is easier to assess than intestinal permeability/absorption, thus expanding the number of class 1 drugs available for a biowaiver. Importantly, the modified system was also used to predict drug disposition, especially when predicting when transport or metabolizing enzymes are clinically relevant, for which it is most appreciated today.

4.06.4.1 Introduction to BDDCS and Comparison With BCS

4.06.4.1.1 Metabolism as a surrogate for absorption

The extent of drug metabolism is often quantified during phase I pharmacokinetic/mass balance studies.[68] Tabulating absorption, on the other hand, requires invasive intestinal perfusion studies in man or portal blood sampling. Absorption is a prerequisite to enzymatic metabolism, which occurs intracellularly in the endoplasmic reticulum or cytosol. Therefore, we can assume that enzymatically metabolized drugs are absorbed. Since metabolism is easier to quantify than absorption/intestinal permeability rate, Wu and Benet proposed that metabolism be used as an alternative measurement to predict absorption. The EMA and recently the FDA[49] have incorporated this suggestion into the guidance recommendations for granting biowaivers, and highly soluble compounds with $\geq$85% metabolism are eligible for biowaivers.

The BDDCS differs from the BCS in two major aspects: (1) the primary goals of the systems and (2) the definition, interpretation, and relationship of "highly permeable drugs."

4.06.4.1.2 Primary goals of the classification systems

The primary goal of the BCS is to grant biowaivers using in vitro methodology to predict drug absorption and its limiting steps. Alternatively, while the BDDCS provides the basis for recommending biowaiver extension to extensively metabolized compounds, the primary goal of the BDDCS is to predict drug disposition.

4.06.4.1.3 Differences in defining permeability

Via application of the BCS, biowaivers are granted based on extent of absorption, which may not always correlate well with intestinal permeability rate. A high permeability rate necessitates drug metabolism as we will discuss later. While high permeability rate also predicts a high extent of absorption, the opposite is not necessarily true. There are many examples of highly absorbed drugs that have a poor passive permeability rate, not reflecting their high absorption extent.[69,70] For example, sotalol, a BDDCS class 3 drug, is poorly permeable in Caco-2 cells, but has an absolute bioavailability of 98%, and thus is highly absorbed.[71–73] Its high absorption is likely mediated by transport[74] since it has a poor in vitro permeability rate, but is a substrate for the gut uptake transporter OATP1A2.[75] While some drugs are considered highly permeable in the BCS because of their high absorption, they are not, in fact, highly permeable in terms of rate measures. This is, in fact, the basis of a major difference between the BCS and BDDCS. Specifically, BCS class 1 and 2 compounds may be class 3 or 4 in the BDDCS, since drugs are classified by metabolism extent, and not absorptive extent. These differences are crucial in predicting drug disposition.

4.06.4.1.4 Development of and dispositional predictions by BDDCS

The BDDCS predicts when disposition is driven by metabolizing enzymes *versus* drug transport or when both are important, especially when transport regulates metabolism in transporter–enzyme interplay. When the BDDCS was initially developed, predictions were made for the gut and the liver. It has since been extended to transporter effects in noneliminating organs such as the brain.

Wu and Benet serendipitously recognized that high-permeability rate drugs were extensively metabolized, while low-permeability rate drugs were primarily eliminated as unchanged drug in the bile and the urine. They were simultaneously carrying out studies involving the transport of metabolized drugs and noticed that they did not recognize any clinically significant transporter interactions for BCS class 1 drugs. They therefore proposed that extent of metabolism and solubility might reflect other aspects of drug disposition, including the clinical relevance of drug transport. The BDDCS therefore classified drugs by their extent

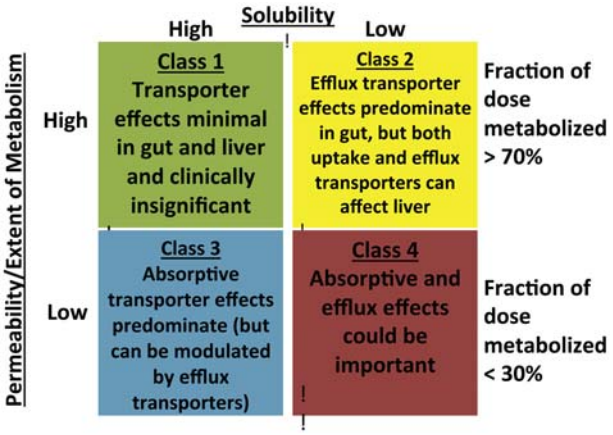

Fig. 3 Biopharmaceutics Drug Disposition Classification System and predicted transporter effects.

of metabolism and solubility (Fig. 3), where each class is associated with a series of predictions that will be thoroughly discussed. Initial applications included predicting when transporters, metabolizing enzymes, or the interplay between the two had clinically meaningful impacts on systemic concentrations and presystemic drug concentrations (after oral dosing), major routes of elimination and therefore drug–drug interactions, pharmacogenomics, and food effects in the intestine and liver.[67] Since then, the BDDCS has been expanded to understanding the effect of end-stage renal disease[76] on hepatic elimination and distribution across the blood–brain barrier. Hypotheses regarding toxicity, drug-induced liver injury (DILI), and clinical relevance in other tissues including the kidney will be discussed.

4.06.4.1.5 Value and appropriate uses of BDDCS

The BDDCS is invaluable during drug development because understanding the effect of transport and metabolizing enzymes is now essential for drug approval. Specifically, new drug applications must include the major routes of drug elimination, the quantitative contributions of enzymes and transporters, and drug–drug interaction studies.[8] The BDDCS can alert developers to which enzymes and transporters are likely important and may even justify negating some studies.

The BDDCS does not predict quantitative values of drug disposition. It can, however, provide qualitative information about the absorption of some compounds, the extent of metabolism, the extent of biliary or renal elimination of unchanged drugs, and distribution. More accurately, it predicts what processes, that is, transport at specific membranes and/or metabolism, will affect each aspect of disposition and the direction of the effect.

4.06.4.1.6 How are interactions defined?

Defining which enzymes and transporters are important in the disposition of a drug can be a cumbersome, though necessary, process. The FDA provides guidance to drug companies regarding appropriate methods to determine substrate, inhibitor, or inducer potential that may influence the safety of a drug prior to approval.[8] It initially consists of determining if a drug is a substrate, inhibitor, or inducer of a transporter or enzyme in vitro. For those drugs with positive identification in vitro, follow-up in vivo studies are conducted. Interactions are considered meaningful if they are "sufficiently large to necessitate a dosage adjustment …"[8] Full drug–drug interaction predictions are outside of the scope of this article.

4.06.4.1.6.1 Pillars of BDDCS

The BDDCS predicts when a transporter or a metabolizing enzyme can clinically regulate the disposition of a drug, whether or not the drug is a substrate. When the BDDCS predicts that drug transport at a membrane is not clinically relevant for a particular drug, it does not presume that the drug is not a substrate for a transporter. In fact, it is likely that almost all drugs are substrates for transporters. Instead, the BDDCS predicts if a transporter significantly contributes to the disposition of a drug compared with passive diffusion. These effects are perhaps most obvious in clinical studies examining the effect of transport inhibition on drug absorption, distribution, metabolism, and elimination. In cases where a transporter or metabolizing enzyme is important in a drug's disposition, affecting one, for example, by inhibiting transport, can cause clinically significant pharmacokinetic changes to elimination, bioavailability, or distribution, observed as changes in the plasma concentration versus time curve (AUC, C_{max}, t_{max}) and altering the parameters CL, V, and F that define dose. These changes may impact the safety or efficacy of the drug, resulting in a dose change. If inhibition of transport does not cause dispositional changes severe enough to necessitate a dosage change, the transporter is not considered clinically significant in the drug's disposition. The BDDCS predicts that extensively metabolized/highly soluble class 1 drugs are not *clinically relevant* substrates of drug transporters, even if in vitro evidence shows an affinity. In other words, while these drugs may have a biochemical affinity to transporters, the contribution of the active transporter to permeation across a membrane is minor compared with passive permeability, and any functional discrepancy of the transporter will not result in a significant change

that requires dose adjustment to achieve safety or efficacy. For class 1 drugs, in vitro studies will provide a false-positive predicting interaction, and studies in vivo or in humans are unlikely to replicate these results.[77] In vivo or clinical interaction studies are costly and time-restrictive. The FDA guidance recommends that P-gp and BCRP be evaluated as transporters for every drug, yet acknowledges that it may not be necessary for BCS class 1 drugs and sponsors may submit class 1 drugs without transporter data.[8] This would more appropriately be acknowledged for BDDCS class 1 drugs, since some BCS class 1 drugs (e.g., sotalol) may be subject to transporter interactions.

Furthermore, the BDDCS does not presume to predict that there *will* be an interaction for every drug in a class, but rather that an interaction *could* exist and should be tested during development. Finally, the BDDCS makes no predictions regarding inhibitor or inducer status.

4.06.4.1.6.2 Drugs as victims and perpetrators

Importantly, even if a transporter or metabolizing enzyme does not clinically affect the disposition of a drug, it does not mean that the drug cannot affect those transporters or metabolizing enzymes. In other words, the BDDCS predicts if a drug can be a victim of a drug interaction, but not whether or not it can be a perpetrator. Consider verapamil. Verapamil is a BDDCS class 1 drug and a P-gp substrate in vitro. As you will see throughout this article, inhibition of transport does not affect the disposition of class 1 drugs. Therefore, when P-gp is inhibited by quinidine, for example, the dispositional change is not severe enough to warrant a dosage change of verapamil. However, verapamil is a moderate inhibitor of P-gp. When verapamil is coadministered with digoxin, a BDDCS class 3 P-gp substrate, it inhibits P-gp, causing the plasma AUC of digoxin to spike into toxic concentrations. Digoxin then requires a lower dose.

4.06.4.2 Role in Predicting Absorption

4.06.4.2.1 Processes affecting absorption

The stomach and enterocytes are the body's initial security screening. The gastrointestinal environment is a harsh habitat. The pH in the stomach is so acidic that a mucosal layer protects the stomach lining. The stomach is responsible for initially grinding and dissolving oral tablets and regulating the release of its contents to the intestine. In the stomach and intestine, the acidic pH and an ecosystem of microorganisms contribute to the breakdown of foods, so that nutrients can be absorbed. Readers who are familiar with the concepts of probiotic diets will understand that bacteria significantly contribute to the breakdown and metabolism of foods. Bacteria are also capable of degrading or metabolizing drugs. To nourish the body, enterocytes must allow entry to many molecules. However, anything we eat may also contain substances toxic to our body. To reduce the harmful impact of xenobiotics, enterocytes are equipped with metabolizing enzymes, which can change a xenobiotic into a generally less toxic and easy to secrete substance, and transporters, which can help pump xenobiotics back into the gut. Transporters may also aid in absorption of nutrients and xenobiotics. One such example is PEPT1, which not only is responsible for bringing oligopeptides in but also helps to absorb compounds such as cefadroxil, a β-lactam antibiotic.[78] Food, other drugs, and endogenous substrates can affect the environment in which the drug is dissolved with their intrinsic chemical properties (e.g., percent fat, pH, and water content), as well as by stimulating physiological changes in the gut and stomach. They may also interact with transporters and metabolizing enzymes, which can regulate the rate and extent to which a drug is absorbed. Factors such as pharmacogenomics can likewise alter drug absorption.

4.06.4.2.2 Requirements of absorption and predicting absorption

For an orally administered drug to be effective at a peripheral location, the drug must obviously be well absorbed. This is, in fact, one of the major barriers during drug development, since oral administration is preferred due to compliance, convenience, and stability reasons. Predicting absorption is therefore very important when selecting drug candidates. As an addendum to the prediction that high passive permeability rate predicts extensive absorption, the BDDCS also predicts that extensively metabolized class 1 and 2 drugs are well absorbed.

As we have just discussed, high-permeability rate compounds are both extensively metabolized and well absorbed from the gastrointestinal tract. However, not all well-absorbed compounds are highly permeable. In other words, the BDDCS predicts that extensively metabolized class 1 and 2 drugs must be well absorbed, but offers no prediction of the extent of absorption of poorly metabolized, poorly permeable class 3 and 4 compounds, which can exhibit highly variable extents of absorption.

4.06.4.2.3 Transporter effects in the gut

4.06.4.2.3.1 Apical uptake

BDDCS class 1 and 2 drugs can so readily permeate enterocytes that gut apical uptake transporters have only a minor contribution to their absorption. Therefore, the BDDCS predicts no effect when uptake transporters are affected for highly permeable compounds since class 1 and 2 can enter enterocytes unaided by transporters.

Class 3 and 4 drugs are poorly permeable and require active uptake transporters to be absorbed, and therefore, alterations to their activity or expression will result in clinical differences in absorption and bioavailability. Specifically, decreased uptake transport functionality results in decreased absorption and increased function with increased absorption. Uptake transport in the gut must therefore be evaluated for BDDCS class 3 and 4 drugs.

4.06.4.2.3.2 Gut apical efflux and transporter–enzyme interplay

Apical efflux transporters counteract net xenobiotic absorption from the gut. Apical efflux transporters include P-gp, MRP2, and BCRP.[79] After a drug is absorbed into an enterocyte, substrates for apical efflux transporters are pumped back into the gut, reducing the effective absorption. Not only can efflux transporters affect parent drug absorption, but also they can regulate the extent of metabolism of some drugs:

- BDDCS class 1 drugs are clinically unaffected by changes in transporter expression or activity in the gut, even if they are substrates. These drugs will be affected only by changes in metabolism, and the degree of metabolism is unaffected by transporters.
- BDDCS class 2: Apical efflux transporters can have a clinical impact on the absorption of class 2 drugs. When efflux is inhibited, an increase in absorption may be observed. BDDCS class 2 drugs are in a unique position because efflux transporters in the gut can impact both their parent drug availabilities and their intestinal metabolism. Wacher and coworkers[80,81] discovered that inhibition of P-gp, even in the absence of CYP3A4 inhibition, decreases intestinal CYP3A4 metabolism, since CYP3A4 accounts for approximately 70% of CYP expression in the gut.[82,83] One might expect that inhibiting efflux in the gut would increase metabolism by forcing a drug to interact with metabolizing enzymes for longer. One might also expect that metabolism would not be affected, but that inhibiting efflux would increase absorption and therefore bioavailability. However, because CYP3A4 and P-gp are coregulated and share so many substrates,[84] P-gp substrates are also likely to be metabolized by CYP3A4. Metabolizing enzymes are located just below the microvillus border in enterocytes.[85] P-gp and CYP3A4 work in concert to eliminate the parent drug from the body. Efflux transporters recycle xenobiotics that have not yet been metabolized by CYP3A4, pumping them back into the gut lumen and allowing them to be absorbed multiple times, giving the drug not only multiple opportunities for drug exposure but also multiple opportunities for metabolism, a process called enzyme–transporter interplay. Therefore, when an enteric efflux transporter is inhibited, a class 2 drug may have decreased metabolism and increased bioavailability greater than would be expected by inhibiting absorption alone. This is specific to enterocytes, and inhibition of efflux transporters in hepatocytes leads to increased concentrations of parent drug and increased metabolism.
- BDDCS classes 3 and 4: Apical efflux transporters play a protective role against poorly permeable class 3 and 4 drugs by effectively limiting absorption of poorly permeable drugs that are substrates for an efflux transporter. Class 3 and 4 drugs that are substrates of apical efflux transporters may see an increase in drug absorption when these efflux transporters are inhibited.

4.06.4.2.3.3 Gut basolateral transporters

Little has been explored regarding basolateral transporters expressed on the enterocyte.[79] It is unlikely that basolateral efflux is extremely important since concentrations in the portal vein will be very low compared with the cell, encouraging passive diffusion. Apical uptake transporters may be necessary for more hydrophilic class 3 and 4 drugs to enter the cell, but leaving the cell requires passage through the hydrophilic portion of the membrane and is likely not a limiting factor.

4.06.4.2.3.4 Effects on absorption rate: flip-flop kinetics

When a drug is given as an extended-release formulation, absorption rate is often slower than elimination. Alternatively, the absorption of an immediate-release drug is generally a relatively quick process compared with elimination. For most immediate-release drugs, elimination is the rate-limiting step. However, a very small number of immediate-release drugs exhibit flip-flop kinetics, where the rate of absorption is the rate-limiting step in the disposition of a drug, instead of elimination. Flip-flop kinetics may be a developmental concern when a compound is poorly permeable/poorly metabolized and also has a relatively short $t_{1/2}$, specifically if it is shorter than gastrointestinal transit time. For drugs displaying flip-flop kinetics, the terminal slope of the systemic concentration–time curve actually reflects absorption processes because absorption rate is not limited for highly permeable/highly soluble drugs. We expect that only class 3 and 4 drugs would demonstrate flip-flop kinetics. Specifically, the absorption rate is probably limited by the affinity to and velocity of gut uptake transporters. Garrison et al. recently evaluated this hypothesis.[80] For 19 drugs exhibiting flip-flop kinetics, 16 were indeed class 3 or 4. While the absorption of class 2 drugs is unlikely limited by uptake transporters, their absorption may be slow as a result of poor dissolution, and very slowly dissolving class 2 drugs may display flip-flop kinetics, but very few examples of this phenomenon have been found.[80]

4.06.4.2.3.5 Pharmacogenomics affecting absorption

Genetics can directly impact a person's ability to absorb a drug. For instance, patients with inflammatory bowel disease have increased MRP1 expression in the intestine,[81] which can result in decreased absorption of class 2, 3, or 4 drugs. Genetic differences within healthy populations can also result in variation in absorption. The variant SLCO2B1*3, which codes for OATP2B1 and has decreased uptake activity, has an allele frequency of 30.9% in Japanese.[82,83] When fexofenadine, a BDDCS class 3 drug, was dosed to a Japanese population, those with the allele had a 37% lower AUC than those without the allele, indicating that genetic differences can impact drug absorption. Alternatively, there was no significant difference observed in AUC when midazolam, a class 1 drug, was dosed.[84] Genetic differences are sometimes highly related to race, highlighting the importance of selecting an appropriate population of healthy volunteers representing common genotypes for dosing in certain countries. Genetics, expression, and activity of metabolizing enzymes and transporters can directly impact absorption and other dispositional functions of a drug and increased or decreased functionality follow the predictions outlined for each class.

4.06.4.2.4 Non-transport-mediated interactions affecting drug absorption

Finally, concomitant food, drug, or supplement administration can potentially alter drug solubility. For instance, some tyrosine kinase inhibitors (TKIs), which are anticancer agents, or the malignancy itself, can cause gastric distress such as gastroesophageal reflux disease. To combat this unpleasant side effect, many patients take proton pump inhibitors, which increase gastric pH. Unfortunately, this can have the effect of decreasing the solubility of some of these weakly basic TKIs, thereby decreasing drug absorption.[85] Yago et al.[86] showed that absorption, presumably by improving drug solubility, could be improved in healthy volunteers with elevated gastric pH (hypochlorhydria) by predosing betaine hydrochloride, which acidified the stomach prior to dosing the TKI dasatinib. Solubility-based drug interactions are likely to affect poorly soluble BDDCS class 2 and 4 drugs only, since the solubility class is defined by the lowest solubility condition possible in the stomach and gut.

Food can have a significant impact on drug absorption by influencing drug solubility and active absorption. The complex interactions with food will be thoroughly covered in section "**Complex considerations: food effects**."

An orally administered drug must be able to bypass a significant degree of gut and hepatic metabolism to be systemically available. Additionally, metabolism is also very important in mediating drug elimination once the drug has entered systemic circulation for both orally and non-orally administered drugs.

4.06.4.3 Role in Predicting Metabolism and Hepatic Elimination

4.06.4.3.1 Metabolism in the gut

The majority of drug metabolism occurs after drug absorption. While metabolizing enzymes are expressed to a significantly smaller extent than in the liver, the gut wall contains relatively high concentrations of metabolizing enzymes compared with other organs. Gut metabolism (F_G) is a component responsible for decreasing a drug's bioavailability. Gut metabolizing enzymes are also frequently responsible for the bioactivation of prodrugs.

CYP3A is only expressed at 1.4% of the level found in hepatocytes,[87,88] but accounts for 70–80% of CYP expression in the gut,[87] and more than 50% of drugs eliminated by metabolism are substrates for CYP3A4[89] and may be presystemically metabolized. As a low-affinity, high-capacity enzyme, it may be particularly susceptible to drug concentration differences,[90] influenced by permeability, transport, or solubility.

The BDDCS predicts that highly permeable BDDCS class 1 and 2 drugs will be metabolized and thus may be subject to intestinal metabolism, which may contribute to a possible reduction in bioavailability. Alterations in gut metabolism may significantly change the bioavailability of these compounds. When metabolism is inhibited, these compounds are predicted to be significantly more available to the systemic circulation and may require a smaller dose. Poorly metabolized class 3 and 4 drugs are unlikely to be metabolized in the gut. Metabolism may not significantly contribute to reduced bioavailability of these compounds. Therefore, they may not experience significant pharmacokinetic changes when intestinal metabolism is inhibited or induced and will not require dose adjustments.

Genetic differences in expression or activity of a metabolizing enzyme or transporter can significantly impact the metabolism or elimination of drugs. For example, a significant percentage of people are poor CYP2C19 metabolizers. Therefore, when a CYP2C19 substrate is prescribed, we would expect increased exposure in these patients. In fact, poor metabolizers have greater acid suppression and ulcer healing than extensive metabolizers when they take proton pump inhibitors such as omeprazole as a result of their increased exposure.[91]

When the BDDCS was developed, a primary observation was that there was a very dichotomous extent of metabolism. Drugs tend toward a primary route of elimination. Specifically, metabolism tends to contribute $>70\%$ of total drug elimination for extensively metabolized drugs or $<30\%$ for drugs that are eliminated as unchanged drug. There are few examples of drugs being eliminated with an intermediate extent of metabolism.

4.06.4.3.2 Hepatic basolateral uptake

After oral absorption, the liver is the first organ to process drugs and so hepatic transport is important. Hepatic drug exposure is often regulated by hepatic basolateral uptake. While at least seven major transporters (OATP1B1, OATP1B3, OATP2B1, NTCP, OCT1, OCT3, and OAT2) and the bidirectional transporters ENT1, ENT2, OAT7, OCTN2, and OSTα-OSTβ facilitate hepatic distribution, the FDA considers OATP1B1 and OATP1B3 to be the most clinically relevant[8] and recommends evaluating hepatically eliminated drugs for their potential to interact with these transporters as substrates, inhibitors, or inducers.

As in the gut, the BDDCS predicts that uptake transport will be clinically irrelevant for class 1 drugs. The BDDCS predicts that hepatic basolateral uptake transporters may play a significant role in class 2 drugs, which differs from predictions for the gut, and are necessary for hepatic exposure of poorly permeable class 3 and 4 drugs. The gut has "leakier" membranes (composed of epithelial cells) than the liver, which is composed of endothelial cells. This may possibly explain the difference in observed uptake transporter effects for class 2 drugs.[68]

Metabolism in hepatocytes is the major eliminating mechanism of class 1 and 2 drugs. Since class 1 and 2 drugs are extensively metabolized and a substantial portion of metabolism occurs hepatically, it follows that hepatic transporters (for class 2 drugs) and/or metabolizing enzymes (for class 1 and 2 drugs) will be significant determinants in their disposition.

Class 1: Class 1 drugs do not depend on uptake for their hepatic access and transporters will have no impact on their disposition.

However, hepatic metabolizing enzymes mediate the majority of elimination of class 1 drugs and their function will affect the

disposition of class 1 drugs. If a hepatic metabolizing enzyme contributing to the clearance of a class 1 compound is inhibited, drug exposure (AUC) is expected to increase, and a lower dosage may be required to avoid toxicity. Alternatively, if the metabolizing enzyme is induced, clearance may be greater than expected, resulting in poor exposure and a potential for drug inefficacy.

Example: St. John's wort is an herbal supplement sometimes taken as an antidepressant. It also acts as an inducer of CYP3A4[92–94] and CYP1A2.[95] In numerous cases, drugs including the anticoagulant warfarin,[96] the immunosuppressant cyclosporine,[97–99] some oral contraceptives, and the HIV protease inhibitor indinavir[100] have seen decreased plasma concentrations or reduced drug-efficacy outcomes when a patient is also taking St. John's wort, presumably as a result of metabolizing enzyme induction. If a patient has a lower drug concentration than expected, it can lead to serious problems with drug efficacy. If, for instance, the efficacy of warfarin is compromised, INR levels can decrease, which indicates quick blood clotting and is potentially life-threatening. Inefficacy of immunosuppressants can instigate organ rejection, while inefficacy of HIV protease inhibitors could potentially see an increase in HIV viral load.

Class 2: The systemic and metabolic disposition of class 2 drugs can be affected by both transport and metabolism. For BDDCS class 2 drugs, the BDDCS predicts that decreased function of a hepatic basolateral uptake transporter may result in increased portal vein concentrations and decreased hepatocyte concentrations. Subsequently, when uptake is inhibited, metabolism in hepatocytes may be decreased, while induction may lead to increased metabolism. Obviously, when metabolism is inhibited, there may be increased plasma or hepatic concentrations of parent drug and decreased elimination.

Classes 3 and 4: Class 3 and 4 drugs are primarily eliminated by either renal or biliary elimination of unchanged drugs. We expect that the poorly permeable class 3 and 4 drugs require a transporter to enter hepatocytes, while biliarily eliminated drugs require active canalicular efflux into the highly concentrated bile. Thus, especially if a compound is biliarily eliminated, inhibition of uptake transporters in the liver may result in increased AUC and increased half-life as a result of decreased clearance. However, since inhibition of hepatic uptake transporters will usually also decrease volume of distribution for hepatically eliminated compounds,[101] the increase in half-life will not be as great as the decrease in clearance. A lower dose may be required for biliarily eliminated compounds whose hepatic uptake has been inhibited.

For instance, rosuvastatin and pravastatin are primarily eliminated as unchanged drug in the bile. They are clinically relevant substrates of OATP1B1, and polymorphisms in the gene encoding OATP1B1, SLCO1B1, or drugs inhibiting 1B1 have been shown to increase plasma concentrations and decrease hepatic concentrations of these drugs.[102,103] Not only does this decrease the efficacy of these statins,[104] whose mechanism of action is in the liver, but also it increases the risk of rhabdomyolysis, a severe muscle toxicity.[105]

4.06.4.3.3 Hepatic apical efflux

Apical efflux transporters regulate parent drug and metabolite entry into the bile. Apical efflux transporters in the liver can contribute to the disposition of some class 2, 3, and 4 drugs. Drugs that are eliminated as parent drug in the bile must be actively transported into the bile by canalicular efflux transporters and follow bile flow through the biliary tree until the biliary contents are dumped back into the duodenum. Some drugs, especially highly permeable class 1 or 2 drugs, may be reabsorbed through the gut. Sometimes, when this happens, the plasma concentration–time curve will show two or more peaks. This process is called enterohepatic recycling, which helps conserve bile salts and, in this case, drugs. Drugs that are not reabsorbed in the gut will be eliminated in the feces. Apical efflux can regulate biliary efflux as well as hepatic retention.

Class 2: When apical efflux is inhibited, concentrations in hepatocytes are increased. For class 2 drugs, this may result in increased metabolism. However, apical efflux inhibition in the gut results in the opposite effect: decreased metabolism. We hypothesize that this is because the drug is exposed to the apical transporter after metabolizing enzymes in the hepatocyte, while the drug interacts with efflux transporters prior to metabolizing enzymes in the gut.

Classes 3 and 4: It has been hypothesized that canalicular efflux does not contribute to the systemic clearance of poorly metabolized drugs.[64] If this is true, there will not be increased exposure of class 3 and 4 drugs. In this case, decreasing the dose may not be necessary to reduce toxic systemic exposure. However, accumulation within hepatocytes sometimes mediates hepatotoxicity, and a decreased dose may be required for this mechanism. There is a paucity of data regarding the effect of apical efflux inhibition on systemic concentrations.

Many parent drugs and metabolites may be (initially) eliminated in the bile. Upon inhibition of biliary efflux, class 2, 3, and 4 drugs may potentially accumulate in hepatocytes. Accumulation of drugs in hepatocytes sometimes leads to DILI. This injury is generally mediated by metabolites. Fortunately, compensatory mechanisms such as increased expression or activity of basolateral efflux transporters can pump some drugs back into the circulation to reduce the chance of injury. Additionally, while it has been generally presumed that unbound concentrations were equivalent throughout the body, we now understand that transporters alter the unbound concentrations of drugs inside a cell. Therefore, since class 1 drugs are not clinically relevant substrates of transporters, pharmaceutical companies presumably have a better understanding of class 1 drug concentrations inside the liver. We therefore expect that DILI may be less of a problem for class 1 drugs or for poorly metabolized class 3 or 4 drugs, but may be a greater problem for class 2 drugs. This hypothesis is currently being investigated. Analogously, the BDDCS may potentially predict as to which drugs may be problematic when dosed to people with dysfunctional efflux transporters, such as in disorders such as Dubin–Johnson syndrome, where MRP2 is poorly functional.

4.06.4.3.4 Insights into metabolism from BDDCS

The BDDCS was pivotal in observing that drugs with a high intestinal passive permeability rate were also extensively metabolized. The rationale behind this observation is that highly permeable drugs, when excreted into hydrophilic secretions, that is, urine and bile, are rapidly reabsorbed due to the high concentration gradients. This gives the drug multiple chances at metabolism, until eventually the compound is changed to a generally more hydrophilic substance that resides in fluidic secretions. Data sets examining reabsorbed compounds support this hypothesis. In a data set published by Dave and Morris,[106] 82% of drugs that were reabsorbed from the kidney tubule were extensively metabolized drugs. In a data set published from Pfizer,[33] slightly more than half of the extensively metabolized drugs were reabsorbed from the kidneys compared with $<20\%$ of class 3 and 4 drugs.[77] Renal reabsorption is primarily a passive process driven by high tubular concentrations compared with the blood, though reabsorptive transporters are functional and can play a role. Analyzing this data set and using permeability rate values generated from the same group, higher permeability rate compounds tended to be reabsorbed, while lower permeability rate compounds were either passively filtered or secreted (ROC AUC $= 0.80$).

Highly permeable drugs might also be reabsorbed directly from the biliary tract. When phenolphthalein glucuronide was dosed directly into the bile and prevented from undergoing enterohepatic recycling, it was recovered in hepatocytes, indicating that reabsorption from the bile is possible.[107] The BDDCS predicts that if highly permeable BDDCS class 1 and 2 drugs are initially secreted into the bile, they will be reabsorbed. This reabsorption process means that drugs will eventually be metabolized as a necessary elimination step. This is particularly important for some low-clearance compounds such as diazepam, which are too lipophilic to remain in secretions.

Passive permeability, not active transport or the extent of absorption, correlates with the extent of metabolism. In this way, extensive metabolism can be predicted with immortal cell lines such as Caco-2 and MDCK, which express low transport levels, or even artificial membranes such as PAMPA. Artificial membranes do not express transporters and accurately reflect passive permeability. This reduces the need for human tissue in evaluating metabolism with microsomes, supersomes, or hepatocytes. Permeability rate does not necessarily correlate with metabolic clearance, however.

Hosey and Benet showed that the extent of metabolism can be predicted with either in vitro or in silico tools.[16] Extreme variability in permeability rate values persists between labs,[60] and therefore, numerical permeability rate cutoffs are incapable of predicting the extent of metabolism or absorption. As a solution to this variability, metoprolol has generally been regarded as a standard to determine high permeability rate.[62] Compounds exhibiting a permeability rate greater than metoprolol were predicted to be extensively metabolized and highly absorbed. However, metoprolol's permeability rate is restrictively high when measured in MDCK or Caco-2,[12,16,108] mispredicting many extensively metabolized drugs because they had lower permeability rates than metoprolol, and the alternative standards labetalol and zidovudine were assigned for Caco-2 and MDCK, respectively,[16] and correctly predicted more compounds across several data sets. While metoprolol was far too conservative to be an effective standard compound in Caco-2 or MDCK, it performs well as a standard in PAMPA.[16] Theophylline was selected as an optimal standard when permeability rate studies are conducted in PAMPA and is also too conservative in MDCK or Caco-2. While the BDDCS predicts that drugs that are highly permeable in vitro will be extensively metabolized clinically, and therefore subject to changes in metabolizing enzymes, in vitro systems are not interchangeable and unique protocols must be established for each.

From 20 data sets, $97 \pm 5\%$ of compounds with a permeability rate greater than metoprolol were extensively metabolized.[16] While most compounds with a permeability rate greater than the selected standards labetalol, zidovudine, or theophylline are extensively metabolized, in many cases, 20–25% of the compounds with a permeability rate lower than these standards are also extensively metabolized. Therefore, while high-permeability rate compounds are almost always extensively metabolized, not all extensively metabolized compounds have a high permeability rate. For increased predictability, a very low-permeability rate marker, chlorothiazide, was established. Most compounds with a permeability rate less than chlorothiazide's are poorly metabolized. The predictability of compounds with a permeability rate between chlorothiazide and the reference standard is only around 50%, however, and these compounds should be investigated in humans.[16]

4.06.4.4 Predicting Bioavailability

Bioavailability depends upon the extent of absorption, the extent of metabolism in the gut and the liver, and drug loss due to first-pass biliary elimination. In addition to understanding the metabolic component of bioavailability, all of these processes can potentially be affected by drug transport.

High absorption does not necessarily predict high bioavailability, especially since many highly absorbed drugs are also extensively metabolized. As such, the BDDCS predicts that highly permeable class 1 and 2 drugs will have good absorption, but not necessarily good bioavailability. There is a caveat to this prediction, however. The BDDCS assumes that metabolized compounds are absorbed compounds. However, there may be some compounds that are not metabolized by phase I or phase II metabolism, but by bacteria in the gut lumen. When over 900 drugs were classified into the BDDCS, extensively metabolized drugs were categorized regardless of the mechanism. However, this is a nascent field and few drugs are currently known to be metabolized in this manner.

Class 1: The bioavailability of class 1 compounds can be affected by metabolizing enzymes and inhibition of metabolism will increase the bioavailability.

Table 2 Effects of gut apical transporters on pharmacokinetic parameters

	Decreased functionality of apical uptake					*Decreased functionality of apical efflux*				
	F	k_a	t_{max}	C_{max}	*AUC*	F	k_a	t_{max}	C_{max}	*AUC*
Class 1	⇔	⇔	⇔	⇔	⇔	⇔	⇔	⇔	⇔	⇔
Class 2	⇔	⇔	⇔	⇔	⇔	↑	↑	↓	↑	↑
Class 3	↓	↓	↑	↓	↓	↑	↑	↓	↑	↑
Class 4	↓	↓	↑	↓	↓	↑	↑	↓	↑	↑

Class 2: Class 2 compounds can be affected by both transporters and metabolizing enzymes. Inhibition of efflux transporters in the gut can lead to increased absorption, decreased metabolism, and increased bioavailability. Inhibition of hepatic basolateral uptake may lead to decreased metabolism and increased bioavailability, while inhibition of hepatic basolateral efflux may lead to increased metabolism and decreased bioavailability. Inhibition of metabolizing enzymes may increase bioavailability.

Classes 3 and 4: Metabolism is not a significant factor in the bioavailability of class 3 and 4 drugs. However, uptake and efflux transporters can potentially regulate bioavailability in both enterocytes and hepatocytes. One would expect decreased bioavailability if an enteric uptake transporter responsible for a drug's uptake was inhibited due to decreased absorption. Conversely, inhibition of enteric apical efflux would result in increased absorption and bioavailability. However, first-pass biliary excretion may play a role. Hepatic uptake is generally considered the rate-limiting step of biliary elimination. Therefore, inhibited hepatic uptake of class 3 and 4 drugs would likely result in a decrease in biliary elimination and an increase in bioavailability. It has been suggested that hepatic canalicular efflux does not regulate systemic clearance, and therefore, inhibition of hepatic canalicular efflux would not likely have an effect on bioavailability; however, given the lack of clinical studies on biliary elimination, there are little data to confirm or deny this hypothesis.

In **Table 2**, we tabulate pharmacokinetic changes that may be expected when the function of an enterocytic drug transporter is decreased for any number of reasons including chemical inhibition from other drugs, food, or endogenous substrates and genetic mutations.

4.06.4.4.1 Complex considerations: food effects

4.06.4.4.1.1 Predicting food effects

Eating a meal can have a substantial impact on pharmacokinetics. In fact, many drug labels advise that the drug be taken either with a meal or separate from a meal. The act of eating causes a cascade of physiological changes in the gastrointestinal system. These can greatly affect the solubility and the transit time of the drug. In turn, the transit time can affect the exposure to intestinal fluids and membranes, as well as the location of drug-membrane exposure, where different segments of the intestine have different properties including membrane tightness, transporter, and metabolizing enzyme expression. Additionally, food, drinks, and supplements can have a biochemical impact on the drug, where components of each can serve as inhibitors of transport or metabolism. Obviously, the effect of food on pharmacokinetics is a multifaceted problem, which makes predicting food effects a priori quite difficult. However, some general predictions have been proposed using BDDCS principles.

Because food effects are multifactorial, predicting them is a very difficult problem. For one, food chemistry is extremely complex. Even a single food can have multiple molecular components that inhibit uptake, efflux, metabolism, or any combination, forcing a complex interaction. For example, grapefruit juice, famous for its ability to inhibit CYP3A4, is composed of many compounds, including flavonoids and furanocoumarins. Because of the complexity of the composition of a food or drink such as grapefruit juice, the mechanism of inhibition has to be sifted from many compounds. While flavonoids were initially expected to be the perpetrators of this interaction, it was ascertained that certain furanocoumarins are the culprits.[109] When taken with antihistamines such as terfenadine and astemizole, grapefruit juice increased drug exposure to dangerous concentrations that caused cardiotoxicity and, in some cases, death. Both drugs were eventually removed from the market. Many drugs metabolized by CYP3A4 are now labeled with cautions against consuming grapefruit juice. Additionally, components in grapefruit juice have been shown to inhibit uptake transporters[110] and P-gp.[111] Meanwhile, human gastrointestinal physiology is incredibly variable, as are the contents of the gastrointestinal tract. Baseline gastric efflux on a fasted or fed stomach and pH can vary markedly between humans. The microbiome, which can break down drugs, having a direct effect, or influence food digestion, causing an indirect effect, is signature to each person. Despite this complexity and variability, the BDDCS is able to predict the effects of food for approximately 70% of drugs.[112]

4.06.4.4.1.2 Physiological responses to meals and their dispositional impact

After eating, some physiological changes occur that can result in dispositional changes to drugs. The predicted dispositional changes as a result of physiological response to food, and more specifically high-fat meals, are tabulated in **Table 3**.

4.06.4.4.1.3 Biochemical inhibition

Components in high-fat meals (a high-fat meal contains 800–1000 calories with 50–65% from fat and 25–30% from carbohydrates and 15–20% protein[125]) may inhibit intestinal transport. Lipids consumed, monoglycerides and fatty acids liberated during fat

Table 3 Dispositional impacts due to physiological changes after a meal

Physiological change	*Effect on absorptive component*	*Class 1*	*Class 2*	*Class 3*	*Class 4*
Gastric fluid increases from 300–500 to 800–900 mL, while intestinal fluid volume increases from 500 to 900–1000 mL[113–115]	Increase volume for drug dissolvation and solvent drag		F ↑		F ↑
Phospholipids and bile salts increase four- to fivefold[116,117]	• Bile salts increase breakdown of fats into monoglycerides • Bile salts inhibit P-gp • Bile salts inhibit uptake • Bile salts increase solubilization • Monoglycerides and lipids liberated by bile salts can inhibit uptake and efflux as well	F ⇔	F ↑	F ↑↓⇔ The majority of class 3 drugs will exhibit decreased F due to inhibition of uptake	F ↑↓⇔
pH decreases with some foods such as juices	Weakly acidic drugs have decreased solubility, while weakly basic drugs have increased solubility	F ⇔	F ↓ for acidic drugs F ↑ for basic drugs	F ⇔	F ↓ for acidic drugs F ↑ for basic drugs
pH generally increases with food	Decreases solubility for weakly basic drugs[115,118]		F ↓ for basic drugs F ↑ for acidic drugs		F ↓ for basic drugs F ↑ for acidic drugs
Splanchnic blood flow is increased	Improve bioavailability[115,119]	F ↑	F ↑	F ↑	F ↑
Gastric emptying is delayed	• Increases time before drug can be absorbed in the gut	t_{peak} ↑	t_{peak} ↑	t_{peak} ↑	
	• Increases interactions with gastric acid, which may contribute to drug decomposition[51,120]	F ↓	F ↓	F ↓	F ↓
Gastric secretions including bile are increased by up to fivefold[121]	• Increased bile volume allows for increased micellular solubilization and increased drug wetting of poorly soluble drugs • Increased bile concentrations • Break down fats into lipids • Bile salts and lipids can interfere with drug transport[122–124] • Aggregation into micelles that help with solubilization		F ↑		

digestion, and bile salts released to aid in digestion have all been shown to inhibit transport, especially that of P-gp[115,122–124,126] but also of uptake.[115]

Components in any food, whether or not it is part of a high-fat meal, have the potential to serve as biochemical inhibitors of transport or metabolism and, if consumed daily, inducers. Certain fruit juices, teas, beer, and wine can cause biochemical inhibition of transporters and/or metabolites. For instance, orange, grapefruit, and apple juice have been shown to inhibit OATPs and P-gp in the gut.[110,111,127]

The specific inhibitors in food can be quite difficult to identify since foods contain small concentrations of many compounds and compounds may have an additive effect.

4.06.4.4.1.4 Chemical solubility effect

Drug solubility depends on the pH of fluid, temperature, volume, and contents of fluid. The lipophilicity of a drug is also correlated with water solubility. The rate and extent of absorption can be altered by food.

Factors that increase the amount of drug solubilized are particularly important for BDDCS class 2 and 4 drugs, whose absorption is limited by their poor solubility. Foods can increase solubility by increasing the volume into which a drug can be solubilized, changing the pH of the fluid, and increasing concentrations of bile salts four- to fivefold.[116,117] After a meal, the volume of intestinal fluids increases two- to threefold, which can potentially increase the amount of drug that is solubilized, meaning more drugs may be available for absorption. Bile salts can improve the solubility of some drugs by acting as surfactants.[128] Changes in the pH of gastrointestinal fluids can alter the solubility of drugs. Acidic drugs will be more poorly soluble in acidic media, while basic drugs will lose solubility in basic media and vice versa.

4.06.4.4.1.5 Overall predicted food effects after consuming high-fat meals for each BDDCS class

Class 1: The overall extent of bioavailability is unlikely to change for BDDCS class 1 drugs since increasing solubility will have no effect and class 1 drugs are not subject to transporter inhibition. Since gastric emptying will be delayed after eating, however, these drugs may be more slowly absorbed, and t_{peak} may be later.

Class 2: When class 2 drugs are administered with a high-fat meal, the bioavailability will likely increase, while time to reach peak concentrations may shift in either direction.

High-fat meals may inhibit P-gp, resulting in increased bioavailability. As we discussed earlier, P-gp inhibition can also limit intestinal metabolism of BDDCS class 2 drugs. Therefore, by decreasing both efflux and metabolism, BDDCS class 2 drugs are likely to be more bioavailable when P-gp is inhibited. Additionally, fatty food and the release of bile acids can form micelles, promoting drug solubilization.

The time to reach a maximum concentration for a class 2 drug can be affected by a multitude of factors, and no single trend is predicted. By delaying gastric emptying, a high-fat meal can increase the amount of time it takes for the drug to be absorbed in the intestine, increasing t_{peak}. The time to reach a maximum concentration may also decrease due to the inhibition of efflux cycling by high-fat meals. Additionally, these processes may compete, causing no effective change in t_{peak}.

Class 3: High-fat meals, bile salts, and chemical components in food can inhibit intestinal uptake transporters, which class 3 drugs rely on to be absorbed. Patients taking a poorly permeable class 3 drug might experience decreased bioavailability and poor exposure when the drug is administered with a high-fat meal. Because their uptake is inhibited, the time to reach C_{max} may also increase. T_{peak} may also increase as a result of delayed gastric emptying after a high-fat meal.

Class 4: BDDCS class 4 drugs are very difficult to predict because of many interacting effects including increased solubility, increased gastric emptying time, and inhibited uptake. With so few class 4 drugs, it is difficult to predict a single trend.

4.06.4.5 Role in Predicting Distribution

Wu and Benet[67] observed that the volumes of distribution were somewhat higher in the highly permeable class 1 and 2 drugs compared with those for class 3 and 4 drugs.

Transporters can markedly affect the volume of distribution by concentrating drug in tissues. When certain major transporters in the liver or kidney are inhibited, Grover and Benet[101] noticed certain trends in distribution.

The liver has a primary effect on the volume of distribution. In peripheral tissues, altered transporter function may have a pharmacodynamic effect and the compound may be attenuated in tissues, but the calculated volume of distribution does not appear to change.

When hepatic uptake is inhibited, there is an increase in plasma concentration coupled with a decrease in hepatic distribution, leading to a decrease in volume of distribution. When hepatic efflux is inhibited, there is also a decrease in the volume of distribution (or is not predictable). Inhibition of hepatic basolateral efflux results in an increase in the volume of distribution.

However, when renal uptake is inhibited, there is generally no effect on the volume of distribution. When renal efflux is inhibited, the volume of distribution often increases. Grover and Benet hypothesize that the discrepancy between changes in volume of distribution due to inhibition of uptake in the liver versus the kidney is likely a result of the larger mass of the liver, coupled with increased capacity for transporter expression and drug sequestration.[101]

Finally, gut transporters will not have an effect on the volume of distribution because volume of distribution is a systemic parameter.

Since class 1 drugs have no clinically relevant transporter effects, we expect no changes in the volume of distribution of class 1 drugs when a transporter has increased or decreased function or expression. Alternatively, since uptake and efflux transporters can affect class 2, 3, and 4 drugs in the liver, we would expect changes to the volume of distribution as described in the preceding text.

4.06.4.5.1 Distribution into the brain

Distribution to various tissues can be predicted by the BDDCS. Specifically, we now understand the conditions necessary for central nervous system penetration. This is a particularly difficult problem during drug development of central nervous system

(CNS)-targeted drugs, as the brain is well protected from xenobiotics with tight junctions and high efflux transporter expression. Understanding and predicting brain penetration are also important to avoid central side effects for a peripherally acting drug. P-gp, BCRP, and various MRPs are expressed on the apical membrane of brain capillary endothelial cells, poised to extrude drugs that gain entry across its membrane. In development, substrate specificity for efflux transporters is a cue that the drug will be unable to successfully penetrate the brain. When the brain is the intended site of action, lipophilic compounds with a low polar surface area are expected to be available to the CNS.[129,130]

The brain is also a particularly concerning tissue for drug resistance. Some diseases, including some cancers and epilepsy, are resistant to drug penetration in the brain as a result of overexpressed P-gp or other efflux transporters. This overexpression is sometimes innate to the disease and sometimes acquired, potentially due to drug treatment. To overcome drug resistance, some scientists have proposed codosing with efflux inhibitors. Alternatively, dosing class 1 drugs may be a more thorough and facile approach when brain concentrations are desired.

Mahar Doan et al.[129] suggested that highly permeable, non-P-gp substrates were likely to cross the blood–brain barrier, while poorly permeable and P-gp substrates are less likely to cross the blood–brain barrier. While this holds true for a majority of compounds, an analysis by Wager et al. revealed that 20% of CNS drugs were both poorly permeable and P-gp substrates.[131] Broccatelli et al.[132] incorporated BDDCS classifications, correctly predicting the CNS distribution of >90% of their data set. Ninety-eight percent of class 1 drugs in their data set were able to cross the CNS, whether or not they were a substrate for P-gp. In fact, after correcting for a misclassified drug, all of the BDDCS class 1 P-gp substrates were able to distribute into the CNS.[77,132] Even when P-gp was able to partially efflux the drug, there was significant brain penetration. In contrast, 75% of P-gp substrates in classes 2, 3, and 4 were unable to traverse the blood–brain barrier. While presumably all of the class 1 drugs have CNS exposure, even if they are P-gp substrates, clearly, 25% of P-gp substrates in other classes were still able to access the brain, likely because they are good substrates for uptake transporters at the brain. While Broccatelli et al. only considered P-gp substrate specificity,[132] other efflux transporters such as BCRP are expressed at the blood–brain barrier and are responsible for extruding drugs. The same principles should apply to substrates of other efflux transporters. Based on these findings, each class is predicted to behave as follows:

Class 1: Transporter effects are minimal and drugs are expected to penetrate the CNS.
Class 2: Efflux transporters at the blood–brain barrier may affect class 2 drugs.
Class 3: Uptake transporters at the blood–brain barrier (OATP1A2 and OATP2B1) are required for brain penetration, while efflux transporters can extrude drugs from the brain.
Class 4: Uptake transporters at the blood–brain barrier are required for brain penetration, while efflux transporters can extrude drugs from the brain.

Therefore, when developing a drug with a CNS indication, a class 1 drug may be preferable for candidate selection, since it will penetrate, regardless of transporter affinity. Class 2 drugs may be developable as long as they are not substrates for efflux transporters. Class 3 and 4 drugs have more stringent requirements. For a class 3 or 4 drug to be effective as a CNS agent, it must be a substrate for an uptake transporter in the gut (if it is orally administered) and at the blood–brain barrier and should not be a substrate for efflux transporters at the blood–brain barrier.

Alternatively, when developing peripherally acting drugs, class 1 drugs may have potential CNS side effects, even if they are substrates for efflux transporters. Class 2 drugs may have central effects if they are not substrates of efflux transporters. To avoid central effects for class 3 and 4 drugs, it is best to avoid substrates of uptake transporters at the blood–brain barrier. Non-class 1 drugs will need to be evaluated as substrates of CNS-expressed transporters to predict brain penetration. In **Table 4**, we show the predicted effects of apical transporters on CNS exposure.

Table 4 Effect of apical transporters on central nervous system distribution

BDDCS class	*Apical uptake*	*Apical efflux*	*CNS exposure*
Class 1	No effect	No effect	Yes
Class 2	• May be necessary for some class 2 drugs to penetrate the brain • Inhibition may lead to decreased CNS exposure	• May decrease CNS exposure • Inhibition may lead to increased CNS exposure	If a nonsubstrate for efflux and may possibly require an uptake transporter
Class 3	• Required for CNS exposure • Inhibition will lead to decreased CNS exposure	• Will prevent exposure to the CNS • Inhibition may lead to increased CNS exposure	If a substrate for an uptake transporter and a nonsubstrate for an efflux transporter
Class 4	• Required for CNS exposure • Inhibition will lead to decreased CNS exposure	• Will prevent exposure to the CNS • Inhibition may lead to increased CNS exposure	If a substrate for an uptake transporter and a nonsubstrate for an efflux transporter

4.06.4.5.2 Potential extensions to other membranes

While distribution and transporters regulating distribution outside of the gut, liver, and brain have not been analyzed with respect to BDDCS dispositional predictions, we expect that most internal tissues (composed of tightly regulated endothelial cells) will behave in a similar manner to the liver and brain and not like the epithelial-based gut. Therefore, we expect that class 1 drugs will distribute to a tissue regardless of transporter function, while class 2 drugs may be affected by the function of uptake transporters regulating drug entry and may have less tissue penetration if they are a substrate of a relevant efflux transporter. Class 3 and 4 drugs will almost certainly require active transport into the tissue, and their distribution will be significantly impacted by efflux transporters expressed in the tissue. For class 1 drugs, there may be some concern about undesired distribution to off-target organs. Scientists can potentially use this information to aid in drug delivery to target tissues, including the heart and skeletal muscles. Distribution across the placenta could also potentially be predicted, which may be advantageous because its distribution cannot be studied for ethical reasons.

4.06.4.5.2.1 Distribution to the kidney

As discussed earlier, renal elimination is a combination of passive filtration processes, reabsorption, and active secretion. Reabsorption is primarily passive, and the vast majority of water and solutes are reabsorbed along the tubule, resulting in only 1 mL of urine production every minute. There are transporters responsible for active reabsorption expressed primarily in the proximal tubule, however. While a number of secretory transporters are expressed along the proximal tubule, OAT1, OAT3, and OCT2 are currently considered the most clinically significant, and the FDA recommends studying renally eliminated drugs for interactions with these transporters.[8] All drugs should be evaluated as substrates of P-gp, as well. However, the ITC lists a number of renal transporters that they consider important to evaluate during drug development, including the bidirectional transporters ENT2, expressed on the basolateral membrane, and ENT1, OCTN1, and OAT4, expressed on the apical membrane. Secretory transporters including OAT2 and OATP4C1, which are expressed on the basolateral membrane, and MATE1, MATE2-K, MATE2, MRP2, and MRP4, all of which are expressed on the apical membrane, are considered relevant by the ITC. They also include the absorptive transporter URAT1, which is expressed on the apical membrane.

Class 1 and 2 drugs are likely to be reabsorbed from the tubule, as we have discussed. We expect that class 2 drugs may interact with basolateral uptake and apical efflux transporters, similar to hepatic predictions. We expect that uptake and efflux transport will be required to contribute to net secretion of class 3 and 4 compounds. However, renal elimination can also be completely passive, and class 3 and 4 compounds are not necessarily substrates of renal transporters even if they are eliminated as unchanged drug in the urine.

4.06.4.5.2.2 Renal impairment

Chronic kidney disease (CKD) is a serious condition, affecting more than 10% of adults in the United States.[133] Since the kidney eliminates many drugs and metabolites, impaired renal function can also seriously decrease renal clearance of these drugs, mandating dose adjustments in patients. One may understandably, but mistakenly, conclude that renal dysfunction should only affect renally eliminated drugs. In fact, metabolism can be dangerously altered in CKD patients, particularly as disease progresses. When the kidneys begin to lose their function, endogenous compounds that are eliminated by the kidneys in healthy people can accumulate to toxic concentrations. These compounds are called uremic toxins. Initially, it was hypothesized that uremic toxins inhibited metabolizing enzymes. Investigations showed that uremic toxins inhibited some, but not all, CYP metabolizing enzymes.[134–139] As it became clear that drug transporters also played a role in controlling drug access to metabolizing enzymes, Reyes and Benet questioned if perhaps uremic toxins could also inhibit transporters, potentially reducing metabolic clearance in vivo.[76] They concluded that uremic toxins could inhibit uptake transporters in hepatocytes. Since the disposition of a class 1 drug is unlikely to be affected by drug transporters, they tested whether uremic toxins inhibited hepatic exposure of propranolol, a class 1 drug. While uremic toxins did not inhibit the uptake of propranolol, some uremic toxins did inhibit the uptake of losartan, a class 2 drug, and eprosartan, a class 4 drug.

In this study, uremic toxins were unable to inhibit phase I metabolism when human uremic serum was incubated with microsomes dosed with propranolol or losartan, both of which are extensively metabolized.[76]

Given previous evidence, it would be unwise to suggest that metabolizing enzymes are not inhibited by uremic toxins. Therefore, decreased metabolism may be observed for class 1 and 2 drugs taken by patients with CKD. Alternatively, uptake transporters are likely inhibited by uremic toxins, which may decrease the metabolism of class 2 drugs and decrease hepatic clearance of class 3 and 4 drugs. All drugs should be tested for increased parent drug exposure, though the mechanism of inhibition will differ between classes.

This is a critical prediction that may (a) increase the safety of drugs in end stage renal disease (ESRD) patients, many of whom require several drugs, and (b) ease the developmental burden. The FDA now recommends that most new molecular entities be evaluated in ESRD patients, excepting drugs predominantly cleared by the lungs, monoclonal antibodies, and drugs intended for single-dose administration.[140] However, generating these studies and recruiting patients are difficult, costly, and variable. Applying BDDCS concepts to pharmacokinetic studies in renal disease may help prioritize what studies are necessary and help understand if clinicians should be concerned about inhibition of transporters, metabolizing enzymes, or both in administering one or multiple drugs.

The BDDCS provides many valuable predictions that can be useful in guiding drug development decisions. It currently relies on the extent of metabolism, which cannot be assessed until phase I studies and solubility studies. It would be extremely useful to have accurate high-throughput methods to predict BDDCS class prior to phase I trials.

4.06.4.6 Predicting BDDCS Class

4.06.4.6.1 In vitro

Based on the recognition of the ability of membrane permeability rate to differentiate extensively versus poorly metabolized compounds in the development of the BDDCS, Varma et al.[141] have confirmed that BDDCS class can be predicted well using in vitro apparent permeability rate as measured in MDCK-LE (low efflux) cells at pH 6.5 for acids and pH 7.4 for bases and solubility measured at pH 1.2 in PBS for acidic compounds and in FaSSIF for all other compounds. They used an internally developed permeability rate cutoff of 5×10^{-6} cm s^{-1}, above which compounds were predicted to be extensively metabolized and below which compounds were predicted as poorly metabolized. Dose strength is generally determined during phase II and III clinical trials. This makes it difficult to accurately predict the dose number of a drug. This group proposed a solubility cutoff of 200 μg mL^{-1}, which corresponds to a 50 mg dose being entirely soluble in 250 mL of water. This approach correctly predicted 84% of the compounds in their data set, specifically 83%, 83%, 88%, and 67% of class 1, 2, 3, and 4 drugs, respectively. Additionally, over 90% of the drugs predicted as class 1 or class 2 actually belonged to those classes, and over 80% of the drugs predicted to be class 3 were actually class 3, while 40% of the drugs predicted to be class 4 actually were class 4. Due to the small number of drugs that actually are class 4 and that are predicted to be class 4, the poor class 4 results should not dissuade the reader from realizing how well this in vitro approach predicted BDDCS class.

4.06.4.6.2 In silico

To ease the time and cost of these predictions during development, an in silico approach is preferable. There have been at least two attempts to predict BDDCS class in silico. In 2007, Khandelwal et al.[142] developed models using machine learning methods including recursive partitioning, random forest, and support vector machines. They used molecular features to assign drugs to one of the four BDDCS classes, predicting 33.3% correctly overall. In 2012, using the extended data set published by Benet et al.,[71] Broccatelli et al.[143] used a binary approach to predict the solubility and the extent of metabolism of the drugs before making a class prediction. Solubility was predicted using naive Bayes, k-nearest neighbor, and support vector machine models, where the solubility class was assigned using a consensus model, which predicted the class based on how it was predicted in a majority of the models. This model was 77% accurate. The extent of metabolism was predicted from a consensus model of a naive Bayes and two support vector machine models. This model was 79% accurate. When combining the solubility and extent of metabolism models to predict BDDCS class, however, this approach was only 55% accurate.

There are currently other efforts ongoing to improve in silico BDDCS class predictions. However, at this time, in vitro approaches provide more accurate predictions.

4.06.5 Conclusions

Predicting drug disposition is often difficult since there are many variables at play, which we do not yet fully understand. While quantitative predictive approaches from in vitro and in vivo models serve a crucial role in drug development, qualitative classification approaches such as the Biopharmaceutics Classification System and the BDDCS can help predict when such in vitro and in vivo studies may provide useful and interpretable results. These systems can potentially reduce both time and cost of drug development, which is ideal for both developers and consumers.

The BCS has been successfully implemented to grant biowaivers to at least 41 drugs,[144] reducing time and costs, which can potentially be passed down to consumers.

The BDDCS makes a broad range of current and potential dispositional predictions. This system can be useful for drugs already on the market to predict potential transporter or metabolizing enzyme effects that were not tested during development, thereby ensuring that these drugs remain safe and efficacious. These predictions can also help guide the development of new drugs, where a complete understanding of transporters and enzymes is required. This system predicts when metabolizing enzymes and transporters will be important in the absorption, metabolism, and elimination of drugs and currently helps us understand where transporters are relevant in the distribution of drugs to the central nervous system, with potential applications to other organs such as the heart, kidneys, and placenta. In this way, important transporters and enzymes will certainly be evaluated during development, whereas transporters or enzymes that are predicted to be clinically irrelevant may be safely dismissed. This can help speed up the process of development and reduce unnecessary costs. The BDDCS has also been used to help understand disposition in special states, such as kidney failure, and is currently being investigated for its predictive utility in toxicology.

We know of no class 1 drugs for which a dose adjustment has been required due to a transporter alteration as a result of drug–drug interactions, food, endogenous substrates, or pharmacogenomics, among other possible alterations. Drug development is trending toward larger, more lipophilic, and less soluble drugs. Therefore, BDDCS class 2 drugs are rapidly becoming the most important class. While these drugs will likely have improved potency, we might also expect more dispositional issues since they

can be affected by both metabolizing enzymes and transporters. Finally, class 3 and 4 drugs are not significant substrates of metabolizing enzymes, but are substrates of many transporters and require transporter investigation.

4.07.1 Introduction

The discovery and development of any new drug is a long, complex, and expensive process with an uncertain outcome. Before reaching the market, drug candidates need to go through the conventional sequence of processes involved in drug discovery and development. This results in the identification of lead series of compounds and chemical optimization leading to candidate selection and then entry into development, including preclinical investigations to evaluate safety followed by clinical evaluations (usually considered in three phases I, II, and III). Currently, the typical development for investigational new drugs takes between 10 and 15 years and is associated with high costs and low rate of approval.[1,2] During discovery and development, the candidate drug has to pass through a series of stages (often referred to as tollgates), in terms of measurable objectives for efficacy and safety, which can enable decisions to be made on further investment, and once in development to gain approval from regulatory authorities such as the Food and Drug Administration (FDA) and European Agency for the Evaluation of Medicinal Products (EMEA), to move from one stage to another and finally gain marketing approval. It has been estimated that a compound entering clinical phase I testing has less than a 10% chance of reaching the market, and for some research areas, the limit can be even lower.[3] The rather low success rate may be due to a number of reasons including the lack of predictive preclinical models and sometimes inadequate and complex clinical trial designs. About 40% of compounds approved for entry into phase I trials do not progress further as a result of inappropriate pharmacokinetics (PK) of the test compound.[4–6] Other drug candidates fail in clinical testing because they do not behave pharmacologically as predicted from the preclinical animal studies used today or exhibit toxicity that was not anticipated based on the same preclinical safety studies.

It can then be summarized that a successful preclinical development program is of great importance when determining if the candidate drug is reasonably safe for initial testing in humans. The preclinical development program consists of a battery of in vitro and in vivo assays with the aim of accurately predicting PK, metabolism, efficacy, and safety in man. Of course, one can expect variability in drug PK and metabolism due to species differences, but good prediction of these properties represents vital factors in defining drug efficacy and side effects, and thus, there is an urgent need to obtain more informative experimental data predicting clinical outcomes. The use of traditional animal models is one of the key areas in the preclinical development of new drugs, and the companies developing drugs have relied on these "traditional" in vivo models for decades. These in vivo experiments are of great

importance and, in combination with, human in vitro data are used for predicting the PK and metabolic behavior of new compounds. The aim of the preclinical program is not only to ensure that a drug does not expose humans to unreasonable risks when used in limited, early-stage, clinical phase I studies but also to select a successful drug that does not fail in the later clinical phases.

The overall pathways of drug metabolism and disposition are highly conserved between species including xenobiotic receptors, biotransformation enzymes, and transporters. However, species differ with regard to isoform expression, catalytic activities, and mode of regulation of drug-metabolizing enzymes. The result is that the substrate specificity and amounts of the individual proteins mediating these processes can vary quite significantly between animals and man. Thus, the prediction of human drug metabolism and disposition by extrapolation from the results obtained using in vivo studies in traditional preclinical animal models is often limited and does not always faithfully predict or model what is observed in the clinic.[7–9] Investigators performing adsorption, distribution, metabolism, and excretion (ADME) studies have been aware of such species differences for almost as long as DMPK has been identified as a discipline and they have now been described for all the major components of the process of drug metabolism and disposition, that is, xenobiotic receptors,[10] oxidoreductases such as the cytochromes P450s,[8,11] conjugative enzymes,[12] and transporters.[13]

There are several approaches available to minimize the impact of the discrepancies between species, especially in the case of rodents, and the most frequently employed involves the use of the recently developed genetically modified humanized mouse models, which are now available on the market. One way to reduce the drug metabolism differences between mouse and human is to replace single or multiple mouse genes with their human counterparts. A great variety of such genetically humanized mouse models, expressing human instead of mouse receptors, drug-metabolizing enzymes, and transporters, have been described.[14,15] An alternative approach to overcome the boundaries associated with the traditional animal models is based on the central role of the liver as the major drug-metabolizing and detoxification organ for most drugs and xenobiotics. In this "chimeric" mouse model, the mouse liver is repopulated in vivo with human hepatocytes. Differently derived chimeric liver-humanized mouse models with human hepatocytes engrafted in their livers have been created.[16–19] Under optimal conditions, up to 95% of the hepatocytes in the mouse liver can be human. In the cases of both genetically humanized and chimeric liver-humanized mouse models, there are now numerous literature examples (see in the succeeding text) where their application has been shown to add value in drug/xenobiotic metabolism and toxicity studies.

The current literature describing both the genetically modified and the chimeric liver-humanized mouse models reveals that they are derived in two fundamentally different ways: In the genetically modified models, human genes are introduced into the mouse genome in order to generate genetically humanized mice, thereby expressing specific human genes on a mouse background. In the second "chimeric" model, human cells are transplanted into competent recipients resulting in tissue-humanized mouse models that may contain in excess of 95% human cells but with a residual unmodified mouse component amounting to 5% or more. While these two approaches are the focus of this article, two additional, nonhumanized models will be described that can aid in determining the role of cytochrome P450s in the gut and/or in the liver,[20,21] which provide additional powerful tools for the selection of the most appropriate humanized mouse model. These models both involve conditional deletion of P450 oxidoreductase (POR), either genetically in the liver through the expression of Cre recombinase driven by the albumin promoter hepatic reductase null (HRN) or chemically in the liver or liver and gut by induction of Cre expression driven by the Cyp1a1 promoter endogenous reductase locus (ERL).

As indicated earlier, the genetically humanized and chimeric liver-humanized mice have been used for a range of applications including components of the immune and hematopoietic system, as models for human aneuploidy and to reflect human diseases and for drug efficacy testing, for cancer research, and to enable infections with human pathogens.[22] In a similar manner, chimeric liver-humanized mice have been used to study human hematopoiesis, immune responses, autoimmunity, infectious diseases, cancer, and regenerative medicine.[23] Two disease areas where this second model has been particularly valuable are in studies on malaria and hepatitis B.[24,25] In addition, from being used as a model system in drug development, this model has also been used successfully in anti-doping research to define routes and rates by which different nutritional supplements are metabolized and excreted.[26–28]

Genetically humanized mice for proteins involved in drug metabolism and toxicity and mice engrafted with human hepatocytes provide powerful in vivo models for improving the prediction of PK, drug–drug interactions (DDI), and safety characteristics of compounds in humans. Certain of the models available at this time are not fully validated and accepted by the regulatory authorities as suitable for use on a regular basis; however, their potential to contribute to drug regulatory processes is being actively discussed. Although knockout models, where mouse genes have been deleted, are not humanized, they allow the murine enzymes involved in drug disposition to be defined. This is of central importance in the interpretation of data obtained using the humanized models. They also play an important role for gaining understanding of the different functions of certain proteins or functions of an organ, in relation to a dosed drug. As with all models, it is important to be aware that there are specific advantages and disadvantages inherent in each of these models and that these should be understood and taken into account in the interpretation of experimental data. In this article, similarities and differences between genetically modified and chimeric liver-humanized mouse models will be defined, and the most studied genetically modified varieties of these models will be described. How the most appropriate model can be selected for a particular pharmacological or toxicological question and the relative strengths and weaknesses of the two models systems will be described.

4.07.2 Genetically Humanized Mouse Models for Xenobiotic Receptors, Drug-Metabolizing Enzymes, and Transporters

In this section, the replacement of single or multiple mouse genes with their human counterparts is described as one way to reduce the differences in drug disposition between mouse and man. Such genetic modifications are transmitted through the germline and are present in all cells of the animal. This distinguishes these models from the chimeric mice discussed later in this article where the liver is the target organ for humanization.

The proteins involved in the different pathways of drug metabolism and disposition can be divided into three groups: receptors, drug-metabolizing enzymes, and transporters. These categories have also been targets for genetic modification in order to gain an increased understanding of the impact a certain protein has on the role in the metabolism, PK, and safety of drugs as an attempt to make the characterization of a drug more predictive for humans. The result of this is the generation of a large number of transgenic mice, grouped with respect to xenobiotic receptors and drug metabolism enzymes either responsible for the functionalization of drugs (the so-called phase I metabolism) or involved in conjugation reactions (the so-called phase II metabolism), transporter enzymes, and composite models of these (Fig. 1). The methods applied by the different research groups to generate these mice have varied significantly and included random insertions of human transgenes, freely segregating mouse or human artificial chromosomes (MACs or HACs) or targeted integrations at defined gene loci. These approaches have often been combined with deletions of the orthologous murine genes. The human transgenes have been expressed off heterologous promoters, the corresponding mouse promoters, or the human promoter of that gene.[14,22]

4.07.2.1 Genetic Modifications of Xenobiotic Receptors

As is well known, drugs and environmental chemicals may cause induction of both drug-metabolizing enzymes and transporters. Three nuclear receptors, pregnane X receptor (PXR), constitutive androstane receptor (CAR), and peroxisome proliferator-activated receptor alpha (PPARα), and the Per-Sim-ARNT domain receptor aryl hydrocarbon receptor (AHR) play a major role in this adaptive response.[29] Mice humanized for all of these receptors have been described.[14] These receptors interact with a vast array of drugs and xenobiotics to regulate the expression of some of the most important drug-metabolizing enzymes and transporters (Table 1). Receptor activation may accelerate not only the metabolism of the drug itself but also that of other drugs given concomitantly. This can result in adverse effects including DDI, loss of efficacy or increased toxicity. It is therefore essential to evaluate whether a drug has the capability to interact with these receptors at therapeutically relevant doses. Today, possible drug–receptor interactions are routinely tested using in vitro methodologies, which have merit in that they are cost-effective and partially scalable to high-throughput screening. However, in the end, there is generally need for the evaluation of these predictions of induction/DDI in vivo, while the in vitro models have made significant progress over the years, there remain some limitations.[30]

For example, a more informative in vitro CAR transactivation assay is required as, because of their high constitutive activity, indirect CAR activators such as phenobarbital do not work, and the potential role of CAR splice variants in CAR activation is not routinely determined. There is also a limitation in the extrapolation of in vitro assays to the more complex in vivo situation. Indeed, issues surrounding in vitro/in vivo correlation (IVIVC) have been the subject of much debate and arise from the fact that the complexities of tissue distribution, free drug fraction, etc. are not taken into account in the in vitro assays. The humanized

receptor animal models, to a significant degree, bridge this gap. The DNA-binding domain of the receptors is usually highly conserved and the species differences in the activation of these receptors by drugs relate to sequence variability in the ligand-binding domains.[31] Applications of receptor-humanized mouse models and examples of their use are provided in Section "Examples of studies using receptor-humanized mice."

4.07.2.1.1 Examples of studies using receptor-humanized mice

The utility of the receptor-humanized mice has been demonstrated by a number of research groups by studying two potent mouse PXR activators (pregnenolone-16α-carbonitrile and dexamethasone) and rifampicin, which is a more selective human PXR activator. The first two compounds induce the expression of PXR-regulated downstream genes in wild-type (WT) mice but not in PXR-humanized mice, whereas the opposite was observed for rifampicin.[32–36] A number of compounds have been reported to activate CAR and its downstream genes in a species-specific manner. For example, the potent mouse CAR activator 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene (TCPOBOP) showed profound induction of the downstream genes in WT animals but to a much lesser extent in humanized CAR mice.[35] The corresponding compound for activating human CAR, 6-(4-chlorophenyl)imidazo-[2,1-b][1,3]thiazole-5-carbaldehyde O-(3,4-dichlorobenzyl)oxime (CITCO), only showed elevated levels of CAR-activated genes in the humanized CAR mouse.[35] In contrast, phenobarbital induced a CAR signature in both WT- and CAR-humanized mice.[35]

Studies have also been performed using the AHR-humanized mouse model where induction of Cyp1a1 and Cyp1a2 genes by 2,3,7,8-tetrachlorodibenzop-dioxin (TCDD) and 3-methylcholanthrene was reported to be much more profound in WT controls compared with AHR-humanized mice.[37] This is in accordance with the fact that the mouse receptor has a higher binding affinity for these compounds than human AHR.[37] In addition, indirubin, a compound with higher affinity for the human receptor, was a more potent Cyp1a1 inducer in the AHR-humanized mouse hepatocytes than in WT samples.[38]

4.07.2.2 Functionalization (Phase I) and Conjugative (Phase II) Drug-Metabolizing Enzymes

Drug-metabolizing enzymes play a pivotal role in the bioavailability and clearance of a vast range of compounds and their metabolites consistent with their evolutionary role in detoxifying potentially harmful xenobiotics. It is widely accepted that the primary organ for metabolism is the liver, and this has led to the use of, for example, hepatocytes and hepatic microsomes as primary screens for metabolism in drug discovery and development. However, as discussed earlier, drug-metabolizing enzymes are also expressed in other organs such as the intestine, kidney, and lung.[39,40] These enzymes introduce new functional groups into xenobiotics via a range of oxidations, reduction or hydrolytic reactions, and the conjugation of suitable functional groups (preexisting or introduced) to endogenous molecules. The bulk of the oxidative reactions that introduce a functional group, such as a hydroxyl moiety onto the target molecule, are catalyzed by the super family of CYP enzymes. In addition to the CYP enzymes, which mediate approximately 75% of oxidative and reductive "functionalization" reactions in humans,[41,42] other enzymes such as the flavin-containing monooxygenases, monoamine oxidases, esterases, and amidases can also play a role in detoxification. Metabolites generated by these enzymes may either be eliminated directly from the body, undergo additional functionalization, or be subject to further biotransformation via conjugation to a range of polar endogenous substrates (most commonly, for example, sulfate and glucuronide but also including acetylation and conjugation to amino acids and glutathione). One major difference in the outcome of functionalization and conjugative metabolism is that the former can result in the production of active metabolites, while the second reaction produces metabolites that are (usually) less active than their substrates.[43] Conjugative metabolism, which can also occur directly on the parent drug itself if a suitable functional group is already present, in addition to providing a reduction in pharmacological/toxicological potency, also (usually) serves to increase the polarity of the xenobiotic/functionalized metabolite, which may aid elimination in urine or bile. Drug conjugation is catalyzed by a large

group of transferases, including the sulfotransferases (SULTs), UDP-glucuronosyltransferases (UGTs), glutathione S-transferases (GSTs), N-acetyltransferases (NATs), or amino acid transferases. It is important to note when looking at species differences in drug disposition that, following P450 reactions, glucuronidation by UGTs accounts for the largest proportion of drug metabolism in humans.[44] There are some major contributors to all UGT reactions with UGT2B7 being the most important (35%), followed by UGT1A4 (20%) and UGT1A1 (15%).[44]

4.07.2.2.1 Functionalization by cytochrome P450 enzymes: species differences

The CYP enzyme family is one of the most conserved across species and appears to have evolved from a single ancestral gene that originated more than 1 billion years ago.[7] Although there are highly conserved amino acid regions in P450s, there is great sequence and structural diversity between individual CYPs and between orthologous CYPs across species. These differences in amino acid sequences can give rise to profound differences in substrate specificity and catalytic activity. Furthermore, significant differences in the multiplicity and regulation of expression of CYPs also exist between species, and these differences are the major causes of the disparity in biotransformation between animals and human.[7] **Table 2** provides an overview of the similarities and differences in the number of major CYPs involved in drug metabolism in humans and the most commonly used preclinical animal species. However, even enzymes that are apparently conserved, according to this table, can show significant differences at a functional level. For example, while CYP1A1, CYP1A2, and CYP1B1 are present in human, mouse, rat, dog, and monkey with a $>80\%$ amino acid identity compared with human, the level and organ specificity of expression and the metabolic activity differ between species.[8,45,46] Thus, significant species differences in the interaction of compounds with drug-metabolizing enzymes sometimes limit the use of animal models to accurately predict human responses. Unforeseen DDIs can also result in adverse responses, life-threatening toxicity, or impaired efficacy. In order to overcome the limitation of traditional animal models in accurately predicting human responses, a large range of mouse models humanized for drug-metabolizing enzymes have been created (**Fig. 1**). Although such humanized mouse models have certain limitations (as further discussed later in this article), there is great potential for their use in basic research and in the testing and development of new medicines. As noted earlier, oxidative drug metabolism in humans mediated by cytochrome P450 enzymes is estimated to account for 75% of the total, and the bulk of this is performed by only 5 of the 57 human P450s (CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4).[41] The following section will highlight cases where mice expressing these human CYPs have been used.

4.07.2.2.2 Examples of studies using CYP P450-humanized mice

In recent years, a large number of CYP P450-humanized mice have been created. These models have application in studying the drug PK, DDI potential, and safety testing of compounds in drug discovery and development and for basic research into the function and QSAR of these enzymes. These models also have the potential to improve the prediction of PK/PD (pharmacodynamic) relationships and in the development of new in silico algorithms for extrapolation to human.

Most work using these models has been with CYP3A4-humanized mice. In the first reports of CYP3A4 transgenic models, the gene had been randomly introduced into the mouse genome without deletion of the mouse Cyp3a genes.[47] This resulted in intestinal, but not hepatic CYP3A4 expression in adult males. The CYP3A4 substrate, midazolam, when orally dosed to these mice and to WT mice was found to have significantly decreased Cmax, area under the curve (AUC) and bioavailability in the CYP3A4 transgenic mice. In addition, it was found that the PK profiles obtained for midazolam after intravenous administration were unchanged compared with the WT mice providing good evidence for the importance of the role of intestinal CYP3A4 in the first-pass metabolism of this compound.

Several other mouse models humanized for CYP3A4 have subsequently been developed; these include a model with liver-specific expression of CYP3A4 with or without deletion of the mouse Cyp3a gene cluster and a mouse line in which the Cyp3a gene cluster has been deleted and replaced with CYP3A4 and CYP3A7.[47–51] In a model where the mouse Cyp3a genes were not deleted, the AUCs of intravenously administered midazolam and cyclosporine A were significantly decreased compared with WT mice.[49,50] In addition, models with either selective gut CYP3A4 expression using an intestinal promoter or a combined model with both intestinal and hepatic CYP3A4 expression have also been generated.[50] The benefit of these models is that they allowed the relative contribution of hepatic and intestinal CYP3A4 to the pharmacokinetic profiles of the test compounds to be determined. In these studies, it was shown that intestinal rather than hepatic CYP3A4 expression decreased the circulating concentration of the chemotherapeutic agent docetaxel after oral administration, while hepatic expression largely accounted for the systemic clearance of intravenously administered drug.[50] This model has also been used to demonstrate that intestinal, but not hepatic, CYP3A4-related first-pass metabolism primarily determined the systemic exposure of triazolam or lopinavir following oral administration.[52,53] The model seems very promising in predicting a clinical outcome, based on the compounds studied; however, potential compensatory changes in murine cytochrome P450 expression need to be taken into account when using these mice.[54] For example, a significantly increased level of expression of mouse Cyp2c enzymes, which have midazolam hydroxylase activity, and compensatory effects in other genes involved in drug metabolism and disposition were identified in the Cyp3a knockout mice. These effects on the levels of CYPs in the knockout mouse were, however, reversed when human CYP3A4 was expressed in either the liver or intestine.[55] Thus, for some substrates, changes in PK may be masked in the knockout model by compensating changes in other metabolizing enzymes or transporters. For this reason, it is important to use the gene cluster KO models as a control in these experiments. Also, it should be noted that CYP3A4 expression in these models was driven off heterologous promoters. This can lead to unphysiologically high levels of expression, which could confound data interpretation.

Table 2 Major drug-metabolizing CYP families in human, rat, mouse, dog, and monkey[8]

Family	*Subfamily*	*Human*	*Mouse*	*Rat*	*Dog*	*Monkey*
CYP1	A	1A1, 1A2	1A1, 1A2	1A1, 1A2	1A1, 1A2	1A1, 1A2
	B	1B1	1B1	1B1	1B1	1B1
CYP2	A	2A6, 2A7, 2A13	2A6, 2A5, 2A12, 2A22	2A1, 2A2, 2A3	2A13, 2A25	2A23, 2A24
	B	2B6, 2B7	2B9, 2B10	2B1, 2B2, 2B3	2B11	2B17
	C	2C8, 2C9, 2C18, 2C19	2C29, 2C37, 2C38, 2C39, 2C40, 2C44, 2C50, 2C54, 2C55	2C6, 2C7, 2C11, 2C12, 2C13, 2C22, 2C23	2C21, 2C41	2C20, 2C43
	D	2D6, 2D7, 2D8	2D9, 2D10, 2D11, 2D12, 2D13, 2D22, 2D26, 2D34, 2D40	2D1, 2D2, 2D3, 2D4, 2D5, 2D18	2D15	2D17, 2D19, 2D29, 2D30
	E	2E1	2E1	2E1	2E1	2E1
CYP3	A	3A4, 3A5, 3A7, 3A43	3A11, 3A13, 3A16, 3A25, 3A41, 3A44	3A1/3A23, 3A2, 3A9, 3A18, 3A62	3A12, 3A26	3A8

This table is published with permission and originates from Martignoni, M.; Groothuis, G. M.; de Kanter, R. Species differences between mouse, rat, dog, monkey and human CYP-mediated drug metabolism, inhibition and induction. *Expert Opin Drug Metab Toxicol.* **2006**, *2*(6), 875–894.

Hasegawa et al.[56] used a humanized CYP3A4/3A7 model, lacking murine Cyp3a genes and also humanized for both CAR and PXR, to rank a range of PXR activators according to their potency to induce CYP3A4 expression in human liver, thus allowing a prediction of DDIs mediated by PXR/CYP3A4. Macleod et al.,[57] using the same model, investigated the role of the PXR/CYP3A4 axis in the disposition of the BRAF inhibitor vemurafenib. Vemurafenib activated PXR at clinically relevant concentrations, and while its disposition was more markedly affected through the regulation of efflux transporters than by CYP3A4 metabolism, there was a case for therapeutic monitoring in patients receiving concomitant medication, which might affect systemic drug levels and affect the outcome of vemurafenib therapy. The CAR/PXR/CYP3A4/3A7 model has also been used to study the role of the human enzyme in the disposition of the anticancer drugs.[58]

The PK of theophylline, predominantly metabolized by CYP1A2, has been investigated in a CYP1A1/1A2-humanized mouse model where the mouse Cyp1a2 gene had been knocked out. The systemic clearance of theophylline in the CYP1A1/1A2-humanized mouse was found to be significantly higher compared with the corresponding Cyp1a2 knockout line.[59] In contrast, oral administration of the polycyclic aromatic hydrocarbon benzo[*a*]pyrene resulted in high exposure in Cyp1a1 and Cyp1a1/1a2 knockout animals, but not in either WT, Cyp1a2 knockout, or CYP1A1/1A2-humanized mice lacking the mouse Cyp1a1/1a2 genes.[60] These results demonstrated the important role of human CYP1A2 in the metabolism of theophylline but not benzo[*a*]pyrene.

Validation of the CYP2A6-humanized mice was performed using the probe compound coumarin. The predicted role of CYP2A6 as the major coumarin hydroxylase in human liver was confirmed as clearance was significantly faster in the transgenic mice with hepatic expression of human CYP2A6 compared with WT controls.[61]

Tolbutamide is a CYP2C9 substrate, and its PK has been studied in WT, Cyp2c knockouts, and CYP2C9-humanized mice on a mouse Cyp2c cluster knockout background. The results showed lower plasma concentrations and AUCs in the WT and humanized mice relative to the knockout animals. These data correlated well with the in vitro results, which confirmed the in vivo contribution of the mouse Cyp2c enzymes and human CYP2C9 in the metabolism and disposition of this substrate.[62]

Debrisoquine is a well-known CYP2D6 probe substrate and has been used as a model compound for CYP-mediated biotransformation in humans and in investigations in both transgenic CYP2D6-humanized mice and chimeric liver-humanized mice (described later). Two different transgenic CYP2D6-humanized mouse models have been described. One carried the CYP2D6 transgene without deletion of the mouse Cyp2d gene cluster.[63] In the other model, the nine genes in the mouse Cyp2d gene cluster were replaced with the human CYP2D6 construct.[64] The systemic clearance of debrisoquine was significantly increased in both humanized models compared with WT controls.[63,64] This result demonstrated a clear species difference between the mouse Cyp2d enzymes and human CYP2D6 in the metabolism of debrisoquine. Evidence in support of this conclusion was the observation that there was no major difference in debrisoquine disposition between WT mice and a Cyp2d gene cluster knockout.[65] While these results confirmed the comparatively low catalytic activity of mouse Cyp2d enzymes toward debrisoquine, the clearance of bufuralol was found to be more rapid in WT compared with CYP2D6-humanized mice, an observation also seen in vitro.[65]

These published examples can be summarized as providing strong evidence that genetically humanized mouse models have significant potential in assessing the role of individual human CYPs in drug metabolism. It is important to note that in many of the humanized mouse lines, the human P450 genes are driven off their endogenous promoter and that they are also on a humanized CAR/PXR background. This allows studies to establish how variability in the expression of these genes affects drug PK and where there is an animal model available, drug efficacy. Also, mice have been made carrying humanizations involving multiple P450s and where the cognate mouse gene clusters have been deleted; for example, Scheer et al.[66] reported a multiple humanized mouse model in which 31 genes from the Cyp2c, Cyp2d, and Cyp3a gene clusters have been deleted and replaced with CYP2C9, CYP2D6, and CYP3A4/3A7, along with humanization for CAR and PXR.[66] These models simplify the interpretation of pharmacokinetic data and negate the need to use multiple individual humanized models if a drug is metabolized by multiple enzymes as is often the case.

4.07.2.2.3 Conjugation enzymes: species differences

Humanizations for the enzymes involved in drug conjugation have received much less attention relative to the P450s. Most of the focus has been on UGT-humanized mice due to the fact that glucuronidation accounts for the largest proportion of conjugation reactions in humans.[44] Within the UGT family, UGT2B7 is the major contributor to all glucuronidations (35%), followed by members of the UGT1A family, such as UGT1A4 (20%) and UGT1A1 (15%).[44] Even though a large number of drugs and their metabolites undergo glucuronidation and the fact that the UGT metabolism in the intestine has been reported to influence the PK of drugs, information concerning the differences in isoforms and their activities between species is limited.

The mRNA expression of 10 UGT isoforms in the intestine of humans and a number of preclinical animal models has been reported, and some of the UGT isoforms are selectively expressed by different species.[67–69] In the human intestine, UGT1A8 and UGT1A10 are selectively expressed,[68] whereas UGT1A2 and UGT1A7 were identified in rats[69] and UGT1A8 in monkeys.[70] However, different expression levels of these UGT isoforms among species may affect intestinal glucuronidation activity, and importantly, mRNA expression for UGTs might not reflect the actual levels of transcribed protein in the intestine and therefore its glucuronidation capacity.

4.07.2.2.4 Examples of studies using UGT- and NAT-humanized mice

The number of humanized mouse models where the UGTs have been humanized is few compared with the range of P450-humanized mice available (Fig. 1), and perhaps as a consequence, there are few reports of studies where UGT-humanized animal models have been utilized. Despite this, the role of UGTs and other conjugation systems remains an important area for

investigation. Caution may be needed when extrapolating PK data from laboratory animals to humans due to differences between isoforms and levels of enzymes expressed between different species. Even though the in vitro intrinsic clearance (CLint and UGT) in intestinal microsomes seems to provide a good correlation between humans and laboratory animals, values tended to be lower in humans than in preclinical animal models.[12] Selected studies where UGT-humanized animal models have been used are discussed in the succeeding text.

The role of UGT1A1 in clearance of 7-ethyl-10-hydroxy-camptothecin (SN-38) was investigated in a mouse model lacking the murine Ugt1 genes and expressing the human UGT1A1*28 allele. The humanized model showed minimal constitutive expression of hepatic UGT1A1 as expected, but even so, a significant increase in parent drug exposure in the humanized mice compared with WT controls following intravenous administration was observed.[71]

The clearance of naloxone and ezetimibe, considered to be substrates to UGT2B7 and UGT1A1, respectively, was also investigated in the same mouse model. However, only minor differences in the clearance between the WT and humanized mice were measured, suggesting no major contribution of UGT1A1 to the in vivo elimination of these compounds.[71]

Although most effort on conjugation reactions has been devoted to the UGTs, an NAT2-humanized mouse, with liver-selective expression on a mouse Nat1/2 null background, has been described. In this model, the AUC values of the human NAT2-selective substrate sulfamethazine were decreased by 97–98% compared with WT controls demonstrating the important role of this enzyme for clearance of this substrate.[72]

4.07.2.3 Drug Transporters

Drug transporters play an important role in the absorption, distribution, and elimination of drugs. This has resulted in a burgeoning literature and the issuing of guidance documents from FDA and EMA in the field.[73,74] In addition, the inhibition or induction of drug transporters can be a mechanism for pharmacokinetic-based DDIs and thus important from a safety perspective.[75] Predicting human PK and the selection of the starting dose in the clinic is challenging as data rely on several allometry-based approaches based on studies conducted in preclinical species such as rat, dog, and monkey. These methods generally perform poorly for transporter substrates due to species differences in substrate specificity for the transporters, differences in expression levels in various organs between species, and the lack of certain orthologues across species.[13]

4.07.2.3.1 Transporter-humanized mice

There are more than 400 human membrane transporters from the two major families, ATP-binding cassette (ABC) efflux pumps and uptake transporters from the solute carrier (SLC) group. In the regulatory guidance document, a relatively small number of transporters are thought to be of most important for drug development[73,74] and the following ABC transporters with most clinical relevance are P-glycoprotein (P-gp)/multidrug resistance (MDR) 1, MDR3, breast cancer-related protein (BCRP), bile salt export pump (BSEP), and the multidrug resistance proteins (MRP) 2, MRP3, and MRP4. The highlighted transporters in the SLC family are the organic anion-transporting polypeptide (OATP) 1B1, OATP1B3, OATP1A2, and OATP2B1; the organic anion transporter (OAT) 1 and OAT3; the organic cation transporter (OCT) 1 and OCT2; the peptide transporter (PEPT) 1 and PEPT2; and multidrug and toxin extrusion (MATE) 1 and MATE2-K.[76,77] Among these 20 transporters in focus, only a few humanized mouse models have been described to date including those for MRP2,[78] MDR1,[79] PEPT1,[80] BCRP,[81] OATP1A2, OATP1B1, and OAT1B3.[82–84]

4.07.2.3.2 Examples of studies using transporter-humanized mice

Two anticancer drugs methotrexate and paclitaxel have been used to investigate the role of transporters in drug bioavailability and disposition[84] and this study examined the influence of human OATP1 transporters on the PK of these drugs in OATP1B1-, OATP1B3-, and OATP1A2-humanized mice.

First, the roles of the mouse OATP1A and OATP1B proteins were illustrated. A significant decrease in liver uptake and an increase in plasma concentrations of both drugs were observed in mice where both transporter gene clusters of Oatp1a and Oatp1b had been knocked out. Human genes coding for OATP1B1, OATP1B3, or OATP1A2 were inserted in the knockout mouse line, and proteins were expressed selectively in the liver. In these studies, it was demonstrated that methotrexate showed significant, but relative to WT controls not completely restored, liver uptake in these three humanized transporter mice compared with the impaired liver uptake observed in the knockout model. The plasma concentrations of methotrexate were lower in the three humanized transporter mice than in the knockout model but not as low as observed in the WT mouse. Thus, methotrexate was found to be transported by all three human OATP1 proteins in vivo.

The reduced hepatic uptake observed in the knockout mouse dosed with paclitaxel was restored to WT levels in the OATP1B3 and in the OATP1A2 mice but not in the OATP1B1-humanized transporter mice. Thus, it was concluded that paclitaxel was transported only by OATP1B3 and OATP1A2, but not OATP1B1 in vivo. Less pronounced but similar effects of the plasma concentrations of the drug levels were observed at low doses of paclitaxel where a clearly reduced hepatic uptake seen in the Oatp1a/1b gene cluster knockout mouse was restored to WT levels in the OATP1B3 or OATP1A2, but not OATP1B1 transgenic mouse lines.

Cisplatin is commonly used for treatment of solid cancers even though the success of therapy is limited due to, for example, kidney injury by accumulation and toxicity of platinum. More than a third of the patients administered the drug develop signs of nephrotoxicity after receiving a single dose of cisplatin,[85] which will delay further treatment and limit the total number of chemotherapy cycles possible for an individual patient. The important role of the drug transporter MRP2 has been shown in

different in vitro assays to confer resistance to toxicity of cisplatin. Thus, Wen et al.[86] assessed the role of Mrp2 in mice in vivo. First, the Mrp2 knockout mice were compared with WT mice in which a twofold higher concentration of platinum was detected in the kidneys and livers of the knockout mice. Hence, the lack of an effective Mrp2 transporter seems to be linked to the in vivo toxicity of the drug. Cisplatin was also dosed to transporter-humanized MRP2 mice[86] in which the platinum concentrations and nephrotoxicity were similar to that of the WT mice and lower than seen for the knockouts. In summary, deficiency in Mrp2 lowers platinum excretion and increases susceptibility to kidney injury, which can be rescued by the human MRP2 orthologue.

These transporter models seem to be informative and helpful for gaining understanding of underlying mechanisms. However, it is important to remember that these mice still express murine transporters in addition to those that have been humanized and murine drug-metabolizing enzymes. Thus, in cases where there are multiple transporters and enzymes contributing to the elimination of drugs, it is still difficult to extrapolate the contribution of transporters to humans quantitatively based on humanized animal models alone.

4.07.3 Chimeric Liver-Humanized Mice

Taking together that drug-metabolizing enzymes and transporters differ between species, the use of a chimeric liver-humanized mouse, having most of its liver populated with human hepatocytes, provides an interesting complement to current preclinical species and genetically humanized mice. A number of different research groups have successfully generated chimeric liver-humanized mouse models, and the different strategies used to achieve the efficient repopulation of the mouse liver with human hepatocytes have led to several differently derived chimeric mouse models. Nevertheless, even though these chimeric mouse models are different, they do have some characteristics in common. First, to avoid rejection of the human transplanted cells, these mice need to carry deficiencies in certain components of the immune system. Secondly, the mouse hepatocytes need to be self-destructive to enable the liver to be "colonized" by the human hepatocytes, which can be achieved by genetic modifications resulting in toxicity within the murine liver cells. It is important to remember that even though the liver is humanized to a high degree, it is still in a mouse with metabolically active residual mouse hepatocytes. It is also important to know how well the human hepatocytes have repopulated the liver as it will have a direct impact on the results, and thus, the degree of humanization of the liver is determined by the replacement index (RI). The RI is the percentage of human hepatocytes in the liver of transplanted chimeric mice and is normally determined by measuring the concentrations of human serum albumin in the blood of the chimeric mice. RIs of up to 95% have been reported in almost all chimeric liver-humanized models. Here, the three most studied models are described: urokinase-type plasminogen activator (uPA)/severe combined immunodeficient (SCID) mice, FRG mice, and TK-NOG mice.

The uPA/SCID mouse, developed in the 1990s, was the first chimeric liver-humanized mouse to be described[87–89] and, as a result, is also the most published of the three models discussed here. This model is based on a SCID mouse, which is a mouse that lacks functional B and T cells, which are important cells in providing an immune response. The model has an albumin-promoted uPA gene inserted in the liver that results in expression of the liver toxic serine protease uPA, which destroys the native murine hepatocytes to allow donor-derived hepatocyte engraftment and proliferation.

The FRG mouse has three genes knocked out. The R stands for the recombination-activating gene 2 (Rag2) and G for the IL-2 receptor subunit g (IL2RG). By knocking out these two genes, an immunocompromised mouse, which lacks B and T cells and NK cells, respectively, is generated.[90] The F in FRG denotes the lack of fumarylacetoacetate hydrolase (FAH), which accounts for the liver failure associated with type 1 hereditary tyrosinemia (TH1) in humans. The lack of the FAH enzyme results in increased, and toxic, amounts of metabolites produced in the catabolic pathway of tyrosine, which is fatal. Both mice and humans survive the disease when treated with 2-(2-nitro-4-trifluoro-*O*-methylbenzoyl)-1,3-cyclohexanedione (NTBC), which inhibits the 4-hydroxyphenylpyruvate oxidase enzyme that generates the toxic metabolites. Thus, the FRG mice transplanted with human hepatocytes are "cycled" on NTBC to ensure that the animals survive with engraftment of human hepatocytes and destruction of the mouse hepatocytes occurring during the periods of NTBC withdrawal.

More recently, another chimeric liver-humanized mouse model TK-NOG, with inducible liver injury, was described.[91] Mouse hepatocyte ablation was achieved here through the liver-specific expression of the herpes simplex virus 1 thymidine kinase (HSVtk) in severely immunodeficient NOG mice. Ganciclovir (GCV) is normally nontoxic, but when administrated to these mice, it is converted by HSVtk into a toxic intermediate, which destroys the native hepatocytes.

4.07.3.1 Examples of Studies Using Chimeric Liver-Humanized Mice

In the preceding sections, selected examples of the use of genetically humanized mouse models were described, while in this section, a similar selection of representative examples for applications of chimeric liver-humanized mice is given.[11,92–99] The chimeric mouse livers have been shown to have expression levels and enzymatic activity of major human P450s and conjugation enzymes similar to that of the donor human hepatocytes.[100–102]These mice also demonstrate a humanlike susceptibility to inhibition and induction of the P450s,[100,103–105] which make these models interesting to study, while the concomitant presence of other human drug receptors and drug-metabolizing enzymes (for both functionalization and conjugation) and transporters provides a further level of sophistication.

4.07.3.1.1 Inhibition and induction studies

The inhibition of the metabolism of debrisoquine by quinidine was studied by Katoh et al.[106] Quinidine is a typical CYP2D6 inhibitor in human and a frequently prescribed antiarrhythmic drug. Debrisoquine is a well-known CYP2D6 substrate forming a human-selective 4-hydroxy metabolite excreted in urine when dosed to human. In rats and mice, there exist many isoforms of the CYP2D subfamily, and the large interspecies difference in the CYP2D6 substrate specificity is likely due to differences in levels of expression and the actual isoforms expressed.[107,108] In this study in chimeric uPA/SCID mice, the human-selective metabolite 4OH-debrisoquine was observed at significantly higher concentrations in the highly humanized chimeric mice (RI $>70\%$) compared with mice with a RI of less than 10%. The quantities of the metabolite decreased in the highly humanized mice when pretreated with quinidine, a selective CYP2D6 inhibitor, and the already small amounts of the metabolite in mice with a lower degree of humanization remained at the same level regardless of the quinidine pretreatment. The overall conclusion of the study was that the chimeric mice with a high RI exhibited a humanized profile of drug metabolism and the inhibition of P450 compared with the control and low RI chimeric mice.

Induction of CYP3A4 in chimeric liver-humanized mice was investigated using dexamethasone as a probe drug and rifampicin as a model drug to induce the enzyme.[103] The urinary excretion of 6β-hydroxydexamethasone and parent compound was measured before and after rifampicin treatment showing that the metabolic ratio (metabolite/parent) was significantly increased after rifampicin treatment. It was also shown by immunohistochemical staining that CYP3A4 was increased after rifampicin treatment. Hence, such chimeric liver-humanized mice could potentially be useful for detecting the induction of CYP3A4 using rifampicin[103] and similar compounds.

4.07.3.1.2 Biotransformation studies

Many research groups have now made studies on humanized chimeric liver mice to evaluate whether these mice can repeat the in vivo human metabolic profile of various xenobiotics. Representative examples of these applications include the CYP2D6-mediated metabolism of debrisoquine to 4-hydroxy debrisoquine[106] described earlier, the CYP2C9-catalyzed conversion of S-warfarin to 7-hydroxywarfarin,[109,110] the comparison with human metabolic profiles of three different GSK drug candidates[111] the metabolism of midazolam,[96] the prediction of human metabolism of FK3453 by aldehyde oxidase (AO),[98] the AO-catalyzed oxidation of zaleplon,[99] and the metabolism of ibuprofen and naproxen.[97] In addition to these studies, Bateman et al.[92] also evaluated the chimeric liver-humanized mouse model for prediction of human hepatobiliary drug metabolism and excretion using a series of compounds known to have a qualitatively distinct metabolic profile in humans relative to rodents. The compounds used in this study were lamotrigine, diclofenac, a Merck drug candidate (named MRK-A), and propafenone. Chimeric liver-humanized mouse models have also been used to study the nonspecific binding by reactive intermediates from idioscyncratic hepatotoxicants to human proteins[112,113] and to investigate the fate of troglitazone,[114,115] an idiosyncratic hepatotoxin in humans.

In human but not in mice, S-warfarin is predominantly metabolized to S-7-hydroxywarfarin, a reaction catalyzed by CYP2C9. As alluded to earlier, following warfarin administration, the concentration of S-7-hydroxywarfarin in the plasma of chimeric mice was approximately sevenfold higher than that in control mice. In addition to in vivo studies, the biotransformation was assessed in vitro using microsomes prepared from chimeric liver-humanized mice, and these showed a 10-fold higher 7-hydroxylase activity compared with those obtained from control mice. Furthermore, this reaction was markedly inhibited by sulfaphenazole in the chimeric liver microsomes, whereas the 7-hydroxylase activity of control mouse microsomes was unaffected.[109,110]

Three candidate drugs (**Fig. 2**) were selected by Serres et al.[111] because of qualitative and/or quantitative differences in routes of metabolism that were observed between humans and the preclinical species. For both the tetrahydroisoquinoline and benzophenone analogs, hepatic metabolic clearance was predominant in the preclinical species and humans. When investigated to assess the ability of chimeric liver-humanized mice to produce the human metabolites circulating systemically, the metabolism and disposition were found to be well represented for the benzophenone analog but less well in the case of tetrahydroisoquinoline. For the third test compound, a fluoropyrrolidine analog, the hepatic and extrahepatic metabolic clearance was used as a probe to see how well the chimeric mice would predict the urinary excretion of the metabolites seen in humans where the renal excretion of drug-related material was higher than found in mice. In the case of fluoropyrrolidine, the authors found that the chimeric mice were somewhat representative of the human situation, and they suggested that, while limitations for the prediction of human metabolism and disposition clearly exist, humanized chimeric mouse models can potentially provide informative new tools in drug discovery and development.[111]

Both ibuprofen and (S)-naproxen are nonsteroidal antiinflammatory drugs metabolized by P450 and UGT, SULT, and amino acid N-acyltransferase for taurine conjugation in the liver. A direct comparison of excretory metabolites in urine between chimeric liver-humanized mice and the published human data was made after administration of these two NSAIDs. Good agreement for the urinary excreted metabolites (percentage of dose) was observed between chimeric and human, providing further evidence that the chimeric liver-humanized mice should be helpful for predicting the quantitative metabolic profiles of drugs mediated by both P450 and conjugation routes in the liver.[97]

The aldehyde oxidase function of chimeric liver-humanized mice was investigated in two studies. In the first study of these species differences, the metabolism of the probe drug FK3453 was assessed using chimeric mice transplanted with either human or rat hepatocytes. Higher concentrations of the human-specific aldehyde oxidase-generated metabolite were present in the excreta for mice modified with human compared with rat hepatocytes, and a twofold higher clearance of the parent compound was observed in the former model. These results were in concordance with the known in vivo PK and metabolism of FK3453 determined

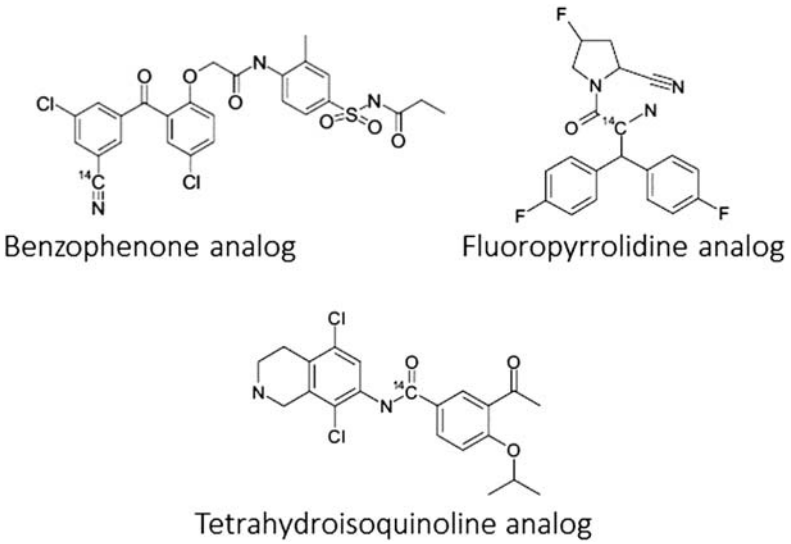

Fig. 2 Structures of benzophenone, fluoropyrrolidine, and tetrahydroisoquinoline. Reproduced from De Serres, M.; Bowers, G.; Boyle, G.; Beaumont, C.; Castellino, S.; Sigafoos, J.; Dave, M.; Roberts, A.; Shah, V.; Olson, K.; Patel, D.; Wagner, D.; Yeager, R.; Serabjit-Singh, C. Evaluation of a chimeric (uPA+/+)/SCID mouse model with a humanized liver for prediction of human. *Xenobiotica* **2011**, *41*(6), 464–475, with permission.

in human and rat.[98] In the second study using zaleplon , which is metabolized to 5-oxo-zaleplon by AO, the results showed that the in vivo concentrations of 5-oxo-zaleplon in the plasma of the chimeric liver-humanized mice were about sevenfold higher than that in control mice.[99]

Bateman et al.[92] investigated the use of chimeric liver-humanized mice using compounds metabolized via oxidation and glucuronidation. The four model drugs lamotrigine, diclofenac, MRK-A, and propafenone were known to exhibit human-specific metabolism. The results demonstrate that chimeric liver-humanized mice were able to reproduce the human-specific metabolite profile for lamotrigine, diclofenac, and MRK-A. However, in the case of propafenone, the metabolite profiles in native and humanized mice were similar and thought to be due to the presence of residual highly active propafenone-metabolizing mouse enzymes in chimeric mice.

The PK and metabolic fate of midazolam after the administration of doses of 0.1, 1, and 10 mg kg^{-1} PO to chimeric liver-humanized and control mice showed significant PK differences between the two with a higher Cmax in the humanized mice and a 14-fold greater exposure to 1′-hydroxymidazolam than to midazolam in the controls.[96] Overall metabolism of midazolam was faster in control versus humanized mice such that no PK profiles could be generated for midazolam in the former following dosing at 0.1 mg kg^{-1}. Both oxidative and conjugative metabolites were detected in the humanized mice with the major circulating metabolites observed in blood (1′-hydroxymidazolam, 4′-hydroxymidazolam, 1′,4′-dihydroxymidazolam, and 1′-hydroxymidazolam glucuronide, corresponding to those seen in humans). In contrast, two of these (4′-hydroxymidazolam and 1′-hydroxymidazolam glucuronide) were absent from samples of control mice, suggesting that the chimeric liver-humanized model might provide a suitable means of predicting circulating human metabolites. These differences are illustrated in the mass chromatograms obtained from pooled blood samples from these mice shown in **Fig. 3**.[96]

The PK, metabolism, and toxic effects of troglitazone were studied following PO administration at 300 and 600 mg kg^{-1}, for 7 days to chimeric liver-humanized and control mice.[115] PK profiles showed similar Tmax values for troglitazone in both groups but with three- to five- and two- to fivefold higher Cmaxs and AUCs, respectively, seen for the humanized animals. Both oxidative and conjugative metabolisms were observed with the primary oxidative pathways in humanized and control mice being mono- and dioxidations but no evidence of glutathione conjugation. With respect to conjugations, a sulfate was seen in greater amounts in humanized mice (4- to 13-fold higher in the liver and blood, respectively), where the major conjugate in control animals was instead a glucuronide. Several of the metabolites detected were unique to the humanized mice only, and the profiles generated in these animals were considered to be similar to those seen in humans. With respect to toxicity, standard clinical chemistry did not show any changes that could be linked to adverse effects on the livers of either mouse line; however, immunohistochemistry showed that human MRP2, but not mouse Mrp2, was downregulated as a result of exposure to troglitazone for 7 days. In a subsequent study[114] where troglitazone was dosed to the humanized mice for 14 or 23 days at 1000 mg kg^{-1} day^{-1} PO, it was seen that circulating ALT was increased by 2.1-fold at 14 days and 3.6-fold after 23 days administration. When coadministered with L-buthionine sulfoximine (BSO), this increase in ALT was not seen, suggesting that the production of reactive metabolites/glutathione depletion was not involved in the drug-related hepatotoxicity (a hypothesis supported by further measurements of hepatic GSH content, oxidative stress markers, and drug-metabolizing enzymes). The conclusion from both of these studies was that humanized mice may provide an animal model for studying the effects of idiosyncratic liver toxins such as troglitazone.

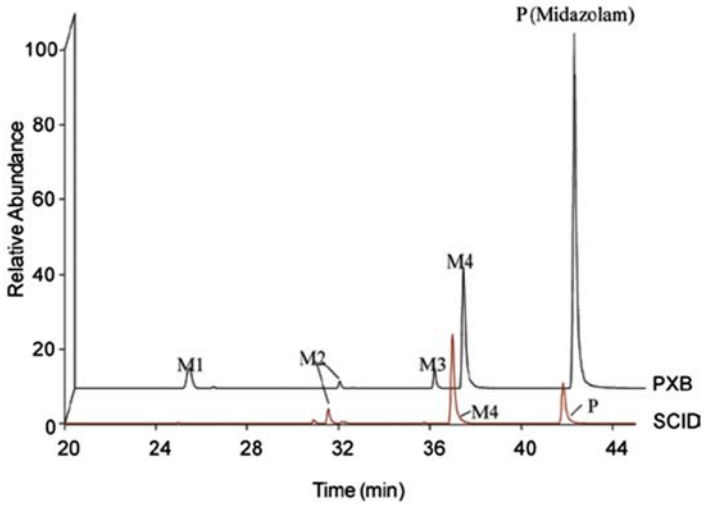

Fig. 3 Composite extracted mass chromatograms for midazolam (m/z 326, P), 1′-hydroxymidazolam glucuronide (m/z 518, M1), 1′,4′-dihydroxymidazolam (m/z 358, M2), 4′-hydroxymidazolam (m/z 342, M3), and 1′-hydroxymidazolam (m/z 342, M4) in chimeric liver-humanized mouse (PXB) and control mouse (SCID) blood samples. These traces are based on a pooled sample (samples from 0.083 to 3 h postdose) utilizing the AUC proportional manner.[96] Reproduced from Samuelsson, K.; Pickup, K.; Sarda, S.; Swales, J. G.; Morikawa, Y.; Schulz-Utermoehl, T.; Hutchison, M.; Wilson, I. D. Pharmacokinetics and Metabolism of Midazolam in Chimeric Mice With Humanised Livers. *Xenobiotica* **2012** *42* (11), 1128–1137, with permission.

Yamazaki et al.[112] studied the nonspecific binding of radiolabeled drugs to human proteins in chimeric liver-humanized mice. Hepatotoxic effects in humans were observed after treatment with a potential analgesic agent, 5-*n*-butyl-7-(3,4,5-trimethoxybenzoylamino)pyrazolo[1,5-a]pyrimidine, leading to its withdrawal from development. As the hepatotoxicity seen in humans was not predicted from regulatory animals or in vitro studies, an attempt was made to identify the underlying mechanism by dosing the structurally related model compound 5-*n*-butyl-pyrazolo[1,5-a]pyrimidine to chimeric liver-humanized mice and comparing these with mice transplanted with rat hepatocytes. The in vivo production of glutathione conjugates and concomitant covalent binding was studied following IV dosing to the mice with covalent binding to liver proteins detected over a period of 0.17–24 h postdose. Chimeric liver-humanized mice were seen to form a 3-hydroxy metabolite and its corresponding glutathione conjugate (detected in both the plasma and liver), while, in contrast, mice engrafted with rat hepatocytes formed a number of rat-specific metabolites. Bioactivation of 5-*n*-butyl-pyrazolo[1,5-a]pyrimidine was found to result in the radiolabel binding nonspecifically to a variety of cytosolic and microsomal proteins, including human P450 1A2, in the livers from chimeric humanized mice with hepatotoxicity perhaps the result.

There is now an extensive literature in the area of biotransformation utilizing chimeric humanized mice, and the results from these studies, including those discussed earlier, demonstrate that chimeric mice were able to reproduce the human-specific metabolite profiles for a many, but not all, of compounds investigated. One has to remember that apart from the liver, all the remaining parts and organs are still those of a mouse. Overall, for compounds where the major site of metabolism is in the liver, these data indicate that chimeric mice with humanized livers have the potential to be a useful tool for the prediction of human-specific metabolism of xenobiotics and warrant further investigation.

4.07.4 Differences Between Genetically Humanized Mice and Chimeric Liver-Humanized Mouse Models

Both genetically humanized and chimeric liver-humanized mouse models have advantages and disadvantages depending on their inherent differences.[116] One characteristic difference between the two models is that the genetically humanized mice are most likely to be modified throughout the whole body where the target gene is naturally present, while the humanization in chimeric liver-humanized mice is, self-evidently, restricted to the liver tissue. However, even though only this single organ is humanized, the human hepatocytes therein have all genes, proteins, and pathways of human origin, while in contrast, even in the most complex, genetically humanized mouse model, with multiple human genes present, they still represent only a minority on a mouse background. Another advantage of the chimeric liver-humanized mouse is that, for certain models, transplantation is possible using hepatocytes from donors with specific features, such as natural polymorphisms in drug-metabolizing enzymes or transporters or from diseased patients. In addition to primary hepatocyte transplantation, it is also possible to simultaneously insert human liver cancer cells to give a combined model. In one such study, Fujiwara et al.[117] divided mice into two groups, one of which was transplanted with human gastric cancer cells (GCCs) alone, while the second received both h-GCCs and human hepatocytes. In this second group, GCCs and hepatocytes repopulated the host liver with colonies of cancer cells forming around the human

hepatocytes to give "typical adenocarcinomatous glandular structures." Human hepatocyte-colonized mice also contained metastasized GCCs, which were not seen for those animals only colonized with the cancer cells alone. The authors concluded that this could be a useful humanized liver animal model for studying liver cancer metastasis in vivo, which would allow drug efficacy testing studies of these cells in a contextual and physiological environment, with human liver metabolism.[117]

A clear drawback of the chimeric liver-humanized mice is the presence of residual mouse liver, which may still represent a significant capacity for biotransformation, especially as livers in such chimeric animals are often 2–2.5 times larger than that of the WT mouse. The number of mouse cells in the chimeric liver is therefore still high. Thus, even in the case where the mouse has an RI of 90% and the remaining 10% may not, at first sight, seem to contribute greatly to the overall metabolic fate of a drug, their presence may complicate interpretation. This may have important consequences, particularly if a compound is efficiently metabolized by a particular drug-metabolizing enzyme present in the mouse but less well represented in humans, such that the rate of metabolism of this compound differs greatly between mouse and human hepatocytes.[92]

The genetically humanized mice, on the other hand, carry the risk of compensatory gene expression, which may change the PK and metabolism of a drug. That said, compared with knockout models, the expression of proteins involved in drug metabolism and disposition in genetically humanized mouse models indicates that this might not be of general concern. However, when knockout models are used as a control for a genetically humanized mouse model, it is recommended that the effect of potential changes in the expression of mouse pathways is taken into account, specifically if these pathways can contribute to the metabolism and disposition of the compound under investigation. Even so, the knockout controls should be seen as an advantage for using the genetically humanized mice. Thus, the availability of genetic knockout controls for a given human gene could be used as a complement to assess the relevance of the corresponding human gene product in the metabolism, disposition, or toxicity of a drug. Importantly, knockout control mice are available for most genetically humanized mice.

The organ responsible for metabolism does matter; however, since the liver is the predominant metabolizing organ in the body, one will be able to find metabolites of drugs derived from human liver enzymes in both chimeric and genetically humanized mice. On the other hand, in compounds known to be metabolized in organs other than the liver, when the liver does not represent the predominant metabolizing organ, no human-selective biotransformation is likely to be observed in chimeric liver-humanized mice. Hence, it is important to know if the compound intended to be dosed to a chimeric liver-humanized mouse predominantly is metabolized by the liver or not.

It is also important to remember that extrahepatic metabolism and transport can make major contributions to the fate of a drug in the human body even though the liver is the dominant organ of drug metabolism and disposition for many compounds.[118]

The chimeric liver-humanized mice make it feasible to use the same human hepatocytes for in vitro and in vivo applications. Primary human hepatocytes can be serially transplanted into the FRG model, and thus, it is possible to increase the number of human cells for in vitro applications.[90] A more accurate IVIVC could be established with this approach and also improve the extrapolation to the clinical situation.

Furthermore, there are other differences that may not be related to the outcome of DMPK investigations. A clear advantage of the genetically humanized compared with their chimeric counterparts is the ease of maintaining the models by simple breeding or cryopreservation of embryos or sperm. In the case for the chimeric liver-humanized mice, each individual mouse needs to be individually transplanted, and the humanization cannot be propagated to the next generation. The differences in how these two models are generated are evidently mirrored in cost of production and the variability between individual mice. The generation of chimeric liver-humanized mice is currently significantly more expensive compared with genetically humanized animals with a cost of a few thousand dollars for a chimeric liver-humanized animal compared with a few hundred dollars per genetically humanized mouse. The relatively high cost of chimeric liver mice is partly due to the fact that the RI in a group of mice will vary; thus, it is almost necessary to set a threshold for RI, for example, $>90\%$ for mice to be used in a study. Hence, a larger number of mice need to be transplanted compared with what will be used in the study, which of course will increase the costs of the mice.

Both types of humanized models are promising complements to traditional in vitro assays, but whether they will be suitable for the long-term (>1 month) toxicity studies required for drug registration has, however, yet to be established. Therefore, these models might help to understand the mechanism of toxicity of such compounds or to evaluate hepatotoxic potential before the first time in man (FTIM or FDIM if one chooses to use the term first dose in man).

4.07.5 Additional Models

The relative contribution of hepatic versus extrahepatic oxidative metabolism is an important factor for the bioavailability and thus also the therapeutic efficacy of a drug. Predicting the clearance of a drug in relation to the P450 metabolism of the drug is critical for new compounds and their progression in the preclinical phase of drug development.[119,120] Additionally, understanding the causes of poor oral bioavailability can also represent a challenge. In order to understand the factors that limit bioavailability and thereby optimize oral drug delivery, it is essential to characterize the contribution of first-pass metabolism in the gut and in the liver. A number of knockout models have been created that enable assessing the contribution of P450s to hepatic and gut/hepatic first-pass metabolism, and two such mouse models, the HRN mouse and the ERL mouse, are described in the succeeding text.

In the HRN mouse, the hepatic cytochrome P450 reductase (POR) is selectively "knocked out," which results in mice that are null only for the liver, but not in other tissues such as the gastrointestinal tract, kidney, and lung.[21] In the absence of a functional P450 reductase enzyme, the ability to reduce oxidized P450s via the transfer of an electron from NADPH via POR is no longer

possible, resulting in the loss of hepatic P450 activity. The HRN mouse provides obvious opportunities, especially in combination with studies using a WT strain, to investigate hepatic P450-related and also conjugative metabolism independently. Furthermore, the HRN mouse can potentially be used to determine whether P450-related metabolism or conjugation reactions are responsible for any covalent binding to cellular macromolecules in the liver, thus aiding the understanding of the relative contribution of such biotransformations to any hepatic effects observed in vivo. An example of the differences that can be seen between control and HRN mice is shown by studies on the metabolism of diclofenac[121] after a single 10 mg kg^{-1} PO dose to WT and HRN mice. In the case of the HRN animals, most of the [^{14}C]-diclofenac-related material was found in the urine/aqueous cage wash within 12 h of administration (~82%) with recovery from the control mice somewhat slower with ca52% found in urine and 15% in feces by 24 h postdose. Metabolism in the HRN mice was dominated by conjugation to either taurine or glucuronic acid to the carboxyl function, while the WT mice showed both oxidative and conjugative metabolisms. Covalent binding studies, however, showed no differences. The ^{14}C profiles obtained from urine for both HRN and WT mice are shown in Fig. 4, and the metabolic fate of diclofenac is illustrated in Fig. 5. The absence of large amount of oxidative metabolites attributable to P450-related metabolism in the HRN mice clearly indicates that the bulk of metabolism for the drug was hepatic. In contrast, when the metabolism of midazolam was studied in these mice while there was a significant increase in AUC compared with WT animals, a considerable amount of oxidative metabolism was still seen, clearly implicating extrahepatic metabolism of the drug and highlighting the utility of the model is detecting such effects.[122]

The benefit of the ERL mouse compared with HRN is that it allows direct comparison of hepatic and intestinal contributions of cytochrome P450 metabolism. In this mouse line, the Cre recombinase is driven off the endogenous Cyp1a1 gene promoter. This line was then crossed onto a floxed POR mouse to generate the ERL mouse.[20] In order to eliminate the expression of POR in both the liver and the small intestine, the mouse is dosed with a 40 mg kg^{-1} of the Cyp1a1 inducer 3-methylcholanthrene (3MC). To generate a mouse that holds the characteristics of an HRN mouse, with only elimination of the POR expression in the liver, the ERL mouse is dosed with 3MC at a 4 mg kg^{-1}. This enables the investigator to examine the effects of deleting both hepatic and intestinal

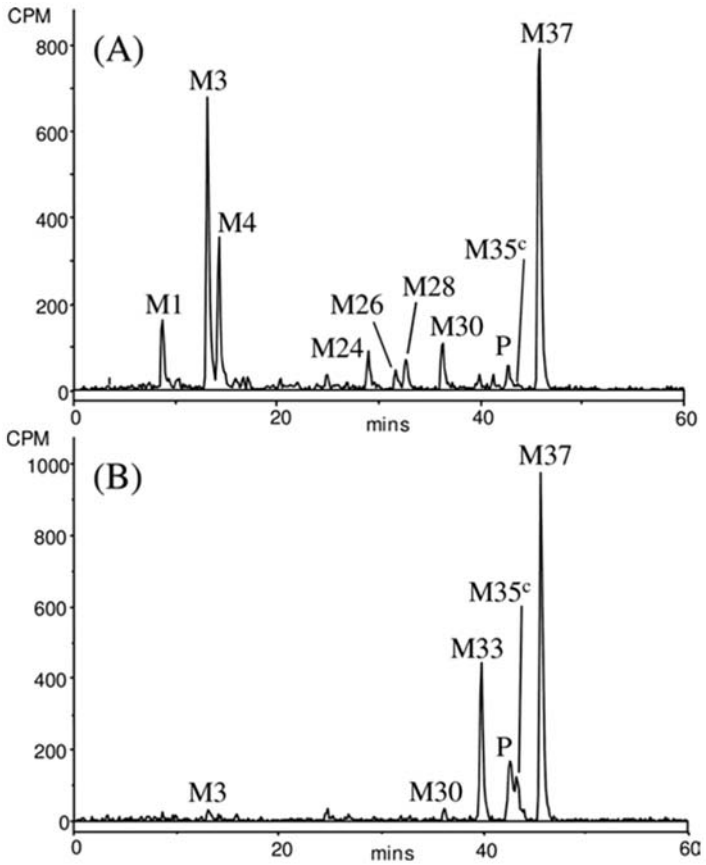

Fig. 4 Representative HPLC–RAD urinary profiles following a single oral dose of 10 mg kg^{-1} [14C]-diclofenac for the samples containing the highest proportion of the dose for each strain: (A) C57BL/6J (12–24 h) and (B) HRN mice (0–12 h). M35c represents a cluster of radio-peaks corresponding to 2,3,4-α/β transacylated acylglucuronide isomers.[121] Pickup, K.; Gavin, A.; Jones, H. B.; Karlsson, E.; Page, C.; Ratcliffe, K.; Sarda, S.; Schulz-Utermoehl, T.; Wilson, I. The Hepatic Reductase Null Mouse as a Model for Exploring Hepatic Conjugation of Xenobiotics: Application to the Metabolism of Diclofenac. *Xenobiotica* **2012**, *42* (2), 195–205, with permission.

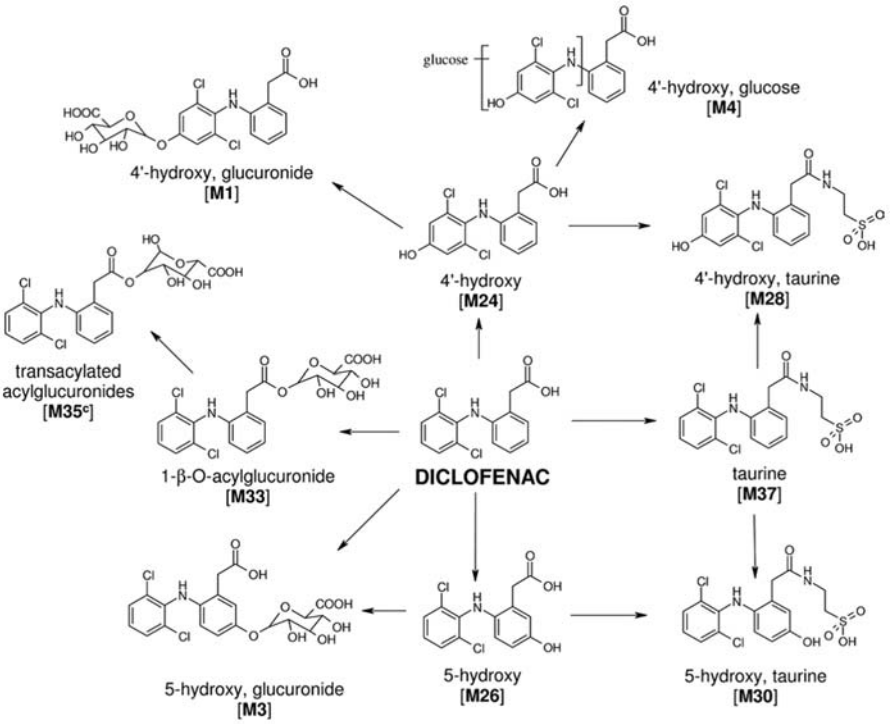

Fig. 5 The major metabolites of diclofenac seen in HRN and C57BL/6J mice as reported by Pickup et al.[121] Pickup, K.; Gavin, A.; Jones, H. B.; Karlsson, E.; Page, C.; Ratcliffe, K.; Sarda, S.; Schulz-Utermoehl, T.; Wilson, I. The Hepatic Reductase Null Mouse as a Model for Exploring Hepatic Conjugation of Xenobiotics: Application to the Metabolism of Diclofenac. *Xenobiotica* **2012**, *42* (2), 195–205, with permission.

P450-related metabolism at will to determine the relative importance of first-pass metabolism of these two important organs, as was demonstrated in studies on the PK of paroxetine, midazolam, and nelfinavir.[20]

These two models may also be of benefit to investigators by the fact that plasma concentrations of drugs with poor bioavailability due to presystemic metabolism by CYPs should be increased in their absence so that efficacy studies can be performed in mouse that would otherwise not be practicable. In addition, metabolism via conjugation of the parent molecule can be more clearly defined in drug disposition studies, as can non-P450-related metabolism. However, in addition, such studies may also act as a guide for the selection of the most appropriate humanized mouse model to choose, as discussed in the succeeding text.

4.07.6 How to Choose a Humanized Mouse Model?

Both the genetically humanized and chimeric liver-humanized mouse models can potentially mimic the human situation in terms of generation of human-selective metabolites and thus produce a humanlike metabolite profile. In addition to simply predicting the metabolic fate of the compound, they have been used to assess the PK and distribution of drug and metabolites and factors such as enzyme induction/inhibition and DDIs (see aforementioned text).

The choice of model (genetically humanized or chimeric) to use needs to be decided on a case-by-case basis as it depends on the question to be answered, which in turn will be defined by facts gathered from previous in vitro and preclinical in vivo assays. While these will be specific for each individual compound, it is still possible to provide some general guidance for the selection of the most appropriate strategy for using these models in problem solving/decision-making. So, in discovery, there may be good data on the metabolites produced from hepatic microsome/hepatocyte incubations, suggesting that there may be unique human metabolites or predicting a risk for unwanted DDIs. In addition, some of the individual P450s/transporters may have been identified as contributing to this potential risk. However, at this stage and in the absence of any IVIVC, it is difficult to recommend the application of any of these models. First, in vivo data may indicate or substantiate a potential risk, which might require further assessment. At this point, it might therefore become important to know the in vivo site of metabolism (hepatic, extrahepatic, and a mixture of both) in order to be able to decide on whether or not a liver only modified chimeric/humanized mouse represents a way forward or not. This information is important in order to avoid unnecessary efforts in dosing a drug to precious chimeric liver-humanized mice, if the problem is not targeted on hepatic uptake, metabolism, or efflux. The HRN and the ERL mouse models may be useful in enabling the site(s) of metabolism for the compound of interest to be determined.

In instances where extrahepatic metabolism via one or a few P450s (or transporters) is considered the most likely cause of the problem under investigation (e.g., a potential DDI or induction of a specific P450), then a chimeric liver-humanized mouse is not the optimum solution. In this situation, a genetically humanized mouse model, specifically modified to express the required human proteins, may represent a better means of investigating the problem, at lower cost.

If the role of individual, defined proteins in drug metabolism, disposition, or toxicity, is to be investigated, the genetically humanized mice are usually preferred, both on the basis of expense compared with chimeric humanized animals and the general availability of both knockout and WT controls, which enables the dissection of the function of a particular human P450 or transporter protein.

Where it seems clear that metabolism is hepatic but the route by which the metabolite is produced is not known or the desire is to predict a potentially complex human metabolite profile, detect/confirm unique human metabolites, etc., then the chimeric liver-humanized mice are the first choice. Essentially chimeric liver-humanized mice can be used to study the liver metabolism of all types of small molecules without any knowledge of the enzymes involved in their turnover. The chimeric liver-humanized mice, which of course have the whole panoply of human hepatic drug-metabolizing enzymes and transporters, may also represent the preferred model for hepatotoxicity testing, which provides the possibility to study the susceptibility of human hepatocytes to the toxicity of a compound and is probably more relevant to human than assessing an effect on mouse hepatocytes in a genetically humanized mouse model.[123,124] Perhaps of note in this respect is the observation by Schulz-Utermoehl et al.[115] that transporter effects caused by troglitazone administration were only observed in the human hepatocytes, but not the residual mouse hepatocytes in chimeric liver-humanized mice. On the other hand, the use of genetically humanized mouse models might add value in understanding the mechanism of action of a hepatotoxic drug when the enzymology has been properly defined. Apart from liver toxicity, genetically humanized mice offer the opportunity to study drug toxicity in extrahepatic tissues.

The same arguments apply to the choice of chimeric liver-humanized mouse or genetically humanized mouse in DDI studies. If the test compound is cleared via hepatic metabolism and in vitro studies indicate multiple enzymes to be involved in its turnover and the codrug inhibits or induces any of these enzymes, chimeric liver-humanized mice might be the preferred model. If it is a single enzyme that dominates the metabolism of the drug such as CYP3A4, any of the two types of models could be used. If oral administration is the preferred route of dosing and gut metabolism significantly contributes to first-pass metabolism of the drug, a genetically humanized mouse with intestinal expression of the desired drug-metabolizing enzyme or transporter would be a better choice than a chimeric mouse.

The selection of the appropriate model for its ability to accurately predict human drug clearance by employing genetically humanized or chimeric liver-humanized mouse models (either alone or in combination) is not trivial and greatly benefits from a proper understanding of the characteristics of both the compound itself and the earlier described advantages and limitations of the humanized models.

4.07.7 Humanized Mouse Models in the Future

Despite the potential utility of humanized mouse models to support various aspects of metabolism and toxicity testing, their limitations in terms of costs, the lack of historical background data, or fragility of immunocompromised animals will most likely restrict the use of these models to case-by-case problem solving rather than leading to generic applications, for the foreseeable future.

Genetically humanized and chimeric liver-humanized mouse models are still emerging, but the models discussed here are promising tools for improved prediction of the PK, disposition, metabolism, DDI, and safety characteristics of compounds in humans. However, these models are not yet fully accepted for ADME studies, and more work will be required to demonstrate their robustness and accuracy in predicting clinical outcomes and to gain wider acceptance. It can be expected that the increasing use of genetically humanized and chimeric liver-humanized mice by academia and industry and the growing number of publications will help to establish a solid database.

However, in our opinion, humanized mice of one sort or another, while unlikely to become "stand-alone" models for predicting human outcomes of all candidate drugs in a pipeline, will be increasingly used for problem solving and decision-making when difficulties arise in discovery and development for particular candidate drug. The results obtained from such studies will then be taken together with in silico predictions, in vitro data, and, if available, clinical results and used as part of the decisions on how to proceed through the discovery/development process. Hence, these in vivo models will be used as a complement to already-established technologies and not a replacement for them. Hopefully, the data obtained from the use of these models will help to de-risk the first single ascending dose and multiple ascending dose studies to human subjects (used to determine the starting doses for clinical studies) or to explain unexpected clinical findings.

A trend in the future is that more complex models, with mice multiply humanized for proteins involved in drug metabolism and disposition, will be generated to investigate interaction of compounds. In addition, there will be an increased number of transporter-humanized mouse models to satisfy the growing demand to consider the role of transporters in drug PK, DDI, and toxicity. Efficacy testing might be increasingly addressed in the future by combining the humanized models described here, with genetically engineered disease models or chemically induced disease phenotypes.

Further developments in the production of chimeric liver-humanized models may lead to an increased robustness in the generation of mice with high RI factors of 90% or more. There might be more liver-humanized mouse models with additional cellular humanizations, as exemplified by Wilson et al.[125] with a double humanization of both the liver and hematopoiesis in a FRG

mouse.[125] It may also be possible to generate chimeric liver-humanized mice using induced pluripotent stem cells (iPSCs) with high RI.

Furthermore, it is possible to predict that genetically humanized and chimeric liver-humanized rats will become available. Today, there are technologies to generate knockout rats,[126,127] and the first attempts to generate chimeric liver-humanized rats have been made,[128–130] but optimization will be required to achieve robust and efficient repopulation of human hepatocytes in the liver of a rat. The benefits of moving from mice to rats for Absorption, Distribution, Metabolism, and excretion - Toxicity (ADMET) studies are the much greater amount of background data available for the latter regarding toxicological readouts, which may help in understanding/interpreting the outcomes of studies performed in a chimeric humanized rat in the future.

Finally, neither genetically humanized or chimeric liver-humanized mice are officially accepted by regulatory authorities nor is their use for any particular application explicitly recommended. Hence, the use of these in vivo models is, at least for now, more for internal decision-making rather than for regulatory purposes. However, representatives from the FDA have taken an open-minded attitude toward the use of humanized mouse models to support regulatory submissions, if scientifically reasonable.[43]

In conclusion, these humanized models are still mostly mice, and studies need to be well thought-out and carefully executed. If undertaken with care studies, these genetically humanized and chimeric liver-humanized mice clearly do have a significant potential to increase the predictability of clinical drug PK, DDIs, and toxicity and to contribute to improving the success rates in drug development.

4.08.1 Introduction

Paracelsus is hailed as the founding father of toxicology often summarized in the quote *All things are poison and nothing is without poison; only the dose makes a thing not a poison*. Almost 500 years later, we have refined this notion, that the portion of the dose, which interacts with the target in the body, the internal dose, is critical. This has revolutionized some parts of in vivo toxicology, especially in drug development. Other areas were left behind, such as the regulation of industrial chemicals or some food regulations based on hazard only.

Another area, which was left behind, is in vitro toxicology. Sure, in vitro models of metabolism and biological barriers exist, but still most in vitro toxicology neglects metabolism and we mostly do not care about the fate of substances in the culture dish, the in vitro biokinetics. However, similar to the impact on interpreting in vivo findings, kinetic phenomena impact on in vitro results and need to be considered for any prediction of the in vivo situation.

To some extent, in silico modeling of aspects of adsorption, distribution, metabolism, and excretion (ADME) has been possible and make especially their addition to integrated testing strategies (ITS) more feasible. While hazard is either a yes/no attribution of a property or ideally linked to some dose/response relationship, kinetics of a substance is a highly dynamic process. This prompts the need for dynamic modeling of toxicokinetics—today mainly used to explain phenomena but increasingly supporting predictive toxicology. The ultimate goal to make quantitative in vitro-to-in vivo extrapolations (QIVIVE)[1] or build a systems toxicology[2] approach clearly needs the integration of in silico and in vitro tools, which combine hazard assessments with ADME considerations.

In the context of developing a roadmap for animal-free systemic toxicity testing, an expert workgroup discussed the contribution of toxicokinetics,[3] which was then discussed in two stakeholder fora in Brussels and Washington.[4] Some key messages were:

- Kinetics is less a stand-alone test requirement but the necessary complement to in vitro approaches.
- Mainly in silico approaches are used that need to be further optimized.
- There is a need for more quality data collections and the incorporation of in vitro data (barrier models).
- Insufficient models exist for bioavailability and urinary excretion.
- All together, the required in vitro and in silico tools are with reasonable investment achievable.

This introduction aims to get the reader started with some food-for-thought before the dedicated chapters detail the state of the art of ADME in toxicology.

4.08.2 The Critical Role of ADME in In Vivo and Human Toxicology—World's Apart

The high attrition rate of drugs once entering human trials has concerned the pharmaceutical field for many years.[5] By 1997, it was reported[6] that poor ADME properties and toxicity accounted for 60% of failures of chemicals in the drug development process. It turned out that many failures could actually be attributed to differences in kinetics from the animal models to humans.[7–11]

Noteworthy, by tackling these issues, the number of failures due to ADME problems has fallen over the years.[12] In 1991, adverse pharmacokinetic and bioavailability results were the most significant cause of attrition (about 40%) dropping by 2000 to less than 10%. The availability of high-throughput and in silico techniques in drug metabolism and pharmacokinetics was critical here.[13–15]

While drug development has embraced the advantage of understanding ADME for predicting and analyzing substance effects,[16–18] other areas have not. For example, the largest regulatory industrial chemical program, the European REACH legislation, has no requirement for ADME data. Similarly, cosmetics are typically registered in Europe without such data,[19] though the ban on animal testing does name kinetics as an information requirement under the 2013 ban. In both cases, kinetics information is if at all used for weight of evidence evaluations and to adjust the impact of a hazard found for risk assessment. However, similar to exposure considerations, which are often similarly neglected, the "internal dose," that is, the kinetics of a given external dose in the organism, could help adapt information requirements and safety factors for risk assessments.

An area where kinetics makes most of the difference is nanotoxicology.[20] New hazards are rare, but we are only starting to understand the dramatically altered kinetics of nanomaterials and the biological consequences in vivo and in vitro.[21]

4.08.3 The Critical Role of ADME for the Future of In Vitro Toxicology

4.08.3.1 Well-Established Uses of ADME in In Vitro Toxicology

4.08.3.1.1 Prediction of metabolites

A broad variety of cellular and subcellular models of metabolism of xenobiotics is available.[22–27] Many focus on liver metabolism because of the enormous metabolic capacity of the organ, its central role in blood circulation, especially seeing first via the portal vein anything absorbed from the intestine, and as an important excretion organ via the bile. The latter is actually difficult to study in vitro and marked differences between rodents and humans also impair in vivo analysis. All together, there are still enormous challenges to predict the in vivo metabolism from in vitro data.[28] More recent developments with regard to hepatic models include the emergence of stem-cell-derived liver cells (still not fully matured though),[29] the more broad access to human primary cells via commercial vendors, and cell lines with some metabolic capacity, such as HepRG cells.[30] Increasingly, the in vitro data can support the prediction of in vivo metabolism of xenobiotics.[31]

4.08.3.1.2 Barrier models

The recent advances in barrier models have been covered in one of our recent workshops.[32] Models of the outer epithelia of the human body—namely the skin, the intestine, and the lung—have found valid applications in both research and industrial settings as attractive alternatives to animal testing. A variety of approaches to model these barriers are currently employed in such fields, ranging from the utilization of ex vivo tissue to reconstructed in vitro models, and further to chip-based technologies, synthetic membrane systems, and, of increasing current interest, in silico modeling approaches. An international group of experts in the field of epithelial barriers was convened from academia, industry, and regulatory bodies to present both the current state of the art of nonanimal models of the skin, intestinal, and pulmonary barriers in their various fields of application, and to discuss research-based, industry-driven, and regulatory-relevant future directions for both the development of new models and the refinement of existing test methods. Issues of model relevance and preference, validation and standardization, acceptance, and the need for simplicity versus complexity were focal themes of the discussions. The reader is referred to this state-of-the-art report.[32]

4.08.3.1.3 Biokinetic modeling of the in vivo situation

Biokinetic models can be divided into two general groups: data-based (classical) models and physiology-based models.[33,34]

Physiology-based biokinetic (PBBK) models are especially useful for in vitro-to-in vivo, route-to-route, and animal-to-human extrapolations because they incorporate relevant anatomical structures that can be parameterized using independently derived parameters.[3,35–37] Our earlier ECVAM workshop[38] addressed the state of physiology-based pharmacokinetic (or toxicokinetic) modeling, highlighting needs and opportunities to meet the 3Rs agenda. The report was instrumental to set up the consortium for the EU consortium Predict-IV, which combined PBPK modeling with long-term exposures and omics technologies to address repeated dose toxicity. The results of the project have been summarized in a special issue of *Toxicology In Vitro* in Dec. 2015.[39]

In contrast to data-based models, PBBK modeling allows the description of the time course of a compound's amount/concentration at the site of its action. In addition, PBBK models incorporating QSAR- and in vitro-derived parameters, coupled with in vitro assays of tissue/organ toxicity, have the potential to replace in vivo animal studies for quantitative assessment of the biological activity of xenobiotics.[40–43] Increasingly, information from barrier models and those of metabolite formation are included into PBPK models, often improving over mere in silico predictions.[44,45] PBPK models are seeing increasing use in risk assessment.[46–49] They offer promise especially for interspecies extrapolations.[50]

4.08.3.2 The Emerging Role of ADME in In Vitro Toxicology

The in vitro toxicology field is increasingly developing methods satisfying the information needs for regulatory toxicology as summarized on behalf of the European Commission[51] and confirmed by independent expert review.[52] Going a step further, a roadmap was developed by expert consensus how to achieve animal-free systemic toxicity testing including toxicokinetics,[3,4] see later.

4.08.3.2.1 In vitro biokinetics

It should be self-evident that the same gain in understanding is provided by kinetics in vivo and in vitro. However, in vitro behavior of an added substance is usually neglected and we use the nominal concentrations. Left aside that the purity claimed by vendors is often not met in reality and already therefore nominal concentrations are often not exact; many other factors affect the effective amount of substance in vitro (Fig. 1):

- solubility of the substance in the solvent and after addition to the culture;
- binding of the substance to culture plastics and medium constituents, such as albumin of fetal calf serum;
- oxidation and other conversions by the environmental conditions;
- metabolism by the cell of interest or cocultured cells;
- evaporation;
- particle sizes (distribution and agglomeration) in case of nanomaterials;
- other substances coapplied in mixtures and formulations.

All this will change the concentration of free substance, which is typically considered effective on a cellular target. However, we should keep in mind that it is not necessarily the concentration (as peak concentration or area under the curve) that matters, but that especially some lipophilic substances can accumulate in the biological systems, therefore making the absolute amount (and thus the proportion of cell culture media vs. cell mass) a determinant of substance's effects.

Another aspect often overlooked is that kinetics in vitro differ completely from those in vivo: While in vivo, especially for oral absorption, some type of Bateman function (slowly starting increase to a peak and the decrease due to redistribution, metabolism, and excretion, more precisely: a one compartment body model as a function of time with first-order invasion and first-order elimination[53]) is observed for blood and with some delay and distortion in the tissue; in vitro the substance is added typically in an instance and remains as we lack most elimination routes. It is not clear, what consequences this has, for example, the slowly increasing concentrations might induce defense mechanisms, which make the cell more resilient.[54]

4.08.3.2.2 The lack of metabolism in vitro

Awareness is high, that in vitro models mostly lack metabolic capacities.[55] However, the question might be raised, whether it is better to have no metabolism than the wrong metabolism (as most animal models represent), since substance metabolism is usually protective? How often might protective metabolism by animal species give false assurance of safety? At the same time, lack of defense mechanisms might be as important as lack of activation by metabolism to bias in vitro effects and thus model predictivity.[54]

4.08.3.2.3 Quantitative in vitro-to-in vivo extrapolation

It is obvious that in vitro toxicology ultimately wants to predict the effects on an organism level, which requires extrapolation (QIVIVE). Bas Blaauboer and colleagues long ago spearheaded a discussion on integrated testing of in vitro, in silico, and ADME information.[1,56–58] Over the years, a number of successful examples have been developed by them and others including neurotoxicity,[57,58] acute oral toxicity and repeated dose toxicity,[59] developmental toxicity,[60,61] and genotoxicity.[62] Within the framework of the European integrated Predict-IV[39], the work was devoted to pharmacokinetic modeling of in vitro experiments, physiology-based pharmacokinetic (PBPK) modeling, mechanistic models of toxicity for the kidney and brain, large-scale dose–response analysis methods, and biomarker discovery tools.[63]

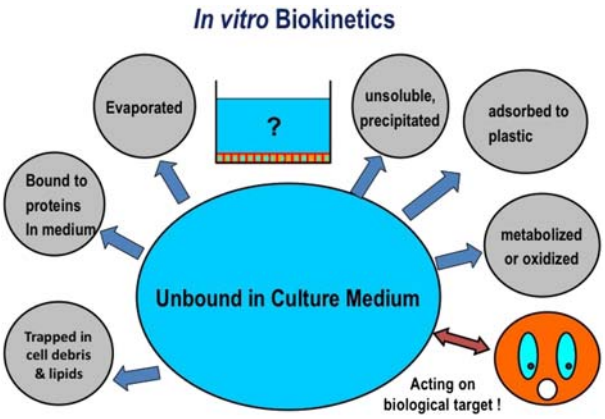

Fig. 1 Aspects of in vitro biokinetics impacting on the unbound portion of substance effecting the target cell.

4.08.3.2.4 ADME contributions to ITS

Increasingly, we acknowledge that our information needs as to the safety of substances cannot be satisfied by single assays. At the same time, a simple battery of tests bears the risk of accumulating false positive results. A more intelligent "integrated" combination of different tests (and in silico tools) promises to optimize resources and predictivity. This has been termed ITS or more recently by OECD Integrated Approaches to Testing and Assessment (IATA).[5,64,65] It is clear that an ideal ITS includes information on ADME to improve the prediction of in vivo results.

4.08.4 The Advent of Systems Toxicology—Need for ADME

The components of the body disturbed by the toxicant represent a network. Systems biology uses the relationships between all elements rather than approaching them separately, and attempts to unite biological fields.[66] Systems biology is defined as[67,68]

> Systems biology: Study of the mechanisms underlying complex biological processes as integrated systems of many diverse, interacting components. It involves (1) collection of large sets of experimental data (by high-throughput technologies and/or by mining the literature of reductionist molecular biology and biochemistry); (2) proposal of mathematical models that might account for at least some significant aspects of this data set; (3) accurate computer solution of the mathematical equations to obtain numerical predictions; and (4) assessment of the quality of the model by comparing numerical simulations with the experimental data.

It is very attractive to apply this concept to toxicology, creating a systems toxicology[69]: The move toward systems toxicology and massively parallel techniques opens new opportunities but, at the same time, raises problems in deriving meaningful information out of the wealth of generated data.[2] Such data is increasingly represented as networks, in which the vertices (e.g., transcripts, proteins, or metabolites) are linked by edges (correlations, interactions, or reactions, respectively). Networks can vary in their functionalities. Some are undirected graphs that enable only the study of structure; others, like the biochemical network, are characterized by interactions of varying strengths, strongly nonlinear dynamics, and saturating response to inputs.[70]

Network analysis has evolved into a very active and interdisciplinary area of research encompassing biology, computer science, social, and information sciences. Many studies are highly theoretical, but they may eventually help in identifying signatures (SoT) and pathways of toxicity (PoT).[71] The network research has three primary goals. First, it aims to understand statistical properties that characterize the network structure in order to suggest appropriate ways to measure these properties. This is very relevant to SoT identification. Second, it aims to create models of networks that can help us understand the meaning of these properties and how they interact with one another. Third, it aims to predict what the behavior of networked systems will be on the basis of measured structural properties. This direction can be very useful in elucidating PoT. Here, the relationship of ADME and systems toxicology is of special interest. Simply said, the ADME aspects are moving hazard data to a systems level. At the same time, the combination of PBPK and QIVIVE in systems biology has improved the prediction of ADME.[72]

Ultimately, systems toxicology aims at modeling the effects of toxicants in metabolic networks.[73,74] Integrating cellular metabolism into a multiscale whole-body model has been attempted[75] and drug effects on these networks (more systems pharmacology) have been proposed.[76] This depends critically on combining dynamic and kinetic information. Thus the avenues toward systems toxicology require the development components for ADME prediction.

4.08.5 Conclusions

Pharmaco- and toxicokinetics, that is, the assessment of adsorption, distribution, metabolism, and excretion of xenobiotics, have transformed our understanding of in vivo pharmacology and toxicology. Astonishingly, some areas of regulatory toxicology still do not request such information, which can boost our understanding of the human relevance of our findings. The respective models of substance kinetics, such as physiology-based pharmacokinetic models, are increasingly refined by the input from in vitro models, for example, for epithelial barrier function or metabolism of test agents. In vitro, kinetic phenomena play a similar role, that is, how the test agent is ultimately available to the cells as similar redistributions and transformations occur, but this is regularly neglected in our interpretations of results. Reverse biokinetics, that is, a quantitative in vitro-to-in vivo extrapolation, is critically important to predict in vivo exposures corresponding to active concentrations on a cell and tissue level, thus making predictive use of in vitro findings. This information represents the complement to hazard identification and characterization by cellular models in order to develop a systems toxicology approach.

The critical role of ADME for interpreting in vivo findings has been shown impressively by improving attrition of drugs in human trials due to such problems. The combination of in vivo, in vitro, and in silico tools is more common here than in many other fields of toxicology. There are enormous needs to move to more use of in vitro tools in toxicology, to improve human predictivity, and spare animal lives. To make ultimately sense of in vitro data, the case is made here that we need to address both the kinetics of substances in the in vitro models and the modeling to extrapolate to the in vivo situation. PBPK methods lend themselves for such reverse kinetics, but examples of their use for QIVIVE are rare and not yet generalizable. The expectation is though that the input from in vitro barrier and metabolism models can improve on the pure in silico models.

4.09.1 Introduction to *In Silico* Tools and Applications

The goal of medicinal chemistry is to discover new pharmaceutical products through the design and synthesis of new compounds. This process simultaneously optimizes desirable biological effects including potency, metabolic stability and so on, at the same time as avoiding adverse effects. Toxicity is a significant adverse effect and one of the main reasons drugs fail in clinical trials or when drugs reach the market.[1] This attrition rate is a major impediment to bringing new drugs to the market and a significant contributor to the high cost of drug development.[2] Traditional approaches to testing compounds for toxicity rely on exposing groups of animals to a chemical or product, observing the pharmacokinetics and pharmacodynamics, gross and histological pathology, and signs of any adverse events. Animal studies are expensive and time-consuming, taking months or years, and costing hundreds of thousands or millions of dollars. In the early phases of drug discovery it is not possible to perform these types of tests because of both the cost as well as the throughput needed to rapidly profile the tens of thousands of compounds typically evaluated in the early phases of drug discovery. *In vitro* and *in silico* approaches are the only viable approaches for assessing toxicity as part of lead identification and optimization.

The use of *in silico* toxicology supports medicinal chemistry by identifying compounds with potential toxicity. The earlier in the drug discovery process a chemical or chemical series can be eliminated from consideration because of toxicity, the greater the impact on the overall productivity (i.e., the "fail early, fail fast" paradigm). Results from *in silico* methodologies can be generated quickly and cheaply based on the chemical structure alone. These methods also provide additional information to support future research directions, such as what areas of the molecule may need to be modified based on any predicted toxicity.

There are a number of areas where *in silico* toxicology is used in pharmaceutical R&D, including:

- *Prioritizing lead series*: It is possible to analyze the core scaffolds or lead series to understand whether they contain any structural elements associated with toxicity. *In silico* toxicology can help prioritize which chemical series to pursue or potentially modify to mitigate any projected toxicity.
- *Lead optimization*: *In silico* toxicology can support the design of analogs as part of lead optimization by helping to determine whether any structural modifications increase or decrease potential toxicity risk.

- *Supporting design of synthetic processes*: *In silico* toxicology can be used to assess the mutagenic potential of synthetic reagents, catalysts and intermediates to identify and reduce the possibility of having DNA-reactive impurities being present in a final drug product.
- *Prioritizing testing*: *In silico* toxicology can also be useful is selecting the order of toxicity testing in preclinical development. It is possible to use the predictions to initially focus on selecting those tests that would de-risk any potential toxicity identified (i.e., target organs). This again supports the "fail early, fail fast" paradigm. Often, low cost *in vitro* tests (such as the mini or modified Ames test or screening hERG assay) are conducted prior to the preclinical safety assessment phase.
- *Supporting regulatory submissions*: *In silico* toxicity predictions can be used to directly support submissions for drug impurities.[3] A computational assessment using *in silico* methodologies to predict the potential mutagenicity of impurities, degradants, intermediates, etc. can be performed.
- *Classification and labeling*: *In silico* approaches can be used to support classification and labeling where a complete battery of toxicity tests has not been performed. Once the potential mutagenicity has been determined using *in silico* approaches, compounds can be classified for control strategies (Muller et al., 2006).[4]

In the last several years, the use of *in silico* tools to predict toxicity has increased significantly as a result of improvements in the performance of the models, improvements in their ease-of-use and their acceptance as part of product development and some regulatory submissions. There are also an increasing number of guidelines to support the interpretation of results, an essential component to gain acceptance.[3,5] *In silico* software programs to predict toxicity combine biology and chemistry with modeling and computational science in order to increase the predictive power in the field of toxicology. *In silico* tools are inexpensive to run (once the model has been built), provide a level of confidence in the prediction and routinely provide an indication of the structural basis for any positive result. These approaches often provide an indication of the biological mechanism of the predicted toxicity. These criteria are useful for medicinal chemists since it is important to understand the basis of the predictions so that decisions can be made about future research directions.

The three most widely used *in silico* toxicity prediction methodologies used today are:

- *Statistical-based*: Statistical-based models, often referred to as Quantitative Structure-Activity Relationship (QSAR) models, are used to predict various toxicity endpoints based on the chemical structure.[6,7] These models are constructed from historical laboratory data (training set) where chemical substructures and molecular properties (descriptors) are generated from the list of chemicals. Statistically-based mathematical models are built using these descriptors to predict the target toxicological effect.
- *Expert rule-based*: Expert rule-based methodology (often referred to as alerts) is an approach to predict toxicity based upon the presence of structural rules.[6,8] Expert knowledge based on toxicity data and mechanisms is used to create rules on the likelihood of toxicity in a structure, with information from all applicable rules used to make an overall prediction. Rules usually are encoded as one or more substructures that are matched against the test chemical. A prediction is made when a predictive alert matches. These rules often indicate a mechanistic basis for any positive prediction.
- *Read-across*: Read-across is a semi-manual approach to making predictions from historical data.[9–12] It relies on the identification of appropriate analogs, based upon a mechanistic-based structural category or some other criteria. Data from these analogs are then used to make the prediction.

Other approaches include 3D modeling (e.g., CoMFA approaches)[13] and quantum chemistry (e.g., whole molecule reactivity descriptors such as E_{HOMO} and E_{LUMO} differences) are also used to a lesser degree.[14,15] Approaches that do not identify the structural basis for a prediction are limited in their applicability to medicinal chemistry.

Table 1 lists the some commonly used systems, the methodology used and the supplier.

All *in silico* approaches have strengths and weaknesses and **Table 2** summarizes them for the three methodologies described. One strength of all three methodologies is that they do not require compounds to be synthesized, and all are limited by the availability of relevant toxicity data. In practice, all three methods are often used together and an expert review based on the weight of the evidence is generated from (1) the prediction results and confidence scores, (2) the underlying basis for the predictions, as well as (3) expert

Table 1 List of common systems and suppliers of *in silico* software

DEREK Nexus	Lhasa Limited (Leeds, UK)	
Toxtree	Ideaconsult Ltd (Sofia, Bulgaria)	

Table 2 Strengths and weaknesses of different *in silico* approaches

Method	*Strengths*	*Weaknesses*
Statistical-based	- Assesses all areas of the molecule, including whole molecular properties - Can often explain the structural basis for the prediction - Quick to generate a model - Fast to compute a prediction	- No direct mechanism provided, but may be elucidated as part of the QSAR explanation - Difficult to model complex *in vivo* outcomes
Expert rule-based	- Capable of precisely identifying reactive groups or pharmacophores that are linked to a mechanism - Includes reasons for activation and deactivation - Fast to compute a prediction	- Usually localized to the presence of a substructure and often does not take into account the whole molecule - Difficult to make supported negative predictions
Read-across	- Easy to understand and interpret - Has potential applicability in predicting complex *in vivo* outcomes where there is data on suitable analogs	- Manual methodology that may result in inconsistent results that are difficult to repeat - Time consuming to generate and fully document the results - Difficult to show that a chemical lacks toxicity

knowledge. This expert review has been shown to improve the accuracy of the overall prediction at the same time as providing an assessment of the overall confidence in the prediction.[16–19]

The Organization for Economic Co-operation and Development (OECD) has published a series of validation principles to help in understanding the applicability of these models for regulatory purposes: "1. *a defined endpoint*; 2. *an unambiguous algorithm*; 3. *a defined domain of applicability*; 4. *appropriate measures of goodness-of-fit, robustness and predictivity*; 5. *a mechanistic interpretation, if possible*".[20] These principles are important to use in assessing any model to use in predicting toxicity. The five validation principles are discussed in detail in this chapter; however, it is important to assess whether the model is fit-for-purpose. For example, a model that does not adhere to the principles may be acceptable for use in prioritizing candidates earlier in the process but not acceptable for regulatory submissions.

In silico models have been built to predict a wide range of endpoints important to assessing toxicity. These include *in vitro* and *in vivo* test results alongside information derived from human adverse events that are reported during clinical trials or post-approval drug monitoring.[21–25] The endpoints include: genotoxicity (*in vitro* and *in vivo*),[26] *in vivo* acute toxicity (oral, inhalation, dermal),[27] skin or eye irritation/corrosion,[28] skin sensitization,[28] repeated dose toxicity,[27] reproductive and developmental toxicity,[29] carcinogenicity,[26] specific organ toxicity and other areas of concern such as phospholipidosis.[30] Certain models identify the presence or absence of a specific hazard, whereas others provide an estimate of a safe dose and can be used to assess risk.

Models are often built from public domain data sources by commercial companies and academic laboratories which provide an off-the-shelf solution. These models are often updated when new data is made available; however, they invariably reflect the chemical space found in public domain compounds. They can be applied to proprietary test chemicals; however, if there is limited overlap in the chemical space they may be unable to make predictions for the types of chemical being assessed. Model and alerts that are built from proprietary data sources may provide suitable coverage of chemistry; however, there is a high cost associated with building such models and keeping them up-to-date. As a hybrid approach, many commercial organizations will work with pharmaceutical companies to ensure the public model correctly reflects proprietary chemical space. This reduces the burden of building such models for the pharmaceutical company and ensures more robust models are available and applicable to their chemistry.

The following chapter outlines the three commonly used *in silico* toxicology methodologies: statistical-based (QSAR) models, expert rule-based, and read-across. A description is provided illustrating how these models are built and how they make predictions. This will help to explain the strengths and limitations of the different methodologies since they may otherwise appear as a "black box". Examples are provided of commercial and academic systems used to make predictions. A case study will be presented to illustrate how all three methodologies can be used to support the prediction of mutagenicity. Finally, the chapter concludes with a discussion of these *in silico* methodologies alongside some future directions.

4.09.2 Statistical-Based Methodology

4.09.2.1 Overview

A statistical-based methodology or QSAR uses a mathematical model that, for a given chemical structure, will estimate a value for a biological effect such as a specific type of toxicity.[6,7] These models are referred to as "statistical-based methodologies" in regulatory guidelines.[3] The only input to the model is the chemical structure, which is an electronic record of the compounds' atoms, bonds and connectivity. These models are built using training sets containing a set of chemicals with a consistently measured toxicity response endpoint, such as positive/negative bacterial mutagenicity data or No Observed Adverse Effect Level (NOAEL) data.

Once a training set has been created, the model building process begins by calculating molecular descriptors directly from the chemical structures in the training set. A data table is generated and prepared containing the molecular descriptors as well as the toxicity response for all the training set compounds. A mathematical model is then built by selecting a subset of molecular descriptors as independent variables (x-variables) to predict the toxic response (y-variable). Once a model has been built and validated, it can be used to predict the toxic effect of test chemicals not present in the QSAR model training set. At this point it is important to be able to interrogate the QSAR model results and examine the underlying reasons for the prediction, especially any structural features of the test chemical that are responsible for a positive prediction.

In addition to the OECD validation principles discussed earlier, there are three important guiding principles when developing QSARs to support the prediction of toxicity:

(1). Keep the models simple with as few and simple descriptors as possible to avoid overtraining, support interpretation and ensure the model's domain is as broad as possible
(2). Generate models that provide a high level of prediction transparency, both the structural basis for the prediction, descriptor weighting, and an indication of the biological significance
(3). Provide information to support a hazard or risk assessment, that is, either classification of specific toxicity or the dosage required for toxic effects to appear

The following sections outline the general process of building, using and explaining QSAR models as well as examples of commercial and other types of QSAR models available today.

4.09.2.2 Building Statistical-Based Models

Constructing a suitable training set is the most important part of building the statistical-based (QSAR) model and often the most time consuming. Information on historical studies is generally publicly available through on-line websites (e.g., the National Toxicology Program (NTP) website[31]), toxicity study reports or in the public literature. Studies may have been generated across different organizations and according to different experimental protocols. When collating an electronic record of this information, it is important to record as much detail as possible about the source, the experimental design and other factors to assess how the study was performed (e.g., GLP status, dose levels, etc.). Criteria should be established as to what type of studies (based on the study protocols, design, quality, and source) to include in the training set. An overall study call (e.g., LD_{50} values or positive/negative mutagenicity) is usually provided alongside individual study findings and observations, such as whether as part of a reproductive study, cleft palates were observed and at what dose. The overall study call generated by the study director may be the biological response to be predicted; however, there will be situations where a different call might be calculated as the purpose for the original call is rarely for QSAR model development. For example, a training set may be based on the presence or dose at which an individual finding was reported (e.g., a cleft palette identified in a reproductive study). This process is important to satisfy OECD validation principle #1 "a defined endpoint." As discussed earlier, it is important to keep models simple, and modeling a specific effect is usually less complex than modeling an overall *in vivo* study (e.g., LD_{50} for an entire reproductive toxicity study covering all types of findings). Models created around specific phenotypes or mechanisms will generally be less complex and be easier to explain.

When combining the data from different sources it is important to ensure the data is recorded consistently. This includes simple checks such as if the data is recorded using the same units and how the chemical structures are recorded. A connection table (electronic record of the atoms, bonds, and connectivity) should be used for each chemical. Commonly used formats for storing chemical structures are an SD file, a list of MOL files or a list of SMILES strings.[6] It is important to determine if or when the same chemical has been tested more than once. This may result when the same chemical is: (1) tested in more than one laboratory, (2) tested in different salt forms and mixtures, (3) reported with different structural representations (e.g., the nitro group is drawn with different formatting conventions) or (4) reported with different stereo-chemical forms (i.e., known-stereo versus partial stereo or non-stereo forms). Different sources may have conflicting study calls resulting from different study protocols and reporting. It is important to establish consistent rules to handle these situations and determine an overall call for each chemical that may be derived from multiple study results.

Once the training set has been harvested, cleaned and processed, the next step is to determine the types of chemicals present in the training set and the frequency distribution of the toxicity data being modeled. Grouping the chemical structures based upon structural similarity will identify the chemical classes in the training set and hence the type of chemicals that the model will be able to ultimately predict. The absence of certain chemical classes may lead to further data harvesting efforts called "gap filling". The distribution of the toxic effect data should be examined and mathematical transformations considered. For example a continuous toxicity response may have an exponential frequency distribution, and to facilitate modeling efforts, it should be transformed using a log transformation.

The next step is to generate molecular descriptors from the chemical structures in the training set. There are many types of molecular descriptors used in statistical QSAR models and several approaches for generation of these descriptors have been developed.[14] One approach is to use a list of pre-defined substructures and match them against the training set.[32,33] Alternatively, different substructures can be generated algorithmically by either tracing paths through the compounds or combining smaller building blocks together into larger scaffold-like substructures.[34] Creation of these substructures may be guided using the toxicity response data to select discriminating substructures associated with predominantly positive or negative compounds in the training set (or compounds with predominantly high or low values). Molecular properties calculated from the whole molecule such as molecular

weight, logP, polar surface area, and so on can also be generated to ensure the model addresses more than just portions of the test compound. These molecular descriptors will also be used to explain the results; hence if it is important to explain the model results using structural features, then structural features need to be included as descriptors.

The different molecular descriptors calculated are added to a data table. The molecular descriptors that encode the presence or absence of structural features can be encoded as a binary property where "1" indicates the presence and "0" indicates the absence of a specific feature. Other properties, such as molecular weight, can be encoded directly after normalization. Further processing of this table is necessary prior to modeling. Again, to satisfy the "as simple as possible" rule, the list of possible descriptors should be reduced. Correlated descriptors should be identified and pruned and non-discriminating descriptors (i.e., those whose presence or absences results in predominantly the same value) should be removed. The toxic effect is also included in this table and can be used to filter these descriptors by magnitude of effect; for example, those descriptors highly correlated with the toxic response variable might be prioritized while descriptors with low correlation might be removed. Knowledge of the problem being modeled can be beneficial in the selection of descriptors. Additional normalization transformations are carried out, such as auto-scaling, to ensure all descriptors are considered equally in the modeling process based upon their population and distribution of values.

The next step is to build and optimize a statistical model that encodes the relationships between the molecular features and the biological response. Selection of the modeling approach should balance the need to keep the models as simple as possible, yet robust enough to model the complexities of the structure-activity relationship data and support prediction of the desired chemical classes. For simple data sets, such as those focused around a specific class of compounds, modeling techniques such as linear regression, logistic regression, and decision trees may be used; whereas more complex and structurally diverse datasets will require the use of modeling approaches such as Partial Least Squares, Partial Logistic Regression, Random Forests, Support Vector Machines, and Artificial Neural Networks.[35–40] All models mathematically encode the relationships between the individual descriptors and the toxic response by calculating one or more weights per descriptor, etc. and optimizing modeling parameters. The use of a specific modeling approach and optimization procedure is described as OECD validation principle #2 "an unambiguous algorithm." Fig. 1 summarizes this process of harvesting the data, generation of molecular descriptors, processing and preparation of a table and creation of a mathematical model relating toxicological response data to the selected descriptors.

4.09.2.3 Assessing Quality and Overfitting

A validation set is used to characterize statistical-based (QSAR) model performance. An external validation set is a list of chemicals not used in building the model (i.e., are not in the model's training set) which has the same toxicity response endpoint. The model predicts the values for this validation set and the performance is quantified by comparing the predictions against the actual values. The best validation set contains enough compounds to test all the chemical classes and toxicophores being modeled and has a distribution of data values similar to that in the training set.

Another approach, referred to as cross-validation, can be used to estimate the performance of the model without the burden of finding external data. It splits the training set into a series of training/test set pairs to predict all the training set compounds using a series of "reduced" models. For example, a 10% cross-validation will split the original training set into 10 different pairs. For each pair 10% is set aside for testing and the remaining 90% is used as a training set to build a reduced QSAR model used to predict the 10% in the test set. A total of ten models are built to predict all the training set compounds ensuring that no test set chemical is part

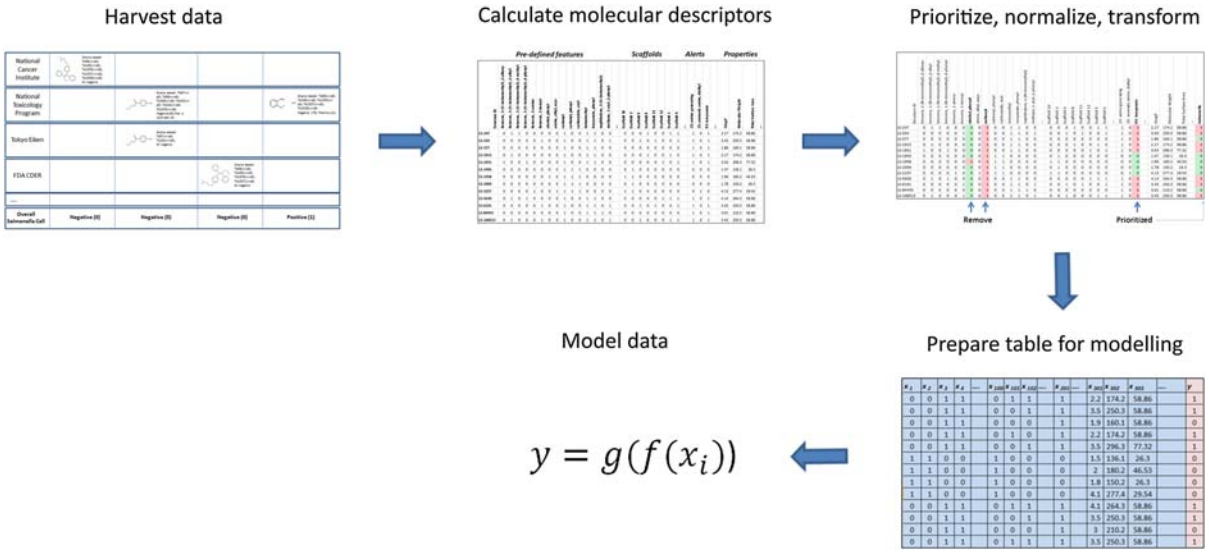

Fig. 1 Process of building a QSAR model from data.

of the model training set used to predict it. Cross-validation predicts every compound in the training set and is useful in estimating the predictive performance of the model in the absence of external data. However, the individual predictions are not representative of individual compound predictivity performance or that of chemical classes as they were not predicted by a complete QSAR model constructed using the entire training set.

The predictive performance of the QSAR model is calculated by comparing the actual and predicted values. When the toxicity response variable is binary (that is, it only contains positive or negative outcomes), the first step in assessing the performance of the model is to calculate a table (Table 3) that summarizes the number of true positive and true negative predictions, as well as the false positives and false negative predictions. These values support calculation of a series of "Cooper statistics",[41] which assess the overall performance of the model (Table 4). For QSAR models where the toxic response data is continuous, it is useful to use scatterplots to visualize the performance of the predicted versus actual data to illustrate regression performance and distribution of the residual values (as shown in Fig. 2). A well performing model has values close to the diagonal on the regression plot, while the residual plot has values randomly distributed about zero with no clear trends or bias. In addition, a number of different common statistics (Table 5) can also be used to assess the overall performance of the QSAR model. The formulas use y_i to represent the individual values of the response data, $\widehat{y}_i$ to indicate the value of the corresponding prediction, and $\bar{y}$ to indicate the mean response value.

4.09.2.4 Using Statistical-Based Methodologies

Any model adhering to OECD principles should initially consider whether each of the test chemicals is within the applicability domain of the QSAR model. This check often examines the model descriptors (e.g., the structural features present in the test chemical) used to make the prediction and whether the test compound is similar enough to the training set compounds to ensure its chemical subclass may be adequately predicted by the QSAR model.

All the QSAR model molecular descriptors are then calculated for the test compound(s). Once calculated, the values of these "x-variables" are used with the model weights (and other terms) to calculate a prediction. This value may be the actual toxic response estimate; however, with certain modeling approaches, this value may represent the probability of the positive outcome. In this case, this probability is usually converted to a classification where values above a threshold (e.g., 0.6) are assigned positive, values below a threshold (e.g., 0.4) are negative while those between these two values (e.g., 0.4 – 0.6) are considered indeterminate or to have equivocal results (since there is a lack of strong evidence and/or conflicting positive and negative evidence).

Once an estimate has been generated, it is important to understand how a model generated the prediction by understanding the structural basis for the prediction and potentially a mechanistic rationale. For simple models (such as a linear regression) inspecting the descriptors along with the model parameters may be sufficient to understand how the model generated the results. For more complex modeling approaches (such as non-linear approaches), it is not as easy to inspect the model parameters and descriptors

Table 3 Computation of the number of true/false positives and negatives

		Predicted		
		Positive	Negative	Total
Observed	Positive	TP	FN	TP+FN
	Negative	FP	TN	FP+TN
	Total	TP+FP	FN+TN	TP+FN+FP+TN

Table 4 Computation of statistics to assess QSAR models for binary endpoints

Statistic	*Formula*	*Description*
Concordance	(TP+TN)/(TP+FN+FP+TN)	Shows the overall accuracy of the model or the proportion of correctly predicted examples
Sensitivity	TP/(TP+FN)	Proportion of correctly assigned positive predictions out of all positive chemicals
Specificity	TN/(TN+FP)	Proportion of correctly assigned negative predictions out of all negative chemicals
Positive Predictivity	TP/(TP+FP)	Proportion of correctly assigned positive predictions out of all positive predictions
Negative Predictivity	TN/(TN+FN)	Proportion of correctly assigned negative predictions out of all negative predictions
False positive rate	FP/(FP+TN)	Proportion of negative chemicals that are incorrectly classified as positive
False negative rate	FN/(FN+TP)	Proportion of positive chemicals that are incorrectly classified as negative
Coverage		Proportion of chemicals in the test set that have been predicted

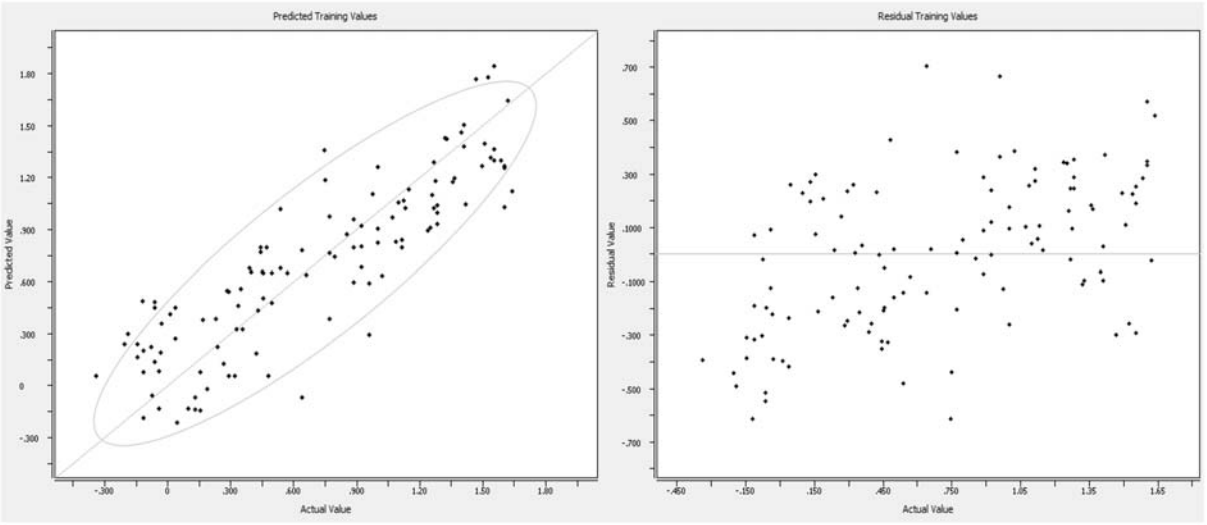

Fig. 2 Comparing predicted with actual values alongside a residual plot.

Table 5 Assessing the performance of QSAR models where the response is continuous

Statistic	*Definition*	*Formula*
MSE	Mean Square Error	$\sum_1^n (y_i - \hat{y}_i)^2 / n$
PRESS	Predictive Residual Sum of Square	$\sum_1^n (y_i - \hat{y}_i)^2$
Q2	Explained variance in the prediction	$\sum_1^n (y_i - \hat{y}_i)^2 / (y_i - \bar{y})^2$

directly. These approaches are usually accompanied by an "explanation" functionality that is capable of identifying the structural basis for the prediction. This structural basis may in turn help elucidate a mechanistic basis for the prediction.

4.09.2.5 Available Models

4.09.2.5.1 Leadscope model applier

The Leadscope® Model Applier is an application in which a series of QSAR models and expert alerts are distributed to support prediction of the potential toxicities of chemicals. All the QSAR models were constructed in collaboration with the U.S. Food and Drug Administration (FDA) by the Division of Applied Regulatory Science (DARS) staff (previously known as the Division of Drug Safety Research). The models were built under a Research Collaboration Agreement (RCA) using the Leadscope Predictive Data Miner software.[21–25,42–46] Complete documentation of the weight of evidence methodology used for the preparation of the model training sets and the sources of the data has been published by the DARS group. The RCA QSAR models were built from public information and include the training set structures and calls as part of the model description. The RCA models are implemented with molecular descriptors that include structural features and up to eight calculated properties. The structural features include Leadscope® default hierarchy features plus the predictive scaffolds constructed specifically for each model. The eight calculated properties include parent molecular weight, parent atom count, LogP, polar surface area, hydrogen bond acceptors, hydrogen bond donors, number of rotational bonds and, Lipinski score (rule violation).

There are currently eight suites containing RCA QSAR models with over 80 biological endpoints. The suites can be divided into two major groups of endpoint models: 1) human clinical endpoints; and 2) non-human toxicity endpoints, as shown in **Table 6**. The majority of the QSAR models are specifically designed to provide decision support for toxicological and clinical endpoints that are considered important in the safety analyses of substances. However, the Model Applier also includes a subset of models that have proven useful for research on toxicological properties of chemicals.

The prediction results for each model are presented as the "prediction" and the "positive prediction probability". The prediction can be "positive", "negative", "indeterminate", and "not-in-domain". The positive prediction probability is given as the likelihood value between 0 (non-toxic) and 1 (toxic). The higher the probability is, the greater chance there is of the test chemical being toxic for a particular endpoint. The model domain is defined for a test compound within the Leadscope application using two criteria: 1) containing structural model features in addition to property descriptors; 2) being within a group of similar structures in the training set.

Table 6 Summary of QSAR models available from Leadscope

Model suite	*Individual models*
Carcinogenicity	Carcinogenicity Male Mouse, Carcinogenicity Female Mouse, Carcinogenicity Male Rat, Carcinogenicity Female Rat, *In vitro* Cell transformation, SHE, BALB/c-3 T3, C3H10T1/2
Genetic Toxicity	*In vitro* Salmonella, In vitro E Coli - Sal 102 A-T Mut, *In vitro* CHO, HGPRT, Mouse Lymphoma, Micronucleus *in vivo* mouse, Chromosome Aberrations in vivo, Chromosome Aberrations In vivo rat, Chromosome Aberrations *in vivo* other rodent, *In vitro* chrom. ab. CHL, *In vitro* chrom. ab. CHO, SCE *in vitro*, SCE *in vitro* CHO, SCE *in vitro* other cells
Reproductive Toxicity	Repro Rat Male, Repro Mouse Male, Repro Rat Female, Repro Mouse Female, Sperm Rat, Sperm Mouse
Developmental Toxicity	Structural Dysmorphogenesis (rodent, rat, mouse, rabbit), Visceral Dysmorphogenesis (rodent, rat, mouse), Fetal Growth Retardation (rodent, rat, mouse, rabbit), Fetal Weight Decrease (rodent, rat, mouse, rabbit), Fetal Death (rodent, rat, mouse, rabbit), Post Implantation Loss (rodent, rat, mouse, rabbit), Pre Implantation Loss (rodent, rat, mouse, rabbit)
Neurotoxicity	Behavioral Toxicity Newborn Rodent, Behavioral Toxicity Newborn Rat, Behavioral Toxicity Newborn Mouse
Human Adverse Cardiological Effects	Conduction Disorders, Coronary Artery Disorders, Electrocardiogram Disorders, Heart Failure Disorders, Arrhythmia Disorders, Bradycardia Disorders, QT prolongation, Tachycardia Disorders, Torsades, Myocardial Infarct Disorders, Myocardial Disorders, Palpitations, Rate Rhythm Disorders
Human Adverse Hepatobiliary Effects	Bile Duct Disorders, Cholestasis, Liver Acute Damage, Liver Enzyme Release Disorders
Human Adverse Urinary Tract Effects	Bladder Disorders, Blood in Urine Disorders, Renal Disorders, Kidney Function Tests, Nephropathy Disorders, Urolithiasis Disorders

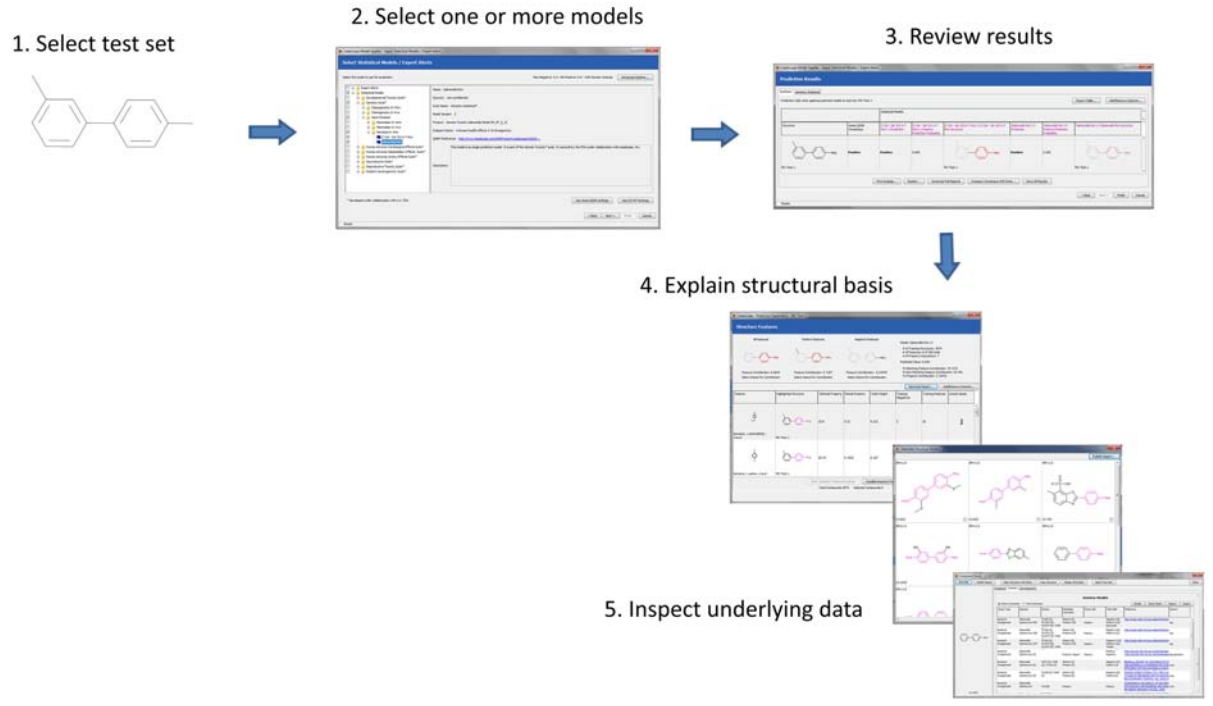

Fig. 3 Using the Leadscope Model Applier to make predictions using QSAR models.

Fig. 3 illustrates how QSAR models for one or more endpoint predict one or more test chemicals and how the information is explained, including the structural basis for the prediction and the underlying data.

4.09.2.5.2 Sarah Nexus

Sarah Nexus (Sarah) is a statistical-based software program that was created to provide mutagenicity predictions from analysis of 2-D chemical structures. The software is based on a hierarchal list of models that combines both global and local features, and will select the most appropriate model for the prediction. While a global model provides broad coverage it may not be as sensitive to local variations, whereas local models are more accurate for fragments within their chemical space, but they are narrower in their scope. The

software retrieves fragments of various sizes matched from the test structure, and includes fragments that overlap to ensure greater accuracy in predictions. Relevant fragments are arranged into local and global networks and information from each fragment is evaluated and a recursive learning method is used to assess each fragment's negative or positive contribution. The confidence associated with each relevant fragment then contributes to an overall prediction. The structural features considered meaningful in the prediction are highlighted in the test structure. A confidence score is provided and is intended to correlate with the accuracy of the prediction.

4.09.2.5.3 TEST

The Toxicity Estimation Software Tool (TEST) has been developed by the U.S. Environmental Protection Agency to allow users to easily estimate toxicity using a variety of QSAR methodologies. TEST provides multiple prediction methodologies (hierarchal, single model, group contribution, Contrera 2003 method, nearest neighbor and consensus). The Hierarchal method uses a variation of Ward's Method[47] to generate a series of individual models based upon clusters (chemicals from entire set which have similar properties) from the training set. Once the clustering process is complete, the clusters are analyzed for QSAR, and if acceptable, a genetic algorithm is used to determine an optimal descriptor set to characterize the toxicity values of chemicals within the cluster. Once the model has been optimized and validated, the test compound is checked to determine if it falls within the domain of applicability for the model before a prediction is determined. The Single Model approach uses a multiple linear regression model fit to the entire training set. The Group Contribution approach is based on methods by,[48] where fragment counts from at least three chemicals in the training set are used to fit a linear regression model to the entire data set. The method based on work from[49] is referred to here as the "Contrera 2003 method" and "FDA" in the documentation provided by EPA.[50] Predictions are made using a unique cluster that contains structurally similar chemicals selected from the overall training set. For the toxicity prediction to be valid, the value must be within the range of experimental values for the chemicals that were used to build the model. The Nearest Neighbor method uses the average toxicity of the three most similar analogous chemicals in the training set. The predicted toxicity from the Consensus method represents the average of the predicted toxicities from all the different QSAR methods incorporated into the TEST software, and this method achieved the best prediction accuracy (concordance) and prediction coverage for the Ames assay. The final dataset of 5743 chemicals were based upon the dataset compiled by Hansen et al., 2009.[51] A summary of the advantages and disadvantages of the different methods are presented in **Table 7**. In TEST, predicted values ≥ 0.50 are considered positive. Several endpoints are available for evaluation, as shown in **Table 8**.

4.09.2.5.4 CaseUltra

CASE Ultra (CU) is a fragment-based QSAR system that employs machine learning techniques from training set data.[52–54] As a QSAR model that evaluates the relationship between a structure and its biological activity, CU was specifically designed to work with "non-congeneric" databases, that is, databases consisting of structurally unrelated molecules. Based on a hypothesis

Table 7 TEST Analysis Methodologies

Method	*Advantages*	*Disadvantages*
Hierarchical	● Produces predictions from multiple models	● May generate predictions from a model based on only a few compounds
Single Model	● Single transparent model can be easily viewed/exported ● The model does not need to rely on clustering the chemicals correctly	● Since the model is fit to the entire dataset it may incorrectly predict the trends in toxicity for certain chemical classes ● Cannot provide external estimates of toxicity for compounds in the training set
Group Contribution	● Single transparent model can be easily viewed/exported ● Estimates of toxicity can be made without using a computer program	● Model doesn't correct for interactions of adjacent fragments ● Since the model is fit to the entire dataset, it may incorrectly predict the trends in toxicity for certain chemical classes ● Cannot provide external estimates of toxicity for compounds in the training set
Contrera 2003 method	● Can generate a new model based the closest analogs to the test compound ● Always provides an external prediction of toxicity	● Close analogs may not exist. The QSAR model must be regenerated and validated for each prediction
Nearest Neighbor	● Provides a quick estimate of toxicity ● Allows one to determine structural analogs for a given test compound ● Always provide an external prediction of toxicity	● Does not use a QSAR model to correlate the differences between the test compound and the nearest neighbors ● Was shown to achieve the worst prediction results during external validation
Consensus	● Was shown to achieve the best prediction results during external validation	● Cannot provide external estimates of toxicity for compounds in the training set

that a relationship does exist between chemical structure and activity, the program works to create a dictionary of molecular descriptors, identify fragments (or substructural units) and then differentiates activating features from deactivating features of the fragments. In CU, activating descriptors are termed 'biophore' and deactivating descriptors as 'biophobe'. The program also considers several other factors, such as molecular weight, octanol/water LogP, water solubility, Lipinski's rule of 5 and intestinal absorption. All of the alert contributions are considered and a scaled feature weight and regression coefficient are used in the final overall probability calculation. Unknown positive (activating) and deactivating features are highlighted in the program, and an overall positive probability is also provided. Case Ultra modules include mutagenicity, carcinogenicity, cardiotoxicity, hepatotoxicity, skin and eye toxicity and several others. Many of the modules were developed in collaboration with the CDER office of the US FDA under a RCA agreement with MultiCASE Inc.

4.09.3 Expert Rule-Based Methodology

4.09.3.1 Overview

Expert rule-based systems (also referred to as expert alerts or structural alert) are a widely used and easy-to-interpret approach to predicting toxicity. These approaches encode intellectually-derived structural rules as "structural alerts" that describe a portion of a chemical that is associated with a specific toxic effect or mechanism. When a test chemical contains any structural alert, it is flagged as potentially toxic. The following sections outline the process of building this type of knowledge base, describe how these alerts are used to make predictions and summarize a number of commonly used commercial and non-commercial systems.

4.09.3.2 Building an Expert Alerts System

In contrast to a statistical-based model (QSAR) which uses a training set to automatically extract knowledge from the data, an expert rule-based system (alerts) uses a reference data set to assess the predictive performance of any alert encoded intellectually or from the literature and support the assessment of applicability domain. This reference set can help refine the definition of the alerts and even identify new alerts. The same principles outlined in the development of a statistical-based model training set should be applied including capturing underlying information on the study protocol, study design and results, processing the chemical structures into a unique set, and preparing the toxicity response data that will be predicted using the expert alerts.

Alerts are often reported in the public literature where individual publications may identify one or more structural alerts, provide a mechanistic justification for the structural features, as well as examples. The information needs to be carefully reviewed before encoding this knowledge into any expert alert system. The same alert may have been described in multiple papers. It is important to understand how each paper described the alert as they may describe the same alert differently. Consolidating alerts from different references is an important part of the process. For example, **Fig. 4** shows different ways aziridines are defined in different publications.[55–58]

A complementary approach to extracting expert alerts from the literature is to analyze structure-activity data in a reference data set or other data sources. This approach helps in refining the definition of the alert and in understanding the limitations of its definition through empirical observation. These restrictions are encoded as structural features or other criteria required to either activate or deactivate the alert. Data analysis may also identify new alerts, by focusing on a chemical series containing positive examples but where no literature alerts exist.

Proprietary data is especially helpful in supporting the development of an expert alerts system. Since this information is not in the public domain, it is necessary to develop methodologies to support the extraction of knowledge while at the same time ensuring proprietary information on chemical structures and test results is not made public. This can be achieved by sharing the data under confidentiality restrictions, analyzing this data to refine existing alerts or identify new alerts and then adding this knowledge into the expert alerts knowledge base. Another approach is to use a SAR Fingerprint to refine specific alert classes.[94] A SAR Fingerprint uses a series of very specific substructures to explore structure-activity relationship (SAR) around a particular class of compounds. The substructures are searched against public and proprietary databases and the frequency of positive and negative compounds matching each substructure are pooled across all data collections. The results help to refine the alert definitions and support an understanding what additional features may activate or deactivate the alert.

The reference set is an essential resource for qualifying the expert alerts. All alerts should demonstrate a positive association with the toxicity response data. To help understand this association, the average toxicity response for compounds containing the alert can

"aromatic and aliphatic aziridinyl derivates" [Ashby 1988]	
"aziridine" [Kazius 2005]	SMARTS: C1NC1
"oriranes and azirdines" [Bailey 2005]	3-membered O- and N-containing rings
"AS_7: epoxides and aziridines" [Benigni 2008, 2011]	
Fig. 4 Example of alerts definitions from different papers.

be compared to the average response for the entire set. A significantly higher than expected mean value for the subset containing the alert compared to the background mean indicates a positive association. This response can be statistically quantified and used to qualify the predictivity of the alert (e.g., as inactive, indeterminate, or high).

In many cases, compound structures possess more than one alert. It is helpful to analyze alert performance when no other alert is present to ensure that the response is attributable to the alert in question, and not another alert(s) that are coincidentally present. Proprietary data can also be used to verify alert predictivity and qualify alerts where no public data is available. Discrepancies between the public and private data are not uncommon and indicate that further restrictions on the alert are needed. For example, if an alert is generating too many false positives when applied to proprietary chemical space, that alert definition needs further refinement. Finally, understanding the biological mechanism(s) for the alert further supports it being active. There will invariably be alerts which lack enough evidence to mark them as active or inactive. These alerts are assigned to another category, such as indeterminate. Table 9 presents some examples of how alerts (developed to predict bacterial mutagenicity) were qualified using data from the reference set.

Once an alert has been identified, refined and qualified, it needs to be encoded into the system's knowledge base. The alert should include its precise structural definition as well as where and how the alert was identified. Supporting information on all plausible mechanisms should be recorded alongside other supporting information including examples. Any alert system can be used to predict the toxicity of a specific toxic response. Usually the presence of a qualified alert in any test compounds is used to generate a positive prediction and the absence of any alert (as long as the chemicals is within the applicability domain described in the next section) is used to support a negative classification. As such, the performance of any expert alert systems may be assessed using a validation set and the same "Cooper statistics" as described in Table 4.

4.09.3.3 Using Expert Alerts

For expert alert systems to adhere to OECD validation principal number 4, there must be an assessment of the applicability domain. This process usually involves an analysis of the chemical space covered by a reference set to define the chemical classes containing toxic chemical features which are adequately predicted by the alert set. Domain analysis may also consider the similarity of the entire test compound to the reference compounds. This qualifies the appropriateness of using alerts in predicting the entire

Table 9 Qualification of alerts using a reference dataset

Alert name	*Alert source*	*Frequency in reference set*	*Mean: Bacterial Mutation*	*Number of positives*	*Number of negatives*	*Status*
All compounds in reference set		10,295	0.49	5048	5247	
allylic alkoxides	Bailey 2005	83	0.46	38	45	Inactive - mean value is lower than background
benzene, 1-amino(NH2)-, 4-aryl-	Galloway 2013; Shamovsky 2011	58	0.91	53	5	Active – mean value is significantly higher than background; primary aromatic amine alert activator
benzene, 1-amino(NH2), - 4(aminosulfonyl)-	Analysis of reference set	18	0.11	2	16	Active – mean value is significantly lower than background; primary aromatic amine alert deactivator

compound beyond just identifying portions of the test compound that contain (or do not contain) active substructural features. This approach is particularly useful in supporting a negative prediction where a test compound has no matching alerts.

For chemicals within the applicability domain of the alert system, a prediction is made where an alert matches the test chemical. In performing the matching, an analysis of the activating and deactivating rules of the alert is also performed. For example, if the primary alert rule matches but a corresponding deactivating alert rule also matches, then no match is made. Wherever a match is present, the structural basis for the alert prediction can be highlighted and supporting information presented to explain the prediction. This includes information on the definition of the alert, the source of the alert, the structural rules for mitigation, the biological mechanism (OECD validation principle number 5), how the alert was qualified, and examples. Examples of how alerts are applied to the chemicals are presented in Fig. 5.

4.09.3.4 Available Systems

4.09.3.4.1 Leadscope expert alerts

The Leadscope expert alerts currently focus on predicting mutagenicity (based on the Ames test results) and is often used to support the ICH M7 guidelines on pharmaceutical impurities.[3] The system is based on a dictionary of structural alerts extracted from the public literature and qualified using a large and diverse database of bacterial mutagenicity data containing 10,295 chemicals (reference set). Activating alerts are encoded as separate rules for each primary alert. Deactivating features are also encoded alongside the primary alert whose mutagenicity they mitigate. A prediction is made when the test chemical is within the applicability domain based upon its structural similarity to reference set compounds. If an alert is present and there are no deactivating features also present in the test chemical, then a positive classification is made; whereas the absence of any alert or the presence of a deactivating fragment will result in the test chemical being predicted as negative. A precision score is also calculated based on data matching the alert from the reference set. The system captures information on the biological mechanisms reported in the literature, the source for the alert (e.g., a literature citation or data analysis), and examples. The alerts were qualified by their performance against a reference data set and against proprietary corporate databases. The performance of specific chemical classes has been improved using the SAR fingerprint methodology previously described. For example, a SAR fingerprint was used to improve the performance of primary aromatic amines by modifying the rules that activate or deactivate their mutagenicity. This resulted in a 39% increase in the specificity of this alert. The alert system is available through the Leadscope Model Applier and an example is shown in Fig. 6.

4.09.3.4.2 DEREK

DEREK Nexus (DEREK) was developed by Lhasa Limited, an organization that specializes in the development of expert computer systems for toxicity and metabolism predictions.[8] DEREK is a knowledge and rule based predictive toxicology software program that makes qualitative estimations of endpoint risk, and Nexus is the interface used to support the program. The qualitative estimations of risk are categorized, in descending order of probability, as 'certain', 'probable', 'plausible', 'equivocal', 'doubted', 'improbable' or 'impossible'. The most recent version of the software contains a new functionality to provide negative ('inactive') predictions for bacterial *in vitro* mutagenicity. When no alert is found for a structure, it is evaluated for unclassified and misclassified features. Unclassified features are those not found in the Lhasa reference set, and misclassified features are those derived from non-alerting mutagens in the Lhasa reference set. If all features in a structure are found and accurately classified in the reference set, a negative prediction (inactive) is displayed. Predictions for structures with misclassified or unclassified features are also called negative (inactive), and these features are highlighted such that they can be further evaluated by the user to de-risk the structure. For misclassified features, the program also displays the most similar compounds from the reference set along with a nearest neighbor similarity score. Negative predictivity has been reported to be 86–94.3% for structures without misclassified features and is more variable with misclassified features, ranging from approximately 83–89%. The Lhasa Ames reference set was composed of six data sets (Vitic NTP, Hansen, FDA CFSAN, ISSSTY, CGX and marketed pharmaceuticals) and is comprised of 10,243 compounds (Lhasa Knowledge Suite, Nexus 1.7 Release Notes). Several endpoints can be evaluated with DEREK, including carcinogenicity, mutagenicity, genotoxicity, skin sensitization, teratogenicity, irritation, respiratory sensitization and reproductive toxicity.

4.09.3.4.3 Toxtree

Toxtree is an open-source, rule-based platform which is able to estimate toxic hazard by applying decision tree approaches, including those listed in (Table 10). The software was developed by Ideaconsult Ltd (Sofia, Bulgaria) and is freely available as a resource to the scientific community. It includes three rule-bases relevant to the Toxicological Threshold of Concern (TTC) assessment, including 1) the Cramer decision tree[59]; 2) the Cramer rule base with extensions; and 3) the TTC decision tree.[60] A more complete description of the software and its use of the Cramer classification scheme can be found Lapenna and Worth, 2011[61] and Patlewicz et al., 2008.[62]

4.09.4 Read-Across Methodology

Read-across is an approach to predicting toxicity which uses experimental data from one or more chemical analogs to generate a prediction of toxicity for a chemical with no data (referred to as the *target* chemical).[9–12] One common use of the read-across method is for evaluation of drug substance impurities, where information on the parent structure is used to predict potential toxicity of the impurity, providing there is enough structural similarity to compare the structures. High quality toxicity databases are an

Table 11 Summary of toxicity databases to use as sources for identifying analogs

Database	*Description*	*References*
Leadscope	Contains over 600,000 studies reported for approximately 190,000 chemicals including (1) reproductive and developmental studies, (2) acute, chronic and subchronic studies, (3) carcinogenicity and genetic toxicity studies from the US FDA CDER (Center for Drug Evaluation and Research) approval packages, US FDA CFSAN (Center for Food Safety and Applied Nutrition) reviews along with data integrated from RTECS, NTP, CCRIS, DSSTox, and other sources.	[63]
RTECS	Registry of Toxic Effects of Chemical Substances, including 26,558 reproductive studies for 6,851 compounds; 279,237 acute studies for 154,702 chemicals; 52,730 multiple dose toxicity studies for 13,953 chemicals; 10,517 tumorigenic studies for 3,724 chemicals and 46,385 genetic toxicity studies for 13,343 chemicals.	[64,65]
ECHA	European Chemicals Agency database for REACH	[66]
ToxRefDB	Toxicity Reference Database containing *in vivo* animal toxicity studies on hundreds of chemicals	[67,68]
HSDB	Hazardous Substances Data Bank	[84]
DART	Developmental and Reproductive Toxicology and Environmental Teratology Information	[69,85]
DSSTox	Distributed Structure-Searchable Toxicity (DSSTox) Database Network	[70]
Mario Negri	Mario Negri Institute for Pharmacological Research developmental and reproductive toxicity database and repeated dose toxicity databases	[71]
VITIC	Commercial data from published and unpublished sources from Lhasa Limited.	[72]
RepDose	Repeated dose toxicity database	[86]
HESS	Hazard Evaluation Support System	[74]
CPDB	Carcinogenicity Potency Database	[75]
IARC	International Agency for Research on Cancer and Carcinogenicity classification	[94]
ISSCAN	Chemical carcinogens: structures and experimental data from Istituto Superiore di Sanita	[91]
CCRIS	Chemical carcinogens: structures and experimental data	[76,92]
NTP	National Toxicology Program database	[77,78]
GENETOX	Mutagenicity test data from the EPA	[93]
IRIS	Data from the EPA in support of human health risk assessment, focusing on hazard identification and dose-response assessment	[79]
IPS INCHEM	International Program on Chemical Safety	[80]
JECDB	Japanese Existing Chemical Data Base	[81]
Pharma Pendium	Toxicity data from FDA and EMA approval documents	[88]
DrugMatrix	Reference database containing studies of the effects of these compounds at multiple time points and in multiple target organs. These studies included pharmacology, clinical chemistry, hematology, histology, body and organ weights, and clinical observations.	[83]

essential resource for identification of these analogs (sometimes referred to as source chemical(s)). Table 11 highlights a number of important databases used to support read-across, as well as expert review of the prediction.

The first step in performing a read-across is to identify analogs similar enough to the target compound such that the toxicity data from these analogs can "read-across" onto the target compound with confidence. The analog selection process first attempts to identify analogs with similar structural features, which would presumably have similar pharmacokinetics and pharmacodynamics properties to the target chemical. A biological justification for any similarity should be generated and evidence gathered to support (or refute) the hypothesis of similar analogs. General structural similarity is often used as a starting point for finding analogs. A structural alert may also be used to generate a preliminary list for the chemical category, as long as the mechanism associated with the alert is relevant to the toxicity endpoint being predicted. Data on the analogs (and possibly the target chemical) such as physico-chemical properties, bioavailability, relevant *in vitro* or *in vivo* data, and so on can be used to filter the list of analogs to those most relevant for prediction. Any information on the projected biological pathway(s) common to both the target and the analogs can strengthen the justification for using the analogs, such as any projected similar metabolic pathways or reactivity, as well as links to common Molecular Initiating Events (MIEs). This process results in the construction of a high-quality "chemical category" of analogs which has knowledge (i.e., structure-activity relationships, properties and mechanisms) specific enough to support justification of a toxicology endpoint value for the category and general enough to extrapolate to a similar test compound.

The following example illustrates a number of concepts in performing a read-across to predict male rat carcinogenicity TD_{50}. Fig. 7 shows the target compound alongside a series of analogs with carcinogenicity data. In this example, the target compound contains an alert – an aliphatic nucleophilic substitution domain (SN1) alert (pyrrolizine alkaloids)[89] – which is highlighted in magenta. This alert was used to form the chemical category by identifying the analogs from a toxicity database containing that alert. Pyrrolizine alkaloids are DNA reactive after a metabolic conversion to a carbenium ion and a subsequent SN1 reaction, which makes this category appropriate for prediction of carcinogenicity.[89]

A data table containing both the target compound and the analogs should be generated to assess the suitability of the selected analogs, as shown in Table 12. Information on all available physico-chemical properties alongside the toxicity data provides input

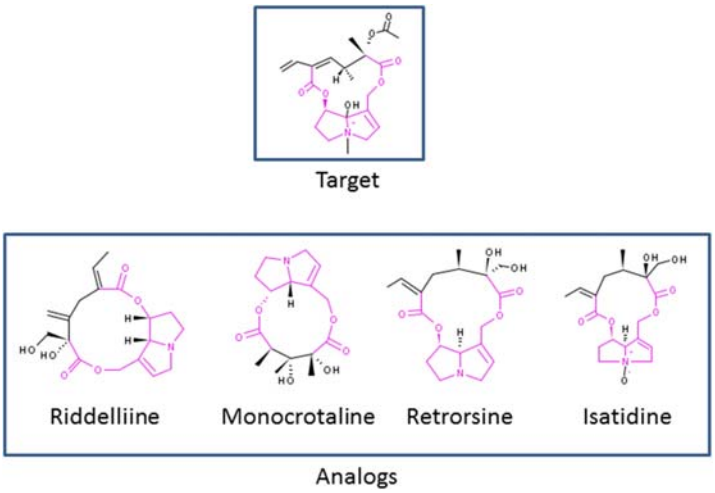

Fig. 7 Identification of analogs to support a read-across.

Table 12 Data table on analogs to support category formation and read-across

Status	*Chemical name*	*Melting point (deg C)*	*Solubility*	*Study Type*	*Species*	*Sex*	*TD_{50}*	*Sites*	*Reference*
Target	Clivorine	149-150	Soluble in chloroform	carcinogenicity	Rat	Male	?		
Analogs	Riddelliine	198	Soluble in chloroform; slightly soluble in water and ethanol	carcinogenicity	Rat	Male	0.119 mg kg^{-1}	System: Hematopoietic Liver System: Cardiovascular	http://toxnet.nlm.nih.gov/cpdb/chempages/RIDDELLIINE.html
Analogs	Isatidine	138	Soluble in water and ethanol	carcinogenicity	Rat	Male	0.716 mg kg^{-1}	Liver	http://toxnet.nlm.nih.gov/cpdb/chempages/ISATIDINE.html
Analogs	Retrorsine	212	Soluble in chloroform; slightly soluble in water and ethanol	carcinogenicity	Rat	Male	0.862 mg kg^{-1}	Liver	http://toxnet.nlm.nih.gov/cpdb/chempages/RETRORSINE.html
Analogs	Monocrotaline	202-203	Soluble in ethanol and chloroform	carcinogenicity	Rat	Male	0.94 mg kg^{-1}	Liver	http://toxnet.nlm.nih.gov/cpdb/chempages/MONOCROTALINE.html

into the weight of evidence to assess the suitability of the analogs for prediction. There should be a degree of consistency in the results to ensure the examples are acting in a similar manner. For example, the TD_{50} values for the selected analogs are within a narrow range and the all analogs indicate that liver is a major target organ. Here the chemical category was formed using a known alert (pyrrolidine alkaloids) that is associated with a known and relevant biological mechanism, which provides additional evidence to consider in assessing the quality of the chemical category.

If the analogs are found suitable for making a prediction, then the analogs' study results can be used to predict the target compound's toxicity. In this example, TD_{50} values from the analogs can be used to predict the TD_{50} value for the target compound. A conservative approach would be to take the minimum value of the analogs to use as the read-across value (0.119 mg kg^{-1}); however, a mean, medium or other approach for estimating the read-across value may be used if it can be justified.

Read-across is a time-consuming and predominantly manual approach to predicting toxicity more akin to an expert review than an automated prediction. The process of selecting analogs needs to be fully documented alongside the justification and an assessment of confidence based on the weight of the evidence.[95] Similarly, the number of studies and the quality of the study data used in the read-across should be assessed and a confidence level established to help support how this information will be used.

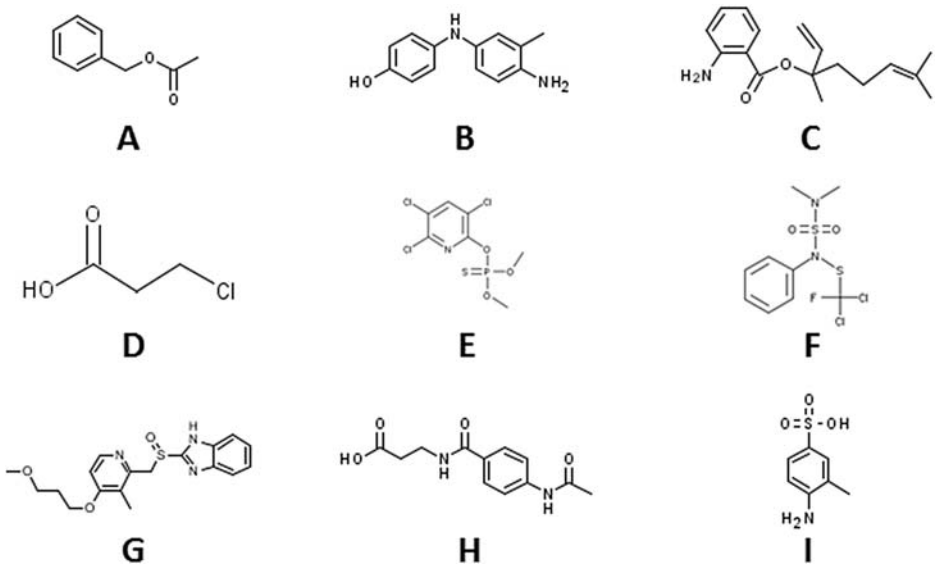

Fig. 8 Nine compounds to be predicted as mutagenic or not mutagenic.

4.09.5 Case Study: Using Statistical-Based (QSAR), Expert Rule-Based (Alerts), and Read-Across to Predict Mutagenicity

This case study illustrates the use of two different *in silico* methodologies (available through the Leadscope Model Applier) to predict whether a series of compounds shown in Fig. 8 are mutagenic or non-mutagenic (based on the results of the bacterial reverse mutation assay or Ames test). The ICH M7 guideline has documented the methodologies and criteria necessary to qualify and control DNA reactive impurities. In this example we will use the same approach to assess these compounds. The ICH M7 guideline recommends the use of the two complementary methodologies: "*expert rule-based*" (i.e., alerts) and "*statistical-based*" (i.e., QSAR). Using two methodologies ensures there will be fewer false negatives, but with a subsequent increase of false positives. The guideline also states that these methodologies "… … *should follow the general validation principles set forth by the Organisation for Economic Co-operation and Development* (*OECD*)." The results from both methodologies are used to predict the compound as either mutagenic or non-mutagenic; however, an expert review may be warranted especially where the results are marginal or conflicting. A read-across assessment of structural analogs is also an important component of such an expert review. Although the Leadscope Model Applier was used in this case study, other methodologies adhering to the requirements of the ICH M7 guideline may be used.

To generate prediction results based on the recommended methodologies, two statistical-based QSAR models were used (Leadscope Salmonella statistical-based QSAR model v3 and Leadscope E.coli/Sal TA102 statistical-based QSAR model v1, run within the Leadscope Model Applier v2.0.1) and a single expert rule-based model (Leadscope Genetox Expert Alerts v2 run within the Leadscope Model Applier v2.0.1), as shown in Fig. 9. The domain assessment was turned on for both methodologies and the QSAR models assigned a positive outcome when the probability was above 0.6, a negative outcome when the probability was below 0.4 and an indeterminate outcome between 0.4 and 0.6. The Figure shows the QSAR model results on the left and includes whether the compound was predicted as mutagenic (positive) or non-mutagenic (negative) as well as the probability of a positive outcome. The QSAR model results also highlight on the chemical structure where model features map onto the chemical structure. Areas of the compound that are not covered by a model feature are shown in black. Model features associated with mutagenic examples are shown in red, while model features associated with a lack of mutagenic examples are shown in green/blue and those lacking any association are shown in gray. Similarly, results from the expert rule-based methodology are shown in the right columns and indicate whether the examples are predicted to be mutagenic (positive) or predicted non-mutagenic (negative). A precision score indicates the proportion of historical compounds matching the alert that were positive. Where no alert matches, this precision score indicates the proportion of compounds in the alert reference set that did not match any alert (i.e., 0.1616 or 16.16%). Where an alert matches a compound, it is highlighted in red, and where an alert is deactivated because of the chemical environment it is highlighted in green/blue. The QSAR models include a probability of a positive outcome and the expert alerts contain a precision score. These values help assess the confidence in the prediction with high values (close to 1) representing higher confidence in a positive outcome and lower values (close to 0) representing higher confidence in a negative outcome.

Fig. 9 provides a summary of the results along with sufficient supporting information to start to assess the results. It shows the classification (positive or negative), the prediction confidence scores and the structural basis for the prediction. It is helpful to use this information to identify compounds that are clearly positive or clearly negative or cases where the results are either marginal, inconclusive or that would require further investigation as part of an expert review. For these example compounds, a simple review

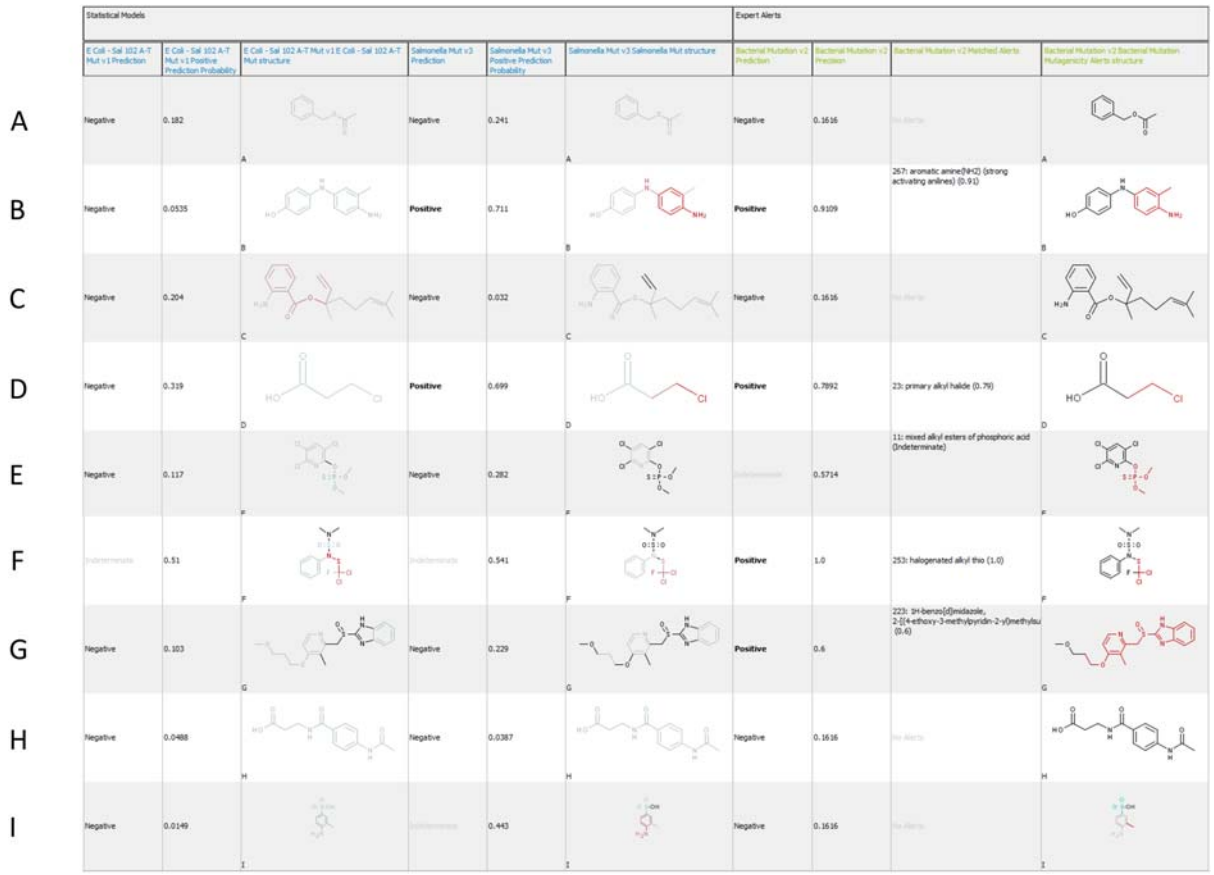

Fig. 9 Prediction of mutagenicity using statistical-based (QSAR) and expert rule-based (alerts).

of the *in silico* data has been used to provide an overall positive or negative prediction. A more in depth evaluation, using expert review, has not been provided here. An expert review may conclude the prediction should be accepted or even refuted; however, this sort of assessment is outside the scope of this chapter.[96]

From a preliminary inspection, compounds A and H were predicted as non-mutagenic in all models. The two statistical-based models considered all areas of the compounds (there are no black atoms or bonds in the QSAR model results) and the confidence scores indicate a high confidence in a negative prediction. The expert rule-based model also showed a high degree of negative predictivity and no alerts fired. These compounds would be predicted as non-mutagenic based on this initial visual inspection of the results.

Compound B was predicted positive in both the expert alerts and the Salmonella statistical-based methodology. This compound contained a strong activating primary aromatic amine structural alert with no identified feature that would deactivate the aromatic amine mutagenicity. This would be an example of a clear positive assignment.

Even though compound C contained a primary aromatic amine (an alert for mutagenicity), it was predicted negative in all models and the confidence scores reflected a high degree of confidence in the negative predictions. Compound C contained no additional feature that would activate the aromatic amine mutagenicity and thus would be considered overall negative.

Compound D is positive in both the expert rule-based and the Salmonella statistical-based methodologies, as it contains a well-known mutagenicity structural alert (alkyl halide[55,57]), which is also highlighted in the Salmonella QSAR model as being primarily responsible for the positive prediction. The positive predictions were marginally positive (<0.8) and while a simple evaluation would dictate a positive mutagenicity prediction, a better approach would include an expert review of the data, analogous structures, etc. to use a weight of evidence approach for an overall prediction.

In examples E, F, and G there are some conflicting results across the different models. In compound E, the Salmonella and E.coli/Sal TA102 statistical-based methodology was negative and the expert rule-based methodology was indeterminate, indicating conflicting Ames data or other information. A read-across inspection of chemical analogs (shown in **Fig. 10**) shows negative examples. Hence, this would support a negative prediction; however, this is another example where expert review would be beneficial.

Compound F was predicted positive in the expert rule-based methodology based on the halogenated alkyl thio group, and no prediction was made in either statistical-based model because of conflicting information. The halogenated alkyl thio group was also highlighted as a positively associated structural feature in the QSAR models. An inspection of the underlying data (although structurally dissimilar) indicated that all examples were positive (see **Fig. 11**). As compound F has no deactivating features (such as steric hindrance near the alkyl thio group) and several analogous structures were positive, this compound would be predicted as positive.

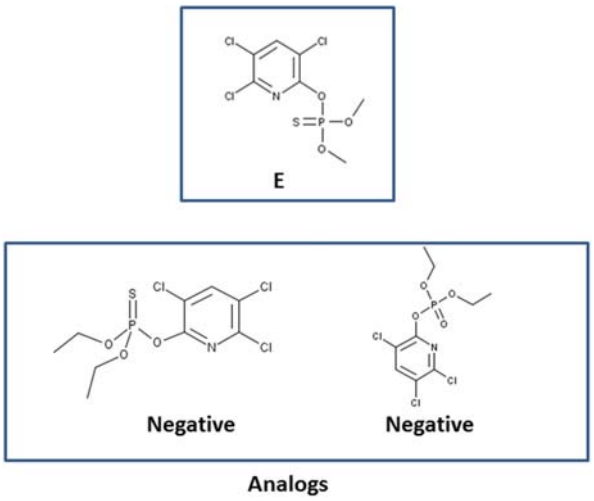

Fig. 10 Analogs of compound E.

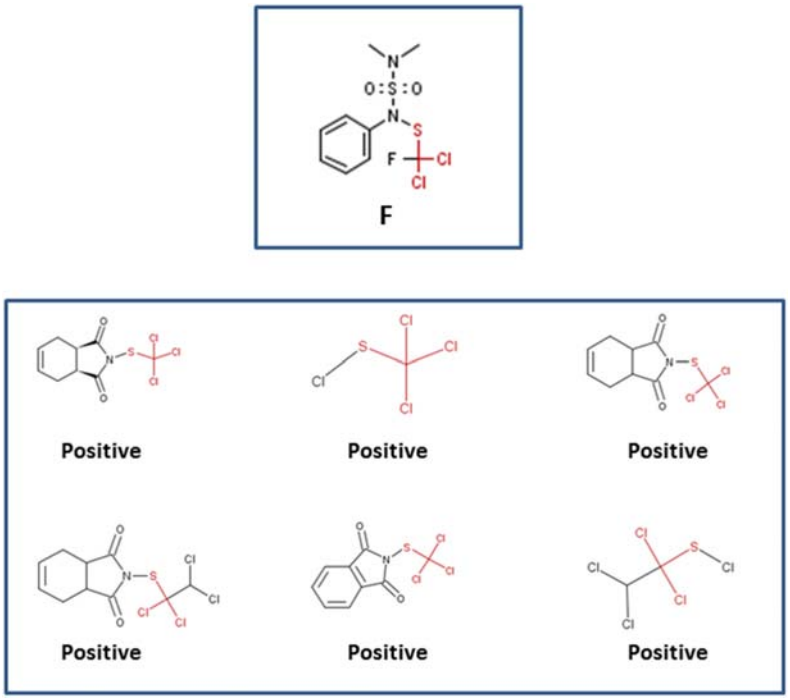

Fig. 11 Compounds matching the halogenated alkyl thio alert.

Compound G also showed conflicting results with the expert alerts predicting positive and the QSAR models predicting negative. When using the *in silico* data only, and one of the methodologies predicts the compound to be positive without any other activating or deactivating features, the overall prediction would be considered positive. This is another example where expert review would be beneficial. Note that expert review is not solely used to review positive predictions, but can also be used to verify negative predictions.

Compound I was predicted negative in the expert alert methodology; however, the Salmonella QSAR model did not generate a prediction and highlighted the primary aromatic amine functional group in red. The alerts system contains rules for activation and deactivation of primary aromatic amines. Compound I did contain a feature to activate the aromatic amine mutagenicity (the methyl group ortho to the amine) but the sulfonic acid in the para position was flagged as deactivating the mutagenicity. The presence of both an activating alert and a deactivating alert resulted in the indeterminate prediction in the Salmonella model. The deactivation of the alert in the Salmonella model along with the two negative predictions (with good negative predictivity scores) in the other models would result in a negative overall prediction for Compound I.

4.09.6 Conclusions

This chapter has summarized three different approaches for predicting toxicity: statistical-based (QSAR) models, expert rule-based (alerts), and read-across. These *in silico* approaches represent the state-of-the-art in toxicity prediction and are used for product design and regulatory decisions as part of pharmaceutical discovery and development. These approaches all have strengths and weaknesses and are often combined within an expert review using a weight of evidence approach. *In silico* approaches provide a great deal of promise in supporting the early detection and circumvention of toxicity as part of the medicinal chemistry process, that might otherwise delay, generate a warning on the drug label or result in withdrawal of a product in clinical trials or even after it reaches the market. *In silico* methods offer a rapid screen for candidate prioritization and often provide an indication of the structural basis (and sometimes a mechanistic basis) for any positive predictions. This information is critical to support decisions on research directions related to the design and/or prioritization of chemical classes, pursuit of individual chemicals, and identification of specific tests necessary to de-risk any predicted toxicity.

The field of *in silico* toxicology is today focusing on several important areas concerning the practical implementation of these methodologies. Despite its on-going expense, the development of toxicity databases, including both the harvesting of additional studies as well as the recording of new endpoints, supports the development of training and reference sets. This in turn leads to new and improved models for prediction and further support for read-across. Additional models and read-across approaches are needed to effectively estimate safe dose levels (with associated confidence intervals) to support an analysis of risk. Models to support an understanding of the margin of safety between the dose required for the drug to be effective and that producing adverse effects are important. These models need to be able to estimate this gap and its associated uncertainty. The development of guidelines, protocols, and workflow tools for application of these methodologies, as well as subsequent expert reviews, is important to ensure results are consistently generated, transparent, fully documented, and defendable. These guidelines can also support how these models are used in the wider context, such as in identifying follow-up tests to use in verifying any positive predictions from these *in silico* models. These guidelines also outline when to include an expert review that either accepts or refutes the prediction as well as the scope of such a review.

4.10.1 Introduction

Within the context of animal experimentation, the 3Rs are acronyms for replace, reduce, and refine meaning that animal tests—ordered by priority—should be replaced, be reduced, or at least take place under the best possible conditions for the animals (refine). To date, toxicology screens necessitate the use of significant numbers of animals, for example, the EU program REACH Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) shall assess the hazard risk of 30,000 chemicals involving estimated up to 54 million additional animals. Alternative testing strategies in the spirit of the 3Rs can achieve a reduction to below 10 million animals. Such an approach is based on human induced pluripotent stem cell (iPSC)-derived cell types for toxicity testing and drug development. iPSCs have the unique capacity to self-renew in the undifferentiated state in vitro while maintaining their ability to differentiate into a broad number of cell types. In addition, iPSCs can be generated from somatic cells of existing individuals with known genetic characteristics. These iPSC-derived hepatocytes, cardiomyocytes, or neuronal cells can model in vitro the patient's genetic disease or metabolic capability, thereby adding a further dimension to the current toxicity testing platforms. An iPSC–HLC-based strategy thus allows large-scale studies impossible to perform in mice, on human primary cell cultures, or from biopsies and also enables studies on hepatocytes genetically susceptible to drug-induced liver injury as in vitro models with genotypic relevance for toxicology screening. By employing patient-specific iPSC-derived hepatocytes, neurons, or cardiomyocytes and systems biology models, we can find strategies to reduce or—where possible—to replace animal tests. Systems biology modeling can provide whole-body human toxicokinetic data by in silico and in vitro methods assessing absorption, distribution, metabolism, and excretion (ADME) processes. These human-specific models can partly circumvent drawbacks of animal models, which cannot fully reflect the human condition.

4.10.2 Pluripotent Stem Cells

The focus of this article will be on the application of human pluripotent stem cells, which encompass both embryonic and induced pluripotent stem cells.

Human embryonic stem cells (hESCs) are derived from the inner cell mass (ICM) of blastocyst-stage embryos. hESCs can be differentiated into all cell types present in the three embryonic germ layers, endoderm (e.g., cells of the gastrointestinal tract), ectoderm (e.g., cells of the nervous system), mesoderm (e.g., cells of the bone and muscle), and also germ cells.

Currently, there are over 400 human embryonic stem cell (hESC) lines established but only a few of these are well characterized (lines H1 and H9) and used by most laboratories worldwide.[1,2]

To bypass ethical and moral concerns, scientists searched for alternative ways to derive embryonic stem cell-like cells. Takahashi and Yamanaka were the first to successfully derive induced pluripotent cells (iPSCs) from mouse fibroblasts. In 2006, they published the reprogramming of mouse fibroblasts to iPSCs employing retroviral transduction and coerced expression of transcription factors, which are normally only expressed in embryonic stem cells.[3] Shortly after that, two groups managed the reprogramming of human adult fibroblasts with viral transfection and overexpression of four transcription factors OCT4, SOX2, KLF4, and c-MYC [4] or OCT4, SOX2, NANOG, and LIN28.[5]

To generate iPSCs, transformation is attained by the use of *KLF4* and *c-MYC*. c-MYC affects p53-dependent apoptosis in fibroblasts, which is in all probability repressed by KLF4. KLF4 activates *p21* and affects proliferation. For this reason, the balance between c-MYC and KLF4 during the reprogramming process is critical. Furthermore, c-MYC enhances the expression of embryonic stem cell-specific genes by activating histone acetylase complexes. The enforced expression of c-MYC and KLF4 can lead to the formation of tumors. Probably OCT4 channels the cell from tumor to induced pluripotent cells. OCT4 and SOX2 synergistically activate target pluripotency-associated genes during the reprogramming process.[6,7]

The requirement of specified amounts of each transcription factor needed for the reprogramming process is realized in a small number of transfected cells. This could also be an explanation for the low efficiency of iPSC generation (>1%). Each cell type needs maybe another combination of factors and different amounts of each factor to achieve higher efficiencies of reprogramming.[3]

Induced pluripotent stem cells have the same properties as human embryonic stem cells, which are pluripotency, self-renewal, and the expression of surface markers such as SSEA-4, TRA-1-60, TRA-1-81, and TRA-2-49 (alkaline phosphatase) and transcription factors, for example, OCT4, NANOG, and SOX2.[4,5,8] Pluripotency is assayed both in vivo by the formation of teratomas when they are injected into immunodeficient mice and also in vitro by the formation of embryoid bodies (EBs). These EBs have the innate capacity to differentiate into endodermal lineages (expressing the marker genes SOX17 and AFP), mesodermal lineages (expressing the marker genes α-SMA and brachyury), and ectodermal lineages (expressing the maker genes TUJ1 and Nestin).[4] A typical assay to demonstrate pluripotency in vitro is shown in **Fig. 1**.

The efficiency of reprogramming human fibroblasts to iPSCs by using retroviruses to transduce OCT4, SOX2, KLF4, and c-MYC is approximately 0.02%.[9] The reprogramming of human fibroblasts to iPSCs through transduction of lentiviral constructs carrying OCT4, SOX2, NANOG, and LIN28 had an efficiency of 0.02–0.0095%.[5] Both methods are robust due to the fact that numerous groups have been able to reproduce the protocols. In addition, there are still unresolved problems, such as the random integration of proviruses into the genome of the reprogrammed cells and the fact that KLF4 and c-MYC are oncogenes that could be reactivated. These conditions cause a high probability of genomic instability and mutagenesis in iPSCs.[10] To enable regenerative medicine applications in the future, safer reprogramming by using fewer factors with OCT4, SOX2, and KLF4 but omitting c-MYC has been suggested.[11] To increase the efficiency of the viral reprogramming method, additional factors have been used such as the viral oncogene SV40LT, which enhances the efficiency of iPSC generation from fibroblasts by inhibition of p53. It has been demonstrated that the inhibition of p53 enhances the iPSC generation from human fibroblasts up to 100-fold.[12] Furthermore, Wang and Adjaye demonstrated that transient inhibition of p53 can increase the efficiency of reprogramming human dermal fibroblasts by approximately sevenfold.[13]

Over the years, a large number of somatic cell types have been reprogrammed, for example, fibroblasts, keratinocytes, amniotic fluid cells, and chorionic villi cells.[5,14–17] The integration of proviruses into genome of viral-derived iPSCs is a risk factor for clinical applications in the future.[18] To avoid this, nonviral integration protocols have been established.[19] Additionally, mRNA, miRNA, and protein-based reprogramming have been established as reviewed in Tavernier et al.[20]

Nonintegration reprogramming methods are established and standardized. Reagents and kits of various methods are also available on the market. One can select from the following methods: Sendai viral, episomal, and mRNA transfection. Sendai virus particles are used to infect the donor cells with RNA, which encode the reprogramming factors *OCT4*, *SOX2*, *c-MYC*, and *KLF4* without integration into the host genome.[21] The episomal vectors are derived from the Epstein–Barr virus without the viral packaging. These oriP/EBNA1 vectors contain DNA of the reprogramming factors OCT4, SOX2, NANOG, LIN28A, c-MYC, and KLF4 and express these independently.[22,23] In vitro transcribed mRNAs of *OCT4*, *SOX2*, LIN28A, c-MYC, and KLF4 have been transfected using the mRNA reprogramming method.[24] The mRNA method is the most inefficient and cumbersome protocol for reprogramming and is not applicable to all cell types. Due to the very short half-life of the mRNAs, daily, up to 7 days transfections are necessary to induce pluripotent stem cells. However, the main advantage of using mRNA to derive iPSCs is the absence of any exogenous viral or plasmid DNA in the host genome.[25]

Recently, numerous studies have been published in demonstrating reprogramming somatic cells with supplementation with small molecules, in addition to the Yamanaka factors.[26,27] Small molecules such as the cyclic AMP analog 8-Br-cAMP, valproic acid (a histone deacetylase inhibitor), and thiazovivin enhance reprogramming efficiency of human somatic cells.[10,13,26] Additionally, there exists a list of small-molecule compounds with the potential for replacing the Yamanaka factors. However, most compounds to date function more in reprogramming mouse cells.[28] **Table 1** lists a selection of small molecules, which increase the efficiency of reprogramming human somatic cells (modified from Lin and Wu 2015).[28]

In summary, iPSCs are promising in vitro tools for the application in tissue replacement therapies, for the generation of disease models, and for drug screening and toxicology studies.

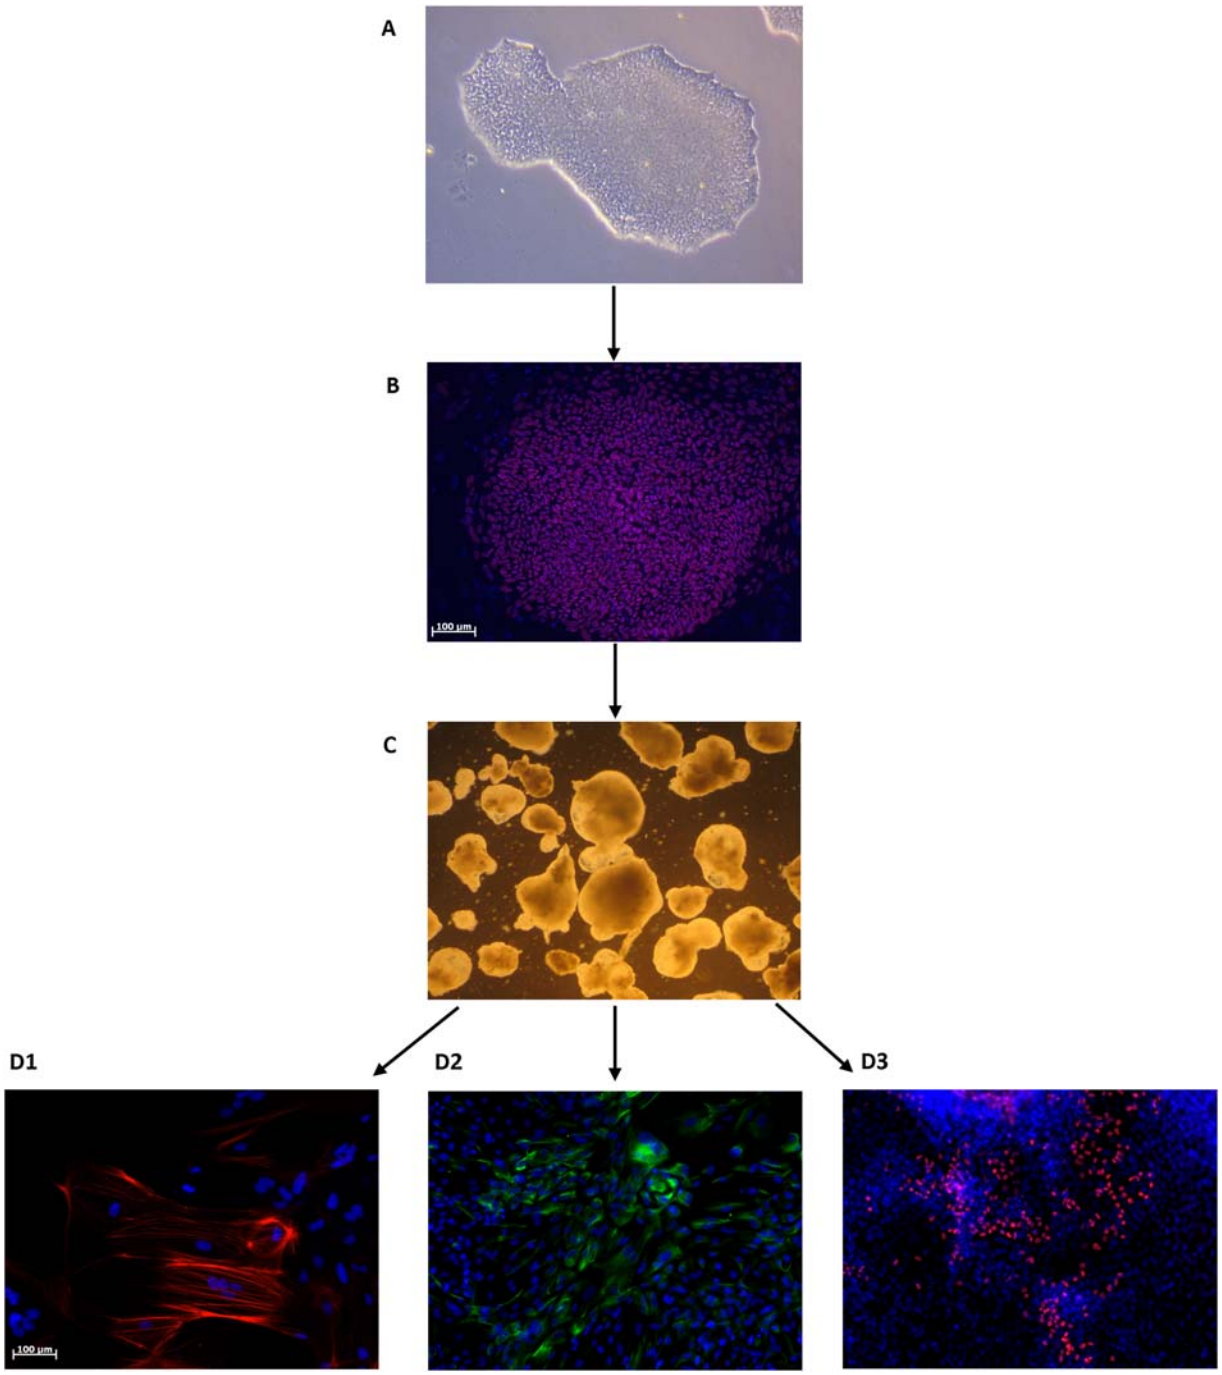

Fig. 1 iPS cells used in embryoid body-based differentiation into the three embryonic germ layers. Induced pluripotent stem cell (*iPSC*) colonies (A) express pluripotency-associated transcription factors such as OCT4 (B) and can be differentiated via embryoid bodies (*EBs*) (C) into cell types representative of the three germ layers (D). Immunofluorescence-based detection of expression of alpha-smooth muscle actin (α-*SMA*) identifies the mesoderm germ layer (D1), Nestin (*NES*) ectoderm (D2), and SOX17 endoderm (D3).

4.10.3 Induced Pluripotent Stem Cell-Derived Hepatocytes

The liver is the largest internal organ and is responsible for several key bodily functions such as metabolizing glucose and fatty acids and degradation of exogenous and endogenous toxins. There are several liver-associated diseases such as fatty liver, steatosis, and hepatitis. A broad range of mechanisms are associated with xenobiotic hepatotoxicity, for example, reactive metabolites, formation of reactive oxygen species (ROS) and impaired transporter, and cytochrome activities.[35,36]

Table 1 Small molecules used for increasing the efficiency of reprogramming human somatic cells into iPSCs

Signaling pathway or target	*Name of compound*	*Efficiency*	*Ref*
ALK4, ALK5, ALK7 inhibitors	SB431542	~200-fold	26
cAMP-dependent protein kinase activator	8-Br-cAMP	6.5-fold	29
DNMT inhibitor, histone deacetylase inhibitor	RSC133	Threefold	30
GSK-3β inhibitor, LSD1 inhibitor	LiCL	>10-fold	29
HDAC inhibitor	Sodium butyrate	100-fold	31
HDAC inhibitor	VPA	>100-fold	32
HIF PHD1 and PHD2 inhibitors	*N*-Oxalylglycine	3.5-fold	33
PDK1 activator	5-(4-Chloro-phenyl)-3-phenyl-pent-2-enoic acid (PS48)	15-fold	33
Phosphofructokinase 1 activator	Fructose-2,6-bisphosphate	Twofold	33
Rho-associated protein kinase inhibitor	Thiazovivin	~200-fold	26
Rho-associated protein kinase inhibitor	Y27632	Improved generation	34
Selective MEK/ERK inhibitor	PD0325901	~200-fold	26
TGF-β inhibitor	A83-01	Sevenfold	33

Modified from Lin, T.; Wu, S., Reprogramming With Small Molecules Instead of Exogenous Transcription Factors. *Stem Cells Int.* **2015,** *2015*, 794632.

Numerous studies have shown that findings in animals cannot be directly extrapolated to human because of species–species differences.[37] Current available in vitro models such as liver cancer cell lines and primary human hepatocytes (PHH) have been established to circumvent animal studies.[38] Advantages of PHHs are the functional cellular architecture, but unfortunately, these cells cannot be kept in culture for long periods.[39] Primary hepatocytes of course are ideal for appropriate drug and toxicity screens due to their high metabolic and functional properties.[40] However, there are several shortfalls associated with the use of primary hepatocytes, among these are variability between donors, low number of donors, and rapid decrease of cell-specific function in vitro.[35] The lack of healthy liver sample donors and the high variability between the samples are shortfalls associated with the use of primary liver cell. Due to this and the poor expandability, these cells are of limitation for high-throughput drug screening and toxicological studies. The current available human liver cell models are somehow limited, and thus, it is of prime importance to find alternatives.[41] Generation of hepatocyte-like cells (HLCs) from induced pluripotent stem cells (iPSCs) could circumvent these drawbacks.[42,43]

Protocols for generating HLCs are based on stepwise differentiation protocols resembling the developmental process in vivo. Most of these so far developed protocols are dependent on cytokines and growth factors, which try to mirror the partial differentiation stages cells go through to become hepatocytes. The first differentiation stage is the definitive endoderm, which is accomplished by supplementation with activin A and in some protocols WNT3a, bFGF, and BMP4. The second stage is the differentiation into hepatic endoderm, which resembles the bipotential hepatoblast stage in vivo. To attain a certain level of maturity, HGF, OSM, DEX, and insulin are used to advance from the hepatic endoderm to HLC stage. Several protocols for deriving HLCs in vitro have been published (**Table 2**).[42,45,46,50–52] Besides the improvement of supplements for derivation of hepatocytes from iPSC, there are several engineering approaches such as micropatterning, microfluidics, and synthetic biomaterials to improve hepatocyte culture for longer periods.[38] Another improvement of iPSC-derived hepatocytes with respect to maturity is culturing in three-dimensional (3-D) spheroids in contrast to the standard 2-D culture.[52] The leading reason why drugs are withdrawn from the market is the induction of drug-induced liver injury (DILI). HLCs could be powerful in predicting such reactions. Numerous groups have shown the functional ability of HLCs to metabolize drugs, which makes it possible to use these cells for toxicology studies.[54] HLCs can also be used to study host and virus interaction during an infection process like hepatitis C.[55] The use of iPSC-derived hepatocytes can also enlighten risk potentials of drugs for pregnant women and the fetus. Furthermore, it has been demonstrated that these cells are functional by metabolizing specific drugs although they do not reach the same level of metabolic activity like primary human hepatocytes, which was also shown on gene expression level.[42,56–59] iPSC-derived hepatocytes are used for drug screening and toxicity tests. Using this approach, it is possible to investigate the influence of the genetics of the outcome of different compounds.[43] For example, it has been shown that HLCs with an SNP in CYP2D6 have a higher persistence to tamoxifen, which is metabolized by CYP2D6 into toxic products. In parallel, these cells had a higher sensitivity to desipramine, which is detoxified by this enzyme. Derivation of a panel of HLCs bearing distinct genetic variations and polymorphisms would be a great tool for the evaluation of specific drug dosages for the particular individual.[52] Furthermore, such a panel of HLCs bearing distinct SNPS and HLA types would be a great tool for high-throughput drug screening and assays on drug metabolism.[43] Recently established methods allow gene editing by CRISPR/Cas9 and TALENs, which could be used for the creation of a pool of genetically distinct iPSC-derived hepatocytes.[43,60] Although transcriptome analysis showed that HLCs share more genes with fetal liver than with adult liver (underlining the lack of maturity in those cells), in vitro HLC differentiation can be used to study the molecular pathways involved in the liver development.

For the future, it will be important to mimic human physiological liver environment in vitro as close as possible to improve the maturity and function of HLCs and thus ensure a better prediction potential for drug screening and toxicology studies.[43] The number of studies using iPSC-derived hepatocytes is increasing with more improved protocols and approaches that try to mimic the liver environment. Future research will provide many possibilities for personalized medicine such as specific drug screenings

to identify the impact of specific genetic alterations for liver function; generation of HLCs from iPSCs from distinct genotypes makes it possible to evaluate new drugs.[61,62]

4.10.4 Induced Pluripotent Stem Cell-Derived Neuronal Cells

Worldwide, approximately one billion people are currently affected by a brain disorder.[63] Neurodegenerative- or neurodevelopmental-diseased persons suffer from the loss of cognitive function, movement, or muscle strength. Intellectual abilities such as communication and behavior are often impaired. Although neurological diseases are widespread, little is known about the underlying molecular mechanisms and hence the lack of effective therapies. Studies into neurological diseases are mostly carried out in animal models and transformed cell lines and tissues from aborted fetuses or poor-quality brain biopsies.[64,65] Experimental data obtained from animals and transformed cells are not representative of human neurological function due to the greater complexity of the human brain and interspecies physiological differences. Furthermore, neurons from different species behave differently with respect to electrophysiology.[66] For example, thalidomide and 13-*cis*-retinoic acid are well-known human teratogens but are harmless in murine models.[67, 68] The sensitivity of the human brain, chemical compounds, environmental changes, and naturally occurring substances has to be addressed in future studies.

Human induced pluripotent stem cell (iPSC)-derived neurons are more representative of human neural physiology than other model systems. They can recapitulate the in vivo conditions of neurodegenerative disorders in vitro and provide a promising tool for drug screening and neurotoxicological tests. In recent years, several neuronal disease models based on patient-specific iPSCs have been established and described.[69–71]

One of the pioneering examples was the establishment of in vitro models of amyotrophic lateral sclerosis (ALS) by differentiation of human embryonic stem cells and iPSCs into motor neurons.[68, 69] Currently, in vitro drug treatment has shown restoration of normal distribution of affected protein(s) for several neuronal diseases such as spinal muscular atrophy, Parkinson's disease, Rett syndrome, mucopolysaccharidosis type IIIB, schizophrenia, and Alzheimer's disease.[70–75] Utilizing iPSC-derived neuronal cells enables characterization of the effect of potential drugs and toxins on distinct cell types present in the human brain. Therefore, neuronal differentiation protocols, which are stepwise and produce distinct cell types of the brain (e.g., neural progenitor cells (NPCs)), represent a tool for neurotoxicity screening assay due to the highly sensitive response to neurotoxins as compared with other neural lineages.[76] So far, neurospheres developed from NPCs have been used to analyze migration, proliferation, viability, and differentiation of neural cells in the presence of different chemicals. Methylmercury chloride was identified as neurotoxic, which negatively impacts differentiation into neural cell types and inhibits the migration.[77]

More effort is needed to realize the promise of human iPSC-derived neurons in enhanced and cost-effective drug discovery and toxicology test for clinical use. A major obstacle is the low homogeneity and immature phenotype of the iPSC-derived neurons. To

develop reliable model system for drug discovery, the derivation of homogenous and more mature cell types is necessary in addition to establishing standardized and optimized protocols.

4.10.5 Induced Pluripotent Stem Cell-Derived Cardiomyocytes

Cardiotoxicity is a major problem not only for drugs targeting heart diseases but also for other compounds that act by systemic administration. Despite extensive testing with a variety of in vitro and animal models, nearly 40% of all drugs in clinical trials have to be withdrawn due to unanticipated cardiotoxic effects.[61,78] A reliable cardiotoxicity screening identifying adverse side effects on the cardiovascular system early in the drug discovering process is needed to reduce time and cost in the development of new compounds.

The action potential of a cardiomyocyte and thereby the overall electric activity of the myocardium originate from the complex interplay of multiple ionic currents. Every second case of cardiotoxicity-related drug withdrawal is caused by a risk of arrhythmia,[79] namely, an extension of the repolarization of the cell membrane detectable with an electrocardiogram as a prolongation of the QT interval. This delayed repolarization might cause a life-threatening ventricular arrhythmia termed *torsades de pointes* (TdP). In this very aspect of membrane repolarization, animal cardiac physiology relies on different currents making rat, mouse, or guinea pig an inappropriate model for human drug testing.[80] Not only in addressing safety concerns animal models lack important qualities but also today's advanced medicine uses monoclonal antibodies specifically designed against human drug targets.[81]

Cardiac physiology is difficult to mimic in vitro; there are high interspecies variation in cardiovascular physiology, which inhibits efficient preclinical testing. The main disadvantage of human adult cardiomyocytes is the limited proliferation rate, and therefore, this postmitotic cell type cannot be cultured for the durations needed for drug screenings.[81] New hopes for better drug screenings, diagnostics, and therapeutic options have been raised by induced pluripotent stem cell-derived cardiomyocytes (iPSC-CM). Theoretically, they provide an endless source of cardiomyocytes that can be kept in culture also for long-term experiments. Grown as a monolayer, iPSC-CM fit into two-dimensional assays and embryoid bodies (EBs), which constitute a three-dimensional assay system. The differentiation of cardiomyocytes from iPSCs is a complicated and multifactorial process. Since the first derivation of iPSC-CM from mouse iPSCs in 2008 [81,82] and from human in 2009,[83] many improved protocols have been established (**Table 2**).[84] Besides recent advantages in the differentiation process, today's iPSC-CM is still immature and resembles more a fetal-like phenotype of a cardiomyocyte than a fully mature adult cell type. This immaturity is, among other features, characterized by an altered current channel density manifesting in the spontaneous release of action potentials due to the less-negative resting potential of fetal cardiomyocytes.[80] Furthermore, the derived population of cardiomyocytes is heterogeneous as it usually consists of the three major subtypes of an atrial-, ventricular-, or nodal-like phenotype. Differences of these phenotypes manifest in different morphologies of the action potential and its response to drugs.[81,85] However, functional assays such as the treatment with cardioactive drugs (e.g., adrenaline, isoproterenol, and verapamil) can be conducted as iPSC-derived cardiomyocytes show a synchronized response in terms of changes in the contractility and the beating rate.[86] Additionally, at the single-cell level, the intracellular transmembrane potential can be measured with a detailed characterization of electrophysiological effects.[80] Even a higher resolution can be provided by the long-established patch clamp technique allowing the recording of current changes of single ion channels. On a larger scale, the extracellular field potential is often measured by a microelectrode array (MEA).[87] The MEA technique has been validated for iPSC-CM models showing a reliable detection of drug-induced arrhythmias and changes in the electric properties.[87,88] In addition to electrophysiological effects on cardiomyocytes caused by drug treatment, a contractile and structural cardiotoxicity (also termed as biochemical cardiotoxicity) is sometimes caused by chemotherapeutics as anthracyclines or kinase-targeted cancer drugs like trastuzumab.[89] Cardiotoxic side effects of noncardiac drugs are often not detected in preclinical or stage I trials. They only become significant during long-term treatment. Furthermore, the aged heart of older cancer patients might be more susceptible to an adverse reaction.

It has been shown in recent studies that long-term culture of iPSC-CM is possible and this results in increased maturity. A vascular coculture and newly designed biometrics also applying mechanical and electric forces have generated cardiomyocytes of higher maturation.[84,90] IPSC lines from patient-derived somatic cells have already been established (**Table 3**).[100,102] Critical mutations, like a missense mutation in the KCNH2 gene that causes one type of the long QT syndrome (LQT2), have been analyzed in functional assays for their response to corresponding drugs. Using MEA analysis, it has been shown that blocking calcium channels in LQT2 patients with nifedipine lead to a shortening of the AP duration and reduce arrhythmic activity.[81,103]

Recent breakthroughs in technological possibilities of genome editing using CRISPR/Cas9 and TALEN further allow the specific insertion or correction of critical mutations.[100] This will lead to a deeper understanding of cardiac disease and drug–target interactions and hold great promise for preclinical safety testing.

4.10.6 Induced Pluripotent Stem Cell-Derived Organoids

Cellular models based on using distinct cell lines, explanted tissues, or animal models all exhibit several limitations.[104–106] Established cell lines are usually immortalized or possess a malignant specimen origin.[107] Due to their long-term cultivation, they acquire several mutations or contaminations, and these probably limit their true biological relevance.[108,109] Furthermore, cell lines that are cultured in a two-dimensional system are not able to mimic human tissue since cells behave differently due to the lack of cell–cell

and cell–matrix interactions.[104,106] Explanted tissues are particularly limited by their availability and their short-term nature.[110] Additionally, primary cell populations can lose their phenotype when they are cultured in two-dimensional systems.[106] In animal models, the performance of drug tests and modeling of diseases can demonstrate the effect on a complete organism. However, certain human diseases have been extremely difficult to model in animals due to their anatomical and physiological divergence.[111] In view of these limitations, attempts are being made to generate more relevant in vitro biological model systems.

In the 1960s, small aggregates of dissociated embryonic cells were shown to reconstitute tissues with an architecture resembling that of the original tissue.[112] Recently, this knowledge was applied into several studies, and in 2009, Sato et al. were able to create an organotypic culture system.[113] These gave rise to an epithelium-only organoid based on a single intestinal cell, which was isolated from murine intestinal crypts. They used Matrigel as an extracellular matrix (ECM) substitute and supplemented the culture medium with key growth factors of the intestinal stem cell niche, such as WNT, Noggin, R-spondin, and EGF. This culture system, referred to as the R-spondin method, appeared to be a major technological advance to the stem cell field. These organoids exhibited near-physiological and self-renewing capabilities and showed similar architecture to the native organ.[113] Observing these principles, organoids resembling tissues such as the eye, gut, breast, pancreas, prostate, liver, kidney, lung, or stomach have been generated by imitating the specific stem cell niche.[104] However, most organoids still lack several key cell types, for example, mesenchymal and endothelial.[105] In addition, they only mimic the very early developmental stages of the organ under investigation.[104] Consequently, these organoids are still limited for scientific research with respect to the physiology of the whole organism. Nevertheless, organoids provide an important bridge between traditional in vitro and in vivo models.

Historically, the term organoid was used for all three-dimensional organotypic cultures.[114,115] Recently, the definition of an organoid has changed. Organoids have to contain more than one cell type, organized similarly to the modeled tissue, and exhibit some functions that are specific to the native organ.[116] In their review, Lancaster and Knoblich defined organoids as cell clusters that "containing several cell types that develop from stem cells or organ progenitors and self-organize through cell sorting and spatially restricted lineage commitment, similar to the process in vivo."[116] Consequently, organoids represent a methodical evolution of an in vitro system called embryoid body (EB). EBs are three-dimensional aggregates of pluripotent stem cells that undergo initial developmental specification as almost identical to the pregastrulating embryo and can further differentiate to form various organized tissues. Nevertheless, not all three-dimensional organoid culture systems make use of an initial EB formation.[117] The term spheroid refers to another traditional three-dimensional culture system. However, spheroids lack the presence of relevant stem or progenitor cell populations performing self-renewal to sustain the three-dimensional cluster.[106]

Self-organization can be realized in organoids due to a growing movement away from the two-dimensional culture, which particularly relies on an artificial ECM. Here, Matrigel is a common and important component that provides a scaffold and additional supplementation of signaling cues.[118] Laminin, fibronectin, and collagen build a physical framework of tissues and influence cell behavior.[119] Due to the fact that Matrigel is not well defined, it disregards special ECM cues, which are required by different tissue types.[106] Current developed biotechnologies allow the incorporation of essential signals from native ECMs into synthetic matrices and produce designer ECMs. These synthetic scaffolds can be constructed from natural macromolecules and synthetic polymers.[119] Here, mechanical signaling can be mimicked by a hydrogel that contains technologies like light-mediated patterning. When exposed to light, photolabile cross-links can undergo local degradation and thereby soften the gel, whereas photoinitiators will cause local stiffness due to additional cross-linking.[120] Moreover, three-dimensional bioprinting is a new technique. The ink comprises a biomaterial with living cells that is precisely positioned in an additive layer-by-layer approach in order to create

Table 4 Advantages and limitations of three-dimensional organoid culture

Advantages	*Limitations*
Near-physiological model system	The lack of native microenvironment
High purity with minimal contributions from other cell types	The absence of several key cell types (e.g., mesenchymal, stromal, immune, neuronal cells)
Can be propagated for a long time without genomic alterations	Currently depend on mouse sarcoma-derived Matrigel (precludes transplantation into human)
Amenable to variety of established experimental techniques for 2-D culture systems	Inability to mimic in vivo growth factor/signaling gradients in Matrigel matrix
Can be derived from multiple sources (ESCs, iPSCs, primary cells/tissue)	Organoids in the same culture are heterogeneous in terms of viability, size, and shape
Limited amounts of starting material can be expanded	Inability to address questions regarding the whole organism
Human diseases that are difficult to model in animals can be studied with patient-derived organoids	Some tissues still remain resistant to 3-D organoid culture

Modified from Fatehullah, A.; Tan, S. H.; Barker, N., Organoids as an in vitro model of human development and disease. *Nat. Cell Biol.* **2016**, *18* (3), 246–254.

three-dimensional biological structures that mimic the structure and function of native tissues and organs.[121] By using this method, researchers were recently able to create a beating heart organoid.[106]

During organoid formation, several factors such as growth factors and small-molecule-based pathway activators or repressors are used to assist self-organization by controlling self-renewal and differentiation of stem cells. This is possible by mimicking the specific stem cell niche that contains ECM and cell–cell interactions and biophysical and biochemical signals.[106] However, cell–cell and cell–matrix interactions are difficult to control. Microfluidic devices, microbeads, and degradable vehicles in the culture matrices can deliver soluble growth factors and ligands by forming a gradient through manipulations.[106, 122] Furthermore, an important consideration in developing functional organoids is permitting sufficient nutrient and oxygen supply. Most attempts to create in vitro vascularization have been a combination of neoangiogenesis and synthetic scaffolds that are used to create micro-engineered three-dimensional structures.[123,124] An essential function is the cellular memory that enables the storage of otherwise transient responses. In this regard, sophisticated memory devices have been a key development to mimic cellular memory via genomic integrated circuits. Many synthetic circuits have been designed by using digital logic gates, relying on transcriptional control using activators, repressors, and other novel mechanisms.[125]

However, there are still tissues that remain to be resolved in three-dimensional organoid culture; among these is the heterogeneous nature of cultured organoids in terms of viability, size, and shape.[105] Regardless, the three-dimensional culture systems of organoids have advantages over the two-dimensional culture systems but still with some limitations (Table 4).[105]

The field of three-dimensional (3-D) organoids derived from human pluripotent stem cells is evolving rapidly, and there are many possibilities for potential applications (Table 5). The organoids have the potential to model adult homeostasis, and disease modeling will probably be a primary focus of future organoid-based studies.[116] The testing of efficacy and toxicity of drug components will be an important aspect, too. This could be applied to organoids that represent models for degenerative conditions. In particular, the development of, for example, human liver organoids would be of enormous relevance, because the liver often metabolizes drugs and animal-based toxicity tests often exhibit other metabolism-related pathways. Therefore, methods to screen

components in an in vitro 3-D human liver model are under investigation. This could be a great opportunity as an alternative in the drug discovery process.[127] So far, several organoid systems have been established, which are associated with human disease modeling (Table 6).[105]

4.10.6.1 Liver Organoids

Primary and adult liver cells are difficult to cultivate, and for decades, laboratory studies have failed to generate vascularized, functional, and complex organotypic cell cultures that resemble native liver.[128] Previous reported three-dimensional hepatic cell clusters were entirely composed of epithelial structures and lacked complex structures such as blood vessels.[129]

The embryonal gastrointestinal tract consists of foregut, midgut, and hindgut.[129] Each of these regions gives rise to different tissues and organs. The foregut gives rise to the oral cavity, pharynx, esophagus, stomach, liver, pancreas, and proximal duodenum. The midgut and hindgut give rise to the distal duodenum, jejunum, ileum, colon, anal canal, urethra, and bladder.[129] During liver development, ductal epithelium and hepatocytes arise from liver progenitor cells, referred to as hepatoblasts.[130] In order to attain maturity, these cells rely on a complex symphony of signals from other nearby cells. This leads to the initiation of human liver-bud formation in the third or fourth week of gestation.[128] By recapitulating these principals, Takebe et al. were recently able to create in vitro liver buds via cocultivation of hepatoblasts with mesenchymal and endothelial cells.[112] They plated the different cell types in two-dimensional conditions, and these cells self-organized into macroscopically visible three-dimensional clusters after 2 days of culture. They detected that the lack of one cell type results in failure of three-dimensional organoid formation. The created organoids were mechanically stable, could be manipulated physically, and were cultivated for 2 months while exhibiting a higher albumin production rate compared with traditional two-dimensional cultures. Takebe et al. discovered that the transplantation of these liver buds into mice led to maturation of the organoids into vascularized and functional human liver. Transplanted liver buds were capable of rescuing drug-induced liver failure in mice.[112]

More advanced methods like 3-D architecture of HLC derivatives in vitro show improvements in experimental outcome. Liver functions such as urea synthesis and activity of distinct cytochromes were higher in the 3-D organoids than in the 2-D culture approaches. Furthermore, these 3-D iPSC-derived hepatocyte-like cells (HLCs) were more susceptible for most of the tested drugs in comparison with the monolayer culture.[52] Furthermore, liver-bud-like tissue generation by self-organization of genetically engineered iPSCs is possible. These organoids are able to perform several liver key functions.[131]

Based on these advances, it is evident that three-dimensional organoid culture systems may be suitable not only for disease modeling, drug test performance, and developmental research but also for cell replacement therapies in the near future.

4.10.6.2 Brain Organoids

The brain is a complex organ. It derives from the neural ectoderm,[132] which gives rise to the neural plate which folds and fuses to form the neural tube. The neural tube is an epithelium with apical–basal polarity that is organized around fluid-filled lumen that likely represents the brain ventricles. The axes are built through concentration gradients and because of these axes the epithelial tube can subdivide into four major brain regions: the forebrain, midbrain, hindbrain, and spinal cord.[116] In general, neural stem cells that are resident next to the ventricles differentiate into neurons.[133] The neural stem cells expand through symmetric proliferative

and asymmetric divisions that give rise to self-renewing progenitors and differentiated cell types which migrate to other zones to generate stratified structures.[116, 134]

In previous studies, in vitro-derived neural stem cells from pluripotent stem cells were used to better decipher the mechanisms of neural differentiation.[135] These homogenous neural stem cells were generated in classical two-dimensional culture systems and could neither show the characteristic apical–basal polarity nor recapitulate the complicated lineage of neural stem cells. To gain knowledge in this field, protocols for generating neurospheres have been developed.[136] Neurospheres are aggregates of neural stem cells and have a self-renewing capacity. Though, neurospheres are not well organized and are limited in their capacity to generate different aspects of brain development.[116] Furthermore, neural tubelike structures and the neural rosettes have also been established. Neural rosettes derive from isolated neuroepithelium or directed differentiation of pluripotent stem cells.[137,138] They have the ability to recapitulate apical–basal polarity and exhibit radial organization similar to that of the neural tube. They show a higher capacity to recapitulate many aspects of brain development including the production of intermediate progenitor cells and the timed production of layer identities similar to those in vivo.[139] However, the two-dimensional aspect of this method results in many limitations in modeling the organization of the developing brain; hence, three-dimensional (3-D) culture methods were established to help overcome some of these limitations.[116,128,140–144] These methods have the potential to recapitulate brain tissue formation. To obtain the 3-D cultures, first, embryoid bodies have to be generated from pluripotent stem cells. Second, after embedding them in Matrigel, which provides an environment that is similar to the extracellular matrix, the embryonic bodies exhibit an outgrowth of large buds of neuroepithelium. These buds have the ability to expand and develop into various brain regions. The cerebral organoids can reach the size of a few millimeters and can be further maintained for over a year by using a bioreactor that provides sufficient oxygen and nutrient supply.[116,145] Cerebral organoids are able to mimic the development and disease conditions.[143] Furthermore, they offer potential for drug testing and even future organ replacement strategies.[146] However, like all in vitro systems, the method does not contain all crucial factors necessary for proper brain development. The surrounding embryonic tissues that have great importance on the interplay of neural and nonneural tissue are missing.[145]

4.10.6.3 Heart Organoids

Heart organogenesis and morphogenesis are complex anatomical processes. In the adult heart, myocardial cells are generated from mesodermal precursors during the embryonic period of heart growth.[147] Distinct signaling pathways lead to the formation of the first and second heart fields and afterward to the four-chambered heart.[148–150] After the forming of the early heart shape, some mesodermal cells from the proepicardium build the epicardium, which is a single layer of cells that envelope the heart.[151] Then, epicardial cells become migratory mesenchymal cells and enter the underlying myocardium and differentiate.[147]

There are three main points to consider, that is, scaffold, cell sources, and signaling factors, when generating three-dimensional (3-D) cardiac tissue for use in cardiovascular therapy or toxicological testing.[147] The differentiation of pluripotent stem cells into cardiomyocytes follows a distinct developmental lineage after mesoderm induction. Generating organoids involve mimicking the 3-D setting of an evolving embryo using embryoid bodies as intermediates.[152] These aggregates of cells are exposed to various growth factors and hypoxic environment for initiating the developmental processes. Other scaffold-free constructs are used by a relatively new developed method: the cell sheet engineering technique. There, a temperature-responsive culture surface is used that detaches myocardial layers as a confluent sheet. This is achieved by lowering the temperature, which then results in the stacking of myocardial layers to produce a 3-D cardiac construct.[153] The monolayers can rapidly attach and form cell–cell connections. However, the thickness of the 3-D construct is limited to three layers.[154] In contrast to the use of embryonic bodies and the cell sheet engineering technique, a scaffold can be used to obtain organoids via other pathways. A scaffold represents the structural platform for a new cellular microenvironment and supports new tissue formation. It provides cell attachment, migration, differentiation, and organization.[155] Biometric scaffolds are made of natural or synthetic polymers or hybrid copolymer and are similar to the native components of the extracellular matrix.[156] In general, biometric scaffolds should not be immunogenic but mechanically stable. They should mimic cardiac tissue flexibility and allow physiological electric propagation and sufficient oxygen and nutrient delivery to the cells and a degradation rate that is appropriate to the rate of native extracellular matrix replacement.[115,157] The biometric scaffolds are used alone or in combination with cells.[158–161] To gain success, the selection of cell types and scaffold material and the incorporation of bioactive molecules and bioreactors should be noted.[147] Another method for generating a 3-D cardiac tissue is the decellularization. Therefore, the success of this depends on specific requirements of the application as high density, high pressure, and stiffness.[162,163] The commonly used methods are microwave radiation and chemical, enzymatic, mechanical, and physical separation. The combination of physical, chemical, and enzymatic methods leads to better results in the decellularization process in whole organ and small tissues in cardiac applications.[164,165] In order to decellularize and recellularize an organ to serve as a scaffold, detergent or an enzymatic solution is first used to remove cellular material and then the stem cell of choice is applied to repopulate the scaffold in the presence of an appropriate culture environment.[147]

4.10.7 Use of Induced Pluripotent Stem Cells for Toxicogenomics

Toxicogenomics—an interdisciplinary between toxicology and genomics—is concerned with identification of potential human and environmental toxicants and their putative mechanisms of action through the use of genomic resources.[166] Measurements on the proteome, genome, and transcriptome level target at the prediction of toxicity, the finding of biomarkers, and the detection of

genetic variants associated with higher predisposition to toxicity. A broader concept of toxicogenomics also includes metabolomics.[167] A plethora of studies have demonstrated the advantages of the toxicogenomic approach.[168] For instance, McBurney et al. proposed a systems toxicology approach to discover toxicogenomic biomarkers to detect a drug's potential for human idiosyncratic drug-induced liver injury and could show that the molecular analyses employed in the study were detecting substantial "off-target" markers.[169] Ellinger-Ziegelbauer et al. could distinguish genotoxic carcinogens from nongenotoxic carcinogens via a toxicogenomic approach employing gene expression profiles from treated rat liver.[170] Based on the gene expression profiles and a support vector machine (SVM), classifiers of the carcinogens were determined in what would have usually required a 2-year evaluation with rodent lifetime bioassays. Obviously, in toxicogenomics, the accessibility of a large amount of existing toxicological information plays an important role. Hence, there is a need for databases making this knowledge accessible to the community and integrating newly acquired knowledge. Here, as an example, the Japanese Toxicogenomics Project consortium (TGP) provides a large-scale toxicogenomics database (open TG-GATEs) consisting of data from 170 compounds (mostly drugs) with the aim of improving and enhancing drug safety assessment.[171] The database (http://toxico.nibio.go.jp/english/index.html) comprises data and metadata including gene expression profiles and pathology and is freely available.

Although toxicity can affect various tissues such as neurotoxicity or kidney toxicity, the liver as a key metabolic organ plays a major role for toxicity studies. Most drugs promote their own metabolism by upregulating the enzyme systems responsible for their activation (phase I) and conjugation (phase II) to biochemical forms that can be excreted in bile or urine. The majority of drugs that are metabolized by the liver through such detoxification pathways induce particular subsets of cytochromes (CYP) P450.[172] The most ubiquitous of these, CYP3A4, is responsible for metabolizing a large fraction of hepatotoxic drugs, and indeed, CYP3A4 induction can be used as an index of exposure to them. The Adjaye group demonstrated the expression of cytochrome P450 family members in induced pluripotent stem cells (iPSCs) and embryonic stem cell (ESC)-derived hepatocyte-like cells, and others have shown the prediction of interindividual differences in hepatic functions and drug sensitivity by using human iPSC-derived hepatocytes.[42,52,58,173] These studies among others have provided evidence that human iPSC-derived hepatocytes can be used as an in vitro hepatocyte model for use in pharmacology and toxicology. **Fig. 2** shows expression of the drug-metabolism-associated absorption, distribution, metabolism, and excretion (ADME) genes in iPSCs differentiated into hepatocytes, cardiomyocytes, and neurons.[41,42,71,100,174] The iPSC-based strategy is also exploited by companies by providing human iPSC-derived hepatocyte cells (iHeps) for use in toxicology screening and studies.[173] The ADME genes have been shown to be associated with drug metabolism and can be grouped into four distinct categories (http://www.pharmaadme.org/):[35]

1. Phase I metabolism enzymes: CYP, DHRS, and CBR
2. Phase II metabolism enzymes: GST, SULT, UGT, CHST, and NAT, which are responsible for the modification of functional groups and the conjugation with endogenous moieties
3. Transporters: SLC, ABC, and MRP, which are responsible for the uptake and excretion of drugs in and out of cells
4. Modifiers: CAT, CDA, RXRA, PPARG, PPARD, SOD, and SERPINA7, which can have dual functions, that is, regulate the expression of other ADME genes or modulate the biochemistry of ADME enzymes

ADME genes can be employed to derive parameters from in vitro models, which can be combined with toxicokinetic (TK) parameters from in vivo models, which increasingly can be derived from physiologically based toxicokinetic (PBTK) modeling.[175]

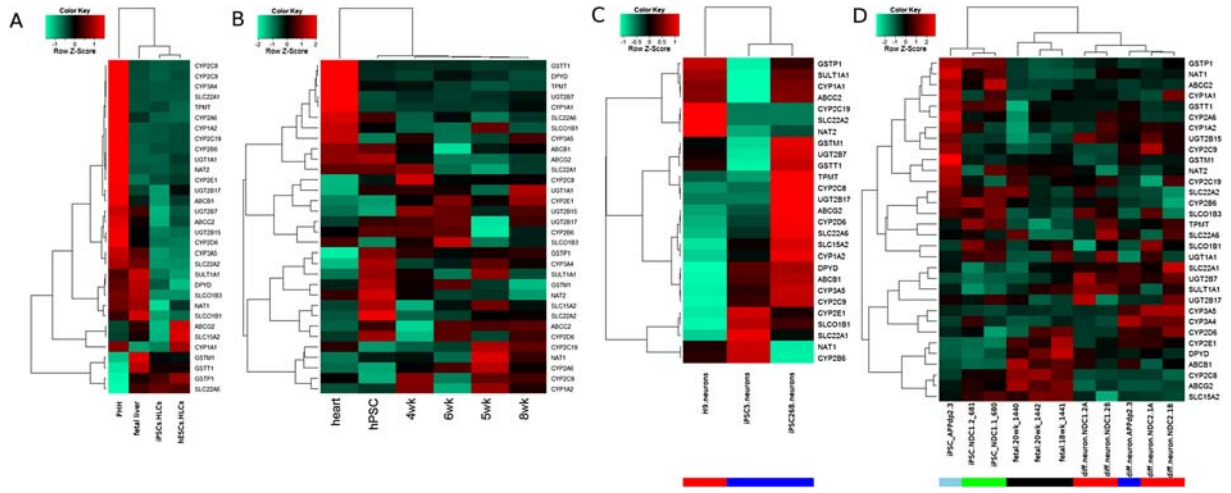

Fig. 2 Gene expression analysis of the ADME genes in iPSCs differentiated into cell types representative of endoderm, mesoderm, and ectoderm. The heatmaps represent genes encoding the core ADME enzymes based on the transcriptome data sets of iPSC- and ESC-derived HLCs (A),[42] cardiomyocytes (B),[100] and neurons for Alzheimer's disease models (C[174] and D).[71] The ADME genes have been shown to be associated with drug metabolism (http://pharmaadme.org/joomla/index.php?option=com_content&task=view&id=14&Itemid=29).[41] Color bars: *blue*, iPSC-derived neuron from AD; *red*, iPSC-derived neuron from healthy control; *light blue*, iPSC from AD; *green*, iPSCs from healthy control; black, fetal brain.

ADME-derived parameters depend on the tested chemicals and can be integrated with chemical-independent physiological and anatomical information in PBTK models to simulate TK profiles. Employing quantitative structure–activity relationship (QSAR) models and in vitro methods, ADME parameters can be determined. PBTK models are valuable tools for extrapolating in vitro results either interspecies or interindividuals and thus are gaining importance in toxicity testing.

4.10.8 The 3Rs

The 3Rs are first mentioned in a report by Russell and Burch originally published in 1959 and are acronyms for replace, reduce, and refine.[176] The first *R* means that as far as possible, animal tests should be replaced. If that is not possible, they should be reduced, and if that is also not possible, the experiments should at least take place under the best possible conditions for the animals (refine).

To date, toxicology screens necessitate the use of significant numbers of animals. In the EU program Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH), the hazard risk of 30,000 chemicals shall be assessed, which had not been tested before. This testing of chemicals required under the REACH regulations has been variously estimated to require up to 54 million additional animals, therefore necessitating the development of alternative testing strategies (http://ec.europa.eu/enterprise/sectors/chemicals/reach/index_en.htm), which could achieve a reduction to below 10 million animals.[177]

3R approaches could tackle this problem by employing patient-specific iPSC-derived hepatocytes, neurons, or cardiomyocytes in order to reduce or—where possible—to replace animal tests. In a strategy paper, the European Union Reference Laboratory for alternatives to animal testing (EURL-ECVAM) outlines the possible use of physiologically based toxicokinetic (PBTK) models for toxicological tests with respect to the 3Rs.[175] These models have the potential to provide whole-body human toxicokinetic data by in silico and in vitro methods assessing ADME processes. Standardization and an infrastructure for these methods are important issues that when properly solved, could leverage their acceptance and use, thus leading to a more efficient use of available human and animal data. Höfer et al. mention the importance of databases and data management to ensure a more ubiquitous accessibility of existing data.[177] Adequate data management strategies are an issue for many scientific disciplines where large amounts of data are generated and, in particular for modern biology disciplines such as toxicogenomics and systems biology, where novel techniques produce data in high throughput.[178]

Predictions based on animals models not always reflect the human reactions but instead display sometimes qualitative and also quantitative differences in their physiology and metabolism; for example, animal test data for acetylsalicylic acid (aspirin) demonstrated that it could cause severe problems in rats but it is harmless to humans.[179–182] Would these animal experiments have been used to test the safety of aspirin, it may not have been permitted for clinical trials. Already in 1988, Lave et al. criticized the reliability and the cost-effectiveness of rodent models for carcinogenicity testing.[183] The report *Toxicity Testing in the 21st Century*: *A Vision and a Strategy* released by the US National Academy of Sciences envisioned toxicity testing firmly based on human biology and thus reducing animal testing.[184] Computational models would simulate dose–response behavior and extrapolate in vitro results to in vivo human blood and tissue concentrations. Thus, human relevance of test results would be increased.

However, a full replacement of animal tests at the moment is not feasible as the models still cannot fully reflect the in vivo reality. This is demonstrated by the demand for animal tests in most guidelines for toxicity testing, for example, the Organisation for Economic Co-operation and Development (OECD) guidelines for the testing of chemicals. In general, guideline methods such as OECD TGs 417 and 427 are based on animal tests.[175,185,186] Only OECD TG 428 for the in vitro method for skin absorption is an exception.[187] However, with the continuous improvement of the toxicological models, replacement can be envisioned as a long-term goal, and meanwhile, the two other *Rs*—reduction and refinement—should be followed as far as possible.

4.11.1 Introduction

Genetic toxicology is a subspecialty of toxicology that studies the effects of chemical and physical agents, on genetic material or deoxyribonucleic acid (DNA) causing alteration(s) in the structural integrity of the genome. Genetic damage is a natural phenomenon occurring endogenously in the cells as a result of oxidative respiration and metabolism, but this damage is continuously being repaired by a variety of DNA repair processes present in all cells. However, when the genetic damage becomes overwhelming for the cellular machinery to handle, it accumulates genetic lesions that could lead to a wide variety of adverse outcomes, including apoptosis or cell death, altered cell division or proliferation, DNA replication and mutagenesis which may result in carcinogenesis. Carcinogenesis is a multistep process but broadly defined as a three-step process, tumor initiation, promotion, and progression. DNA damage plays an important role in the initiation step of carcinogenesis, where a carcinogen or its activated metabolite covalently binds to DNA forming a DNA adduct, which may be repaired or following cell division may be fixed as a mutation leading to a heritable alteration in the DNA sequence. The field of genetic toxicology uses a wide array of in silico, in vitro, and in vivo assays to measure the DNA damage that can be caused by a wide range of endogenous and exogenous agents including but not limited to biological and chemical agents.

Genetic toxicology encompasses the study of a wide variety of DNA damage endpoints, including but not limited to mutagenicity, clastogenicity, and aneugenicity. Mutagenicity refers to the ability of an agent to alter the nucleotide sequence of DNA. Mutations are categorized as base-pair substitutions, frameshifts, additions, and deletions of nucleotide base(s) or chromosomes. Mutations are heritable and hence may pose a permanent or long lasting adverse effect on the health of an organism. Although, mutations naturally arise during evolution or DNA replication, most of them occur in areas of DNA that do not exert any harmful effects to organism and are referred to as silent mutations. However, if mutations occur in the coding regions (e.g., genes) or in the noncoding (e.g., regulatory regions of genes), then it may lead to adverse effects due to altered gene expression patterns, or formation of nonfunctional or altered proteins and enzymes, thus impacting the functional activities of the cells.

Clastogenicity and aneugenicity describe a type of DNA damage characterized by structural or numerical alterations to chromosomes. The DNA damage can be either chromosomal, affecting both sister chromatids of a chromosome, or of chromatid, involving only one of the two sister chromatids. Different types of DNA damages are accumulated due to clastogenicity, including insertions, deletions, translocations, inversions, and chromatid aberrations. Aneugenicity refers to the numerical changes to the number of chromosomes, resulting in polyploidy or monosomy or trisomy conditions. Aneugenicity occurs due to errors in chromosomal segregation, altered tubulin polymerization, and spindle apparatus instability. Aneugenic DNA damage is considered indirect DNA damage or secondary DNA damage, unlike clastogenicity which is considered direct DNA damage.

A wide variety of in silico, in vitro, and in vivo assays are used to predict the three common types of genotoxic damages, mutagenicity, clastogenicity, and aneugenicity. In vitro assays in general are designed to achieve high sensitivity in detecting DNA damage caused by chemicals or agents. High sensitivity of these in vitro assays often leads to decreased specificity in predicting the carcinogenic potential of chemicals. In vivo genotoxic assays on the other hand have high specificity but tend to exhibit low sensitivity in predicting the carcinogenic potential of chemicals. Therefore, to increase the specificity and sensitivity of detecting DNA damage,

Table 1 List of OECD guidelines for the genotoxicity assays discussed in this book article

OECD test number	*Genetic toxicology assay*
Test no. 471	Bacterial reverse mutation test
Test no. 487	In vitro mammalian cell micronucleus test
Test no. 474	Mammalian erythrocyte (in vivo) micronucleus test
Test no. 473	In vitro mammalian chromosome aberration test
Test no. 475	Mammalian bone marrow chromosome aberration test
Test no. 489	In vivo mammalian alkaline comet assay
Test no. 490	In vitro gene mutation assay using the TK locus

Table 2 Databases with genotoxicity and carcinogenicity information

Database name, information and link
ACToR (www.epa.gov/actor)
Aggregates toxicity data from 500 public sources on over 500,000 environmental chemicals
CPCD (Carcinogenicity Potency Database) (http://potency.berkely.edu/cpdb.html)
Contains information on carcinogenicity studies on 1547 chemicals
NTP (http://ntp.niehs.gov)
Contains data on subchronic, chronic, in vitro and in vivo genotoxicity assays, and carcinogenicity studies.
TOXNET (http://toxnet.nlm.nih.gov)
Contains mutagenicity, genotoxicity, carcinogenicity and tumor inhibition, and promotion tests results of over 9000 chemicals
ToxRefDB (http://www.epa.gov/ncct/toxrefdb)
Includes subchronic, chronic carcinogenicity, reproductive, and developmental studies
Tox Benchmark (http://ml.cs.tu-berlin.de/toxbenchmark/)
Ames mutagenicity dataset for 6500 chemicals
PharmaPendium (www.pharmapendium.com)
It offers searchable Food and Drug Administration (FDA) and European Medical Agency (EMA) approval packages with excerpted preclinical, clinical, and postmarketing safety data into a single longitudinal database
VITIC (www.lhasalimited.org/vitic_nexus)
Vitic (pronounced V-eye-tick) Nexus is a chemically intelligent database, emphasizing useful in (Quantitative) Structure-Activity Relationship (QSAR) modelling
SciFinder (www.cas.org/products/scifinder)

a combination of in vitro and in vivo genotoxicity assays is used, commonly referred to as "battery approach," for predicting the rodent bioassay outcomes, considered as a gold standard assay to predict human carcinogenicity potential of a test article. The use of a genotoxic battery approach has been proven to have high sensitivity and specificity (~85%–90%).[1]

The main emphasis of this article has been placed on providing a general overview of how genetic toxicology (genotoxicity) assessment is performed on chemical agents across diverse biological, chemical, and pharmaceutical industries. It is beyond the scope of this article to discuss in detail the guidelines on how to conduct the genotoxicity assays discussed as part of this article. Comprehensive details on the conduct of commonly used genetic toxicology assays can be reviewed by accessing the Organization for Economic Co-operation and Development (OECD) guidelines (www.oecd.org). OECD guidelines for the genetoxicity assays discussed in this book article are listed in **Table 1**. In addition, resources/websites where genotoxicity/carcinogenicity data can be found are listed in **Table 2**.

4.11.2 Genetic Damage (Genotoxicity) Detection Methods

4.11.2.1 In Silico Approaches

As indicated earlier and discussed next in this article, there are several in vitro and in vivo genotoxicity testing assays that are available to aid in identifying genotoxic damage. However, the global call for reduced animal usage with emphasis on 3Rs (Reduce, Refine, and Replace) and to phase out animal testing has led to the rapid expansion and evolution in a myriad of in vitro and in silico genetic toxicology screening assays. The objective of in silico screening techniques is to apply mathematical, statistical, chemical, and computational tools to the existing genetic toxicology data from the literature and to develop efficient and effective genotoxicity predictive models. These predictive models can be used to screen large numbers of untested new chemicals to predict their genotoxic potential. In silico genotoxicity screening methods offer a fast, reliable, and economical solution for preliminary screening of large numbers of chemicals. The crux of in silico models has its roots in structure activity relationship (SAR). The earliest examples of SAR were the Ashby–Tennant alerts, which associated certain chemical structures with mutation, based on the expert

knowledge and experience of these scientists. Others have continued to expand the list of structural alerts associated with DNA reactivity based on known chemical reactivity and expert knowledge. Later, an alternative approach was used based on quantifying structure activity relationships (QSARs) using statistical correlation and quantum chemical properties. QSAR models use linear free energy relationships to describe reaction rates and equilibrium. There are a wide variety of in silico tools that have been packaged into software programs capable of predicting a variety of genotoxic endpoints, but the best validated are models predicting bacterial mutagenicity endpoint. These in silico tools can be divided into three main categories: databases, virtual screening programs, and prediction systems.

The primary step in in silico assessment of a chemical is to perform a search in public databases to determine if any genotoxicity data exists for the chemical under investigation. The databases collect and store genotoxicity data obtained from multiple sources including published literature, public data sources, and proprietary in-house historical data from within a testing laboratory obtained over the years of conducting genotoxicity testing. The databases are either open to public use free of cost or available commercially, where the users pay service charges to access them. Examples of free databases are Toxicology Data Network (TOXNET), Aggregated Computational Toxicology Resource (ACToR) of EPA (http://www.epa.gov/actor/), National Toxicology Program (NTP), Carcinogenic Potency Database (CPDB), etc. (**Table 2**). Examples of commercial databases include Pharmapendium, SciFinder, STN, etc. There are some tools that serve the dual purpose of a database and prediction system. Examples include deductive estimation of risk from existing knowledge (DEREK), VITIC, Leadscope, etc.

Prediction systems are software programs that enable us to make prediction on species and assay-specific endpoints such as in vivo mouse micronucleus test, in vitro chromosome aberration test, mouse lymphoma assay, in vitro micronucleus in several species. These software programs use different types of algorithms to compute the propensity of a specific chemical to induce genotoxicity. The algorithms for these systems can be divided into three main categories—knowledge-based, statistical methods, and read-across systems. Knowledge-based predictive systems focus on organizing relevant experimental genotoxicity data as knowledge guidelines or rules in a computer program. The in silico software compares the structure of the chemical of interest/investigation with the chemicals in the knowledge library of the database. For example, one of the widely used commercial knowledge-based predictive systems is DEREK version 14 which comprises 82 rules or alerts for mutagenicity. The DEREK rules are written and maintained by experts from the nonprofit organization LHASA limited (www.lhasalimited.org).

A structural fragment statistically related to the biological activity is called as a biophore. Biophores of known genotoxic chemical(s) are compared in databases through biological activity or QSAR modeling. For example, the presence of the N−N═O (nitrosamine) fragment is strongly statistically correlated with mutagenicity of both aromatic and aliphatic chemicals. Biophores or structure moieties that are related to toxic or therapeutic endpoints are referred to as "toxicophore" and "pharmacophore," respectively. If a biophore is present, then the software predicts the chemical as active, and if no biophore is found the software predicts the chemical as inactive.[2,3] Based on the distribution of a biophore and its correlation to toxicity the statistical systems give a statistical value or predictive value of the biophore. For example, if the database contains 50 nitrosamines, and all of these are active, then the presence of the N−N═O biophore is a very strong predictor of toxicity. On the other hand, if only half of the nitrosamines in the ;database are active and half are inactive, then the confidence that chemicals containing N−N═O are active will be only 50%. The term "structural alert" has also been applied in computational toxicology, meaning a chemical moiety that serves as an indicator of toxic outcome.[2,3] The two widely used commercial statistically fragment based in silico systems are Leadscope (www.leadescope.com), whose QSAR models were developed by Informatics and Computational Safety Analysis Staff of Food and Drug Administration, and MultiCASE (www.multicase.com), whose QSAR models were based on proprietary statistical algorithms developed by Klopman.[4] There are also several free open source statistically fragment based in silico predicting software such as ToxTree (www.opentox.org/toxicity-prediction), Bioclipse-DS (www.bioclipse.net), etc. In read-across systems, the endpoint result of one chemical is used to predict the endpoint of a structurally similar chemical. The QSAR toolbox (www.oecd.org/toolbox) and AIM (Analog Identification Method) (www.epa.gov/oppt/sf/tools/aim.html) are examples of in silico tools that can be used to find structurally similar chemicals.

Although the in silico systems provide an economical, faster, and easy screening of large set of chemicals, they are far from replacement of in vitro and in vivo genetic toxicology screening assays, due to lack of strong correlation between the in silico prediction and experimental outcomes. However, currently, they serve as great tools for early genetic toxicology screening of chemicals, impurities, and degradants.

4.11.2.2 In Vitro and In Vivo Assays for Genotoxicity Evaluation

4.11.2.2.1 Ames assay

Ames assay is an in vitro bacterial assay, that measures bacterial revertant colony formation, named after Bruce Ames who first identified and reported the utility of this assay in detecting mutations in 1974.[5] In the Ames assay, auxotrophic bacteria that require the amino acid histidine for growth are treated with test chemical or vehicle or positive control on an agar plate consisting of growth media that lack histadine. Therefore, only bacteria that have reverted back to wild type histidine locus are now capable of growth and form colonies. Increased numbers of revertant colonies in test chemical treated plates compared to concurrent untreated or vehicle control plates are an indication of the mutagenic potential of the test chemical. A series of genetically modified *Salmonella typhimurium* and *Escherichia coli* bacterial strains were created to be used in Ames assay that are capable of detecting frameshift or base pair substitution mutations.

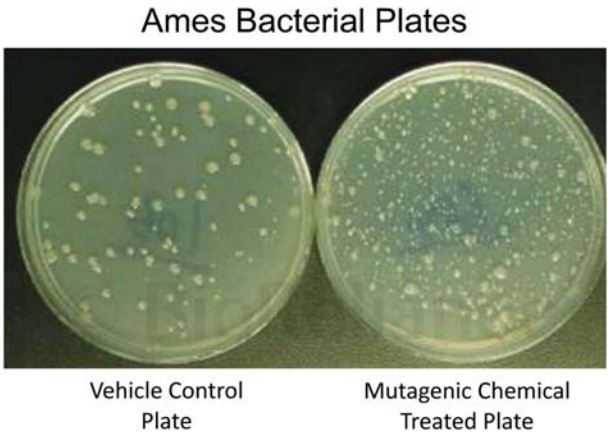

Fig. 1 Ames assay plates showing the increase revertant colony formation in mutagenic chemical treated plated relative to vehicle control plates. Images courtesy of James Wojciechowski and Andrew Henwood, Bristol Myers Squibb, NJ, USA.

It is a well known fact that mutations in the DNA sequence may trigger a cascade of reactions that may adversely impact cellular events such as replication, transcription, or translation and may eventually result in apoptosis (cell death). Mutations can be classified into two main types: inherited and acquired. Inherited mutations occur as a result of passage of the mutated DNA from the parent cell to the daughter cell. Acquired mutations occur as a result of DNA damage due to environmental agents such as nuclear radiation, UV exposure, chemical exposure (exogenous or endogenous), errors during the DNA replication or transcription process. Elegant repair mechanisms exist to revert DNA damage caused by various mutagens and to repair errors that occur during replication or transcription; however, these repair mechanisms have their limitations and are not able to sufficiently restore the damage that is caused by potent mutagens. During cell division, when an acquired mutation is passed on from the parent cell to the daughter cell, it becomes an inherited mutation. Gene mutation refers to changes that affect a single or multiple genes. These mutations may occur as a result of deletion of a nitrogenous base(s), insertion of nitrogenous base(s), or substitution of nitrogenous base(s).

Ames assay is the most commonly used assay to predict mutagenic potential of a test compound across several scientific disciplines and industries. The Ames assay is so widely used because, historically those chemicals shown to be positive in the Ames assay have also been shown to be positive in the in vivo rodent bioassay (~65% concordance), used to measure carcinogenic potential of a test chemical and is considered as a gold standard assay to predict human carcinogenic potential of a chemical by health regulatory authorities globally (Kirkland and Ardema, 2005). Ames assay is commonly carried out using several bacterial strains. The *S. typhimurium* strains detect base-pair substitution and frameshift mutations at GC base pairs, while *E. coli* strains damage at AT base pairs. These strains are genetically manipulated to increase their sensitivity to detect mutation frequency. A list of commonly used Ames bacterial strains and detailed assay guidelines can be obtained in OECD test 471 guideline (OECD 471, 1997).[6] Bacteria like several other rodent or human cell lines lack or have limited metabolic activation potential; thus Ames assay is almost always carried out with and without exogenous metabolic activation, usually in the presence of induced rat liver S9 fraction (Fig. 1)

4.11.2.2.2 Micronucleus assay

A micronucleus (MN) is often a broken chromosome fragment or rarely an entire chromosome that remains outside the nucleus after cell division. A MN may be formed following direct DNA damage (clastogenic mechanism) or following secondary interaction with DNA replication apparatus (indirect aneugenic mechanism). During anaphase stage of cell division process, acentric DNA fragments formed due to DNA damage may not be incorporated into the nucleus. Hence, chromosome fragments result in the formation of MN after telophase and cytokinesis stages of cell division. Micronuclei formed can be of various sizes but typically varies from 1/10th to 1/100th the size of original nucleus. Increased incidence of micronuclei formation serves as a good biomarker for genotoxic damage. MN assay can be performed either in vitro or in vivo. Micronuclei in peripheral human blood samples have been used to adjust doses of chemotherapy agents (Fig. 2).

The formation of MN can be readily measured in both in vitro in different cell types (in vitro MN assay) and in vivo samples (in vivo MN assay) including peripheral blood, bone marrow, and tissues of rodents and other species using MN assay. Although in principle the in vitro MN assay can be performed in any cell type (primary or immortalized cells), the most commonly used cell types are Chinese hamster ovary (CHO) strain -K1 and -WBL cells, Chinese hamster V79 lung epithelial cells, and L5178Y mouse lymphoma cells, TK6 human lymphoblastoid cells, and primary human lymphocytes. The in vitro MN assay is typically carried out with and without exogenous metabolic activation. For the in vivo MN assay, bone marrow or peripheral blood samples from rodents treated with multiple doses of test compound, vehicle, and appropriate positive control are analyzed for the formation of MN. Cell division (one mitosis) is required for the formation of micronuclei, and use of cytochalasin B (CytoB) blocks the cells in binucleated stage with micronuclei, hence this is called cytochalasin-blocked MN assay. Cells treated with CytoB undergo karyokinesis but not cytokinesis, resulting in binucleated cells, so by evaluating only binucleated cells only those cells which have

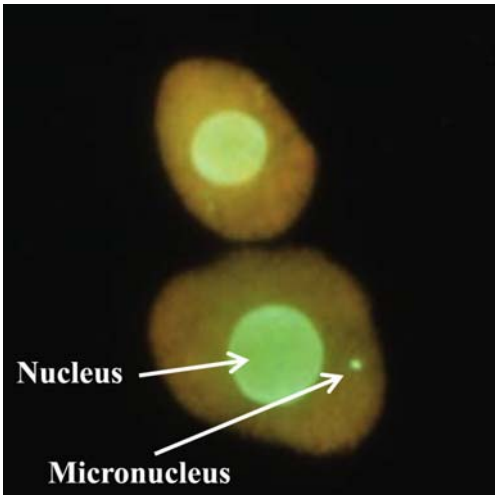

Fig. 2 Image showing the micronuclei formation in hepatocytes. Images courtesy of Rie Takashima, Mitsubishi Chemical Medience Corporation, Japan.

undergone one cell replication are evaluated. MN formation can be either due to a clastogenic and/or an aneugenic DNA damaging event. However, MN formed by clastogens lacks centromeres, while those micronuclei resulting from loss of an entire chromatid or chromosome (aneugenic event) contain a centromere. Hence, by centromere staining using various methods, such as fluorescence in situ hybridization (FISH) or other immunofluorescence methods, one can determine if micronuclei are a result of clastogenic or aneugenic events.[7–9] Although, yet debated, the size of MN can also serve as an indicator of an aneugenic or a clastogenic event, the size of MN formed due to aneugenic events is generally larger than those resulting from a clastogenic event.[10] Advanced and high-throughput MN detection technologies, such as flow cytometry and imaging-based technologies, make this a popular biomarker to measure genotoxic damage. More details on the conduct, analysis, and interpretation of in vitro and in vivo MN assays can be obtained in the OECD guidelines (OECD Test 474, 2012; OECD Test 487, 2010).[11–14]

4.11.2.2.3 Chromosomal aberrations assay

One of the traditional and direct cytogenetic methods to detect genotoxic damage is based on a direct observation of the changes in the chromosomes after exposure to a chemical insult in cell populations under a microscope. Chromosomal aberrations (CA) can be measured by the CA assay and are commonly used in both clinical and nonclinical settings. Different types of CA are accumulated due to genotoxic damage such as insertions, deletions, translocations, endoreduplication, poliploidy, chromatid aberrations, chromosomal gain, and chromosomal loss. Depending on the relative abundance of a particular type of CA in comparison with other types of aberrations occurred due to treatment with a chemical, it is possible to understand the mechanism of action of test chemical, for example abnormal number of chromosomes suggests aneuploidy, rather than clastogenicity. While numerical changes can be observed in the CA assay, the MN assay is far more sensitive to chemicals inducing this type of DNA damage. CA studies can be carried out in both in vitro and in vivo test models. In vitro CA studies may be conducted with primary or immortalized cells, but regardless of cell used all require addition of exogenous S9 liver metabolic fraction to enable detection of chemicals requiring metabolism to the ultimate genotoxicant. For in vivo CA studies bone marrow or peripheral blood samples from rodents are commonly used (**Fig. 3**).

CAs are usually studied in cell populations at metaphase stage of the cell division because chromosomes are condensed and damaged and can be easily visualized at this stage. The cell populations can be arrested in metaphase by treatment with chemicals such as colcemid. Similar to MN detection, in principle the CA assay can be performed in any cell type. However, CHO cells are most commonly used in the in vitro studies because of large size of chromosomes, fewer chromosomal numbers, stable and well-defined karyotype, and relatively shorter cell division interval. Although detection of CA assay is a direct subjective method of measuring genotoxicity levels, it is not amenable to automation and requires skilled cytogeneticists to analyze and score the CA. Invention of new technologies, such as FISH and chromosome painting, allows scientists to identify CA with relative ease and also to determine insertions and translocations more precisely which is not possible with traditional CA assay. More details on the conduct, analysis, and interpretation of the CA assay data can be inferred from Ref. 15.

4.11.2.2.4 Comet assay

Comet assay or single cell gel electrophoresis (SCGE) assay detects single or double strand breaks measured at the individual cell level. Unlike the other assays described above, the comet assay measures transient genetic damage that is not a permanent change or alteration to the DNA. The single or double strand breaks can be repaired by cellular machinery; hence, the comet assessments need

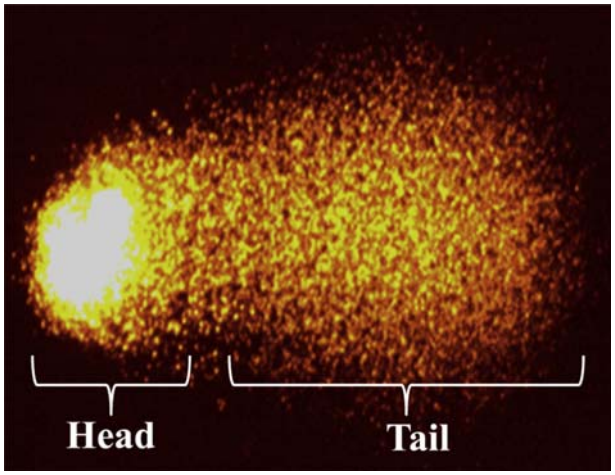

Fig. 3 Image showing the comet formation comprising of head (undamaged DNA) and tail (damaged DNA).

to be performed generally within 3–4 h after the exposure to a chemical agent. The comet assay can be conducted in vitro using single cells from immortalized cell lines or in vivo for any tissue that can be dispersed to a single cell suspension.

At the molecular level, the formation of comet in the DNA of cells upon genotoxic insult can be visualized through the method of gel electrophoresis and indicates DNA strand breaks, as the damaged DNA migrates at a different rate than nondamaged DNA during electrophoresis. In the comet assay, when damaged DNA containing single cell suspension embedded in low melting agarose is electrophoresed, the damaged DNA migrates away from undamaged DNA containing nucleoid body, resembling the structure of a "comet," hence the name comet assay. In the comet structure the undamaged DNA nucleoid part is referred to as "head" and the trailing damaged DNA streak is referred to as "tail." The percentage of DNA in the tail is directly proportional to the percentage of DNA damage that has occurred in a particular cell. Thus by counting a representative sample of ~100–300 cells per tissue it is possible to arrive at the average percentage of DNA damage accumulated in a particular tissue due to genotoxic stress. The comet assay is also referred to as SCGE assay. This assay was first developed by Ostling and Johansson in 1984, which was later revised by Singh et al. in 1988. With the advent of recent technological innovations such as fluorescent DNA stains and automated comet scoring for analysis, comet assay has emerged as a popular assay to detect DNA damage (Fig. 4).

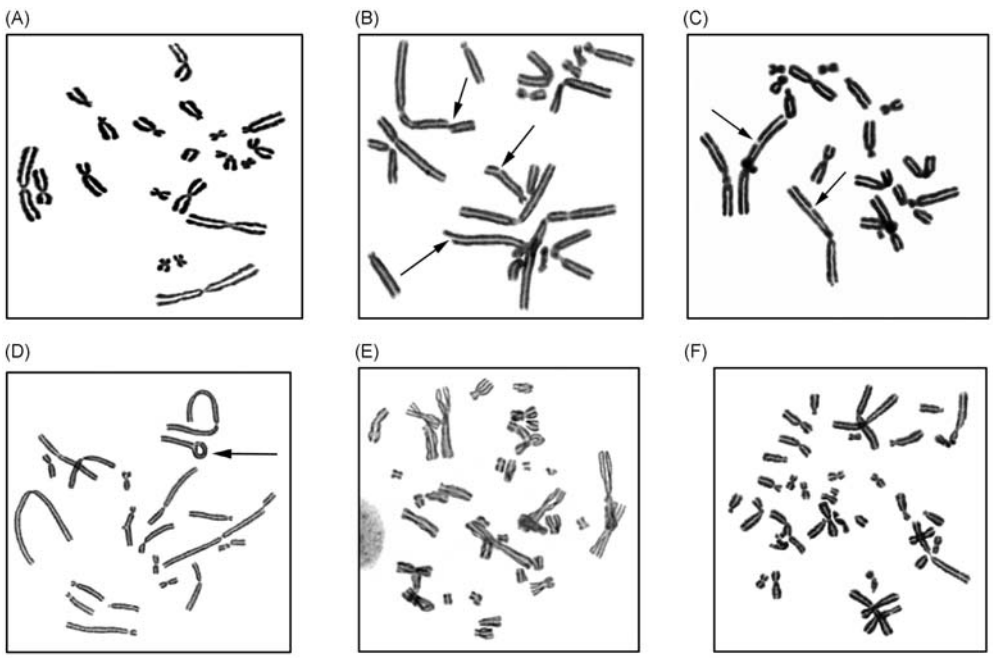

Fig. 4 Images showing different chromosomal aberrations in CHO cells normal (A), chromatid breaks (B), chromatid gaps (C), chromosome intra-change (D), endoreduplication (E), and polyploidy (F). Images courtesy of James Wojciechowski and Louis Nimzroff, Bristol Myers Squibb, NJ, USA.

The in vitro comet assay can be performed in any rodent, human cancer cell lines and human lymphocytes. It is typically carried out with and without exogenous metabolic activation, usually by supplementing with induced rat liver S9 fraction as indicated in other assays detailed earlier in this article. Although in principle any tissue can be used for in vivo comet assay analysis, high blood circulating organs such as liver, kidney, spleen are the target organ tissues that are analyzed. Also, if the route of administration is oral, then the site of contact or exposed tissue such as stomach mucosal cells is commonly used for comet analyses. More details on the conduct, analysis, and interpretation of the comet assay data can be inferred from Refs. 16–18.

4.11.2.2.5 Mouse lymphoma assay

The mouse lymphoma can be used to detect mutations and clastogenicity. The mouse lymphoma test utilizes a forward mutation assay in the heterozygous thyamidine kinase (tk+/−) locus in mammalian cell lines to determine the mutagenicity of chemicals. In this assay, L5178Y cells that acquire inactivating mutations of the wild type tk allele become resistant to triflurothymidine induced toxicity that are measured by determining cloning efficiency on soft agar. The increased mutant frequency from exposure to chemicals can be directly proportional to the mutagenic potential.

Cells in suspension or monolayer culture are exposed to the test substance, both with and without metabolic activation, for a suitable period of time and subcultured to determine cytotoxicity and to allow phenotypic expression prior to mutant selection. The treated cultures are maintained in growth medium for a sufficient period of time, characteristic of each selected locus and cell type, to allow near-optimal phenotypic expression of induced mutations. Mutant frequency is determined by seeding known numbers of cells in medium containing the selective agent to detect mutant cells, and in medium without selective agent to determine the cloning efficiency (viability). After a suitable incubation time, colonies are counted. The mutant frequency is derived from the number of mutant colonies in selective medium and the number of colonies in nonselective medium. This assay is able to detect mutagenicity (point and frameshift mutations evidenced by large colonies) and small deletions (small colonies) that involve the tk locus, either directly or through metabolic activation by S9 liver microsomes.

4.11.2.2.6 Pig-a assay

The Pig-a assay is a relatively new assay for measuring in vivo gene mutation in blood cells from humans, rats, mice, and monkeys. The *Pig-a* (phosphatidylinositol glycan, Class A) gene codes for a catalytic subunit of the *N*-acetylglucosamine transferase complex involved in an early step of glycosylphosphatidyl inositol (GPI) cell surface anchor synthesis. *Pig-a* is the only gene involved in GPI anchor synthesis that is on the X-chromosome, and research into the origins of an acquired genetic disease involving GPI anchor deficiency (paroxysmal nocturnal hemoglobinuria) indicates that cells lacking GPI anchors, or GPI-anchored cell surface proteins, almost always have mutations in the *Pig-a* gene.

This test detects mutations at the Pig-a gene that cause failure of "GPI anchors." Without these anchors, specific markers on the exterior of cells will not be present. This assay measures the frequency of cells without these surface markers, also known as "Pig-a mutant cells." Single-step forward mutations result in the loss of the GPI anchors and the surface marker phenotype, and these neutral mutations can be detected early in immature red blood cells (reticulocytes) by flow cytometry. Although the assay can be performed in vitro, it is commonly used as an in vivo follow up assay, to evaluate the positive mutagenicity findings from an in vitro bacterial Ames assay or similar assay. Although there exists no OECD guideline at this time for this assay there is sufficient literature available with well-defined principles and guidelines to conduct the assay in a scientifically sound manner. This assay can be used to support the approved regulatory assays to determine the mutagenicity potential of a chemical under investigation, based on weight-of-evidence approach.

4.11.2.2.7 Toxicogenomic signatures

Toxicogenomic studies in relation to genetic toxicology utilize the comprehensive gene expression data to identify gene expression signatures that strongly correlate with genetic toxicity. The use of these approaches has a long history and only in the past decade due to rapid development in gene expression technologies such as microarrays, real time PCR, RNA sequencing, and other bioinformatics tools the field of toxicogenomics has emerged as an area that may have immense potential for genotoxicity testing. In toxicogenomics studies, changes in gene expression patterns in response to genotoxic stress are most commonly studied but changes in protein expression or metabolite formation can also be investigated. In addition, toxicogenomics approaches have potential to overcome some of the limitations posed by traditional genotoxicity testing approaches such as use of limited number of animals especially when changes in a limited set of genes are being investigated. Also, toxicogenomics approaches are easily amenable for high-throughput and high-content screening than traditional methods, thus aiding in reducing the costs associated with genetic toxicity screening and risk assessment.

Several investigators to date have reported different toxicogenomic signatures both in vitro using rodent and human cancer cell lines and in vivo in rodent models, to predict carcinogenicity in rodents and/or in humans.[19–21] Although toxicogenomic signatures have been proposed to differentiate genotoxins versus nongenotoxins, aneugens versus clastogens, carcinogens versus noncarcinogens, genotoxic carcinogens versus nongenotoxic carcinogens, etc., there exists no general consensus on their usage in genetic toxicology testing. This is primarily because of diverse test models, gene expression analysis, and bioinformatics technologies used to arrive at these toxicogenomic signatures, independently by different groups. To address these challenges genetic toxicologists across industry, academia, and government are forming consortia (e.g., HESI Genomics Technical Committee, Safety Prediction Consortia) to identify and validate unique toxicogenomic signatures that can be utilized for identifying different classes of genotoxins, hazard identification, and risk assessment.

4.11.3 Genotoxicity Testing Paradigm in Pharmaceutical Industry

Genotoxicity testing in pharmaceutical industry follows ICH guidelines S2R1 that were revised in 2012 (www.fda.gov/downloads/Drugs/Guidances/ucm074931.pdf). The revised guideline provides two different options for genotoxicity evaluation of chemicals/drugs under investigation. These options follow a "battery" approach using multiple in vitro and in vivo tests capable of characterizing genotoxicity hazard of chemicals/drugs. The first option takes a tiered approach with a series of in vitro followed by in vivo genotoxicity evaluation assays. However, the second option takes a less tiered approach by using primarily in vivo genotoxicity evaluation assays in rodents, in addition to in vitro Ames mutagenicity test. The details of both options are listed below

Option 1

(a) A test for gene mutation in bacteria (Ames assay).
(b) A cytogenetic test for chromosomal damage (the in vitro metaphase chromosome aberration test or in vitro micronucleus test) or an in vitro mouse lymphoma tk gene mutation assay
(c) An in vivo test for genotoxicity, generally a test for chromosomal damage using rodent hematopoietic cells, either for micronuclei or for CAs in metaphase cells.

Option 2

(a) A test for gene mutation in bacteria (Ames assay).
(b) An in vivo assessment of genotoxicity with two different tissues, usually an assay for micronuclei using rodent hematopoietic cells and a second in vivo assay. Typically, this would be a DNA strand breakage assay in liver (Comet assay), unless otherwise justified.

Under both standard battery options, either acute or repeat-dose study designs in vivo can be used. In case of repeated administrations, attempts should be made to incorporate the genotoxicity endpoints into toxicity studies, if scientifically justified. When more than one endpoint is evaluated in vivo, it is preferable that they are incorporated into a single study. Often sufficient information on the likely suitability of the doses for the repeat-dose toxicology study is available before the study begins and can be used to determine whether an acute or an integrated test would be suitable.

For compounds that give negative results, the completion of either option of the standard test battery, performed and evaluated in accordance with current recommendations, will usually provide sufficient assurance of the absence of genotoxic activity and no additional tests are warranted. Compounds that give positive results in the standard test battery might, depending on their therapeutic use, need to be tested more extensively.

4.11.4 Concluding Remarks

Screening for genotoxic damage using a "battery" approach that includes in silico, in vitro, and in vivo screening assays is an important part of pharmaceuticals and chemical safety testing across wide range of industries. Existing genotoxic battery testing that investigates and monitors biomarkers of genotoxic damage, such as increased bacterial revertant colonies, MN formation, comet formation, and CAs, is of tremendous help in genotoxic hazard identification and risk assessment. However, currently there are no sensitive and specific short-term in vitro or in vivo assays to evaluate carcinogenicity of chemicals caused via nongenotoxic or epigenetic mechanisms. The 2-year in vivo rodent bioassay that is used currently to evaluate carcinogenicity of chemicals is extremely time-consuming and cost prohibitive for screening a plethora of potential genotoxic chemicals. In this regard, cutting edge technologies such as toxicogenomics, high-content imaging, FISH and high-throughput approaches, such as Next-Generation or NextGen Sequencing (NGS) technologies, would be valuable to gain insights into genotoxic, nongenotoxic, and epigenetic mechanisms that play an important role in carcinogenesis.

4.12.1 Introduction

This article will provide an overview of drug-induced liver toxicity. Drug-induced liver injury (DILI) and drug hepatotoxicity generally are important issues both for those developing drugs and for those prescribing them. Following absorption, the liver is one of the first sites exposed to ingested xenobiotics and this may result in a variety of types of local damage. Because of the role of the liver in xenobiotic metabolism, toxicity may also result from metabolites, even if the parent compound is nontoxic.

Therapeutically valuable drugs are often toxic to the liver. During the drug development process, hepatotoxicity of a new compound may be detected at a number of different points. If the toxicity is detected in animal toxicology studies during preclinical development, this will usually lead to the development project being abandoned. Approximately 80% of project closures during the preclinical development stage are for safety reasons, including hepatotoxicity.[1] Sometimes, compounds showing hepatotoxicity at high doses in animals may still be taken forward if the risk–benefit ratio is considered favorable. If hepatotoxicity is detected either during preclinical studies or early in clinical development, it is likely to be a concentration-dependent event. A good example of such predictable toxicity is that seen in acetaminophen overdose which is discussed in more detail in Section "**Concentration-dependent DILI**." Unfortunately many drugs cause a different, more complex form of hepatotoxicity which is unlikely to be detected during phases 1 to 3 because it is rare and less concentration-dependent. This form of hepatotoxicity, which is usually referred to as idiosyncratic DILI, is much more difficult to detect during drug development. There are a number of recent examples of drugs withdrawn from the market due to causing idiosyncratic DILI such as troglitazone (Section "**Troglitazone**"). Though most patients who develop idiosyncratic DILI recover well following drug withdrawal, it is estimated that up to 10% of patients with drug-induced hepatitis, one form of idiosyncratic DILI (see Section "**Phenotypes in DILI**"), may develop potentially fatal acute liver failure (ALF).[2] Between 11% and 13% of all ALF cases in the United States and United Kingdom may be due to idiosyncratic DILI.[3] Despite some high profile market withdrawals in recent years, many drugs that occasionally cause idiosyncratic DILI remain on the market with appropriate warnings to the prescriber. Some specific drug examples will be discussed in Section "**Idiosyncratic DILI**."

Developing improved strategies to prevent idiosyncratic DILI by detecting drugs with a propensity to cause this toxicity early in development is an important priority. Understanding genetic risk factors so that individuals at risk of developing this toxicity can be identified prior to prescription is also a potentially useful approach, especially in preventing the removal of otherwise valuable drugs from the market. Both these issues will be discussed in more detail in this article.

4.12.2 Clinical Aspects of DILI

4.12.2.1 Structure and Function of the Liver

The liver has a large number of vital functions, including normal metabolism of dietary components, synthesis, and storage of vitamins, production of bile but also the metabolism of foreign compounds to promote their excretion. Many hepatic functions are carried out by the most abundant cell type, the hepatocyte, but a number of other cell types contribute to the various functions including endothelial cells which form specialized vessels transporting blood and bile, macrophage-like Kupfer cells which help protect the liver from pathogens, and stellate cells which store vitamin A and can differentiate to form fibroblasts. During drug metabolism, levels of the drug within the hepatocyte may be considerably higher than plasma levels, increasing the risk of local damage from hepatotoxic compounds.

4.12.2.2 Phenotypes in DILI

Hepatotoxic drugs can damage the liver via several different mechanisms. Generally there is a distinctive pattern of damage seen with individual drugs. As described in detail elsewhere,[4] typically the drug will cause one or more of the following: hepatocyte necrosis, hepatitis where inflammation occurs, cholestasis where the normal flow of bile through the bile duct is impaired, or steatosis where lipid accumulates. Idiosyncratic DILI generally involves hepatitis and/or cholestasis.[4] Necrosis is more common when the toxicity is directly concentration-dependent (e.g., in acetaminophen toxicity). Steatosis can also be induced by a number of relatively commonly prescribed drugs such as methotrexate and tamoxifen but is generally a more benign condition than drug-induced hepatitis or cholestasis. As mentioned in Section "**Introduction**," up to 13% of patients suffering from drug-induced hepatitis (also known as hepatocellular DILI) may progress to ALF. Drug-induced cholestasis is rarely fatal but may result occasionally in chronic liver disease.

Diagnosis of DILI is not straightforward but relies on a combination of measuring liver enzymes, physical symptoms, and drug history. The most important liver enzymes used as markers are the transaminases, especially alanine transaminase (ALT) but also aspartate transaminase. These enzymes are released into the circulatory system when hepatocellular damage (including necrosis) occurs. For cholestatic injury, increased plasma levels of the enzyme alkaline phosphatase indicate damage to the biliary tree rather than the hepatocyte. Elevated plasma bilirubin levels are also associated with cholestatic injury but also occur in hepatocellular injury, especially when this is severe. Liver biopsy provides valuable phenotypic data including, for example, the presence of inflammatory cells or damage to the biliary tree. For research studies and clinical trials, scoring systems to assess the probability that symptoms of liver disease are due to drug exposure have been developed. This is discussed in detail elsewhere.[5]

4.12.3 Detecting Hepatotoxicity During Drug Development

4.12.3.1 Animal Models

As discussed elsewhere,[6] preclinical animal toxicology studies normally involve administering the drug to at least two species (one rodent, one nonrodent) at a range of doses for multiple durations, including chronic administration for typically 6 months in rodents and 12 months in nonrodents. These studies do not always predict human hepatotoxicity, especially when it is immune-mediated.[6] If hepatotoxicity is seen at very high doses in animal models, this does not necessarily predict that the compound will be hepatotoxic in humans. However, further in vitro studies are likely to be required for the development to continue. Issues such as the intended patient population and planned dose in humans may determine suitability to proceed to clinical testing.

Increasingly, there is the possibility to use "humanized" animals for drug safety testing. Up to the present, most of the advances have involved development of human-chimeric mice including mice where human hepatocytes have replaced the normal mouse liver.[7] The development of such animals is very valuable for many aspects of drug development but for complete assessment of potential for hepatotoxicity, it seems likely that an immune system more similar to the human system will also be required.

4.12.3.2 Cell Culture

A variety of cell culture systems are in use to investigate the hepatotoxic potential of new drugs. The most widely used, at least up to recently, has been the human hepatoblastoma cell line HepG2. These cells are relatively easy to culture and have hepatocyte-like features. Some recent studies have evaluated the effect of a relatively large number of hepatotoxic drugs on a range of parameters such as cytotoxicity, mitochondrial function, and oxidative stress in HepG2 cells to evaluate the suitability of using these cells to screen for hepatotoxic potential of new drugs.[8] Most known hepatotoxic drugs appeared positive for several of the parameters evaluated, though a few well-established causes of hepatotoxicity did not. Overall these cells appear to show sensitivities and specificities for detection of hepatotoxicity of up to 90% providing a range of different screening tests are used. Cultured human hepatocytes are more difficult to source and have a limited lifespan. They are less suitable for high-throughput screening than HepG2 but have the advantage of retaining high levels of expression of cytochromes P450 and other drug-metabolizing enzymes. They also respond more strongly to enzyme inducers such as rifampicin and phenobarbital. Another more recently isolated human cell line, HepaRG, is being increasingly used to assess hepatotoxicity.[9] This cell line has a phenotype more comparable to that of

primary human hepatocytes than HepG2 but also has the ability to form cholangiocytes, the specialized cells lining the biliary tract. It may be possible to adapt the screening tests already developed for HepG2 cells for use in HepaRG cells and this could increase the overall sensitivity of cell-based systems in detected hepatotoxicity. There are also now improved methods for human hepatocyte culture available involving coculture with other cells (mainly fibroblasts) that may lead to improved sensitivity for detecting hepatotoxic compounds.[10] In general, none of the cell culture systems currently available to detect hepatotoxicity are completely specific, but intensive efforts are underway to improve this situation because of the importance of identifying drugs that cause DILI at an early stage in the development process.

4.12.3.3 In Silico Approaches

Using computer-based approaches to predict whether a newly developed drug will cause hepatotoxicity is attractive, especially in view of the limitations of both animal and in vitro screening discussed in Sections "**Animal Models**" and "**Cell Culture**." This approach often depends on establishing quantitative structure–activity relationships where a mathematical model to link a chemical structure with some aspect of a compounds biology is developed and is described in more detail elsewhere.[11] However, other in silico approaches may simply be based on data mining. Using any in silico approach to predict idiosyncratic hepatotoxicity remains challenging because the underlying mechanisms for the toxicity are still not completely clear, there is involvement of an immune response in many cases of DILI and though a relatively large number of compounds are now known to cause hepatotoxicity, data is still relatively scarce. The difficulties of developing an in silico model for DILI have been well summarized recently.[12] That article also mentions that interindividual variation due to genetic and environmental factors should be considered in any model. Current ability to do this is limited though there is increasing collection of both biological samples and clinical data which may facilitate this in the future.[13]

4.12.4 DILI in Patients Including Patient-Specific Risk Factors

4.12.4.1 The Nature of DILI

4.12.4.1.1 Concentration-dependent DILI

As mentioned previously, some forms of DILI are directly concentration-dependent. The classic example is DILI relating to acetaminophen overdose. This form of DILI may result in ALF; it is now well accepted that acetaminophen overdose is a common cause of ALF, representing approximately 45% of all ALF cases in the United States in several surveys, though DILI relating to other drugs may also sometimes progress to ALF and represents 11% of all ALF cases in a recent large study.[3b] The quantity of acetaminophen ingested for toxicity to occur in an adult is considered to be a minimum of 10–15 g[14] compared with the normal maximum recommended total daily dose of 4 g. The precise level of overdose which will lead to DILI may vary between patients, but a plasma acetaminophen level of 150 ug mL^{-1} 4 h after the overdose is generally considered the minimum level where treatment with *N*-acetylcysteine to replenish cellular glutathione and prevent DILI is initiated. Toxicity arises due to metabolism to the reactive imine *N*-acetyl-p-benzoquinone imine (NAPQI) by cytochromes P450 (**Fig. 1**). This compound binds to macromolecules including

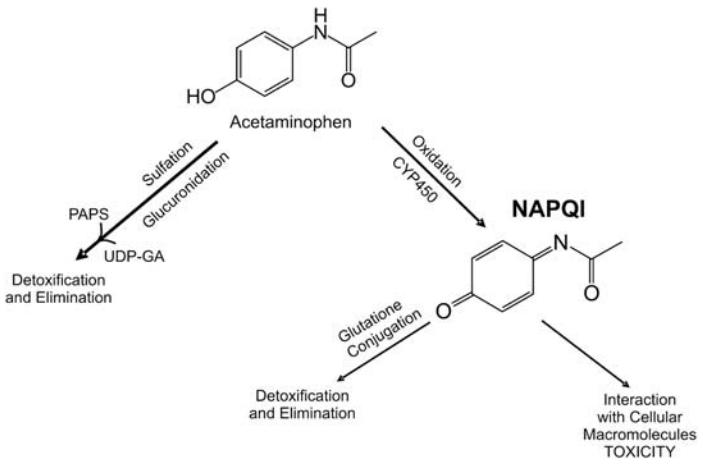

Fig. 1 Acetaminophen metabolism. Acetaminophen is metabolized by glucuronide, sulfate, and glutathione conjugation. Glucuronidation and sulfation produce nontoxic metabolites. *N*-acetyl-p-benzoquinoneimine (NAPQI) is a toxic intermediate produced by cytochrome P450-mediated oxidation. NAPQI can be conjugated by glutathione to form a nontoxic metabolite or may interact with cellular macromolecules triggering toxicity. From Moyer, A. M.; Fridley, B. L.; Jenkins, G. D.; Batzler, A. J.; Pelleymounter, L. L.; Kalari, K. R.; Ji, Y.; Chai, Y.; Nordgren, K. K.; Weinshilboum, R. M., Acetaminophen-NAPQI Hepatotoxicity: A Cell Line Model System Genome-Wide Association Study. *Toxicol. Sci.* **2011,** *120*(1), 33–41, Reproduced with permission from Oxford University Press.

protein, lipid, and DNA in hepatocytes. The formation of NAPQI adducts and cellular depletion of GSH trigger a still poorly understood sequence of events which result in cellular necrosis. Importantly, these events all occur very shortly after the overdose is taken with symptoms of liver injury including raised a large elevation in ALT evident between 24 and 72 h following drug ingestion. Though there is some limited evidence to suggest a role for genetic factors in susceptibility to acetaminophen-induced liver injury (see Section "**Acetaminophen**"), it is generally considered that all individuals are at high risk if sufficient drug is ingested. It is also generally accepted that DILI does not occur when acetaminophen is taken in accordance with dosing guidelines. However, approximately 40% of healthy adults receiving 4 g acetaminophen per day over a 14-day period were found to show moderately elevated ALT levels in excess of three times above upper limit of normal.[15] This rise was seen after 3 days of drug treatment, but ALT levels returned to normal in all participants within 14 days of the end of the 14-day treatment period. The elevated ALT observed here would normally be considered clinically important, especially during drug development. It was suggested that it may be an example of adaptation where the elevation resolves spontaneously even if drug treatment continues, but this has not yet been shown conclusively.[15]

4.12.4.1.2 Idiosyncratic DILI

Most cases of human DILI are of an idiosyncratic nature which is not predictable on the basis of plasma drug concentration. However, this does not mean that drug concentration is not relevant. It simply may be one of a number of factors that contribute to the development of DILI. There is data suggesting that when the normal dose of a drug is relatively high (>50–100 mg per day), the risk of DILI is higher.[16] For the purposes of this article, all forms of DILI with the exception of that induced by acetaminophen overdose are considered idiosyncratic. As summarized in **Table 1**, a large number of different prescribed drugs can give rise to DILI. The majority of drugs listed in **Table 1** are antimicrobial agents, but the basis for why DILI is relatively common with drugs of this class is still unclear. The fact that such a wide range of commonly prescribed drugs cause DILI and can still be prescribed may seem surprising, but this partly reflects the absence of a good nonhepatotoxic alternative to some of these drugs. The drug information sheets for these and other licensed hepatotoxic drugs normally provide clear warnings to prescribers about the possibility of liver toxicity.

The incidence of idiosyncratic DILI reactions tends to be low, but the precise frequency depends on the individual drug. A number of estimates of overall population frequency for idiosyncratic DILI generally are now available. A French study observed that while spontaneous adverse drug reaction reporting suggested an incidence of 0.9 cases of DILI per 100,000 per year, the rate from a rigorous, case-finding population study was higher at 13.9 per 100,000.[17] In the United Kingdom, the incidence of

Table 1 Common causes of idiosyncratic DILI

Drug	*Class*
Amoxicillin–clavulanate	Antimicrobial
Atorvastatin	Statin
Azathioprine	Thiopurine
Azithromycin	Antimicrobial
Ciprofloxacin	Antimicrobial
Diclofenac	Nonsteroidal antiinflammatory drug
Doxycycline	Antimicrobial
Flucloxacillin	Antimicrobial
Infliximab	Antitumor necrosis factor alpha
Isoniazid	Antimicrobial
Levofloxacin	Antimicrobial
Minocycline	Antimicrobial
Nitrofurantoin	Antimicrobial
Phenytoin	Anticonvulsant
Propylthiouracil	Thiourylene
Sulfamethoxazole–trimethoprim	Antimicrobial
Terbinafine	Antifungal
Valproic acid	Anticonvulsant

hepatic adverse drug reactions reported to the government regulator is approximately 4 cases per 100,000 population per year,[18] but a more detailed epidemiological survey reported a higher incidence similar to the French study.[19]

The underlying mechanism for DILI is still not clear though some limited new insights have been obtained recently. As discussed in more detail in Section "**HLA associations**," human leukocyte antigen (HLA) genotype is an important determinant of susceptibility to a number of forms of DILI and it is now recognized that the immune system has a more important role in these reactions than originally thought. Up to recently, two main mechanisms for immune-mediated DILI reactions involving HLA associations and the adaptive immune system were postulated. One involved formation of a covalent complex between the drug or a metabolite and cellular proteins.[20] This complex could then be presented to T-cells by particular HLA molecules resulting in an inappropriate local T-cell response and damage to cells. An alternative mechanism proposed that drugs interact directly with HLA molecules resulting in a T-cell response without the need to form a covalent complex (p–I concept).[21] However, recent data on T-cell responses to the anti-HIV drug abacavir are more consistent with a third mechanism involving modification of the p–I concept. Abacavir does not cause DILI but instead a general hypersensitivity reaction in individuals positive for a particular HLA allele, *B*57:01*. Using several different approaches, it has been shown that abacavir binds to the *B*57:01* gene product and induces a conformational change in this protein. This results in incorrect recognition of self peptides as foreign by the immune system, triggering an inappropriate immune response.[22]

Not all DILI is HLA-associated though the innate immune system may still contribute to non-HLA-associated DILI by promoting local inflammatory responses following an initial cell damaging event. In some forms of DILI, the drug or a metabolite may have a direct toxic effect within the liver in a manner analogous to that known to occur during acetaminophen overdose.[2] Direct effects on a variety of organelles including mitochondria may occur resulting in cellular apoptosis or necrosis. A further mechanism for toxicity may involve accumulation of bile acids within hepatocytes at toxic levels due to inhibition of ABC transporters by the hepatotoxic drug. This may also result in apoptosis or necrosis.[23]

4.12.4.1.3 Nongenetic Risk Factors for DILI

The question of why so few patients develop DILI when treated with drugs that can cause this toxicity is an important ongoing question. Some answers have emerged recently, especially from genetic studies, but we are still some distance from being able to predict susceptibility. Risk factors can be subdivided into patient-related factors and environmental risk factors. This section will consider a range of nongenetic risk factors for DILI.

4.12.4.1.4 Age

Age is an extensively studied risk factor for DILI. The risk of developing DILI is generally higher in people aged 60 or more. Amoxicillin–clavulanate-related DILI and isoniazid-related DILI are two well-studied examples. For amoxicillin–clavulanate, a broad-spectrum antimicrobial agent, the incidence is 1.3 per 10,000 prescriptions in patients under 65 compared with 3.2 per 10,000 in those over this age.[24] For isoniazid, which is an important drug in the treatment of tuberculosis (TB), the overall DILI incidence is higher than that for amoxicillin–clavulanate with a rate of 5.6 per 1000 seen in a US study.[25] When this is examined across the age range, younger patients (<35 years) had a rate of 4.4 per 1000 compared with 20.83 for those ≥ 50 years. Despite these differences in incidence across age groups, there does not appear to be an age-related difference in overall outcomes following an occurrence of DILI.[26] The reason why older people are more susceptible to DILI is not completely clear but does not appear to relate simply to older people being prescribed the causative drugs more commonly than younger people. In the case of isoniazid, prescription of this drug is generally more common in a younger age group. Two possible explanations are that older people are more likely to be prescribed other drugs which could result in higher levels of the hepatotoxic agent in the liver if there is an interaction slowing its metabolism or overall clearance. In addition, blood flow to the liver is lower in the elderly[27] and this could also result in higher local drug concentrations.

4.12.4.1.5 Gender

Gender as a risk factor for DILI has also been well studied though the results obtained are less clear-cut than the effects seen for age. For some drugs where DILI has been suggested to be more common in women such as nitrofurantoin, minocycline, and flucloxacillin, prescription of these agents may also be more common in women because of the nature of the conditions they are used to treat. Similarly, amoxicillin–clavulanate-related DILI may be seen more commonly in men but could reflect use of this drug to treat conditions such as respiratory infections which may be more common in elderly males who smoke heavily. However, one interesting example of a drug-inducing DILI at a higher incidence in females than males is nevirapine. This anti-HIV drug is not prescribed more commonly in females than males but appears to cause DILI more commonly in women.[24] Pharmacokinetic data indicates a lower rate of clearance in females with both the parent drug and certain oxidative metabolites generated by cytochromes P450 present at higher plasma concentrations.[28] This could reflect differences in expression of certain cytochrome P450 isoforms between men and women which is now well established.[29]

4.12.4.1.6 Preexisting liver disease

It has been assumed that patients who have already suffered liver damage due to exposure to a toxic compound or infectious age will be more likely to develop DILI if exposed to a drug known to cause this adverse reaction. However, evidence to support this assumption strongly is still lacking. There are many instances where patients with a chronic liver disease may benefit from treatment with

drugs associated with idiosyncratic DILI. The best-studied examples relate to statin treatment of patients with nonalcoholic fatty liver disease (NAFLD) or hepatitis C infection and treatment of TB in patients with viral hepatitis or cirrhosis.

NAFLD is the most common liver disease in the developed world and a substantial proportion of patients are prescribed statins, mainly to protect against cardiovascular disease which is very common in NAFLD patients. There is also some evidence that statins may protect against the progression of the simple steatosis seen in most NAFLD cases to nonalcoholic steatohepatitis (NASH)[30] and may prevent symptoms such as insulin resistance in patients with chronic hepatitis C infection.[31] There is still controversy about whether statins can cause DILI, but it is increasingly accepted that statin-related DILI, though rare, does exist with serious consequences including some cases of liver failure.[32] One study of patients with raised ALT due to a variety of different liver diseases found no increase in statin-related DILI compared with a control population, suggesting the preexisting liver disease was not a risk factor.[33] In addition, in spite of the large numbers of NAFLD patients worldwide taking statins, no reports of substantial rises in DILI incidence have been reported.

Patients suffering from TB may also suffer from other infectious diseases, especially viral hepatitis and HIV. DILI is relatively common during treatment with anti-TB drugs and it has been suggested by the American Thoracic Society that avoiding treatment with isoniazid and, also in patients with very severe liver disease, pyrazinamide could be appropriate.[34] Alternative drug combinations avoiding these agents have been proposed.[34] Several studies have compared the incidence of DILI in TB patients with viral hepatitis or liver cirrhosis with TB patients without liver disease when standard drug treatment protocols involving isoniazid, rifampicin, pyrazinamide, and ethambutol are used. A Hong Kong-based study found hepatitis B carriers with TB were significantly more likely to develop DILI compared with noncarriers,[35] but this could not be confirmed in a similar study in Korea.[36] For hepatitis C infection, a US-based study suggested these patients were more likely to show elevated liver enzymes during anti-TB drug treatment but none of 68 patients with hepatitis C developed moderate to severe DILI, whereas there were 2 cases among 258 controls without hepatitis C.[37]

There is limited data on DILI due to other drugs in NAFLD patients, but one small study of NAFLD and hepatitis C cases followed up for 6 years suggests a small but significant increase in the incidence of DILI generally with most cases seen in patients with NASH.[38] A recent study of NASH patients investigated the pharmacokinetics of morphine and reported increased plasma levels of morphine glucuronide and altered plasma bile acids.[39] It seems possible that the findings for morphine, which is not generally hepatotoxic, can be extended to drugs known to cause DILI, especially since reactive acylglucuronide production is already known to contribute to risk for some types of DILI.[40] More studies of DILI in patients with NAFLD and NASH are needed, but the current data indicates there may be some increased risk but possibly this is drug-specific.

4.12.4.1.7 Smoking and alcohol consumption

Despite being an inducer of certain cytochrome P450 isoforms, there is little evidence that smoking has any significant effect on DILI susceptibility. However, ethanol, another P450 inducer, which can also itself cause liver toxicity has a more complex relationship with the risk of DILI. Though ethanol consumption combined with acetaminophen intake within recommended levels does not appear to increase risk of DILI, the situation is different in those consuming high levels of alcohol chronically who also take an acetaminophen overdose. Because ethanol is an inducer of CYP2E1, a key enzyme in NAPQI formation from acetaminophen, this may result in higher levels of this compound being generated if CYP2E1 is induced.[41] In addition, hepatic glutathione levels in alcoholics may be lower than normal.[42] It has been demonstrated that alcoholics were common among a large group of patients with ALF following acetaminophen overdose.[43] However, slightly paradoxically, consuming large quantities of alcohol concomitantly with acetaminophen overdose decreases the risk of ALF, probably due to competition for CYP2E1 binding between ethanol and acetaminophen.[44]

Some of the findings for acetaminophen toxicity such as the decreased levels of hepatic glutathione in alcoholics may also be relevant to risk of idiosyncratic DILI. It has been suggested that heavy alcohol consumption increases the risk of isoniazid-related DILI,[45] possibly because CYP2E1 which can produce reactive metabolites of isoniazid is induced. However, isoniazid is itself an inducer of CYP2E1 and not all studies suggest an increased incidence of DILI in those consuming high levels of alcohol.[46]

4.12.4.1.8 Infection

Many of the common causes of DILI are drugs used to treat infections or inflammatory conditions. As discussed in Section "**Idiosyncratic DILI**," there is increasing evidence for a role for the innate and adaptive immune systems in DILI so in many situations where potentially hepatotoxic drugs are prescribed, there is already an immune response triggered with high levels of inflammatory mediators. It is also well established that infection and inflammation are associated with downregulation of expression of cytochromes P450 and other drug-metabolizing enzymes and transporters.[47] Studies in animal models show that stimulation of release of inflammatory mediators and cells can affect severity of acetaminophen toxicity and also hepatotoxic responses to some drugs associated with idiosyncratic DILI in humans, most notably diclofenac and trovafloxacin.[48] It is therefore possible that a combination of decreased drug clearance with the presence of inflammatory cells and mediators results in an environment favorable to the onset of inappropriate immune responses to drug and local cellular damage leading to DILI.

4.12.4.1.9 Drug–drug interactions

The possibility that decreased cytochrome P450 levels could be important in DILI has been mentioned in Section "**Infection**." One of the most common causes of decreased cytochrome P450 activity is the inhibition of activity of particular isoforms in drug–drug interactions. Many of the predominantly elderly individuals who suffer idiosyncratic DILI will be taking a number of different

prescribed drugs. Very few systematic studies on the influence of multiple drug prescription on risk of DILI have been performed but one population study found a significant increased risk in individuals taking two or more drugs known to be hepatotoxic.[49] Though the US DILIN network has failed to confirm this finding in a prospective study,[50] this could reflect differences between the studies in design and power.

4.12.4.2 Genetic Factors Affecting DILI Due to Specific Drugs

4.12.4.2.1 Introduction

Evidence for a genetic component in susceptibility to idiosyncratic DILI continues to emerge. The first studies on DILI genetics date from the 1980s. There are studies dealing with both HLA genes and genes relevant to drug metabolism. These studies predated widespread human gene cloning and the human genome project and used a candidate approach where the frequency of a chosen phenotype was compared between cases (those with DILI) and population controls. Two examples of positive findings on DILI from the 1980s are an association between the HLA serotype DR2 and halothane-related DILI[51] and the finding that patients who were poor metabolizers of the drug debrisoquine were more likely to develop hepatitis when treated with the antianginal drug perhexiline.[52] Gene cloning and development of PCR-based genotyping methods have enabled more specific genetic associations to be investigated. Initially, this involved a candidate gene approach similar to the early studies on phenotype except that specific genes were being studied not just phenotypes. Candidate genes examined included HLA, genes encoding enzymes relevant to drug metabolism and transport, and genes encoding components of the innate immune response. The main limitation with genetic studies on DILI is that case finding is difficult so most studies have been small which limits the power to detect associations reliably. Replicating associations has also been difficult. The development of genome-wide association studies (GWAS) where the contribution of all genes in the human genome to disease susceptibility can be investigated[53] has been a useful development in understanding the genetics of DILI better but lack of large numbers of cases continues to be a limitation.

It is increasingly clear that when performing studies to identify genetic risk factors for DILI, it is essential to consider individual drug causes separately. As discussed in Section "**HLA associations**," there is some overlap in genetic risk factors for DILI due to different unrelated drugs but in general different risk factors have been detected for different drugs. This section will consider HLA gene associations with DILI caused by a number of drugs but will then consider other genetic associations on an individual drug basis. One of the key aims of these genetic studies is to develop strategies to enable patients at risk of DILI due to particular to be identified and prescribed alternative drugs. Unfortunately, the findings obtained so far are generally not sufficiently specific for this to be possible.

4.12.4.2.2 HLA associations

The proteins encoded by HLA genes are important in presenting foreign peptides, usually derived from invading pathogens, to T lymphocytes. A number of HLA genes are located in a large gene cluster on chromosome 6 in an area of the genome referred to as the major histocompatibility complex. More detailed descriptions of HLA genes and their biological roles are widely available.[54] HLA genes are divided into two types, classes I and II. The proteins encoded by these gene classes have overlapping but slightly different functions in the immune response. Class I genes tend to be expressed on most cells in the body and to have a role in presenting peptides to cytotoxic T-cells which may cause local damage. On the other hand, class II genes tend to be expressed mainly on immune system cells and to have a more important role in stimulating T-helper cells to produce proteins such as cytokines which may induce inflammation. HLA genes are subject to a large amount of genetic variation or polymorphism. This probably arose originally to help protect the body from pathogens but increasingly certain alternative forms of HLA genes (alleles) are considered to be risk factors for some types of autoimmune disease (e.g., multiple sclerosis or type I diabetes) and also for adverse drug reactions such as DILI. As discussed in Section "**Idiosyncratic DILI**," there is increasing evidence that some types of DILI involve an inappropriate immune response to a drug, possibly after a covalent link between the drug and a cellular protein has been formed. HLA proteins are likely to contribute by presenting the complex to T-cells.

Well-established and replicated HLA associations have been described for hypersensitivity reactions affecting various tissues, particularly the skin, and for DILI. Those carrying certain HLA alleles have an increased risk of these reactions. For DILI, some of the HLA-associated reactions do not show obvious features of a hypersensitivity reaction so findings of strong HLA associations have been slightly unexpected. For DILI, the first reports linking HLA with susceptibility to this type of reaction involved the general anesthetic halothane, which was used widely until the 1980s but was also an important cause of idiosyncratic DILI. This association, which was detected by an immunoassay and reported before the HLA genes, was well understood, concerned an increased risk of DILI in those with the HLA class II serotype DR2.[51] Other reports of associations between various HLA serotypes and DILI induced by particular drugs subsequently emerged though these usually involved very small numbers of patients and did not show statistical significance. More recently, HLA associations with DILI have been studied directly by genotyping rather than serotype determination and studies have been slightly larger than previously. The first HLA genotyping studies were candidate gene association studies on amoxicillin–clavulanate-related DILI. This form of DILI does not generally show classical immune-related features, but two independent candidate gene association studies reported an identical association with the *HLA-DRB1*15:01* allele, which corresponds to the DR2 serotype, which may be relevant to the original observation on halothane DILI.[51] Further studies have found additional HLA class I and II associations for DILI, including a second HLA association for amoxicillin–clavulanate-related toxicity (**Table 2**). Effect sizes vary depending on the drug with odds ratios for risk of DILI of between 2 and 80 reported. The strongest HLA association reported to date for DILI is for reactions due to the antimicrobial flucloxacillin, which is used in some countries to treat gram-

Table 2 HLA alleles associated with DILI

Compound	*No. of cases*	*HLA allele*	*Odds ratio (95% CI)*	*Reference*
Flucloxacillin	51	*B*57:01*	80.6 (22.8–284.9)	55
Amoxicillin–clavulanic acid	201	*A*02:01*	2.3 (1.8–2.9)	56
		*DRB1*15:01-DQB1*06:02*	2.8 (2.1–3.8)	
Lumiracoxib	41	*DRB1*15:01-DQB1*06:02*	5.0 (3.6–7.0)	57
Lapatinib	35	*DRB1*07:01-DQA1*02:01*	2.9 (1.3–6.6)	58
Ximelagatran	74	*DRB1*07:01-DQA1*02:01*	4.4 (2.2–8.9)	59
Ticlopidine	22	*A*33:03*	13.0 (4.4–38.6)	60

positive bacterial infections. This was detected in the first GWAS performed for any type of DILI. A very strong association (odds ratio 80) for development of flucloxacillin DILI was seen with the class I HLA allele *B*57:01*.[55] This allele had been shown previously to be a strong risk factor for hypersensitivity reactions to the drug abacavir but as mentioned in Section "**Idiosyncratic DILI**," these reactions generally do not involve the liver. Importantly, the underlying mechanism involved in the flucloxacillin DILI reaction appears to be different to the mechanism reported for abacavir.[61] No other DILI associations with *B*57:01* have been identified to date. However, other reported HLA associations may involve two different chemically unrelated drugs; for example, carrying the HLA class II allele *DRB1*15:01* is a risk factor for DILI related to both amoxicillin–clavulanate and lumiracoxib (**Table 2**) and could also be relevant to halothane-related DILI.

The observed HLA associations are interesting but even for flucloxacillin DILI, only 1 in every 500–1000 patients carrying the risk allele *B*57:01* develop the reaction when given the drug. This means additional risk factors contribute to risk and these may include the factors such as age and gender discussed earlier. Additional non-HLA genes may also contribute.

4.12.4.2.3 Non-HLA associations

After HLA genes, the best-studied genetic risk factors for DILI are polymorphisms relevant to drug disposition. Though recent GWAS studies have not found evidence that polymorphisms in these genes are significant contributors to DILI, candidate gene studies, mainly focusing on single genes only, have found limited evidence for some contribution. Most studies on this type have involved small numbers of cases and generally have not been replicated as yet, with the exception of an apparent association between *N*-acetyltransferase 2 (*NAT2*) and susceptibility to DILI relating to the anti-TB drug isoniazid. Isoniazid-related DILI is discussed in more detail further. Associations between DILI and particular cytochrome P450 genotypes have also been investigated but few positive findings have emerged, despite a key role for the cytochromes P450 in the formation of reactive metabolites. Phase 2 drug metabolism genes, genes encoding ABC transporters, genes relevant to the innate immune system, and oxidative stress have also been investigated. Some positive associations have been identified from these studies, as described here.

4.12.4.2.3.1 Isoniazid

Use of the drug isoniazid remains important in treatment of TB but approximately 1% of all patients treated with this drug develop moderate to severe DILI. A larger percentage (approximately 10%) develop elevation of transaminase enzymes soon after treatment, but the level of elevation may not be sufficient to require cessation of treatment and enzyme levels may revert to normal quite rapidly in an adaptation response. Even if treatment is stopped and then restarted after a few weeks, reintroduction of isoniazid may not result in a further transaminase elevation because of adaptation. Isoniazid is usually used in combination with rifampicin and there is considerable evidence that this combination is more hepatotoxic than either drug used alone. A third drug, pyrazinamide, which is used in the first 2 months of most treatment regimens is also hepatotoxic, even when used as a single agent. The complexity of TB treatment regimens has made genetic studies on DILI complicated, since it is not usually possible to assess the contribution of individual drugs separately. Despite these limitations, there is an extensive literature suggesting an association between the *NAT2* slow acetylator genotype and susceptibility to DILI in patients treated with isoniazid-containing treatment regimens. NAT2 has a key role in the metabolism of isoniazid and slow acetylators who essentially have no enzyme activity present have higher plasma levels of the parent drug but may also metabolize the drug via an alternative pathway probably involving a carboxyesterase enzyme to form hydrazine.[62] All studies showing an association between NAT2 genotype and susceptibility to isoniazid-related DILI have been candidate gene studies.[63] However, not all candidate gene studies confirm an association with *NAT2* and no significant association has been seen in a GWAS.[64] Importantly, however, the GWAS also failed to detect any HLA association for isoniazid-related DILI. There are some reports that the innate immune system is an important contributor to isoniazid toxicity[65] and this could occur independently of HLA genotype.

Both isoniazid itself and hydrazine can be converted to reactive metabolites by cytochromes P450, particularly CYP2E1. Genetic polymorphism in CYP2E1 is well studied though the functional effects of the various polymorphisms remain unclear.[66] A variant allele (*CYP2E1*5*) has a polymorphism in the upstream sequence close to a binding site for the transcription factor HNF-1 which results in higher transcriptional activity.[67] In one early study, patients homozygous for the normal "wild-type" *CYP2E1* allele had a significantly increased risk of developing isoniazid-induced DILI compared to those positive for *CYP2E1*5*.[68] This association has been confirmed recently in an independent study,[69] but other studies have failed to confirm any association. *CYP2E1* remains an

interesting candidate gene for isoniazid-induced DILI because of the role of the enzyme in isoniazid metabolism but its relevance as a risk factor can only be further investigated if larger numbers of cases can be collected.

Glutathione S-transferases (GST) contribute to the detoxication of a variety of drugs by glutathione conjugation and protect against reactive oxygen species (ROS). Two GST isoforms, GSTM1 and T1, are absent in significant numbers of individuals due to large gene deletions which are often referred to as null alleles. There is no specific role for either of these isoforms in the metabolism of isoniazid but the possibility that *GSTM1* and *T1* genotype influences the risk of isoniazid-related DILI related has been investigated. Two studies reported a higher frequency of *GSTM1* null genotypes among cases compared with controls but no difference with respect to *GSTT1*,[70] while a third reported no difference for *GSTM1* null genotype frequency in DILI cases compared to controls but a higher frequency of *GSTT1* null individuals among cases.[71] As discussed in Section "**Troglitazone**," GSTM1 and GSTT1 are also of relevance to DILI relating to troglitazone.

It seems likely that damage to cellular macromolecules by ROS leading to cellular damage may occur in at least some forms of DILI. A few studies on the mitochondrial manganese-dependent superoxide dismutase (MnSOD) as a risk factor for isoniazid-related DILI have been reported. A common polymorphism in the *SOD2* gene, which codes for MnSOD, was found to be a predictor of isoniazid-related DILI.[70b] The association between DILI and *SOD2* genotype was with an allele predicted result in high MnSOD activity, but it was suggested that this might be due to hydrogen peroxide generated by MnSOD also being toxic in addition to the superoxide substrate.[70b]

In summary, the *NAT2* genotype remains the most promising genetic factor for predicting risk of DILI due to isoniazid. A randomized clinical trial based in Japan involving differential dosing for the three different *NAT2* genotype groups has provided some encouraging data.[72] This study showed significant benefits with decreased incidence of DILI in a slow acetylator group. Patients predicted to show high NAT2 activity were given a higher than normal isoniazid dose in the genotype-guided arm and showed a lower rate of treatment failure. This encouraging study still needs replication.

4.12.4.2.3.2 Diclofenac

Diclofenac is a widely prescribed nonsteroidal antiinflammatory drug and, after flucloxacillin and amoxicillin–clavulanate, is among the most common drugs causing idiosyncratic DILI. It has been estimated that diclofenac-related DILI occurs in 4 in every 100,000 people prescribed this drug.[49] Susceptibility to diclofenac-related DILI does not appear to relate to HLA genotype.[64] Instead, it has been suggested that reactive metabolites may bind to hepatocyte proteins triggering local damage and inflammation. Diclofenac undergoes a relatively complex pattern of metabolism involving both cytochromes P450 and UDP-glucuronosyltransferases (UGT) (**Fig. 2**). Studies on polymorphisms relevant to diclofenac metabolism have indicated no role for CYP2C9 genotype,[73] a possible role for CYP2C8 genotype,[74] and a more likely role for UGT2B7 genotype[64,74] in susceptibility to diclofenac DILI. The underlying mechanism for the toxicity may involve the formation of a reactive acyl glucuronide by UGT2B7.

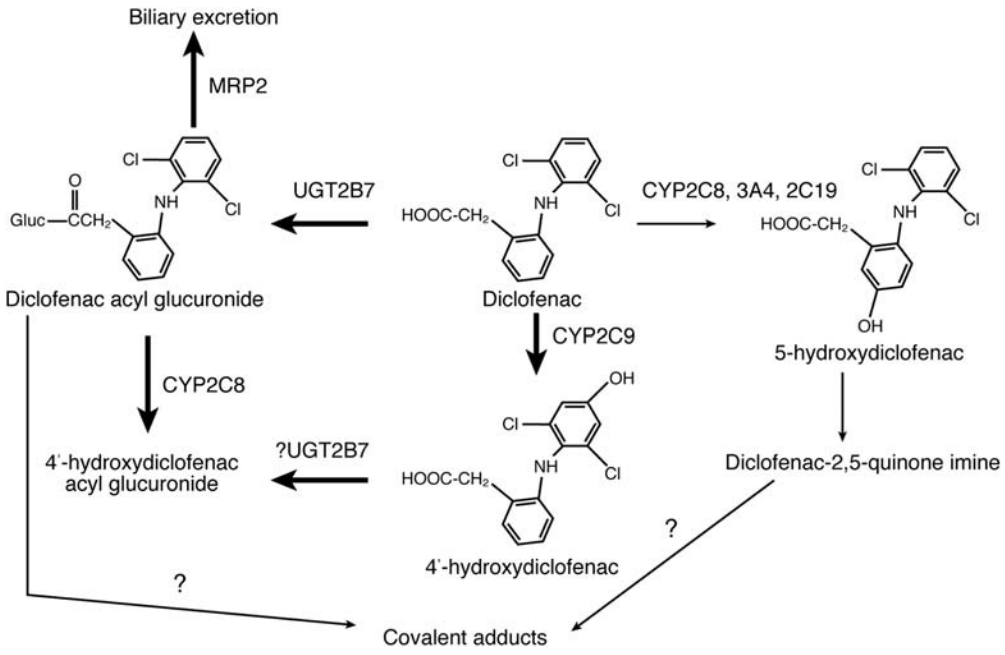

Fig. 2 Diclofenac metabolism. The main metabolic pathways for diclofenac and metabolites in the liver are indicated. Both the acyl glucuronide and the imine metabolite derived from 5-hydroxydiclofenac are believed to form protein adducts. From Daly, A. K.; Aithal, G. P.; Leathart, J. B.; Swainsbury, R. A.; Dang, T. S.; Day, C. P., Genetic Susceptibility to Diclofenac-Induced Hepatotoxicity: Contribution of UGT2B7, CYP2C8, and ABCC2 Genotypes. *Gastroenterology* **2007,** *132*(1), 272–281, © 2007 AGA Institute, Reproduced with permission from Elsevier.

Acyl glucuronides are well established to form adducts with proteins[75] and there is evidence that diclofenac acyl glucuronide is a reactive molecule based on low half-life in aqueous and protein solutions.[40,76] Drug glucuronide conjugates are often eliminated from hepatocytes by the canalicular drug transporter MRP2 which is coded for by *ABCC2*. There is also some evidence that carriage of a polymorphism in *ABCC2* which is associated with decreased levels of MRP2 expression and might therefore result in increased acyl glucuronide accumulation in the hepatocyte is a risk factor for diclofenac DILI.[74]

Formation of adducts between protein and a drug metabolite may not be sufficient to trigger DILI. It seems likely that in DILI patients, additional inflammatory responses occur within the liver once adduct formation has occurred. There is preliminary evidence that polymorphisms affecting cytokine expression may also be risk factors for diclofenac-related DILI.[77] Essentially therefore, it appears that both metabolic and inflammatory genotypes will affect the risk of this form of DILI.

4.12.4.2.3.3 Troglitazone

Troglitazone is a thiazolidinedione drug which is an agonist of the peroxisome proliferator receptor gamma and was approved by the FDA for treatment of type II diabetes in 1997. After a number of reports of serious hepatotoxicity, including at least 94 cases of liver failure in the United States,[78] the drug was withdrawn from the US market in 2000. The basis for this serious toxicity is still not entirely clear. No evidence for liver toxicity was seen during preclinical studies in animals and there was very limited collection of samples from those affected by DILI. However, there is a large body of in vitro data now available which provides some useful insights both in relation to troglitazone DILI specifically and to DILI more broadly. The major metabolite of troglitazone is troglitazone sulfate generated by the sulfotransferase enzyme ST1A3.[79] It has been demonstrated that both troglitazone and the sulfate metabolite inhibit the two ABC transporters BSEP and MRP4 (encoded by ABCC11 and ABCC4, respectively).[80] Both transporters have key roles in bile acid efflux from hepatocytes across both the canalicular and sinusoidal membranes. In the absence of biological material from those who suffered the toxicity, it has been possible recently, using a systems toxicology approach, to predict that the extent of inhibition of transporter activity by troglitazone and the sulfate metabolite would be sufficient to cause extensive bile acid accumulation in humans mainly in the form of the highly toxic lithocholic acid, whereas this is less likely to occur in the rat models used in toxicology studies.[80] The reason why toxicity was only seen in a relatively small number of exposed individuals is still unclear, but possibly low expression of the relevant bile acid transporters could be one factor. The only genetic study available on troglitazone toxicity indicates that individuals who showed significantly raised plasma transaminase levels during troglitazone treatment were likely to be positive for null genotypes for the GST *GSTM1* and *GSTT1*.[81] This finding seems quite consistent with glutathione conjugation being a route of metabolism for troglitazone, especially in the detoxication of a reactive and cytotoxic quinone metabolite, though this is mainly catalyzed by GSTM1 with no effect from GSTT1.[82]

4.12.4.2.3.4 Acetaminophen

Generally DILI due to acetaminophen is concentration-dependent with no risk of DILI at the normal recommended dose and a very high risk of developing DILI in overdose if treatment with *N*-acetylcysteine or a related compound is not administered within a specific timeframe after overdose. However, as discussed in Section "**Concentration-dependent DILI**," some individuals who take the recommended dose of acetaminophen over a prolonged period develop elevated transaminase enzymes but later appear to adapt.[15] In addition, there is some evidence that occasionally DILI develops in patients who unintentionally consume large quantities of acetaminophen, often over a more prolonged period than for the typical deliberate overdose.[43] A nonsynonymous polymorphism in the gene CD44, which codes for a protein that is involved in inflammation and cell communication, was shown to be more common in individuals showing transaminase elevation in response to acetaminophen treatment[83] and more recently in an unintentional overdose cohort.[84] In addition, polymorphisms in UGT1A and CYP3A5 also affected susceptibility in a cohort showing liver failure after acetaminophen overdose group in a biologically plausible manner.[84] Overall, the observed effects of the polymorphisms are not large, but an apparently genetic effect on susceptibility to overdose is novel and worth further investigation.

4.12.5 Conclusions

DILI continues to be an important issue in drug development. The absence of tests that can reliably identify hepatotoxic drugs at an early stage of development is a problem and developing such systems remains a priority for the pharmaceutical industry. The recent study on the mechanistic basis for troglitazone DILI using only in vitro data is an important advance.[80] Performing similar studies on newly developed molecules may be valuable. There is also increasing availability of genetically well-defined human hepatocyte-like cell lines derived from induced pluripotent stem cells. As the ability to generate hepatocytes in vitro improves, a range of such cell lines may prove useful as a screen for hepatotoxicity.[85] For example, cell lines could be isolated from individuals who had suffered idiosyncratic DILI previously but have now recovered. Such a cell line with a hepatocyte phenotype might have a general susceptibility to DILI, though there is still insufficient data from genetic studies on whether such a general susceptibility exists.

Considerable progress in identifying risk factors, especially genetic risk factors, for DILI has been made in the past 10 years. However, it is still not possible to provide a reliable prediction of individual susceptibility. This may become more feasible in the future as further genetic risk factors are identified by use of more sensitive techniques and larger number of cases. The contribution of other risk factors such as age and disease will also need to be considered and need to be understood better.

Diagnosis of DILI depends on phenotype and expert clinical judgment. Up to the present, marker enzymes such as ALT have been important in diagnosis and this is likely to continue. However, more sensitive biomarkers such as plasma microRNA (miRNA) levels are now available.[86] These appear to provide information about DILI earlier than ALT and other plasma enzyme levels and may be of particular value in the treatment of acetaminophen overdose where an antidote needs to be administered. Their relevance to diagnosis of idiosyncratic DILI is less clear since current approaches to diagnosis (Section "**Phenotypes in DILI**") appear adequate. However, it is possible that measurement of various miRNA molecules in plasma might provide novel insights into the underlying mechanisms for idiosyncratic DILI which remain poorly understood. Whether collection of suitable samples during the onset of DILI will be feasible remains unclear.

4.13.1 Introduction

Adverse drug reactions (ADRs) are a major clinical problem in terms of patient morbidity and mortality, cost to healthcare systems, and failure of drugs in development. Of all the different forms of ADRs, the liver is among the most susceptible organs to drug toxicity. Drug-induced liver injury (DILI) is a particularly challenging for the pharmaceutical industry, while in the clinic, DILI accounts for more than 50% of acute liver failure cases.[1] Although many of these cases are attributable to intentional and unintentional acetaminophen overdose, a significant proportion is also due to idiosyncratic hepatotoxicity. DILI is a key cause for attrition of drugs in development and is the major reason for withdrawal of a drug post-marketing.[2,3,173] The main reason for this unsatisfactory situation is that current preclinical drug testing does not work to predict DILI in humans. A huge worldwide effort is therefore being applied to improve the assessment of potential hepatotoxic risk of new compounds.

A key truism concerning DILI is that it is a multidimensional and multifaceted disease. This means that it is inherently intractable to simple solutions, including some of the single-cell screening strategies used for many years in pharma, which with the benefit of hindsight seem overly simple. Some companies may screen for reactive metabolites and mitochondrial dysfunction, in sandwich cultures and micropatterned cocultures as well as in organelles to identify drugs causing DILI, but even these methods, which take us beyond a simple liver cancer cell line, that is, HepG2, in 2-D culture, and are good at identifying drugs that have no idiosyncratic DILI (90–95% predictability), perform less well for positive predictions (50–89%).[4–6]

At the heart of the efforts to improve the failing status quo, there is therefore the growing consensus that a much better understanding of the mechanisms underlying DILI is essential, particularly in the design and construction of the new improved predictive models that are likely to emerge. As part of this effort, the Innovative Medicines Initiative MIP-DILI Consortium here proposes current likely key mechanisms underlying DILI in all of its known guises, in order to ensure that these are properly addressed in the new and emerging models of DILI. While a number of reviews and perspective papers have been published over the last few years on the impact on drug development of idiosyncratic DILI,[7] chemically reactive metabolites,[8] genetic risk factors in ADRs,[9] and predictive models for DILI,[10] these have not covered in detail the likely individual mechanisms underlying DILI, from molecular reactivity, through intracellular organellar function, to the role of the immune system.

A graphic outline of the scope and scale of the mechanisms likely to underlie many of the different forms of DILI and that feature in this perspective is shown in **Fig. 1**. The overall thesis of this perspective is that only through a more comprehensive understanding of the mechanisms of human DILI will we be able to improve our efforts in the application of more meaningful models in the lab and thereby improve human prediction.

4.13.2 The Role of Reactive Drug Metabolites in DILI

4.13.2.1 Introduction

The work of many groups over many decades has clearly demonstrated that during the metabolic breakdown of chemicals, highly reactive metabolites are often produced. As early as the 1940s, the Millers demonstrated that the carcinogenicity and hepatotoxicity of aminoazo dyes result from their bioactivation to electrophilic species that bind covalently to DNA and proteins.[11,12] Since then, it has been demonstrated that a large number of pharmaceuticals known to cause DILI are also converted to electrophilic metabolites by drug-metabolizing enzymes, in particular by the cytochromes P450.[8,13–16] The chemical modification of biological macromolecules, which may lead to loss of function or which can trigger immune responses, is generally considered to play an important role in the onset of hepatotoxicity.[8,17] Therefore, a large number of analytic methodologies have been developed to detect and quantify the formation of reactive metabolites during drug development. Trapping of reactive metabolites by low-molecular-weight nucleophiles, such as GSH, GSH-analogs, cyanide, and model peptides, is now widely used to characterize the bioactivation of potentially toxic drugs. However, despite that fact that these qualitative studies have generated a large amount of knowledge about structural elements that are prone to bioactivation to reactive metabolites, that is, the so-called structural alerts, it is not yet possible to predict the toxic potential of drugs based on these types of covalent binding studies[18] (**Box 1**).

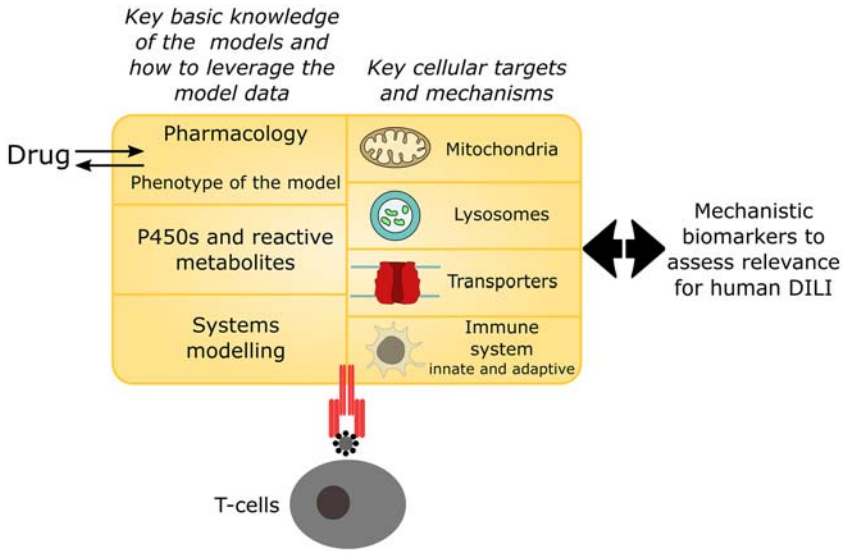

Fig. 1 Overview of the key likely DILI mechanisms that are covered in this review. While the field of mechanistic biomarkers is outside of the scope of this review, it is included in this scheme to illustrate how they should be used to "bridge back" from human clinical DILI to tell us whether our laboratory models are relevant.

Box 1

Linking protein modification with function: The holy grail of the reactive metabolite field?

Improvements in protein separation technology and detection of protein modification by mass spectrometry have enabled significant progress in the identification of specific target proteins that are chemically modified by reactive metabolites. For more than 48 chemicals, including APAP, diclofenac, flucloxacillin, and tienilic acid, several hundred target proteins have been identified and deposited in a web-accessible database (http://tpdb.medchem.ku.edu:8080/). Through bioinformatic approaches, efforts have been made to distinguish target proteins that might be critical for acute cytotoxicity. Initially, only a relatively small overlap of target proteins was observed when comparing different toxicants, which strongly suggests that this fairly laborious methodology may not be able to distinguish critical from noncritical targets. More recently, however, a new bioinformatic approach that assesses the disruption of protein–protein interactions resulted in the ranking of several target proteins that might play an important role in cell death.[19] Several target proteins, such as heat shock proteins, calreticulin, and glutathione *S*-transferase P1-1, were proposed as key target proteins, which upon chemical modification result in cytotoxicity. However, further studies will be required to confirm the critical causative role of modifications in these target proteins for cell death and their role in cell perturbation elicited by other hepatoxicants.

Assessment of the covalent binding of radiolabeled drugs or drug candidates to hepatic fractions is often considered as the gold standard to quantify the total amount of covalent binding of reactive metabolites in in vitro and in vivo model systems. In the perspective article by Evans et al. in 2004, a threshold of covalent binding of $\sim$1 nmol mg^{-1} microsomal protein was defined, which was considered as a high risk for hepatotoxicity, based on in vitro covalent binding studies of a range of hepatotoxic chemicals.[20] Subsequent studies, however, showed that many nontoxic drugs also produced relatively high levels of covalent binding when measured in a similar fashion as proposed by Evans et al.[20] Therefore, measuring covalent binding in vitro does not distinguish between toxic and nontoxic compounds. Consequently, several approaches have been developed to improve the capability to distinguish toxic from nontoxic compounds. The first approach was to combine in vitro covalent binding with total daily dose in order to estimate the body burden of covalent binding.[21] This approach significantly improved the correlation between covalent binding and hepatotoxicity of drugs and most likely explains why drugs that are dosed at less than 10 mg day^{-1} typically do not cause idiosyncratic drug reactions. However, many unresolved questions still remain regarding the factors that will determine whether or not a high-dose drug that is bioactivated to reactive metabolites will actually cause DILI, whether or not the reactive metabolites play a (crucial) role in the onset of DILI, and which individual is susceptible for DILI.

4.13.2.2 Selectivity of Covalent Binding: Critical Versus Noncritical Covalent Binding?

Although covalent binding is often considered as one of the mechanisms that can initiate the events leading to DILI, it has been observed that the total body burden of covalent binding as such is not predictive for hepatotoxicity. For example, both acetaminophen (APAP) and its structural analog 3-hydroxyacetanilide (AMAP) produce an equal amount of covalent binding to hepatic proteins after administration to mice; however, only APAP causes hepatotoxicity in mice. To account for this, it was proposed that the reactive metabolites of APAP and AMAP have different selectivities of covalent binding at the subcellular organelle level,

with APAP preferentially binding to mitochondrial proteins and AMAP preferentially binding to cytosolic targets.[22] Therefore, not only the total amount of covalent binding but also the selectivity of covalent binding seems to be critical for the toxic outcome.

For some drugs causing DILI, it has been shown that in patient serum, antibodies are found that are directed against the enzymes involved in their bioactivation.[23] For example, in the serum of patients suffering from tienilic acid-induced hepatitis, antibodies against CYP2C9 were detected.[24] Tienilic acid is a suicide substrate for CYP2C9, and an adduct of tienilic acid with CYP2C9 was identified by mass spectrometry in in vitro incubations.[25] By as yet unresolved mechanisms, the tienilic acid-CYP2C9 adducts appear to be processed by the immune system leading to an immune response.

4.13.2.3 Are Other Types of Reactive Intermediates More Important for the Onset of DILI?

The analytic methodologies to determine the role of bioactivation in drug toxicity are mainly focused on the covalent binding of electrophiles to proteins or trapping agents, since for covalent binding, many drug-specific radiochemical, mass spectroscopic, and immunochemical detection methods are available.[16,20] However, using these methods, the involvement of other types of toxicologically relevant reactive intermediates, such as oxidants, radicals, reactive oxygen species (ROS), and reactive nitrogen species, usually is not considered. It is well known that quinones are not only electrophiles that bind covalently to protein thiols but also oxidants that can oxidize GSH and protein thiols to (mixed) disulfides.[26] Because the hydroquinones formed can be reoxidized again to the quinones by cytochromes P450, redox cycling of the quinone/hydroquinone couple can cause a shift in the redox state of proteins to their oxidized state.[27] In contrast to covalent binding, where one electrophile molecule inactivates or haptenizes only a single protein, by redox cycling, multiple proteins can be oxidized per molecule of (hydro)quinone. Furthermore, quinones can redox cycle by one-electron reduction processes, by cellular reductases, or by interference with the mitochondrial respiration chain.[28,29] The concomitant production of massive amounts of superoxide anion radicals in turn can cause lipid peroxidation processes, which can instigate the formation of a large number of secondary electrophilic breakdown products (such as 4-hydroxynonenal), which might lead to much higher levels of covalent binding than the primary electrophilic drug metabolites.[30] As an example of this phenomenon, troglitazone is metabolized by CYP3A4 to a quinone metabolite, which is fully substituted and therefore cannot bind covalently to protein thiols.[31] The fact that troglitazone causes lipid peroxidation and cytotoxicity in CYP3A4-transfected cells, after downregulation of superoxide dismutase 2, shows that the redox-cycling properties, rather than the electrophilic properties of the quinone metabolite per se, plays an important role in cytotoxicity.[32]

Therefore, there is a need for additional analytic methodologies that can detect the types of reactive intermediates that are not covered by the covalent binding studies and that can quantify the body burden of exposure to potentially toxic oxidants, radicals, and ROS.

4.13.2.4 Does an Imbalance in Activation and Inactivation of Drugs Determine Human Susceptibility to DILI?

It is now well recognized that drugs which are administered at a relatively high daily dose and that undergo extensive metabolism are more likely to cause idiosyncratic drug reactions.[33,34] Nevertheless, it is still not completely understood why the large majority of patients treated with these high-dose drugs do not suffer from DILI. Therefore, patient-specific factors such as genetic polymorphisms at the level of adsorption, distribution, metabolism, and excretion (ADME)-related processes and/or human leukocyte antigen (HLA) also may determine the risk for DILI.[35–37] Although hepatocytes contain high levels of cytochromes P450 that can bioactivate drugs to reactive metabolites, they are also rich in GSH and protective enzymes such as glutathione *S*-transferases, epoxide hydrolases, and NADPH-quinone oxidoreductases (NQO) that inactivate reactive metabolites.[38] Also, the high activity of UDP-glucuronosyl transferases and sulfotransferase can divert metabolism of drugs away from the bioactivation pathway. In the case of APAP, at normal doses, metabolism is mainly by glucuronidation and sulfation; CYP-dependent bioactivation only occurs at high dose levels when cofactors of these protective pathways become depleted.[39] Therefore, it can be envisaged that for most individuals, the capacity of the protective enzyme systems is apparently high enough to deal with the burden of reactive metabolites. Furthermore, through the Nrf2-mediated stress response system, the levels of protective enzyme systems and antioxidants can be strongly upregulated, thereby further protecting against protein modifications.[40,41] It therefore can be hypothesized that the risk for DILI can be significantly increased in individuals in which the balance of activation and inactivation is disturbed by genetic factors or nongenetic factors. For example, several association studies suggest that genetically determined deficiencies in GSTM1-1 and GSTT1-1 increase the risk of idiosyncratic DILI.[31,42,43] However, because of the low number of cases in these association studies, the statistical power of these studies is relatively poor and requires confirmation by larger population studies or by mechanistic in vitro models.

4.13.2.5 Can We Link the Formation of Drug Reactive Metabolites to the Onset of DILI in Humans?

It remains a significant challenge to determine unequivocally whether or not reactive metabolites have any predictive value for the risk of DILI. It is also worth pointing out that while it is becoming clear that the majority of hepatotoxicities in humans involve the immune system (innate and/or adaptive), modeling the first chemical perturbation (through reactive metabolite formation or exposure to parent compound) of the likely initial target cell (hepatocyte) that will provide a danger signal will still be essential and is the only current feasible route for prediction (no in vitro recapitulation of the interaction of perturbed hepatocytes with components of the immune system is yet possible).[17]

4.13.3 Assessment and Prediction of Mitochondrial Dysfunction (In Vitro and In Vivo)

4.13.3.1 Introduction

More than 1000 recently developed drugs can induce liver injury, with various clinical consequences.[7,8] Of 300 drugs assessed, 50–60% of those that can elicit idiosyncratic toxicity cause mitochondrial perturbation, whereas among non-DILI drugs, this falls to $<5\%$.[44] Furthermore, there is also a positive correlation (89%) between exposure to idiosyncratic drugs and disruption of isolated mitochondria.[45]

Since 45% of idiosyncratic DILI cases have been shown to be caused by antimicrobials, a link can be suggested because of the bacterial ancestry of mitochondria.[46] Bacteria share many genetic and structural similarities with mitochondria; therefore, there is a strong argument to suggest that antibiotics may directly harm mitochondria to promote DILI. Many drugs showing idiosyncratic toxicity, such as amiodarone and valproic acid, directly disrupt mitochondria, thereby eliciting cellular stress in hepatocytes.

4.13.3.2 Mitochondrial Toxicity

Mitochondria harbor several key processes that are important for interactions with drugs causing mitochondrial toxicity and cell toxicity. The major ones are (i) the mitochondrial respiratory chain and oxidative phosphorylation, (ii) mitochondrial permeabilization, (iii) fatty acid oxidation, and (iv) mitochondrial DNA (mtDNA) synthesis. Inhibition of the first two pathways causes necrosis and/or apoptosis, whereas inhibition of fatty acid oxidation can induce microvesicular steatosis causing liver failure. The impairment of fatty acid oxidation indirectly inhibits the mitochondrial respiratory chain. These reactions can be triggered by inhibiting the respiratory chain or uncoupling of oxidative phosphorylation by the formation of drug cations in the acidic intermembrane space of the mitochondria. Inhibition of the respiratory chain causes increased formation of ROS and subsequent ROS-dependent toxicities. Since 13 proteins of the mitochondrial respiratory chain are encoded by mtDNA, drug-induced damage of the mtDNA or inhibition of mtDNA replication can impair oxidative phosphorylation.[47] Indeed, a recent review of drug-induced mitochondrial toxicity reveals that inhibition of mitochondrial respiration and inhibition of fatty acid oxidation are very common for about 50 different drugs.[48] Two of the mitochondrial processes likely to be sensitive to drug-induced perturbation, that is, mitochondrial respiration and/or β-oxidation, are shown in Fig. 2. Drugs that inhibit these processes are also shown in Table 1.

4.13.3.3 Key Intracellular Signaling Pathways Implicated in Drug-Induced Mitochondrial Perturbation

4.13.3.3.1 JNK signaling

c-Jun N-terminal kinase (JNK) is activated by ROS and cellular stress and after APAP toxicity when glutathione has been depleted by more than 90%. The early phase of JNK activation involves glycogen synthase kinase 3 beta (GSK-3β) and mixed lineage kinase 2 (MLK2).[45] GSK-3β can activate JNK through MEKK1- or MLK-dependent pathways. However, the late phase of JNK activation is believed to be mediated by apoptosis signal-regulating kinase 1 (ASK1) in the liver. Both ASK1 and JNK can be influenced by thioredoxin that binds to and inhibits ASK1 and by GST-Pi that binds to and inhibits JNK and phosphatases acting on JNK.

Upon activation by autophosphorylation, JNK translocates to the mitochondria where it binds to SH3-domain binding protein associating with Btk (Sab), a scaffold protein located on the outer membrane of the mitochondria. Silencing of Sab in knockout mice protects the liver from APAP toxicity.[49] The action of JNK in the mitochondria is believed to be through binding to Sab, which causes increased mitochondrial ROS formation and induction of mitochondrial permeability transition (MPT) in damaged mitochondria. The MPT involves increased permeability of the inner mitochondrial membrane resulting in mitochondrial swelling and death. Crucially, the action of JNK appears more prominent when the mitochondria have been primed for stress. Such stress can be achieved by the reactive metabolite of acetaminophen, NAPQI. However, the exact mechanism for JNK–Sab-mediated modulation of the electron transport chain and the increase in ROS and MPT are unknown.[46]

4.13.3.3.2 Inhibition of fatty acid oxidation and lipid transport

Drugs such as valproic acid, ibuprofen, tianeptine, amiodarone, and tamoxifen can directly inhibit fatty acid oxidases.[50–52] The action of valproic acid is likely to be exerted to a great extent by the D2,4-VPA-CoA reactive metabolite that irreversibly inactivates fatty acid oxidases. The ability of acetaminophen to induce steatosis in some individuals might also be caused by the ability of its major reactive metabolite, NAPQI, to cause similar inhibition. As well as the inhibition of the fatty acid synthases, the exact identity of which is not yet known, the inhibition of carnitine palmitoyltransferase-1 is a key point for the action of drugs such as amiodarone and tamoxifen. In addition, troglitazone is able to inhibit long-chain acyl-CoA synthase, thereby influencing the mitochondrial uptake of the long-chain fatty acids.[53]

4.13.3.4 The Hepatic Specificity of Action for Drugs That Cause Mitochondrial Dysfunction

Mitochondrial dysfunction has long been associated with a large variety of human disorders, such as cardiovascular and neurodegenerative diseases, cancer, migraine, infertility, kidney, and liver diseases.[54] It is evident, however, that the drugs that cause mitochondrial impairment and that are hepatotoxic largely exert their toxic effects specifically in the liver. The reasons for this are yet to be defined and would likely be inherent in two major tissue-specific processes, namely, (i) the capability of the liver to bioactivate

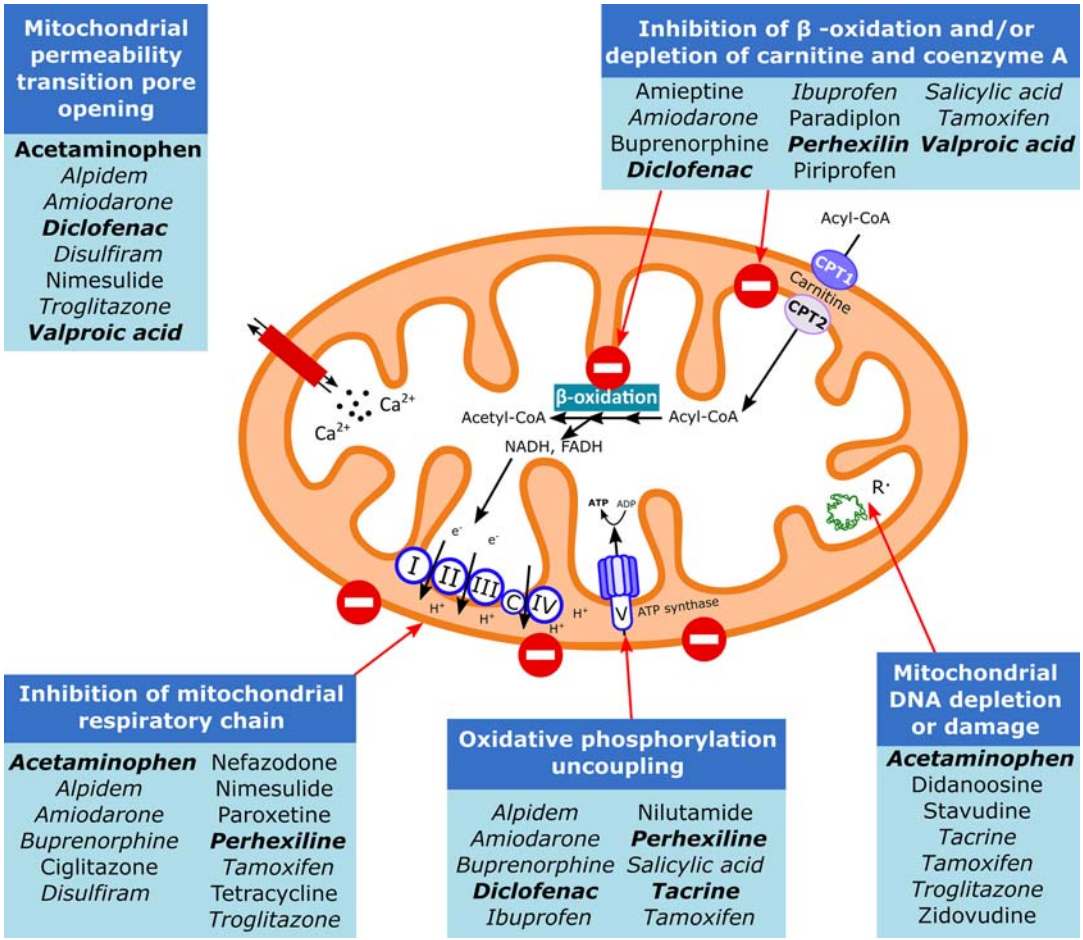

Fig. 2 Mechanisms of drug-induced mitochondrial perturbations. Examples are shown for selected drugs where the evidence for the mechanism of action is high. Drugs marked in bold require metabolic activation, and those in italics act on mitochondria at multiple sites.
