Preface

Important Notice (Please Read)

1. **Introduction / 1**  
DOUGLAS D. RICHMAN, RICHARD J. WHITLEY,  
AND FREDERICK G. HAYDEN

## Section I

---

### VIRAL SYNDROMES AND GENERAL PRINCIPLES

2. **Respiratory Infections / 9**  
JOHN J. TREANOR
3. **Viral Infections of the Central Nervous  
System / 31**  
KEVIN A. CASSADY AND RICHARD J. WHITLEY
4. **Gastrointestinal Syndromes / 47**  
EYAL LESHEM AND UMESH D. PARASHAR
5. **Viral Hepatitis / 61**  
ZINA S. VALAYDON, STEPHEN A. LOCARNINI,  
AND ALEXANDER J.V. THOMPSON
6. **Viral Infections in Organ Transplant  
Recipients / 75**  
JOHN A. ZAIA
7. **Viral Heart Disease / 99**  
BRUCE M. McMANUS, MICHAEL SEIDMAN,  
KARIN KLINGEL, AND HONGLIN LUO
8. **Viral Diseases of the Skin / 115**  
ZEENA Y. NAWAS AND STEPHEN K. TYRING
9. **Viral Hemorrhagic Fevers / 141**  
GAIL CARSON, MIKE BRAY, AND CATHY ROTH
10. **Viral Disease of the Eye / 151**  
HOWARD M. NEWMAN

11. **Antiretroviral Agents / 169**  
CHRISTINE J. KUBIN, BARBARA S. TAYLOR,  
AND SCOTT M. HAMMER
12. **Antiherpetic Agents / 215**  
CLAIRE L. GORDON, CHRISTINE J. KUBIN,  
AND SCOTT M. HAMMER
13. **Anti-Hepatitis Virus Agents / 239**  
MATTHEW L. SCHERER, CHELSEA SAMMONS,  
BRIAN NELSON, SCOTT M. HAMMER,  
AND ELIZABETH VERNA
14. **Antirespiratory Virus Agents / 271**  
MARCUS R. PEREIRA, BENJAMIN A. MIKO,  
MONICA MEHTA, AND SCOTT M. HAMMER
15. **Diagnosis of Viral Infections / 291**  
GUY BOIVIN, TONY MAZZULLI,  
AND MARTIN PETRIC
16. **Immune Responses to Viral Infection / 321**  
HENDRIK STREECK, TODD J. SUSCOVICH,  
AND GALIT ALTER
17. **Immunization Against Viral Diseases / 351**  
JULIE E. LEDGERWOOD  
AND BARNEY S. GRAHAM
18. **Chronic Fatigue and Postinfective Fatigue  
Syndromes / 371**  
ANDREW R. LLOYD

## Section II

---

### THE AGENTS

#### PART A: DNA VIRUSES

19. **Poxviruses / 387**  
STUART N. ISAACS AND R. MARK BULLER
20. **Herpes Simplex Viruses / 415**  
RICHARD J. WHITLEY AND BERNARD ROIZMAN
21. **Cercopithecine Herpesvirus 1 (B Virus) / 447**  
RICHARD J. WHITLEY

- 22. Varicella-Zoster Virus / 459**  
ANNE A. GERSHON AND MICHAEL D. GERSHON
- 23. Cytomegalovirus / 481**  
PAUL DAVID GRIFFITHS AND MATTHEW REEVES
- 24. Human Herpesvirus 6 and Human Herpesvirus 7 / 511**  
KOICHI YAMANISHI AND YASUKO MORI
- 25. Epstein-Barr Virus / 523**  
JOYCE FINGEROTH
- 26. Kaposi's Sarcoma-Associated Herpesvirus (KSHV/HHV8) / 549**  
YUAN CHANG, SHOU-JIANG GAO,  
AND PATRICK S. MOORE
- 27. Adenoviruses / 575**  
OLLI RUUSKANEN, JORDAN P. METCALF,  
MATTI WARIS, AND GÖRAN AKUSJÄRVI
- 28. Polyomaviruses / 599**  
JOHN E. GREENLEE AND HANS H. HIRSCH
- 29. Papillomavirus / 625**  
WILLIAM BONNEZ
- 30. Human Parvoviruses / 679**  
MARIA SÖDERLUND-VENERMO,  
KEVIN E. BROWN, AND DEAN D. ERDMAN
- 31. Anelloviridae / 701**  
PETER SIMMONDS AND COLIN P. SHARP
- 32. Hepatitis B Virus / 713**  
DARREN J. WONG, STEPHEN A. LOCARNINI,  
AND ALEXANDER J.V. THOMPSON
- PART B: RNA VIRUSES**
- 33. Human Lymphotropic Viruses: HTLV-1 and HTLV-2 / 771**  
ROBERTA L. BRUHN, RENAUD MAHIEUX,  
AND EDWARD L. MURPHY
- 34. Human Immunodeficiency Virus / 795**  
JOHN C. GUATELLI, ROBERT F. SILICIANO,  
DANIEL R. KURITZKES, AND  
DOUGLAS D. RICHMAN
- 35. Colorado Tick Fever and Other Arthropod Borne Reoviridae / 841**  
STEVEN YUKL AND JOSEPH K. WONG
- 36. Rotaviruses / 853**  
MANUEL A. FRANCO, JUANA ANGEL,  
AND HARRY B. GREENBERG
- 37. Respiratory Syncytial Virus, Human Metapneumovirus, and Parainfluenza Viruses / 873**  
JOHN V. WILLIAMS, PEDRO A. PIEDRA,  
AND JANET A. ENGLUND
- 38. Measles / 903**  
WILLIAM J. MOSS AND DIANE E. GRIFFIN
- 39. Mumps Virus / 929**  
JOHN W. GNANN, JR. AND DONALD R. LATNER
- 40. Zoonotic Paramyxoviruses / 949**  
DANIELLE E. ANDERSON AND LIN-FA WANG
- 41. Rhabdoviruses / 967**  
ALAN C. JACKSON
- 42. Filoviruses / 981**  
MIKE BRAY AND DANIEL S. CHERTOW
- 43. Influenza Virus / 1009**  
FREDERICK G. HAYDEN AND PETER PALESE
- 44. Bunyaviridae: Orthobunyaviruses, Phleboviruses, Nairoviruses, and Hantaviruses / 1059**  
GREGORY J. MERTZ, CLAS AHLM,  
AND COLLEEN B. JONSSON
- 45. Arenaviruses / 1089**  
DANIEL G. BAUSCH
- 46. Enteroviruses / 1113**  
JOSÉ R. ROMERO
- 47. Rhinovirus / 1143**  
WAI-MING LEE AND JAMES E. GERN
- 48. Hepatitis A Virus / 1165**  
SARA E. WILLIFORD AND STANLEY M. LEMON
- 49. Human Caliciviruses / 1189**  
ROBERT L. ATMAR AND MARY K. ESTES
- 50. Hepatitis E Virus / 1209**  
HARRY R. DALTON, NASSIM KAMAR,  
AND JACQUES IZOPET
- 51. Astrovirus / 1231**  
CARLOS F. ARIAS AND TOMÁS LÓPEZ
- 52. Coronaviruses / 1243**  
J.S.M. PEIRIS
- 53. Arthropod-Borne Flaviviruses / 1267**  
LYLE R. PETERSEN AND ALAN D.T. BARRETT
- 54. Hepatitis C Virus / 1313**  
CHRISTOPHER KOH, QISHENG LI,  
AND JAKE LIANG
- 55. Alphaviruses / 1347**  
DAVID W. SMITH, JOHN S. MACKENZIE,  
ILYA V. FROLOV, AND SCOTT C. WEAVER
- 56. Rubella Virus / 1381**  
DAVID W. KIMBERLIN
- 57. Infections Caused by Bornaviruses / 1395**  
RALF DÜRRWALD, NORBERT NOWOTNY,  
MARTIN BEER, AND JENS H. KUHN
- PART C: SUBVIRAL AGENTS**
- 58. Hepatitis D / 1409**  
MARIO RIZZETTO, ANTONINA SMEDILE,  
AND ALESSIA CIANCIO
- 59. Prion Diseases / 1425**  
CHRISTINA J. SIGURDSON, MEE-OHK KIM,  
AND MICHAEL D. GESCHWIND
- Subject Index / 1449**

# Conflicts of Interest

**Robert Atmar** (chapter 49) has received research grant funding from and is a consultant to Takeda Vaccines, Inc.

**Yuan Chang** (chapter 26) holds patents that are assigned to his university on KSHV-related inventions.

**Harry R. Dalton** (chapter 50) has received travel and accommodation costs and consultancy fees from GlaxoSmithKline, Wantai, and Roche; travel, accommodation, and lecture fees from Merck, Gilead, and GFE Blut GmbH; and travel and accommodation fees from the Gates Foundation.

**Mary K. Estes** (chapter 49) is named as an inventor on patents related to cloning of the Norwalk virus genome and has served as a consultant to Takeda Vaccines, Inc.

**Gao Shou-Jiang** (chapter 26) holds patents that are assigned to his university on KSHV-related inventions.

**Anne Gershon** (chapter 22) has received service contracts (molecular VZV diagnosis for vaccine safety) and is a Merck ad hoc consultant and chair of the Data and Safety Monitoring Board (DSMB): GSK (on VZV) AAG

**John Greenlee** (chapter 28) receives honoraria as author and associate editor for Medlink and as chapter author for the Merck Manual. Dr. Greenlee's research is supported by the United States Department of Veterans Affairs.

**Frederick G. Hayden** (chapter 43) is a nonpaid consultant to multiple companies engaged in developing and/or marketing influenza antivirals and therapeutics. He receives personal compensation for service as SAB member on the University of Alabama NIAID-sponsored Antiviral Drug Discovery and Development Consortium, which is looking for novel influenza inhibitors. The University of Virginia has received honoraria payments since 2013 for Dr. Hayden's activities from Hologic (consulting), Singapore Institute of Infectious Diseases and Epidemiology (consulting), Gilead Sciences (DSMB), Sanofi-Pasteur (DSMB), and GSK (consulting).

**Hans H. Hirsch** (chapter 28) receives honoraria for scientific advisory boards from Chimerix Inc., Merck, and Oxford Immunotec; his research has been supported by unrestricted appointment grants of the University of Basel and by grants research from Chimerix Inc. and Novartis.

**Nassim Kamar** (chapter 50) has received travel and accommodation costs and consultancy fees from Novartis and Merck; travel, accommodation, and lecture fees from Gilead, Novartis, Astellas, BMS, Amgen, and Fresenius; and travel and accommodation fees from the Gates Foundation.

**Steven A. Locarinini** (chapter 32) receives consulting fees (eg: advisory boards)—Gilead Sciences Inc. and Arrowhead Research Corp. and fees for non-CME services received directly from a commercial interest or their agent from Arrowhead Research Corp.

**Patrick Moore** (chapter 26) holds patents that are assigned to his university on KSHV-related inventions.

**Pedro A. Piedra** (chapter 37) previously served on the speaker bureau at MedImmune and as a scientific advisor for AstraZeneca.

**Alexander Thompson** (chapter 32) receives consulting fees (e.g., advisory boards) from Gilead Sciences Inc. and Arrowhead Research Corp. and fees for non-CME services received directly from a commercial interest or their agent from Arrowhead Research Corp.

**John Williams** (chapter 37) serves on the Scientific Advisory Board of Quidel and an Independent Data Monitoring Committee for GlaxoSmithKline.

# Preface

Virology is currently one of the most dynamic areas of clinical medicine. Challenges related to novel viruses, changing epidemiologic patterns, new syndromes, unmet vaccine needs, antiviral drug resistance, and threats of bioterrorism are balanced against improved insights into viral pathogenesis, better diagnostic tools, novel immunization strategies, and an expanding array of antiviral agents. The demands on clinicians, public health workers, and laboratorians will continue to increase as will the opportunities for effective intervention. This text, now in its fourth edition, is designed to inform scientists and health care professionals about the medically relevant aspects of this rapidly evolving field.

*Clinical Virology* has two major sections. The first addresses infections and syndromes related to particular organ systems, as well as the fundamentals of modern medical virology, including immune responses and vaccinology, diagnostics, and antivirals. The second provides agent-specific chapters that detail the virology, epidemiology, pathogenesis, clinical manifestations, laboratory diagnosis, and prevention and treatment of important viral pathogens. In a multiauthored text like *Clinical Virology*, the selection of authors is key. The senior authors for individual chapters were chosen because of their in-

ternationally recognized expertise and active involvement in their respective fields. In addition, common templates for the syndrome-specific and separately for the agent-specific chapters allow the reader to readily access material. Since publication of the third edition in 2009, all of the chapters have been extensively revised to incorporate new information and relevant citations. The timeliness and presentation of the fourth edition have been enhanced by publication of chapters online as they have become available and by the increased numbers and incorporation of color figures into the text. New chapters on Bornaviruses and Anelloviruses have been added, and the rapidly expanding field of antiviral drugs demanded dividing the subject into four chapters.

We have been particularly fortunate in receiving invaluable help from our administrative assistants, Mayra Rodríguez, Dunia Ritchey, and Lisa Cook. In addition, we express our appreciation for the enthusiastic professional support provided by Christine Charlip, Lauren Luethy, and Larry Klein of ASM Press.

## **Important Notice (Please Read)**

This book is intended for qualified medical professionals who are aware that medical knowledge is constantly changing. As new information becomes available, changes in treatment, diagnostic procedures, equipment, and the use of drugs and biologicals become necessary. The editors, authors, and publisher have, as far as it possible, taken care to ensure that the information is up-to-date but cannot guarantee that it is.

Consequently, readers are strongly advised to confirm that the information, especially with regard to drug usage, complies with the latest legislation and standards of practice. The authors, editors, and publisher make no warranty, expressed or implied, that the information in this book is accurate or appropriate or represents the standard of care for any particular facility or environment or any individual's personal situation.

# Introduction

DOUGLAS D. RICHMAN, RICHARD J. WHITLEY, AND FREDERICK G. HAYDEN

## 1

Clinical virology incorporates a spectrum of disciplines and information ranging from the x-ray crystallographic structure of viral proteins to the global socioeconomic impact of disease. Clinical virology is the domain of molecular biologists, geneticists, pharmacologists, microbiologists, vaccinologists, immunologists, practitioners of public health, epidemiologists, and clinicians, including both pediatric and adult health care providers. It encompasses events impacting history that range from pandemics and Jennerian vaccination to the identification of new pathogens, mechanisms of disease, and modern countermeasures like antiretrovirals. For example, since the previous edition of this text, sequencing techniques from human specimens have led to the identification of numerous new members of several virus families, including polyomaviruses, orthomyxoviruses, and bunyaviruses (1–3). New viral pathogens have emerged or been recognized, including a camel-associated coronavirus causing the SARS-like Middle East respiratory syndrome, the tick-borne zoonotic orthomyxovirus (Bourbon virus) (2), the bunyaviruses (severe fever with thrombocytopenia virus) (3) and Heartland virus (4, 5), and newly emerged avian and swine influenza viruses causing zoonotic infections (H7N9, H5N6, H6N1, H10N8, H3N2v) (6–10). A bornavirus, belonging to a virus family known to cause disease in animals but with an unproven role in human disease, has been isolated in a cluster of encephalitis cases (11). Well-recognized pathogens like Chikungunya and Zika viruses have spread geographically to cause major outbreaks in the Western Hemisphere (12, 13). The political and social consequences of vaccine denialism have delayed the eradication of polio and measles globally and resulted in re-emerging outbreaks of measles in Europe and North America. Most dramatically, the pattern of relatively limited, albeit lethal, outbreaks of Ebola virus in central Africa over the past 40 years changed in 2014 with the West African outbreak that caused over 28,000 infections leading to over 11,000 fatalities, including more than 500 health care workers, before coming under apparent control in 2016 (<http://www.who.int/csr/disease/ebola/en/>).

On the positive side, the development of new diagnostic technologies has provided dramatic advances for the detection of new pathogens and the diagnosis and management of virus infections in the clinic. Human “virome” projects based on high-throughput serologic screening, se-

quencing, and other technologies have documented the frequent but individually unique patterns of infection that we have with these microbes (14–16). Since the previous edition we have seen the revolutionary impact of combination antiviral therapy for HIV, with approximately 15 million people under treatment globally in 2015, followed by the development of 8- to 12-week interferon-free regimens for hepatitis C, with cure rates of over 95%. Modified viruses have become therapeutic tools in treating some forms of malignancy (e.g., herpes simplex virus for glioblastoma) (17, 18). In addition, promising new antiviral drugs and vaccines are in development for many other virus infections. The editors hope that the fascinating breadth and importance of the subject of clinical virology will be conveyed by this text. In this fourth edition, the editors have attempted to update and expand upon the information in the previous edition, while making the content more accessible with Internet-based technology.

A few words about nomenclature are necessary. Students (among others) are plagued by virus classification. Historically, classification reflected the information available from general descriptive biology. Viruses were thus classified by host (e.g., plant, insect, murine, avian), by disease or target organ (e.g., respiratory, hepatitis, enteric), or by vector (e.g., arboviruses). These classifications were often overlapping and inconsistent. Molecular biology now permits us to classify viruses by genetic sequence and biophysical structure, which can be quantitative and evolutionarily meaningful. Table 1, which shows the taxonomy of human viruses, is derived from the comprehensive Ninth Report of the International Committee on Taxonomy of Viruses (19).

The list in Table 1 represents viruses known to infect humans. Many of the agents are primarily animal viruses that accidentally infect humans: herpesvirus B, rabies, the Arenoviridae, the Filoviridae, the Bunyaviridae, and many arthropod-borne viruses. The role of intraspecies transmission of viruses is becoming increasingly appreciated. Although its contribution to zoonotic infections like H5N1 and antigenic shift of influenza A virus is well documented, the role of intraspecies transmission is a major consideration in the “emerging” diseases caused by Sin Nombre virus and related hantaviruses, Nipah virus, Ebola virus, arenavirus, hemorrhagic fevers, variant bovine spongiform encephalopathy, and most importantly, the human immunodeficiency viruses.

<sup>a</sup>Human virus with no recognized human disease.

Although not a documented risk, the theoretical threats of organ transplants from primates and pigs prompted a section on xenotransplantation in the chapter on transplantation. In addition, a number of human viruses have not been recognized to cause human disease, including spumaretroviruses, reoviruses, anelloviruses, and the adeno-associated parvoviruses. The text does not elaborate on these viruses in detail, but the editors did elect to include a chapter on Torque teno virus and related anelloviruses, despite any proven disease association, because of their remarkably high prevalence in human populations globally and the remarkably high titers achieved in blood. We have also added a new chapter on bornaviruses, which may represent either a newly recognized zoonosis or an emerging infection.

In order to provide a comprehensive yet concise treatment of the diverse agents and diseases associated with human viral infections, the editors have chosen to organize the textbook into two major sections. The first provides information regarding broad topics in virology, including immune responses, vaccinology, laboratory diagnosis, and principles of antiviral therapy, and detailed considerations of important organ system manifestations and syndromes caused by viral infections. The second section provides overviews of specific etiologic agents and discusses their biology, epidemiology, pathogenesis of disease causation, clinical manifestations, laboratory diagnosis, and management. We have attempted to ensure that the basic elements are covered for each of the viruses of interest, but it is the authors of each of these chapters that have done the real work and to whom we owe our gratitude and thanks.

## ACKNOWLEDGMENTS

The editors would like to express their appreciation for the enthusiastic, professional support provided by Lauren Luethy, Larry Klein, Megan Angelini, and Christine Charlip of ASM Press.

## Section I

# Viral Syndromes and General Principles

# Respiratory Infections

JOHN J. TREANOR

## 2

Respiratory viral infections have a major impact on health. Acute respiratory illnesses, largely caused by viruses, are the most common illness experienced by otherwise healthy adults and children. Data from the United States, collected in the 1992 National Health Interview Survey, suggest that such illnesses are experienced at a rate of 85.6 illnesses per 100 persons per year and account for 54% of all acute conditions exclusive of injuries (1). A total of 44% of these illnesses require medical attention and result in 287 days of restricted activity, 94.4 days lost from work, and 182 days lost from school per 100 persons per year. The morbidity of acute respiratory disease in the family setting is significant. The Tecumseh study, a family-based surveillance study of respiratory illness, estimated that approximately one-quarter of respiratory illnesses result in consultation with a physician (2). Illness rates for all acute respiratory conditions are highest in young children, and children below the age of 9 have been estimated to experience between five and nine respiratory illnesses per year (3).

Mortality due to acute viral respiratory infection in otherwise healthy individuals in economically developed countries is rare, with the exception of epidemic influenza and possibly respiratory syncytial virus. However, acute respiratory infection is a major cause of childhood mortality in low- and middle-income countries (4), and it is estimated that 4.5 million children under 5 years of age die annually from acute respiratory infection. Viruses are estimated to play a contributing role in approximately 20% to 30% of these deaths (4). In response, the World Health Organization has undertaken a major new initiative, the Battle against Respiratory Viruses (or BRaVe) to foster research on these pathogens (5).

Both RNA and DNA viruses are responsible for these infections, producing clinical syndromes ranging in severity from merely uncomfortable to life threatening. Each of these viruses may be responsible for different clinical syndromes depending on the age and immune status of the host. Furthermore, each of the respiratory syndromes associated with viral infection may be caused by a variety of specific viral pathogens (Table 1; also see Table 1 in Chapter 52). This chapter describes the clinical syndromes of respiratory virus infection, the spectrum of viruses associated with these syndromes, and the pathophysiology of these illnesses. Specific features of the virology and pathophysiology of

disease induced by individual viral agents are described in greater detail in each of the virus-specific chapters.

### SEASONAL PATTERNS OF RESPIRATORY VIRUS INFECTION

Many of the viruses associated with acute respiratory disease display significant seasonal variation in incidence (Fig. 1). Although the exact seasonal arrival of each virus in the community cannot be predicted with precision, certain generalizations are useful diagnostically and in planning control strategies. For example, both influenza and respiratory syncytial virus epidemics occur predominantly in the winter months, with a peak prevalence in January to March in the northern hemisphere. Although the periods of peak incidence for these two viruses usually do not coincide, there is often overlap between the two seasons. Parainfluenza virus type 3 (PIV-3) infections show a predominance in the spring, while types 1 and 2 (PIV-1 and PIV-2) cause outbreaks in the fall to early winter. Rhinoviruses may be isolated throughout the year, with increases in frequency in the spring and fall. The peak prevalence of enteroviral isolations is in late summer and early fall, while adenoviruses are isolated at roughly equal rates throughout the year. The herpesviruses do not show significant seasonal variation in incidence, except for varicella, which occurs throughout the year, but more commonly in late winter and early spring.

### COMMON COLDS

#### Clinical Features and Syndrome Definition

Common colds are familiar to most adults and are usually self-diagnosed. Most observers consider colds to include symptoms of rhinitis with variable degrees of pharyngitis; the predominant associated symptoms include nasal stuffiness, sneezing, runny nose, and sore throat. Patients often report chills, but significant fever is unusual. Cough and hoarseness are variably present and may be more frequent in the elderly (6). Headache and mild malaise may occur. Although a multitude of viruses may be associated with this syndrome, the pattern of symptoms associated with colds does not appear to vary significantly among agents. Physical findings are nonspecific and most commonly include nasal discharge and

**TABLE 1** Estimated frequency<sup>a</sup> with which individual viral respiratory syndromes are caused by specific common viral pathogens

Virus	Colds	Pharyngitis	Tracheobronchitis	Croup	Bronchiolitis	Pneumonia		
						Children <sup>b</sup>	Adults	Immuno-compromised
RNA viruses								
Influenza virus								
Type A	+ <sup>b</sup>	++	+++	++	+	++	++++	++
Type B	+	++	++	+	+	+	++	+
Parainfluenza virus								
Type 1	+	++	+	++++	+			
Type 2	+	++	+	++	+			
Type 3	+	++	+	+++	++	+++	+	+
Respiratory syncytial virus	++	+		++	++++	++++	++	++
Human metapneumovirus	+				++	++	+	±
Measles virus			+	+		+	+	+
Rhinovirus	++++	++	+	+	+++	++	++	+
Enterovirus	++	++			+	+	±	
Coronavirus	++	+		++	+		+	+
DNA viruses								
Adenovirus		++	+	++	++	++	++	++

Epstein-Barr virus		++					±	+
Cytomegalovirus		+				++	±	+++

<sup>a</sup>The relative frequency of causation is graded semiquantitatively as follows: ±, rarely if ever reported, occasional case reports; +, causes some cases (1%-5% of cases); ++, fairly common cause, (5%-15% of cases); +++; common cause, (15%-25% of cases); +++++, major cause (>25% of cases)

<sup>b</sup>Individuals under the age of 5.

<sup>c</sup>In affected regions during outbreaks.

pharyngeal inflammation. More severe disease, with higher fever, may be seen in children.

Overall, colds are one of the most common of disease experiences. Adults average 6 to 8 colds per 1,000 person-days during the peak cold season and from 2 to 4 colds per person per year (7). Rates of colds are higher in children, who average 6 to 8 colds per year. Adults with children at home have a higher frequency of colds, and women are generally affected more often than men.

Colds are self-limited, with a median duration of illness of approximately 9 to 10 days in adults (8) and longer in children (9). Recognized complications of colds include secondary bacterial infections of the paranasal sinuses and middle ear and exacerbations of asthma, chronic bronchitis, and emphysema. Involvement of the middle ear is common, and changes in middle ear pressures have been documented following both experimentally induced as well as naturally occurring rhinovirus (10) and influenza virus (11) infection. These abnormalities are likely due to eustachian tube dysfunction and probably account for the frequency with which otitis media complicates colds. Colds are associated with symptomatic otitis media in approximately 2% of cases in adults (12) and in a higher proportion in young children (13). Rhinoviruses and other common cold viruses have been detected in middle ear fluids in approximately 20% to 40% of cases of otitis media with effusion in children (14). Infections with RSV, influenza, and adenoviruses are often also associated with otitis media (13).

Colds are also associated with detectable abnormalities of the paranasal sinuses that may or may not be evident clinically. Mucosal thickening and/or sinus exudates have been

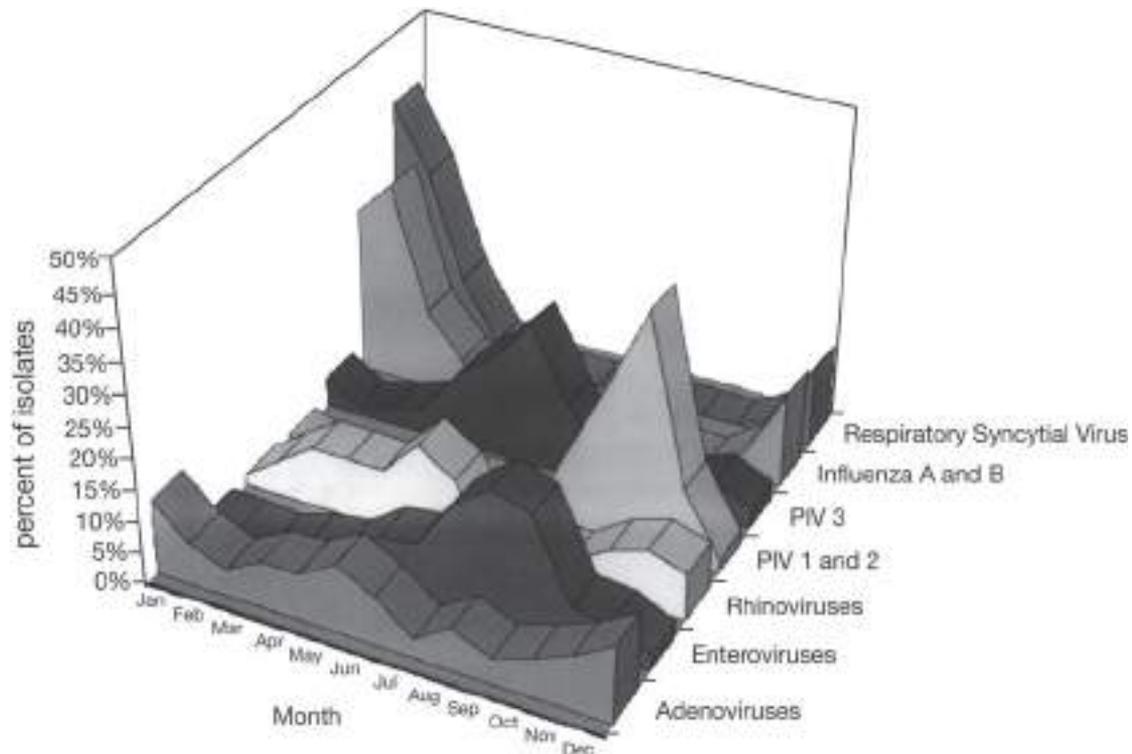

observed by computerized tomography in as many as 77% of subjects with colds (15, 16). However, clinically manifest acute sinusitis is seen only in a small (0.5% to 5%) proportion of adults with naturally occurring colds.

Clinical colds in atopic individuals may be more severe or more likely to result in wheezing than in normal individuals, and rhinoviruses have been identified as major causes of asthma exacerbations in children and adults (17). The mechanism of this increased susceptibility is unclear but may be related to an altered immune response to infection. Rhinovirus colds may increase asthma by augmenting airway allergic responses such as histamine release and eosinophil influx after antigen challenge. Rhinoviruses have also been identified as important causes of exacerbations of chronic obstructive pulmonary disease (18, 19).

### Etiology and Differential Diagnostic Features

The majority of common colds are associated with infection with rhinoviruses or other picornaviruses, particularly when very sensitive techniques, such as reverse-transcriptase-polymerase chain reaction (RT-PCR), are used for diagnosis (8). Other agents frequently associated with common colds include coronaviruses and nonprimary infections with parainfluenza and respiratory syncytial viruses, with a variety of other agents implicated occasionally (Table 1).

The differential diagnosis of individuals presenting with typical signs and symptoms is limited. However, in the presence of additional signs or symptoms which are not part of this clinical description, such as high, persistent fever, signs of respiratory distress, or lower respiratory tract disease, alternative diagnoses should be sought. Allergic causes

**FIGURE 1** Many of the viruses that affect the respiratory tract exhibit a seasonal variation in prevalence. In this figure, numbers of virus isolates from children seen in private pediatric practices in Rochester, NY, are plotted by month of isolation. Data represent the 6-year average from 1990 to 1995 and are expressed as the percentage of all isolates of that virus that occurred in the given month.

should be considered in individuals who present with recurrent symptoms restricted to the upper respiratory tract.

### Pathogenesis

Studies of the pathogenesis of the common cold have largely focused on rhinoviruses, the most commonly implicated viral etiology. Transmission of most of the viruses responsible for the common cold is by direct contact, with inoculation of virus into the upper respiratory tract. *In situ* hybridization studies of nasal biopsy specimens from rhinovirus-infected subjects demonstrate that infection is largely confined to relatively small numbers of ciliated nasal mucosal epithelial cells (20), although occasional non-ciliated cells are also infected (20). Sloughing of these epithelial cells is seen in naturally occurring colds, but the epithelial lining remains intact, with structurally normal cell borders (21). Infection is not associated with significant increases in the numbers of lymphocytes in the nasal mucosa (22), but increases in the numbers of polymorphonuclear leukocytes have been detected in nasal mucosa and secretions, probably due to elaboration of IL-8 by infected cells (23). Although rhinoviruses are not able to grow efficiently at core body temperature, virus can be detected within cells of the lower airway even in uncomplicated colds in healthy subjects (24).

In general, the number of infected cells appears to be quite limited, even in fairly symptomatic individuals (20). Such findings suggest that virus-induced cellular injury is not the direct cause of symptoms in rhinovirus colds and that inflammatory mediators and neurogenic reflexes play important roles. The nasal secretions during the initial response to rhinovirus infection are predominantly the result of increased vascular permeability, as demonstrated by elevated

levels of plasma proteins in nasal secretions (25). Glandular secretions (lactoferrin, lysozyme, and secretory IgA) predominate later in colds (25). Similar observations have been made in allergic rhinitis. However, in contrast to the situation in allergic rhinitis, histamine does not appear to play a role in the induction of symptoms in colds, because nasal histamine levels do not increase, and therapy with selective (nonsedating) H1 antihistamines is not effective (26–28).

Local cytokine production is associated with symptoms in colds. Nasal secretion of kinin, IL-1, IL-6, and IL-8 levels increases during colds, and kinin and IL-8 concentrations correlate with symptoms (26). The low IL-6 production polymorphism has been associated with greater symptom magnitude following experimental rhinovirus challenge in susceptible adults (29) while polymorphisms in I-L10 or TNF $\alpha$  do not have a discernable effect. Intranasal administration of bradykinin mimics the induction of signs and symptoms in the common cold, including increased nasal vascular permeability, rhinitis, and sore throat (27, 30). Enhanced synthesis of proinflammatory cytokines and cell adhesion molecules in the middle ear may also contribute to the pathogenesis of otitis media associated with colds (31).

### Treatment and Prevention

Treatment of colds in clinical practice is directed toward alleviation of symptoms. Symptoms of sneezing and rhinorrhea can be alleviated with nonselective antihistamines such as brompheniramine, chlorpheniramine, or clemastine fumarate, at the cost of some sedation (32, 33). The effect is probably due to the anticholinergic properties of these drugs because, as mentioned earlier, treatment with selective H1 inhibitors is not effective. Topical application of

vasoconstrictors such as phenylephrine or ephedrine provides temporary relief of nasal obstruction but may be associated with a rebound of symptoms upon discontinuation if used for more than a few days. Studies of pseudoephedrine have demonstrated measurable improvements in nasal air flow consistent with a decongestant effect (34, 35). Non-steroidal anti-inflammatory drugs such as naproxen moderate the systemic symptoms of rhinovirus infection (36). Symptomatic therapy with systemic anticholinergic drugs or anticholinergic-sympathomimetic combinations has not been shown to confer any benefit and to be associated with significant side effects (37). In particular, the use of the decongestant phenylpropanolamine has been shown to be associated with an increased risk of hemorrhagic stroke (38, 39), and this drug has been removed from over-the-counter cold remedies. However, topical application of ipratropium, a quaternary anticholinergic agent that is minimally absorbed across biologic membranes, reduces rhinorrhea significantly in naturally occurring colds (40). This agent probably exerts its major effect on the parasympathetic regulation of mucous and seromucous glands.

As expected, there is no benefit in treatment of colds with antibacterial agents, although they are frequently prescribed in colds, particularly in children. Echinacea has been suggested as having efficacy in colds, but a recent randomized trial showed no benefit (41), and administration of this remedy is not associated with a shorter duration of symptoms (42). Zinc gluconate may slightly reduce the duration of colds but does not reduce symptom severity and is associated with a high frequency of adverse events (43).

### Clinical Features and Syndrome Definition

Pharyngitis is a common complaint of both adults and children and is one of the more common reasons for seeking outpatient medical care. In general, this syndrome refers to individuals who present with the primary complaint of sore throat and should probably be reserved for those individuals who manifest some objective evidence of pharyngeal inflammation as well. The clinical manifestations of pharyngitis are dominated by the specific causative agent and can be divided into those cases in which nasal symptoms accompany pharyngitis, which are predominantly viral in nature, and those cases without nasal symptoms, which have a somewhat more diverse spectrum of etiologic considerations, including both group A and nongroup A streptococci, chlamydia (strain TWAR), mycoplasma, and other agents (44).

### Etiology and Differential Diagnostic Features

Viral pathogens associated with acute pharyngitis are summarized in Table 1. Rhinovirus colds are frequently accompanied by pharyngitis, although objective signs of pharyngeal inflammation are uncommon. Adenovirus infections are frequently associated with pharyngitis, and a specific syndrome of pharyngoconjunctival fever, consisting of fever, pharyngitis, and bilateral conjunctivitis is associated with adenovirus types 3 and 7. A variety of enteroviral serotypes are associated with febrile pharyngitis. Herpangina is a specific coxsackievirus-induced pharyngitis in which small (1 to 2 mm) vesicular lesions of the soft palate rupture to become small white ulcers. Pharyngitis is a typical component of acute influenza in which individuals experience the sudden onset of systemic symptoms of fever, myalgias, and malaise accompanied by upper respiratory signs and symptoms including pharyngitis. Primary oral infection with herpes simplex virus may present with pharyngitis, typically

with vesicles and shallow ulcers of the palate, and cervical lymphadenopathy.

Pharyngitis will be a significant complaint in approximately one-half of cases of the acute mononucleosis syndrome due to Epstein-Barr virus (45). Pharyngitis in this syndrome is generally exudative and is accompanied by cervical and generalized lymphadenopathy, as well as fever, hepatosplenomegaly, and other systemic symptoms. The heterophile antibody test is typically positive in the second week of illness. Cytomegalovirus can cause an identical syndrome that is monospot-negative and may be associated with pharyngitis more commonly in children than in adults. An acute mononucleosis-like syndrome with pharyngitis may also be the presenting manifestation of primary HIV infection. Viruses associated with hemorrhagic fever, such as Ebola, Marburg, or Lassa, produce an acute pharyngitis that occurs early in the disease, before skin lesions appear.

The differential diagnosis of acute pharyngitis generally centers upon the differentiation of streptococcal from viral etiologies. Features suggestive of streptococcal pharyngitis include tonsillar swelling, moderate to severe tenderness on palpation, enlargement of lymph nodes, presence of scarlatiniform rash, and absence of coryza (46). The bacterium *Fusobacter necrophorum* has also been recognized as frequently associated with acute pharyngitis in adults and has a clinical presentation similar to that of streptococcal pharyngitis (47).

The presence of nasal symptoms or of conjunctivitis favors a viral etiology, and as described above, some viral syndromes may present with distinguishing characteristics that help in their identification. Generally, acute pharyngitis in children less than 3 years of age is predominantly viral in origin. The presence of exudate is suggestive of bacterial etiology, but exudates may also be seen with adenovirus or EBV. Rapid diagnostic tests for the office identification of group A streptococci are widely available and are indicated in most cases where the etiology is uncertain. When highly sensitive tests are used, backup cultures are generally not necessary (48).

### Pathogenesis

The pathophysiology of those virus infections for which pharyngitis is part of the clinical presentation is described in the individual virus-specific chapters of this book. As described above, pharyngitis in the common cold is probably the result of chemical mediators of inflammation, which are potent stimulators of pain nerve endings. Potentially similar mechanisms may account for pharyngitis in other viral syndromes as well. Direct viral damage and other host inflammatory responses may also contribute.

### Treatment and Prevention

The treatment of most cases of viral pharyngitis is symptomatic, as noted in the section on common colds. Patients suspected of having influenza pharyngitis who are seen within the first 2 days of illness can be treated with antiviral therapy (see Chapters 14 and 43). In immunosuppressed patients with chronic herpetic pharyngitis or normal hosts with primary gingivostomatitis, acyclovir therapy is recommended (see the discussion on herpes simplex virus).

Treatment of group A streptococcal infections with antimicrobial agents is generally initiated to prevent rheumatologic complications of this infection and is associated with more rapid resolution of symptoms, although the absolute benefits are rather modest (49). Rapid diagnostic tests are widely available for the office identification of group A

streptococci and are indicated in most cases where the etiology is uncertain. Antibiotic treatment based on only positive rapid test or throat culture results can reduce unnecessary use of antibiotics for treatment of pharyngitis (50).

## CROUP (ACUTE LARYNGOTRACHEOBRONCHITIS)

### Clinical Features and Syndrome Definition

Croup, or viral laryngotracheobronchitis, is a clinically distinct illness that predominantly affects children under the age of three. The illness typically begins with upper respiratory tract symptoms of rhinorrhea and sore throat, often with a mild cough. After 2 or 3 days, the cough deepens and develops a characteristic brassy, barking quality, which is similar to a seal's bark. Fever is usually present, generally between 38° and 40°C, although those with croup due to respiratory syncytial virus may have normal temperatures. The child may appear apprehensive and most comfortable sitting forward in bed. The respiratory rate is elevated but usually not over 50; this contrasts with bronchiolitis, in which more severe tachypnea is often seen. Chest wall retractions, particularly in the supraclavicular and suprasternal areas, may be observed. Children with this finding on presentation have a higher risk of hospitalization or of requiring ventilatory support.

The characteristic physical finding of croup is inspiratory stridor. Inspiration is prolonged, and in very severe cases, some degree of expiratory obstruction may also be seen. Rales, rhonchi, and wheezing, which reflect the characteristic involvement of the lower respiratory tract, may be heard on physical examination. A fluctuating course is typical, and the child may appear to worsen or improve within an hour. Hypoxemia occurs in 80% of children with croup severe enough to require hospitalization. The degree of hypoxia is generally difficult to ascertain clinically, but continuous monitoring of pulse oximetry does not correlate with respiratory distress and may lead to increased hospitalization rates.

Children who develop respiratory insufficiency as a result of increasing fatigue also may have elevations in PaCO<sub>2</sub>. Other routine laboratory assays are generally unremarkable. Children with croup characteristically exhibit subglottic narrowing of the tracheal air shadow on PA films of the neck, the so-called "steeple" sign (Fig. 2). This finding may be useful in differentiating croup from epiglottitis. Chest X-rays may reveal parenchymal infiltrates which are part of the characteristic involvement of the lower respiratory tract in this syndrome.

Croup is predominantly a disease of young children, with a peak age incidence in the second year of life. In the Seattle virus watch family study, the annual incidence of croup was 5.2 per 1,000 in the first 6 months of life, 11.0 per 1,000 in the second 6 months, 14.9 per 1,000 in the second year of life, and 7.5 per 1,000 in those 2 to 3 years of age, with a marked drop after that age (51). Boys are somewhat more likely to be affected than girls (52).

### Etiology and Differential Diagnostic Features

Overall, viruses are recovered from croup cases more frequently than from other types of respiratory illnesses. An estimate of the relative importance of individual infectious agents in croup is shown in Table 1. The parainfluenza viruses are the most common viruses responsible for croup, accounting for about 75% of cases (52). Of the parainfluenza viruses, types 1 and 2 are most commonly associated with croup (52), and the seasonal incidence of croup reflects the

**FIGURE 2** Posteroanterior roentgenogram of the neck of a child with viral croup that shows the characteristic narrowing of the air shadow of the trachea in the subglottic area. (Courtesy of Dr. Carolyn B. Hall, University of Rochester)

seasonal variations in parainfluenza virus incidence (Fig. 1). Less common causes of croup include respiratory syncytial virus, influenza A or B viruses, rhinoviruses, and adenoviruses, as well as *Mycoplasma pneumoniae*. Recent studies have also shown a strong association with the novel coronavirus NL63 (53). Measles is a relatively less common cause of croup but is associated with especially severe disease (54). *Mycoplasma pneumoniae* and influenza viruses tend to be isolated more commonly from older children with croup (52). Parainfluenza virus type 2 and influenza A viruses are associated with more severe disease (55), but generally the clinical presentation of the croup syndrome due to individual agents is similar. Specific viral diagnosis is not routinely performed since the clinical syndrome is sufficient for diagnosis, and management generally does not depend on identification of the specific agent.

The majority of cases of inspiratory stridor in children are caused by viral croup. However, it is critical to distinguish these syndromes from other, potentially more serious causes of airway obstruction such as bacterial epiglottitis and tracheitis early in clinical management. Epiglottitis is an acute cellulitis of the epiglottis and surrounding structures. Patients present with acute respiratory distress and drooling, but the barking cough of croup is absent. Epiglottitis in children is usually caused by *Hemophilus influenzae* type b (Hib). The incidence of invasive Hib infections has declined remarkably since the introduction of polysaccharide-conjugate vaccines, and the incidence of epiglottitis in children has also declined considerably (56). In adults, and rarely in children, epiglottitis may be caused by a variety of other bacterial agents such as *Haemophilus parainfluenzae* or  $\beta$ -hemolytic streptococci, which may spread from a contiguous focus of infection. Bacterial tracheitis is a relatively rare syndrome that mimics croup. Abundant purulent sputum is often present. Bacterial tracheitis is usually caused by *Staphylococcus aureus* or Hib; other bacteria such as  $\beta$ -hemolytic streptococci and *Streptococcus pneumoniae* have also been associated with this syndrome. Other infectious causes of stridor, including peritonsillar or retropharyngeal

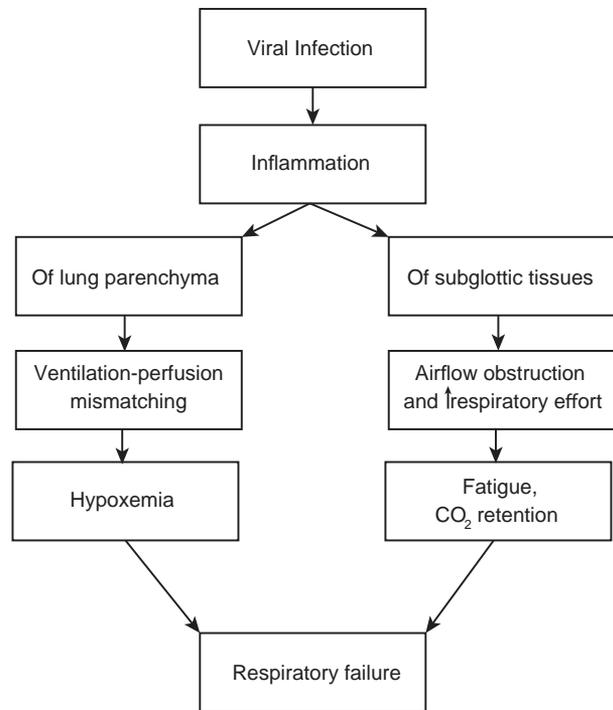

**FIGURE 3** Lateral neck films of the neck in a child with epiglottitis demonstrates the characteristic thickening of the epiglottis in this disease and may be helpful in distinguishing this illness from croup or retropharyngeal abscess. (Courtesy of Dr. Caren B. Hall, University of Rochester)

abscess or diphtheria, and noninfectious causes of stridor such as trauma or aspiration of a foreign body, should be considered.

Direct visualization of the epiglottis may be necessary to exclude bacterial etiologies, and facilities and personnel for this procedure and for emergency airway management should be available. Lateral neck radiographs may show edema of the epiglottis in epiglottitis (Fig. 3) or thickening of the retropharyngeal space in individuals with retropharyngeal abscess. However, radiographs are limited in accuracy and should be performed with caution in individuals with respiratory distress. It may be useful to administer racemic epinephrine, because a rapid response is suggestive of croup.

### Pathogenesis

The severity of clinical symptoms in viral croup appears to be directly related to the level of virus replication (57). This results in inflammation in both the upper respiratory tract and the lung parenchyma. The classic signs of croup, including the barking cough and inspiratory stridor, arise mostly from inflammation occurring in the larynx and trachea. Inflammatory changes are seen by histology in the epithelial mucosa and submucosa of the larynx and trachea. The cellular infiltrate includes histiocytes, lymphocytes, plasma cells, and polymorphonuclear leukocytes. The inflammation and obstruction are greatest at the subglottic level, which is the least distensible part of the airway because it is encircled by the cricoid cartilage. Consequently, localized inflammation and edema lead to obstruction of airflow. The impeded flow of air through this narrowed area produces the classic high-pitched vibration. Obstruction is greater during inspiration because the narrowing occurs in the extrathoracic portion of the airway and is enhanced in small children because the walls of the airways in these individuals are relatively compliant and can collapse to a greater extent. Obstruction of airflow results in an initial decline in tidal volume, which is compensated by an increase in respiratory rate to maintain adequate alveolar ventilation. However, if the obstruction increases, the work of breathing may increase until the child tires, and as the respiratory rate declines, the child develops hypercarbia and respiratory failure.

**FIGURE 4** Pathophysiology of croup. Both mechanical obstruction of airflow and ventilation-perfusion mismatching due to parenchymal infection of the lung are responsible for the hypoxia and respiratory distress of croup. (Modified from Hall, Reference 206, with permission)

Involvement of the lower respiratory tract is integral to the pathophysiology of croup (Fig. 4) (58). Inflammatory changes are noted throughout the respiratory tract, including the linings of the bronchi, bronchioles, and even the alveoli. Consistent with these findings, hypoxemia is detected in about 80% of children hospitalized with croup. Although some degree of hypoxia can be explained on the basis of hypercarbia, the major pathophysiologic mechanism is ventilation-perfusion mismatching. Pulmonary edema may complicate severe croup and upper airway obstruction (59). The onset of pulmonary edema often occurs immediately following intubation. Pulmonary edema in these cases does not appear to be due to pulmonary artery hypertension but to local hypoxia and increased alveolar-capillary transmural pressure.

### Treatment and Prevention

Because the majority of hospitalized children are hypoxic, oxygen is the mainstay of treatment for severe disease and should be given to all hypoxemic patients. Humidified air or mist therapy is commonly used and has several potential roles. Desiccation of the inflamed epithelial surfaces is decreased, and the viscosity of the exudate is reduced. However, the value of mist therapy has not been proven, and removal of the child from the parents and placement in a mist tent can be more distressing to the child than beneficial.

Corticosteroids have been shown to confer significant benefits in the management of mild, moderate, and severe croup, including more rapid improvement in symptoms, reduced length of hospital stay, and reduced rates of intubation. Administration of a single dose of 0.6 mg/kg dexamethasone

intramuscularly (60), an oral dose of between 0.6 to 0.15 mg/kg orally (61), or of 2 mg of budesonide by nebulizer (62) are all effective, and comparative trials have shown all three strategies to be equally effective (63, 64). Administration of single-dose corticosteroid therapy in this setting has not been associated with significant side effects and should probably be used in most patients with significant illness (65).

Administration of nebulized racemic epinephrine generally gives rapid, symptomatic relief in croup (66). It is believed that  $\alpha$ -adrenergic stimulation by this drug causes mucosal vasoconstriction, leading to decreased subglottic edema. Several randomized trials have demonstrated a rapid beneficial effect on airway obstruction (67, 68). The onset of action is rapid, often within minutes, but the duration of relief is also limited, lasting 2 hours or less. Therefore, treated subjects should be observed closely for clinical deterioration. While symptomatic relief is considerable, use of epinephrine is not associated with improvements in oxygenation, probably because the defect in oxygen is associated with ventilation-perfusion mismatching due to lower respiratory tract involvement. In addition tachycardia may occur. Thus, inhaled epinephrine is generally reserved for children who fail to respond to more conservative management (69). Oxygen mixed with helium (heliox) has been suggested as an intervention to reduce the work of breathing; however, its role in the routine management of croup remains undetermined (70).

Antiviral agents effective against some of the viruses responsible for croup are available but have not been tested for efficacy in this situation. However, the potential benefit of the use of antiviral agents in the typical self-limited course of croup would likely be limited. Since croup is a viral illness, antibiotic therapy is of no benefit.

## BRONCHIOLITIS

### Clinical Features and Syndrome Definition

Bronchiolitis is a characteristic syndrome of infants whose presenting symptoms are dominated by the major pathophysiologic defect, obstruction to expiratory airflow (71). The onset of lower respiratory symptoms is usually preceded by rhinitis, often with nasal congestion and discharge. More severe symptoms characteristically occur 2 to 3 days later but in some cases are concurrent with the onset of upper respiratory symptoms. In many instances, there may be a history of exposure to an adult or sibling with a cold or other minor respiratory illness or history of exposure to other cases of bronchiolitis in the daycare setting.

The hallmark of disease is wheezing, which can be quite marked, with flaring of the nostrils and use of accessory muscles of respiration. Cough may or may not be prominent initially, and when cough is present, it may be paroxysmal in nature. Slight cyanosis is often observed, but the presence or absence of cyanosis is not a reliable indicator of the degree of oxygenation or of the severity of disease. Physical findings are generally confined to the chest, with development of rales, which are usually musical in the beginning and then become more moist. Hyper-resonance of the chest may be observed, and the liver may be displaced downward due to hyperinflation. The respiratory rate is elevated, with rates of 50 to 80 breaths per minute. Fever is frequently present at the beginning of the illness but may no longer be present at the time lower respiratory tract involvement develops. Among hospitalized infants, one-third or more are afebrile, despite marked lower respiratory tract disease. Thus, the presence or

absence of fever does not indicate the severity of the child's illness. Mild conjunctivitis is noted in about a third of cases, with pharyngitis of varied severity in about half, and otitis media in 5% to 10%. The hospital course is variable, but most infants will show improvement in 3 to 4 days (72).

Radiologic findings are generally nonspecific, with reported findings including air trapping, consolidation, and collapse (73). Air trapping is particularly indicative of respiratory syncytial virus (RSV)-associated bronchiolitis and may be the only radiologic finding (Fig. 5). However, there is no correlation between the radiographic findings and the clinical course (74). Chest radiographs should be obtained to rule out alveolar filling defects suggestive of bacterial pneumonia and in those infants with severe disease, sudden deterioration, or underlying disorders (75). Results of routine laboratory tests are generally unremarkable, and the peripheral white blood cell count is usually not elevated. Abnormal water, electrolyte, and endocrine homeostasis may be seen during acute illness, including elevated antidiuretic hormone secretion and low fractional excretion of sodium (76). Electrolyte disturbances, most notably hyponatremia, may be seen with severe disease, particularly if excessive amounts of hypotonic fluid are administered (77). Acute disease may be associated with elevations in pulmonary artery pressure, but echocardiographic studies are usually unremarkable in infants with structurally normal hearts (78).

Bronchiolitis is a disease predominantly of infancy, and the epidemiology of this disease closely parallels that of the major infectious cause, respiratory syncytial virus. The peak age incidence is between 2 and 6 months of age, with over 80% of cases occurring in the first year of life (79). The risk of hospitalization of infants during the first 12 months of life for bronchiolitis has been estimated to be approximately 10 per 1,000 population (80), with the peak age of hospitalization between 1 and 3 months. Hospitalization rates are highest in children who reside in industrialized urban settings (81). Among lower socioeconomic status groups, bronchiolitis hospitalization rates of 0.5% to 1% of the entire population of infants in the first year of life are not uncommon (82).

**FIGURE 5** The CXR in bronchiolitis characteristically shows hyperinflation due to obstruction to airflow. A variety of other findings may be present, including interstitial infiltrates or lobar consolidation. (Courtesy of Dr. Caren B. Hall, University of Rochester)

The risk of hospitalization and severe bronchiolitis is particularly high in infants with congenital heart or lung disease or immunodeficiency (83, 84). In addition, infants born prematurely and those who are less than 6 weeks of age at the time of presentation are also at risk (85). More severe disease has also been documented in children with a family history of asthma (85) and those exposed to cigarette smoke in the family setting (86).

### Etiology and Differential Diagnostic Features

The spectrum of viruses associated with bronchiolitis is shown in Table 1. RSV causes the majority of cases of bronchiolitis, and during the RSV epidemic season, essentially all cases are due to this virus (87). Overall, RSV is recovered from about three-fourths of all infants admitted to the hospital with bronchiolitis (71). Children hospitalized with bronchiolitis due to RSV tend to be younger than those with other viruses (88). Children with a higher viral load on nasopharyngeal aspirates have a higher risk of ICU admission (89). Human metapneumovirus (hMPV) is also a significant cause of bronchiolitis (90–92). The clinical picture most closely resembles that of RSV, and bronchiolitis is the major manifestation in children. Clinical features include wheezing and hypoxia. There are no clinical features that can distinguish between disease caused by hMPV and RSV, although generally RSV may be more severe.

Rhinoviruses have recently been recognized as associated with a significant proportion of cases of bronchiolitis and represent the second most common virus detected using sensitive nucleic acid tests in children with bronchiolitis. The true attribution of RV to this syndrome must take into account the frequent detection of this virus in asymptomatic children as well. Rhinoviruses can also mimic RSV infection in infants with bronchopulmonary dysplasia (93).

Other respiratory viruses causing bronchiolitis include parainfluenza viruses, influenza virus, mumps, and rhinoviruses. Adenoviruses types 3, 7, and 21 are relatively uncommon causes but may be associated with more severe disease, including bronchiolitis obliterans (94). Novel human coronaviruses, such as NL-63, have also been associated with lower respiratory tract disease in infants (95). An additional recently described human parvovirus, the human bocavirus, has been found in as many as 12% of cases of acute wheezing in young children (96).

The differential diagnosis of diseases characterized by expiratory airflow obstruction in infants is relatively small. Pertussis can occasionally be confused with bronchiolitis; more frequent vomiting, more paroxysmal cough, and lymphocytosis are clues to the diagnosis. Differentiation of acute infectious bronchiolitis from the initial presentation of allergic asthma is difficult and contributes to the difficulty in assessing therapeutic interventions in this disease. Anatomic defects such as vascular rings can cause obstruction of the airway. Foreign bodies should be considered strongly, especially in young infants. Gastroesophageal reflux is an additional consideration.

RSV and some of the other viral agents responsible for bronchiolitis can be isolated from nasopharyngeal secretions in cell culture, but nucleic acid detection techniques are more sensitive and detect a wider range of viruses (97). Rapid antigen detection techniques are widely used, but the sensitivity of such techniques is dependent on the quality of the nasopharyngeal specimen, with nasopharyngeal aspirates superior to brushings or swabs (98). Their utility in routine management is unclear, although they may be useful for infection control purposes.

### Pathogenesis

The pathophysiology of infectious bronchiolitis has been described most completely in the case of infection with RSV. The basic pathophysiologic changes in bronchiolitis are summarized in Figure 6 (71). Viral infection of epithelial cells of the bronchioles leads to destruction and necrosis of the ciliated epithelium. Leucocytes, predominantly lymphocytes, can be seen in increased numbers in the peribronchial tissues (99). The submucosa becomes edematous, and there is increased production of mucus. Ultimately, dense plugs of alveolar debris and strands of fibrin form within small bronchi and bronchioles, which may partially or completely obstruct airflow. The pathogenic basis for respiratory difficulty in bronchiolitis is related to obstruction of these small airways (71). Hypoxemia is the major abnormality of gas exchange, with ventilation-perfusion imbalance the major cause of the hypoxemia. In addition to hypoxia, hypercarbia, and respiratory acidosis have been observed in some severely ill infants.

Infants appear to be particularly susceptible to the consequences of viral infection because the peripheral airways are disproportionately narrow in the early years of life. In addition, collateral channels of ventilation, such as the pores of Kohn, are deficient both in number and size in the infant lung. Finally, the airways of infants are intrinsically more reactive to bronchospastic stimuli than are the airways of older children (100). It is not clear how RSV infection results in the observed histologic damage, and the reasons some children experience relatively mild disease while others go on to respiratory failure are unknown.

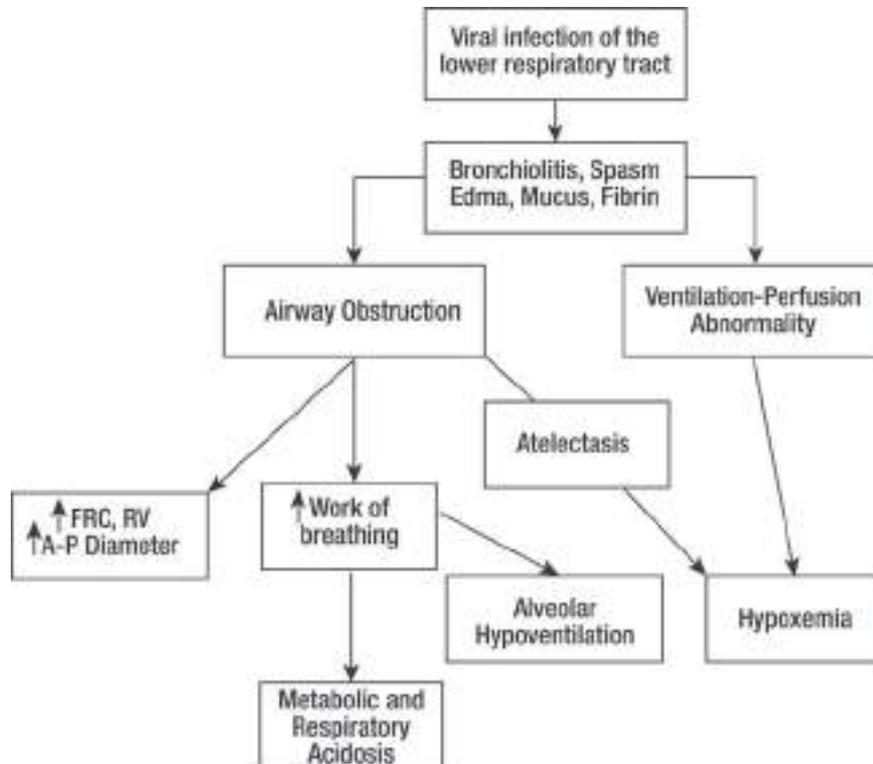

The possibility that immune responses are involved in the pathogenesis of RSV bronchiolitis has received considerable attention. Factors identified as potentially playing a role include overproduction of IgE in response to infection, alteration in the cytokine phenotype of responding T cells, and release of leukotrienes in the airways (101). In addition, neural mechanisms of airway smooth muscle tone may be disrupted by RSV (102).

The innate immune response also plays an important role in the pathogenesis of RSV disease in infants, and it has been recognized that single nucleotide polymorphisms in several genes that control the inflammatory response have an important impact on the severity of RSV disease. Examples include polymorphisms in the genes for IL-4, IL-8, and IL-13, and in TLR-4 and the CCR5 receptor, among others (103).

Following recovery from acute bronchiolitis, some children experience continued episodes of wheezing, especially during apparently viral upper respiratory infections. Estimates are that the risk of either infrequent or frequent wheezing following recovery from documented RSV lower respiratory tract infection is increased by about 3- to 4-fold (104). The risk of subsequent wheezing is also increased in children with bronchiolitis associated with RSV. The mechanisms underlying this increased risk are unknown. Other studies have shown no difference in the rate of subsequent asthma in monozygotic twins discordant for RSV hospitalization (105). A history of maternal asthma may be associated with more severe disease in children with rhinovirus-associated bronchiolitis but not RSV (106, 107).

### Treatment and Prevention

Recommendations regarding the treatment and prophylaxis of bronchiolitis have been summarized recently (108). Correction of hypoxemia is the most important aspect of

**FIGURE 6** Pathophysiology of bronchiolitis. Viral infection of the lower respiratory tract results in inflammation and increased mucus production. Both airway obstruction and ventilation-perfusion mismatching are responsible for the clinical findings of hypoxia, hyperinflation, and hypoventilation. If uncorrected, these defects can lead to apnea or sudden death. (Modified from Wohl and Chernick, Reference 71, with permission)

managing RSV lower respiratory tract disease. Oxygen should be administered to infants whose saturation consistently falls below 90%, but the role of continuous monitoring of oxygen saturation is controversial. Inhaled hypertonic saline has been suggested as a modality to rehydrate the airway and may reduce the risk of hospitalization, although not affecting length of stay (109). Some studies have suggested that a humidified high-flow nasal cannula or continuous positive airway pressure may be useful in children who are at risk for respiratory failure (110).

Because of the dehydrating effect of tachypnea and reduced oral intake in some hospitalized infants, parenteral rehydration is often needed, but care must be taken to avoid inducing hyponatremia. Fluid intake and electrolyte concentrations should be carefully monitored in all infants with severe bronchiolitis, because hyponatremia and syndrome of inappropriate secretion of antidiuretic hormone (SIADH) may occur.

Other therapies are generally not routinely recommended in the treatment of bronchiolitis. Generally, bronchodilators produce modest short-term improvements in clinical scores but do not improve oxygenation, rates of hospitalization, or duration of hospital stay (111). The majority of studies of systemic corticosteroids have also failed to demonstrate a beneficial effect in acute bronchiolitis, and oral corticosteroids do not appear to have beneficial effects (112). Antibacterial drugs, including azithromycin, are of no benefit (113).

A humanized neutralizing monoclonal antibody to the RSV F protein, palivizumab (Synagis®), has had significant protective efficacy in a population of infants with pre-

maturity or bronchopulmonary dysplasia, as well as in children with hemodynamically significant congenital heart disease. Administration of palivizumab intramuscularly at a dose of 0.15 mg/kg of body weight once per month resulted in a 55% reduction in RSV-related hospitalizations and a lower incidence of intensive care unit admissions in this population (114). Recommendations for the use of passive antibody prophylaxis in the United States have been recently revised (115). Palivizumab should generally be used only in the first year of life during the RSV epidemic season. Use is recommended in preterm infants who were born before 29 weeks' gestation (who would be expected to receive little placental transfer of maternal antibody), preterm infants of any gestational age who develop chronic lung disease of prematurity, and infants with hemodynamically significant chronic heart disease. Use can also be considered during the first year of life in infants with anatomic pulmonary disorders or neuromuscular disorders that impair clearing of secretions. The risk of severe RSV in the second year of life is considerably less, but use of palivizumab can be considered in infants with chronic lung disease of prematurity who continue to require medical support, and infants who are profoundly immunocompromised. Routine use in children with cystic fibrosis is not currently recommended.

Interruption of nosocomial transmission may be facilitated by thorough handwashing, decontamination of surfaces and inanimate objects, and isolation or cohorting of infected infants. Use of disposable eye-nose goggles by pediatric staff reduces the risk of nosocomial RSV infection in both staff and patients. Regular use of gowns, gloves, and possibly masks by hospital staff caring for infected children

may also reduce the risk of nosocomial RSV spread. Protective isolation of high-risk infants or deferring their elective admission has been recommended during institutional outbreaks of RSV.

Vaccines are available to prevent bronchiolitis due to influenza virus and mumps, but there is no vaccine currently available for prevention of bronchiolitis due to RSV or PIV. There are multiple significant hurdles to the development of such vaccines, including the very young age at which the disease presents, the suppressive effect of maternal antibody on vaccine responses, and in the case of RSV, the potential for enhanced disease in vaccine recipients (116).

## TRACHEITIS AND TRACHEOBRONCHITIS

### Clinical Features and Syndrome Definition

In addition to causing croup and bronchiolitis, viral infection of the trachea and bronchi may cause tracheitis or tracheobronchitis. Tracheitis is characterized by tracheal tenderness, which can be elicited by gentle pressure on the anterior trachea just below the cricoid cartilage. Substernal discomfort on inhalation, and nonproductive paroxysmal cough are noted. Paroxysmal nonproductive cough is also characteristic of tracheobronchitis and is usually much more severe at night. Later in the course of illness, small amounts of clear or whitish sputum may be produced. Accompanying symptoms may include fever, headache, myalgias, malaise and anorexia. After several days of coughing, chest wall or abdominal discomfort, which is muscular in nature, may be noted. Physical findings are generally nonspecific; examination of the chest may reveal no adventitious sounds but more commonly scattered rhonchi and occasional wheezing. Physical signs such as egophony, pleural friction rubs, or areas of dullness to percussion should suggest the presence of other diagnoses such as pneumonia or pleural effusion.

### Etiology and Differential Diagnostic Features

Tracheobronchitis is most typically caused by influenza A or B virus (Table 1). Herpes simplex has been associated with necrotizing tracheobronchitis in non-immunocompromised hosts (117); this syndrome is often accompanied by refractory bronchospasm. The differential diagnosis of acute bronchitis includes nonviral infections and non-infectious etiologies such as cough-variant asthma. *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* infections cause prolonged cough. *Bordetella pertussis* infection should also be considered in the differential diagnosis of prolonged cough illness. In otherwise healthy persons, workup of acute cough should be directed toward determining the presence of pneumonia.

### Treatment and Prevention

Treatment of bronchitis is primarily symptomatic with antipyretics, and cough suppression. In the absence of signs of pneumonia or documented bacterial infection such as pertussis, treatment of cough with antibacterial agents is of no benefit (118, 119).

## VIRAL PNEUMONIA

### Clinical Features and Syndrome Definition

The development of pneumonia is defined by the development of abnormalities of alveolar gas exchange accompanied by inflammation of the lung parenchyma, often associated

with visible changes on radiologic studies. Although there can be considerable variety in the presentation of viral pneumonia depending on the age and immunologic competence of the host and the specific viral pathogen, there are certain general features of viral pneumonias. Physical findings are often nonspecific. The patient generally appears acutely ill, conjunctivitis and rhinitis may be noted, and the trachea may be somewhat tender if accompanied by viral tracheitis. Chest exam reveals increased respiratory rate, diffuse rales, and often wheezes. The sputum is relatively scant, generally shows few polymorphonuclear leukocytes, and Gram stain usually reveals minimal numbers of bacteria. The clinical presentation of viral pneumonia in children typically includes fever and lower respiratory tract signs and symptoms, such as difficulty breathing, nonproductive cough, and physical findings of wheezing or increased breath sounds. Young infants may present with apneic episodes with minimal fever. The clinical presentation may be dominated by the associated croup or bronchiolitis, which are frequently present.

A number of underlying conditions may increase the risk or severity of viral pneumonia. These features have been identified most clearly for influenza but probably impact the severity of other forms of viral pneumonia. Underlying cardiopulmonary diseases, such as valvular heart disease or chronic obstructive pulmonary disease, are well-recognized risk factors for viral pneumonia in adults and children. Neuromuscular conditions that impair clearance of respiratory secretions are also risk factors for influenza (120) and presumably other viral lower respiratory disease. Obesity has also been recognized as an important risk factor (121, 122). Individuals with compromised immune systems are susceptible to a range of pathogens that would not cause significant disease in immunologically intact individuals.

Pregnancy has long been recognized as a major risk for more severe influenza. The risks associated with pregnancy were dramatically demonstrated during the recent A(H1N1) pdm09 pandemic, where pregnant women were substantially over-represented among patients requiring hospitalization, ICU admission, and ventilatory support (123, 124). The increased risk of severe influenza extends throughout pregnancy and the immediate postpartum period. While the effects of pregnancy are most pronounced during pandemics, pregnancy has also been recognized as a risk factor for cardiopulmonary hospitalizations in the interpandemic period (125).

Bacterial superinfection is a common complication of viral lower respiratory tract infection, particularly in adults. The classic presentation is that of a typical episode of viral illness with more or less complete recovery, followed 2 to 14 days later by a recurrence of fever and development of cough and dyspnea (126). Chest X ray reveals lobar infiltrates, and the clinical course is typical of bacterial pneumonia. In addition, combined bacterial and viral pneumonia, with clinical features of each, are common. Bacterial superinfection of viral pneumonia can occur with many bacteria, but the most common bacterium responsible for bacterial pneumonia complicating influenza is *Streptococcus pneumoniae*. There are also increases in the relative frequency of *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA) and *Hemophilus influenzae* (127).

The impact of viral pneumonia and the spectrum of associated viral agents are highly dependent on the age group and immune status of the host. Further details are provided in the pathogen-specific chapters. While viruses are clearly important and frequent causes of pneumonia in young children, their role is less apparent in older children. In

healthy adults, pure viral pneumonia is less common but may be associated with a variety of viruses. Elderly adults may experience more significant lower respiratory tract signs and symptoms following infection with agents that normally cause upper respiratory tract illness in younger adults. Finally, viral pneumonia is an important cause of morbidity and mortality in individuals with compromised immune systems, with a broader spectrum of viral agents than seen in immunologically intact individuals. The manifestations of viral lower respiratory tract disease in different populations are described below.

### Immunocompetent Adults

Viruses are relatively less common causes of acute pneumonia in adults, but sensitive nucleic acid detection tests suggest that viruses can be detected in as many as one-third of adults with acute pneumonia (128). Influenza has been well recognized as a cause of pneumonia in adults, primarily during seasonal epidemics. In case series of community acquired pneumonia (CAP), viruses are detected in 20% to 30% of cases, frequently in combination with bacterial pathogens (129–134). RSV is generally the most commonly detected viral agent, but essentially all of the respiratory viruses have been associated with CAP (Table 2). Clinically, cases caused by RSV are not distinguishable from those associated with other viral pathogens.

Adenoviruses have been described as causes of significant outbreaks of atypical pneumonia in military recruits and less often in civilians. Illness is typically mild and clinically resembles that due to *M. pneumoniae*, but more severe disseminated infections and deaths have been reported (135). Multiple X-ray patterns are noted; there may be large pleural effusions. Prodromal symptoms of upper respiratory infection are reported by most patients, and pharyngitis is often found on presentation. Bacterial superinfection, particularly with *N. meningitidis*, may occur. Adenovirus serotypes 4 and 7 are most often implicated, but recent reports have emphasized the emergence of a relatively rare adenovirus serotype 14 responsible for severe community acquired pneumonia in adults and children (136).

Varicella is generally more severe in adults than in children, especially among smokers. Chest radiographs taken in adults with varicella will reveal infiltrates in 10% to 20%, most frequently with a nodular infiltrate in a peribronchial distribution involving both lungs; however, the majority of these individuals are asymptomatic. More severe illness is seen occasionally, and fatal varicella pneumonia has been reported in pregnancy. The severity of the pulmonary lesions in varicella generally correlates better with the diffuseness of the rash than with findings on pulmonary exam. Following recovery from varicella, the development of diffuse pulmonary calcifications has been documented.

RSV frequently causes detectably altered airway reactivity in adults (137), and on occasion, lower respiratory tract involvement becomes clinically manifest as pneumonia in otherwise healthy adults (138). RSV is being increasingly recognized as a cause of significant lower respiratory tract disease in the elderly (139). It has been estimated that 2% to 4% of pneumonia deaths among the elderly in the United States may be due to RSV (140). Parainfluenza viruses have also been reported as occasional causes of pneumonia in adults and in the elderly (141). Measles can be complicated by clinically severe pneumonitis in a small percentage of healthy adults, and bacterial superinfection is common. Diffuse pneumonitis and respiratory failure have been described in association with EBV acute mononucleosis in otherwise healthy adults.

Hantaviruses are associated with hantavirus cardiopulmonary syndrome (HCPS), characterized by the onset of severe pulmonary dysfunction after a 2- to 3-day prodrome of nonspecific influenza-like symptoms, fever, myalgias, cough, gastrointestinal symptoms, and headache (142). Coryza or upper respiratory tract symptoms suggest an alternative diagnosis. Laboratory abnormalities include leukocytosis, increased hematocrit due to hemoconcentration, and thrombocytopenia with coagulopathy. However, clinical bleeding is unusual, in contrast to other systemic hantavirus syndromes (142). Moderately elevated levels of serum lactate dehydrogenase and aspartate aminotransferase are typically seen. A variety of radiographic abnormalities have been described; those that may help to distinguish HPS from adult respiratory distress syndrome (ARDS) include early, prominent interstitial edema and nonperipheral distribution of initial airspace disease (143).

Novel human coronaviruses have been associated with severe lower respiratory tract disease and acute respiratory distress syndrome (ARDS) during outbreaks, including the severe acute respiratory syndrome (SARS) coronavirus or SARS CoV in 2003 (144), and more recently the Middle East respiratory syndrome (MERS) coronavirus, or MERS-CoV (145–147). Clinical characteristics of these illnesses are similar to those of progressive respiratory distress and hypoxia (147–149).

## Children

Viruses are more commonly recognized causes of pneumonia in children than in adults (128) (Table 2). In one recent series, viruses were detected in 66% of children with radiographic pneumonia, with dual bacterial and viral pathogens detected in 7% of cases (150). The frequency of virus-associated CAP begins to decrease after age 5 years. RSV has been associated with the largest proportion of viral pneumonia in young children, particularly if accompanied by bronchiolitis (87, 150, 151) (Table 1). Bronchiolitis and pneumonia represent a spectrum of lower respiratory tract involvement with RSV virus, frequently coexist, and are not clearly distinguishable. The most typical radiographic finding is diffuse interstitial pneumonitis, although lobar or segmental consolidation are evident in about one-fourth of children with RSV lower respiratory tract disease, often involving the right upper or middle lobe.

The PIVs are second only to RSV as causes of pneumonia in this age group. As described earlier, lower respiratory tract involvement is integral to the pathophysiology of croup, but pneumonia with pulmonary infiltrates is most commonly associated with PIV-3 and 4 (152). Influenza A and B viruses are both significant causes of pneumonia in children, especially during periods of epidemic prevalence (153). In in-

fants and children, the most frequent manifestation of influenza pneumonia is an interstitial pneumonitis similar in appearance and course to those of the other predominant viral agents of pneumonia in this age group, except that a secondary bacterial pneumonia may occur more frequently than with RSV or PIV.

Rhinoviruses have also been associated with a significant proportion of CAP in children, despite their apparent temperature sensitivity. Recent studies using sensitive PCR-based diagnostics have suggested that RV may be the second or third most common virus detected in acute pneumonia in children (150, 151, 154). However, RV is detected almost as frequently in age- and site-matched asymptomatic controls (150). Adenoviruses are also frequently isolated from children with respiratory disease and are implicated in about 10% of childhood pneumonias. However, the true impact of adenoviruses as causes of pneumonia in this age group is difficult to assess because of the long and intermittent asymptomatic respiratory shedding of these viruses in children. Hilar adenopathy on chest X ray is somewhat more common with this form of pneumonia than other types (155). Pneumonia is the most frequent serious complication of measles. Other viruses that may occasionally cause viral pneumonia in children include enteroviruses, rubella virus, and herpes simplex virus. Premature infants are at risk for pneumonia due to cytomegalovirus because of lack of maternal antibodies.

Pneumonia is the most frequent serious complication of measles. The prodrome of typical measles lasts 2 to 8 days and is characterized by fever, malaise, anorexia, cough, coryza, and conjunctivitis. Koplik's spots, which are erythematous macular lesions with central white-yellow or gray puncta, appear on the buccal or labial mucous membranes toward the end of the prodromal period. The maculopapular, erythematous eruption begins about the face and neck and progresses to involve the upper body, trunk, and extremities. The rash typically disappears after 5 to 6 days in the order in which it appeared. Defervescence and symptom improvement occur several days after the appearance of the rash, although persistent cough is common. Leukopenia is common during the prodromal and early exanthematous stages of measles. Pronounced leukopenia (less than 2,000 cells/mm<sup>3</sup>) is associated with a poor prognosis. The development of neutrophilic leukocytosis suggests the possibility of bacterial superinfection or other complications.

## Immunocompromised Individuals

Individuals with diminished host immunity may develop severe, life-threatening pulmonary infections with the entire spectrum of RNA and DNA viruses, including both viruses that are typical causes of lower respiratory tract disease in normal hosts and other more opportunistic viral pathogens (Table 1). DNA viruses have received the most recognition in this regard.

CMV is a frequent cause of severe pneumonitis in immunosuppressed individuals, particularly transplant recipients (156). The highest risk in the transplant population is 1 to 3 months post-transplantation, with the peak incidence at 8 weeks' post-transplantation. Diffuse interstitial pneumonitis is the most frequent manifestation, but multiple other radiographic presentations have been reported, including nodular infiltrates. Multiple associated findings are present in severe infection and reflect the disseminated nature of the infection; the presence of neutropenia, abnormalities of liver function tests, and mucosal ulcerations may be clinical clues to the diagnosis.

Herpes simplex virus pneumonia has been reported largely in immunocompromised or debilitated individuals. These cases are variably preceded by clinically evident mucocutaneous disease. The majority of cases present as a focal pneumonia as a result of contiguous spread from the upper respiratory tract; diffuse interstitial disease resulting from hematogenous spread occurs in up to 40% of cases (157). Risk groups include neonates, transplant recipients, burn patients particularly with inhalation injury, and those who have experienced prolonged mechanical ventilation, cardiothoracic surgery, or trauma.

Varicella-zoster virus is an important problem in individuals with hematological malignancies and others with iatrogenic immunosuppression, with the greatest risk seen in organ transplantation. Prolonged fever and recurrent crops of lesions are predictors of visceral dissemination, and pneumonia is generally seen in this setting. Pulmonary manifestations may include pleuritic chest pain due to vesicular lesions of the pleura, and, as also true in normal hosts, the chest radiographs may demonstrate diffuse nodular lesions.

Adenoviruses are significant causes of morbidity and mortality in immunocompromised patients, particularly after transplantation. In contrast to infection in normal hosts, infection in immunocompromised subjects tends to be disseminated, with isolation of virus from multiple body sites including lung, liver, gastrointestinal tract, and urine (158). In addition, the spectrum of serotypes includes both those found in immunocompetent individuals as well as a markedly increased frequency of isolation of higher-numbered serotypes found rarely in immunologically normal subjects (159).

Common respiratory viruses have also received increasing recognition as potential causes of significant morbidity and mortality in this population (160). RSV has been well recognized as a cause of severe pneumonia in recipients of bone marrow (161) and solid organ transplantation (162). Nosocomial transmission of RSV in this setting has been well documented and may be the source of many infections in this susceptible population. The illness typically begins with nondescript upper respiratory symptoms that progress over several days to severe, life-threatening lower respiratory tract involvement. Mortality of 50% or higher is typical if pneumonia supervenes, particularly if disease occurs in the pre-engraftment period (163). Parainfluenza viruses have also been reported as an infrequent lower respiratory tract pathogen in both solid-organ and bone marrow transplantation. PIV-3 has been most common serotype isolated, but all four serotypes have been implicated (160). Influenza virus may also cause severe disease in transplant recipients (164) and patients with leukemia. Rhinoviruses and coronavirus infections in this population are also common but tend to be associated less frequently with lower respiratory tract disease (165). In transplant recipients, infections with community respiratory viruses may result in long-term impairment of respiratory function (166).

Measles giant cell pneumonia is a severe, usually fatal form of pneumonia in immunosuppressed individuals, including those who are severely malnourished. Most cases have occurred in those with hematological or other malignancies or in individuals with AIDS (167). Such hosts do not mount the cellular immune responses involved in the pathogenesis of measles rash or other typical manifestations of measles, and a high index of suspicion must be maintained (167). Giant cell pneumonia also occurs in significantly malnourished individuals. Multinuclear giant cells with in-

tranuclear inclusions are seen and may be demonstrable in fluid obtained by bronchoalveolar lavage.

## Diagnosis

Evaluation of the specific cause of acute pneumonia, and in particular, attribution of pneumonia to a particular viral etiology, is complicated by difficulty in obtaining appropriate samples of lower respiratory tract secretions, and the frequent asymptomatic shedding of some viruses, such as rhinovirus, herpes viruses, or adenoviruses in the upper respiratory tract.

The clinical presentation, epidemiology, and presence of associated features such as rash, may provide strong clues regarding the specific viral etiology of pneumonia, especially in children. However, distinguishing purely viral from bacterial or combined viral and bacterial lower respiratory tract disease remains an extremely difficult challenge. This is a particularly important goal in reducing the unnecessary use of antibacterial therapy, and reducing rates of antibiotic resistance and complications such as *Clostridium difficile*.

Highly sensitive multiplex nucleic acid detection tests are now widely available in well-resourced settings and increasingly used to detect respiratory viruses in both upper and lower respiratory tract samples (see Chapter 15). Interpreting the results of such tests is complicated by the reality that detection of a virus does not rule out the presence of a coexisting bacterial infection nor represent compelling evidence that antibacterial therapy is not needed.

Radiologic findings also do not reliably distinguish viral from bacterial, or between viral causes of pneumonia (168). Recently, a number of biomarkers have been proposed for this purpose. The most widely used is probably the serum procalcitonin test, with the presence of a high procalcitonin associated with a higher likelihood of bacterial infection (169). The C reactive protein (CRP) is also sometimes used in the same way (170). However, there is debate whether the sensitivity and specificity of these tests is in the range to be able to guide decision-making for antimicrobial use (171). Recently, the use of a combination of markers, essentially developing a transcriptional profile of responding cells, has been demonstrated to have better sensitivity and specificity in this regard (172), and may pave the way for more accurate determination of the cause of pneumonia.

## Pathogenesis

The pathogenesis of viral infections of the lower respiratory tract can be conveniently considered in terms of infections initiated in and primarily confined to the respiratory tract, such as with influenza or RSV; processes in which infection is initiated in the respiratory tract with subsequent systemic manifestations, such as in measles or varicella; and processes where respiratory tract involvement is secondary to a systemic infection, such as with cytomegalovirus. Each of these situations may lead to what is recognized clinically as a viral pneumonia. The general features of primary viral pneumonia are discussed below using influenza as a model, and pathogenesis of other forms of viral pneumonia is discussed briefly in comparison.

In primary viral pneumonia, virus infection reaches the lung either by contiguous spread from the upper respiratory tract or by inhalation of small particle aerosols. Infection initially occurs in ciliated respiratory mucosal epithelial cells of the trachea, bronchi, and lower respiratory tract and leads to widespread destruction of these cells. The mucosa is

hyperemic, and the trachea and bronchi contain bloody fluid. Tracheitis, bronchitis, and bronchiolitis are seen, with loss of normal ciliated epithelial cells. Submucosal hyperemia, focal hemorrhage, edema, and cellular infiltrate are present. The alveolar spaces contain varying numbers of neutrophils and mononuclear cells admixed with fibrin and edema fluid. The alveolar capillaries may be markedly hyperemic with intra-alveolar hemorrhage. Acellular, hyaline membranes line many of the alveolar ducts and alveoli (see Figure 10 in Chapter 43). Pathologic findings seen by lung biopsy in nonfatal cases during non-pandemic situations are similar to those described in fatal cases (173).

The pathologic changes in the lower respiratory tract in children with viral pneumonia due to RSV and PIV are nonspecific and include epithelial necrosis with bronchiolar mucus plugging and widespread inflammation and necrosis of lung parenchyma, and severe lesions of the bronchial and bronchiolar mucosa as well (99) (see Figures 4 and 5 in Chapter 37). In fatal cases of RSV pneumonia in children, hemorrhagic pneumonia with peribronchial mononuclear infiltration and cytoplasmic inclusion bodies in epithelial cells are seen. Giant cell pneumonia with virally induced multi-nucleated syncytial cells may be seen in RSV, PIV, or measles infections in immunocompromised hosts.

Bacterial superinfection is a well-recognized complication of viral pneumonia and accounts for a large proportion of the morbidity and mortality of viral lower respiratory tract disease, especially in adults. Consequently, the spectrum of disease and pathophysiology of bacterial superinfection has been studied intensively, and a number of factors in viral respiratory disease have been identified which could play a role in increasing the risk of bacterial infection. The disruption of the normal epithelial cell barrier to infection and loss of mucociliary clearance undoubtedly contribute to the enhancement of bacterial pathogenesis (174). In addition, increased adherence of bacteria to virus-infected epithelial cells has been demonstrated. Polymorphonuclear leukocytes and mononuclear cells are susceptible to abortive infection by some respiratory viruses with resulting decreased function which may also contribute to enhanced bacterial infection (175). Virus-induced impairment of repair functions has also been proposed (176).

Infection with influenza, RSV, PIV, and adenoviruses is usually limited to the respiratory tract by mechanisms which are not completely clear. In contrast, respiratory tract infection with measles or varicella virus leads to dissemination and systemic manifestations. In more severe cases of varicella, vesicles may be found within the tracheobronchial tree and on pleural surfaces. Microscopic examination demonstrates interstitial pneumonitis with edema, and intranuclear inclusion bodies within septal cells, and peribronchiolar inflammation.

The Hantavirus pulmonary syndrome represents an additional example of a viral infection which involves the lung as part of a systemic infection. The pathogenesis of HPS involves extensive infection of endothelial cells throughout the body, which is particularly intensive within the vascular endothelial cells of the lung (177). Abundant viral antigen and nucleic acid can be detected within these cells. Microscopic examination of the lung reveals mild to moderate interstitial pneumonitis with variable degrees of congestion, edema, and mononuclear cell infiltration (see Figure 4 in Chapter 44). The cellular infiltrate is composed of a mixture of small and large mononuclear cells, which consist predominantly of T-lymphocytes, and macrophage/monocytes.

The picture is one of immune mediated capillary leak and not of cell necrosis or inflammatory pneumonitis. High levels of cytokines have been detected in the blood and likely mediate the endothelial damage.

There are several features of CMV pneumonitis in the transplant setting that suggest that both host and viral factors interact in pathogenesis (178). CMV pathogenicity is enhanced in transplant recipients and frequently occurs at the site of the transplanted organ. The risk of CMV pneumonitis is also highest in individuals at the highest risk for graft versus host disease (179).

### Treatment and Prevention

Therapy of viral pneumonia is dependent on the severity of disease, the age and immune status of the host, and the specific causative viral agent. General supportive measures, particularly the management of hypoxia, are critically important, and some patients have required high frequency ventilation or extracorporeal membrane oxygenation. Although inflammatory responses contribute to the pathogenesis of viral pneumonia, early corticosteroid treatment is generally associated with worse outcomes (180–182). Since mixed viral-bacterial infections or bacterial superinfections are common, antibacterial agents may be required as indicated by appropriate microbiologic studies.

Antiviral therapy should be guided by the results of diagnostic tests (Table 3). The neuraminidase inhibitors zanamivir and oseltamivir are active against both influenza A and B viruses (183). It should be noted that these agents have mostly been studied in uncomplicated influenza in healthy adults, where the main effect is in reduction of the duration of illness. However, observational studies in hospitalized patients (184, 185) have shown the mortality benefit of early oseltamivir therapy, and surveillance data suggesting that therapy as late as 5 days improved survival of hospitalized patients (186). Inhaled zanamivir may be difficult to reliably and safely deliver in severe influenza, but an intravenous formulation has been used with apparent benefit, including in infections due to oseltamivir resistant A (H1N1) viruses. The neuraminidase inhibitor peramivir has also recently been approved for intravenous use in the United States, although a small study did not demonstrate benefit in hospitalized patients (187). Although the M2 inhibitors are highly effective drugs for the prophylaxis and therapy of influenza A virus, currently circulating seasonal influenza A viruses are uniformly resistant to these agents (188). However, there may be a role for these drugs in combination therapy of influenza (189), and studies to evaluate this in humans are in progress.

The only option currently available for the other RNA viruses is ribavirin, but there is little evidence of efficacy of this agent for treating established viral pneumonia (see bronchiolitis, above). In immunocompromised hosts, treatment of RSV pulmonary infection associated with respiratory failure has not been successful. One approach that appears promising is treatment with ribavirin, possibly in combination with immunoglobulin, early in the illness when URI symptoms predominate (160). Controlled trials in parainfluenza virus infection are not available, although anecdotal reports suggest potential efficacy (190). Limited controlled trials have suggested that aerosolized ribavirin may reduce the severity of symptoms in children with measles, and some immunocompromised patients with measles pneumonia have done well following treatment with aerosolized (167) or intravenous forms of the drug (191). Intravenous ribavirin is effective in the treatment of hemorrhagic

**TABLE 3** Therapies of potential benefit in viral pneumonia

Viral Etiology	Potential Therapies	Comments
Respiratory syncytial virus	Ribavirin	May be considered for use in high-risk or severely ill children. Preemptive use in transplant patients.
	Palivizumab (Synagis)	Effective prevention of RSV bronchiolitis/pneumonia in high-risk premature infants who lack maternal antibody.
Parainfluenza virus	DAS-181	Case reports of efficacy in hematologic transplant, investigational, may be available for compassionate use.
	Ribavirin	Case reports of efficacy of IV or oral ribavirin in parainfluenza virus infection, aerosolized ribavirin not recommended. Addition of IVIG may be helpful.
Influenza virus	Neuraminidase inhibitors	Timely oseltamivir therapy associated with reduced rates of pneumonia development and mortality in hospitalized patients. Indicated for severe or progressive disease and in high-risk patients. IV zanamivir is active against most oseltamivir-resistant variants. IV peramivir also available.
	Oseltamivir (oral)	
	Zanamivir (intravenous)	
	Peramivir (intravenous)	
Measles virus	Ribavirin	Aerosolized or IV ribavirin may shorten the duration of illness in children with measles. Use in measles pneumonia is unproved.
	IVIG	IVIG may decrease risk of measles when administered to susceptible individuals, and may decrease symptoms in those infected.
Adenovirus	Cidofovir, brincidofovir	Cidofovir is active <i>in vitro</i> and multiple case reports suggest efficacy. Brincidofovir has less renal toxicity; recent clinical trial suggests efficacy against adenovirus pneumonia in transplant patients.
Herpes simplex virus	Acyclovir (Valacyclovir, Famciclovir)	Controlled trials have demonstrated efficacy of acyclovir in a variety of HSV diseases. Cross resistance between agents.
	Foscarnet, cidofovir	May be useful for treatment of herpes viruses resistant to acyclovir.
Varicella-zoster virus	Acyclovir (Valacyclovir, Famciclovir)	Demonstrated efficacy of IV acyclovir in varicella and in varicella pneumonia, must use relatively high doses.
	Foscarnet	May be useful for management of acyclovir-resistant cases.
Cytomegalovirus	Ganciclovir	Clinical efficacy in CMV pneumonitis in AIDS and solid-organ transplantation. In bone marrow transplant patients, efficacious when combined with IVIG.
	Foscarnet, cidofovir	Predominant use in ganciclovir-resistance or in individuals who cannot tolerate ganciclovir due to hematological toxicity.

Note: Listing of potential therapies only, not to be considered a recommendation for use. Please see pathogen-specific chapters and Chapter 14 on antivirals for respiratory viruses for more detailed treatment recommendations.

fever with renal syndrome, but does not appear to be useful for treatment of the hantavirus pulmonary syndrome (192).

An experimental agent that has shown some promise in treatment of severe parainfluenza virus infection in immunosuppressed hematopoietic stem cell transplant recipients is the sialidase construct DAS-181 (193). The drug is administered by inhalation, and mechanism of action is thought to be removal of sialic acid receptors from the host respiratory tract. Two investigational RSV antivirals, the fusion inhibitor presatovir (GS-5806) and the polymerase ALS-8176, have shown promising activity in experimentally induced RSV infections in adults (194, 195) and are undergoing clinical trials in serious RSV infections at present.

Acyclovir is active *in vitro* against herpes simplex virus types 1 and 2 and against varicella-zoster virus, but it does not have clinically useful activity for treatment of cytomegalovirus or Epstein-Barr virus disease. Although controlled clinical trials of this drug in herpes simplex pneumonia have not been conducted, the drug has proven clinical efficacy in other herpesvirus infections and would be indicated in any serious HSV lower respiratory tract infection. Acyclovir is also effective in the therapy of varicella, and intravenous acyclovir has been effective when initiated early in the course of varicella pneumonia (196). The related drugs valacyclovir, famciclovir, and penciclovir are similar to acyclovir in their spectrum of activity against herpes and varicella viruses. Viruses resistant to the activity of these

drugs have been isolated from treated immunocompromised patients, and may be susceptible to the antiherpes drug phosphonoformic acid (foscarnet).

Guidelines for management of CMV disease in transplant patients have recently been published (197, 198). Transplant candidates should be screened for evidence of CMV immunity, and CMV-seronegative recipients of transplants from CMV-positive donors are at the highest risk of CMV disease. One strategy for prevention of CMV disease is to provide prophylaxis with ganciclovir or valganciclovir during the period of highest risk, over the first 3 to 6 months after transplantation. Alternatively, some centers favor a preemptive therapy approach, where patients are monitored with serial PCR and antiviral therapy is initiated when CMV PCR becomes positive and reaches a predefined threshold.

Once CMV pneumonitis is established, particularly in allogeneic bone marrow transplant patients, it can be very difficult to treat. Ganciclovir is highly active against CMV *in vitro*, and intravenous ganciclovir therapy is generally recommended in cases of severe disease, although the orally available drug valganciclovir can be used in less-severe cases. Cidofovir and foscarnet are considerations for CMV resistant to ganciclovir. The combination of ganciclovir therapy and intravenous CMV immune globulin or IVIG can reduce mortality in stem cell transplant recipients (199, 200) and is generally recommended in this situation.

Antiviral treatment of proven value for adenovirus infection is not available. Cidofovir is active against adenovirus *in vitro*, and there are several case reports or case series of successful therapy of adenovirus infection in immunocompromised patients with cidofovir (201, 202). However, cidofovir has substantial renal toxicity, which limits its utility in this application. A newly derived series of lipid ester derivatives of cidofovir are orally bioavailable and have less renal toxicity. One of these agents, brincidofovir, has shown preliminary evidence of efficacy against adenovirus infections in bone marrow transplant recipients (203–205).

Although recent years have witnessed a significant increase in the spectrum and potency of available antiviral agents, drug therapy of viral pneumonia remains burdened by the toxicity of drugs, the development of antiviral resistance, and the complex pathogenesis of many viral syndromes in which viral replication is only part of the disease process. Vaccines of variable effectiveness currently exist for influenza, measles, and varicella virus. Development of additional effective vaccines for the viral pathogens causing pneumonia will contribute to the control of this important problem.

# Viral Infections of the Central Nervous System

KEVIN A. CASSADY AND RICHARD J. WHITLEY

## 3

Central nervous system (CNS) symptoms (headache, lethargy, impaired psychomotor performance) are frequent components of viral infections; however, viral infections of the CNS occur infrequently and most often result in relatively benign, self-limited disease. Nevertheless, these infections have tremendous importance because of their potential for causing neurologic damage and death. The CNS is exquisitely sensitive to metabolic derangements and tissue injury. Clinical recovery is slow and often incomplete (1, 2). Patient history, while frequently suggestive of a diagnosis, remains an unreliable method for determining the specific etiology of CNS disease (1, 3). Tumors, infections, and autoimmune processes in the CNS often produce similar signs and symptoms (3). Different diseases may share common pathogenic mechanisms and therefore result in a similar clinical presentation. Furthermore, understanding disease pathogenesis provides a rational basis for the development of therapeutics including antivirals and strategies for the prevention of viral CNS infections.

The definitions of viral CNS disease are often based on both virus tropism and disease duration. Inflammation may occur at multiple sites within the CNS and accounts for the myriad clinical descriptors of viral neurological disease. Inflammation of the spinal cord, leptomeninges, dorsal nerve roots, or nerves results in *myelitis*, *meningitis*, *radiculitis*, and flaccid paralysis and *neuritis*, respectively. *Aseptic meningitis* is a misnomer frequently used to refer to a benign, self-limited viral infection causing inflammation of the leptomeninges (4). The term hinders epidemiologic studies because the definition fails to differentiate between infectious (fungal, tuberculous, viral, or other infectious etiologies) and non-infectious causes of meningitis. *Encephalitis* refers to inflammation of parenchymal brain tissue and is frequently associated with *encephalopathy* or depressed level of consciousness, altered cognition, and frequently focal neurological signs. *Acute encephalitis* occurs over a relatively short period of time (days) while *chronic encephalitis* presents over weeks to months. The temporal course of *slow infections* of the CNS (kuru, visna, variant Creutzfeldt-Jacob disease) overlaps with the chronic encephalitides. Slow infections of the CNS are distinguished by their long incubation period combined with a slow replication rate, eventually resulting in death or extreme neurological disability over months to years (5).

Viral disease in the CNS can also be classified by pathogenesis. Neurological disease is frequently categorized as either *primary* or *postinfectious*. *Primary encephalitis* results from direct viral entry into the CNS that produces clinically evident cortical or brainstem dysfunction (4). Subsequent damage results from a combination of viral-induced cytopathic effects and host immunopathologic responses. Viral invasion, however, remains the initiating event (4). The parenchyma exhibits neuronophagia and the presence of viral antigens or nucleic acids. *A postinfectious* or *parainfectious encephalitis* produces CNS signs and symptoms, either following or temporally associated with a systemic viral infection, respectively, without evidence of direct viral invasion in the CNS. Pathology specimens show demyelination and perivascular aggregation of immune cells, without evidence of virus or viral antigen, leading some to hypothesize an autoimmune etiology (4).

Meningitis and encephalitis represent separate clinical entities; however, a continuum exists between these distinct forms of disease. A change in a patient's clinical condition can reflect disease progression through involvement of different regions of the brain. Therefore, in many cases it is difficult to accurately and prospectively predict the etiology and eventual extent of CNS infection. Epidemiologic data (patient demographics and immune status; season, geographical location; vector, animal, and other exposures) in many cases provide clues to the etiology of the illness. An overview is difficult, as each pathogen fills a different ecological niche with unique seasonal, host, and vector properties (Tables 1 and 2 a, b) (4). Instead it is useful to analyze the prototypes of viral CNS infection, meningitis, and encephalitis and the approach to patients with presumed viral infections of the CNS.

## VIRAL MENINGITIS

### Epidemiology

Acute viral meningitis and meningoencephalitis represent the majority of viral CNS infections and frequently occur in epidemics or in seasonal patterns (4, 6). While there have been changes in the epidemiology of viral meningitis in North America because of the recent introduction of West Nile virus, enteroviruses cause the majority of viral

**TABLE 1** DNA viruses: type of disease, epidemiologic data, and pathogenesis of viral infections of the CNS

Viral agent	CNS disease	Temporal course	Transmission	Pathway to CNS	Relative frequency	Laboratory confirmation
<i>Herpetoviridae</i>						
Herpes simplex virus	Encephalitis	Acute (congenital)	Human	Neuronal, Blood	+++	PCR—CSF Cell culture—brain biopsy sample
HSV type 1		Sporadic (latent)		Neuronal		
HSV type 2	Meningitis Encephalitis	Primary, recurrent Acute (congenital)	Human	Neuronal, Blood Blood, Neuronal	++	Cell culture—genital, rectal, skin PCR—CSF
Cytomegalovirus (CMV)	Encephalitis (neonate and immunosuppressed)	Acute Subacute	Human	Blood	++	PCR Cell culture—brain biopsy or CSF
Epstein-Barr virus (EBV)	Encephalitis Meningitis Myelitis, Guillain-Barré syndrome	Acute	Human	Blood	+	PCR
Varicella zoster virus (VZV)	Cerebellitis, Encephalitis, Meningitis, Myelitis	Postinfectious (acute) Latent reactivation (zoster)	Human	Blood Neuronal	++	PCR, clinical findings, cell culture from a lesion, brain biopsy or, rarely, necroscopy
Human herpesvirus 6 (HHV-6)	Encephalitis, febrile seizures, latent form?	Acute	Human	Blood		PCR
B virus (Cercopithecine herpesvirus 1)	Encephalitis	Acute	Animal bite and human	Blood	+	Culture, PCR (high frequency of detection, unknown significance)

meningitis infections. Arboviruses constitute the second most common cause of viral meningitis in the United States (1, 7–9). Mumps virus remains an important cause of viral CNS disease in countries that do not immunize against this virus. The risk of meningitis from natural mumps infection outweighs the risk of aseptic meningitis associated with the vaccine; nonetheless, not all countries vaccinate against mumps (1, 10). There are more than 74,000 cases of viral meningitis a year in the United States (11). Most cases occur from the late spring to autumn months reflecting increased enteroviral and arboviral infections during these seasons (1, 11). A retrospective survey performed in the 1980s found that the annual incidence of “aseptic meningitis” was approximately 10.9/100,000 persons or at least four times the incidence passively reported to the CDC during the period (6). Virus was identified in only 11% of patients in this study. With the advent of improved nucleic acid-based diagnostic methods, etiologic diagnosis rates now approach 50% to 86% (1, 12, 13).

The pathogenesis of viral meningitis is incompletely understood. Inferences regarding the pathogenesis of viral meningitis are largely derived from data on encephalitis,

experimental animal models of meningitis, and clinical observations (4). Viruses use two basic pathways to gain access to the CNS: hematogenous and neuronal spread. Most cases of viral meningitis likely occur following a high-titer secondary viremia although some, such as meningitis associated with genital herpes or herpes zoster, are related to neuronal routes. A combination of host and viral factors combined with seasonal, geographic, and epidemiologic probabilities influence the proclivity to develop viral CNS infection. For example, arboviral infections occur more frequently in epidemics and show a seasonal variation, reflecting the prevalence of the transmitting vector (1, 14). Enteroviral meningitis occurs with greater frequency during the summer and early autumn months in temperate climates, reflecting the seasonal increase in overall enteroviral infections. Enteroviral infections also exemplify the difference host physiology plays in determining the extent of viral disease. In children less than 2 weeks of age, enterovirus infections can produce a severe systemic infection, including meningitis or meningoencephalitis (11). Ten percent of neonates with systemic enteroviral infections die, while as many as 76% are left with permanent sequelae. In children over 2

**TABLE 2a** RNA viruses: type of disease, epidemiologic data, and pathogenesis of viral infections of the CNS

Viral taxonomy	CNS disease	Case fatalities	Vector	Geographic distribution
<i>Togaviridae—Alphavirus (Arbovirus)</i>				
Western equine encephalitis virus	Meningitis, encephalitis	3%–10%	Mosquitoes, birds	United States—west of Mississippi river
Eastern equine encephalitis virus		> 30%		United States—Atlantic and Gulf Coast states
Venezuelan equine encephalitis virus		< 1%	Mosquitoes, horses	Central and South America, Southwestern United States and Florida
<i>Flaviviridae—Flavivirus (Arbovirus)</i>				
Japanese encephalitis virus	Meningitis, encephalitis	25%	Mosquitoes, swine, birds	Japan, China, Korea, Taiwan, S.E. Asia, India, Nepal
St. Louis encephalitis virus		7%		United States
West Nile fever virus		Higher attack rate in elderly 11%–33%		Africa, Middle East, India, Eastern Europe, recently imported into United States, spreading rapidly
Murray Valley virus	Encephalitis	20%–60%		Australia
Tick-borne encephalitis virus (TBE complex)		20%	Ticks, unpasteurized milk	Eastern Russia and Central Europe
<i>Bunyaviridae—(Arbovirus)</i>				
California (La Cross) encephalitis virus	Meningitis, encephalitis	< 1%	Mosquitoes, rodents	Northern Midwest and Northeastern U.S.
<i>Reoviridae—Coltivirus (Arbovirus)</i>				
Colorado tick fever virus	Meningitis, encephalitis	< 1%	Ticks, rodents	U.S. Rocky Mountains, Pacific Coast states Coast States United States
<i>Picomaviridae—(Enterovirus)</i>				
Poliovirus	Meningitis, myelitis	4.5%–50% <sup>a</sup>	Fecal oral	Worldwide

<i>Arenaviridae</i>				
Lymphocytic choriomeningitis virus	Meningitis, encephalitis	< 2.5%	Rodent	Worldwide

<sup>a</sup>Fatality from poliomyelitis is increased in sporadic cases. With vaccination, the epidemic forms of polio have decreased as has morbidity. In turn, the calculated case fatality rate in the United States has increased as sporadic and vaccine-associated disease has increased relative to the number of cases of disease.

<sup>b</sup>Rarely fatal except in neonates and agammaglobulinemic patients where fatality rates can approach 50% even with treatment.

**TABLE 2b** RNA viruses: type of disease, epidemiologic data, and pathogenesis of viral infections of the CNS

weeks of age, however, enteroviral infections are rarely associated with severe disease or significant morbidity with the exception of enterovirus D68, for which substantial morbidity has been documented (11).

The sequence of viral hematogenous spread to the CNS is illustrated in Figure 1 (4). A virus must first bypass or attach to and enter host epithelial cells to produce infection.

Virus then spreads and initially replicates in the regional lymph nodes (e.g., measles, influenza) or alternatively enters the circulatory system where it seeds other tissues (e.g., arboviruses, enteroviruses, varicella) (4). Primary viremia allows virus to seed in distant locations of the body and frequently marks the onset of clinical illness. In rare circumstances such as disseminated neonatal herpes simplex

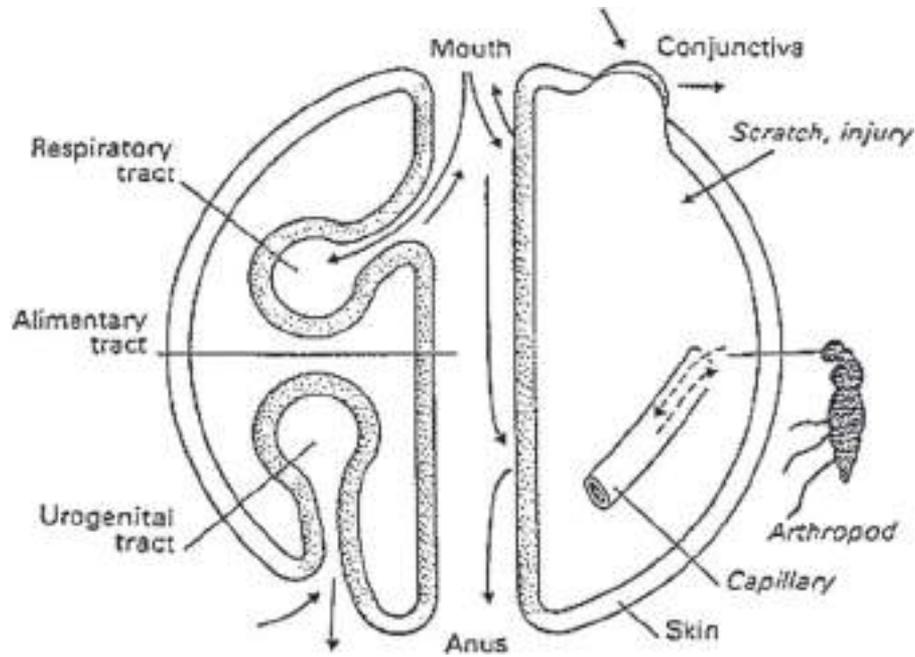

FIGURE 1 Body surfaces as sites of virus infection and shedding.

virus (HSV) infection, viruses infect the CNS during primary viremia (15, 16); however, most viral infections involve an intermediate organ prior to reaching the CNS. The liver and spleen provide ideal locations for secondary viral replication and hematogenous spread because of their highly vascular nature. Secondary viremia may result in high titers of virus in the bloodstream for prolonged periods of time, facilitating viral CNS spread. The pathophysiology of viral

transport from blood to brain and viral endothelial cell tropism are poorly understood. Virus infects endothelial cells, leaks across damaged endothelia, passively channels through endothelium (pinocytosis or colloidal transport), or bridges the endothelium within migrating leukocytes (4). This trans-endothelial passage occurs in vessels of the choroid plexus, meninges, or cerebrum, as depicted in Figure 2.

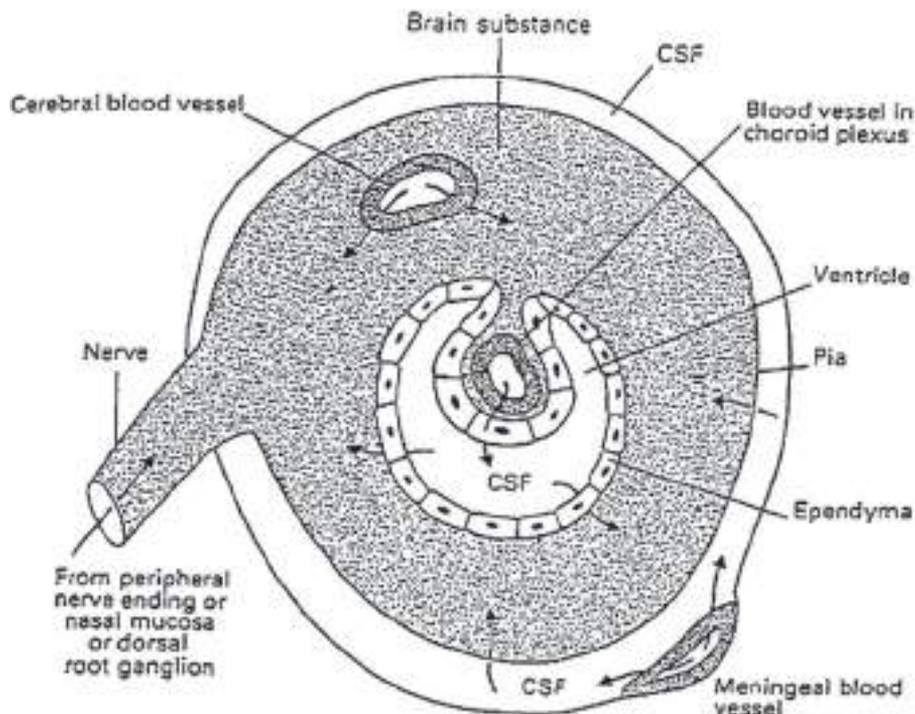

FIGURE 2 Routes of viral invasion of the central nervous system. CSF, cerebrospinal fluid.

Numerous barriers and host defenses limit viral dissemination to the CNS. The skin and mucosal surfaces possess mechanical, chemical, and cellular defenses that protect the cells from viral infection (4). Leukocytes and secretory factors (interleukins, interferons, antibodies) further augment these defenses and help eliminate viruses that bridge the epithelial layer. Local innate immune responses are crucial in limiting systemic viral infection; a swift inflammatory response can limit viremia. In the liver and spleen, the high degree of parenchymal contact and large number of fixed mononuclear macrophages provide an excellent opportunity for host eradication of viremia (4). The blood-brain or blood-CSF barrier, a network of tight endothelial junctions sheathed by glial cells that regulate molecular access to the central nervous system, further limits viral access to the CNS (17, 18).

Viral meningitis is a relatively benign, self-limited illness and pathological specimens are rarely available for study (11). The CSF, however, is frequently sampled and demonstrates a mononuclear immune cell response to most viral infection. Certain viral infections, most notably mumps and some enterovirus infections, elicit a CSF polymorphonuclear cell response early during disease. The initial CSF cellularity mimics bacterial meningitis and later shifts to mononuclear cell predominance. Viral antigen presentation by mononuclear histiocytes stimulates the influx of immune cells. Recruited immune cells release soluble factors (interleukins, vasoactive amines) that mobilize other cells and change the permeability of the blood-brain barrier (1, 19). The viral etiology and type of CNS disease (meningitis vs. encephalitis) can produce differences in CSF IFN  $\gamma$ , IL2, IL6, IL12, procalcitonin, and lactate levels (20–24). While research data suggests that these may be used to differentiate CNS disease, CSF cytokine measurements are not a routine commercial diagnostic method and are often limited to research institutions. Furthermore, these biomarkers are also elevated in autoimmune CNS disease or can be affected by pretreatment with antibiotics (25).

Physical and chemical changes in the blood-brain barrier allow the entry of serum proteins such as immunoglobulins and interleukins, further augmenting the antiviral process. The cell-mediated immune response is important for eliminating virus from the CNS; however, immunoglobulin also has a role in protecting the host in some viral infections. This is best illustrated by the devastating clinical course of enteroviral meningitis in agammaglobulinemic patients and in those with X-linked hyper IgM syndrome (11, 26, 27). Patients with impaired cell-mediated immunity have a higher incidence of CNS infections with certain viruses such as varicella zoster virus (VZV), measles virus, and cytomegalovirus (CMV) (4).

### Clinical Manifestations

The patient's age and immune status and the viral etiology influence the clinical manifestations of viral meningitis. Patients with enteroviral meningitis often present with nonspecific symptoms such as fever (38 to 40°C) of 3 to 5 days duration, malaise, and headache (1, 11). Approximately 50% of patients have nausea or vomiting (1). While nuchal rigidity and photophobia are hallmark manifestations in meningitis, 33% of patients with viral meningitis have no evidence of meningismus (1) and less than 10% of children younger than 2 years of age develop signs of meningeal irritation. The majority of these children present with fever and irritability (28). Children may also present with seizures secondary to fever, electrolyte disturbances, or the infection

itself. The clinician must have a high index of suspicion for meningitis, especially in younger patients. In the immunocompromised host, enteroviral infection presents both a diagnostic quandary and a potentially life-threatening disease. Immunocompromised patients frequently do not mount a brisk cellular immune response, so CSF analysis does not reflect inflammatory changes indicating CNS involvement.

Symptoms of meningitis (stiff neck, headache, and photophobia) occur in approximately 11% of men and 36% of women with primary HSV-2 genital infection. In one study, 5% of patients with primary HSV-2 genital infection had severe enough meningitis to require hospitalization. All of the hospitalized patients had evidence of a lymphocytic pleocytosis upon CSF analysis (1). In another study, HSV-2 was detected in the CSF of 78% of patients with meningitis symptoms during primary genital infection. These patients also exhibited a CSF leukocytosis and increases in CSF antibody titers (29). Recurrent HSV-2 meningitis (with or without genital lesions) is seen, as is Mollaret's syndrome, but meningitis is more commonly associated with primary infection (30). Mollaret's syndrome, or benign recurrent lymphocytic meningitis, is linked to HSV and sometimes VZV infection; self-limited meningitis is characterized by CSF pleocytosis notable for large "endothelial" cells, neutrophil granulocytes, and lymphocytes. HSV meningitis may spread to the CSF along the sacral nerves. Alternatively, the virus may reach the CSF by hematogenous spread, as the virus has been cultured from the blood buffy coat layer (1). VZV, CMV, Epstein-Barr Virus (EBV), and parainfluenza virus have all been cultured or detected by PCR from the CSF of patients with meningitis (1, 12, 31). The three herpesvirus infections occur more frequently in immunocompromised patients and usually progress to involve the parenchyma.

### Laboratory Findings

Initial CSF samples, while frequently suggestive of a diagnosis, lack the necessary predictive value to discriminate viral from bacterial etiology in all cases (32). Instead, epidemiologic trends, patient history, and accompanying laboratory information are important adjuncts in determining the etiology of meningitis. CSF in patients with viral meningitis typically exhibits a pleocytosis with 10 to 500 leukocytes  $\text{mm}^3$  and a slightly elevated protein level ( $< 100\text{mg/dl}$ ). The glucose level in the CSF is typically greater than 40% of a simultaneously drawn serum sample. Tremendous variation in CSF formulas exists, however, with significant overlap between viral and bacterial CSF laboratory findings (32). In a retrospective review of over 400 patients with acute viral or bacterial meningitis performed before the *Haemophilus influenzae B* conjugate vaccine was available, investigators found that approximately 20% of the CSF samples that grew bacteria exhibited a CSF pleocytosis of less than 250  $\text{WBC/mm}^3$  (1). Fifteen percent of the patients with bacterial meningitis had CSF lymphocytosis, while 40% of the patients with viral meningitis had a predominance of polymorphonuclear cells. Some investigators recommend repeating the lumbar puncture 6 to 12 hours later, because the CSF profile of patients with viral meningitis will shift from polymorphonuclear to lymphocytic pleocytosis over this period (1). However, in one study performed during an echovirus epidemic, eight of nine children with presumed enteroviral meningitis failed to develop CSF lymphocyte predominance when a lumbar puncture was repeated 5 to 8 hours later (32). A retrospective study found that 51% of patients demonstrated a CSF polymorphonuclear predominance 1 day after

symptom onset. Of note, the investigators in this study were unable to confirm the etiology of meningitis in most cases because this was a retrospective study (32). Other investigators have confirmed that the change in the lymphocytic CSF profile occurs 18 to 36 hours after illness onset (33). A multifactorial method examining the CSF profile, peripheral blood profile, and history of seizures to develop a bacterial meningitis score has also been investigated to differentiate bacterial from viral meningitis. This provides improved sensitivity but still failed to detect all cases of bacterial meningitis, including some cases in infants (34). With the increasing use of highly sensitive and specific nucleic-acid diagnostic techniques, a viral etiology for meningitis can often be established within 24 to 36 hours, thereby limiting the duration of hospitalization, antibiotic use, and additional diagnostic procedures (7, 9, 13).

### Etiologic Diagnosis

Historically, the techniques for identifying viral meningitis were insensitive and often impractical, with an agent identified in only 25% to 67% of presumed CNS infections (1, 12, 35). The diagnosis of viral meningitis relied on viral culture, and CSF viral culture rates differ based on etiology (1).

A synopsis of viral detection techniques for different viruses is presented in Tables 1 and 2 (4). The rapidity and sensitivity of enterovirus detection, as well as for many other viral infections, has improved with the advent of nucleic acid amplification techniques such as RT-PCR (9, 11). Demonstration of viral nucleic acid in the CSF of patients with symptoms of meningitis has replaced viral isolation and serologic diagnosis for acute management, although one of the advantages of viral culture is the ability to identify enterovirus serotypes for epidemiologic studies (9, 11). As with any RT-PCR-based technique, nucleic acid contamination of the laboratory area is a concern and results must always be interpreted within the clinical context, although use of deoxyuridine triphosphatase (dUTP) and modifications to real-time PCR methods have reduced this risk (36, 37).

In the past, serologic testing confirmed the clinical suspicion of an arboviral infection. While many of these viruses can be cultured from CSF during the early stages of infection, serologic testing has very limited availability and little utility in acute management. The use of RT-PCR for diagnosis of arbovirus infections in the CNS has met with mixed results because of the diverse viral etiologies of arboviral infection. The development of specific primers that can hybridize across multiple viral families (*Alphaviridae*, *Flaviviridae*, *Bunyaviridae*) has been difficult. Currently there is an emphasis on the development of improved “universal group primers” to perform an initial group screening followed by RT-PCR using higher specificity primers as a second viral diagnostic test (38). Many laboratories have chosen instead to concentrate efforts on establishing diagnostic studies for more common regional viral etiologies as a more cost-effective method for diagnosis and patient management (7).

### Differential Diagnosis

Unusual but treatable infections should always be considered and investigated in patients with CSF pleocytosis and negative conventional bacterial cultures. Spirochetes (*Treponema*, *Borrelia*, *Leptospira*), mycoplasma, bartonella, and mycobacteria can produce pleocytosis that has both negative Gram stain and bacterial cultures. Fastidious bacteria (*Listeria*) may fail to grow in culture and occasionally produce a

mononuclear pleocytosis similar to viral meningitis. This is of particular concern in infants, elderly, and immunocompromised patients. Some bacteria, while not directly infecting the CNS, can release toxins that create a change in the level of consciousness, specifically *Staphylococcus aureus* and *Streptococcus pyogenes* exotoxin-mediated toxic shock syndrome. Frequently, children with streptococcal throat infections present with “neck stiffness” secondary to localized pharyngeal inflammation and tender anterior cervical lymphadenopathy. Parameningeal infections, especially from infected sinuses, produce CNS symptoms and pleocytosis presenting with nuchal rigidity, focal neurologic changes, and altered mental status. Similarly, partially treated bacterial infections can have CSF findings resembling viral meningitis. Questions regarding history of self-medication with leftover antibiotics should be included in a review of systems.

Fungal and parasitic infections can produce both meningitis and parenchymal CNS infections. Coccidiomycosis and *Cryptococcus*, the leading causes of fungal meningitis (1), characteristically produce meningitis rather than any focal CNS disease. Fungal infections such as candidiasis, aspergillosis, histoplasmosis, and blastomycosis most frequently cause focal parenchymal disease when infecting the CNS. These fungi are frequently in the differential diagnosis for an immunocompromised host with CNS disease but can cause disease in select patient populations (e.g., premature infants and patients with CNS trauma and diabetes mellitus). Parasites such as *Naegleria fowleri* or *Balamuthia mandrillaris* produce meningoencephalitis with purulent CSF findings (39, 40). A history of recent summertime swimming in a stagnant pond or recent travel in Central or South America should raise suspicion for these infections.

Noninfectious processes that can produce true aseptic meningitis include hematologic malignancies, medications (especially immunomodulatory, nonsteroidal antiinflammatory, and trimethoprim/sulfa medications), autoimmune diseases, and foreign material and proteins. Leukemia produces CSF pleocytosis with cancerous cells and occurs most frequently with acute lymphocytic leukemia, although subarachnoid involvement can also occur in acute myelogenous leukemia. Immunomodulatory drugs such as intravenous immunoglobulin or antilymphocyte globulin (OKT-3) also cause aseptic meningitis. Of the medications associated with meningitis, nonsteroidal antiinflammatory agents, sulfa-containing drugs, and cytosine arabinoside are the most common offenders. Drug-induced aseptic meningitis frequently occurs in patients with underlying connective tissue or rheumatologic diseases. A patient with drug-induced aseptic meningitis warrants investigation for a possible underlying autoimmune disease (41). Epithelial or endothelial cysts can rupture and spill their contents (keratin, protein), producing a brisk inflammatory response that mimics acute viral meningitis.

### Treatment and Prognosis

The fundamental principle of therapy for viral meningitis lies in the identification of potentially treatable diseases. Until recently, no therapy existed for most cases of viral meningitis. Efforts instead focused on preventive strategies (largely through vaccination) as well as identification of treatable nonviral etiologies of meningitis. The clinician must also anticipate and treat the complications of viral CNS disease (seizures, syndrome of inappropriate antidiuretic hormone secretion [SIADH], hydrocephalus, increased intracranial pressure). Supportive therapy includes hydration, antipyretics, and analgesics.

In the normal host, viral meningitis is a relatively benign self-limited disease. A prospective study in children less than 2 years of age, for example, found that even in the 9% of children who develop evidence of acute neurologic disease (complex seizures, increased intracerebral pressure, or coma) their long-term prognosis is excellent. During long-term follow up (42 months of age), children with acute CNS complications performed neurodevelopmental tasks and achieved developmental milestones as well as children with an uncomplicated course (28). An overview of the approach to a patient with suspected viral CNS disease is presented in a later section.

Antibody preparations and the antiviral agent pleconaril have shown activity against enterovirus in small series (42, 43) and animal studies (44–46). However, randomized controlled trials have not supported their routine use in enterovirus meningitis (47, 48). The literature contains case reports of immunoglobulin preparations improving outcome in agammaglobulinemic patients with enteroviral meningitis. However, immunoglobulin use in these patients does not eliminate the virus from the CSF or prevent chronic enteroviral meningitis (1). Enteroviral infections in neonates frequently produce overwhelming viremia and CNS disease. Ten percent of neonates with systemic enteroviral infections die, and as many as 76% are left with permanent sequelae. Standard intravenous immunoglobulin does not provide clinical benefit for neonates with severe life-threatening enteroviral infection (42). While the role of antibody lies in immunocompromised patients with life-threatening enteroviral infections remains debatable, there are currently no data supporting the use of immunoglobulin preparations for non-life-threatening infections in the normal host.

Specific antiviral agents are available for meningitis of several other etiologies. Although no definitive clinical trials have been conducted, most experts recommend the use of IV acyclovir for HSV meningitis, as it decreases the duration of primary herpes disease and may limit meningeal involvement (49). Recurrent HSV-2 meningitis is rare, and recently a single case of meningitis associated with HSV-1 reactivation was reported. At this time there are no data on benefits of antiviral treatment or suppressive therapy for recurrent HSV CNS disease (1, 50). Effective antiviral therapy exists for VZV infections of the CNS and should be instituted in these patients (51, 52). For CMV CNS infection in the immunocompromised host, therapy is problematic and should be tailored based upon the clinical likelihood of infection.

## VIRAL ENCEPHALITIS

### Epidemiology and Prevalence

Similar to the case with viral meningitis, passive reporting systems underestimate the incidence of viral encephalitis (1). An estimated 20,000 cases of encephalitis occur each year in the United States; however, the CDC received only 740 (0.3/100,000) to 1340 (0.54/100,000) annual reports of persons with encephalitis from 1990 to 1994 (1). A review of the cases in Olmsted County, Minnesota, from 1950 to 1980 found the incidence of viral encephalitis was at least twice as frequent as that reported by the CDC (6). A prospective study in Finland demonstrated similar results, with the incidence of encephalitis being 10.5/100,000 (53).

Although nucleic acid-based diagnostic testing has enhanced the detection of many viruses, a viral etiology is not found in the majority (83%) of cases of encephalitis (12). While the etiology of encephalitis has changed with alter-

tations in the viral reservoirs in North America, the overall death rates from encephalitis have not changed since the late 1970s to 1980s (54). HSV CNS infections occur without seasonal variation, affect all ages, and constitute the majority of fatal cases of endemic encephalitis in the United States (1). Arboviruses, a group of over 500 arthropod-transmitted RNA viruses, are the leading cause of encephalitis worldwide and in the United States (4). Arboviral infections occur in epidemics and show a seasonal predilection, reflecting the prevalence of the transmitting vector (1). Asymptomatic infections vastly outnumber symptomatic infections. Patients with disease may develop a mild systemic febrile illness or viral meningitis (1). Encephalitis occurs in a minority of people with arboviral infections, but the case-fatality rate varies extremely, from 5% to 70%, depending upon viral etiology and age of the patient. Neuroinvasive WNV infections now far outnumber other arboviral causes of encephalitis in the United States (55), although it is unknown if this is because of improved testing and more active surveillance. Historically, LaCrosse encephalitis has been the most commonly reported arboviral disease in the United States, while St. Louis encephalitis is the most frequent cause of epidemic encephalitis (1, 56). Characteristically, Eastern equine encephalitis (EEE) and most arboviral infections occur in the late summer following amplification of the virus due to peak mosquito activity (1). In warm climates the clinician must have a high index of suspicion for insect-borne diseases.

Japanese B encephalitis and rabies constitute the majority of cases of documented encephalitis cases outside of North America. Japanese encephalitis virus, a mosquito-transmitted member of the flavivirus genus, occurs throughout Asia and causes epidemics in China despite routine immunization (1, 57). In warmer locations, the virus is endemic (1, 58). The disease typically affects children, although adults with no history of exposure to the virus are also susceptible (1). As with the other arboviral infections, asymptomatic infections occur more frequently than symptomatic infections. However, the disease has a high case-fatality rate and leaves half of the survivors with a significant degree of neurologic morbidity (1).

Rabies virus remains endemic in much of the world. In the United States human cases have decreased over the last decades to 1 to 3 cases per year as a result of the immunization of domesticated animals. Bats are increasingly recognized as a source of infection. In one study, 15% percent of bats tested carried rabies virus (59). Since 1990, bat-associated variants of the virus have accounted for 24 of the 32 cases in the United States. In most cases there was no evidence of a bite, although in half of the cases direct contact (handling of the bats) was documented (60). In areas outside the United States, human cases of rabies encephalitis number in the thousands and are caused by unvaccinated domestic animals, principally dogs, developing infection following contact with infected wild animals and exposure to bat guano (61).

Postinfectious encephalitis, an acute demyelinating process also referred to as acute disseminated encephalomyelitis (ADEM) or autoimmune encephalitis, accounts for approximately 100 to 200 additional cases of encephalitis annually in the United States (1, 62). The disease historically was responsible for approximately one third of the encephalitis cases in the United States and was associated with preceding measles, mumps, and other exanthematous viral infections (1, 62). Postinfectious encephalitis in the United States is now associated with antecedent upper respiratory virus (notably influenza virus) and varicella infections (1).

Measles continues to be the leading cause of both acute encephalitis, in the absence of vaccination, and post-infectious encephalitis worldwide and complicates 1 of every 1000 measles infections (1). Autoimmune CNS damage and an ADEM process has also been reported following cases of acute encephalitis and in paraneoplastic syndromes. Some patients develop N-methyl-D-aspartate (NMDA) autoantibodies with their paraneoplastic syndrome 1 to 4 weeks following acute encephalitis (34, 63). Recent studies suggest that antigenic variation in the N-terminal domain of the NMDA receptor may predispose some patients to the autoimmune encephalitis (35, 64).

The slow infections of the CNS or transmissible spongiform encephalopathies (TSE) occur sporadically worldwide. The prototypical TSE is Creutzfeldt-Jacob disease (CJD); occurs at high rates within families and has an estimated incidence of 0.5 to 1.5 cases per million populations (5). In 1986, cases of a TSE in cattle termed bovine spongiform encephalopathy (BSE) were reported in the United Kingdom. In addition to affecting other livestock throughout Europe that were fed supplements containing meat and bone meal, cross-species transmission of BSE has been documented, leading to a ban in the use of bovine offal in fertilizers, pet food, and other animal feed (5). A decrease in recognized cases of BSE has occurred since the institution of these restrictions. Concomitant with the increased cases of BSE in Europe, an increase in cases of an atypical Creutzfeldt-Jacob disease also occurred, suggesting animal-to-human transmission. The report of atypical CJD (unique clinical and histopathologic findings) affecting young adults (an age at which CJD rarely has been diagnosed) and a characteristic methionine at the polymorphic codon 129 led to the designation of a new disease, variant Creutzfeldt-Jacob disease (vCJD). As of 2006, a total of 160 cases of vCJD were diagnosed in the United Kingdom (UK) and 28 cases outside of the UK (65).

### Pathogenesis

The pathogenesis of encephalitis requires that viruses reach the CNS by hematogenous or neuronal spread. Similar to meningitis, viruses most frequently access the CNS after a high-titer secondary viremia and cell-free or cell-associated CNS entry (4). Other than direct entry via cerebral vessels, the virus can initially infect the meninges and CSF and then enter the parenchyma across either ependymal cells or the pial linings. Viruses exhibit differences in neurotropism and neurovirulence; receptor requirements are one determinant of viral neurotropism. For example, enteroviruses with similar receptors produce very different diseases. Five coxsackie B viruses (types B1 to B5) readily produce CNS infections while type B6 rarely produces neurologic infection (4, 66). Viral genes have been discovered that influence the neurovirulence of HSV-1 (67). Mutant HSV-1 viruses with either  $\gamma_134.5$  gene deletions or stop codons inserted into the gene have a decreased ability to cause encephalitis and death following intracerebral inoculation in mice as compared to wild-type virus (67, 68).

In addition to viral factors, host physiology is also important in determining the extent and location of viral CNS disease. Age, sex, and genetic differences among hosts influence viral infections and clinical course (11, 69). Host age influences the clinical manifestations and sequelae of viral infections. For example, sindbis virus infection produces lethal encephalitis in newborn mice, while weanling mice experience persistent but nonfatal encephalitis. The reason for the difference in outcome is twofold. Mature neurons re-

sist viral-induced apoptosis and older mice have an improved antibody response, thus limiting viral replication (69). Variations in macrophage function among individuals can result in clinically distinct infections and disease. Moreover, macrophage-antigen response can change with age and is important in limiting spread of infection within a patient (1). In addition to age, physical activity may be another important host factor that determines the severity of infection. Exercise has been associated with increased risk for paralytic poliomyelitis and may result in an increased incidence of enteroviral myocarditis and aseptic meningitis (1). Increasingly, host differences are recognized as equally important determinants of disease at the cellular and molecular levels.

Historically, the peripheral neural pathway was considered the only pathway of viral neurologic infection, although contemporary data demonstrate that the circulatory system is more commonly implicated (1). Herpes simplex virus and rabies are examples of viruses that infect the CNS by neuronal spread. Sensory and motor neurons contain transport systems that carry materials along the axon to (retrograde) and from (anterograde) the nucleus. Peripheral or cranial nerves provide access to the CNS and shield the virus from immune regulation. Lastly, olfactory nerve transport to the CNS is a logical explanation for HSV infections of the brain when the nasopharynx is a site of viral replication.

Rabies classically infects through the myoneural route and provides a prototype for peripheral neuronal spread (4, 60). Rabies virus replicates locally in the soft tissue following a bite by a rabid animal. After primary replication, the virus enters the peripheral nerves by binding to acetylcholine receptors. Once in the muscle the virus buds from the plasma membrane, crosses myoneural spindles, or enters across the motor end plate (4). The virus travels by anterograde and retrograde axonal transport to infect neurons in the brainstem and limbic system. Eventually the virus spreads from the diencephalic and hippocampal structure to the remainder of the brain, killing the animal (4).

Virus also infects the CNS through cranial nerves. Animal studies have shown that HSV can infect the brain through the olfactory system as well as the trigeminal nerve (4). Early HSV encephalitis damages the inferomedial temporal lobe that contains direct connections with the olfactory bulb (1). The route of human HSV infections, however, is less clear. Despite data supporting olfactory and trigeminal spread of virus to the CNS, definitive proof in humans is lacking. The association of viral latency in the trigeminal ganglia, the relative infrequency of herpes simplex encephalitis (HSE), and the confusing data regarding encephalitis from HSV reactivation suggest that the pathogenesis is more complex than described above (49).

In patients with acute encephalitis, the parenchyma exhibits neuronophagia and cells containing viral nucleic acids or antigens. The pathologic findings are unique for different viruses and reflect differences in pathogenesis and virulence. In the case of typical HSV encephalitis, hemorrhagic necrosis occurs in the inferomedial temporal lobe with evidence of perivascular cuffing, lymphocytic infiltration, and neuronophagia (4). Pathological specimens in animals with rabies encephalitis have microglial proliferation, perivascular infiltrates, and neuronal destruction. The location of the pathological findings can be limited to the brainstem areas (dumb rabies) or the diencephalic, hippocampal, and hypothalamic areas (furious rabies) based on the immune response mounted against the infection (4).

Some viruses do not directly infect the CNS but produce immune system changes that result in parenchymal damage.

Patients with postinfectious encephalitis (ADEM) exhibit focal neurologic deficits and altered consciousness temporally associated with a recent (1 to 2 week) viral infection or immunization (62). Pathologic specimens, while they show evidence of demyelination by histologic or radiographic analysis, do not show evidence of viral infection in the CNS in culture or antigen tests. Patients with postinfectious encephalitis have subtle differences in their immune systems, and some authors have proposed an autoimmune reaction as the pathogenic mechanism of disease (1). Postinfectious encephalitis occurs most commonly following measles, VZV, mumps, influenza, and parainfluenza infections. With immunization the incidence of postinfectious encephalitis has decreased in the United States; however, measles continues to be the leading cause of postinfectious encephalitis worldwide (1). As noted above, in addition to the postinfectious process, patients with paraneoplastic syndrome and autoantibodies to NMDA autoantibodies have also recently been described (34). Recent studies suggest that antigenic variation in the N-terminal domain of the NMDA receptor may predispose these patients to autoimmune encephalitis (35). A subset of patients developed anti-NMDA autoantibodies 1 to 4 weeks following HSE that leads to recurrent immune-mediated encephalitis, complicating their recovery.

The TSEs are noninflammatory CNS diseases involving the accumulation of an abnormal form of a normal glycoprotein, the prion protein (PrP) (1). These encephalopathies differ in mode of transmission. While most of the TSEs are experimentally transmissible by direct inoculation in the CNS, this mode rarely occurs except for iatrogenic transmissions (70). The scrapie agent spreads by contact and lateral transmission. There is no evidence for lateral transmission for BSE or vCJD and all cases appear to have occurred following parenteral or ingestion of affected materials. The transmissible agents remain infectious after treatments that would normally inactivate viruses or nucleic acids (detergent formalin, ionizing radiation, nucleases) (1). Most of the experimental work on TSEs has involved analysis of the scrapie agent. The current working model is that post-translational alteration of the normally  $\alpha$ -helical form of the PrP protein results in a protease resistant  $\beta$ -pleated sheet structure that accumulates in neurons leading to progressive dysfunction, cell death, and subsequent astrogliosis. In studies on the scrapie agent and vCJD, gastrointestinal tract involvement with infection of abdominal lymph nodes occurs first, followed by hematogenous spread through the reticuloendothelial system and brain involvement a year or more later (1, 71). Experimental subcutaneous inoculation in mice and goats also led to local lymph node involvement, followed by splenic spread and then CNS involvement. Cases of vCJD through blood transfusion have also occurred (72). Based upon animal studies, there is an equal distribution of the agent associated with leukocytes and free in the plasma, with negligible levels associated with the red blood cells and platelets (73).

### Clinical Manifestations

Patients with encephalitis have clinical and laboratory manifestations of parenchymal disease; however, infection rarely involves only the brain parenchyma. Some viruses (rabies, herpes B virus) produce encephalitis without significant meningeal involvement; however, most patients with encephalitis have concomitant meningitis. Most patients also have a prodromal illness with myalgias, fever, and anorexia, reflecting the systemic viremia. Neurologic

symptoms can range from fever, headache, and subtle neurologic deficits or change in level of consciousness to severe disease with seizures, behavioral changes, focal neurologic deficits, and coma (4). Clinical manifestations reflect the location and degree of parenchymal involvement and differ based on viral etiology. For example, HSE infects the inferomedial frontal area of the cortex, resulting in focal seizures, personality changes, and aphasia. These symptoms reflect the neuroanatomical location of infection with inflammation near the internal capsule and limbic and Broca's regions (4). Paraesthesias near the location of the animal bite and changes in behavior correlate temporally with the axoplasmic transport of rabies and the viral infection of the brainstem and hippocampal region (1, 74). Rabies has a predilection for the limbic system, thereby producing personality changes. The damage spares cortical regions during this phase, so that humans may vacillate between periods of calm, normal activity and short episodes of rage and disorientation (4). Alternatively, Japanese encephalitis virus initially produces a systemic illness with fever, malaise, and anorexia, followed by photophobia, vomiting, headache, and changes in brainstem function. Most children die from respiratory failure and frequently have evidence of cardiac and respiratory instability, reflecting Viremia spread via the vertebral vessels and infection of brainstem nuclei (4). Other patients have evidence of multifocal CNS disease involving the basal ganglia, thalamus, and lower cortex and develop tremors, dystonia, and parkinsonian symptoms (4).

Encephalitis, unlike meningitis, often has high mortality and complication rates but these differ based on the viral etiology and host factors (91, 75). For example, St. Louis encephalitis virus has an overall case mortality of 10%; the rate is only 2% in children but increases to 20% in the elderly (76). Other viruses like Western equine and Eastern equine encephalitis produce higher mortality and morbidity in children than in adults (76).

The TSEs are slowly progressing diseases with long incubation periods. Sporadic CJD occurs between the ages of 50 and 70 years of age and is characterized by dementia, tremors, and, more rarely, abnormal movements and ataxia. Unlike sporadic CJD, vCJD disease affects young adults and adolescents; it produces cerebellar ataxia and sensory involvement (dysesthesias) with florid amyloid plaques detected in the brain on autopsy. Neurologic deterioration progresses relentlessly, and most patients die less than a year after onset of their neurologic manifestations.

### Laboratory Findings and Diagnosis

Establishing a diagnosis requires a meticulous history, knowledge of epidemiologic factors, detailed microbiologic studies, and a systematic evaluation of other possible treatable diseases. In the past, investigators failed 50% to 75% of the time to identify an etiology for encephalitis depending on the study and diagnostic tests used (1). CSF pleocytosis usually occurs in encephalitis but is not necessary for the diagnosis. White blood cell counts in CSF typically number in the 10's to 100's in viral encephalitis (1). Cerebrospinal glucose levels are usually normal although some viral etiologies (e.g., EEE) produce CSF parameters consistent with acute bacterial meningitis (1). Some viruses (e.g., HSV) produce a hemorrhagic necrosis and the CSF exhibits this by moderately high protein levels and evidence of red blood cells. Supratentorial and cerebellar tumors can produce increased intracranial pressure and can mimic encephalitis. A careful fundoscopic exam and appropriate radiographic imaging should be performed prior to obtaining CSF to rule out

any evidence of papilledema and increased intracranial pressure.

Unlike meningitis, encephalitis often requires additional laboratory and radiologic tests to establish the diagnosis. Historically, the standard for diagnosis was brain biopsy and viral isolation. For many viruses (e.g., HSV, enterovirus, EBV, VZV, John Cunningham [JC] virus, HHV6, tick-borne encephalitis [TBE]) detection of viral nucleic acids by PCR or RT-PCR from the CSF has replaced culture and brain biopsy as the standard for diagnosing encephalitis (1, 77, 78). Computerized tomography (CT scan) and magnetic resonance imaging (MRI) are needed to look for focal encephalitic changes, parenchymal necrosis or bleeding, demyelination, and mass lesions. The increased sensitivity of MRI to alterations in brain water content and the lack of bone artifacts make this the neuroradiologic modality of choice for CNS infections (79, 80). MRI and especially diffusion-weighted imaging detect parenchymal changes earlier than CT scan and better defines the extent of a lesion (81). Furthermore, MRI is more sensitive for detecting evidence of demyelinating lesions in the periventricular and deep white matter, thus enabling differentiation of parainfectious from acute viral encephalitis. Patients with viral encephalitis frequently have diffuse or focal epileptiform discharges with background slowing on electroencephalogram (EEG) (4). These EEG changes precede CT scan evidence of encephalitis and provide a sensitive although nonspecific diagnostic test. EEG changes in the temporal lobe area strongly support the diagnosis of HSE; however, the absence of these changes does not rule out HSE.

Historically, patients with viral encephalitis required a battery of different diagnostic tests. HSV encephalitis, for example, could be diagnosed acutely by brain biopsy and viral culture or retrospectively by CSF antibody and convalescent serologic tests (4). The diagnosis of enterovirus meningitis previously required acute virus isolation from the throat or rectum acutely or retrospective serologic studies. Molecular techniques are not routinely used for the diagnosis of most viral CNS infections (4, 82). Primers also exist for the detection of certain arboviral encephalitides (California encephalitis group, Japanese encephalitis, West Nile, St. Louis encephalitis, dengue fever serotypes 1–4, and yellow fever viruses); however the development of universal arboviral primers has been more difficult (1, 4, 38). The successful detection of viral nucleic acids in the CSF is influenced by the duration, extent, and etiology of disease. The laboratory test is relatively rapid, has high sensitivity, and provides a less invasive means to diagnose encephalitis. For example, only 4% of CSF cultures are positive in patients with sporadic HSE; in patients with biopsy-proven HSE, CSF PCR has a sensitivity of greater than 95% and a specificity approaching 100% (83). Interestingly, in the three cases where the CSF PCR was positive but the brain biopsy negative, biopsy samples had been improperly prepared prior to viral culture or the biopsy site was suboptimal (1). Recently, efforts have focused on correlating viral nucleic acid copy as an indicator of virus quantity to predict clinical outcome (84).

The clinical diagnosis of a TSE is supported by detection of characteristic EEG changes (periodic sharp and slow wave complexes), presence of 14–3–3 protein in the CSF, and characteristic MRI findings (increased signal in the basal ganglia in vCJD or evidence of increased signal in the posterior pulvinar in vCJD) (85). Most laboratory tests are of little value in the diagnosis in humans. CSF examination shows normal values or slightly elevated protein levels. The

EEG in classic CJD reveals generalized slowing early in the disease and biphasic or triphasic peaks late in the disease with the onset of myoclonus. MRI changes late in the illness reveal global atrophy with hyperintense signals from the basal ganglia (5). Diffusion-weighted imaging and fluid attenuation inversion recovery (FLAIR) remain the most reliable and sensitive imaging techniques for CJD (85, 86). Histopathologic examination of the brain using a specific antibody to the PrP-res protein confirms the disease. In addition, evidence of gliosis, neuronal loss, and spongiform changes support the diagnosis. In cases of vCJD, characteristic microscopic amyloid plaques (so-called florid plaques) define the disease. The florid plaques are not seen in other TSEs and consist of flower-like amyloid deposits surrounded by vacuolar halos. The detection of PrP-res in the tonsillar tissue by immunohistochemical staining is also strongly supportive of a vCJD diagnosis (5).

### Differential Diagnosis

Identifying treatable disease expeditiously is a priority in patients presenting with neurologic changes. In patients with suspected HSE undergoing brain biopsy for confirmation, alternative diagnoses are frequently found. Of 432 patients, only 45% had biopsy-confirmed HSE and 22% had another etiology established by brain biopsy (3). Of these, 40% had a treatable disease (9% of the biopsy group) including bacterial abscess, tuberculosis, fungal infection, tumor, subdural hematoma, or autoimmune disease. The majority of the remaining 60% identifiable but non-treatable causes for encephalitis were of viral etiology. Disease in a third group of 142 patients (33%) went undiagnosed even after brain-biopsy and the conventional diagnostic tests.

Pathologic processes in the CNS have limited clinical expressions and thus often produce similar signs and symptoms (4). Other causes of encephalitis are presented in Table 3. Mass lesions in the CNS (tumor, abscess, or blood) can cause focal neurologic changes, fever, and seizures, similar to encephalitis. Metabolic (hypoglycemia, uremia, inborn errors of metabolism) and toxin-mediated disorders (ingestion, tick-related paralysis, or Reye syndrome) can cause decreased consciousness, seizures, and background slowing on EEG. Limbic encephalitis can produce protracted encephalitis and is caused by paraneoplastic phenomena. Furthermore, treatable infectious causes of encephalitis must be vigorously investigated. Mycoplasma produces demyelinating brainstem encephalitis in approximately 0.1% of infections.

### Prevention

Prevention of the initiating viral infection remains the best means to reduce risk of viral encephalitis. Live attenuated vaccines against measles, mumps, and rubella have resulted in a dramatic decrease in the incidence of encephalitis in industrialized countries. Measles continues to be the leading cause of postinfectious encephalitis in developing countries, however, and complicates 1 of every 1000 measles infections (1). Widespread polio vaccination has eradicated the disease at present from the Western Hemisphere and most other countries. Vaccines exist for some arboviral infections and, of course, rabies. Vaccination against Japanese encephalitis virus has reduced the incidence of encephalitis in Asia but cases still occur annually (57, 87, 88).

Vaccination and antiviral chemoprophylaxis are either not available or cost-effective for preventing many viral infections. For example, vector avoidance, the use of mosquito deterrents, and mosquito abatement programs are less costly strategies for preventing arboviral encephalitides in

the United States (1, 89). Pre- and immediate postexposure prophylaxis are the only ways known to prevent death in rabies-exposed individuals (90). Individuals exposed to rabies require vigorous cleansing of the wound, postexposure vaccination, and direct administration of rabies hyper-immunoglobulin at the site of the animal bite. Individuals with frequent contact with potentially rabid animals (veterinarians, animal control staff, workers in rabies laboratories, and travelers to rabies-endemic areas) should receive preexposure vaccination. The FDA has implemented guidelines eliminating whole blood or blood components prepared from individuals who later developed CJD or vCJD to reduce the potential exposure to TSE agents in the blood supply. While four cases of transfusion associated vCJD have been reported, the risk associated with packed red blood cells (PRBC) and platelet transfusion is less than that for patients receiving large amounts of whole blood (73). Changes in agricultural practices in Europe, testing for affected cattle, and bans on infected cattle have been associated with decline in cases of vCJD. In North America no cases of vCJD have been reported and the Department of agriculture has programs in place to monitor for TSEs in livestock (91).

### Treatment

Patients with encephalitis require treatment tailored to the etiology and clinical situation. Currently few antiviral medications are available to treat CNS infections. Antiviral therapy exists for HSV-1, HSV-2, VZV, CMV, and HIV. The introduction of acyclovir has resulted in a sharp decline in

mortality and morbidity from HSV infections; neonatal mortality from disseminated HSV disease and HSE has declined from 70% to 40% and antiviral treatment also reduces the severity of neurologic impairment (1). Varicella immunoglobulin (VZIG) and acyclovir have reduced the complications from primary VZV infection and zoster in neonates and immunocompromised patients. Although controlled trials have not evaluated the efficacy of acyclovir in VZV encephalitis, the medication is routinely used to treat this complication (1, 92). Ganciclovir and foscarnet are used for the treatment of CMV encephalitis although controlled clinical trials have not confirmed the efficacy of this treatment. Antiretroviral therapy appears to decrease the frequency and severity of HIV CNS disease, but studies have not determined if this is because of a direct reduction in HIV viral activity in the CNS or a secondary effect as a result of improved immune function and decreased opportunistic infections affecting the CNS (93).

In cases of postinfectious encephalitis or ADEM, no randomized controlled trial has confirmed the benefit of immunomodulatory drugs. In practice clinicians often treat ADEM with different immunomodulators in an attempt to limit T-cell-mediated destruction of the CNS (62). It must be emphasized, however, that immunomodulatory therapy is based on isolated case reports and series. Clinical failures and iatrogenic morbidity from a therapeutic modality are rarely ever reported.

### Approach to Patients with Viral CNS Disease

The approach to a patient with a presumed CNS viral infection must be tailored to the severity and distribution of neurologic involvement. The degree of diagnostic as well as therapeutic intervention differs based on the type of CNS disease. The examination and radiographic and laboratory studies available for establishing a diagnosis must be prioritized based on the likely etiology and the stability of the patient. For example, a patient with photophobia and nuchal rigidity but a nonfocal neurologic examination does not require invasive intracranial pressure monitoring as would a patient with encephalitis and evidence of increased intracranial pressure. After establishing the degree of CNS disease by history and physical exam and stabilizing the patient (airway, breathing, and circulation), the clinician next must ascertain a diagnosis.

Treatable causes of CNS dysfunction require rapid evaluation and intervention in an effort to prevent further or permanent CNS damage. Potentially treatable diseases (e.g., HSE, VZV, fungal infections, partially treated bacterial meningitis, tuberculous meningitis, parameningeal infection, mycoplasma, and fastidious bacterial infections) can mimic viral CNS disease and should be vigorously investigated before attributing the illness to a viral etiology for which no specific antiviral is available. The same logic applies to treatable viral infections and noninfectious etiologies. After establishing a presumptive diagnosis and instituting therapy, the clinician must vigilantly anticipate and treat complications associated with the viral CNS disease or the therapeutic interventions. Seizures secondary to direct viral CNS damage, inflammatory vasculitis, and electrolyte changes require anticonvulsant therapy with benzodiazepams, phenytoin, and barbiturates (1). Patients with cerebral edema may require intracranial pressure monitoring and hyperventilation, osmotic therapy, and CSF removal in an attempt to maintain cerebral pressures (1). The ultimate goal of intracranial pressure monitoring is to maintain adequate cerebral perfusion. While a physician

struggles to maintain an adequate intravascular blood volume, intracranial pressures can rise to dangerous levels as capillary leaks complicate the patient's course. The risks of increased intracranial pressure from aggressive fluid resuscitation or the syndrome of inappropriate antidiuretic hormone release necessitates fastidious fluid management and frequent electrolyte monitoring. Cardiac arrhythmias can also develop in patients with encephalitis secondary to electrolyte changes or brainstem damage. Cardiac and respiratory arrest can occur early in disease; therefore, equipment for intubation and cardioversion should be readily available for a patient with encephalitis. In addition to the direct damage the virus can cause in the CNS, certain viruses can also produce systemic damage that complicates the management of the CNS disease. Patients can develop overwhelming hepatitis, pneumonitis, disseminated intravascular coagulation, and shock. Patients in coma from encephalitis can recover after long periods of unconsciousness. The physician should strive to limit the amount of iatrogenic damage and vigorously support the patient during the acute phase of the illness.

# Gastrointestinal Syndromes

EYAL LESHEM AND UMESH D. PARASHAR

## 4

Gastroenteritis is a major cause of morbidity and mortality in humans, and viruses are important causes of this disease. While many viruses have been associated with diarrhea in humans, we know most about rotavirus because the methods used to detect it are best developed. Rotavirus remains the most important cause of severe diarrhea in children worldwide. Implementation of effective vaccines has resulted in a substantial reduction of the rotavirus disease burden. As rotavirus incidence drops in countries with mature vaccination programs, norovirus is increasingly being recognized as a major cause of pediatric diarrhea.

The gastroenteritis viruses fall into two distinct epidemiologic groups: those that cause common childhood diarrhea in early life—rotavirus, adenovirus, caliciviruses (norovirus and sapovirus), and astrovirus—and those responsible for epidemic disease, primarily noroviruses but also astrovirus and group B rotavirus.

All of these viruses cause a clinical syndrome of diarrhea and vomiting that is generally similar, extraintestinal manifestations of disease are rare. Some groups of people are at particularly high risk for disease with these agents by virtue of their age (the young and the old), their extent of exposure, or their host susceptibility.

The primary treatment of all these diseases is fluid and electrolyte replacement. Prevention of the main childhood disease, rotavirus diarrhea, is based on widely used live-attenuated oral vaccines. Prevention of viral gastroenteritis epidemics will rest with the identification of the vehicle of infection, interruption of the mode of transmission, and the potential development of vaccines.

### INTRODUCTION

Gastroenteritis is one of the most common illnesses affecting infants, children, and adults and accounts for over 500,000 deaths annually in children under 5 years of age worldwide (1, 2). The term *gastroenteritis* implies an inflammation of the stomach and intestine, but, depending on the specific etiology, the pathophysiology of illness can be quite diverse. In fact, gastroenteritis can be caused by multiple different pathogens—viruses, bacteria, parasites—many of which produce no inflammation and some of which are increasingly being recognized as potential vaccine preventable diseases. The clinical presentation can vary widely from purely upper

gastrointestinal symptoms of vomiting (e.g., winter vomiting disease) to acute diarrhea without any upper gastrointestinal complaints (3). Although gastroenteritis most often presents as mild diarrhea, it is a frequent cause of severe disease, leading to hospitalizations and deaths among infants, children, and the elderly, particularly among infants and children in developing countries. Acute gastroenteritis episodes are characterized by a range of symptoms, including abdominal cramping, malaise, anorexia, headache, myalgia, nausea, vomiting, and diarrhea. These symptoms can appear alone or together and can mimic illness caused by toxins, drugs, or other medical conditions. In this chapter, we will use the terms gastroenteritis and diarrhea interchangeably and will concentrate on those illnesses caused specifically by viruses.

### HISTORICAL BACKGROUND

Our understanding of the role played by gastrointestinal viruses has been determined by our ability to detect these agents through direct observation, measurement of an immune response to infection or through genetic analysis of clinical specimens collected from patients (Table 1). Historically, viruses have been implicated as agents of acute gastroenteritis when no other pathogens could be identified in fecal specimens (4). Moreover, as recently as 1970, infectious agents could be identified in such a small percentage of patients with diarrhea that explanations such as the diarrhea of malnutrition, weaning, or physiologic constitution were invoked as the underlying cause of these disease episodes.

The ability to detect viral agents of gastroenteritis has followed the major historical advances in virology (Table 1). Early investigators demonstrated that “transmissible agents” present in fecal filtrates were able to transmit gastroenteritis to animals and humans (4). With the refinement of cell culture techniques for growing viruses from the 1950s through 1970s, a new generation of advances saw a number of viruses—echoviruses, adenoviruses, and coxsackie A and B viruses—isolated from fecal specimens of patients with diarrhea (5–8). Although these viruses were identified from patients with symptoms of gastroenteritis, establishing these agents as causes of disease has been challenging because these viruses have also been isolated from patients who had other syndromes or were asymptomatic.

**TABLE 1** Historical advances in the identification of viral agents of gastroenteritis

Year	Agent	Advance and comment
1940–1950	“Transmissible” agents	Fecal filtrates transmit gastroenteritis in animals and humans
1950–1970	Echoviruses, adenoviruses, Coxsackie A and B viruses	Viruses cultivated from stools of patients with diarrhea; causal relationship to disease unclear
1972	Norwalk virus Rotavirus group A	First virus clearly associated with diarrhea (9) Virus discovered by Bishop et al. (10) in duodenal mucosa and now recognized as the most common cause of severe diarrhea in children
1975	Enteric adenovirus serotypes 40 and 41, group F Astrovirus	Unique serotypes and group of fastidious adenoviruses associated with diarrhea Virus rarely identified in fecal specimens now recognized to be a more common cause of disease in children
1979	Calicivirus	“Classic” human calicivirus associated with disease in children, genetically related to the Norwalk family of viruses
1980s	Rotavirus groups B and C	Pathogens recognized in animals found to cause disease in humans; animal and human strains distinct
1970s–1980s	Norwalk-like viruses or SRSVs now recognized to be human caliciviruses, e.g., Snow Mountain agent, Hawaii agent, Toronto agent, minireovirus, Parramatta agent, Taunton agent, Montgomery County agent, and Desert Storm virus	Each virus morphologically identical but antigenically and genetically distinct; variant in the family <i>Caliciviridae</i>
1980s–1990s	Novel agents, e.g., torovirus, picobirnavirus, and enterovirus 22	Found in fecal specimens of patients with diarrhea more often than controls, but full association with disease is unclear
2000s–2015	Population based viral gastroenteritis burden studies	Following widespread rotavirus vaccine implementation, norovirus shown to be the most common cause of medically attended acute gastroenteritis in the U.S. (21)

In 1972, the Norwalk agent became the first virus discovered that was determined to be a causative agent of gastroenteritis (9). Using immune electron microscopy, Kapikian visualized grape-like clusters of small, round structured viruses (SRSVs) in fecal specimens of patients in an outbreak of diarrhea, but not in controls, and applied the same technique to document the patients’ immune response. Since then, electron microscopy has been critical to identifying or confirming all the new viral agents of gastroenteritis including rotaviruses (10), adenovirus (11), astroviruses (12), and the “classic human” caliciviruses (13). Human caliciviruses have been placed in their own genus, *Norovirus* (previously called “Norwalk-like viruses”), along with *Sapovirus* (previously denoted as “Sapporo-like viruses”) (14).

While many viruses have been identified in fecal specimens, the etiologic association of these viruses with disease requires further investigation and must meet four essential criteria for causality. In order to document an infection causing disease, the patient should exhibit a measurable immune response to the specific agent. The virus should also be present more often in patients with gastroenteritis than in persons without gastroenteritis (typically asymptomatic controls) (15). The onset of clinical signs and symptoms should temporally correspond with the onset of virus detection, and the termination of disease should in some way correspond with the end of detection. Some viruses from fecal filtrates have been given to animals to demonstrate the biological plausibility of illness, as well as to volunteers to fulfill Koch’s postulates of disease causation. Consequently, while many viruses have been found in fecal specimens, some like torovirus (16), picobirnavirus (17), parechoviruses (15), coronaviruses (18), aichiviruses (19), and pestivirus

(20), have yet to fulfill these strict criteria and be accepted as pathogens of the gastrointestinal tract in humans (15). These agents will require further laboratory, clinical, and epidemiologic investigations in order to confirm their association with gastrointestinal disease.

We now suspect that—at least in the United States—most gastrointestinal illnesses in children are due to viruses (15, 21). However, our understanding of the full spectrum of disease associated with these viruses, with the exceptions of rotavirus and to some extent norovirus, remains incomplete.

## VIRAL AGENTS

The viral agents that are proven causes of gastroenteritis fall into four distinct families—rotaviruses (*Reoviridae*), human caliciviruses (*Caliciviridae*), enteric adenoviruses (*Adenoviridae*), and astroviruses (*Astroviridae*) (Table 2; Figure 1) (15). The diversity in viral genomic structures among these agents ranges from those containing single-stranded RNA (astroviruses, caliciviruses) to those with double-stranded RNA (rotaviruses), and to those with double-stranded DNA (adenoviruses). Despite the diversity of these agents and their epidemiologic characteristics, the clinical presentations of disease caused by these agents are indistinguishable. Moreover, while viruses in the same families also cause disease in animals, the amount of transmission between animals and humans is likely to be limited, if present at all. All of these viruses can be detected using electron microscopy, but the amount of virus shed in fecal specimens ranges from  $10^{12}$  particles per gram (rotavirus) to subdetectable levels ( $<10^6$ ) in norovirus infections. Our knowledge of the epidemiology of these agents is a direct function of both this level of

**TABLE 2** Microbiological and epidemiological characteristics of viral agents that cause gastroenteritis

Virus	Microbiological characteristics		Epidemiological characteristics	
	Morphology	Detection method	Setting	Comment
Rotavirus				
Group A	70 nm double-capsid wheel-shaped (“rota”) virus with 11 segments of dsRNA	EIA, EM, PAGE, RT-PCR, culture	Endemic in children  Outbreaks in high-risk groups in adults	Globally, the most common cause of severe diarrhea in children; accounts for ca. 13% hospitalizations for diarrhea in U.S. children; mode of transmission unknown  Affects travelers, immunocompromised patients, parents of infected children, elderly residents of aged-care facilities, and caretakers in day care centers
Group B	Same as group A	EM, PAGE, EIA, RT-PCR	Epidemic	Associated with cholera-like disease in adults; transmitted by water
Group C	Same as group A	EM, PAGE, EIA, RT-PCR	Epidemic	Worldwide distribution; outbreaks in children (newborns to school-age); mode of transmission and prevalence of outbreaks unknown
Noroviruses (human calicivirus)	27 to 32 nm SRSV with ssRNA	EM (IEM), RT-PCR/Southern blot hybridization; RT-PCR; seroconversion using expressed antigens	Epidemic and endemic in all age groups	The most common cause of childhood diarrhea in the U.S.; accounts for 17% of diarrhea hospitalizations in children aged <5; most common cause of sporadic gastroenteritis and diarrheal outbreaks; all age groups affected; transmission via person to person contact, contaminated food, shellfish, and water
Sapoviruses (human calicivirus)	Distinguishable by EM from Norwalk by calices and Star-of-David morphology; otherwise identical	Expressed antigens not available; otherwise identical	Endemic in children	Mode of transmission unknown
Adenovirus, enteric (serotypes 40,41)	70 nm icosahedral virus with dsDNA; serotypes 31, 40, and 41 associated with diarrhea	EM, EIA for hexon and serotypes 40 and 41	Endemic in children	Disease may be more severe than rotavirus-induced diarrhea
Astrovirus	27 to 32 nm, ssRNA small round virus (star configuration)	EM, EIA, RT-PCR	Endemic in children; may cause outbreaks	All children infected in first 3 years of life; less severe than rotavirus; mode of transmission unknown; outbreaks reported in day care centers, schools, and nursing homes; winter seasonality

EIA, enzyme immunoassay; EM, electron microscopy; PAGE, polyacrylamide gel electrophoresis; IEM, immunoelectron microscopy; dsRNA, double-stranded RNA; ssRNA, single-stranded RNA.

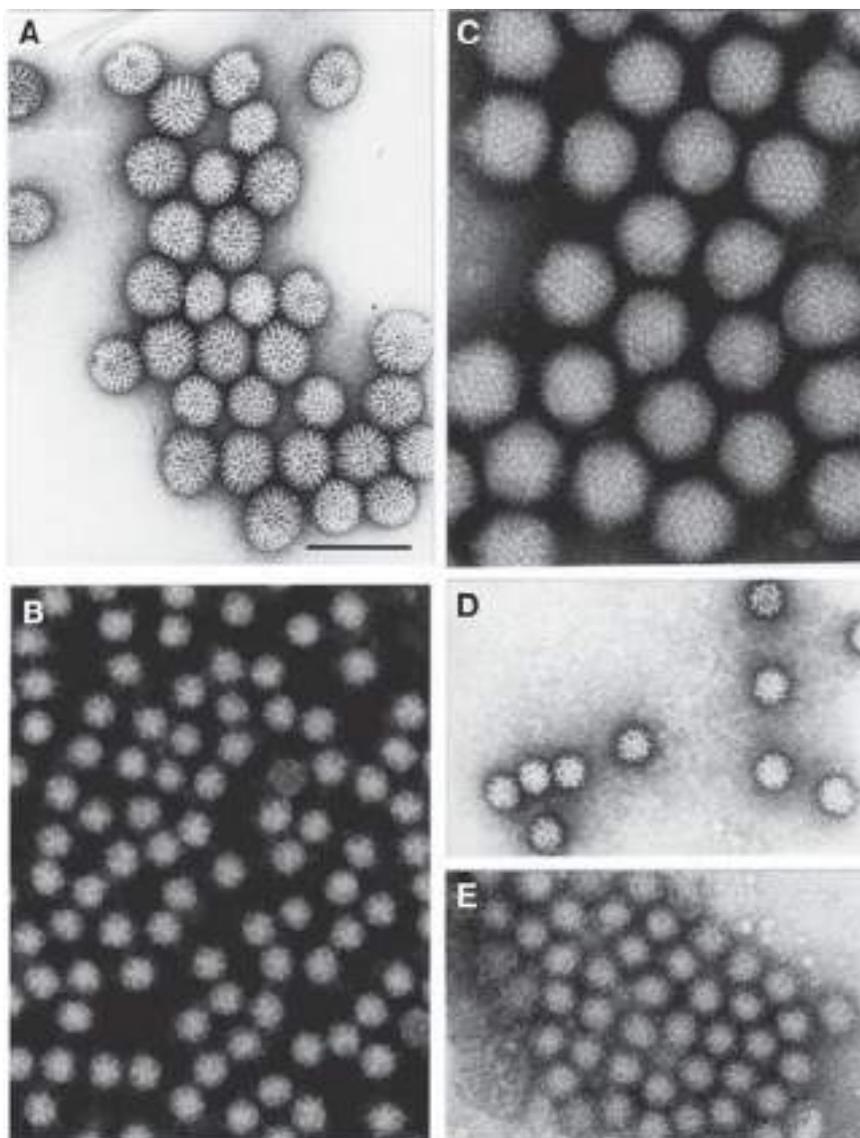

shedding and the quality of techniques available to detect the virus present in fecal specimens.

## EPIDEMIOLOGY

Viral gastroenteritis occurs in two distinct epidemiologic settings: childhood diarrhea (i.e., endemic disease) and outbreaks (i.e., epidemic disease) (Table 3). The majority of the diarrheal illnesses in children aged less than 5 years is due

to a variety of viral agents—rotavirus (15, 21–23), adenovirus (11, 15, 24–27), calicivirus (15, 21, 28), and astrovirus (15, 27, 29). Infants may be infected in the first few months of life, and the prevalence of antibody to these agents approaches 100% by 5 years of age (30).

Globally, rotavirus is the most common cause of severe gastroenteritis in children <5 years of age, accounting for approximately 200,000 deaths per year in children less than 5 years of age, with deaths among children in the poorest

**FIGURE 1** Electron micrographs showing agents of viral gastroenteritis. (A) rotavirus; (B) astrovirus; (C) adenovirus; (D and E) Norwalk-like viruses of the family *Caliciviridae*.

countries accounting for more than 85% of the total (1, 31); however, widespread implementation of highly effective rotavirus vaccines since 2006 has resulted in a dramatic shift in the epidemiology of pediatric viral gastroenteritis in early introducer countries. Substantial reductions in the burden of

severe rotavirus gastroenteritis were observed following rotavirus vaccine implementation (21, 32–34), and in many countries, noroviruses have overtaken rotavirus to become the predominant cause of severe gastroenteritis in the pediatric population (21, 35, 36).

**TABLE 3** Contrasting epidemiological patterns of viral gastroenteritis

Characteristic	Pattern in:	
	Childhood diarrhea (endemic)	Outbreaks (epidemic)
Viruses	Rotavirus group A, human caliciviruses, adenovirus, astrovirus	Human caliciviruses, rotavirus groups B and C ± astrovirus or rotavirus (special settings)
Age	<5 yr	All ages
Antibody interpretation	Seroprevalence is 100% by age 5	Seroprevalence is variable but seroconversions in affected cases
Mode(s) of transmission	fecal-oral, contact, droplet	Person-to-person, food (shellfish), water
Prevention and control	Effective vaccines for rotavirus licensed and in use	Public health measures to stop transmission by disinfection, exclusion of ill persons, and removing contaminated food or water

Norovirus is estimated to cause 18% of severe diarrheal disease in children under the age of 5 years worldwide; 17% of inpatient cases and 24% of community episodes (37). Following implementation of rotavirus vaccination, among children under 5 years old in the United States studied in an active surveillance network, norovirus accounted for 21% of gastroenteritis requiring medical attention—17% among inpatient cases and 28% of community episodes (21). Other important viral causes of gastroenteritis include adenoviruses, and astroviruses accounting each for about 5 to 10% of acute gastroenteritis episodes in medically attended children. Recently, adenoviruses 40/41 were found in 12% of children aged < 5 years suffering from acute gastroenteritis in the United States, and astroviruses were detected in 5% of children in this cohort (15).

All the major enteric viruses are transmitted primarily through close person-to-person contact via the fecal-oral route (38). Noroviruses are present in vomitus of ill people. Droplet spread through exposure to vomitus has been demonstrated to be a mechanism of transmission both in healthcare and community settings (39, 40). Additionally, noroviruses are spread through contaminated food and therefore are a major cause of foodborne and occasionally waterborne disease (41–43). The modes of transmission of adenovirus are less well understood, but it is presumed to be primarily through close contact by fecal-oral spread. Spread through fomites is possible for each of the agents, and may play an important role in disease acquired in institutional settings and group childcare (44). Epidemiologic studies suggest that transmission within families, communities, and special settings may occur despite the availability of sanitary food and water.

Outbreaks of viral gastroenteritis occur in all age groups and in many different settings (43, 45). Since viral gastroenteritis is often mild, we know much more about large outbreaks that occur in identifiable settings (e.g., weddings, cruise-ships, long-term care facilities, hospital wards), than small outbreaks or sporadic cases, where the source of infection cannot easily be traced (3). Noroviruses are the leading cause of reported outbreaks of acute gastroenteritis in the United States (42, 46). Outbreaks of norovirus infections are also frequently reported in institutional settings, such as nursing homes and day care centers (45). Large outbreaks of group B rotavirus have also been well documented in China (47), and smaller outbreaks of group C rotavirus have been identified among children and adults in a global distribution (48, 49). Outbreaks of astrovirus (50) and rotavirus (51, 52), two endemic viruses of children, have also been documented among people who should already be immune following their first infections as children. Rotavirus outbreaks among attendants in day care centers (53), mothers of children with rotavirus (53), travelers (54), formal dinner attendants (55), retirement communities (52), and patients in long-term care facilities (56), may be due to alternate modes of transmission in which direct contact with a large fecal inoculum overwhelms an individual's pre-existing immunity.

In epidemics of viral gastroenteritis, particularly those caused by noroviruses, a mode of transmission can often be documented (46, 57). Contaminated food (43, 58), especially raw shellfish (59) and water (60), are commonly identified vehicles for transmission, perhaps because the spread of viruses by airborne droplets (61), vomitus (62), or direct person-to-person contact (57, 61) is more difficult to prove (45). Even produce, such as raspberries, contaminated before retail distribution, may be a source of infection (63).

Contamination of environmental surfaces with noroviruses has occurred during outbreaks in institutional settings and may serve as a reservoir that sustains an outbreak (64). Inapparent contamination of restrooms may be a source of infection in many settings (65). Primary prevention efforts can be directed at interrupting transmission by removing the contaminated vehicle of infection.

While rotaviruses and noroviruses occur in distinct epidemiologic patterns, there is considerable crossover in presentation. Winter seasonal epidemics among infants and children are the most common presentation of rotavirus, but these agents do cause disease in adults and the elderly, suggesting that these groups may be exposed to unusually large inocula in the context of special settings, or that immunity to rotaviruses wanes over time (52). Epidemics of caliciviruses are common in older children and adults despite the fact that most children possess antibody to both genres of the family *Caliciviridae*—noroviruses and the sapoviruses (66). Noroviruses are now known to be common in children presenting to medical care (15, 21). Although a rapid and accurate diagnostic assay is not commonly available for diagnosing norovirus infections, epidemiologic features are useful in confirming norovirus as a cause of outbreaks (67). Epidemiologic criteria were validated to be highly specific in discriminating norovirus outbreaks from other etiologies and could continue to be used until diagnostic assays become widely available (68).

Risk factors for fatal disease include social- and health-care system characteristics such as the access to proper rehydration therapy, and biological factors such as the nutritional status and immunocompetence of the child (33, 69). Diarrheal deaths are not uncommon in the elderly (70, 71), and have been identified among patients who became ill in norovirus outbreaks (72). In these patients, electrolyte disturbances and secondary infections in patients with pre-existing health problems have appeared to place these individuals at particular risk (72).

## CLINICAL MANIFESTATIONS AND PATHOGENESIS

Viral infections of the intestinal tract cause clinical syndromes that can range from asymptomatic infections to severe, complicated, dehydrating diarrhea, and death. In infants and young children, mortality rates due to rotavirus are particularly high in developing low-income countries (1, 31). The key clinical feature determining disease severity of viral gastroenteritis is the degree and rate at which fluids and electrolytes are lost, and the rapidity with which these losses can be replaced by oral or parenteral rehydration therapy (73).

Despite the variety of viral agents that cause gastroenteritis, a number of key features in their epidemiology and clinical presentation can be explained by the pathophysiology of infection and disease. For those agents studied, the inoculum size is small; fewer than 100 norovirus viral particles properly buffered can cause disease (74). The small inoculum size would permit transmission by airborne droplet spread or direct contact, although the importance of these modes of spread has been difficult to document (57, 61, 62). Following ingestion but prior to the onset of clinical manifestations, the virus replicates in the epithelial cells of the small intestine during an incubation process that can range from 12 to 48 hours, depending upon the inoculum size (75). The incubation period of 12 to 36 hours for viral gastroenteritis (e.g., norovirus) helps in distinguishing these agents

from organisms that produce a preformed bacterial toxin (e.g., *Staphylococcus aureus* or *Bacillus cereus*) and typically have a shorter incubation period (<12 hours).

Viral replication may be associated with a low-grade fever, myalgia, and malaise. Disease is generally of short duration and lasts from 3 to 5 days, perhaps representing the time period required for the small intestine to replace cells damaged by infection and to mount the immune response necessary to clear the infection (76). Shedding of virus can persist at low levels for days to weeks after the clinical illness, depending upon the sensitivity of the assays used for detection (44).

Acute episodes of viral gastroenteritis are distinguished by the presence of watery diarrhea and vomiting. A majority of patients with diarrhea experience vomiting as an associated symptom, but some patients may present with vomiting alone (e.g., winter vomiting disease) (77). The mechanism of emesis during viral gastroenteritis is poorly understood, but is likely different from the mechanism of the associated secretory diarrhea. While diarrhea was traditionally believed to result from cellular damage in the intestine, some data for rotavirus indicate that tissue invasion may not be necessary to cause disease (78), as inactivated rotavirus can cause a secretory diarrhea in animal models. Although bloody diarrhea has been occasionally described in the context of rotavirus infections, classic dysentery associated with tissue invasion and an intense cellular infiltration of the intestinal mucosa is not recognized in viral gastroenteritis. Indeed, the lack of blood in the stool distinguishes viral diarrheas from the bacterial or amoebic dysenteries. While viral gastrointestinal infections are generally confined to the intestine, rotavirus and norovirus infections can result in antigenemia and the presence of nucleic acid in the blood of ill patients (79). While extraintestinal disease is rare, asymptomatic infection is common, especially for norovirus (28), and is thought to play a role in disease transmission (80).

Chronic, prolonged diarrhea may be associated with coronaviruses and picobirnaviruses, specifically in patients infected with HIV (81); however, proof of pathogenicity has not been established (82).

## HIGH-RISK GROUPS

Hospital wards, day care centers, and extended care facilities for the elderly provide special settings where outbreaks of viral gastroenteritis commonly occur (45, 52, 83). Similarly, infections with viral agents are common in persons traveling from well-resourced countries to middle and low-income countries (84). Even childhood pathogens such as rotavirus can cause gastroenteritis in immune travelers, suggesting that the inoculum to which they are exposed may be large enough to overwhelm preexisting immunity and involve alternate routes of transmission, such as the respiratory tract (54). Viral gastroenteritis remains an important cause of illness among U.S. military personnel, accounting for an estimated 68% of all acute gastroenteritis episodes during 2002 to 2012 (85). Large outbreaks of gastroenteritis due to noroviruses have also been documented among tourists aboard cruise ships (65) and on commercial airplane flights (86), where viral gastroenteritis can spread rapidly, disable passengers and crew, and pose challenging problems for control (62).

Some populations are at particularly high risk of viral gastroenteritis due to either their increased exposure to the viruses or their increased susceptibility to infection (Table 4).

**TABLE 4** Groups at high risk for viral gastroenteritis

Increased exposure to viruses
Children and the elderly
Parents and caretakers of children
Hospital wards, day care centers, nursing homes
Travelers in developing countries
Increased susceptibility
Children and the elderly
Immunodeficient
Congenital, e.g., SCID
Acquired, e.g., HIV infection
Chemotherapy, e.g., bone marrow transplant
Individuals with functional FUT2 enzyme (i.e., secretors)

The predisposition of young children and the elderly to viral gastroenteritis probably reflects a lack of immunity, or waning immunity with age, plus a concentrated exposure to the agents in settings such as day care centers or long-term care facilities, where hygienic precautions can be easily breached (52, 87, 88).

In the early studies with volunteers challenged with noroviruses, approximately 13 to 40% of volunteers never became infected, and only 50% developed illness. Further investigations showed that susceptibility to norovirus infection, and possibly rotavirus infection, depends on the presence of histocompatibility-blood group antigen (HBGAs) receptors in the guts of susceptible hosts (89–93). HBGAs are carbohydrates expressed on mucosal epithelia, which are recognized as receptors allowing norovirus attachment and cellular entry (89). The expression of HBGAs is determined by three gene families expressing the ABO (A/B enzymes), secretor (FUT2) gene, and Lewis-type (FUT3). Single nucleotide gene polymorphisms can inactivate the expression of these gene products, interrupting norovirus binding and the infection process. Mutations in the FUT2 gene leading to the absence of HBGA expression (nonsecretor phenotype) have been associated with resistance to norovirus infection, in particular to the GII.4 genotype, which is the predominant genotype worldwide (89, 90, 94–96). The host-specificity may also explain why persons with higher levels of preexisting antibody to noroviruses were more likely to develop illness on rechallenge with norovirus (97). Those without antibodies to noroviruses may not get infected because they lack genetic susceptibility to infection and thus never mount an immune response to that particular strain. Recent evidence points to lower susceptibility of nonsecretors to rotavirus infections in various populations (91–93).

Children, as well as adults, with congenital or acquired immunodeficiencies are easily infected with viral agents that cause gastroenteritis and often experience prolonged shedding of these viruses (82, 98). Severe and prolonged diarrhea associated with each agent has been reported among children with malnutrition, and among children with congenital or acquired immunodeficiencies (82, 99–102). In HIV-infected patients, in whom viruses have been intensively sought, both common viruses (rotaviruses, enteric adenoviruses), as well as the less common agents (astroviruses and caliciviruses) have been identified (101); however, in a large study in Malawi, severity and duration of clinical symptoms from rotavirus disease were no different in children with and without HIV infection (103).

## OTHER VIRAL AGENTS OF GASTROENTERITIS

In addition to detection of picobirnaviruses in immunocompromised patients, other viruses have been identified in humans in association with gastroenteritis. Toroviruses (enveloped, positive-stranded RNA viruses in the family *Coronaviridae*) have been shown to cause infection and diarrhea in animals, but their role as a cause of gastroenteritis in humans remains unclear (104, 105). Toroviruses have been identified by electron microscopy in human stool with confirmation by enzyme immunoassay (EIA) using reagents to bovine toroviruses. A survey of specimens found torovirus present in 8% of 2,800 specimens screened (105). One study reported torovirus detection among 35% of 206 hospitalized children with nosocomial gastroenteritis, compared with 14% of 206 controls without gastroenteritis (104). Patients infected with torovirus were more often immunocompromised and infected in the hospital compared with patients infected with rotavirus or astrovirus. Clinically, patients with torovirus exhibit bloody diarrhea more often, but vomiting less often compared with patients infected with rotavirus or astrovirus.

Coronaviruses are important causes of respiratory infections in humans and other species, and have been identified as a cause of gastroenteritis in several animal species. Earlier studies in humans found coronavirus in association with diarrhea and tropical sprue (18, 106). Coronaviruses have been observed by electron microscopy in 0 to 6% of stool specimens examined (107, 108). In 2002, a novel coronavirus was identified as the cause of the newly emerging severe acute respiratory syndrome (SARS). Interestingly, over a third of the SARS patients had diarrhea and in some, diarrhea was the presenting symptom (109). Fecal-oral transmission was documented and fecal shedding occurred in one patient for 73 days after onset of illness (110). Gastrointestinal coronavirus infection during global SARS outbreak demonstrates the public health and clinical importance of this finding with regard to interruption of fecal-oral transmission and use of stool samples to diagnose illness, since stool samples have the highest yield for SARS and pose less risk for transmitting illness to the healthcare workers collecting the samples. The recently described Middle East Respiratory Syndrome coronavirus (MERS-CoV) has been associated with diarrhea in a large proportion of patients (111), and MERS-CoV RNA has been detected in blood and stool in some patients. In the future, use of molecular-based diagnostic tests may help clarify the role of coronaviruses as a cause of both sporadic and epidemic gastroenteritis in humans.

It should be noted that gastroenteritis has been increasingly recognized with other respiratory infections, particularly avian and pandemic influenza, and, more recently, Ebola.

## ASSOCIATED DISEASES

The group of viruses that cause gastroenteritis in humans also cause a variety of other illnesses in other animal species. Rotavirus and astrovirus can cause fatal hepatitis in SCID mice and normal ducks, respectively, and a calicivirus (hepatitis E virus) causes hepatitis, while other caliciviruses cause a variety of bullous lesions in many animal species (112, 113). Nonenteric adenoviruses have a wide diversity of clinical presentations in humans. Yet, despite these biological similarities, it has been difficult to document important extraintestinal manifestations of this group of human gastrointestinal viruses in humans.

Rotavirus has been found in extraintestinal sites such as the hepatic tissue of children who have died with SCID (114) and in the cerebrospinal fluids of children with rotavirus diarrhea who had convulsions (115, 116). These systemic complications have been unusual findings, but antigenemia and viremia after rotavirus infection may be more common than previously suspected (115). A reduction in childhood seizures has been associated with rotavirus vaccination of children (117). While rotavirus detection has been reported in children with a wide variety of clinical problems—including gastrointestinal bleeding (118), Sudden Infant Death Syndrome (119), ulcerative colitis (120), Reyes syndrome (121), Kawasaki disease (122), intussusception (123), and necrotizing enterocolitis (124)—the association with disease has not been confirmed and rotavirus is probably not the causal agent of disease for most of these conditions.

## DETECTION METHODS

The greatest impediment to our understanding of the viral agents of gastroenteritis has been the lack of simple and sensitive diagnostic tests—with the exception of tests for rotavirus—that would permit physicians to make a rapid diagnosis and epidemiologists to study the burden and spread of disease. A diagnosis of viral gastroenteritis rests on finding the virus or one of its components in a fecal specimen, or detecting a rise in significant antibody titer in the sera of an infected patient. Shortly after the first identification of rotavirus as a cause of infant gastroenteritis, simple enzyme immunoassays were developed that were sensitive, specific, inexpensive, and easy to use in the field (125, 126). Currently, commercial diagnostic tests based on immunoassays are available to detect rotavirus, norovirus (low sensitivity), and adenovirus in fecal specimens.

Molecular diagnostic methods have markedly improved understanding of the etiology of gastroenteritis, e.g., documenting that noroviruses are one of the leading causes of diarrhea worldwide (22, 127, 128). Real-time (quantitative) PCR (RT-PCR) is the preferred laboratory method for detecting noroviruses. These assays are highly sensitive and are able to detect as few as 10 norovirus copies per reaction and provide a semiquantitative estimate of viral load. The assay is generally used to detect norovirus in stool, but can also be used for vomitus, foods, water, and environmental specimens for outbreak investigations, though with reduced sensitivity. Norovirus genotyping is conducted by sequence analysis of the RT-PCR products (129). Given the exquisite sensitivity of RT-PCR for norovirus, and the high frequency with which the virus can be found in healthy individuals (21, 28), diagnostic results should be interpreted in the light of clinical characteristics and, if available, the background level of detection in a control population. A commercial EIA for norovirus was approved in the United States in 2011; however, these assays have low sensitivity and are not recommended for diagnosing norovirus infection in sporadic cases (130–132). Norovirus EIAs may be useful in outbreak investigations, where even confirmation of norovirus in a proportion of patients would help determine the etiology of the outbreak.

Caliciviruses and other viruses can sometimes be visualized by electron microscopy in fecal specimens if the concentration of virus exceeds  $10^{6-7}$ /gram of stool, the threshold for detection (133). It is not surprising that we know most about rotavirus since this virus is shed in huge numbers (up to  $10^{12}$ /gram of stool) during the acute illness. Unfortunately some viruses (e.g., astrovirus, calicivirus) often cannot be

visualized by electron microscopy even during acute diarrheal episodes, indicating that their concentration in stool is below the level of detection. Virus is shed in greatest concentrations during the period of acute diarrhea. Thus, fecal samples collected within 48 hours of disease onset are most likely to yield a positive diagnosis. Virus can be shed in smaller quantities for several hours before the onset of disease and for days to weeks after the illness is resolved, but special research techniques (e.g., nucleic acid detection, cultivation) are needed for detection (134).

For epidemiologic research, serosurveys can provide additional understanding of the extent of infection. While current methods may not detect virus in fecal specimens, documentation of a rise in antibody titer to a specific agent can help confirm that the patient was infected, even though the patient's illness has usually passed. For norovirus, serology has long been utilized for outbreak investigations, since it is often easier to collect and test paired sera from many patients than it is to detect virus in stool (135). Seroprevalence studies have also increased appreciation of caliciviruses as a common infection in young children, and the virus can now be detected in their stool samples (66, 127). The discrepancy between a high seroprevalence of antibodies to the virus, but low rates of detection noted in the past, can now be explained because past assay of virus in stool specimens were quite insensitive (136). Serologic assays have been developed for the other viral agents of gastroenteritis (e.g., groups B and C rotavirus, astrovirus), but are only available in reference laboratories.

Efforts to cultivate noroviruses in available cell culture systems or to develop an animal model have long been unsuccessful (137). Recently, B cells were identified as a cellular target of human noroviruses and enteric bacteria as a stimulatory factor for norovirus infection, leading to the development of an *in vitro* infection model for human noroviruses but this system is not widely available (138).

## TREATMENT AND PREVENTION

No virus-specific therapies are available for viral gastroenteritis. Case management depends on accurate and rapid assessment of the severity of dehydration, correction of fluid loss and electrolyte disturbances, and maintenance of adequate hydration and nutrition (73). In 2004, the WHO and UNICEF recommended low-osmolarity Oral Rehydration Solutions (ORS) (245 milliosmoles/liter), which were shown to exert decreased stool output and vomiting in comparison with children treated with traditionally recommended ORS (311 milliosmoles/liter).

Oral rehydration therapy may also be used for traveler's diarrhea of either viral or bacterial origin (139). Breastfed infants should continue to nurse on demand. As tolerated, patients should begin taking food early in the illness since adequate caloric intake has been found to enhance patient recovery.

Intravenous rehydration may be required for children with severe dehydration ( $\geq 10\%$  fluid deficit, shock, or near shock), intractable vomiting, or ORS failure. Factors such as young age, unusual irritability or drowsiness, progressive course of symptoms, or uncertainty of diagnosis might indicate a need for close observation (73).

The volume of fluid to be replaced may be assessed clinically by determining the severity of dehydration. When severe dehydration is present, more rapid fluid replacement may be necessary using intravenous fluids (140). Great attention must be paid to infants and younger children pre-

senting with diarrhea, vomiting, and clinically significant dehydration (i.e., moderate-severe dehydration). Such patients require early oral or parenteral fluid plus electrolyte replacement. In the case of rotavirus diarrhea, vomiting and diarrhea may occur together, but diarrhea and subsequent dehydration often persist from 4 to 8 days after onset, necessitating persistent and regular fluid replacement (140). In some settings, elderly patients may develop acute vomiting and diarrhea. Such illnesses in high-risk elderly patients who may be immunocompromised or undernourished, or who have underlying diabetes or heart disease, must be recognized as potentially life-threatening (141). Given these risk factors for gastroenteritis in the elderly, prompt attention and treatment of dehydration and electrolyte imbalances during acute gastroenteritis may be critical to patient survival. Routine infection control procedures during care of ill residents, including hand-washing and barrier precautions (e.g., gloves), should help reduce transmission of viral gastroenteritis in long-term care facilities for the elderly.

There is no role for antibiotic therapy for the treatment of uncomplicated viral gastroenteritis in children. Indiscriminant use of antibiotics may result in adverse consequences such as spread of antibiotic resistant bacteria and treatment-related adverse events. While diphenoxylate or loperamide may reduce symptoms such as abdominal cramping or stool frequency, they have not been demonstrated to reduce intestinal fluid losses, have no practical value, and should be avoided since they may be harmful in some cases, particularly those younger than 3 years of age (142, 143). There is conflicting evidence regarding the use of oral probiotics, such as *Lactobacillus* species, to reduce the duration of diarrhea caused by rotavirus (144–146). Zinc, used both as supplement and treatment, reduces severity, duration, and incidence of diarrhea in low-middle income countries and is considered one of the mainstays of pediatric acute gastroenteritis treatment in developing countries (147, 148).

Those patients in the special populations discussed above with persistent or chronic diarrhea may need additional nutritional support in conjunction with fluid and electrolyte replacement. Selected children who are immunodeficient and develop chronic rotavirus illness may be treated with oral feedings of human milk containing antirotavirus antibody (149). At the present time, no specific antiviral agents have been recommended to treat gastroenteritis due to viral agents, although several agents including protease inhibitors have been studied (150).

While no chemoprophylaxis for agents of viral gastroenteritis is currently available, many investigators feel that breast milk protects against the development of clinically severe rotavirus diarrhea with dehydration in feeding infants (151, 152). In premature infants, oral human serum globulin that contains rotavirus antibody has been administered prophylactically and shown to protect against rotavirus gastroenteritis. Also, bovine colostrum containing antirotavirus antibodies has been administered to infants and young children as a form of passive immunization, and this was found to prevent rotavirus diarrhea (152).

Prevention of viral gastroenteritis depends upon the epidemiologic setting. For childhood disease, prevention strategies other than vaccination may be of limited value. Recommendations include proper diaper handling and disposal of feces by caregivers, double-diapering of infants, routine hand-washing, and use of barrier precautions to reduce transmission in hospital and day care settings. For outbreaks associated with norovirus, identification of the

mode of transmission can lead to specific public health interventions to remove contaminated foods or water.

In 2006, two live oral rotavirus vaccines—pentavalent human-bovine reassortant RotaTeq (Merck Vaccines, Whitehouse Station, NJ) and monovalent attenuated human Rotarix (GlaxoSmithKline Biologicals, Rixensart, Belgium)—were licensed for use in many countries. Large prelicensure clinical trials of each of these vaccines have demonstrated high efficacy (85 to 98%) against severe Group A rotavirus (i.e., the most common cause of endemic diarrhea in children <5 years of age) disease and a good safety profile (153, 154). The use of these vaccines was shown to be highly effective in reducing rotavirus disease burden and the overall impact from diarrhea among children in the several countries, including high and middle income settings (33, 34, 155, 156). A third live attenuated oral monovalent human-bovine (116E) rotavirus vaccine has recently been successfully tested in Indian infants (157).

The observation that adults are at risk of repeated infections with the caliciviruses suggests that either immunity is short-lived (158), or that the antigenic diversity of strains is too great to permit natural immunity to all the virus strains most often responsible for human disease (159); however, several human norovirus vaccine candidates are in various stages of clinical trials (160, 161). In a norovirus challenge trial of a vaccine candidate composed of bivalent virus-like particles (VLPs), the vaccine reduced vomiting and diarrhea in healthy volunteers (161). Phase 3 trials are about to begin for this vaccine candidate. Vaccines against other viruses may be warranted when the full disease burden of these infections can be fully assessed.

# Viral Hepatitis

ZINA S. VALAYDON, STEPHEN A. LOCARNINI, AND ALEXANDER J.V. THOMPSON

## 5

Viral hepatitis describes a characteristic clinical syndrome resulting from necro-inflammatory pathology of the liver that is caused by one of the recognized hepatitis viruses. There are five established human hepatotropic hepatitis viruses: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV), and hepatitis E virus (HEV). Acute hepatitis can also be a manifestation of other systemic viral infections, including herpesviruses (Epstein-Barr virus, cytomegalovirus, and herpes simplex virus) and yellow fever. Although the human hepatitis viruses can all cause the syndrome of acute hepatitis, they have distinct virology, phylogeny, routes of transmission, and risk of chronicity. In this chapter, we discuss the typical clinical syndromes and pathological features of viral hepatitis due to the hepatitis viruses A-E (Table 1), as well as the diagnostic evaluation of patients presenting with suspected viral hepatitis.

### Historical Perspectives

The identification and characterization of the different hepatitis viruses has been among the most significant medical breakthroughs in the last 50 years, leading to effective vaccines and drug development that will save millions of lives. The first account of the clinical syndrome of hepatitis dates as far back as the 3rd millennium BC, based on descriptions of jaundice engraved on Sumerian clay tablets. In 460 BC Hippocrates described epidemic jaundice and fulminant liver failure in patients who died within 11 days (1). By the Middle Ages, jaundice had become a well-recognized entity, although its etiology remained anchored in mythical roots. The first description of an epidemic of “serum hepatitis” was documented by Lurman in 1885 among 191 German ship workers in Bremen after a smallpox vaccination campaign using human lymph (2). Multiple outbreaks of acute hepatitis have been reported during military campaigns. The largest documented outbreak of “serum hepatitis” occurred in 1942 when 50,000 U.S. army men were hospitalized with jaundice following vaccination with yellow fever vaccine that was contaminated by plasma, in an epidemic affecting 300,000 servicemen. (3, 4). This outbreak led to the conclusion that there was an infectious agent in the human lymph administered with the smallpox vaccine, a conclusion subsequently confirmed by the prospective demonstration that viral hepatitis was

transmissible to volunteers following administration of filtered inocula (5).

The existence of more than one hepatitis virus was first proposed in 1946 by MacCallum with the suggestion of “serum” vs “infectious” hepatitis (6), now recognized as associated with HBV and HAV, respectively. A series of experiments from 1958 to 1964 led by Krugman and colleagues at the Willowbrook State School in Staten Island, NY, confirmed the distinct incubation periods and primary modes of transmission of serum and infectious hepatitis (7). These experiments also demonstrated the protective effects of inoculating susceptible individuals with boiled HBV serum as well, the first step towards developing an effective HBV vaccine (8, 9). This work was not without controversy, involving the intentional infection of mentally disabled children and, with the Tuskegee Syphilis Study (10), was one of a number of clinical experiments leading to the National Research Act (1974) and the Belmont Report: Ethical Principles and Guidelines for the Protection of Human Subjects of Research (1979) in the United States, the foundation for guidelines for ethical human research. Despite the recognition of the distinct clinical syndromes of “serum” and “infectious” hepatitis, the causative agents remained elusive, until 1964 when Blumberg and colleagues serendipitously discovered a novel antigen in the serum of an Australian Aborigine that precipitated antibody in patients with acute leukemia who had received multiple blood transfusions. Termed the *Australia antigen*, it was initially postulated as a biomarker to aid the diagnosis of leukemia. Three years later, the association between Australia antigen and “serum” (posttransfusion) hepatitis was recognized (11). The Australia antigen, the HBV surface antigen (HBsAg) that forms the viral envelope, would become the prototypal seromarker of HBV infection (12). Blumberg would go on to win the Nobel Prize in medicine for his work. Dane and colleagues later took HBsAg positive sera and visualized the complete hepatitis B virion using electron microscopy (13). HBV was found to be a 3020–3320 nucleotide DNA virus of the family *Hepadnaviridae* (Table 1). More detailed virological characterization followed, with the identification of the HBV e protein (HBeAg) (14), and the later definition of HBeAg-negative chronic hepatitis B (15, 16). HBsAg and HBeAg were identified as biomarkers for risk of hepatocellular carcinoma (HCC) (17), with prospective studies then showing that much of this risk was explained by persistent

**TABLE 1** Clinical and epidemiological features of viral hepatitis

Feature	HAV	HBV	HCV	HDV	HEV
Classification	<i>Picornavirus</i> ssRNA (+)	<i>Orthohepadnavirus</i> dsDNA	<i>Flavivirus</i> ssRNA (+)	<i>Deltavirus</i> ssRNA (-)	<i>Hepevirus</i> ssRNA (+)
Incubation period (clinical)	15–45 d	45–160 d - HBV DNA detectable 10–30 d - HBsAg detectable 3 weeks after HBV DNA	10–160 d - HCV RNA detectable 10–50 d - Anti-HCV detectable 4–10 wks	30–60 d	15–60 d
Development of chronic hepatitis	0	Neonates >90% Adults <5%	50–75%	Common (invariable in superinfection)	<1% (chronicity reported in immunosuppressed)
Transmission					
- Enteric	+++	-	-	-	+++
- Percutaneous	-	+++	+++	+++	-
- Sexual	-	++	+	++	-
- Perinatal	-	+++	+	+	-
Acute liver failure	0.1%	0.1–1%	Rare	5–20%	1–2% (10–20% in pregnancy)
Prognosis	Excellent	Liver related mortality associated with chronic infection = 15–40% without treatment	Variable Liver related morbidity more common in patients with comorbidities including alcoholism and nonalcoholic steatohepatitis	Chronic infection has a poor prognosis	Good except in pregnant women
Vaccine	10 year protection	3 injections, lifetime protection	None available	None available	Investigational (approved in China)

high-level HBV DNA replication (18, 19), a key determinant of long-term risk of liver cirrhosis and HCC. The development of experimental models of HBV replication, and recognition of the similarity between the HBV DNA polymerase and the HIV reverse transcriptase, has also led to effective nucleos(t)ide analogue therapy for HBV, starting with lamivudine in 1998 (20), paving the way for the current first-line agents entecavir and tenofovir.

An effective HBV vaccine has been available since 1982 (21). The first plasma-derived HBV vaccine was developed following the recognition by Krugman and colleagues that boiling serum containing HBV inactivated the virus but preserved HBsAg antigenicity. Soon after, the second generation vaccine containing recombinant HBsAg was released. The HBV vaccine is on the World Health Organization (WHO)'s list of essential medicines. WHO recommends universal neonatal HBV vaccination. In countries with low or intermediate endemicity, all children and adolescents younger than 18 years old and not previously vaccinated should receive the vaccine. Adults in high-risk groups in these countries should also be vaccinated, including people who inject drugs, people in custodial settings, men who have sex with men, family members of people with hepatitis B infection, and healthcare workers. In high prevalence countries, HBV vaccination programs have now been shown to reduce the prevalence of chronic hepatitis B infection, as well as rates of fulminant hepatitis and hepa-

tocellular carcinoma in young adults. It is possible with broad vaccine coverage that HBV could be eliminated as a public health problem.

The first description of “infectious” hepatitis, or HAV, was in the early 20th century in separate reports by Cockayne and Blumer (22, 23). They described epidemic outbreaks of hepatitis that were not related to parenteral exposures. These outbreaks were transmitted by person to person contact, developing 7 to 10 days following exposure, and mostly affected children and young adults. Krugman later confirmed the distinct mode of transmission and incubation period of “infectious” hepatitis in his Willowbrook hepatitis studies, but the virus itself remained elusive. Hepatitis A virus was finally identified in 1973 by Feinstone and colleagues using electron microscopy to examine filtrates of feces from infected individuals (24). Detailed virological, serological, and clinical characterization showed that HAV was an RNA virus of the family *Picornaviridae* causing acute, transient hepatitis (Table 1). The virus was grown in tissue cultures and an inactivated HAV vaccine was developed 20 years later. Despite vaccination programs, more than 1.5 million cases of symptomatic HAV infection continue to occur annually. Levels of endemicity correlate with hygienic and sanitary conditions, with most cases reported in the developing world.

Hepatitis D virus, also known as delta virus, was identified next, when in 1977 Rizzetto and colleagues first

detected a novel “delta” antigen in the nucleus of hepatocytes in HBsAg-positive patients (25). Clinical and chimpanzee studies then demonstrated the dependency of the HDV life cycle on coinfection with HBV. HDV is a defective RNA virus that requires the presence of HBsAg for viral packaging and secretion. Because HDV requires the presence of HBV for replication, it is always present as part of a dual infection with HBV. Hepatitis D virus infection may occur during primary coinfection with HBV by superinfection of individuals who are chronically infected with HBV. The two viruses share common routes of transmission (Table 1). Coinfection with HDV-HBV is typically more aggressive disease, and can cause fulminant acute hepatitis, as well as rapidly progressive chronic hepatitis. The treatment of chronic HDV-HBV coinfection is challenging; interferon- $\alpha$  is the only available therapy, and efficacy is modest. The goal of treatment is to suppress HDV replication, and ultimately, to effect HBsAg clearance, as HDV cannot persist after HBsAg clearance. There is no preventative vaccine for HDV.

Until the early 1970s, it was assumed that there were only two types of viral hepatitis. However, once serological assays for HBV and HAV became available, cases of posttransfusion hepatitis were identified that could not be attributed to either HBV or HAV. In fact, most sera from stored samples of prospectively collected cases of posttransfusion hepatitis were sero-negative (26, 27). This new entity was labeled “non-A, non-B” hepatitis. It was another 15 years before hepatitis C virus (HCV) was identified. By extracting nucleic acid from plasma and cloning it in an expression vector, the techniques employed in the discovery of HCV heralded the development of molecular diagnostic virology (28). For the first time a pathogenic agent was identified without serology, tissue culture, or electron microscopy. HCV is a single-stranded RNA virus of the family *Flaviviridae*, and is classified into 7 genotypes. The prevalence of chronic HCV infection globally is approximately 80 to 170 million (29, 30), second only to HBV. Chronic HCV infection is a leading cause of cirrhosis and HCC in the Western world, and the most common indication for liver transplantation. The HCV-replicon system was first developed in 1999 by Lohmann, Bartenschlager and colleagues as an experimental model for HCV replication (31). Together with the crystallization of the nonstructural HCV proteins, including the NS3 protease and the NS5B RNA-dependent RNA polymerase, this allowed high throughput screening of antiviral candidates. The therapeutic developments for HCV over the past 2 decades represents one of the true success stories for translational biomedical research, starting with standard interferon- $\alpha$  monotherapy in the early 1990s, the combination with ribavirin (1998), the synthesis of long-acting peginterferon- $\alpha$  (2001), and more recently, the introduction of direct-acting antiviral agents (DAA) (2011), first in combination with peginterferon and ribavirin, followed by interferon-free combination regimens (2014). In 2016, the standard of care treatment for HCV is the combination of all oral, well tolerated and highly effective DAA combination regimens that confer cure rates  $\geq 95\%$  in clinical trials (see Chapters 13 and 54). The efficacy of these regimens is such that the WHO has proposed targets for the elimination of HCV by 2030, including 90% reduction in new cases of chronic HCV infection, 65% reduction in hepatitis C deaths, and 80% of treatment-eligible persons with chronic hepatitis C infections treated (32).

Hepatitis E virus (HEV), the most recently discovered hepatitis virus, causes an acute HAV-like illness (Table 1).

The first epidemic outbreak recorded was in 1955 when 29,000 people in New Delhi developed an acute hepatitis from a water-borne source (33). It had an impressively high mortality, particularly in pregnant women in whom rates of acute liver failure were reported as high as 30%. This outbreak, as well as other similar waterborne epidemics of acute hepatitis on the subcontinent, was initially attributed to HAV, but subsequent serological testing in the early 1980s failed to implicate HAV or HBV. Further, the age distribution was older than was typical for HAV, puzzling because the Indian population is almost universally immune to HAV from childhood exposure. In 1983, Russian virologist Mikhail Balayan confirmed the existence of a non-A, non-B hepatitis transmitted via the fecal-oral route, by ingesting infected stool extracts and developing an acute hepatitis himself. He then used his own stool for electron microscopy and identified HAV-like viral particles, to which antibodies appeared during convalescence (34). However, the virus could not be grown in cell culture, and HEV was not cloned until 1990 (35). HEV is a single stranded RNA virus. Previously classified in the *Caliciviridae* family, HEV has now been classified into the *Hepeviridae* family (genus *Orthohepevirus*). Ingestion of contaminated feces is the most common route for transmission, responsible for most epidemic outbreaks, and in the West, cases are almost exclusively limited to returned travelers from endemic areas. More recently, animal reservoirs have been described, most commonly swine as well as rabbits, deer, and possibly rats. There are emerging case reports of human transmission after consumption of pork, wild boar, and uncooked deer meat in Western countries, although the rate of transmission to humans by this route, and the public health importance of this, are still unclear (36). While HEV infection almost always causes an acute, self-limited hepatitis, in immunocompromised subjects, particularly in solid organ transplanted patients, HEV may cause a chronic infection (36), with the risk of progressive liver fibrosis and cirrhosis. HEV can be particularly aggressive in pregnant women and has been associated with a high mortality rate of up to 20% due to fulminant hepatitis. There are only case reports of ribavirin being an effective antiviral agent for the treatment of chronic HEV infection (37). A recombinant HEV vaccine has been developed and was licensed in China in 2012.

Although these 5 hepatitis viruses are responsible for >95% of acute and chronic viral hepatitis, rare sporadic cases of non-A-E hepatitis continue to occur. Despite considerable effort, no novel viral hepatitis agents have been discovered in the past two decades. Candidates have included GB virus A/B, GB virus C/hepatitis G virus, TT virus, and SEN virus, but to date the data are not convincing that these agents cause hepatitis or other disease in humans.

## Epidemiology

**Enterically Transmitted Agents—HAV, HEV**  
HAV is one of the most frequent causes of food and waterborne infection worldwide and every year there are an estimated 1.5 million symptomatic cases (38). Acute hepatitis A is typically a subclinical infection of childhood. Infection in adulthood is more likely to be symptomatic, but fulminant liver failure is uncommon (0.1%), and the mortality rate of HAV is low in Western countries. However, it remains a significant cause of morbidity globally. There are distinct geographic patterns of HAV distribution, and regions of high seroprevalence are typically in the developing world, where poor sanitation, crowding, and lack of access to clean water

are common (39). Regions of high endemicity include Africa, Southeast Asia, India, and Nepal, where most children are infected before age 5. High seroprevalence rates have also been noted in South America and the Middle East, but the numbers are declining thanks to improvements in sanitation (40). Paradoxically, as sanitation improves, and fewer children are infected (40), the number of adults with protective HAV antibodies in endemic areas has declined, both increasing the risk of outbreaks due to poor herd immunity and the age-related risk of severe infection. In contrast, urbanized Asian countries such as Singapore and Japan, as well as most Western countries, have a low seroprevalence. Scandinavia boasts the lowest seroprevalence worldwide; Eastern and Southern European countries have intermediate seroprevalence, possibly a reflection of socioeconomic status. In Western populations, travel to endemic countries remains the most common risk factor for contracting HAV (41).

HEV is also enterically transmitted, either by drinking contaminated water or food. HEV is endemic in many developing countries including India and China with seroprevalences in adults of 20 to 45% (42). Outbreaks are typically seasonal and often associated with monsoon periods due to the breakdown in clean water supplies. These outbreaks can be severe, with a clinical attack rate of 1 in 2, affecting tens of thousands of people (43). The predominant genotypes in developing countries are HEV 1 and HEV 2. In industrialized, nonendemic countries, a different pattern of infection prevails, and the epidemiology of HEV is evolving. Travel to regions with high HEV endemicity remains the most common risk factor for infection, but there are recent reports of autochthonous HEV in Europe, North America, Japan, Australia, and New Zealand (36, 44). The source is zoonotic transmission from the consumption of undercooked pork, game, and offal (43), and the most prevalent genotypes are HEV 3 and HEV 4. A significant proportion of patients will have been misdiagnosed with drug-induced liver injury. In immunocompetent hosts, HEV follows the same acute, self-limiting clinical course as HAV. Adults are more likely to be symptomatic, and the average age of infection with HEV is older than for HAV. Infection during pregnancy is associated with a particularly high mortality rate at up to 30% (45). In immunocompromised hosts, HEV can persist and cause chronic hepatitis. Although uncommon, chronic autochthonous genotype 3 HEV has been reported in solid organ transplant recipients, patients with advanced HIV, and patients with hematological malignancy on rituximab chemotherapy.

#### Percutaneous Transmission—HBV, HCV, HDV

The transmission of HBV, HCV, and HDV is human to human, via percutaneous, sexual, or vertical transmission. There are no known animal or environmental reservoirs of the virus.

The introduction of the HBV vaccine has had a dramatic impact on the reported incidence of acute hepatitis B (AHB). The reported rate of acute HBV infection in the United States has declined since 1990, falling from 8.5 to 0.9 per 100,000 population in 2011, the lowest rate ever recorded (46, 47). Symptomatic AHB is primarily a disease of adulthood; in the same survey, the highest rates of AHB occurred among persons aged 30 to 39 years (2.0 per 100,000), and the lowest rates among persons <19 years (0.04 per 100,000). The most common risk factors were sexual exposure (multiple sexual partners, men having sex with men, and sexual contact with a person known to have

HBV infection) and injecting drug use (IDU). Similar trends have been seen in other countries including Italy and Egypt, where the frequency of acute HBV infection as a cause of symptomatic hepatitis decreased from 43.4% in 1983 to 28.5% in 2002, following the introduction of childhood immunization in 1991 (48).

Between 240 to 400 million people have been estimated to have chronic hepatitis B (CHB) (49). HBV infection is the 10th leading cause of death worldwide (49), and 15 to 40% of patients with CHB develop serious liver disease, leading to 1.2 million deaths per year. Chronic hepatitis B is endemic in Southeast Asia, China, sub-Saharan Africa, Micronesia, and Polynesia, and the indigenous populations of Alaska, Northern Canada, Greenland, Australia, and New Zealand. More than 7% of the population is chronically infected in these high prevalence regions (50). Most infections are acquired early in childhood and the risk of chronicity is inversely related to the age of infection. Perinatal infection leads to chronicity in >90% cases. In contrast, infections acquired later in life tend to have a symptomatic acute phase but only a small proportion of immunocompetent patients develop chronic HBV (<5%) (51). Approximately 45% of the global population lives in an area of high prevalence. Moderate prevalence rates of 2 to 7% are seen in the Southern regions of Eastern and Central Europe, the Amazon Basin, the Middle East, and the Indian subcontinent. Low prevalence regions include much of North America, the United Kingdom, and Northern Europe, where the incidence of chronic HBV infection is less than 2%. In these countries, HBV is seen predominantly in immigrants from countries with high prevalence, and their unvaccinated offspring, as well as in specific groups with percutaneous and sexual risk factors.

Ten different HBV genotypes (A-J) have been identified, which differ by >8% of the nucleotide sequences across the genome (52). Genotype prevalence varies according to geography. Genotype A is common in Northern Europe, America, and Africa, genotype D is prevalent in the Mediterranean basin and the Middle East, whereas Asian patients are almost exclusively infected with genotypes B and C HBV. Genotypes may influence the natural history of HBV, including the timing of HBeAg seroconversion, the risk of hepatocellular carcinoma (HCC) and response to interferon- $\alpha$ .

Of the 240 to 400 million carriers of CHB, it is estimated that 15 million are coinfecting with HDV (53). While there is a similar worldwide distribution to HBV, there is marked geographic and subpopulation variation of HDV prevalence within HBV cohorts. This discrepancy is likely due to the differences in the modes of transmission. Perinatal transmission of HDV is rare, whereas percutaneous transmission via IDU, household contact, and sexual transmission are the most common routes of infection. Coinfection is highest in the Pacific Islands, Mediterranean Europe, the Middle East, South Africa, and parts of Asia (54). In the Pacific Islands rates of coinfection have been reported of up to 90%. One survey of HBsAg positive patients in mainland China reported HDV prevalence varying from 0.8% in Sichuan 1987 to 13.3% in Guangzhou in 1990 (55). Since the introduction of the HBV vaccine there has been an overall decline in HDV. Rates in Italy have fallen from 23% in 1983 to 8.3% in 1997 (56). However there has been a recent resurgence, with the decline in Italy plateauing and rates in London, United Kingdom, rising from 2.6% in the 1980s to 8.5% in 2005 and in Germany where rates rose from 6.8% in 1997 to 8.3% in 2010 (57). While immigration from

endemic countries is partly responsible for this trend, high risk behaviors such as intravenous drug use (IVDU) and sexual practices may play a role. HDV has 4 major genotypes defined by nucleotide variation >40% across the entire genome (58); genotype 1 HDV is the most predominant in the West. The clinical relevance of HDV genotypes remains unclear.

Chronic HCV affects 130 to 150 million people globally and about 500,000 people die of HCV liver-related complications every year (59). HCV is the main cause of liver transplantation in developed countries (60). There is a significant geographic variability in prevalence. Asia, North Africa, and the Middle East are areas of high prevalence. Southeast Asia, Sub-Saharan Africa, Australasia, Latin America, and Europe have moderate prevalence, while North America and the Asia Pacific are regions of low prevalence of <1.5% (61). The transmission of HCV in developed countries is largely from IVDU, whereas in the developing world, the major route of transmission has been nosocomial through contaminated blood supply and inadequate sterilization of medical equipment, particularly unsafe injection practices. In Mediterranean countries, contaminated vaccination practices 50 years ago may explain the high prevalence in the elderly population. In Egypt, more than 10% of the population is chronically infected with HCV as a result of infection secondary to shared needles during mass antischistosomal treatment programs (62). There are six HCV genotypes, defined by sequence heterogeneity >30%, and over 50 subtypes of HCV (63). HCV genotype varies by geography also; the most common genotype globally is genotype 1 HCV. HCV genotype is very relevant clinically, as it determines the treatment regimen and likelihood of cure. Emerging data suggest that the natural history of genotype 3 HCV may be more aggressive than genotype 1 HCV (64).

## PATHOPHYSIOLOGY

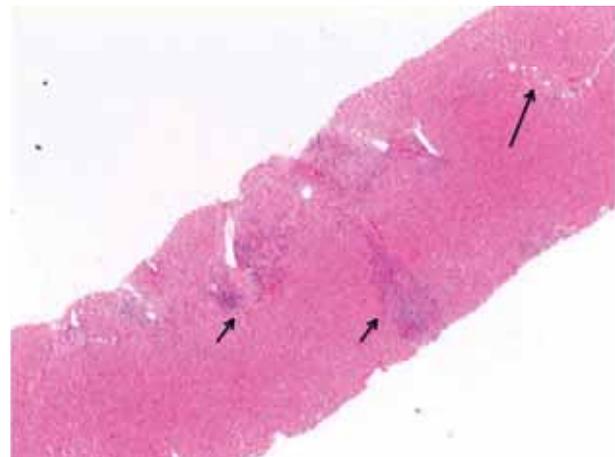

The pathophysiology of each hepatitis virus is complex and beyond the scope of this chapter. However, there are common features that characterize acute hepatitis. The acute injury observed in nonhepatotropic viruses such as herpes zoster, HSV-1, HSV-2, and adenovirus appears to be mediated by direct viral toxicity and the innate immune response and is characterized by necrosis of hepatocytes. In contrast, for the hepatotropic viruses, it is thought that host immunity is responsible for the acute liver injury, rather than a direct cytopathic effect of the virus. Both innate and adaptive immune responses have been implicated in hepatocyte injury as well as viral clearance, including the Toll-like receptor signaling pathway, PD-1/PD-L1 expression, NK cells, and cytotoxic T lymphocytes and regulatory T-cells. Symptomatic acute hepatitis correlates with greater intrahepatic inflammation, but the host determinants of symptomatic versus subclinical hepatitis are not fully understood (65). HAV and HEV cause a self-limiting hepatitis in immunocompetent hosts, whereas HBV and HCV may persist to cause chronic hepatitis. Age of infection is the most important determinant of HBV persistence, but the underlying mechanism is not understood. Host IL28B genotype is the most important determinant of spontaneous clearance of HCV infection (66, 67). Viral factors may however influence disease course. Fulminant liver failure is more common in the setting of acute HDV superinfection in individuals with chronic hepatitis B infection. Coinfection of HBV with HCV, or HBV with HAV, can also increase the severity of

acute hepatitis. Variants of HBV, including the basal core promoter variant (A1762T/G1764A), have also been implicated in causing greater disease severity.

Hepatitis viruses may be directly cytopathic. This is rare, but may occur in immunosuppressed hosts. Fibrosing cholestatic hepatitis (FCH) due to HBV is caused by very high level HBV replication and massive accumulation of HBsAg within hepatocytes. FCH occurs in the immunosuppressed state post-liver transplantation; a similar syndrome is described involving aggressive recurrent HCV infection post-transplantation.

The histopathology of acute viral hepatitis is characterized by hepatocyte injury and necrosis, with predominantly sinusoidal and lobular mononuclear cell infiltrate, occasional neutrophils and eosinophils, and Kupffer cell hyperplasia (Figure 1) (68). Hepatocyte injury may be spotty or panlobular, and manifests as ballooning degeneration and apoptosis, with scattered acidophilic apoptotic bodies or Councilman bodies. Cholestasis is variable, and may be more prominent in HAV/HEV infection. Large hepatocytes with a "ground-glass" cytoplasmic appearance may be seen in HBV infection, with the cytoplasmic appearance reflecting accumulation of HBsAg. Hepatocellular steatosis may be present, but is normally mild in the acute setting. More prominent steatosis occurs in the setting of chronic infection with genotype 3 HCV infection as a direct viral effect. In HBV infection immunohistochemistry will demonstrate HBsAg in the cytoplasm of hepatocytes. Hepatitis B core antigen is normally found in the hepatocyte nucleus, but low concentrations may be found in the cytoplasm and on the cell membrane. The reticulin framework of the liver is preserved in uncomplicated acute viral hepatitis. In more severe cases of acute hepatitis, bridging hepatic necrosis may be seen. Bridging necrosis describes the confluent loss of hepatocytes in multiple acini, with the appearance of extensive hepatic necrosis linking venules to portal tracts. In fulminant hepatitis there is massive necrosis and dropout of liver cells in most lobules, with extensive collapse of the reticulin framework.

There is a spectrum of histological change in chronic viral hepatitis, with variable degrees of necro-inflammatory activity as well as liver fibrosis progression. Minimal necro-inflammation is confined to the portal tract. Moderate

**FIGURE 1** Viral hepatitis. Top long arrow shows focal steatosis and bottom arrows show portal inflammation. Source: Prof Richard Williams, Anatomical Pathologist, St Vincent's Hospital, Melbourne.

inflammation involves piecemeal necrosis (interface hepatitis), in which the inflammatory infiltrate disrupts the limiting plate of periportal hepatocytes and extends beyond the confines of the portal tract. As the inflammation extends deeper into the liver parenchyma, lobular hepatitis develops. Severe lobular hepatitis is often accompanied by bridging necrosis. Surviving hepatocytes can cluster together forming “rosettes.” There is usually no bile plugging in chronic hepatitis. Marked cholestasis is suggestive of an alternative diagnosis such as drug induced liver injury. Necro-inflammatory activity drives liver fibrosis progression as part of the “wound-healing” response. Progression of fibrosis is a sequential process, involving enlargement of portal tracts, the development of periportal fibrous septae, and eventual bridging septae that connect portal tracts (bridging fibrosis). The development of intrahepatic nodules with architectural distortion is the hallmark of cirrhosis. There are a number of scoring systems for hepatic necro-inflammatory activity and fibrosis stage in viral hepatitis, including the METAVIR score, the Knodell Index, and the Scheuer score. Fibrosis can regress with treatment of viral hepatitis.

Fibrosing cholestatic hepatitis is a syndrome involving massive accumulation of viral antigens within hepatocytes. As noted, it is most common in immune-suppressed individuals post-liver transplantation. It was first described for HBV, but a similar syndrome may occur with HCV posttransplant. The pathological features include marked periportal fibrosis and cholestasis, with relatively minor inflammatory infiltrate, but widespread ballooning degeneration of hepatocytes, which likely reflects a direct cytopathic effect of the virus. Rapid progression and liver decompensation occur without treatment, but fortunately viral suppression with potent antivirals is now very effective.

## CLINICAL FEATURES

### Acute Viral Hepatitis

#### Clinical Presentation

Acute viral hepatitis presents with a characteristic syndrome that is common to all five hepatitis viruses. The spectrum and presentation of acute viral hepatitis can vary from a subclinical infection to severe fulminant liver failure. Subclinical infection is common in children, whereas adults are more commonly symptomatic. Onset of symptoms follows a variable incubation period (Table 1). Prodromal symptoms are typically nonspecific and include constitutional symptoms such as anorexia, nausea, fatigue, mild right upper quadrant abdominal pain, and low-grade fevers. Prodromal symptoms coincide with an elevation in aminotransferases and typically precede the onset of jaundice by 1 to 2 weeks. As the icteric phase begins the prodromal symptoms often settle. Clinical jaundice is associated with dark urine, pale stools, and pruritus. The liver becomes swollen and tender, with right upper quadrant pain, nausea, and anorexia. Jaundice may last for a number of weeks; biochemical tests can take longer to settle. Complete clinical and biochemical recovery normally occur in 1 to 2 months after the onset of HAV/HEV. A similar time course for clinical and biochemical recovery from icteric acute hepatitis B or C is observed when spontaneous clearance occurs; persistence and chronicity for HBV and HCV infection is defined by HBsAg or HCV RNA persistence for more than 6 months.

Beyond this stereotypical presentation, there are variations characteristic for each virus. These are best characterized for acute hepatitis A and B. HAV can have an

atypical course with a prolonged cholestatic phase with the usual symptoms of pruritus, anorexia, and diarrhea caused by an accumulation of toxic mediators, primarily bile salts (69, 70). Despite a high serum bilirubin, aminotransferases can be normal during this phase. Cholestatic HAV has an excellent prognosis. HAV can also follow a relapsing course. Although acute HAV infection normally confers lifelong immunity, a small proportion of patients experience a relapsing form of the disease (71, 72). IgM anti-HAV is present, but there is evidence of viral shedding in the stool and patients are infectious. Relapses are typically mild and transient, before eventually resolving.

HAV may also be associated with extra-hepatic manifestations including a transient rash and arthralgia. Clinical manifestations of immune complex formation (involving IgM anti-HAV) are uncommon but include vasculitis, glomerulonephritis, cryoglobulinemia, and blood dyscrasias. Several reports describing an episode of HAV immediately prior to the onset of autoimmune hepatitis (AIH) suggest a possible association between HAV and AIH, although causality has not been established.

The majority of acute HBV infections are clinically silent, especially in children. Icteric hepatitis is more common in adults. The disease tends to be more severe if the patient is coinfecting with another hepatitis virus or has underlying liver disease. Chronicity of HBV infection is determined by the age of infection, size of the inoculum, and immune response of the host. As noted, age of infection is the most important determinant of persistence. Extrahepatic manifestations of HBV infection include the serum sickness-like prodrome of acute HBV infection, polyarteritis nodosa, HBV-associated glomerulonephritis, mixed essential cryoglobulinemia, and neurological manifestations and are also thought to be mediated by circulating immune complexes (73). A serum sickness-like prodrome precedes acute HBV infection by 1 to 6 weeks in 10 to 30% of cases. Also known as the “arthritis-dermatitis” syndrome, it is characterized by a symmetrical generalized inflammatory arthritis, typically involving the small joints of the hands and feet. The joint lesions are nondestructive. Fever is common. Skin manifestations are variable, occurring in more than 50% of those with joint symptoms. Lesions described include maculopapular, petechial or purpuric rash, palpable purpura, Henoch-Schönlein-type purpura, erythema multiforme, toxic erythema, lichenoid dermatitis, and urticaria. Renal involvement with proteinuria or hematuria is much less common. Angioneurotic edema may rarely occur. Polyarteritis nodosa (PAN) is a rare but serious complication of HBV infection. The syndrome normally presents within 4 months of the clinical onset of HBV infection, with abdominal pain due to arteritis of medium-sized vessels causing ischemia of the intestine and gallbladder. Angiography demonstrating microaneurysms of blood vessels in the renal, hepatic, or mesenteric circulations is virtually pathognomonic. Tissue biopsy of affected organs reveals inflammation of the medium-sized arteries. The prognosis is poor without treatment, with mortality of up to 50%. Glomerulonephritis (GN) and other HBV-related manifestations are more common in the setting of chronic HBV infection and will be discussed below.

#### Fulminant Viral Hepatitis

Fulminant viral hepatitis is the most severe form of acute hepatitis presenting as acute liver failure (ALF). ALF is defined by the development of severe acute liver injury with encephalopathy and impaired synthetic function

International Normalised Ratio (INR) of  $\geq 1.5$ ) in a patient without cirrhosis or preexisting liver disease. ALF is often associated with multisystem organ failure, disseminated intravascular coagulation, and it is often complicated by sepsis and cerebral edema. Patients with ALF should be managed by a liver transplant service in the intensive care unit. The mortality rate for ALF very high, but outcome post-liver transplantation is good. Viral hepatitis is the most common cause of ALF in developing countries (74) and develops in approximately 0.3% of HAV patients and in approximately 0.5% of HBV patients. It is more common in adult-onset infection and when infection occurs in an individual with premorbid liver disease; e.g., acute HAV infection in a person with chronic hepatitis C, especially if cirrhotic. Coinfection of super-infection with HDV confers a significant risk for ALF and testing for delta virus is recommended in all cases of HBV-related ALF (75). It is very rare for HCV to be associated with ALF. Where HCV is associated with ALF, it is normally in the setting of HBV or HAV coinfection. The majority of patients with fulminant HCV are coinfecting with HBV. HEV is an important cause of ALF in endemic areas with a fatality rate of up to 25% in pregnant women, especially in the third trimester (76). HSV in pregnancy, although rare, is also associated with a fulminant course with high mortality and morbidity. Timely administration of acyclovir can reduce the risks to mother and infant (77, 78).

#### Liver Function Tests

All forms of acute viral hepatitis cause biochemical abnormalities in liver function tests. Typical laboratory abnormalities include marked elevations of the aminotransferases, alanine aminotransferase (ALT), and aspartate aminotransferase (AST), which indicate hepatocellular injury. Serum ALT is usually higher than AST in viral hepatitis. Bilirubin also rises acutely and may continue to rise even after the aminotransferases have started declining. Once bilirubin exceeds approximately 3 mg/dl (50 micromol/l), jaundice becomes clinically apparent, with yellow pigmentation of

the sclera and dark urine. The titer of serum aminotransferases and bilirubin can be quite impressive, but they are not markers of severity or prognosis. Coagulopathy is a marker of fulminant hepatitis (see below). Fulminant hepatitis is indicated by a loss of synthetic function acutely with prolongation of the prothrombin time.

It is important to recognize that a presentation with acute hepatitis on clinical and biochemical grounds is not specific to viral hepatitis. Important differential diagnoses to consider for acute hepatitis include systemic viral infections, drugs and toxins, ischaemia, autoimmune hepatitis, Wilson's disease, Budd-Chiari Syndrome, and pregnancy-related liver disease amongst others (see Table 4). In children, rubella has been associated with hepatitis. In returned travelers, the hemorrhagic fever viruses (including Ebola, Marburg, Lassa viruses) and yellow fever (group B arbovirus) have been associated with hepatitis as part of a severe systemic illness.

The pattern of abnormalities of laboratory tests may be suggestive of a diagnosis but imaging and specific tests are required to confidently establish the etiology.

#### Virus-Specific Serologic Features

The acute viral hepatitis can be differentiated on the basis of serology (Table 2).

##### HAV

HAV is diagnosed based on the presence of anti-HAV antibodies in the serum. The gold standard diagnostic for acute HAV infection is the presence of anti-HAV IgM, which, in presence of the features of an acute hepatitis, is sufficient to confirm the diagnosis. Anti-HAV IgM is positive by the time of symptom onset, peaks during the icteric phase and remains positive for approximately 6 months. Anti-HAV IgG appears in the convalescent phase, remains detectable for decades, and correlates with immunity against further HAV infections. HAV can also be detected in fecal samples by electron microscopy or measuring HAV RNA but

**TABLE 2** Common serological patterns of viral hepatitis

Virus	Serologic pattern	Interpretation
HAV	IgM anti-HAV+	Acute infection
	IgG anti-HAV+	Past infection
HBV	HBsAg+, IgM anti-HBc+	Acute infection
	HBsAg+, IgG anti-HBc+, HBeAg+, HBV DNA +	Chronic, replicative infection
	HBsAg+, IgG anti-HBc+, HBeAg-, anti-HBe+ HBV DNA $>10^4$ copies/ml	Chronic, replicative infection with precore or core promoter mutant
	HBsAg+, IgG anti-HBc+, HBeAg-, anti-HBe+ HBV DNA $<10^4$ copies/ml	Chronic, minimally replicative infection
HDV	HBsAg-, HBV DNA+	Occult HBV
	Anti-HDV+, HBsAg+	HDV infection
	HBsAg +, IgM anti-HBc+, low titer anti-HDV	Acute coinfection
	HBsAg+, IgG anti-HBc+, HDV RNA +, rapidly increasing titers anti-HDV	Acute superinfection
HCV	HBsAg+, IgG anti-HBc+, HDV RNA+, High titers anti-HDV	Chronic HDV
	Anti-HCV+, HCV RNA+	HCV infection
HEV	Anti-HCV+, HCV RNA-	Past infection or false positive antibody
	IgM anti-HEV+	Acute infection
	IgG anti-HEV+	Past infection

these remain research tools. Serology is the simplest and most convenient test available and is therefore the gold standard.

### HBV

The standard serology panel for diagnosis of HBV infection, past or present, should include HBsAg, anti-HBs, and anti-HBc. Hepatitis B surface antigen (HBsAg) is the first serologic marker to appear at approximately 1 to 10 weeks after inoculation. HBsAg precedes the onset of biochemical or clinical abnormalities. In patients who achieve spontaneous clearance, HBsAg will decline to be undetectable at 6 months. HBsAg persisting beyond the 6-month mark is by definition chronic HBV infection. HBsAg levels can be quantified, and in the setting of chronic hepatitis B, have been correlated with HCC risk as well as interferon- $\alpha$  treatment response (see below) (79). Resolution of HBV infection is marked by the appearance of anti-HBs antibodies in the serum. There may be a lag of weeks to months between the clearance of HBsAg and the appearance of anti-HBs (the serological “window” period). During this window period, the only serological evidence of HBV infection is the presence of antibodies against hepatitis B core antigen (IgM anti-HBc). Anti-HBs antibodies also become detectable following vaccination; protective immunity following the standard 3 dose vaccine course is indicated by and anti-HBs titre > 10 IU/ml.

HBV core antigen (HBcAg) forms the capsid of the virus, and is found in infected hepatocytes rather than serum. However, antibodies to HBcAg, or anti-HBc, are detectable in serum approximately 1 to 2 weeks after the appearance of HBsAg. IgM anti-HBc appears first. The presence of anti-HBc IgM, especially at high titer, is a marker of acute HBV infection, and can help differentiate true acute infection from a relapse of chronic HBV infection. For the first 6 months of infection, the predominant class of anti-HBc is IgM. As noted, anti-HBc may be the only serological marker of acute HBV infection during the window period. Titers of anti-HBc IgM decline over 6 months, after which IgG appears and becomes the predominant class of anti-HBc. Anti-HBc persists long term. Anti-HBc is a marker of HBV exposure. Anti-HBc differentiates immunity due to past infection from vaccine-induced immunity. Anti-HBc may be the only marker indicating past infection in older patients as anti-HBs levels wane. Testing for anti-HBc is particularly important when screening patients for HBV prior to immunosuppression. Isolated anti-HBc has been reported in approximately 2% blood donors in areas of low endemicity but approximately 10 to 20% in areas of high prevalence and in the HIV population (80–82). There is a risk of fulminant HBV reactivation in people who are HBsAg negative, anti-HBs negative, but anti-HBc positive (e.g., in the setting of the anti-CD20 monoclonal antibody rituximab).

The hepatitis B “e” antigen (HBeAg), or precore protein, is a secreted, soluble protein that can be detected in serum. Although it is not necessary for viral replication, HBeAg is believed to act as a tolerogen to attenuate the immune response to HBV and promote viral persistence. HBeAg is considered a surrogate marker of HBV replication and infectivity. HBeAg is almost always present during acute HBV infection. Seroconversion to anti-HBe occurs with viral clearance as the HBV DNA falls, and often precedes the appearance of anti-HBs. However there are viral variants defective for the HBeAg, the most common carrying a G1896A precore mutation which abrogates HBeAg production. This variant is commonly selected in the course of

chronic hepatitis B, emerging as an immune escape variant to cause HBeAg-negative CHB. Testing for HBeAg provides limited clinical information in the acute setting, but is important for patients diagnosed with chronic hepatitis B as it helps identify the phase of infection as well as the emergence of immune escape variants.

Polymerase chain reaction (PCR) testing for serum HBV DNA can be positive in patients as early as 10 days post-infection. Recovery from HBV is associated with clearance of HBV DNA from the serum. As for HBeAg, measuring HBV DNA levels in the setting of acute HBV infection provides little extra information and is not routine. In the setting of chronic hepatitis B, HBV DNA levels are very important for prognostication and monitoring treatment response.

### HCV

The screening test for HCV infection is serology, and anti-HCV antibodies are detectable in the majority of patients at presentation, becoming positive 4 to 10 weeks following infection (Table 1). Anti-HCV indicates exposure, but remains positive following spontaneous clearance. Therefore, diagnostic testing for HCV includes serology as a screening test followed by confirmatory testing with molecular assays that quantify viral load (HCV RNA). Anti-HCV can be falsely negative early in acute HCV as the antibodies can take 2 to 6 months to appear. Serum HCV RNA is more sensitive and becomes detectable as early as 10 days postinfection.

### HDV

HDV depends on HBV coinfection, so HBsAg should be included in any testing algorithm for HDV. HDV antigen (HDAG) appears early but is short-lived as circulating anti-HDV interferes with the assay. Testing for anti-HDV is more reliable. As for HCV, serology for HDV should be considered a screening test, to be confirmed by molecular virology. Although there are no licensed assays for serum HDV RNA, most specialty laboratories will offer an in house assay. It is likely that there will be an approved assay in the near future. The differentiation of acute HDV/HBV coinfection vs HDV superinfection is most commonly made on clinical grounds. The pattern of anti-HBc serology may help; detectable anti-HBc IgM is suggestive of acute coinfection, while anti-HBc IgG suggestions superinfection. Acute coinfection typically presents as a severe acute hepatitis that then resolves. The majority of HDV superinfections (> 70%) become chronic.

### HEV

The routine screening test for the diagnosis of HEV is serology. IgM anti-HEV appears early before waning over months. IgG appears shortly after IgM and persists for years after the illness, providing protective immunity. Antibody tests in HEV are not optimal as they are associated with frequent false positive and negative results. Moreover the assays can be variable depending on which commercial testing kit is used (83). HEV RNA testing of serum or stool is offered by research laboratories, and can be considered when there is diagnostic doubt. HEV RNA testing must be performed early in the disease course. HEV can be detected in the stool about a week before symptoms appear and until two weeks after resolution of the infection. Fecal shedding implies infectiousness.

### Chronic Viral Hepatitis

HBV and HCV are the most common causes of chronic viral hepatitis. Most patients with chronic hepatitis B or

**TABLE 3** Screening for HBV and HCV is recommended in people with the following risk factors

People who inject drugs
People with a history of tattooing or body piercing
People in custodial settings
Sex workers
Sexual partners of an HCV-infected person should be tested for HCV
Partners and other household and intimate contacts of people who have acute or chronic hepatitis B infection should be tested for HBV infection
Children born to HCV- or HBV-infected mothers
Pregnant women
People who received a blood TF/organ Tx prior to 1990
People infected with HIV or HBV/HCV, respectively
People with evidence of liver disease (persistently elevated ALT level)
People who have had a needle-stick injury
Migrants from high prevalence regions (Egypt, Pakistan, Mediterranean and Eastern Europe, Africa, and Southern Asia)

hepatitis C are asymptomatic. Screening strategies targeted to high-risk individuals are important (Table 3). The common symptoms attributed to chronic hepatitis are malaise, fatigue, and anorexia. The long-term hepatic complications of viral hepatitis include progressive liver fibrosis, cirrhosis, liver failure, and hepatocellular carcinoma. Chronic hepatitis B is associated with a particularly high risk of HCC, which may arise in the noncirrhotic liver. Viral hepatitis is the most common cause of HCC globally, and a major cause of global mortality. The clinical features and natural history of chronic hepatitis B and C are discussed in detail in Chapters 32 and 54, respectively.

Extrahepatic manifestations of chronic viral hepatitis warrant consideration here. They are an indication for antiviral therapy. Glomerulonephritis (GN) is commonly associated with CHB. The most common presentation is nephritic syndrome. A number of patterns of glomerular injury have been described, including membranoproliferative GN, membranous GN, and rarely mesangial proliferative GN. In children the disease is usually self-limited; however, progression to renal failure has been described in adults. The association of HBV infection with mixed essential cryoglobulinaemia is controversial. Rare cases have been reported; however, the majority of cases are now recognized to be associated with HCV infection (73).

CHC is also associated with extra-hepatic manifestations. Mixed cryoglobulinemia is a systemic problem that results in the deposition of immune complexes in small and medium blood vessels. It is common in HCV and typically presents as a purpuric, vasculitic rash usually on the shins, arthralgia, and glomerulonephritis. HCV can be associated with a membranoproliferative glomerulonephritis and membranous nephropathy (84). HCV is also associated with autoimmune disorders including immune thrombocytopenic purpura, autoimmune hemolytic anemia, thyroid problems, and myasthenia gravis.

### Role of Liver Biopsy

Liver biopsy is now rarely performed in patients with viral hepatitis. Liver biopsy is not usually necessary for either the

diagnosis of acute hepatitis or for differentiating etiology. Liver biopsy is indicated when there is diagnostic doubt. Liver biopsy was used for many years to stage liver fibrosis in patients with chronic viral hepatitis, for determining prognosis, and identifying treatment candidates. However, the recent introduction and wide availability of noninvasive markers for liver fibrosis, including transient elastography and serum biomarkers, has largely replaced histology for staging liver fibrosis. Liver biopsy is reserved for those patients in whom the results of less invasive techniques are unclear, and when clinical decision-making will be directed by the result of the biopsy.

## SPECIAL POPULATIONS

### Transmission in Healthcare Workers

Healthcare workers are at risk of infection from blood-borne pathogens including HBV, HCV, and HIV through occupational exposure to blood products and body fluids. All body fluids and tissue should be considered potentially infectious. Needle stick injuries from contaminated needles are the most common route of transmission in the healthcare setting, but transmission can also occur through exposed mucosa or abraded skin. The risk of acquiring HBV following occupational exposure depends on the serum HBV DNA level and HBeAg status of the source (85). HBV is highly infectious; the risk of transmission is 20 to 60% depending on the HBeAg status of the source. HBV transmission in healthcare workers is dropping thanks to routine recommendations for HBV immunization among healthcare workers (86). The risk of HCV transmission is significantly less than HBV, of the order of 1 to 4% (87), but the risk of chronicity is high. Unfortunately there is no preventative vaccine for HCV. Risk minimization and management should be a central part in occupational health and safety programs, as well as the infection control plans of any healthcare facility. This includes staff education, the use of protective equipment, sharps disposal facilities, universal HBV vaccination, and postexposure prophylaxis. Standard precautions including hand hygiene and the use of gloves, gowns, and protective eyewear should be strictly adhered to.

Following exposure, wound care with flushing of the site should be immediately instituted. If the healthcare worker has evidence of anti-HBs, either from previous exposure or vaccination, postexposure management is not required. If there is no preexisting protection against HBV, hepatitis B immunoglobulin (HBIg) should be administered as soon as possible, which can reduce the risk by 75% (88). HBIg should be administered concurrently with the first dose of the HBV vaccine. There is no postexposure prophylaxis for HCV. The recent development of oral highly effective antiviral therapy for HCV is likely to lead to studies of the use of these agents for postexposure prophylaxis, particularly in endemic areas, or in healthcare workers who might face exclusion from the workplace pending diagnostic evaluation.

### Hepatitis in Pregnancy

The most common cause of jaundice in pregnancy globally is viral hepatitis (89). Acute HAV during pregnancy is associated with preterm labor, but the clinical course is otherwise unremarkable. HAV is not vertically transmitted. The HAV vaccine is safe in pregnancy and should be administered to pregnant women traveling to endemic areas (103). Similarly HAV immunoglobulins are safe and can be administered following exposure to HAV. HEV in pregnancy can lead to

**TABLE 4** Differential diagnoses for acute liver injury

Differential diagnosis	Clues on diagnostic tests
Systemic infections	Markedly elevated transaminases, leukopenia, low bilirubin
• Herpes Simplex Virus (HSV-1, HSV-2)	
• Cytomegalovirus (CMV)	
• Epstein Barr Virus (EBV)	
• Varicella Zoster virus (VZV)	
• Parvovirus B19	
Drugs/Toxins	Very high enzyme elevation, low bilirubin
• Acetaminophen	
• Idiosyncratic drug reactions	
• Herbal preparations	
• <i>Amanita Phalloides</i> mushroom	
Ischaemic hepatitis	Very high aminotransferase levels (25 to 250 times the upper limit of normal), elevated serum LDH levels
Autoimmune hepatitis	Auto-antibodies (ANA, ASMA, ALKM-1)*
Wilson's disease	Coombs-negative hemolytic anemia, aminotransferase levels <2,000 IU/l, AST to ALT ratio of >2, normal or markedly subnormal ALP (<40 IU/l), ALP to total bilirubin ratio <4, low uric acid levels
Veno-occlusive disease	Doppler ultrasound
• Budd-Chiari	
• Portal vein thrombosis	
Pregnancy-related liver failure	Aminotransferase levels <1,000 IU/l, elevated bilirubin, low platelet count
• Acute fatty liver of pregnancy	
• HELLP syndrome	

\*ALP: Alkaline phosphatase, ANA: Anti-nuclear antibody, ASMA: Anti smooth muscle antibody, ALKM-1: Anti liver kidney micosomes.

fulminant liver failure with a high mortality of up to 25% in the third trimester. It is a major cause of maternal and fetal mortality in areas of high endemicity such as India, China, and Africa. HEV infection in pregnancy not only carries a high maternal mortality risk, but is also associated with a higher rate of obstetric complications and poor fetal outcomes including spontaneous abortion, stillbirth, preterm delivery, and antepartum hemorrhage (90). A high rate of vertical transmission has been reported in HEV (91) especially if the maternal viral load is high. There is no current treatment for HEV in pregnancy. Ribavirin is teratogenic and is therefore contraindicated in pregnancy and there is no evidence of efficacy in the pregnant patient. There are no safety or efficacy data for the new HEV vaccines in the pregnant population.

Acute HBV during pregnancy is usually not severe as pregnancy is a state of immunosuppression. There have been reports of prematurity and low birth weight, but there is no increased risk of mortality or teratogenicity. In chronic HBV, HBV DNA levels tend to be stable throughout pregnancy.

HBV may flare in the postpartum period because of immune reconstitution and HBe seroconversion can occur during those flares. The perinatal transmission rate in untreated HBeAg positive mothers is approximately 90% (92). Most infections appear to occur at the time of delivery. HBV screening during pregnancy and universal vaccination of all newborns has reduced transmission rates. Prophylactic administration of HBIg at birth followed by routine vaccination reduces transmission rates to 5 to 10%. The most important risk factor for vertical transmission is the mother's viral load. Antiviral therapy is now recommended in the third trimester for mother's with a serum HBV DNA level >10<sup>6</sup> IU/ml (93). The baby should still receive HBIg and vaccine immediately postpartum. The nucleotide analogue, tenofovir is a Category B drug that can be used safely in pregnancy. Lamivudine is classified a Category C but it has been used extensively in the HIV population with a reasonable safety profiles. Normal vaginal delivery is recommended as Cesarean delivery does not reduce the risk of infection (94); breastfeeding is safe (95).

Vertical transmission of HCV is much less efficient than of HBV, but the ~5% risk is higher in the setting of HIV coinfection (96), in which the viral load is higher (97). Most pregnancies are uncomplicated although a lower birth weight has been reported. As with HBV, normal vaginal delivery and breastfeeding are still recommended (98). Newborns will test positive for anti-HCV as they automatically acquire maternal antibodies so they need to be tested for HCV RNA.

Chronic viral hepatitis with cirrhosis causes a unique set of challenges for pregnancy. Cirrhosis is associated with infertility; those who become pregnant have a variable course. There is a risk of hepatic decompensation. The risk of poor fetal outcomes including miscarriage, stillbirths, and preterm labor is increased. Portal hypertension may worsen in pregnancy due to the increase in total blood volume and the risk of variceal hemorrhage is significant. Screening for varices and prophylactic banding should be considered prior to pregnancy.

Viral hepatitis is not the only cause of liver problems in pregnancy. Differential diagnoses unique to pregnancy must be also be considered during assessment and include hyperemesis gravidarum, acute fatty liver of pregnancy, intrahepatic cholestasis of pregnancy, and preeclampsia/HELLP syndrome (a variant of preeclampsia presenting with hemolysis, thrombocytopenia, and liver disease). Symptomatic gallstones are common in pregnancy.

### Viral Hepatitis in the HIV Population

With shared transmission risks, the prevalence of chronic hepatitis B and hepatitis C is higher in the HIV-infected population. With improved control of HIV disease with antiretroviral therapy, liver disease has emerged as one of the leading causes of death in patients with HIV (30). HIV impacts directly on the outcome of HCV and HBV infection, complicating its natural history, diagnosis, and management. For reasons that remain unclear, liver damage, especially fibrosis, progresses at a faster rate than in HCV or HBV mono-infection, despite hepatic necro-inflammation typically being less severe. Levels of HCV or HBV viremia tend to be higher. This is possibly due to increased replication in the setting of the relative immunosuppressive effect of HIV or a direct effect of the HIV itself that facilitates the engagement of coreceptors (99). Therefore, all patients with HIV should be screened for HBV and HCV infection. It is recommended that testing for both anti-HBc and HBsAg be

performed, as patients with HIV can have occult HBV, with high levels of HBV DNA and anti-HBc, but not HBsAg. Similarly, all HBV/HCV patients should undergo HIV testing (24). In the past, treatment of both HBV and HCV has been less effective in HIV coinfecting patients. This is no longer the case with potent first line direct DAAs, and response rates are generally equivalent to those observed in the mono-infected population. The management of drug-drug interactions is more complicated in patients taking HAART and there is a risk of hepatotoxicity. Flares of hepatitis due to immune reconstitution have also been reported (100, 101). However the benefit of HAART is thought to outweigh the risk as it is associated with a slower rate of liver fibrosis (102). HCV/HIV and HBV/HIV coinfection will be considered in further detail in separate chapters.

### Hepatitis in Patients Undergoing Immunosuppressive Therapy

Screening for HBV and HCV infection is recommended for all patients being considered for immunosuppressive therapy. Monoclonal anti-CD20 therapy, and stem cell transplantation are particularly high risk. Immunosuppression is associated with risk of severe hepatitis flares in patients with chronic hepatitis B infection. This can be prevented by the use of nucleos(t)ide analogue therapy. In patients with chronic hepatitis C, immunosuppression is associated with higher levels of serum HCV RNA and more rapid fibrosis progression; this can be prevented by curative antiviral therapy. Specific details regarding recommendations for testing and treatment are considered in pathogen-specific chapters.

### Liver Transplantation in Viral Hepatitis

HBV and HCV are common causes of cirrhosis and HCC and remain the main indications for liver transplantation. HCV is the most common indication for liver transplantation. Following liver transplantation for HCV, graft recurrence has been universal, and the progression to fibrosis in the graft may be rapid due to the concurrent use of immunosuppressants. There is also a risk of fibrosing cholestatic hepatitis. However, these events can now be prevented by complete HCV suppression with DAA therapy pretransplant. New DAA therapies for HCV are also very effective posttransplant, and can prevent rapid fibrosis progression, as well as effectively treat FCH. Graft recurrence with HBV is also universal and requires posttransplant prophylaxis with nucleos(t)ide analogue therapy and HBIg. The prognosis post-liver transplantation for patients with chronic hepatitis B is excellent.

# Viral Infections in Organ Transplant Recipients

JOHN A. ZAIA

## 6

Solid organ transplantation (SOT) and hematopoietic cell transplantation (HCT) represent continually expanding fields of medicine, and, with many innovative methods for allograft management, new and unusual presentations of virus infections continue to occur. These new drugs or modalities aim to protect the SOT recipient from rejection of the newly acquired organ by the endogenous immune system or to protect the recipient from attack by the graft (Graft vs. Host Disease, GVHD). For example, in the mid-1960s, with the introduction of cytotoxic drugs such as azathioprine and cyclophosphamide in renal transplantation, pneumonitis associated with human cytomegalovirus (CMV) infection was first observed (1). Soon thereafter, it was noted that transplant recipients with Epstein-Barr virus (EBV) infection developed a previously unrecognized clinical syndrome, posttransplantation lymphoproliferative syndrome (PTLD) (2). In populations with a high prevalence of human herpesvirus 8 (HHV-8) infection, Kaposi sarcoma became a problem following SOT (3). With time, most of the endogenous herpesviruses and polyomaviruses of humans have emerged as particular problems. At the same time, respiratory viruses and hepatitis viruses complicate successful management of the SOT and HCT recipient as methods of iatrogenic immunosuppression change. The donor tissue itself can be the source of transmission of virus infection, including rabies (4), West Nile virus (5), human T leukemia virus type I (6), human immunodeficiency virus (7), lymphocytic choriomeningitis virus (8), and B19 parvovirus (9).

Complex factors determine when and which active infection will occur and whether it will progress to disease. The time of onset of the most common viral infections after transplantation is fairly predictable (Fig. 1), and during the first year, infections with CMV, EBV, HHV-6, HHV-8, and BK virus (BKV) become a major focus of attention for the clinician. Consequently, management of these virus infections will be emphasized in this chapter. Correct management of hepatitis B virus and hepatitis C virus infections (Chapters 32 and 54) and of the several respiratory virus infections (Chapters 27, 37, 43) are equally important in patient outcome, but are discussed elsewhere in this volume.

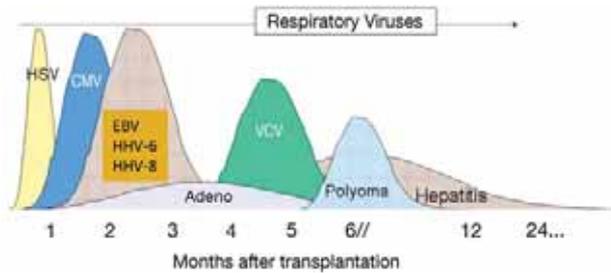

## CYTOMEGALOVIRUS INFECTION

### Epidemiology, Risk Factors, and Pathogenesis of CMV Disease

#### Epidemiology

Human cytomegalovirus (CMV) (Chapter 23) was initially identified, and, in fact, was named because of its effect on the fetus (10), but the virus has come to be recognized as a major pathogen in the organ-transplant recipient (11). Beyond the newborn, CMV produces disease almost exclusively in the immunologically impaired individual, and, in doing so, it demonstrates considerable variability in the types of clinical syndromes that are seen in different at-risk groups. Thus, in the fetus and in the child with perinatal infection, there can be hearing loss, central nervous system disease, and retinal damage (12). In SOT recipients, chronic CMV infection produces mononucleosis-like syndromes, arthralgia, enteritis and hepatitis, and pneumonitis (13, 14). With the introduction of preventive antiviral strategies, there has been a significant change in the occurrence of life-threatening CMV infection and in the management of transplant patients. In the 1980s, the CMV-related mortality was 10 to 30% for recipients of allogeneic HCT (15), but, with the use of ganciclovir, mortality has dropped to 2 to 6% in this population (14, 16, 17).

The use of antiviral chemotherapy has altered the natural course of posttransplantation CMV. In the pre-antiviral era, the onset of disease occurred at 2 to 3 months post transplant, but with the use of antiviral suppression, CMV reactivation and disease onset is delayed and occurs in the 4- to 12-month period post transplant (16). Of note, however, in the HCT population, the best antiviral agents have not been able to prevent late CMV disease (18). In a review of 9,469 recipients of allogeneic HCT between 2003 and 2010, CMV reactivation remained a significant risk factor for lower overall survival (17). Thus, with a shift in disease onset to later times after transplantation and with the side effects of antiviral treatment, the strategies for management of the transplant recipient have become more complicated. Treatment plans must weigh these risks, including costs, against the anticipated benefits and develop a rational

**FIGURE 1** Occurrence of the most frequent virus infections after transplantation. The time after both solid organ and marrow transplantation correlates with characteristic types of virus infections, ranging from herpes simplex virus (HSV) at the earliest time, to cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpesvirus type 6 (HHV-6), and herpesvirus type 8 (HHV-8) at 1 to 3 months after transplantation and with adenovirus, varicella zoster virus (VZV), polyomavirus, and hepatitis viruses at later times.

approach. Thus, the person with responsibility for the care of transplant recipients must be familiar with the changing aspects of CMV infection and prevention.

#### Risk Factors for CMV Infection in the Allograft Recipient

The management of HCT and SOT recipients is based on patient risk factors, and, in order to better understand the biologic aspects of CMV infection and to minimize CMV complications in these patients, it is important to recognize these factors (Table 1). The most significant one is the development of CMV infection itself, and for that reason, patient age > 20 years, a prior infection of the donor with CMV, and a prior infection of the recipient with CMV are most important. Early sero-epidemiologic (11), as well as molecular (19), evidence indicated that the donated organ is the source of CMV reinfection in most instances. Primary CMV infection can occur, but, more frequently, reinfection occurs in the recipient who has had prior CMV infection and acquires a new CMV strain from the donor (19). Cadaver organ transplants are also associated with more CMV infection than are organs from living donors (20). Thus the serostatus, defined as positive (+) or negative (-) CMV antibody in serum, of the donor (D) and the recipient (R) are

**TABLE 1** Risk factors for CMV complications in the transplant recipients

CMV Infection

Immune Status
Immunosuppressive regimen
CMV-specific lymphocyte immunity

used to group patients by risk. D+/R- SOT transplants are at highest risk of CMV infection and disease (21). Without preventive measures, 80 to 100% of D+/R- recipients will develop CMV infection, and 50 to 70% will develop disease (22). But the risk for D+/R+ recipients is reduced, and the risk for a D-/R- transplant is nil. Next in the hierarchy of risks for CMV-related complications are the type of organ, the age of donor and recipient, the type and intensity of immunosuppression, the time since transplant, coinfections, and presence of organ rejection (23). Regarding the type of organ, lung, small bowel, pancreas, and combined kidney-pancreas SOT recipients are at the highest risk for CMV infection (13, 24). Liver and lung recipients are at intermediate risk, and kidney recipients are at lowest risk (13, 24). Absolute CMV load, as measured by PCR in plasma, has also been associated with risk for CMV disease (25). In this regard, the CMV load is usually higher in association with more potent immunosuppression. However, with the use of an m-TOR-based immunosuppressive regimen, such as sirolimus or everolimus, there is a decreased incidence of CMV infection and disease (26). One study, comparing sirolimus-mycophenylate mofetyl-corticosteroid versus tacrolimus-mycophenylate mofetyl-corticosteroid, found a decrease in CMV infection (3% vs. 12%,  $P = 0.02$ ) with no difference in rejection rates (27, 28). The presumed explanation for this is that m-TOR inhibitors regulate CD8 memory T-cell development and enhance both the quantity and quality of the immune response (26). Also, sirolimus has been reported to inhibit CMV replication *in vitro* (29). In both the SOT and HCT transplant recipient, age is a risk factor; the pediatric recipient is more likely to be R- and subject to CMV infection on this basis depending on the donor serostatus. Finally, the induction of immunosuppression with antilymphocyte therapy is particularly associated with CMV infection, and any added immunosuppression for organ rejection or GVHD increases the risk for CMV infection (30).

In considering risk factors of CMV disease after transplantation, immunosuppression is, in fact, considerably important. Patients who have detectable cytotoxic T-lymphocyte (CTL) activity targeted to CMV have significantly less disease than those without such CTLs (31–33). In addition, the absence of CMV-specific CD4<sup>+</sup> T-cell function is a marker for CMV disease (34, 35). The frequency of CMV-specific CD4 and CD8<sup>+</sup> T cells can be assessed and evaluated quantitatively (36), and studies have linked the absolute numbers of CMV-reactive T cells to protection from disease (37–39). In HCT, the posttransplant reacquisition of CMV-specific cellular immunity following marrow ablation is improved when the donor has prior immunity to CMV (40). Similarly, in solid organ transplantation, the influence of cellular immune modification by the use of anti-T-cell antibody or of other agents that can influence CTLs, will significantly increase the risk of progressive CMV infection (20, 41).

#### Pathogenesis of CMV Infection after Allograft Transplantation

CMV-associated diseases in transplant populations are acquired through transmission of infection from the transplanted organ or from reactivation of endogenous infection in the recipient (11, 19). As with other herpesviruses, CMV can reactivate from a latent infection and lead to persistent infection that progresses to organ-specific disease if there is an absence of functional CMV-specific cell-mediated immunity (16). Local recovery of CMV at sites, such as urine or throat, do not correlate with incidence of disease, whereas

CMV viremia and asymptomatic pulmonary infection strongly correlate with subsequent disease (13, 14). It appears, then, that progression of CMV from local to disseminated infection is necessary before the onset of serious CMV disease in the setting of immunosuppression.

As with CMV infection in the non-transplant setting, the syndromes that occur with CMV infection in the transplant recipient can range from severe disease to mild forms of mononucleosis. For example, encephalitis, enteritis, pneumonitis, and other organ-specific syndromes occur, as seen in AIDS and in neonatal CMV infection (42, 43). However, the usual course includes fever, malaise and fatigue similar to infection in healthy adults (44). The usual asymptomatic course of CMV infection of normal persons is also seen with CMV infection in some transplant recipients (45, 46). Interestingly, although the rates of infection with CMV and the timing of infection post transplant are nearly identical when renal, heart/lung, and marrow transplant populations are compared, the severity of disease is much greater in heart/lung and HCT patients than in renal transplantation. However, the neurotropism of CMV infection, seen in AIDS and in the fetus and young infants, is less frequently seen in HCT and SOT recipients (13, 41, 46, 47). The principal differences in presentation of CMV disease between these groups are the predominance of mononucleosis-like symptoms in the HCT patients and direct involvement of the transplanted organ in the case of SOT (13, 41, 48).

In addition to direct effects of viral infection on organ function, CMV infection after transplantation is associated with events such as graft rejection, atherosclerosis, and increased rates of bacterial and fungal infections (13, 49–51). Because these effects have been associated with immunological abnormalities specific for transplantation populations, such as host-versus-graft disease or GVHD, the symptom complex associated with CMV appears to be due not only to a direct cytotoxic effect of infection on cell or organ function but also to a secondary or indirect effect on host responses to infection. Therefore understanding the pathogenesis of CMV disease in the transplant recipient involves elements related to (a) onset and progression of virus infection and (b) the effect of this infection on general cellular function and on specific immune function.

## Monitoring the Immune Status of the Patient

### Assays for Nonspecific Monitoring on Immune Status

In the ideal world, a transplant physician would be able to monitor the immunologic status of the patient and tailor immunosuppressive therapy to the needs of the patient based on risk and organ function (52). When assessing the net state of immunologic function, the conventional approach has been to monitor the immunosuppressive drug level and to record the cytopenia status. These are nonpathogen specific and can be generally useful, but, given individual variation in pharmacokinetics and pharmacodynamics, drug levels do not provide sufficient means to assess immune function (53). Other nonpathogen specific biomarkers of immune function are immunoglobulin levels (54), serum complement factors, peripheral blood lymphocyte subpopulations, soluble CD30, and intracellular concentrations of ATP in stimulated CD4 cells (52). These are associated with risk for bacterial infection and will not be discussed here, but certain biomarkers have been associated with risk for virus infection. For example, hypogammaglobulinemia (HGG) is

not uncommon in the first year post transplant (55, 56), especially in those receiving mycophenolate mofetil (55), in those with bronchiolitis obliterans (57, 58), and in those receiving corticosteroid pulses after heart transplant (59). Although HGG is usually associated with bacterial infection (60), one meta-analysis (54) reported a nearly 3-fold higher risk of CMV during HGG. Clearly, transplant patients should be monitored for IgG levels, and IgG replacement therapy has shown improved outcome in certain groups of transplant recipients (61–63). With regard to complement activation biomarkers, C3 has not been associated with risk for virus infection. However, the lectin activation pathway for complement is influenced by mannose-binding lectin (MBL), and, in SOT recipients, MBL levels have been associated with an increased risk for CMV relapse post valganciclovir therapy (64). However, there is no clear consensus at this time on the need to monitor MBL levels.

Probably the best nonpathogen specific biomarker for infection is lymphopenia post SOT/HCT (16, 65). In general CD4+ lymphopenia is associated with CMV infection (66) and other infections. In the HCT recipient, lymphopenia can be related to GVHD, and it is likely that there are factors that influence the occurrence of both GVHD and CMV (67, 68). In liver allograft recipients, CD4+ cell counts <300/μl place a patient at increased risk for CMV infection (52), and, in the HIV-1-infected SOT patient, a CD4+ lymphocyte count <200/μl is associated with severe risk of infection similar to that seen in the general HIV-1 population, prompting the use of prophylactic antibiotics (69).

Finally, there are two other laboratory assays for non-specific measurements of immune function. The first is based on the circulating level of soluble CD30, a glycoprotein related to the tumor necrosis/nerve growth factor family (70). In SOT, high levels have been linked to risk for graft loss (71), although the sensitivity and specificity of the assay used in this way is modest (72). CD30 levels still have not been convincingly correlated to risk of infection after transplantation. The second is the *in vitro* measurement of iATP in CD4+ T cells after nonspecific stimulation with phytohemagglutinin, a commercially available assay called ImmuKnow (73). Studies have linked low iATP to risk for CMV infection post lung transplant (74), EBV infection, and BK virus infection (75). At present, however, there is no recommendation on how best to use the iATP assay because its consistent performance is complicated by lack of sufficient experience in prospectively observed studies and by the vagaries of collection and processing time (52, 76). At this time, no recommendation can be made for use of the assay in SOT and HCT patient management.

### CMV-Specific Immune Monitoring

Since the CMV serostatus itself imparts the main risk for CMV infection (77), the question arises as to how best to monitor the patient for CMV-specific T-lymphocyte function or lack of such function (78). The ability of T cells to make interferon gamma (IFNγ) correlates with protection from CMV, and this raises the obvious question as to whether the IFNγ response to CMV can guide preventive or therapeutic strategies (39, 79–81). Five commercial tests have become available for 4 types of CMV-specific assays of immune function; these include a CMV-peptide inducible intracellular cytokine release assay, the MHC-tetramer stain that measures the binding of antigen-specific HLA complexes to the T cell, the QuantiFERON-CMV assay (Qiagen

Inc.), and the ELISpot assay (T-Track CMV, Lophius Biosciences GmbH, Regensburg, Germany) and T-SPOT.CMV (Oxford Immunotec Ltd, Oxford, UK, and Marlborough, MA, USA) (82). The QuantiFERON-CMV assay is based on the release of interferon-gamma as measured by ELISA after an overnight incubation of whole blood with CMV-specific peptides, and this test has been most studied post SOT/HCT. In one such study (83), approximately one-third of CMV seropositive recipients actually lack demonstrable CMV immunity when inducible INF-gamma production is measured, and these patients are at risk for post SOT-CMV infection (80). In a multicenter study that focused on high-risk D+/R- recipients after discontinuation of antiviral prophylaxis, those with a positive QuantiFERON-CMV result at time 0, 1 month, or 20 months post valganciclovir prophylaxis had less late-onset CMV disease than those with a negative result (84). Results with the QuantiFERON-CMV assay suggest that spontaneous clearance of viremia occurs in 92% of patients with a positive assay result (81). The assay has FDA approval to claim that it “may assist” the clinician’s ability to predict risk of CMV infection and guide decision-making in regard to treatment. Finally, the T-Track CMV- and T-SPOT. CMV-ELISpot assays are both in clinical evaluation in the setting of transplantation. While both methods are very promising, their role as clinical tools for assisting patient management remains to be determined.

## Clinical CMV Disease, Treatment, and Prevention

### Disease Course

In SOT patients, CMV-associated complications have not changed since the early descriptions of fever, malaise, with or without neutropenia and thrombocytopenia, and with or without subsequent fungal and bacterial complications (13, 14). In both SOT and HCT, the most dreaded CMV-associated complication is interstitial pneumonia (CMV-IP), but enterocolitis and hepatitis are more frequently seen complications. CMV-IP presents with dyspnea and oxygen desaturation and can quickly progress to respiratory failure. The use of antiviral prophylaxis has markedly reduced serious CMV-IP, but this complication remains a late problem both in the allogeneic HCT recipient with chronic GVHD (14) and in the SOT recipient on long-term immunosuppression. In fact, late onset CMV disease occurs in approximately 18% of SOT recipients depending on D/R serostatus, and late CMV disease has been observed in as many as 34% of D+/R- SOT recipients when prophylaxis is stopped at 3 months (78). Late occurrence of disease is due to a failure of development of CMV-specific cellular immunity in the R-recipient during the months of anti-CMV prophylaxis (79). Of interest, delayed implementation of CMV prophylaxis by as few as 14 days post transplantation has been associated with less late-onset CMV disease (85). This suggests that providing some limited exposure to CMV is important for reconstitution of CMV immunity after SOT is consistent with the known control of CMV in R+ SOT recipients with CMV-specific cellular immunity (86).

CMV disease can present in a variety of ways, and several serious syndromes are associated with the specific transplant patient groups. For example, with heart and lung transplantation, bronchiolitis obliterans can occur following CMV infection and following acute rejection. Bronchiolitis obliterans is defined as a decline in forced expiratory volume in one second, <80% posttransplantation baseline, or histological presence of obliterative bronchiolitis (87). In both

HCT and SOT, CMV infection can be associated with significant indirect effects, including poor graft function with acute and chronic rejection (88), increased bacterial and fungal infection (13), and graft loss (89), as well as increased mortality (17, 90). Acute rejection is associated with CMV infection in all solid organ settings (88), e.g., for heart transplant (91), for lung transplant (92), for kidney transplant (49, 93), and for liver transplant (94).

### Prevention of CMV in the Seronegative Transplant Recipient

For the CMV-seronegative transplant recipient, for whom there is a CMV-seronegative organ donor, the risk of infection is determined by the exposure to posttransplantation blood product support. Except for the chance of community- or sexually acquired CMV infection, virtually all primary CMV infections can be prevented by careful preparation or processing of the blood components (95). For the CMV-seronegative HCT recipient of a graft from a CMV-positive donor, the risk of infection is a function of the number of cells in the graft (96). Overall, in HCT, virtually 90% of all CMV disease occurs in the CMV-seropositive recipient. In SOT, however, the option to use CMV-seronegative organ donors is not usually available, and the CMV-seronegative recipient of an organ from a CMV-seropositive donor will get a CMV infection in 80 to 100% of cases, and disease can occur in 50 to 70% if not given antiviral prophylaxis (13, 22) (Table 2).

### CMV Disease Prevention: Antiviral Strategies

The approved antiviral agents for CMV prophylaxis following organ transplantation are IV ganciclovir, oral ganciclovir, oral valganciclovir (excluding liver SOT), and oral acyclovir (kidney SOT only). With ganciclovir (GCV), two strategies have been used; either all at-risk patients are treated for a defined period, or only transplant recipients with documented CMV infection are treated. The first approach is termed “general prophylaxis,” and the second strategy is termed “preemptive” or early antiviral therapy. In either HCT or SOT, there is no best strategy for use of ganciclovir, in part because of its toxicity, and the clinical situation determines the appropriate approach. For example, the patient at high risk for CMV deserves prophylaxis, and the less risky patient is treated preemptively. In reality, hybrid strategies have developed in which prophylaxis is used during the highest period of risk, e.g., day 1 to 100 post SOT, and then preemptive therapy is used during periods of low risk (Table 2).

Regarding acyclovir in prevention programs, acyclovir was used with surprising success in modifying CMV infection and disease after HCT and SOT in the pre-ganciclovir era (97, 98). The mean 50% inhibitory dose of acyclovir for CMV strains is  $63.1 \pm 30.2 \mu\text{M}$  (99), and peak acyclovir levels in the plasma can range from 25 to 100  $\mu\text{M}$  depending on the regimen. Valacyclovir, a prodrug of acyclovir, achieves blood levels comparable to IV acyclovir, and when given at a dose of 2 grams orally 4 times daily for >900 days after renal transplantation, significantly reduces the risks of CMV disease in high-risk D+R- patients (45% vs. 16%,  $P < 0.001$ ) and of acute rejection episodes (52% vs. 26%,  $P < 0.001$ ) (100). Similar inhibition of CMV reactivation has been reported in allogeneic HCT recipients (101). Despite this, neither acyclovir nor valacyclovir is approved for prophylaxis or treatment of CMV infection, and their use is only as an adjunctive agent in CMV prophylaxis regimens

**TABLE 2** Prevention of CMV infection in transplant recipients

Transplant Organ	CMV Exposure	Risk Level	Preventative Regimen	Duration of Therapy	Comment
HCT-allo	D+ / R+ D - / R+	Intermediate to high	Preemptive	4 weeks	Continue preemptive therapy for high-risk patients <sup>a</sup>
HCT-auto	R+	Low	Preemptive	4 weeks	Monitor for CMV to D-60 for high risk patient
Kidney	D+ / R+	Low	Prophylactic	2–4 weeks GCV	Duration of therapy is based on immune status
	D - / R+	Intermediate	Prophylactic	3 months VGCV	
				2–4 weeks GCV	
Liver	D - / R+	Intermediate	Prophylactic	2–4 weeks GCV	Duration of therapy is based on immune status
	D+ / R-	High	Prophylactic	3–6 months GCV	
				2–4 weeks GCV	
Heart	D - / R+	High	Prophylactic	2–4 weeks GCV	Duration of therapy is based on immune status
	D+ / R-	High		6 months VGCV	
Lung	D - / R+	High	Prophylactic	2–4 weeks IVGCV	Consider using CMVIG <sup>b</sup>
	D+ / R-	High		6 months VGCV	
Small Bowel	D - / R-	Low	Preemptive	—	Consider using CMVIG <sup>b</sup>
	D - / R+	High	Prophylactic	2–4 weeks GCV	
	D+ / R-	High		6–12 months VGCV	
SOT not Small Bowel	D - / R-	Low	Preemptive	2–4 weeks GCV	Continue preemptive therapy for high-risk patients <sup>a</sup>
				6–12 months VGCV	

D = donor; R = recipient; + = CMV seropositive; - = CMV seronegative; GCV = ganciclovir; VGCV = valganciclovir; SOT = solid organ transplant; HCT = hematopoietic cell transplant; allo = allogeneic; auto = autologous.

<sup>a</sup>High risk = grade >2 GVHD; haploidentical donor; cord blood donor.

<sup>b</sup>Some experts recommend using CMVIG.

for select lower-risk populations for which ganciclovir or valganciclovir cannot be used.

### Prevention of CMV after Solid Organ Transplantation

In SOT recipients, the management strategies are based on the variable risks for CMV based on organ type, D/R serostatus, and immunosuppressive regimen (Table 2). Unlike HCT in which rapid marrow recovery is the goal, in SOT there is less concern about the effects of marrow toxicity and prophylaxis with ganciclovir is the recommended approach. The advantages of prophylaxis are that it prevents CMV infection during the highest risk period of immunosuppression, decreases the indirect effects of CMV on the allograft, and removes the need for CMV monitoring. Prophylactic ganciclovir has been associated with both a reduction in organ rejection events and in coinfections (23, 102–104). A meta-analysis of 17 studies showed the clear superiority of prophylactic therapy over preemptive therapy for all SOT types (104). Prophylaxis versus preemptive therapy was associated with reduced rejection rates (26% vs. 53%) and reduced bacterial and fungal coinfections. The disadvantages are the side effects, including neutropenia, potential for the development of antiviral drug resistance, and prevention of CMV-specific cell-mediated immunity resulting in late-onset disease when the prophylaxis is stopped (23, 79). For this reason, prophylaxis does not prevent late-onset CMV disease, and approximately one-third of SOT recipients have been reported to get late-onset CMV infection post prophylaxis with D+/R- being at highest risk (105). When comparing prophylactic versus preemptive valganciclovir for kidney recipients, a double-

blinded study showed increased CMV disease in the preemptively treated group (4.4% vs. 19.2%,  $P=0.003$ ) (106). Hence, international guidelines recommend the use of a risk-based management plan in which those at highest risk, namely D+/R- recipients of SOT, receive prophylaxis; D+/R+ recipients at intermediate risk receive either prophylactic or preemptive therapy; and D-/R- recipients at lowest risk receive preemptive therapy (82).

The recommended duration of prophylaxis is 3 to 6 months for heart, liver, pancreas, and kidney SOT recipients and 6 months for lung and small bowel (Table 2) (80, 82, 104, 106–109). The kidney recipient is at lowest risk even in the D+/R- category presumably because of the lower tissue burden of CMV transferred to the recipient (110), and lung and small bowel SOT recipients are at the highest risk for CMV infection and require a longer period of prophylactic treatment. The current recommendations of the International Transplantation Society for CMV prevention in SOT are to begin with prophylaxis and then, based on the risk group, introduce preemptive therapy at the appropriate time (Table 2) (82). This type of approach has been shown to be effective in D+/R- liver transplant recipients, in which the strategy reduced CMV disease to approximately 10% at 2 years post SOT (111). During the preemptive therapy phase, weekly monitoring is done using a CMV PCR or antigen assay for 3 months and then spacing the monitoring according to need, based on concurrent immunosuppressive therapy. Quantitative PCR has been shown to be a more sensitive assay for detection of infection than the CMV antigen assay (94% vs. 24%) (89). The benefit of preemptive therapy is the reduction in side effects, less drug resistance, a reduction in cost, and, especially for the pediatric

patient, a reduction in the daily number of oral medications. However, this strategy creates a need to monitor, report, and act on results, and, in the real world of transplantation, this requirement in the critical posttransplantation period can be a burden. Several questions arise in the management of the SOT recipient:

- What is the correct dose of ganciclovir? Ganciclovir is given at a dose of 5 mg/kg IV twice daily. To lessen the potential marrow toxicity, the regimen has been converted to 5 mg/kg ganciclovir IV daily or 900 mg oral valganciclovir daily Monday through Friday.
- What is the optimal duration of prophylaxis? A large multicenter randomized study (100 days vs. 200 days of prophylaxis) demonstrated that the longer duration was significantly better in preventing CMV infection at 1 year post SOT [36.8% vs. 16.1%] with similar occurrence of adverse events (108). The longer duration of prophylaxis was associated with less CMV infection and minimal disease, but side effects of therapy prevented continued prophylaxis in some patients (105).
- Is there a use for oral ganciclovir? Oral ganciclovir is poorly absorbed, but its use has been approved in the U.S. for CMV prophylaxis after SOT based on its efficacy in control of CMV disease (22). In contrast, oral valganciclovir is well absorbed and can be substituted for intravenous drug during maintenance therapy for control of CMV reactivation. A large study comparing oral ganciclovir to valganciclovir in D+/R- organ recipients showed equivalence of the two drugs (112). However, valganciclovir is approved only for patients with AIDS or kidney, heart, and kidney-pancreas transplants. The dose of oral ganciclovir is 1 gram 3 times daily; the dose of valganciclovir is 900 mg once daily. Hence, valganciclovir is preferred for the convenience. The toxicity of these drugs is similar to the IV formulation of ganciclovir.
- How important is the duration of prophylactic therapy? Late CMV disease is a significant problem after the discontinuation of ganciclovir/valganciclovir prophylaxis. In a comparison of 100-day versus 200-day prophylaxis, the incidence of CMV disease was significantly less in the 200-day treatment group (37% vs. 23%) (108).
- Does use of preemptive therapy put a patient at significantly increased risk compared to the patient receiving prophylaxis? There have been no published randomized studies comparing these two strategies in nonrenal SOT. However, there have been comparative studies of preemptive versus prophylactic ganciclovir in renal SOT, with mixed outcomes. One such study in renal transplant recipients showed more CMV DNAemia in the preemptive group and more late CMV disease in the prophylactic group (113). A meta-analysis evaluating these strategies in SOT recipients concluded that both strategies for ganciclovir use, as well as prophylactic acyclovir, reduced CMV organ disease, but only prophylactic ganciclovir reduced the associated bacterial and fungal infection and death (104).
- Should valganciclovir be used in a liver transplant recipient? Valganciclovir is not approved for use in liver SOT recipients. Valganciclovir showed some inferiority to IV ganciclovir in this population due to an increased incidence of CMV disease in the valganciclovir group (112).
- What is the role for CMVIG? CMVIG is an immunoglobulin product derived from screening outdated plasma

for elevated CMV antibody levels (114). A meta-analysis of randomized trials, comparing CMVIG with no treatment or with an antiviral, showed that CMVIG reduced the overall mortality and the CMV-related mortality and the incidence of CMV disease; however, it did not reduce the CMV infection or organ rejection (115). In heart transplant recipients treated with CMVIG, compared with those not treated or treated with antiviral only, the CMVIG group had significantly increased patient and organ survival at 7 years. Similar results have been observed in kidney and liver SOT recipients (13). Current guidelines recommend prophylaxis with either val-GCV or GCV, used orally or IV, with or without CMVIG for both heart and lung SOT recipients (82).

### Prevention of CMV in the HCT Recipient

The prevention of CMV disease with intravenous ganciclovir was first shown in studies after marrow transplantation (116, 117). In HCT recipients, ganciclovir preemptive treatment has been shown to be associated with improved survival, whereas routine prophylaxis has no survival advantage (117, 118). The benefit of a preemptive strategy using ganciclovir was established in HCT when this marrow-toxic agent was given only to asymptomatic transplant recipients at the time of first laboratory evidence of active pulmonary CMV infection, a strategy that significantly reduced progression to subsequent CMV disease (116). Asymptomatic CMV pulmonary infection occurs after HCT (119), and approximately 60 to 70% of these patients will subsequently develop CMV-IP (116). Ganciclovir has also been used pretransplant (2.5 mg/kg IV every 8 hours on days -8 to -1 pretransplant and resumed at 6 mg/kg daily for 5 days per week at the time of engraftment) (120), with significant reduction in rate of CMV infection (20% vs. 55%) but with no significant reduction in CMV disease (10% vs. 24%). The problem is that prophylactic ganciclovir is associated with marrow toxicity and failure to develop CMV-specific immunity. Drug-related neutropenia occurs in approximately 30% of transplant recipients receiving ganciclovir (121). The median time of onset of neutropenia is 36 days (range 6–74 days) after starting treatment, and the neutropenia persists for a median of 12 days (range 4–20 days) (117, 118). Thus, strategies have been developed using short-course prophylactic GCV, followed by monitoring for CMV, and preemptive treatment when infection occurs.

As with prophylactic management, indicated in Table 2, ganciclovir is given at a dose of 5 mg/kg IV given twice daily for 7 days, and then maintained at 5 mg/kg once daily for 5 to 6 days per week for 2 to 6 weeks, based on the clearance of CMV DNA from blood. Thus, the use of preemptive ganciclovir is effective in preventing the morbidity of CMV infection, while sparing the toxicity of ganciclovir in those who are at lesser risk for disease. However, the need to identify those with significant CMV infection places a requirement for continued monitoring, and accurate monitoring is limited by the sensitivity of the assays used to detect CMV.

Several questions arise in management of the SOT/HCT recipient involving alternative antiviral agents:

- Foscarnet. The optimal method for prevention of CMV disease after HCT relies on a preemptive strategy using ganciclovir. At times, however, because of marrow toxicity, foscarnet should be used instead of ganciclovir. When the WBC falls to 1,000/ $\mu$ l, ganciclovir should be stopped and foscarnet begun. Also, during ganciclovir

treatment, it is not unusual to observe breakthrough CMV viremia, and this is usually associated with increased immunosuppressive therapy and not with drug-resistant virus (122). However, resistance to ganciclovir occurs, especially in SOT recipients (123), and, in this situation, foscarnet can be used alone or in combination with ganciclovir for CMV suppression (see discussion of Drug Resistance below). Although renal toxicity can be limiting, foscarnet can be safely used in the HCT population by following recommendations regarding pre-treatment hydration (124).

- **Cidofovir.** Cidofovir has been used in transplant patients as second-line therapy for patients with CMV disease unresponsive to ganciclovir or foscarnet (125), but its renal toxicity severely limits its use.
- **Letermovir.** Letermovir is an orally available agent and has activity against both naturally occurring CMV and ganciclovir-resistant CMV (126). In a phase II placebo-controlled trial, the agent was shown to be very effective when used for prophylaxis in HCT patients (127). A phase II study using a preemptive strategy was evaluated in kidney transplant recipients and demonstrated a significant reduction in CMV DNAemia from baseline treatment (128). A phase III trial (NCT02137772) in HCT patients has completed enrollment and was in the analysis phase in 2016.
- **Maribavir.** Maribavir is an oral benzimidazole riboside, which blocks CMV DNA maturation by inhibition of UL97 protein kinase and has activity against strains resistant to CMV (129). In a study of 233 D+/R- liver SOT recipients randomized to receive either 1,000 mg ganciclovir orally three times daily or 100 mg maribavir orally twice daily, there was no difference in the incidence of CMV disease at 6 months post SOT, but when disease occurred, it occurred earlier in the maribavir group and more maribavir-treated patients had CMV DNAemia at 100 days and at 6 months (130). In addition, maribavir failed to meet endpoints in a phase III trial in HCT patients (131). It remains to be determined whether higher doses of maribavir would be effective.
- **Brincidofovir.** Brincidofovir, previously called CMX-001, is a lipid conjugate of the nucleotide analog cidofovir. In a placebo-controlled study in HCT recipients, the incidence of CMV events was significantly lower among patients treated with 100 mg twice weekly compared with placebo. This oral agent does have dose-limiting gastrointestinal toxicity, and diarrhea is a common adverse event in patients at doses of 200 mg weekly or higher (132). In a blinded study in 452 HCT recipients, 100 mg brincidofovir given twice weekly failed to meet the 24-week primary endpoint of prevention of CMV infection compared to placebo (Chimerix press release, December 28, 2015). Of note, there was less CMV infection through week 14 of treatment, but, in the 10-week post-treatment period, there was an increase in CMV infection compared to control. This was felt to be related to a higher use of immunosuppressive agents for treatment of presumed GVHD in the brincidofovir-treated group. Phase III trials in SOT were closed prematurely following the release of this information.
- **Cyclopropavir.** Cyclopropavir is a methylene cyclopropane analogue that inhibits CMV by UL97 kinase inhibition but with *in vitro* antiviral potency slightly greater than that of ganciclovir (133). This agent inhibits CMV by its effect on DNA synthesis, and, because resistance to

cyclopropavir involves a different site on UL97, it is active against some ganciclovir-resistant strains of CMV (133). A phase I safety and pharmacokinetic study sponsored by the National Institute of Allergy and Infectious Diseases is being completed in normal volunteers (NCT02454699), and future clinical use of this agent will be based on these results.

- **Leflunomide.** Leflunomide, an inhibitor of protein kinase activity and pyrimidine synthesis, has broad antiviral activity, including *in vitro* activity, against CMV. It has immunosuppressive activity, is approved only for treatment of rheumatoid arthritis at a dose of 100 mg/day for 3 days (loading dose) and then 20 mg/day (maintenance dose) in patients without risk for hepatotoxicity (134). Leflunomide can be hepatotoxic and has produced liver failure and/or activation of hepatitis B virus in patients (135), and it can also cause myelosuppression. Although the drug does not reduce CMV DNA replication or protein synthesis *in vitro*, it does impair protein processing and viral assembly (136). There is a case report of clinical effect in drug resistant CMV (137), but there are no controlled studies to support antiviral effect (13). The largest published experience of leflunomide use for treatment of CMV in transplant patients was a single-center retrospective study of 17 patients who failed conventional treatment (137). In this report, there were a variety of CMV syndromes, and treatment with a loading dose of leflunomide at 100 mg/day for 3 days and then 20 mg/day maintenance dose for a median of 3.5 months was associated with clearance of CMV DNA from blood in 82% of cases, with a median time to clearance of the DNAemia of 1.9 months. A consensus of experts has recommended that caution be advised when leflunomide is used in SOT recipients for cases of severe CMV disease or in those with high viral loads (82). Similarly, in HCT recipients, there are mixed results with leflunomide and insufficient information from controlled trials to support its use (16).
- **Artesunate.** Artesunate has also been suggested as an alternative agent for drug-resistant CMV. This natural product is a derivative of artemisinin, the traditional Chinese medicinal used for malaria, and it has *in vitro* inhibitory activity against CMV (138). However, there is no convincing evidence of effect clinically (139), and there is no recommendation for its use in the setting of drug-resistant CMV.

### Drug Resistance

Drug resistance to anti-CMV agents is most prevalent in the SOT populations and usually occurs as resistance to ganciclovir-related drugs. Resistance is seen in the HCT patient, but, perhaps because preemptive strategies are the more common approach in such patients, it is relatively rare in this population. The risk factors for emergence of drug resistance by CMV are D+/R- status, duration of ganciclovir/valganciclovir treatment, level of immunosuppression, and suboptimal drug dosing. In either SOT or HCT patients, when ganciclovir resistance occurs, it is usually after 6 weeks of therapy. CMV DNAemia often increases in the first 2 weeks post-ganciclovir preemptive treatment, and this is unlikely to be due to drug resistance (82). Drug resistance should be suspected if the patient has been on ganciclovir and CMV DNAemia persists. To confirm resistance, the CMV isolate is tested genotypically for mutations in either UL97 (CMV codons 400–670) or UL54 (codons 300–1,000). UL97 encodes the enzyme necessary for phosphorylating

GCV to its active form, and, because this mutation accounts for 90% of resistant strains, this assay is done first. UL54 encodes the viral DNA polymerase necessary for CMV DNA replication and is evaluated after the UL97 results, if necessary. The UL97 mutation prompts the switch to foscarnet. UL54 resistant CMV has more cross-resistance to both foscarnet and cidofovir, and thus is more problematic.

How does one treat a drug-resistant CMV infection? An international consensus group has developed an algorithm for managing a patient with ganciclovir-resistant CMV (82). For life-threatening or sight-threatening disease, the first action is to reduce the immunosuppression if possible. Then, foscarnet is added to the regimen while the patient's CMV isolate is sent to the laboratory for genotyping for likely drug resistance. For a major UL97 mutation, the switch to foscarnet is maintained. If there is no response in CMV DNAemia, mutations in UL54 are investigated and other antivirals are considered, but at this point there is no guidance from evidence-based medicine. Recommended approaches include increasing the ganciclovir dose to 10 mg/kg/dose, combining ganciclovir with foscarnet, adding CMVIG, or using other antivirals (82). If there is a UL97 mutation, cidofovir is likely to show cross-resistance and should not be used. Immunotherapy, using CMV-specific T cells for adoptive therapy, should be considered based on the patient status.

#### Cellular Immunotherapy for CMV

It was observed for many years that patients who were able to develop CMV-specific CTL function after allogeneic HCT survived serious CMV infection, and those who failed to develop a positive response to CMV infection often succumbed with CMV-IP (31). The posttransplant cellular immune response likely develops from memory cells present in the donor graft for patients receiving non-T cell depleted transplants (140). The possibility of augmenting donor- or recipient-derived viral immunity through adoptive immunotherapy has been a goal because the initial use of this method in a high-risk group of HCT recipients showed an absence of both CMV disease and CMV infection (141). Subsequent to this, several groups have demonstrated the feasibility of adoptive cellular therapy in this setting using various methods (142–145). Administration of CMV-, AdV-, and EBV-specific donor-derived T cells has been reported in small cohorts (146–148). It is even possible to derive CMV-specific T cells from CMV-seronegative donors (149) by induction of immunity *in vitro* or to use automated methods for cell product preparation outside of a GMP facility (150). The more recent ability to use third-party donors, sharing at least one HLA class I antigen, has shown promise in both SOT and in HCT recipients (151–154). The further ability to induce multivalent T-cell pools that recognize AdV, EBV, CMV, BKV, HHV6, and CMV greatly expands the potential for adoptive transfer as part of patient management (155, 156). In the near future, transplant physicians will be able to provide adoptive immunity to patients who have failed conventional antiviral therapies.

#### Vaccines for CMV

CMV induces neutralizing antibodies (NAb) during natural infection that prevent virus infection of either fibroblasts or epithelial/endothelial cells when studied *in vitro* (157, 158). NAb, targeting the gB, gM/gN, and gH/gL glycoproteins of CMV, block infection primarily of fibroblasts. The more potent NAb is one that is induced by a pentameric complex of gH/gL/UL128/UL130/UL131A and that inhibits epi-

thelial/endothelial cell infection, protecting the human placental cytotrophoblast from infection (158). Induction of anti-gB antibody by vaccine in SOT recipients has been associated with shorter duration of CMV DNAemia and fewer days of ganciclovir treatment (159). An MVA-based vaccine encoding the pentameric complex has been developed and protects against infection in nonhuman primates (160). The evidence indicates that the vaccine can block endothelial cell infection (158), which suggests a role for the vaccine in protection not only of neonates but also of transplant recipients in the future.

For the transplant recipient undergoing graft-protective or GVHD-therapeutic immunosuppression, however, it is the loss of CMV-specific T-cell immunity that would need to be corrected by vaccination. For that reason, vaccines that target CMV proteins recognized by T cells are in the process of development. The first vaccine to complete a phase II trial in the transplant population was ASP0113 (TransVax, Vical/Astellis Pharmaceuticals Inc.), a DNA-based vaccine that encodes CMVpp65 and CMVgB proteins (161). In a placebo-controlled double-blind trial, the 80 donor-recipients had less CMV DNAemia, but not a significant reduction of CMV-specific antiviral treatments, than did the unpaired recipients. Based on these results, a phase III trial is now in place (NCT01877655) in the HCT setting. In addition, this vaccine is being evaluated in D+/R- kidney transplant recipients (NCT01974206) and in dialysis patients (NCT02103426).

A CMV peptide vaccine (CMV PepVax), in which a CD8-specific CMV pp65 peptide epitope is fused to a tetanus-derived helper cell epitope and used with a TLR9 agonist, is safe and immunogenic in volunteers (162). In a randomized nonplacebo controlled trial in HCT recipients (NCT01588015), CMV PepVax significantly decreased not only CMV DNAemia but also the use of anti-CMV therapy (163). Surprisingly, the vaccine group also had fewer leukemia/lymphoma relapses in the first year post HCT and an improved overall survival (163). Thus, there are encouraging data that suggest the potency of vaccines used in the SOT and HCT populations even during immunosuppressive therapy post transplantation. It is possible that, in the future, vaccines will become available for improved patient management.

## EPSTEIN-BARR VIRUS INFECTION

### Epidemiology, Risk Factors, and Pathogenesis of EBV Disease

In the general population, EBV infection is the cause of infectious mononucleosis (164, 165) and is associated with important neoplastic diseases, such as nasopharyngeal carcinoma (166), Burkitt's lymphoma (167, 168), non-Hodgkin's lymphoma in AIDS (169), and Hodgkin lymphoma (170) (see Chapter 25). In the transplant population, all aspects of these clinical manifestations of EBV infection can be seen, and, for this reason, EBV is one of the most important infectious problems after either SOT or HCT. Chronic immunosuppression, necessary to maintain the viability of the solid organ graft or the suppression of GVHD, permits either prolonged or more extensive EBV infection to occur, and it is in this setting that the various elements of EBV pathogenesis are seen.

From a historical perspective, it is important to appreciate the conceptual development, which explains the pathobiology of EBV-related diseases. The occurrence of

lymphomas in renal transplant recipients was first documented in 1969 (171), and a clear link to immunosuppression seemed apparent with the observation of a lymphoid malignancy at the actual site of injection of antilymphocyte globulin (172). Shortly thereafter, both the association of lymphoid malignancies with immunodeficiency and the interesting observation that the neoplasms associated with organ transplantation can regress with cessation of immunosuppressive therapy were made (173). The seminal observation that linked this clinical syndrome to EBV was the description of the X-linked lymphoproliferative syndrome in 1975 (see reviews [2, 174]). Subsequently, EBV was linked to malignant lymphoproliferation after infectious mononucleosis (175), organ transplantation (176, 177), and other immunodeficiency conditions (2).

The most significant feature of EBV infection in SOT recipients is the development of posttransplant lymphoproliferative disorder (PTLD). PTLD is an abnormal proliferation of lymphoid cells and can be heterogeneous in morphology, ranging from indolent polyclonal disease to aggressive proliferation of lymphocytes and plasma cells (2, 174, 177). PTLD was first reported in 1968 in two renal transplant recipients (178), and the prevalence of PTLD varies with the type of SOT and HCT. PTLD occurs rarely after T-cell-replete HCT, but the risk of PTLD is increased 30-fold by the use of T-cell depletion and 12-fold by the use of anti-T-cell therapy for graft versus host disease (179). In SOT, the incidence increases based on organ type, moving from low incidence in renal, to higher incidence in liver, then heart-lung, and then kidney/pancreas organ transplants (174, 180, 181).

#### Pathogenesis of EBV-Related Diseases after Transplantation

EBV infection usually begins with an initial lytic infection of the nasopharyngeal epithelial cells (182), and by this route, the virus gains access to the lymphoreticular system where latent infection of B lymphocytes and other cells occurs (2, 183). From early in the history of SOT, EBV infection was observed to be a major risk factor in PTLD in renal transplant recipients (184), and use of polymerase chain reaction methods have confirmed that quantitative assessment of EBV infection can identify those at greatest risk for PTLD (185). In healthy persons, an immune response controls the infection, but the total immunopathologic response to EBV infection, involving activated B, T, and NK cells, leads to enlarged lymph nodes, painful cervical lymphadenitis, tonsillitis, and splenomegaly, resulting in the clinical syndrome called “infectious mononucleosis.” In the HCT/SOT recipient, EBV infection can occur in as many as 75% of patients (186), but in the absence of robust immunologic control on B-cell infection, progressive EBV infection occurs and results not only in the mononucleosis syndrome but also in B-cell lymphoproliferative disorders (187).

The EBV replication cycle involves two phases: a lytic phase in which proteins are made that lead to virus replication and cell death, and a latent phase in which the virus has an episomal existence, producing proteins that trigger tumor formation. Among the latent proteins, the latent membrane protein-1 (LMP-1) signals B cells for growth and differentiation, activating downstream pathways that lead to expression of anti-apoptotic cellular elements (188). Telomerase activity, which extends chromosomal telomeres and prevents cell senescence and apoptosis, depends on telomere-specific reverse transcriptase (TERT) and is crucial for most tumors. LMP-1 upregulates the expression of TERT,

which further upregulates Notch2 and the transcription factor BATEF, both important in B-cell function, and upregulation of gene expression causes an inhibition of an EBV lytic protein, BZLF-1, a major regulator of the EBV lytic cycle (189, 190). The overall effect is to force the EBV further into latency and extend the transformation process, potentially resulting in PTLD.

Similar to CMV, the source of the EBV in persons with PTLD appears to be the donor organ. In one case cluster, analysis of the EBV strains from a single donor and two recipients showed that the virus associated with the PTLD in both recipients was identical to that detected in the donor (191). However, using a DNA minisatellite probe to distinguish the DNA from lymphoblasts isolated from PTLD specimens, the B-cell lymphoid proliferation was recipient specific. With some exceptions, the cell of origin for PTLD is usually from the recipient after SOT, but in HCT PTLD it derives from the donor lymphoid cells, presumably because the recipient marrow is ablated (191, 192). The exceptions to this rule are noteworthy because of their importance to our understanding of the full spectrum of pathogenesis. In this regard, some studies have shown both recipient and donor cells in PTLD post marrow transplant (193) and PTLD of donor-cell origin after renal transplantation (194).

#### Pathology of PTLD

PTLD lesions are usually derived from B cells, with some occurrence of T-cell lymphoma (195), and the lesions contain B cells in all stages of differentiation with clonal, oligoclonal, or polyclonal characteristics. Clonal disease refers to the presence of one type of cell or EBV strain in a specimen. Oligoclonal disease refers to PTLD with more than one cell or virus characteristic, and polyclonal disease means that the PTLD specimen(s) contain many markers for either B cells or EBV (2, 196). For a description of the histopathology of PTLD, please search the University of Pittsburgh Transplantation Pathology Internet Services (<http://tpis.upmc.com/changeBody.cfm?url=/tpis/PTLD/PTLDOver.jsp>).

#### Risk Factors for PTLD

The risk factors for PTLD include type of transplant, age of recipient, and type and duration of immunosuppression (197–199). The incidence of PTLD is highest for intestinal and multivisceral transplantation, followed by lung and heart transplants, and the lowest incidence occurs in kidney and lung transplants (200). However, since more than three-fourths of all SOT involve kidney and liver transplants, most PTLD is seen in these patient groups. The most recent report on the incidence of PTLD in the time period 2010 through 2015 indicates a range from 0.5 to 2.9% in renal transplants and 0.8 to 3.6% in liver recipients (201). Ninety percent of these PTLD cases occurred within the first year after transplantation, and most, but not all, were EBV positive (201).

Based on the pathogenetic process outlined here, certain well-recognized risk factors determine which patients are more likely to develop PTLD. The development of EBV infection, especially primary infection, is the most important factor (202), and the amount of detectable EBV in the blood is directly related to occurrence of PTLD (186). Sequential analysis of EBV-DNA levels in peripheral blood leukocytes, from subjects with PTLD compared to SOT controls without PTLD, have shown that EBV-DNA levels increase in both groups with the induction of immunosuppression, but markedly elevated levels of EBV DNA are seen in the majority of patients before or at the onset of PTLD (203). PCR assays for EBV DNA in blood can detect elevated levels of

EBV DNA up to 3 weeks prior to onset of PTLD, and prospective use of quantitative PCR assays for EBV DNA can be used for early detection of PTLD (204). Of the immunosuppressive regimens that influence the ability to control EBV infection, the antibodies, which directly target T lymphocytes, such as the polyclonal antilymphocyte globulins and OKT3, are generally accepted to be very important risk factors for PTLD (205). In addition, cyclosporin A (CsA) and tacrolimus (FK506), which are used prophylactically to suppress graft rejection or graft versus host disease, are also accepted as significant risk factors for PTLD (206). As noted, the type of organ transplanted will also affect the risk of PTLD, with heart/lung having the highest risk among SOT recipients and T-cell-replete HCT having the lowest (180, 181). However, in HCT, it has been observed that certain subgroups, such as those with T-cell-depleted transplants, especially with higher numbers of stem cells (207), and matched unrelated marrow recipients (208), have a higher incidence of PTLD than allogeneic-related transplant recipients.

### Clinical Manifestations of EBV Infection after Transplantation

#### Mononucleosis-Like Syndrome

Similar to infection in immunocompetent persons, a mononucleosis syndrome can occur in association with EBV infection in transplant recipients (205, 206). Thus, the clinical triad of sore throat with exudative pharyngitis, fever, and lymphadenopathy appears and can include other signs and symptoms, such as malaise, headache, anorexia, myalgias, and hepatosplenomegaly. Central nervous system complications, including aseptic meningitis, encephalitis, and the Guillain-Barré syndrome, can occur. Unlike infection in immunologically normal persons, in which the T-lymphocyte response contributes the “mononuclear” element to the hematologic findings, in the transplant recipient individual, one usually does not expect to see a true hematologic mononucleosis. The symptom complex of pharyngitis, fever, and lymphadenopathy should suggest EBV infection in this population. The serologic findings normally utilized for diagnostic purposes are not reliable in the immunosuppressed population, and direct EBV detection methods should be used for assessing infection (186, 196, 203).

#### Posttransplant Lymphoproliferative Disease

Although nonspecific signs of fever and malaise can be a hallmark of PTLD, especially persisting nonspecific signs and symptoms in the patient who has been treated for CMV infection, this disease ultimately presents as a focal or multifocal occurrence of lymphoid proliferation (206). The most common areas for disease are the central nervous system, the gut, and the allograft itself. The involvement of the allograft is particularly frequent in heart/lung recipients, where the differential diagnosis will include pneumonitis, graft rejection, and PTLD. Aggressive immunoblastic lymphoma can occasionally be seen, and this usually occurs in the first 100 days post transplant. For a complete review of this disease, see the online resource of University of Pittsburgh Transplantation Pathology Internet Services (<http://tpis.upmc.com/changeBody.cfm?url=/tpis/PTLD/PTLDOver.jsp>).

#### Hairy Leukoplakia

As in AIDS, chronic EBV infection of the transplant recipient can cause hairy leukoplakia (169). Oral hairy leukoplakia is a white or gray lesion on the tongue or oral

mucosa due to epithelial hyperplasia. EBV and human papillomavirus have been associated with this syndrome. When EBV is present, it can be detected in the epithelial cells in these lesions, and it is known to replicate in linear form with high copy numbers of infectious virus. The lesion rarely undergoes malignant transformation.

#### Immune Monitoring for EBV Risk

As with CMV, demonstration of EBV DNA in the blood is a surrogate for inadequate immune control of virus replication (209, 210). As with monitoring for CMV immunity, EBV-specific immunity can be assessed using MHC-tetramer binding (211), T-cell intracellular cytokine release in response to EBV antigens (212), and ELISpot assays (213). These assays are not readily available to most clinicians, and therefore, at present, the monitoring of EBV DNA in blood is the best way to determine if the patient's T-cell immunity is functionally able to control EBV infection.

### Treatment of EBV Infection

#### General Approach

PTLD is a life-threatening complication of transplantation and is associated with a mortality of more than 50%. Treatment involves a sequential combination of approaches, including reduced immunosuppression, use of rituximab with or without surgery, adoptive immunotherapy, and antiviral therapy. Reduction in immunosuppression can result in regression of PTLD, and therefore monitoring for EBV infection using PCR analysis and preemptive reduction in immunosuppression is the first aspect of patient management (214). The problem is 2-fold: graft rejection or GVHD can develop during such reduction in immunosuppression, and restoration of immunity can take longer than the progression of the PTLD. For gastrointestinal presentations of PTLD, local control of disease is often necessary, particularly if the disease associated with gastrointestinal bleeding, and, in general, surgical removal of the tumor at the site of bleeding. The role of antiviral therapy is unknown, but there are interesting anecdotes in which antiviral therapy appeared to improve PTLD. The treatment of PTLD was changed dramatically with the observations that adoptive humoral and cellular immunotherapy could positively affect disease progression (215). At present, treatment includes reduction of immunosuppression, surgical control of local disease, anti-B-cell therapy, introduction of donor T cells, and use of antiviral chemotherapy.

#### Antiviral Therapy

EBV is inhibited *in vitro* by several antiviral agents including acyclovir, ganciclovir, foscarnet, penciclovir, and interferon (216), as well as newer agents, such as maribavir and brincidofovir. However, except for oral hairy leukoplakia, in which acyclovir is effective therapy (217), there is little clinical benefit from antiviral agents during infectious mononucleosis (218), chronic mononucleosis (219), and even fulminant infection associated with X-linked immunoproliferative syndrome (220). The reason for the lack of clinical benefit is that antiviral agents are active only during the lytic phase of EBV infection and are not active during the latency phase. During lytic infection, EBV utilizes a virus-encoded DNA polymerase for DNA replication, yielding an extracellular infectious virion and causing cell death (221). During latent infection, EBV exists as a circularized, extrachromosomal, DNA plasmid (episome), and DNA replication is completed by means of cellular

polymerases (165). Because certain antiviral agents are inhibitors of viral DNA polymerase but not of cellular polymerase, antiviral agents are active in lytic, but not latent, infection (222). A primary example of a disease seen during lytic infection is hairy leukoplakia, which does respond to antiviral therapy (217). The latent form of EBV infection occurs primarily in B cells and results in activation and transformation of these cells into EBV-transformed, continuously replicating, lymphoblastoid cell lines. Thus, EBV-seropositive persons treated with acyclovir, years after the acute lytic infection, continue to have culturable EBV in circulating latently infected lymphocytes (223). For this reason, the effect of an antiviral on PTLD is usually less than desirable. Nevertheless, the outcome for PTLD is inversely related to the EBV-DNA levels in blood, and there are sufficient case reports associating antiviral use with patient improvement to suggest that a reduction in EBV DNA during the waning lytic phase may have an effect on the outcome of disease. Acyclovir, ganciclovir, and foscarnet in SOT have been associated with successful treatment in some patients (186, 224–227). Thus, although guidelines do not recommend the antiviral treatment in PTLD, it is rational to use antiviral agents early in the course of EBV infection in the immunosuppressed patient in an attempt to lower the EBV-DNAemia levels. Ganciclovir is more active than acyclovir against EBV *in vitro* and can effectively reduce the nasopharyngeal excretion of EBV after transplantation (186). Prophylactic ganciclovir for CMV has been shown to reduce the incidence of PTLD by as much as 6-fold in SOT (228). For this reason, and because the patient usually needs anti-CMV coverage, ganciclovir is the agent of choice for treatment of the patient with rising EBV levels; treatment is provided as an adjunct to the reduction in immunosuppression.

In the future, antiviral agents may be used with TERT inhibitors for the treatment of PTLD. As noted, TERT is important in maintenance of tumor induction, and the inhibition of TERT can lead to expression of BZLF-1 and return of EBV to its lytic phase in EBV-positive tumor cells (189). Therefore, a proposed research strategy for treating PTLD would be to reactivate the EBV-lytic infection with a TERT inhibitor in an attempt to induce tumor cell death (189, 229–232). This would also promote immune recognition of EBV antigens and further enhance tumor killing. It has been shown that when ganciclovir is used with inducers of EBV-lytic infection, there is enhancement of cell death *in vitro* (233). It remains to be seen whether the combination of antiviral agents with inducers of the EBV-lytic phase will become effective therapies for PTLD.

### Cellular Immunotherapy

Because remissions of both polyclonal and monoclonal tumors can occur after reduction or withdrawal of immunosuppressive therapy, adoptive cellular immunotherapy, directed toward improvement of immune function, has been attempted with remarkable results. Infusion of unirradiated donor leukocytes (approximately  $1 \times 10^6$  CD3+ T cells/kg) into recipients of T-cell-depleted marrow transplantation, who developed PTLD, resulted in clinical responses within 8 to 21 days after infusion, including sustained remissions in 3 long-term survivors (215). Methods for preparing EBV-specific CTLs of donor origin have been developed, and these cells have been safely infused into both SOT and HCT recipients with PTLD (147, 153). Transfer of an EBV-specific T-cell receptor to produce a chimeric EBV-specific T cell has been shown to be feasible for treatment of EBV-associated malignancies (234). The more common approach is to in-

duce panels of HLA-typed EBV-specific T cells and use these as third-party T cells for treatment of PTLD. In a phase II trial of transplant recipients with PTLD who failed conventional therapy, 33 patients were treated with EBV-specific T cells that were at least partially HLA matched to the recipient, with a 50% clinical response rate at 6 months (153). This type of approach illustrates the potential for cellular therapy to eliminate EBV complications after transplantation.

### Humoral Immunotherapy for PTLD of B-Cell Origin

The availability of monoclonal antibody therapy for these B-cell lymphoid abnormalities has greatly improved the management of PTLD. An initial experience suggested that anti-CD21 and anti-CD24 antibodies could contribute to the control of oligoclonal B-cell PTLD (235, 236). Rituximab, a mouse-human chimeric monoclonal antibody with specificity for CD20, a B-cell surface antigen, has been approved for treatment of B-cell lymphomas (237), and this agent has become useful in both prevention and treatment of PTLD. Rituximab, at a dose of 375 mg/m<sup>2</sup> for 4 infusions over 1 month, resulted in an overall response rate of 69% in 32 PTLD patients and 20 complete responses. The initial approach to PTLD is reduction in immunosuppression, then rituximab therapy, and, for resistant disease, conventional lymphoma chemoradiotherapy (238, 239). Current recommendations suggest that rituximab should be used preemptively when EBV-PCR assays indicate increasing infection despite reduced immunosuppression (189).

## HUMAN HERPES VIRUSES TYPE 6 AND TYPE 7

### Epidemiology, Risk Factors, and Pathogenesis of CMV Disease

#### Epidemiology

For consideration in management of the SOT/HCT recipient, much more is known about HHV-6 than about HHV-7 (see Chapter 24). Consequently, the focus here will be on HHV-6, but differences in management of the two viruses will be noted. HHV-6 infection occurs early in life, and SOT/HCT donors and recipients typically have previously been infected with these agents. HHV-6 occurs as two variants: HHV-6A and HHV-6B, the latter accounting for most infections in children and reactivation in SOT/HCT recipients (240, 241). Following HCT, HHV-6 reactivates in 36 to 46% of recipients, and this occurs during the first 2 to 4 weeks post transplant (241–243). The exception is the pediatric transplant recipient who is HHV-6 negative and at risk for primary HHV-6 infection from the allograft (244). The incidence of HHV-7 infection is not as well documented (241).

#### Risk Factors

Specific risk factors for severe HHV-6 infection are not known, but the degree and duration of immunosuppression are undoubtedly important (245, 246). In addition, T-cell-depleting immunosuppressive regimens have been associated with virus infection (247). As with the other herpesviruses, the infection-naïve recipient of an allograft from an HHV-6 donor is at highest risk for disease (248).

#### Pathogenesis

The pathogenesis of disease during HHV-6 infection is not definitely described but is likely a function of progressive lytic infection in the patient with inadequate T-cell immunity.

## Clinical CMV Disease, Treatment, and Prevention

### Clinical Disease

Despite the relative frequency of HHV-6 infection post transplant (241), overt clinical disease, due solely to HHV-6, is estimated to occur in no more than 1% of transplant patients (249, 250). Clinical syndromes associated with HHV-6 infection include febrile dermatosis (251), encephalitis (252), gastroenteritis/colitis (253, 254), and hepatitis (255). In healthy children, HHV-6 is known to be neurotropic and is associated with febrile seizures, and an evaluation of encephalitis after allogeneic HCT has suggested a correlation with HHV-6 infection (243, 256). Prospective neurocognitive patient assessment and monitoring for HHV-6 infection in HCT recipients have associated HHV-6 infection with periods of delirium (243). In a separate study, HHV-6 DNA was observed in cerebrospinal fluid (CSF) specimens from HCT recipients with CNS symptoms in as many as one-quarter of cases (257). HHV-6 encephalitis is associated with seizures and an abnormal EEG but not with CSF pleocytosis or pathognomonic findings from imaging studies. In addition, HHV-6 infection overlaps with CMV infection and has been associated with pneumonitis and with marrow failure in syndromes similar to CMV.

### Diagnosis

The diagnosis of HHV-6 infection is based on direct detection of HHV-6 in blood, CSF, or tissues. The most reliable assays are the HHV-6 DNA PCR on noncellular body fluid or an RNA-based nucleic-acid detection assay (258). Testing of cellular material, such as peripheral-blood mononuclear cells (PBMC), runs the risk of detection of latent virus (241). In addition, approximately 1% of seropositive persons have HHV-6 DNA integrated into host genomic DNA, and if DNA PCR is performed on PBMC, the result can be misinterpreted as a high HHV-6 viral load (259).

### Antiviral Treatment

HHV-6 is susceptible to ganciclovir and foscarnet and relatively less susceptible to acyclovir (260). The problem with treatment is deciding whether a clinical syndrome is due to HHV-6 and worthy of treatment. In general, HHV-6 detection is not a clear indication for treatment because most infections are asymptomatic and transient (261). Organ-specific syndromes should have specific pathogens excluded before concluding that HHV-6 is the causal agent. Ganciclovir, foscarnet, and cidofovir are active against HHV-6 (260), but these agents are not approved for treatment of HHV-6. Nevertheless, despite the absence of large published studies, treatment is recommended, particularly for HHV-6-associated encephalitis, using one of these agents, usually ganciclovir or foscarnet.

- Should HHV-6 infection be monitored and treated preemptively? HHV-6 infection occurs more frequently than does HHV-6 related disease, and, for this reason, it is not recommended currently to monitor and treat preemptively (241).
- Should ganciclovir or foscarnet be used for treatment of HHV-6? There has not been a head-to-head clinical comparison of these two agents in HHV-6 encephalitis; however, there are anecdotal reports of success with either ganciclovir or foscarnet (241). *In vitro*, HHV-6B is usually susceptible to both agents, and both HHV-6A and HHV-6B are resistant to acyclovir and penciclovir (260). Of note, among HHV-6A isolates, more are resistant to ganciclovir than to foscarnet, and HHV-7 is resistant to

ganciclovir (260). The decision about which agent to use must be made on clinical grounds by the physician.

- Does preventive treatment for CMV with ganciclovir protect against HHV-6 disease? It is likely that ganciclovir has an effect on HHV-6 reactivation during preventative ganciclovir use, but there is no clear documentation of this. The median time for HHV-6 infection is 20 days in HCT recipients (243), prior to preemptive ganciclovir use. There is a rare case report of HHV-6 encephalitis that occurred during ganciclovir preemptive therapy (262). There is also an observation of HHV-6 encephalitis following discontinuation of foscarnet therapy (263).

## HUMAN HERPES VIRUS TYPE 8

### Epidemiology, Risk Factors, and Pathogenesis of CMV Disease

HHV-8 (see Chapter 26), like EBV, is associated with tumors in the transplant setting, and, like EBV, there are both neoplastic and nonneoplastic complications of HHV-8 infection (264). HHV-8, also known as Kaposi sarcoma herpesvirus (KSHV), was discovered in 1969 (265), and the first case in SOT occurred in 1994 (265). HHV-8 is a problem in HIV-infected recipients of SOT because of its association with male-to-male sexual transmission. The virus has also been transmitted in the D+/R- setting (seronegative recipients of HHV-8 positive allografts [266, 267]) with resultant disease (268). Donor-derived KS tissue itself can also be transmitted to the immunosuppressed D+/R- recipient (266). Unlike the SOT experience, the occurrence of PTKS is rarely seen in HCT recipients (269). In SOT, there is a rare occurrence post transplant of HHV-8-associated primary effusion lymphoma (PT-PEL) and multicentric Castleman's disease (PT-MCD) (see review 269).

### Clinical HHV-8 Disease, Treatment, and Prevention

The incidence of posttransplant KS (PTKS) varies with the prevalence of HHV-8 seropositivity of the region (270). Like EBV PTL, PTKS is most commonly seen in kidney and liver SOT because these are the most frequent allografts (271, 272). Disease occurs a median of 30 months post transplant with 70% of patients presenting with cutaneous or mucosal lesions and the rest, with visceral lesions (269). Nonneoplastic disease, associated with high virus load and poor outcome, can be seen in patients presenting with high fever, maculopapular rash, and sepsis-like signs and symptoms (269). Patients can have a plasmacytic lymphoproliferation, lymphadenopathy that mimics EBV PTL, acute bone marrow failure, hepatosplenomegaly, and liver-enzyme elevation mimicking acute hepatitis, with or without hemophagocytic syndrome (HPS) (269).

### Diagnosis

The diagnosis of HHV-8 associated PTKS or PTL is made by HHV-8 DNA level in blood and tissue and by clinical pathologic review of tissue biopsy. However, the latter is most important in diagnosis since >50% of PTKS can be HHV-8 DNA negative in blood (269). But like EBV and CMV, in patients with elevated HHV-8 DNA, the virus load in blood can be monitored as a marker of disease.

### Treatment

As with EBV PTL, the initial treatment of PTKS is reduction in immunosuppression or change to regimens

containing sirolimus (273, 274). The effect of reduced immunosuppression in this disease can be very effective (264, 275). For selective lesions, especially if associated with bleeding, surgical excision or cautery (276) will be necessary.

#### Antiviral and Other Chemotherapy

Like EBV, antiviral agents are inhibitory during the lytic phase of infection; thus, ganciclovir, valganciclovir, foscarnet, and cidofovir are active against the virus *in vitro* (277, 278). Antiviral treatment of KS has met with mixed success with small studies indicating some good outcomes (279–281) and larger studies showing minimal effect on KS (282). A preemptive treatment study using ganciclovir in high-risk patients has reported a decrease in PTKS (283). As with EBV, it is possible that the role of the antiviral is to minimize the lytic phase of the infection and reduce the progression to a latent state of infection. In general, antivirals, such as ganciclovir, valganciclovir, or foscarnet, are indicated for high HHV-8 DNAemia (284). Direct intracavitary instillation of cidofovir has been used successfully for treatment of PT-PEL (285). It is not known which of the antivirals is most effective, but there is a report of foscarnet treatment for a severe primary HHV-8 infection with fever, pancytopenia, and hemophagocytic syndrome (286). In HIV-1 infected SOT recipients, it is important to control the HIV-1 viremia with appropriate antiretroviral therapy, and this alone can reduce HHV-8 viremia and produce an antitumor effect in KS (287, 288). For primary HHV-8 infection, there is a recommendation for cautious use of rituxan in HIV-1 infected SOT recipients (289, 290). For management of cancer chemotherapy for PTKS, PT-MCS, and PT-PEL, see a recent review (269).

### OTHER HERPESVIRUSES

#### Herpes Simplex Virus and Varicella Zoster Virus

HSV presents clinically after transplantation with the same type of infection and severity as seen in other immunosuppressed populations, and these will not be reviewed here in detail. Infection usually derives from reactivation of latent virus, with HSV presenting as an oral or genital skin infection, with the potential for visceral infection in the gastrointestinal system or brain. VZV usually presents as herpes zoster with dissemination of infection in a proportion of patients depending on level of immunosuppression. HSV reactivation occurs in approximately 70% of HSV-seropositive transplant recipients and can be suppressed with acyclovir (250 mg/m<sup>2</sup> IV twice daily for 1 month after transplant). VZV reactivation occurs in as many as 50% of allogeneic transplant recipients, and this can be prevented by long-term use of acyclovir (800 mg orally twice daily), although this is not an approved indication (291, 292). For acyclovir-resistant HSV or VZV infection, foscarnet is substituted for treatment.

### POLYOMAVIRUS INFECTIONS IN TRANSPLANT RECIPIENTS

Polyomaviruses are ubiquitous in humans, and asymptomatic infection is acquired at an early age (293). In the setting of immunosuppression, however, unusual syndromes can occur, the most common of which are due to BK virus, a cause of nephropathy (294), and to JC virus, a cause of progressive multifocal leukoencephalopathy (295). Excretion in the urine of both BK and JC virus is common in transplant populations (296). In addition, there are 11 other human polyomaviruses (297, 298) that can complicate post-

transplant patient management, including TS virus found in the proliferative skin disorder trichodysplasia spinulosa (299), Merkel cell carcinoma virus (300), human polyomavirus 7–associated epithelial hyperplasia (301), and other human polyomaviruses (297).

#### BK Virus Infection

##### Epidemiology, Risk, and Pathogenesis of Disease

The polyomaviruses of humans are BK virus (BKV) and JC Virus (JCV), and these are reviewed in detail elsewhere in this volume (see chapter 28). BKV infection is ubiquitous in the population (302), and virus becomes latent in kidneys and urothelial tissue. It was isolated from the urine of a renal transplant patient in 1971 (294). In such patients, latent infection reactivates in approximately 15% in year 1 post transplant (SG), and progressive infection of renal tubules, glomeruli, and interstitium can lead to BKV nephropathy. Approximately one-third of such BKV reactivations will progress to BKV DNAemia, and 1 to 10% of patients with viremia will develop BKV nephropathy (see chapter 28 and review 303). In addition to renal allograft recipients, the disease is seen in HCT recipients and less frequently in other SOT recipients (304, 305).

##### Risk

High BK virus DNAemia is associated with nephropathy (306). Levels of BKV of 10<sup>7</sup> genome copies/ml in urine and 10<sup>4</sup> genome copies/ml in plasma are not unusual for patients with BK nephropathy (307). BKV DNAemia is more sensitive for prediction of BKV nephropathy (308). A variety of other risk factors leading to BKV reactivation have been reported relating to donor BKV serostatus and HLA mismatch with recipient, age, race, and presence of diabetes, but, except for immunosuppression, none have been substantiated (see review 303). As with other virus-related complications in SOT/HCT recipients, T-cell immunity is a key risk factor for disease, with BKV-specific CD8 T-cell responses serving to decrease the relative risk for disease (309–311).

##### Clinical Disease

BKV infection is silent in most infected transplant patients and presents either with declining renal function or hemorrhagic cystitis (312). BKV infection of the kidney produces an interstitial nephritis that mimics acute rejection, but it can be differentiated from rejection effects by the presence of viral antigen/DNA and by an increase in B-cell infiltrates (313). In addition to interstitial nephritis, BK virus is linked to ureteric stenosis and hemorrhagic cystitis.

##### Diagnosis

A classical sign of BK nephropathy is the presence of decoy cells containing viral inclusions in the urine (303); however, decoy cells and BK viremia are less sensitive than BK-virus DNAemia for positive predictive value for BK nephropathy (303). A kidney biopsy is recommended for patients with BKV DNAemia of  $\geq 10^4$  GC/ml. The kidney biopsy is the definitive method of diagnosis. Biopsy will show viral cytopathology in the tubular epithelium, glomeruli, and collecting ducts, and interstitial inflammation and fibrosis, in which the pathognomonic sign is the presence of large T antigen of BKV on immunostaining of the tissue (314).

##### Treatment

Reduction in immunosuppression is the first approach to therapy. Screening with reduction of immunosuppression in BKV-infected patients has been shown to prevent allograft

loss due to BKV nephropathy (315, 316). It may be necessary to convert the immunosuppressive regime to an everolimus- or sirolimus-containing regimen (317, 318). In terms of antiviral agents, cidofovir and leflunomide have been used, but no survival benefit has been observed (319). In a randomized blinded, placebo-controlled prophylaxis trial, a 3-month course of levofloxacin, started at day 5 post renal allograft transplantation, was not able to prevent BKV viraemia (320). Similarly, there are no controlled studies that support the use of cidofovir for BK virus infection. Nevertheless, although cidofovir is unapproved for this indication, single-center studies exist that support the use of low-dose cidofovir (1 mg/kg 3 times weekly) for treatment of symptomatic BKV infection (321). Brincidofovir has been used for BK virus nephropathy in case reports (322), but there is no evidence-based recommendation for its use at present. Other questions arise in management of this infection:

- When should SOT patients be screened for BKV viraemia? Several studies have confirmed that BKV viraemia occurs in approximately one-third of patients and peaks at approximately 3 months post transplant (323, 324), but, of the early infections, it is rare to see BKV nephropathy. But BKV DNAemia is more sensitive for disease prediction (308), and so the better screening test is the BKV-DNA PCR assay in plasma. For that reason, at centers with relatively low rates of BKV nephropathy, routine screening of blood can begin at 3 months post transplant and continue to 24 months (303, 315). However, for centers with higher rates of BKV infection, guidelines suggest starting at month 1 and continue with monthly plasma BKV-PCR DNA testing for 6 months until 24 months (325, 326).
- What BKV-specific immunologic monitors are available? As with CMV and EBV, demonstration of virus DNA in the blood or urine is a surrogate for inadequate immune control of virus (325). As with CMV-immunity monitoring, BK-virus T-cell immunity can be assessed using antigen-specific T-cell immunity (311, 327, 328), BK-specific T-cell immunity is associated with recovery of kidney graft function in recipients with biopsy-proven BK-nephropathy (311, 328). But until immunological assays are generally available, the monitoring of BK-virus DNA in blood or urine is the best way to determine if the patient's T-cell immunity is functionally able to control infection.

### JC Virus Infection

Progressive multifocal leukoencephalopathy (PML) is a rare but serious occurrence in SOT and marrow transplantation (329). JC virus infects oligodendrocytes of the CNS leading to a fatal demyelinating disease characterized by hemiparesis, seizures, deteriorating mental status, and death. JC virus infection, although thought of as a CNS problem, has been observed in 37% of patients with interstitial nephritis after renal transplantation (296). At present, there is no specific treatment for this infection.

# Viral Heart Disease

BRUCE M. McMANUS, MICHAEL SEIDMAN, KARIN KLINGEL, AND HONGLIN LUO

## 7

Viral pathogens are well known to cause injury, inflammation, tissue destruction, and remodeling of heart muscle. Indeed, viruses are among the most common inciting agents to cause a condition termed acute myocarditis. This condition may also be provoked by bacteria, other pathogens, as well as toxins and autoimmune diseases, each of which could mimic the appearance of viral myocarditis. The reason for this phenotypic mimicry is that myocarditis is a process characterized pathologically by an inflammatory infiltrate of the myocardium with death or degeneration of adjacent myocytes, not typical of the ischemic damage associated with atherosclerotic coronary artery disease. The inflammation and damage may involve myocytes, interstitium, vascular elements, and pericardium. The inflammatory process affects cardiac function adversely, causing either ventricular dysfunction, arrhythmias, or both. The acute process may persist and manifest as chronic low-grade tissue inflammation and fibrosis associated with cardiomyopathy and frank heart failure.

Many viruses can cause the same syndrome, and a particular virus can cause infections leading to a highly varied constellation of manifestations. Clinically, viral heart disease and acute myocarditis most commonly commence with a “flu like” picture, followed within days by symptoms and signs of congestive heart failure, including shortness of breath, exercise intolerance, and fatigue, and may be associated with abdominal pain, chest pain, palpitations, syncope, and sudden death. In infancy and childhood, viral myocarditis is usually a fulminant process with left ventricular (LV) or right ventricular (RV) systolic dysfunction with or without ventricular dilation, whereas adults may present less abruptly and mimic dilated cardiomyopathy (DCM), mainly with LV dilation and systolic dysfunction.

In recent years, the main advances in our thinking about viral syndromes are that the attack on heart muscle is part of a more holistic viral-immune-inflammatory-pathological-clinical systemic syndrome with multiorgan involvement, and that there is a temporal connection between acute viremic states and long-standing immunovirological perturbation and cardiomyopathy. Certainly, the contribution of inflammatory mediators in transient, acute cardiac dysfunction is also now recognized (1). Yet the challenge often arises that a thorough evaluation of the myocardial tissue in

biopsies or at autopsy is not possible or inconclusive for accepted features of myocarditis.

### ETIOLOGY

Most cases of community-acquired myocarditis in the North America and Western Europe result from viral infections (2–4). Early detection of viral infection relies on viral isolation and serology; however, these diagnostic approaches lack sensitivity and specificity. Molecular detection of viral genomes in heart tissue derived from biopsy, explants, or autopsy has enhanced these approaches. Although fraught with challenges of false-positives and the possibility of molecular detection in absence of commensurate myocardial pathology, PCR evaluation of cardiac samples from subjects suspected of having myocarditis has demonstrated a variety of viral genomes in human hearts.

In previous eras, mumps virus was found by molecular interrogation in association with endocardial fibroelastosis (EFE), a previously important cause of heart failure in children that has disappeared over the past 20 years (5). This form of cardiomyopathy was identified in children until the late 1960s, with an incidence of 1 in 5000 live births in the United States. Mumps virus genomic RNA sequences were found in 90% of myocardial samples from EFE patients analyzed (5, 6). Since that time, the incidence has declined significantly due to mumps immunization, and the status of mumps myocarditis in mumps-susceptible populations has not been recognized in recent years.

In the 1960s through the early 21st century, adenoviruses, especially serotypes 2 and 5 (7, 8), along with enteroviruses [coxsackievirus A (CVA) and B (CVB), echoviruses, and poliovirus], and particularly CVB (9–12), were the most commonly identified viral etiologies. Recently, parvovirus B19 has become the predominantly detected virus in patients with suspected myocarditis, especially in European countries (13, 14); however, a causal relationship with myocarditis has been more difficult to affirm (10, 14–18). In Japan, hepatitis C virus (HCV) has been suggested to be a common etiologic agent of heart muscle disease, with the other viruses typically seen in North America and Europe playing a lesser role (19–21).

In addition to the frequently detected viruses mentioned above, other viral causes of myocarditis have also been

reported, particularly in children, including influenza A and B viruses (22–25), cytomegalovirus (CMV) (26), herpes simplex virus (HSV) (27), rubella virus (28), varicella-zoster virus (29), Epstein-Barr virus (EBV) (30), human immunodeficiency virus (HIV) (31, 32), human herpesvirus 6 (HHV-6) (33, 34), dengue virus (35, 36), respiratory syncytial virus (RSV) (37), human metapneumovirus (38), Crimean-Congo hemorrhagic fever virus (39), parechoviruses (40–42), and chikungunya virus (43, 44). The acute stage of infection with chikungunya virus is characterized by fever, polyarthritides, and occasional rash and can be complicated by myocarditis and pericarditis (43, 44). Pericarditis is frequently a part of the phenotype of myocardial involvement by cardiotropic viruses, including classical clinical signs of friction rubs and pleuritic pain, and such membranous inflammation may become persistent (9).

The identified viral causes of myocarditis are summarized in Table 1.

## EPIDEMIOLOGY

Myocarditis is a disorder that is clinically difficult to diagnose and thus underdiagnosed (2–4). In autopsy series, the prevalence of the usual lymphocyte-predominant form of myocarditis ranges from 4 to 5% from reports of young men dying of trauma (45) to as high as 16–21% in children dying

suddenly. In adults with unexplained DCM, the proportion affected ranges from 3 to 63% (46, 47), although the large multicenter Myocarditis Treatment Trial, which was based on specific and strict diagnostic criteria (the so-called Dallas criteria; see below) reported a 9% prevalence (48). Hospital discharge data suggest an approximately 0.5–4.0% incidence of myocarditis as a percentage of prevalent heart failure (49). The thresholds for defining myocarditis are variable and depend on whether the diagnosis is derived clinically, serologically, pathologically, and/or molecularly. This variability contributes to the uncertainty surrounding the incidence of the condition (49).

Usually sporadic, viral myocarditis can also occur as an epidemic (45). Epidemics usually are seen in newborns, most commonly in association with CVB. Intrauterine myocarditis occurs during community epidemics as well as sporadically (50). Postnatal spread of coxsackievirus is via the fecal-oral or respiratory route (51, 52). The World Health Organization (WHO) reports that this ubiquitous family of viruses results in cardiovascular sequelae in less than 1% of infections, although this increases to 4% when CVB alone is considered (45). Other important viral causes, like adenoviruses (53, 54) and influenza A virus, are transmitted primarily via the respiratory route.

## PATHOGENESIS

The process of myocardial and pericardial viral infection depends on viremic dissemination to target tissues following initial infection at the portal of entry. The portal (e.g., respiratory or gastrointestinal mucosa) affects the first and subsequent points of contact between the pathogen and the host's immune system (see Chapter 16). The elicitation of antigen-specific humoral and cellular immune responses in lymphoid tissues has a dominant influence on the pathophysiology of the viral infection, including the potential for immunopathologic responses within the heart.

## Animal Model Studies

The immunopathogenesis of CVB and encephalomyocarditis virus has been studied quite extensively in murine models. CMV, HIV, and adenovirus models also have been described (55–62). In wild-type mice, CVB viremia occurs 24–72 hours after infection, and maximum tissue viral loads develop at 72–96 hours (12). Virus titers subsequently decline, with infectivity being rarely detectable beyond 14 days after inoculation, depending on the mouse strain and viral variant. Neutralizing antibody concentrations decline as virus titers increase, supporting a role for such antibodies in the viral clearance process. Along with T lymphocytes and natural killer (NK) cells, macrophages appear within 5–8 days after infection in the murine CVB model of myocarditis (12). Risk factors for severe myocarditis include age, mouse strain, viral variant, exercise, and gender (12). Pathogenetic mechanisms include direct viral myofiber destruction (63–65) and T-lymphocyte cytolysis (56–58, 66, 67). Animals with absent or blocked T-cell function may have less evident myocardial injury, although the recognition that an extensive amount of damage is already done by viral mechanisms before immune cell responses occur is now widely appreciated. In most murine strains, the adolescent period is the one of most severe in viral heart disease. In BALB/c mice, great susceptibility also occurs between 16 and 18 weeks of age; males appear to have a more rapid and severe course of myocarditis than females. Estradiol has been shown to decrease severity, and testosterone increases immune-mediated

cytolytic activity in males. Either a preferential stimulation of T-helper cells or an inadequate stimulation of T-regulatory (cytolytic/suppressor) cells could explain why antibody responses to various antigens may be enhanced and cellular immune responses depressed in female murine models.

The NK cell population, especially the activating receptor NKG2D, is important in the pathogenesis of myocarditis (68). Animals depleted of NK cells prior to infection with coxsackievirus develop more severe myocarditis (56). NK cells are activated by interferon (IFN), an indirect and direct protective modulator of myocardial injury. Murine skin fibroblasts serve as target cells for CVB-sensitized cytotoxic T cells. The NK cells specifically limit the non-enveloped virus infection by killing the virally infected cells. Male mice are less efficient in activating NK cells. Presumably, the more efficiently viral clearance occurs, the less virally induced neoantigen production occurs, reducing recognition by cytotoxic T lymphocytes. T cells can effect injury by multiple mechanisms—causing accumulation of activated macrophages, helping with production of antibody, mediating antibody-dependent cell-mediated cytotoxicity, direct lysis by antibody and complement, and direct action of cytotoxic T cells (69).

In recent years, the roles of various matrix metalloproteinases (MMPs) in the pathogenesis of viral myocarditis have received attention (70–73). In essence, MMP-9 and MMP-12, through modulation of IFN-beta and -alpha, respectively, play a prominent role in the early inflammatory phase of myocarditis, complementing the roles of MMPs in later tissue remodeling and healing of injured myocardium (70–73).

Host genetic factors have been shown to affect the severity of disease, as well as the pathogenic mechanisms that participate in disease development (55, 60, 62, 74). Cytolytic T cells mediate a considerable amount of injury in myocarditis in BALB/c mice, with two distinct cytolytic T-cell populations being implicated—one recognizing virus-infected cells and producing direct myocytolysis and another that destroys uninfected myocytes and is believed to be an autoreactive lymphocyte. Complement depletion increases the amount of inflammation in this species, and no reactive immunoglobulin G (IgG) antibody is found in the myocytes. In DBA/2 mice, the T-helper cells indirectly mediate the course of disease, and complement depletion reduces inflammation. Cytolytic T cells are produced but apparently are not pathogenic; IgG antibody is found in the myocytes.

### Human Observations

In humans, antibody-mediated cytolysis is found among 30% of patients with suspected myocarditis, as well as in almost all patients with proven infections with CVB or influenza A virus (67). A muscle-specific antimyolemmal antibody has been found in these patients and correlated with the degree of *in vitro*-induced cytolysis of rat cardiocytes. A CVB-specific cDNA hybridization probe detected virus nucleic acid sequences in patients diagnosed as having active or healed myocarditis or DCM (75, 76). Patients with unrelated disorders had no virus-specific sequences (75), suggesting that viral genomic material persists in patients with congestive cardiomyopathy or healing myocarditis for weeks or months. Although viral cultures are usually negative, continued viral replication may occur at a low level or abortively. The latter may conceal viral antigens by a process that prevents correct posttranslational processing of capsid proteins. Adult patients with myocarditis often have high neutralizing antibody responses to CVB1 to CVB6 (77). One hypothesis is

that sequential infection and immune responses against several types of CVB are essential in the development of myocarditis; however, certain cases of myocarditis clearly involve exposure to only one type of CVB.

Defective cell-mediated immunity, compared with that in healthy controls, occurs in patients with myocarditis and DCM. The pathogenesis of adenoviral myocarditis differs from that of CVB (57, 66, 78), and the inflammatory infiltrate is substantially less in adenoviral infection (8, 79, 80), specifically the numbers of CD2, CD3, and CD45RO T lymphocytes seen in the adenovirus-infected patients as compared to those with myocarditis not due to adenovirus (80). Adenoviruses have a number of strategies for modulating the immune response that could affect the number of activated lymphocytes in the adenovirus-infected myocardium (57). Adenovirus E3 protein can protect cells from tumor necrosis factor (TNF)-mediated lysis, as well as downregulating major histocompatibility complex class I antigen expression. The early-region 1A (E1A) proteins can promote the induction of apoptosis (81) and inhibit interleukin 6 (IL-6) expression, as well as interfere with IL-6 signal transduction pathways. These functions of E1A may be pertinent to the development of the myocardial pathology seen in DCM. IL-6 promotes lymphocyte activation, which is reduced in adenovirus-infected patients. Apoptotic cells are also observed in the myocardium of patients with DCM.

### Pathophysiologic Consequences

In the heart, viral infection triggers both interstitial inflammation and myocardial injury, resulting in loss of myocardial integrity, with consequent cardiac chamber enlargement and an increase in the ventricular end-diastolic volume (47, 52, 54, 82). Normally, an increase in volume results in an increased force of contraction, improved ejection fraction, and improved cardiac output as described by the Starling mechanism. However, in the setting of myocarditis, the myocardium is unable to respond to these stimuli and cardiac output is compromised. A series of interacting adverse changes occurs, reflecting the composite pathophysiological response of patients afflicted by myocarditis:

1. Interactions with the sympathetic nervous system may preserve systemic blood flow via vasoconstriction and elevated cardiac afterload. This sympathetic nervous system input results in tachycardia, a feeling of weakness, and diaphoresis.
2. Congestive heart failure ensues with disease progression. A progressive increase in ventricular end-diastolic volume and pressure results in increased left atrial pressure. This pressure elevation is transmitted retrograde to the pulmonary venous system, causing increasing hydrostatic forces that overcome the colloid osmotic pressure that normally prevents fluid transudation across capillary membranes. The associated symptoms include increasing shortness of breath, anxiety and even chest pain, and the consequence may be overt pulmonary edema.
3. Concomitantly, all cardiac chambers dilate depending on the extent of virus- and immune system-mediated injury, particularly when the LV is involved. This dilation, in addition to poor ventricular function, creates worsening pulmonary edema and worsening cardiac function. Ventricular dilation also results in stretching of the mitral annulus and resultant mitral regurgitation, further increasing left atrial volume and pressure.

4. During the healing stages of myocarditis, the fibroblast population expands and produces increased extracellular matrix, replacing previously normal myofibers and resulting in patchy interstitial and replacement scar formation. Reduced elasticity and ventricular performance can result in persistent heart failure. In addition, ventricular arrhythmias commonly accompany this fibrotic process as tissue inhomogeneity progresses.

## **PATHOLOGY**

### **Gross Findings**

Pathological findings are nonspecific in myocarditis, with similar gross and microscopic changes noted irrespective of the causative agent (47, 52, 77). Typically, the heart weight is increased and all four chambers are affected. The muscle is flabby and pale, with petechial hemorrhages often seen on the epicardial surface, especially in cases of CVB infection. A sero-sanguinous pericardial effusion may also be seen relating to the often-combined finding of pericarditis. The ventricular wall is frequently thin, although thickening related to edema may be found as well. The valves and endocardium are not usually involved. Mural thrombi may occur along the inflamed endocardium in the LV and RV, and small emboli are often found in the coronary and cerebral vessels (83). Coronary emboli, although rare, may produce areas of ischemia or injury with resultant cardiac arrhythmias that sometimes occur during the acute disease.

In cases of chronic myocarditis, the valves may be glistening white, suggesting that EFE may be the result of an *in utero* viral myocarditis (82).

### **Findings by Microscopy**

An interstitial collection of mononuclear cells, including predominantly lymphocytes and phagocytic cells with occasional eosinophils (Fig. 1), is typical of early viral myocarditis (12). Polymorphonuclear cells are uncommon in acute viral heart disease. Viral particles have only rarely been documented, but molecular detection of viral genomes (discussed below) is readily possible during the first 10 days of infection. Extensive cell death can be seen on examination by light microscopy, a result of both necrotic and apoptotic processes in the myocardium (63, 84); evident effacement of cross striations in cardiac muscle fibers and accompanying edema is seen in severe infections, but especially with coxsackievirus. Perivascular accumulation of mononuclear cells has been described with CVB myocarditis, but infiltration by leukocytes is patchy and more aligned with sites of viral replication and injury than with the vasculature. In disease due to rickettsiae, varicella-zoster virus, and trypanosomes or other parasites, and in reactions to sulfonamides, vasculo-centric lesions are a much more prominent finding (85–90).

Diphtheria myocarditis is frequently complicated by arrhythmias and complete atrioventricular block (91). The diphtheria exotoxin attaches to conductive tissue and interferes with protein synthesis by inhibiting a translocating enzyme in the delivery of amino acids (92). Triglyceride accumulates, producing fatty changes of the myofibers.

Bacterial myocarditis produces microabscesses and patchy focal suppurative changes. A combined perimyocarditis is also encountered frequently. Parasitic myocarditis caused by *Trichinella* has a focal infiltrate with lymphocytes and eosinophils, but larvae are usually not identified (85).

A severe myocarditis caused by *Trypanosoma cruzi* (88, 89) results in Chagas' disease. Rare in North America,

Chagas' disease is endemic in South America, affecting up to 50% of some populations. Examination by microscopy reveals the organism as well as neutrophils, lymphocytes, macrophages, and eosinophils.

Sudden death in infancy may result from myocardial inflammation. James (93) described a resorptive, degenerative process in the His bundle and left margin of the atrioventricular node with the absence of inflammatory cells in cases he studied of infants who died in Northern Ireland. Further definition of the nature of involvement of the conduction system by viral infection has not been forthcoming since that early observation.

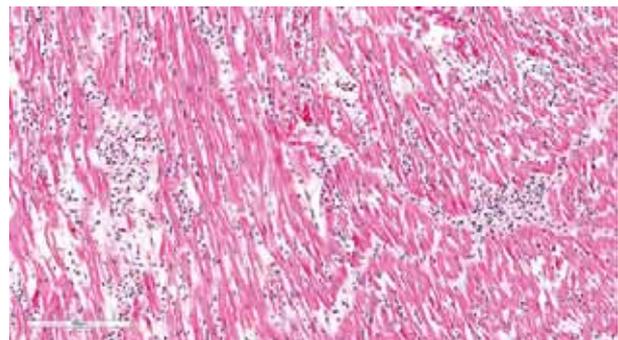

Giant cell myocarditis occurs with tuberculosis, syphilis, rheumatoid arthritis, rheumatic heart disease, sarcoidosis, and fungal or parasitic infections (94–100). Giant cells also occur in idiopathic (Fiedler's) myocarditis. There are two types of giant cells: cells originating from the myocardium and cells derived from interstitial histiocytes.

## **CLINICAL MANIFESTATIONS**

Presentation of viral heart disease depends on the age of the affected individual, immune status, specific viral trigger, genetic factors, and the environment (10, 52, 77). Nonspecific influenza-like illness or episodes of gastroenteritis, respiratory illness, or rash may precede symptoms of congestive heart failure.

### **Newborns and Infants**

Newborns or infants present with poor appetite, fever, irritability or listlessness, periodic episodes of pallor, and diaphoresis. Sudden death may occur in this subgroup of children (10, 52, 101). On physical examination, pallor and mild or moderate cyanosis in addition to classic symptoms of congestive heart failure are commonly noted. It is important to keep in mind that the younger the child, the more likely that the disease was triggered as an intrauterine event. While this form of myocarditis may be expressed as a chronic disease that mimics chronic DCM (5, 10), indeed the severity of acute illness is often profound and fatal. The earlier the infection, the more likely severe illness will be observed, reflecting the immaturity of the immune system and the comparative inability to fight a lytic viral infection. The prognosis of acute myocarditis in newborns is poor (102, 103). In one study, a 75% mortality rate was observed in 25 infants with suspected CVB myocarditis (102); most deaths occurred in the first week of the illness.

**FIGURE 1** Endomyocardial biopsy specimen from a 19-year-old man with heart failure. Histopathology includes multifocal mononuclear cell infiltrates, areas of myocardial cell death, and apparent edema. Hematoxylin and eosin (H & E) stain; scale bar, 200  $\mu$ m.

Children with myocarditis alone typically have symptoms for less than 2 weeks, whereas those with EFE have “viral” signs and symptoms for more than 4 months (Fig. 2). Mumps virus and CVB3 have been identified in the myocardium of infants with EFE (5), although a precise cause-and-effect relationship remains to be confirmed.

### Children, Adolescents, and Adults

Older children, adolescents, and adults commonly have a recent history of nonspecific illness, typically with upper respiratory or gastrointestinal symptoms (with or without fever) 10–14 days prior to presentation (52). Initial symptoms may include lethargy, low-grade fever, and pallor. A child usually has decreased appetite and may complain of abdominal pain. Diaphoresis, palpitations, rashes, exercise intolerance, and general malaise are common signs and symptoms. Later in the course of illness, respiratory symptoms, such as breathlessness and cough, become more evident; syncope or sudden death may occur due to cardiac arrhythmias or arrest. Findings on physical examination are consistent with congestive heart failure (7, 52), as discussed above. Unlike with newborns, jugular venous distention and pulmonary rales may be observed, and resting tachycardia may be prominent. Arrhythmias, including atrial fibrillation, supraventricular tachycardia, or ventricular tachycardia, as well as atrioventricular block, may occur (52, 104).

Older infants and children have a better prognosis, with a mortality rate between 10 and 25% in clinically manifest cases. However, a subgroup of patients will present to urgent care centers in extremis from acute heart failure or arrhythmias, or die outside of care. Children may present with signs and symptoms of very common childhood disorders, such as a viral respiratory illness, gastroenteritis, or dehydration, and therefore are treated for these disorders initially. However, over hours or days, these children may rapidly deteriorate and succumb, usually after a cardiac or respiratory arrest. On autopsy, myocarditis is diagnosed. They may have associated hepatitis, pancreatitis, or encephalitis. These patients are extremely difficult to diagnose and, even if identified, have limited therapeutic options.

Complete recovery occurs in about 50% of patients (105, 106). Twenty-five percent of the patients continue to have an abnormal electrocardiogram or cardiomegaly on chest radiograph even though they were clinically asymptomatic. Abnormalities in the resting electrocardiogram may not be seen, but they may be brought out with exercise. Adult patients who recover may be asymptomatic at rest or with light exertion, but may demonstrate a reduced working capacity with exercise stress testing. As noted earlier, certain patients will have persistent pericardial inflammation as well (9).

## DIAGNOSTIC EVALUATION

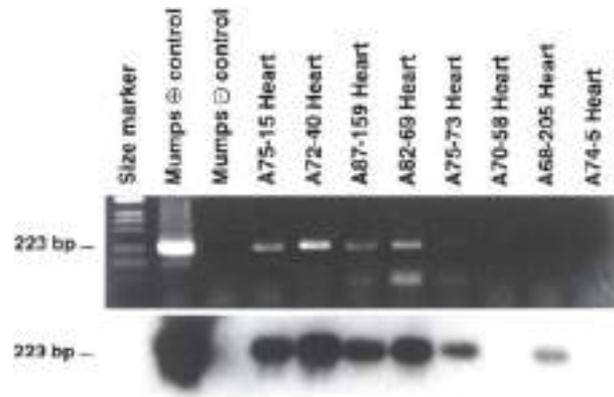

The diagnosis of myocarditis is often difficult to establish, but should be suspected in any patient who presents with unexplained congestive heart failure or ventricular tachycardia, especially in the absence of predisposing cardiac conditions. Appropriate diagnostic studies include the following (107).

### Chest Radiography

Cardiomegaly with pulmonary edema is classically demonstrable on chest imaging.

### Electrocardiography

Sinus tachycardia with low-voltage QRS complexes with or without low-voltage or inverted T waves are classically de-

**FIGURE 2** PCR analysis of fixed heart samples obtained from infants with endocardial fibroelastosis (EFE). Note the PCR-positive bands at 223 bp indicative of mumps virus. Sequence analysis confirmed the viral genome as that consistent with mumps.

scribed. A pattern of myocardial infarction with wide Q waves and ST-segment changes also may be seen (108) (Fig. 3). Ventricular tachycardia, supraventricular tachycardia, atrial fibrillation, or atrioventricular block occurs in some patients (106, 109, 110).

### Echocardiography, Ventriculography, and Magnetic Resonance Imaging

A dilated and dysfunctional LV consistent with DCM is seen on two-dimensional and M-mode echocardiography. Segmental wall motion abnormalities are relatively common, but global hypokinesis is the predominant finding. The regional dysfunction is at times shown to correspond with the areas of most intense myocarditis at various locations in the myocardium. Pericardial effusion frequently occurs. Doppler and color Doppler commonly demonstrate mitral regurgitation of a functional nature. Dilatation of all cardiac chambers may be seen. Cardiac catheterization shows low cardiac output and elevated end-diastolic pressures. Cardiac magnetic resonance (CMR) imaging with gadolinium enhancement has emerged as a valuable diagnostic tool for myocarditis, providing evidence of locale and extent of inflammation in acute myocarditis (111–115).

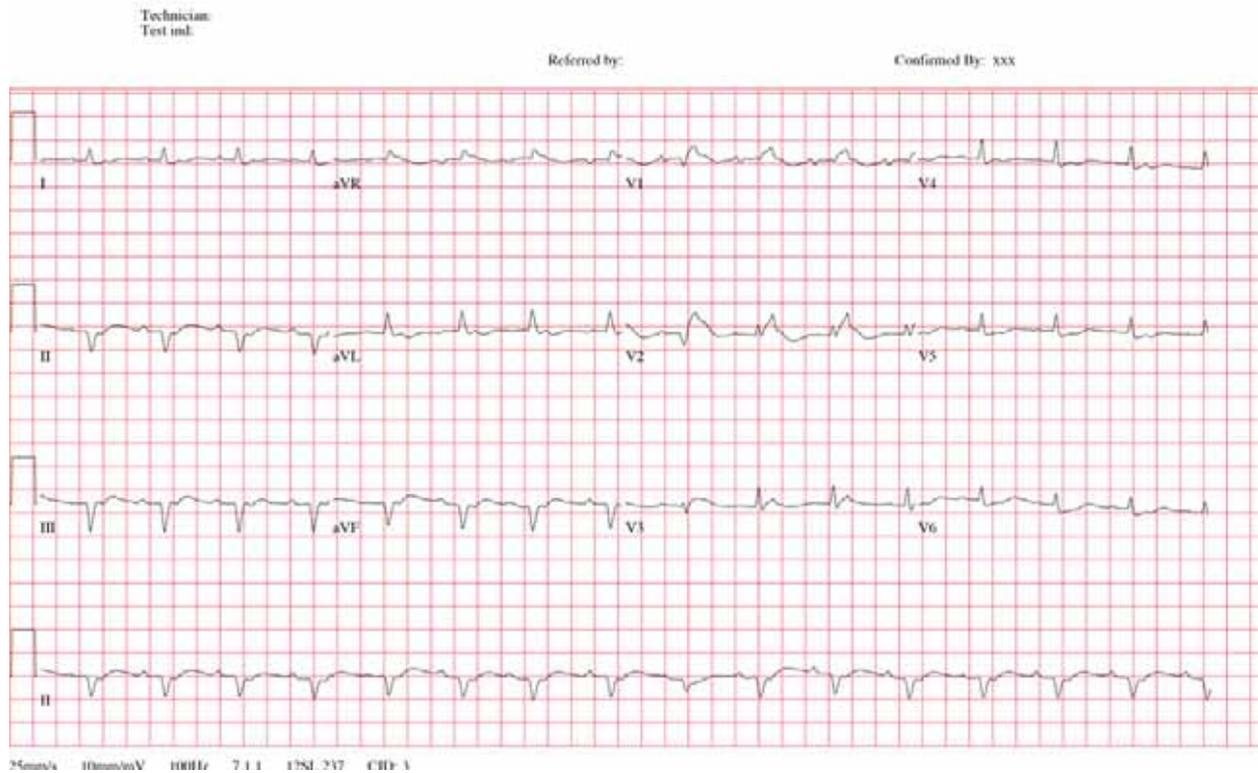

### Blood Tests

Indicators of inflammation, like white cell counts, C-reactive protein, and erythrocyte sedimentation rate, may be elevated in the blood during a myocarditis episode, but these are not in any way specific for myocarditis or subtypes caused by viruses. Given that myocardial injury does occur during acute myocarditis, it is not surprising that laboratory tests aimed at documenting such injury including markers such as creatine kinase MB isozyme (CK-MB), troponin I or T, or myosin light chains and others are typically elevated in the setting of myocardial injury (116–118). However, specific markers for acute viral myocarditis in routine blood studies are not available, and clinical context must be strongly considered in their interpretation.

### Endomyocardial Biopsy

Right or left ventricular endomyocardial biopsy is used to examine pathological evidence of myocarditis, as well as for detection of viral pathogens. Pathologically, the features

67 yr	Vent. rate	94	BPM	NORMAL SINUS RHYTHM
Male	PR interval	190	ms	LEFT AXIS DEVIATION
Room:	QRS duration	64	ms	RIGHT BUNDLE BRANCH BLOCK
Loc:	QT/QTc	250/312	ms	LOW VOLTAGE QRS
	P-R-T axes	64 -69	107	POSSIBLE INFERIOR INFARCT
				ABNORMAL ECG

**FIGURE 3** Electrocardiogram from a 67-year-old man with no prior history of heart disease, normal coronary arteries, and now severe acute heart failure and viral myocarditis. Sinus tachycardia and low-voltage QRS complexes with inverted myocardial injury pattern, particularly in the inferior ventricular wall, as well as left axis deviation and right bundle branch block are present.

include an inflammatory infiltrate and tissue damage (see Fig. 1), which is usually patchy and widely distributed in the ventricular myocardium. A mononuclear cell infiltrate inclusive of lymphocytes and macrophages, as visualized by immunohistochemistry, is always present in viral myocarditis and is required for the diagnosis of myocarditis (2). Myocardial biopsy has a widely variable diagnostic sensitivity, ranging from 3 to 63% of cases depending on the patient selection, biopsist capability, and expert level in pathological interpretation of findings (52,119–122). Because there are risks associated with biopsy, particularly in young children or those with severe ventricular dilation, certain centers have abandoned this procedure, particularly in young and small children (<10 kg) and those with severe ventricular failure. For each patient, the purpose of obtaining a definitive tissue diagnosis by cardiac biopsy is balanced by the risks versus the ultimate benefit in clinical decision-making.

### The Dallas Criteria

The Dallas criteria are based on histopathologic findings and define myocarditis as “a process characterized by an inflammatory infiltrate of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of ischemic damage” due to coronary artery or other disease (119). These criteria were evolved to standardize diagnosis for a major myocarditis treatment trial conducted in adult patients (106, 123). At the time of initial biopsy, a specimen may be classified as active myocarditis, borderline myocarditis, or no

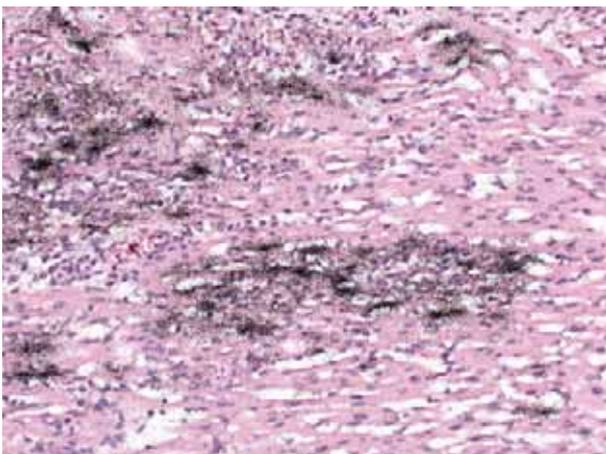

myocarditis, depending on whether an inflammatory infiltrate occurs in association with myocyte degeneration or necrosis (active) or only sparse infiltrate or no myocyte degeneration is evident (borderline) (48, 76). Repeat endomyocardial biopsy may be appropriate in cases where strong suspicion of myocarditis exists clinically; on repeat endomyocardial biopsy, histology may be classified as ongoing myocarditis, resolving myocarditis, or resolved myocarditis. The Dallas criteria more recently have been criticized as not reflecting the lower grade of inflammation that separates truly normal hearts from failing hearts with subtle immune cell infiltrates (124). Also, both active and passive cell death occur in the myocardium of patients and in model systems of myocarditis; thus, both apoptotic and necrotic features may be seen by microscopy (125–127).

### Viral Studies

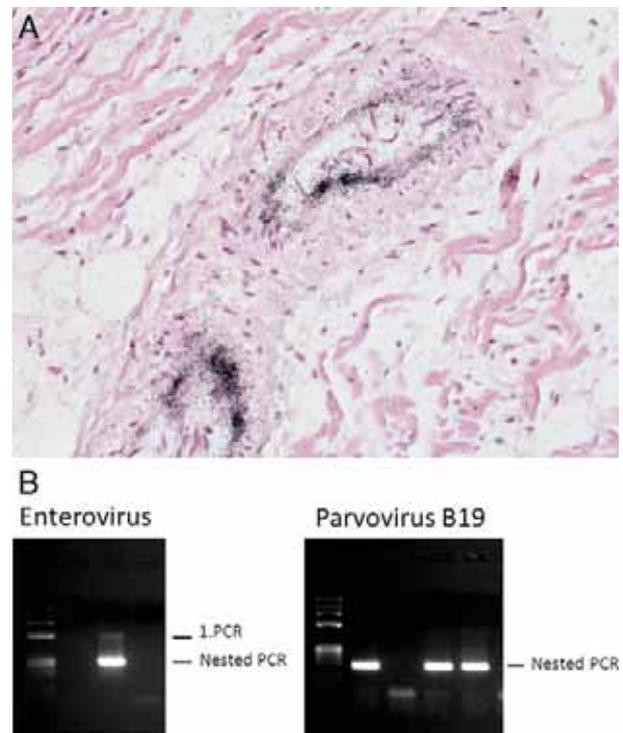

A positive viral culture from myocardium has been considered the diagnostic standard in the past. Viral culture of peripheral specimens, such as blood, stool, or urine, is commonly performed but is unreliable in identifying the causative infection. A 4-fold increase in virus-specific antibody titer correlates with recent infection (128, 129). However, these studies are nonspecific, because prior infection with the causative virus is commonplace, potentially yielding a greater rise in antibody titer than would be seen in a primary infection, and also because cross-reactive responses to related viruses may be observed.

First reported in 1986, *in situ* hybridization (ISH) was performed on myocardial tissue using molecular cDNA probes for coxsackievirus (Fig. 4) (75, 76) and more recently for parvovirus (Fig. 5A). While originally based on radioactive probes, ISH evolved to rely on nonradioactive probes and became more user friendly. Properly established under standard laboratory operating procedures, this method can detect as few as 50 copies of viral genomes in infected cells or tissues. The ISH technique, while very well described in experimental studies (63, 130), is highly specialized and not readily applied in most hospital settings, despite the fact that along with histopathological evaluation this technique provides evidence of active or resolving infections with enteroviruses and allows colocalization of injury, inflammation, and viral genomes (131, 132).

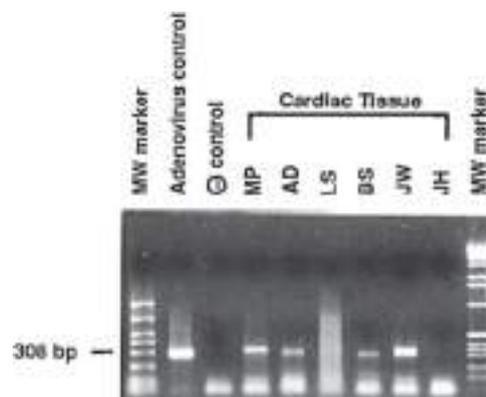

Detection and amplification of viral sequences by PCR from cardiac tissue samples is extremely sensitive and is typically specific (7, 8, 79). In 25–50% of cases, the enterovirus genome was initially identified by reverse transcriptase PCR (RT-PCR) (Fig. 5B, left panel) (8–10, 16, 51, 79, 123, 133–135); however, no other viral genomes were sought in these early studies (133, 136, 137). Subsequently, PCR has been used to screen for other viral genomes within cardiac tissue specimens. Parvovirus (Fig. 5B, right panel) and adenoviruses (Fig. 6) were identified as commonly as enterovirus in heart tissue specimens of pediatric patients with myocarditis or DCM (Table 2) (7, 8, 10, 79). PCR analysis usually does not identify the viral genome in the peripheral blood of patients with myocarditis, but the viral genome can be identified in tracheal aspirates of intubated children with myocarditis (53). The great risk of PCR techniques is the common problem of sample or laboratory contamination and the possibility of finding genomes that are deemed a causative association with the clinical status, but in the absence of histopathological evidence of a myocarditic process. Similarly, viruses found by PCR in the respiratory tract do not secure a diagnosis of myocarditis. These realities temper one's belief in the molecular epidemiological profile of viral heart disease as currently known globally.

**FIGURE 4** *In situ* hybridization for coxsackievirus B3 genome in myocardium of a newborn with lethal enteroviral myocarditis. Note replication of the virus in myocytes as visualized by radioactive RNA/RNA *in situ* hybridization (black dots) in close association with mononuclear inflammatory cells. Magnification, 400 $\times$ .

**FIGURE 5** (A) *In situ* hybridization of acute parvovirus B19 infection of the heart is restricted to endothelial cells of small vessels as demonstrated by radioactive RNA/DNA hybridization. Cardiac inflammation is less prominent as compared to enteroviral myocarditis. Magnification, 400 $\times$ . (B) PCR detection of enteroviral RNA (left panel) and parvovirus B19 DNA (right panel) by nested PCR in the myocardium of different patients with histologically proven myocarditis. Automatic DNA sequencing of viral amplification products confirms specificity of the PCR and allows the analysis of virus genotypes.

**FIGURE 6** Nested PCR for the adenovirus genome. The agarose gel demonstrates a 308-bp PCR-positive band in the adenovirus-positive control lane, as well as in lanes designated MP, AD, BS, and JW, in which DNA was extracted from myocardial tissue samples obtained from patients with myocarditis. Patients designated LS and JH are PCR negative, as is the negative (–) control lane. MW, molecular weight.

**TABLE 2** Viral etiologies of myocarditis in children by PCR analysis

Diagnosis	No. of samples	No. of PCR-positive samples	PCR amplicon (no.)
Myocarditis	624	239 (38%)	Adenovirus 142 (23%)
			Enterovirus 85 (14%)
			Cytomegalovirus 18 (3%)
			Parvovirus 6 (<1%)
			Influenza A5 virus (<1%)
			Herpes simplex virus 5 (<1%)
			Epstein-Barr virus 3 (<1%)
			Respiratory syncytial virus 1 (<1%)
DCM	149	30 (20%)	Adenovirus 18 (12%)
			Enterovirus 12 (8%)
Controls	215	3 (1.4%)	Enterovirus 1 (<1%)
			Cytomegalovirus 2 (<1%)

DCM, dilated cardiomyopathy.

## DIFFERENTIAL DIAGNOSIS

Any cause of acute circulatory failure may mimic myocarditis. Other nonviral etiologies include other infectious agents such as rickettsiae, bacteria, protozoa and other parasites, fungi, and yeasts (83, 85,87–91,138–142); various drugs, including antimicrobial medications (47), antipsychotics (143), and antitumor drugs (144); hypersensitivity, autoimmune, or collagen-vascular diseases (145–151), such as systemic lupus erythematosus, mixed connective tissue disease, rheumatic fever, rheumatoid arthritis, and scleroderma; toxic reactions to infectious agents (5, 30, 67, 152) (e.g., mumps or diphtheria); or other disorders such as Kawasaki disease and sarcoidosis (98, 153, 154). In most cases, however, the cause goes unrecognized or is poorly defined, and idiopathic myocarditis must be diagnosed (155).

## LONG-TERM SEQUELAE

In patients in whom resolution of cardiac dysfunction does not occur, chronic DCM results, characterized by a dilated LV chamber, with or without LV diastolic dysfunction and/or right ventricular dilation and dysfunction (8, 51, 102,156–158). The underlying etiology of DCM is uncertain, but viral persistence and autoimmunity have been widely speculated. In addition, cytoskeletal protein disruption has also been demonstrated (159). Enteroviral protease 2A directly cleaves the cytoskeletal protein dystrophin, resulting in dysfunction of this protein (160–162). Because mutations in dystrophin are known to cause an inherited form of DCM (as well as the DCM associated with the neuromuscular diseases Duchenne muscular dystrophy and Becker muscular dystrophy), it is possible that this contributes to the chronic DCM seen in enteroviral myocarditis (163, 164). Adenoviruses also have enzymes that cleave membrane structural proteins or result in activation or inactivation of transcription factors, cytokines, or adhesion molecules to cause chronic DCM (57, 165, 166). Thus, it appears as if a complex interaction between the viral genome and the heart muscle tissues and cells occurs and determines the long-term outcome of affected patients.

As in mice, myocarditis in humans may have a genetic basis (167). Support for this tenet includes the frequent finding of myocardial lymphocytic infiltrates in patients with familial and sporadic DCM (168), as well as the few reports of families in which two or more related individuals have been diagnosed with myocarditis on endomyocardial biopsy. Of note, the shared receptor for four common viral causes of myocarditis (CVB3 and CVB4 and adenoviruses 2 and 5) is the human coxsackievirus and adenovirus receptor (CAR) (169, 170). The CAR plays an important role in embryonic development and the maintenance of normal cardiac function (64,171–173). Patients with DCM and young adults were shown to express increased levels of the CAR in the heart, suggesting a mechanism responsible for susceptibility to myocarditis (173). Genetic variants in the genome of this receptor might result in host differences leading to myocarditis, although this hypothesis requires study. The role of decay-accelerating factor (DAF), the coreceptor for CVB infections (174), also requires further exploration.

## SUPPORT FOR VIRAL CAUSE-AND-EFFECT RELATIONSHIP WITH MYOCARDITIS

The increasingly common association of viral genomes within the myocardium in patients with myocarditis (80, 175, 176) is tempered by limited definitive data to prove that the virus causes ventricular disturbances directly leading to the clinical phenotype. Myocarditis has traditionally been defined as an inflammatory disorder, yet, even in this regard, definitive data to support the inflammatory concept are limited. In many cases of human myocarditis, frank, fulminant inflammation with lymphocytic or other infiltrate, edema, and cell necrosis with or without fibrosis is seen. But in other circumstances, little infiltrate, necrosis, or edema is seen in subjects with acute-onset heart failure and ventricular dysfunction. In both situations, the viral genome can be identified in up to 70% of those studied by PCR (80, 175, 176). In addition, PCR analysis of “control” specimens from subjects not thought to have clinical symptoms consistent with myocarditis and not having recent infectious or febrile illness very rarely detects a viral genome. However, because a relatively low percentage of biopsies are currently performed in children suspected of having myocarditis and, of those, a limited number have PCR performed on the myocardium, definitive cause-and-effect data are sparse. Occasional autopsy case materials provide definitive links between the enteroviruses and fatal heart muscle disease (177).

One human model system exists that has been used to study the relationship between the detection of viral genomes in the myocardium and ultimate heart failure. Cardiac transplant recipients undergo routine surveillance biopsies for rejection at most institutions, and in all cases, histopathological assessment is performed. At Texas Children's Hospital, all patients also undergo myocardial PCR analysis with screening for adenovirus, enteroviruses (including coxsackievirus), parvovirus B19, CMV, and EBV (178, 179). Detection of the viral genome in these heart biopsy samples has been shown to correlate with outcome. Heart transplant patients not having any PCR-positive studies during a 5-year follow-up period had a 96% 5-year survival rate, whereas those with at least a single PCR-positive result had a 5-year survival rate of 67% (163, 180, 181). Survival did not closely correlate with the level of inflammatory infiltrate seen on histopathology, and the specific virus identified in the myocardium appeared to be an

important variable regarding both the outcome and the inflammatory response. For instance, adenovirus has been shown to cause a lower level of inflammatory infiltrate than enteroviruses or parvovirus B19 (134, 181). Similar findings have been obtained for lung transplant recipients (182). How these posttransplant studies, complicated by the presence of an allo-immune response and by the presence of varied immunosuppressive agents, relate to the pretransplant connection between viral infection of heart muscle and patient outcomes is less clear. The experience of numerous laboratories with murine model studies has taught us the most thus far, with inference for the protean, difficult, and temporally vague human phenotype of myocarditis (70, 183, 184).

## MANAGEMENT

Care of a patient presenting with a clinical picture and history strongly suggestive of myocarditis depends on the severity of myocardial involvement and the clinical status (2–4). Many patients present with relatively mild disease, with minimal or no respiratory compromise, and only mild signs of congestive heart failure. Such is the case because the most commonly recognized cardiotropic viruses are generally “high-attack, low-virulence” pathogens. These patients require close monitoring to assess whether the disease will progress to worsening heart failure and the need for intensive medical care. Experimental animal studies may suggest that bed rest may prevent an increase in intramyocardial viral replication in the acute stage (185–187). Thus, it appears to be prudent to place patients under this restriction at the time of diagnosis. Normal arterial blood oxygen levels should be maintained for any patient with compromised hemodynamics resulting in hypoxemia.

### Management of Acute Heart Failure Related to Myocarditis

The current strategy for therapy in acute myocarditis includes hemodynamic support to achieve end-organ perfusion and urine output without “driving” the myocardium with inotropic agents. In the setting of hypotension, vasopressor infusions need to be used to maintain adequate blood pressure. The agents of choice include norepinephrine, epinephrine, and vasopressin. Inotropic agents such as dobutamine and dopamine may improve blood pressure and increase cardiac output but may have the associated cost of increasing heart rate and increasing mechanical stress on the heart, as well as increasing the possibility for arrhythmias. Phosphodiesterase inhibitors, such as intravenous milrinone, have been used to provide both inotropy and afterload reduction. However, their use may be limited by low blood pressure. Furthermore, the routine use of milrinone for acute heart failure (HF) was not associated with improved outcomes in the OPTIME-HF study (188). Digoxin therapy can also be instituted early, as it may provide positive inotropic effects while lowering the heart rate. If the patient is not requiring vasopressors, acute oral therapy with modulators of the renin-angiotensin-aldosterone systems (e.g., angiotensin-converting enzyme inhibitors) and sympathetic nervous system (e.g., beta-adrenergic blockers) can be started. When chronic oral therapy is necessary and hypotension is not present, an afterload-reducing drug, such as captopril, ramipril, or enalapril (189), may be used with beta-blockers, such as carvedilol or metoprolol. Diuretics therapy may be required to maintain a euvolemic state.

Although arrhythmias are commonly present in the acute setting, they should not be treated unless they are contributing to the symptoms or causing hemodynamic compromise (104). Sustained supraventricular tachyarrhythmias, such as atrial fibrillation, atrial flutter, or AV nodal re-entry tachycardia, may respond to digitalis or intravenous amiodarone. Sustained ventricular arrhythmias should be treated with cardioversion if associated with hypotension or hemodynamic compromise or an infusion of intravenous amiodarone if the patient is stable. Despite aggressive treatment of these arrhythmias, rapid deterioration to ventricular fibrillation, especially in the very young, may occur and should be treated immediately by direct-current cardioversion. The use of an implantable cardioverter defibrillator is rarely necessary in the acute phase. Chronic arrhythmias may persist long after the acute disease has passed (104). Thus, children who recover from myocarditis, regardless of etiology, should be monitored indefinitely. Complete atrioventricular block requires a temporary transvenous pacemaker because the patient may be dependent on a higher heart rate to generate an adequate cardiac output.

If the patient deteriorates despite maximal medical attempts at maintaining adequate tissue perfusion, then consultation for implantation of mechanical circulatory support should be considered (190–193). Some options include placement of a temporary ventricular assist device (VAD) like the TandemHeart (CardiacAssist, Inc., Pittsburgh, PA) or Impella (ABIOMED, Danvers, MA), or placing the patient on extracorporeal membrane oxygenation (ECMO) until the acute phase resolves. In the absence of resolution of shock, consideration for placement of a durable VAD such as Heartmate II (Thoratec Corporation, Pleasanton, CA) or HVAD (HeartWare, Framingham, MA) should be undertaken. In some circumstances, transplantation becomes necessary (163, 167), and outcomes may be best in patients who present most fulminantly (158). The number of such patients who definitely have a viral etiology is not established.

### Immunomodulatory and Antiviral Therapies

Immunosuppressive agents have not been shown to improve outcomes in patients with acute viral myocarditis (106), but may improve outcomes in those with giant cell myocarditis (194). The use of immunosuppressive agents in suspected or proven viral myocarditis is controversial (195–197). Some animal studies have suggested an exacerbation of virus-induced cytotoxicity in the presence of immunosuppressive drugs, possibly due to reduced interferon production. The NIH-funded Myocarditis Treatment Trial analyzed the use of immunosuppressive therapy, including corticosteroids with either cyclosporine or azathioprine (106). Although the study was performed with adult patients, the results are potentially applicable to children. There was no difference in survival outcomes among patients treated with azathioprine and prednisone, cyclosporine and prednisone, or conventional supportive therapy (106). Immunosuppressive therapy was not beneficial in most patients with histologically confirmed myocarditis.

Another important therapeutic option is the use of intravenous gamma globulin in children with myocarditis. One nonrandomized clinical trial (74) used this agent in 21 of 46 children with myocarditis; patients who received this drug had better LV function at follow-up and a trend toward a higher survival rate at 1 year. Whether this approach proves to be beneficial or whether these early results mirror the early-published experience with corticosteroids remains to be seen (198, 199).

The efficacy of type-I IFN treatment in myocarditis has been studied with respect to viral clearance and prevention of progressive deterioration of LV function (136, 198, 200). These uncontrolled studies reported some effectiveness of IFN- $\alpha$  or - $\beta$  treatment in viral clearance and cardiac function improvement in patients with PCR-proven enteroviral or adenoviral myocarditis. Unfortunately, this impression was not confirmed in a multicenter clinical trial later on.

Potential therapeutics for enterovirus infections that involve the heart have been in progress for many years. Of note, pleconaril was developed as a steric inhibitor of picornaviral capsid protein binding to the CAR and other receptors (201, 202). While this investigational antiviral was widely used in the late 1990s and early 2000s on a compassionate care basis for treatment of acute, severe human myocarditis (203), it never received FDA regulatory approval. Vapendavir is a recently developed, more potent, and broader-spectrum capsid inhibitor; however, its efficacy in the treatment of myocarditis remains to be tested (204). Clearly, an antiviral strategy is especially pertinent to infants and young children whose lives literally depend on the balance between viral pathogenesis and host immune responses, and for which a drug like pleconaril or vapendavir may serve a pivotal role in tipping this deadly duel in favor of the host. Meanwhile, a vast amount of fundamental work on signaling mechanisms underlying enteroviral infections has been pursued with a view to identifying other targetable molecules.

There are also several available agents for influenza, adenovirus, and herpesviruses; however, clinical evidence of their value in the treatment of myocarditis is still lacking. For example, the phase III study of brincidofovir showed efficacy for adenovirus viremia in transplant patients, but this agent has not been studied for myocarditis (205).

### Vaccination

Vaccination, except for influenza, is not currently available for the principal viral agents causing human myocarditis. The efficacy of the polio vaccine has led to the suggestion that a broadly reactive enteroviral vaccine, if possible, or at least a CVB-specific vaccine, could be beneficial for reducing the incidence of myocarditis or associated DCM. Early work indicates that immunization can be protective in mice (206). The possibility of success in this regard is supported by the success of the mumps vaccine, which all but eliminated this form of DCM.

# Viral Diseases of the Skin

ZEENA Y. NAWAS AND STEPHEN K. TYRING

## 8

Viral infections cause a variety of cutaneous and mucosal manifestations that are either the result of primary viral replication within the epidermis or a secondary effect of viral replication elsewhere in the body. Three groups of viruses represent most primary epidermal viral replications: human papillomaviruses (HPV), herpesviruses, and poxviruses. Multiple virus families, including retroviruses, paramyxoviruses, togaviruses, parvoviruses, and picornaviruses, produce skin lesions secondarily. Other viruses, such as orthomyxoviruses and reoviruses, rarely induce skin lesions. Recognition of characteristic mucocutaneous manifestations of a variety of viral diseases is crucial. It either directly helps determine the etiologic agent or assists the clinician in deciding which additional diagnostic tests to order. Proper management of the patient can be initiated from the results of such tests.

### CLINICAL MANIFESTATIONS

A wide spectrum of skin lesions can result from viral infections. For example, while infection with HPV is best known for causing verrucous papules, other manifestations of this viral infection include erythematous macules in epidermodysplasia verruciformis (EV), smooth papules in Bowenoid papulosis, and fungating Buschke-Lowenstein tumors. Vesicles are considered the primary lesion in herpes simplex virus (HSV), varicella-zoster virus (VZV), and many coxsackievirus infections. However, the vesicles are often preceded by erythema and papules and followed by pustules, crusts, or shallow ulcers. Ulcers without other stages can be seen with cytomegalovirus (CMV) infections of the skin and mucous membranes as well as with HSV, VZV, or coxsackievirus infections of mucous membranes. Both macules and papules are seen with measles and rubella. Macules coalescing into larger erythematous patches are seen in Epstein-Barr virus (EBV), human herpesvirus 6 (HHV-6), and parvovirus B19 infections.

Some viruses induce skin changes that are highly suggestive of the diagnosis, such as the verrucous papules seen with papillomavirus infection or the smooth umbilicated papules resulting from poxvirus infection. However, other viruses produce nonspecific skin lesions, including urticaria, erythema multiforme, and petechiae. In these cases, a differential including viral and nonviral etiologies must be considered. Depending on the clinical picture, vesicles in-

duced by HSV type 1 (HSV-1), HSV-2, or VZV may be diagnostic or may necessitate a broad differential diagnoses. Other herpesviruses, such as EBV, CMV, and HHV-6, produce skin manifestations less frequently and are most accurately diagnosed when the systemic manifestations of the viral infection are also considered. Cutaneous manifestations of viral diseases can range from very specific (e.g., dermatomal vesicles of herpes zoster) to very general (e.g., urticaria), and the differential diagnosis must take the patient's total clinical presentation into consideration.

### PATHOPHYSIOLOGY

Viruses infect the skin via three different routes: direct inoculation, spread from an internal focus, and systemic infection. Viruses that infect the skin by direct inoculation include primary HSV, papillomaviruses, and most poxviruses (except smallpox). Primary VZV produces systemic infection with viremia and dissemination to the skin and mucous membranes. Recurrent VZV (shingles) or recurrent HSV reaches the skin from the sensory ganglia.

The effect of viral replication on infected cells may directly produce skin lesions, or the skin lesions may result from the host response to the virus. Alternatively, the lesions may be the result of the interaction between the viral replication and the host response. In general, viruses that replicate in the epidermis produce skin lesions directly. On the other hand, viruses that replicate elsewhere in the body typically produce skin manifestations via the host's response to viral replication. For example, the host's cell-mediated immune response to rubella and measles viruses is thought to be at least partly responsible for the skin manifestations associated with these viruses, and rashless measles can manifest as pneumonitis or central nervous system (CNS) disease in highly immunocompromised hosts.

### DIAGNOSIS

#### Laboratory Diagnosis

Five general methods of laboratory diagnosis are available to confirm suspected viral diseases: viral culture, microscopic examination of infected tissue, detection of viral antigens, detection of viral DNA or RNA, and serology (see Chapter 15). Viral culture or polymerase chain reaction (PCR) are

the preferred methods of diagnosis; both require adequate specimens. Viral culture is highly specific (>99%), but sensitivity depends on stage of lesion and proper collection technique and declines rapidly as lesions begin to heal (1). Sensitive virus isolation systems are not available for many viruses. If HSV-1 or HSV-2 is responsible for the lesion, a positive culture can be obtained within 1–2 days. Viral cultures are most likely to be positive if the sample is taken from the vesicular stage, whereas later stages of healing have lower yield. Positive cultures are more difficult to obtain from VZV, even when fresh vesicular fluid is used to inoculate the cell culture.

Evaluation of the involved skin by microscopy can reveal histologic changes consistent with a particular virus family, but is usually not helpful in identifying the specific virus responsible. For example, benign warts caused by different HPV types have a similar histologic appearance under the microscope. Histologic changes induced by HSV-1 and HSV-2, as well as by VZV, are similar to each other but distinctive from changes associated with other herpesviruses. A more rapid procedure in suspected HSV-1, HSV-2, and VZV infection is the Tzanck smear. Using fluid from an intact vesicle, the Tzanck smear is positive if acantholytic keratinocytes or multinucleated giant acantholytic keratinocytes are detected. Multinucleated giant cells are found in herpes simplex, varicella, and zoster. The Tzanck smear is insensitive (50%) and nonspecific. Another viral infection that can be diagnosed directly from smears from a skin lesion is molluscum contagiosum (MC). The presence of intracytoplasmic inclusion bodies will help to distinguish papules associated with MC virus from skin lesions of *Cryptococcus neoformans*, which can appear very similar in human immunodeficiency virus (HIV)-infected patients.

Among rapid diagnostic tests, perhaps the most frequently used for detection of viral infections of the skin is PCR and fluorescent antibody detection of HSV-1, HSV-2, and VZV. This technique distinguishes among these three viruses, in contrast to the Tzanck smear. Immunoperoxidase techniques are sometimes used to detect HPV capsid antigens; however, these techniques can lead to false-negative results in oncogenic types of HPV because the viral DNA may not have associated capsid antigens. Labor-intensive techniques such as electron microscopy or immunoelectron microscopy can be used to detect viral particles or viral antigens.

Assays to detect viral nucleic acid are becoming more widely used, especially when no effective culture or serologic assay is available. *In situ* hybridization allows not only detection of the viral nucleic acid but also histologic localization of the virus to specific cells. PCR primers can be designed to detect a range of viruses within a particular family (i.e., consensus primers) or may be specific for a particular virus (i.e., type-specific primers). Further information can be gained from *in situ* PCR, which combines the sensitivity of PCR with localization of the virus on histology. The application of PCR for diagnostic purposes is detailed in each chapter.

### Differential Diagnosis

The differential diagnosis of various types of viral exanthemata requires the consideration of a spectrum of both viral and nonviral conditions. Vesicles may be due to HSV-1, HSV-2, VZV, poxviruses, hand-foot-and-mouth disease (HFMD) viruses, and other coxsackieviruses. Most vesicles develop into pustules during the process of healing. Therefore, the differential diagnosis of a vesiculopustular rash must include nonviral entities such as bullous impetigo, insect

bite reactions, drug eruptions, contact dermatitis, gonococemia, erythema multiforme, and sweet syndrome. Macules may be observed in rubella, EBV infection (infectious mononucleosis), and HHV-6 infection (roseola), as well as a variety of coxsackievirus A and B and echovirus infections. Nonviral etiologies of macules may include drug eruptions and bacterial infections (scarlet fever, Rocky Mountain spotted fever, and erysipelas). Macules may manifest with papules in measles, echovirus infections, and human parvovirus B19 infections (erythema infectiosum). Maculopapular lesions may also be seen in erythema multiforme, which is commonly of viral etiology (HSV) or may be associated with nonviral infections or drug eruptions.

Papules are seen in a variety of poxviruses and HPV infections, as well as in Gianotti-Crosti syndrome, which may be a manifestation of hepatitis B or another viral infection. Papules may also be seen with bacterial infection (*Bartonella* and *Mycobacterium*), fungal infections (*Cryptococcus*), and noninfectious conditions (seborrheic keratoses and basal cell carcinomas). Nodules may be observed in poxvirus infections (orf and milker's nodules), HPV (squamous cell carcinomas associated with HPV-16), or HHV-8 (Kaposi's sarcoma), as well as in mycobacterial and *Bartonella* infections (bacillary angiomatosis) and noninfectious tumors (basal cell carcinomas, squamous cell carcinoma, melanoma, and pyogenic granuloma).

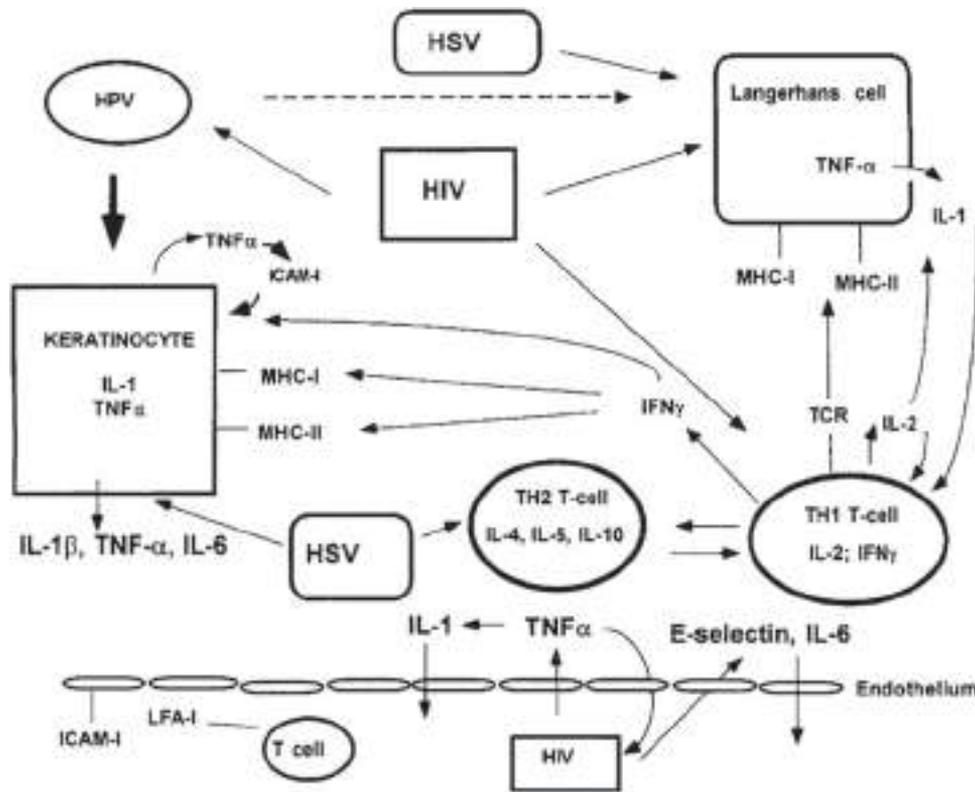

Urticaria is usually associated with allergic reactions, including drug eruptions, but may be due to hepatitis B virus or coxsackievirus infections. Petechiae are seen in multiple viral infections, such as dengue fever and other hemorrhagic fevers (Lassa fever), but may occur in nonviral conditions producing thrombocytopenia. Ulcerations of the mucous membranes commonly occur with HSV-1, HSV-2, VZV, CMV, and HFMD viral infections. Anogenital ulcers in immunocompromised persons are sometimes due to CMV or may involve a coinfection of CMV and HSV. Oral ulcers of viral etiology must be distinguished from nonviral ulcers such as aphthous ulcers. Cutaneous ulcers may be related to stasis dermatitis or to other causes of decreased circulation.

### LOCAL IMMUNITY TO VIRAL INFECTIONS

Not only does the epidermis serve as a primary line of defense against infections, but because of its anatomic structure, it also contains the basic elements needed for the immune response against infection. Therefore, the concept of skin-associated lymphoid tissue (SALT) has been proposed (2). SALT is made up of the following: (1) keratinocytes, which phagocytize foreign particles, release cytokines, and express major histocompatibility complex (MHC) class II antigens upon incubation with interferon- $\gamma$  (IFN- $\gamma$ ); (2) epidermal Langerhans cells, which have surface expression of MHC class II, CD1, C3b1R, and CD4 molecules and are the predominant scavenger antigen-presenting cell of the epidermis; (3) skin-tropic T cells, which in the epidermis include mainly "inactive" memory T cells of predominantly CD8<sup>+</sup> phenotype, although CD4<sup>+</sup> and CD4<sup>-</sup> CD8<sup>-</sup> *gd*<sup>+</sup> T cells are also present; and (4) skin endothelial cells, which direct cellular traffic in and out of the skin (Fig. 1).

### DNA VIRUSES

The following sections highlight the mucocutaneous manifestations, diagnosis, and management of common viral infections. The reader should consult pathogen-specific

**FIGURE 1** Pathways of the cutaneous immune response to infection with human papillomavirus (HPV), herpes simplex virus (HSV), and human immunodeficiency virus (HIV).

chapters for details on the virology and other features of individual viral agents.

### Human Papillomaviruses

#### Epidemiology

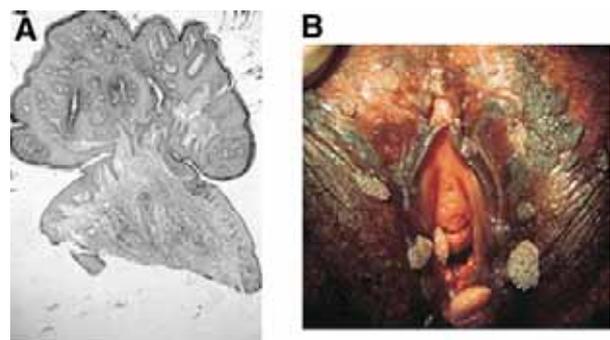

Anogenital HPV infection is extremely common, with an annual incidence of 5.5 million cases in the United States (3, 4). Approximately 75% of sexually active adults will have had an HPV infection by age 50. Of these, approximately 60% have resolved infection, 14% have subclinical infection, and 1% have clinically evident lesions (5). Peak prevalence of anogenital HPV is in women younger than 25 years old; there is a second peak in women over age 55 (6).

Condyloma acuminata, or genital (venereal) warts, are the most frequently diagnosed sexually transmitted disease, with an annual incidence of approximately 1 million new cases in the United States (Fig. 2). Over 90% of cases of condyloma acuminatum are due to HPV-6 or HPV-11 and are clinically benign. Genital warts are most often spread by sexual contact, with a 60% transmission rate during sexual contact with an infected partner. The mean incubation period of HPV is 2–3 months but ranges from 3 weeks to beyond 8 months (7, 8).

HPV infection also appears to be very common in men but is less well studied. Most studies report prevalence in men comparable to that in women. However, men have lower seropositivity of HPV-6, -11, -16, and -18 (9).

The most significant risk factor for anogenital infection in both men and women is the number of sexual partners. HPV has also been positively correlated with smoking. A possible association with oral contraceptive use has been

suggested (10). Male circumcision appears to reduce the prevalence of genital HPV in males (11), significantly reduces the prevalence and incidence of both low-risk and high-risk HPV infections, and increases clearance of high-risk HPV infections in their female partners. Male circumcision has been recommended as an effective intervention for reducing the prevalence and incidence of HPV infections in female partners (12). The mechanism by which circumcision helps protect against HPV infection is unclear but is thought to go beyond increased probability of good penile hygiene (13) and probably involves the reduction of HPV carriage in the penis (12). Furthermore, the keratinized stratified squamous epithelium of the penile shaft is likely

**FIGURE 2** (a) Photomicrograph of condyloma acuminatum showing acanthosis, papillomatosis, and parakeratosis. (b) Condyloma acuminatum associated with human papillomavirus 6 (HPV-6).

less vulnerable to infection than the nonkeratinized mucosal lining of the prepuce (13).

Nongenital cutaneous HPV infections occur in 10% of children, with a peak incidence between the ages of 12 and 16 (14). Adults are also affected by cutaneous HPV but less commonly than children. Close personal contact is the main risk factor for transmission, as these lesions spread by direct skin-to-skin or skin-to-mucosa contact. However, transmission of both anogenital and nongenital cutaneous HPV infections depends on lesion location, HPV quantity in the lesion, type of contact, and immune status of the exposed individual.

### Clinical Features

HPV infections can be categorized based on regional tropism—that is, whether they cause genitomucosal lesions, nongenital cutaneous lesions, or lesions associated with EV. The most prevalent clinical form of genitomucosal lesions is condyloma acuminata. These warts are exophytic, cauliflower-like lesions typically located near moist surfaces. Papular warts and flat lesions occur less commonly. These lesions are smaller and less obvious on exam than condyloma acuminata. Examination under a colposcope or other type of magnification may be necessary for identification (15). Anogenital HPV infection is commonly associated with cancer, as described in more detail below (see Chapter 28).

An uncommon manifestation of genital HPV infection is the Buschke-Lowenstein tumor, or “giant condyloma.” This lesion typically manifests as a slow-growing, large, malodorous, cauliflower-like mass. These lesions resemble condyloma acuminata histologically, but exhibit both downward and upward growth, thus appearing locally invasive. Recurrences of Buschke-Lowenstein tumors are common (15).

Bowenoid papulosis is an anogenital neoplasia that manifests as multiple, verrucous, brown-red papules that may coalesce. Lesions are more common in females, in whom they occur around the labia minora and majora, inguinal folds, and perianal areas. In men, lesions occur on the glans or shaft of the penis (15).

Nonanogenital mucosal disease can occur in the nares, mouth, larynx, and conjunctiva. HPV from genital lesions can be transmitted to distant mucous membranes via orogenital sex (causing oral condyloma acuminatum) or nonsexually, as in cases of vertical transmission during vaginal delivery (16). In the latter case, HPV from vaginal warts may be transmitted to the oral or respiratory tract of the infant and manifest as respiratory (laryngeal) papillomas (17). Alternatively, anogenital warts may develop in infants within a few months of birth as a result of acquisition during vaginal delivery. Children may also develop anogenital warts due to incidental spread from cutaneous warts or from sexual abuse (18).

Cutaneous HPV lesions are common and can manifest as verruca vulgaris (HPV-2), plantar warts (HPV-1), or verruca plana (HPV-3). These common warts can manifest on any skin surface but are most commonly seen on the hands and fingers. They manifest as flesh-colored exophytic papules and nodules that are usually benign and self-limited; however, they can be annoying and difficult to eradicate.

Cutaneous warts in EV, on the other hand, can lead to major morbidity and mortality (19). EV is a rare autosomal recessive genodermatosis and was the first model of cutaneous viral oncogenesis in humans. EV patients develop disseminated warty papules and erythematous macules during childhood. These lesions progress to cutaneous carci-

**FIGURE 3** Multiple primary squamous cell carcinomas associated with human papillomavirus 8 (HPV-8) on the forehead of a man with enterovirus (EV).

nomas in adulthood in approximately one-half of these patients (Fig. 3). At least 19 HPV types are associated with EV. Several of these genotypes have oncogenic potential, most notably HPV-5 and HPV-8 (20). Nonsense mutations in the adjacent novel genes *EVER1* and *EVER2*, which encode integral membrane proteins in the endoplasmic reticulum (21), are associated with EV. Oncogenic HPV genotypes in EV appear to be necessary but not sufficient for malignant transformation. The most important cofactor, in the case of EV, is UV irradiation, which is illustrated by the fact that the highest incidence of carcinomas in EV patients is in areas of greatest sunlight exposure (22).

### Diagnosis

Often no laboratory tests are carried out if, by clinical appearance, the lesion is presumed to be HPV related and benign. When biopsies of verrucae are carried out, the following general patterns may be observed in tissues: acanthosis, papillomatosis, hyperkeratosis, parakeratosis, and prominent and often thrombosed dermal capillary vessels. Koilocytes, large keratinocytes with an eccentric, pyknotic nucleus surrounded by a perinuclear halo, are often observed. Frequently, a biopsy is conducted to determine if the lesion is dysplastic or neoplastic. In the general population, such biopsies would most likely be taken in the anogenital region. In this population, dysplastic or neoplastic lesions are most frequent on the cervix and therefore would be detectable via cytopathology taken with the Pap smear.

Immunohistochemical staining for HPV capsid antigens provides more specific detection of HPV. Because dysplastic or neoplastic lesions contain few, if any, capsid antigens, this method may give false-negative results with such lesions. HPV cannot be readily grown in tissue culture, and serology is not routinely useful; thus, the only specific method of diagnosing HPV is via DNA or RNA detection methods. The Hybrid Capture 2 High-Risk HPV DNA test and the Cervista HPV High-Risk DNA test detect presence of 13–14 oncogenic HPV types, whereas the Cervista HPV 16/18 DNA test only detects oncogenic HPV-16 and HPV-18. The Digene HC2 HPV DNA test detects 13 oncogenic or five nononcogenic HPV types. The Cobas 4500 test detects 14 oncogenic HPV DNA types and can detect individual types HPV-16 and HPV-18, whereas the APTIMA HR HPV test detects 14 oncogenic HPV types of HPV mRNA (23).

Verrucae are usually clinically evident, and they may resemble seborrheic keratoses, nevi, or acrochordons. *Verrucae planae* may mimic papules of lichen planus. *Condyloma acuminatum* must be differentiated from *condyloma latum*, the skin lesion associated with secondary syphilis. Bowenoid papulosis can be confused with lichen planus, psoriasis, seborrheic keratoses, or *condyloma acuminata* (15). Benign verrucae also must be differentiated from dysplastic and neoplastic lesions.

### Treatment

Treatment for most benign verrucae consists of surgery, cryotherapy, or topical chemotherapy. In each case, the objective is to eradicate the lesion and allow the immune system to hold latent HPV in surrounding (normal-appearing) tissue in check so as to prevent recurrences. Surgical therapy includes simple excision, electrodesiccation, and removal with a CO<sub>2</sub> laser. Cryotherapy involves application of liquid nitrogen, which induces dermal and epidermal cellular necrosis. Topical chemotherapy options include podophyllin resin, purified podophyllotoxin, 5-fluorouracil, retinoic acid, cantharidin, salicylic acid, lactic acid, bichloroacetic acid, and trichloroacetic acid (24). Selection of the most appropriate therapy depends on the size and location of the wart, as well as on the history of previous therapies.

IFN- $\alpha$  is also approved for treatment of *condyloma acuminatum*. Combinations of IFN and other treatments do not appear to be more effective than other treatments used alone. IFN is costly and inconsistently effective and should not be considered a primary treatment (24). The Toll-like receptor 7 (TLR7) agonist imiquimod has been shown to be very effective for *condyloma acuminatum* (25). It is applied topically by the patient and produces minimal local inflammation and no systemic side effects. Its mode of action is via induction of endogenous IFN- $\alpha$  as well as a host of other cytokines. In contrast to therapies without antiviral or immunomodulatory mechanisms of action, a very low rate of recurrence is observed following clearance of *condyloma acuminatum* with imiquimod. Use of imiquimod in conjunction with surgical treatment may be even more effective. One retrospective study found that the rate of recurrent anogenital warts was much lower in patients treated with a 16-week course of imiquimod (5% cream) monotherapy and surgical excision of residual warts than in those treated with surgical excision alone (26).

### Prevention

Two vaccines—Cervarix and Gardasil—protect against the two HPV types (HPV-16 and HPV-18) that cause 70% of cervical cancers, 80% of anal cancers, 60% of vaginal cancers, and 40% of vulvar cancers (27). These vaccines also protect against precancerous cervical lesions, most HPV-induced oral cancers, and other rare genital cancers. Gardasil also protects against the two HPV types (HPV-6 and HPV-11) that cause 90% of genital warts. Both vaccines are given in a series of three shots over 6 months. HPV vaccination is recommended for girls and boys at age 11 or 12 years. Women can get HPV vaccine through age 26, and men can get vaccinated through age 21. Recently, a third vaccine has been approved—Gardasil 9—which covers five additional HPV strains (HPV-31, HPV-33, HPV-45, HPV-52, and HPV-58) that are responsible for 20% of cervical cancer, in addition to the four HPV strains covered by the first-generation Gardasil vaccine. Gardasil 9 is approved for use in females ages 9–26 and males ages 9–15.

## Poxviruses

### Epidemiology

Smallpox was endemic throughout the world but has been eradicated by a worldwide vaccination program. Vaccination against smallpox has not been given routinely in the United States for over 30 years. Virtually all citizens are currently susceptible to variola because vaccination is believed to be protective for only 5–10 years (28). Currently, smallpox virus is known to exist in only two laboratories: the Centers for Disease Control and Prevention in Atlanta, Georgia, and a laboratory in Novosibirsk, Russia. However, there is concern that the virus exists elsewhere and could be used in biological warfare. Viral transmission is primarily via respiratory droplets. Historically, the incidence of infection was highest in the winter and early spring because aerosolized variola virus survives better at lower temperatures and low humidity levels (29).

Monkeypox has historically been significant only in sub-Saharan Africa, where it was recognized as a distinct disease in 1970, despite its presumable existence for thousands of years. Early studies suggested that most cases occurred in children under age 10 and were associated with animal contact, although secondary human-to-human transmission did occur. The first documentation of monkeypox in the Western Hemisphere was a cluster of cases in the U.S. Midwest in 2003. This outbreak was spread by prairie dogs that apparently acquired the virus from Gambian rats when housed with them at a distribution center in Illinois (30). Person-to-person spread of monkeypox through close contact with infected individuals appears to occur inefficiently. Vaccination with vaccinia virus is protective against monkeypox (31).

MC is the most prevalent poxvirus infection and commonly occurs on the trunk in children and as a sexually transmitted disease in the genital area of adults. MC spreads primarily by direct skin-to-skin contact, including auto-inoculation; spread via fomites can also occur. Most children with MC are healthy and younger than 8 years of age. Fewer than 5% of children in the United States have clinical evidence of MC virus infection (32). MC virus most commonly infects individuals 15–29 years old (32, 33). Infection with MC virus occurs at increased rates among immunocompromised individuals, and the prevalence of MC among HIV-positive patients is 5–8% (33). The occurrence of MC virus infection in HIV-positive patients has decreased significantly since the introduction of highly active antiretroviral therapy (HAART). Other immunodeficient states, including systemic corticosteroid use and perhaps atopic dermatitis, can also predispose to MC virus infection.

### Clinical Features

**Smallpox.** Following viremic dissemination, smallpox virus replicates in the epidermis and mucosae. It is spread not only via direct skin contact and fomites but also by respiratory transmission. Preceding the development of skin lesions, patients typically experience 3 days of apprehension, sudden prostrating fever, severe headache, back pain, and vomiting. Erythematous macules then develop and progress to tense, deep-seated papules and vesicles (Fig. 4). The vesicles are followed by pustules, then crusts, and finally scar formation. The rash appears in a centrifugal distribution with all lesions in the same stage of development. Overall, the mortality rate with smallpox is approximately 30%, but the hemorrhagic form results in almost 100% mortality even before development of skin lesions. Variola minor, caused by a less virulent

FIGURE 4 Variola major (smallpox).

strain of variola virus, has similar clinical manifestations but lesser severity and mortality (<1%) (34).

When smallpox was epidemic, it was occasionally confused with chickenpox, dengue fever, or enterovirus infections. An important distinguishing feature between smallpox and chickenpox is that the crops of lesions are in the same stage of development in smallpox infection, whereas lesions occur in different stages of development in chickenpox. The hemorrhagic form of smallpox has to be distinguished from other viral hemorrhagic exantheams, coagulation disorders, typhus, and meningococcal septicemia.

**Vaccinia.** Vaccination with vaccinia virus is no longer routine but is still used in certain target populations. The live virus vaccine occasionally leads to serious complications, including bacterial superinfections, vaccinia necrosum, generalized vaccinia, eczema vaccinatum, erythema multiforme, accidental inoculation, and encephalitis (35). These manifestations are discussed in Chapter 18.

**Monkeypox.** The clinical picture of human monkeypox virus infection resembles that of smallpox. There is a 10- to 14-day incubation period followed by a prodromal illness consisting of fever, malaise, and lymphadenopathy. After 1–3 days, patients break out in a maculopapular rash that usually begins on the trunk and spreads peripherally. Lesions can occur on the palms and soles and on mucous membranes. The mortality rate is 10%, and death usually occurs during the second week of the illness (31).

Monkeypox and smallpox have very similar clinical manifestations. One distinguishing feature clinically is lymphadenopathy, which is common in the prodromal phase of monkeypox virus infection but not smallpox (31). However, these poxviruses cannot be readily identified from one another except by PCR assay (34).

**Molluscum Contagiosum.** The incubation period of MC is 2–6 weeks. It manifests as 3- to 6-mm skin-colored dome-shaped papules with a central umbilication. Although four different strains of MC virus (I through IV) have been identified (based on restriction endonuclease digestion patterns), all strains produce similar clinical pictures. MCV I is responsible for the vast majority of infections in immunocompetent hosts in the United States. Clinical presentations of MC often follow one of two patterns in immunocompetent individuals: widespread papules on the trunk and face of children, transmitted by direct skin-to-skin (nonsexual) contact, or genital papules in adults, spread by sexual contact. In either case it is unusual to see more than 15 lesions in an individual patient. In immunocompromised persons, es-

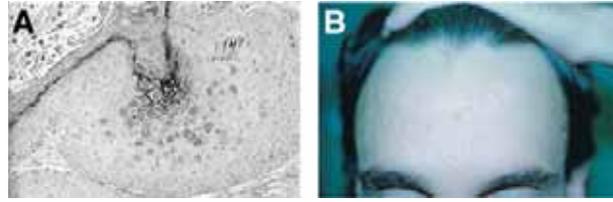

FIGURE 5 (a) Photomicrograph of molluscum contagiosum (MC) demonstrating central umbilication and epidermal hyperplasia containing intracytoplasmic inclusions (Henderson-Paterson bodies) compressing nuclei. (b) Disseminated molluscum contagiosum in an AIDS patient.

pecially those who are HIV positive, MC can manifest with thousands of papules and be a major source of morbidity (Fig. 5); HIV-positive patients also commonly have facial involvement as well as increased likelihood of bacterial superinfection and treatment resistance (32).

A number of entities can mimic MC in the healthy host, such as warts, basal cell carcinomas, and lichen planus. In HIV-positive patients, MC must be distinguished from cutaneous cryptococcal infection (36).

**Orf.** Orf, contagious ecthyma, is a less common poxvirus infection that is transmitted from sheep, goats, and other animals to the hands of humans (Fig. 6). Orf manifests as cutaneous nodules averaging 1.6 cm in diameter associated with regional lymphadenopathy, lymphangitis, and fever. Lesions spontaneously progress through six stages, resulting in healing in about 35 days (37).

**Milker's Nodules.** Milker's nodules are caused by parapoxvirus. Clinically similar to orf, the lesions result from manual contact with teats of infected cows and have an incubation period of 4–7 days. Also similar to orf, the nodules heal in 4–6 weeks after progressing through six clinical stages (38).

Orf and milker's nodules can mimic one another or can be confused with pyogenic granulomas, sporotrichosis, or atypical mycobacterial infection.

#### Treatment

For patients with smallpox or disseminated vaccinia, management of symptoms and prevention of bacterial superinfection are paramount. See Chapter 18 regarding antiviral therapy. There is no proven effective treatment for monkeypox, but vaccination is highly protective.

MC is a self-limited condition, but resolution may take 6 months to 5 years. Therefore, most physicians recommend treatment, particularly for genital lesions, to reduce the risk

FIGURE 6 Nodular stage of orf on the hand of a shepherd from Mexico.

of spread and patient discomfort. Treatment options include local excision by electrocautery, curettage, or cryotherapy and chemical ablation via application of trichloroacetic acid or podophyllin. Patients may opt to treat their lesions at home by self-administering topical treatments such as podophyllotoxin, retinoic acid, or imiquimod cream (33). Recurrences are common in immunocompromised persons. Lesions of orf or milker's nodules can be removed via excision and cautery, but this is usually not necessary as spontaneous resolution can be expected in approximately 6 weeks.

### Human Herpesviruses—Herpes Simplex Virus (HSV-1, HSV-2)

#### Epidemiology and Clinical Manifestations

HSV-1 is the primary cause of oral herpes or herpes labialis and an increasing number of genital infections. The virus is typically transmitted via direct inoculation of the skin and mucous membranes. Herpes labialis is extremely common, with up to 90% of adults having serologic evidence of HSV-1 infection (39). While the majority of primary infections with HSV-1 are asymptomatic, the virus remains dormant in the host's neuronal ganglia and can reactivate to produce recurrent symptomatic disease. Recurrent episodes occur in up to one-third of infected individuals and can be induced by stress, trauma, menstruation, fever, colds, and ultraviolet (UV) light. Upon reactivation, the virus travels down the sensory nerve, producing prodromal sensations of pruritus or tingling. When the virus reaches the skin, grouped vesicles with surrounding erythema form on or near the vermilion border of the lip. There is often regional lymphadenopathy and occasionally fever, headache, and malaise. Vesicles ulcerate, crust, and resolve in 2–4 weeks, frequently with postinflammatory hypo- or hyperpigmentation.

At least 50 million individuals in the United States, or one in four adults, are estimated to be seropositive for HSV-2 (40). HSV-2 is the primary cause of genital herpes or herpes genitalis. As with HSV-1, most primary infections with HSV-2 are asymptomatic, with only 10–25% of seropositive individuals indicating a history of genital ulcers (40). Primary HSV-2 infection classically manifests with widespread genital vesicles and ulcers with surrounding erythema (Fig. 7). There may be associated edema, pain, inguinal lymphadenopathy, discharge, dysuria, malaise, fever, and photophobia. These signs and symptoms typically occur within 3–14 days of sexual contact with an infected individual. Viral shedding from active lesions lasts up to 14 days in women and approximately 10 days in men (41); however, HSV-2-seropositive individuals can still shed the virus and infect others when no lesions are present. Symptoms are typically more severe in women than in men, and skin lesions often require 3–4 weeks for complete healing.

Similar to HSV-1, recurrences of HSV-2 may be triggered by a variety of factors, such as emotional or physical stress or mild trauma. Recurrent episodes of HSV are usually less severe than initial outbreaks and often heal in 7–10 days without therapy. Men suffer 20% more recurrences than women, which may contribute to the higher rate of herpes transmission from men to women. In immunocompromised individuals, HSV recurrences may be chronic and result in significant morbidity if untreated.

Up to 30% of first-episode genital herpes is due to HSV-1, which is often attributable to orogenital contact. Genital herpes due to HSV-1 is usually less severe than disease due to HSV-2. In addition, genital herpes due to HSV-1 recurs less frequently than HSV-2-associated disease.

**FIGURE 7** First-episode genital herpes due to herpes simplex virus 2 (HSV-2) in a man who gave a history of always using condoms during sex.

In addition to herpes labialis and genitalis (Fig. 8), HSV-1 and HSV-2 can also cause gingivostomatitis, herpetic whitlow (Fig. 9), HSV gladiatorum, neonatal herpes, herpetic keratoconjunctivitis, aseptic meningitis, and herpes encephalitis. Complications of HSV infection include erythema multiforme (Fig. 10) and eczema herpeticum due to autoinoculation of the virus onto areas of atopic dermatitis. In immunocompromised patients, infection with HSV-1 or HSV-2 can lead to widespread local infection, as well as disseminated cutaneous and visceral infection.

Neonatal herpes is caused by HSV-1 or HSV-2 transmitted *in utero*, intrapartum, or postnatally. The details of newborn HSV infection are described in Chapter 19.

#### Diagnosis

Diagnosis of HSV-1 and HSV-2 infection is often made clinically but can be confirmed by viral culture, Tzanck

**FIGURE 8** Recurrent herpes simplex virus 2 (HSV-2) infection of the buttock.

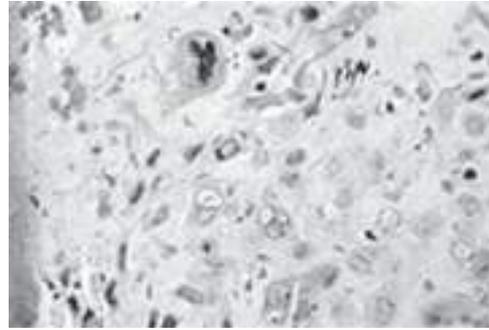

**FIGURE 9** Herpes whitlow due to herpes simplex virus 2 (HSV-2) in a health care worker following a puncture wound from a needle used to culture genital herpes.

smear (Fig. 11), PCR, serology, and antigen detection. HSV-1 and HSV-2 typically grow readily within 1 to 2 days in cell culture (42), but real-time HSV PCR assays have emerged as a more sensitive method to confirm HSV infection in clinical specimens obtained from genital ulcers and mucocutaneous sites. Because the prognosis is different for herpes genitalis caused by HSV-1 versus HSV-2, differentiating between the two is important for patient counseling. Serology not only can differentiate between HSV-1 and HSV-2 but also can be helpful in distinguishing primary genital herpes with a predominance of immunoglobulin M (IgM) antibodies from nonprimary genital herpes with a high proportion of IgG.

The differential diagnosis for vesicular lesions associated with HSV infection includes contact dermatitis, bullous impetigo, and insect bites. For lesions that are located specifically in the orolabial region, aphthous stomatitis, HFMD, and herpangina should be considered. In addition, erythema multiforme should be considered, as HSV is the most common identifiable etiologic agent (43). The differential for lesions in the genital region includes urethritis, urinary tract infections, tinea cruris, and vaginitis.

#### Treatment and Prevention

HSV-1 and HSV-2 are commonly treated with acyclic nucleoside analogues that block viral DNA polymerase, such as acyclovir. Topical, oral, and intravenous acyclovir are available, although the topical formulation is rarely used due to its limited penetration of the stratum corneum. Oral acyclovir, especially if started early, accelerates the rate of

**FIGURE 11** Photomicrograph of an ulcer resulting from herpes simplex virus 2 (HSV-2), in which multinucleated giant cells with eosinophilic intranuclear inclusions can be seen.

lesion crusting in oral and genital herpes (44). In patients with severe or frequent recurrences or with ocular HSV, suppressive therapy with acyclovir has been shown to decrease the recurrence rate by 50% (44). Acyclovir has also been shown to reduce asymptomatic viral shedding of HSV-2 by 95% (45).

In immunocompromised patients with mucocutaneous HSV, especially in disseminated disease, intravenous acyclovir is favored. Intravenous acyclovir is also used for infection in neonates, eczema herpeticum, and herpes encephalitis (45). Foscarnet is approved for the treatment of acyclovir-resistant HSV infections.

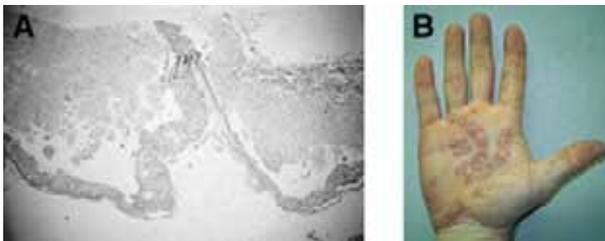

Currently, valacyclovir and famciclovir along with acyclovir are the mainstay drugs for treating as well as suppressing genital herpes. One study demonstrated a 50% decrease in HSV-2 transmission with once-daily valacyclovir (40). Famciclovir has also been shown to be an effective, well-tolerated option for the suppression of genital herpes among individuals with multiple recurrences (46).

The development of an effective vaccine against HSV-1 and HSV-2 has proven challenging, and no vaccine is currently available. Two studies of a prophylactic glycoprotein D2 alum/monophosphoryl lipid A (MPL) vaccine demonstrated prevention of genital herpes disease in 73% (first study) and 74% (second study) of seronegative women whose regular sexual partner had a history of genital herpes (47). A second prophylactic vaccine (ICP10DPK, AuRx) was shown to prevent recurrent disease in 44% of immunized subjects and to reduce the frequency and severity of recurrences in subjects that were not fully protected (48). A more recent study of HSV-2 glycoprotein D has shown 58% efficacy against HSV-1, but was not efficacious against HSV-2 (49).

#### Varicella-Zoster Virus

##### Epidemiology and Clinical Manifestations

VZV, or human herpesvirus type 3 (HHV-3), is a highly prevalent pathogen, with 98% of the adult population in the United States having serologic evidence of previous infection. VZV causes two distinct diseases: primary varicella (chickenpox) and herpes zoster (shingles). Before the introduction of a vaccine in 1995, 3–4 million cases of varicella leading to approximately 11,000 hospitalizations and 100 deaths were reported each year (50). Transmission occurs via direct contact or airborne droplets. Currently, more than 1,000,000 cases of herpes zoster occur each year in the United States; however, the use of the VZV vaccine will significantly alter the epidemiology of both syndromes.

**FIGURE 10** (a) Photomicrograph of erythema multiforme associated with herpes simplex virus 1 (HSV-1), showing subepidermal vesicles, necrotic keratinocytes, and balloon cell degeneration. (b) Erythema multiforme following an outbreak of herpes labialis.

Primary varicella typically manifests in younger children as low-grade fever, malaise, and disseminated pruritic vesicles classically described as “dewdrops on a rose petal.” Skin lesions first appear on the face and trunk as erythematous macules and rapidly progress over 12–14 hours to papules, vesicles, pustules, and crusts (Fig. 12). Most of the lesions are seen centrally and on the proximal extremities. Vesicles also appear on mucous membranes, but they erode rapidly to form shallow, painful ulcers. Due to the rapid evolution of successive crops of lesions, varicella is characterized by the simultaneous presence of lesions in all stages of development within the same anatomic region. In older children and adults, the exanthem is often preceded by up to 3 days of prodromal symptoms, including headache, myalgias, anorexia, nausea, and vomiting.

The most common cutaneous complication of varicella in young, immunocompetent individuals is scarring, which is often secondary to bacterial superinfection with *Staphylococcus aureus* or *Streptococcus pyogenes*. In adults and immunocompromised individuals, significant morbidity and occasional mortality can result from complications of VZV infection, including myelitis, large vessel granulomatous arteritis, encephalitis, varicella pneumonia, and varicella hepatitis (51). Maternal infection with VZV in the first trimester is associated with a 2% risk of congenital malformations, such as intrauterine growth retardation, limb hypoplasia, cataracts, chorioretinitis, microcephaly, cortical atrophy, and skin lesions (52). The skin lesions typically consist of areas of hypertrophic scarring with induration and erythema located especially on the extremities.

In 20% of immunocompetent individuals and in up to 50% of immunocompromised individuals, VZV reactivates years or even decades later to produce herpes zoster. Although in most cases the exact trigger for reactivation is unknown, advancing age is an important factor, with the

majority of cases occurring in individuals over 50. A family history of shingles also appears to increase the risk of herpes zoster (53). Upon reactivation, the virus spreads down the sensory nerves, and transient viremia occurs with associated prodromal symptoms of pain, fever, regional lymphadenopathy, and malaise (54). After a few days to weeks of pain, vesicles appear along the distribution of the sensory nerve (Fig. 13). Although vesicles generally occur only along one dermatome, it is not unusual for a few lesions to appear in neighboring dermatomes. The predilection for zoster to appear in certain anatomic regions (face and trunk) usually corresponds to the areas most affected by primary varicella. After a few days, the vesicles become pustules, and within 1–2 weeks the pustules become crusts. The skin lesions found in herpes zoster can shed VZV and cause primary varicella in seronegative individuals.

Although scarring can occur, particularly in darker-skinned individuals, cutaneous complications of herpes zoster are rare. The most prevalent complication is post-herpetic neuralgia, which is defined as persistent pain for more than 8–12 weeks after initial rash appearance (51). The pain, which may be extremely severe, can last for months to years and be highly resistant to treatment. Other complications of herpes zoster include vision impairment or blindness with involvement of the ophthalmic branch of the trigeminal nerve and painful facial paralysis (Ramsay Hunt syndrome) with involvement of the facial and auditory nerves (55). Rarely, sensory defects, motor paralysis, and encephalomyelitis can occur (56, 57). Dissemination of herpes zoster, defined as more than 20 vesicles outside the primary and adjacent dermatomes, is rare in healthy hosts but can occur in up to 40% of severely immunocompromised individuals. Cutaneous dissemination may be a marker of visceral involvement (liver, lungs, and the CNS) and therefore can herald significant morbidity and mortality.

### Diagnosis

Varicella and herpes zoster are often diagnosed clinically on the basis of the characteristic vesicular lesions, which are widespread in chickenpox (varicella) or restricted in a dermatomal pattern with associated neuritis in shingles (herpes zoster). However, laboratory confirmation is useful in circumstances where the clinical presentation is atypical and challenging, especially in immunocompromised patients. The diagnostic techniques include viral culture, direct immunofluorescence testing, serology testing, and PCR assay, which is the most sensitive test. Virus isolation by culture is insensitive, requires prolonged incubation, and associated with low yield (approximately 60–75%) when compared with PCR testing (58).

FIGURE 12 Primary varicella in an adult Japanese man.

FIGURE 13 Thoracic herpes zoster in an otherwise healthy man.

### Treatment

For most children, primary varicella is a benign, self-limited disease and treatment is largely supportive. However, pregnant women and neonates are at considerable risk for morbidity and mortality and are treated with antivirals such as intravenous acyclovir (58, 59). Treatment for herpes zoster includes antivirals and analgesics for pain control. Acyclovir, valacyclovir, and famciclovir are FDA approved for the management of acute herpes zoster, although they may not decrease the rate of development of postherpetic neuralgia (58). Antiviral therapy is imperative in patients with herpes zoster that involves the ophthalmic branch of the trigeminal nerve to prevent vision loss (58). Pain management is especially difficult with conventional analgesics in herpes zoster patients who develop postherpetic neuralgia. Tricyclic antidepressants, selective serotonin and norepinephrine reuptake inhibitors (duloxetine and venlafaxine), opioid, calcium channel  $\alpha_2$ - $\delta$  ligands (gabapentin and pregabalin), topical capsaicin, and topical lidocaine have been shown to reduce the pain associated with postherpetic neuralgia (60). Of these medications, only gabapentin, pregabalin, 5% lidocaine patch, and 8% capsaicin patch have been approved by the FDA specifically for the treatment of postherpetic neuralgia (61). Adding gabapentin to an antiviral in patients with acute herpes zoster appears to reduce significantly the incidence of postherpetic neuralgia (62). In January of 2011, the FDA approved Gralise™ as a once-daily medication for the treatment of postherpetic neuralgia (63). Gralise is an extended-release form of gabapentin that not only has been shown to decrease postherpetic neuralgia pain scores significantly, but may also be associated with fewer side effects than its immediate-release counterpart. In 2012 the FDA approved Horizant™, gabapentin enacarbil, for the once-daily therapy of postherpetic neuralgia.

### Prevention

Vaccines are currently available for prophylaxis of varicella (Varivax vaccine) and herpes zoster (Zostavax vaccine). The live attenuated viral vaccine (Oka strain) was approved in 1995 and produces a 95% seroconversion rate (64). Significant adverse events with the vaccine are rare, with fewer than 5% experiencing a mild varicella-like disease. There has been a significant decrease in varicella since the vaccine was instituted, and vaccination will likely alter the epidemiology of herpes zoster as well (65). Children should get the first dose of the vaccine at 12–15 months and the second dose at 4–6 years. Varicella vaccine doses given to persons 13 years or older should be separated by 4–8 weeks. The VZV vaccine is contraindicated in immunocompromised individuals, in persons with a history of anaphylactic or anaphylactoid reactions to gelatin or neomycin, and in pregnant women (66). Varicella-zoster immunoglobulin is recommended for post-exposure prophylaxis in immunocompromised persons, pregnant women, and neonates born to mothers who acquired varicella a week before or up to 2 days after delivery.

In a clinical trial involving more than 38,000 adults 60 years of age or older, the vaccine was shown to reduce the incidence of herpes zoster by 51% and the incidence of postherpetic neuralgia by 67% (67). In 2006, the Advisory Committee on Immunization Practices recommended a single dose of zoster vaccine for adults 60 years of age or older, whether or not they have had a previous episode of herpes zoster (68). A subsequent clinical trial that studied Zostavax in patients aged 50 to 59 years showed that the vaccine efficacy for preventing herpes zoster was 69.8% in this age group. In 2011 the FDA approved Zostavax for patients 50 to

59 years of age (69). An adjuvanted herpes zoster subunit vaccine (HZ/su), that is currently being studied but is not yet approved, was shown to significantly reduce the risk of herpes zoster among adults who were 50 years of age or older. However, unlike Zostavax, the HZ/su vaccine efficacy was well preserved among participants who were 70 years of age or older (70).

### Epstein Barr Virus

#### Clinical Manifestations

The EBV, or HHV-4, causes infectious mononucleosis, also known as “the kissing disease,” because the virus is typically transmitted through oral secretions. Infectious mononucleosis first manifests as prodromal symptoms of malaise, headache, and fatigue, followed by fever, sore throat, and cervical adenopathy. Hepatomegaly and splenomegaly can also occur. Cutaneous manifestations of infectious mononucleosis include macules, papules, and, less commonly, erythema, vesicles, and purpura. These lesions are the result of viral replication and manifest during the first week of illness. In approximately one-third of patients, small petechiae are observed at the border of the hard and soft palates. If infectious mononucleosis is treated inappropriately with ampicillin or other penicillins, a high percentage of patients develop erythematous macules and papules over the trunk and extremities (71). These lesions persist for about 1 week, followed by desquamation.

EBV has a pathogenic role in the development of many cancers, especially in immunocompromised individuals; these cancers include Burkitt’s lymphoma, Hodgkin’s disease, nasopharyngeal carcinoma, and posttransplantation B-cell lymphoma (51). EBV expression has also been detected in cutaneous T-cell lymphomas, including mycosis fungoides, although its role is yet to be determined (72). Mycosis fungoides initially manifests as annular pink scaly patches that over time develop into patches and plaques that may resemble psoriasis. Finally, large irregular tumors form that may ulcerate. EBV DNA has also been detected in epithelial cells of oral hairy leukoplakia, an oral lesion closely associated with HIV infection (73) (Fig. 14). Finally, Gianotti-Crosti syndrome, manifested as symmetric, nonpruritic, lichenoid papules of the face, limbs, and buttocks, has also been associated with primary EBV infection (74) (Fig. 15).

#### Diagnosis

Diagnosis is usually made through the detection of specific antibodies to EBV (see Chapter 24: Epstein-Barr Virus).

**FIGURE 14** Oral hairy leukoplakia associated with Epstein-Barr virus (EBV) in an AIDS patient.

**FIGURE 15** Papules of Gianotti-Crosti syndrome associated with Epstein-Barr virus (EBV).

Authors: Katherine Luzuriaga, John L. Sullivan). In particular, the monospot test, which detects heterophile antibodies, is used to diagnose infectious mononucleosis. This test is not commonly used for children due to its high false-negativity rate. Peripheral smears can support the diagnosis if greater than 10% atypical lymphocytes are noted.

The differential diagnosis for the classic symptoms of sore throat, malaise, and lymphadenopathy associated with infectious mononucleosis includes streptococcal pharyngitis and other viral causes of pharyngitis. Acute HIV syndrome can also manifest as malaise, lymphadenopathy, and nonspecific mucocutaneous manifestations. Acute CMV infection can cause infectious mononucleosis similar to EBV mononucleosis. The cutaneous manifestations of infectious mononucleosis may resemble a number of nonspecific viral exanthems. However, if the findings are preceded by the recent administration of ampicillin, the probability of EBV infection is high.

#### Treatment

Treatment for infectious mononucleosis due to EBV is largely supportive. Antivirals, such as acyclovir, and corticosteroids have not been shown to be effective (75, 76). The development of anti-B-cell antibodies, such as rituximab, has greatly enhanced the therapeutic options for EBV-associated cancers (77, 78).

### Cytomegalovirus

#### Epidemiology and Clinical Manifestations

CMV is an ubiquitous virus that is transmitted through infectious secretions. In developing countries, close to 100% of the adult population are seropositive, while in developed countries only about 50% of adults have evidence of infection. Primary infection is usually subclinical in immunocompetent individuals, although CMV mononucleosis syndrome occurs. Symptoms include fever, fatigue, and, less commonly, lymphadenopathy, sore throat, and organomegaly. Up to one-third of patients with CMV mononucleosis develop a maculopapular generalized rash.

Primary CMV infection in pregnant women poses a serious threat to the fetus. Maternal CMV infection is considered a leading viral cause of congenital malformations, CNS injury, and hearing loss in the neonate. If primary maternal infection occurs during pregnancy, especially during the first trimester, the rate of transmission is about 40% (79). Many of these infants have clinical manifestations at birth, including intrauterine growth retardation, microcephaly, cerebral atrophy, periventricular calcifications, chorioretinitis, sensorineural hearing loss, thrombocytopenia,

and hepatosplenomegaly. Cutaneous manifestations include jaundice and purpuric macules and papules, secondary to persistent dermal hematopoiesis, resulting in the clinical picture of the “blueberry muffin baby.” With recurrent maternal infection during pregnancy, the risk of transmission is only about 1%, and most of these infants have clinically silent disease at birth (79).

In immunocompromised patients, in whom CMV is associated with a variety of clinical entities, including retinitis, hepatitis, and colitis, infection may be associated with a variety of skin lesions, from vesicles to verrucous plaques. The most prevalent cutaneous manifestation is ulceration, especially in the perianal area (80). These cutaneous ulcerations are the result of CMV infection of the vascular endothelium and subsequent destruction of blood vessels.

#### Diagnosis

CMV DNA levels in acute CMV infection can provide prognostic information for immunocompromised patients. Histology can also be beneficial in diagnosis. CMV-infected cells have characteristic intranuclear inclusions surrounded by clear halos resembling “owl’s eyes.”

In the neonate with congenital CMV infection, the differential diagnosis includes other congenital infections, including toxoplasmosis, rubella, HSV, syphilis, and lymphocytic choriomeningitis virus. For older patients, the differential diagnosis for CMV infectious mononucleosis includes EBV mononucleosis. The monospot test is generally negative in CMV mononucleosis.

#### Treatment

Ganciclovir, a nucleoside analog of guanosine, has been shown to be effective in the treatment and prophylaxis of CMV infections (81, 82). Valganciclovir, a prodrug of ganciclovir, is available orally and has significantly increased bioavailability compared to ganciclovir, with similar safety and efficacy profiles (82). Valganciclovir has been approved for the treatment of CMV retinitis in adult patients with acquired immunodeficiency syndrome (AIDS), as well as for prophylaxis of CMV disease in organ transplant recipients (83). For ganciclovir- and valganciclovir-resistant CMV infections, intravenous foscarnet or cidofovir are the drugs of choice. For further discussion, see also Chapters 12 and 22.

### Human Herpesviruses—HHV-6 and HHV-7

#### Epidemiology and Clinical Manifestations

HHV-6 and HHV-7 are highly prevalent infections; 90% of children have serologic evidence of HHV-6 infection by 2 years of age (84). HHV-7 infection usually occurs later, with most children seropositive by 5–6 years of age (85). Transmission is through oropharyngeal secretions. Primary infection with HHV-6 is a common cause of fever, irritability, and rhinorrhea in children. One study found that primary HHV-6 infection accounted for 20% of fevers in children between 6 and 12 months of age (86). HHV-6, as well as HHV-7, is also associated with the common childhood exanthem roseola infantum (exanthem subitum or sixth disease). Roseola infantum manifests as a high fever lasting 3–5 days followed by the development of a nonpruritic, blanchable, pink, maculopapular rash on the neck and trunk. Other cutaneous manifestations include palpebral edema and lesions on the soft palate. Roseola infantum is usually self-limited but can, rarely, cause seizures and encephalitis (87).

HHV-7 is also suspected to play a role in the pathogenesis of pityriasis rosea, another acute, self-limited exanthem.

Pityriasis rosea begins with the development of a herald patch, a single plaque that is salmon-colored to red with fine scale at the periphery. The herald patch is followed by the development of pink papules and plaques in a “Christmas tree” distribution on the trunk.

### Diagnosis

Diagnosis is usually made clinically but can be confirmed via serology, peripheral blood mononuclear cell culture, or PCR (86). The clinical presentation of roseola infantum and its rapid resolution distinguish it from other entities on the differential diagnosis, including drug eruptions, scarlet fever, rubella, measles, erythema infectiosum, and other viral exanthems. The differential diagnosis for pityriasis rosea includes drug eruptions, secondary syphilis, guttate psoriasis, erythema multiforme, and tinea corporis. The presence of a herald patch and the resolution of pityriasis rosea without treatment can aid in diagnosis.

### Treatment

Treatment is largely supportive. There have been no controlled trials of antiviral therapy or specific recommendations for the management of HHV-6 and HHV-7 (88).

## Human Herpesvirus 8

### Epidemiology

The prevalence of HHV-8 infection varies significantly in populations worldwide. In the United States, less than 5% of adults have serologic evidence of HHV-8, whereas in highly endemic areas, such as Africa, more than 50% are seropositive (89). HHV-8 is predominantly shed in the saliva and to a lesser degree in semen and other body fluids. In low-prevalence areas, transmission is mainly through sexual contact, whereas in high endemic areas, transmission is typically from mother to child and between siblings (89). HHV-8 is associated with the development of Kaposi's sarcoma (KS) in both HIV-infected and HIV-negative persons (90, 91).

KS is the most common AIDS-associated malignancy in the developed world and one of the most common cancers in developing nations. KS in HIV-negative patients is rare. Two groups are at risk to develop non-AIDS related KS: elderly men mainly of Mediterranean origin and persons with iatrogenic immunosuppression.

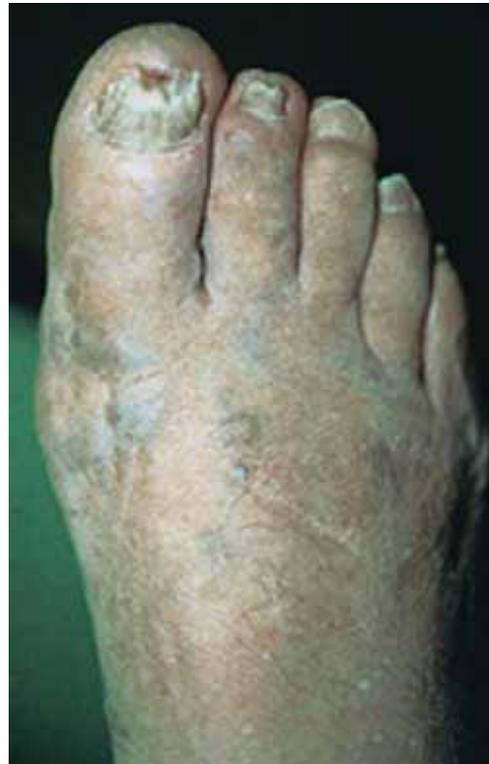

### Clinical Manifestations

KS are vascular neoplasias that initially present as deep red-purple macules (Fig. 16). The macules evolve into papules, plaques, and tumors that can be pink, red, purple, or brown. Classically, the lesions begin on the feet and hands and spread proximally. There is often associated lymphedema, especially of the lower extremities. KS can present with oral lesions as well and involve almost any internal organ.

HHV-8 is also associated with primary effusion lymphoma and multicentric Castleman's disease. Castleman's disease is caused by the hyperproliferation of B cells forming tumors in lymph nodes throughout the body. In addition, HHV-8 DNA has also been detected in squamous cell carcinomas and other epithelial lesions in organ transplant recipients (91). The role of HHV-8 in the pathogenesis of these epithelial tumors is still unclear.

### Diagnosis and Differential Diagnosis

The differential for KS includes dermatofibroma, pyogenic granuloma, hemangioma, bacillary (epithelioid) angioma-

**FIGURE 16** Kaposi's sarcoma associated with human herpesvirus 8 (HHV-8) in an HIV-negative elderly Italian man.

tosis, melanocytic nevus, ecchymosis, granuloma annulare, stasis dermatitis, and insect bites (92). Both PCR and serologic markers can aid in diagnosis, although skin biopsy is usually necessary for confirmation (93, 94) (Fig. 17).

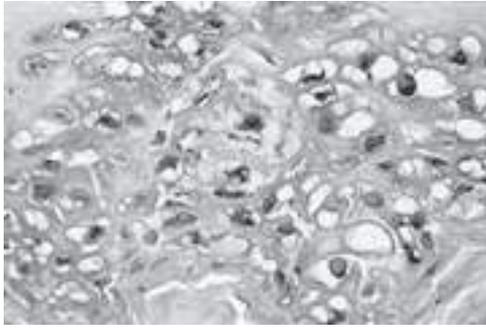

### Treatment

Although ganciclovir, foscarnet, and cidofovir have *in vitro* activity against HHV-8 and limited studies indicate these agents may be associated with reduced KS disease progression or lesion regression, larger and more definitive studies are needed to determine whether antiviral therapy has a useful role in managing HHV-8-associated diseases. KS regression has been documented after ganciclovir or foscarnet therapy, although one study indicated cidofovir was ineffective (95).

The use of intravenous (i.v.) ganciclovir or oral valganciclovir is an option for treatment of multicentric Castleman's disease. A 3-week course of twice-daily i.v. ganciclovir or oral valganciclovir was associated with remissions in multicentric Castleman's disease in one report, and a combination of valganciclovir and high-dose zidovudine given for 7–21 days led to durable clinical remissions of the disease (96, 97). Rituximab also is an effective alternative to antiviral therapy in the treatment of multicentric Castleman's disease, although up to one-third of patients treated with rituximab may have subsequent exacerbations or emergence of KS. (27, 28,98–101)

## B Virus (Herpesvirus Simiae)

An animal herpesvirus, B virus (herpesvirus simiae), can also rarely cause human disease, most significantly a fatal encephalomyelitis. This virus usually infects humans following a bite or scratch from a macaque monkey. Erythema, induration, and vesicles develop at the inoculation site

**FIGURE 17** Photomicrograph of Kaposi's sarcoma associated with human herpesvirus 8 (HHV-8), demonstrating neovascularization, endothelial proliferation, and plump hyperchromatic atypical nuclei lining vascular spaces.

and are followed by fever, lymphangitis, lymphadenopathy, gastrointestinal symptoms, and myalgias. These symptoms are followed by rapid progression to the neurologic signs and symptoms of encephalomyelitis (102). Although many nonhuman herpesviruses exist, B virus is of particular importance due to the high mortality rate in infected humans (103). Diagnosis is typically made through viral culture. The virus can be recovered from vesicular skin lesions at the point of inoculation, as well as from vesicles following reactivation of the latent B virus.

### Parvovirus B19

#### Epidemiology

Parvovirus B19 infection is common worldwide and occurs both sporadically and as epidemics. Parvovirus B19 has been recognized since the 1980s as the cause of erythema infectiosum (fifth disease) (104). This syndrome presents most commonly in children 4–10 years of age and often in epidemics in late winter and early spring (105). Viremia appears 6–14 days after a susceptible patient contracts parvovirus B19 via the respiratory route, but the rash appears 17–18 days following infection. Approximately 60–70% of adults are parvovirus B19 IgG seropositive, with prevalence rates increasing with age (106). The rate of primary parvovirus B19 infection in adults is much higher in those who are immunocompromised. Parvovirus B19 typically affects 1–5% of pregnant women, but higher attack rates (up to 20%) occur during an epidemic. Infection of a pregnant woman, particularly during the first or second trimester, can lead to nonimmune hydrops fetalis and fetal death (107).

The virus is spread by respiratory droplets, but nosocomial infections have been described (108). Parvovirus B19 has also been transmitted by blood products, especially pooled factor VIII and factor IX concentrates. Since January of 2002, producers of plasma derivatives have voluntarily instituted quantitative measurements of B19 DNA to reduce the risk of iatrogenic transmission. Iatrogenic transmission of parvovirus B19 via blood products continues to occur in part because the virus's small size, heat resistance, and high viral load make it difficult to eradicate from blood and plasma derivatives (109).

#### Clinical Features

Erythema infectiosum begins with nonspecific symptoms approximately 4–14 days after exposure to parvovirus B19 but can begin as late as 21 days after exposure (110). Confluent erythematous, edematous plaques appear on the

cheeks with circumoral pallor after about 2 days of low-grade fever, headache, and coryza. The rash gives the cheeks a “slapped” appearance (Fig. 18) and is accompanied by continuation of the above-mentioned symptoms and the appearance of cough, conjunctivitis, pharyngitis, malaise, myalgias, nausea, diarrhea, and occasional arthralgias. After 1–4 days, the facial rash fades coinciding with the appearance of erythematous macules and papules with a reticulated pattern on the extensor surfaces of the extremities, neck, and trunk. The rash can be pruritic and usually lasts for 1–2 weeks, but it can persist for months. The rash may be evanescent, and recurrences can be provoked by exposure to sunlight, heat, emotional stress, or exercise. Patients with erythema infectiosum appear to be infectious only before the appearance of the rash, as parvovirus B19 is usually not found in respiratory secretions or in the serum after the appearance of cutaneous manifestations. Parvovirus myocarditis (111) and heart failure (112) have followed fifth disease in a small number of cases. Parvovirus infection has been associated with severe but self-limited hepatitis in a few children (113).

The gloves-and-socks syndrome, an exanthem localized to the hands and feet, with edema, erythema, paresthesia, and pruritus, has also been linked to parvovirus B19 (114). Chronic fatigue syndrome may follow infection with parvovirus B19 (115). Meningitis, encephalitis, and a variety of neurologic complications may occur with fifth disease and parvovirus infection (116). In adults, primary parvovirus B19 infection is often associated with an acute arthropathy without rash. Other clinical presentations of parvovirus B19 infection, uncommonly accompanied by rash, include transient aplastic crisis in patients with chronic hemolytic anemia, parvovirus-related chronic anemia in immunocompromised patients, and nonimmune fetal hydrops (117).

#### Diagnosis

Detection of serum IgM directed to parvovirus B19 indicates recent infection. The serum IgM levels start to decline after 1 month, but IgM is still detectable for 6 months after infection. Parvovirus B19-specific IgG can be detected 1 week following infection and persists for years. Severely immunocompromised hosts may fail to mount antibody responses. PCR is available for detection of the virus.

The macular and papular stages of erythema infectiosum must be differentiated from drug eruptions, bacterial infections (such as scarlet fever and erysipelas), and other viral infections (such as those due to enteroviruses and rubella, measles, and roseola viruses).

**FIGURE 18** Erythema infectiosum (fifth disease) associated with parvovirus B19.

## Treatment

Because erythema infectiosum is a self-limited and mild illness, no treatment is usually indicated. No specific antiviral therapy exists for parvovirus B19, but intravenous immunoglobulin with specific neutralizing antibody is useful in treating infections in immunocompromised hosts (118, 119). Nonsteroidal anti-inflammatory drugs are often used to relieve arthralgias and arthritis.

## RNA VIRUSES

### Enteroviruses

#### Epidemiology

Enteroviruses are highly contagious and are typically transmitted by human oral–oral and fecal–oral routes. Direct contact with fluid from cutaneous and ocular lesions, fomites, and contaminated water sources may also be mechanisms of transmission. The gastrointestinal tract may remain infected, thereby releasing virus into the feces for days, weeks, or even months after initial infection, thus allowing the potential for spread (120, 121).

Enterovirus infections occur worldwide. It has been estimated that each year there are approximately 10–15 million symptomatic enterovirus infections in the United States (122). These infections tend to have a seasonal preference for summer and fall, and a higher incidence in children younger than 10 years of age has been reported (123).

#### Pathogenesis

After infection via the buccal mucosa, pharynx, or gastrointestinal tract, the virus travels to regional lymph nodes, and a secondary viremia results in the virus seeding secondary locations, including mucocutaneous sites among others, resulting in intraepidermal vesicles containing neutrophils, mononuclear cells, and proteinaceous eosinophilic material. The subvesicular dermis is edematous and contains a perivascular polymorphous infiltrate composed of lymphocytes and neutrophils.

#### Clinical Features

Enteroviruses can cause a variety of clinical manifestations. Common mucocutaneous presentations (Table 1) and less common manifestations (Table 2) are recognized. While a variety of enteroviruses, particularly coxsackieviruses, cause mucocutaneous manifestations, the two most distinctive syndromes are HFMD and herpangina.

**Hand-Foot-and-Mouth Disease.** HFMD is a mucocutaneous manifestation that usually affects persons in their preteen and teenage years (124). Serotypes CVA16 and EV71 are responsible for most epidemic cases of HFMD, but

	Acute paralysis

occasionally HFMD may be associated with CVA4–CVA7, CVA9, CVA10, CVB1–CVB3, CVB5, and echovirus 4 (125). EV71 is a major public health issue across the Asia-Pacific region and beyond. Since the late 1990s, large EV71 epidemics with significant numbers of fatalities have been reported in Malaysia, Taiwan, Mainland China, and other Southeast and East Asian countries (126).

After an incubation period of 3–6 days, a prodrome characterized by low fever, malaise, and abdominal or respiratory symptoms precedes the mucocutaneous lesions by 12–24 hours. Adult cases of CVA6 in Europe and the United States have been associated with severe systemic symptoms and occasional onychomadesis (127).

Oral lesions typically appear first and are most common on the hard palate, tongue, and buccal mucosa. The lesions can vary in number from 1 to 10 and typically begin as macules that rapidly progress to 2- to 3-mm vesicles and then to shallow, yellow-gray painful ulcers with an erythematous halo.

Cutaneous vesicles appear concomitantly with or soon after the oral lesions and are most prevalent on the hands and feet, including the palms and soles, but can appear on the face, legs, and buttocks. These lesions can vary in number from a few to over 100. Cutaneous lesions also begin as erythematous macules, but are larger (3–7 mm) and develop into cloudy, white oval vesicles with a red halo (128). Both oral and cutaneous lesions are usually tender or painful and resolve in 5–10 days without treatment or scarring.

HFMD can cause neurologic manifestations that range from aseptic meningitis to acute flaccid paralysis and brainstem encephalitis, which can be associated with systemic features, such as severe pulmonary edema and shock, in many cases (129, 130).

**Herpangina.** Herpangina is a self-limiting, acute illness that characteristically affects the posterior oropharyngeal structures. Herpangina is usually caused by CVA2, CVA4, CVA5, CVA6, CVA8, or CVA10; however, less commonly, the syndrome can be caused by various group B coxsackieviruses, echoviruses, and nonspecific enteroviruses. Herpangina usually affects children from 1 to 7 years of age (131) and begins abruptly with a high fever, sore throat, dysphagia, anorexia, and malaise (132). Small, gray-white vesicles (less than 5 mm) surrounded by erythema appear on the posterior palate, uvula, and tonsils; the vesicles usually ulcerate. Systemic symptoms usually resolve within 4–5 days, and the ulcers heal spontaneously within 1 week.

#### Diagnosis

Exanthematous enteroviral infections are usually diagnosed on the basis of clinical presentation. In both HFMD and herpangina, a mild leukocytosis (i.e., 10,000–15,000/mm<sup>3</sup>) may be seen. If a specific diagnosis must be made, virus

isolation, type-specific serology, or reverse transcriptase (RT) PCR may be used to identify the responsible virus type. RT-PCR-based assays used to detect enterovirus serotypes are superior to viral culture for diagnosis of severe enterovirus infections, such as aseptic meningitis and encephalitis (133, 134). When a patient presents with vesicles, it is best to take samples from both throat swabs and vesicle swabs in attempts to isolate the virus or detect by RT-PCR. For those patients who do not have vesicles, it is best to take throat and rectal swabs (135).

Oral lesions of HFMD and herpangina can be distinguished from each other on the basis of the total clinical presentation (e.g., cutaneous and anterior oral lesions in HFMD) as well as serology. Oral lesions can sometimes be confused with aphthous stomatitis, which are larger and less uniform than the oral erosions in HFMD. More importantly, the mucous membrane ulcers should be differentiated from those associated with HSV and VZV. Cutaneous vesicles of HFMD should also be differentiated from HSV and VZV infections as well as from erythema multiforme, rubella, drug eruptions, and gonococemia.

### Therapy

There is no specific antiviral therapy for HFMD or herpangina; management is symptomatic. Fluid replacement and limited physical activity are strongly encouraged. Proper hygiene and avoiding contaminated food can help prevent viral infection. Breast feeding has also been found to reduce the number of enterovirus infections in infants and provides an overall protective effect (136).

Three vaccines against enterovirus 71 (EV71) have completed Phase III clinical trials with good safety and efficacy results (137). On December 3, 2015, the China Food and Drug Administration (CFDA) approved the first inactivated EV71 whole virus vaccine for preventing severe HFMD (138).

## Measles Virus

### Epidemiology

Measles, also known as rubeola, is a highly contagious childhood infection. Measles outbreaks typically occur in the late winter to early spring. Transmission is through respiratory droplets from sneezing and coughing. Infected persons are contagious for several days before signs and symptoms develop. Since the development of the measles vaccine in 1963, the incidence of measles has decreased by 98% in the United States (139), but 644 measles cases were reported in the United States in 2014, the highest number in the 21<sup>st</sup> century (due to noncompliance with recommended vaccinations). In many developing nations, however, measles is still highly prevalent; mortality rates range from 1% to 5% and can reach 30% in malnourished children and in refugee areas (140). Approximately 800,000 people worldwide still die from measles virus infection every year, with over half of these deaths in Africa (141).

### Clinical Features

Infection is characterized by a prodromal phase of fever, coryza, cough, and conjunctivitis for 3–4 days. Splenomegaly and lymphadenopathy may also be noted. Cutaneous manifestations include pathognomonic Koplik's spots and a maculopapular morbilliform eruption. Koplik's spots, which appear several days before the onset of the rash, are characterized by clusters of blue-white spots on an erythematous base located on the buccal mucosa. The rash first appears

on the forehead and behind the ears and then spreads inferiorly to the face, then the trunk and extremities, and finally to the palms and soles (Fig. 19). The macules and papules may coalesce, especially on the face. As the exanthema progresses, the systemic symptoms typically subside. The rash gradually fades to a yellow-tan color with faint desquamation, resolving entirely in 4–6 days. The measles rash is thought to be due to a hypersensitivity reaction. Children with defective cell-mediated immunity can develop measles without the characteristic rash, hindering clinical diagnosis.

Complications of measles virus infection include otitis media, pneumonia, encephalitis, diarrhea, purpura, and thrombocytopenia. In immunocompromised patients, both pneumonitis and encephalitis are more common. HIV-infected children have a higher rate of hospitalization from measles, a younger age of presentation, and a higher fatality rate (142). Atypical measles occurred in individuals previously given the formalin-inactivated (killed) measles vaccine that was in use in the United States from 1963 to 1968 (143). Coryza, conjunctivitis, and Koplik's spots are absent in atypical measles. Unlike in typical measles, the eruption spreads centripetally, usually beginning on the hands and feet. Initially, the exanthema consists of erythematous macules and papules which may progress to vesicular and petechial lesions (144). About 5% of measles-mumps-rubella vaccine recipients develop rash. The rash typically occurs 7–10 days after vaccination and lasts about 2 days.

### Diagnosis

Diagnosis is usually made clinically, but serology using enzyme-linked immunosorbent assay (ELISA), complement fixation, neutralization, or hemagglutination inhibition tests

FIGURE 19 Measles in an infant.

FIGURE 20 Bacillary angiomatosis associated with *Bartonella quintana* in a human immunodeficiency virus (HIV)-positive man.

can be used for confirmation. In addition, virus isolation, antigen detection, and RT-PCR can be used. On cytological examination of secretions, multinucleated giant cells can be seen. Biopsy of the measles exanthem reveals hyaline necrosis of epithelial cells, formation of a serum exudate around superficial dermal vessels, and proliferation of endothelial cells, followed by a leukocytic infiltrate of the dermis and lymphocytic cuffing of vessels.

The differential diagnosis for measles includes other viral exanthems, such as rubella, roseola, and enterovirus, as well as drug eruptions, scarlet fever, Kawasaki disease, infectious mononucleosis, toxoplasmosis, and *Mycoplasma pneumoniae* infection (92).

#### Treatment

Measles is a self-limited disease in most patients, and treatment is largely supportive. Vitamin A deficiency is a risk factor for severe measles virus infection, and the WHO recommends vitamin A supplementation for all hospitalized patients in areas of high endemicity (145). There are currently no antiviral drugs specifically approved for the treatment of measles. Passive immunity via serum immunoglobulins may modify or prevent measles if administered within 6 days of exposure to the virus. Ribavirin may be beneficial in patients with severe complications of measles (146).

### Rubella Virus

#### Epidemiology

Rubella, also known as German measles, is an acute viral illness typically seen in children, although all age groups are susceptible. Transmission is through airborne droplets and can occur up to 7 days before and after the onset of symptoms. Before the development of a vaccine in 1969, rubella was a worldwide disease with epidemics every 6–9 years, typically in the spring. Since the implementation of the vaccine, the incidence of rubella has decreased by 99% in the United States (92). However, with inadequate immunization programs in developing countries, rubella virus infection continues to be a significant health concern.

#### Clinical Features

Fifty percent of rubella virus infections are asymptomatic. When symptoms do occur, they usually begin with prodromal symptoms starting 14–21 days after infection. Prodromal symptoms are more prominent with increasing age and consist of low-grade fever, headache, conjunctivitis, upper respiratory tract symptoms, and sore throat. Lymphadenopathy is common, especially in the posterior auricular, sub-

occipital, and posterior cervical lymph nodes. Arthritis and splenomegaly can also occur, especially in adults. From 1 to 4 days after the initiation of the prodrome, an erythematous macular to papular rash appears. It begins on the face and spreads to the neck, trunk, and extremities within 24 hours. Lesions often coalesce to form a scarlatiniform eruption. The cutaneous manifestations typically resolve completely within 3 days without residual pigment changes. The rash appears simultaneously with a rise in antibody titers, suggesting that the exanthem may be due to the inflammatory effects of antibody–virus complexes rather than direct viral infection.

Rubella virus infection is typically a self-limited illness, although complications such as encephalitis, neuritis, orchitis, and thrombocytopenia can occur (147). Infection during pregnancy, especially in the first trimester, can lead to congenital malformations in approximately 50% of infected neonates. Neonates with congenital rubella can present with cataracts, deafness, congenital heart defects, intrauterine growth retardation, microcephaly, mental retardation, thrombocytopenia, hepatosplenomegaly, and encephalitis. Infection of the bone marrow produces the characteristic cutaneous findings of petechiae and ecchymoses (148).

#### Diagnosis

Diagnosis is typically made clinically, although it can be difficult to differentiate rubella from other viral exanthems. Increased numbers of atypical lymphocytes and plasma cells may be found in peripheral blood but are not diagnostic.

The mainstay of laboratory confirmation is the detection of rubella-specific IgM antibodies in serum samples. Alternative samples such as dried blood spots and oral fluids have been used for diagnosis by antibody detection. Oral fluids can also be used to detect viral RNA, and their use is becoming increasingly common because samples can be obtained safely and noninvasively, without the risks associated with blood collection. Thus, it improves patient compliance with specimen collection, as the procedure is simple and painless (149–151).

Diagnosis of congenital rubella can be made through viral culture, RT-PCR, or serology using samples from amniocentesis, cordocentesis, and chorionic villous sampling (147). During the first trimester, RT-PCR of a sample of amniotic fluid can provide a diagnosis of prenatal infection with rubella virus within 48 hours (152). After delivery, the detection of rubella-specific IgM antibodies can make the diagnosis of congenital rubella, as the maternally derived antibody is IgG.

The differential diagnosis for rubella includes other infectious exanthems, adverse drug eruptions, scarlet fever, and enterovirus infection (92). If arthritis is present, the differential diagnosis also includes acute rheumatic fever, rheumatoid arthritis, and erythema infectiosum (92). Congenital rubella syndrome may resemble other congenital infections due to toxoplasmosis and CMV.

#### Treatment

Rubella is typically a self-limited illness, and treatment is symptomatic. There are currently no antiviral medications specifically approved for rubella virus infection. Prevention is carried out with a live attenuated vaccine that is often administered as part of the measles, mumps, and rubella (MMR) vaccine or the recently developed measles, mumps, rubella, and varicella (MMRV) vaccine. Since the implementation of the vaccine, rubella is no longer considered endemic in the United States (153).

## Hepatitis C

### Epidemiology

It is estimated that approximately 3% of the world's population are living with chronic hepatitis and that about 3–4 million people are infected per year (154, 155). In the United States, approximately 2.7 million persons have chronic HCV infection. The infection is most prevalent among those born during 1945–1965. The incidence of HCV has decreased from approximately 230,000 per year in 1980 to the current level of approximately 30,000 cases per year (155).

The predominant risk factor for HCV transmission is injection drug use. Other risk factors include blood transfusion (although rare since routine testing of the blood supply for HCV began in 1990), needle stick, sex, and nosocomial transmission. HCV infection becomes chronic in approximately 75–85% of cases (155).

### Clinical Manifestations

Multiple dermatologic diseases may be associated with hepatitis C virus (HCV) infection including porphyria cutanea tarda (PCT), lichen planus, leukocytoclastic vasculitis, mixed cryoglobulinemia, and necrolytic acral erythema (156).

PCT is a disease caused by altered activity of the enzyme uroporphyrinogen decarboxylase (UROD), which leads to buildup of uroporphyrinogen in the blood and urine (157). A systematic review including 50 studies and 2167 patients with PCT found an overall prevalence of HCV of 50% (158). The exact mechanism by which HCV infection increases PCT risk is unknown.

The characteristic skin findings of PCT are photosensitivity and skin fragility, with which exposure to the sun and/or minor trauma can lead to skin erythema and the development of vesicles and bullae that may become hemorrhagic. Hyperpigmentation, hypopigmentation, hirsutism, and sclerodermatous changes may occur over time. Precipitating factors (sun exposure, polyhalogenated hydrocarbons, alcohol, estrogens, and iron overload) are thought to be necessary to provoke PCT. The diagnosis of PCT is suspected clinically and is confirmed by the presence of markedly elevated urine uroporphyrin levels. Management of PCT in patients with HCV infection includes avoiding precipitating factors and treating HCV infection. Improvement of PCT during HCV treatment has been described (159).

Leukocytoclastic vasculitis may occur in conjunction with essential mixed cryoglobulinemia, presenting with palpable purpura and petechiae that usually involve the lower extremities. Skin biopsy demonstrates cutaneous vasculitis with dermal blood vessel destruction and a neutrophilic infiltration in and around the vessel wall.

Lichen planus (LP) is characterized by flat-topped, violaceous, pruritic papules involving the skin, oral mucosa, scalp, nails, and genitalia. LP can be seen in patients in a variety of liver diseases including primary biliary cirrhosis and chronic active hepatitis or cirrhosis of unknown cause (160–163).

Anti-hepatitis C virus (HCV) antibodies are present in 10–40% of these patients, although a causal association is uncertain. There are reports of the development or exacerbation of LP during chronic HCV treatment with IFN. In one case report, the lesions improved when IFN was stopped (164).

Necrolytic acral erythema is a pruritic, psoriasis-like skin disease characterized by sharply marginated, erythematous to hyperpigmented plaques with variable scale and erosion on

the lower extremities. In a series of 30 patients who presented with the disorder, all were found to have antibodies to HCV (165). Biopsy specimens showed psoriasiform changes, keratinocyte necrosis, and papillomatosis. Topical and systemic corticosteroids have a variable benefits. Other reports have confirmed improvement with IFN- $\alpha$  and also suggest a benefit from oral zinc sulfate (166–168).

### Diagnosis

Initial diagnostic evaluation for chronic HCV begins with an antibody test (anti-HCV). A reactive antibody test should be followed by HCV RNA to confirm viremia. The average time to detection of anti-HCV after exposure is 4–10 weeks after infection. Anti-HCV can be detected in >97% of patients by 6 months after exposure.

### Treatment

Treatment selection varies by genotype and other patient factors (see Chapter 53: Hepatitis C Virus Authors: Yaron Rotman, T. Jake Liang). Until recently, the mainstay of treatment for chronic HCV infection has been pegylated IRN (peg-IFN) and ribavirin, with possible addition of protease inhibitors (boceprevir and telaprevir) for HCV genotype 1 infection. This treatment for 24–48 weeks resulted in a cure in 50–80% of patients (higher in patients with HCV genotypes 2 and 3 than genotype 1) (169). In late 2013, the FDA approved two new direct-acting antiviral drugs, sofosbuvir (nucleotide analogue inhibitor of HCV NS5B polymerase enzyme) and simeprevir (protease inhibitor) to treat chronic HCV infection. Clinical trials have shown that these new medications achieve sustained virological response (SVR) in 80–95% of patients after 12–24 weeks of treatment (169).

Some of the cutaneous manifestations that may respond to treatment for HCV include PCT, leukocytoclastic vasculitis, mixed cryoglobulinemia, and necrolytic acral erythema.

## Human Immunodeficiency Virus

### Epidemiology

HIV type 1 (HIV-1) and other retroviruses can cause significant mucocutaneous manifestations. These manifestations are often the signs and symptoms that first raise suspicion for HIV infection and prompt serologic testing for it (170). Similarly, a variety of mucocutaneous manifestations may serve as clinical markers of progression from asymptomatic HIV infection to full-blown AIDS (171).

Transmission of HIV is primarily via sexual contact with an infected person, significant exposure to infected blood or blood products, or perinatally from an infected mother to her child. After sufficient contact with HIV, the virus infects CD4<sup>+</sup> T lymphocytes by binding to its receptor, the CD4 molecule, and coreceptors (CCR5 or CXCR4). Other CD4<sup>+</sup> cells, such as monocytes and macrophages, are also infected by HIV and help to spread the virus to susceptible cells in the brain, lymph nodes, skin, lungs, and gastrointestinal tract. HIV pathophysiology involves killing CD4<sup>+</sup> cells as well as the induction of an immune response and cytokine production.

### Clinical Features

Patients with acute primary HIV infection often become symptomatic 3–6 weeks after exposure and manifest fever, mononucleosis-like symptoms, and a characteristic erythematous, maculopapular exanthem appearing on the trunk and extremities. The exanthem and symptoms of the

**TABLE 3** Dermatologic findings of opportunistic diseases in HIV-infected patients

Organism(s)	Dermatologic findings
Viruses	
Molluscum contagiosum (MC) virus	Dome-shaped, flesh-colored papules with a central umbilication; larger, coalescent, and persistent lesions occur in HIV-infected patients; lesions may be widespread and atypical; observed in unusual sites such as the face, neck, and scalp; unusual forms include solitary, endophytic, aggregated, inflamed, and giant MCs (73)
Herpes simplex virus (HSV)	Clusters of vesicles that may rupture, crust, and form multiple small or large confluent painful ulcers; recurrent oral and anogenital HSV may lead to chronic ulcerations in HIV-infected patients (127)
Herpes zoster virus (shingles)	Dermatomal eruption of vesicles that arise in clusters from a red base that either umbilicate or rupture before forming crusts; in HIV-infected patients, the eruption may also be multidermatomal, recurrent, ulcerative, and widely disseminated with systemic involvement (29)
Varicella-zoster virus (VZV; chickenpox)	HIV-infected patients often have chronic infections that begin as vesicles and progress to necrotic, nonhealing ulcers (77)
Human papillomavirus (HPV; warts)	Flesh-colored papules that evolve into dome-shaped, gray-to-brown, hyperkeratotic discrete, and rough papules, often with black dots on the surface; HIV-infected patients can have severe, widespread, and chronic warts, which may arise on mucosal surfaces, the face, perianal region, and the female genital tract; HPV is associated with cervical cancer in women (81) and anal cancer in both sexes
Epstein-Barr virus (EBV; oral hairy leukoplakia)	White plaques with hair-like projections localized on the lateral aspect of the tongue (113)
Cytomegalovirus (CMV)	Persistent perineal ulcers are the most common presentation; ulcers may be coinfecting with HSV; also associated with nonspecific cutaneous lesions such as verrucous or purpuric papules, vesicles, morbilliform eruptions, and hyperpigmented indurated plaques (29, 81, 91)
Bacteria	
<i>Staphylococcus aureus</i>	Primary infections include impetigo, folliculitis, furuncles, carbuncles, abscesses, and necrotizing fasciitis; recurrent infections are common due to increased prevalence of nasal and perineal colonization in HIV-infected patients (63, 177)
<i>Pseudomonas aeruginosa</i>	Ecthyma gangrenosum, infection of catheter sites, and secondary infection of underlying disorders such as Kaposi's sarcoma in advanced HIV disease (81)
<i>Bartonella</i> spp. (bacillary angiomatosis)	Bacillary angiomatosis is characterized by red-to-purple papules, nodules, or plaques resembling Kaposi's sarcoma (Fig. 20); any site except the palms, soles, and oral cavity may be involved; hematogenous or lymphatic dissemination to bone marrow and other lymphoid organs may occur (175)
<i>Mycobacterium tuberculosis</i>	Cutaneous tuberculosis is rare; multifocal lupus vulgaris, tuberculous gummata, orofacial tuberculosis, scrofuloderma, and miliary abscesses may be seen (81)
<i>Mycobacterium avium-intracellulare</i> complex	Cutaneous manifestations are extremely rare, and some reports describe scaling plaques, crusted ulcers, ecthyma-like lesions, verrucous ulcers, inflammatory nodules, pustular lesions, and draining sinuses (81)
<i>Treponema pallidum</i> (syphilis)	Although the classic papulosquamous secondary lesions are often seen, unusual presentations may be observed in HIV-infected patients, including rapidly progressing noduloulcerative forms, papular eruptions that mimic MC, and lues maligna (110)
Fungus or infection	
<i>Candida</i> (candidiasis)	Generally causes mucosal disease (cutaneous, oropharyngeal, vulvovaginal, and esophageal); recurrent and persistent mucocutaneous candidiasis is common in HIV-infected patients; manifests as whitish, curd-like exudates on the dorsal or buccal mucosa that are easily scraped away; recurrent vulvovaginal candidiasis presents with creamy-white vaginal discharge, with itching and burning pain; the vaginal mucosa is inflamed, and pseudomembranous plaques are often seen (63, 105)

Tinea versicolor (dermatophytosis)	Numerous small, circular, white, scaling papules on the upper trunk; may involve the upper arms, neck, and abdomen; in HIV-infected patients, cutaneous involvement is often more atypical in appearance, widespread, and resistant to therapy (58)
<i>Cryptococcus neoformans</i> (cutaneous cryptococcosis)	Translucent, dome-shaped, umbilicated lesions resembling MC on the head, face, and neck; cellulitis, ulcers, papules, plaques, and pustules are other presentations (81)
<i>Histoplasma capsulatum</i> (cutaneous histoplasmosis)	Mucocutaneous erosions, oral ulcerations, disseminated and erythematous macules and papules, cellulitis-like eruptions, MC-like lesions (108)
<i>Coccidioides immitis</i> (coccidioidomycosis)	Begins as papules and evolving to pustules, plaques, or nodules with minimal surrounding erythema; hemorrhagic papules or nodules; lesions may resemble MC (81)
<i>Sporothrix schenckii</i> (sporotrichosis)	Hematogenous dissemination to the skin may manifest as papules to nodules that become eroded, ulcerated, crusted, or hyperkeratotic, usually sparing the palms, soles, and oral mucosa (79)
<i>Penicillium marneffei</i> (penicilliosis)	Most common skin lesions are umbilicated papules resembling MC, occurring most frequently on the face, ears, upper trunk, and arms (81)
<i>Aspergillus</i> spp.	Necrotic papulonodules; subcutaneous nodules (138)
Parasites	
<i>Leishmania donovani</i> (leishmaniasis)	Papular, maculopapular or nodular lesions; typically ulcerated nodules on the extremities; in atypical presentations, the lesions are disseminated (99)
<i>Acanthamoeba castellanii</i> (acanthamebiasis)	Dissemination to the skin is common in AIDS; necrotic nodules and painful ulcerations of the trunk and extremities develop in HIV-infected patients (29, 146)
<i>Toxoplasma gondii</i> (toxoplasmosis)	Cutaneous involvement is rare; manifests as an eruption of macules, papules, or vesicles involving the trunk and extremities (81)
<i>Pneumocystis carinii</i>	Disseminated infection may appear as MC-like papules, bluish cellulitic plaques, and deeply seated abscesses in the external ear or nares (81)
Malignancies	
Kaposi's sarcoma	Purple patches on the distal lower extremities that progress proximally and become multifocal; individual lesions darken and thicken, eventually becoming brown and verrucous; lesions in HIV-infected patients have a predilection for the face, torso, and oral mucosa (7)
Non-Hodgkin's lymphoma	Non-Hodgkin's lymphoma tends to be more progressive and aggressive (88); pink-to-purple papules are usually seen when the skin is affected; the lesions often ulcerate and sometimes stimulate panniculitis (176); younger age of onset, more advanced stages, and extranodal site involvement at presentation, in particular the central nervous system, intestine, and skin, are found in HIV-infected patients (87)
Squamous and basal cell carcinomas	In HIV infection, these tumors appear earlier and more often on unexposed sites such as the trunk and extremities; metastases of basal cell carcinoma have been recorded (103, 152)
Malignant melanoma	Appears to be more aggressive, with shorter disease-free periods and lower overall survival rates in patients with melanoma and HIV than in patients with melanoma without HIV (2)

---

TABLE 4 Antiretroviral therapy cutaneous adverse effects

Adverse effect	Nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs)	Nonnucleoside reverse transcriptase inhibitors (NNRTIs)	Protease inhibitors (PIs)	Integrase strand transfer inhibitors (INSTIs)	Entry inhibitor
Rash	Emtricitabine: hyperpigmentation	All NNRTIs	Atazanavir, darunavir, fosamprenavir, lopinavir/ritonavir, tipranavir	Raltegravir, elvitegravir	Maraviroc
Hypersensitivity reaction (HSR)	Abacavir: median onset 9 days; 90% of reactions occur within first 6 weeks of treatment	Nevirapine: hypersensitivity syndrome of hepatotoxicity and rash that may be accompanied by fever, general malaise, fatigue, myalgias, arthralgias, blisters, oral lesions, conjunctivitis, facial edema, eosinophilia, renal dysfunction, granulocytopenia, or lymphadenopathy	N/A	Raltegravir: HSR reported when raltegravir given in combination with other drugs known to cause HSR	Maraviroc: reported as part of a syndrome related to hepatotoxicity

acute illness generally resolve spontaneously within 2 weeks (167). Biopsy material from the exanthem associated with primary HIV infection usually demonstrates nonspecific changes, such as a superficial perivascular and perifollicular mononuclear cell infiltrate predominantly composed of CD4<sup>+</sup> cells. The production of anti-HIV antibodies at detectable levels usually requires several weeks and in some cases may follow infection by more than 1 year.

As the CD4<sup>+</sup> T cells decline and the disease progresses from asymptomatic HIV infection to AIDS, over 90% of patients will develop mucocutaneous manifestations (168). These may be a direct consequence of the primary HIV-1 infection or the result of secondary infectious, neoplastic, inflammatory, or other processes. The dermatologic findings of opportunistic HIV/AIDS-related pathogens include viral, bacterial, fungal, and parasitic infections, as well as malignancies (Table 3). Inflammatory diseases (e.g., psoriasis and Reiter's disease), vascular diseases, hypersensitivities to drugs, insect bites, and ultraviolet light, pruritus, xerosis, ichthyosis, and seborrheic dermatitis are all common non-neoplastic/noninfectious etiologies.

Mucocutaneous manifestations of acute HIV infection are nonspecific and can resemble those of a variety of infectious diseases, including enterovirus infection, infectious mononucleosis, secondary syphilis, acute infection with hepatitis A or B viruses, roseola, and toxoplasmosis (172, 173). The papulosquamous eruption of HIV most closely mirrors that of secondary syphilis, but drug eruptions are also included in the differential diagnosis. Because a wide variety of skin problems develop in persons with advanced HIV disease, the differential diagnosis usually expands into a myriad of possibilities that often can be differentiated one from another only via a skin biopsy.

### Diagnosis

ELISA is used to screen for HIV infection, and the Western blot assay is used to confirm the diagnosis. Although seroconversion does not occur until approximately 6 weeks after the acute illness, viremia can be detected approximately 10 days after infection (174). The presence of HIV may be detected by PCR or isolation of virus from the blood or demonstration of HIV p24 antigenemia. Semiquantification

of HIV RNA in the serum, which is useful in assessing the response to antiretroviral therapy, can also be done using PCR. Disease progression is also accompanied by a marked decline in CD4<sup>+</sup> cells, an increase in CD8<sup>+</sup> cells, and an inverted CD4/CD8 cell ratio.

### Treatment

There is an expanding number of drugs that have been approved for treatment of HIV infection (see Chapters 11 and 33). Multiple antiretroviral therapy causes rash and hypersensitivity reaction (HSR) (Table 4) (178).

# Viral Hemorrhagic Fevers

GAIL CARSON, MIKE BRAY, AND CATHY ROTH

## 9

The term viral hemorrhagic fever (VHF) designates a syndrome resulting from infection with any of at least 30 different RNA viruses from four different taxonomic families (Table 1). Although they differ in certain features, all types of VHF are characterized by fever and malaise, a fall in blood pressure that can lead to shock, the development of coagulation defects that can result in bleeding, and for many VHF agents, high mortality. With the exception of dengue virus, which is maintained among human populations by mosquito transmission, all of the VHF agents persist in nature through cycles of infection in animals. In the past, therefore, the geographic range of each disease reflected that of the reservoir species. Human illness is an accidental event resulting from contact with an infected animal or its excretions or the bite of an infected arthropod. Subsequent human-to-human transmission through contact with infectious blood or secretions occurs with multiple haemorrhagic fever (HF) viruses and can cause devastating nosocomial outbreaks. Pathogenesis in humans, in most instances, only indirectly reflects the mechanisms by which the causative agent replicates in its reservoir host, but high levels of viremia are typical. Treatment is supportive for most VHFs, but progress is being made gradually in developing specific therapeutics. Vaccines are widely available for yellow fever, and recent studies indicate that effective dengue and Ebola virus vaccines are possible.

### HISTORICAL PERSPECTIVES

The various types of VHF have presumably occurred for millennia, whenever humans have come into contact with reservoir animals or been bitten by infected arthropods. The first to be recognized by the European medical community was yellow fever (YF), which was encountered by early travelers to sub-Saharan Africa and was transferred to the New World through the slave trade. Its frequently fatal outcome was long attributed to the severe hepatic damage and jaundice that gave the disease its name, but it was eventually realized that gastrointestinal hemorrhage and compromised renal function resulting from hypovolemic shock were more common causes of death. A correct appreciation of the role of diminished intravascular volume in this disease did not emerge until clinical tools for blood pressure measurement were developed in the 1920s, when urban YF had been largely suppressed by mosquito control

efforts. Recent studies have in fact shown that host inflammatory responses are as important in the pathogenesis of severe YF as in other types of VHF (1, 2).

Other types of VHF began to be identified in the early 1900s, when severe hantaviral infection that is now termed HF with renal syndrome (HFRS) was described in Siberia, and a milder form, nephropathia epidemica, was recognized in Scandinavia (3, 4, 5). However, it was not until several thousands of cases of HFRS occurred among United Nations troops in the Korean War that VHF was brought forcefully to the attention of western medicine. Over the ensuing five decades, a number of “new” types of VHF have been described and their causative agents have been isolated. The Old World arenavirus Lassa fever virus and the New World agent Machupo virus were both characterized during investigations of disease outbreaks in the 1960s. Marburg virus was discovered in 1967 as a result of the inadvertent importation of infected monkeys from Uganda to Europe, while the other filovirus genus, Ebola virus, came to attention when its Zaire and Sudan species caused large epidemics in Africa in 1976. Rift Valley fever (RVF), first recognized in the 1930s, caused a massive mosquito-borne outbreak in Egypt in 1977. The list of arenaviruses causing a VHF syndrome has also continued to grow with the recognition of fatal human infections caused by Whitewater Arroyo virus in California (6). Lujo, a “new” arenavirus, emerged in Zambia in 2008, and was exported to South Africa, where it caused a small but deadly outbreak with a case/fatality rate of 80% (7). Its natural reservoir has never been identified, and there have been no further outbreaks in the intervening years, but its emergence serves as a reminder that there is no reason to believe that the list of HF viruses is now complete. That is exactly what happened in 2009 in the Democratic Republic of Congo with the discovery of a novel rhabdovirus, called Bas-Congo virus, as a cause of an outbreak including haemorrhagic presentation and fatalities and with emergence of tick-borne phleboviruses causing Severe Fever with Thrombocytopenia Syndrome (SFTS) in Asia and cases of a similar illness due to Heartland virus in the United States (8, 9, 10).

The West African outbreak of Ebola virus disease (EVD) of 2013 to 2016, in which the estimated number of cases was beyond all previous experience and expectations, has changed our understanding of VHFs and in particular EVD

**TABLE 1** Some epidemiological features of the principal types of VHF

Virus family	Disease	Virus	Geographic distribution	Reservoir host	Patients <sup>a</sup> and areas affected; seasonal pattern
<i>Arenaviridae</i>	Argentine HF	Junin virus	North-central Argentina	Mouse ( <i>Calomys musculinus</i> )	M; corn harvest; March–June
	Bolivian HF	Machupo virus	Northeastern Bolivia	Mouse ( <i>Calomys callosus</i> )	All ages, both sexes; villages; February–July
	Chapare	Chapare virus	Bolivia	Unknown rodent	
	Venezuelan HF	Guanarito virus	Central Venezuela	Mouse ( <i>Zygodontomys brevicauda</i> )	All ages, M = F; houses, gardens; no seasonality
	Brazilian HF	Sabia virus	Unknown	Unknown rodent	Two cases in the Sao Paulo state and two in lab workers
	Lassa fever	Lassa virus	West Africa	Mouse ( <i>Mastomys natalensis</i> )	All ages, both sexes; villages; no seasonality
	Lujo	Lujo virus	Zambia	Unknown rodent	Only one small outbreak; difficult to comment on any patterns or at risk groups
<i>Bunyaviridae</i>	CCHF	CCHF virus	Africa, central to east Europe, Middle East to west China	Livestock, crows, hares, <i>Hyalomma</i> ticks	Adults, M > F; cattle, pasture contact; summer
	RVF	RVF virus	Africa	Livestock, several mosquito genera	All ages, M > F; late summer; arthropods
	HFRS	Hantaan, Seoul, and Puumala viruses	Northern Asia and Europe, including the Balkans and Scandinavia	Mice and rats ( <i>Apodemus</i> , <i>Rattus</i> , <i>Clethrionomys</i> )	Mostly adults, M > F; rodent excreta; fall-winter
	Hantavirus cardiopulmonary syndrome	Sin Nombre, Andes, many others	North, Central, and South America	Mice ( <i>Peromyscus</i> sp., <i>Sigmodon hispidus</i> , ?others)	Adults, M = F; rodent excreta; late spring-summer peak
<i>Flaviviridae</i>	YF	YF virus	Tropical Africa, Amazon basin	Primates, including humans; tree hole mosquitoes	M > F, all ages; arthropod contact; dry season
	Dengue HF/shock syndrome	Dengue virus types 1–4	Southeast Asia, Caribbean, South and Central America	<i>Aedes aegypti</i> > <i>Aedes albopictus</i>	Children < 12 yr; peak in late rainy, early dry seasons
	Kyasanur Forest disease	Kyasanur Forest virus	Karnataka State (India)	Monkeys, birds, livestock, ixodid ticks	Adults, M > F; tick contact; summer-fall, dry season
<i>Filoviridae</i>	Omsk HF	Omsk virus	Western Siberia	Vole ( <i>Arvicola terrestris</i> ), ixodid ticks	Adult males; muskrat hunt; winter
	Marburg and Ebola HF	Marburg and Ebola viruses	Sub-Saharan Africa & West Africa	Fruit bat species likely reservoir	Mainly adults, M = F; sporadic; late summer

<sup>a</sup>M, male; F, female.

in many ways (see chapter 42). These include advances in understanding the molecular epidemiology and biology of the virus, investigating new drugs and vaccines, defining standards of care and their delivery, and highlighting the impacts on survivors, including viral persistence and associated sequelae. However, many unanswered questions remain concerning fundamental aspects of EVD pathogenesis and clinical management. Despite unprecedented efforts, few therapeutic and vaccine trials came to completion for various reasons, including inability to meet enrolment targets due to declining case numbers as the epidemic waned. All of these experiences have led to a global consensus that new approaches must accelerate the necessary research and product development (diagnostics, drugs, and vaccines) to prevent devastating epidemics of all future VHF diseases. In 2015 the World Health Organization (WHO) launched its R&D Blueprint in response to the call for greater coordination and leadership for research and development (R&D) (11). The R&D Blueprint is a global strategy and preparedness plan to ensure that targeted R&D can strengthen the emergency response by bringing medical technologies to patients during epidemics. The Blueprint aims to reduce the time between the detection of a disease likely to cause a public health emergency and the availability of effective tests, vaccines, and medicines that can be used to save lives and avert crisis. Of note, one-half of the infections on the list of priority diseases for R&D are VHFs.

## CAUSATIVE AGENTS

The principal HF viruses belong to four different families, the *Arenaviridae* (chapter 45), *Bunyaviridae* (chapter 44), *Filoviridae* (chapter 42), and *Flaviviridae* (chapter 53). All are enveloped viruses with single-stranded RNA genomes. The flavivirus genome consists of one strand of positive-sense RNA. Viruses in the other three families have negative-sense genomes, which consist of a single strand in the case of the filoviruses, two separate segments for the arenaviruses, and three for the bunyaviruses. These agents differ widely in cellular replication strategies, natural hosts and transmission cycles, geographic distribution, routes of transmission to humans, and disease pathogenesis (Table 1). This chapter provides a general survey of VHFs, comparing individual diseases to each other and to other types of human illness. Additional information on individual viruses and the diseases they cause can be found in the pathogen-specific chapters of this book, as well as those on viral infections that may uncommonly be associated with hemorrhagic manifestations (e.g., measles, fulminant hepatitis, and historically smallpox).

## EPIDEMIOLOGY

For a zoonotic virus to cause illness, appropriate cell surface receptors and intracellular cofactors must be present to permit its replication in human cells, and innate defenses must fail sufficiently to permit its intrahost spread. VHF represents the extreme end of the spectrum of possible outcomes of cross-species virus transfer, in which an agent replicates so well and overcomes or interacts with host immune defenses to cause a severe inflammatory syndrome.

Reservoirs have been identified for nearly all of the HF agents (Table 1). In several cases, the natural reservoir is a species of rodent, probably because these animals' large numbers and high population density favor the continuous circulation of viruses. Arenaviruses, which are split into "Old World" (Africa) and "New World" (the Americas)

complexes on the basis of phylogenetic and geographical distinctions, all have rodent species as the natural reservoir. Old and New World primates are reservoirs for sylvatic YF, and a variety of species are involved in the circulation of Crimean-Congo HF (CCHF) virus. The reservoir host for the filoviruses is believed to be various bat species (see chapter 42). Other animals may be infected and act as intermediaries in transmission to man.

The transmission of a virus from animals to humans can occur through direct physical contact, exposure to virus-containing excretions, or the bite of an infected mosquito or tick. The identity of the host and the mode of transmission strongly influence the pattern of human disease. For example, CCHF, which is transmitted by tick bite or direct contact with the tissues of an infected animal during slaughter, tends to occur as sporadic single cases or small clusters. By contrast, mosquito-borne agents such as YF virus and dengue virus can be carried from person to person by the vector, or, as in the case of RVE, animal to person and person to person by the vector to yield explosive epidemics. The modern health care setting offers opportunities to amplify sporadic cases into outbreaks if appropriate infection prevention and control practices are not observed; health care workers are often among the earliest casualties.

The arenaviruses and hantaviruses provide interesting examples of coevolution, in which each agent has a single rodent species as its primary host (12). Animals that harbor arenaviruses display partial immune "tolerance," permitting chronic viremia and viruria; the latter probably represents the major source of environmental exposure. The epidemiological pattern of arenaviral HF is determined by the intersection of rodent ecology and human activities. In Argentina and Venezuela, animal reservoirs are found in or adjacent to cultivars, placing adult males who harvest corn in the fall at greatest risk of infection. In contrast, because the reservoir rodents invade dwellings and gardens, Bolivian HF and Lassa fever are largely acquired in or near houses, and persons of both sexes and all ages are at risk. Lassa fever is a truly endemic disease, because the *Mastomys* reservoir breeds year round, and a nearly constant fraction of animals are chronically infected. Hantaviruses also cause chronic infection in their rodent hosts, which excrete virus in saliva and feces for short periods and in urine for many months. Human infection is most often associated with agriculture, mining, or military activity. Nephropathia epidemica has a well-marked cyclic activity, in which rodent population density and prevalence of infection correlate with transmission to humans.

The epidemiology of arthropod-borne VHF reflects the biology of viral infection in the mosquito or tick vector. Both vectors acquire the virus through blood feeding, indicating that viremia occurs in the animal reservoir. Mosquitoes competent to transmit flaviviruses become chronically infected, and there may be transovarial transmission to subsequent generations of mosquitoes, allowing for persistence and recrudescence when the seasonal or other environmental conditions permit. Multiple human infections are often the result of interrupted blood feeding and movement to a second host. Among the various types of VHF, CCHF, Kyasanur Forest disease, Alkhurma HF, SFTS, and Omsk HF are transmitted by ticks. "Vertical" (transstadial and transovarial) transmission is an important feature of their natural history. Ticks use the blood of birds and mammals primarily as an energy source for the next stage of their life cycle. Because far less than 100% of eggs from an adult female are infected, vertebrate viremia is also important for tick-borne transmission of virus to humans.

Dengue fever is the exception to the rule that the HF viruses are zoonotic in nature. The disease may at one time have been confined to a small region of the tropics and maintained through infection of wild primates, in a manner similar to YF. However, the successful adaptation of the virus to person-to-person transmission by mosquitoes, combined with a vast increase in the human population in tropical regions and a failure of mosquito control efforts, has permitted the agent to disperse widely and evolve into four distinct serotypes (13). As discussed below, the circulation of more than one serotype in the same geographic region sets the stage for the occurrence of secondary infections, in which non-neutralizing antibodies are believed to enhance virus uptake into cells, causing intense inflammation and increased vascular permeability (dengue HF/shock syndrome). Even though only a small fraction of cases result in HF, because of its global distribution, dengue virus is the most important cause of VHF.

Once an individual becomes ill with a VHF, there is great variation in the potential for further human-to-human transmission, because the pathogenesis of the diseases and sites of viral replication within the infected human host are so diverse. A number of diseases, including RVF and dengue, rarely spread directly from person to person and thus pose little threat to medical personnel. However, some of the most virulent agents, including Ebola, Marburg, Lassa, Lujó, and CCHF viruses, cause prolonged high titer viremia, and can therefore be spread through direct contact with blood and other body fluids and tissues. Hospital-based outbreaks have occurred when case detection has been slow, staff have been overwhelmed by the workload, or appropriate infection prevention and control measures have not been observed. In low-technology health care settings in developing countries, the necessary disinfection and personal protective equipment required to implement the appropriate measures are often not available (14).

The extent to which asymptomatic or mildly symptomatic individuals are involved in onward transmission of infection and extension of outbreaks varies among the VHFs, and has not been well explored, even for those diseases where mildly symptomatic infection is not uncommon, e.g., Lassa fever. Asymptomatic infection and continuing human-to-human transmission had always been assumed to occur extremely rarely, if at all, in filovirus outbreaks. Sexual transmission in Ebola and Marburg was recognized in the past, but more evidence has been collected during the recent West African epidemic, where on several occasions it has instigated new cases and clusters long after the apparent end of virus circulation in specific communities. In one survivor, semen was positive for viral RNA 284 days after symptom onset (15). The full extent of “sanctuary sites,” and duration of the survival of viable virus in those sites after an individual’s apparent recovery from illness, have not yet been determined, but studies continue to explore this in survivors of the EVD epidemic in West Africa. There are anecdotal reports of CCHF being transmitted sexually, and therefore this route of transmission should be considered in subsequent outbreaks. Sexual transmission may have a role in some other VHFs, including Lassa, Junin, and Machupo; better studies are required to determine the frequency and importance of sexual transmission in the propagation of outbreaks of these and other VHFs. During VHF outbreaks, transmission by infectious blood products is also a possibility.

## PATHOGENESIS

The transmission of HF viruses from animals to humans is generally unidirectional: infected patients do not often ap-

pear to serve as a source of infection for the reservoir or other intermediary host. Because human infections are “dead-end” events from the point of view of virus evolution, the pathogenesis of VHF does not represent the outcome of viral adaptation or “survival strategy,” but simply reflects the fortuitous ability of an animal virus to replicate efficiently in human cells. In contrast to diseases such as viral hepatitis or encephalitis, VHFs do not generally localize to one organ or organ system. However, the persistence of pathogens like Ebola virus in semen and the associated possibility of onward transmission raise new concerns. In general, HF viruses replicate primarily in monocytes, macrophages, and dendritic cells. The fact that these cells, which normally serve as the first line of defense against microbial invaders, are the principal sites of viral replication goes far to explain the ability of these pathogens to cause rapidly overwhelming infection. However, HF viruses differ in their abilities to infect other types of cells. At one end of the spectrum, dengue virus principally infects only these cell types, without causing their death. At the other extreme, Ebola and Marburg viruses show a very broad tissue tropism. Material released from dying cells is itself a stimulus for inflammation, contributing further to the fulminant systemic illness. Most HF viruses produce a degree of tissue damage intermediate between the minimal injury of dengue fever and the massive destruction caused by the filoviruses, with the liver as the principal target. Hepatic involvement probably begins with the spread of virus through the bloodstream to fixed macrophages (Kupffer cells) in sinusoids, from which infection then extends to parenchymal cells. As noted, hepatic injury is a prominent feature of YF, causing the jaundice that gave the disease its name, and is seen in some cases of RVF and dengue. It also occurs in CCHF and some other infections, but without producing the high levels of bilirubin that lead to jaundice.

For many reasons, studying the pathogenesis of the VHFs is challenging due to biosafety requirements, limitations of animal models in recapitulating human disease, and the challenge of obtaining samples during outbreaks. One of the most studied VHFs is EVD, yet many questions remain unanswered regarding its pathogenesis and multiple factors likely contribute (see chapter 42). The current data in some ways support the hypothesis presented by Bray and Mahanty in 2004 following the Ugandan outbreak of Ebola Sudan that the multiorgan syndrome induced by Ebola virus (EBOV) is similar to that of septic shock (16). With its broad cell tropism, Ebola virus infects monocytes, macrophages, dendritic cells, endothelial cells, fibroblasts, hepatocytes, adrenal cortical cells, and several types of epithelial cells (17, 18, 19, 20, 21). An early, well-regulated inflammatory response has been associated with recovery, whereas a dysregulated proinflammatory response has been described in fatal EVD (22). Depletion of lymphoid cells including apoptosis of these cells may partly explain the lymphopenia and associated failure of adaptive immune responses in filoviral infections and probably in other types of severe HF (23, 24).

The VHF agents differ in their interactions with the immune system, but most share a common feature of the inhibition of the type 1 interferon response. A number of HF agents, including filoviruses, RVF virus, dengue virus, and some arenaviruses, have been shown to block interferon responses through a variety of mechanisms (25, 26, 27). The importance of the interferon system to the control of viral dissemination helps to explain why all of the HF agents are RNA viruses. Because the double-stranded RNA molecules that are generated in the course of their transcription and genome replication are a strong stimulus for type I interferon

responses, each RNA virus must evolve ways of evading or suppressing interferon responses in its host, to the extent needed to ensure its own continued survival. The outcome of human infection with a novel virus will therefore depend in part on the extent to which the agent blocks human interferon responses. The HF viruses may constitute that small subset of RNA viruses that suppress human interferon responses so effectively that they cause rapidly overwhelming disease. The most severe diseases, such as fatal Ebola and Marburg HF, are also characterized by a failure of humoral and cellular immune responses. Others like RRVF and HFRS proceed despite the host's adaptive immune response. Most RRVF cases are acute, self-limited febrile episodes in which viremia may be very high at onset but disappears within 3 to 5 days, by which time virus-specific antibodies are detectable. However, about 1 to 2% of patients continue to have virus in the blood, respiratory secretions, and spinal fluid, even in the presence of antibodies, and progress to fulminant VHF with hepatitis, jaundice, and hemorrhage. Uncontrolled viral replication in these RRVF patients therefore resembles that seen in filoviral HF, but it appears to result from a defective immune response in certain patients rather than the increased virulence of a viral strain. In another disease variant, some RRVF patients appear to be stable or improving after 5 to 15 days of illness and then develop an apparently immune-mediated meningoencephalitis or retinal vasculitis. The neurologic disease has been temporally associated with the greatest production of antiviral antibodies seen in any of the forms of RRVF. Clarification of the mechanisms of RRVFV invasion into the CSF requires further study. Virtually all patients with hantavirus infections have circulating virus-specific immunoglobulin M, immunoglobulin G, or both at the time of diagnosis. Viral antigens are detectable on the surfaces of capillary endothelial cells, in the kidneys in HFRS (28). The development of HFRS and its resolution take much longer, indicating that tissue damage is greater, needs more time for repair, and may be partly the result of viral destruction of cells or the effects of immune viral complexes.

Dengue HF has a unique pathogenesis that is a consequence of the virus's evolution into four different serotypes. Primary dengue infection causes an unpleasant, but rarely fatal, influenza-like illness that results from the transient release of proinflammatory cytokines from virus-infected monocytes and macrophages. Viremia is already declining by the time of symptom onset, and the illness resolves uneventfully. The recovered individual is thenceforth resistant to reinfection by that serotype. In a small percentage of cases, however, reinfection by a second serotype results in severe disease in which viremia persists and high levels of Interleukin 6 (IL-6), Tumour Necrosis Factor alpha (TNF- $\alpha$ ), and other mediators in plasma induce vascular leak and shock (29). Two immune mechanisms are thought responsible for the occurrence of dengue HF: nonneutralizing antibodies resulting from a previous infection are believed to enhance viral replication by linking virions to Fc receptors on the surfaces of target cells, which then take them up into the cytoplasm, thus increasing the number of infected cells, the number of viral particles that enter each cell, and the release of cytokines and other vasoactive mediators. Second, cross-reactive memory CD8+ T cells can attack monocytes and macrophages expressing viral epitopes on their surfaces, triggering an explosive inflammatory response.

Although early discussions of the pathogenesis of VHF attributed vascular leak and hemorrhage to viral infection or injury of the endothelial cells of blood vessels, it now appears more likely that alterations in vascular function and the

development of coagulopathy represent physiological responses to circulating proinflammatory mediators. In VHF, the release of large amounts of these substances into the plasma causes vascular dilatation and increased permeability, with catastrophic effects on intravascular volume and blood pressure. This pathogenic process does not mean that viral infection of blood vessel linings cannot also occur. Infected endothelial cells have been observed, for example, in tissues from persons with fatal cases of CCHF (30). Despite the syndrome's dramatic name, hemorrhage is generally a minor feature of VHF. Instead, as in other severe inflammatory syndromes such as septic shock, the major pathophysiological lesion is an increase in vascular permeability ("capillary leak") brought about by mediators released from infected cells. Careful physiological management to maintain sufficient blood flow to critical organs is therefore a hallmark of patient care. The recognized hemorrhagic tendency may be related to decreased synthesis of coagulation and other plasma proteins because of hepatocellular necrosis and the development of a disseminated intracellular coagulation picture. However, massive blood loss is infrequent in EVD, and as in CCHF, confined mainly to the gastrointestinal tract.

## CLINICAL MANIFESTATIONS

Most of the signs and symptoms of VHF reflect the release of proinflammatory mediators from virus-infected cells and their effects on temperature regulation, cardiac function, gastrointestinal tract motility, control of vascular tone and endothelial permeability, and the blood clotting system. Fever, malaise, myalgia, and headache are typical early manifestations that tend to evolve insidiously in the case of Lassa fever but can begin so abruptly in YF, CCHF, and the filovirus diseases that patients can report the hour of onset. Fever is usually high and often unremitting; however, it may be absent in some subgroups of patients, including pregnant women and the elderly (31). Bradycardia may be notable, particularly in arenavirus and filovirus diseases and in YF. Vomiting and severe diarrhea frequently occur in filovirus HFs, emphasizing the need for early supportive care often including the administration of intravenous fluids. Abdominal pain can be sufficiently prominent to lead to surgical intervention; hospital-based outbreaks of CCHF and Ebola HF have begun in this fashion. Bleeding rarely is the presenting symptom, but it can occur, e.g., epistaxis in CCHF, which is one reason why the health care workers must be aware of the risk factors and presentation of these diseases to prevent nosocomial spread.

Vasodilatation and increased permeability of the endothelial linings of blood vessels are manifest in a number of physical signs. Capillary dilatation is often signaled by diffuse erythema of the skin of the upper trunk and face that blanches on pressure. Conjunctival injection with petechial hemorrhages is common. An erythematous rash is characteristic in early Marburg, Ebola, CCHF, and dengue, but may be difficult to see in dark-skinned persons. Edema of the face and sometimes of the extremities, observed in Lassa fever, is another manifestation of a capillary leak syndrome, but it may only become evident when a severely ill, dehydrated patient is treated with intravenous fluids. The development of coagulation defects leads to easy bruising, failure of venipuncture sites to clot, hemorrhage from the gastrointestinal and urinary tracts, and menorrhagia. Large ecchymoses are a characteristic sign of CCHF but are rare in the other diseases. Although massive bleeding can occur in severely ill or moribund patients, it is much less common than popular descriptions of these diseases would suggest.

Other clinical manifestations reflect the involvement of specific organ systems. Some degree of hepatic infection and damage is seen in most types of VHF, but the severity varies markedly among the different diseases. Serum levels of aspartate and alanine aminotransferase are markedly elevated in filoviral HF, YF, and RVEF, but clinical jaundice is commonly observed only in the latter two conditions. Higher serum aspartate than alanine aminotransferase levels indicate sources other than liver alone. Cough, dyspnea, low oxygen saturations, and the need for mechanical ventilation have all been described in EVD, and difficulty breathing has been associated with a fatal outcome in patients with EVD due to pulmonary edema (32). Gross pathological findings in Lassa fever deceased patients include pulmonary edema.

Renal dysfunction is common in some VHFs. In EVD this may be due to a number of reasons, including hypovolemic shock, acute kidney injury, rhabdomyolysis, and interstitial nephritis. (33, 14) A number of the repatriated cases from the West African EVD outbreak received renal support. The renal compromise phase of HFRS is characterized by severe oliguria with increased blood urea nitrogen and creatinine levels; a diuretic phase typically follows.

The systemic inflammation of VHF leads to numerous changes in clinical laboratory tests, none of which are specific to these diseases. Blood leukocyte patterns vary widely. Leukopenia is frequently observed, but patients with dengue HF usually have normal white blood cell counts. Leukopenia is minimal in Lassa fever, and fatal disease may be heralded by a frank polymorphonuclear leukocytosis. Thrombocytopenia is a universal finding, but it is usually not severe enough in itself to account for hemorrhagic manifestations. Signs of hemoconcentration include a rise in the hemoglobin, hematocrit, and plasma protein levels. Monitored sequentially, these can provide an index of the loss of plasma volume resulting from the capillary leak syndrome and the efficacy of therapeutic countermeasures. Proteinuria is commonly found in VHFs and may be severe in Lassa, Marburg, and Ebola fevers as well as in HFRS. Coagulation factors are variously reduced, but major increases in prothrombin and partial prothrombin times are common only in YF, CCHF, RVEF, and the filoviral diseases. Limited testing during outbreaks has shown that fibrin split products and d-dimers, indicative of disseminated intravascular coagulation, are present in EVD and CCHF; they would probably be found in many of the other diseases if testing capability were available.

VHFs can lead to severe complications during pregnancy, leading to fetal loss and life-threatening illness of the mother. In some VHF, including Lassa and filovirus infections, third trimester infection is associated with extremely high rates of maternal and fetal mortality, which may approach 100%. The range and degree of outcomes following infection in pregnancy has not been well explored for all VHFs, including such widespread diseases as dengue. This is an important topic for investigation in future outbreaks of all VHFs.

A range of neurological complications including visual disturbance have been described as a result of RVEF infection. These may occur as early or late complications. Examples include encephalitis and loss of vision. The retinal vasculitis of RVEF can result in permanent loss of central vision (34, 35, 36, 37).

A few of the VHFs have well recognized sequelae. As in Marburg Virus Disease, EVD has been noted to cause uveitis, with live virus being isolated in some instances from the aqueous. In fact, a range of ocular symptoms was described prior to the West African outbreak, in the Kikwit outbreak in 1995 and the Gulu EVD outbreak in 2001. About 3% of

Lassa fever survivors have permanent eighth-nerve damage, making it the most common cause of deafness in young people in its region of endemicity. HFRS has led to sequelae from severe complications occurring during the acute phase of the illness, such as intracranial hemorrhage or renal rupture. Persistence of viral replication in immunologically protected "sanctuary" sites may lead to late sequelae, recrudescence of illness, or late transmission through sexual or other routes, with a risk of rekindling outbreaks, as recently observed for Ebola. The recent Ebola epidemic in West Africa has led to the recognition of a range of sequelae and chronic health impacts, which were not previously well characterized, including arthralgia, new visual problems, and hearing impairment. (38, 39) This recognition has led to continuing research to more carefully characterize the long-term impacts and persistence of infection among large cohorts of survivors. Careful, prospective follow-up of recovered patients has not generally been performed for many other VHFs, therefore generalizations about lack of sequelae should be avoided.

## DIAGNOSIS

The signs and symptoms of VHF resemble those of a wide range of infectious diseases, so a specific diagnosis can be made only by means of specialized laboratory tests that directly identify the pathogen. This is particularly true in the early stages of infection, when institution of the correct disease control measures and the appropriate patient management strategy can protect the community and yield the best outcome for the individual patient. Until recently, such assays were generally not performed by hospital laboratories, and required a containment reference facility. Advances in diagnostic technologies have permitted the development of diagnostic platforms and sensitive assays for the suspect VHFs, which can be performed by operators who do not possess advanced laboratory skills, for use in hospitals and field laboratories. Mobile laboratories have been employed which can be easily transported to outbreak sites lacking appropriate laboratory infrastructure and basic services. In the recent EVD outbreak in West Africa, even virus sequencing capacity was brought to the field. However, such capacity is not often on hand at the beginning of an outbreak, and often a combination of clinical and epidemiologic findings will raise the suspicion. For certain VHFs, this may sometimes be in the context of recognition of disease in animals (e.g., waves of abortion in livestock for RVEF), or due to an occupational association with animals or their slaughter. Only in rare circumstances in developing countries will the clinician evaluating an acutely ill patient proceed directly to requesting specialized tests, as the symptoms and early clinical features of most VHFs are nonspecific and may be similar to many other endemic illnesses. VHF would be high on the list of likely diagnoses when a patient reports having been exposed to an ill person or a cluster of ill persons, or during an identified VHF outbreak.

A travel and exposure (e.g., animals, ticks, ill persons, healthcare settings) history should always be elicited in returning travelers; more often the patient's recent travel history will only suggest a range of possibilities, rather than a specific diagnosis. Although someone who develops fever and malaise soon after returning from central Africa could be infected with Ebola or Marburg virus, it is much more likely that he or she has a more common (and easily treatable) disease, such as malaria, typhoid fever, or shigellosis. VHF risk has been conservatively estimated at <1 in 1 million

travel episodes to African countries where infection is present, and febrile patients returning from these countries are at least 1,000 times more likely to have malaria than Lassa fever or another VHF (40). Yet, cases of imported VHF have been missed or misdiagnosed in returning travelers (41). The consequences both of missing a treatable infection and missing a diagnosis of a VHF are very serious, so to follow a diagnostic algorithm which considers both is important. An appropriate diagnostic strategy for the clinician faced with a possible case of VHF would therefore be to obtain advice regarding appropriate and safe sample collection to diagnose the most likely diseases, based on the physical examination and history (including the travel history), and assessment of the epidemiological context. Advice should also be sought on how to handle, package, and transport the samples to a laboratory able to perform the necessary tests under the correct biosafety conditions.

A variety of diagnostic tests have been developed for VHF. Viral antigens and antibodies are now detected most commonly by enzyme-linked immunosorbent assay, often employing recombinant antigens and monoclonal antibodies as defined reagents. Molecular tests like reverse transcription polymerase chain reaction (RT-PCR) are being utilized with great success to identify virus-specific sequences. Because many types of VHF are characterized by prolonged viremia, blood is generally considered to be the best sample for testing. However, oral fluid and oral swabs have been used with good results for detecting filoviruses, and oral fluid has been used for diagnosis of Lassa fever. RT-PCR is not the perfect solution for all VHF diagnostics, and indeed for hantavirus infections, in which the viremia occurs early and is short lived in relation to clinical symptoms, serology proves more useful. This may also sometimes be the case for dengue and some other flavivirus infections, in which the viremia may have decreased below the detection limits by the time the patient presents to a health care facility (42).

There have been recent advances in the development of true point-of-care (PoC) tests, performed at the bedside by health workers without specialized laboratory skills. PoC tests with panels to distinguish the potential differential etiologies are in development and should be available for clinical diagnosis and surveillance in the not-too-distant future. Information on diagnostic assays for various types of VHF, including the collection, processing, and disposal of diagnostic specimens, can be found in the appropriate chapters of this book and on a number of infectious-disease websites. In the United States, further information can also be obtained by contacting the Viral Special Pathogens Branch, Centre for Disease Control (CDC), and contact numbers can be found on that webpage (<http://www.cdc.gov/nceizid/dhcpp/vspb/diseases.html>).

## CLINICAL MANAGEMENT

### Infection Prevention and Control

The first priority in treating a patient with VHF is to prevent the further spread of infection. The risk of person-to-person transmission varies greatly for the different diseases. Although respiratory spread appears to be rare for most types of VHF, a hospital outbreak of Lassa fever occurred in Nigeria in which a patient in an open ward had a persistent cough. The Andes strain of hantavirus has also been transmitted from patients to medical personnel or family members (43). Several diseases characterized by prolonged, high titer viremia, including Lassa, Ebola, and Marburg fevers and CCHF, can be spread through direct contact with body fluids. In the

case of the filoviruses, the body fluids posing a transmission risk includes blood, saliva, vomitus, feces, semen, breast milk, amniotic fluid, and even sweat. The risk of transmission is obviously highest when a specific diagnosis has not yet been made and family members and medical personnel are not taking precautions to avoid contamination.

Whatever type of VHF is being treated, medical personnel must observe standard precautions in handling the patient and diagnostic specimens, and take special care to avoid exposure to aerosolized material, whether during patient care procedures or in the laboratory. Gloves, gowns, and other standard protective measures against blood-borne or enteric diseases should be supplemented with face or eye protection when relevant. The choice of face mask or respirator will be defined by WHO or national agencies and affected by availability. Particular attention should be paid to potential aerosol-generating procedures. The patient's room should be under negative directional air pressure, if possible. Up-to-date advice on the disposal of clinical waste and other aspects of biohazard management during patient care is available from WHO and the U.S. Centers for Disease Control and Prevention.

### Supportive Care

Therapeutic interventions for VHF can be divided into general supportive and virus-specific measures. The West African Ebola outbreak experience, including use of intensive monitoring and supportive care (e.g., blood products, renal replacement therapy, and mechanical ventilation) in some treatment centers, and also in small numbers of repatriated health care workers, has resulted in a deeper understanding of the supportive medical care required by EVD patients (44, 11). General supportive management should, whenever possible, be based on careful monitoring of circulating blood volume and correction of electrolyte abnormalities (45, 46, 47). Inotropic agents and vasopressors may also be indicated. During VHF outbreaks where malaria coinfection is common, MSF's recent experience with artesunate-amodiaquine would suggest that artesunate-amodiaquine is preferable to artemether-lumefantrine in patients with confirmed EVD (48). Amodiaquine has some *in vitro* activity and there are concerns over QT intervals and lumefantrine in patients who are likely to be hypokalemic and hypomagnesemic due to diarrhea and vomiting. Although corticosteroids in various doses have been administered to patients with many types of VHF, there is no evidence that they are of benefit for any of these conditions, and should be avoided unless required for other medical indications like adrenal support. It is also advised the Non Steroidal Anti Inflammatory Drugs (NSAIDs) and aspirin are avoided for risk of bleeding, and some patients have impaired renal function.

### Antiviral Treatment

Specific therapeutic measures are available for only a few of these diseases and there remains doubt over the efficacy of these drugs. Intravenous administration of the guanosine analogue ribavirin appeared to improve the survival rate in severe Lassa fever in a clinical trial in Sierra Leone in the 1980s (49), and treatment has also reduced the rate of mortality from HFRS (50). However, two systematic reviews have concluded that insufficient evidence exists to support the claim of therapeutic efficacy of ribavirin in CCHF (51, 52). Ribavirin has been used for postexposure prophylaxis of CCHF in health care workers (53).

Convalescent plasma with uncertain specific antibody content did not appear effective in reducing mortality in EVD (54). However, convalescent plasma with neutralizing

antibodies has been successfully used in Argentine HF. A placebo-controlled trial in the late 1970s showed that such therapy significantly reduced the case fatality rate, providing it was initiated before the eighth day of illness (55). Yet in contrast to untreated patients who undergo a typical HF syndrome, patients who receive immune plasma sometimes relapse a few weeks after the completion of therapy with a variety of neurologic abnormalities. The etiology of this “late neurologic syndrome” is unknown and merits further study as these therapies are often some of the first to be considered (55). Despite promising results from the use of convalescent plasma in Lassa in Nigeria in 1984 (56) subsequent laboratory studies explored the titer levels and the need for a good match between the patient and plasma donor. Once ribavirin was thought to be beneficial in Lassa, the option of convalescent plasma was largely abandoned.

A number of experimental therapies have shown efficacy in laboratory animal models of various types of VHF, as described in the corresponding chapters of this book. Most of the drug development efforts over the years have gone into Ebola and a number of these therapeutics were trialed in the recent West African outbreak (see chapter 42). However, no individual drug (e.g., favipiravir) or immunotherapeutic (e.g., ZMapp) has demonstrated convincing antiviral or therapeutic benefits in rigorously controlled trials (58), in part because studies were under-enrolled and/or observational in nature. Several of these compounds were also used in expatriated patients, but for multiple reasons, including administration of multiple therapies, no conclusions can be drawn about their efficacy (14). One recently described prodrug of an adenosine analogue, designated GS-5734, is a potent inhibitor of Ebolavirus replication *in vitro* and in experimentally infected Rhesus macaques (59); this agent was used in several cases with apparent benefit.

If these approaches prove to be safe and effective in humans, they could have many applications in the setting of a disease outbreak, and could be lifesaving for a laboratory worker accidentally exposed to a pathogen. In contrast, developing an effective treatment for full-blown VHF, with its combination of vascular insufficiency, disseminated intravascular coagulation, tissue damage, and impaired immune function, is likely to remain a challenging medical problem for the foreseeable future.

## PREVENTION

It is impossible to prevent all sporadic cases of VHFs, especially those involving spillover from wildlife or a domesticated animal source. Early detection and response remain fundamental to preventing the extension of outbreaks from such events. This entails the strengthening of surveillance systems, health care worker awareness, diagnostic capacity, and adherence to the International Health Regulations (2005). Local health care workers should be trained to recognize the signs and risk factors of early VHF infection. Analyses of the weaknesses in controlling the West Africa Ebola epidemic noted the need for improved national surveillance and response systems, as required by the International Health Regulations (IHR), along with strong global leadership and coordination in responding to such events.

### Transmission Reduction Strategies

For VHFs like EVD that can have delayed sexual transmission, it is important that WHO recommendations are followed regarding safe sex practices, including sexual abstinence or condom use until semen has tested negative on two occasions with

an identified interval. Ideally, men should be offered testing of their semen regularly for Ebola RNA from 3 months after the onset of symptoms. If not possible, then precautions should continue for at least 6 months after the onset of symptoms. For vector-borne VHFs personal protection should be used when possible, including mosquito repellants. For Crimean Congo Haemorrhagic Fever Virus (CCHFV) and ticks, animal husbandry practices should be reviewed as animals often roam easily amongst tick-infested grassland and towns. Safe and quick removal of ticks should be taught to all at-risk communities. During VHF outbreaks, transmission-based precautions should be taken to avoid contamination of the blood supply.

### Vaccines

Only a few vaccines are in regular use in humans for the prevention of VHF. The live attenuated 17D YF vaccine, first introduced in the 1930s, remains one of the most effective vaccines ever developed, but its use in tropical countries, where sylvatic infection is endemic, is unfortunately insufficient to prevent recurrent epidemics as is the current situation in sub-Saharan Africa with outbreaks affecting a number of countries. Effectiveness of reduced dosing of the vaccine is currently being studied in the attempt to make it available to more people. The attenuated Candid-1 vaccine for Argentine HF has also proven to be highly effective and has played an important role in reducing the incidence of disease in its zone of endemicity. Some older vaccines against RVF are used for specified groups of at-risk humans in very limited settings in a few countries. A vaccine against Omsk HF is used for high occupational risk persons in the endemic area. The most problematic disease from the point of view of vaccine development has been dengue fever. As discussed above, the immunity that follows infection by one of the four dengue virus serotypes can predispose an individual to severe disease if he or she is later exposed to a second serotype. So as not to place vaccinees at risk of severe illness, it is now generally accepted that a dengue vaccine must protect against all four serotypes (60). One dengue vaccine has recently completed clinical evaluation; the current status is described in chapter 53.

Several vaccines were fast tracked for evaluation against Ebola during the West African epidemic. These included recombinant vesicular stomatitis virus (rVSV) and chimpanzee adenovirus vectored vaccines expressing the Ebola surface glycoprotein. Both of these have been demonstrated to be safe and immunogenic, but due to declining case numbers, only the rVSV vaccine has gone far enough to yield interim results indicating protection against EVD (61). These vaccines, and other candidates, must be evaluated for efficacy in future outbreaks, but safety and immunogenicity studies can be carried out in the intervals between outbreaks, so that the necessary clinical trials can be initiated with minimal delay when the outbreaks begin. Some of the newer vaccine technologies, which were explored for Ebola, may also be adaptable to other VHFs, and work is under way to assess these vaccine platforms for application to one or more of the other VHFs mentioned in this chapter.

The various disease control needs, such as vaccination for VHF outbreak control or the vaccination of potential frontline workers or other at-risk groups, may necessitate different vaccination strategies, and indeed, different vaccines. Immediate use to curtail an outbreak demands a one-dose schedule with rapid induction of immunity. Protection of frontline workers or populations facing repeated exposure over a long time period may require multiple doses or combination of vaccines, e.g., a prime-boost strategy. In addition, while there

are a variety of candidate vaccines for VHF, the absence of a lucrative commercial market to drive their development and manufacture has led to slow progress in moving them through the development pipeline. One consequence of the West Africa Ebola epidemic was increased awareness of a need for better available vaccines and vaccine preparedness at the global level. It is hoped that this will translate into the attention and funding required to accelerate their progress and to make them available when and where they are needed.

# Viral Disease of the Eye

HOWARD M. NEWMAN

## 10

The eye is a fascinating organ not only because of its complex anatomy but also because it is a partly immunologically privileged site, which protects itself from potentially destructive systemic immune responses. This characteristic, however, may hinder defense against infectious agents, including numerous viruses, which may manifest with a variety of ocular diseases (Table 1). The first part of this chapter discusses ocular anatomy and physiology, as well as the principle clinical syndromes, which are usually classified according to the affected anatomic structures. The latter part discusses the major viral ocular pathogens and highlights selected risk groups, such as infants and patients infected with human immunodeficiency virus (HIV).

### ANATOMY AND PHYSIOLOGY

Figure 1 illustrates the anatomy of the eye, which is a complex organ within which three layers can be distinguished. The outer layer consists of the cornea and sclera. The middle one consists of the iris, ciliary body and choroid, collectively known as the uvea. The retina forms the inner layer of the eye and is a complex multilayered sheet of neural tissue closely applied to a single layer of pigmented epithelial cells (1, 2). The three transparent structures surrounding these layers are the aqueous, the vitreous, and the lens. The eye can also be divided into anterior and posterior segments, with the dividing line just behind the lens (3).

The cornea, which is the window of the eye, is not only transparent but also avascular; it consists of five distinct layers: the corneal epithelium, Bowman's membrane, stroma, Descemet's membrane, and the corneal endothelium. The surface of the cornea is covered by tear film, which protects against foreign substances, including infectious agents (1, 2). There are several antimicrobial substances in tear film, such as lactoferrins and lipocalin, which may interfere with viral attachment to cells, as well as immunoglobulins (IgG and IgA), which may neutralize viruses, thus preventing ocular infection (4). All these characteristics allow the cornea to perform its main function: to refract and transmit light to the lens and retina and to protect the eye against infection and structural damage to deeper parts (1).

The sclera forms a connective tissue coat which helps maintain the shape of the eye. It contains collagen fibrils arranged haphazardly, and therefore it is opaque rather than

clear. The outer layer of the sclera is the episclera, a highly vascular connective tissue (2). The cornea and the sclera connect at the limbus, while the conjunctiva covers the visible part of the sclera. The iris (in the middle layer) controls the size of the pupil, thereby controlling the amount of light entering the eye. The ciliary body controls the power and shape of the lens and is the site of aqueous production, while the vascular choroid provides nutrients to the outer retinal layers (1). Inflammation of the uvea (uveitis) would therefore affect these functions to varying degrees. Aqueous humor contains components of both innate and adaptive immunity but also contains several substances, such as the cytokine TGF-beta 2 (transforming growth factor), which may suppress the activation of T-helper cells, thus contributing to immune privilege (5).

The retina, the tissue that lines the inner surface of the eye, is an essential ocular component with its primary purpose being photoreception. It surrounds the vitreous cavity containing the vitreous humor. Like the aqueous humor, the vitreous humor is also subject to innate and adaptive immune responses, which protect against infection, and immune privilege is also present in the vitreous (6).

Adnexal structures such as the eyelid, periocular skin, and lacrimal glands and associated structures are often overlooked when considering the anatomy of the eye, yet they are important sites for many viral diseases.

In the eyelid and conjunctival sac, immune cells line the sites at which ocular exposure to antigens occurs. Lymphocytes and antigen-presenting cells of the conjunctival-associated lymphoid tissue (CALT) form a distinct layer in the substantia propria and, in places, cluster to form follicles. The CALT is considered part of the mucosa-associated lymphoid tissue. These tissues are protected primarily by immunoglobulin A (IgA) antibodies and T-cell-mediated immune responses (7).

Visual function is critically dependent on normal structural integrity, as functional repair processes are incapable of remodeling all ocular components if extensive tissue damage occurs, which sometimes may be a direct result of an overzealous host immune response. To reduce this likelihood, the eye has evolved mechanisms, which evoke specific immunological adaptations. These adaptations have been termed anterior chamber-associated immune deviation, or "immune privilege," and consist of suppression of relatively

**TABLE 1** Common viruses affecting the eye

Virus	Family	Transmission
HSV-1	<i>Herpesviridae</i>	Close personal contact
VZV		Respiratory droplets
CMV		MTC, kissing, sex, blood transfusions, transplant recipients
EBV		Contact with infected saliva
HIV	<i>Retroviridae</i>	Sexual intercourse, MTC, needle-stick injuries
Adenovirus	<i>Adenoviridae</i>	Faecal-oral, aerosol inhalation → depends on type of adenovirus
Enterovirus	<i>Picomaviridae</i>	Faecal oral, respiratory route, direct contact
Measles	<i>Paramyxoviridae</i>	Respiratory aerosols
Rubella	<i>Togaviridae</i>	Respiratory droplets

nonspecific, delayed-type hypersensitivity responses, with preservation of specific noncomplement fixing humoral immunity and up-regulation of specific T-cell responses. In addition, blood-ocular barriers (tight cellular junctions of capillary endothelial cells and retinal pigment epithelium) in the retina and anterior segment, limit ocular immune responses by restriction of cellular macromolecular traffic, and programmed intra-ocular apoptosis of inflammatory cells may occur. These immune modulations and adaptations modify the severity and extent of nonspecific intraocular inflammation and serve to reduce collateral damage (7).

## MAJOR CLINICAL SYNDROMES

Table 2 illustrates the major clinical syndromes, as well as their viral etiologies and special features.

### Conjunctivitis

Conjunctivitis refers to inflammation of the conjunctiva and has four main causes—viruses, bacteria, allergens, and irritants (8)—with viral causes being the most common. Viral causes of conjunctivitis are numerous, with adenovirus being one of the more common etiologies. In addition, conjunctivitis often occurs in association with keratitis (keratoconjunctivitis).

**FIGURE 1** Anatomy of the eye. Courtesy of the National Eye Institute, National Institutes of Health, USA.

Conjunctival inflammatory responses are divided into nonspecific papillary responses (as a consequence of tissue edema) and follicular responses (due to the formation of aggregates of activated lymphocytes) (7). In severe cases, transudates rich in protein and fibrin may coagulate to form membranes and pseudomembranes on conjunctival surfaces.

Clinical features include mild pruritus, foreign body sensation, matted eyelids, generalized conjunctival injection, and discharge (8,9).

### Keratitis

Keratitis refers to inflammation of the cornea. Herpes simplex virus (HSV), in particular, may cause severe keratitis resulting in blindness (10). However, numerous other viruses, such as adenovirus and measles, may also present with corneal manifestations. The resultant clinical syndrome will depend on the anatomical location of the lesion. Epithelial disease may present with dendritic or amoebic/geographical ulcers, whereas stromal disease may present with disciform or interstitial keratitis. Significant inflammation affecting the cornea results in limbal vascular dilatation with erythema, most marked at the corneo-scleral limbus (7).

Symptoms include ocular pain, which is usually moderate to severe, photophobia, which is thought to be due to reflex inflammation and spasm of the iris in response to light, and a watery discharge as a result of reflex lacrimation and mucous buildup. Visual compromise may occur as a consequence of reactive blepharospasm or, more significantly, inflammatory cell infiltration and structural damage and perforation (7).

Early and accurate diagnosis with effective treatment is essential if permanent damage is to be avoided. To this end, specific laboratory diagnosis is useful.

### Scleritis and Episcleritis

Scleritis is a severe ocular inflammation that is often associated with more severe ocular complications and is nearly always treated with systemic medications. In patients with scleritis, the vasculature is engorged, whereas in the healthy eye, the scleral vessels are not prominent (11, 12). If the anterior sclera is involved, the external surface of the eye becomes red and tender, with the redness being diffuse or localized. Anterior scleritis can therefore be divided into diffuse, nodular or necrotizing types, with the latter being less common. Posterior scleritis is rare and may present with pain and decreased vision.

Episcleritis is inflammation of the tissue that lies immediately superficial to the sclera, deep into the conjunctiva. Differentiation of episcleritis and scleritis, which may be

**TABLE 2** Viral causes of ocular clinical syndromes

Clinical syndrome	Virus	Features
Conjunctivitis	Adenovirus	Follicular, pseudomembranous/membranous
	HSV	Follicular conjunctivitis, neonatal ophthalmia
	VZV	Mucopurulent conjunctivitis with lid margin lesions
	EBV	Follicular or membranous conjunctivitis
	Measles	Keratoconjunctivitis with conjunctival Koplik's spots
	Mumps	Follicular or papillary conjunctivitis
	Enterovirus	Acute haemorrhagic conjunctivitis
	Influenza	Papillary conjunctivitis

HSV, herpes simplex virus; VZV, varicella zoster virus; EBV, Epstein Barr virus; CMV, cytomegalovirus; HIV, human immunodeficiency virus; HZO, herpes zoster ophthalmicus.

caused by several viruses, can be difficult (Table 2), but correct identification is crucial as the prognosis of episcleritis is better than for scleritis (9). Other than viral causes for these syndromes, there are numerous other systemic and autoimmune conditions which may present with scleritis or episcleritis. These range from rheumatoid arthritis and systemic lupus erythematosus to metabolic conditions, such as gout, plus many others. (13)

Initial treatment of scleritis usually involves systemic anti-inflammatory agents, but cytotoxic agents are sometimes required to control inflammation (7).

### Uveitis

Uveitis is the term used to describe many forms of intra-ocular inflammation involving the uveal tract (iris, ciliary body, and choroid) and adjacent ocular structures (retina, vitreous, and optic nerve) (14). The classification of uveitis into anterior, posterior, or diffuse is based on the physical appearance of the inflamed eye (14).

In anterior uveitis there is often vascular congestion of the conjunctiva and sclera. The infiltration of inflammatory cells between the anterior iris and cornea may result in closure of the anterior chamber angle, resulting in increased

intraocular pressure. Alternatively, intraocular pressure may decrease as a result of uveitis, and aqueous humor production is diminished. Chronic or recurrent anterior uveitis often leads to opacification of the lens.

In posterior uveitis, vision often decreases as a result of opacity formation in the vitreous or from inflammation or vascular occlusions of the macular area of the optic nerve (14).

Anterior uveitis is typically associated with limbal hyperemia, pain, photophobia, and reflex lacrimation (7). Although several viruses are associated with anterior uveitis (Table 2), it is usually associated with rheumatoid-negative spondyloarthropathies, such as ankylosing spondylitis and Reiter's syndrome.

Treatment is usually aimed at reducing the ocular inflammation with topical or systemic steroids or nonsteroidal anti-inflammatory drugs, while treating any underlying etiology where applicable.

### Retinitis

Infections of the retina are potentially sight-threatening. Viral causes of retinitis have become more prominent with the global AIDS pandemic (7). This is particularly true for cytomegalovirus (CMV) retinitis, which is an AIDS defining illness and usually occurs in patients with severe immunosuppression (15), particularly with compromised cellular immunity. On the other hand, viruses, such as varicella zoster virus (VZV) and HSV, may cause retinitis in immunocompetent individuals (15). Nonviral etiologies include *Toxoplasma gondii*, syphilis, fungal infections, and tuberculosis, whereas noninfectious causes include autoimmune conditions, such as sarcoidosis, as well as inherited conditions, such as retinitis pigmentosa, all of which need to be considered in the differential diagnosis of retinitis.

Retinal inflammatory cellular infiltrates and retinal ischemia may result in damage to blood-retinal barriers, which may allow inflammatory cells to enter the vitreous cavity and produce opacities, giving rise to symptoms of visual floaters (7).

Acute retinal necrosis (ARN), classically described in immunocompetent individuals, may involve one or both eyes and may be characterized by anterior uveitis, vitritis, and retinal vasculitis with diffuse or patchy areas of retinal necrosis (15). In contrast, progressive outer retinal necrosis (PORN) is seen mainly in immunocompromised patients and is characterized by outer retinal discoloration in the posterior pole, which rapidly spreads throughout the fundus (15, 16). Together, ARN and PORN are classified as necrotizing herpetic retinopathies (NHR) (3), with the primary etiologic agents being VZV and HSV 1 and 2, although CMV and Epstein–Barr virus (EBV) are also implicated (7, 15, 17). The visual prognosis for NHR is poor, especially when caused by VZV (18).

### Ocular Adnexal Disease

The ocular adnexa comprise anatomically related tissues such as the eyelids, lacrimal apparatus, the extraocular muscles, and periocular skin. Numerous viruses result in adnexal disease. Disease features depend on the structures involved and are beyond a general description.

## VIRAL OCULAR PATHOGENS

### HIV and the Eye

By 2015, over 35 million people worldwide were living with HIV (see Chapter 34). As access to lifesaving antiretrovirals

**TABLE 3** Ocular HIV manifestations

increases, this number is expected to steadily rise (19). The impact that this pandemic has had on all specialties within medicine, ophthalmology included, has been immeasurable. Eye clinics in developing countries, in particular, where the prevalence of HIV is high, have been put under immense strain to provide clinical care. This is not surprising, since HIV can affect the eye directly, or, by causing severe immunosuppression, make the eye susceptible to a variety of devastating infectious diseases, including other viral infections. As such, HIV has to be considered a major ocular viral pathogen.

Eye infections tend to be more severe and are more commonly multicentric and bilateral. Approximately 70% of AIDS patients will develop eye disease during the course of their illness (20). HIV ophthalmic manifestations, illustrated in Table 3, fall within four major groups: microvasculopathy, opportunistic infections, neoplasms, and neuro-ophthalmic disorders (21). Anterior segment findings include keratitis, keratoconjunctivitis sicca, iridocyclitis, and others. Posterior segment findings include HIV-associated retinopathy and opportunistic infections of the retina and choroid (20).

Microvasculopathy, which is the most common form of posterior segment involvement in AIDS patients, may affect the conjunctiva or retina, with the latter also referred to as HIV retinopathy (22, 23). It is hypothesized that the pathogenesis of conjunctival and retinal microvasculopathy is possibly similar and may include increased plasma viscosity, circulating immune complexes and infectious damage of the vasculature (3, 20).

Conjunctival microvasculopathy, which may result in asymptomatic microvascular changes, usually requires no treatment (20). The microvascular changes include microaneurysms and vascular dilatations and narrowings (7, 20).

Although being the most common retinal manifestation of HIV, most cases of HIV retinopathy are asymptomatic. Fundoscopic changes (Figure 2) include cotton wool spots, intraretinal hemorrhages and retinal microaneurysms (3, 24). The possible opportunistic infections that may affect the eye are numerous (Table 3) and include viruses, bacteria, fungi, and protozoa (25). Among the viral opportunistic infections, CMV, HSV, and VZV can cause severe disease, especially in those with severe immunosuppression, and are discussed in more detail in the sections to follow.

**FIGURE 2** HIV retinopathy with cotton wool spots. Courtesy Retinal Gallery and S Cohen (<http://retinagallery.com/displayimage.php?pid=3301>).

Orbital and adnexal manifestations of HIV are rare, with the most common being opportunistic viral infections, such as molluscum contagiosum, as well as HIV-associated conditions such as Kaposi sarcoma and conjunctival microvasculopathy (26). In addition to infectious complications, HIV may cause optic neuropathies by various mechanisms, including compression on the optic nerve by tumors and vaso-occlusion (3). In children, ocular manifestations of HIV are much less frequent than in adults for reasons which are still unclear. However, the commonest ocular manifestation of HIV in children is keratoconjunctivitis sicca, or dry eyes (20, 27).

With close to 10 million people worldwide receiving highly active antiretroviral therapy (HAART) by 2012 (28), immune-recovery uveitis is a syndrome expected to occur more frequently. It entails paradoxical worsening of intraocular inflammation after receiving antiretrovirals, which may be caused by an immune response to CMV and other infectious agents present in the eye (3, 27), and is characterized by recovery of CD4 cell counts and function. Although specific treatment of opportunistic infections is also important, the mainstay of treatment for ocular complications of HIV would be HAART, which is discussed elsewhere and is mentioned in the following sections.

## Herpesviruses

Viruses of the *Herpesviridae* family have biological features of latency and cytopathic effects, which are important characteristics with respect to ocular manifestations. These viruses may evade the host immune system by a variety of mechanisms, including latency, which allows for persistent, life-long infections, and the potential for reactivation with or without disease (3).

Table 4 shows the various herpesviruses and their common ocular manifestations. Herpes simplex virus 1 and 2 (see chapter 20) (HSV-1, HSV-2), CMV (see chapter 23), and VZV (see chapter 22) are the herpesviruses with the greatest propensity for severe disease, which may or may not result in blindness.

### Herpes Simplex Virus

HSV-1 generally enters the host via the oropharyngeal mucosa, where initial replication occurs. This is followed by the establishment of latency in the trigeminal ganglia or sacral ganglia, depending on the mode of transmission. HSV-2, on the other hand, is usually transmitted sexually with initial replication in the genital mucosa, followed by latency in the sacral ganglia. HSV-2 infection acquired congenitally may or may not have ocular manifestations (29, 30). HSV-1 and -2 have similar clinical ocular manifestations and produce a wide spectrum of diseases. However, HSV-1 predominates with regard to ocular infections.

Ocular manifestations of HSV-1 include blepharitis, conjunctivitis, keratitis, uveitis, and retinitis (31, 32, 33, 34), with keratitis being the most common. HSV keratitis is also the commonest cause of infectious blindness in developed countries (35). Keratitis may manifest as corneal edema, epithelial ulceration, or stromal inflammatory infiltrates. Due to the inability of the repair process to precisely remodel the orthogonal collagen fibers of the original corneal structure, inflammatory processes may produce permanent scarring and decreased visual acuity (7).

### Pathogenesis

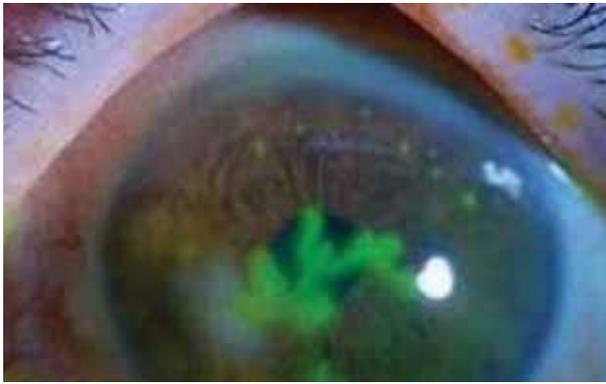

There are two major routes for primary ocular infection: direct infection by contact with infectious secretions or initial infection at a nonocular site with neural spread along the nerves supplying the cornea (36). Autoinoculation appears to be an unlikely source of intraocular infection (37).

Primary infection may be followed by intermittent reactivation (38), both of which may produce ocular disease. Reactivation episodes may be responses to various stimuli including fever, stress, exposure to ultraviolet light, hormonal imbalances, among others, and is made possible by

**TABLE 4** Ocular manifestations of herpesviruses

**FIGURE 3** Herpes simplex virus keratitis with dendritic ulcer, visible after fluorescein staining.

the virus's ability to remain latent in the sensory ganglia of the first division of the trigeminal nerve.

Infectious epithelial keratitis with dendritic or geographical ulcers is associated with the formation of multinucleated giant cells and intranuclear inclusion bodies, as well as necrosis of the cells bordering the area of ulceration and infiltration with neutrophils in the underlying stroma (7). In stromal keratitis, in addition to the influx of neutrophils, lymphocytes are present and are important in predisposing to chronic inflammatory sequelae. How HSV enters the stroma still needs to be fully elucidated, but it seems likely that virus present in the epithelial cells migrates into the superficial stroma from the subepithelial nerve plexus and then enters the keratocytes, with subsequent dissemination into the stroma through intercellular spread. This spread would be enhanced when immune responses are reduced by corticosteroid use (7, 39).

HSV antigens can be detected in keratocytes, endothelial cells, and epithelioid hystiocytes, together with multinucleated giant cells in necrotizing stromal keratitis. With inactive disease, no viral antigens are apparent. Endotheliitis, on the other hand, is associated with HSV DNA in the aqueous humor. Endothelial cells are dysfunctional due to direct infection with HSV and as a consequence of anterior chamber inflammation.

#### *Clinical manifestations*

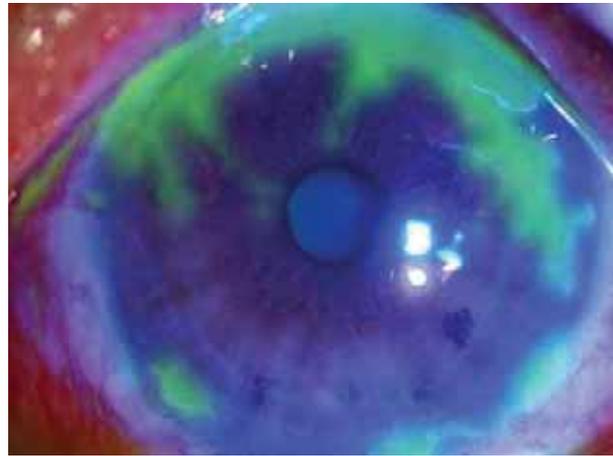

HSV may cause epithelial ulcerative keratitis, which is generally self-limiting and responds rapidly to antiviral therapy. The typical dendritic ulcer caused by HSV-1 is a form of infectious epithelial keratitis and occurs as a result of active viral replication (Figure 3). Stromal keratitis results in temporary or permanent loss of corneal transparency, and loss of corneal sensation is a useful clinical sign of its occurrence (7).

Primary ocular infection is rare and may manifest as vesicular lesions on the eyelid, follicular inflammatory response in the conjunctiva, or dendritic ulcers in the cornea.

In recurrent disease, stromal involvement may occur, while other manifestations include iridocyclitis, panuveitis, and ARN, the latter being rare and usually occurring in immunocompetent hosts (40).

Epithelial disease causes moderate to severe pain, watering, and photophobia. Infections are usually unilateral, and recurrences are associated with triggers, such as fever, stress, and exposure to sunlight (41).

Dendritic ulcers are narrow and branching and are best visualized after instilling fluorescein drops. Untreated, these ulcers usually heal in 5 to 12 days (7). In malnourished

**FIGURE 4** Herpes simplex virus keratitis with geographical ulcer. Courtesy of Hee K. Yang, Young K. Han, Won R. Wee, Jin H. Lee, and Ji W. Kwon; Department of Ophthalmology, Seoul National University College of Medicine, Seoul, Korea (<http://www.jmedicalcasereports.com/content/5/1/328/figure/F1>).

children with measles virus infection, or in cases where corticosteroids were erroneously used to treat a dendritic ulcer, these lesions may evolve into more extensive amoeboid or geographical ulcers (Figure 4).

Stromal keratitis is an inflammatory reaction and is the most common sight-threatening manifestation of ocular HSV (42). Spread of viral particles from the epithelium is prevented by relative barriers, such as the basement membrane of the epithelium and Bowman's layer. However, in approximately 30% of patients with ulcerative disease, viruses may still penetrate into the corneal stroma (7, 43, 44). Permanent stromal scarring generally follows. Scarring may not be sufficient to cause permanent visual handicap, but when it affects the visual axis, it may result in significant visual compromise for which a corneal transplant may be required (45).

#### *Diagnosis*

HSV keratitis is usually diagnosed clinically, but, in doubtful cases, specific diagnostic tests are indicated. Table 5 illustrates the common laboratory tests for the common ocular viral infections. Detection of viral DNA by polymerase chain reaction (PCR) is more sensitive than viral culture or antigen detection (3, 34). Intraocular infection can be demonstrated by PCR amplification of viral DNA found in the anterior chamber or vitreous fluids. In addition, locally produced antibody may be detected, and, by comparing with total immunoglobulin G (IgG), one can calculate the Goldmann-Witmer coefficient (GWC), which is the quotient of two ratios, namely the specific antibody titer in the aqueous humor over the total IgG in the aqueous humor and the specific antibody titer in the serum over the total IgG in the serum. A value of 3 or more indicates infection with the specific virus involved. Using a combination of PCR and GWC allows for a more comprehensive laboratory diagnosis (46).

#### *Treatment*

The goal of treatment is to inhibit viral replication and to reduce the inflammatory reaction in the stroma that may lead to long-lasting damage to the collagen fibrils (47, 48). Topical steroids are never used in isolation for epithelial keratitis because the virus can replicate freely in the presence

**TABLE 5** Laboratory diagnosis of common ocular viral infections

Virus	Specimen	Laboratory test options
HSV	Aqueous humour, biopsy specimens	PCR, Goldman-Witmer coefficient (GWC), culture
VZV	Aqueous humour, biopsy specimens	PCR, GWC, culture
CMV	Vitreous humour, biopsy specimens, blood	PCR, culture, serology and viral load on blood (complementary tests)
EBV	Biopsy specimens, blood	PCR, serology on blood (complementary test)

of local steroid-induced immunosuppression, potentially resulting in more extensive geographical ulcers. Prior to antivirals being available, alternative treatment modalities were used, including cautery with carbolic acid, ether, or iodine (7), which were associated with stromal scarring. Debridement using a cotton-tipped applicator to gently remove loose epithelium is an alternative when antiviral treatment is unavailable (49).

### Antivirals

Antiviral agents are the mainstay of treatment in HSV infections. The decision whether to use topical or systemic agents depends on the anatomical site involved, severity of infection, and immune status of the patient (3). Available topical agents include acyclovir and trifluridine, with the former being the most widely used. Systemic agents other than acyclovir includes valacyclovir (the prodrug of acyclovir) and famciclovir.

Topical antivirals are used to treat HSV blepharitis, conjunctivitis, and infectious epithelial keratitis and are also used as prophylaxis to cover corticosteroid treatment of certain forms of keratitis. Systemic agents are used in certain cases of endotheliitis and severe uveitis in immunocompromised patients, in pediatric patients not responding to topical treatment, or as prophylaxis (3). Intravenous acyclovir is generally reserved for patients with posterior pole involvement (30, 33).

For recurrent epithelial or stromal keratitis, as well as corneal graft failure in patients with a history of recurrent HSV keratitis, long-term prophylaxis with oral acyclovir appears to reduce their occurrence (50–52).

Resistance to acyclovir has been reported, particularly in AIDS patients, where isolates were shown to have mutant thymidine kinase (53).

### Corticosteroids

The use of corticosteroids to reduce inflammation in HSV ocular disease is controversial, since it may lead to increased severity of HSV infection by suppressing the local immune response. However, in certain cases they are very beneficial in reducing scarring and neovascularization. Topical steroids are usually reserved for moderate to severe cases of stromal keratitis, endotheliitis, and uveitis. Systemic steroids are only used in very severe forms of stromal and endothelial keratitis, uveitis, and retinitis after initiating antiviral therapy (33, 54). High-dose corticosteroids should be tapered over days to weeks to avoid the risk of a severe rebound inflammatory response (55).

### Cytomegalovirus

CMV retinitis (Figure 5) is the most common severe ocular infection in AIDS patients. It is an AIDS-defining illness,

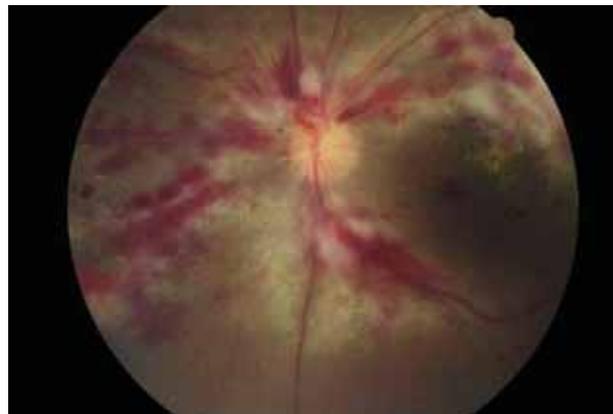

typically occurring in patients with a CD4+ lymphocyte count below 50 cells/mm<sup>3</sup> (56). CMV retinitis may also occur in other immunosuppressed patients and occasionally in neonates, albeit much rarer than in late stage HIV infection. The availability of HAART has led to a significant decline in the incidence of CMV retinitis (57, 58).

### Pathogenesis

The virus may be spread vertically or horizontally and is shed from multiple sites. Risk factors for severe disease include primary infection, high viral load, and immune suppression (59). CMV remains latent in immunocompetent individuals until there is an abrogation of the immune response (60).

CMV retinitis occurs following chronic CMV viremia. The virus is thought to reach the retina via infected monocytes, or, rarely, by direct extension from the CNS via the optic nerve (7). HIV microvasculopathy possibly facilitates the passage of CMV infected cells into the retina and may explain the higher incidence of CMV retinitis in AIDS patients than in patients with immunosuppression due to another cause.

Histologic examination reveals extensive retinal necrosis with little inflammatory response. Cells containing intranuclear and intracytoplasmic inclusion bodies may be found in all layers of the retina. Some of these are large with a surrounding halo, giving rise to the characteristic “owl’s eye” appearance. Indeed the virus’s name was derived from these cytopathic effects seen in cell culture, namely “cytomegaly” (61). Occasionally, multinucleate giant cells may be seen. CMV antigens, DNA, and virions have been found in the

**FIGURE 5** Cytomegalovirus retinitis with retinal haemorrhages and exudates. Courtesy Retinal Gallery and Don Gass (<http://retinagallery.com/displayimage.php?pid=3989>).

nuclei and cytoplasm of infected cells using techniques such as immunohistochemistry, *in situ* hybridization and electron microscopy. Gliosis or calcium deposits mark areas of burned-out disease where retinal vessels show perivascular fibrosis and narrowing (7).

#### *Clinical manifestations*

CMV retinitis is typically painless but may be associated with mild discomfort. Symptoms will depend upon the location of lesions and upon complications, such as retinal detachment (62). CMV retinitis is bilateral in approximately half of cases. In approximately 80% of those with unilateral disease, the contralateral eye will be affected, as well, in the absence of treatment (63).

When the optic nerve head or macula is affected, vision may be markedly reduced. However, many cases are asymptomatic, requiring regular screening, particularly in those with CD4+ cell counts below 100 cells/mm<sup>3</sup>.

The necrotic process of CMV retinitis usually starts in the periphery and slowly progresses. Untreated, the entire retina is destroyed within 6 months. Symptomatic patients may complain of blurred vision, visual field defects, or floaters. Fundoscopy may reveal large, unifocal, sometimes multifocal, areas of cheesy, yellow-white, full-thickness retinal necrosis with associated intraretinal hemorrhages (7).

Typically, the vitreous cavity, choroid, and anterior segment show little or no inflammatory reaction, although fine scattered deposits are commonly observed on the corneal endothelium (64). Other than retinitis, other ocular manifestations of CMV include anterior uveitis and corneal endotheliitis (65), as well as acute retinal necrosis (66).

#### *Diagnosis*

The differential diagnosis of hemorrhagic retinal necrosis in an HIV-positive individual includes ARN, PORN, toxoplasma retinochoroiditis, fungal infection, syphilitic retinitis, intraocular lymphoma, and HIV microvasculopathy (67). The slow progression, unifocality, characteristic appearance, and absence of intraocular inflammation aid in establishing the diagnosis of CMV retinitis. However, although the diagnosis is usually made clinically, additional laboratory testing may be necessary and includes PCR assessment of blood and ocular fluids, as well as serum antibody testing (68). In atypical cases the diagnosis may be aided by electron microscopy or PCR amplification of viral DNA obtained from an endoretinal, choroidal, or vitreous biopsy. Virus isolation from blood or urine may help confirm the diagnosis (69).

#### *Treatment*

Without treatment the disease progresses relentlessly, resulting in little or no visual function. The management of CMV retinitis involves treatment with an antiviral drug in conjunction with HAART for HIV-positive patients. Antiviral treatment may be administered systemically, as intravitreal injections, or as a long-acting intravitreal implant. Systemic antiviral agents include the nucleoside analogue ganciclovir and its prodrug, valganciclovir, which has excellent oral bioavailability and offers the benefits of an orally bioavailable drug with pharmacokinetics comparable to intravenous ganciclovir (70, 71). Both require induction doses, which are given twice a day, followed by maintenance doses, given once daily. However, some HIV positive patients on HAART, who respond well to treatment, may no longer require maintenance treatment (71–76).

Ganciclovir-resistant mutants, usually the result of a mutation in the unique long 97 (UL97) region of the genome, may emerge (77). Other available drugs for the treatment of CMV disease includes foscarnet, a pyrophosphate analogue, and the nucleotide analogue, cidofovir. Systemic treatment with ganciclovir, valganciclovir, foscarnet, or cidofovir leads to suppression of the retinitis and delays progression of disease (78). Further, it has the advantage of treating associated systemic disease and protecting the contralateral eye (7).

Local treatments usually take the form of intravitreal injections containing ganciclovir or formivirsen (no longer available in the U.S.), a synthetic antisense oligonucleotide that blocks viral mRNA translation (54). Other options include intravitreal injections with foscarnet or cidofovir or implantation of a sustained-release device delivering ganciclovir slowly (79–81). Intravitreal cidofovir may precipitate hypotony and is therefore generally avoided.

Although systemic drug toxicity is avoided, there are complications associated with repeated intraocular injections, including hemorrhage, endophthalmitis and retinal detachment (7). Intraocular injections also do not address occurrence of the frequent extraocular complications of CMV infection. Laser retinal photocoagulation has not been proven to contain the spread of retinal infection but may be of use in treating retinal breaks and localized peripheral detachments. Treatment of full-blown retinal detachments is best performed by pars plana vitrectomy, internal silicone oil tamponade, and endolaser (7).

#### *Varicella Zoster Virus*

Varicella zoster virus (VZV) is spread via respiratory droplets and is highly infectious. After primary infection the virus remains latent in one or more posterior root ganglia, usually in the trigeminal or thoracic nerves. During periods of lowered immunity the virus may reactivate and travel from the ganglia down the peripheral nerves to the skin, resulting in the typical lesions of herpes zoster, occurring typically in a dermatomal distribution (3). Damage to the eye may be due to a number of processes, including viral replication and inflammatory responses to the virus. Postherpetic neuralgia is a serious complication of herpes zoster ophthalmicus (HZO), which is more likely to occur with advanced age and severe eruptions (82). Unfortunately, postherpetic neuralgia is not prevented by early systemic antivirals or corticosteroids.

#### *Clinical manifestations*

Primary VZV infection occasionally may result in vesicular lesions on the eyelids, conjunctiva, or limbus. Lid lesions may develop into excavated ulcers that cause considerable inflammation, and VZV may rarely induce severe scleritis (83, 84). The cornea may also be involved with primary infection, which may show a punctate keratitis and marginal keratitis in the presence of limbal pustules (7). Later in the disease course, after the resolution of the exanthema, corneal involvement may still occur. In addition, bleb-like lesions in the presence of corneal edema have been described, as well as disciform keratitis, which appears to be identical to HSV keratitis (7).

Approximately 10 to 20% of all cases of herpes zoster present as HZO (85). The presentation of ophthalmic zoster can be complex due to the structure and complexity of the eye. It may involve the eyelid, conjunctiva, sclera, cornea, and iris, with iritis and keratitis being the most common complications (86). The typical erythematous, pustular rash

of HZO occurs in the distribution of the first division of the trigeminal nerve. The rash may extend from the nose and the eye to the skull vertex but does not cross the midline (Figure 6). Involvement of the nasociliary branch of the trigeminal nerve occurs commonly and correlates with ocular involvement in approximately 50% of patients with this sign (7). When this does occur, Hutchinson's sign, which is a vesicular lesion at the tip of the nose, may precede the development of HZO.

Eyelid vesicles resolve with pitting pigmentation and scarring, sometimes yielding eyelid retraction, malposition, and corneal exposure. The eyelash follicles and meibomian glands may also be damaged (7). Nodular and diffuse scleritis and keratitis may occur, sometimes months later. Damage to corneal nerves may result in corneal anesthesia.

Acute retinal necrosis has been described in older patients (87) as has PORN, which is most commonly caused by VZV, which can be diagnosed by PCR amplification of viral DNA found in fluid obtained from the anterior chamber (87, 88). Also associated with ocular VZV infection is anterior uveitis, both granulomatous and nongranulomatous (89). Cranial nerve palsies and CNS involvement are occasionally seen. Long-term sequelae include postherpetic neuralgia, permanent scarring of the eyelids, entropion, keratoconjunctivitis sicca, and neurotrophic keratopathy (7).

In congenital varicella syndrome, where mothers suffer VZV infection in the first or second trimester of pregnancy, ocular involvement may be present in the newborn.

**FIGURE 6** Herpes zoster ophthalmicus. Courtesy of William Charles Caccamise and Ophthalmic Atlas Images by EyeRounds.org, The University of Iowa. Note the dermatomal distribution of the lesion and scar of Hutchinson's sign at the tip of the nose which may precede the development of herpes zoster ophthalmicus.

### Treatment

The treatment of VZV infection is generally aimed at treating the symptoms, speeding up recovery, and reducing complications (7). There are currently three antivirals used for the treatment of HZO, namely acyclovir, valacyclovir, and famciclovir. Intravenous acyclovir is the drug of choice for immunosuppressed patients to prevent disseminated infection. Oral acyclovir commenced within 72 hours of onset hastens the resolution of skin lesions, reduces acute pain, and reduces the incidence of ocular complications. Valacyclovir and famciclovir are at least as effective as acyclovir in preventing ocular complications and have simpler dosing schedules because of higher oral bioavailability (90, 91). In addition, topical acyclovir has been shown to hasten the resolution of corneal epithelial disease and reduce the incidence of recurrence (92).

### Epstein-Barr virus

Epstein-Barr virus (EBV) infection usually follows contact with infectious saliva, and generally infects B-cells but can also replicate in subpopulations of squamous epithelial cells (see chapter 25) (93). Previous studies have found various presentations of corneal epithelial and stromal infections associated with EBV (35). However, the most common ocular manifestation of acute mononucleosis is periorbital edema and follicular conjunctivitis (94). Posterior segment diseases have been reported but are very rare. There have also been reports of ocular lymphomas including B- and T-cell lymphomas associated with EBV (35). Sero-epidemiologic studies have implicated EBV in conjunctivitis, episcleritis, keratitis, retinitis, and uveitis, with uveitis being reported in numerous case reports. Indeed, EBV has been detected in all ocular tissues except the optic nerve (94, 95, 96).

No specific treatments for EBV infections of the eye have been proven effective. Treatment is usually supportive, including lubricants, analgesia, and topical steroids in cases of uveitis. The antiviral agents acyclovir and foscarnet have been used but with limited success. Interferon-alpha has also been used to treat cases with apparent success, following a poor response to acyclovir (95).

### Other Herpesviruses

The other less common herpesviruses that may affect the eye include human herpesvirus-6 (HHV-6) and human herpesvirus-8 (HHV-8), with the latter also known as Kaposi sarcoma-associated herpesvirus (see chapters 24 and 26). There have been rare reports of optic neuritis and conjunctivitis being caused by HHV-6 (61, 97). HHV-8 may cause conjunctival Kaposi sarcoma and possibly uveitis (3, 35, 98).

### Adenoviruses

The ocular manifestations of adenoviruses are not strain-specific (99), and while the prevalence of milder forms of ocular disease is unclear, local epidemics of more severe infections occur episodically, including in eye clinics, where water and instrument contamination may facilitate transmission (100). These nonenveloped viruses are particularly resistant to inactivation and can survive on inanimate objects for prolonged periods (see chapter 27).

### Pathogenesis

Adenoviral pathology results from a combination of viral replication and cell lysis. Histopathologically, adenoviruses produce intranuclear inclusion bodies, as well as the so-called "smudge cells", which contain large amounts of capsid

TABLE 6 Adenoviral ocular syndromes

Syndrome	Adenoviral species	Common serotypes involved
Epidemic keratoconjunctivitis	Human mastadenovirus D	8, 19, 37
Pharyngoconjunctival fever	Human mastadenovirus B Human mastadenovirus E	3, 4, 7, 11, 14
Nonspecific follicular conjunctivitis	Human mastadenovirus B Human mastadenovirus D Human mastadenovirus E	3, 4, 7
Chronic keratoconjunctivitis	Very rare—caused by many of the serotypes mentioned above	

protein. The toxic effect of large amounts of structural protein, as well as the immune response, may also contribute to adenoviral pathology (101,102).

#### Clinical manifestations

Ocular manifestations of adenoviral infection usually results in acute, self-limiting disease, which may vary considerably in severity. The incubation period ranges from 2 to 14 days, and viral shedding in ocular secretions occurs up to 2 weeks after onset. Symptoms vary and include pain, lacrimation, and foreign body sensations in more severe cases. Corneal involvement and anterior uveitis may produce considerable discomfort and photophobia. Vision may be reduced in acute stages by corneal epithelial and stromal inflammation and in the latter stages, by scarring. Generally the contralateral eye also becomes infected but not as severely as the primary eye (7).

Ocular manifestations of adenoviral infection are classified into four syndromes: epidemic keratoconjunctivitis (EKC), pharyngoconjunctival fever (PCF), acute nonspecific follicular conjunctivitis (NFC), and chronic keratoconjunctivitis (CKC) (Table 6) (103). In addition, adenovirus infection has been linked to acute hemorrhagic conjunctivitis.

PCF most commonly occurs in children and is usually due to serotype 3, but serotypes 1, 4, 5, 6, 7, and 14 have also been implicated. It usually presents with fever and sore throat after an incubation period of about 12 days. Ocular involvement is usually bilateral, with burning, irritation, and photophobia. A punctate keratitis may develop, followed by corneal infiltrates (103).

EKC is most commonly associated with serotype 8 and 19, although serotypes 2, 3, 4, 7 to 11, 14, 16, and 29 have also been linked. This condition is highly contagious and is most common during autumn and winter. Keratitis occurs in the minority of cases, whereas subepithelial corneal infiltrates are the hallmark of EKC; corneal infiltrates may lead to visual loss (103, 104).

Follicular conjunctivitis is the most common ocular manifestation of adenoviral infection, which usually produces a mild conjunctivitis that is self-limiting. However, conjunctival hemorrhages may occur and range from petechiae to frank subconjunctival hemorrhage. The more severe forms may also produce exudation and membrane, or pseudomembrane, formation.

Although acute disease is self-limiting, subepithelial punctate opacities may persist for weeks to years, producing the final syndrome of ocular adenoviral disease, namely CKC, which is very rare but which may result in symptoms of ocular irritation and visual disturbance.

#### Diagnosis

Diagnosis requires a thorough history and examination, looking for associated systemic features, as well as a history of

infectious contacts. Definitive laboratory diagnosis can be made with techniques such as virus isolation either by conventional culture or shell vial culture, and PCR assessment, with the latter being more sensitive and specific, thus facilitating a more rapid and reliable diagnosis (105–107).

#### Treatment

In 2015, no specific antiviral agent had yet been approved for adenoviral disease; however, brincidofovir has good *in vitro* activity with anecdotal reports of successful human therapy. At the present the most important step in the management of adenoviral conjunctivitis is prevention of transmission. Treatment is directed at symptom relief with analgesia, lubricants, and cold compressors, as well as prevention of serious sequelae. In the acute stage, antibiotic drops are often given to prevent secondary infection, and cycloplegic agents may be offered for pain relief. Generally, however, antibiotics are not indicated. Povidone-iodine drops to treat conjunctivitis are cost-effective and can be beneficial due to the broad spectrum of coverage (33).

Membranes and pseudomembranes can be managed with surgical removal and careful administration of topical steroids. Treatment of keratitis and uveitis, secondary to severe adenoviral conjunctivitis, may be managed with topical steroids but under close supervision as recurrences are possible after withdrawal of treatment (3).

#### Picornaviruses

Of the three genera within the *Picornaviridae* family that affect humans, species within the genus Enterovirus (See chapter 46) and Parechovirus are known to cause ocular disease. Ocular manifestations include conjunctivitis, keratoconjunctivitis, and uveitis (108–110). Enteroviral eye disease may result from direct inoculation via hand-to-eye contact, or may spread to the eye after initial replication in the gastrointestinal tract.

Various serotypes have been associated with conjunctivitis. Echovirus 7, 11, and others, as well as coxsackie B2, have been isolated from the conjunctiva in sporadic cases, with echovirus additionally reported to cause keratoconjunctivitis (110).

Acute hemorrhagic conjunctivitis (Figure 7) is caused by one of two enteroviruses, a variant of coxsackie A24 and enterovirus 70 (108). In addition, enteroviral uveitis, caused by echovirus 19 and two types of echovirus 11, has been reported (109).

Parechovirus, which was previously grouped under the human enteroviruses, has recently been isolated from ocular fluids in patients with uveitis (111).

#### Clinical Manifestations

Ocular infection is typically bilateral, with the usual symptoms of pain, foreign body sensation, and lacrimation.

**FIGURE 7** Haemorrhagic conjunctivitis. Courtesy of William Charles Caccamise and Ophthalmic Atlas Images by EyeRounds.org, The University of Iowa.

Clinical features include eyelid edema, follicular conjunctivitis, chemosis, and subconjunctival hemorrhages. Corneal involvement is limited to superficial epithelial keratitis, while bacterial superinfection has also been reported, particularly in patients treated with topical steroids (112).

#### Diagnosis

Diagnosis of picornaviral ocular disease is based upon clinical examination in addition to laboratory testing, such as viral isolation or PCR evaluation from conjunctival scrapings, with neutralizing antibody tests being less helpful (113).

#### Treatment

Ocular disease due to picornaviruses is usually self-limiting, allowing conservative management with cold compressors and lubrication. Various agents have been shown to inhibit enteroviral replication *in vitro*, but none are available as chemotherapeutic agents (103). Topical steroids should be avoided because of the risk of corneal perforation (33).

#### Measles

Measles virus, a member of the *Paramyxoviridae* family of single-stranded RNA viruses, is transmitted via the respiratory route and is highly contagious (114, 115). After an incubation period of 8 to 12 days, the symptoms of fever, cough, coryza, and conjunctivitis begin. The typical rash lasts for 3 to 7 days. Complications of measles may be caused by disruption of epithelial surfaces, as well as by immunosuppression (see chapter 38) (114).

The ocular manifestations of measles first appear during the prodrome and include subepithelial conjunctivitis with elevated papules (Koplik spots) (7). These may develop into epithelial keratoconjunctivitis that first appears on the exposed parts of the conjunctiva and progresses toward the centre of the cornea. Involvement of the cornea gives rise to photophobia that is characteristic of measles virus infection (7). In general, most patients will develop conjunctivitis, while keratitis occurs less often. In resource-poor countries with poor sanitation and malnutrition, particularly with vitamin A deficiency, measles may result in corneal disease with ulceration, keratomalacia, secondary bacterial infections, and corneal perforation (116). Indeed, measles virus is the most important cause of blindness in children in developing countries (115). Acute measles virus infection depresses the serum retinol concentration, which may

manifest as xerophthalmia and eventually result in blindness. Blindness may also result from cortical damage from measles encephalitis (114).

Treatment of conjunctivitis is symptomatic, and recovery is usually complete and without sequelae. In poorer countries, where measles is often associated with vitamin A deficiency, keratomalacia is a severe complication and should be treated with urgency. Systemic vitamin A supplementation is required, while local lubrication, topical retinoic acid, and sometimes surgical intervention may be required (54).

#### Poxviruses

##### Molluscum contagiosum

Molluscum contagiosum virus is a fairly common viral disease, which is spread by direct contact and causes a papular eruption on skin and mucous membranes anywhere on the body (see chapter 19) (3). In patients with HIV infection, the lesions may be atypical and extensive (117) and are recognized as an ocular complication of AIDS. Such lesions are also being reported in patients undergoing systemic steroid therapy (118). The typical umbilicated nodules are most common on the trunk or in the axilla, but the periocular skin and, rarely, the conjunctiva, may be affected (Figure 8).

The virus may affect the eyelid, conjunctiva, and cornea, predominantly in young adults (119). A unioocular chronic follicular conjunctivitis is typical and represents a reaction to virus particles shed into the tear film (7).

Most lesions resolve spontaneously over weeks. Should treatment be required, such as in highly immunosuppressed patients, options include cryosurgery or curettage. In addition, cidofovir has been shown to contribute toward clearance of advanced lesions in HIV-associated disease (120).

##### Vaccinia Virus

With the eradication of smallpox and discontinuation of vaccination programs in the 1970s, ocular disease due to vaccinia virus is rare. However, with a recent resurgence of vaccinations, several cases of ocular vaccinia have been reported (see chapter 19) (121). The clinical manifestations are more severe in immunosuppressed patients and include ulcerating eyelid pustules, blepheroconjunctivitis, eyelid edema, and papillary conjunctivitis, while corneal involvement occurs in about 30% of cases. Although ocular complications of vaccinia virus are usually self-limiting in

**FIGURE 8** Eyelid molluscum contagiosum with typical umbilicated lesion. Courtesy Jesse Vislise and Ophthalmic Atlas Images by EyeRounds.org, The University of Iowa.

immunocompetent individuals, treatment may be required in certain cases. Options include vaccinia immune globulin, which is the only FDA approved medication for the management of complications resulting from smallpox vaccination (7, 122). Experimental agents include the nucleoside analogues cidofovir and brincidofovir, which have shown *in vitro* activity against poxviruses, with the latter having less renal toxicity and greater oral bioavailability. (123,124). Another investigational agent is the compound ST-246 (tecovirimat), which inhibits the release of infectious virus from infected cells and was shown to work in animal models (125). Other agents that have activity against vaccinia are adefovir and ribavirin, which have been considered for treatment of serious complications of smallpox vaccination. (126,127).

### Human Papillomavirus

Human papillomaviruses (see chapter 29) may cause a variety of ocular epithelial disorders, including common warts on the eyelids, conjunctival papillomas in the fornices or at the limbus, conjunctival squamous cell carcinoma in associations with types 16 and 18, and non-neoplastic conditions, such as climatic droplet keratopathy (128), which is a disease characterized by accumulation of transparent material in the superficial layers of the corneal stroma (129).

Lesions occurring on the eyelids share the general histologic features of lesions occurring on other keratinizing epithelia. Eyelid lesions may be disfiguring or result in ptosis, while those on the eyelid margin may cause chronic papillary conjunctivitis or a punctate epithelial keratitis (7). While types 16 and 18 are associated with conjunctival carcinoma, types 6 and 11 cause benign papillomas (130).

Treatment of conjunctival lesions is usually by surgical excision. Adjunctive therapies include cryotherapy and cautery to the base of the lesion. Incomplete excision may result in recurrence. Recurrence or severe disease may be treated with systemic interferon or topical cytotoxic agents (7).

### Ocular Disorders Associated with Systemic Viral Illness

Numerous other viruses are reported to manifest with an ocular complication as part of the spectrum of disease. Some of these occur very rarely and include influenza virus, mumps, BK virus, human T-cell leukemia virus type 1 (HTLV-1), Rift Valley fever, dengue, Lassa virus, and other arenaviruses (131), plus other viruses more commonly associated with hemorrhagic fevers, and hepatitis C virus. Many systemic viral infections are associated with conjunctival injection and retro-orbital pain.

#### Influenza (see chapter 43)

The H7 subtype of avian influenza virus is the predominant influenza virus associated with conjunctivitis (132, 133), although this has not been a feature of the recent avian H7N9 outbreak. The commonest influenza viruses able to infect numerous ocular cell types are the highly pathogenic avian influenza viruses H7N7 and H5N1 (3, 132). The neuraminidase inhibitor oseltamivir has recently been shown to inhibit H7N7 and H7N3 replication in the ocular tissue of mice (134) and is thus a potential treatment option.

#### Mumps

Most patients with mumps present with parotitis, and complications include orchitis, oophoritis, aseptic meningitis,

encephalitis, pancreatitis and, very rarely, ocular complications (see chapter 39) (135). The most common form of ocular involvement is dacryadenitis, although conjunctivitis, which may be associated with subconjunctival hemorrhage, is not unusual (136). An association between mumps virus infection and keratitis and iritis has been reported previously (137). Corneal involvement is unilateral, along with painless interstitial keratitis. Visual acuity is usually decreased in the affected eye, but recovery is complete and long-term sequelae rare (3).

#### Human T-cell Leukemia Virus Type 1

The two important diseases caused by HTLV-1 are adult T-cell leukemia/lymphoma and HTLV-1-associated myelopathy/tropical spastic paresis (HAM/TSP), but HTLV-1 can cause uveitis (see chapter 33). The uveitis caused by HTLV-1 is characterized by granulomatous and nongranulomatous inflammation with associated vitreous opacities and retinal vasculitis in one or both eyes (138). The uveitis may occur as a primary event or may occur with HAM/TSP. Other ocular manifestations include opportunistic chorioretinal infections, lymphomatous infiltrates in patients with adult T-cell leukemia/lymphoma, retinal pigmentary degeneration, episcleritis, keratouveitis, and keratoconjunctivitis sicca in patients with HAM/TSP (3, 139). Diagnostic laboratory tests include serology for IgG and IgM, as well as PCR of blood or ocular tissues.

#### BK Virus

BK virus, a member of the *Polyomaviridae* family (see chapter 28), may reactivate under conditions of immune suppression and spread to other organs (140). Reactivation of latent infection may present as an atypical retinitis (141).

#### Hepatitis C virus

The extrahepatic complications of hepatitis C (see chapter 54) can include ocular involvement of the cornea, conjunctiva, and accessory lacrimal glands, with dry eye syndrome being a common manifestation of chronic hepatitis C. Retinal involvement has also been reported (3, 142). Treatment of chronic hepatitis C has resulted in improvement in certain ocular hepatitis C manifestations. On the other hand, treatment with interferon and ribavirin is also associated with ocular disease, including retinopathy (143).

#### Viruses Associated with Hemorrhagic Fevers

Viral hemorrhagic fevers (VHF) usually present as an acute febrile illness, characterized by increased vascular permeability, malaise, and eventually prostration. Symptoms are usually due to damage to the endothelium, which commonly is associated with conjunctival injection and may manifest with ocular symptoms (144). The filoviruses, Ebola and Marburg (see chapter 42), may cause conjunctivitis as part of the disease syndrome. In addition, the convalescent phase of Ebola virus disease has recently been associated with severe unilateral uveitis, where viable Ebola virus was isolated from aqueous humor (145). In addition to conjunctivitis, arboviruses such as Rift Valley fever virus (RVFV) (see chapter 44) and dengue (see chapter 53), may affect other parts of the eye as well.

RVFV may be associated with uveitis and chorioretinitis (146), and conjunctivitis is common, sometimes associated with subconjunctival hemorrhages. Dengue fever has also been implicated in ocular disease, albeit very rarely. Retinal and conjunctival diseases due to dengue virus infection have been reported (147).

**TABLE 7** Common congenital viral infections with ocular manifestations

Virus	Congenital ocular features
CMV	Retinitis, cataract, optic atrophy
Rubella	Pigmentary retinopathy, cataract, glaucoma, microphthalmia
VZV	Optic atrophy, chorioretinitis, cataract, microphthalmia
HSV	Ophthalmia neonatorum, keratitis, cataract, microphthalmia

CMV, cytomegalovirus; VZV, varicella zoster virus; HSV, herpes simplex virus.

Chikungunya virus (see chapter 55) may uncommonly present as a viral hemorrhagic fever. In a recent retrospective review out of India, chikungunya was also associated with ocular complications, mostly iridocyclitis, retinitis, and episcleritis (148).

### Viruses Associated with Congenital Ocular Disease

A variety of infectious agents result in congenital infection, some of which may manifest with an ocular complication. The viruses associated with congenital ocular disease are illustrated in Table 7. Although CMV, VZV, and HSV may rarely result in congenital ocular disease, congenital rubella (see chapter 56) is well known for producing ocular complications.

Approximately 10% of neonates with congenital CMV will have symptoms at birth (149). Of these, approximately 10% will present with chorioretinitis and/or optic atrophy, while the frequency of symptomatic infection has recently been shown to be similar for maternal primary infection versus reactivation (149,150). A previous study, however, found that ocular symptoms in congenital CMV were more common among patients born after a primary maternal infection than among those born after a recurrent maternal infection. (151).

Neonatal HSV may occur as a result of intrauterine infection (rare), perinatal infection (approximately 85%), or postnatal infection (approximately 10%). Ocular involvement most commonly consists of blepheroconjunctivitis or keratitis. (152).

### Congenital Rubella

The Australian ophthalmologist, Norman Gregg, first described the teratogenic effects of the rubella virus in the 1940s (153). Other than Fuchs heterochromic iridocyclitis, the ocular manifestations are generally limited to the congenital rubella syndrome (154–156). Damage to the fetal endothelial cells within the first 12 weeks of pregnancy is the result of viral replication, since the immune system has not developed by this time (157). In addition, retardation of mitosis in infected cells contributes to the pathogenesis.

In a study from the early 1990s, ocular disorders were found to be the most common signs in patients with congenital rubella syndrome (CRS) (158). Ocular defects include cataract, glaucoma, retinopathy, microphthalmia, and iris hypoplasia. The most common of these were pigmentary retinopathy and cataract. Cataracts may be bilateral, nuclear, lamellar, or total and may progress to complete opacity. Persistence of live virus in the lens after birth may result in the development of cataracts after birth in previously clear lenses (159).

Retinopathy is usually bilateral and affects the retinal pigment epithelium in isolation, resulting in widespread, irregular pigment deposits of variable size, most numerous at the macula (7). Glaucoma associated with CRS probably results from aberrant development of the anterior chamber angle, while chronic uveitis and an enlarged cataract lens may also contribute.

The diagnosis of CRS can be made by demonstrating rubella specific IgM synthesized by the fetus, which is present at birth. An absence of IgM in the neonatal period virtually excludes symptomatic CRS (157). Culture methods, as well as molecular methods such as PCR, may also be used for direct viral detection. Oral fluid, urine, blood, CSF, lens aspirates, and postmortem tissues are all suitable specimens (3).

Management of CRS is aimed at treating complications, such as performing cataract surgery, and the management of secondary glaucoma. For infections occurring after birth, which may manifest as conjunctivitis or keratitis, symptomatic treatment may be necessary, although the condition is usually self-limiting (33).

# Antiretroviral Agents

CHRISTINE J. KUBIN, BARBARA S. TAYLOR, AND SCOTT M. HAMMER

## 11

In 1987, zidovudine became the first approved agent in the United States for the treatment of human immunodeficiency virus type 1 (HIV-1) infection. Almost 30 years later, more than 26 additional agents in six drug classes have been approved. These include nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), a fusion inhibitor (entry inhibitor), a chemokine coreceptor antagonist (entry inhibitor), integrase strand transfer inhibitors (Table 1), and pharmacokinetic enhancers. This success is the result of a prodigious effort to dissect the virus' replication cycle and the virion's interaction with its CD4 target cells to identify promising drug targets. It also illustrates the interdependency of the drug development process, knowledge of disease pathogenesis, and use of sensitive therapeutic monitoring tools like plasma HIV-1 RNA levels and drug resistance testing.

The expanding availability of fixed-dose combinations (FDCs) (Table 6) has revolutionized treatment over the past 20 years by providing high potency and excellent safety profiles, simplifying treatment, improving quality of life, and facilitating adherence to therapy (Table 1). In resource-rich settings with full formulary access to approved drugs and FDCs, the expectation is that viral suppression can be achieved in more than 90% of individuals, including those with high degrees of treatment experience and multidrug-resistant virus (1).

This chapter describes the major characteristics of antiretroviral agents that are currently approved, or at a promising stage of clinical development, and is organized according to the virus' replication cycle (Fig. 1). This chapter complements chapter 34, which discusses the virologic, pathogenetic, and clinical aspects of HIV disease and in which the principles of antiretroviral treatment and the prevention of resistance are discussed.

### HIV-1 ENTRY INHIBITORS

HIV cell entry is characterized by a series of complex virus-host cell interactions that are each a potential step for inhibition. HIV entry into the CD4 cell requires nonspecific interactions with the cell surface heparin sulfates, followed by highly specific binding to the CD4 receptor and either the CCR5 or CXCR4 coreceptor, leading to conformational

change in the envelope transmembrane subunit, and finally, virus-host cell membrane fusion (2–4). Both viral envelope (gp120 and gp41) and cellular receptors (CD4 and CCR5/CXCR4) are involved in HIV fusion and entry and are attractive targets for drug development (Fig. 1) (5). Currently, two drugs are approved in this class with several others in clinical development. Selected investigational agents are summarized in Table 2.

### Enfuvirtide

Enfuvirtide (Fuzeon, T-20; formerly DP-178, pentafuside) is a membrane fusion inhibitor that interferes with HIV gp41 protein-mediated virus-cell fusion (Figs. 1 and 2). The agent is a 36-amino-acid synthetic peptide that is derived from the second heptad repeat (HR2) of HIV-1 gp41. This molecule interacts with sequences within the first heptad repeat (HR1) of the pre-hairpin intermediate, thereby perturbing the transition of gp41 into an active state (3, 23).

Enfuvirtide's 50% inhibitory concentrations (IC<sub>50</sub>) for wild-type strains average 1.7 ng/ml. Several *in vitro* studies have suggested that susceptibility to enfuvirtide may vary by coreceptor usage, but virologic and clinical outcomes do not differ by coreceptor specificity (23–25). Enfuvirtide inhibits a broad range of non-clade B viruses and strains resistant to other classes of antiretroviral agents but has no activity against HIV-2, exhibiting additive to synergistic activity when combined with members of other antiretroviral drug classes. Although enfuvirtide is a gp41 derivative, its pharmacokinetic and antiviral effects are not affected by preexisting or developing anti-gp41 antibodies.

### Pharmacology

The low oral bioavailability of enfuvirtide necessitates parenteral administration. It is available in powder form and must be reconstituted with sterile water before administration by subcutaneous injection. The current dosage in adults is 90 mg twice daily (b.i.d.) administered subcutaneously into the arm, thigh, or abdomen with all sites having comparable pharmacokinetics. The bioavailability of the 90-mg dose is about 84% with a mean steady-state trough level of 3.3 µg/ml and a mean elimination half-life ( $t_{1/2}$ ) of 3.8 h (1.8 h after intravenous dosing). The drug is approximately 92% protein bound. No dose adjustments are required in the setting of hepatic or renal impairment.

**TABLE 1** Commonly used antiretroviral agents: indications and dosing regimens

Antiretroviral agent (year approved)	HIV-1	HIV-2	HBV <sup>a</sup>	Standard adult dosing for HIV
<b>Fusion and entry inhibitors</b>				
Enfuvirtide (2003)	✓			90 mg (1 ml) s.c. twice daily <sup>b</sup>
Maraviroc (2007)	✓	✓		300 mg orally twice daily Dose adjustments: • 150 mg orally twice daily with CYP3A inhibitors • 600 mg orally twice daily with CYP3A inducers
<b>NRTIs</b>				
Zidovudine (1987)	✓	✓		300 mg orally twice daily
Lamivudine (1995)	✓	✓	✓	300 mg orally once daily or 150 mg orally twice daily <sup>c</sup>
Abacavir (1998)	✓	✓		600 mg orally once daily or 300 mg orally twice daily
Emtricitabine (2003)	✓	✓	✓	200 mg orally once daily <sup>d</sup>
Tenofovir disoproxil fumarate (2001)	✓	✓	✓	300 mg orally once daily
Tenofovir alafenamide (2015)	✓	✓		25 mg orally once daily <sup>e</sup>
<b>NNRTIs</b>				
Nevirapine (1996)	✓			Initial: 200 mg orally once daily for 2 weeks Maintenance: 400 mg once daily extended release or 200 mg orally twice daily immediate release
Efavirenz (1998)	✓			600 mg orally once daily in the evening <sup>f</sup>
Etravirine (2008)	✓			200 mg orally twice daily
Rilpivirine (2011)	✓			25 mg orally once daily <sup>g</sup>
<b>INSTIs</b>				
Raltegravir (2007)	✓	✓		400 mg orally twice daily
Dolutegravir (2013)	✓	✓		50 mg once daily <sup>h</sup>
Elvitegravir (2014)	✓	✓		150 mg once daily with cobicistat <sup>i</sup>
<b>PIs<sup>j</sup></b>				
Lopinavir/ritonavir (2000)	✓	✓		400 mg/100 mg orally twice daily
Tipranavir (2005)	✓	✓		500 mg orally twice daily
Atazanavir (2003)	✓	✓		300 mg once daily with pharmacokinetic booster 400 mg once daily without booster for ART naïve only
Darunavir (2006)	✓	✓		800 mg orally once daily ≥1 darunavir-resistance associated mutations: 600 mg twice daily
<b>Pharmacoenhancers</b>				
Ritonavir (1996)	✓	✓		100–400 mg orally per day as a pharmacokinetic booster
Cobicistat (2014)				150 mg once daily with appropriate PI or INSTIs

<sup>a</sup>Tenofovir alafenamide has activity against HBV, but is not FDA approved to treat HBV. Emtricitabine is approved for HBV treatment in combination with tenofovir disoproxil fumarate. Please see chapter 13 for comprehensive information on dosing for HBV disease. Dosing presented in this table is for HIV alone.

<sup>b</sup>s.c., subcutaneously.

<sup>c</sup>Lamivudine dosing for HBV disease without HIV infection is 100 mg once daily, see chapter 13.

<sup>d</sup>Alternative emtricitabine oral solution: 240 mg (24 ml) once daily.

<sup>e</sup>Tenofovir alafenamide is currently only available for those with CrCl ≥30 ml/minute in combination with emtricitabine, or as a single-dose formulation with elvitegravir, cobicistat, and emtricitabine.

<sup>f</sup>Efavirenz dose adjustments required if given with rifampin or voriconazole.

<sup>g</sup>Rilpivirine must be taken with a normal to high-calorie meal (at least 533 calories) to ensure absorption and cannot be given with proton pump inhibitors.

<sup>h</sup>Dolutegravir is given 50 mg twice daily for INSTI-experienced patients with certain INSTI-associated resistance mutations and when coadministered with carbamazepine, efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin.

<sup>i</sup>Elvitegravir dosing is 150 mg once daily if given with cobicistat, darunavir/ritonavir, fosamprenavir/ritonavir, or tipranavir/ritonavir. Dosing is 85 mg once daily if given with atazanavir/ritonavir or lopinavir/ritonavir.

<sup>j</sup>All protease inhibitors must be given with a pharmacoenhancer, either ritonavir or cobicistat, unless otherwise noted.

## Adverse Effects

Adverse effects include local inflammation around the injection site, which may be related to its action as a phagocyte chemoattractant and a chemotactic agonist via the phagocyte *N*-formyl peptide receptor (26). Painful, erythematous, indurated nodules have been reported to occur in as many as 98% of individuals participating in clinical studies, but this

uncommonly led to drug discontinuation (7% of subjects) or local infection (1.7%) in clinical trials. The majority of individuals experience their first injection site reaction during the initial week of treatment. Bacterial pneumonia has been reported to occur with greater frequency among patients on enfuvirtide. Risk factors for pneumonia include low initial CD4 cell count, high initial viral load, intravenous drug use,

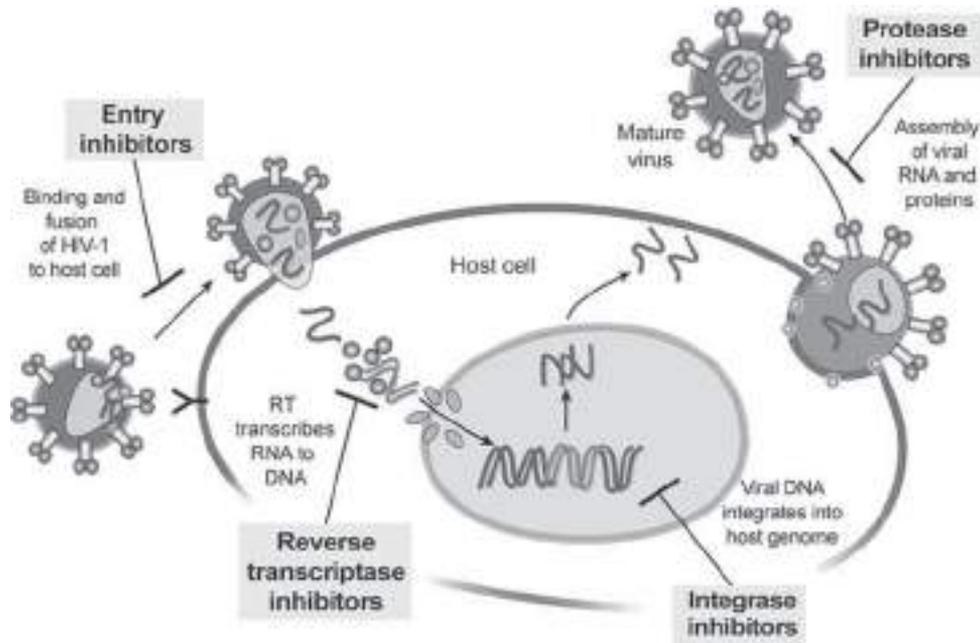

FIGURE 1. Replication cycle of HIV-1 with current targets for antiretroviral therapy.

smoking, and a history of lung disease, but direct causality has not been proven (27). Laboratory abnormalities include development of eosinophilia in 10.1%.

#### Drug Interactions

Enfuvirtide is not an inhibitor of cytochrome P450 (CYP450) enzymes. No clinically significant interactions with other antiretroviral agents have been identified to date.

#### Resistance

Resistance to enfuvirtide *in vitro* is associated with amino acid mutations at positions 36 to 43 within the first heptad repeat (HR1) target domain of gp41 (28). These changes confer alterations in HR1 binding affinities and corresponding increases, up to 34-fold, in the  $IC_{50}$  (29). Enfuvirtide has a low genetic barrier to resistance, and resistant variants appear within 2 to 4 weeks during monotherapy. In patients with early treatment failure, the most common amino acid mutations are G36D/S and V38A/M/E; mutations at codons 40 (Q40H) and 43 (N43D) seem to emerge more slowly than those at codons 36 and 38 (30). Other mutations associated with enfuvirtide resistance emerging during treatment include I37V, Q39R, and N42T (31, 32). These findings highlight the importance of combining enfuvirtide with other active agents to ensure the probability of virologic suppression. In growth competition assays, enfuvirtide-resistant isolates containing I37T, V38M, or G36S/V38M HR1 domain mutations appear to be less fit (33). The N43D single mutation confers decreased fitness for which the E137K mutation can compensate.

These mutations in the envelope gene do not appear to diminish the susceptibility of HIV-1 to other classes of viral entry inhibitors, including coreceptor (CCR5 and CXCR4) antagonists (34). In patients with virologic failure, changes other than those described for the HR1 region may contribute to the poor response (24), such as mutations or polymorphisms in the HR2 region, as well as CCR5 coreceptor usage and density (35). Increased affinity for the gp120

coreceptor is also associated with increased resistance to both enfuvirtide and maraviroc (a CCR5 antagonist) (36).

#### Clinical Applications

In treatment naïve individuals, enfuvirtide, when given as an intensification of combination therapy, neither improves the immunologic response nor reduces the latent viral reservoir (37, 38). Enfuvirtide has proven beneficial, however, in highly treatment-experienced patients when treatment options are limited. Studies of patients with preexisting multidrug class resistance have established that (i) addition of enfuvirtide to an optimized background significantly improves rates of viral suppression to <400 copies/ml and results in greater CD4 cell increases (39, 40); (ii) enfuvirtide-naïve patients who add enfuvirtide to the protease inhibitors, darunavir-ritonavir or tipranavir-ritonavir, and with raltegravir and maraviroc achieve better rates of virologic suppression to <50 copies of HIV-1 RNA/ml than patients whose optimized background did not include enfuvirtide (41, 42). The greatest benefit of enfuvirtide has been seen in patients with CD4 cell counts of >100 cells/mm<sup>3</sup>, plasma HIV-1 RNA levels <100,000 copies/ml, and at least two active drugs in the background regimen (43). The week 12 virologic and immunologic responses to enfuvirtide are highly predictive of subsequent response (44). Advances in antiretroviral therapy have marginalized the use of enfuvirtide, which is now essentially reserved for rare, difficult multidrug-resistant cases for which a suppressive oral regimen cannot be devised. Much was learned about the molecular mechanisms of HIV entry during enfuvirtide's development, however.

#### CCR5 Antagonists

The rationale for development of CCR5 antagonists in the treatment of HIV-1 infection was based on the observations that (i) R5 HIV-1 uses the CCR5 chemokine receptor for entry into human cells and (ii) a 32-bp deletion in the CCR5 coding region confers natural resistance to infection

TABLE 2 Selected investigational agents

Agent	Mechanism of action	Study phase	Comments
Fostemsavir (BMS-663068)	Attachment inhibitor	III	Attaches to gp140. Prodrug of temsavir. Active regardless of tropism. Phase IIb study compared to atazanavir/ritonavir showed similar response rates at 48 weeks (6, 7).
Cenicriviroc (CVC, TAK-652, TBR-652)	CCR5 Inhibitor	IIb	Dual inhibitor of CCR2 and CCR5. Similar viral suppression rates for patients taking 100 mg cenicriviroc (76%), 200 mg cenicriviroc (73%), and with efavirenz (71%) (8).
Ibalizumab (Hu5A8, TMB-355, TNX-355)	Entry inhibitor	III	Humanized monoclonal antibody directed at CD4 receptor. In a 24-week study of ibalizumab plus optimized background as a bi-monthly intravenous injection in treatment-experienced patients, 82.5% of patients met the primary endpoint of $\geq 0.5$ log <sub>10</sub> decrease in viral load at 7 days (9). Subcutaneous and intramuscular injection dosage forms under development.
PRO 140 (PA14)	Entry inhibitor	IIb / III	Humanized IgG4 monoclonal antibody directed against CCR5. Studied as subcutaneous injections. A phase IIb study as single-agent maintenance therapy has maintained virologic suppression for 1.5 years in some patients (10).
Sifuvirtide	Entry inhibitor	II	Peptide that is more efficient in inhibiting HIV fusion compared to enfuvirtide (11).
HGS101	Entry inhibitor	Preclinical / I	Monoclonal antibody directed at CCR5. Derivative of HGS004 that shares the same characteristics, but has 5 to 10 times the potency of the original drug HGS004. Maraviroc more active against resistant HIV-1 and more potent against sensitive HIV-1 when combined with HGS004 or HGS101 (12).
Doravirine (MK-1439)	Reverse transcriptase inhibitor	III	NNRTI. <i>In vitro</i> activity against virus with K103N and Y181C mutations. In a phase IIb study, overall treatment response at 48-weeks comparable in those treated with doravirine and those taking efavirenz (76% vs. 71%, respectively) with less drug-related adverse events including CNS adverse events in those treated with doravirine (13). Doravirine primarily metabolized by CYP3A4 without inhibitory or inductive potential.
Dapivirine (TMC120)	Reverse transcriptase inhibitor	III	NNRTI. Intravaginal ring being developed as a pre-exposure prophylaxis strategy. Reduced the incidence of HIV-1 infection by 27% compared to placebo with further reductions in patients with increased adherence (14).
Censavudine (Festinavir, BMS-986001, OBP-601)	Reverse transcriptase inhibitor	II	NRTI. Thymidine analog (derivative of stavudine) more potent against HIV-2 than HIV-1 but with potentially less toxicity than stavudine (15). Viruses with thymidine analogue mutation (TAM) pattern 1 and pattern 2 have reduced susceptibility to censavudine.
MK-8591	Reverse transcriptase inhibitor	I	Long-acting NRTI with the triphosphate form having a half-life of 150–160 h in human PMBCs. Single 10 mg dose in naïve patients resulted in a mean viral load reduction of 1.67 log <sub>10</sub> at 168 h post-dose that declined thru day 10 (16). Potential for weekly oral dosing and long-acting parenteral formulation dosed every 6 months or longer.
KM-23 (KM-023)	Reverse transcriptase inhibitor	I	NNRTI. KM-023 has demonstrated dose- and time-dependent nonlinear pharmacokinetic properties over a dose range (75–600 mg) in healthy subjects (17).
Bictegravir (GS-9883)	Integrase strand transfer inhibitor	III	Part of fixed-dose combination product containing bictegravir/emtricitabine/tenofovir alafenamide. Improved resistance profile compared to other integrase inhibitors.

(Continued)

TABLE 2 Selected investigational agents (Continued)

Agent	Mechanism of action	Study phase	Comments
Cabotegravir (S/GSK1265744)	Integrase strand transfer inhibitor	IIb	Studied as a long-acting (half-life 21–50 days) parenteral nanosuspension administered via intramuscular or subcutaneous injection and a shorter half-life (40 hours) oral dosage form. Oral cabotegravir effective as a two-drug maintenance therapy with rilpivirine from weeks 24 to 72 compared to efavirenz plus two NRTIs (68–84% vs. 63% virologic suppression at 96 weeks, respectively) (18). Intramuscular long-acting cabotegravir plus rilpivirine every 4 weeks or every 8 weeks as maintenance therapy in patients with undetectable viral loads was as effective as oral agents at 32 weeks (94–95% vs. 91% maintained viral suppression, respectively) (19).
BMS-955176	Maturation inhibitor	II	Second-generation maturation inhibitor. Activity maintained against reverse transcriptase, protease, and integrase inhibitor-resistant viruses, with EC <sub>50</sub> s similar to those for the wild-type virus (20).
GSK 2838232	Maturation inhibitor	I	IC <sub>50</sub> of 0.8–4.3 nM against a broad spectrum of 26 isolates covering a range of genotypes. Antiviral activity similar in subjects with wild-type HIV-1 or HIV-1 with Gag polymorphisms (V362, Q369, V370, and T371). Antiviral response increased with doses up to 40 mg daily, with a plateau of about 1.64 log <sub>10</sub> c/ml observed at 40–120 mg daily (21).
GS-9620	Toll-like receptor-7 (TLR-7) agonist	I	Oral toll-like receptor agonist. In a placebo-controlled study in SIV-infected rhesus macaques, the use of GS-9620 after viral suppression induced transient and variable increases in plasma SIV RNAs and found significant reductions of virus in multiple tissues (22).

CCR: C-C motif chemokine receptor; NRTI: nucleoside reverse transcriptase inhibitor; NNRTI: non-nucleoside reverse transcriptase inhibitor; PMBC: peripheral blood mononuclear cell.

with R5 virus; and (iii) individuals failing to express the receptor are otherwise well (45–48). The current therapeutic niche of CCR5 inhibitors is as one component of combination regimens for patients with multidrug-resistant R5 virus. These agents are not active against HIV-1 strains that use CXCR4 (49).

### Maraviroc

Maraviroc {4,4-difluoro-N-[(1S)-3-[(1S,5R)-3-(3-methyl-5-propan-2-yl-1,2,4-triazol-4-yl)-8-azabicyclo[3.2.1]octan-8-yl]-1-phenylpropyl]cyclohexane-1-carboxamide; Selzentry, UK-427,857} (Figs. 1 and 2) is a selective, slowly reversible antagonist that blocks the interaction between HIV-1 gp120 and the chemokine receptor CCR5 on host cells (50), thereby preventing gp41 from inserting the fusion peptide into the host cell membrane. Maraviroc is only active against CCR5-tropic virus, and patients should be screened for their virus coreceptor tropism before initiating treatment with maraviroc. Maraviroc is the only antiretroviral drug of its class yet approved. *In vitro*, maraviroc demonstrates no antagonism with existing antiretroviral agents and additive or synergistic activity in combination with enfuvirtide.

### Pharmacology

Formulations of maraviroc include 150- and 300-mg film-coated tablets. The recommended dosage is 150, 300, or 600 mg b.i.d., depending on the CYP3A inhibitory and induction

potential of concomitant therapy. The bioavailability of the 100-mg dose is 23%, and that of the 300-mg dose is predicted to be 33%. Coadministration of this agent with a high-fat meal reduces its area under the concentration-time curve (AUC) by 33%, although in clinical trials the antiviral effects of maraviroc have not been affected by food. It can therefore be administered without food restrictions. Approximately 76% of the drug is protein bound, and it has a volume of distribution of approximately 194 liters. The plasma elimination  $t_{1/2}$  of the 300 mg b.i.d. dosage regimen is around 14–18 h. It is primarily excreted via feces, with only a limited amount of renal excretion (25%). Drug concentrations and associated adverse effects may be increased in patients with either renal impairment [Creatinine clearance (CrCl) < 50 ml/min] or concomitant administration of CYP3A inhibitors (51).

### Adverse Effects

Hepatotoxicity has been reported with maraviroc. Evidence of a systemic allergic reaction (e.g., pruritic rash, eosinophilia, or elevated immunoglobulin E) may occur before the development of hepatotoxicity. The safety of this agent has not been adequately studied in patients with significant underlying liver disease, including concomitant hepatitis B or C virus infection, and caution is advised in such patients. Five-year clinical trial follow-up data suggest hepatic events are uncommon (52). An increase in cardiovascular events

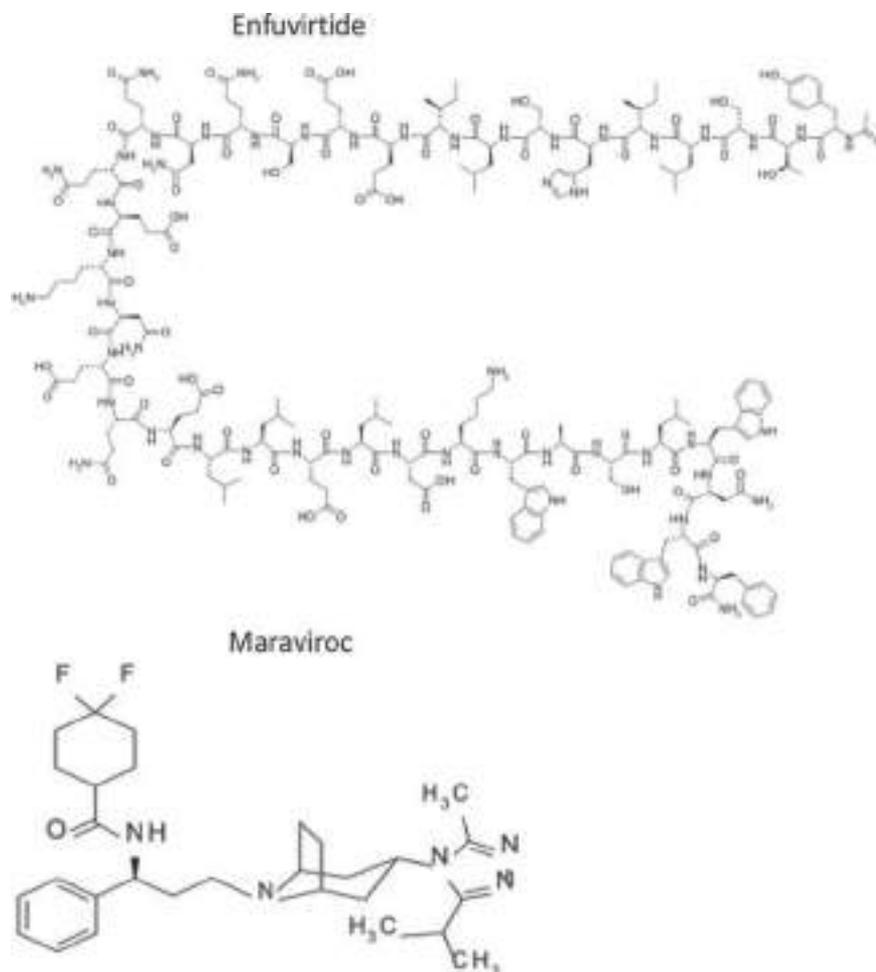

FIGURE 2. Chemical structures of HIV entry inhibitors.

(1.3%) was seen in clinical trials compared with placebo. Other more common adverse events reported were cough, pyrexia, upper respiratory tract infections, rash, musculoskeletal symptoms, abdominal pain, and dizziness, but these were infrequently associated with the need to discontinue maraviroc. Maraviroc does not adversely affect lipid profiles.

The consequences of targeting a CCR5 coreceptor on host defenses, particularly in the setting of underlying immunodeficiency, remain uncertain (47). The possibility that pharmacological blockade might increase the risk of opportunistic events, including malignancies, has not been substantiated in long-term safety data to date (52). An increase in susceptibility to severe West Nile virus infection and tick-borne encephalitis in European populations is a concern with pharmacological blockade of CCR5, given the reports of this complication in individuals who do not express an intact CCR5 coreceptor (53, 54).

#### Drug Interactions

Maraviroc is metabolized by CYP3A, so inhibitors of CYP3A (e.g., ketoconazole, lopinavir-ritonavir, ritonavir, atazanavir, clarithromycin) increase the concentrations of maraviroc in plasma, while CYP3A inducers (e.g., efavirenz, rifampin, phenytoin, St. John's wort) decrease maraviroc exposure. Maraviroc is not an inhibitor or inducer and will

not cause clinically significant changes in concentrations of other drugs metabolized by this route.

#### Resistance

Two mechanisms of resistance to maraviroc have been described. Individuals with a subpopulation of CXCR4-tropic virus at baseline demonstrate a reduced virologic response to maraviroc (55). CXCR4- or dually tropic virus may emerge from a preexisting reservoir of X4 virus not detected before the initiation of treatment (56). The primary mechanism of *de novo* resistance in clinical isolates derived from maraviroc-treated patients is not related to conversion of R5 to X4 viruses *per se* although outgrowth of preexistent X4 populations can occur. Rather, R5 virus can acquire mutations that allow it to utilize the CCR5 coreceptor even in the presence of bound drug (57). Two or three amino acid mutations in the V3 loop region of the gp120 envelope allow the protein to interact with CCR5 in the drug-bound conformation and are the most likely cause of the resistance phenotype. The  $IC_{50}$  may not shift with maraviroc resistance; rather, a subset of the virus population attaches to the drug-bound coreceptor, resulting in a flattening of the high end of the susceptibility curve (57). Examining the entire susceptibility curve and reporting  $IC_{90}$  is more helpful in this circumstance.

### Clinical Applications

Maraviroc is approved as part of combination treatment of HIV-1 infected patients with pure CCR5-tropic virus. However, it is not recommended as first-line treatment because it requires twice-daily dosing and does not have virologic benefits equivalent to other regimens. A trial comparing maraviroc and efavirenz-based therapy for treatment naïve patients with CCR5-tropic virus was discontinued early for not meeting prescribed efficacy criteria (58). *Post hoc* efficacy analysis at 48 weeks demonstrated non-inferiority to efavirenz in those patients with CCR5-tropic virus confirmed using a more sensitive tropism assay (59), and long-term safety and efficacy were comparable to efavirenz at five years (60).

In treatment-experienced patients, two large efficacy trials have demonstrated significantly higher rates of virologic suppression to HIV-1 RNA levels of <50 copies/ml and higher mean increases in CD4 cell counts in the maraviroc group than in the placebo group. Among patients who experienced virologic failure on maraviroc, the majority harbored X4 virus at baseline. It is therefore important to use the most sensitive tropism assay available to the clinician when contemplating use of maraviroc.

CXCR4-tropic or dually tropic virus emerges more frequently in patients with disease progression and with antiretroviral treatment experience (61). Patients infected with CXCR4-tropic, mixed-tropic, or dually tropic virus do not derive benefit from the addition of maraviroc to their regimen as do those with pure R5 virus. Of note, 44% of screened patients in the major efficacy trials harbored CXCR4-tropic or dually/mixed-tropic virus, and among treatment-experienced patients or those with first-line regimen failure, the prevalence of dually tropic virus is even higher (25, 62).

Maraviroc has also been tested in preexposure prophylaxis in HIV-negative persons (63). In a study of 406 men who have sex with men (MSM), maraviroc was shown to be safe and well tolerated in a double-blind, placebo-controlled trial which compared maraviroc, maraviroc-tenofovir disoproxil fumarate (TDF), and emtricitabine/TDF. No judgment could be made regarding efficacy since the study was not powered to detect differences in HIV-1 acquisition. The viral isolates from five seroconverters were R5 and drug-susceptible.

### INVESTIGATIONAL HIV-1 ENTRY INHIBITORS

A number of investigational agents are in various stages of clinical and preclinical testing in 2016 (Table 2). They include two promising agents in later stages of development, (i) an attachment inhibitor (fostemsavir; BMS-663068) which blocks the gp120-CD4 interaction, and (ii) a humanized anti-CD4 monoclonal antibody (ibalizumab; TNX-355; TMB-355). In phase 2 testing, fostemsavir (in combination with raltegravir and TDF) yielded a similar virologic response rate at 24 weeks (61–82%) compared to ritonavir-boosted atazanavir (71%; with the same background regimen) with fewer adverse effects. In treatment-experienced patients in combination with optimized background therapy, intravenous ibalizumab resulted in as much as a 0.96 log<sub>10</sub> reduction in the HIV-1 RNA level at 48 weeks. It is in phase 3 testing and can be obtained through an expanded access program (ClinicalTrials.gov NCT02707861); (iii) PRO-140, a humanized monoclonal antibody directed at the

CCR5 coreceptor which has shown antiviral activity (1.0–1.5 log<sub>10</sub> reductions in plasma HIV-1 RNA levels) and safety in human trials to date (64–70).

### BROADLY NEUTRALIZING MONOCLONAL ANTIBODIES

HIV-infected individuals with chronic antigen exposure may produce highly potent, broadly neutralizing, cross-subtype antibodies through somatic hypermutation (71, 72). These antibodies are of great interest in preventive vaccine research. The technology for isolating these antibodies has progressed, and dozens of these broadly neutralizing monoclonal antibodies (bnAbs) have been characterized. A fraction of these have reached clinical testing for pharmacokinetics, safety, and *in vivo* anti-HIV activity (73–81). Combinations of bnAbs, bispecific bnAbs, and bnAbs in combination with long-acting antiretroviral agents (e.g., cabotegravir, rilpivirine-LA), are also under consideration (82–84). One bnAb, VRC01, directed at the CD4 binding site, has recently entered phase 2b, efficacy testing in persons at risk for HIV-1 acquisition in the Americas and southern Africa (85). For further discussion of HIV monoclonal antibodies in the context of vaccine development, please see chapter 34.

### NUCLEOSIDE ANALOG REVERSE TRANSCRIPTASE INHIBITORS

Reverse transcriptase catalyzes the conversion of single-stranded genomic viral RNA into double-stranded DNA with duplicated long terminal repeats, which is subsequently integrated into cellular DNA by the viral integrase enzyme. The mature p66/p51 heterodimeric reverse transcriptase is generated by the viral protease from a homodimer by cleavage of the C-terminal RNase H domain during maturation of the viral particle. The polymerase and RNase H catalytic sites are located on p66, while p51 plays a structural role. Nucleoside analogs require intracellular triphosphorylation by host cell enzymes before incorporation by reverse transcriptase into the growing chain of viral DNA. All the currently approved nucleoside analogs target the polymerase activity of the reverse transcriptase. As with the other nucleoside analogs, the HIV-1-inhibitory concentrations of NRTIs *in vitro* depend on a number of factors, including the assay system, cell type, and virus isolate used. The pharmacology and adverse effects of these agents are summarized in Table 3.

As more potent, less toxic, and simpler regimens have moved up the priority list, others have either been discontinued or are rarely used. For agents in this category (e.g., zalcitabine, stavudine, didanosine) please see the previous edition of this chapter. An exception is being made for zidovudine given its historic significance and the fact that it is still in use globally.

#### Zidovudine

Zidovudine (3'-azido-3'-deoxythymidine; azidothymidine, Retrovir) (Figs. 1 and 3; Tables 1 and 3) is a synthetic thymidine analog with an azido group substituting for the 3'-hydroxyl group on the ribose ring. In peripheral blood lymphocytes, zidovudine has an IC<sub>50</sub> for HIV-1, which ranges between 3 and 13 µg/ml. It has *in vitro* inhibitory activity against other retroviruses, including HIV-2 and human T lymphotropic virus type 1 (HTLV-1).

**TABLE 3** Commonly used reverse transcriptase inhibitors: pharmacokinetic, major toxicity, and drug interaction characteristics

Agent	Oral bioavailability	Effect of food on AUC	$t_{1/2}$ (intracellular $t_{1/2}$ ), h	Major route of elimination	Adjust for renal insufficiency	Major toxicities	Major drug interactions
Zidovudine	64%	Modest decrease	1 (3)	Major inactive metabolite, G-zidovudine is renally excreted	Yes	Neutropenia, anemia, myopathy, nausea, headache, lactic acidosis, and hepatic steatosis (rare)	Myelosuppressive agents (e.g., ganciclovir): increased risk of neutropenia, anemia Rifampin, rifabutin: decreased zidovudine levels Probenecid, valproic acid, atovaquone, fluconazole, phenytoin, methadone: increased zidovudine levels
Lamivudine	86%	No	3–4 (10.5–15.5)	Mainly renally excreted unchanged	Yes	Peripheral neuropathy and pancreatitis in pediatric patients	No known significant interactions
Abacavir	83%	No	1.2 (20.9)	Metabolized by alcohol dehydrogenase and glucuronyl transferase to inactive forms which are then mainly renally excreted	No	Potentially fatal hypersensitivity reaction in 3% of cases. Asthenia, abdominal pain, headache, diarrhea, dyspepsia, and transaminitis are also reported	Methadone: decreased levels by abacavir and decreased abacavir levels
Emtricitabine	93%	No	10 (>20)	Renally excreted	Yes	Headache, nausea, insomnia; lactic acidosis and hepatomegaly with steatosis (rare), hyperpigmentation of palms and soles	No known significant interactions
Tenofovir disoproxil fumarate	>25%	Increase	>12	Mainly renally excreted unchanged	Yes	Neutropenia, headache, fatigue, renal insufficiency, bone density loss	May decrease levels of atazanavir; administer 300 mg of atazanavir with 100 mg of ritonavir when used as part of a tenofovir-containing regimen
Tenofovir alafenamide	unknown	Absorption increased >85% with high fat meal	0.5 (150-180)	CatA in PBMCs, then hepatic (carboxyesterase 1)	No, not recommended for CrCl <30ml/min	Nausea, less decrease in renal function and bone mineral density	Tipranavir-ritonavir, carbamazepine, oxcarbazepine, phenobarbital, phenytoin, rifamycins, St. John's wort: decreased tenofovir alafenamide levels Ritonavir, cobicistat: increased tenofovir alafenamide levels

(Continued)

**TABLE 3** Commonly used reverse transcriptase inhibitors: pharmacokinetic, major toxicity, and drug interaction characteristics (*Continued*)

Agent	Oral bioavailability	Effect of food on AUC	$t_{1/2}$ (intracellular $t_{1/2}$ ), h	Major route of elimination	Adjust for renal insufficiency	Major toxicities	Major drug interactions
Nevirapine	>90%	Not available	>24	Hepatic (CYP450 system)	No	Rash, including Stevens-Johnson syndrome; fever; myalgias; hepatic toxicity, including acute hepatic failure	Etravirine, methadone: decreased levels by nevirapine Rifabutin, rifampin: decreased nevirapine levels Fluconazole: increased nevirapine levels
Efavirenz	40–50%	A high-fat meal increases the oral bioavailability in humans by 50%	40–55	Hepatic enzymes CYP3A and CYP2D6	No	Rash, CNS symptoms (e.g., dizziness, abnormal dreams), hepatotoxicity	Lopinavir/ritonavir, atorvastatin, carbamazepine, diltiazem, methadone, rifabutin, simvastatin: decreased levels by efavirenz Carbamazepine, phenobarbital, phenytoin, rifampin: decreased efavirenz levels
Etravirine	Unknown	Food increases oral bioavailability; should be taken following a meal	41	Hepatic (CYP450 system)	No	Nausea, rash	Efavirenz, clarithromycin, rifabutin: decreased levels by etravirine Clarithromycin, fluconazole, voriconazole: increased etravirine levels Lopinavir/ritonavir, ritonavir, nevirapine, tipranavir, rifabutin, rifampin: decreased etravirine levels

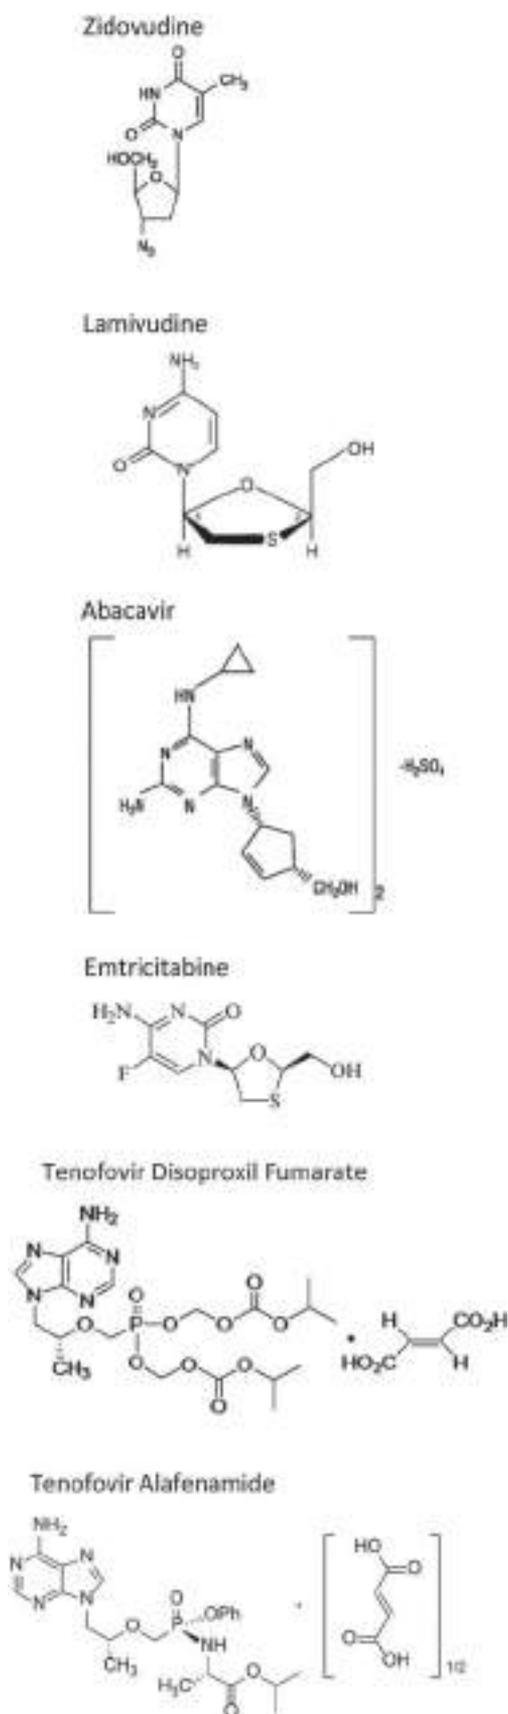

FIGURE 3. Chemical structures of HIV nucleoside/nucleotide reverse transcriptase inhibitors.

### Mechanism of Action

The antiviral activity of zidovudine is mediated by its intracellular 5'-triphosphate derivative. The mono- and diphosphate forms of zidovudine are generated by cellular thymidine and thymidylate kinases, respectively. The formation of zidovudine diphosphate appears to be a rate-limiting step, as reflected by higher intracellular zidovudine monophosphate levels due to inhibition of thymidylate kinase. The final phosphorylation is completed by a cellular nucleoside diphosphate kinase. Zidovudine triphosphate then acts as a competitive substrate for the HIV reverse transcriptase and is incorporated into the elongating 3' end of the yet-unintegrated proviral DNA. This results in the premature termination of chain elongation due to the inability of the nucleoside analog to form a normal 3'-5' phosphodiester linkage.

Zidovudine and the other nucleoside analogs often vary in their antiviral activities across different primary cell types *in vitro*. Zidovudine is more potent in activated cells than nonactivated cells. The thymidine kinase required for zidovudine phosphorylation is an S-phase-specific enzyme and thus has increased activity in stimulated cells and lowered activity in resting cells.

### Pharmacology

Zidovudine is available in capsule, syrup, and intravenous formulations and in fixed-dose combinations with lamivudine (Combivir) and with abacavir and lamivudine (Trizivir), with no differences in bioavailability or side effects compared to each of the drugs taken separately. The oral forms of zidovudine are rapidly absorbed and undergo extensive first-pass metabolism. The resulting oral bioavailability is ~64%, and food has no significant impact on oral absorption. Zidovudine reaches a plasma  $C_{max}$  at 0.5 to 1.5 h after a 200-mg dose. The mean  $t_{1/2}$  of zidovudine in serum is approximately 1 h after oral dosing, but the intracellular  $t_{1/2}$  of zidovudine 5'-triphosphate is approximately 3 hours.

Zidovudine has limited plasma protein binding (30–38%). Cerebrospinal fluid (CSF)-to-plasma ratios vary widely (15 to 135%) but average 50% 2 to 4 hours after dosing. The median CSF drug concentrations in adults is 74  $\mu\text{g/l}$  and independent of dose over a dose range of 200 to 1,250 mg. Drug appearance in semen correlates with clearance/suppression of infectious HIV-1 from that compartment. The semen/blood ratios of the concentrations of zidovudine, amprenavir, and lamivudine average 12.9, <1, and 5.3, respectively (86). Zidovudine levels in breast milk and serum are comparable after a single dose. Zidovudine rapidly crosses the placenta by passive diffusion; fetal and maternal concentrations are proportional. Pregnancy does not appear to alter the pharmacokinetics of zidovudine.

Zidovudine is predominantly metabolized hepatically by a uridine diphosphoglucuronosyl transferase (UGT) to its major active metabolite, zidovudine glucuronide, which undergoes renal elimination with a plasma  $t_{1/2}$  of 0.61 to 1.73 hours. Urinary recoveries of zidovudine and the glucuronide are 14 and 74%, respectively. Patients with hepatic dysfunction have 2- to 3-fold increases in the peak plasma zidovudine level and elimination  $t_{1/2}$  (87). The metabolism of zidovudine also leads to the formation of a minor but cytotoxic compound, 3'-amino-3'-deoxythymidine, which may be partially responsible for the hematologic adverse effects of zidovudine (87). This metabolite has a plasma  $t_{1/2}$  of approximately 2.7 h. Renal dysfunction (mean CrCl, 18 ml/min) doubles zidovudine's AUC; total reduced daily dosages of 300 to 400 mg are therefore recommended for

patients with severe renal impairment (CrCl < 15 ml/min). Although zidovudine glucuronide is effectively removed by dialysis, negligible amounts of zidovudine are cleared by either hemodialysis or peritoneal dialysis, and a dose adjustment is recommended in these patients.

### Adverse Effects

The most prominent zidovudine toxicities are neutropenia and anemia, which occur at higher doses in 16% and 24% of patients, respectively. In zidovudine-induced anemia, the reticulocyte count is usually depressed and the erythropoietin level is elevated, suggesting inhibition of erythroid stem cell lines. Myelosuppression has been associated with increased doses and duration of zidovudine exposure, as well as with lower baseline hematologic parameters (e.g., CD4 cell count, neutrophil count, hemoglobin concentration, and vitamin B<sub>12</sub> levels).

Anemia occurs as early as 2 to 4 weeks after initiation of therapy and in nearly 7% of patients with advanced HIV disease, compared to 1% in those with early asymptomatic infection. Although macrocytosis (elevated RBC mean cell volume) occurs in more than 90% of zidovudine recipients, it does not correlate with the development of anemia. Neutropenia is also seen more frequently in advanced HIV infection (37%) than in the early stages (8%) and is usually detected within 6 to 8 weeks after initiation of therapy. In addition to zidovudine dose reduction or discontinuation, management options for zidovudine-related hematologic toxicity include the use of hematopoietic growth factors (erythropoietin or granulocyte colony-stimulating factors).

Zidovudine is also associated with both skeletal and cardiac muscle toxicities. Zidovudine-related polymyositis occurs in approximately 6 to 18% of patients who have been treated for more than 6 months. Clinically, this myopathy is manifested by the insidious onset of myalgias, muscle tenderness, and proximal-muscle weakness, mainly in the lower extremities. Diagnostic features include elevated creatine phosphokinase levels and a myopathic pattern on electromyography. Muscle biopsy reveals minimal to moderate inflammation and myonecrosis with an excess of abnormal mitochondria and a decrease in mitochondrial DNA, probably secondary to the inhibition of DNA polymerase  $\gamma$ . The cessation of zidovudine treatment usually results in a gradual resolution of these abnormalities over the ensuing 6 to 8 weeks.

Nausea, abdominal discomfort, headache, insomnia, malaise, and fatigue are relatively common side effects. These are early symptoms in a substantial number of patients, but often resolve despite continued drug administration. Gastrointestinal effects such as bloating, dyspepsia, hepatitis, and esophageal ulceration have also been described. Zidovudine can cause nail and skin hyperpigmentation. Zidovudine-related seizures and macular edema have been reported as have sometimes fatal cases of lactic acidosis characterized by elevated liver transaminase levels and hepatomegaly due to steatosis.

Zidovudine has been associated with abnormalities of body fat distribution and lipid metabolism (88). In a key study comparing zidovudine/lamivudine with tenofovir/emtricitabine, each with efavirenz in treatment-naïve patients, more patients taking zidovudine experienced loss of limb fat as assessed by dual-energy X-ray absorptiometry scans than in the tenofovir arm. No teratogenicity in human studies has been reported thus far; zidovudine is mutagenic and carcinogenic in rodents.

### Drug Interactions

Agents that interfere with the hepatic metabolism or renal excretion of zidovudine can accentuate zidovudine-associated toxicities. Probenecid increases zidovudine levels by inhibiting glucuronidation and renal excretion. Valproic acid, atovaquone, fluconazole, and methadone have been associated with increased zidovudine levels while rifampin and phenytoin can lower zidovudine concentrations. Other drugs which also have myelosuppressive effects, such as ganciclovir, dapsone, flucytosine, and oncological chemotherapeutic agents, may add to the hematologic adverse effects of zidovudine.

### Resistance

There are three pathways to zidovudine resistance that can affect multiple NRTIs. In the first, thymidine analog mutations (TAMs) evolve in one of two distinct pathways: (i) T215Y alone or with M41L, L210W (TAM1) and (ii) T215F, which commonly occurs with D67N, K70R, and K219Q or E (TAM2) (89, 90). The level of zidovudine resistance increases with the accumulation of mutations in reverse transcriptase, and susceptibility to most other NRTIs is affected. Two additional multi-nucleoside resistance mutational pathways have been described that confer resistance to multiple NRTIs. The 151 complex affects all NRTIs except tenofovir-based NRTIs: tenofovir disoproxil fumarate and tenofovir alafenamide fumarate. The 151 complex includes A62V, V75I, F77L, F116Y, and Q151M, with the Q151M mutation being the critical mutation for multidrug resistance. The second pathway is the 69 insertion complex, a 2-amino-acid insertion at reverse transcriptase position 69, along with one or more TAMs: M41L, A62V, K70R, L201W, T215 Y or F, and K219 Q or E (28, 91). This mutational complex confers resistance to all current NRTIs. Other amino acid changes at codon 69, without the insertion, can also be associated with resistance to multiple NRTIs.

Two mechanisms of resistance to zidovudine illustrate the complexity of resistance mutational interactions: (i) impairment of the incorporation of the analog into DNA; and (ii) removal of the analog from the prematurely terminated DNA chain (92, 93). Thymidine analog mutations at positions 41, 67, 210, 215, and 219 promote ATP-mediated pyrophosphorolysis with excision of the incorporated terminator (94). The M184V mutation, most associated with lamivudine and emtricitabine resistance, severely compromises pyrophosphorolysis and can result in a resensitization of the virus to zidovudine and other NRTIs, including tenofovir, affected by this pathway of resistance (95).

Most resistance assays evaluate the polymerase domain and do not assess resistance mutations in the connection and RNase H domains of the HIV-1 reverse transcriptase. RNase H cleaves the RNA template as the DNA reverse transcript elongates. Mutations in the RNase H domain increase NRTI resistance, probably by decreasing RNase H activity, allowing more time for excision of zidovudine (96). The clinical relevance of these mutations remains unclear and is complicated by subtype-specific variations in mutations selected in treatment-experienced patients (97). Some mutations, particularly in combination with M184V or other TAMs, can confer reduced susceptibility to zidovudine and nevirapine *in vitro* (98), but thus far they have not been shown to impact response to antiretroviral therapy (99).

### Clinical Applications

Zidovudine was the first approved antiretroviral agent and for two decades was one of the agents most widely studied in

clinical trials and used in clinical practice. Zidovudine in combination with another nucleoside analog and either a protease inhibitor (with or without ritonavir enhancement) or a NNRTI became one of the standard-of-care regimens in the era of potent antiretroviral therapy beginning in 1996. As part of initial therapy, the combination of zidovudine and lamivudine was a key dual-NRTI component in multiple clinical trials and demonstrated considerable durability, tolerability, and clinical benefit (100–102).

Comparison of zidovudine with abacavir, in combination with lamivudine and efavirenz, showed similar virologic response in both arms; however, the CD4 cell count rise was greater in the abacavir/lamivudine-treated patients than in the zidovudine/lamivudine-treated patients (103). A comparison of zidovudine/lamivudine with tenofovir/emtricitabine as part of an efavirenz-based regimen in treatment-naïve patients demonstrated lower rates of virologic suppression to <50 copies/ml and higher rates of anemia with the zidovudine regimen (104). Zidovudine/lamivudine has been supplanted by tenofovir/emtricitabine and abacavir/lamivudine as recommended dual-nucleoside components of initial combination regimens for treatment-naïve patients (105).

Zidovudine was the first antiretroviral agent evaluated as a prophylactic agent in HIV-infected pregnant women and accidentally exposed health care workers. In a landmark study (ACTG 076), zidovudine reduced the risk of mother-to-child transmission of HIV-1 by two-thirds compared to placebo (106). For accidentally exposed health care workers, a retrospective case control study found that zidovudine reduced the hazard of HIV transmission by 81% (107). Combination therapy is now, of course, recommended when HIV-1 prophylaxis is indicated.

### Lamivudine

Lamivudine [2',3'-dideoxy-3'-thiacytidine; Epivir (Figs. 1 and 3; Tables 1 and 3)] is the (–) enantiomer of a cytidine analog with a sulfur substituted for the 3' carbon atom in the furanose ring. To streamline the dosing of the nucleoside analog component of combination therapy, fixed-dose formulations of lamivudine/zidovudine (Combivir), lamivudine/zidovudine/abacavir (Trizivir), lamivudine/abacavir (Epzicom), and lamivudine/abacavir/dolutegravir (Triumeq) in single tablets have been approved. The standard dosage of lamivudine is 150 mg twice daily or 300 mg once daily.

Lamivudine displays activity against HIV-1 and -2, as well as hepatitis B virus (HBV). Inhibitory concentrations range from 0.46 ng/ml to 3.45 µg/ml in *in vitro* susceptibility assays. Synergy has been noted in combination with the thymidine analogs and tenofovir.

### Mechanism of Action

Although both lamivudine enantiomers have *in vitro* antiviral activity, the (–) enantiomer form is both more potent, possibly on the basis of its resistance to 3'–5' exonuclease excision, and less cytotoxic because (–) enantiomers of nucleosides are poorly recognized by mammalian polymerases. Lamivudine requires phosphorylation to the triphosphate metabolite for antiviral activity; the triphosphate competitively inhibits the viral reverse transcriptase and interrupts proviral DNA chain elongation.

### Pharmacology

Oral lamivudine is rapidly absorbed, and bioavailability in adults is approximately 86%. Peak plasma concentrations

range from 2.6 to 5.8 µg/ml after a 300-mg dose. Although absorption of lamivudine is slowed in the postprandial state, there is no significant decrease in the AUC with food. Lamivudine has low protein binding (<36%). The mean plasma elimination  $t_{1/2}$  is approximately 2 to 4 hours, but the intracellular  $t_{1/2}$  of lamivudine triphosphate varies between 10.5 and 15.5 hours. As a consequence of predominant renal elimination of lamivudine via glomerular filtration and active tubular excretion, dose adjustments are required in individuals with renal impairment.

### Adverse Effects

Lamivudine has a very favorable toxicity profile and is well tolerated at dosages ranging from 0.5 to 20 mg/kg/day (108). A trend toward neutropenia is seen only with the highest doses. Insomnia, headache, diarrhea, abdominal pain, and pruritus have been reported but are infrequent (108). Reports of rash, arthralgias, myalgias, pancreatitis, hepatitis, and peripheral neuropathy have an unclear association with lamivudine in adults. In children, rare associations of pancreatitis or hepatitis with lamivudine have been noted.

### Drug Interactions

Trimethoprim-sulfamethoxazole decreases the renal clearance of lamivudine and consequently increases its systemic exposure (109). Lamivudine and emtricitabine have nearly identical resistance profiles, have minimal additive antiviral activity, and should not be used together.

### Resistance

Resistance to lamivudine develops rapidly and uniformly in treated patients who are not on a fully suppressive antiretroviral regimen or who are poorly adherent through mutations at two codons: 65 and 184. K65R/E/N conveys resistance to lamivudine, as well as several other NRTIs. Mutations at codon 184 that lead to either an isoleucine or a valine substitution for methionine occur rapidly and confer 100- to 1,000-fold decreases in susceptibility (110). The M184V mutation generates lamivudine resistance by decreasing the efficiency of incorporation of lamivudine monophosphate 20- to 100-fold relative to those of the wild-type reverse transcriptase HIV strains (95).

There are potentially beneficial impacts of the M184V mutation. It reverses reduced susceptibility to the thymidine analogs and tenofovir conferred by the TAMs. The M184V mutation, although decreasing the rate of incorporation of lamivudine monophosphate and conferring lamivudine resistance, also reduces pyrophosphorolytic rescue of viral DNA synthesis from chain-terminating zidovudine triphosphate (95). The presence of M184V is also associated with a reduction in viral fitness (111). These effects may, in part, underlie the efficacy of combination therapy of lamivudine or emtricitabine with thymidine analogs and tenofovir.

Although low-level cross-resistance (2- to 4-fold) has been noted with M184V for didanosine and abacavir, the presence of the M184V mutation in isolation does not appear to compromise treatment with didanosine- or abacavir-containing regimens (112, 113). The multidrug-resistance mutations and mutation clusters that impact most NRTIs (69 insertion complex, 151 complex, and TAMs) may also confer various degrees of cross-resistance with lamivudine.

### Clinical Applications

Lamivudine (or emtricitabine; see below) is a key component of current initial regimens in treatment-naïve persons

with drug-susceptible virus because of its potency and excellent tolerability. It is typically combined with abacavir or tenofovir (in the case of emtricitabine) to form the dual-nucleoside component of recommended treatment regimens. In patients with viruses containing M184V, there may be a benefit in continuing lamivudine to maintain this mutation because viruses with M184V replicate less well than wild-type viruses when a fully suppressive new regimen cannot be constructed (114). Lamivudine and emtricitabine are essentially clinically interchangeable; the choice depends on which nucleoside or nucleotide analog it is paired with, given the availability of fixed-dose combinations.

### Abacavir

Abacavir sulfate [(1S-cis)-4-[2-amino-6-(cyclopropylamino)-9H-purin-9-yl]-2-cyclopent-1-methanol; Ziagen] is a carbocyclic guanine analog (Figs. 1 and 3; Tables 1 and 3). It is available as both a 300 mg tablet and a 20 mg/ml solution, as well as in fixed-dose formulations as lamivudine/abacavir (Epzicom), zidovudine/lamivudine/abacavir (Trizivir), and lamivudine/abacavir/dolutegravir (Triumeq). Abacavir has an  $IC_{50}$  of 0.07  $\mu$ g/ml in human peripheral blood lymphocytes for HIV-1 strains, being additive with NNRTIs, PIs, and other nucleoside analogs.

### Mechanism of Action

Abacavir undergoes intracellular metabolism to its active triphosphate form, which interrupts HIV proviral DNA chain elongation. However, abacavir is also a prodrug that, prior to triphosphorylation, requires modification to carbovir. Thus, abacavir activation is characterized by an initial phosphorylation by adenosine phosphotransferase to a monophosphate form, which is then further processed by a cytosolic 5'-nucleotidase to produce carbovir monophosphate; the latter is subsequently converted to di- and triphosphates of carbovir by cellular kinases.

### Pharmacology

Abacavir sulfate is well absorbed, with an oral bioavailability of 83% with no important food effects. Similar pharmacokinetic profiles are seen with the abacavir/zidovudine/lamivudine fixed-dose formulation as well as if the three drugs are given separately. The serum  $C_{max}$  of 2.87 and 4.73  $\mu$ g/ml are attained in less than 2 h after dosages of 300 mg b.i.d. and 600 mg, respectively. As the most lipophilic of the nucleoside analogs, abacavir exhibits good central nervous system (CNS) distribution, with mean levels in CSF that are twice the  $IC_{50}$  for wild-type HIV-1 and CSF-to-plasma AUC ratios ranging from 27% to 33% (115). Despite a plasma elimination  $t_{1/2}$  of 1.2 h for abacavir, the intracellular  $t_{1/2}$  of carbovir triphosphate at an abacavir dosage of 300 mg/day is 20.6 h. Thus, the prolonged intracellular  $t_{1/2}$  of the active carbovir triphosphate supports the approved twice or once-daily dosing. Abacavir is metabolized to inactive metabolites by alcohol dehydrogenase and glucuronyl transferase with subsequent elimination of metabolites in the urine. Based on increased abacavir AUC and prolonged  $t_{1/2}$  in patients with mild hepatic impairment, dosage adjustment is recommended but controversial. Abacavir use in severe hepatic impairment is not recommended.

### Adverse Effects

Because abacavir is a relatively selective inhibitor of the HIV reverse transcriptase as compared to cellular DNA polymerases, myelotoxicity is infrequent (116). Abacavir is

generally well tolerated, with asthenia, abdominal pain, headache, diarrhea, and dyspepsia being the most commonly reported side effects. Laboratory abnormalities include elevations in liver enzyme levels.

The most significant adverse effect associated with abacavir is the idiosyncratic hypersensitivity reaction. This syndrome has an incidence of approximately 8% and is characterized by the appearance over several days of fever (80%), rash (70%), gastrointestinal symptoms (50%), malaise (40%), and respiratory symptoms (30%). Fever or rash occurs in 98% of cases. Hypersensitivity cases typically occur within 6 weeks of the initiation of abacavir therapy (94%), with a median onset of 11 days. Accompanying laboratory abnormalities can include lymphopenia, thrombocytopenia, and elevated transaminase or creatine phosphokinase levels. This syndrome usually improves within days after the discontinuation of abacavir therapy. Rechallenge in individuals suspected of having this condition is contraindicated because severe allergic reactions, including fatalities, may occur within hours. Individuals who have tolerated abacavir in the past are unlikely to experience hypersensitivity reactions after reinitiating treatment; several severe or fatal exceptions, however, have been reported among these individuals (117, 118). HLA B\*5701 predicts abacavir hypersensitivity (119), and screening for HLA B\*5701 before initiating the drug is recommended (120, 121). It is important to note, however, that hypersensitivity can still occur in HLA B\*5701-negative persons (122). The mechanism of this delayed hypersensitivity appears to be related to abacavir binding to the peptide-binding groove of HLA-B\*5701 and presentation of altered class I MHC binding peptides which trigger CD8 T-cell responses (123).

Abacavir use may be associated with an increase in cardiovascular disease and events (124–126). An international cohort study including >23,000 HIV-infected patients reported abacavir as one of the agents associated with increased risk of myocardial infarction (124). A follow-up analysis adjusting for 10-year risk of coronary heart disease also found that abacavir (as well as didanosine) use in the previous 6 months was associated with an increased risk of myocardial infarction. Other studies, however, have failed to identify an association (127, 128), and, as such, the significance of these findings remains controversial. Practically, the potential for such risk should be taken into account when considering treatment of individuals with either a history of cardiovascular disease or a high risk for cardiovascular events.

### Drug Interactions

Abacavir and ethanol share a similar metabolic pathway, and coadministration has been shown to increase the abacavir AUC by 41% in males. A small study examining the interaction of abacavir with methadone suggested that methadone clearance increased by 22%, which may only be significant in a very small proportion of patients.

### Resistance

Selection for resistance to abacavir *in vitro* is characterized by the accumulation of multiple mutations in the HIV-1 reverse transcriptase. An initial M184V mutation, conferring a 2- to 5-fold increase in resistance, is followed by the appearance of either L74V and K65R/E/N or L74V and Y115F. While individually these mutations are associated with a low-level (2- to 4-fold) loss of susceptibility, M184V-containing double mutants have increased (7- to 11-fold) resistance. Abacavir-resistant isolates containing combinations of these

mutations have various degrees of cross-resistance to lamivudine and didanosine.

Isolates obtained after abacavir monotherapy revealed mutations at codons 65, 74, and 184. The addition of zidovudine delayed the selection of the M184V mutation. *In vivo* studies identified the following mutations: K65R, L74V, Y115F, and M184V, as well as TAMs M41L, D67N, K70R, L210W, T215F/Y, and K219E/Q; the Q151M complex, usually in combination with V75I, F77L, F116Y; and T69 insertion mutations (28). Increasing numbers of TAMs (>4) result in a loss of virologic response to abacavir (129). Multinucleoside analog resistance-associated insertions at position 69 and the 151 complex also confer cross-resistance to abacavir (28).

### Clinical Applications

Abacavir has demonstrated durable efficacy in combination with lamivudine and a third active antiretroviral drug (a boosted PI, NNRTI or INSTI) in treatment-naïve patients with baseline HIV-1 RNA levels <100,000 copies/ml (103, 105, 130–134). Abacavir may be administered either as a separate pill or in a more convenient fixed-dose combination, single-pill formulation that might favorably impact drug adherence. Abacavir-lamivudine and zidovudine-lamivudine regimens, each combined with efavirenz in treatment-naïve individuals, show comparable rates of virologic suppression to <50 copies/ml, but there is a greater increase in CD4 cell counts in the abacavir-lamivudine group (209 cells/mm<sup>3</sup> versus 155 cells/mm<sup>3</sup>) (103, 135). A study that compared abacavir-lamivudine to tenofovir disoproxil-emtricitabine, both regimens combined with efavirenz, demonstrated a lower proportion of patients achieving virologic suppression to <50 copies/ml of HIV-1 RNA but similar adverse event rates in both arms. In combination with lopinavir/ritonavir, abacavir-lamivudine is noninferior to tenofovir disoproxil-emtricitabine (136). Data from ACTG A5202, a study comparing abacavir-lamivudine with tenofovir-emtricitabine in combination with either efavirenz or atazanavir-ritonavir in treatment-naïve patients, showed that individuals with baseline HIV-1 RNA levels ≥100,000 copies/ml were more likely to experience virologic failure in the abacavir-lamivudine arm than in the tenofovir-emtricitabine arm; there was no difference in time to virologic failure for participants with HIV-1 RNA levels <100,000 copies/ml (137, 138). When compared to a single tablet regimen of efavirenz/tenofovir disoproxil/emtricitabine, the single tablet combination of dolutegravir/abacavir/lamivudine led to higher proportions of participants with HIV-1 RNA levels <50 copies/ml at 48 weeks, shorter median time to viral suppression, and fewer adverse events (139). For the treatment of antiretroviral-experienced patients, the use of abacavir-containing regimens has also demonstrated clinical utility (140, 141).

### Emtricitabine

Emtricitabine {5-fluoro-1-(2R,5S)-2-[hydroxymethyl]-1,3-oxathiolan-5-yl}cytosine; Emtriva) is a cytidine analog that is the (–) enantiomer of a thio analog of cytidine; it differs from other cytidine analogs in that it has a fluorine in the 5 position (Figs. 1 and 3; Tables 1 and 3). It is available as both a 200 mg capsule and a 10 mg/ml oral solution, as well as in multiple fixed-dose formulations with TDF (Truvada), with TDF and efavirenz (Atripla), with TDF and rilpivirine (Complera), with TDF, elvitegravir, and cobicistat (Stribild), with tenofovir alafenamide (TAF) (Descovy), with TAF and rilpivirine (Odefsey), and with TAF, elvitegravir,

and cobicistat (Genvoya). Emtricitabine is administered in a once-daily dosage of 200 mg.

Emtricitabine is 4- to 10-fold more potent than lamivudine; for a laboratory-adapted strain, it has an IC<sub>50</sub> of 0.002 to 0.124 µg/ml in human cell lines (142). This heightened potency may be the result of a greater efficiency of incorporation of emtricitabine triphosphate than of lamivudine triphosphate by the HIV-1 reverse transcriptase (143). In addition, emtricitabine triphosphate has a longer intracellular *t*<sub>1/2</sub> (see below). The drug has activity against HIV-1, HIV-2, and HBV. The role of emtricitabine as an anti-HBV agent is discussed in chapter 13. Emtricitabine has demonstrated synergistic or additive activity with other nucleoside analogs, PIs, and NNRTIs.

### Mechanism of Action

Emtricitabine undergoes serial intracellular phosphorylations to an active triphosphate form that inhibits the activity of the HIV-1 reverse transcriptase by competing with the natural substrate deoxycytidine 5'-triphosphate. Because it lacks a hydroxyl group at the 3' position of the oxathiolane moiety (144), incorporation of emtricitabine 5'-triphosphate interrupts HIV proviral DNA chain elongation in susceptible strains (143).

### Pharmacology

Emtricitabine is rapidly absorbed with high oral bioavailability (~93%) that is not affected by coadministration of food. After a 200-mg dose, the mean peak concentration is 1.8 µg/ml. The oral bioavailability of the oral solution is lower (~75%) and as such requires a slightly higher daily dose. The drug has low protein binding (<4%). The plasma elimination *t*<sub>1/2</sub> averages approximately 10 h, and the intracellular *t*<sub>1/2</sub> of emtricitabine triphosphate is longer than 20 h, allowing once daily dosing. Emtricitabine is predominantly renally eliminated by both glomerular filtration and active tubular secretion; thus, dosing interval adjustments are required in individuals with renal impairment.

### Adverse Effects

Emtricitabine, like lamivudine, is well tolerated. Adverse effects attributed to emtricitabine have been mild to moderate CNS and gastrointestinal symptoms (Table 3). Skin hyperpigmentation is also possible and is more common (as high as 32%) in children. Exacerbations of hepatitis B in coinfecting individuals have been reported after discontinuation of emtricitabine.

### Drug Interactions

There are no clinically significant drug interactions.

### Resistance

As with lamivudine, high-level resistance to emtricitabine is associated with K65R/E/N and M184I/V reverse transcriptase mutations (28). The combination of tenofovir with emtricitabine in clinical studies was less likely to select for the M184V mutation than the zidovudine-lamivudine combination. The emtricitabine-containing regimen may also be less likely to select for the K65R mutation than lamivudine in the presence of tenofovir (145).

### Clinical Applications

Emtricitabine is recommended as a component of initial antiretroviral therapy for treatment-naïve patients and can be used interchangeably with lamivudine but should never

be used in combination with lamivudine (105). Emtricitabine has also shown efficacy in treatment-experienced patients with plasma HIV-1 RNA levels of <400 copies/ml who switched from lamivudine- or PI-containing regimens to emtricitabine-containing ones. The simplification to once-daily emtricitabine does not affect the proportion of patients with plasma HIV-1 RNA level suppression to <400 or <50 copies/ml. Emtricitabine in combination with TDF has demonstrated considerable potency and durability of virologic control as part of PI- or NNRTI-based regimens (146).

### SELECTED INVESTIGATIONAL NRTIS

Nucleoside analog drug development continues with the goals of improving safety, pharmacokinetics, potency, and activity against drug-resistant strains. Selected new agents in this drug class are listed in Table 2.

### NUCLEOTIDE ANALOG REVERSE TRANSCRIPTASE INHIBITORS

#### Tenofovir Disoproxil Fumarate (See also Tenofovir Alafenamide)

Tenofovir {9-[(R)-2-[[bis[(isopropoxycarbonyl)oxy]methoxy]phosphinyl]methoxy]propyl}adenine fumarate; Viread (Figs. 1 and 3; Tables 1 and 3) is a prodrug of the cyclic nucleoside phosphonate 9-R-(2-phosphonomethoxy-propyl)adenine (PMPA). This agent is approved for once-daily dosing and is available in 300-mg tablets and powder for oral use. It is available in combination with emtricitabine (Truvada), with emtricitabine and efavirenz (Atripla), with emtricitabine and rilpivirine (Complera), and with emtricitabine and elvitegravir and cobicistat (Stribild) in fixed-dose combinations. Tenofovir disoproxil fumarate (TDF) is an inhibitor of retroviruses, including HIV-1, simian immunodeficiency virus, and feline leukemia virus, as well as hepadnaviruses.

#### Mechanism of Action

TDF is converted to tenofovir by diester hydrolysis and phosphorylation to form tenofovir diphosphate. As a nucleotide analogue, only two intracellular phosphorylation steps are needed to convert the drug to its active form. The mechanism of reverse transcriptase inhibition is as described for the nucleoside analogs.

#### Pharmacology

Because of the drug's hydrophilic properties, tenofovir demonstrates a permeability-limited oral absorption and has a bioavailability of 25 to 40% as the *bis*-ester prodrug, TDF (147). The AUCs of the tablet and oral powder formulations are similar despite a lower  $C_{max}$  for the oral powder. Administration of TDF with a high-fat meal increases the AUC of tenofovir by ~40%, an effect not seen with a lighter meal. Tenofovir has a plasma  $t_{1/2}$  of approximately 17 hours and an intracellular  $t_{1/2}$  of the diphosphate form of 12 to 15 hours in activated PBMCs and 33 to 50 hours in resting PBMCs, thus permitting once-daily dosing. The drug is excreted renally by both glomerular filtration and active tubular secretion and requires dosage adjustment in patients with renal impairment.

#### Adverse Effects

A small proportion of patients taking TDF experience increases in serum creatinine, glycosuria, hypophosphatemia, and acute tubular necrosis. However, renal impairment de-

velops uncommonly in patients with normal renal function at baseline (148). Patients with more advanced HIV disease, greater treatment experience, concomitant PI use, and pre-existing renal impairment may be at an increased risk of this complication (149). The mechanism may be a direct toxic effect of free tenofovir in renal tubular cells (150). The agent should be used with caution in individuals with preexisting renal disease, and alternative nucleoside analogs should be considered. In individuals coinfecting with HBV, discontinuation of TDF may cause flares of viral replication and hepatitis; close monitoring of such patients is advised.

Fat maldistribution is not commonly seen with TDF-based regimens (151), and switching from zidovudine- or stavudine-containing regimens to TDF or abacavir may slow or halt the progression of this syndrome. TDF may have a more pronounced effect on bone loss than other agents (152). While low bone mineral density and fractures appear more common in HIV patients compared to non-HIV patients, the impact of antiretrovirals on loss of bone mineral density suggests a contribution of antiretroviral therapy, which may be more noteworthy with agents such as TDF and PIs (153–156). The safety of tenofovir in pregnancy has not been definitively established, and some animal studies have reported impaired fetal growth and decreased fetal bone porosity within 2 months of starting maternal therapy. However, data from infants exposed *in utero* to tenofovir do not suggest an increase in growth or bone abnormalities (157). The drug is now routinely used in pregnancy.

#### Drug Interactions

TDF decreases the AUC of atazanavir by 25%; therefore, patients who receive concomitant therapy with TDF should only use ritonavir- or cobicistat-boosted atazanavir. The combination of TDF and didanosine has been associated with increased didanosine toxicity and a high rate of early virologic failure as well as CD4 cell decline in treated individuals, although conflicting data exist on this point (158, 159). Coadministration of TDF with ritonavir-boosted PIs may result in increased tenofovir absorption by ~30% due to inhibition of p-glycoprotein.

#### Resistance

Tenofovir retains activity against a range of nucleoside-resistant HIV strains. *In vitro*, the K65R/E/N mutation of HIV-1 confers a 9-fold decrease in sensitivity to tenofovir; the M184V mutation partially reverses this resistance. The K70E mutation and insertions at codon 69 also confer decreased susceptibility to tenofovir (160). The effect of the 69 insertion complex is potentiated in the presence of the M184V mutation. Nonresponse to tenofovir is more likely to occur when the drug is added to a failing regimen in heavily pretreated patients, as opposed to its use as a part of a new regimen with other active medications. Clinical data suggest that the presence of >2 TAMs, including M41L or L210W, is associated with decreased susceptibility to tenofovir. The activity of tenofovir is retained in the presence of the 151 complex (161, 162).

#### Clinical Applications

TDF has been an essential component of initial treatment regimens for treatment-naïve patients, that traditionally were combined with lamivudine or emtricitabine plus an agent from one of three other classes: NNRTIS, PIs, or INSTIs. Its availability in multiple fixed-dose drug combinations also increases its clinical utility. Potent and durable virologic suppression occurs in treatment-naïve individuals

with TDF and lamivudine or emtricitabine in combination with efavirenz (151). In direct comparison with lamivudine-zidovudine, TDF-emtricitabine demonstrates a greater increase in CD4 cell counts and a higher rate of virologic suppression to <50 copies/ml sustained over 144 weeks (163). As described above, compared to abacavir-lamivudine in combination with either efavirenz or atazanavir-ritonavir, TDF-emtricitabine shows a more favorable virologic efficacy and side-effect profile.

In treatment-experienced individuals with incomplete virologic suppression and baseline nucleoside resistance mutations, the addition of TDF to stable regimens has resulted in significant reductions in plasma HIV-1 RNA levels (164) with the caveat that incremental monotherapy is discouraged. In patients with suppressed viral loads at baseline, switching the nucleoside component to TDF-emtricitabine results in fewer treatment failures and drug discontinuations than switching to abacavir-lamivudine (165).

TDF is also recommended, in combination with emtricitabine in a fixed-dose combination, as preexposure prophylaxis for prevention of HIV infection in high-risk populations including sexually active men who have sex with men, heterosexually active men and women at substantial risk for HIV infection, injection drug users, and heterosexually active men and women whose partners are living with HIV (166, 167).

### Tenofovir Alafenamide

Tenofovir alafenamide [isopropyl (2S)-2-[[[(1R)-2-(6-aminopurin-9-yl)-1-methyl-ethoxy]methyl-phenoxy-phosphoryl]amino]propanoate; GS-7340] is a nucleotide reverse transcriptase inhibitor prodrug of tenofovir associated with reduced risk of renal adverse effects. It is currently available only in fixed-dose combinations with emtricitabine (Descovy), with emtricitabine and rilpivirine (Odefsey), and with emtricitabine, elvitegravir, and cobicistat (Genvoya).

### Mechanism of Action

Tenofovir alafenamide is 1,000- and 10-fold more active against HIV *in vitro* than tenofovir and TDF, respectively. Conversion to tenofovir occurs intracellularly with higher active metabolite concentrations seen in peripheral blood mononuclear cells (PBMCs) than with TDF. Tenofovir enters cells where it undergoes ester hydrolysis by lysosomal carboxypeptidase cathepsin A (CatA). A key intermediate formed with alanine eventually releases tenofovir, which is subsequently phosphorylated to the active metabolite tenofovir-diphosphate. Intracellular cleavage by CatA occurs rapidly in HIV-target cells, and this, coupled with metabolites that are trapped in cells, results in accumulation of the active metabolite tenofovir diphosphate (168).

### Pharmacology

Tenofovir alafenamide is rapidly absorbed, reaching mean peak concentrations of 0.16 µg/ml within 1 hour. Administration with a high fat meal increases the AUC ~85%. Tenofovir alafenamide is ~80% bound to plasma proteins. Tenofovir alafenamide is primarily metabolized first by CatA in PBMCs and macrophages and then by carboxylesterase 1 in hepatocytes. The terminal plasma  $t_{1/2}$  is ~30 minutes but that of tenofovir diphosphate is ~150–180 hours within PBMCs. Renal impairment has no impact on concentrations of TAF. Tenofovir alafenamide results in 90% lower serum tenofovir levels compared to TDF with consequently diminished renal and bone toxicity.

### Adverse Effects

The most common adverse effect reported during clinical trials was nausea (≥10%). Of note, TAF has been associated with smaller mean serum creatinine increases, less proteinuria, and a smaller decrease in bone mineral density at the spine and hip than TDF (169, 170).

### Drug Interactions

Tenofovir alafenamide is a substrate of P-glycoprotein, and drugs that strongly affect P-glycoprotein activity may alter TAF absorption. Coadministration of tipranavir/ritonavir, carbamazepine, oxcarbazepine, phenobarbital, phenytoin, rifamycins, and St. John's wort with TAF is not recommended.

### Resistance

As TAF is a prodrug of tenofovir, the resistance pattern is identical to that of TDF (171). Because TAF achieves higher intracellular concentrations and is more potent than TDF, there is speculation that it may retain activity against viral strains with known mutations, but confirmatory clinical data are lacking at this time (172).

### Clinical Applications

Tenofovir alafenamide is included in the regimens recommended for first-line therapy of treatment-naïve patients with estimated creatinine clearances of ≥30 ml/min, in the form of the fixed-dose combination elvitegravir/cobicistat/TAF/emtricitabine (105). The side-effect profile of TAF is favorable compared with TDF when in combination with elvitegravir-cobicistat or darunavir-ritonavir, including improved renal and bone safety parameters (173, 174). It is an increasingly popular clinical choice, and it is likely that the alafenamide form of the prodrug will replace the disoproxil fumarate form.

## NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

Although structurally diverse, the NNRTIs share similar HIV-1 reverse transcriptase binding sites and function by noncompetitive allosteric binding to a hydrophobic pocket created by the p66 palm-and-thumb subdomains of the reverse transcriptase (175). This alters the structure and function of the HIV-1 reverse transcriptase (176). When the NNRTI is bound to this site, it interacts with multiple amino acid residues within the pocket. Mutations of these key amino acids alter inhibitor binding properties and form the mechanistic basis for NNRTI resistance. The binding of an NNRTI to the enzyme-DNA complex is proposed to slow reverse transcriptase-mediated catalysis by causing a distortion of the normal spatial configuration of the carboxyl groups and associated Mg<sup>2+</sup> ions of three aspartic acid residues in the adjacent polymerase active site (177). As a consequence, nucleotide triphosphate molecules destined to be added to the elongating proviral DNA chain are bound but inefficiently utilized. The narrow spectrum of antiviral activity is conferred by a tyrosine at amino acid position 181 in HIV-1, but which is not present in HIV-2 or the HIV-1 O clade (subtype), against which these compounds are inactive (178).

### Nevirapine

Nevirapine (11-Cyclopropyl-4-methyl-5,11-dihydro-6H-dipyrido[3,2-b:2',3'-e][1,4]diazepin-6-one; Viramune) (Figs. 1

and 4; Tables 1 and 3) formulations include 200-mg tablets, a once-daily extended release 400 mg tablet, and a 50 mg/5 ml oral suspension. Nevirapine antiviral activity is limited to HIV-1, with an  $IC_{50}$  of 0.003  $\mu\text{g}/\text{ml}$  to 0.03  $\mu\text{g}/\text{ml}$ , while 50% cytotoxicity concentrations are more than 300-fold higher.

### Pharmacology

Nevirapine is rapidly absorbed with an oral bioavailability of >90%. An initial serum  $C_{\text{max}}$  of 2.0  $\mu\text{g}/\text{ml}$  (7.5  $\mu\text{M}$ ) is reached approximately 4 hours after a 200-mg oral dose. Steady-state trough concentrations average 4.5  $\mu\text{g}/\text{ml}$  (17  $\mu\text{M}$ ) at a nevirapine dosage of 400 mg/day. Concentrations in plasma do not appear to be altered by food or antacids. Secondary peak levels are seen, which may reflect enterohepatic recirculation. Plasma protein binding is approximately 60%. Nevirapine is highly lipophilic, and CSF concentrations are about 45% of plasma values (179). Nevirapine crosses the placenta and is present in breast milk and semen.

Nevirapine is metabolized by CYP3A and CYP2B6 and also induces these enzymes. The clearance of nevirapine

increases through the first 2 to 4 weeks of dosing, such that its plasma elimination  $t_{1/2}$  decreases from 45 hours after single doses to 25 to 30 hours with multiple dosing. Detectable levels of nevirapine have been found in chronically treated children and adults for as many as 7 days after cessation (180). Detectable levels may persist longer in treatment-naïve women who receive single-dose nevirapine for prophylaxis of mother-to-child transmission of HIV-1.

### Adverse Effects

The most common adverse reaction associated with nevirapine is a nonpruritic macular rash distributed on the face, trunk, and extremities, excluding the palms and soles; the rash usually occurs within the first 6 weeks of therapy. Rash has occurred in 48% of nevirapine recipients who received 400 mg/day. The rash may be accompanied by hepatotoxicity, fever, and myalgias.

The incidence of rash does not appear to be related to plasma drug levels, stage of HIV disease, history of rash with other agents, sex, or race. The risk may be attenuated by administering a lower initial dosage of 200 mg/day for 2 weeks and then increasing the dosage to 200 mg b.i.d. Liver toxicity occurs in about 4% of patients. The risk of hepatotoxicity is higher in women and in patients with higher CD4 cell counts (>250 cells/ $\text{mm}^3$  in women and >400 cells/ $\text{mm}^3$  in men), and thus nevirapine should not be initiated in these populations. Coinfection with HBV or HCV increases the risk of liver toxicity. Life-threatening and fatal cases of hepatotoxicity, as well as severe, even fatal, skin reactions, including Stevens-Johnson syndrome, toxic epidermal necrolysis, and hypersensitivity reactions, have been reported and can occur during the first 18 weeks of therapy. The overall rate of hypersensitivity reactions has been about 6%; increased risk has been associated with high pretreatment plasma HIV-1 RNA levels, high CD4 cell counts, and female sex.

### Drug Interactions

Nevirapine induces the hepatic CYP450 enzyme. As such, it affects its own metabolism as well as coadministered drugs that also utilize the CYP3A4 metabolic pathway. Nevirapine decreases the AUCs of the PIs. Coadministration of rifampin and nevirapine is associated with lower nevirapine concentrations and greater variability in plasma drug levels. Some data suggest that combining efavirenz or nevirapine at standard doses in combination with rifampin results in comparable virologic and clinical outcomes (181, 182). Nevirapine-induced methadone withdrawal has been reported, and the methadone dose should be increased before commencing nevirapine (183).

### Resistance

The nevirapine binding site is created mainly by amino acid residues at positions 100 to 110 and 180 to 190, comprising the  $2\beta$  sheets that form the binding pocket in the HIV-1 reverse transcriptase. Consequently, mutations associated with resistance generally fall within these regions. *In vitro* and clinical isolate data indicate mutations conferring nevirapine resistance include L100I, K101P, K103N/S, V106A/M, V108I, Y181C/I, Y188C/L/H, G190A, and M230L (28). Several of these engender variable cross-resistance to other NNRTIs (184).

*In vivo*, nevirapine-resistant isolates are genetically mixed populations, and the most common ones in patients with virologic failure occur at positions 103, 181, 190, 188, and 106. Each mutation reduces nevirapine susceptibility by at least 50-fold (28). The nevirapine-associated Y181C substitution

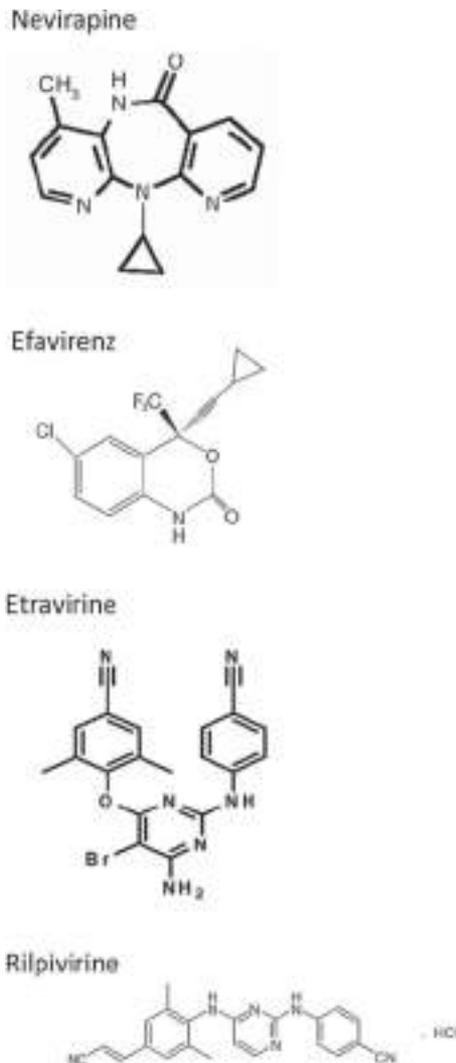

FIGURE 4. Chemical structures of HIV nonnucleoside reverse transcriptase inhibitors.

in zidovudine-resistant HIV strains increases zidovudine susceptibility *in vitro*. Mutations at positions 138 and 227, selected by etravirine, appear to reduce susceptibility to nevirapine and efavirenz, and V179F in combination with Y181C causes high-level resistance to nevirapine and etravirine (185).

### Clinical Applications

Nevirapine's role as part of initial antiretroviral regimens continues to diminish, but its historic position as the lead compound in the NNRTI class is well established. In a direct comparison with efavirenz and nevirapine, both given in combination with stavudine and lamivudine, nevirapine demonstrated a similar rate of virologic suppression to a plasma HIV-1 RNA level of <50 copies/ml, without differences in treatment failure between regimens (186). Despite these data, nevirapine's twice-daily dosing and risk of hepatotoxicity make it a less attractive option as initial therapy than efavirenz or other NNRTIs. The prevalence of NNRTI-resistant virus in treatment-naïve patients also limits nevirapine's utility as first-line treatment (105). In low- and middle-income countries, nevirapine still plays a role in initial regimens because of its low cost and availability in fixed-dose generic combinations (187).

Nevirapine is safe in women with CD4 cell counts <250 cells/mm<sup>3</sup>, including pregnant women. Administering single-dose nevirapine to both the mother and infant in the peripartum period significantly reduces vertical transmission of HIV-1 but is associated with a substantial incidence of nevirapine-resistance emergence in women (up to 40 to 60%) and infants (33 to 87%), especially if techniques for low-frequency viral variant detection are employed (188, 189). Addition of a short course of nucleoside analogs (zidovudine-lamivudine or tenofovir-emtricitabine) decreases the development of maternal and pediatric resistance after single-dose nevirapine (190, 191). For infants infected by mother-to-child transmission after exposure to nevirapine, a strategy of induction and virologic suppression with a lopinavir/ritonavir-based regimen, followed by transition to nevirapine-based treatment, is associated with long-term virologic response, sustainable up to three years, and is not significantly impacted by resistance (192, 193). Advances in access and guideline advice have made these approaches outmoded, but the principles are important to remember when women present at term or in labor and a new HIV diagnosis is made in that setting.

### Efavirenz

Efavirenz [(4S)-6-chloro-4-(2-cyclopropylethynyl)-4-(trifluoromethyl)-1H-3,1-benzoxazin-2-one; L-743,726, DMP 266, Sustiva] is available in tablet and capsule formulations (Figs. 1 and 4; Tables 1 and 3). It is also available as a fixed-dose combination tablet with emtricitabine and tenofovir (Atripla). It has an IC<sub>90</sub> ranging from 0.95 µg/l to 2.84 µg/l for wild-type clinical and laboratory HIV-1 isolates.

### Pharmacology

The bioavailability of efavirenz in humans has not been reported. Administration with food increases the efavirenz AUC by ~17–28% while increasing the plasma C<sub>max</sub> more significantly, as high as 79%. The plasma C<sub>max</sub> at steady-state averages 1.26 mg/l and the C<sub>min</sub> averages 0.5 mg/l at a 600-mg daily dosage. Efavirenz is highly protein bound (>99%), and CSF concentrations are only about 0.26 to 1.19% of plasma concentrations. Efavirenz is primarily

metabolized by CYP3A and CYP2B6 to hydroxylated metabolites, with subsequent glucuronidation, and these metabolites are excreted in the urine. The terminal t<sub>1/2</sub> is approximately 40–55 hours after multiple doses. Efavirenz achieves therapeutic concentrations in semen throughout the dosing interval and can suppress HIV-1 levels in the seminal compartment.

### Adverse Effects

Efavirenz toxicities include maculopapular rash, dizziness (27% versus 9% in the control group), impaired concentration (11% versus 4%), depression (9% versus 5%), abnormal dreaming (6% versus 1%), and euphoria (5% versus 2%). CNS adverse events occur more often in subjects taking efavirenz (54% versus 27%), although these symptoms tend to resolve over the course of a few weeks, probably due to self-induction of hepatic metabolism and increased clearance of the drug. The incidence of adverse events does not differ with the timing of the dose, splitting of the dose, or age of the subject, although when efavirenz is taken at night, the CNS side effects may be more tolerable. Controversy remains whether efavirenz increases the propensity for suicide, but more recent data have failed to find such an association (194–196). The incidence and severity of rash are not related to dose. Efavirenz administration can generally be continued despite the occurrence of a rash, which resolves over 3 to 4 weeks. As with other NNRTIs, metabolic abnormalities, such as lipoatrophy and elevations in high-density lipoprotein cholesterol and total cholesterol, occur in subjects taking efavirenz (103, 197). Efavirenz has been associated with an increased risk of lipoatrophy compared to lopinavir-ritonavir, whereas derangements in lipid profiles (triglycerides in particular) were similar in the two groups (197).

Efavirenz has been reported to cause neural tube defects in infants whose mothers have been exposed to efavirenz during the first trimester, although a causal relationship is not established (198). In pregnant cynomolgus monkeys treated throughout pregnancy with doses of efavirenz resulting in plasma levels similar to those in humans dosed with 600 mg/day, craniofacial malformations (anencephaly, unilateral anophthalmia, microphthalmia, and cleft palate) occur. Recommendations for the use of efavirenz in pregnancy have evolved since the drug was first approved. Women who wish to become pregnant or who are in their first trimester should not be started on efavirenz if alternatives are readily available. However, for women who are already on efavirenz and have been pregnant for 6–8 weeks by estimated dates, it is reasonable to continue the efavirenz as the risk period for neural tube defects will have passed (199, 200). The global rollout of antiretroviral therapy has provided reassurance concerning the potential teratogenic effects of efavirenz as clusters of cases of birth defects have not been reported. The recent prevalence of birth defects following first trimester efavirenz exposure is 2% with a relative risk of birth defects in efavirenz-containing regimens to non-efavirenz-based regimens of 0.85 (95% CI 0.61–1.20) (201). Women should undergo pregnancy testing before starting efavirenz and should receive counseling regarding contraceptive practices.

### Drug Interactions

Efavirenz is a substrate of CYP450 and thus affects the hepatic metabolism of many coadministered drugs. It has been characterized as an inducer of CYP3A and CYP2B6 and an

inhibitor of CYP2C9 and CYP2C19. When coadministered with protease inhibitors, efavirenz may decrease protease inhibitor AUCs and boosting is recommended. Efavirenz also significantly decreases AUCs of maraviroc, simeprevir, azole antifungals, statins, oral contraceptives, and methadone. Coadministration with rifabutin requires a 50% dose increase of rifabutin, while coadministration with rifampin requires a dose increase of efavirenz to 800 mg once daily in patients > 50 kg based on pharmacokinetic modeling data.

### Resistance

Efavirenz selects for multiple reverse transcriptase mutations: L100I, K101P, K103N/S, V106M, V108I, Y181C/I, Y188L, G190S/A, P225H, and M230L (28). The K103N mutation confers cross-resistance to nevirapine but not to etravirine or rilpivirine. Isolates containing the K103N or G190S mutations from patients failing efavirenz combination therapy have shown 19- to 36-fold or 280-fold reduced susceptibility *in vitro*, respectively. Resistance to efavirenz increases to 100-fold with the development of additional mutations at codons 106, 188, and 190 (202). Several nucleoside analog mutations (e.g., 118I, 298Y, and 215Y) can result in hypersusceptibility to efavirenz in patients with extensive NRTI experience (203). The underlying mechanism may include increased reverse transcriptase enzyme susceptibility to the NNRTI (e.g., with 118I/215Y) or decreased virion-associated levels of reverse transcriptase (with 208Y/215Y and 118I/208Y/215Y).

### Clinical Applications

Current clinical practice has moved away from the use of efavirenz in antiretroviral-naïve patients initiating treatment because of its CNS toxicities (105) and the availability of integrase strand-transfer inhibitors. However, the virologic efficacy of efavirenz-based regimens at 24 weeks remains comparable to many other recommended regimens. Efavirenz-containing regimens compare favorably to PI-based therapy, including atazanavir and lopinavir/ritonavir-based regimens (100, 101, 204). In combination with the dual-nucleoside backbone of tenofovir-emtricitabine, zidovudine-lamivudine, or abacavir-lamivudine, efavirenz has achieved high rates of virologic suppression (103, 151, 205), and the fixed-dose combination of tenofovir/emtricitabine/efavirenz demonstrated superior virologic suppression and CD4 cell-count response when compared with the combination of zidovudine-lamivudine plus efavirenz (206). Efavirenz compared with nevirapine, each in combination with lamivudine-stavudine, showed no significant differences in rates of virologic suppression or increases in CD4 cell counts (186). Efavirenz-based regimens showed comparable rates of virologic failure to atazanavir-ritonavir-based regimens in the ACTG 5202 study (137) but were less likely to be associated with virologic failure than lopinavir/ritonavir based regimens in the ACTG 5142 study (207). Efavirenz in its single-tablet regimen formulation (tenofovir/emtricitabine/efavirenz) was noninferior to the elvitegravir/cobicistat/tenofovir/emtricitabine fixed-dose regimen (208). Comparisons to rilpivirine are discussed in that section.

### Etravirine

Etravirine [4-((6-amino-5-bromo-2-((4-cyanoanilino)pyrimidin-4-yl)oxy)-3,5-dimethylbenzotrile; Intelence, TMC 125] (Figs. 1 and 4; Tables 1 and 3) is a diaryl-pyrimidine derivative that binds to HIV reverse transcriptase with mutations within the hydrophobic pocket. It is approved for use in

individuals who have experienced virologic failure with other NNRTIs and harbor a multidrug-resistant virus (209). Formulations of this agent include 25-mg, 100-mg, and 200-mg tablets. Etravirine exhibits activity against laboratory as well as wild-type strains of HIV-1, with a median IC<sub>50</sub> ranging from 0.9 to 5.5 nM (0.4 to 2.4 ng/ml).

### Pharmacology

The oral bioavailability of etravirine has not been reported. Its plasma AUC is diminished by 50% under fasting conditions; therefore, etravirine should be taken with food. The plasma C<sub>max</sub> averages 390 ng/ml at 4 hours after dosing. It is highly protein bound, and its distribution in other compartments (CSF and genital tract secretions) has not been evaluated to date. Etravirine is metabolized by the CYP3A, CYP2C9, and CYP2C19 enzymes. Although the plasma elimination t<sub>1/2</sub> of etravirine (41 hours) is long enough to support once-daily dosing, such dosing has not been tested in controlled trials to date. It is primarily excreted via feces, with only a limited amount of renal excretion (1.2%).

### Adverse Effects

The most commonly reported adverse effects are nausea and rash (210). The rash is mild to moderate in severity, occurs most frequently in the second week of therapy, and generally resolves within 1 to 2 weeks on continued therapy. It is a rare cause of drug discontinuation (210–212). There are no observable effects on lipids or liver function enzymes.

Rare cases of serious skin reactions, including Stevens-Johnson syndrome and erythema multiforme, were reported during clinical development, but the risk appears to be low (no cases among over 500 treated patients in phase III studies). Patients with a history of NNRTI-related rash did not appear to be at an increased risk for the development of rash while taking etravirine.

### Drug Interactions

Like nevirapine and efavirenz, etravirine is metabolized by the CYP450 system. It is both a substrate and an inducer of CYP3A4, as well as an inhibitor of CYP2C9, CYP2C19, and p-glycoprotein. As a result, coadministration of etravirine with inhibitors or inducers of these CYP450 enzymes may alter levels of etravirine in serum. Conversely, coadministration of etravirine with drugs that are substrates of these enzymes may alter their levels in serum. Certain antiretrovirals should not be coadministered with etravirine, including other NNRTIs, all unboosted PIs, and ritonavir-boosted tipranavir or fosamprenavir. Dolutegravir concentrations are significantly decreased by etravirine, so dolutegravir should only be administered with etravirine when coadministered with atazanavir-ritonavir, darunavir-ritonavir, or lopinavir/ritonavir. The AUC of maraviroc is decreased by 53%, requiring dosage adjustment to 600 mg twice daily if coadministered with etravirine. If maraviroc is dosed with a ritonavir-boosted PI as well as etravirine, the maraviroc dosage is 150 mg twice daily. Etravirine can be combined with the integrase inhibitor raltegravir without dose adjustments.

### Resistance

Multiple reverse transcriptase mutations present pretreatment affect the response to etravirine: V90I, A98G, L100I, K101E/H/P, V106I, E138A/G/K/Q, V179D/F/T, Y181C/I/V, G190A/S, and M230L (28, 210,213–215). Most data on

etravirine resistance are derived from studies of treatment-experienced patients where it is used in combination with darunavir-ritonavir. Algorithms have been developed that predict etravirine susceptibility by assigning a score based on genotypic and phenotypic cutoffs (216). The L100I, K101P, or Y181C/I/V are considered “major” mutations as the presence of any of these alone confers decreased susceptibility to etravirine *in vitro*, and is associated with decreased virologic response at 24 weeks for treatment-experienced patients receiving an etravirine-based regimen (217). The presence of at least three of these mutations at baseline (particularly V179D/E, Y181V, and G190S) has been associated with a diminished drug response (211, 212). The highest levels of resistance to etravirine *in vitro* were observed for HIV-1 harboring a combination of mutations: V179F plus Y181C (187-fold change), V179F plus Y181I (123-fold change), or V179F plus Y181C plus F227C (888-fold change). The K103N mutation does not confer resistance to etravirine. Cross-resistance within the NNRTI class is common. Patients may develop resistance to etravirine if failing nevirapine or efavirenz-based regimens (218), and the development of resistance to etravirine was seen in 90% of patients failing a rilpivirine-based regimen (219).

### Clinical Applications

Etravirine's clinical utility is limited to treatment-experienced patients, but its tolerability and side-effect profile make it an appealing treatment option in combination with other active agents, particularly for those retaining etravirine susceptibility after failing other regimens. Etravirine monotherapy demonstrated considerable potency and tolerability over 7 days in treatment-naïve individuals (220). In treatment-experienced individuals failing initial NNRTI regimens, etravirine has virologic activity against NNRTI-resistant virus (217, 221). The addition of etravirine in highly treatment-experienced individuals results in an increased proportion of individuals achieving sustained virologic suppression to <50 copies/ml and greater increases in CD4 cell counts than with placebo (211, 212). The efficacy of etravirine in highly treatment-experienced patients is adjunctive and often difficult to separate from the durable virologic response of other fully active drugs included in the new, combination regimens (210).

### Rilpivirine

Rilpivirine [4-((4-(4-((1E)-2-cyanoethenyl)-2,6-dimethylphenyl)amino)-2-pyrimidinyl)amino)benzotrile; TMC 278, Edurant] (Figs. 1 and 4; Tables 1 and 3) is a diaryl-pyrimidine analog that demonstrates conformational “flexibility” enabling it to bind to the hydrophobic pocket of reverse transcriptase of both wild-type and drug-resistant variants (222). The  $IC_{50}$  is <1 nM (0.37 ng/ml). It is available as 25-mg tablets or in fixed-dosed combinations with emtricitabine and TDF (Complera) or with emtricitabine and TAF (Odefsey). A nanosuspension formulation of rilpivirine is under study, in combination with cabotegravir, and is being considered for both maintenance treatment in HIV positive persons and prevention in HIV negative persons (1, 63).

### Pharmacology

The oral bioavailability of rilpivirine is unknown but peak concentrations of ~160 ng/ml are achieved within 4–5 hours. Administration in the fasting state or with only a nutritional supplement decreases the AUC by 40–50%, so rilpivirine should be administered with meals. Rilpivirine is

highly protein bound (>99%), and CSF concentrations average only 1.4% of plasma concentrations (223). Rilpivirine is metabolized by CYP3A. The terminal  $t_{1/2}$  is about 50 h allowing for once-daily oral dosing. Rilpivirine-LA is a nanosuspension which is administered intramuscularly and demonstrates a  $t_{1/2}$  of 33–35 hours (224).

### Adverse Effects

The most common adverse effects associated with rilpivirine are headache, insomnia, and rash. In clinical trials, the frequency of neurologic and psychiatric adverse events, lipid elevations, and rash were less with rilpivirine compared to efavirenz. Severe skin and hypersensitivity reactions are still of concern. Liver function tests should be monitored in patients with underlying liver disease. Higher doses of rilpivirine (75 mg daily) have been associated with a maximum QTcF interval-prolongation of ~10.7 msec at 16 hours post-dosing. At therapeutic dosing (25 mg daily) rilpivirine has not been associated with a significant prolongation of the QTc interval, although some abnormalities were noted and several events had a delayed onset that may not have been observed in earlier studies. The drug is better avoided in individuals with QTc prolongation at baseline and in those likely to be prescribed other drugs that may confer this risk.

### Drug Interactions

Rilpivirine is a substrate of the CYP3A4 isoenzyme. Exposure to rilpivirine is increased during coadministration with ritonavir, but no dosage adjustments of rilpivirine are recommended with boosted PIs. Rilpivirine concentrations are decreased by the coadministration with rifabutin. Due to increased gastric pH and impaired rilpivirine absorption, caution must be exercised with antacids, histamine 2-receptor antagonists (H2RA), and proton pump inhibitors. Antacids should be administered 2 hours before or 4 hours after a rilpivirine dose. H2RAs decrease rilpivirine AUC ~76% and should be administered at least 4 hours after or 12 hours before a rilpivirine dose. Proton pump inhibitors are contraindicated.

### Resistance

Rilpivirine has a somewhat low barrier to resistance, and, when compared to efavirenz-based regimens, those failing rilpivirine-based regimens were more likely to develop resistance mutations, although the role of tolerance and adherence needs to be taken into account in assessing how much pressure was placed on the virus (225). Mutations associated with rilpivirine resistance include L100I, K101E/P, E138A/G/K/Q/R, V179L, Y181C/I/V, Y188L, H211Y, F227C, and M230I/L. The K103N/R/S and V179D mutations do not confer resistance as single mutations but do when detected in the combinations L100I plus K103N/S or L100I plus K103R and V179D (28, 226). The E138A mutation and others may occur more frequently as natural polymorphisms in non-B subtype viruses (227). The M184I resistance mutation, which confers resistance to the NRTIs lamivudine and emtricitabine also potentiates rilpivirine resistance conferred by E138K and K101E (28, 228–230).

### Clinical Applications

Rilpivirine is used in treatment-naïve patients with an HIV-1 RNA level <100,000 copies/ml. Virologic failure is more common when rilpivirine-based regimens are initiated in those with HIV-1 RNA levels >100,000 copies/ml, compared with those with lower HIV-1 plasma RNA levels and those receiving efavirenz-based regimens (225, 231, 232).

However, those on rilpivirine-based regimens have had fewer adverse events when compared to efavirenz-based regimens. Few data are available on treatment combinations other than rilpivirine plus tenofovir-emtricitabine. The restriction on using rilpivirine in those with high-baseline HIV-1 RNA levels, as well as the requirement that it must be taken with at least a 400-calorie meal and in the absence of acid-lowering agents, restrict its utility for many treatment-naïve patients. However, the small rilpivirine pill size or the fixed-dose combination rilpivirine/tenofovir/emtricitabine makes it an appealing option.

## INVESTIGATIONAL NNRTIS

A number of investigational NNRTI compounds continue through preclinical and clinical development. These agents are typically characterized by activity against HIV-1 strains with K103N and Y181C mutations and possess improved safety profiles. Doravirine (MK-1439) is one in a new class of compounds called diarylpyrimidines whose 48-week efficacy data suggest comparable *in vivo* activity to efavirenz with HIV viral loads <100,000 copies/ml. Selected agents are listed in Table 2.

## INTEGRASE STRAND TRANSFER INHIBITORS

HIV integrase is a virally encoded enzyme that is responsible for integrating the viral DNA into the genome of the host cell (233). Integration is a multistep event that involves processing of the viral DNA by removing the terminal dinucleotides, formation of the preintegration complex, and integration of the DNA strand into the cellular DNA. The enzyme incorporates viral DNA strands into the host chromosome through strand transfer. Integrase inhibitors belong to a class of antiretroviral agents that selectively inhibit the strand transfer function of the HIV integrase enzyme, thereby preventing integration and inhibiting HIV replication (234, 235).

### Raltegravir

Raltegravir {N-[2-[4-[(4-fluorophenyl)methyl]carbamoyl]-5-hydroxy-1-methyl-6-oxopyrimidin-2-yl]propan-2-yl]-5-methyl-1,3,4-oxadiazole-2-carboxamide; MK-0518, Isentress} (Figs. 1 and 5; Tables 1 and 4) was approved by the FDA in October 2007 at a dosage of 400 mg orally twice daily as the lead compound in this crucial drug class.

### Pharmacology

Raltegravir is active against viruses resistant to all other classes of antiretrovirals, with an  $IC_{95}$  of  $31 \pm 20$  nM against the H9IIIB variant of HIV-1 in human cell lines. The plasma  $C_{max}$  averages  $4.94 \mu\text{M}$  1 hour after a single dose of 200 mg in healthy volunteers (236), and levels in plasma decline below the limits of detection by 24 hours. Food increases the variability of raltegravir bioavailability, but the clinical significance is unknown and raltegravir can be administered without regard to food. In single and multiple dose-ranging studies in healthy and infected subjects, concentrations in serum declined in a biphasic manner, with an initial-phase elimination  $t_{1/2}$  of approximately 1 h and a terminal-phase elimination  $t_{1/2}$  of 7 to 12 hours. About 83% of raltegravir is protein bound; CSF concentrations have been estimated at 5.8% of plasma concentrations. The major mechanism of clearance of raltegravir in humans is by hepatic UGT1A1 to a glucuronidated metabolite excreted primarily in feces

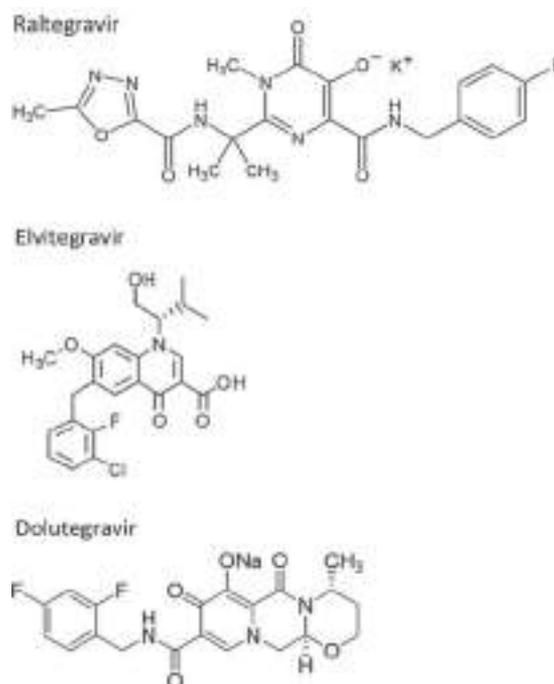

FIGURE 5. Chemical structures of HIV integrase inhibitors.

(51% of the dose) and urine (32% of the dose) (236). No dose adjustment appears necessary in patients with severe renal insufficiency.

### Adverse Effects

Raltegravir is generally well tolerated and does not seem to be associated with lipid abnormalities. Possible side effects include nausea, headache, dizziness, and fatigue. Symptomatic skeletal muscle toxicity including creatine phosphokinase elevations and rhabdomyolysis have been associated with raltegravir therapy (237, 238).

### Drug Interactions

Raltegravir is eliminated primarily by the UGT1A1-mediated glucuronidation pathway; therefore, it may be subject to drug interactions when coadministered with UGT1A1 inducers or inhibitors (e.g., atazanavir, rifampin). Levels of raltegravir in plasma may be mildly increased during concomitant use with tenofovir, atazanavir with or without ritonavir, and omeprazole while raltegravir may be mildly decreased during concomitant use with efavirenz, etravirine, and tipranavir-ritonavir. However, no raltegravir dose adjustments are recommended during coadministration of these drugs. Rifampin significantly decreases raltegravir AUC by 40%, but increasing the dose of raltegravir to 800 mg b.i.d. compensates for this decrease (239). The impact of other UGT1A1 inducers (e.g., phenytoin) on the pharmacokinetics of raltegravir remains unknown.

### Resistance

HIV-1 develops resistance to raltegravir with mutations in the active site of the integrase gene, and cross resistance between currently available integrase inhibitors, particularly between raltegravir and elvitegravir, is common for individuals failing either agent (28). Virologic failure was associated with mutations Q148H/K/R and N155H, which represent signature mutations that define two pathways of

**TABLE 4** Integrase inhibitors: pharmacokinetic, major toxicity, and drug interaction characteristics

Agent	Oral bioavailability	Effect of food on AUC	$t_{1/2}$ (h)	Route of metabolism	Adjustment for hepatic and renal insufficiency	Major toxicities	Major drug interactions
Raltegravir	Unknown	Variable	9	Hepatic metabolism via UGT1A1; excretion: 51% feces, 32% urine	none	Well tolerated, no lipid abnormalities; possible nausea, headache, dizziness, fatigue, rare rhabdomyolysis	Aluminum hydroxide, magnesium salts: decreased levels of raltegravir UGT1A1 inhibitors (tenofovir, atazanavir, and omeprazole): increased levels of raltegravir UGT1A1 inducers (efavirenz, etravirine, rifapentine, rifabutin, and rifampin): decreased levels of raltegravir, requires increased dose of raltegravir
Elvitegravir	Unknown	Fasting decreases AUC by 50% (must be taken with food)	12.9 <sup>a</sup>	CYP3A with hepatobiliary elimination	If combined with cobicistat, do not initiate if CrCl < 70ml/min, stop therapy if CrCl < 50ml/min; not recommended in severe hepatic impairment	Nausea, diarrhea	CYP3A inducers (carbamazepine, efavirenz, phenytoin, nevirapine, oral contraceptives, rifapentine, rifabutin, and rifampin): decreased levels of elvitegravir CYP3A inhibitors (azoles): increased levels of elvitegravir
Dolutegravir	Unknown	Food increases AUC by 33–66%	14	Hepatic metabolism via UGT1A1, small CYP3A contribution	No adjustments but not recommended for CrCl < 30ml/min or severe hepatic impairment	Well tolerated; nausea, diarrhea, insomnia, headache; no lipid abnormalities	CYP3A inducers (carbamazepine, etravirine, nevirapine, phenytoin, phenobarbital, carbamazepine, oxycarbazepine, St. Johns Wort): decreased dolutegravir levels, avoid coadministration; Increase to 50 mg bid if given with efavirenz, rifampin, or some ritonavir-based regimens; administer 4 hours before or 6 hours after cation containing antacids.

<sup>a</sup>If elvitegravir given with pharmacokinetic enhancer.

resistance. Each of these mutations is typically accompanied by one or more additional mutations in isolates derived from patients exhibiting virologic failure on raltegravir. The Q148H/K/R pathway consists of L74M plus E138A/K or G140A/S. The N155H pathway minor mutations are L74M, E92Q, or T97A, plus T97A, Y143R/H/C, G162K/R, V151I, or D232N (28, 240, 241). The F121 mutation is considered a major mutation and also confers some cross-resistance to dolutegravir and elvitegravir (242); G118R, though rare in those failing raltegravir, also confers resistance to raltegravir, elvitegravir, and dolutegravir (243). The presence of R263K, a minor mutation, confers 2- to 5-fold reductions in susceptibility to all currently approved integrase inhibitors but also conveys a loss of viral replicative capacity (28, 244).

### Clinical Applications

Raltegravir has been evaluated as part of initial therapy in treatment-naïve individuals and as salvage therapy in individuals harboring a multidrug-resistant HIV strain. Tolerability and limited adverse effects have led to its inclusion as recommended initial therapy for treatment-naïve patients. Its twice-daily dosing has made it less appealing for some patients when compared with single-tablet regimens, but data suggest that a once-daily 1200-mg dose is noninferior to twice-daily dosing (245). Compared with efavirenz, in combination with tenofovir and lamivudine, raltegravir demonstrates higher rates of early virologic suppression to <50 copies/ml; at 48 weeks, however, comparable rates of virologic suppression and mean changes in CD4 cell counts (144 to 221 cells/mm<sup>3</sup>) are seen in both groups (246–248).

When used in combination with optimized background therapy in treatment-experienced individuals with evidence of resistance to at least one drug in each of the three classes, raltegravir has resulted in as much as a 2- $\log_{10}$  decrease in week 24 HIV-1 RNA levels compared to optimized background therapy alone. Significantly greater proportions of patients in the raltegravir treatment arm achieved HIV-1 RNA levels of <50 copies/ml. Higher doses of the drug resulted in greater CD4 cell recovery (249). Favorable responses have been sustained at 48 weeks (249), thus leading to the selection of raltegravir at 400 mg orally twice daily as the dosage to take forward in clinical development.

In two pivotal studies, week 48 data confirmed the superior potency and durability of raltegravir compared to placebo, each in combination with an optimized background therapy, in individuals with triple-class resistant virus: 64% in the raltegravir arm achieved viral suppression to <50 copies/ml, compared to 34% in the placebo arm (250, 251). The availability of raltegravir has contributed substantially to achieving full virologic suppression (i.e., plasma HIV-1 RNA level of <50 copies/ml) in highly treatment-experienced patients with multidrug-resistant virus.

### Elvitegravir

Elvitegravir {6-[(3-chloro-2-fluorobenzyl)-1-[(2S)-1-hydroxy-3-methylbutan-2-yl]-7-methoxy-4-oxo-1,4-dihydroquinoline-3-carboxylic acid; GS-9137, JTK-303, Vitekta} (Figs. 1 and 5; Tables 1 and 4) is a modified quinolone antibiotic that inhibits HIV-1 integrase. It was approved in 2012 as a fixed-dose combination with cobicistat, emtricitabine, and TDF (Stribild). It is now also available in combination with the same drugs except for the substitution of TAF (Genvoya) for the older disoproxil fumarate component. It is also available as a standalone agent in 85-mg and 150-mg tablets. Dosing is based on concomitant antiretrovirals. Elvitegravir inhibits strand transfer with an IC<sub>50</sub> of 7.2 nM (3.2 ng/ml) and has

an EC<sub>50</sub> of about 0.9 nM (0.4 ng/ml) in HIV-1 infection assays. Elvitegravir is also effective against HIV-2 (252). In a 10-day dose-finding monotherapy study in treatment-naïve and -experienced patients with HIV-1 RNA levels between 10,000 and 300,000 copies/ml, elvitegravir resulted in a  $\geq 1.0$   $\log_{10}$  reduction of HIV-1 RNA (253).

### Pharmacology

Elvitegravir achieves a C<sub>max</sub> concentration of  $\sim 1.5$   $\mu\text{g/ml}$  after a 150-mg dose with ritonavir approximately 4 hours post dose. Fasting decreases the elvitegravir AUC by 50% and thus must be taken with food. Protein binding is very high (>98%). Elvitegravir is metabolized by CYP450-mediated oxidation and glucuronidation (UGTs 1A1 and 1A3) with subsequent hepatobiliary elimination. The terminal t<sub>1/2</sub> is about 8.7 h when administered in combination with the pharmacoenhancers ritonavir or cobicistat.

### Adverse Effects

The most common adverse effects associated with elvitegravir are nausea and diarrhea.

### Drug Interactions

The CYP3A isoenzyme pathway is responsible for the metabolism of elvitegravir, and thus, drugs that induce or inhibit this pathway will decrease or increase elvitegravir levels, respectively. Ritonavir and cobicistat are used as pharmacoenhancers of elvitegravir such that ritonavir 100 mg and cobicistat 150 mg each provide near-maximal boosting of elvitegravir resulting in lower clearance, higher bioavailability, and longer t<sub>1/2</sub> (254, 255). When used with a PI, the dosing recommendations reflect the impact of the boosted PI on elvitegravir kinetics. Coadministration with lopinavir/ritonavir or atazanavir-ritonavir necessitates an elvitegravir dose of 85 mg daily while coadministration with boosted darunavir or fosamprenavir or tipranavir requires an elvitegravir daily dose of 150 mg.

### Resistance

Integrase mutations leading to elvitegravir resistance in treatment-naïve and experienced patients include T66I/A/K, E92Q/G, T97A, F121Y, S147G, Q148H/K/R, N155H, and R236K (208, 256, 257). Mutations T66I, E92Q, F121Y, S147G, G148H/K/R, and N155H are all considered major mutations, those that substantially reduce elvitegravir susceptibility in the absence of other mutations. Cross-resistance is common between raltegravir and elvitegravir, and sequential use is not recommended (28, 83, 258–260).

### Clinical Applications

Elvitegravir, boosted with cobicistat, is used in a fixed-dose combination with emtricitabine and TAF or TDF as initial therapy for treatment-naïve patients (105). When compared with an atazanavir, ritonavir plus TDF-emtricitabine regimen, elvitegravir/cobicistat/emtricitabine/TDF had similar rates of virologic failure and a favorable side effect profile (261, 262). Elvitegravir also had similar efficacy and safety to raltegravir when combined with a ritonavir-boosted PI in treatment-experienced patients, over 60% of whom had two-class drug resistance (263).

### Dolutegravir

Dolutegravir {(4R,12aS)-N-[(2,4-difluorophenyl)methyl]-7-hydroxy-4-methyl-6,8-dioxo-3,4,12,12a-tetrahydro-2H-pyrido[5,6]pyrazino[2,6-b][1,3]oxazine-9-carboxamide; GSK1349572, Tivicay} (Figs. 1 and 5; Tables 1 and 4) is the

most recently approved integrase inhibitor of HIV-1. It is effective in the presence of most raltegravir- and elvitegravir-associated mutations. It is available as 50-mg tablets and in combination with abacavir and lamivudine (Triumeq).

### Pharmacology

Dolutegravir exhibits potent antiviral activity with a median  $IC_{50}$  of 1.07 nM against 9 wild-type isolates. It is administered without regard to food, although food increases the dolutegravir AUC by 33–66%. Dolutegravir trough concentrations exceed the  $IC_{90}$  of most viral strains by at least 5-fold (264). Dolutegravir is primarily hepatically metabolized by UGT1A1 with some contribution of CYP3A. The elimination  $t_{1/2}$  is ~14 hours, negating the need for a pharmacoenhancer and allowing for once-daily dosing. Renal elimination accounts for <1% of a dose, but patients with severe renal impairment ( $CrCl < 30$  ml/min) have an AUC that is 40% less compared to healthy matched controls. The mechanism of these lower exposures is unknown, but it is thought to be clinically significant only in treatment-experienced patients.

### Adverse Effects

Dolutegravir, as with other members in this class, is generally well tolerated. The most common adverse effects are nausea, diarrhea, insomnia, and headache. Effects on lipids are minimal and comparable to raltegravir. An increase in serum creatinine of ~0.11 mg/dl occurs in the first 4 weeks of treatment and remains stable through 48 weeks of treatment, due to the cobicistat component that mediates the inhibition of creatinine secretion by the organic cation transport system; there is no impact on glomerular filtration rate.

### Drug Interactions

Potent inducers of CYP3A4 decrease dolutegravir concentrations, necessitating an increased dose or in some cases alternative agents. Coadministration with etravirine (without select boosted PIs), nevirapine, phenytoin, phenobarbital, carbamazepine, oxcarbazepine, and St. John's wort is not recommended. When dolutegravir is used concomitantly with efavirenz, fosamprenavir-ritonavir, tipranavir-ritonavir, and rifampin, dolutegravir should be dosed at 50 mg twice daily. Efavirenz and rifampin decrease the dolutegravir AUC to 43% and 46% of usual exposure, respectively, which can be overcome with twice-daily dosing. Dolutegravir absorption is adversely affected by cation-containing antacids, sucralfate, iron, calcium supplements, and buffered medications (decrease absorption ~75%) such that dolutegravir must be administered either 2 h before or 6 h after these medications.

### Resistance

Dolutegravir has a relatively high barrier to resistance, and several mutations are required in combination to induce high-level resistance (28, 265–267). The major mutation, Q148H/R, occurs in patients failing raltegravir- or elvitegravir-based regimens but has minimal effect on dolutegravir susceptibility alone (83, 268). Dual mutation combinations with E138A/K or G140A/S can cause more than a 10-fold decrease in dolutegravir susceptibility (269). Other minor mutations associated with dolutegravir resistance, when combined with other mutations, include F121Y, N155H, and R263K (28). The majority of dolutegravir-associated resistance mutations also confer resistance to raltegravir and elvitegravir, making cross-resistance a problem.

### Clinical Applications

Dolutegravir has been extensively studied in treatment-naïve patients, and its efficacy and tolerability resulted in its being recommended as one of the preferred components of initial therapy by treatment guidelines committees (1, 105). Once-daily dolutegravir is noninferior to twice-daily raltegravir in combination with either tenofovir-emtricitabine or abacavir-lamivudine in treatment-naïve patients (270). Dolutegravir plus abacavir-lamivudine has superior rates of virologic suppression compared to the fixed-dose combination efavirenz/TDF/emtricitabine and primarily because of treatment discontinuation with efavirenz (139, 271). Dolutegravir-based regimens are also superior to darunavir-ritonavir-based regimens because of more frequent treatment discontinuation with the PI regimen (272, 273).

Dolutegravir has also shown efficacy, tolerability, and a high barrier to resistance in trials for treatment-experienced patients. A phase IIb study assessing the activity of dolutegravir plus optimized background regimens in patients with raltegravir resistance found that twice-daily dolutegravir dosing was more effective than once-daily (269). Dolutegravir-based regimens are superior to raltegravir-based regimens in treatment-experienced patients with at least two-class drug resistance but no prior exposure to integrase inhibitors, demonstrating higher rates of virologic suppression and lower risk for development of resistance (274).

## INVESTIGATIONAL INTEGRASE INHIBITORS

In the current era of increased use of integrase inhibitors, additional agents with a focus on potency and less frequent dosing are being developed (see Table 2). Bictegravir (GS-9883) has more favorable pharmacokinetics, comparable tolerability, and an improved resistance profile compared to other INSTIs, including dolutegravir. Bictegravir is being formulated as a combination product containing bictegravir/emtricitabine/TAF and is currently in phase 3 clinical trials. A novel agent in this class is cabotegravir (S/GSK1265744). Its structure is similar to that of dolutegravir with an elimination  $t_{1/2}$  of ~40 hours following oral administration. Cabotegravir is also formulated in a long-acting injectable as nanoparticles resulting in an extended half-life of 21–50 days following a single dose that would potentially allow for bimonthly, intramuscular injections (275), but this is still under study. It is being developed for both the treatment and prevention of HIV-1 infection.

## HIV PROTEASE INHIBITORS

Retrovirus replication requires virus-mediated proteolytic cleavage of *gag* and *gag-pol* polypeptide precursors mediated by the dimeric viral aspartyl protease. There are currently nine approved HIV PIs that share several characteristics: (i) are peptidomimetics; (ii) bind to the active site with a noncleavable scissile bond; (iii) have potent *in vivo* activity against HIV-1 when used in combination regimens; (iv) have *in vitro* activity against both HIV-1 and HIV-2; (v) have various degrees of cross-resistance that can be treatment limiting; and (vi) have pharmacological profiles that confer a significant potential for drug interactions with other antiviral and non-antiviral agents. For a number of agents in this class, this latter characteristic can be exploited to improve pharmacological profiles with “boosting” using either ritonavir or cobicistat. The unique resistance characteristics

(e.g., large number of mutations required to confer resistance) and antiviral efficacy of boosted PIs make them attractive choices for initial as well as salvage therapy (276, 277). Second-generation PIs such as tipranavir and darunavir present additional options for patients who are highly treatment-experienced and have HIV-1 strains resistant to other PIs.

Potential interactions with PIs may result from the coadministration of drugs that affect the CYP3A4 isozyme. Major drug interactions for PIs are listed in Table 5. Specific drugs and drug classes of this kind (e.g., astemizole and terfenadine, midazolam, triazolam, simvastatin, lovastatin, cisapride, and ergot alkaloids) may lead to severe toxicity and, therefore, are contraindicated in combination with CYP3A4-metabolized PIs. Conversely, inducers of the CYP3A4 isozyme (e.g., rifabutin and rifampin) can enhance PI clearance and lead to subtherapeutic levels.

Caution is required in administering PIs along with nonprescription herbal remedies. Since the currently available PIs are P-glycoprotein substrates and since constituents of St. John's wort are P-glycoprotein inducers, their coadministration should be avoided because therapeutic failure could result from reduced PI bioavailability.

Metabolic disorders have been increasingly recognized in the era of more potent antiretroviral therapy. Beginning in the late 1990s, case reports and studies began implicating PIs in causing abnormal glycemic control, insulin resistance, and increased triglyceride and cholesterol levels as soon as 14 days after treatment initiation. Accompanying body morphology changes have been described (278–280). These include fat distribution changes like truncal obesity, dorsocervical fat (“buffalo hump”), lipomatosis, and gynecomastia, as well as lipoatrophy from the buttocks, face, and extremities. The lipoatrophic changes have also been attributed to nucleoside analog therapy, and attempts to dissect the causality of the morphological changes continue. Lipodystrophic changes may be accompanied by insulin resistance and hypertriglyceridemia.

The PI era began in earnest in the mid-1990s with the reporting of the virologic and clinical benefits of indinavir-zidovudine-lamivudine and ritonavir (281–283). The fortunate parallel development and implementation of plasma HIV-1 RNA assays facilitated the performance of clinical trials and were a boon to clinicians and patients as monitoring tools (284, 285). The era of truly potent, fully suppressive antiretroviral therapy (ART) began in 1996 and sparked further drug development to make regimens simpler, more effective, and less toxic. Saquinavir was the first PI approved but was hampered by poor absorption. Thus, the *in vivo* potency of this class of drugs was realized by full-dose ritonavir and indinavir that resulted in durable virologic suppression; reductions in HIV-related disease progression and death followed. Saquinavir and indinavir are now little used, and ritonavir's use is restricted as a low-dose pharmacoenhancer of other antiretrovirals. The next wave of PI development brought nelfinavir, amprenavir, fosamprenavir, and lopinavir/ritonavir, with the latter becoming an important part of therapeutic regimens worldwide. Thus, this section will detail the characteristics of lopinavir/ritonavir, atazanavir, tipranavir, and darunavir. The other approved but currently little used PIs, are discussed in the third edition of this textbook.

### Lopinavir (Coformulated with Ritonavir)

Lopinavir {(2S)-N-[(2S,4S,5S)-5-[[2-(2,6-dimethylphenoxy)acetyl]amino]-4-hydroxy-1,6-diphenylhexan-2-yl]-3-methyl-

2-(2-oxo-1,3-diazinan-1-yl)butanamide; Kaletra} is structurally related to ritonavir (Figs. 1 and 6; Tables 1 and 5). For pharmacological enhancement, it is formulated in a fixed-dose combination with ritonavir in a tablet containing 200 mg of lopinavir and 50 mg of ritonavir. The liquid formulation contains 80 mg of lopinavir and 20 mg of ritonavir per ml; the capsule formulation has been discontinued. The more recent formulation offers lower pill burden, less drug level variability, enhanced tolerability, and heat stability. In the absence of significant mutations, drug interactions, and pregnancy, ritonavir-boosted lopinavir is approved for once-daily dosing.

Lopinavir was designed primarily to reduce the dependence of PI activity on the drug molecule interacting with the isopropyl side chain of the V82 amino acid of the target HIV-1 protease. As a result, lopinavir exhibits more potent activity against both wild-type and mutant HIV-1 strains than does ritonavir. The  $IC_{50}$  of lopinavir is approximately 10-fold lower than that of ritonavir. The mean  $IC_{50}$  of lopinavir ranges from 4 to 11 nM (0.003–0.007  $\mu$ g/ml) for HIV-1 subtype B clinical isolates.

### Pharmacology

In healthy volunteers, a 400-mg dose of lopinavir alone only transiently produces plasma drug levels of  $>0.1$   $\mu$ g/ml due to rapid metabolism. To compensate for these low levels, lopinavir was developed with pharmacokinetic enhancement by ritonavir to inhibit lopinavir metabolism. The resulting lopinavir/ritonavir combination has an  $AUC_{0-24h}$  that is 77-fold greater than that of lopinavir alone, and it has a plasma elimination  $t_{1/2}$  of about 10 hours. Women in their second and third trimester of pregnancy have 40% lower trough concentrations of lopinavir compared to post-partum; this difference is considered clinically significant for women who harbor viruses with reduced susceptibility. Lopinavir is more than 98% protein bound, but the CSF penetration of lopinavir/ritonavir results in levels which exceed the  $IC_{50}$  for wild-type HIV-1. Lopinavir is metabolized by CYP3A4; lopinavir metabolism results in the formation of at least 13 inactive oxidative compounds.

### Adverse Effects

Gastrointestinal adverse effects (diarrhea, abdominal discomfort, and nausea) are the most commonly reported adverse effects. These symptoms typically occur in the initial 2 months of therapy and subsequently diminish in frequency. Lopinavir/ritonavir has a greater impact on cholesterol, particularly on triglycerides, than do atazanavir-ritonavir and saquinavir-ritonavir (286); some of these abnormalities may be reversible upon switching to another PI (e.g., atazanavir or a NNRTI). Like other PIs, lopinavir/ritonavir may contribute to abnormalities of body fat redistribution.

Diarrhea has been reported with a greater frequency at the 800-mg/200-mg once-daily dosing schedule approved for antiretroviral-naïve patients than with conventional dosing (17% vs. 5%, respectively) (287). Hepatotoxicity and pancreatitis have been reported. Changes in the lipid profile typically occur in the first month of treatment (288). Prolongation of the QT and PR intervals are of concern and caution is necessary in patients at risk.

### Drug Interactions

Lopinavir/ritonavir is an inhibitor of CYP3A4. Efavirenz reduces the levels of lopinavir/ritonavir due to its CYP450-inducing activity; therefore, the dose of lopinavir/ritonavir should be increased when used in combination with efavirenz.

**TABLE 5** Commonly used protease inhibitors: pharmacokinetic, major toxicity, and drug interaction characteristics

Agent	Oral bioavailability	Effect of food on AUC	$t_{1/2}$ (h)	Route of metabolism	Adjustment for hepatic and renal insufficiency	Major toxicities	Major drug interactions
Lopinavir/ ritonavir	Unknown	Increased by 48–130%	5–6	CYP3A4 inhibitor and substrate	Hepatic: no Renal: no	Diarrhea, nausea, vomiting, elevated transaminases, hyperlipidemia, hypertriglyceridemia, fat redistribution, metallic taste, asthenia, potential for increased bleeding in patients with hemophilia	Decreased methadone levels
Tipranavir	Unknown	None	6	CYP3A4 inducer and substrate; combined with ritonavir CYP3A4 inhibitor and CYP2D6 inhibitor; potent inducer of P-glycoprotein	Hepatic: use with caution in moderate to severe impairment Renal: no	Rash (especially patients with sulfonamide allergy); nausea; vomiting; diarrhea; hepatotoxicity, including hepatic decompensation (especially with underlying liver disease); hyperlipidemia; hypertriglyceridemia; fat redistribution; case reports of intracranial hemorrhage; potential for increased bleeding in patients with hemophilia	Clarithromycin, azole antifungals: increased tipranavir levels Erectile dysfunction agents: increased levels by tipranavir-ritonavir Lipid-lowering agents (atorvastatin, simvastatin): increased levels by tipranavir-ritonavir and increased potential for myopathy or rhabdomyolysis Amiodarone: increased potential for serious or life-threatening cardiac arrhythmias Rifampin and St. John's wort: decreased tipranavir levels Etravirine, zidovudine: decreased levels by tipranavir
Atazanavir	Unknown	Increased	7	CYP3A4 inhibitor and substrate	Hepatic: yes Renal: no	Prolonged PR interval and first-degree AV block (asymptomatic), indirect hyperbilirubinemia, abnormal liver enzymes, hyperglycemia, fat redistribution, potential for increased bleeding in patients with hemophilia	Proton pump inhibitors decrease atazanavir absorption, and concurrent administration is contraindicated; other antacids and H <sub>2</sub> blockers should be used with caution Efavirenz: decreased atazanavir levels; addition of ritonavir may compensate for the interaction Etravirine: decreased atazanavir levels and etravirine levels increased by atazanavir; coadministration not recommended

(Continued)

**TABLE 5** Commonly used protease inhibitors: pharmacokinetic, major toxicity, and drug interaction characteristics (*Continued*)

Agent	Oral bioavailability	Effect of food on AUC	$t_{1/2}$ (h)	Route of metabolism	Adjustment for hepatic and renal insufficiency	Major toxicities	Major drug interactions
Darunavir	37%; 82% with ritonavir	Increase	15 (with ritonavir)	CYP3A4 inhibitor and substrate	Hepatic: yes Renal: no	Rash; diarrhea; nausea; headache; cold-like symptoms, including runny nose or sore throat; elevated transaminases; hyperlipidemia; hypertriglyceridemia	Lipid-lowering agents, calcium channel blockers, antiarrhythmics, erectile dysfunction agents, clarithromycin, tenofovir: increased levels by darunavir or darunavir-ritonavir Rifampin: decreased darunavir levels Rifabutin: increased levels by darunavir, requires reduced rifabutin dose Caution with lopinavir-ritonavir or efavirenz (decreased darunavir levels and increased coadministered drug levels) Maraviroc: increased levels; adjust dose to 150 mg b.i.d. when combined with darunavir-ritonavir

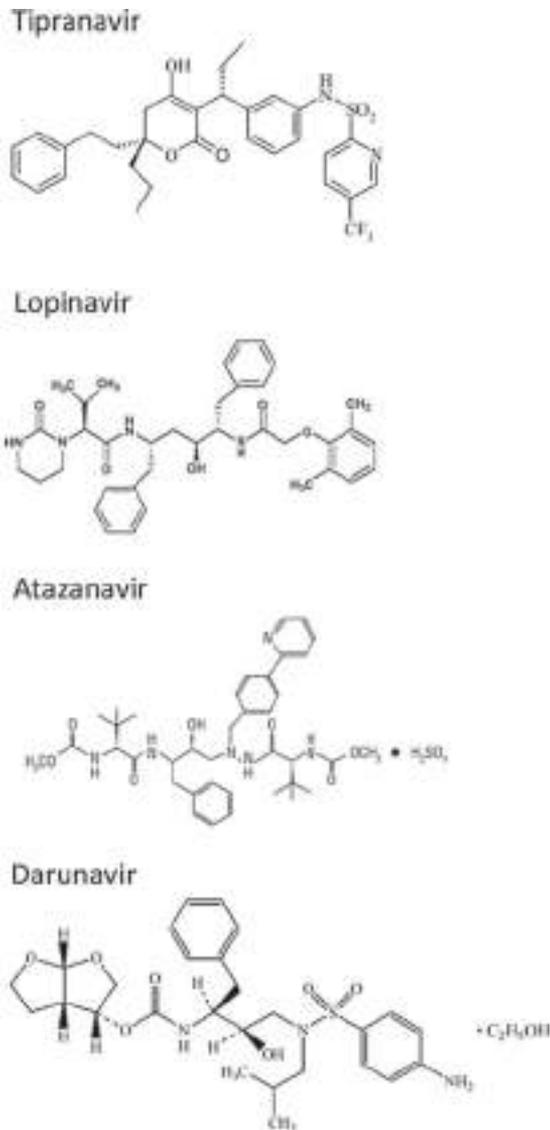

FIGURE 6. Chemical structures of HIV protease inhibitors.

Tipranavir decreases lopinavir levels significantly and should not be coadministered. Rifampin decreases lopinavir levels by 75%, an effect that may be overcome by administering 800 mg lopinavir/200 mg ritonavir twice daily or 400 mg lopinavir/400 mg ritonavir twice daily (289). Lopinavir has been shown to significantly reduce methadone levels, resulting in opiate withdrawal symptoms.

### Resistance

Coformulated lopinavir/ritonavir demonstrates a high genetic barrier to resistance, requiring six or more mutations for reduced virologic response (290, 291). At least 10-fold reductions in susceptibility are needed before a change in virologic response is observed, and  $\geq 60$ -fold reductions in susceptibility are required before the activity of a standard dose of the drug is no longer sufficient to reduce plasma HIV-1 RNA levels by half a log. The characterization of *in vitro*-selected lopinavir-resistant HIV-1 strains reveals a sequential accumulation of mutations in the protease gene that include L10F/I/R/V, K20M/R, L24I, V32I, L33F, M46I/L, I47V/A,

I50V, F53L, I54V/L/A/M/T/S, L63P, A71V/T, G73S, L76V, V82A/F/T/S, I84V, and L90M (28), with major mutations being those at positions 32, 47, 76, and 82. The V32I and I47A mutations are associated with high-level resistance (292–294). In lopinavir/ritonavir-naïve patients with wild-type virus who experience virologic failure, emergence of resistance mutations is rare (293, 294).

### Clinical Applications

Lopinavir/ritonavir is no longer a preferred regimen for treatment-naïve patients because of its high pill burden (four per day) and the side effects associated with its higher doses of ritonavir. However, it has a robust track record of safety and efficacy, a relatively high barrier to resistance, and is more affordable than darunavir. Thus, it is widely used in resource-constrained settings, particularly as the linchpin for second-line therapy following virologic failure on an NNRTI-based regimen (295). A direct comparison of lopinavir/ritonavir, either once or twice daily, to darunavir-ritonavir once daily, both combined with tenofovir-emtricitabine in treatment naïve patients, showed superior virological response and a more favorable adverse events profile with fewer gastrointestinal toxicities in the darunavir-ritonavir arm (296). Better virologic responses were also seen with an efavirenz-based regimen than with a lopinavir/ritonavir-based regimen, but better CD4 cell responses and less resistance were seen following virologic failure with lopinavir/ritonavir plus two NRTIs (197). Atazanavir-ritonavir and twice daily lopinavir/ritonavir, each in combination with tenofovir-emtricitabine, show similar efficacies, although atazanavir-ritonavir confers better lipid profiles and fewer gastrointestinal side effects (297, 298). Lopinavir/ritonavir twice daily plus lamivudine is one of the few recommended alternative regimens for treatment-naïve individuals that use fewer than two NRTIs (299).

Lopinavir/ritonavir also is used in salvage therapy. In combination with NNRTIs and NRTIs, lopinavir/ritonavir has resulted in virologic suppression to  $< 400$  copies of HIV RNA/ml in patients failing to respond to their initial or multiple PI regimens (300). In patients failing an NRTI plus NNRTI-based first-line regimen, the combination of raltegravir plus lopinavir/ritonavir is noninferior to lopinavir/ritonavir plus two or three NRTIs with respect to the proportion of patients with plasma HIV-1 RNA levels under 200 copies/ml (301). In patients with prior failure on a PI-based regimen, lopinavir/ritonavir demonstrates an efficacy comparable to that of ritonavir-boosted atazanavir for suppression of plasma HIV-1 RNA levels to  $< 50$  copies/ml (302). The greatest benefit has been seen in patients with  $\geq 4$  major protease mutations at baseline (303). In lopinavir-naïve, treatment-experienced patients, the more recently introduced PIs such as darunavir-ritonavir or tipranavir-ritonavir proved noninferior to lopinavir/ritonavir treatment (304). Once-daily dosing is not recommended in PI-experienced patients.

While some data support the use of lopinavir/ritonavir monotherapy following a fully suppressive regimen, its use as simplification therapy is not recommended (305, 306). Two studies found that large proportions of patients on lopinavir/ritonavir monotherapy after initial virologic suppression experienced suboptimal virologic responses compared to those who continued use of combinations (307, 308). Lopinavir/ritonavir monotherapy also led to less virologic suppression than combination lopinavir/ritonavir plus tenofovir-emtricitabine in patients failing NNRTI-based regimens (309).

**TABLE 6** Fixed-dose single-tablet regimens. All are given as one tablet orally, once daily.

Agent	Components	Comments
Atripla	Efavirenz 600 mg Tenofovir disoproxil fumarate 300 mg Emtricitabine 200 mg	Alternative regimen for treatment-naïve patients because of association with suicidality in some studies Take on an empty stomach Nighttime dosing recommended to reduce impact of associated drowsiness, dizziness, and other central nervous system side effects.
Complera	Rilpivirine 25 mg Tenofovir disoproxil fumarate 300 mg Emtricitabine 200 mg	Alternative regimen for treatment-naïve patients Only for patients with pre-treatment HIV RNA level <100,000 copies/ml and CD4+ cell count >200 cells/mm <sup>3</sup> Must be taken with a meal (≥400 calories)
Genvoya	Elvitegravir 150 mg Cobicistat 150 mg Tenofovir alafenamide 10 mg Emtricitabine 200 mg	Recommended regimen for treatment-naïve patients Only for patients with pre-treatment estimated creatinine clearance ≥30 ml/min
Odefsey	Rilpivirine 25 mg Tenofovir alafenamide 25 mg Emtricitabine 200 mg	Must be taken with a meal (≥400 calories) Only for patients with pre-treatment HIV RNA level <100,000 copies/ml Only for patients with pre-treatment estimated creatinine clearance ≥30 ml/min
Stribild	Elvitegravir 150 mg Cobicistat 150 mg Tenofovir disoproxil fumarate 300 mg Emtricitabine 200 mg	Recommended regimen for treatment-naïve patients Only for patients with pre-treatment estimated creatinine clearance ≥70 ml/min
Triumeq	Dolutegravir 50 mg Abacavir 600 mg Lamivudine 300 mg	Recommended regimen for treatment-naïve patients Only for patients who have tested negative for HLA-B*5701

### Tipranavir

Tipranavir {(N-[3-[(1R)-1-[(2R)-6-hydroxy-4-oxo-2-(2-phenylethyl)-2-propyl-3,4-dihydro-2H-pyran-5-yl]propyl]-phenyl]-5-(trifluoromethyl)-2-pyridinesulfonamide; Aptivus)} is a nonpeptidic PI belonging to the class of 4-hydroxy-5,6-dihydro-2-pyrone sulfonamides (Figs. 1 and 6; Tables 1 and 5). It is available as a 250-mg soft-gelatin capsule co-administered with ritonavir.

Tipranavir is active against a wide range of drug-resistant isolates and has a mean IC<sub>50</sub> of 0.14 mg/l for highly multidrug-resistant clinical isolates (310). Potential mechanisms of its enhanced potency against PI-resistant virus include the ability to bind to the active site of the HIV protease with fewer hydrogen bonds, thereby creating greater flexibility at the active site (310) or strong hydrogen bonding interaction with the amide backbone of the protease active-site Asp30 (311, 312).

### Pharmacology

Maximum mean tipranavir concentrations of 47 to 57 mg/l are achieved within 3 hours post-dosing. Food does not impact tipranavir absorption. Tipranavir is >99% protein bound with a plasma elimination *t*<sub>1/2</sub> of 6 hours. As tipranavir is a substrate for CYP3A4, boosting with ritonavir is necessary to achieve a desirable pharmacodynamics profile. Ritonavir increases tipranavir concentrations 24- to 70-fold. To achieve adequate concentrations, tipranavir 500 mg must be coadministered with 200 mg of ritonavir twice daily. The higher dose is required because tipranavir is both a substrate and potent inducer of P-glycoprotein and may initially induce its own metabolism (313, 314). Tipranavir use is contraindicated in patients with moderate to severe hepatic impairment.

### Adverse Effects

The most common adverse effects associated with tipranavir are predominantly gastrointestinal and include diarrhea, dyspepsia, abdominal distention, and pancreatitis. In two large clinical trials (RESIST 1 and RESIST 2) of more than 1,400 patients, which included patients coinfecting with HBV or HCV but with stable liver enzymes at baseline, hepatic and lipid-related adverse effects occurred with greater frequency in the tipranavir-ritonavir arm but were rarely a cause for drug discontinuation. Hepatitis virus coinfection and a baseline CD4 cell count of >200 cells/mm<sup>3</sup> were predictors of liver function abnormalities (315). Cases of clinical hepatitis and hepatic decompensation in patients with chronic HBV or HCV infection who received tipranavir-ritonavir have been reported.

Ritonavir-boosted tipranavir was linked to cases of intracranial hemorrhage, sometimes fatal, but a direct causative effect has not been proven, and many of the patients had other contributing risk factors. *In vitro* and *in vivo* data suggest that tipranavir can inhibit platelet aggregation and thus should be used with caution in patients receiving antiplatelet agents, anticoagulants, supplemental high doses of vitamin E, or who are at risk of increased bleeding after trauma or surgery (316).

### Drug Interactions

Tipranavir both inhibits and induces the CYP450 enzyme system, and when tipranavir is used in combination with ritonavir, the net effect is inhibition of the CYP3A4 enzyme. Tipranavir is also an inducer of the P-glycoprotein transporter. Thus, tipranavir may alter the concentrations of many other drugs metabolized by these pathways (Table 4). Tipranavir decreases the concentrations of atazanavir,

fosamprenavir, lopinavir/ritonavir, and saquinavir and nucleoside analogs like abacavir, zidovudine, and didanosine. Coadministration of tipranavir-ritonavir with enfuvirtide may affect the volume of distribution and elimination  $t_{1/2}$  of tipranavir, thereby resulting in a 45% increased  $C_{\min}$  of tipranavir, although this interaction does not appear to result in an increased risk of hepatotoxicity.

### Resistance

Tipranavir retains activity against many HIV-1 isolates with resistance to previously approved PIs such as nelfinavir, fosamprenavir, atazanavir, and lopinavir/ritonavir (310). Ninety percent of highly resistant clinical isolates (>10-fold resistance to three or more PIs) remain susceptible to tipranavir, and only 2% have >10-fold resistance to tipranavir (310); durable virologic responses are associated with a tipranavir resistance score of  $\leq 2$  at baseline (42). Major mutations include codons I47V, Q58E, T74P, V82L/T, N83D, and I84V (28). Minor mutations that correlate with a decreased response to tipranavir-ritonavir therapy in treatment-experienced patients are L10V, L33F, M36I/L/V, K43T, M46L, I54A/M/V, H69K/R, and L89I/M/V.

### Clinical Applications

Tipranavir is approved for use, in combination with ritonavir, for treatment-experienced patients with resistance to more than one other PI (42). However, drug interactions, the need for 200 mg twice daily of ritonavir, the pill burden, and the possibilities of serious hepatotoxicity and perhaps intracranial hemorrhage, have led many providers to choose options other than tipranavir for treatment-experienced patients (105). Its use has been limited to the rare patient with darunavir resistance and with maintained susceptibility to tipranavir.

### Atazanavir

Atazanavir {methyl N-[(2S)-1-[2-[(2S,3S)-2-hydroxy-3-[[[(2S)-2-(methoxycarbonylamino)-3,3-dimethylbutanoyl]amino]-4-phenylbutyl]-2-[(4-pyridin-2-ylphenyl)methyl]hydrazinyl]-3,3-dimethyl-1-oxobutan-2-yl]carbamate; BMS-232632, Zrivada, Reyataz} (Figs. 1 and 6; Tables 1 and 5) is an azapeptide aspartyl PI. It is available in capsule formulations of 150, 200, and 300 mg and 50-mg oral powder packets and as a fixed-dose combination with cobicistat (Evotaz).

Atazanavir has activity against laboratory and clinical HIV-1 isolates grown in peripheral blood mononuclear cells and macrophages ( $IC_{50}$ , 2 to 5 nM) and variable activity against HIV-2 isolates (1.9 to 32 nM). Clinical isolates that are resistant to first-generation PIs may remain susceptible to atazanavir. However, isolates with high-level resistance, and hence, a larger number of mutations in the protease gene, are more likely to be associated with resistance to atazanavir.

### Pharmacology

Atazanavir has rapid absorption that requires food and gastric acid; coadministration of a single dose with a light meal increases the AUC by 70%. A 400-mg once-daily dose attains mean steady-state  $C_{\max}$  of 3.2  $\mu\text{g}/\text{ml}$  and AUC of 22.3  $\mu\text{g}^*\text{h}/\text{ml}$ , well above the protein-binding-adjusted  $IC_{90}$ . Atazanavir is 86% protein bound and has a plasma elimination  $t_{1/2}$  of approximately 7 hours. It is metabolized by hepatic CYP3A4 with only 13% of unmetabolized drug excreted in the urine. Atazanavir can be boosted by ritonavir 100 mg daily or cobicistat 150 mg daily.

The daily dose should be reduced to 300 mg daily in patients with moderate hepatic impairment due to a 46%

increase in AUC. It is not recommended in patients with severe hepatic impairment, and boosted atazanavir is not recommended in any degree of hepatic impairment. The CSF-to-plasma ratio is 0.002 to 0.02, comparable to that of indinavir.

### Adverse Effects

The most prominent adverse effect of atazanavir is reversible indirect hyperbilirubinemia, typically occurring in the first 60 days of treatment (Table 4). It is more frequent in persons with the UGT1A1-28 genotype or the CC genotype of the 3435C $\rightarrow$ T polymorphism in the multidrug resistance (MDR1) gene (317–320). Patients with Gilbert and Crigler-Najjar syndromes harbor polymorphisms in the UGT1A1 gene and demonstrate higher levels of indirect bilirubin after treatment with either indinavir or atazanavir than do untreated patients. Prolongation of the PR and QTc intervals has been noted. A case of torsade de pointes has been reported (321). Caution is advised when coadministering atazanavir with other drugs that cause PR interval prolongation.

Nephrolithiasis due to drug crystals may occur with use of ritonavir-boosted or unboosted atazanavir (322). Lipid abnormalities are slightly more pronounced in patients receiving ritonavir-boosted atazanavir than in those receiving atazanavir alone, but both regimens still have less of an impact on lipids than lopinavir/ritonavir and efavirenz.

### Drug Interactions

Atazanavir is a substrate and inhibitor of CYP3A and UGT1A1 and a weak inhibitor of CYP2C8. Therefore, atazanavir should not be coadministered with agents with narrow therapeutic windows that are substrates of these isoenzymes (Table 4). Atazanavir, however, does not appear to induce its own metabolism. Drugs that induce or inhibit CYP3A activity may decrease or increase, respectively, plasma concentrations of atazanavir. Coadministration with tenofovir decreases serum atazanavir concentrations and increases concentrations of tenofovir (323); addition of low-dose ritonavir compensates for this interaction. Efavirenz decreases atazanavir levels and a higher boosted dose of atazanavir (400 mg with 100 mg ritonavir) is recommended. Atazanavir requires acidic gastric pH for dissolution; therefore, administration with proton pump inhibitors, which raise the gastric pH, significantly interferes with the absorption of atazanavir and can cause subtherapeutic serum atazanavir levels. H<sub>2</sub> receptor antagonists may be an alternative if atazanavir is administered simultaneously or  $\geq 10$  hours after the H<sub>2</sub> receptor antagonist.

### Resistance

*In vitro*, accumulation of the mutations I50L, N88S, I84V, A71V, and M46I decreases susceptibility to atazanavir 93- to 183-fold. Changes are also observed at the protease cleavage sites following drug selection. In PI-naïve patients failing unboosted atazanavir, I50L is the most commonly observed mutation (324), but it occurs less frequently in patients receiving ritonavir-boosted atazanavir (28). Recombinant viruses containing the I50L mutation display increased *in vitro* susceptibility to other PIs (fosamprenavir, indinavir, lopinavir, nelfinavir, ritonavir, and saquinavir). A genotypic resistance score composed of 8 mutations (10F/I/V, G16E, L33I/F/V, M46I/L, D60E, I84V, I85V and L90M) has predicted that the occurrence of >3 of these mutations correlated with a reduced virologic response at 3 months, particularly when L90M is present (325). The presence of a

mutation at positions 46, 73, 84, or 90 at baseline is associated with a poorer virologic response (303). For unboosted atazanavir, the presence of 0, 1 to 2, 3, or  $\geq 4$  of the following mutations has been associated with 83, 67, 6, and 0% response rates: G16E, V32I, K201/M/R/T/V, L33F/I/V, F53L/Y, I64L/M/V, A71I/T/V, I85V, and I93L/M.

### Clinical Applications

Atazanavir as a once-daily administered PI with a favorable lipid profile and a higher genetic barrier to resistance than many NNRTI- or INSTI-based regimens is an alternative choice for both antiretroviral-naïve and -experienced individuals (105). In treatment-naïve patients, ritonavir-boosted atazanavir has efficacy similar to that of unboosted atazanavir but is associated with fewer virologic failures and a higher barrier to development of resistance. Atazanavir boosted with cobicistat appears pharmacokinetically similar to atazanavir-ritonavir (326). Unboosted atazanavir and atazanavir-ritonavir demonstrate potency comparable to that of efavirenz, each in combination with two nucleoside analogs (101, 327). Atazanavir-ritonavir plus tenofovir-emtricitabine is comparable in rates of virologic suppression to elvitegravir/cobicistat/tenofovir/emtricitabine for treatment-naïve patients at 96 weeks of treatment (328). When compared with darunavir-ritonavir or raltegravir plus tenofovir-emtricitabine, atazanavir-ritonavir plus tenofovir-emtricitabine shows a higher rate of discontinuation secondary to adverse events (329). Atazanavir-ritonavir has been used successfully in treatment-experienced patients (286), but it has not performed as well as tipranavir-ritonavir and darunavir-ritonavir in patients failing to respond to multiple PI regimens (41). Transitioning from boosted atazanavir to unboosted atazanavir plus abacavir-lamivudine is a safe strategy for virologically suppressed patients and improves bone and renal biomarkers (330, 331).

### Darunavir

Darunavir  $\{[(3aS,4R,6aR)-2,3,3a,4,5,6a\text{-hexahydrofuro}[2,3\text{-}b]\text{furan-4-yl}] \text{N-}[(2S,3R)\text{-4-}[(4\text{-aminophenyl)sulfonyl-(2-hydroxy-2-methylpropyl)amino]-3-hydroxy-1-phenylbutan-2-yl]carbamate; \text{Prezista, TMC-114}\}$ , is approved for treatment-naïve or -experienced persons (Figs. 1 and 6; Tables 1 and 5). It is available as 75-mg, 150-mg, 400-mg, 600-mg, and 800-mg tablets and a 100-mg/ml oral suspension as well as in a fixed-dose combination with cobicistat 150 mg (Prezcobix). Darunavir requires boosting to attain adequate systemic exposure, either with ritonavir or cobicistat. Darunavir exhibits activity against HIV-1 and HIV-2, with median  $IC_{50}$ s ranging from 1.2 to 8.5 nM (0.7 to 5.0 ng/ml) in PBMCs.

### Pharmacology

Darunavir's oral bioavailability alone and after coadministration with a pharmacoenhancer averages 37% and 82%, respectively. The  $C_{max}$  in plasma is reached in 2.5 to 4 hours. Administration with food increases the darunavir AUC by 40%. Darunavir is approximately 95% protein bound. In the presence of ritonavir at 100 mg, darunavir has a rapid distribution and elimination phase followed by a slower elimination phase, yielding a terminal elimination  $t_{1/2}$  of 15 hours. Darunavir is metabolized by hepatic CYP3A isoenzymes. No dosage adjustments are recommended for either renal or hepatic insufficiency. Considering darunavir's metabolism, caution is recommended in its administration to individuals with severe hepatic insufficiency.

### Adverse Effects

The most common adverse effects are diarrhea, abdominal pain, and headache. Mild to moderate, typically self-limited maculopapular skin eruptions are uncommon ( $< 5\%$ ), and severe skin rash, including erythema multiforme and Stevens-Johnson syndrome, is rare. Darunavir contains a sulfonamide moiety and should be used with caution in patients with a known sulfonamide allergy. There are reports of severe hepatitis, including fatal cases, occurring in approximately 0.5% of patients, particularly those with pre-existing liver disease, including viral hepatitis.

### Drug Interactions

Darunavir is both a substrate and an inhibitor of the CYP3A isoenzyme. As with other PIs, coadministration with drugs primarily metabolized by CYP3A may alter concentrations of darunavir and the other drug in plasma (Table 5).

### Resistance

Major mutations associated with a diminished response to darunavir include I47V, I50V, I54M/L, L76V, and I84V, and minor mutations include V11I, V32I, L33F, T74P, and L89V (28, 332). In treatment-experienced patients, the presence of three or more of these mutations at baseline is correlated with a diminished virologic response to darunavir-ritonavir (41). In a clinical trial of darunavir-ritonavir as salvage therapy, the mutations V32I and I54L/M were present in more than 30% and 20% of isolates derived from patients with virologic failure, respectively, and the median darunavir  $IC_{50}$  of the virologic failure isolates was 21-fold higher at baseline and 94-fold at failure, compared to the reference virus strain. A higher probability of virologic response to darunavir-ritonavir occurs if the baseline darunavir change in the  $IC_{50}$  (compared with reference darunavir susceptibility) is less than 10-fold (41); 10- to 40-fold or  $> 40$ -fold changes in phenotypic susceptibility to darunavir are a commonly used cutoff to differentiate between an intermediate or low likelihood of response to darunavir-ritonavir, respectively. Cross-resistance of darunavir with other PIs including atazanavir, lopinavir/ritonavir, and tipranavir is possible, but darunavir resistance mutations in patients failing other PIs is uncommon (333–335).

### Clinical Applications

Darunavir, in combination with ritonavir or cobicistat pharmacoenhancement, is a robust backbone of first-line therapy for treatment-naïve patients and as salvage therapy for treatment-experienced patients. Darunavir-ritonavir has been shown to be superior to lopinavir-ritonavir, and equivalent to atazanavir-ritonavir or raltegravir-based regimens in treatment-naïve patients (296, 329). A darunavir-ritonavir plus two NRTIs regimen was inferior to a dolutegravir-plus-two-NRTI regimen, largely because of discontinuation from adverse events in the darunavir-based arms (272). Darunavir-ritonavir plus tenofovir-emtricitabine is also recommended for treatment-naïve patients who need to initiate antiretroviral therapy prior to HIV-1 genotype testing (105).

In treatment-experienced patients with evidence of resistance to PIs, darunavir-ritonavir in combination with nucleoside analogs provides higher rates of viral suppression to  $< 50$  copies/ml and immunologic recovery than in patients in the ritonavir-boosted PI comparator group (41, 336). Darunavir-ritonavir in patients with limited treatment experience (82% were susceptible to  $> 4$  PIs, all lopinavir/

ritonavir naïve) demonstrates noninferiority to lopinavir/ritonavir with respect to virologic suppression. Individuals with virologic failure on darunavir-ritonavir are more likely to maintain susceptibility to other PIs than individuals failing lopinavir/ritonavir regimens. Darunavir/ritonavir must be used in its twice-daily dosing format in patients with darunavir-associated resistance mutations, but can be used in a once-daily formulation for those with other PI mutations. The efficacy and durability of once-daily darunavir-ritonavir monotherapy and darunavir-ritonavir plus raltegravir as simplification strategies are also under consideration but are not recommended at this time (67, 337, 338).

## INVESTIGATIONAL HIV-1 PROTEASE INHIBITORS

While PIs exhibit potent *in vitro* activity and the recent addition of second-generation PIs has marked a major advance in antiretroviral therapy, patients continue to experience virologic failure on these regimens. The search for newer agents with improved efficacy and toxicity profiles continues. Selected investigational PIs are described in Table 2.

## PHARMACOENHANCERS

### Ritonavir

Ritonavir {1,3-thiazol-5-ylmethyl N-[(2S,3S,5S)-3-hydroxy-5-[[[(2S)-3-methyl-2-[[2-methylpropyl-[(2-propan-2-yl)-1,3-thiazol-4-yl)methyl]carbamoyl]amino]butanoyl]amino]-1,6-diphenylhexan-2-yl]carbamate; Norvir} (Figs. 1 and 7; Table 1) is a C<sub>2</sub>-symmetric HIV PI that is used as a pharmacoenhancer of coadministered PIs. Ritonavir is available in tablet and oral solution formulations.

### Pharmacology

Ritonavir was developed as a fully active PI but now is used solely as a pharmacoenhancer at lower doses, which improves its tolerance. Ritonavir is metabolized by hepatic microsomes, predominantly by the CYP3A4 and -3A5 isozymes

and to a lesser extent by CYP2D6. In addition to being a hepatic microsomal substrate, ritonavir exhibits potent inhibitory activity against CYP3A4 and CYP2D6. It may also induce CYP3A, CYP1A2, CYP2C9, CYP2C19, and CYP2B6 and glucuronosyl transferase. Consequently, significant drug interactions are to be expected, and in the case of its interaction with other PIs, this can be exploited to boost their drug levels.

### Adverse Effects

The most common adverse effects observed in clinical trials include gastrointestinal symptoms and paresthesias. Laboratory abnormalities typically observed with ritonavir at dosages of 400 mg twice daily or higher include hypercholesterolemia, hypertriglyceridemia, and elevated liver enzyme levels (339, 340). Ritonavir used in combination with other PIs is also associated with abnormalities in glucose metabolism and body fat distribution (278, 341–343).

### Drug Interactions

See Pharmacology section above

### Resistance

At the low dose employed for boosting of other PIs, ritonavir is thought to exert very limited to no anti-HIV-1 activity *in vivo* and therefore contributes to the emergence of PI-associated resistance mutations indirectly through the selective pressure exerted by the paired PI which is boosted.

### Clinical Applications

Ritonavir is never used alone but is used as a pharmacoenhancer for other PIs. The commonly used PIs darunavir and lopinavir must be taken with ritonavir or cobicistat (for darunavir only as lopinavir is coformulated with ritonavir). Atazanavir can be used without ritonavir or cobicistat in treatment-naïve patients only. Ritonavir pharmacoenhancement of other PIs leads to improved antiretroviral regimens by (i) enhancing antiviral activity by elevating the trough levels of the coadministered PI well above the IC<sub>50</sub> or IC<sub>90</sub> associated with certain drug-resistant isolates and (ii) improving the ease of administration by diminished frequency of dosing and elimination of food effects. Intolerance to, or side effects from, ritonavir, even when used at a low dose, may be limiting.

### Cobicistat

Cobicistat {1,3-thiazol-5-ylmethyl N-[(2R,5R)-5-[[[(2S)-2-[[methyl-[(2-propan-2-yl)-1,3-thiazol-4-yl)methyl]carbamoyl]amino]-4-morpholin-4-yl]butanamido]-1,6-diphenylhexan-2-yl]carbamate; GS-9350, Tybost} (Fig. 1 and 7; Table 1) is an inhibitor of CYP3A metabolism that increases the concentrations of CYP3A substrates. Cobicistat has no antiviral activity of its own and is better tolerated than ritonavir. It is currently approved to be used in fixed-dose combinations with atazanavir and darunavir once daily as an alternative to ritonavir in both treatment-naïve and treatment-experienced patients. As such, it is available as 150-mg tablets, but it is also available in fixed-dose combinations with atazanavir (Evotaz), with darunavir (Prezcobix, Rezolsta), with emtricitabine, TDF, elvitegravir (Stribild), and emtricitabine, TAF, elvitegravir (Genvoya).

### Pharmacology

Cobicistat reaches its C<sub>max</sub> of 0.99 µg/ml within 3.5 h post-dose. There are no specific data for cobicistat with regard to food, and recommendations are based on the concomitant

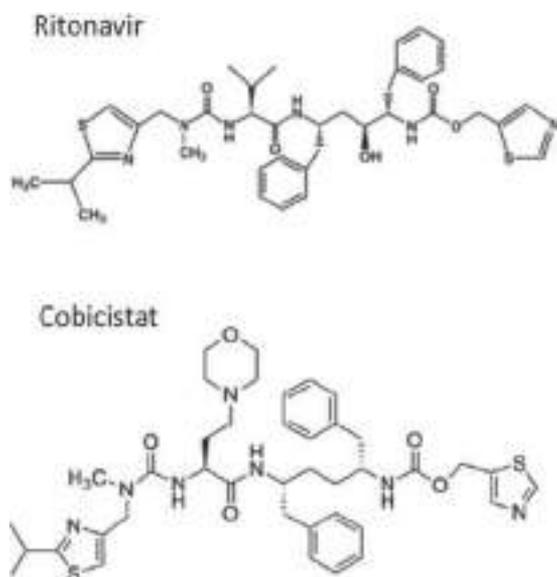

FIGURE 7. Chemical structures of pharmacoenhancers.

antiretrovirals. When administered with atazanavir and darunavir, doses should be administered with food. Cobicistat is >97% protein bound. It is metabolized by CYP3A and CYP2D6 (minor pathway) and eliminated via the liver with a  $t_{1/2}$  of ~3 to 4 hours. No significant pharmacokinetic changes are noted in patients with mild to moderate hepatic impairment or in those with severe renal impairment. When combined with atazanavir in HIV-infected subjects, it shows comparable pharmacodynamics to ritonavir-boosted atazanavir and is noninferior in rates of virologic suppression (326, 344). Similarly, cobicistat-boosted darunavir results in similar plasma concentrations and adverse events as ritonavir-boosted darunavir in HIV uninfected healthy volunteers.

### Adverse Effects

The most significant adverse effects reported in clinical trials combined with atazanavir were jaundice (6%) and rash (5%). Cobicistat also inhibits tubular secretion of creatinine without affecting glomerular filtration function. Thus a rise in serum creatinine may be seen that is not reflective of true renal toxicity. The mean decrease in estimated (but not actual) glomerular filtration rate in clinical trials has been 15 ml/min. No appreciable impact on lipid profiles has been noted.

### Drug Interactions

Cobicistat has potent CYP3A inhibitory activity with 95% inhibition at a dose of 200 mg, similar to 96% with a ritonavir dose of 100 mg (255). Compared to ritonavir, cobicistat is a weaker inhibitor of CYP2D6 and demonstrates no inhibitory activity against other CYP450 isoenzymes. Cobicistat also inhibits P-glycoprotein, which further enhances concomitant antiretroviral absorption. Coadministration of cobicistat with the following combinations is not currently recommended due to concerns for low concentrations and virologic failure: 1) darunavir with efavirenz, nevirapine, or etravirine, 2) atazanavir with etravirine, 3) atazanavir with efavirenz in treatment-experienced patients, 4) darunavir twice daily, and 5) fosamprenavir, or saquinavir, or tipranavir. Cobicistat should also not be used with other ritonavir-boosted regimens. Cases of acute renal failure and Fanconi syndrome have been reported with concomitant use of cobicistat and TDF.

### Resistance

Resistance to other antiretrovirals can develop during treatment with cobicistat-boosted regimens.

### Clinical applications

Cobicistat has no direct antiretroviral activity but is used as a pharmacokinetic enhancer for protease inhibitors and the integrase inhibitor, elvitegravir. It is currently available in coformulations to boost elvitegravir, darunavir, and atazanavir. Rates of virologic suppression and adverse events during treatment with darunavir-cobicistat in HIV-infected individuals are similar to historical data from treatment with darunavir-ritonavir (345).

## MATURATION INHIBITORS

Agents targeting later stages of the life cycle of the virus, such as BMS-955176, represent a new class of antiretroviral drugs, the maturation inhibitors (Table 2). This second-generation agent disrupts a late step in the processing of HIV-1 Gag that inhibits the last protease cleavage event

between capsid protein p24 and spacer peptide 1 in Gag resulting in production of noninfectious virions with abnormal capsid morphology. As a second-generation agent, BMS-955176 binds reversibly but with greater affinity to HIV-1 Gag than its predecessor (bevrimat) and retains activity in the presence of Gag polymorphisms associated with reduced bevrimat susceptibility (346). Mutations for resistance to the drug have been found at the p25-to-p24 cleavage site. The drug is administered once daily and has generally been well tolerated in clinical studies in combination with boosted and unboosted atazanavir.

# Antiherpesvirus Agents

CLAIRE L. GORDON, CHRISTINE J. KUBIN, AND SCOTT M. HAMMER

## 12

### ANTIHERPESVIRUS AGENTS

The first effective agents against herpesviruses were nucleoside analogs, such as idoxuridine, vidarabine, and trifluridine. Their use was eventually supplanted by the highly successful drug, acyclovir, which had significantly less toxicity. In early studies, intravenous acyclovir was shown to be superior to vidarabine for treating herpes simplex virus (HSV) encephalitis in healthy hosts and varicella zoster virus (VZV) infections in immunosuppressed subjects and to be equivalent to vidarabine in treating neonatal HSV infections.

#### Acyclovir

Acyclovir, 9-(2-hydroxyethoxy)methyl]guanine (Zovirax), (Fig. 1; Tables 1 and 2) represents a landmark in the history of antiviral drug development. The anti-HSV activity of acyclovir demonstrated that analogs of guanosine were active and that acyclic side chains could substitute for the ribose moiety, conferring specificity by the selective uptake and activation of acyclovir in HSV-infected cells.

#### Spectrum of Activity

Acyclovir's greatest, and clinically most important, activity is against HSV type 1 (HSV-1), HSV-2, and VZV. The inhibitory concentrations for susceptible isolates of HSV-1 average 0.04 µg/ml. HSV-2 is approximately 2-fold less susceptible, and VZV is approximately 8-fold less susceptible, than HSV-1. Acyclovir also has lower activity against Epstein-Barr virus (EBV) (1). Cytomegalovirus (CMV) susceptibilities are quite variable, and the range of susceptibilities is beyond achievable acyclovir levels for treatment (1). In addition, acyclovir has low efficacy at preventing CMV infection (2). Human herpesvirus (HHV)-6 is only modestly susceptible to acyclovir (3). HHV-8 is not susceptible to acyclovir (4, 5).

#### Mechanism of Action

Acyclovir is a poor substrate for cellular enzymes. Intracellular phosphorylation of acyclovir monophosphate is mediated by HSV or VZV thymidine kinase. In HHV-8- and EBV-infected cells, acyclovir is monophosphorylated by the viral protein kinases (6, 7). The di- and triphosphorylation of acyclovir occurs by cellular kinases to generate the active form of the drug, acyclovir triphosphate. Selectivity for HSV is conferred by the high affinity for acyclovir by HSV

thymidine kinase and DNA polymerase, in contrast to the low affinity exhibited by host cell enzymes (8). Acyclovir triphosphate is both a competitive inhibitor of the viral DNA polymerase and a chain terminator. Because acyclovir lacks the 3'-hydroxy group necessary to form 3'-5' phosphodiester bonds, incorporation of acyclovir triphosphate into the growing viral DNA chain leads to chain termination. Cellular DNA polymerases are much less susceptible to inhibition by acyclovir triphosphate (10- to 30-fold), which is another component of the selectivity of acyclovir.

#### Adverse Effects

The widespread use of acyclovir in both healthy and immunocompromised hosts for more than 30 years demonstrates that acyclovir is remarkably well tolerated. Following intravenous administration, local reactions at the injection site have been reported, and headache and nausea may occur. Neurotoxicity, albeit relatively rare, may manifest as tremors, myoclonus, confusion, lethargy, agitation, and hallucinations, as well as dysarthria, ataxia, hemiparesis, and seizures. Symptoms of neurotoxicity usually appear within the first 24 to 72 hours of administration and are more likely to occur when levels in plasma are elevated, as with intravenous administration or in the setting of renal insufficiency (9). Acyclovir is relatively insoluble in urine, with a maximum solubility of 2.5 mg/ml at physiological pH. As a result of the low urine solubility, acyclovir crystallization may occur in kidney tubules, especially in the setting of elevated plasma acyclovir levels, rapid intravenous bolus administration, and dehydration (10). Because of acyclovir's low isoelectric point (pI), the drug is less soluble at acid pH; therefore lowering the pH of the urine reduces the risk of crystallization. Prevention of acyclovir crystal deposition can be accomplished by volume repletion prior to drug administration and avoidance of rapid infusions. Acute tubular toxicity leading to renal failure has also been reported with acyclovir, especially for patients with underlying renal disease or receiving concomitant nephrotoxic drugs (11). Topical acyclovir is usually well tolerated, but there have been reports of local burning, stinging, and erythema (10).

*In vitro*, acyclovir is neither immunosuppressive nor toxic to bone marrow precursor cells. Although mutagenic in some preclinical assays, acyclovir at therapeutic doses lacks carcinogenicity and teratogenicity in animal studies. A large Danish cohort study and pregnancy registries found no

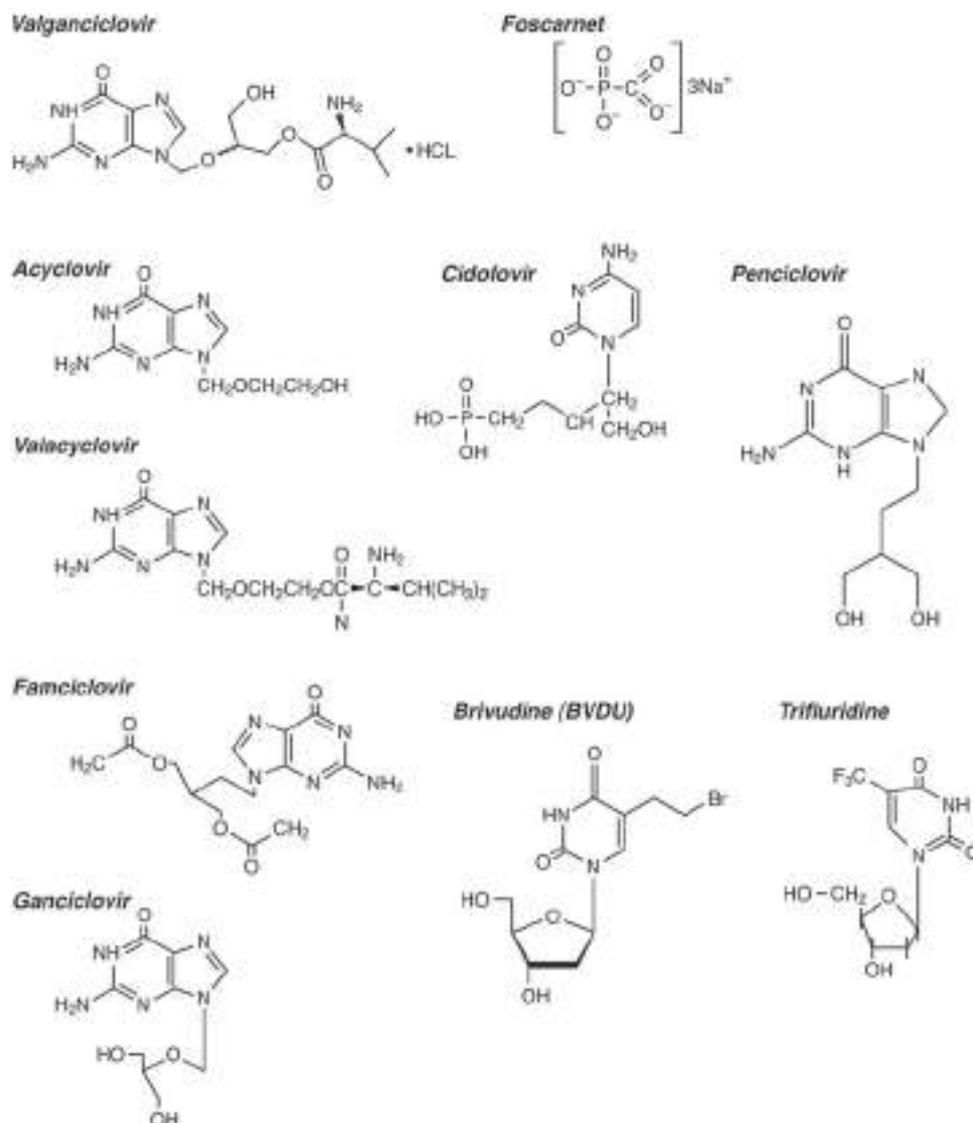

FIGURE 1 Chemical structures of antiherpesvirus agents. (Reprinted with permission from reference [230]).

association between acyclovir exposure and major birth defects (12, 13). In healthy subjects receiving chronic prophylaxis for genital HSV infection for over a decade, no chronic toxicities, including abnormalities of spermatogenesis, have been reported. HSV-specific immune responses can be diminished by acyclovir treatment of primary infection, which may be related to diminution of antigen expression (14).

#### Pharmacokinetics

Oral, intravenous, and topical preparations of acyclovir are available. Ophthalmic formulations are available outside the United States. The maximum plasma concentrations ( $C_{max}$ ) average approximately 10  $\mu\text{g/ml}$  after an intravenous infusion of 5 mg/kg of body weight and 0.6  $\mu\text{g/ml}$  following a 200-mg oral dose; the levels in plasma proportionately increase with increasing doses (15). Concentrations achieved in the cerebrospinal fluid are approximately 50% of plasma values (15). Oral bioavailability is 15 to 30% and may be lower, on average, in immunocompromised hosts (15).

Minimal, if any, drug is absorbed after topical administration. Acyclovir-elimination half-life ( $t_{1/2}$ ) in plasma averages 3 hours in subjects with normal renal function. The initial intracellular  $t_{1/2}$  of acyclovir triphosphate is 1.2 hours and reaches a plateau after 6 hours (16). The primary mode of excretion is renal and occurs through both glomerular filtration and tubular secretion. Approximately 85% of administered drug is excreted unchanged in the urine; the remainder is metabolized to 9-carboxymethoxymethylguanine before excretion. Dose adjustments for renal insufficiency, dialysis, and continuous renal replacement therapy are necessary. Where available, therapeutic drug monitoring may be helpful in guiding optimal therapy for patients in whom achieving therapeutic drug levels is especially critical (e.g., neonatal herpesvirus infection).

#### Drug Interactions

Few potentially important drug interactions have been noted. Caution should be exercised when other potentially nephrotoxic or neurotoxic agents are being used concur-

**TABLE 1** Antitherpesvirus agents: approved and potential indications and dosing regimens

Agent	Formulation	Indication	Standard adult dosing <sup>a</sup>	
Antitherpesvirus agents				
Acyclovir	Oral	Immunocompetent host	400 mg p.o. t.i.d. for 7–10 days or 200 mg p.o. 5×/day for 7–10 days or apply topically 6×/day for 7 days.	
		Genital HSV infection	Primary	For more severe cases (e.g., accompanied by aseptic meningitis, etc.), 5–10 mg/kg i.v. q8h initially, followed by p.o. to complete at least 10 days of total therapy
			Recurrent	400 mg p.o. t.i.d. for 5 days or 800 mg p.o. b.i.d. for 5 days or 800 mg p.o. t.i.d. for 2 days initiated at earliest sign or symptom of recurrence
	Intravenous	Suppression	400 mg p.o. b.i.d.	
		Herpes labialis	Apply 5×/day for 4 days	
	Topical		400 mg p.o. 5×/day for 5 days	
		Herpes simplex encephalitis or other invasive syndromes	10 mg/kg i.v. q8h for 14–21 days for encephalitis and 7–10 days for meningitis	
		Varicella, chickenpox	800 mg p.o. 5×/day for 5 days or 10–15 mg/kg i.v. q8h for 10–14 days if invasive (e.g., encephalomyelitis)	
		Herpes zoster, shingles	800 mg p.o. 5×/day for 7–10 days	
		Immunosuppressed host	400 mg p.o. 5×/day for 7–10 days or 5 mg/kg i.v. q8h in more severe cases for 7 days	
	Valacyclovir	Oral	Mucocutaneous HSV	Apply 6×/day for 7 days
			Herpes labialis	400–800 mg p.o. b.i.d. or t.i.d.
			Suppression	10 mg/kg i.v. q8h for 14–21 days and 7–10 days for meningitis
			Herpes zoster, shingles	10 mg/kg i.v. q8h for 7 days
			Varicella, chickenpox	800 mg p.o. 5×/day for 7 days or 10–15 mg/kg i.v. q8h for 10–14 days if invasive (e.g., encephalomyelitis)
Immunocompetent host			1 g p.o. b.i.d. for 7–10 days	
Genital HSV infection			Primary	500 mg p.o. b.i.d. for 3 days or 1 g p.o. daily for 5 days
			Recurrent	1 g p.o. daily or 500 mg p.o. daily
Suppression			2 g p.o. b.i.d. for 1 day	
Herpes labialis			1 g p.o. t.i.d. for 7 days	
Herpes zoster, shingles				
HIV-infected host	1 g p.o. b.i.d. for 5–10 days			
Famciclovir	Oral	Genital HSV	500 mg p.o. b.i.d.	
		Recurrent		
		Suppression		
		Immunocompetent host	250 mg p.o. t.i.d. for 7–10 days	
		Genital HSV infection	1 g p.o. b.i.d. for 1 day or 125mg p.o. b.i.d. for 5 days or 500mg once, followed by 250mg p.o. b.i.d. for 2 days	
Penciclovir	Topical	Primary	250 mg p.o. b.i.d.	
		Recurrent	1,500 mg p.o. in one dose, initiated at earliest sign	
		Suppression	500 mg p.o. t.i.d. for 7 days	
Brivudine	Oral	Herpes labialis	500 mg p.o. t.i.d. for 7 days	
		Herpes zoster, shingles	Apply q2h for 4 days	
Trifluridine	Ophthalmic	Herpes zoster, shingles	125 mg p.o. daily for 7 days in immunocompetent host	
		Herpes simplex keratitis	Apply to conjunctiva 5×/day	
Ganciclovir	Ophthalmic	Herpes simplex keratitis	1 drop of 1% solution q2h (maximum, 9 drops/day) for 10 days	
	Intravenous	HIV-infected host	5 mg/kg i.v. q12h for 14–21 days for induction treatment, followed by maintenance therapy (5 mg/kg i.v. daily for 7 days/wk or 6 mg/kg i.v. daily for 5 days/wk or 1 g p.o. t.i.d. or 500 mg 6×/day)	
		CMV retinitis		

(Continued)

**TABLE 1** Antiherpesvirus agents: approved and potential indications and dosing regimens (*Continued*)

Agent	Formulation	Indication	Standard adult dosing <sup>a</sup>
Valganciclovir	Oral	CMV, gastrointestinal	5 mg/kg i.v. q12h for 21–28 days (need for maintenance not proven, but advisable)
		Other immunosuppressed host	5 mg/kg i.v. q12h for 14–21 days (maintenance therapy not generally necessary)
		CMV infection	
		Prophylaxis or preemptive therapy of CMV in transplant recipients	5 mg/kg i.v. q12h for 7–14 days and then 5 mg/kg i.v. daily 7 days/wk or 6 mg/kg i.v. daily 5 days/wk during “risk” period for transplant patients or 1 g p.o. t.i.d. in solid-organ transplant patients
		CMV pneumonia in bone marrow transplant recipients	5 mg/kg i.v. q12h for 10–14 days combined with i.v. immune (or CMV hyperimmune) globulin
Foscarnet	Intravenous	HIV-infected host	900 mg p.o. b.i.d. for 21 days for induction therapy, followed by 900 mg p.o. daily for maintenance
		CMV retinitis	900 mg p.o. daily
		CMV prophylaxis in high-risk kidney, heart, and kidney-pancreas transplant patients	
		HIV-infected host	60 mg/kg i.v. q8h or 90 mg/kg i.v. q12h for 14–21 days for induction treatment, followed by maintenance therapy (90–120 mg/kg i.v. daily)
Cidofovir	Intravenous	CMV retinitis	60 mg/kg i.v. q8h or 90 mg/kg i.v. q12h for 14–21 days (need for maintenance therapy not proven, but advisable)
		Other immunosuppressed host	60 mg/kg i.v. q8h or 90 mg/kg i.v. q12h for 14–21 days
		CMV disease	
		HIV- or non-HIV-infected immunosuppressed host	40 mg/kg i.v. q8h or 60 mg/kg i.v. q12h for 14 days
		Acyclovir-resistant HSV or VZV infection	
Docosanol	Topical	Invasive HHV-6 disease	60 mg/kg i.v. q8h or 90 mg/kg i.v. q12h for 14–21 days
		Recurrent herpes labialis	5 mg/kg i.v. every wk for 2 wks and then 5 mg/kg i.v. every other wk (combined with probenecid and hydration for nephroprotection)
			Apply topically 5×/day

<sup>a</sup>Abbreviations: p.o., per os; i.v., intravenously; 5×, five times; q.a.m., every morning; q.p.m., every evening.

rently, but whether there is additive toxicity with specific agents is unclear. *In vitro*, mycophenolate mofetil potentiates the anti-HSV activity of acyclovir through depletion of dGTP pools, but the clinical significance of this observation is unclear (17).

### Resistance

The descriptions of persistent or progressive clinical disease with acyclovir-resistant HSV or VZV isolates in immunocompromised hosts, particularly patients with human immunodeficiency virus (HIV) infection, helped to establish the clear-cut clinical significance of antiviral resistance (18, 19). In the era of potent antiretroviral therapy, the incidence of this complication in HIV-infected persons has dramatically declined. The prevalence of acyclovir-resistant HSV infections in immunocompromised patients has increased in recent years and ranges from 3.5 to 11% (20–22). Hematopoietic stem cell transplant (HSCT) recipients are at greatest risk of acyclovir-resistant HSV infections with prevalences up to 47% in allogeneic HSCT recipients (20). HSV resistance in immunocompetent individuals generally occurs at a very low prevalence of 0.3–0.7% (23–25). Immunocompetent individuals receiving long-term acyclovir as prophylaxis for recurrent herpetic keratitis are at increased risk for resistance due to the immune-privileged nature of

the cornea allowing for rapid selection of resistant strains in the absence of immune surveillance (26–29).

The vast majority of HSV resistance is based on mutations in the viral thymidine kinase gene, UL23, with the remainder of resistance based in the DNA polymerase gene, UL30 (30). Thymidine kinase-based resistance may be the result of absent or low-level enzyme production or the elaboration of a thymidine kinase with altered substrate specificity. Thymidine kinase deficiency is more often due to production of a truncated protein than to production of a functional, but altered, enzyme. Acyclovir-resistant subpopulations exist among clinical isolates of HSV in the absence of drug exposure, but the clinical expression of resistance only occurs in the face of drug treatment (31, 32). Such isolates may be the result of the selection of a preexisting drug-resistant subpopulation or a new mutational event.

Although acyclovir-resistant HSV strains are less pathogenic in animal models 33–37, they can cause serious clinical disease in immunocompromised hosts. In such hosts, HSV resistance is usually manifested by chronic mucocutaneous ulceration, but invasive visceral and central nervous system (CNS) disease, which may be fatal, occurs with either HSV-1 or HSV-2 (38). Following resolution of mucocutaneous lesions due to resistant HSV, subsequent recurrences are usually acyclovir susceptible (in the absence of acyclovir

**TABLE 2** Antiherpesvirus agents: pharmacokinetics, major toxicities, and drug interaction characteristics

Agent	Oral bioavailability (%)	Effect of food on AUC	t <sub>1/2</sub> (h) in adults	Major route of elimination	Adjustment for renal insufficiency	Major toxicities	Major drug interactions
Acyclovir	15–30	No	3	85% renally excreted unchanged, catabolite also renally excreted	Yes	Headache, nausea, nephrotoxicity, neurotoxicity	Possible additive effects with other nephrotoxic or neurotoxic agents
Valacyclovir	55 (of acyclovir)	No	3	Renal	Yes	Same as acyclovir; possible association with HUS/TTP <sup>b</sup> when used in immunocompromised persons at high dosages	Same as acyclovir; cimetidine and probenecid decrease the rate but not the degree of valacyclovir-to-acyclovir conversion
Famciclovir	77	No	2	Penciclovir catabolite is renally excreted	Yes	Headache, nausea	Probenecid, theophylline: increased plasma famciclovir levels Digoxin levels increased
Brivudine	30	No	16	Metabolized by liver to inactive metabolite	No	Nausea, headaches	Potentiates toxicity of 5-FU or other fluoropyrimidines
Trifluridine	NA <sup>a</sup>	NA	NA	Negligible systemic absorption and metabolism	No	Local eye irritation; mutagenic, carcinogenic, and teratogenic potential	None reported
Ganciclovir	5	Increases by 8–9%	3–4	Mainly renally excreted unchanged	Yes	Neutropenia, thrombocytopenia	Bone marrow-suppressive agents: increased risk of myelosuppression
Valganciclovir	61	Increases by 14–30%	3–4	Mainly renally excreted unchanged	Yes	Neutropenia, thrombocytopenia	Bone marrow-suppressive agents: increased risk of myelosuppression
Foscarnet	NA	NA	4.5–8.2	Renal	Yes	Nephrotoxicity, electrolyte disturbances, neurotoxicity, anemia, neutropenia	Nephrotoxic agents: increased risk of foscarnet nephrotoxic adverse effects Pentamidine: increased risk of hypocalcemia
Cidofovir	NA	NA	2.6	Renal	Yes	Nephrotoxicity, neutropenia, uveitis, rash, iritis (with intravitreal administration)	Probenecid: nephroprotective at cidofovir doses of > 3 mg/kg
Docosanol	NA	NA	NA	NA	No	Rash, pruritus, dry skin, burning and stinging at application site	None reported

<sup>a</sup>NA, not applicable.<sup>b</sup>HUS/TTP, hemolytic-uremic syndrome/thrombotic thrombocytopenic purpura.

exposure), demonstrating that HSV-1 strains sensitive and resistant to acyclovir can coexist in latently infected ganglia (39). Recurrent disease due to thymidine kinase-altered virus in an immunocompetent host has been reported. Mutants retaining low-level production of thymidine kinase are able to reactivate more readily than thymidine-kinase deficient mutants (40, 41). HSV acyclovir resistance testing, where available by select commercial laboratories, can assist in identifying drug-resistant strains in refractory HSV infection. Identified genotypic mutations need to be confirmed as conferring resistance using established databases or phenotypic methods (30).

Clinical isolates of VZV, resistant to acyclovir from immunocompromised patients, present as chronic skin lesions unresponsive to therapy and are associated with significant morbidity and mortality due to visceral dissemination (42–44). The prevalence of acyclovir-resistant cases in different immunocompromised populations has not been determined, although a recent report suggested that approximately 27% of hemato-oncological patients with persistent VZV infections have acyclovir resistance (45). Similar to HSV, the majority of acyclovir resistance in VZV is due to mutations in the viral thymidine kinase and, less frequently, to mutations in the viral DNA polymerase gene (46).

Thymidine kinase-deficient or -altered isolates of HSV or VZV resistant to acyclovir remain susceptible *in vitro* to foscarnet, cidofovir, and brivudine but are fully cross-resistant to ganciclovir and famciclovir. When resistance is due to a DNA polymerase mutation, cross-resistance to foscarnet may exist, but susceptibility to cidofovir and brivudine is usually maintained (47).

### Clinical Applications

Acyclovir has been extensively studied for the prophylaxis and treatment of herpesvirus infections in both immunocompetent and immunocompromised hosts. For serious mucocutaneous, visceral, or CNS disease due to HSV or VZV, parenteral acyclovir is the agent of choice unless acyclovir resistance is suspected. For patients with normal renal function, a dosage of 5 mg/kg every 8 hours (q8h) is appropriate for mucocutaneous disease. A dosage of 10 mg/kg q8h should be used for VZV infections and for invasive HSV disease. For neonatal HSV disease, a dosage as high as 20 mg/kg q8h has been recommended. Acyclovir at 10 mg/kg q8h is indicated for VZV disease because of the generally lower susceptibility of VZV isolates.

Acyclovir does not appear to be beneficial for patients with acute infectious mononucleosis, despite the demonstration of a decrease in EBV shedding, or for patients with chronic fatigue syndrome. There are limited data suggesting that acyclovir in conjunction with corticosteroids may be effective in severe primary EBV infection in immunocompetent patients (48). Oral hairy leukoplakia regresses with acyclovir treatment. Acyclovir has been reported anecdotally to induce regression in some patients with polyclonal B-cell posttransplantation lymphoproliferative disorders (PTLD). Antiviral therapy is often used in conjunction with reduced immunosuppression and other therapies in PTLD in the absence of clear evidence of acyclovir efficacy. Most EBV-infected cells within PTLD lesions are transformed B cells that are not undergoing viral lytic replication or expressing viral thymidine kinase and therefore will not be inhibited by acyclovir or ganciclovir. Prophylactic use of acyclovir or ganciclovir after transplantation may reduce the risk of PTLD, especially during the first posttransplantation year (49).

In healthy hosts, the intravenous and oral forms of acyclovir decrease the period of viral shedding and speed healing in patients with primary genital HSV infection (50). Of note, therapy for primary infections with intravenous acyclovir does not prevent the establishment of latency. Topical acyclovir ointment demonstrates some efficacy for primary genital HSV infection (51), but it is inferior to systemic therapy. For recurrent genital HSV infection, oral acyclovir for 5 days reduces the duration of pain and viral shedding. Topical acyclovir is clinically ineffective for recurrent genital HSV infection. Short-course acyclovir therapy, consisting of 2 days of 800 mg three times daily (t.i.d.), started within 12 hours of symptom onset, decreases time to healing and episode duration by 2 days compared to placebo (52). For recurrent orolabial HSV, a 5% acyclovir cream preparation has been approved by FDA (53), and oral acyclovir at 400 mg five times per day has been demonstrated to be effective.

Oral acyclovir is also beneficial for the treatment of herpes zoster in adults and varicella in children. The acute pain of herpes zoster is consistently diminished by acyclovir. A recent meta-analysis found that acyclovir was ineffective in preventing postherpetic neuralgia (PHN) (54). There is currently insufficient data to determine if valacyclovir and famciclovir are effective in preventing PHN (54). Oral acyclovir alone, or in combination with prednisolone, does not improve the likelihood of complete recovery from Bell's palsy beyond the benefit of prednisolone alone (55).

Acyclovir is also effective for prophylaxis of HSV infections in immunosuppressed patients undergoing solid-organ or bone marrow transplantation and in patients receiving cancer chemotherapy (56). Although therapeutically ineffective for established CMV infections, acyclovir does have efficacy for the prophylaxis of CMV infection in renal, liver, and bone marrow transplant recipients (57); however, this role has been largely supplanted by valganciclovir. Antiviral medications used to prevent CMV replication during preventative or treatment strategies (e.g., ganciclovir, valganciclovir, acyclovir, valacyclovir) also prevent HSV replication.

In healthy hosts, oral acyclovir is very effective for the suppression of recurrent genital herpes, reducing recurrences by approximately 90% (58, 59). Safety, efficacy, and lack of emergence of resistance for periods up to 10 years have been demonstrated (60). Subclinical shedding of HSV-2 from the genital tract still occurs during antiviral therapy and may account for ongoing transmission during suppressive antiviral therapy (61). Prevention of herpetic whitlow and recurrent erythema multiforme associated with recurrent HSV infection is also possible. Short-term prophylaxis of recurrent oral HSV infection can be effective when initiated prior to a known stimulus for reactivation, such as occurs with exposure to UV light (e.g., in skiers).

The use of intravenous acyclovir for the treatment of CNS infections and neonatal herpes is discussed in Chapter 20.

### Valacyclovir

Valacyclovir (2-[2-amino-1,6-dihydro-6-oxo-9H-purin-9-yl-methoxy]ethyl-L-valinate hydrochloride, Valtrex) (Fig. 1; Tables 1 and 2) is the L-valyl ester of acyclovir. It was designed to enhance the oral bioavailability of the parent compound and is one of a series of such compounds that has been investigated. Valacyclovir is hydrolyzed to acyclovir by first-pass metabolism in the liver, prior to anabolic phosphorylation in the infected cell, thus avoiding toxicity. The antiviral spectrum of activity of valacyclovir is identical to that of acyclovir.

### Mechanism of Action and Pharmacokinetics

The L-valyl esterification of acyclovir increases the bioavailability of acyclovir and does not alter the mechanism of action of the drug. Absorption of valacyclovir in the gastrointestinal tract is facilitated by a stereospecific transporter system; first-pass intestinal and hepatic hydrolysis by valacyclovir hydrolase yields complete conversion of valacyclovir to acyclovir, resulting in a 3- to 5-fold increase in acyclovir bioavailability. Once the drug is converted to acyclovir, the elimination  $t_{1/2}$ , excretion, and metabolism are the same as those noted for acyclovir. In healthy volunteers, given doses of 500 and 1,000 mg of valacyclovir, acyclovir  $C_{max}$  is reached in 1.5 to 1.75 hours and averages 3.3 and 5.7  $\mu\text{g}/\text{ml}$ , respectively (62). Pharmacokinetic parameters in patients with advanced HIV infection are similar to those in healthy volunteers. Valacyclovir at 1,000 mg t.i.d. achieves concentrations in the vitreous within the inhibitory ranges of HSV-1, HSV-2, and VZV (63). This dose regimen also provides inhibitory acyclovir levels in the cerebrospinal fluid of patients with HSV encephalitis and may have utility in resource-poor settings where intravenous acyclovir is unavailable but use of valacyclovir for this indication is not recommended (64).

### Drug Interactions and Adverse Effects

The drug interaction and side effect profiles are similar to those of acyclovir. In patients with advanced HIV infection, gastrointestinal complaints and neutropenia were seen in 31 and 19% of subjects, respectively (65). Cases resembling thrombotic microangiopathy have been reported for subjects with advanced HIV infection and for recipients of allogeneic bone marrow transplants treated with high dosages of valacyclovir (8,000 mg/day) for prolonged periods for CMV prophylaxis (66), but such events have not been reported for immunocompetent or HIV-infected subjects receiving valacyclovir for suppression of genital herpes. Although a causal association with valacyclovir has not been elucidated, the implication is that the occurrence of thrombotic microangiopathy is restricted to severely immunocompromised individuals receiving high dosages of valacyclovir or sometimes other drugs. Safety data for acyclovir in pregnancy may be extrapolated to valacyclovir (12).

### Resistance

Acyclovir-resistant HSV or VZV may emerge during valacyclovir therapy, and the mechanisms are similar to those reported for acyclovir.

### Clinical Applications

Valacyclovir has demonstrated efficacy in the treatment of herpes zoster and genital HSV infections. Valacyclovir, at 1,000 mg twice a day (b.i.d.), was found to be comparable to acyclovir at 200 mg five times daily in terms of efficacy and safety for the treatment of initial genital herpes infection (67). Valacyclovir at 1,000 or 500 mg b.i.d. for 5 days has an efficacy comparable to that of acyclovir at 200 mg five times daily for 5 days in immunocompetent individuals with recurrent genital herpes (68). Short-course therapy with valacyclovir at 500 mg b.i.d. for 3 days was equivalent to the 5-day course of valacyclovir (69). For suppressive therapy for recurrent genital herpes, once-daily dosing with 500 or 1,000 mg valacyclovir appears to be as effective as acyclovir at 400 mg b.i.d. (59, 70). Valacyclovir, 2,000 mg b.i.d. for 1 day, is approved for the treatment of recurrent herpes labialis. Valacyclovir at 1,000 mg t.i.d. is an effective therapy for herpes zoster (71) and may be superior to acyclovir in reducing the

risk of acute pain with herpes zoster (72). Valacyclovir alone does not prevent PHN; however, valacyclovir in combination with gabapentin, commenced during an episode of acute herpes zoster, has been shown to reduce rates of PHN (73). Oral valacyclovir at a dosage of 2,000 mg four times daily is effective in the prophylaxis of CMV (and HSV) infections in renal- and stem-cell-transplant recipients (74). In HIV-infected persons, valacyclovir appeared to be superior to acyclovir in preventing CMV disease in one report, but the study was terminated early because of a higher mortality rate in the valacyclovir arm, a finding that is unexplained (75). Valganciclovir has largely replaced valacyclovir for prophylaxis of CMV disease.

Valacyclovir at a dosage of 1,000 mg t.i.d. is an option for systemic oral antiviral treatment of acute retinal necrosis due to herpesviruses (76) and is preferred over oral acyclovir, as a step-down therapy after intravenous acyclovir, due to its superior penetration into the vitreous fluid (63).

### Famciclovir and Penciclovir

Famciclovir, 9-(4-hydroxy-3-hydroxymethylbut-1-yl)guanine (Famvir) (Fig. 1; Tables 1 and 2), is the diacetyl 6-deoxy prodrug ester of penciclovir, 9-(4-hydroxy-3-hydroxy-3-hydroxymethylbut-1-yl)guanine, an acyclic nucleoside analog of guanosine.

### Spectrum of Activity

Famciclovir is a prodrug lacking intrinsic antiviral activity and must be converted to penciclovir triphosphate, which is its active form. HSV-1, HSV-2, and VZV are susceptible to penciclovir; the average inhibitory concentrations are 0.4, 1.5, and 5.0  $\mu\text{g}/\text{ml}$  in MRC-5 cells, respectively (77). EBV and hepatitis B virus (HBV) are also susceptible *in vitro*, but HHV-6 and HHV-8 are not susceptible to penciclovir (4). Famciclovir also shows antiviral activity in animal models of hepatitis B virus infection but is not a clinically useful anti-HBV agent.

### Mechanism of Action

Penciclovir is selectively monophosphorylated by the HSV or VZV thymidine kinase; formation of penciclovir di- and triphosphate is catalyzed by cellular kinases. Penciclovir triphosphate competitively inhibits the viral DNA polymerase and can also be incorporated into the growing viral DNA chain. Because of the presence of the hydroxyl group on the acyclic side chain, viral DNA chain extension may occur to a limited extent after incorporation (77). This aspect of its mechanism of action contrasts with that of acyclovir triphosphate, which is an obligate chain terminator. Penciclovir triphosphate is a less potent inhibitor of HSV DNA polymerase than acyclovir triphosphate, but this lower inhibition is balanced by much higher intracellular levels of penciclovir triphosphate and by its much longer intracellular  $t_{1/2}$ . The intracellular  $t_{1/2}$  of penciclovir is 10 to 20 hours in HSV-infected cells and 9 hours in VZV-infected cells (77).

### Pharmacokinetics

Famciclovir is rapidly converted to penciclovir by deacetylation and oxidation in the liver. Famciclovir undergoes extensive first-pass metabolism, with aldehyde oxidase probably responsible for the oxidation at the 6 position. Following an oral dose of 500 mg of famciclovir, a penciclovir  $C_{max}$  of 3.3  $\mu\text{g}/\text{ml}$  is achieved within 1 hour (78). Sixty to 70% of the drug is excreted as penciclovir in the urine by both glomerular filtration and tubular secretion. The remainder is excreted in the feces or is eliminated as

6-deoxy-penciclovir and other minor metabolites in the urine or feces (78). In subjects with hepatic disease, the time-to-peak plasma drug level and the concentration achieved are decreased relative to those in healthy volunteers, but overall exposure is not reduced. Dosage adjustment is required in patients with renal insufficiency and in those receiving hemodialysis. There are currently no data to guide dosing in peritoneal dialysis and continuous renal replacement therapy. Oral famciclovir achieves intravitreal concentrations of penciclovir within the inhibitory ranges for HSV and VZV (79). Topical penciclovir preparations are available.

#### Adverse Effects

Famciclovir is generally very well tolerated. Headache and nausea are the most common side effects. Famciclovir and penciclovir have shown positive results in some preclinical carcinogenesis models, including rodent tumor induction and mutagenesis assays, although not in tests of teratogenicity. Famciclovir use in pregnancy has not been associated with major birth defects, although the data are more limited than for acyclovir (12).

#### Drug Interactions

Probenecid, or other drugs significantly eliminated by active renal tubular secretion, would predictably increase plasma penciclovir concentrations because of the inhibition of renal tubular secretion of the drug, but formal interaction studies have not been performed. Theophylline can increase penciclovir levels moderately, but dose adjustments are not necessary. Allopurinol has no effect on penciclovir pharmacokinetics. Penciclovir, on the other hand, can increase digoxin levels modestly (mean increase, 19%) but does not alter the digoxin area under the concentration-time curve (AUC). Drugs which are also metabolized by hepatic aldehyde oxidase (80) have the potential to interact with famciclovir, although no reports documenting clinical interactions have been identified (81).

#### Resistance

The prevalence of penciclovir-resistant HSV isolates among subjects participating in clinical trials involving penciclovir (topical and intravenous) or famciclovir were 0.2 to 0.3% and 2.1% in immunocompetent and immunocompromised subjects, respectively (82, 83). Most HSV and VZV isolates, resistant to acyclovir on the basis of thymidine kinase deficiency, are cross-resistant to famciclovir and penciclovir. Interestingly, mutations associated with penciclovir resistance in the thymidine kinase gene are distributed throughout the gene, in contrast to those associated with acyclovir, which are preferentially localized to the homopolymeric hot spots (82). Some acyclovir-resistant isolates with altered thymidine-kinase substrate specificity may still retain their ability to phosphorylate penciclovir and remain susceptible.

#### Clinical Applications

Famciclovir is approved in the United States for the treatment of genital herpes, herpes labialis, and herpes zoster. For recurrent genital herpes, famciclovir at 125 mg was similar to acyclovir at 200 mg in 5-day treatment courses (84). Short courses of famciclovir are approved for treatment of recurrent genital herpes (1,000 mg b.i.d. for 1 day) and herpes labialis (1,500-mg single dose) (85, 86). Topical 1% penciclovir cream has moderate efficacy in treatment of orolabial herpes, decreasing the time to healing, in comparison to placebo, by a median of 1 day (87). In the treatment of

herpes zoster, famciclovir at 500 mg t.i.d. decreases the time to lesion healing and reduces pain (88). In a controlled trial comparing famciclovir dosages of 250, 500, and 750 mg t.i.d. to acyclovir at 800 mg five times per day in immunocompetent adults, acute measures of healing and pain were equivalent (89). Famciclovir at 500 mg t.i.d. has efficacy and tolerability similar to that of acyclovir at 800 mg five times daily in immunocompetent persons with ophthalmic zoster (90) and similar to that of valacyclovir at 1,000 mg t.i.d. in immunocompetent persons over 50 years of age with herpes zoster (91). Similar to acyclovir, famciclovir does not prevent PHN (54). Famciclovir at a dosage of 500 mg t.i.d. is an option for systemic oral antiviral treatment of acute retinal necrosis due to herpesviruses (76) as a step-down therapy from intravenous acyclovir (63).

#### Brivudine

Brivudine, (E)-5-(2-bromovinyl)-2'-deoxyuridine (Zostex, Zerpex, Brivirac, Helpin), is a selective nucleoside analog (Fig. 1; Tables 1 and 2) utilized for treatment of herpes keratitis and herpes zoster in immunocompetent patients in Europe.

#### Spectrum of Activity

Brivudine is a potent and selective inhibitor of HSV-1 and VZV replication. EBV is also sensitive to brivudine, but CMV and HSV-2 are relatively resistant to its antiviral action (92). *In vitro*, the 50% effective concentration (EC<sub>50</sub>) of brivudine is 0.0024 µg/ml for VZV, compared to 4.64 µg/ml for acyclovir (93).

#### Mechanism of Action and Pharmacokinetics

Brivudine activation depends upon a specific phosphorylation by the HSV-1 or VZV thymidine kinase that converts brivudine to its 5'-monophosphate and 5'-diphosphate. HSV-2-encoded thymidine kinase is unable to phosphorylate brivudine 5'-monophosphate to 5'-diphosphate (94). After further phosphorylation by cellular kinases, brivudine 5'-triphosphate interacts with viral DNA polymerase either as a competitive inhibitor or as an alternative substrate allowing incorporation into the growing DNA chain. Incorporation may affect both the stability and function of viral DNA during the replication and transcription processes (95).

Brivudine has low bioavailability (30%) and is highly protein bound (>95%) to plasma protein. The C<sub>max</sub> at steady state (1.7 µg/ml) is achieved 1 hour after administration of once-daily oral brivudine at 125 mg and is 1,700-fold greater than the *in vitro* 50%-inhibitory concentration (IC<sub>50</sub>) for VZV. Brivudine is rapidly metabolized into inactive compounds, BVU [(E)-5(2-bromovinyl)uracil] and 2-deoxyribose-1-phosphate, by thymidine phosphorylase in the liver. However, BVU can be reconverted *in vitro* and *in vivo* to brivudine through a pentosyl transfer reaction, which restores the antiviral potential of the compound (96). Renal elimination predominates with 65% of the dose eliminated in the urine as metabolites; the plasma-terminal elimination t<sub>1/2</sub> is approximately 16 hours. No dose adjustments are necessary in patients with kidney or liver disease.

#### Adverse Effects

Oral brivudine is generally well tolerated, and the incidences of potentially treatment-related adverse events are similar for brivudine (8%) and acyclovir (10%), with nausea being the most commonly reported adverse event (97).

### Drug Interactions

The main metabolite of brivudine, BVU, irreversibly inhibits dihydropyrimidine dehydrogenase, the enzyme that regulates the metabolism of natural nucleosides like thymidine and other pyrimidine derivatives, including the fluoropyrimidine, 5-fluorouracil (5-FU). Coadministration of brivudine and 5-FU increases the systemic exposure to 5-FU and increases its toxicity. When a congener analog, bromovinyl arabinosyl uracil (BVaraU), was administered in Japan to patients receiving 5-FU, several deaths occurred. In healthy adults who received brivudine at 125 mg once daily for 7 days, dihydropyrimidine dehydrogenase activity was fully restored by 18 days after the final dose of brivudine. Therefore, coadministration of brivudine and fluoropyrimidine derivatives, or administration of these agents within 4 weeks of each other, is contraindicated (98).

### Resistance

Brivudine resistance occurs with viral strains that are thymidine-kinase deficient. There are no reports of clinical isolates with brivudine resistance that developed during therapy. A broad variety of HSV-1 clones can be selected under a single round of high-dose brivudine, including acyclovir-susceptible, but brivudine-resistant, phenotypes. Mutations associated with brivudine resistance occur in the homopolymer stretches of Gs and Cs of the thymidine kinase gene (99). Serial passage of VZV strains under the pressure of acyclovir, brivudine, or BVaraU yields variants cross-resistant to all drugs that depend on the viral thymidine kinase for activation (100). In contrast, virus strains selected under pressure of penciclovir are resistant to acyclovir but not to brivudine.

### Clinical Applications

Brivudine is available in Europe for topical treatment of herpetic keratitis as 0.1% eye drops and orally for treatment of VZV and HSV-1. The efficacy of brivudine at 125 mg orally once daily for 1 week for treatment of herpes zoster in immunocompetent subjects >50 years of age is generally comparable to that of acyclovir (97) or famciclovir (101). Incidence of postherpetic neuralgia was lower with brivudine than with acyclovir (33%, versus 44%, respectively) (97), but similar to that with famciclovir (21% vs. 20%, respectively) (101). Brivudine appears to be effective for treatment of herpes zoster in immunocompromised patients but at higher doses than for acyclovir, 7.5 mg/kg/day in divided doses (102) or 125 mg every 6 hours (103). Topical brivudine has also been utilized to treat herpetic keratitis that is clinically resistant to other antiviral agents (104).

### Trifluridine

Trifluridine, 5-trifluoromethyl-2'-deoxyuridine (Viroptic), is a fluorinated thymidine analog (Fig. 1; Tables 1 and 2) that is approved in the United States for the treatment of herpetic keratitis.

### Spectrum of Activity

Trifluridine has activity against the DNA viruses HSV-1 and -2, CMV, and vaccinia virus; there is inconsistent activity against adenovirus. Inhibitory concentrations for strains of HSV average 10 µg/ml, and, importantly, acyclovir-resistant strains of HSV remain susceptible to trifluridine (105).

### Mechanism of Action and Pharmacokinetics

Trifluridine is anabolically phosphorylated by cellular kinases to the triphosphate form, which is a competitive

inhibitor of the HSV DNA polymerase. Trifluridine is available only as a 1% ophthalmic solution in the United States. There is no significant systemic absorption.

### Adverse Effects

The most frequent adverse reactions reported during clinical trials were mild, transient burning or stinging upon instillation (5%) and palpebral edema (3%). Other, less common adverse reactions were superficial punctate keratopathy, epithelial keratopathy, hypersensitivity reaction, stromal edema, keratitis sicca, hyperemia, and increased intraocular pressure. The potential for corneal epithelial keratopathy is lower with trifluridine than with topical idoxuridine. Trifluridine has shown carcinogenic, mutagenic, and, potentially, teratogenic activities in preclinical assays.

### Drug Interactions

No adverse drug interactions have been reported with the simultaneous treatment of the eye with topical antibacterial, steroid, or atropine preparations.

### Resistance

No reports of clinical isolates of HSV resistant to trifluridine have appeared, although there is one report of laboratory selection of trifluridine resistance (106).

### Clinical Applications

The primary and approved indication for topical trifluridine is for primary keratoconjunctivitis and recurrent epithelial keratitis due to HSV types 1 and 2. Topical trifluridine and acyclovir are comparable in therapeutic effectiveness, and both appear more effective than idoxuridine or vidarabine (107). Topical trifluridine has also demonstrated clinical utility in the treatment of persistent cutaneous ulcers, due to acyclovir-resistant HSV infections in patients with AIDS, and can be considered when faced with HSV ulcers that are due to acyclovir- and foscarnet-resistant strains.

### Ganciclovir

Ganciclovir, 9-(1,3-dihydroxy-propoxymethyl)guanine (Cytovene) (Fig. 1; Tables 1 and 2), is an acyclic nucleoside analog of guanosine that is structurally similar to acyclovir, differing only by the presence of a hydroxymethyl group at the 3' position of the acyclic side chain. This difference confers markedly improved activity against CMV but also a different toxicity profile.

### Spectrum of Activity

The clinical usefulness of ganciclovir derives from its improved anti-CMV activity; inhibitory concentrations are 0.1 to 1.6 µg/ml for susceptible clinical isolates in contrast to 2.2 to 25 µg/ml with acyclovir (108). Ganciclovir also has activity against HSV-1 and -2, VZV, and EBV, with *in vitro* inhibitory concentrations in the range of 1- to 3-, 1- to 2-, and 1- to 5 µg/ml, respectively (108). It is inhibitory for HHV-6 and HHV-8 (7). Activity against HBV has also been demonstrated but is not clinically useful.

### Mechanism of Action

As with other nucleoside analog antiherpes viral agents, ganciclovir requires intracellular phosphorylation to transform to its active form. Monophosphorylation in HSV- and VZV-infected cells is mediated by the virus-encoded thymidine kinase that phosphorylates acyclovir (108). In CMV-infected cells, ganciclovir is monophosphorylated by a

phosphotransferase, which is the product of the viral UL97 gene. In HHV-6-infected cells, ganciclovir is monophosphorylated by the viral U69 kinase (109). In HHV-8 and EBV-infected cells, ganciclovir is monophosphorylated by viral protein kinases (6, 7). Ganciclovir monophosphate is converted to the di- and triphosphorylated derivatives by cellular kinases. Ganciclovir triphosphate is a competitive inhibitor of herpesviral DNA polymerases and is incorporated into the growing viral DNA chain, where it slows chain elongation (108). The intracellular  $t_{1/2}$  of ganciclovir triphosphate in CMV-infected cells is >18 hours; the prolonged intracellular  $t_{1/2}$  of ganciclovir triphosphate compared with that of acyclovir triphosphate may be partially responsible for the improved anti-CMV activity of ganciclovir.

### Pharmacokinetics

Ganciclovir is available in intravenous and ophthalmic formulations and can be administered by direct intravitreal injection and through an implantable intraocular device (no longer available in the United States). Following an intravenous dose of 5 mg/kg, the  $C_{max}$  is 8  $\mu$ g/ml; dose-independent kinetics have been observed at intravenous doses of  $\leq 5$  mg/kg (110). Intravitreal levels averaging 1.2  $\mu$ g/ml have been reported for patients on induction doses of intravenous ganciclovir (111). Despite poor oral absorption, peak levels in plasma of 1  $\mu$ g/ml can be achieved with a single oral dose of 1,000 mg taken with food. However, the bioavailability of oral valganciclovir, which results in plasma ganciclovir levels comparable to that seen with parenteral administration, has supplanted the use of oral ganciclovir, which is no longer available. CNS penetration occurs, with ratios of drug concentrations in cerebrospinal fluid (CSF) to those in plasma ranging from 0.24 to 0.70. Ganciclovir is mainly renally excreted in an almost unchanged form with an average elimination  $t_{1/2}$  of 2 to 4 hours in subjects with normal renal function. Dosage adjustments are necessary in patients with renal impairment, receiving dialysis, or on continuous renal replacement therapy.

### Adverse Effects

Hematologic toxicity is the most important adverse reaction noted following intravenous ganciclovir administration (112). Absolute neutrophil counts below 1,000/mm<sup>3</sup> have been noted in approximately 40% of patients with HIV infection and in 7% and 40% of heart and bone marrow transplant recipients, respectively. Thrombocytopenia (platelet counts of <50,000/mm<sup>3</sup>) occurs with a reported frequency of 13% in HIV-infected subjects and in 8 to 57% of transplant recipients. Granulocyte and granulocyte-macrophage colony-stimulating factors are effective in reversing the neutropenia associated with ganciclovir and permit its continued use at efficacious doses (113).

Other adverse effects noted in patients receiving ganciclovir include headache, neurotoxic reactions, fever, rash, gastrointestinal complaints (including diarrhea) in subjects taking the oral capsule formulation, anemia, and abnormal liver enzymes (112).

Retinal detachment may occur during the course of treatment of CMV retinitis (114). Detachment results from scarring and retraction as the infection is controlled or as the disease progresses. Detachments are probably not due to a direct toxic effect of the drug and are also seen in untreated patients, especially newborns with congenital CMV infection. In patients treated locally with ganciclovir via an implanted device, local inflammatory reactions, scleral thinning, and retinal detachments have been

described. Ganciclovir is mutagenic, carcinogenic, and teratogenic in preclinical assays and inhibits the growth of bone marrow progenitor cells *in vitro*.

### Drug Interactions

In HIV-infected subjects, the use of zidovudine in combination with induction doses of ganciclovir results in a high incidence of neutropenia that often precludes their simultaneous use, unless granulocyte or granulocyte-macrophage colony-stimulating factor support is employed. Similarly, caution must be exercised when administering potential marrow-suppressive agents to any individual receiving ganciclovir.

### Resistance

HSV and VZV isolates, that are resistant to acyclovir on the basis of thymidine kinase deficiency, exhibit cross-resistance to ganciclovir. HSV isolates, resistant to acyclovir on the basis of mutations in the viral DNA polymerase, may remain susceptible to ganciclovir. Given the relative infrequency compared to DNA polymerase mutants to thymidine kinase-deficient mutants, ganciclovir should not be used empirically in cases in which acyclovir resistance is suspected or proven, unless the resistance mechanism is known to be DNA polymerase. *In vitro* studies have shown the potential for HHV-6 to exhibit resistance to antivirals; however, few clinical cases have been reported (115–117).

Two basic mechanisms cause resistance to ganciclovir in CMV clinical isolates. The first, and more common, is due to point mutations in the UL97 phosphotransferase gene, which encodes a protein kinase responsible for the monophosphorylation of ganciclovir. Almost all mutations of the UL97 gene have been found within two clusters of codons, codons 460 to 520 and 590 to 607, spanning the proposed ATP-binding and substrate-recognition sites, respectively (118). Eight UL97 mutations (single amino acid substitutions M460V/I, H520Q, C592G, A594V, L595S, L595F/W or C603W) account for ganciclovir resistance in most cases (119, 120), conferring a 3- to 15-fold increase in the ganciclovir concentration required to reduce viral growth *in vitro* (119). The overall level of drug resistance increases as mutations accumulate (119). High-level ganciclovir-resistant isolates are associated with the presence of both UL97 and DNA polymerase mutations (121). Less frequent UL97 mutations in the codon range 590 to 607 confer varying levels of ganciclovir resistance. Isolates, resistant to ganciclovir on the basis of UL97 gene mutations, remain susceptible to foscarnet and cidofovir. The second, and less common, mechanism of ganciclovir resistance in clinical CMV isolates consists of mutations in the conserved subdomains of the UL54 DNA polymerase gene (118). In such instances, cross-resistance to cidofovir or foscarnet may be present. Mutations in UL54 are diverse and cluster in particular functional domains. Mutations in the exonuclease and thumb domain generally confer ganciclovir and foscarnet cross-resistance, possibly by overcoming the idling of the polymerase complex to permit chain extension beyond the misincorporated base (122). Mutations in both the UL97 and UL54 genes may coexist and lead to high-level ganciclovir resistance. Some UL97 or UL54 mutations confer low levels of ganciclovir resistance and may be amenable to ganciclovir dose escalation (up to 10 mg/kg b.i.d.) in the absence of severe disease.

Before the advent of the era of potent antiretroviral therapy, the degree of immunosuppression in individuals with AIDS, combined with the need to continue

maintenance therapy in subjects with retinitis, provided an appropriate milieu for viral resistance to emerge (123). In one series of CMV retinitis patients, 7.6% excreted resistant virus following 3 or more months of ganciclovir therapy (123). Infection with ganciclovir-resistant CMV has been associated with increased morbidity and mortality in solid organ transplant recipients (124–126). In this population, long durations of oral ganciclovir or valganciclovir prophylaxis have not been associated with an increase in ganciclovir-resistant CMV disease due to a lack of viral replication (126). An alternative option to the prevention of CMV disease after transplant, the preemptive approach, has a higher frequency of drug-resistance emergence (127–129). CMV seronegative recipients of CMV-seropositive donor organs (D+/R-) are at increased risk for CMV drug resistance, with resistance developing in 5 to 12% (126). Other groups at risk of ganciclovir resistance include haplo-identical or allogeneic HSCT recipients (incidence of 15%) and infants receiving long-term ganciclovir or valganciclovir therapy for congenital CMV infection (129–131). CMV ganciclovir resistance should be suspected in transplant recipients who have received several weeks of full-dose ganciclovir therapy and show a persistent or increasing CMV viral load or disease progression. CMV resistance testing can assist in identifying drug-resistant strains in refractory CMV infection. Genotypic assays detect the presence of viral-sequence variations known to be associated with antiviral resistance and are commonly used in clinical practice (119). Newly identified genotypic mutations need to be confirmed as conferring resistance using phenotypic methods available in research laboratories (119). Subtherapeutic ganciclovir dosing can lead to incomplete inhibition of viral replication and to selection of drug-resistant strains (132). Therapeutic drug monitoring may provide dosage guidance but is not routine and has not been validated in prospective studies (118, 126).

### Clinical Applications

Ganciclovir is useful for the treatment and prophylaxis of CMV infections in immunocompromised hosts. In HIV-infected patients with CMV retinitis, rates of initial response to intravenous ganciclovir are generally 75 to 85% (133). Induction courses of 5 mg/kg b.i.d. for 14 to 21 days must be followed by maintenance therapy for at least 3 to 6 months, until the CD4+ cell count has risen to  $>100/\text{mm}^3$  on antiretroviral therapy (ART) and with the concurrence of an ophthalmologist; otherwise, predictable recurrence and progression of CMV retinitis will occur in the absence of immune restoration by potent antiretroviral therapy. Foscarnet is comparable to ganciclovir as primary therapy for CMV retinitis and was reported to confer a median 4-month survival advantage before the availability of potent antiretroviral therapy (134). Ganciclovir, delivered locally by ocular implants, is effective in controlling CMV retinitis in patients intolerant of systemic ganciclovir. The combination of ganciclovir implants and oral ganciclovir has been shown to provide both systemic and local drug activity with decreased progression of existing disease and decreasing incidence of new CMV disease (135). However, the use of implants has declined dramatically in the era of potent antiretroviral therapy, and they are no longer manufactured. The immune-response inflammatory syndrome can occur in patients with CMV retinitis who are treated with ART, so close monitoring for this complication is indicated.

Ganciclovir is effective for gastrointestinal disease due to CMV in HIV-infected subjects, although the need for

maintenance therapy is still debated in the absence of anti-retroviral therapy. CNS disease and CMV polyradiculopathy have more variable response rates. Combination regimens with foscarnet suggest that these two agents can be used safely when administered concurrently or in alternating regimens (114). In severe or immediately life-threatening circumstances, such as CMV encephalitis, combined initial treatment with ganciclovir and foscarnet is a consideration. *In vitro* data suggest that a combination of ganciclovir and foscarnet is synergistic against ganciclovir-susceptible or weakly resistant CMV isolates; however, there are insufficient clinical data to determine whether combination antiviral therapy is superior to monotherapy.

In other immunocompromised hosts, such as solid-organ transplant recipients, ganciclovir appears to be effective for treating invasive CMV disease, but responses in bone marrow transplant recipients are variable. Ganciclovir monotherapy is ineffective in treating CMV pneumonia in this population, and ganciclovir was not better than placebo for CMV gastrointestinal disease (136). Early studies showed improved outcomes with ganciclovir combined with immunoglobulin for the treatment of CMV pneumonia in HSCT recipients. However, a recent large retrospective study showed a modest improvement in outcomes over the past 25 years, largely attributed to antiviral treatment and changes in transplant practices rather than to immunoglobulin-based treatments (137).

Ganciclovir has been studied extensively for prevention of CMV disease in organ transplant recipients. Effective strategies include prophylaxis, targeted prophylaxis, and preemptive therapy. Prophylaxis refers to administration of ganciclovir to all patients prior to detection of CMV viremia during the highest-risk period, usually for a predetermined time after transplantation. Targeted prophylaxis refers to administration of drug during a defined period of increased immunosuppression, such as OKT3 or antilymphocyte globulin treatment for rejection, prior to detection of CMV viremia. Preemptive therapy refers to initiation of treatment following the detection of CMV viremia or a positive CMV antigen test in the absence of clinically evident CMV disease.

Ganciclovir and foscarnet are considered first line therapies for established HHV-6 disease in transplant recipients. Ganciclovir in combination with other therapies may be efficacious in multicentric Castleman's disease because of the presence of active HHV-8 replication in association with this disease (138). Intravitreal ganciclovir can be used for acute retinal necrosis due to herpesviruses in combination with systemic antivirals (76).

Topical ganciclovir is licensed for the treatment of herpes simplex keratoconjunctivitis.

### Valganciclovir

Valganciclovir, L-valine, 2-[(2-amino-1,6-dihydro-6-oxo-9H-purin-9-yl)methoxy]-3-hydroxypropyl ester, monohydrochloride (Valcyte), is the L-valyl ester of ganciclovir and was designed, in a manner similar to that for valacyclovir, as a prodrug to enhance the oral bioavailability of the parent compound (Fig. 1; Tables 1 and 2). It has been approved for treatment of CMV retinitis in patients with HIV infection and for prevention of CMV disease in high-risk kidney, heart, and kidney-pancreas transplant patients.

### Spectrum of Activity

Since valganciclovir is completely converted to ganciclovir, their spectra of activity are identical.

### Pharmacokinetics

Valganciclovir is available in oral formulations. Valganciclovir is rapidly absorbed and hydrolyzed by intestinal and hepatic esterases to ganciclovir and exhibits an approximately 10-fold increase in oral bioavailability compared to oral ganciclovir (139). Ganciclovir levels are detected in serum within 15 minutes of valganciclovir administration. In healthy volunteers, given 900 mg of valganciclovir,  $C_{max}$  averaged 5.6  $\mu\text{g/ml}$ . The  $C_{max}$  and the time to attain the peak were greater and shorter, respectively, than those achieved with oral ganciclovir. A dose of 900 mg of valganciclovir produces the same drug exposure as a 5-mg/kg intravenous dose of ganciclovir in liver transplant recipients (140). Dosage adjustments are necessary in patients with renal impairment. Limited data support the use of valganciclovir in patients receiving dialysis. For treatment of CMV infection in hemodialysis patients, a recent guideline recommends 200 mg of the oral powder formulation three times weekly for induction and 100 mg three times weekly for maintenance (141). For CMV prophylaxis, 450 mg two- or three times weekly has been shown to be safe and effective in patients receiving hemodialysis (142). For patients receiving continuous renal replacement therapy, 450 mg every 48 hours for been recommended for CMV prophylaxis based on data in two patients (143).

### Adverse Effects

In the pharmacokinetic studies to date, headache, nausea, and diarrhea have been most frequently noted, with neutropenia also seen with longer-term dosing.

### Drug Interactions

No formal drug interaction studies with valganciclovir have been reported, but the profile would be expected to be similar to that for ganciclovir.

### Resistance

Ganciclovir-resistant CMV may emerge during valganciclovir therapy, and the mechanisms are similar to those reported for ganciclovir. Initial studies in solid-organ transplant patients receiving valganciclovir prophylaxis suggest that genotypic resistance is rare (144). However, among 225 CMV donor-seropositive (D+)- recipient-seronegative (R-) kidney, pancreas, liver, and heart transplant recipients, 9 of 65 (15%) patients who developed CMV disease had clinically suspected drug-resistant virus, and 4 had confirmed UL97 or UL54 mutations (145). Allograft loss and mortality occurred in two of four patients with proven drug-resistant CMV disease and in three of five patients with clinically suspected drug-resistant CMV disease. Among 607 lung transplant recipients (D+/R- and R+), receiving valganciclovir prophylaxis for  $\geq 6$  months, CMV infections were diagnosed in 28% (170/607), and UL97 resistance mutations were detected in 9.4% (16/170) (124).

### Clinical Applications

In HIV-infected subjects, oral valganciclovir (900 mg b.i.d. for 3 weeks and then 900 mg once daily for 1 week) has been shown to be comparable to intravenous ganciclovir in the induction phase of treatment for CMV retinitis (146). At week 4, 86% of ganciclovir recipients and 88% of valganciclovir recipients showed no evidence of disease progression by fundoscopic photography, and the percentage of subjects with CMV viremia declined comparably in both groups. The approved dosage of valganciclovir is 900 mg orally b.i.d. for

induction therapy of CMV disease and 900 mg once daily for maintenance and prophylaxis after transplantation, adjusted for renal function. Valganciclovir and intravenous ganciclovir are both recommended for the treatment of nonsevere CMV disease (147), when gastrointestinal disease does not impair adequate bioavailability of valganciclovir. Length of treatment is determined by the monitoring of weekly CMV viral loads and continuing treatment until one or two consecutive negative samples are obtained with a minimum treatment course of 2 weeks.

The benefit of valganciclovir therapy to prevent CMV disease after solid-organ transplantation is well established, but the best strategy (preemptive or prophylactic), treatment regimen (full-dose or low-dose valganciclovir), and duration have not yet been fully delineated (128). Prophylaxis is preferred for D+/R- heart or lung transplant recipients based on the data suggesting better graft survival and clinical outcomes (148). Recommended durations of prophylaxis for high-risk D+/R- recipients is 6 to 12 months for lung transplant recipients, more than 6 months for intestinal transplant recipients, 6 months for renal recipients, and 3 to 6 months for liver, heart, and pancreas transplant recipients (128). Variation in duration of prophylaxis is dependent on the degree of immunosuppression, including the use of antithymocyte antibodies. Recommended durations of prophylaxis for R+ recipients are  $\geq 6$  months for lung transplant recipients, 3 to 6 months for those receiving potent immunosuppression or intestinal transplant recipients, and 3 months for kidney, pancreas, liver, and heart transplant recipients (128). There are insufficient data to support the use of half the recommended dose of valganciclovir for prophylaxis (i.e., 450 mg daily in patients with normal renal function) although some centers have reported success (128). Furthermore, prolonged low ganciclovir levels may result in high rates of ganciclovir resistance, as reported with prolonged oral ganciclovir use (149). CMV preemptive therapy is more widely used than prophylaxis in HSCT recipients because of the bone marrow toxicities of ganciclovir and the equivalence of clinical outcomes (150).

There are conflicting reports on the benefit of preemptive anti-CMV therapy in HIV-infected patients with persistently low CD4+ T cells, and any benefit must be balanced with risk of drug toxicity and the low rate of CMV end-organ disease in the potent ART era (151–153).

Symptomatic congenital CMV disease involving the central nervous system is routinely treated with 6 weeks of intravenous ganciclovir or oral valganciclovir. A recent randomized controlled trial demonstrated the benefit of 6 months of valganciclovir, as compared to 6 weeks, on long-term audiologic and neurodevelopmental outcomes. See Chapter 23 (154).

### Foscarnet

Foscarnet, trisodium phosphonoformate (Foscavir) (Fig. 1; Tables 1 and 2) is a pyrophosphate analog that differs from the other major antiherpes viral agents in that it is not a nucleoside or nucleotide analog.

### Spectrum of Activity

Foscarnet has *in vitro* activity against HSV-1 and -2, VZV, CMV, EBV, HHV-6, HIV, and HBV. Inhibitory concentrations of foscarnet for viral DNA polymerases are 0.4 to 3.5  $\mu\text{M}$  for HSV-1, 0.6 to 22  $\mu\text{M}$  for HSV-2, 0.4  $\mu\text{M}$  for VZV, 0.3  $\mu\text{M}$  for CMV, 0.5 to 3.0  $\mu\text{M}$  for EBV, and 0.1 to 0.5  $\mu\text{M}$  for HIV. Inhibitory concentrations for viral replication vary considerably. For example, the  $\text{IC}_{50}$  of foscarnet for isolates

of HSV, CMV, and HIV are 10 to 130, 100 to 300, and 10 to 25  $\mu\text{M}$ , respectively (155). The different concentrations needed for enzyme inhibition and inhibition of viral replication are due to inefficient transport of this highly charged molecule across cell membranes. Isolates of HSV, VZV, and CMV, resistant to acyclovir and ganciclovir on the basis of diminished ability to phosphorylate these agents, remain susceptible to foscarnet.

### Mechanism of Action

Foscarnet differs from nucleoside-analog inhibitors in a number of important respects: foscarnet does not require intracellular metabolism for activation, is a noncompetitive inhibitor of viral DNA polymerases, and is not incorporated into the growing viral DNA chain. It blocks the pyrophosphate-binding site on the viral DNA polymerase, thereby interfering with pyrophosphate exchange from deoxy-nucleotide triphosphate moieties.

### Pharmacokinetics

Foscarnet is available as an intravenous formulation and can be administered as a continuous or intermittent infusion. Following intravenous administration of doses of 60 and 90 mg/kg, the  $C_{\text{max}}$  is 509 and 766  $\mu\text{M}$ , respectively (156). The initial elimination  $t_{1/2}$  in plasma is 4.5 to 8.2 hours in subjects with normal renal function, but there is a more prolonged terminal elimination  $t_{1/2}$  that may extend as long as 88 hours. This prolongation relates to the deposition of the drug in bone, which can account for 20% of an administered dose (156). Foscarnet is mainly eliminated by the renal route, by glomerular filtration and tubular secretion. The CSF-to-plasma ratio of foscarnet averages 0.66, but a wide interpatient variability exists (157). Dose adjustments for renal insufficiency are necessary. Foscarnet is not recommended for patients undergoing hemodialysis because dosage guidelines have not been established.

### Adverse Effects

Foscarnet has a number of important potential side effects. The most frequent is nephrotoxicity, with elevations of creatinine noted in the majority of treated subjects. Nephropathy related to foscarnet is due to reversible tubular lesions caused by degeneration of tubular epithelial cells often associated with foscarnet crystals, tubulointerstitial lesions resulting from toxic tubular injury, and glomerular lesions with obstructing foscarnet crystals. Systemic foscarnet crystal precipitation with intravascular obstruction has been reported and can lead to multiorgan failure (158, 159). Saline hydration can reduce the risk of nephrotoxicity.

Metabolic abnormalities include hypo- and hypercalcemia, hypomagnesemia, hypokalemia, and hypo- and hyperphosphatemia. Direct complexing of ionized calcium by foscarnet in the plasma may be responsible for hypocalcemia, and inhibition of the tubular reabsorption of phosphate may be responsible for the hypophosphatemia. Decreases in ionized calcium may not be reflected by the total serum calcium, and thus close observation for manifestations of hypocalcemia, such as paresthesias and tetany, is important.

Neurologic toxicities include tremor, altered sensorium, and seizures; the last is potentiated by the tendency for foscarnet to cause hypocalcemia. Anemia and neutropenia occur in as many as 33 and 17% of patients, respectively. Other side effects include headache, nausea, vomiting, and genital ulcerations, the last probably the result of local toxicity from the high concentrations of foscarnet excreted in the urine. In some test systems, foscarnet has demon-

strated mutagenic and teratogenic effects, and its safety in pregnancy has not been evaluated. Its poor solubility requires administration of large fluid volumes; slow infusion is needed to minimize the risks of seizures and other manifestations of hypocalcemia.

### Drug Interactions

Foscarnet should be used with particular caution in patients receiving pentamidine, because hypocalcemia can be potentiated by their concomitant use. Zidovudine and foscarnet exhibit no pharmacokinetic interactions, but together they may increase the risk for anemia (160). Elimination of foscarnet may be impaired by medications that inhibit renal tubular secretion. Any potentially nephrotoxic agent should be used with caution in patients receiving foscarnet. Ganciclovir exhibits no pharmacokinetic interactions with foscarnet, but dose adjustments of both drugs are necessary if a decrease in creatinine clearance occurs.

### Resistance

Since foscarnet does not require intracellular activation, resistance to this agent occurs exclusively at the level of the viral DNA polymerase. Clinical isolates of HSV, CMV, and VZV, resistant to foscarnet, have been described, and the *in vitro* susceptibility of HSV strains derived from HIV patients correlates with foscarnet treatment success or failure (24, 161–170). For resistant isolates of HSV, CMV, and VZV, there are 3- to 8-fold increases in inhibitory concentrations, and progressive CNS disease has been associated with foscarnet-resistant HSV strains (171). Foscarnet-resistant HSV and CMV strains may remain susceptible to acyclovir and ganciclovir, respectively, although dually resistant clinical isolates have been described (172–174). For such isolates, cidofovir remains a therapeutic option. Resistance of HIV to foscarnet has been linked to mutations in reverse transcriptase.

### Clinical Applications

Foscarnet is a well-established antiviral option in immunocompromised patients, and it is usually administered as a second-line option to ganciclovir. Foscarnet is an effective treatment for CMV retinitis, either as primary therapy or when there is suspicion or proof of ganciclovir resistance. Foscarnet is also useful for acyclovir-resistant mucocutaneous HSV or VZV infection, described mainly in patients with HIV infection and some hematology-oncology patients (175–179). One comparative trial of foscarnet and ganciclovir found that the two drugs were equivalent with respect to CMV outcome, but the foscarnet group exhibited an improved survival rate, with foscarnet extending life by an average of 4 months (134). When used as maintenance therapy for established CMV retinitis, the time to recurrence is inversely proportional to the foscarnet dosage employed. Therefore, a maintenance dosage of 120 mg/kg/day results in a delayed time to progression compared to that obtained with 90 mg/kg/day (180). Switching to foscarnet is recommended for CMV disease in transplant recipients if higher-level ganciclovir resistance emerges or if CMV disease is severe and low-level ganciclovir resistance is present or suspected. Uncontrolled studies suggest a benefit for foscarnet in visceral CMV disease, except for CMV pneumonitis in bone marrow transplant and lung transplant recipients (124). Foscarnet can be used safely in conjunction with ganciclovir given either concomitantly in full doses for severe syndromes, such as CMV ventriculoencephalitis in patients with AIDS or in alternating maintenance regimens

(181). Intravitreal foscarnet has been employed in CMV retinitis and acute retinal necrosis due to herpesvirus infection (76).

Foscarnet may have a particular role in the prophylaxis of CMV infections in hematopoietic stem cell transplant (HSCT) recipients. In allogeneic HSCT patients with CMV antigenemia or viremia, preemptive foscarnet therapy demonstrated an efficacy similar to that of ganciclovir but was associated with a lower rate of neutropenia and treatment-limiting hematologic toxicity (182). Although foscarnet exhibits *in vitro* and *in vivo* anti-HIV activities, its toxicity profile and requirement for parenteral administration preclude its use. It has been ineffective for HBV.

A topical cream containing 1% foscarnet was effective in the treatment of mucocutaneous HSV infections unresponsive to acyclovir (183) and avoids the adverse effects associate with intravenous administration. However, topical foscarnet creams are not commercially available.

### Cidofovir

Cidofovir, (S)-1-[3-hydroxy-2-(phosphonylmethoxy)propyl] cytosine (Vistide) (Fig. 1; Tables 1 and 2), is an acyclic phosphonate nucleotide analog, which belongs to a family of phosphonylmethoxyalkyl derivatives of purines and pyrimidines.

### Spectrum of Activity

Cidofovir has been primarily developed as an anti-CMV agent, but it has broad spectrum antiherpesvirus activity in addition to *in vitro* activity against human papillomaviruses, adenoviruses, poxviruses, and polyomaviruses. The *in vitro* IC<sub>50</sub> for clinical CMV isolates is in the range of 0.1 µg/ml (184). In general, ganciclovir- and foscarnet-resistant strains of CMV and HSV remain susceptible to cidofovir.

### Mechanism of Action

Cidofovir is taken up by both virally infected and uninfected cells and does not require the action of a virus-induced kinase to be converted to its active moiety (185). The structure of cidofovir represents a monophosphorylated nucleotide. This highly charged phosphonate poorly penetrates cell membranes, limiting its activity and contributing to renal toxicity. Cellular enzymes convert cidofovir to its diphosphate form, which, as an analog of a nucleotide triphosphate, is a competitive inhibitor of the viral DNA polymerase and causes premature chain termination. Cidofovir diphosphate has an intracellular  $t_{1/2}$  of >48 h, an important factor that permits intermittent dosing schemes not previously possible for other anti-CMV agents. There is a 25- to 50-fold selectivity of cidofovir diphosphate for the viral, compared to the cellular, DNA polymerase (185).

### Pharmacokinetics

Cidofovir can be administered intravenously, topically, and by ocular implant (no longer available). Direct intraocular injection of cidofovir is contraindicated. Plasma C<sub>max</sub> averages 3.1 to 23.6 µg/ml with intravenous doses of 1.0 to 10.0 mg/kg, respectively. Cidofovir has poor CSF penetration, and ocular penetration has not been well characterized. The elimination  $t_{1/2}$  in plasma is 2.6 hours, and 90% of the drug is excreted in the urine, with renal tubular secretion contributing substantially to clearance (186). Dose reduction is necessary, in the setting of renal insufficiency, if the benefit of the drug is thought to outweigh the risk of worsening renal function.

### Adverse Effects

The major adverse effect of cidofovir is nephrotoxicity, which appears to result from renal tubular damage (187). At a dosage of 5 mg/kg twice weekly without concomitant probenecid, renal toxicity is common and is manifested by proteinuria and glycosuria (187). Concomitant use of high-dose probenecid appears to permit 5 mg/kg weekly or biweekly dosages of cidofovir to be tolerated. Cardiomyopathy occurred in one HIV-infected subject treated simultaneously with stavudine, and erythematous cutaneous eruptions have been described in subjects treated with cidofovir and probenecid (187). Iritis and hypotony (decreased intraocular pressure) are notable complications of both systemically and intravitreally administered cidofovir (188). Topical corticosteroids are effective in controlling the iritis associated with cidofovir if it is deemed in the patient's best interest to continue the drug. Neutropenia occurs in approximately 20% and requires monitoring. When cidofovir is administered with probenecid, hypersensitivity reactions, nausea, vomiting, and diarrhea occur commonly. Preclinical studies indicate that cidofovir has mutagenic, gonadotoxic, embryotoxic, and teratogenic effects. Cidofovir is associated with tumors in rats.

### Drug Interactions

Probenecid has a nephroprotective effect in animal models and likely in humans. At cidofovir doses of 3 mg/kg, probenecid does not affect the clearance of cidofovir. However, at higher doses of cidofovir, probenecid given pre- and post-infusion reduces renal clearance (189). This differential effect of probenecid, dependent on the cidofovir dose, is not fully explained but has been hypothesized to reflect the presence of multiple tubular secretion pathways (189). The first may be high-affinity, probenecid-insensitive, and saturable. Once saturated, a probenecid-sensitive secretory mechanism may then be operative. Coadministration of cidofovir with probenecid is recommended to reduce nephrotoxicity. Coadministration with other nephrotoxic drugs, such as foscarnet or aminoglycosides, should be avoided.

### Resistance

CMV resistance to cidofovir may emerge during chronic use. After 3 months of cidofovir therapy for CMV retinitis, 29% of subjects had CMV isolates with reduced susceptibility to cidofovir (190). However, reduced susceptibility to cidofovir *in vitro* may not predict clinical progression (191). Most of the known mutations that confer cross-resistance between ganciclovir and cidofovir map to the exonuclease domains located between amino acids 300 and 545 of UL54 (192). HSV and HHV-6 resistance to cidofovir emerges under drug-selection pressure *in vitro* but has not been reported in clinical isolates (30).

### Clinical Applications

Cidofovir is effective in some HIV-infected patients with CMV retinitis and failure to respond or intolerance to ganciclovir and foscarnet. An induction course of cidofovir of 5 mg/kg weekly for 2 weeks is followed by dose-frequency reduction to every other week. In patients with relapsed CMV retinitis, the 5-mg/kg-every-other-week maintenance regimen was more effective in delaying recurrence but was associated with a higher incidence of nephrotoxicity than the lower-dose regimen (3 mg/kg) (193). Cidofovir may be considered in transplant recipients with CMV infections resistant to ganciclovir and foscarnet, although there is little

information on the efficacy of cidofovir in this setting, and dose-limiting nephrotoxicity is frequent (128).

Cidofovir can also be considered for the treatment of acyclovir-resistant and foscarnet-resistant mucocutaneous HSV infections, either by the intravenous route or topically, as a gel, which is not available as a commercial formulation (194–198). Clinical experience with the use of cidofovir for the treatment of drug-resistant VZV disease is very limited (199). Cidofovir, in addition to antiretroviral therapy, is not effective for the treatment of HIV-associated progressive multifocal leukoencephalopathy (200). Cidofovir is commonly used for the treatment of adenoviral infection in bone marrow and solid organ transplant recipients, although no randomized trials have been performed (201, 202). Cidofovir 1% ointment (not commercially available) has also been studied as an investigational drug for the topical treatment of human papillomavirus infections in immunosuppressed patients and for intralesional treatment of respiratory papillomatosis (203, 204).

Cidofovir interferes with poxviral DNA replication at concentrations well below those that are toxic for human cells and has a remarkably long intracellular  $t_{1/2}$ , making it an attractive agent for prophylaxis against smallpox were it to be utilized in a bioterrorism attack. Aerosolized doses of cidofovir prevented lethal intranasal or aerosol cowpox virus infection in murine models (205). Cidofovir may be clinically useful against other poxvirus diseases, including recalcitrant molluscum contagiosum and in immunosuppressed populations (206).

### Other Antitherpesvirus Agents

#### Docosanol

Docosanol,  $C_{22}H_{46}OC$  (Abreva), is a 22-carbon saturated alcohol that inhibits replication of HSV-1 and -2. A highly lipophilic compound, docosanol inhibits entry of lipid-enveloped viruses into target cells by fusion with the cell plasma membrane. As a result, the virus remains on the cell surface and is blocked from entering the nucleus for viral replication. Docosanol lacks direct virucidal activity (207), and cellular metabolism may be required for its antiviral activity. Topical docosanol was approved by the FDA in July 2000 for the treatment of recurrent herpes labialis in adults and children aged 12 years and older. It is the only nonprescription drug available for this indication. However, topical acyclovir is more effective than docosanol for treating HSV infections. Mild side effects, including headache and application site reactions, have been reported with docosanol.

#### Imiquimod

Imiquimod, 1-(2-methylpropyl)-1H-imidazo[4,5-c]quinolin-4-amine (Aldara), is an agonist for Toll-like receptor 7

(TLR-7). Binding promotes maturation of dendritic cells as well as production of IFN- $\alpha$ , IFN- $\gamma$  (indirectly), interleukin 12 (IL-12), IL-6, IL-8, and/or tumor necrosis factor from dendritic and other innate immune cells. There is no direct antiviral effect.

Imiquimod is available as a 5% topical cream. Following application to affected skin, some systemic absorption is seen, with levels in serum ranging from 0.1 to 3.5 ng/ml, depending on the dose and location of application. Urinary recoveries of as much as 0.15% are seen following thrice-weekly treatment with 75 mg for 16 weeks. Use of imiquimod is often limited by local toxicity, which, although usually mild or moderate, can be severe (skin weeping, erosion). Common adverse events include erythema, burning, pain, erosion, induration, and edema.

Imiquimod is approved for the treatment of actinic keratosis, superficial basal cell carcinoma, and external genital or perianal warts. Because of its immunomodulatory and consequent antiviral effects, it has been studied for treatment of both oral and genital HSV infection. Several case reports have noted more rapid healing of primary HSV-2 lesions and decreased viral shedding in patients with acyclovir-resistant HSV lesions. In an open-label, controlled study for treatment of herpes labialis, subjects receiving imiquimod had a longer time to recurrence, but the trial was stopped early due to severe local toxicity in the imiquimod group (208). A controlled dose-ranging study for herpes genitalis found no effect of imiquimod on time to recurrence (209).

### Investigational Antitherpesvirus Agents

There are several novel and potentially effective compounds under preclinical and early clinical investigation, some of which are listed in Table 3. New antitherpesvirus drugs include inhibitors of immediate early-gene expression, non-nucleoside DNA polymerase inhibitors, helicase-primase inhibitors, inhibitors of protein-protein interactions among DNA replication proteins, and inhibitors of assembly, encapsidation, and nuclear egress (192, 210).

#### Brincidofovir

The lipophilic derivative of cidofovir, brincidofovir, hexadecyloxypropyl-cidofovir ([HDP-CDV] (CMX001) (Fig. 2), shows much improved oral bioavailability, increased cellular uptake, and lack of nephrotoxicity. Brincidofovir is absorbed in the small intestine and transported throughout the body as a phospholipid; it penetrates cell membranes more readily than cidofovir and is converted intracellularly to cidofovir diphosphate after cleavage of its lipid moiety and phosphorylation by cellular kinases (211). Brincidofovir achieves higher levels of intracellular cidofovir diphosphate than cidofovir and is highly active against many human

**TABLE 3** Selected investigational antitherpesvirus drugs

Agent	Chemical backbone	Spectrum	Mechanism(s) of action	Stage of development
ODE-CDV <sup>a</sup>	Alkoxyalkyl ester of cidofovir	CMV, smallpox virus	Inhibition of DNA synthesis	Preclinical
Pritelivir (BAY 57-1293; AIC316)	Thiazole urea derivative	HSV-1, HSV-2	Helicase-primase inhibitor	Phase II
Amenavir (ASP2151)	Oxadiazazolephenyl derivative	HSV-1, HSV-2, VZV	Helicase-primase inhibitor	Phase III
BILS 179 BS	Thioazolylphenyl compound	HSV-1, HSV-2	Helicase-primase inhibitor	Preclinical
Valomaciclovir (EPB 348, H2G)	Prodrug of acyclic guanosine analog	HSV-1, HSV-2, EBV, VZV	Nucleoside analog	Phase II

<sup>a</sup>ODE-CDV, octadecyloxyethyl-cidofovir.

DNA viruses (212, 213). Brincidofovir was shown to suppress CMV disease in hematopoietic cell transplant in a phase 2 clinical trial (214). Myelosuppression or nephrotoxicity was not increased in the brincidofovir group. Diarrhea was a dose-limiting adverse effect; however, a dose of 100 mg twice weekly was effective at preventing CMV infection and resulted in milder diarrhea. A pivotal phase 3 clinical trial in hematopoietic stem-cell transplant recipients was recently terminated for the lack of efficacy. Preliminary results from a phase 3 study evaluating brincidofovir for the treatment of adenovirus infection showed a reduction or clearance of adenovirus during therapy (215). Brincidofovir has shown a survival benefit in an animal model of smallpox infection (216). *In vitro* studies have demonstrated activity against Ebola virus, an RNA virus, which is probably attributable to cellular toxicity. A subsequent clinical trial was halted by the manufacturer, citing an insufficient number of patients (217, 218). In contrast to DNA viruses, activity against Ebola virus requires the lipid moiety, and phosphorylation of cidofovir to the diphosphate form appears unnecessary (218). Brincidofovir is available for compassionate use.

### Maribavir

Maribavir, 5,6-dichloro-2-(isopropylamino)-1- $\beta$ -L-ribofuranosyl-1H-benzimidazole (GW1263W94) (Fig. 2), belongs to a new class of drugs, the benzimidazole ribosides, and has a novel mechanism of action that differs from those of available CMV drugs. Maribavir does not require intracellular activation, and its phosphorylated forms do not directly inhibit the viral DNA polymerase. Instead, maribavir's main mechanism is related to blocking the nuclear egress of newly formed CMV virions by inhibiting UL97's phosphorylation of Lamin A/C (219, 220). Maribavir has activity against only two of the human herpesviruses, CMV and EBV. It is an oral agent with a plasma elimination  $t_{1/2}$  of 3 to 5 hours and is extensively metabolized to an inactive metabolite by the hepatic cytochrome P450 3A4 isozyme (221).

A phase II dose-ranging study for CMV prophylaxis in allogeneic stem-cell transplant recipients compared maribavir 100 mg twice daily, 400 mg once daily, and 400 mg twice daily, with placebo. Within the first 100 days after

transplantation, the incidence of CMV infection was lower in each maribavir dosing group (222). Two subsequent Phase 3 prophylaxis studies, one in allogeneic stem-cell transplant recipients (223) and one in liver transplant recipients (224), were conducted utilizing the 100 mg twice-daily dose. In stem-cell transplant recipients, maribavir failed to prevent CMV disease compared to placebo. The study in liver transplant recipients, which was stopped early, found that maribavir was inferior to oral ganciclovir. Failure in these studies has largely been attributed to the use of the lower 100 mg twice-daily dose (225). Maribavir has *in vitro* activity against ganciclovir- or cidofovir-resistant CMV, and small case series suggest a possible clinical benefit at higher doses in patients who failed to respond to other therapies and/or had known ganciclovir-resistant CMV (226). In all of these studies maribavir was well tolerated, with taste disturbance being the most significant adverse effect noted (223). An additional Phase II study for treatment of resistant or refractory CMV infections in transplant recipients, with doses as high as 1200 mg twice daily, has recently been completed ([clinicaltrials.gov](http://clinicaltrials.gov) NCT00002373). Maribavir may be available for compassionate use if specific criteria are met.

### Letermovir

The CMV terminase complex is comprised of two proteins, pUL89 and pUL56, whose main function is to cleave CMV DNA concatemers into functional CMV monomers (227, 228). Letermovir (AIC246, MK-8228) (Fig. 2) is a 3,4-dihydroquinazolin-4-yl-acetic acid derivative and the most advanced viral-terminase complex inhibitor. Letermovir has activity only against CMV and, because of its novel mechanism, has no cross-resistance with other approved anti-CMV agents. A Phase II study in allogeneic hematopoietic-cell transplant recipients found oral letermovir effective in reducing the incidence of CMV infection compared to placebo and without any significant adverse effects (229). In this study, the highest dose of 240 mg/day had the greatest anti-CMV activity. A phase 3 study for prevention of CMV in allogeneic hematopoietic stem-cell transplant recipients examining intravenous or oral letermovir 240 mg or 480 mg once daily (dose dependent on concomitant administration of cyclosporin) is ongoing ([clinicaltrials.gov](http://clinicaltrials.gov) NCT02137772). Letermovir is not available for compassionate use.

# Anti-Hepatitis Virus Agents

MATTHEW L. SCHERER, CHELSEA SAMMONS, BRIAN NELSON,  
SCOTT M. HAMMER, AND ELIZABETH VERNA

## 13

Antiviral therapy for hepatitis viruses, in particular hepatitis C virus (HCV), has evolved dramatically over the past 5 to 10 years. This chapter reviews agents that have been, or are being, developed to treat hepatitis B virus (HBV) (Chapter 32) and HCV (Chapter 54) infections. Detailed information is provided for approved agents and those in advanced stages of clinical development. Agents in earlier stages of development are described more briefly. Agents approved but rarely if ever used for a specific pathogen have been removed from this edition (e.g., interferon- $\alpha$  and HBV). The reader is referred to the respective disease-specific chapters for full discussions of the viral agents and the diseases they cause.

### ANTIVIRAL AGENTS FOR HEPATITIS B INFECTION

#### Lamivudine

##### Clinical Use

Lamivudine's (4-Amino-1-[(2R,5S)-2-(hydroxymethyl)-1,3-oxathiolan-5-yl]-2(1H)-pyrimidinone; Epivir, Epivir-HB) mechanism of action against HBV parallels its mechanism against HIV. Lamivudine inhibits HBV DNA polymerase-reverse transcriptase (Table 1). For a full discussion of the pharmacology of lamivudine, refer to Chapter 11 on antiretroviral agents. Treatment with 100 mg of lamivudine daily for 12 months normalizes the serum alanine aminotransferase (ALT) level and improves histologic inflammatory scores in 50% to 70% of chronic hepatitis B patients (1). A loss of HBeAg is seen in up to 30% of patients treated with lamivudine, and HBeAg seroconversion, defined as the loss of HBeAg, undetectable levels of serum HBV DNA, and the appearance of antibodies against HBeAg, is seen in up to 20% of patients (2). HBeAg seroconversion is associated with durable antiviral responses. For several years, lamivudine was recommended for the initial treatment of individuals with chronic HBV infection who had active virus replication and active liver disease, defined as a positive serum HBV DNA and elevated serum ALT level with evidence of moderate to severe hepatitis on liver biopsy. With growing concern about lamivudine resistance (see below) and the development of alternative agents with higher

barriers to resistance, monotherapy with lamivudine is now discouraged. Lamivudine is effective in the treatment of IFN- $\alpha$ 2b nonresponders and in the prophylaxis of HBV recurrence in liver transplant patients (3, 4). The combination of lamivudine with IFN- $\alpha$  for the treatment of chronic HBV infection has been disappointing, with most trials showing no long-term clinical benefit (5, 6). Lamivudine has also been studied in combination with other antiviral agents such as adefovir and telbivudine but has not shown significant clinical benefit when compared to currently recommended monotherapy options (7, 8). In HIV-negative patients, lamivudine has been used at 100 mg daily; however, it is recommended that HIV-infected patients receive the standard 150-mg-b.i.d. or 300-mg-twice daily dosage utilized for the treatment of HIV in combination with other antiretroviral agents. Such regimens should also include two agents active against HBV to try to prevent the emergence of HBV resistance.

##### Resistance

Resistance of HBV to lamivudine develops with prolonged therapy and is a major impediment to successful treatment. The frequency of genotypic resistance mutations increases from 24% of isolates after the first year to 67% after 4 years of therapy (9). Even higher rates of mutation have been seen in HIV- and HBV-coinfected patients given HIV treatment doses of lamivudine for long periods. The predominant lamivudine resistance mutations in HBV-infected patients are found in the catalytic domain of HBV polymerase in the tyrosine (Y), methionine (M), aspartate (D), aspartate (D) motif, principally M204I or M204V. These mutations appear to decrease viral replication competence, but a frequently associated mutation, L180M, may restore viral fitness (10). Although withdrawal of therapy results in repopulation with wild-type virus, retreatment with lamivudine results in rapid emergence of resistant strains (11). Failure to achieve a  $> 1$ -log<sub>10</sub> drop in HBV viral load after 3 months of therapy is associated with the emergence of lamivudine resistance.

#### Emtricitabine

Emtricitabine (4-Amino-5-fluoro-1-[(2S,5S)-2-(hydroxymethyl)-1,3-oxathiolan-5-yl]-2(1H)-pyrimidinone; Emtriva)

TABLE 1 Key information on anti-HBV medications

Medication	Usual dosing	Mode of elimination	Considerations for renal impairment	Considerations for hepatic impairment	Major toxicities
Lamivudine	100 mg once daily HIV coinfection: 150 mg twice daily OR 300 mg once daily	Renal	Safe in mild, moderate, or severe renal impairment and in hemodialysis (HD) with appropriate dose reduction	None	Abdominal pain, nausea, vomiting
Emtricitabine	200 mg once daily	Renal	Safe in mild, moderate, or severe renal impairment and in HD with appropriate dose reduction	None	Dizziness, headache, diarrhea, rash, weakness, cough, rhinitis, anemia, neutropenia
Adefovir	10 mg once daily	Renal	Dose reduction recommended for CrCL 30–50 ml/min and hemodialysis. Not recommended for CrCl < 30 ml/min	None	Rash, pruritus, abdominal pain, nausea, diarrhea, renal impairment
Entecavir	Nucleoside naïve: 0.5 mg once daily Lamivudine experienced: 1 mg once daily	Renal	Safe in mild, moderate, or severe renal impairment and in HD with appropriate dose reduction	None	Hepatitis, headache, dizziness, hematuria
Telbivudine	600 mg once daily	Renal	Safe in mild, moderate, or severe renal impairment and in HD with appropriate dose reduction	None	Abdominal pain, elevated creatinine kinase, headache, nasopharyngitis, upper respiratory infection, malaise/fatigue, lactic acidosis, hepatitis
Tenofovir disoproxil (TDF)	300 mg once daily	Renal	Dose reduction recommended for CrCL < 50 mL/min. If TDF is potentially the cause of renal impairment alternative therapy should be considered	None	Diarrhea, nausea, renal impairment, weakness

(Figure 1; Table 1) is a 5'-fluorinated analogue of lamivudine with the same mechanism of action and potency (see Chapter 11 on antiretroviral agents). Although not United States Food and Drug Administration (FDA) approved for the treatment of HBV, several studies have demonstrated the clinical efficacy of emtricitabine in chronic HBV infection. As with lamivudine, resistance develops rapidly when the drug is used as monotherapy.

#### Clinical Use

Nucleoside/tide analogue naïve chronically infected HBV patients treated with 48 weeks of emtricitabine 200 mg daily have superior histologic improvement and loss of detectable HBV DNA compared to placebo. Resistance to emtricitabine was observed in 13% of patients (12). No studies have compared emtricitabine to lamivudine but neither agent appears to offer a clinically relevant benefit compared to the other. Emtricitabine has a minimal role as monotherapy in the treatment of chronic HBV but may be used when coformulated with tenofovir.

#### Adefovir Dipivoxil

Adefovir dipivoxil (bis-pivaloyloxymethyl-9-(2-phosphorylmethoxyethyl) adenine; Hepsera) is the orally bioavailable prodrug of adefovir, an adenine nucleotide analog.

#### Spectrum of Activity

Adefovir dipivoxil has activity against several DNA and RNA viruses, including retroviruses, herpesviruses, and hepadnaviruses. It was initially developed for use against HIV, but this use was abandoned because of safety concerns at the dosing levels needed to inhibit HIV. It retains activity against HBV, however, at doses that are not associated with excessive toxicity. The EC<sub>50</sub> of adefovir for HBV is approximately 0.003 µg/ml, making it 10-fold more potent than tenofovir but half as potent as lamivudine *in vitro* (13). Because of its low oral bioavailability, however, adefovir is inferior to both lamivudine and tenofovir at doses used clinically.

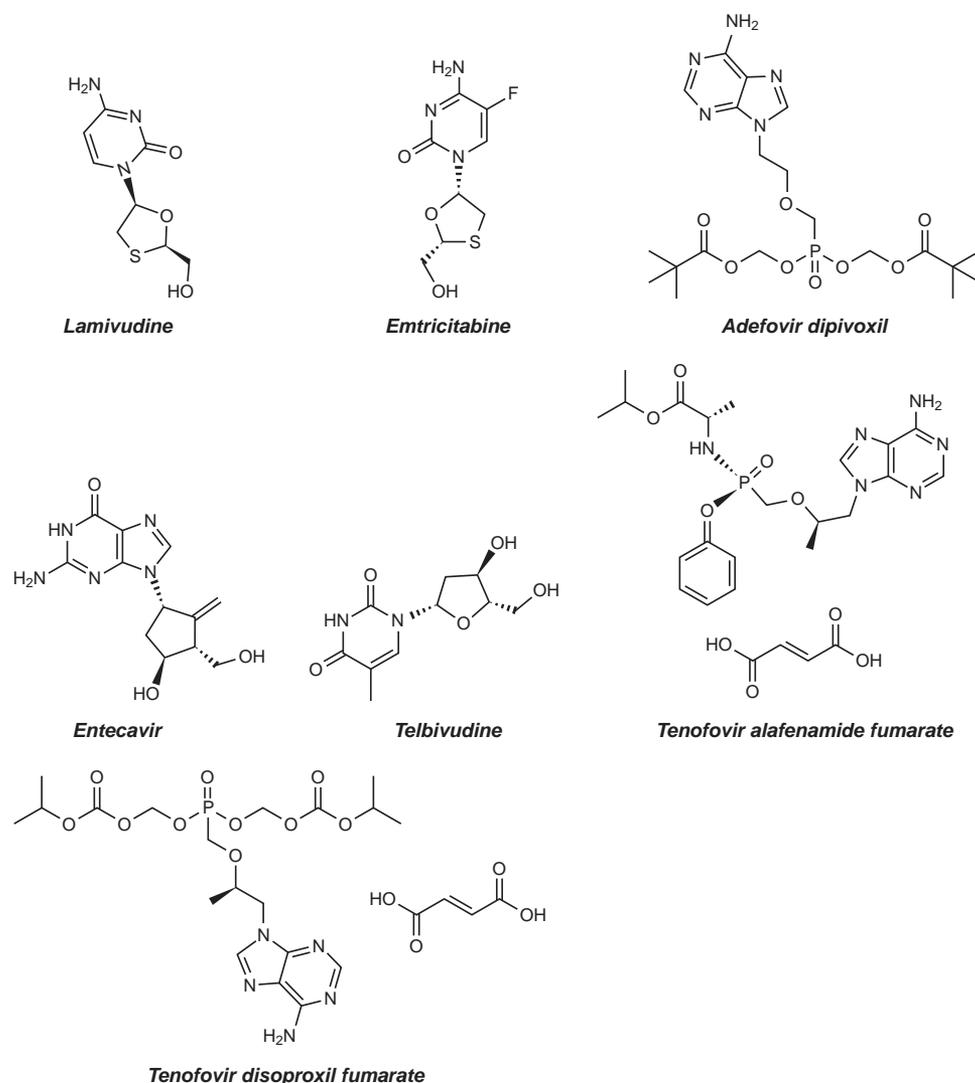

FIGURE 1 Chemical structures of agents with activity against hepatitis B virus.

### Mechanism of Action

Once absorbed, adefovir dipivoxil is converted to adefovir, which then undergoes two intracellular phosphorylation steps. The active intracellular metabolite of adefovir, 9-[2-(phosphonomethoxy)ethyl]adenine (PMEA) diphosphate, inhibits viral DNA polymerases by competing with dATP and terminating the DNA chain (14).

### Pharmacology

Absorption of adefovir does not appear to be affected by food or stomach pH. About 10% of the absorbed dose is converted intracellularly to the active form, the long elimination half life ( $t_{1/2}$ ) (18 h) of which allows for once-daily dosing. Adefovir is not metabolized by cytochrome P450 enzymes. The activity of adefovir appears to be unaffected or enhanced when the drug is combined with other anti-HBV agents.

### Adverse Effects

The toxicities of adefovir at the doses used for treating HBV have been primarily gastrointestinal and hepatic, including nausea and transient increases in transaminase levels. At the higher doses used to treat HIV, gastrointestinal disturbances,

elevated liver enzyme levels, and delayed renal effects, including renal tubular dysfunction mimicking the Fanconi syndrome, occurred (15).

### Resistance

Resistance to adefovir develops more slowly than resistance to lamivudine, with approximately 29% of patients demonstrating resistance after 5 years of adefovir monotherapy. Of note, only 20% of the patients had evidence of viral rebound and 11% had elevations in ALT (i.e., clinical resistance) (16). Several mutations are associated with adefovir resistance, including N236T and A181V (16). Although these mutations decrease susceptibility by only 3% to 15% *in vitro*, hepatitis flares and decompensation are seen (17). Primary adefovir resistance has been associated with the I233V mutation, but viruses with this mutation do retain susceptibility to tenofovir and entecavir (18). Adefovir is a potential option for treating lamivudine-resistant HBV.

### Clinical Applications

Adefovir is effective for the treatment of chronic HBV infection in both HBeAg-positive and HBeAg-negative

subjects. After 48 weeks of treatment with adefovir at 10 mg daily, the mean decrease in HBV DNA in HBeAg-positive subjects was 3.52 log<sub>10</sub> copies/ml (19). Results were similar in the trial of HBeAg-negative subjects (20). Adefovir therapy also resulted in greater improvements in liver histology, decreases in ALT, and, in subjects who were HBeAg positive at the start of the study, higher rates of HBeAg seroconversion. Because of the substantial rates of resistance seen with prolonged adefovir therapy, however, the use of adefovir monotherapy is generally discouraged. The addition of lamivudine to adefovir therapy appears to reduce the emergence of adefovir resistance both in those with lamivudine resistance and in those who have never received treatment (8, 21). Tenofovir is preferred to adefovir due to its more potent antiviral activity and superior safety.

### Entecavir

Entecavir (2-amino-1,9-dihydro-9-[(1S, 3R, 4S)-4-hydroxy-3-(hydroxymethyl)-2-methylenecyclopentyl]-6H-purin-6-one, monohydrate; Baraclude) is a guanine nucleoside analog (Figure 1; Table 1).

#### Spectrum of Activity

Entecavir possesses potent and selective activity against hepadnaviruses. In cell culture, it is between 30- and 1,000-fold more active than lamivudine (22). Preclinical studies originally suggested that entecavir possessed no anti-HIV-1 activity, but *in vivo* activity resulting in an approximately 1-log<sub>10</sub> reduction in plasma HIV-1 RNA level in humans has been described (see “Resistance” below) (23).

#### Mechanism of Action

After it is phosphorylated, entecavir interferes with multiple functions of HBV polymerase, including priming, reverse transcription, and DNA-dependent DNA synthesis (24).

#### Pharmacology

With once-daily dosing, steady state is achieved after 6 to 10 days. In healthy volunteers receiving 0.5 mg daily for 14 days, the plasma C<sub>max</sub> averaged 4.2 ng/ml and the elimination t<sub>1/2</sub> was 130 h (25). The intracellular t<sub>1/2</sub> for entecavir triphosphate is approximately 15 h. Oral administration of entecavir with a high-fat meal or a light meal results in significant delays in absorption, decreases in C<sub>max</sub>, and decreases in area under the curve (AUC). Consequently, entecavir should be administered on an empty stomach. Entecavir is primarily eliminated unchanged by the kidneys, and the dosage should be adjusted in subjects with a creatinine clearance of less than 50 ml/min. Coadministration of entecavir with adefovir, lamivudine, or tenofovir results in no significant pharmacokinetic interactions (26). No interactions with other medications have been reported.

#### Adverse Effects

The adverse effects most frequently associated with entecavir in clinical trials were headache and upper respiratory infection, and these were generally mild. Elevations in liver enzymes occur less frequently than with lamivudine monotherapy (27, 28).

#### Resistance

Entecavir resistance rarely emerges in subjects with no prior nucleoside exposure, even after 2 years of monotherapy. Interestingly, although the M204V/I mutation associated with lamivudine resistance does not confer resistance to entecavir, it appears to be a prerequisite for such resistance to

emerge. When combined with one of the lamivudine resistance mutations (M204V/I and L180M), three known mutations confer entecavir resistance (T184A/I/S, S202C/G, and M250I/L), although alone they are insufficient to cause such resistance (29). In a study of lamivudine-refractory subjects treated with entecavir for 2 years, viral rebound occurred in 1% of subjects after 1 year and 9% after 2 years (29).

In preclinical testing, entecavir had no reported anti-HIV activity and was therefore used to treat HIV- and HBV-coinfected patients who did not yet need treatment for their HIV. However, HIV coinfected individuals have developed an M184V mutation in HIV reverse transcriptase while on entecavir monotherapy (23). Entecavir should not be prescribed to HIV coinfected individuals who are not on a completely suppressive antiretroviral regimen.

### Clinical Applications

Entecavir monotherapy has been compared to lamivudine in two large trials of HBeAg-positive and HBeAg-negative subjects with elevated ALT, detectable HBV DNA, and evidence of inflammation on liver biopsy. After 52 weeks, entecavir was superior to lamivudine for the frequency of histologic improvement (72% versus 62% in HBeAg-positive subjects (27) and 70% versus 61% in HBeAg-negative subjects (27)). Entecavir was also superior to lamivudine in frequency of undetectable HBV DNA (67% versus 36% in HBeAg-positive subjects and 90% versus 72% in HBeAg-negative subjects). Compared to adefovir, entecavir was associated with a greater reduction of HBV DNA after treatment for 52 weeks. The mean change in HBV DNA was significantly greater with entecavir (-6.23 versus -4.42 log<sub>10</sub> copies/ml) (30). Despite the resistance issues noted above, entecavir has been shown to be effective in HBeAg-positive subjects who are refractory to lamivudine (31), although a dose increase to 1 mg daily is recommended for patients with known resistance to lamivudine. However, entecavir is generally not recommended in those with lamivudine resistance unless they are unable to tolerate tenofovir. It may be used in those with resistance to adefovir unless they have previously been treated with lamivudine (32). Long-term entecavir therapy for 5 years has been associated with normalized aminotransferase levels and a decrease in inflammation and fibrosis scores (33).

### Telbivudine

Telbivudine (1-(2-Deoxy-β-L-erythro-pentofuranosyl)-5-methyl-2,4(1H,3H)-pyrimidinedione; Tyzeka) is a nucleoside analog approved for the treatment of chronic HBV infection.

#### Spectrum of Activity

Telbivudine is a competitive inhibitor of the HBV DNA polymerase. Telbivudine has no activity against any human viruses other than HBV and does not inhibit human cellular polymerases. Inhibition of human mitochondrial DNA polymerase γ is felt to be the cause of much of the toxicity seen with other nucleoside analogs (e.g., neuropathy, myopathy, and lactic acidosis) (34).

#### Mechanism of Action

Telbivudine requires biotransformation to the triphosphate form, but unlike lamivudine, it preferentially inhibits anti-complementary (second-strand) DNA (35). Because it lacks a 3'OH group, it acts as a chain terminator once incorporated into the growing DNA strand.

### Pharmacology

In pharmacokinetic studies,  $C_{max}$  following an oral dose of telbivudine occurs in 0.8 to 2.8 h (36) and ranges from 0.20 to 5.46  $\mu\text{g/ml}$ , with an AUC of approximately 26  $\mu\text{g/ml}\cdot\text{h}$ . Telbivudine is cleared primarily via the kidneys and elimination is biphasic, with an intracellular  $t_{1/2}$  of approximately 14 h and an elimination  $t_{1/2}$  of approximately 40 h. Dose adjustments should be made in patients with a creatinine clearance of  $<50$  ml/min.

### Adverse Effects

Telbivudine is generally well tolerated. Elevations in serum creatinine kinase have been more common in those receiving telbivudine than in those receiving lamivudine, although these were not associated with muscle-related adverse events (37). The package insert for all nucleoside analogs carries a boxed warning for lactic acidosis, though this has not yet been reported with telbivudine specifically.

### Resistance

Resistance to telbivudine has developed at less than half the rate of resistance to lamivudine (5% versus 11% for HBeAg-positive subjects and 2.3% versus 10.7% for HBeAg-negative subjects) (37). The signature mutation associated with telbivudine resistance has been an M204I substitution in the HBV DNA polymerase (38). Telbivudine is active against strains with an isolated M204V mutation but inactive against strains with M204V plus L180M. *In vitro*, telbivudine remains active against strains resistant to adefovir.

### Clinical Applications

One large study comparing telbivudine to lamivudine monotherapy showed that telbivudine is not inferior to lamivudine after 52 weeks (38). In the subgroup of HBeAg-positive subjects, telbivudine was superior to lamivudine for the primary endpoint (viral load of  $<5$  log<sub>10</sub> copies/ml coupled with normalization of ALT or loss of HBeAg), and both HBeAg-positive and HBeAg-negative subjects achieved greater and faster reductions in HBV DNA if they were receiving telbivudine. A 2-year follow-up study found that telbivudine was superior to lamivudine for the same primary endpoint in both HBeAg-positive and -negative subjects (39). Rates of resistance were also lower in the telbivudine group (25% versus 40%). When compared directly with adefovir in HBeAg-positive subjects, telbivudine treatment for 52 weeks resulted in a greater mean reduction in HBV DNA than adefovir treatment for 52 weeks or 24 weeks of adefovir followed by 28 weeks of telbivudine (40). Subjects in the telbivudine-only arm were also significantly less likely to experience primary treatment failure (2% versus 29% in the adefovir-only arm).

### Tenofovir Disoproxil Fumarate

Tenofovir disoproxil fumarate (Bis{[(isopropoxycarbonyl)oxy]methyl} {[(2R)-1-(6-amino-9H-purin-9-yl)-2-propanyl]oxy}methyl}phosphonate (2E)-2-butenedioate; TDF, Viread) is an oral prodrug of tenofovir, a nucleotide analog. TDF is approved for the treatment of both HIV and chronic HBV infections, and is the preferred agent for treating HBV in the context of HIV/HBV coinfection (41). For further details on TDF pharmacology, drug interactions, and adverse effects, see Chapter 11. It is a nucleoside inhibitor of the HBV polymerase and also acts to block protein priming. In HBV mono-infection, changing to TDF often results in

excellent viral suppression in subjects resistant to lamivudine who have viral breakthrough on adefovir (42). A large study examining nucleoside-naïve HBeAg-positive subjects found that TDF 300 mg daily for 48 weeks resulted in more frequent reduction of HBV DNA levels of  $<400$  copies/ml when compared to adefovir (43). The efficacy of TDF was comparable to adefovir in HBeAg-negative subjects. TDF is also the preferred agent for those with prior exposure to lamivudine, with a retrospective study showing 100% treatment response at an average follow-up of 23 months (44).

Studies comparing TDF alone to combination therapy of TDF with emtricitabine have generally found little benefit to the addition of emtricitabine. In one randomized study of patients with HBV mutations associated with lamivudine resistance, rates of virologic suppression at 96 weeks were comparable between the monotherapy and combination therapy groups, suggesting that emtricitabine does not enhance the antiviral activity of TDF in this context (45). Another study comparing TDF monotherapy and TDF in combination with emtricitabine in patients who did not achieve adequate virologic suppression on adefovir resulted in similar rates of viral suppression (84% versus 82%) in the combination therapy and monotherapy arms (46). Further, viral kinetic curves were reported as identical between the two groups. In a separate trial of treatment-naïve patients with high initial viral loads and normal ALT levels, HBV DNA levels were undetectable in 55% of patients who received TDF monotherapy and 76% of those who received TDF in combination with emtricitabine (47). However, viral kinetic curves were similar between the two groups, HBeAg seroconversion and hepatitis surface antigen loss were rare in either group, and no participant in either group developed tenofovir-resistant virus. Although it has been speculated that monotherapy may predispose to the development of minor variant quasispecies, this was not seen in a small study that compared the development of quasispecies in subjects receiving TDF monotherapy to those receiving combination therapy with emtricitabine (48). Further, resistance of HBV to TDF has not yet been shown to develop, even with long-term use (49). Therefore, TDF monotherapy remains the preferred strategy for management of chronic HBV in the absence of HIV at the present time. This may well change as more data emerge.

### Tenofovir Alafenamide Fumarate

Tenofovir alafenamide fumarate (Isopropyl N-[(S)-{[(2R)-1-(6-amino-9H-purin-9-yl)-2-propanyl]oxy}methyl}(phenoxy)phosphoryl]-L-alaninate (2E)-2-butenedioate (2:1); TAF) (Figure 1), a novel prodrug of tenofovir, is currently FDA approved for the treatment of HIV infection in multiple fixed-dose combinations (and is in phase 3 trials for the treatment of chronic HBV infection). Please refer to Chapter 11 for a detailed review of pharmacology, drug interactions, and adverse events. It results in much lower plasma levels of tenofovir and provides higher intracellular levels of active drug allowing lower daily doses and decreased renal toxicity compared to TDF. In a study of patients coinfecting with HIV and chronic HBV who had been virologically suppressed on antiretrovirals with activity against HBV, subjects were switched to a single tablet formulation of elvitegravir 150 mg, cobicistat 150 mg, emtricitabine 200 mg, and TAF 10 mg. Through week 48 of treatment, HIV and HBV viral suppression was maintained in the same proportion of participants, confirming acceptable activity of TAF against HBV (50).

## ANTIVIRAL AGENTS FOR HEPATITIS C VIRUS INFECTION

Unlike HIV and HBV, which have persistent DNA reservoirs in infected cells even with effective antiviral suppression, complete cure of HCV infection is possible with medical therapy. In clinical studies of anti-HCV medications, an undetectable HCV viral load 12 or 24 weeks after the end of treatment (termed sustained virologic response [SVR] 12 or 24) has been considered a proxy for cure. Before 2011, the standard of care for treatment of HCV was pegylated interferon plus ribavirin, a regimen that led to SVR24 only slightly more than 50% of the time and was often associated with moderate or worse toxicity (51, 52). Development of anti-HCV direct-acting agents (DAAs), medications with direct anti-HCV activity, began in earnest in the early 2000s following the development of the HCV replicon, in which key components of the HCV genome could be made to replicate *in vitro*, allowing for the study of inhibitory compounds (53). At around the same time, detailed crystal structures of the key viral proteins became available, allowing for rational modeling and development of antiviral compounds. The first approved DAAs, boceprevir, and telaprevir, received regulatory approval in 2011 in combination with pegylated interferon and ribavirin. The number of anti-HCV agents in clinical development and with regulatory approval has increased dramatically in recent years. As of 2016, interferon-free regimens are the standard of care for treatment of all genotypes of HCV. Figure 2 presents a timeline outlining key events in the development of modern HCV therapies.

Table 2 gives an overview of the key characteristics of DAA-based regimens approved for treatment of HCV infection by the U.S. FDA or with regulatory approval expected within the 2016 calendar year. Medications in earlier stages of clinical development are listed in Table 3. As new agents are being approved at a rapid pace, the reader is referred to [hcvguidelines.org](http://hcvguidelines.org) for the most up to date information on drug and regimen approvals.

### Interferons

Interferons (IFNs) are part of the repertoire of human cytokines that have important multifunctional capabilities, including antiviral, immunomodulatory, and antiproliferative effects. There are currently nine approved IFN preparations for clinical use, of which five are approved for the treatment of chronic HCV. The nomenclature for this group of cytokines has evolved over the past four decades, although the term interferon stems from the original discovery of these compounds, which interfered with viral replication. There are two major types of human IFNs that have been studied clinically: IFN- $\alpha/\beta$  (leukocyte/fibroblast) and IFN- $\gamma$ . There are over 12 subtypes of IFN- $\alpha$  but only 1 IFN- $\beta$  subtype and 1 IFN- $\gamma$  subtype. It is not clear why an array of closely related IFN- $\alpha$  subtypes exist, but one postulate is that the redundancy ensures that this natural defense system remains operative.

### Spectrum of Activity

IFNs possess inhibitory activity against a broad array of DNA and RNA viruses. IFN- $\alpha$  and - $\beta$  typically have greater antiviral activity than does IFN- $\gamma$ , and the subspecies of IFN- $\alpha$  may express differential activities against a particular viral agent.

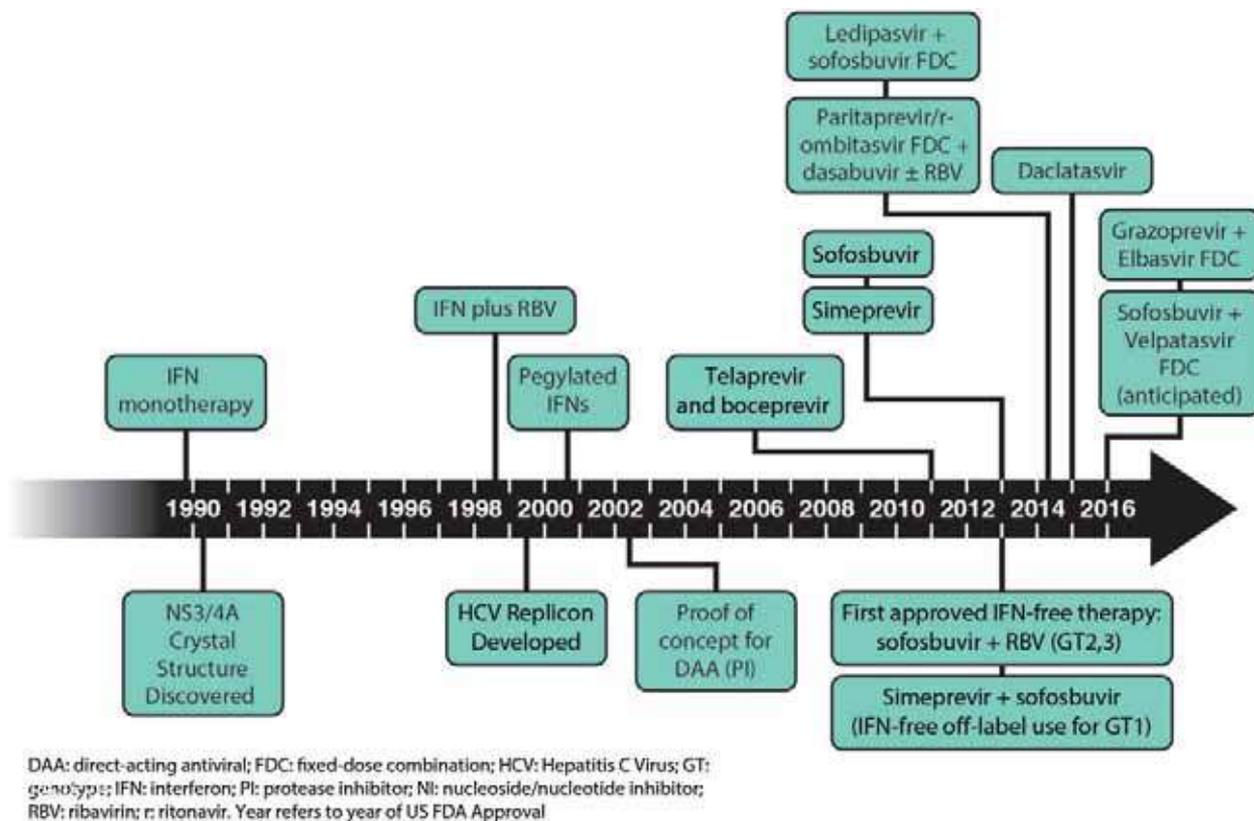

FIGURE 2 Timeline of key historical events in the development of anti-HCV direct-acting agents.

**TABLE 2** Key information on anti-HCV DAA regimens

Regimen	Class	Standard Dose	FDA Approved Genotype	Duration	Mode of Elimination	Considerations in Renal Impairment	Considerations in Hepatic Impairment	Major Toxicities
Ombitasvir/ paritaprevir/ ritonavir FDC + dasabuvir	Ombitasvir: NS5A inhibitor	ombitasvir 12.5 mg/ paritaprevir 75 mg/ ritonavir 50 mg FDC	1	Genotype 1a without cirrhosis: 12 weeks + RBV	Hepatic	Safe in mild, moderate, or severe renal impairment No data in HD Care must be taken if ribavirin coadministered	CTP A: Safe CTP B: Not recommended CTP C: Contraindicated	Fatigue, nausea, rash, pruritus, insomnia, LFT elevations
	Paritaprevir: NS3/4A inhibitor	two tablets once daily		Genotype 1a with cirrhosis: 24 weeks + RBV				
	Dasabuvir: NS5B inhibitor (non-nucleoside)	plus dasabuvir 250 mg twice daily		Genotype 1b without cirrhosis: 12 weeks				
	ritonavir: CYP3A4 inhibitor			Genotype 1b with cirrhosis: 12 weeks + RBV				
Ombitasvir/ paritaprevir/ ritonavir FDC	see above	ombitasvir 12.5 mg/ paritaprevir 75 mg/ ritonavir 50 mg FDC two tablets once daily	4	12 weeks + RBV	Hepatic	see above	see above	see above
Sofosbuvir	NS5B inhibitor (nucleoside)	400 mg daily	1-4	Genotype 1: In combination with ledipasvir, simeprevir, or daclatasvir as below Genotype 2: In combination with RBV x12 weeks. May consider expanding to 16 weeks or more in patients with cirrhosis. May consider in combination with daclatasvir in patients with contraindication to RBV but data is limited. Genotype 3: In combination with daclatasvir as below, OR for 12 weeks with RBV and peg-IFN OR for 24 weeks with RBV alone (IFN ineligible) Genotype 4: See FDC with ledipasvir below	Renal	Mild/moderate: no dose adjustment Severe (CrCl < 30 ml/min or HD): No safe dose established	None	Fatigue, headache

**TABLE 2** Key information on anti-HCV DAA regimens (*Continued*)

Regimen	Class	Standard Dose	FDA Approved Genotype	Duration	Mode of Elimination	Considerations in Renal Impairment	Considerations in Hepatic Impairment	Major Toxicities
Sofosbuvir/ ledipasvir FDC	Sofosbuvir: NS5B inhibitor (nucleoside)  Ledipasvir: NS5A inhibitor	sofosbuvir 400 mg/ ledipasvir 90 mg FDC once daily	1	Treatment-naïve: 12 weeks (may give 8 weeks if baseline VL <6 million)  Treatment-experienced, noncirrhotic: 12 weeks  Treatment-experienced with cirrhosis: 24 weeks, +/-RBV	Renal	See sofosbuvir	None	Fatigue, headache, insomnia, and nausea
Simeprevir	NS3/4A inhibitor	150 mg daily	1	Used in combination with sofosbuvir  No cirrhosis: 12 weeks Cirrhosis: 24 weeks (+/- RBV)	Hepatic	None	CTP A: Safe CTP B: Not recommended CTP C: Not recommended	Hyperbilirubinemia Photosensitivity Rash
Daclatasvir	NS5A inhibitor	30–90 mg daily (depending on drug interactions)	3	Used in combination with sofosbuvir  No cirrhosis: 12 weeks Cirrhosis: 24 weeks (+/- RBV)	Hepatic	None	None	Fatigue, headache
Grazoprevir/ Elbasvir FDC	Grazoprevir = NS3/4A inhibitor  Elbasvir= NS5A inhibitor	grazoprevir 100 mg/ elbasvir 50 mg FDC once daily	1 and 4	12–16 weeks +/- RBV based on genotype, baseline NS5A polymorphisms, treatment history	Hepatic	Safe in ESRD, including HD	CTP A/B: Safe CTP C: No data	Headache, fatigue, nausea, LFT elevations
Velpatasvir/ sofosbuvir FDC	Ledipasvir: NS5A inhibitor	sofosbuvir 400 mg/ velpatasvir 100 mg FDC once daily	Pending, see text	12–24 weeks +/- RBV based on genotype, cirrhosis status, and treatment history	Hepatic	None	None	Headache, fatigue, nasopharyngitis, and nausea

TABLE 3 Other anti-HCV drugs in phase 1 and 2 not in text

Mechanism	Drug	Stage of Development	Comments
<b>NS5A Inhibitors</b>			
	Odalasvir	Phase 2	Being studied with ACH-3422 for genotype 1 Has activity in viruses with resistance to first-gen. NS5A inhibitors
	Samatasvir	Phase 2	Pan-genotypic Low SVR4 rates when combined with simeprevir and ribavirin
	MK-8408	Phase 1	Pan-genotypic Being studied as potential FDC with grazoprevir and MK-3682 in genotype 1 and 3 HCV
	TD-6450	Phase 1	Heterodimeric structure designed to increase potency against virus with key NS5A RAVs
<b>NS5B Inhibitors</b>			
	Mercitabine	Phase 2	
	MK-3682	Phase 2	Uridine-based nucleoside prodrug Being studied as potential FDC with grazoprevir and MK-8408 in genotype 1 and 3 HCV
	TMC647055	Phase 2	Nonnucleoside, macrocyclic compound that binds to “thumb pocket 1” binding site
	VX-135	Phase 2	Uridine-based nucleoside prodrug
	ACH-3422	Phase 1	Uridine-based nucleoside prodrug High barrier to resistance, pan-genotypic Being studied with odalasvir for genotype 1
	AL-335	Phase 1	Nucleoside NS5B inhibitor Being studied in combination with odalasvir and simeprevir for genotype 1
	GSK2878175	Phase 1	Nonnucleoside inhibitor To be studied in combination with RG-101
<b>NS3/4A Inhibitors</b>			
	Danoprevir	Phase 2	Highly effective with pegIFN/RBV for genotype 1b. Unclear role for future all DAA combinations
	Sovaprevir	Phase 2	High SVR12 rates seen in genotype 1b patients when combined with odalasvir and ribavirin; GT1a patients developed NS3 RAVs
<b>Other</b>			
	Miravirsen	Phase 2	Antisense oligonucleotide that targets miR122, a hepatic microRNA necessary for HCV replication.
	RG-101	Phase 2	Anti-miR122 antisense oligonucleotide conjugated to GalNac to allow for possible single-visit therapy (injectable) Being studied in combination with numerous DAAs
	BIT225	Phase 2	Novel mechanism of action; Inhibitor of p7 protein, small membrane protein required for HCV replication
	SB 9200	Phase 1	Immune modulatory medication that activates RIG-1 and NOD2, regulators of interferon signaling in response to HCV May move forward in combination with DAAs

### Mechanisms of Action

IFNs are synthesized in response to a wide variety of infections and stimuli of the innate immune system and are an integral component of the complex cytokine network. Nearly all cell types can produce IFN- $\alpha$  and - $\beta$ , while IFN- $\gamma$  is produced largely by T and natural killer (NK) cells. Once produced, IFNs possess no inherent antiviral activity, but act by inducing an antiviral state within target cells. IFNs bind to specific receptors on the cell surface: IFN- $\alpha$  and - $\beta$  have the same receptor. These receptors are composed of at least two subunits that must be present to ensure that full IFN action is induced (54). Following receptor binding, receptor-associated tyrosine kinases (Tyk2 and JAK1 for IFN- $\alpha$  and - $\beta$

and JAK1 and JAK2 for IFN- $\gamma$ ) are activated and, in turn, phosphorylate specific cytoplasmic proteins (termed STAT proteins). These proteins move to the nucleus, where they bind to specific *cis*-acting elements in the promoter regions of IFN-inducible genes (55). Transcription of these genes occurs within minutes of IFNs' binding to the cell receptors.

Depending upon the viral agent and cell type, IFNs can inhibit viral replication at nearly all steps from penetration to particle release. Several mechanisms of IFN-induced antiviral activity have been described: (i) 2'-5' oligoadenylate synthetases are activated by double-stranded (viral) RNA and are responsible for the conversion of ATP into a series of oligonucleotides designated 2',5'-oligo(A)s. The 2',5'-oligo

(A)s then activate an RNase, RNase L, which can cleave single-stranded mRNAs (56). (ii) A double-stranded RNA-dependent protein kinase termed PKR (P68 kinase, P1, DAI, dsl, and eukaryotic initiation factor 2 [eIF2] kinase) is activated by double-stranded (viral) RNA and autophosphorylated, which in turn, phosphorylates the alpha subunit of eIF2. This prevents the recycling of eIF2 with inhibition of protein synthesis (57). (iii) The induction of a phosphodiesterase inhibits peptide chain elongation. (iv) MxA protein, which binds to cytoskeletal proteins and inhibits viral transcriptases, is synthesized (58). (v) Nitric oxide synthetase is induced by IFN- $\gamma$  in macrophages (59).

Although some of the IFN-inducible functions have been linked to the inhibition of replication of individual viruses, for the most part there is uncertainty in trying to dissect out single activities of IFNs in this process, since more than one mechanism may be operative simultaneously. In addition, some antiviral effects of IFNs result indirectly from stimulation of antiviral immune functions. For example, the immunomodulatory activities of IFNs, such as induction of cytotoxic T-cell and NK cell activity and the induction of major histocompatibility complex proteins, may also help control viral infections (see Chapter 16).

### Pharmacology

For treatment of chronic HCV, IFNs must be administered intravenously, intramuscularly, or subcutaneously. The elimination  $t_{1/2}$  of IFN- $\alpha$  in plasma following intravenous administration is 2 to 3 h, which is extended to 4 to 6 h following intramuscular or subcutaneous administration, with 80% of an administered dose absorbed following injection by the latter routes. The levels achieved in plasma are dose proportional. The relevance of classic pharmacokinetic parameters of IFNs in relation to their antiviral activity is questionable, since systemic effects are measurable in the absence of detectable IFN levels in plasma. Two long-acting, slow-release formulations of IFN combined with polyethylene glycol (pegylated) are currently available (PegIntron and Pegasys). These products can be administered subcutaneously once per week and achieve sustained levels in blood equivalent to those of standard IFN given three times a week. Penetration into CSF and respiratory secretions is minimal.

### Adverse Effects

IFNs cause a broad range of side effects, most commonly systemic and hematologic. Dose-related influenza-like symptoms are common with initiation of treatment and generally include fever, chills, headache, nausea, myalgias, and arthralgias. Gradual dose escalation may be helpful; tolerance to these side effects can develop with time, but this is not uniform. The most common hematologic side effects are leukopenia and thrombocytopenia, and thus treatment of immunocompromised hosts or patients taking other myelotoxic agents can be difficult. Other important side effects include neurotoxicity (including somnolence, confusion, electroencephalographic changes, behavioral changes, and seizures), psychiatric disturbances (especially depression), hepatotoxicity, nephrotoxicity, thyroiditis, and alopecia.

### Drug Interactions

Few formal drug interaction studies with the approved preparations of IFNs have been performed. Care must be exercised when coadministering other potentially myelosuppressive or neurotoxic drugs. Pegylated IFN- $\alpha$ 2a and - $\alpha$ 2b (collectively referred to hereafter as "peg-IFN" unless specified otherwise) inhibit cytochrome P450 (CYP) 1A2 en-

zymes, but do not affect the pharmacokinetics of drugs metabolized by CYP2C9, CYP2C19, CYP2D6, or CYP3A4 hepatic microsomal enzymes. No studies of drug interactions have been published with IFN- $\beta$ .

### Resistance

Many viruses have developed strategies to evade or inhibit IFN-mediated antiviral effects. However, acquired resistance to the actions of IFNs through specific mutations during therapeutic administration has not been well documented. Variability in the response of chronic HCV infection to IFN therapy has been associated with amino acid substitutions in the NS5A protein, although the significance of this association remains unclear. Specifically, heterogeneity between codons 2,209 and 2,248 may affect the ability of IFN to bind to double-stranded-RNA-dependent protein kinase, thereby reducing the host antiviral response (60). In HCV replicon cell culture models, IFN-resistant HCV strains have decreased expression and activity of Tyk2 and JAK1, two proteins in the JAK-STAT pathway that are intermediates in IFN-mediated intracellular signaling (61).

### Clinical Applications

IFN- $\alpha$  preparations are beneficial in the treatment of chronic HBV and HCV infections, although responses are not uniform and relapse rates after discontinuation of treatment are substantial. The response to IFN therapy in patients with chronic hepatitis C is higher than in patients with hepatitis B and depends on numerous host factors, most importantly IL28B genotype (62, 63), but also age, stage of liver disease, ethnicity, and hepatocyte HLA antigen expression. Virologic factors, including viral load and HCV genotype, also affect IFN responsiveness, with genotypes 2 and 3 having better rates of response to IFN than genotypes 1 and 4 (51, 64). Peg-IFN in combination with ribavirin achieves rates of viral response superior to those of standard IFN-ribavirin therapy and peg-IFN alone (51, 52) including in patients coinfecting with HIV and HCV (64). Response rates were even higher when peg-IFN and ribavirin were given in conjunction with a third DAA, such as a protease inhibitor (telaprevir or boceprevir) or the NS5B inhibitor sofosbuvir (see below). However, given the newer DAA combinations available with shorter treatment duration, improved side effect profiles, and vastly superior response rates, IFN-based regimens are no longer the standard of care in almost all cases of HCV infection.

### Ribavirin

Ribavirin (1- $\beta$ -d-ribofuranosyl-1,2,4-triazole-3-carboxamide; Rebetol, Copegys, Ribapak, Ribasphere, Virazole) is a synthetic nucleoside analog of guanosine approved in the United States for the treatment of RSV infection and in combination with IFN- $\alpha$  for the treatment of HCV infection.

### Spectrum of Activity

Ribavirin has *in vitro* activity against a broad range of both RNA and DNA viruses, including flaviviruses, paramyxoviruses, bunyaviruses, arenaviruses, retroviruses, herpesviruses, adenoviruses, and poxviruses. In structure-activity studies, both the ribose moiety and the base are essential for maintenance of antiviral activity.

### Mechanism of Action

The mechanism of action of ribavirin is incompletely understood and possibly multifactorial. Ribavirin is phosphorylated by host cell enzymes to ribavirin triphosphate. In the

case of influenza virus, ribavirin triphosphate interferes with capping and elongation of mRNA and may directly inhibit viral RNA polymerase activity. Some studies have suggested a direct antiviral effect of ribavirin on HCV, although the data are not consistent and this effect, if present, is probably small. Ribavirin inhibits HCV RNA polymerase, but only at concentrations exceeding those achieved clinically. Inhibition of inosine-5'-monophosphate dehydrogenase by ribavirin monophosphate depletes the intracellular pools of guanosine triphosphate required for RNA synthesis. Ribavirin may also act indirectly by immunomodulatory effects, causing a change in the host T-cell response from a T-helper 2 (Th2) to a Th1 response. For hepatitis C, the shift to a Th1 profile with production of Th1 cytokines, especially IFN- $\gamma$ , is believed to halt virion production, increase lysis of infected hepatocytes, stop transformation to neoplastic cells, and limit fibrogenesis (65). Finally, ribavirin may act as a mutagen, increasing the error rate in replicating RNA strands and pushing the virus over the threshold of replicative incompetence. There is evidence to support this theory from HCV replicon studies, but human data remain inconclusive.

### Pharmacology

Aerosol, oral, and intravenous formulations of ribavirin exist, but the aerosol and oral preparations are the only ones approved in the United States and only oral preparations are used to treat HCV infection. Concentration of ribavirin in plasma after a single oral dose has three phases: rapid absorption, rapid distribution, and a long elimination phase. Following a 600-mg dose, the  $C_{max}$  was 782 ng/ml, the elimination  $t_{1/2}$  was 79 h, and the AUC was 13,394 ng·h/ml. Administration with food enhances absorption and results in a 70% increase in the concentration in plasma. The plasma to CSF ratio is approximately 0.7.

### Adverse Effects

Oral and intravenous administration is associated with anemia, which is related to intravascular hemolysis and bone marrow-suppressive effects. Depression, pruritus, rash, nausea, and cough have been reported. When the drug is given as an aerosol preparation, bronchospastic reactions can occur, and ocular irritation has been reported. Ribavirin also has immunosuppressive effects. *In vitro*, antigen- and mitogen-driven lymphocyte proliferative responses are suppressed by ribavirin, and release of mast cell mediators may be inhibited. Ribavirin has teratogenic, carcinogenic, and mutagenic properties in preclinical assays, and therefore its use in pregnant women is contraindicated.

### Drug Interactions

*In vitro* studies suggest that ribavirin can antagonize the activity of zidovudine by inhibiting its phosphorylation, although such an effect has not been observed *in vivo* (66). Conversely, ribavirin can potentiate the anti-HIV activity of didanosine by facilitating its phosphorylation, but there have been reports of severe mitochondrial toxicity resulting in fatal and nonfatal lactic acidosis in patients receiving didanosine and ribavirin concurrently (67). In patients coinfected with HIV and HCV, these drugs should not be used together but with improvements in the agents available to treat both infections, this question has become moot.

### Resistance

Replicon studies with HCV Huh7 strains have demonstrated the appearance of the B415F-to-Y mutation in the NS5B

RNA polymerase when exposed to ribavirin. Strains with the 415Y mutation have a replicative advantage over the 415F strains in the presence of ribavirin, but when ribavirin is removed, all strains revert to the 415F variant and demonstrate improved replicative capacity over the 415Y mutant. In another study, the G404S and E442G mutations in the NS5A protein were both associated with low-level ribavirin resistance (68). There have been no reports of RSV, influenza virus, or HIV isolates resistant to ribavirin.

### Clinical Applications

Ribavirin is approved for the treatment of HCV in combination with a number of IFN-containing as well as IFN-free DAA regimens. Despite marked advances in response rates with DAA combinations, ribavirin is still recommended to be given with these agents in several of the most difficult to treat patient populations, such as treatment-experienced patients with cirrhosis.

### Direct-Acting Agents: NS5B Inhibitors

NS5B is the HCV RNA-dependent RNA polymerase necessary for viral replication. There are two classes of NS5B inhibitors available or in development. The first class includes the nucleoside/nucleotide inhibitors, which bind at the active site of the polymerase and prevent chain elongation of the viral RNA. Because there is little variation in the enzymatic active site across the different HCV genotypes, and because any mutations in the active site tend to render the virus unfit to replicate efficiently, nucleoside/nucleotide NS5B inhibitors tend to have activity across a range of genotypes and tend to have a high barrier to resistance (69, 70). The second class is the nonnucleoside NS5B inhibitors, which bind outside of the active site and cause allosteric changes that hinder polymerase activity. Because there is less conservation of non-active site amino acids across genotypes, these inhibitors are generally not pan-genotypic and have a lower barrier to resistance. Figure 3a shows the chemical structures of commonly prescribed NS5B inhibitors.

### Sofosbuvir

#### Spectrum of Activity

Sofosbuvir ((S)-Isopropyl 2-((S)-(((2R,3R,4R,5R)-5-(2,4-dioxo-3,4-dihydropyrimidin-1(2H)-yl)-4-fluoro-3-hydroxy-4-methyltetrahydrofuran-2-yl)methoxy)-(phenoxy)phosphorylamino)propanoate; Sovaldi) is active against HCV genotypes 1 through 6 with varying  $EC_{50}$  values. The  $EC_{50}$  values of sofosbuvir for genotypes 1a, 1b, 2a, 2b, 3a, 4a, 5a, and 6a range from 0.014 to 0.11  $\mu$ M (71).

#### Mechanism of Action

Sofosbuvir, also known as GS-7977, is a monophosphate prodrug converted to its pharmacologically active triphosphate form (GS-461203) within hepatocytes. Its design was based upon experiments with older DAAs that suggested it would be possible to develop a monophosphate prodrug that could be delivered to hepatocytes where it would then be metabolized into highly active triphosphate. This design strategy amplifies the intracellular concentrations of the active metabolite to allow for lower oral doses, more favorable pharmacokinetics, increased potency, and the ability to coformulate the drug in fixed-dose combinations with other DAAs. After phosphorylation, the nucleotide analog is incorporated into HCV RNA via the NS5B polymerase resulting in premature chain termination and disruption of transcription of the viral polyprotein (70–73).

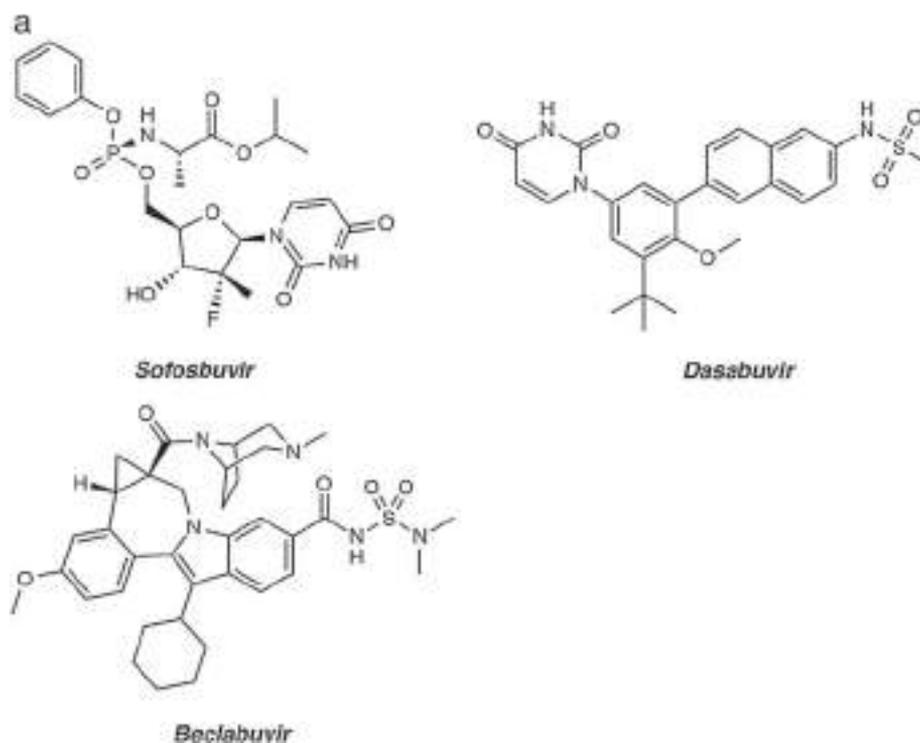

FIGURE 3a Chemical structures of HCV NS5B inhibitors.

### Pharmacology

Sofosbuvir is absorbed rapidly, reaching peak plasma concentration in 0.5 to 2 hours.  $AUC_{0-24}$  is 969 ng•hr/ml for the parent compound sofosbuvir and 6,790 ng•hr/ml for the predominant inactive metabolite GS-331007, which accounts for >90% of drug-related systemic exposure. There is no difference in drug absorption when administered with a high fat meal or fasting conditions, so sofosbuvir can be taken without regard to meals. Sofosbuvir is metabolized in the liver through sequential hydrolysis, phosphoramidate cleavage, and subsequent phosphorylation to its pharmacologically active nucleoside analog triphosphate form (71).

The major pathway of elimination is renal; 78% of drug is recovered in the urine as GS-331007. The half-lives of sofosbuvir and GS-331007 are 0.4 hours and 27 hours, respectively. Overall exposure of sofosbuvir and GS-331007 are increased in patients with mild renal impairment compared to patients with normal renal function. Dose adjustments are not needed in mild or moderate renal impairment, but sofosbuvir is not recommended to be given when  $CrCl$  is <30 ml/min as safety and efficacy have not been established in this setting. Overall exposure is also increased in moderate and severe hepatic impairment; however, this is not thought to be clinically significant (71).

### Adverse Effects

The most common side effects associated with sofosbuvir are fatigue and headache, which occur in >20% of patients, and tend to occur more frequently in patients who receive longer courses of sofosbuvir and/or coadministered ribavirin. Other side effects include nausea, insomnia, pruritus, and anemia. However, these may be attributable to coadministered ribavirin. Discontinuation of sofosbuvir due to

adverse events attributable to the drug has been rare in clinical trials (74–76).

### Drug Interactions

Sofosbuvir is a substrate of the P-gp efflux pump and is not recommended to be used with P-gp inducers due to the risk of decreased sofosbuvir exposure. P-gp inducers include medications such as rifamycins and anticonvulsants like carbamazepine, phenytoin, phenobarbital, and oxcarbazepine. However, sofosbuvir can be used concomitantly with P-gp inhibitors, and it does not have interactions with drugs metabolized by the CYP 3A4 enzyme system (71).

Postmarketing analysis revealed cases of symptomatic bradycardia, including fatal cardiac arrest, when sofosbuvir, in combination with another DAA, was used concomitantly with the antiarrhythmic amiodarone. Onset of symptoms is usually hours to days after medication administration but may be delayed up to 2 weeks in some cases. Therefore, the combination of sofosbuvir and amiodarone is not recommended unless there are no available treatment alternatives (71, 77).

### Resistance

Amino acid substitutions leading to reduced susceptibility to sofosbuvir have been identified in cell culture and clinical trials but their clinical significance is unknown. The sofosbuvir associated resistance substitution NS5B S282T confers 2- to 18-fold reduced susceptibility to sofosbuvir *in vitro*. However, this variant was absent at baseline and in all failure isolates in phase 3 clinical trials. Treatment emergent substitutions L159F, V321A, C316N, S282R, and L320F detected in phase 3 trials were inconsistently associated with treatment failure. Resistance-associated variants

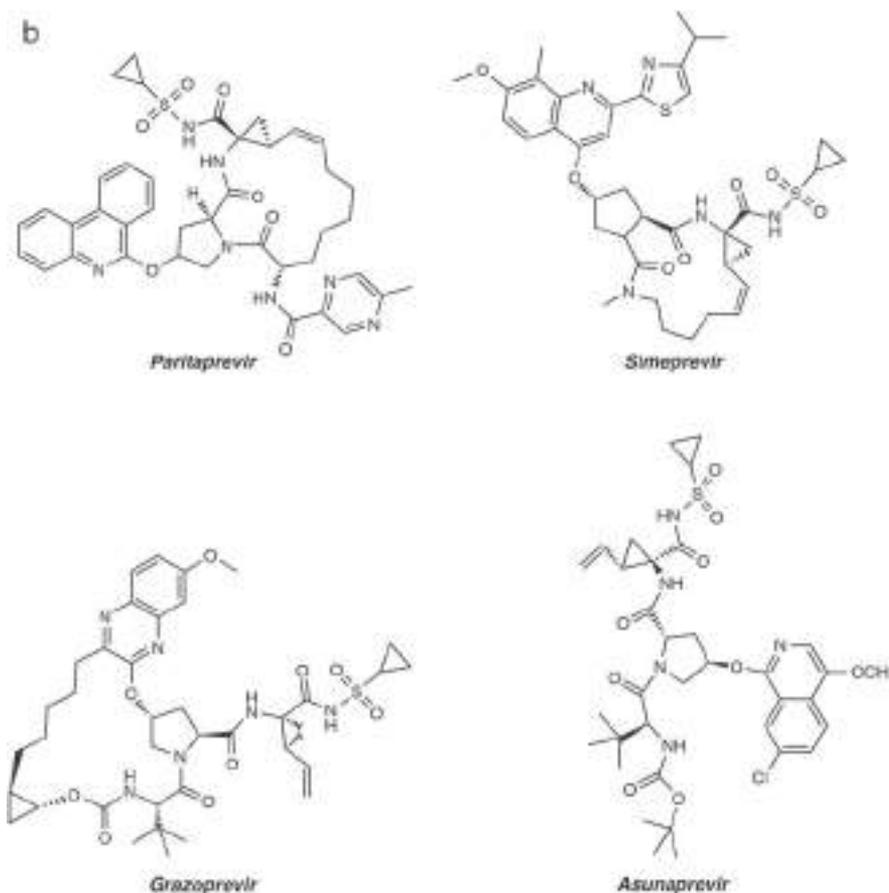

FIGURE 3b Chemical structures of HCV NS3/4A inhibitors.

(RAVs) associated with other DAAs appear to have a limited effect on susceptibility to sofosbuvir (71).

### Clinical Applications

Sofosbuvir has been extensively studied in multiple combination regimens against HCV genotypes 1 through 6 and has revolutionized anti-HCV treatment. Early clinical studies of sofosbuvir in combination with peg-IFN and ribavirin in patients with genotype 1 led to SVR12 rates of 90% to 93% (78, 79). However, regimens containing peg-IFN and ribavirin are no longer recommended when alternatives are available. Sofosbuvir has been studied in IFN-free combinations with daclatasvir, ledipasvir, simeprevir, and velpatasvir. For detailed descriptions of the clinical trial results related to these regimens, please refer to the sections below pertaining to these agents.

Sofosbuvir with ribavirin, even in the absence of a second DAA or IFN, has been studied in patients with genotypes 2 and 3. A landmark trial showed identical SVR12 rates of 67% with sofosbuvir and ribavirin compared to peg-IFN and ribavirin (79). In patients for whom IFN is not an option, sofosbuvir and ribavirin for 12 weeks achieved overall SVR12 rates of 78% in patients with genotype 2 or 3 HCV infections; however, genotype 3 and cirrhosis were both negative predictors of response, with SVR12 rates of 93% versus 61% for patients with genotype 2 compared to genotype 3 and SVR12 rates of 81% versus 48% in patients without cirrhosis compared to patients with cirrhosis. Longer durations of therapy are needed for patients with genotype 3,

especially in those with cirrhosis (80). With the advent of multiple ribavirin-free all-DAA regimens with activity against genotypes 2 and 3, it is likely that the regimen of sofosbuvir plus ribavirin will fall out of favor.

### Dasabuvir

#### Spectrum of Activity

Dasabuvir (*N*-{6-[5-(2,4-Dioxo-3,4-dihydro-1(2*H*)-pyrimidinyl)-2-methoxy-3-(2-methyl-2-propanyl)phenyl]-2-naphthyl}methanesulfonamide) inhibited the activity of genotype 1 polymerases *in vitro* at  $IC_{50}$  ranging from 2.2 to 10.7 nM. It does not have inhibitory activity against polymerases from HCV genotypes 2 to 4 (81).

#### Mechanism of Action

Dasabuvir is a nonnucleoside inhibitor of the viral NS5B polymerase. Although the exact mechanism is unknown, based upon resistance data, it is believed to act mechanistically like the benzothiadiazine NS5B inhibitors, binding to the palm I site of the enzyme and inhibiting RNA chain initiation allosterically (82–84).

#### Pharmacokinetics

Dasabuvir is available in 250 mg tablets and dosed twice daily. Absorption is increased by 30% when taken with food. Dasabuvir achieves peak levels approximately 4 hours after administration. The average plasma elimination  $t_{1/2}$  in healthy volunteers is 9.2 hours (85). It is greater than 99.5% protein-bound. Dasabuvir is primarily excreted through the

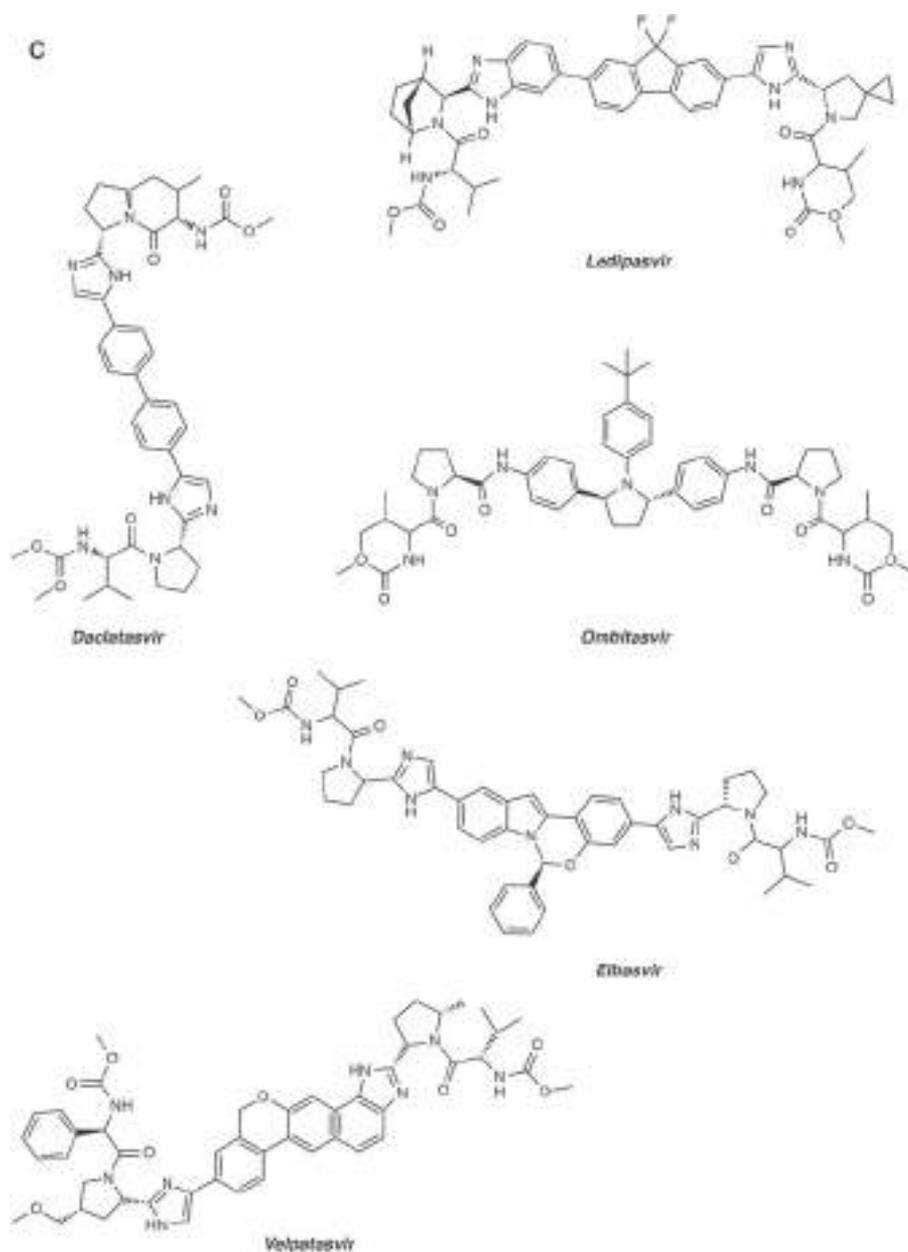

FIGURE 3c Chemical structures of HCV NS5A inhibitors.

biliary system into the feces, both as unchanged dasabuvir and as dasabuvir M1 metabolite (86). Urinary excretion is minimal. Dasabuvir and dasabuvir M1 AUC in subjects with Child-Pugh A or B cirrhosis is similar to that of subjects with normal hepatic function. However, in subjects with Child-Pugh class C cirrhosis, dasabuvir AUC is increased by over 300%, and dasabuvir M1 AUC is increased by 70% (85). It is therefore contraindicated in individuals with Child-Pugh class C cirrhosis.

#### Adverse Effects

There are minimal data on the adverse effects associated specifically with dasabuvir because in clinical studies, dasabuvir has always been coadministered with paritaprevir, ritonavir, and ombitasvir. For a detailed review of the adverse effects associated with this regimen, please refer to the om-

bitasvir section. In a clinical trial of ombitasvir, paritaprevir, and ritonavir, with or without ribavirin for genotype 4 HCV, rates of fatigue were lower than rates seen in most studies of the same regimen plus dasabuvir for genotype 1 HCV (87). Rates of other adverse events were comparable. Therefore, it is possible that the fatigue might have been attributed to the dasabuvir.

#### Drug Interactions

Dasabuvir is primarily metabolized by CYP2C8, which forms the basis for most of the clinically significant drug-drug interactions. There also may be some metabolism by CYP3A. Dasabuvir is an *in vitro* inhibitor and substrate of P-gp and breast cancer resistance protein (BCRP), although the clinical significance of this is uncertain (88). Co-administration with CYP2C8 inhibitors, such as gemfibrozil,

is associated with a significant increase in dasabuvir levels, and is contraindicated. For additional discussion of drug-drug interactions associated with coadministered ombitasvir, paritaprevir, ritonavir, and ribavirin, please refer to the sections pertaining to these medications.

### Resistance

In a replicon model of HCV genotype 1a, the major RAVs selected by dasabuvir were S556G and C316Y, which conferred 30-fold and 1,472-fold resistance, respectively. In a similar model using genotype 1b virus, the primary variants selected were C316Y and M414T, which were associated with 1,569-fold and 470-fold resistance, respectively. *In vitro*, dasabuvir demonstrated wild-type levels of activity against variants with the S282T polymorphism, the main variant associated with resistance to nucleoside/nucleotide analogs (81). In clinical studies of patients with HCV genotype 1a, the S556G/S variant was the most common baseline variant associated with treatment failure and also the most common treatment-emergent RAV (89). The emergence of resistance was much rarer in individuals with genotype 1b.

### Clinical Applications

Dasabuvir has only been studied in combination with coformulated ombitasvir/paritaprevir/ritonavir, with or without ribavirin for genotype 1 HCV. For a description of relevant clinical trials, please refer to the section on ombitasvir.

### Beclabuvir

#### Spectrum of Activity

In phase 1 studies beclabuvir ((1aR,12bS)-8-Cyclohexyl-N-(dimethylsulfamoyl)-11-methoxy-1a-(((1R,5S)-3-methyl-3,8-diazabicyclo[3.2.1]oct-8-yl)carbonyl)-1,1a,2,12b-tetrahydrocyclopropa[d]indolo[2,1-a][2]benzazepine-5-carboxamide)), a nonnucleoside NS5B inhibitor, resulted in an approximately 2.5 log<sub>10</sub> decline of HCV RNA in genotype 1a and 1b infected subjects within 24 hours after a single dose of 300 mg (90). In cell culture 50% EC<sub>50</sub> values for beclabuvir were 3 nM and 6 nM for genotypes 1a and 1b, respectively (91). Similar values were observed for genotypes 3a, 4a, and 5a; however, activity versus genotypes 2 and 6a were variable.

#### Pharmacokinetics

The pharmacokinetics of beclabuvir were evaluated in combination with daclatasvir and asunaprevir (92). Using a dose of 75 mg twice daily, peak plasma concentrations were 1,375 ng/ml for beclabuvir and 318 ng/ml for its active metabolite BMS-794712; levels were comparable in cirrhotic patients. Peak concentrations were achieved in 2.5 to 3.0 hours. The AUC<sub>12</sub> values observed at steady-state were 6,755 ng•h/ml and 1,174 ng•h/ml. Beclabuvir is metabolized to its equipotent metabolite, BMS-794712 via CYP3A4 (93). *In vitro* it has been shown to be a weak inducer of CYP3A4. In a phase 1 study, coadministration with beclabuvir resulted in mildly decreased exposure to midazolam (94). Beclabuvir in combination with asunaprevir and daclatasvir resulted in 32% and 38% decreases in C<sub>max</sub> levels of escitalopram and sertraline, respectively (95).

#### Adverse Effects

Beclabuvir is being developed exclusively in fixed-dose combination with asunaprevir and daclatasvir. In clinical trials, this coformulation has been generally well tolerated. The most commonly reported adverse events have included headache, fatigue, asthenia, diarrhea, nausea, pruritus, and abdominal pain. In clinical trials, all adverse effects con-

sidered treatment-related were mild to moderate in intensity and did not lead to drug discontinuation (96, 97).

### Resistance

In preclinical studies, the main NS5B RAVs associated with beclabuvir exposure were primarily at a single site (P495A/S/L/T) (91). The most common treatment emergent NS5B RAVs in patients with virologic failure in clinical trials of beclabuvir, in combination with daclatasvir and asunaprevir, were at NS5B amino acid 495, most notably P495L (96, 97).

### Clinical Applications

In a phase 3 trial of noncirrhotic patients with genotypes 1a and 1b treated with the fixed-dose combination of beclabuvir, daclatasvir, and asunaprevir, SVR12 rates were 91.3% and 89.3% for treatment-naïve and treatment-experienced patients, respectively (97). In a separate trial, SVR12 rates were also high in patients with cirrhosis, regardless of prior treatment experience, and regardless of whether ribavirin was administered concomitantly (98). A small study also showed an SVR12 rate of 91.5% for this regimen in persons with genotype 4 HCV infection (99).

### GS-9669

GS 5-(3,3-dimethylbut-1-ynyl)-3-[[[4-hydroxy-4-[(3S)-tetrahydrofuran-3-yl]oxymethyl]cyclohexyl]-[(1R)-4-methylcyclohex-3-ene-1-carbonyl]amino]thiophene-2-carboxylic acid) is a nonnucleoside inhibitor of the NS5B polymerase that binds at the allosteric thumb site II location. GS-9669 is active against HCV genotype 1 and is currently being studied as part of various combination regimens with other DAAs including sofosbuvir and ledipasvir (100). In a phase 2A trial, treatment-naïve patients treated with 6 weeks of ledipasvir, sofosbuvir, and GS-9669 achieved 95% SVR12 (101).

### Direct-Acting Agents: NS3/4A Inhibitors

The NS3/4A serine protease is responsible for posttranslational processing of HCV and also functions in the evasion of the host innate immune response (102). NS3/4A interferes with signaling of RIG-1, a cellular helicase that binds HCV RNA, and activates factors that result in IFN-β production. NS3 also cleaves Cardiff, an additional factor downstream of RIG-1, to further decrease IFN-β production (103), and blocks Toll-IL-1 receptor domain-containing adaptor (TRIF), which normally serves as another activator for interferon regulatory factor 3 and NF-κB (104).

The first-generation NS3/4A inhibitors, boceprevir and telaprevir, were the first DAAs to gain regulatory approval in the United States, in 2011. Highlighting the rapid pace of HCV DAA development, manufacturing and distribution of both boceprevir and telaprevir have been discontinued in the United States as these agents have quickly been eclipsed by drugs with greater efficacy and fewer side effects. HCV protease inhibitors that either have regulatory approval or are expected to have approval soon are described in detail below, as are several agents in late phase 2 clinical development. Medications in earlier clinical development are summarized in Table 3. Figure 3b shows the chemical structures of NS3/4A inhibitors commonly used in clinical practice.

### Simeprevir

#### Spectrum of Activity

Simeprevir (2R, 3aR, 10Z, 11aS, 12aR,14aR)-N-(cyclopropylsulfonyl)-2-[[2-(4-isopropyl-1,3-thiazol-2-yl)-7-methoxy-8-methyl-4-quinolinyl]oxy]-5-methyl-4,14-dioxo-2,3,3a,4,5,6,7,8,9,11a,12,13,14,14a-tetradecahydrocyclopenta

[cyclopropa]g[1,6]diazacyclotetradecine-12a(1H)-carboxamide; Olysio) has antiviral activity against HCV genotypes 1a, 1b, and 4. EC<sub>50</sub> values for genotype 1a range from 23 to 28 nM and for genotype 1b range from 3.7 to 25 nM (105).

### Pharmacology

Simeprevir is absorbed to its maximum concentration between 4 and 6 hours after oral administration. The bioavailability of simeprevir is increased when administered with food, resulting in a 60% to 70% increase in AUC and a 1 to 1.5 hour delay in absorption. It is therefore recommended to be administered with food. Accumulation of simeprevir occurs after repeated dosing and steady-state concentrations are achieved after 7 days of therapy (106). Elimination of simeprevir is via the biliary system with >91% of drug recovered in the feces. Terminal elimination half-life is 41 hours in HCV infected patients. Renal elimination is negligible and there are no recommended dose adjustments at any level of renal insufficiency (107).

Simeprevir relies heavily on the CYP 3A4 enzyme for metabolism. Therefore, use of moderate to strong CYP3A4 inhibitors and inducers in combination with simeprevir is not recommended due to clinically significant variations in simeprevir exposure. Additionally, simeprevir mildly inhibits intestinal CYP3A4 (no effect on hepatic CYP3A4), CYP1A2, OATP1B1/3, and P-gp activity and may result in increased exposure of drugs that are metabolized or transported by these enzymes (107).

### Adverse Effects

Adverse effects of simeprevir that have been reported in >10% of study participants when used in combination with sofosbuvir include fatigue, headache, nausea, insomnia, pruritus, dizziness, and diarrhea. Elevations in direct and indirect bilirubin have been seen early after initiation with simeprevir therapy with peak bilirubin levels seen after 2 weeks of treatment, although these are usually <2.5 × the upper limit of normal (ULN) and resolve rapidly after treatment discontinuation. Close monitoring of hepatic function is warranted as cases of hepatic decompensation, hepatic failure, and death have been reported in post-marketing analyses with the majority of these cases in patients with advanced or decompensated cirrhosis. Due to these risks, simeprevir is not recommended in Child-Pugh B or C, histologic classification of hepatitis C and treatment discontinuation should be considered when elevated bilirubin is accompanied by elevations in liver transaminase or other signs of hepatic decompensation (107).

Rash and photosensitivity reactions have been reported to occur in 28% of patients treated with simeprevir with 56% of these reactions occurring in the first 4 weeks of treatment. Most of these reactions were mild to moderate in severity. Although simeprevir has a sulfonamide moiety, patients with a history of a sulfa allergy have not experienced an increased incidence of rash or photosensitivity in clinical trials of simeprevir. To decrease the incidence of photosensitivity reactions, all patients taking simeprevir should be instructed to use sun protection measures (107).

### Resistance

Variants harboring Q80K/R, S122R, R155K, and D168A/V/E substitutions were all found to decrease susceptibility to simeprevir *in vitro*. The most common simeprevir-associated RAVs to emerge in patients who failed to achieve SVR in clinical trials were Q80R, R155K, and D168E/V/X. Efficacy of simeprevir is significantly reduced in patients with HCV

genotype 1a with a baseline Q80K polymorphism; screening all genotype 1a patients for this polymorphism before treatment initiation is strongly recommended. Cross-resistance may occur for other NS3/4A inhibitors; patients who have failed treatment with protease inhibitors should not receive simeprevir (107).

### Clinical Applications

Simeprevir has been studied in clinical trials among various combination regimens for the treatment of chronic HCV genotype 1. In placebo-controlled randomized phase 3 trials including treatment-naïve, genotype 1 HCV-infected patients, simeprevir in combination with peg-IFN and ribavirin achieved higher SVR 12 rates compared to peg-IFN and ribavirin (80% versus 50%) ( $P < 0.0001$ ) (108, 109). In genotype 1 HCV infected patients who relapsed after previous treatment, simeprevir in combination with peg-IFN and ribavirin achieved SVR 12 rates of 79.2% compared to 36.1% with peg-IFN and ribavirin ( $P = 0.001$ ) (110).

Simeprevir has also been studied in combination with sofosbuvir in genotype 1 HCV infected patients. In previous nonresponders with fibrosis stage ranging from F0 to F2, simeprevir in combination with sofosbuvir with or without ribavirin for 12 to 24 weeks achieved overall SVR12 rates of 90%. In a cohort including treatment-naïve patients as well as previous nonresponders with fibrosis stage ranging from F3 to F4, simeprevir in combination with sofosbuvir with or without ribavirin for 12 to 24 weeks achieved overall SVR 12 rates of 94% (111). In all the subgroups, neither addition of ribavirin nor extension of the treatment duration to 24 weeks had a clinically significant impact on SVR 12 rates. SVR12 rates with simeprevir and sofosbuvir combination therapy are high even in patients with the Q80K polymorphism (111). Simeprevir in combination with sofosbuvir is more effective at achieving SVR 12 than peg-IFN, ribavirin, and sofosbuvir in patients with HCV genotype 1a related Child-Pugh A cirrhosis (93% versus 75%,  $P = 0.02$ ) (112).

Simeprevir in combination with peg-IFN and ribavirin has also been studied in patients coinfecting with HCV genotype 1 and HIV-1, yielding SVR 12 rates of 57.1%, 70%, 86.7%, and 79.2% in prior null responders, prior partial responders, prior relapsers, and treatment-naïve patients, respectively (113). Post-liver transplant patients with histological evidence of HCV genotype 1 recurrence were treated with simeprevir in combination with sofosbuvir with or without ribavirin and achieved SVR 12 rates of 90%, although these rates were slightly lower in patients with Metavir F3 to F4 fibrosis (114).

### Paritaprevir

#### Spectrum of Activity

Paritaprevir (2R,6S,12Z,13aS,14aR,16aS)-N-(Cyclopropylsulfonyl)-6-(((5-methyl-2-pyrazinyl)carbonyl)amino)-5,16-dioxo-2-(6-phenanthridinyloxy)-1,2,3,6,7,8,9,10,11,13a,14,15,16,16a-tetradecahydrocyclopropa[e]pyrrolo [1,2-a][1,4]diazacyclopentadecine-14a(5H)-carboxamide is an NS3/4a inhibitor with EC<sub>50</sub> of 1.0, 0.21, 5.3, and 0.09 nM against HCV genotypes 1a, 1b, 2a, and 4a, respectively. EC<sub>50</sub> against genotype 3 is diminished (19 nM), likely related to the presence of the D168Q variant in the NS3 gene (115). It is currently commercially available only in coformulation with ritonavir and ombitasvir and should only be used for treatment of HCV genotype 1a or 1b (in combination with dasabuvir) or genotype 4.

### Pharmacokinetics

In healthy volunteers, paritaprevir achieves peak concentration at about 4 hours after administration and has a plasma elimination  $t_{1/2}$  of 5.8 hours (85). Median steady state  $AUC_{0-24}$  is 2,220 ng × hr/ml. Administration with a fatty meal leads to a 220% increase in AUC compared to fasting conditions (116). It is 97% to 99% protein bound. Approximately 90% is excreted through the biliary tract, and there is only minimal urinary elimination. In individuals with Child-Pugh class C cirrhosis, AUC of paritaprevir was 950% higher than normal controls; therefore, its use is contraindicated in this population. However, paritaprevir may be administered to individuals with Child-Pugh class A or B cirrhosis, as the increase in levels was more moderate in these groups (85).

Paritaprevir is primarily metabolized by CYP3A. It requires coadministration with ritonavir, a potent inhibitor of CYP3A, which allows for once-daily dosing of paritaprevir at a lower dose. Paritaprevir is both an inhibitor and substrate of organic anion transporting polypeptide (OATP) 1B1/B3 and an inhibitor and substrate of P-glycoprotein (P-gp) and BCRP (88). There are many clinically significant drug interactions associated with paritaprevir and ritonavir, primarily caused by the inhibition of CYP3A by ritonavir.

Coadministration with strong CYP3A inducers, such as carbamazepine, phenytoin, or rifampin is contraindicated. Paritaprevir and ritonavir will increase levels of HMG-CoA reductase inhibitors and increase risk of associated adverse events; coadministration of lovastatin and simvastatin are contraindicated. If rosuvastatin is used, it cannot be dosed at more than 10 mg per day. Ergot derivatives are contraindicated with paritaprevir and ritonavir, as are alpha-1 adrenergic antagonists. In clinical trials, coadministration of coformulated ombitasvir/paritaprevir/ritonavir and dasabuvir with products containing ethinyl estradiol was associated with abnormalities in liver function tests, and is therefore contraindicated. Sildenafil coadministration is contraindicated as its levels will be significantly increased (117). Administration with ketoconazole is associated with nearly 100% increase in paritaprevir AUC; if ketoconazole or itraconazole are to be coadministered, a reduced dose of paritaprevir should be given. Voriconazole is also contraindicated with paritaprevir and ritonavir, due to significant reduction in voriconazole levels (118). Fluticasone coadministration with ritonavir has been associated with Cushing's syndrome, and alternatives should be considered (119). Care must also be taken with coadministration of antiarrhythmics and immunosuppressants with therapeutic drug levels monitored whenever possible (120).

With regard to antiretrovirals, paritaprevir has only been studied with atazanavir, raltegravir, and tenofovir/emtricitabine. If coadministered with coformulated ombitasvir/paritaprevir/ritonavir, atazanavir must be given without the usual extra dose of 100 mg of ritonavir. Coadministration with atazanavir is associated with indirect hyperbilirubinemia (121). Rilpivirine, efavirenz, and coformulated lopinavir/ritonavir cannot be given with paritaprevir. For a full account of drug-drug interactions associated with coformulated ombitasvir and coadministered dasabuvir and ribavirin, please refer to the sections pertaining to these medications.

### Adverse Effects

There are no data available on the adverse effects of paritaprevir alone, as it was coformulated with ritonavir and ombitasvir early in drug development. For a detailed review

of adverse events associated with this coformulation, please refer to the section on ombitasvir.

### Resistance

The most common RAV seen in the NS3 protein in patients experiencing virologic failure after receiving paritaprevir is the D168V, which is associated with a 96-fold change in  $EC_{50}$  compared to wild-type virus (89, 115). Other common RAVs associated with high-level resistance include Y56H and R155K (89).

### Clinical Applications

Paritaprevir is only commercially available coformulated with ombitasvir and ritonavir. For a description of clinical studies involving paritaprevir, please refer to the section on ombitasvir.

### Grazoprevir

#### Spectrum of Activity

Grazoprevir (1aR,5S,8S,10R,22aR)-5-*tert*-butyl-*N*-{[(1R,2S)-1-[(cyclopropylsulfonyl)carbamoyl]-2-ethenylcyclopropyl]-14-methoxy-3,6-dioxo-1,1a,3,4,5,6,9,10,18,19,20,21,22,22a-tetradecahydro-8H-7,10-methanocyclopropa[18,19][1,10,3,6]dioxadiazacyclononadecino[11,12-*b*]quinoxaline-8-carboxamide) has pan-genotypic activity, and has a sub- to low-nM  $EC_{50}$  value *in vitro* against genotypes 1a, 1b, and 2 (122).

#### Mechanism of Action

Grazoprevir is a macrocyclic NS3A/4 protease inhibitor that has a novel mechanism of noncovalent binding to the S2 site of the enzyme that prevents it from interacting with the R155 or D168 residues at the S2 subsite, as do most other macrocyclic compounds. It is this property that is believed to allow grazoprevir activity against variants with RAVs at these sites (122–124).

### Pharmacology

Grazoprevir peak levels of 165 ng/ml are achieved an average of 3 hours after administration of medication (125, 126). Plasma elimination  $t_{1/2}$  is 35 to 39 hours in subjects without renal or hepatic impairment (125, 126). In individuals with severe renal impairment, although grazoprevir exposure is increased somewhat, renal clearance is minimal. Therefore, it is believed to be safe to administer to patients with end-stage renal disease (125). In subjects with Child-Pugh B cirrhosis, AUC and  $C_{max}$  are both increased approximately 5-fold compared to healthy controls (126).

Grazoprevir is a substrate of CYP3A4, P-gp, and OATP1B1. It is also a weak CYP3A4 inhibitor and an inhibitor of CYP2C8 and UGT1A1. As a substrate of CYP3A4, levels of grazoprevir are significantly increased when it is coadministered with ritonavir-boosted HIV protease inhibitors; coadministration is, therefore, contraindicated. Although it has not been studied with cobicistat, coadministration is not recommended given the same concern. Although efavirenz coadministration is not recommended, coadministration of fixed-dose combination grazoprevir/elbasvir with rilpivirine did not result in clinically significant changes in levels of any of the three medications, so coadministration is allowable (127). Coadministration with raltegravir or dolutegravir is considered safe (128, 129). Grazoprevir may be safely coadministered with pitavastatin and pravastatin; however, both atorvastatin and rosuvastatin should be avoided (130).

### Adverse Effects

There are limited data available on the adverse effects specifically attributable to grazoprevir, as all phase 2 and 3 studies have included coformulated elbasvir. For details of the adverse effects associated with the grazoprevir/elbasvir fixed-dose combination, please refer to the section on elbasvir.

### Resistance

Grazoprevir demonstrated a sub-nM potency *in vitro* against the virus with R155K and D168V/Y substitutions (122), which are commonly associated with treatment failure of first-generation NS3/4A inhibitors. EC<sub>50</sub>s against strains with the A156T substitution were notably higher.

In phase 2 and 3 studies, SVR12 rates were similar in patients with baseline NS3/4A RAVs compared to those without RAVs. The most common NS3 RAVs seen in patients not achieving SVR12 were Y56H, Q80K, A156T, and D168A (131, 132). In a study of grazoprevir/elbasvir in patients who had previously failed treatment that had included a first-generation NS3/4A inhibitor, all three patients who failed developed the emergent R156T substitution, in addition to the reemergence of other baseline RAVs (133).

### Clinical Applications

Grazoprevir is in clinical development exclusively in fixed-dose combination with elbasvir, an NS5A inhibitor, so all clinical trial data of grazoprevir pertains to this coformulation. For further detail, please refer to the section on elbasvir.

### Asunaprevir

#### Spectrum of Activity

Asunaprevir (tert-Butyl{[(2S)-1-[(2S,4R)-4-[(7-chloro-4-methoxyisoquinolin-1-yl]oxy)-2-[(1R,2S)-1-[(cyclopropanesulfonyl)carbamoyl]-2-ethenylcyclopropyl]carbamoyl]pyrrolidin-1-yl]-3,3-dimethyl-1-oxobutan-2-yl]carbamate; Sunvepra) is an NS3/4A inhibitor with activity against HCV genotypes 1a, 1b, and 2 with EC<sub>50</sub> values of 4, 1.2, and 230 nM, respectively. Antiviral activity against genotype 1 is greater than genotype 2 (134).

#### Pharmacology

Asunaprevir's C<sub>max</sub> of 123 ng/ml is achieved in 2.5 hours. Absorption parameters were not significantly affected by food; therefore, asunaprevir can be taken without regard to meals. Steady-state concentrations are achieved after 5 days and total drug exposure is 804.1 ng•h/ml. The primary route of metabolism is through the CYP3A pathway and the majority of drug is eliminated via the biliary route. Asunaprevir accumulates in hepatic dysfunction and is not to be used in patients with Child-Pugh B or C cirrhosis or in patients with decompensated cirrhosis (135–137).

Asunaprevir is a substrate of CYP3A and thus concomitant administration of strong inducers or inhibitors of CYP3A is contraindicated. Asunaprevir is also a substrate of P-gp and OATP 1B1 and 2B1, which are involved in the distribution of asunaprevir to the liver. Strong inhibitors of these enzymes may increase plasma concentrations of asunaprevir while decreasing liver distribution and therapeutic efficacy. Asunaprevir induces CYP3A and inhibits CYP2D6, OATP 1B1, 1B3, and 2B1 and P-gp and may alter exposure of drugs metabolized by these pathways (134, 135).

#### Adverse Reactions

Elevations in aspartate aminotransferase (AST), ALT, and bilirubin can occur with asunaprevir. It is recommended to monitor liver function tests every 2 weeks for the first 12

weeks of therapy and every 4 weeks thereafter. Treatment should be discontinued permanently if ALT values rise above 10 times the ULN. Other adverse reactions occurring in more than 5% of patients in clinical trials include headache, pyrexia, eosinophilia, nasopharyngitis, and diarrhea (138, 139).

### Resistance

Asunaprevir resistant substitutions may occur at the D168 active site and result in EC<sub>50</sub> values 16- to 280-fold that of the wild-type strain. Cross-resistance to other NS3/4A inhibitors is a concern (140).

### Clinical Applications

Although asunaprevir is not approved in the United States, it is widely used internationally as part of combination regimens to treat chronic HCV genotypes 1 and 4. Although early clinical trials of asunaprevir with peg-IFN and ribavirin yielded SVR24 rates ranging from 64% to 89%, these regimens are no longer recommended (141). Recommended regimens include asunaprevir in combination with daclatasvir as well as in combination with daclatasvir and beclabuvir. A fixed-dose combination of asunaprevir, daclatasvir, and beclabuvir is available internationally and clinical applications of this regimen are described in the beclabuvir section.

Several clinical trials performed in Japan evaluated asunaprevir in combination with daclatasvir for genotype 1b HCV. In treatment-naïve patients, the combination of asunaprevir and daclatasvir for 12 weeks achieved SVR12 rates of 90% (142). In previous nonresponders, 24 weeks of this regimen induced SVR12 in 80% to 90% of patients. In IFN-ineligible or intolerant patients, SVR12 rates ranged from 63% to 87% with 24 weeks of therapy (142–144).

Asunaprevir will continue to be an option for combination therapy regimens against HCV genotypes 1 and 4 internationally; however, there are no plans to seek regulatory approval in the United States for this agent.

### Vedoprevir

Vedoprevir (1R, 2R-1-[(2S, 4R)-1-[(2S)-2-[[1R,5S)-3-bicyclo[3.1.0]hexanyl]oxycarbonylamino]-3,3-dimethylbutanoyl]-4-[8-chloro-7-(2-morpholin-4-ylethoxy)-2-[2-9propan-2-ylamino)-1,3-thiazol-4-yl]quinolin-4-yl]oxypyrrrolidine-2-carbonyl]amino]-2-ethylcyclopropane-1-carboxylic acid) is a selective NS3 inhibitor currently in clinical trials for the treatment of genotype 1 HCV. In replicon studies, the EC<sub>50</sub> was 13 nM in genotype 1a cell lines and was 5.4 nM in genotype 1b cell lines (145). Vedoprevir monotherapy is associated with substitutions at positions 155 and 168 that conferred a >152-fold change in EC<sub>50</sub> (146). In a phase 2 study of patients given vedoprevir for 6 weeks in combination with sofosbuvir and ledipasvir, 19 (95%) reached SVR12 (101). In a study of this regimen in patients with F3 fibrosis or cirrhosis, the SVR12 rate was 76% (147).

### GS-9857

GS-9857 is an NS3/4A inhibitor with pan-genotypic activity. In preclinical studies, it has shown activity against many NS3 RAVs selected by other NS3/4A inhibitors, suggesting a possible role in NS3/4A treatment-experienced patients (148). In a phase 2 study of 6 weeks of treatment with GS-9857 in a fixed-dose combination with sofosbuvir and velpatasvir in genotype 1 patients, SVR12 rates were 93%, 87%, and 67% among treatment-naïve noncirrhotic patients, treatment-naïve cirrhotic patients, and patients

with treatment failure on prior DAA-based regimens, respectively (149). Phase 2 studies of the fixed-dose combination in other genotypes and to evaluate different lengths of treatment are ongoing.

### Glecaprevir (ABT-493)

Glecaprevir (ABT-493, Cyclopropanecarboxamide, N-(((1R,2R)-2-((4,4-difluoro-4-(3-hydroxy-2-quinoxalinyloxy)cyclopentyl)oxy)carbonyl)-3-methyl-L-valyl-(4R)-4-hydroxy-L-prolyl-1-amino-2-(difluoromethyl)-N-((1-methylcyclopropyl)sulfonyl)-, cyclic (1->2)-ether, (1R,2R)) is a pan-genotypic NS3/4A inhibitor being developed in combination with pibrentasvir, a pan-genotypic NS5A inhibitor. Current studies are evaluating various doses of these two drugs in combination with or without ribavirin in patients with genotypes 1, 2, and 3. In noncirrhotic patients with genotype 1 HCV, the combination of glecaprevir and pibrentasvir for 8 weeks achieved SVR12 in 97% of patients, and there were no virologic failures (150). In noncirrhotic patients with genotypes 2 and 3 and who were either treatment-naïve or -experienced, glecaprevir in combination with pibrentasvir for 12 weeks achieved 96% to 100% SVR12 in genotype 2 patients and 83% to 94% SVR12 in genotype 3 patients (151, 152). Adverse effects associated with this regimen include fatigue, nausea, diarrhea, and headache, and are typically mild; however, two patients discontinued therapy due to adverse effects in one trial (150–152). This regimen also has a high barrier for resistance and is active against common HCV harboring NS3/4A and NS5A RAVs (153).

### Direct-Acting Agents: NS5A Inhibitors

The NS5A protein plays an essential role in HCV replication, although the specific function of this protein remains unclear. Regardless, NS5A inhibitors have been shown to have high potency against HCV and are generally active against multiple genotypes. The first compounds with activity against NS5A were found by high throughput screening with the genotype 1b replicon. A variety of strategies to refine early compounds were employed to improve the bioavailability, broaden activity to other genotypes, and produce more favorable pharmacokinetics. As a class, these agents tend to have a low barrier to the development of resistance, and as such, are only administered in combination with other HCV DAAs. Characteristics of specific agents that have regulatory approval or are in late stages of clinical development are described below. Medications in earlier clinical development are summarized in Table 3. Figure 3c shows the chemical structures of NS5A inhibitors commonly used in clinical practice.

### Daclatasvir

#### Spectrum of Activity

Daclatasvir (carbamic acid,N,N'-[[1,1'-biphenyl]-4,4'-diylbis[1H-imidazole-5,2-diyl-(2S)-2,1-pyrrolidinediyl]](1S)-1-(1-methylethyl)-2-oxo-2,1-ethanediy]]bis-,C,C'-dimethyl ester, hydrochloride (1:2); Daklinza) has antiviral activity against genotypes 1 through 5. Median EC<sub>50</sub> values for genotypes 1a, 1b, 2, 3, 4, and 5 are 0.008 nM, 0.002 nM, 16 nM, 0.2 nM, 0.025 nM, and 0.004 nM, respectively (154). Daclatasvir was the first NS5A inhibitor to be reported to have antiviral activity in patients with HCV. The development of a dimeric molecule was noted to be an important step in improving the potency of the molecule. On the basis

of resistance data, it is believed to bind to the N terminus of the NS5A protein, where the protein is anchored to the endoplasmic reticulum membrane (155).

### Pharmacology

Peak plasma concentrations of daclatasvir are observed within 2 hours of administration. The oral bioavailability is 67% yielding mean AUC<sub>0–24h</sub> values of 10,973 ng•h/ml (156). It is metabolized through the CYP3A4 pathway; however, >97% of drug-related compound measured in plasma is the parent compound. Primary route of elimination is biliary with 88% recovered in feces. The plasma elimination t<sub>1/2</sub> of daclatasvir is approximately 12 to 15 hours. Pharmacokinetics are not altered in renal or hepatic impairment (157, 158).

Daclatasvir is predominantly metabolized by CYP3A4 and has clinically significant drug interactions with CYP3A4 inducers and inhibitors. When administering daclatasvir with strong CYP3A4 inhibitors, the dose of daclatasvir should be decreased from 60 mg to 30 mg. Administering strong inducers of CYP3A4 (e.g., rifampin, phenytoin, and carbamazepine) with daclatasvir is contraindicated due to risk of lower drug exposure, loss of efficacy, and development of resistance. However, moderate inducers of CYP3A4 can be coadministered with daclatasvir if the dose of daclatasvir is increased to 90 mg (159).

Daclatasvir inhibits P-gp, OATP1B1 and 1B3, and BCRP and can increase the exposure of medications that rely on these pathways for metabolism such as digoxin and dabigatran.

### Adverse Effects

The most common adverse effects observed in clinical trials were headache and fatigue, which occurred in greater than 10% of patients. All adverse reactions were mild to moderate in severity and did not lead to treatment discontinuation (163–167).

### Resistance

HCV variants with reduced susceptibility to daclatasvir have been identified in cell culture and in clinical studies and occur frequently in patients who experience virologic failure after treatment with daclatasvir. In one phase 3 study, every patient who experienced virologic failure harbored a virus with an NS5A resistance-associated substitution, including A30K/S, L31I, and S62A/L/P/T, with the most common substitution identified at the time of virologic failure being Y93H (160). Treatment emergent resistance-associated substitutions persist at detectable levels for more than 1 year. While baseline polymorphisms are not always associated with decreased efficacy, a baseline Y93H variant is associated with decreased SVR rates (54% versus 92% in those without). Cross-resistance to other NS5A inhibitors is expected; however, effect on other direct-acting antiviral classes is unlikely.

### Clinical Applications

Daclatasvir has been studied in clinical trials as part of a variety of regimens against multiple HCV genotypes. In genotype 1 patients, daclatasvir in combination with sofosbuvir given for 12 weeks achieves SVR12 rates of 98% regardless of genotype subtype (1a 98% versus 1b 100%) and previous treatment (treatment-naïve 98% versus prior treatment failure 98%). Neither extending the duration of therapy to 24 weeks nor the addition of ribavirin made an impact on rates of SVR 12 in genotype 1 patients (161). The combination of daclatasvir and sofosbuvir for 24 weeks

achieved SVR12 rates of 92% in untreated genotype 2 patients and of 89% in untreated genotype 3 patients. The addition of ribavirin to the regimen did not improve SVR12 rates in patients with genotype 2 or 3 (162). When the duration of therapy was decreased to 12 weeks in genotype 3 patients, the SVR 12 rates were 90% in treatment-naïve patients and 86% in treatment-experienced patients. Decreasing the length of treatment to 8 weeks is associated with lower SVR12 rates (76%, genotypes 1 to 4), although this may be considered in patients with HCV RNA levels less than 2 million IU/ml (100% SVR12) (163). Subjects with cirrhosis and HCV genotype 3 who received 12 weeks of treatment without ribavirin also had considerably lower SVR12 rates (63%) (160).

SVR12 rates were high (>97%) in patients coinfecting with HIV, regardless of genotype or prior treatment experience (160). In post-liver transplant patients with severe recurrent HCV treated with daclatasvir and sofosbuvir, with and without ribavirin for 24 weeks, 75% achieved undetectable levels by the end of treatment; however, 25% of patients died during antiviral therapy. Anti-HCV therapy to treat HCV recurrence after liver transplantation should be initiated at early stages before the onset of cholestasis and liver decompensation to obtain the greatest benefit (164).

## Ledipasvir

### Spectrum of Activity

Ledipasvir (methyl [(2S)-1-[(1R,3S,4S)-3-[5-(9,9-difluoro-7-{2-[(6S)-5-[(2S)-2-[(methoxycarbonyl)amino]-3-methylbutanoyl]-5-azaspiro[2.4]hept-6-yl]-1H-imidazol-4-yl]-9H-fluoren-2-yl)-1H-benzimidazol-2-yl]-2-azabi cyclo[2.2.1]hept-2-yl]-3-methyl-1-oxo-2-butanoyl] carbamate) has antiviral activity against genotypes 1 through 6, but is most active against genotype 1 with EC<sub>50</sub> values of 0.018 nM for genotype 1a and 0.006 nM for genotype 1b. Ledipasvir is the least active against genotypes 2a, 2b, 3a, and 6e with EC<sub>50</sub> values of 21 to 249 nM, 16 to 530 nM, 168 nM, and 264 nM, respectively (165). Ledipasvir, unlike most other NS5A inhibitors, was not developed as a dimeric molecule, but rather is asymmetric. The compound was designed specifically for optimization of coformulations with other DAAs, most notably sofosbuvir (166).

### Pharmacology

The plasma concentrations of ledipasvir after a single dose of 90 mg peak approximately 4 hours post dose at 116.5 ng/ml and the AUC<sub>0-24</sub> is 1,320 ng•h/ml. Ledipasvir absorption is not affected by fat content of meals and can be administered without regard to food intake. Pharmacokinetics are not altered by renal or hepatic impairment. Metabolism occurs via a slow oxidative process. It is eliminated primarily as unchanged parent compound in the feces. The terminal plasma t<sub>1/2</sub> of ledipasvir is 47 hours (167, 168).

Ledipasvir solubility increases as pH decreases (pH of <2.3) and is practically insoluble between pH of 3 to 7.5. Consequently, it requires an acidic environment to be absorbed and must be appropriately separated from acid reducing pharmacologic agents. Administering ledipasvir under basic conditions can result in lack of absorption and therapeutic effect. Ledipasvir is a substrate of the P-gp efflux pump and use with P-gp inducers is not recommended as there is a risk of a decreased therapeutic effect of ledipasvir. However, ledipasvir can be used concomitantly with P-gp inhibitors. Ledipasvir also inhibits P-gp and BCRP and may increase absorption of coadministered substrates of this transporter.

## Adverse Effects

Adverse effects related to ledipasvir are usually mild and rarely cause patients to discontinue therapy (≤1%). The most common side effects seen in clinical trials include headache, fatigue, insomnia, and nausea. Adverse events due to ledipasvir are more common in patients treated with more prolonged courses of therapy (162, 169, 170).

## Resistance

Multiple NS5A variants, including Y93H/N, Q30R, and L31M, have been associated with ledipasvir resistance both *in vitro* and in clinical trials, either at baseline and/or at time of virologic failure. In phase 3 clinical trials of ledipasvir-containing regimens, 55% of patients with genotype 1a and 88% of patients with genotype 1b had emergent NS5A resistance-associated substitutions at the time of ledipasvir failure. Baseline resistance-associated variants were seen in 16%, 14%, and 18% of study participants in ION-1, ION-2, and ION-3, respectively. However 89% to 96% of these patients still achieved SVR12 (165, 171, 172). NS5A resistance-associated variants observed in clinical trials with ledipasvir may decrease susceptibility to other NS5A inhibitors (165).

## Clinical Applications

Ledipasvir is only commercially available as a fixed-dose combination tablet also containing sofosbuvir. In treatment naïve, genotype 1 patients, ledipasvir used in combination with sofosbuvir for 12 weeks achieved SVR12 rates of 99% (169). Treatment duration may be shortened to 8 weeks in selected patients who are noncirrhotic and have a pretreatment HCV RNA level less than 6 million IU/ml (170). In treatment-experienced patients with HCV genotype 1, the ledipasvir and sofosbuvir combination achieved SVR12 rates of 94% when used in a 12-week regimen and 99% in a 24 week regimen. Patients with cirrhosis had significantly higher SVR12 rates when treated for 24 weeks compared to 12 weeks (95% versus 86%, *P* = 0.007) (162).

Ledipasvir and sofosbuvir combination therapy has also been studied in treatment-naïve and treatment-experienced patients with genotypes 4 and 5 with SVR12 rates ranging from 93% to 95% in genotype 4 and 95% in genotype 5 (171). Studies including patients with genotype 3 are being developed.

Combination therapy with ledipasvir and sofosbuvir has also been studied in patients with HCV and HIV coinfection yielding SVR12 rates of 96% in genotype 1 patients and 100% in genotype 4 patients. The incidence of SVR12 was not affected by cirrhosis or history of treatment (172). Post-liver transplant patients have also been treated with ledipasvir and sofosbuvir in combination with ribavirin for 12 and 24 weeks for chronic HCV with genotypes 1 and 4. SVR rates decreased as liver disease became more advanced with SVR rates ranging from 96% to 98% in fibrosis and Child-Pugh A cirrhosis to 60% to 67% in Child-Pugh C cirrhosis (173).

## Ombitasvir

### Spectrum of Activity

Ombitasvir (Dimethyl [(2S,5S)-1-[4-(2-methyl-2-propanyl)phenyl]-2,5-pyrrolidinediyl]bis[4,1-phenylenecarbamoyl(2S)-2,1-pyrrolidinediyl][(2S)-3-methyl-1-oxo-1,2-butanediyl]]) biscarbamate) has activity against HCV genotypes 1 through 5 at an EC<sub>50</sub> range of 1.7 to 19.3 pM and 366 pM against genotype 6a (174). Ombitasvir, which was the first FDA-approved NS5A inhibitor, was developed as a symmetrical,

pyrrolidine-based structure on the basis of previous observations that dimeric forms of the NS5A protein can possess anti-HCV activity and that inhibitors with dimer-like or symmetric structures seemed to have increased potency against HCV (174). Ombitasvir is coformulated with paritaprevir and ritonavir and administered with dasabuvir as part of the Viekira Pak formulation for genotype 1 HCV and without dasabuvir (Technivie) for genotype 4 HCV. Although ombitasvir and paritaprevir were initially developed by different pharmaceutical companies, a unique licensing agreement between the two allowed the medication to move forward as a coformulation after early clinical trials with ombitasvir and dasabuvir alone failed to show adequate efficacy for some patients with genotype 1 HCV (175).

### Pharmacokinetics

Ombitasvir, in its coformulation with paritaprevir and ritonavir, achieves a mean peak concentration of 101 ng/ml at 4 to 5 hours after administration. Mean AUC is 82% higher when administered with a moderate fat meal compared with administration while fasting (116). Plasma elimination  $t_{1/2}$  is 25.5 to 32 hours (89). Steady state occurs 12 days after initiation of therapy (86). Ombitasvir monotherapy causes a mean reduction of 3.1  $\log_{10}$  IU/ml in HCV viral load in the first 3 days of treatment (89). Ombitasvir is dosed at 25 mg in the currently available fixed-dose combination pill, but efficacy is similar at doses ranging from 5 mg to 200 mg per day (88). Elimination is primarily through the feces with minimal renal excretion. Concentrations are not affected by renal insufficiency. Ombitasvir, in its coformulation with paritaprevir and ritonavir, is contraindicated in patients with severe hepatic impairment (Child-Pugh C) because of accumulation of paritaprevir (85). P450 enzymes play a minimal role in the metabolism of ombitasvir. It is an inhibitor of UGT1A1 and a substrate of p-glycoprotein and BCRP. Carbamazepine can cause a significant decrease in serum levels of ombitasvir, and their coadministration is contraindicated (88). For a full account of drug-drug interactions associated with coformulated ombitasvir/paritaprevir/ritonavir and coadministered dasabuvir and ribavirin, please refer to the sections pertaining to those medications.

### Adverse Effects

Ombitasvir has only been studied as monotherapy in small pharmacokinetic studies with few participants, and no adverse effects were reported (89). Ombitasvir has been studied more widely in phase 3 trials in combination with paritaprevir, ritonavir, and dasabuvir, with or without ribavirin, and it is difficult to know which adverse effects reported in these trials, if any, can be attributed directly to ombitasvir. In two placebo-controlled trials of ombitasvir in combination with paritaprevir, ritonavir, dasabuvir, and ribavirin, subjects in the treatment arm reported increased rates of nausea, pruritus, rash, insomnia, and fatigue (176, 177). Fatigue and nausea were less common in phase 3 studies in which subjects received the direct-acting agents in the absence of ribavirin (178, 179). The incidence of skin reactions reported in phase 3 trials ranged from 7% to 24% of participants and occurred less frequently in subjects not treated concomitantly with ribavirin. There were no reports of Stevens Johnson syndrome or erythema multiforme.

Approximately 1% of patients in phase 3 studies developed ALT elevations greater than 5 $\times$  the upper limit of normal. The incidence of this elevation was greatly increased among women taking ethinyl estradiol ( $\times$ ). Serum total bilirubin elevation of >2 $\times$  ULN was noted in 15% of

subjects on concomitant ribavirin, and rarely required discontinuation of therapy. Thirty-five percent of HIV coinfecting subjects treated concomitantly with ribavirin had serum bilirubin rises to >3 $\times$  ULN on treatment; however, the majority of these subjects were also receiving atazanavir for HIV infection (121). A drop in baseline hemoglobin level below the lower limit of normal was relatively common in subjects receiving coadministered ribavirin but across all phase 3 studies, no subjects receiving the ombitasvir/paritaprevir/ritonavir plus dasabuvir without coadministered ribavirin experienced a hemoglobin drop below 10 g/dl (87, 178, 179).

### Resistance

In a genotype 1a replicon system, ombitasvir selects for resistance variants with substitutions M28T/V, Q30R, H58D, and Y93C/H/N in the NS5A protein. These variants are associated with resistance of 58-fold or greater. Two additional substitutions, Q30H and L31M, were associated with lower-level resistance (2- to 3-fold) (89). In a genotype 1b replicon, the most commonly selected resistant variant was Y93H. The addition of other substitutions leads to higher-level (>400-fold) resistance. In the genotype 4a replicon model, L28V was the only RAV selected, and it was associated with 23-fold resistance to ombitasvir. In clinical trials, the most common NS5A RAV to occur in subjects failing treatment with ombitasvir was the Y30E/K/R, followed by the M28A/T/V. Among all subjects who developed NS5A resistance after receiving ombitasvir in phase 2 trials, 100% had persistence of the RAVs 48 weeks after treatment (86).

### Clinical Applications

Ombitasvir has only been studied clinically in combination with paritaprevir, ritonavir, and dasabuvir for genotype 1a and b HCV and in combination with paritaprevir and ritonavir for genotype 4 HCV. In noncirrhotic treatment-naïve subjects with genotype 1a, the DAA regimen, when coadministered for 12 weeks with ribavirin, achieved SVR12 rates of 96%. Similar SVR12 rates were seen in treatment-experienced patients without cirrhosis (176, 179). In a separate study, ombitasvir/paritaprevir/ritonavir plus dasabuvir was associated with a lower SVR12 rate (90%) when administered for 12 weeks without ribavirin (179). Therefore, it is recommended that all noncirrhotic individuals with HCV genotype 1a be treated for 12 weeks with coadministration of weight-based ribavirin, without regard to treatment history. In two studies of noncirrhotic subjects with genotype 1b HCV who received 12 weeks of ombitasvir/paritaprevir/ritonavir plus dasabuvir without ribavirin, SVR12 was achieved in 100% of both treatment-experienced (178) and treatment-naïve patients (179), so this group may receive 12 weeks of treatment without ribavirin.

In treatment-naïve cirrhotic patients with genotype 1a HCV, treatment for 12 or 24 weeks with ombitasvir in combination with paritaprevir, ritonavir, dasabuvir, and ribavirin leads to an SVR12 rate of 94%. Among genotype 1a patients with cirrhosis and a prior null response to treatment, 24 weeks of treatment was associated with higher SVR12 rates than 12 weeks of treatment (93% versus 80%) (180). Among the cirrhotic patients with genotype 1b HCV, response rates were high regardless of history of prior treatment response or whether 12 or 24 weeks were given. Therefore, for patients with cirrhosis and genotype 1b HCV, 12 weeks of therapy with coadministered ribavirin may be given regardless of prior treatment history. Patients with HIV coinfection treated with ombitasvir in combination with

paritaprevir, ritonavir, and dasabuvir for 12 weeks also had an SVR12 rate of 94% (121). The regimen has also been associated with a high SVR12 rate (97%) when given for 24 weeks to patients following liver transplantation (181).

In patients with genotype 4 HCV, 100% of patients (treatment-naïve and -experienced) achieved SVR12 with ombitasvir coformulated with paritaprevir and ritonavir and coadministered with ribavirin (87). SVR12 rates were lower without the coadministration of ribavirin.

## Elbasvir

### Spectrum of Activity

In both preclinical and clinical studies, elbasvir (dimethyl *N*, *N'*-((6*S*)-6*H*-indolo[1,2-*c*][1,3]benzoxazine-3,10-diyl)bis[1*H*-imidazole-5,2-diyl-(2*S*)-pyrrolidine-2,1-diyl]((2*S*)-1-oxo-3-methylbutane-1,2-diyl))biscarbamate) had activity against a range of genotype 1a and 1b strains as well as genotype 3 strains (182, 183). In a replicon assay, the EC<sub>90</sub> against genotype 1a virus was under 0.02 nM and for genotype 1b virus was under 0.03 nM.

### Pharmacology

Elbasvir has a median T<sub>max</sub> of 2 to 4 hours, C<sub>max</sub> of 121 mg/ml, and mean plasma elimination t<sub>1/2</sub> of 19 to 27 hours, making it amenable to once-daily dosing. Steady-state levels are achieved within 5 days of initiation of therapy (182). Less than 0.15% of the dose is eliminated renally, although C<sub>max</sub> is 66% higher in individuals with severe renal impairment compared to matched healthy controls, and AUC is 86% higher. It is minimally dialyzable (125).

Elbasvir is a substrate of CYP3A4, P-gp, and OATP *in vitro*. It may also be an inhibitor of BRCP (130). Co-administration with efavirenz was associated with a 50% decrease in elbasvir levels (185). Co-administration with ritonavir-boosted HIV protease inhibitors was associated with large increases in elbasvir AUC; atazanavir/ritonavir was associated with a 4.8-fold rise, lopinavir/ritonavir with a 3.7-fold rise, and darunavir-ritonavir with a 1.7-fold rise (186). Co-administration with raltegravir or dolutegravir has no effect on elbasvir levels (128, 185). Elbasvir coadministration with tenofovir also causes slight increases in the AUC of tenofovir (185).

Coadministration with rosuvastatin is not recommended as this combination can result in large increases in rosuvastatin AUC and C<sub>max</sub>. Pravastatin levels are more modestly affected, so this should be considered if coadministration of an HMG-CoA reductase inhibitor is indicated (130).

### Adverse Effects

There are limited data on the adverse effects attributed specifically to elbasvir. In clinical trials of elbasvir in combination with grazoprevir, the most common adverse effects reported were headache, fatigue, and nausea. Across all of the studies, only one serious adverse event, an episode of abdominal pain, was potentially medication related. There have been infrequent reports of late elevations of AST or ALT; in only one instance was this >5 × ULN (131, 132, 184).

### Resistance

Treatment of a genotype 1a replicon with elbasvir *in vitro* was associated with the development of the Q30D and Y93N substitutions in NS5A (183). L31F, Y93H, and V121I were the main variants seen in a genotype 1b replicon model treated with elbasvir. Changes at locus 93 were particularly

associated with high-level elbasvir resistance. In an elbasvir dose-ranging study, the most common variants to develop were M28T, Q30R, L31V, and Y93H in genotype 1a, and the L31V and Y93H variants in subjects with genotype 1b. The majority of these persisted at 2 months posttreatment (183). In clinical trials of elbasvir/grazoprevir, the presence of baseline NS5A RAVs, especially at position 93 and in subjects with higher baseline viral loads, is associated with lower rates of SVR12, especially in subjects with genotype 1a HCV. The most common NS5A RAVs discovered after virologic failure of elbasvir and grazoprevir were M28A/V/T, Q30H/L/R, L31M, and Y93H/N. These occurred more frequently in patients with genotype 1a (131, 132, 184).

### Clinical Applications

Elbasvir is being studied exclusively in fixed-dose combination with grazoprevir, an NS3/4A protease inhibitor. In a large, multisite phase 3 study, 92% of patients with genotype 1a achieved SVR12, as did 99% of participants with genotype 1b, 100% of participants with genotype 4, and 80% with genotype 6 (132). A separate study confirmed high rates of SVR12 among previously untreated genotype 1 participants with cirrhosis treated for 12 weeks without co-administered ribavirin (184). Subjects with HIV/HCV coinfection with genotypes 1, 4, and 6, also achieved high rates of SVR12 with 12 weeks of elbasvir/grazoprevir without ribavirin (131, 187). In individuals who had previously been treated for HCV, SVR12 rates were slightly higher in individuals who received at least 16 weeks of elbasvir/grazoprevir plus ribavirin compared to 12 weeks with no ribavirin, particularly in cirrhotics (100% versus 89% to 91%) (184, 188). In patients with genotype 1 who had previously failed therapy that had included an early generation NS3/4A inhibitor, 96% achieved SVR12 when given elbasvir/grazoprevir plus ribavirin for 12 weeks (133). High rates of SVR12 were also reported in people with Child-Pugh B cirrhosis (189). Elbasvir/grazoprevir given without dosage adjustment was found to be safe and effective in a population of patients with end-stage renal disease, including patients on hemodialysis (190).

## Velpatasvir

### Spectrum of Activity

Velpatasvir (methyl ((2*S*)-1-((2*S*,5*S*)-2-(9-((2*S*,4*S*)-1-((2*R*)-2-((methoxycarbonyl)amino)-2-phenylacetyl)-4-(methoxymethyl)pyrrolidin-2-yl)-1*H*-imidazol-4-yl)-1,11-dihydro[2]benzopyrano[3',4':6,7]naphtho[1,2-*d*]imidazol-2-yl)-5-methylpyrrolidin-1-yl]-3-methyl-1-oxobutan-2-yl)carbamate) has antiviral activity against genotypes 1 through 6. EC<sub>50</sub> values for genotypes 1a, 1b, 2a, 2b, 3a, 4a, 5a, and 6a are 13 pM, 15 pM, 9 pM, 10 pM, 13 pM, 9 pM, 59 pM, and 7 pM, respectively (191).

### Pharmacology

Velpatasvir achieves its C<sub>max</sub> of 414 ng/ml at 2.3 hours after a 100 mg dose with an overall AUC of 2,745.3 ng•hr/ml. Velpatasvir undergoes minimal metabolism via hydroxylation and methylation, and parent drug represents approximately 99% of systemic exposure (192, 193). Velpatasvir is predominantly eliminated in the feces with <1% of the dose excreted in the urine. Pharmacokinetics were not significantly altered in patients with renal insufficiency and there are no dose adjustments required in mild, moderate, or severe renal impairment. Velpatasvir has a half-life of 15.3 hours (192, 193).

Velpatasvir is a substrate of CYP3A4, CYP2C8, CYP2B6, and P-gp and may be affected by medications that inhibit or induce these enzymes. Velpatasvir is also a substrate of BCRP and OATP. Velpatasvir also inhibits P-gp, BCRP, and OATP and can increase exposure to medications that rely on these pathways for elimination (197).

#### Adverse Reactions

Velpatasvir is generally well tolerated with the most common adverse events being headache, fatigue, nasopharyngitis, and nausea. Out of greater than 1,000 patients included in phase 3 studies, <1% discontinued treatment due to adverse drug reactions (194–196).

#### Resistance

Velpatasvir has improved activity against resistant variants selected by first generation HCV NS5A inhibitors such as daclatasvir and ledipasvir (198). In one phase 3 trial of velpatasvir in combination with sofosbuvir, 60% of patients had baseline NS5A RAVs; however, all of these patients reached SVR12 (195). However, in a different phase 3 trial, SVR12 rates were lower (88%) among patients with baseline RAVs, and the Y93H substitution was most strongly associated with virologic failure (195). The addition of ribavirin or extension of the regimen to 24 weeks may increase SVR12 rates in patients with baseline NS5A RAVs (196).

#### Clinical Applications

Velpatasvir is currently being studied as a fixed-dose combination with sofosbuvir in patients with HCV genotypes 1 through 6. In patients with genotypes 1, 2, 4, 5, and 6, velpatasvir and sofosbuvir for 12 weeks achieved SVR12 rates of 99%. Nineteen percent of subjects in this study had compensated cirrhosis and 32% were treatment experienced, although patients who had been previously treated with NS5B or NS5A inhibitors were excluded. Rates of SVR were not affected by genotype or the presence of cirrhosis (194). In a study of patients with genotypes 1, 2, 3, 4, and 6 with decompensated cirrhosis, 83% achieved SVR12 with 12 weeks of velpatasvir and sofosbuvir; 94% with 12 weeks of velpatasvir, sofosbuvir, and ribavirin; and 86% with 24 weeks of velpatasvir and sofosbuvir. These differences were not statistically significant (196).

In a separate study, patients with genotype 2 had SVR12 of 99% with velpatasvir and sofosbuvir compared to 94% with sofosbuvir and ribavirin ( $P = 0.02$ ). In genotype 3 patients, the SVR12 rate in the velpatasvir plus sofosbuvir group was 95% compared to 80% in those treated with sofosbuvir and ribavirin ( $P$  of  $<0.001$ ). SVR12 rates among patients receiving velpatasvir and sofosbuvir were lower among subjects with cirrhosis (91% versus 97%) and subjects who had experienced previous treatment failure (90% versus 97%) (195).

#### Pibrentasvir (ABT-530)

Pibrentasvir (ABT-530) (Methyl {(2S,3R)-1-[(2S)-2-[5-[(2R,5R)-1-{3,5-difluoro-4-[4-(4-fluorophenyl)piperidin-1-yl]phenyl]-5-(6-fluoro-2-[(2S)-1-[N-(methoxycarbonyl)-O-methyl-L-threonyl]pyrrolidin-2-yl]-1H-benzimidazol-5-yl]pyrrolidin-2-yl]-6-fluoro-1H-benzimidazol-2-yl]pyrrolidin-1-yl]-3-methoxy-1-oxobutan-2-yl]carbamate) is a pan-genotypic NS5A inhibitor being developed in combination with glecaprevir, a pan-genotypic NS3/4A inhibitor. Phase 2 data suggest that this regimen is highly efficacious with relatively few adverse events and a high barrier to resistance.

For more detail of early clinical trials, please refer to the section on glecaprevir.

#### Ravidasvir (PPI-668)

Ravidasvir (PPI-668, Methyl N-[(2S)-1-[(2S)-2-[5-(6-[(2S)-1-[(2S)-2-[(methoxycarbonyl)amino]-3-methylbutanoyl]pyrrolidin-2-yl]-1H-imidazol-4-yl]naphthalen-2-yl)-1H-benzimidazol-2-yl]pyrrolidin-1-yl]-3-methyl-1-oxobutan-2-yl]carbamate) is an NS5A inhibitor with pan-genotypic activity at a sub- to low-nM  $EC_{50}$  against all genotypes (199). High rates of SVR12 were noted when given to patients with genotype 1a in combination with faldaprevir and deleobuvir with or without ribavirin, although it is no longer in development with these agents. It is currently being studied in combination with sofosbuvir in patients with genotype 4 infection.

#### Direct-Acting Agents: Other Mechanisms

##### Alisporivir

##### Spectrum of Activity

Alisporivir (3S,6S,9S,12R,15S,18S,21S,24S,27R,30S,33S)-25,30-diethyl-33-[(E,1R,2R)-1-hydroxy-2-methylhex-4-enyl]-1,4,7,10,12,15,19,27,28-nonamethyl-6,9,18-tris(2-methylpropyl)-3,21,24-tri(propan-2-yl)-1,4,7,10,13,16,19,22,25,28,31-undecazacyclotriatriacontane-2,5,8,11,14,17,20,23,26,29,32-undecan) has activity against replicons of HCV of all genotypes tested at a sub-nM  $EC_{50}$  (200, 201).

##### Mechanism of Action

Alisporivir is a second-generation, nonimmunosuppressive cyclophilin inhibitor. This class of medications was developed after the observation that cyclosporine A, a cyclophilin inhibitor used as an immunosuppressant after liver transplantation, has activity against HCV *in vitro* and some efficacy in clinical trials when used in combination with IFN (202–204). The mechanism of action of alisporivir remains incompletely understood. Alisporivir binds to cyclophilin A, a host cytosolic protein that interacts with the HCV NS5A protein and may induce NS5A binding to HCV RNA. It may also impact the activity of NS5B, and, as a result, directly impact viral replication. Cyclophilin A also binds IFN regulatory proteins, making immune modulation another potential mechanism of action (205).

##### Pharmacology

Alisporivir reaches peak levels an average of 2 hours after administration (206). The formulation being studied in clinical trials is a microemulsion, which is believed to lead to increased bioavailability of the compound (207). Terminal  $t_{1/2}$  is 100 hours, which allows for once-daily dosing. Steady state is reached by day 14. Alisporivir is excreted through bile. Mean reduction in serum HCV viral load with alisporivir monotherapy is greatest with genotype 3 virus (206). Alisporivir is both a substrate and an inhibitor of CYP3A4 so is expected to have clinically significant interaction with inhibitors, inducers, and substrates of CYP3A4 (207).

##### Resistance

Based upon data from a replicon model, alisporivir is believed to have a high genetic barrier to resistance, requiring multiple substitutions in the NS5A domain to increase the  $EC_{50}$  to clinically significant levels (208). In clinical trials, the most common variant associated with treatment failure is the D320E in the NS5A domain, which is associated with a 3- to 5-fold increase in  $EC_{50}$ . D316E/N and R347R/G/W

are also RAVs that have been associated with alisporivir exposure (209, 210).

### Clinical Applications

Alisporivir does not have regulatory approval for use in clinical practice. In a phase 3 study of response-guided therapy with coadministered peg-IFN- $\alpha$ 2a and ribavirin, 69% of participants receiving alisporivir achieved SVR12. However, a partial clinical hold placed on alisporivir midway through the study limited exposure to medication. In the subset of patients who received at least 24 weeks of 400 mg of alisporivir twice daily along with peg-IFN and ribavirin, 90% achieved SVR12 (209). Five cases of pancreatitis, one fatal, were noted in the group that received alisporivir, though similar rates were noted in a control group receiving peg-IFN and ribavirin alone, so it is unclear if this was a direct effect of the alisporivir (208). In a phase 2b study in patients with genotypes 2 and 3, patients were initiated on varying doses of alisporivir with or without ribavirin with a planned treatment course of 24 weeks. Those who did not have rapid virologic response (HCV VL < 25 IU/ml at week 4 of treatment, RVR) were also given IFN for the final 20 weeks of treatment. SVR12 rates ranged from 80% to 85%, slightly higher in participants with genotype 3, although the majority of patients did not reach RVR and were administered interferon (210). A trial of alisporivir with ribavirin without IFN in subjects with genotype 2 or 3 is ongoing. It remains to be seen whether this will be a viable treatment option or if alisporivir might be administered in combination with other DAAs.

# Antirespiratory Virus Agents

MARCUS R. PEREIRA, BENJAMIN A. MIKO, MONICA MEHTA, AND SCOTT M. HAMMER

## 14

This chapter reviews antiviral agents that have been, or are being, developed to treat or prevent respiratory viral infections. Detailed information is provided for approved agents and those in more advanced stages of clinical development. Agents in Phase I human studies or promising approaches that are still in preclinical development are described briefly. The reader is referred to the respective pathogen-specific chapters for full discussions of the viral agents and the diseases they cause.

### INFLUENZA VIRUS

#### Amantadine

Amantadine (1-adamantane amine hydrochloride; Symmetrel), a tricyclic amine with a “birdcage-like” structure (Figs. 1 and 2; Tables 1 and 2), was approved initially in the United States in 1966 for the treatment of influenza A. It is also indicated for Parkinson’s disease. Amantadine belongs to the class of drugs known as adamantanes, which also includes rimantadine. Currently the adamantanes should not be used to treat influenza due to widespread resistance among circulating strains, but the class remains important given the lessons learned and the potential susceptibility of future influenza strains. For example, the seasonal oseltamivir-resistant influenza A (H1N1) virus that circulated globally in 2008–2009 retained susceptibility to adamantanes.

#### Spectrum of Activity

Amantadine is active against influenza A virus strains only. The inhibitory concentrations of susceptible isolates are generally in the range of 0.1 to 0.4  $\mu\text{g/ml}$ . At approximately 100-fold-higher concentrations, *in vitro* inhibitory activity against other viral agents, such as influenza B virus and flaviviruses (1), can be demonstrated, but these concentrations are not achievable in humans at non-toxic doses.

#### Mechanism of Action

Amantadine predominantly inhibits an early step in influenza A virus replication by interfering with the function of the viral M2 protein (2). In the replication cycle (Fig. 2), the homotetrameric M2 protein acts as a transmembrane ion channel facilitating the acidification of the virion interior; hydrogen ion-mediated dissociation of the matrix protein from the nucleoprotein enables release of viral RNA seg-

ments into the cytoplasm (Fig. 3). M2 also modulates the pH of the *trans*-Golgi network during transport of viral hemagglutinin (HA). Thus, amantadine may also act at a later step in the influenza A virus replication cycle by altering HA formation for certain strains (3, 4).

#### Pharmacokinetics

Amantadine is well absorbed, reaching the maximum serum concentration ( $C_{\text{max}}$ ) in 2 to 4 hours following an oral dose. Concentrations in the range of 0.5 to 0.8  $\mu\text{g/ml}$  are typically achieved with the standard dosage of 100 mg twice daily; levels in nasal secretions approximate those in plasma (5). The primary route of elimination is renal, and over 90% of the drug is excreted unchanged in the urine. The plasma elimination half-life ( $t_{1/2}$ ) is 12 to 18 hours in healthy young adults but is substantially prolonged in the setting of renal insufficiency and in the elderly. Dose adjustments are needed for these groups. Patients over the age of 65 years should receive half of the recommended dosage, i.e., 100 mg per day. Patients with a creatinine clearance (CrCl) less than 50 ml/min should also receive a reduced dose.

#### Adverse Effects

The major adverse effect of amantadine is neurotoxicity. Generally, central nervous system (CNS) effects are minor and include lightheadedness, restlessness, insomnia, and mild cognitive difficulties. Such side effects may occur in up to one-third of patients. More serious neurotoxic reactions, including tremor, seizure, and coma, typically occur in situations in which amantadine accumulates, as in elderly subjects or those with renal failure. The availability of rimantadine in some countries, including the United States, allows prescribers to avoid the use of amantadine in patients with a history of seizure disorder or psychosis. Minor gastrointestinal side effects are also common. Less common adverse effects, usually seen with prolonged dosing, include livedo reticularis, fluid retention, orthostatic hypotension, and urinary retention, the latter presumably related to the anticholinergic properties of the drug. Amantadine has been found to be teratogenic and thus should be avoided during pregnancy unless the potential benefit outweighs the risk (Pregnancy Category C) (6). It is also excreted into human milk, and therefore, should be avoided in nursing mothers.

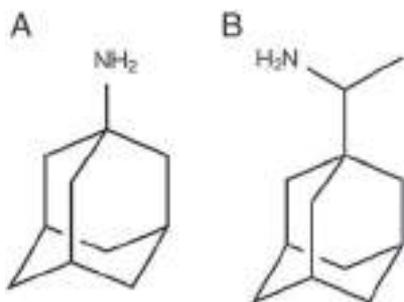

FIGURE 1 Molecular structures of M2 protein inhibitors amantadine (A) and rimantadine (B).

### Drug Interactions

The major drug–drug interactions include exposure to agents that potentiate the neurotoxic side effects. Therefore, drugs with antihistaminic or anticholinergic activity should be avoided, particularly in older individuals. Drugs that have been reported to decrease the excretion of amantadine include trimethoprim-sulfamethoxazole, triamterene, and hydrochlorothiazide (7). Amantadine can prolong the cardiac QTc interval and should be used with caution when combined with other QTc-prolonging medications, such as some antipsychotics, fluoroquinolones, and quinidine gluconate.

### Resistance

Markedly reduced susceptibility (>100-fold changes) to amantadine and rimantadine is mediated by specific substitutions in the M2 protein of influenza A virus at positions 27, 30, 31, or 34 (8). Resistant isolates have been recovered readily from persons exposed to these drugs. Adamantane-resistant strains can be isolated from 30% of treated subjects within 2 to 5 days, and resistant isolates are transmissible to household or institutional contacts (9). These variants cause

typical influenza illness and have no apparent loss of fitness. Although immunocompetent subjects in whom resistant strains emerge generally resolve their illness in the usual time frame when receiving amantadine, the transmission of resistant isolates abrogates the usefulness of amantadine or rimantadine prophylaxis. Prolonged shedding of resistant variants occurs in immunocompromised hosts.

Since 2003, the prevalence of resistance to adamantanes in circulating influenza A isolates has risen dramatically such that they are not recommended for empiric therapy of acute influenza infection. Adamantane-resistant influenza A virus strains typically possess a substitution in the M2 gene that leads to a serine-to-asparagine substitution at position 31 (S31N) and confers full cross-resistance to rimantadine but does not affect susceptibility to neuraminidase inhibitors (10, 11). Essentially all recently circulating A (H3N2) and A (H1N1) pdm09 viruses are resistant (12, 13). In pre-clinical models, combinations of amantadine, ribavirin, and oseltamivir have greater therapeutic activity than single agents or dual combinations for influenza A viruses, including adamantane-resistant strains (14), and this triple drug regimen is undergoing a controlled clinical study in outpatients at increased risk for influenza complications.

### Clinical Applications

Amantadine is approved for prophylaxis and treatment of susceptible influenza A virus infections, but its use is currently not recommended because of widespread resistance (see Chapter 43 on influenza virus). When this drug is given at the standard dosage of 200 mg/day in adults, the prophylactic efficacy has been consistently reported to be in the range of 70% to 90% for susceptible strains (4, 15, 16). Efficacy has also been shown for postcontact prophylaxis in households, when ill index cases are not treated concurrently, and for outbreak control in closed populations. Amantadine treatment of uncomplicated influenza begun promptly after the onset of symptoms can decrease the duration of fever and

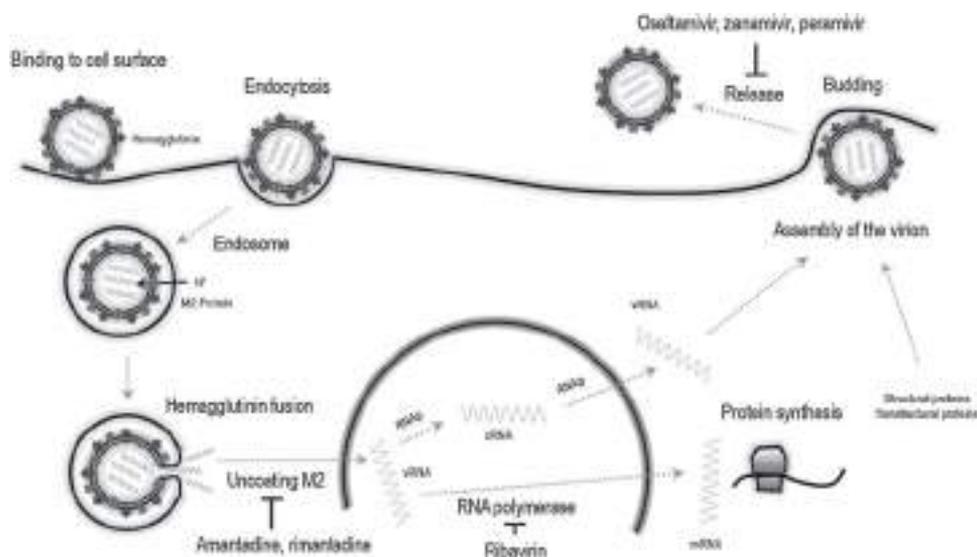

FIGURE 2 Replicative cycle of influenza virus. The influenza virus is shown binding to the surface of an airway epithelial cell via the interaction of hemagglutinin (HA) with sialic acid residues. HA is subsequently cleaved by a protease, and the virus is endocytosed. The M2 protein allows hydrogen ions to enter the virion, promoting the dissociation of ribonuclear protein and release of viral nucleic acids into the cytoplasm (uncoating). Viral RNA replication occurs in the nucleus by the viral RNA polymerase (RNAP) complex. Following replication of viral RNA and synthesis of structural/nonstructural proteins, virions are assembled and released. Sites of action of antiviral compounds are shown by a solid line.

**TABLE 1** Antirespiratory virus agents approved in the United States: indications and dosing regimens

Agent	Route	Indications	Adult dosing	Pediatric dosing	Geriatric dosing (≥65 years)	Indications for dose adjustment	
						Renal insufficiency	Hepatic insufficiency
Amantadine	Oral	Prophylaxis	100 mg p.o. b.i.d. during risk period	Use of amantadine among children aged < 1 year has not been evaluated adequately 1–9 years: 5 mg/kg per day in 2 divided doses; maximum daily dose, 150 mg/day ≥ 10 years and < 40 kg: 5 mg/kg per day in two divided doses; maximum daily dose, 200 mg/day ≥ 10 years and ≥ 40 kg: 100 mg twice daily	Maximum dose of 100 mg/day for prophylaxis or treatment For certain older persons, dose should be reduced further	CrCl 30–50 mL/minute: administer 200 mg on day 1, then 100 mg/day CrCl 15–29 mL/minute: administer 200 mg on day 1, then 100 mg on alternate days CrCl < 15 mL/minute: administer 200 mg every 7 days Hemodialysis: administer 200 mg every 7 days Peritoneal dialysis: no supplemental dose is needed Continuous renal replacement therapy: 100 mg once daily or every other day	No dosage adjustment
		Treatment	100 mg p.o. b.i.d.; discontinue within 3–5 days or within 24–48 hours after symptoms disappear	Refer to prophylaxis dosing	Refer to prophylaxis dosing	Refer to prophylaxis dosing	No dosage adjustment
Rimantadine	Oral	Prophylaxis	100 mg p.o. b.i.d. during risk period	Use of rimantadine among children aged < 1 year has not been evaluated adequately Children 1–9 years: 5 mg/kg per day in one to two divided doses; maximum dose, 150 mg/day Children ≥ 10 years who weigh < 40 kg: 5 mg/kg per day in two divided doses; maximum daily dose, 200 mg/day Children ≥ 10 years who weigh ≥ 40 kg and adults, 100 mg twice daily	Maximum dose of 100 mg/day, including elderly nursing home patients	CrCl ≥ 30 mL/minute: no dosage adjustment necessary CrCl < 30 mL/minute: maximum dose, 100 mg daily	Severe dysfunction: maximum, 100 mg daily
		Treatment	100 mg p.o. b.i.d. for 5 days	Refer to prophylaxis dosing	For persons in the community, a reduction in dosage to 100 mg/day should be considered if they experience side effects when taking a dosage of 200 mg/day For nursing home residents, dosage should be reduced to 100 mg/day	Refer to prophylaxis dosing	

(Continued on next page)

**TABLE 1** Antirespiratory virus agents approved in the United States: indications and dosing regimens (*continued*)

Agent	Route	Indications	Adult dosing	Pediatric dosing	Geriatric dosing (≥65 years)	Indications for dose adjustment	
						Renal insufficiency	Hepatic insufficiency
Oseltamivir	Oral	Influenza A and B viruses Prophylaxis	75 mg p.o. daily for 10 days (up to 6 weeks)	(Off-label) <3 months: not recommended unless situation judged critical because of limited data on use in this age group <sup>a</sup>  (Off-label) 3–11 months: 3 mg/kg per dose once daily for 10 days <sup>a</sup>  ≤15 kg: 30 mg p.o. once daily for 10 days  >15 kg to ≤23 kg: 45 mg p.o. once daily for 10 days  >23 kg to ≤40 kg: 60 mg p.o. once daily for 10 days  >40 kg: 75 mg p.o. once daily for 10 days	No reduction in dosage based on age; usually reduced based on renal impairment	CrCl >60 mL/minute: no dosage adjustment necessary CrCl >30–60 mL/minute: 30 mg once daily CrCl >10–30 mL/minute: 30 mg every other day ESRD not undergoing dialysis: use is not recommended IHD (CrCl ≤10 mL/minute): 30 mg after every other hemodialysis session for recommended prophylaxis duration CAPD: 30 mg once weekly for the recommended prophylaxis duration. Administer immediately after a dialysis exchange	Mild-to-moderate impairment (Child-Pugh score ≤9): no dosage adjustment necessary  Severe impairment: no dosage adjustment provided in manufacturer's labeling
		Treatment	75 mg p.o. b.i.d. for 5 days (up to 14 days)	(Off-label) <3 months: 3 mg/kg per dose once daily for 5 days (up to 14 days) <sup>a</sup>  (Off-label) 3–11 months: 3 mg/kg per dose once daily for 5 days (up to 14 days) <sup>a</sup>  ≤15 kg: 30 mg p.o. twice daily for 5 days (up to 14 days)  >15–23 kg: 45 mg p.o. b.i.d. for 5 days (up to 14 days)  >23–40 kg: 60 mg p.o. b.i.d. for 5 days (up to 14 days)  >40 kg: 75 mg p.o. b.i.d. for 5 days (up to 14 days)		CrCl >60 mL/minute: no dosage adjustment necessary CrCl >30–60 mL/minute: 30 mg twice daily for 5 days CrCl >10 to 30 mL/minute: 30 mg once daily for 5 days ESRD not undergoing dialysis: use is not recommended IHD (CrCl ≤10 mL/minute): 30 mg after every hemodialysis session for 5 days CAPD: 30 mg for one dose to provide a 5-day duration. Administer immediately after a dialysis exchange	

Zanamivir	Inhalational <sup>b</sup>	Influenza A and B viruses Prophylaxis (household) Prophylaxis (community)  Treatment	Two oral inhalations (10 mg) once daily for 10 days  Two oral inhalations (10 mg) once daily for 28 days  Two oral inhalations (10 mg) b.i.d. for 5 days	Household setting: children ≥ 5 years and adolescents, two inhalations (10 mg) once daily for 10 days; begin within 36 hours following onset of signs or symptoms of index case  Community outbreak: adolescents, two inhalations (10 mg) once daily for 28 days; begin within 5 days of outbreak  Children ≥ 7 years and adolescents: two inhalations (10 mg) twice daily for 5 days. Doses on first day should be separated by at least 2 hours; on subsequent days, doses should be spaced by ~12 hours. Begin within 2 days of signs or symptoms. Longer treatment may be considered for patients who remain severely ill after 5 days	No dosage adjustment	No dosage adjustment	No dosage adjustment
Peramivir	Intravenous	Influenza A and B viruses Treatment	300 mg (Japan) or 600 mg (U.S.) intravenously over 15–30 minutes one time only. May consider giving daily for five days in high risk or severely ill hospitalized patients.	28 days to 16 years: 10 mg/kg i.v. over 15–30 minutes one time only	No dosage adjustment	CrCl ≥ 50 mL/minute: no dosage adjustment necessary CrCl 30–49 mL/minute: 200 mg as a single dose CrCl 10–29 mL/minute: 100 mg as a single dose ESRD IHD: 100 mg as a single dose, administered after dialysis	No dosage adjustment
Ribavirin	Inhalational <sup>c</sup>	RSV	(Off-label) 2 grams (over 2 hours) every 8 hours <sup>d</sup>	Continuous aerosolization: 6 grams administered over 12–18 hours/day for 3–7 days  Intermittent aerosolization: 2,000 mg over 2 hours three times daily in nonmechanically ventilated patients for 3–7 days. Use of high-dose therapy in individuals with an endotracheal tube in place is not recommended	No dosage adjustment	No dosage adjustment	No dosage adjustment

<sup>a</sup>Osetamivir is not approved by the FDA for use in children aged <1 year. An Emergency Use Authorization (EUA) was issued by the FDA on April 28, 2009, but it expired on June 23, 2010.

<sup>b</sup>Intravenous formulation of zanamivir is not approved for use in the United States but may be made available through the Zanamivir Compassionate Use Program for qualifying patients for the treatment of serious influenza illness. For information, contact the GlaxoSmithKline Clinical Support Help Desk at 1-866-341-9160 or [gskclinicalsupportHD@gsk.com](mailto:gskclinicalsupportHD@gsk.com).

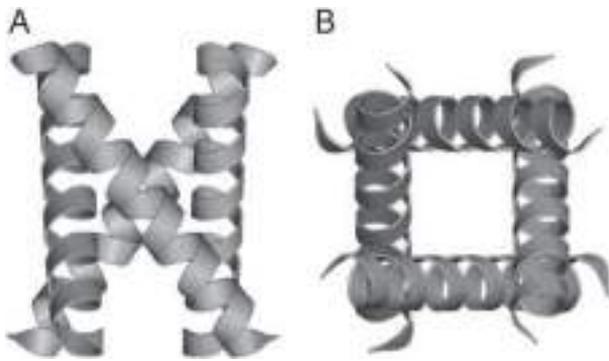

<sup>c</sup>Oral and intravenous formulations are not approved for RSV infection but are used off-label in immunocompromised or severely ill patients. Intravenous ribavirin can be authorized for use as a result of an Emergency Investigational New Drug (EIND) application as investigational treatment for patients with serious viral infections. For information, contact the Valeant Pharmaceutical U.S. medication information at (877) 361-2719.

<sup>d</sup>Aerosol inhalation formulation of ribavirin is not approved by the FDA for use in adults. Off-label use in those patients is often restricted to hematopoietic cell or heart/lung transplant recipients with RSV infection.  
p.o., per os; b.i.d., twice per day; CrCl, creatinine clearance; ESRD, end-stage renal disease; IHD, intermittent hemodialysis; CAPD, continuous ambulatory peritoneal dialysis; i.v., intravenous; RSV, respiratory syncytial virus.

**TABLE 2** Antirespiratory virus agents approved in the United States: pharmacokinetics, major toxicities, and drug interactions

Agent	Oral bioavailability (%)	Effect of food on AUC	$t_{1/2}$ (h) in adults	Major route of elimination	Major toxicities	Major drug interactions	Comments
Amantadine	90	No	12–18	Over 90% renally excreted unchanged	Neurotoxicity (e.g., lightheadedness, insomnia, seizures less common); nausea; livedo reticularis; orthostatic hypotension; urinary retention	Neurotoxic agents may potentiate amantadine neurotoxic effects; trimethoprim-sulfamethoxazole and triamterene hydrochlorothiazide decrease amantadine excretion. Avoid with QTc-prolonging agents	
Rimantadine	>90	No	24–36	Mainly hepatically metabolized; <25% renally excreted unchanged	Neurotoxicity (less compared to amantadine); nausea, vomiting	None	
Oseltamivir	>75	No	6–10	Hepatic metabolism to active form; renally eliminated	Nausea, vomiting; closely monitor for any neuropsychiatric symptoms in children Monitor for any serious skin and hypersensitivity reactions (e.g., Stevens-Johnson Syndrome, exfoliative dermatitis, or rash) Psychiatric effects (abnormal behavior and hallucinations)	None	Higher doses and longer courses may be used in critically ill patients
Peramivir	N/A	N/A	20	90% renally excreted unchanged	Diarrhea; ALT elevation; glucose elevation; CPK elevation; neutropenia (no difference incidence compared to placebo) Monitor for any serious skin and hypersensitivity reactions (e.g., Stevens-Johnson Syndrome, exfoliative dermatitis, or rash) Psychiatric effects (abnormal behavior and hallucinations)	None	No clinical benefit over oral oseltamivir. Use in patients who cannot tolerate oral medications (e.g., gastric stasis, gastrointestinal bleeding, or vomiting)
Zanamivir	4–17	N/A	2–5	Renal, unchanged	Inhaled: bronchospasm, decreased FEV <sub>1</sub> , rash, oropharyngeal edema, headache, cough, nasal symptoms i.v.	None	
Ribavirin	Inhaled: N/A Oral: 64%	N/A	9	Renal and hepatic	Bronchospasm, anemia, neurotoxicity; teratogenic, carcinogenic and mutagenic potential	Azathioprine: levels may be increased of azathioprine's active metabolite Didanosine: toxicity Zidovudine: may increase toxicity of ribavirin	

AUC, area under the curve;  $t_{1/2}$ , half-life; N/A, not applicable; ALT, alanine transaminase; CPK, creatine phosphokinase; FEV<sub>1</sub>, forced expiratory volume; i.v., intravenous.

**FIGURE 3** Schematic representation of the closed-state structure of the M2 protein channel by solid-state nuclear magnetic resonance (NMR) spectroscopy. Tetrameric assembly is shown from the side (A) and top (B). (Source: Nishimura K et al., *Biochemistry* 2002;41:13170–13177.) This image is cited as being in the public domain.

other symptoms by 24 to 48 hours (15). Its usefulness in reducing complications of influenza virus infection or in the management of established influenza A pneumonia is unproven.

### Rimantadine

Rimantadine (alpha-methyl-1-adamantane methylamine hydrochloride; Flumadine, Roflual) (Figs. 1 and 2; Tables 1 and 2) is a tricyclic amine that is closely related structurally to amantadine. It was approved for prophylaxis and treatment of influenza in the United States in 1993 (17).

### Spectrum of Activity

The activity of rimantadine is exclusively against influenza A viruses at clinically achievable drug concentrations. It is up to 10-fold more active *in vitro* than amantadine, with inhibitory concentrations ranging from 0.01 to 0.1  $\mu\text{g/ml}$  (18). Rimantadine has an inhibitory effect on flaviviruses at higher concentrations *in vitro*, but this has not been shown to correlate with clinical efficacy (19).

### Mechanism of Action

The mechanism of action of rimantadine against influenza A virus is identical to that of amantadine.

### Pharmacokinetics

Rimantadine, like amantadine, is well absorbed from the gastrointestinal tract, achieving a  $C_{\text{max}}$  of 0.4 to 0.5  $\mu\text{g/ml}$

after repeated dosing (20). Food does not affect the rate or extent of absorption. However, in contrast to amantadine, rimantadine is concentrated in nasal secretions at a maximal achievable ratio of 1.75:1 (21). The plasma elimination  $t_{1/2}$  of rimantadine is 24 to 36 hours, substantially longer than that of amantadine, and only 15% to 20% of an administered dose is excreted unchanged in the urine. The remainder is metabolized hepatically to *ortho*-, *para*-, and *meta*-hydroxy metabolites, which have 100- to 300-fold-less inhibitory activity than the parent compound (22), and then is excreted renally. Older individuals have higher plasma drug levels than young adults when given the same dosage of 200 mg/day. Thus, the dosage should be halved in individuals older than 65 years. In patients with advanced liver or renal disease, the dosage should also be reduced by 50%.

### Adverse Effects

The frequency of neurotoxic side effects is lower for rimantadine than amantadine, with treatment cessation rates in clinical trials averaging less than 5%. However, insomnia, minor cognitive difficulties, and, rarely, seizures have occurred. Minor gastrointestinal side effects (e.g., nausea) are common. Rimantadine should be avoided during pregnancy unless the potential benefit outweighs the risk (Pregnancy Category C). It is also excreted into human milk, and, therefore, should be avoided in nursing mothers. As with amantadine, any other drug with neurotoxic potential should be used with caution in rimantadine-treated subjects.

### Resistance

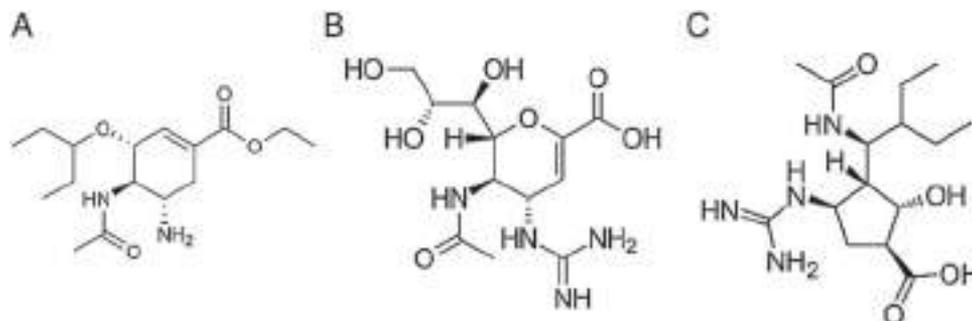

The mechanism of resistance to rimantadine is identical to that of amantadine (see above), and complete cross-resistance exists between these two agents. Amantadine- and rimantadine-resistant isolates remain susceptible to the neuraminidase inhibitors.

### Clinical Applications

Rimantadine has an efficacy comparable to that of amantadine for either prophylaxis or treatment of uncomplicated, susceptible influenza A virus infections. Rimantadine's improved side effect profile and patient tolerance make it the preferred agent for use in elderly and high-risk persons, when an adamantane is indicated. As with amantadine, rimantadine is currently not recommended for influenza treatment and prevention.

### Zanamivir

Zanamivir (5-acetylamino-4-[aminoiminomethylamino]-2,6-anhydro-3,4,5-trideoxy-d-glycero-d-galacto-non-2-enonic [o10] acid; Relenza) (Figs. 2 and 4; Tables 1 and 2), is an

**FIGURE 4** Molecular structures of the neuraminidase inhibitors oseltamivir (A), zanamivir (B), and peramivir (C).

influenza virus neuraminidase inhibitor that was approved in the United States for the treatment of influenza A and B virus infections in 1999 and for prophylaxis in 2006.

#### Spectrum of Activity

Zanamivir was the first approved drug of a class of antiinfluenza agents that potently and selectively reduce the replication of influenza A and B viruses through competitive inhibition of influenza virus neuraminidase activity. The mean zanamivir 50% inhibitory concentration values ( $IC_{50}$ s) for influenza virus neuraminidase were found to be 0.76, 1.82, and 2.28 nM for the subtype H1N1 (N1), H3N2 (N2), and B neuraminidase, respectively, in enzyme inhibition assays (23, 24). It has no activity against other viral neuraminidases or influenza C virus.

#### Mechanism of Action

Zanamivir was specifically designed to bind to the highly conserved active enzyme site of influenza virus neuraminidase (25). Neuraminidase is a surface glycoprotein that catalyzes cleavage of the terminal sialic acid residues attached to glycoproteins and glycolipids that are recognized by viral HA; this action is necessary for release of influenza virions from host cells and for spread of the virus through respiratory mucus. Inhibition of influenza virus neuraminidase by zanamivir and related neuraminidase inhibitors interferes with progeny virus dispersion and reduces infectivity. Zanamivir is a transition state analog of sialic acid that interacts somewhat differently than oseltamivir with viral neuraminidase and consequently has a different spectrum of antiviral activity.

#### Pharmacokinetics

Zanamivir is currently commercially available only as a dry-powder oral inhalation via a proprietary disk inhaler. Its absolute oral bioavailability is very low (4%), but an intravenous formulation has been developed and used clinically, although not licensed at present for this route of administration. Following a 10-mg inhaled dose of zanamivir, the majority of the drug is deposited in the oropharynx after inhalation, but approximately 13% reaches the lower respiratory tract (26). Less than 15% of the total dose is absorbed with resulting plasma  $C_{max}$  of about 40 to 50 ng/ml. The plasma elimination  $t_{1/2}$  varies from 2.5 to 5.1 hours, but high sputum concentrations persist up to 12 hours after the dose (27). Because so little is absorbed systemically, the increased drug exposure in individuals with severe renal impairment is not considered clinically relevant; no dosage adjustment is recommended for renal insufficiency or people older than 65 years of age. Elderly patients, especially those with cognitive impairment, may experience difficulty in using the inhaler device.

Intravenously administered zanamivir provides high levels in blood (mean  $C_{max}$  >39,000 ng/ml with repeated 600-mg doses), is distributed to the respiratory mucosa, and protects against infection and disease after challenge with experimental human influenza A virus (27).

#### Adverse Effects

Bronchospasm, decreased forced expiratory volume ( $FEV_1$ ), and decreased peak expiratory flow rates have been seen uncommonly in individuals treated with orally inhaled zanamivir. Severe respiratory distress, particularly in influenza-virus-infected patients with preexisting lung disease, has been associated with hospitalization, and rarely, death. As a result, zanamivir is not recommended in individuals with

underlying airway disease, although its use in influenza patients with mild or moderate asthma appears to be safe (28). The commercial lactose-containing formulation of inhaled zanamivir should not be used in mechanically ventilated patients because blockage of filters may occur (29). Adverse events include headache, bronchitis, nausea, vomiting, and diarrhea, all of which occurred in no more than 3% of treated subjects, comparable to the effects of placebo. Allergic reactions, including oropharyngeal edema and skin rashes, occur rarely with zanamivir.

Zanamivir may be administered to pregnant patients because available data suggest that neuraminidase inhibitors are not teratogenic (30–32) and the benefit of treatment outweighs the risk of influenza complications. Gravid rats given 1000 times the human dose of zanamivir delivered offspring with a variety of skeletal alterations; however, at lower doses, there were no malformations, maternal toxicity, or embryotoxicity observed in pregnant rats or rabbits receiving intravenous (i.v.) zanamivir. No increase in adverse pregnancy outcomes or fetal abnormalities has been observed in zanamivir-exposed pregnant women to date (33). Zanamivir is excreted in breast milk in rats, but it is unknown if it is found in human milk.

#### Drug Interactions

Drug interactions with zanamivir are unlikely. Zanamivir is not an inducer or inhibitor of cytochrome P450 isoenzymes, is not metabolized by the liver, and does not affect drug metabolism in human liver microsomes. Protein binding is low. Inhaled zanamivir does not affect the humoral immune response to injected influenza vaccine but, if administered concurrently, could potentially interfere with immune responses to live-attenuated influenza vaccine.

#### Resistance

Clinical isolates resistant to zanamivir are very uncommon but have been found in immunocompromised individuals during zanamivir treatment (34). Prolonged treatment of one immunocompromised child with influenza B resulted in the emergence of a dual HA and neuraminidase mutant (position 152) virus with reduced sensitivity (35). An immunosuppressed child with influenza B virus infection had an aspartic acid-198/asparagine (Asp198Asn) substitution, with decreased sensitivity to both oseltamivir and zanamivir (36). In a Japanese study examining 74 children with influenza B virus infection who had received oseltamivir treatment, one had a viral isolate with decreased sensitivity to the neuraminidase inhibitors with a G402S substitution. Among 422 children and adults with untreated influenza virus infection, 7 had isolates with reduced susceptibility to oseltamivir and zanamivir with D198N, I222T, or S250E substitutions (37). During the first 3 years of neuraminidase inhibitor use, from 1999 to 2002, only two (<0.1%) influenza A (H1N1) viral isolates showed >10-fold-decreased susceptibility to zanamivir (38). Zanamivir resistance was not observed in other subtypes during the same period (39). Oseltamivir-resistant variants with H275Y in N1 and E119V in N2 neuraminidases remain sensitive to zanamivir; the R292K substitution in N2 or N9 confers reduced zanamivir susceptibility.

#### Clinical Applications

Inhaled zanamivir is effective in the treatment of uncomplicated influenza A and B virus infections if given within 48 hours of the onset of symptoms (40). Depending in part on time to initiating therapy, zanamivir reduces the duration of

symptoms by 1 to 3 days (40). Early treatment with orally inhaled zanamivir also reduces antibiotic usage in adults and adolescents with influenza (41), but there are insufficient data to establish that zanamivir treatment prevents serious complications of influenza or that it is safe and effective in treating severe influenza. Zanamivir, given at the usual adult dosage of 10 mg twice daily, is safe and effective in children aged 5 to 12 years. Because of a low estimated treatment effect and inadequate inhalation technique in children aged 5 to 7 years, zanamivir treatment is approved by the FDA only for children older than 7 years. Zanamivir prophylaxis is approved for children older than 5 years.

The protective efficacy of zanamivir has been approximately 79% in studies of postexposure prophylaxis (41). Postexposure prophylaxis with zanamivir for amantadine-resistant influenza A virus has also been demonstrated to be safe and efficacious (42). Because zanamivir therapy does not affect antibody responses to injected influenza vaccination, it may safely be given in combination with inactivated vaccine for immediate protection of at-risk persons (43).

Concerns exist about the effectiveness and safety of orally inhaled zanamivir in treating severe influenza, particularly with respect to effective delivery to sites of infection in the lower respiratory tract. Nebulized zanamivir lacking the lactose carrier has received clinical study and use (44, 45). In animal models and *in vivo*, zanamivir is active against influenza A (H5N1) virus, including highly oseltamivir-resistant strains with the H275Y substitution; however, use of zanamivir for A (H5N1) in humans has not been assessed directly (46).

At this time, *i.v.* zanamivir is only available as an investigational agent in the United States. In an open-label study, *i.v.* zanamivir was generally well tolerated and appeared to be associated with antiviral effects in critically ill patients (47). A Phase III randomized controlled trial found no significant difference between *i.v.* zanamivir and oseltamivir in regard to time to clinical response (48). However, *i.v.* zanamivir is generally well-tolerated and remains of clinical investigative interest, in part because its spectrum of activity includes many oseltamivir-resistant variants. For hospitalized patients infected with oseltamivir-resistant influenza virus (e.g., [H1N1] pdm09 virus), *i.v.* zanamivir can be obtained under an emergency Investigational New Drug (IND) (Table 1).

### Oseltamivir

Oseltamivir [ethyl(3R,4R,5S)-4-acetomido-5-amino-3-(1-ethylpropoxy)-1-cyclohexene-1-carboxylate; Tamiflu] (Figs. 1 and 3; Tables 1 and 2), is a neuraminidase inhibitor that was approved for treatment of influenza in the United States in 1999 and for prevention of influenza in 2000. It is registered in more than 100 countries and, as of April of 2014, had been used in more than 130 million patients since introduction (49).

### Spectrum of Activity

Oseltamivir carboxylate is a potent competitive inhibitor of influenza virus neuraminidase activity. It is specific for influenza A and B virus neuraminidases, and no clinically relevant activity is seen against other viral neuraminidases. Differences in levels of susceptibility to oseltamivir have been demonstrated among influenza A and B viruses, with a lower inhibitory effect on influenza B viruses. In one study, the mean  $IC_{50}$ s for influenza A virus clinical isolates in neuraminidase inhibition assays ranged from 0.67 to 1.53 nM, whereas the mean  $IC_{50}$ s for influenza B virus

clinical isolates varied from 10.01 to 11.53 nM (50). Similarly, in another study, the median  $IC_{50}$ s for influenza A virus H1N1 and H3N2 strains were 0.45 and 0.37 nM, respectively, while the median  $IC_{50}$  for influenza B virus was 8.50 nM (51). These differences in susceptibility may explain the reduced efficacy of oseltamivir in treating influenza B virus infection in children (52).

Whether oseltamivir has direct immunomodulatory effects is unresolved. One animal model study showed that oseltamivir decreased  $CD8^+$  T-cell-mediated immunity to RSV infection, perhaps by blocking endogenous sialidase activity in host lung mononuclear cells, and delayed RSV clearance (53), but the clinical relevance of this finding is unclear.

### Mechanism of Action

Oseltamivir is the orally available ethyl ester prodrug of oseltamivir carboxylate, a highly potent influenza virus neuraminidase inhibitor. The carboxylate is a carbocyclic transition state analog of sialic acid that binds to conserved residues within the active sites of influenza A and B virus neuraminidases and dissociates very slowly, effectively inhibiting enzymatic function (53). In preclinical studies, influenza virus neuraminidase has been reported to cleave sialic acid from pulmonary cells to expose receptors for *Streptococcus pneumoniae* adherence. Neuraminidase inhibitors can inhibit this effect and reduce the mortality of secondary bacterial pneumonia in such models (54).

### Pharmacokinetics

After oral administration, oseltamivir phosphate (the inactive prodrug) is readily absorbed from the gastrointestinal tract and converted to its active carboxylate metabolite with a bioavailability of at least 75%. The carboxylate is detectable in plasma within 30 min of administration, and reaches a  $C_{max}$  of 348 to 551 ng/ml within 3 to 4 hours of a standard 75-mg dose. Administration of food has no significant effect on peak levels and has the advantage of reducing the risk of adverse gastrointestinal effects. In rat models, peak levels of drug within the bronchoalveolar-lining fluid are approximately the same as those in plasma and decline more slowly (55). Oseltamivir and the carboxylate have very low penetration into the CNS with a mean observed  $C_{max}$  of 2.4 ng/ml for oseltamivir and 19 ng/ml for oseltamivir carboxylate in the CNS (56). Oseltamivir phosphate is rapidly converted by esterases into its active metabolite in the liver. Neither oseltamivir phosphate nor carboxylate interacts with cytochrome P450 mixed-function oxidases or glucuronosyltransferases (57).

The active metabolite is cleared unchanged by glomerular filtration and active tubular secretion in the kidneys, with a  $t_{1/2}$  in plasma of 6 to 10 hours in healthy young adults. Because clearance of the drug depends on renal function, individuals with a creatinine clearance less than 60 ml/minute or on hemodialysis (HD) should receive a lower dose (57). Exposure to both oseltamivir and its active metabolite is increased in elderly patients by approximately 25%, but no dose adjustment is necessary for this group because of the drug's relatively benign safety profile. In persons with mild and moderate hepatic disease, the  $C_{max}$  of oseltamivir was  $\leq 6\%$  lower in persons with hepatic impairment than that in healthy subjects, whereas the  $C_{max}$  of oseltamivir carboxylate was  $\leq 19\%$  lower (58). The mean area under the curve (AUC) of oseltamivir was 33% higher than that in healthy subjects, whereas the mean AUC of the active metabolite was  $\leq 19\%$  lower. Consequently, no dose adjustment of

oseltamivir is needed routinely in persons with hepatic impairment. Polymorphisms affecting oseltamivir pharmacokinetics have been described *in vitro*, but are thought to be of low clinical significance in humans (59).

### Adverse Effects

Oseltamivir is generally well tolerated. The most common adverse effects are nausea and vomiting, which occur in 3% to 15% of subjects (57). Abdominal pain, dizziness, and headache were reported to occur in 2% to 20% of subjects, rates comparable to those for patients given placebo (57). Most of these adverse effects resolve after 1 to 2 days of treatment (59). Administration of oseltamivir with food decreases the risk of gastrointestinal side effects. Serious reactions such as aggravation of diabetes, arrhythmia, confusion, seizures, orofacial edema, toxic epidermal necrolysis, and unstable angina occur with a frequency of less than 1%, although a direct causal relationship has not been proven (60).

Serious neuropsychiatric adverse events related to oseltamivir therapy in adolescents were reported in Japan in 2007, prompting Japanese authorities to recommend against prescribing oseltamivir to persons aged 10 to 19 years in that country. In November 2007, the U.S. FDA recommended that revised precautions about serious neuropsychiatric events associated with pediatric oseltamivir use be included in package labeling for the drug. Physicians are advised to monitor patients closely for symptoms of abnormal behavior during oseltamivir treatment and to assess the risks and benefits of continuing therapy in patients who develop these symptoms. In a 2011 publication, the Japanese Ministry for Health, Labour and Welfare issued a preliminary analysis concluding no causal relationship between oseltamivir therapy and occurrence of severe neuropsychiatric events. An American Academy of Pediatrics publication described the incidence of these events to be in the range of 1 in 10,000 to 100,000 treatment courses and with uncertainty regarding whether the effects are from oseltamivir, influenza virus illness, or an interaction of the two (61). Similar types and rates of adverse effects were found in high-risk populations, such as those who have undergone hematopoietic stem cell transplantation and the frail elderly (59).

Pregnant women have a higher risk of complications due to influenza. According to the U.S. CDC, oseltamivir is the preferred treatment agent in pregnant women; treatment should be started as soon as possible after the onset of illness, and prophylaxis should be considered after exposure to influenza (13). In a rabbit model, a maternal dosage of 150 to 500 mg/kg per day resulted in a dose-dependent increase in minor skeletal abnormalities. Studies to date have not found evidence for adverse pregnancy outcomes or teratogenic effects in humans (62–64). Oseltamivir has been detected in breast milk of lactating women, but concentrations were low and unlikely to lead to toxicity in infants (65).

### Drug Interactions

Neither oseltamivir nor its carboxylate interacts with cytochrome P450 enzymes. Both compounds have low protein binding. Coadministration of oseltamivir with cimetidine, an inhibitor of cytochrome P450 and competitor for renal tubular excretion, resulted in no effect on the levels of oseltamivir or its metabolite in plasma. Probenecid coadministration results in a 2-fold increase in oseltamivir exposure, but no dose adjustments are required due to the safety margin of oseltamivir. One *in vitro* study suggested that concurrent clopidogrel may reduce the antiviral activity of oseltamivir

by inhibiting its hydrolysis to the carboxylate form; the clinical relevance of this effect is unproven (66).

### Resistance

Oseltamivir treatment may result in the development of neuraminidase active-site substitutions that decrease neuraminidase binding affinity for oseltamivir carboxylate and confer reduced susceptibility. Various neuraminidase substitutions have been recognized in clinical isolates, most commonly R292K or E119V in A (H3N2) and A (H7N9) viruses, H275Y in A (H1N1) and A (H5N1) viruses, N294S in A (H5N1) virus, and D198N or I222T in B virus (67). The H275Y substitution, found in N1-containing viruses, confers highly reduced susceptibility to oseltamivir (>400-fold higher 50% effective concentration [EC<sub>50</sub>] in enzyme inhibition assays), but not to zanamivir (68).

Global surveillance results from the Neuraminidase Inhibitor Susceptibility Network during the first 3 years of clinical use of the drug class showed a >10-fold decline in oseltamivir susceptibility in 8 (0.33%) of 2,287 influenza virus clinical isolates. None of these isolates were from persons who had previously received treatment with neuraminidase inhibitors (38). However, during the 2007–2008 season, influenza A (H1N1) viruses with an H275Y substitution emerged and spread globally to replace susceptible strains in the apparent absence of selective drug pressure, in part because of enabling amino acid changes in the neuraminidase that conferred fitness (69). Emergence of resistance in the pandemic A (H1N1) 2009 virus has been much less common, although its prevalence has increased recently and sometimes has been associated with community transmission (70–73). Data from the 2014–2015 influenza season revealed that >98% of A (H1N1) pdm09 strains were susceptible to oseltamivir and peramivir and 100% were susceptible to zanamivir (13).

Emergence of oseltamivir resistance during treatment occurs more frequently in children than in adults (74) and is a particular risk in immunocompromised hosts (75). This may be explained by higher viral titers and longer periods of viral shedding in children (10) and immunocompromised hosts. Most influenza viruses resistant to oseltamivir have mostly remained susceptible to zanamivir and laninamivir, a related investigational neuraminidase inhibitor, but are variably susceptible to peramivir (10).

The H275Y substitution has also emerged in two of eight influenza A (H5N1) virus-infected patients given oseltamivir, both of whom died (76). Emergence of neuraminidase R292K substitution was found in two patients with influenza A (H7N9) virus, resulting in reduced susceptibility to zanamivir and especially oseltamivir though notably, these patients were also receiving corticosteroids (77).

### Clinical Applications

Oseltamivir is approved for treatment and prophylaxis of influenza in adults and children (at least 2 weeks of age for treatment and at least 1 year of age for prophylaxis). Oseltamivir is effective for treatment of influenza A and B virus infections in ambulatory adults if given within 36 hours of the onset of symptoms and in children if given within 48 hours or perhaps longer (78). Treatment reduces the risk of complications leading to antibiotic use, including otitis media and perhaps pneumonia in children (79). Oseltamivir treatment of influenza in outpatients is associated with a lower rate of lower respiratory tract complications, necessitating antibiotic therapy and a lower rate of hospitalization (60).

Observational studies in seasonal influenza, pandemic 2009 A (H1N1) pdm09, and avian A (H5N1) infections indicate

that timely oseltamivir therapy can reduce mortality in seriously ill patients. Prompt initiation of oseltamivir reduced risk of mortality, intensive care unit (ICU) admission, and respiratory failure in patients infected with pandemic H1N1 2009 influenza, including pregnant women and immunocompromised hosts both in adults and children (59,80–82). During the 2009 H1N1 pandemic, multiple studies showed that oseltamivir use within 48 hours of illness onset resulted in a shorter duration of viral shedding compared to treatment at a later stage of illness (83–85). However, double-dose oseltamivir therapy does not appear to be more effective than standard dose in hospitalized patients, except possibly in influenza B (86).

For influenza A (H5N1) infection, a survival benefit was observed in persons with oseltamivir treatment compared to those with no treatment (29% to 67% survival rate, versus 0% to 33%). Factors associated with poor prognosis were late initiation of treatment and persistence of viral replication after completion of standard therapy. It is unclear if severe diarrhea and gastroparesis experienced by persons with A (H5N1) infection affect drug absorption and bioavailability (87). A standard 5-day course of oseltamivir is advised. Modified treatment options, such as higher dosages of oseltamivir (150 mg twice daily in adults), prolonged duration (course increased to a total of 10 days), and combination regimen with the adamantanes, should be decided on a case-by-case basis (87).

Postexposure prophylaxis of household contacts with oseltamivir (75 mg once daily) is protective, with an efficacy of 89% (88). Long-term prophylaxis with oseltamivir (75 mg once or twice daily) for 6 weeks during peak influenza virus activity resulted in a protective efficacy of 74% to 82% in adults, depending upon the rate of influenza virus infection in the area, and up to 92% in elderly residents of nursing homes (89, 90). Oseltamivir therapy does not appear to interfere with antibody responses to natural infection or influenza vaccination.

### Peramivir

Peramivir (BCX-1812; Rapivab) (Figs. 2 and 4; Tables 1 and 2) is a novel cyclopentane compound that inhibits influenza virus neuraminidase. Its parenteral formulation makes peramivir an important addition to the class in hospitalized patients when oral absorption is compromised. Prior to FDA approval for uncomplicated influenza in adults in the United States in 2014, it was used under emergency authorization in adults and children with serious influenza A (H1N1) pdm09 infection (91–93).

### Spectrum of Activity

Peramivir has *in vitro* activity against both influenza A and B viruses (94), including avian influenza A (H5N1) and A (H7N9). Peramivir shares structural similarities with oseltamivir and generally has a comparable *in vitro* spectrum of activity, although with somewhat greater inhibitory effects for influenza B neuraminidases. The median neuraminidase inhibitory activities ( $IC_{50}$ s) of peramivir are 0.16 nM (range 0.01–1.77 nM) against A (H1N1), 0.13 nM (range 0.05–11 nM) for A (H3N2), and 0.99 nM (range 0.04–1.77 nM) against influenza B viruses (95).

### Mechanism of Action

Peramivir shares the same basic mechanism of action as zanamivir and oseltamivir. The drug has a strong affinity for influenza neuraminidase as well as a slow off rate. This feature and its pharmacokinetic properties enable one-time dosing in uncomplicated infections (96).

### Pharmacokinetics

Following a single i.v. dose of 600 mg over 30 minutes, an average  $C_{max}$  of 46,800  $\mu$ g/mL is reached at the end of infusion. The pharmacokinetic parameters indicate a linear relationship between dose and  $C_{max}$  and AUC for doses ranging from 100 to 800 mg (96). *In vitro* protein binding is less than 30%.

Peramivir is eliminated primarily by glomerular filtration, with more than 90% of the drug excreted unchanged in the urine. Following a single infusion, plasma elimination of the agent follows a multiexponential decline with a mean residence time of approximately 3 hours; the terminal half-life for the slow phase of elimination is approximately 20 hours (97). The dose should be reduced in patients with a creatinine clearance less than 50 ml/min. Peramivir is removed by dialysis with systemic exposure reduced by 73% to 81% after a 4-hour HD session (97). Peramivir has not been evaluated in patients with liver disease, but is not anticipated to accumulate in such cases because it is not metabolized hepatically (98). Peramivir is not a substrate for CYP enzymes or P-glycoprotein-mediated transport and does not affect glucuronidation. There are no reported drug interactions.

### Adverse Effects

In clinical studies, adverse events reported in subjects receiving peramivir included diarrhea, alanine transaminase (ALT) elevation, glucose elevation, creatine phosphokinase (CPK) elevation, and neutropenia. The incidence rates of these effects were similar in study participants receiving placebo. Serious skin and hypersensitivity reactions (Stevens-Johnson syndrome, exfoliative dermatitis, and rash) as well as psychiatric effects (abnormal behavior and hallucinations) have been observed in postmarketing experience in Japan (94). Other serious but rare adverse events possibly associated with peramivir administration include severe thrombocytopenia (99) and exacerbation of myasthenia gravis (100).

No well-controlled studies of peramivir have been conducted in pregnant women, but reproductive studies in rats and rabbits have demonstrated potential developmental toxicities, including abortion, premature delivery, and fetal anomalies, such as reduced renal papilla and dilated ureters (95). Given that, the agent should generally be avoided during pregnancy unless the potential benefit outweighs these risks (Pregnancy Category C). The drug has not been studied in nursing mothers, but data from rats indicate that the agent is excreted in milk at levels below the mother's plasma drug concentration levels (95, 98).

### Resistance

Influenza A and B virus isolates with reduced susceptibility to peramivir have been observed in cell culture and *in vivo*. Reduced susceptibility may be conferred by amino acid substitutions (including H275Y in influenza A [H1N1] as well as R292K and N294S in influenza A [H3N2]) in viral neuraminidase (95). These isolates with reduced susceptibility have been identified in community surveillance studies, including patients who have not been exposed to peramivir (95). In 2014, a community cluster of influenza A (H1N1) pdm9 with an H275Y substitution was found to exhibit cross-resistance among oseltamivir and peramivir in 6 patients (101). This resistance substitution has also emerged during i.v. peramivir use in immunocompromised hosts (102).

### Clinical Applications

In the United States, peramivir is approved for the treatment of acute uncomplicated influenza in patients 18 years and

older who have been symptomatic for no more than 2 days. In two double-blind, placebo-controlled studies of adults with acute, uncomplicated pneumonia (101, 103) an integrated analysis showed that peramivir offered a reduction in time to alleviation of symptoms compared to placebo (113.2 hours vs. 134.8 hours; unadjusted  $P=0.047$ ). The duration of fever was also shortened by approximately 24 hours ( $P=0.004$ ) (103). Despite these results, a subsequent Phase II multicenter, randomized, placebo-controlled study of intramuscular (i.m.) peramivir (104) failed to show a difference in time to alleviation of symptoms between the study drug and placebo (91.1 hours vs. 106.9 hours, respectively,  $P=0.22$ ) (105). These results have been attributed to a high prevalence of influenza A (H1N1) with the H275Y substitution conferring resistance to peramivir (105).

Peramivir i.v. has also been evaluated in both outpatients and in those hospitalized with influenza (94, 96, 106). A multicenter, Phase III study performed in Korea, Japan, and Taiwan comparing single-dose i.v. peramivir (either 300 mg or 600 mg) to 5 days of oral oseltamivir in outpatients with uncomplicated influenza found similar times to alleviation of symptoms across all study groups (106). A Phase II study of 122 hospitalized patients with influenza randomized to receive one dose of i.v. peramivir (200 mg or 400 mg) or standard oseltamivir revealed no significant difference in time to clinical stability between groups (107). An interim analysis of a Phase III study comparing hospitalized patients with suspected influenza to either peramivir (600 mg i.v. once daily for 5 days) or placebo also showed no significant improvement in time to clinical resolution (42.5 hours vs. 49.5 hours, respectively,  $P=0.97$ ) (94). These results prompted early termination of the trial, and the agent has not been approved for this patient population. Despite these findings, there remain few options for hospitalized patients who are critically ill and cannot tolerate oral medications. In such circumstances, a longer course of daily peramivir may be appropriate (94). As there are not clinical trials directly comparing i.v. peramivir with i.v. zanamivir, the optimal agent and duration of therapy remains unclear.

## RESPIRATORY SYNCYTIAL VIRUS

### Palivizumab

Palivizumab (Synagis) is a humanized monoclonal antibody directed against an epitope in the A antigenic site on the F surface protein of respiratory syncytial virus (RSV). It is approved for the prevention of serious lower respiratory tract disease caused by RSV in high-risk pediatric patients. In a large, randomized, multicenter trial including over 1,500 high-risk patients, palivizumab prophylaxis resulted in a 55% reduction in hospitalization as a result of RSV (107). The American Academy of Pediatrics (2014) recommends RSV prophylaxis with monthly palivizumab (up to five doses) during RSV season for infants born before 29 weeks or patients who qualify on the basis of congenital heart disease or chronic lung disease of prematurity (109). In terms of safety, fever, rash, injection site reactions, and transaminitis are possible, but very few serious adverse events have been reported, and only 0.05% of patients experienced a hypersensitivity reaction deemed possibly or probably related to palivizumab (108, 110).

### Ribavirin

Ribavirin (1- $\beta$ -D-ribofuranosyl-1,2,4-triazole-3-carboxamide, Virazole) (Fig. 5; Tables 1 and 2) is a synthetic nucleoside

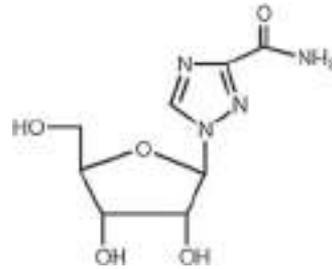

FIGURE 5 Molecular structure of ribavirin.

analog of guanosine approved in the United States in 1980 for treatment of RSV infections in hospitalized infants and young children, particularly those with severe lower respiratory tract RSV and underlying compromising conditions (e.g., prematurity, cardiopulmonary disease, or immunosuppression). In its oral form, it is approved for use in combination with interferon- $\alpha$  (IFN- $\alpha$ ) for treatment of hepatitis C virus (HCV) (see Chapter 13 on Antih hepatitis Virus Agents). It is available in oral formulations and solution for inhalation, as well as an investigational intravenous formulation.

Inhaled ribavirin (Virazole) results in plasma concentrations ranging from 0.44 to 1.55  $\mu$ M (with a mean concentration of 0.75  $\mu$ M) when given via face mask for 2.5 hours daily for 3 days and has a half-life of 9.5 hours (Virazole prescribing information). Reported adverse effects include nausea, headache, worsening of bronchospasm, rash, and conjunctivitis, as well as precipitation on contact lenses (111).

Ribavirin is well known to be teratogenic and contraindicated in pregnancy; therefore, health care workers and pregnant women should be protected against exposure. It has been found to cause congenital anomalies of limbs, ribs, eyes, CNS, and death in offspring of rodents (112).

Controversy exists about the role of ribavirin for treatment of lower respiratory tract RSV infections in children (see Chapter 37 on RSV), because studies have not consistently shown virologic and/or clinical benefit in recipients and some have been criticized for design flaws (113). Ribavirin is also used to treat serious RSV infections in immunocompromised adults. Inhaled ribavirin has been found to decrease progression of upper respiratory tract disease to lower respiratory tract disease and mortality in adult hematopoietic cell transplant patients compared to no therapy (114). Either oral or inhaled forms of ribavirin may prevent progression of RSV infections from the upper respiratory tract to lower respiratory tract in bone marrow transplant patients (114, 115).

In addition to its systemic use in several viral hemorrhagic fevers (hantavirus hemorrhagic fever with renal syndrome, Lassa fever, Crimean-Congo hemorrhagic fever, Rift Valley fever), systemic ribavirin has been used in treatment of a number of respiratory viral infections, including influenza virus, parainfluenza virus, measles virus, and adenovirus, but its effectiveness remains unclear in these situations. Following encouraging initial reports, a controlled study of the oral triple-drug regimen of ribavirin, amantadine, and oseltamivir is progressing in influenza virus infection (116, 117). Ribavirin is active against human metapneumovirus *in vitro* and in animal studies, and one case report indicated a favorable outcome with i.v. ribavirin treatment in a lung transplant recipient with human metapneumovirus pneumonia complicated by respiratory failure and sepsis (118).

**TABLE 3** Selected investigational (in the United States) antirespiratory virus agents in clinical development

Agent	<i>In vitro</i> spectrum	Mechanism of action	Stage of development in United States	Comments
Favipiravir (T-705)	Influenza A and B, many others including various filo-, flavi-, arena-, bunya-, alpha-, and enteroviruses	RNA polymerase inhibitor	Approved in 2014 in Japan only for outbreaks of novel or re-emerging influenza strains in which other influenza drugs are not effective or insufficiently effective. Phase III completed in 2016 in United States. Results pending	Oral administration. Phase II trial showed good tolerability and both antiviral and clinical efficacy in uncomplicated illness. Results of Phase III not yet published. Active against influenza strains resistant to current antiviral drugs and emerging strains such as A (H1N1) pdm09, A (H5N1), and A (H7N9) avian virus. Potentially synergistic with oseltamivir. Teratogenic in multiple species, contraindicated in pregnancy. Hyperuricemia. No data in severe influenza or children.
JNJ-872 (formerly VX-787)	Influenza A	Polymerase (PB2) inhibitor	Phase II	Oral administration associated with dose-related antiviral effects in experimental human influenza. Synergistic with NAIs in preclinical models. Phase II studies in uncomplicated illness and in combination with oseltamivir in hospitalized patients in progress.
Laninamivir (CS-8958)	Influenza A and B	Neuraminidase inhibitor (long acting)	Approved in Japan since 2010 for therapy and subsequently prophylaxis. In the United States, Phase II trial in adults with influenza A/B is completed	Long-acting NI (LANI) delivered by oral inhalation. Antiviral spectrum similar to zanamivir. In Japan, approved as single-day dosing for therapy. In the United States, the Phase II trial failed to achieve statistically significant primary endpoint of symptom alleviation in uncomplicated disease.
Nitazoxanide	Influenza A and B, many others including various flavi-, hepadna-, retro-, reo-, and caliciviruses.	Blocks the maturation of viral hemagglutinin at the post-translational level	Phase III trial completed	Phase II study found reduced symptom duration and antiviral effects in uncomplicated illness. Phase III trial as monotherapy and in combination with oseltamivir completed; results pending.
DAS-181	Influenza A and B, parainfluenza and enterovirus EV-D68	Sialidase that removes host cell sialic acid receptors	Phase IIb for uncomplicated influenza Phase II for severe parainfluenza in immunocompromised patients	Delivered by inhalation. Modest antiviral and nonsignificant clinical effects in uncomplicated influenza. Case reports of antiviral activity and clinical benefit in severe PIV illness in transplant recipients; adequate tolerability.
Verdinexor (KPT-335)	Influenza A and B	Selective inhibitor of nuclear export. XPO1 antagonist	Phase I	Oral administration. Phase I completed, results pending.
AVI-7100	Influenza A	Interference with expression of the M1 and M2 genes	Phase I	Phosphorodiamidate morpholino oligomer containing three modified linkages (PMOplus). Active after intranasal or intraperitoneal administration in ferret model of influenza. Intravenous administration in humans. Phase I estimated to be completed in November 2016.

(Continued on next page)

**TABLE 3** Selected investigational (in the United States) antirespiratory virus agents in clinical development (*continued*)

Agent	<i>In vitro</i> spectrum	Mechanism of action	Stage of development in United States	Comments
Presatovir (GS-5806)	RSV	Fusion inhibitor	Phase II	Oral administration. In healthy adults experimentally infected with RSV, early treatment resulted in significant reductions of viral load, mucus weight, and symptom scores. Currently in Phase II in hospitalized elderly patients, lung transplant recipients and HSCT recipients with upper or lower respiratory infections due to RSV. Treatment emergent F gene mutations conferring reduced susceptibility to presatovir occur.
JNJ-678	RSV	Fusion Inhibitor	Phase IIa	Oral administration. As of April 2016, two studies have been completed—a multiple ascending-dose study in infants infected with RSV and an experimental RSV infection in healthy adult; results pending.
ALX-0171	RSV	Fusion inhibitor	Phase I/IIa	Inhaled antibody/nanobody that inhibits RSV replication by binding the F protein. Currently in Phase I/IIa trial of healthy infants and toddlers with RSV-related LRTI.
BTA-585	RSV	Fusion inhibitor	Phase II	Selective and potent RSV fusion inhibitor <i>in vitro</i> (EC50 = 8.4 nM for RSV A2).
ALS-8176 (pro-drug of AL-8112)	RSV	Polymerase inhibitor	Phase II	Orally administered nucleoside analog. In healthy adults experimentally infected with RSV, early treatment resulted in significant reductions of viral load, mucus weight, and symptom scores. Currently in Phase II in adults and Phase I in infants hospitalized with RSV infection. High threshold to development of resistance.
ALN-RSV01	RSV	Small interfering RNA to N gene	Phase II	Intranasal delivery demonstrated significant antiviral activity against experimental RSV infection in adults. Phase II trials of inhaled siRNA in RSV infected lung transplant recipients found trends toward reduced BOS at 180 days.
Brincidofovir (CMX-001)	Adenovirus, CMV, HSV, VZV, EBV, HHV-6A, HHV-8, BKV, JCV, HPV	DNA polymerase inhibitor	Phase III	Orally administered lipid ester prodrug of cidofovir with greater potency and low risk for nephrotoxicity. Dose-limiting gastrointestinal side effects. Preliminary data from Phase III trial on adenovirus infection in immunocompromised patients showed decreased viremia and mortality. Failed primary endpoint for CMV in Phase III.
rIFN- $\beta$ (SNG001)	Rhinovirus, other respiratory viruses	Recombinant IFN- $\beta$ 1a	Phase II	Oral inhalation. A randomized, double-blind, placebo-controlled trial in asthmatics with a history of URTI-induced exacerbations reporting new URTI symptoms missed its primary endpoint (change in asthma symptoms assessed by an asthma control questionnaire) but reached this endpoint in subset of more severe asthmatics and resulted in better lung function and fewer severe exacerbations.
Vapendavir (BTA 798)	Rhinovirus, enterovirus (including polio)	Capsid inhibitor	Phase IIb	Orally administered twice daily. Initial Phase II study found trends toward fewer exacerbations in asthmatics with rhinovirus infections. Phase II trial of adult asthmatics with rhinovirus ongoing, estimated to be completed in August 2016.

NAI, neuraminidase inhibitor; PIV, parainfluenza virus; XPO1, exportin 1; RSV, respiratory syncytial virus; HSCT, hematopoietic stem cell transplantation; LRTI, lower respiratory tract infection; EC50, half-maximal effective concentration; BOS, bronchiolitis obliterans syndrome; CNV, cytomegalovirus; URTI, upper respiratory tract infection.

Oral ribavirin along with corticosteroids was used extensively as an empirical regimen during the early stages of the global outbreak of severe acute respiratory syndrome (SARS) caused by SARS-associated coronavirus, but was later shown to lack *in vivo* antiviral activity or to provide clinical benefit (119, 120). Combinations of interferons and oral ribavirin have been used in Middle East respiratory syndrome coronavirus (MERS-CoV)-infected persons with no clear evidence for benefit (121–123).

## INVESTIGATIONAL AGENTS

Research into new drugs against influenza is ongoing, but relatively few agents are in advanced stages of development (Table 3). These include the polymerase inhibitor favipiravir, which has activity against influenza viruses resistant to current classes of inhibitors as well as a number of other viruses (124–126), the polymerase PB2 inhibitor JNJ-872 (formerly VX-787) (126, 127), the long-acting neuraminidase inhibitor laninamivir, already approved in Japan but with an uncertain future in the United States due to mixed results in a Phase II trial (128, 129), and nitazoxanide, which is being studied as both monotherapy or in combination with oseltamivir (130–132) (Table 3).

Development of anti-RSV agents seems to be near a breakthrough, with several new agents showing promising results in proof-of-concept studies during the last few years. The most advanced of these in clinical development include presatovir, a F protein inhibitor (133), and ALS-8176, a nucleoside analog that inhibits viral polymerase with a high threshold for resistance (134–136) (Table 3). Meanwhile, the inhaled sialidase DAS-181 is being tested for severe parainfluenza virus infections (137, 138) and brincidofovir (139) for the treatment of invasive adenovirus infections in immunocompromised hosts. The capsid binder vapendavir (140) and inhaled IFN- $\beta$  (141) are also advancing in clinical trials for rhinovirus infections with focus currently on asthmatic patients. RNA interference (RNAi) targeting the N protein ALN-RSV01 has been evaluated in lung transplant recipients infected with RSV, with a particular focus on reducing development of chronic rejection in the form of bronchiolitis obliterans syndrome (142, 143).

Drug development for other respiratory viruses remains in the preclinical phase. GS-5734 is a RNA polymerase inhibitor shown to have not only therapeutic activity in rhesus macaques infected with Ebola virus but also *in vitro* activity against MERS and RSV (144).

The clinical development of monoclonal and polyclonal antibodies as therapeutic options against influenza and other respiratory viral infections shows much promise as well. A number of monoclonal antibodies targeting conserved epitopes on the HA stem have broad-spectrum neutralizing activities for influenza A viruses and are advancing in development. CR62621 is currently in Phase II in healthy volunteers infected experimentally with A (H1N1) pdm09 influenza virus. VIS410, which targets group 1 and 2 HAs, has shown therapeutic benefit for experimentally induced A (H1N1) pdm09 infection and is currently in Phase II trials (145–147). Among anti-HA stem monoclonal antibodies inhibitory for both group 1 and 2 HAs, MEDI8852 is in Phase Ib/IIa with or without oseltamivir and MHAA4549A (148) is currently in Phase II as monotherapy in uncomplicated influenza or in combination with oseltamivir for severe infections. One major concern with this approach is the potential for antibody-dependent enhancement of dis-

ease, but this has not been found in early clinical trials with MHAA4549A and VIS410 (126).

Among other viruses, the monoclonal anti-RSV antibody MEDI8897 has a lower EC<sub>90</sub> than palivizumab (126) and was found to be safe in Phase II (149). REGN222, a monoclonal antibody against RSV-F, was well tolerated in Phase II trials (150) and is currently in a Phase III study assessing the safety and efficacy in preventing RSV among preterm infants during RSV season. Polyclonal antibodies against MERS-CoV, derived from bovines genetically modified to produce large quantities of fully human polyclonal IgG antibodies, have been shown to be safe and effective for therapy and prevention in mice (151), with Phase II studies currently being planned. Developing effective neutralizing monoclonal antibodies against SARS-CoV has been challenging, in part due to emergence of escape variants, even with administration of dual combination monoclonal antibodies (152). Apart from monoclonal antibody therapy, several studies have supported the use of convalescent plasma and hyperimmune globulin for influenza (153, 154), RSV (155), and SARS-CoV (156). The role for such an approach remains unclear, but several influenza studies are ongoing. Please refer to the pathogen-specific chapters for RSV (Chapter 37), Coronaviruses (Chapter 52), and Influenza (Chapter 43).

# Diagnosis of Viral Infections

GUY BOIVIN, TONY MAZZULLI, AND MARTIN PETRIC

## 15

The clinical virology laboratory is an important and leading component of general microbiology that provides significant benefits to patient care. The traditional epidemiologic and academic reasons for diagnosis of viral infections have been expanded by rapid, often quantitative, assays that can impact on therapeutic management and public health decisions. This development is the result of many advances in diagnostic virology including improvement in cell culture (shell vial assays, mixed cell cultures, genetically engineered cell lines), availability of specific reagents such as monoclonal antibodies and, most importantly, the introduction of molecular techniques mostly based on polymerase chain reaction (PCR), which allow the sensitive and rapid detection of slowly growing or uncultivable viruses. The impact of the latter procedure is illustrated by the recent identification of several respiratory viruses including the human metapneumovirus (1), multiple coronaviruses including severe acute respiratory syndrome (SARS) (2) and Middle East respiratory syndrome (MERS) (3), human bocavirus (4), etc.

Apart from technological advances, the expanded role of the diagnostic virology laboratory can be also attributed to the increased pool of immunocompromised patients (e.g., HIV-infected individuals and transplant recipients) at risk of serious opportunistic viral infections and the increasing number of antiviral agents available for herpesviruses, HIV, influenza viruses, and hepatitis viruses. These factors have driven the development of rapid, sometimes point-of-care, diagnostic methods and new approaches including viral load measurement, antiviral drug susceptibility testing, and determination of viral genotypes and quasispecies.

Many laboratories now employ nucleic acid-based technologies as their main approach to virus diagnosis. Nevertheless, multiple methods for detecting virus infections remain in use in clinical laboratories. Viral culture, electron microscopy, histopathology, detection of viral antigens, and nucleic acids can be used to detect active viral infection, whereas serological testing is performed to assess the presence of virus-specific immune responses. Such diversity of methods has made it increasingly complex for physicians to request the appropriate procedure and to interpret the results. This necessitates excellent and frequent communication between the physician and the virology laboratory for the optimal use of diagnostic tests.

### SPECIMENS

The performance of viral diagnostic tests is strongly influenced by the quality of the specimen that is received in the laboratory. Detection of viral pathogens is highly dependent on three important variables: 1) obtaining an adequate specimen from the appropriate site; 2) proper timing of specimen collection relative to onset of symptoms; and 3) effective and timely processing of the specimen. The specimen site should be determined by the clinical syndrome and the suspected viruses. The specific procedures for collecting clinical specimens are addressed in clinical laboratory manuals (5). The physician should be aware that the selection of specific clinical specimens could strongly affect the performance of a diagnostic test. This is particularly true for the diagnosis of respiratory virus infections, where nasopharyngeal aspirates or nasal washes are generally preferred to nasal or throat swabs. Also, the type of materials used for specimen collection could have an impact on test results. For example, dacron or rayon swabs are recommended in the case of vesicular lesions, since both herpes simplex virus (HSV) and varicella-zoster virus (VZV) have been shown to be inactivated by cotton and calcium alginate swabs (6, 7). In addition, flocked swabs can retrieve more epithelial cells than fiber (rayon) swabs for the detection of respiratory viruses (8). In general, nucleic acid-based diagnostic tests, because of their increased sensitivity, are more robust in terms of specimen quality.

For many acute virus infections, viral shedding begins shortly before the symptoms occur, peaks rapidly after the onset of symptoms, and then declines steadily as the illness resolves. Thus, in general, specimens should be collected as soon as possible after the onset of symptoms. However, there are some exceptions, such as for SARS-coronavirus infections in which viral load in respiratory specimens peaked at week 2 after the onset of symptoms (9).

Transport to the laboratory should be accomplished as soon as possible after specimen collection to ensure integrity. This is a critical requirement for cell culture procedures which require viable viruses but may be less relevant for detection of viral antigens or nucleic acids. In general, nonenveloped viruses (e.g., adenoviruses, enteroviruses) are more stable than viruses surrounded by a lipid envelope (e.g., VZV and respiratory syncytial virus [RSV]). Specimens other than blood should usually be kept at 4°C (wet ice) during

transport, especially if transport will require more than one hour. If a delay of several days before testing is anticipated, the specimen should generally be frozen at a temperature of  $-70^{\circ}\text{C}$  or lower (dry ice). However, freezing in a standard freezer ( $-20^{\circ}\text{C}$ ) is generally associated with greater loss of infectivity than holding at  $4^{\circ}\text{C}$  for several days and should be avoided. Swabs and tissue specimens should be placed in a viral transport medium (VTM) to preserve the quality of the sample. Many VTM formulations exist, which generally contain a salt solution to ensure appropriate ionic concentrations, a buffer to maintain pH, a source of protein for virus stability, and antibiotics/antifungals to prevent microbial contamination. Some nucleic acid tests (NATs) have their own special VTM, which have been optimized for specific specimens.

Laboratories should receive specimens after proper storage and transport and with relevant clinical information either on an appropriate requisition form or electronically. Key information that should accompany the specimen includes sampling site, time of specimen collection, the diagnostic concerns of the physician (possibly with suspected virus[es]) and accurate identifying information for the patient.

## CELL CULTURE

All methods used for viral isolation require living cells because viruses are obligate intracellular parasites. Historically, the systems used to isolate viruses of medical importance consisted of laboratory animals, embryonated eggs, and cultured cells. However, most diagnostic virology laboratories no longer routinely perform viral isolation in either laboratory animals or embryonated eggs, but now rely solely on cell culture. Although it is gradually being replaced by immunologic and molecular methods that are either more rapid and/or more sensitive, cell culture retains the following advantages for viral diagnosis: 1) The method is relatively sensitive based on the inherent amplification of the virus during the replication process and is specific in that only the virus will be amplified; 2) viral culture has the potential to detect many different viruses if a sufficient number of sensitive cell lines are available to the laboratory. Therefore, one of the most important principles of designing a virus isolation protocol is the selection of cell lines that propagate important viruses from each sample type received by the laboratory; and 3) culture provides a viral isolate that can be further characterized if necessary (e.g., sero/genotyping, antiviral drug susceptibility testing).

There are also limitations to viral isolation for the diagnostic laboratory: 1) Certain viruses do not grow or grow very slowly in available cell lines so that the result is not clinically useful; 2) techniques for detecting a viral infection in lieu of virus isolation are more cost effective; and 3) successful isolation in cell culture depends on the viability of the virus in the specimen. However, several new approaches (enhanced cell culture) have shortened the time of virus isolation to more clinically useful timeframes and they will be discussed below.

### Standard Cell Cultures

The utility of cell culture for use in viral isolation was pioneered by two important discoveries. First was the work of Gey who developed monolayer cell culture techniques (10). This was followed by the work of Enders, Weller, and colleagues who demonstrated that vaccinia virus (11) and polioviruses (12) could be grown and detected in roller tube

cell cultures by characteristic cytopathic effects. Previously, the systems used for viral isolation had been either animal or embryonated egg inoculation. Following this landmark discovery, the number and type of cell lines that are useful for viral isolation have continued to expand and change.

The types of cell culture routinely used for viral isolation can be placed in one of three categories: primary cells, diploid (also called semi-continuous) cell lines, and heteroploid cell lines. Primary cells (e.g., monkey cells and chick embryo cells) are derived from tissue and have been propagated *in vitro* for the first time. These cells have the same chromosome number as the parental tissue and generally can only be subcultured once or twice. Diploid cell lines (e.g., human embryonic lung fibroblasts) develop during subculture of primary cells. A diploid cell line will consist of 75 to 100% of cells having the same karyotype as cells from the species of origin and can be subcultured 20 to 50 times prior to cell death. Heteroploid or continuous cell lines (e.g., HEp-2 and HeLa cells) exist as a population of cells with less than 75% of the population having a diploid chromosome constitution. The most important feature of this type of cell line is the ability of indefinite passages due to cell immortalization, which facilitates continuous access to cells for virus isolation. The two issues that have fostered the development of additional cultured cell lines for viral isolation are susceptibility (Table 1) and speed of replication (Table 2). Each cell culture type displays a differential susceptibility to each group or member of the virus families. Thus, multiple cell lines are required for a given sample type to detect the families of viruses capable of infecting a given organ system. In addition, isolation of viruses may not always use cell culture in monolayers. Suspension cultures of lymphocytes are used for isolation of retroviruses such as HIV-1 and 2, and several herpesviruses such as

**TABLE 1** Susceptibility of cell culture types to commonly isolated human viruses<sup>a</sup>

Culture type	Viruses propagated
<b>Primary</b>	
Monkey kidney	Influenza, parainfluenza, enteroviruses
Rabbit kidney	Herpes simplex
Human embryonic kidney	Enteroviruses, adenoviruses
<b>Diploid</b>	
Fibroblast	Cytomegalovirus, varicella-zoster, herpes simplex, adenoviruses, rhinoviruses, enteroviruses (some)
<b>Continuous</b>	
HEp-2	Respiratory syncytial, adenoviruses, herpes simplex, enteroviruses (some)
A549	Adenoviruses, herpes simplex, enteroviruses (some)
LLC-MK2	Parainfluenza, human metapneumovirus
MDCK	Influenza
RD (rhabdomyosarcoma)	Echoviruses
Buffalo green monkey kidney	Coxsackieviruses

<sup>b</sup>12 of these were also detected on day 2 by shell vial assay.

<sup>c</sup>462 additional isolates were detected on day 1 or 2 by shell vial assay.

<sup>d</sup>18 of these were detected on day 1 by fluorescent antibody (FA) staining.

<sup>e</sup>734 additional specimens were positive on day 1 by FA staining or enzyme immunoassay.

<sup>f</sup>61 additional specimens were positive on day 1 by FA staining.

<sup>g</sup>30 additional specimens were positive on day 1 by FA staining.

Epstein-Barr virus (EBV), as well as human herpes viruses 6 and 7 (HHV-6 and HHV-7).

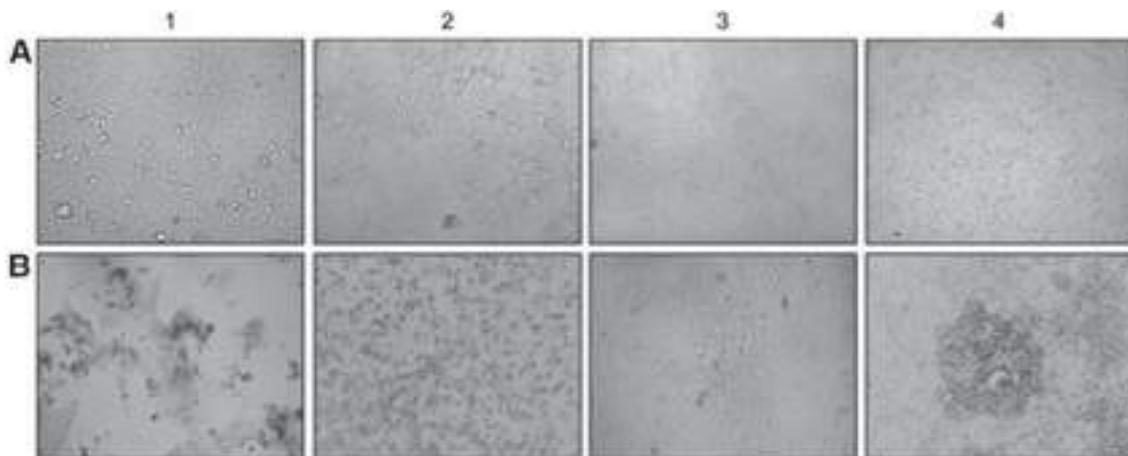

The cell culture systems used for viral isolation will, in general, depend on the type of specimen submitted to the laboratory. Traditionally, three cell types have been used for viral isolation: a primary cell culture such as a Rhesus monkey kidney, a diploid line such as a human embryonic lung, and a heteroploid line such as HEp-2. While this may still be a reasonable approach for some specimen types, it is no longer feasible or desirable for the isolation of all viruses. Due to cost and cell access considerations, some laboratories have replaced primary cells by a panel of continuous cell lines. It is also reasonable, both scientifically and financially, to use a single cell line when a specimen is submitted only for isolation of selected viruses such as HSV, cytomegalovirus (CMV), or VZV. The selection and types of cell cultures used in a laboratory offering virus isolation will depend on

many factors, including the clinical or epidemiological need for viral isolation, the common specimen types received, cost to prepare or purchase the needed cell lines, and the availability of experienced personnel.

The general procedure for viral isolation starts with the processing of the clinical specimen. In most cases, this consists of the addition of antibiotics to the sample prior to inoculation of the appropriate cell lines. Each cell culture to be inoculated should be visually inspected prior to inoculation and only recently prepared cells should be used since older cell cultures are less susceptible to virus replication. The standard tube used for cell culture is a 16 × 125 mm screw-capped tube. These tubes facilitate incubation following sample adsorption in either a roller drum or in stationary racks. In either case, the system must slant the tubes at a 5 to 7° angle. In general, the inoculated tubes are incubated at 35 to 37°C, but lower temperatures (33°C) facilitate the isolation of some viruses (e.g., rhinoviruses). Some laboratories have replaced tubes by microwell plates for cell culture, which facilitates the use of multiple cell lines for optimal recovery of several viruses.

### Cytopathic Effect

Each inoculated cell culture tube is examined with a light microscope to detect morphological changes typically daily for the first week and less frequently thereafter for up to 21 days. Morphological changes that are the result of viral replication are termed cytopathic effects (CPE). The observations of inoculated cell culture must be compared to sham-inoculated control monolayers from the same batch of cells. The CPE observed in cell culture may be characterized by the following: cell rounding, refractile cells, cell clumping, vacuolation, granulation, giant cells, syncytium formation, and cell destruction. The type of specimen, the cell line displaying CPE, and the type of CPE may be used as preliminary evidence for the identification of the replicating virus. For example, a respiratory sample inoculated into HEp-2 cells displaying large syncytia is consistent with the presence of RSV. A cerebrospinal fluid (CSF) inoculated into RD (rhabdomyosarcoma) cells displaying cell rounding and desintegration is consistent with an echovirus. A urine sample inoculated into fibroblast cells displaying isolated foci of swollen cells is consistent with CMV (Figure 1).

**FIGURE 1** Cytopathic effects induced by some viruses. Panel A shows uninfected cell lines including HEp-2 (1), RD (2), fibroblast (3), and Vero (4) cells. Panel B shows the same cell lines infected with respiratory syncytial virus (1), enterovirus (2), cytomegalovirus (3), and herpes simplex virus (4).

The replication of certain viruses in cell culture may not produce any CPE. The replication of these agents can be detected by alternative techniques such as hemadsorption or interference assays. Hemadsorption is commonly used to detect the replication of orthomyxoviruses and some paramyxoviruses. Cells infected by influenza viruses, parainfluenza viruses, mumps and measles viruses display viral glycoproteins (hemagglutinin, hemagglutinin-neuraminidase) on their plasma membrane as an integral part of the process of viral replication. The viral glycoproteins promote attachment of certain species of red blood cells (e.g., guinea pig erythrocytes) to the infected cell membrane. Hemadsorption can be observed with a light microscope and, like CPE, is preliminary evidence that one of these viruses is replicating in the cell culture. Some other viruses, notably rubella, can be detected by taking advantage of the phenomenon of interference. For instance, when rubella grows in primary monkey kidney cells, the latter become resistant to challenge with an echovirus type 2 strain.

Identifying a virus replicating in a cell culture is confirmed using more definitive criteria of reaction with monospecific or monoclonal antibodies. Generally, these reagents are chemically conjugated to fluorochromes so that the reaction with a specific antibody can be determined by fluorescent microscopy. The immunofluorescence technique can be either indirect or direct. The indirect technique uses an unconjugated primary antibody to react with the infected cells followed by a fluorochrome-conjugated secondary antibody usually directed against the species specificity of the primary antibody. The direct technique consists of the primary antibody that is conjugated to a fluorochrome so that only a single staining and washing of the infected cells is necessary. Alternatively, some virology laboratories may use monospecific or pooled antisera to prevent the infection of susceptible cells, a process known as neutralization. Most virology laboratories use an immunofluorescence microscopy method for viral identification, whereas the neutralization method is primarily used to determine enterovirus serotypes.

In some clinical situations, the process of observing cells for CPE and then confirming that the CPE can be attributed to viral replication occurs too slowly. Over the past few decades, several enhanced cell culture methods have facilitated more rapid detection of viral replication.

### Shell Vial Culture

The ability to detect viral infection prior to the development of CPE was first demonstrated with CMV (13). This method uses low-speed centrifugation to enhance the infection of human diploid embryonic fibroblast cells (MRC-5) in shell vials by CMV, followed by overnight incubation to establish the infection in which CMV-specific proteins assemble in the nucleus and, finally, detection of these by immunofluorescence microscopy after staining for an immediate early CMV protein. A shell vial is a vial containing a coverslip onto which a monolayer of cells has been grown. After centrifugation and incubation for 18 to 48 h, immunofluorescent staining is performed on the cells on the coverslip using monoclonal antibodies recognizing proteins that are expressed very early in the CMV replicative cycle. The speed and relative sensitivity of the shell vial system for CMV stimulated the application of shell vial systems for other viruses such as HSV, VZV, adenoviruses, and respiratory viruses. The detection of respiratory viruses requires inoculation of a greater number of shell vials with different cell types, increasing the incubation times, and using pools or cocktails of monoclonal antibodies capable of detecting each

respiratory virus. Each antibody in the pool for detecting respiratory viruses has a unique staining pattern that can be used as a means to give a preliminary identification of the virus present in the shell vial monolayer. A second shell vial can then be subsequently stained with a single monoclonal to confirm the preliminary identification.

### Mixed Cell Cultures

Viral isolation can be accomplished by using a shell vial cell culture with a mixture of cells in the monolayer. Such a mixture provides more susceptible cell types for a number of viruses, the low speed centrifugation enhances infectivity, and replication of the virus can be rapidly detected by immunofluorescence microscopy. The mixed cell systems have been developed to target viruses from specific types of specimen. The rapid respiratory virus mix, R-Mix (Quidel Corporation, San Diego, CA), is a combination of mink lung cells and A549 (human lung epithelial) cells (14) for detection of RSV, parainfluenza viruses, influenza viruses, and adenoviruses. An H&V-Mix is a combination of CV-1 (human kidney fibroblasts) and MCR-5 cells for detection of HSV, CMV, and VZV. The Super E-Mix is a combination of BGMK (buffalo African green monkey kidney) and A549 cells for detection of enteroviruses and other viral agents. The R-Mix with immunofluorescent staining performs comparably with either conventional tube culture or single cell shell vial culture with immunofluorescent staining but is generally more rapid (15). This system is a reasonable approach for laboratories that want to continue using shell vials for viral detection.

### Genetically Engineered Cell Lines

Genetically engineered cell lines to be used for virus isolation were first developed for HSV (16). A baby hamster kidney cell line (BHK-21) was stably transformed with an HSV-inducible promoter (UL39 gene) attached to a functional *E. coli* beta-galactosidase gene. Infection of this cell line by either HSV 1 or 2 (specifically HSV proteins ICP0 and VP16) induces beta-galactosidase enzyme activity. Addition of a substrate, X-gal, for this enzyme results in the formation of a colored product in HSV-infected cells. This system is commercially available as an enzyme-linked virus-inducible system (ELVIS HSV ID; Quidel). The advantages of this system include rapid detection with a result available after overnight incubation followed by addition of the substrate; visual signal by detection of either CPE and/or the blue color; and adaptability to large volume laboratories and potential automation. A modification of the ELVIS system now allows subsequent staining directly on the monolayer with type-specific, fluorescent-labeled HSV monoclonal antibodies. The concept of virus specific indicator cell lines may be feasible for other viruses (17), and a format has been developed for rapid HSV antiviral susceptibility testing (18).

The measles virus can be difficult to grow in cell cultures. This is believed to be due to strains of measles having tropism for different host cell receptors. A Vero cell line, stably transformed with the receptor hSLAM (human Signaling Lymphocytic Activation Molecule), has proven ideal for growing measles virus from patient specimens (19).

## ANTIVIRAL SUSCEPTIBILITY TESTING

### Introduction

In the past two decades, safe and effective antiviral drugs have been developed for the treatment of many acute and chronic viral infections. Not surprisingly, the increased and

**TABLE 3** 50% inhibitory concentration (IC<sub>50</sub>) cutoffs for herpes simplex virus and cytomegalovirus antiviral resistance using the plaque reduction assay

Virus	Drug	Susceptible	Intermediate	Resistant
Herpes simplex virus	Acyclovir	<9 μM		≥9 μM
	Foscarnet	<330 μM		≥330 μM
Cytomegalovirus	Ganciclovir	≤6 μM	6–12 μM	>12 μM
	Foscarnet	≤400 μM		>400 μM

Note: Resistance is also defined by a greater than 2- to 3-fold increase in IC<sub>50</sub> values compared to a pretherapy isolate or a wild-type control virus.

prolonged use of these drugs, most notably in immunocompromised patients, has been accompanied by the emergence of drug-resistant viruses. However, clinical failure may not only be due to the presence of a drug-resistant virus but can also depend on factors such as the patient's immunological status, compliance, and the pharmacokinetics of the drug in that patient. Examples of clinical situations which warrant the use of antiviral susceptibility testing for herpesviruses include failure of HSV or VZV cutaneous lesions to resolve, the appearance of new lesions while on acyclovir (valacyclovir or famciclovir) therapy (20, 21), and progressive retinal or visceral CMV disease during ganciclovir (valganciclovir) therapy (22, 23). Ganciclovir-resistant CMV infections were first reported among HIV-infected subjects with CD4 T cells of  $<50 \times 10^9/l$  (24) and are now an important problem in solid organ transplant recipients, particularly in the context of a primary infection after organ transplantation (CMV-seropositive donor and CMV-seronegative recipient) (25, 26). Also, continuous influenza shedding during therapy with amantadine/rimantadine or the neuraminidase (NA) inhibitors (oseltamivir/zanamivir) in immunocompromised patients should lead to suspicion of antiviral drug resistance and may warrant antiviral testing (27, 28). Resistance testing for clinical management of HIV-1 infection is recommended at entry into care, in the case of treatment failure (worsening clinical disease, increase in viral load, decrease in CD4 T lymphocytes), primary infection, and pregnancy (29–31). Several recent review articles have been published on the mechanisms of antiviral drug resistance for herpesviruses (32, 33), influenza (34), and HIV-1 (35).

### Phenotypic Assays

Phenotypic assays measure the effect of an antiviral drug on the growth of a virus. This can be determined by infectivity (e.g., plaque or yield reduction) assays, viral antigen or viral nucleic acid production, and enzyme activity. Such assays directly measure and quantify the effect of antiviral drugs on viral growth. However, they generally require isolation and passage of the virus in cell culture, followed by viral titration before antiviral drug susceptibility testing begins. Thus, these tests tend to be slow, labor intensive, and difficult to standardize. In addition, *in vitro* passages can introduce unintended viral mutations. Phenotypic results are typically expressed as the drug concentration that inhibits 50% or 90% of viral growth relative to a no-drug control (IC<sub>50</sub> or IC<sub>90</sub>). Importantly, because these assays have been difficult to standardize, resistant and susceptible control strains should be tested with each batch of clinical isolates. Phenotypic antiviral susceptibility assays are currently in use for herpesviruses (HSV, VZV, CMV), influenza viruses, and HIV-1. A standard procedure for HSV antiviral susceptibility testing by plaque reduction assay (PRA) has been approved by the Clinical and Laboratory Standards Institute (formerly

NCCLS) in 2004 (36). A similar PRA has been described for CMV (37).

The PRA has classically been the standard method of susceptibility testing to which new methods are compared. In this assay, a standardized viral inoculum is added into multiple wells of a plate containing susceptible cells and serially decreasing concentrations of an antiviral agent. A solidifying agent such as agarose is usually added to the cell culture medium to allow the formation of discrete viral plaques. Following an incubation period (which varies according to the virus), the plates are fixed and stained with a dye (crystal violet) and the plaques are counted. The IC<sub>50</sub> and sometimes the IC<sub>90</sub> values are determined and compared to those obtained for susceptible and resistant control strains. Breakpoint resistance values have been proposed for HSV and CMV (Table 3) although it should be emphasized that many variables can affect the results such as the cell line, the viral inoculum, the incubation period, etc. For a slow-growing virus such as CMV, the time involved for initial growth, viral stock preparation, and antiviral susceptibility testing is >6 to 8 weeks, whereas it can take <2 weeks in the case of HSV. Another drawback of the PRA is the possibility of selecting some genotypes in a mixed viral population (“quasispecies”) during the initial passages in cell culture in the absence of drug (38).

Other phenotypic assays (see more detailed procedures in (39)) include the dye uptake assay for susceptibility testing of HSV (40). This is a colorimetric method that involves the quantification of a vital dye (neutral red) by viable cells but not by infected (nonviable) cells. The assay is semi-automated and is reproducible with the use of 96-well microtiter plates and a spectrophotometer. A DNA hybridization assay (Hybriwix assay, Diagnostic Hybrids, Inc., Athens, OH) was developed to measure HSV, CMV, and VZV drug susceptibilities (41) but this assay is no longer commercially available. Reporter genes (e.g., luciferase or alkaline phosphatase) can also be introduced in cell lines (42) or recombinant viruses (43) allowing high throughput testing.

For influenza phenotypic susceptibility testing to the NA inhibitors (zanamivir, oseltamivir), the currently preferred method consists of directly measuring inhibition of NA activity (44). After incubation of the virus containing the NA with different concentrations of NA inhibitors, a fluorescent or chemiluminescent substrate is added, then fluorescence or chemiluminescence is quantitated. The working group on surveillance of influenza antiviral susceptibility has proposed cutoff values for influenza testing against NA inhibitors (Table 4) (45). Of note, the NA assay cannot detect drug resistance caused by the presence of hemagglutinin mutations, which have been less commonly reported than NA mutations (46).

Phenotypic assays for susceptibility testing of HIV-1 were traditionally performed in cell culture using primary

**TABLE 4** Breakpoints for influenza virus susceptibility testing against the neuraminidase inhibitors<sup>a</sup>

Virus	Reduced inhibition <sup>b</sup>	Highly reduced inhibition <sup>b</sup>
Influenza A	10–100×	> 100×
Influenza B	5–50×	> 50×

<sup>a</sup>Based on the recommendations from the working group on surveillance of influenza antiviral susceptibility (45).

<sup>b</sup>Fold increase in IC<sub>50</sub> values compared to wild-type (control) virus.

peripheral blood mononuclear cells from HIV-1-negative donors (47). In this assay, virus replication in the presence or absence of an antiretroviral drug is monitored by quantifying the HIV-1 p24 antigen using enzyme immunoassay (EIA)-based tests. Nowadays, recombinant virus phenotypic assays (48) involve insertion of the reverse transcriptase, polymerase and integrase genes of HIV-1 from a patient into a vector consisting of a rapidly replicating laboratory viral strain that also contains a reporter gene (e.g., luciferase) to measure viral growth in the presence of a drug compared to a wild-type virus. Some recombinant virus assays have been developed commercially such as the PhenoSense assay (Monogram BioSciences-LabCorp) and the Antivirogram assay (Tibotec-Virco, now discontinued) (49). Other types of phenotypic assays beyond the scope of this chapter include the yield reduction assay (50), EIA-based tests (51), and flow cytometry testing (52).

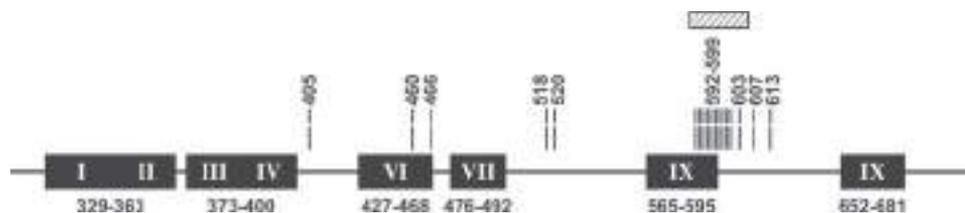

### Genotypic Assays

Genotypic assays allow for the rapid detection of genetic mutations associated with antiviral drug resistance. Most of these tests first involve a round of nucleic acid amplification for the specific viral genes implicated in resistance to a certain drug, followed by direct sequencing of the amplified product, and finally comparison of the viral sequence to that of a pretherapy isolate or a reference strain. These assays are particularly useful for detecting evidence of resistance, when a discrete number of characterized resistance mutations are known. Genotypic assays have been most widely used for detecting ganciclovir-resistant CMV or antiretroviral-refractory HIV-1 infections, since phenotypic assays for these viruses are slow and tedious. However, such tests have also been used to distinguish genetic variants of hepatitis B virus (HBV) associated with lamivudine resistance (53), M2 mutants associated with influenza A resistance to amantadine (54), NA and/or hemagglutinin influenza mutations associated with resistance to NA inhibitors (55, 56), and HSV or VZV mutations conferring resistance to acyclovir (20, 21). In the latter case, development of genotypic assays has been hampered by the fact that the thymidine kinase and DNA

polymerase genes of herpesviruses are highly polymorphic and that drug-resistance mutations are scattered throughout the gene. Also, phenotypic assays for HSV are generally more convenient due to rapid growth of this virus (typically in 24 to 48 h).

Genotypic assays for CMV have been developed mainly to detect UL97 (protein kinase) and also UL54 (DNA polymerase) mutations associated with ganciclovir (or valganciclovir) resistance (Figure 2). PCR amplification of a short fragment of the UL97 gene followed by either restriction endonuclease digestion or direct sequencing have been used to detect the most frequent ganciclovir resistance mutations at codons 460, 520, 594, and 595, which are responsible for approximately 80% of resistance cases (57, 58). The major advantage of this method consists of its rapidity since resistance-associated mutations can be detected directly in clinical samples such as whole blood, leukocytes, plasma, urine, etc. within a few days after sample collection (23). For more comprehensive analysis of ganciclovir resistance but also to detect CMV resistance to cidofovir and foscarnet, PCR amplification and DNA sequencing of the catalytic regions of the UL54 gene must also be undertaken. These genotypic assays can be performed by commercial laboratories such as Viracor-IBT. However, the genetic map of CMV UL54 mutations associated with drug resistance has not been completed yet and an important problem consists of discriminating between polymorphic (natural variations) and resistance mutations. Recombinant viruses based on bacterial artificial chromosomes (BAC) or overlapping cosmids must be generated to definitively determine that a particular mutation is associated with drug resistance (59, 60), which is beyond the scope of the general virology laboratory.

The development of HIV resistance to all antiretroviral agents is a significant clinical problem. Direct sequencing of PCR-amplified reverse transcriptase, protease, or integrase genes is considered to be the gold standard for assessing HIV-1 drug resistance (reviewed in (29, 35, 61)). Commercially available FDA-approved sequencing-based methods for HIV genotyping include for instance the Trugene HIV-1 (Siemens Healthcare GmbH, Erlangen, Germany) and the ViroSeq HIV-1 (Abbott Molecular, Des Plaines, IL) assays. Both systems are similar with respect to the complexity of the assays and have a detection limit of ≈ 20% for minor quasispecies according to the manufacturers' instructions. Hybridization techniques, as an alternative to complete sequencing, may be used to detect specific mutations associated with drug resistance. In the INNO-LiPA HIV-1 line probe assay (Fujirebio Europe N.V., Zwijnaarde, Belgium), codon-specific oligonucleotide probes are applied as discrete lines on a nitrocellulose membrane in a strip format. Hybridization of biotin-labeled test isolate amplicon with

**FIGURE 2** Cytomegalovirus (CMV) UL97 mutations associated with ganciclovir resistance. CMV UL97 conserved regions are represented by shaded boxes. Numbers under the boxes indicate the positions (codons no.) of these conserved regions. Vertical bars indicate the presence of amino acid substitutions while the hatched box indicates a region (codons 590–607) in which diverse deletions (from 1 to 17 codons) have been reported.

the probes for specific codons (wild-type and mutants) leads to the production of color in the presence of avidin enzyme complex and substrate. Some researchers have concluded that the clinical utility of LiPA is limited by the high rate of indeterminate results (62) and this test is no longer commercially available. In another hybridization method, the microarray chip-based technology, over 16,000 unique oligonucleotide probes are used for hybridization with fluorescein-labeled target nucleic acid (HIV PRT GenChip, Affymetrix, Inc., Santa Clara, CA). This method was shown to be less reliable as compared to dideoxynucleotide sequencing and is no longer commercially available (63). The final step in the process of genotypic resistance testing is the analysis of generated sequences. Interpretation of the genotype can be based either on rule-based algorithms or on “virtual phenotypes.” The sequences may be aligned using different software programs included in commercially available genotypic assays or with on-line databases. In “virtual” phenotyping, the genotypic mutation profile of a viral strain is compared with the available paired genotypes and phenotypes in the database.

In summary, phenotypic or genotypic assays can be used depending on the virus and the clinical situation. Phenotypic assays offer the advantage of providing a direct measurement of viral susceptibility to any antiviral drugs and of quantifying the level of resistance. On the other hand, genotypic assays offer the distinct advantages of greater speed and efficiency in analyzing a large number of viral strains, but only identify known drug resistance mutations. Discordance between phenotypic and genotypic assays can result from the presence of viral quasiespecies (genotypic mixture of wild-type and mutant viruses) and the presence of complex patterns of mutations (resistance and compensatory mutations). In recent years, the advent of next-generation sequencing has resulted in a lowering of the threshold for detecting minor resistant subpopulations from 20% to 1 to 2% compared to conventional (Sanger) DNA sequencing. This promising technology (see section on nucleic acid tests) has already been used in the context of detecting CMV (64), influenza (65), and HIV-1 (66) drug resistance mutations in clinical samples.

## DIRECT DETECTION OF VIRUS OR VIRAL ANTIGEN

With the increasing availability, decreasing cost, and improved turnaround time of molecular techniques for the detection of viral nucleic acids, the use of direct detection methods for virus or viral antigen has diminished in the clinical laboratory. Despite their generally lower sensitivity than molecular tests, some clinical laboratories may continue to offer these tests when expertise in molecular techniques is lacking, cost of molecular tests is prohibitive, and/or test requests for certain viruses are too low in number to justify in-house use of molecular tests.

### Immunoassays

Of all the nonmolecular techniques for the direct detection of viruses or viral antigens within clinical specimens, immunoassays remain the most widely used. These assays utilize antibodies (antisera) which may be monoclonal or polyclonal directed against a specific viral antigen or antigens (67). The resulting antibody–antigen complexes can be detected using a number of different techniques ranging from direct visualization methods to those that detect viral anti-

gens using solid-phase immunoassays (SPIA) such as EIA and enzyme-linked immunosorbent assays (ELISA).

### Direct Visualization Immunoassays

Visualization of viral antigens within tissue samples or individual cells is most commonly achieved by either direct or indirect staining methods (68). Not only can one detect the presence or absence of viral antigens within cells, one can also determine the location (e.g., nucleus, cytoplasm, inclusion bodies, etc.) of the viral antigens. In the direct method, the antibody (antisera) directed against the virus of interest is conjugated with either an enzyme (e.g., horseradish peroxidase, alkaline phosphatase, others) or a fluorescent label (e.g., fluorescein isothiocyanate [FITC]). The antibody is added onto a glass slide to which the patient sample has been fixed. Once the antibody–antigen reaction is allowed to occur, a substrate is added for the conjugated enzyme, which, when acted upon by the enzyme, results in a color reaction that is visible using a light microscope. If the antibody label used is FITC, the presence of antibody–antigen complexes can be visualized using an immunofluorescence microscope set at the appropriate wavelength. In the indirect method, the initial antibody (e.g., mouse monoclonal antibody) directed against the virus of interest is not conjugated to an enzyme or a fluorescent label. After it is allowed to bind to the virus or viral antigen (if present in the patient sample), a second conjugated or labeled antibody directed against the first (e.g., goat anti-mouse antibody) is allowed to bind to the antibody within the antigen–antibody complex. Visualization is then performed as for the direct method. The advantage of the indirect method is that it can “amplify” the signal because many secondary antibodies may bind to the initial antibody resulting in a stronger signal.

Fluorescent antibody immunoassays including direct immunofluorescence (DFA) and indirect immunofluorescence (IFA) microscopy continue to be used in diagnostic virology because they are relatively easy to perform and inexpensive (Table 5). They are applicable to a wide variety of specimen types and can be used for the detection of many different viruses or viral antigens with high specificity, particularly when monoclonal antibodies are used. Pooling of monoclonal antibodies, each labeled with a different fluorescence molecule, allows for the simultaneous detection of different viruses in the same sample. For example, a pool of monoclonal antibodies directed against influenza viruses A and B, RSV, parainfluenza viruses 1, 2, and 3, and adenovirus is often used to screen respiratory specimens such as nasopharyngeal swabs and washings. If the screen is positive, then individual slides can be prepared and stained using separate antibodies to identify the specific virus or viral antigen present in the specimen. Fluorescent antibody staining is used in many laboratories as initial screening for HSV and VZV in skin and mucous membrane samples, and for respiratory viruses in a variety of respiratory specimens (69, 70). Detection of CMV pp65 antigens using direct immunofluorescent staining of peripheral blood leukocytes (PBLs) continues to be used in many centers as an alternative to molecular techniques for the detection and quantitation of CMV in blood specimens. By using a fixed number of PBLs per slide, one can provide a measure of the number of positive fluorescent cells per fixed number of PBLs which can be used to monitor CMV activity in patients with primary or reactivated CMV infection/disease following organ and bone marrow transplantation (71). More recent guidelines, however, recommend that molecular assays be used in place of immunostaining techniques (72).

**TABLE 5** Detection of viral antigens by direct fluorescent antibody (DFA) staining

Clinical presentation	Possible viral agents detectable by DFA	Specimen source
Colorado tick fever	Colorado tick fever virus	Blood (erythrocytes)
Congenital infections	Rubella, CMV, HSV	Nasopharyngeal, throat, lesion scrapings, tissue
Conjunctivitis, keratitis	HSV, adenovirus, measles virus	Conjunctival cells, corneal scrapings
Disseminated disease, immunocompromised host	HSV, CMV, VZV, EBV	Tissues, lesion scrapings
Encephalitis	HSV Rabies virus Mumps virus	Brain biopsy Brain tissue Throat, urine sediment
Macular or maculopapular exanthems	Measles virus, rubella virus, mumps virus, adenovirus	Nasopharyngeal, throat, urine sediment
Mucocutaneous vesicles or ulcers	HSV, VZV, adenovirus	Scrapings from base of the lesion, mucosal cells
Respiratory infection	Influenza A and B viruses, parainfluenza viruses, adenovirus, RSV, human metapneumovirus, measles virus, mumps virus	Nasopharyngeal swabs, washes, or aspirates; throat swab; lung biopsy; bronchoalveolar lavage, wash, or brushing

### Solid Phase Immunoassays

Solid phase immunoassays for the direct detection of viral antigens in clinical specimens include EIA, ELISA, latex agglutination (LA), membrane-immunoassays (also known as lateral flow immunochromatographic assays), and radioimmunoassay (RIA) (67). In many laboratories, EIAs and ELISAs remain the predominant solid-phase immunoassay techniques used for viral diagnosis. Many EIAs and ELISAs have been automated which has improved consistency in the performance of these tests, objectivity in the interpretation of the results, as well as increased throughput and reduced turnaround times. Although the terms EIA and ELISA have slightly different meanings, they are often used interchangeably to denote any assay that utilizes an enzyme rather than radioactivity as the reporter label. For simplicity, ELISA will be used in the remainder of this section.

ELISAs can be used to detect either antigens or antibodies in a clinical sample (73). The most common ELISA formats for the detection of viral antigens include direct, sandwich, and competitive ELISAs. It should be noted that there are slight differences in the literature with respect to the use of these terms with some overlap between the term 'indirect' ELISA and 'sandwich' ELISA. In the direct ELISA method for the detection of viral antigens, the surface of a solid phase (e.g., the wells of a polystyrene microtiter plate) is coated with primary antibodies directed against the antigen of interest. When the sample is added to the solid phase, the specific viral antigen of interest, if present, will bind to the primary antibody forming an antigen-antibody complex that is fixed to the solid phase. Once the excess sample is removed by several washing steps, a second antibody conjugated with a reporter enzyme is added and allowed to also bind to the antigen of interest. Detection is achieved by the addition of a substrate (appropriate for the reporter enzyme) which when acted upon, results in a color reaction. Different reporter enzymes can be used including horseradish peroxidase, alkaline phosphatase, beta-glucosidase, and others. The presence and intensity of the color generated is then read using a spectrophotometer which yields the result as an optical density (OD) value. With standardization of the assay, the OD value can be converted into a quantita-

tive value and reported in international units per milliliter (IU/ml).

A sandwich ELISA for the detection of viral antigen(s) is performed in essentially the same way as a direct ELISA except that the secondary antibody is not conjugated with an enzyme. Instead, once the secondary antibody is allowed to bind to the antigen, an enzyme-conjugated antibody directed against the Fc region of the secondary antibody is added. This is then followed by the addition of an appropriate substrate. By using an enzyme-linked antibody that binds to the Fc region of other antibodies, this same enzyme-linked antibody can be used in a variety of different assays for different antigens, thus making them somewhat universal.

For competitive ELISAs, the primary antibody directed against the antigen(s) of interest is mixed with the patient sample directly resulting in the formation of antibody-antigen complexes. These antibody-antigen complexes are then added to an antigen-coated well in a polystyrene microtiter plate. Following incubation, the plate is washed in order to remove unbound primary antibodies. In general, the more antigens present in the patient sample, the more antigen-antibody complexes are initially formed, leaving fewer unbound antibodies available to bind to the antigens fixed to the wells of the polystyrene microtiter plate. The plate is again washed after an incubation period to remove any remaining unbound primary antibody. This is followed by the addition of a secondary enzyme-conjugated antibody, which is directed against the primary antibody followed by the addition of an appropriate substrate. In a competitive ELISA therefore, if specific antigen was present in the original patient sample, the signal generated is reduced and thus the OD value is low.

The solid phase can be a membrane rather than a microtiter plate. This format has been developed for detection of such viral antigens as influenza virus, RSV, rotavirus, and others (74). Modifications of the standard EIA and ELISA methods by the use of tiny beads (microparticles) to increase the surface area for the coating of antigens or antibodies, thus potentially increasing sensitivity, has led to the introduction of micro-enzyme immunoassays (MEIA). This has resulted in a shortening of the time required to complete the

assay from 3 to 4 hours for standard ELISAs to less than one hour.

Chemiluminescent immunoassays (CLIA) and chemiluminescent micro-enzyme immunoassays (CMIA) follow the same general principle as ELISAs, but use an enzyme/substrate combination that results in the generation of emitted light rather than a color signal (75). The emitted light is detected using a luminometer which generates a value reported as relative light units (RLU). Regardless of whether a color reaction is produced or a light signal is generated, the signal strength is typically proportional to the amount of antigen present in a sample. However, not all assays are quantitative and therefore one cannot assume that a high OD or RLU value always correlates with the presence of more antigens in the patient sample. Some assays include quantitation standards which are used to generate a standard curve for quantifying the amount of antigen in a patient sample.

ELISAs are very sensitive and are capable of detecting antigens at the picomolar to nanomolar range ( $10^{-12}$  to  $10^{-9}$  moles/l) (73). However, chemiluminescent assays tend to be even more sensitive and have a wider dynamic range than standard ELISAs. ELISAs have been developed for the detection of numerous different viral antigens. Most assays have been developed and validated using a limited number of different sample types (e.g., serum and/or plasma) and their use for detection of antigens in other sample types such as CSF or other body fluids may give erroneous results. Non-specific or cross-reactions can occur with ELISAs depending on whether the antibodies used in the assay are monoclonal or polyclonal and how similar (or different) the antigens are amongst different viruses (e.g., HSV-1 and HSV-2) (70).

### Histopathology/Cytopathology

Standard light microscopy examination of stained clinical material may identify direct cellular changes which may be the first evidence of a viral infection. For some viruses, infected cells and tissues may exhibit cytological alterations that are pathognomonic for a specific virus (Table 6), while for others, the changes may be nonspecific and simply raise the possibility of a viral infection. Some stains allow for the detection of viral inclusions, but cannot provide a definitive identification of the specific viral agent. During viral latency and possibly at other times during viral replication, cells may appear entirely normal with no histologic changes to suggest a viral infection. Therefore, one cannot rule out a viral infection using histopathology/cytopathology methods alone.

None of the usual cytologic stains (e.g., hematoxylin and eosin [H & E], Wright-Giemsa, Giemsa [Tzanck preparation], Papanicolaou) is specific for detecting the presence of a viral infection and all lack sensitivity (76). For example, the classic Tzanck preparation cannot be used to distinguish HSV from VZV infections, an important clinical distinction required for proper management, infection control, and counseling of patients.

One of the key areas where cytological examination plays an important role has been the Pap smear for cervical scrapings as part of screening for early changes indicative of cervical cancer (77). Virtually all cervical cancers are associated with specific oncogenic subtypes of human papillomavirus (HPV). Thus the presence of atypical squamous cells of undetermined significance (ASCUS) and atypical glandular cells of undetermined significance (AGUS) coupled with newer molecular tests which can detect the presence of most of the oncogenic subtypes of HPV is rapidly

becoming the standard for managing women for cervical cancer prevention.

In renal transplant patients, up to 10% of recipients may develop polyomavirus-associated nephropathy (PVAN) which may result in loss of the renal graft. Histological diagnosis using light microscopy plays an important role in these patients (78). However, because the pathological changes of PVAN are heterogeneous and the intranuclear viral inclusions are indistinguishable from other viruses such as adenovirus and herpesviruses, immunohistochemical staining, electron microscopy, or molecular testing is required for making a definitive diagnosis. Similarly, although cytological examination of cells shed in urine may identify “decoy cells” which are cells containing intranuclear inclusions, it cannot distinguish between the different types of polyomavirus (e.g., BK versus JC) or from adenovirus-infected cells (79).

Cytological examination may also play a role in distinguishing viral shedding from active infection in some clinical situations. For example, the presence of cytological changes, including the presence of cytomegalic inclusion bodies in a bronchoalveolar lavage (BAL) sample, is more suggestive of active CMV infection than the detection of CMV in the same sample without evidence of cytological changes. The latter may simply represent asymptomatic shedding.

### Electron Microscopy

In most diagnostic laboratories, electron microscopy (EM) for the diagnosis of viral infections has been supplanted by other methods, and many reviews of specific diagnostic recommendations fail to even mention the potential role of EM. Some laboratories may continue to use EM for screening stool samples for viruses associated with acute gastroenteritis because of the wide array of potential viral pathogens that may be detected, and the lack of a simple, single assay for detection of the multiple viral pathogens (80, 81). EM also plays an important role in the detection of BK-polyomavirus in tissue biopsies and urine samples from renal transplant patients with suspected BK-virus associated nephropathy (78, 82).

Virtually any specimen type can be examined by EM for viruses. In general, liquid samples such as CSF, saliva, tears, urine, vesicle fluid, etc. may be used directly, while others may need to be rehydrated (e.g., dried tissue samples) or clarified (e.g., fecal material) before examination by EM. Specimens to be examined by EM must first be adsorbed onto a thin plastic and/or carbon film adherent on the surface of an EM grid before staining (83, 84). In order to improve the sensitivity of EM, the use of either pooled human immunoglobulins or specific antibodies during the adsorption step can be used (e.g., solid-phase immunoelectron microscopy [SPIEM]). In addition, ultracentrifugation of the original sample followed by re-suspension in a smaller volume or direct centrifugation of the sample onto the EM grid may also help increase the probability of detecting virus particles by EM. Once the grid has been prepared with the specimen, it is subjected to either positive or negative staining. Both methods use heavy metal ions (e.g., lead, tungsten, and uranium ions) to generate sufficient image contrast and resolution (84). Because positive staining is technically more demanding and requires considerably more time to perform, it is impractical for routine clinical specimens and has been replaced by negative staining. The most common negative stains are 1% aqueous uranyl acetate and 1% phosphotungstic acid. These electron-dense stains penetrate the virion and provide contrast for visualization of the

**TABLE 6** Cytological changes associated with selected viral infections

Virus	Clinical presentation	Cytological findings
Adenovirus	Upper respiratory tract infections, pneumonia, acute keratoconjunctivitis	Small multiple eosinophilic intranuclear inclusions (early); large single dense basophilic intranuclear inclusions ("smudge cells," late)
	Hemorrhagic cystitis	Dense basophilic intranuclear inclusions in transition cells
BK virus	Urethral stenosis (renal transplant patients) and interstitial nephritis (immunosuppressed patients)	Large full mucoid intranuclear inclusions (early); dense full basophilic inclusions bulging from cytoplasm (late)
Cytomegalovirus	Pneumonia	Cytomegaly; large, single amphophilic intranuclear inclusions (Cowdry A); small basophilic intracytoplasmic inclusions
Herpes simplex virus	Herpes genitalis, tracheobronchitis, corneal vesicle, or ulcer	Large ground-glass nucleus (early); eosinophilic intranuclear inclusions (late) with peripheral chromatin condensation; multinuclearity with nuclear molding
	Generalized infection or local cystitis	Ground-glass nuclei (early); eosinophilic intranuclear inclusions (late); multinuclearity; may be part of tubular cast
Human papillomavirus	Condyloma acuminatum, cervical dysplasia	Enlarged hyperchromatic nucleus; rare basophilic intranuclear inclusions; perivascular cytoplasmic clearing and vacuolar degeneration (koilocytic change)
Human polyomavirus	Progressive multifocal leukoencephalopathy (PML)	Enlarged oligodendrocytes with enlarged nuclei containing large basophilic inclusions
	Polyomavirus-associated nephropathy (PVAN)	Enlarged basophilic inclusions and displaced chromatin in renal tubular epithelium and urothelium; basophilic ground-glass nuclear inclusions in epithelial cells ("decoy cells") in urine
Measles virus	Prodromal	Mulberry-like clusters of lymphocytic nuclei in nasal secretions
	Measles with exanthema	Multinucleated giant cells with intracytoplasmic and intranuclear inclusions
Molluscum contagiosum	Reddish papular lesions of eyelid or conjunctiva	Large dense basophilic intracytoplasmic inclusions displacing the nucleus
	Vaginal, penile, or perineal papule with central umbilication	Large dense basophilic intracytoplasmic inclusions displacing the nucleus; squamous cells often bean-shaped
Nipah virus	Encephalitis	Intracytoplasmic eosinophilic inclusions
Parainfluenza virus	Bronchitis	Cytomegaly; single or multiple nuclei; small eosinophilic intracytoplasmic inclusions
Parvovirus B19	Aplastic crisis, hydrops fetalis	Nuclear inclusions in erythroid precursor cells, bone marrow, or liver (fetus)
Respiratory syncytial virus	Tracheobronchitis, pneumonia	Large multinucleated cells; intracytoplasmic basophilic inclusions with prominent halos
Varicella-zoster virus	Vesicular eruptions in dermatome (shingles) or accompanying varicella	Multinucleated cells with intranuclear eosinophilic inclusions

surface detail of virus particles. Negative staining allows for examination and morphologic detection of viruses in a sample within 10 min (84). Based on the unique morphology of different virus families and measurement of the size of the virus particle, EM allows for a virus to be classified into a particular family relatively easily.

Many limitations to EM exist, so that it is usually only available in reference centers. The availability of EM is limited by the cost of the instrument and the need for expertise in reading grids. EM is not well suited for screening

large numbers of routine samples, as may be required in a clinical diagnostic laboratory. Estimates on the amount of virus needed in order to be detectable by EM have ranged from  $10^5$  to  $10^8$  particles/ml, making it less sensitive than other techniques (84, 85).

## NUCLEIC ACID DETECTION

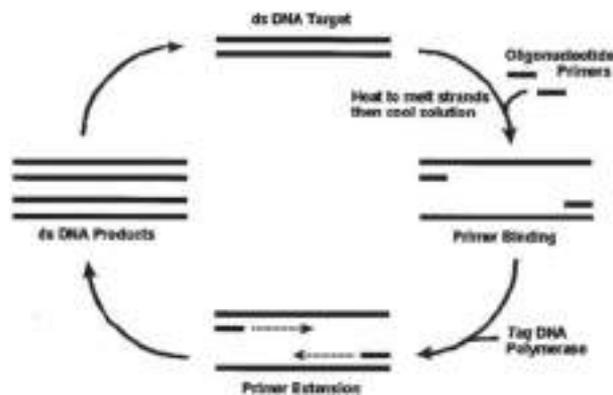

Identification of viral nucleic acids is based on relatively conserved and unique nucleotide sequences which can be

copied into complementary oligonucleotides by polymerases, cut at defined sequence-specific sites by restriction endonucleases, and differentially annealed to complementary sequences under defined conditions. The relatively short length of viral genomes has made viruses ideal candidates for nucleic acid-based diagnosis.

NATs were used to a limited extent before the advent of current amplification assays such as PCR. These consisted of simple hybridization assays such as in the case of the human papillomaviruses (86) as well as detection of defined size segments of viral genome present either endogenously in the case of rotavirus, or resulting from restriction endonuclease digestion as in the case of herpes and adenoviruses (87, 88). With the advent of the PCR assay, NAT-based diagnosis has been extended to nearly all recognized viruses. The PCR assay has evolved from conventional PCR, where products are identified by agarose gel electrophoresis, to real-time PCR, where products are identified using probes or intercalating dyes within the reaction and has now progressed to the development of microarray-based assays either in chip or bead-based formats. Finally, PCR assays have been adapted for quantitation of specific viruses in a specimen.

### Polymerase Chain Reaction (PCR) Assay

The development of the PCR assay for DNA virus diagnosis, combined with the preceding reverse transcriptase step for RNA viruses, was a major breakthrough in diagnostic virology. This methodology allows for greatly enhanced levels of viral detection, because for every infectious unit there are numerous defective or otherwise noninfectious particles, all containing the target genome. As shown in Figure 3, the PCR assay is based on cycling a mix of specimen DNA, virus specific oligonucleotide primers in high excess, a thermostable polymerase, and nucleotide triphosphates at a high temperature at which the target DNA strands separate, and a low temperature stage at which the primers anneal to their complementary sites, and an intermediate temperature stage

**FIGURE 3** Polymerase chain reaction. The strands of the target DNA are separated by heating (melting) and on cooling they anneal with the complementary primers present in excess. The thermostable DNA polymerase extends the primers forming two double-stranded DNA molecules. On subsequent heating, the strands separate and each anneals with the complementary primer. The cycling of temperature between melting, annealing, and primer extension is repeated multiple times and the number of product strands is doubled with each cycle. (Reprinted from reference (185) with permission.)

optimal for the polymerase to elongate the complementary strand as an extension from the primers (89). Each time the cycle is repeated, the number of copies or amplicons doubles such that after 20 cycles, there are potentially over one million amplicons from a single target molecule.

Primers are the major determinant of the sensitivity and specificity of each PCR assay. Since the sequences of most viral genomes are known, at least at the genus level, identifying oligonucleotide primers to conserved regions of the virus genome is feasible. While primers for “in house” assays are known, those for commercial assays may not be readily available. In PCR assays for RNA viruses, a virus-specific primer or a random hexamer primer have been found acceptable for the initial reverse transcriptase reaction to produce the complementary DNA product for amplification. The sensitivity and specificity of these assays is also influenced by the enzymes, buffers, and cycling temperatures and these must be optimized for each specific assay.

### Extraction of Nucleic Acid from Specimens

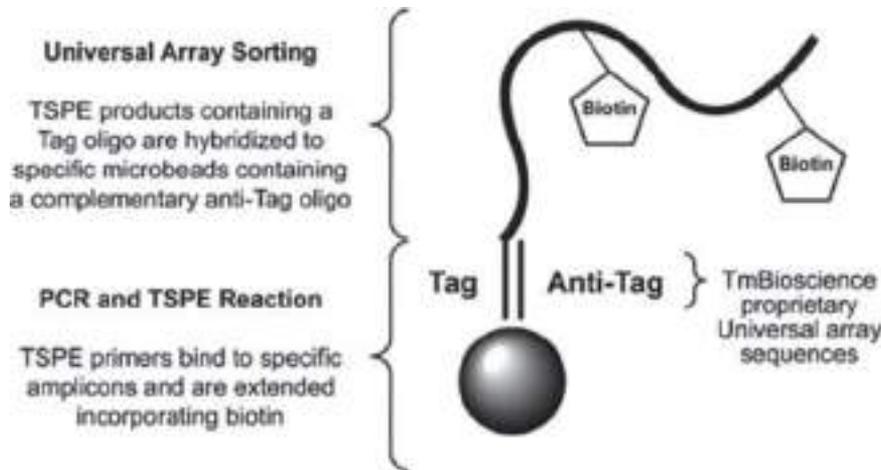

Because of their sensitivity, NATs such as PCR are less fastidious as to the nature of the specimen, such as the need of infectious viruses for isolation, or intact, infected cells for immunofluorescence microscopy. Nucleic acids are generally extracted using commercial kits which are based on the differential binding of the nucleic acid to silica under conditions of different ionic strength. Extracted DNA is stable in EDTA solutions which chelate the magnesium required for DNase activity. RNA, which is less stable, can be preserved using an RNase inhibitor. Likewise, extracted RNAs and DNAs are stable when frozen at  $-80^{\circ}\text{C}$ . Automated extractors allow for scaled up extractions of specimens.

### Detection of Amplicons

Conventional detection of amplicons has been by agarose gel electrophoresis with staining by ethidium bromide. Other DNA intercalating dyes such as SYBR<sup>®</sup> Green are an option, as they are less toxic and easier to dispose of but also more expensive. Digestion of the amplicon preparation with restriction endonucleases before electrophoresis enhances the specificity of the assay and allows for more precise identification of the virus at the level of genus and type (90). For enhanced detection, the amplicons resolved on gel electrophoresis can be transferred to a membrane and probed by Southern blotting (91). This can also be accomplished by performing the hybridization of the PCR products in a microtitre plate format which allows for final analysis with a plate reader, an approach utilized in commercial kits.

### Multiplex PCR

Multiple viruses can be responsible for the same clinical presentation such as in a respiratory infection. Diagnosis on a single specimen can be performed by a PCR assay that can detect multiple genome targets. Such multiplex assays, though feasible, require careful design to ensure that the primers chosen have similar annealing temperatures, do not react with other primers to reduce the sensitivity, and that the amplicons can readily be detected based on their size or by probes specific for each viral amplicon sequence (92). Multiplexing has been elegantly addressed in recently developed commercial respiratory virus assays. In an example of such an assay, any RNA viral genomes are reverse transcribed to complementary DNA using random primers (93). The preparation is then subjected to a multiplex PCR reaction with primers to all target virus sequences. The PCR products are then subjected to a multiplex target specific

**FIGURE 4** The RVP assay (Luminex Corporation, Austin, TX). Identification of the target-specific primer extension reaction that had been captured on the microbead is achieved through the oligonucleotide tag. Sorting of the microbeads occurs in the Luminex 100 flow cell instrument, which identifies colored beads with one laser and a phycoerythrin signal on the attached extended amplicon with a second laser. TSPE: target-specific primer extension.

extension reaction using primers specific for the viral cDNA sequences which also have respective proprietary target-specific oligonucleotide tags at the 5'-end in a reaction mixture that contains biotinylated deoxyribonucleoside triphosphates. The products of this extension reaction are reacted with microbeads with covalently attached anti-tag sequences unique to each virus type to which the complementary tagged sequences hybridize. The preparation is then analyzed by passage through the Luminex flow cell, where the unique signals of each bead type and the common signal

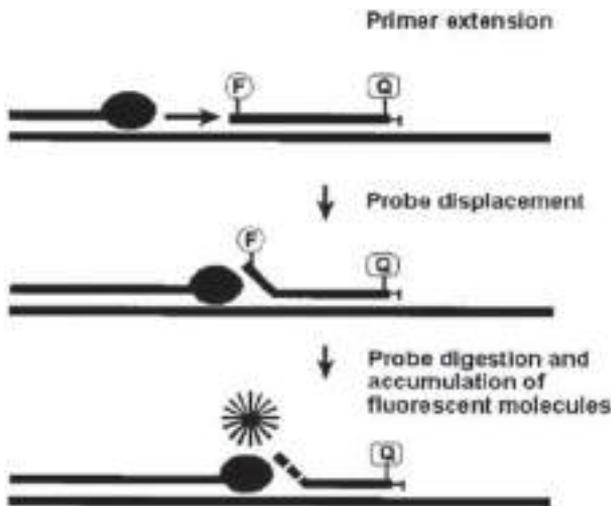

from the biotin-streptavidin phycoerythrin conjugate are measured as illustrated in Figure 4.

### Real-Time PCR

Real-time PCR is an enhancement of the conventional PCR reaction in which amplicons are detected in a closed system after each cycle. This initially involved the detection of fluorescence of the SYBR Green dye that had intercalated into the amplicons before each melting step of the cycle (94). Subsequent detection systems incorporate the energy transfer reactions between fluorescent dyes in a process called fluorescence resonance energy transfer (FRET). This consists of 2 dyes one of which is called the donor dye and the other, the acceptor dye. When they are brought close together through the annealing of two adjacent primers to the target, the upstream one labeled at the 3'-end with the donor dye (for example, fluorescein) and the downstream one at the 5'-end with the acceptor dye (for example, cy5), light is absorbed by the donor dye and emitted by the acceptor thereby creating a signal (95).

An alternative configuration is a single probe labeled at the 5'-end by a reporter dye and at the 3'-end by a quencher dye (96). The probe exhibits minimal fluorescence in the unhybridized state when the oligonucleotide is variably folded on itself, but exhibits strong fluorescence at defined wavelengths when the quencher becomes separated from the reporter fluorophore i.e., when the probe is linearized by hybridization to a target sequence. Such structures are called a molecular beacon (97). Alternatively, the reporter fluorophore and quencher, both of which are linked to the probe, may be separated after the probe hybridizes to the amplicon by the 5'-exonuclease action of the thermostable polymerase in the "TaqMan" platform, as illustrated in Figure 5 (98). In this case, the fluorophore accumulates in the reaction mixture in increasing quantities with each cycle.

Real-time PCR has a number of advantages: it is more rapid than conventional PCR; does not include post-amplification processing, thereby minimizing amplicon contamination; and is applicable to quantitative assays. Disadvantages include the inherent difficulty of readily monitoring for amplicon size, which precludes the utilization of digestion with restriction endonucleases as a control,

**FIGURE 5** Real-time PCR. TaqMan process. In this thermocycling reaction, the internal probe, which is conjugated to the fluorescent dye F and the quencher dye Q hybridizes with the denatured target DNA. When these two dyes are present in close proximity on the probe, the fluorescence of the F dye is quenched. When the new strand being synthesized as an extension of the terminal primers, reaches the probe, it is digested by the 5'-exonuclease activity of the thermostable polymerase liberating the F dye resulting in the generation of a fluorescent signal. (Reprinted from reference (185) with permission.)

difficulty of performing nested PCR, and limitations on the size of amplicons and probes. Furthermore, a mutation occurring in the sequence targeted by the probe would preclude the detection of the amplicon in contrast to it still being detected by analysis of the products by gel electrophoresis. Nevertheless, the advantages of speed, sensitivity, and reduction of amplicon contamination have made real-time PCR the platform of choice in diagnostic virology.

### Fully Integrated Automated Systems

Integrated systems that perform extraction of the nucleic acid, amplification, and analysis of the findings have been developed. These allow virus diagnosis within a short period of time in a setting of minimal laboratory requirement. Examples of these are the application of the Cepheid GeneXpert to the rapid diagnosis of respiratory viruses and enteroviruses (99, 100).

### Non-PCR-Based Nucleic Acid Amplification Systems

Nucleic acid amplification can be performed using approaches other than PCR.

#### Strand Displacement Amplification

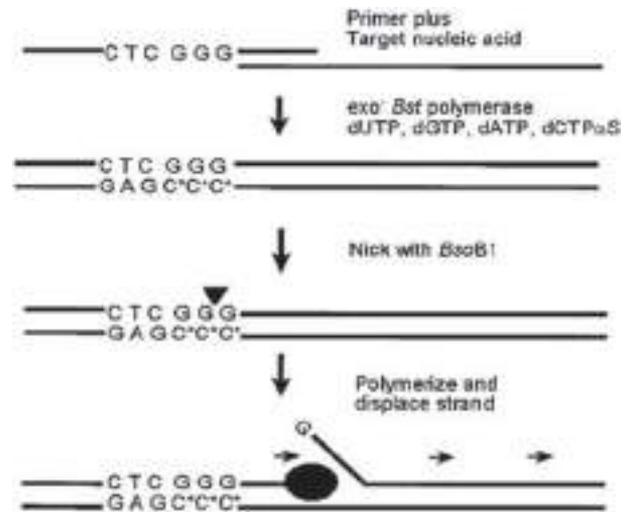

This approach is based on the use of oligonucleotide primers containing a restriction endonuclease cleavage site, a DNA polymerase deficient in 5'-exonuclease activity, the cognate restriction endonuclease, and nucleotide triphosphates of which dCTP has an alpha-thiol group (101). In the reaction, the primer binds to the target sequence on the viral genome, and the polymerase synthesizes a double-stranded product with the endonuclease cleavage site at the 5'-end of the new strand. The restriction endonuclease introduces a nick in the primer site of the new amplicon but not in the complementary strand that has the thiolated dCTP. The nick is recognized by the DNA polymerase which extends the oligonucleotide downstream from the nick and displaces the nicked strand. Annealing of the antisense primer also containing the restriction endonuclease site allows the process to continue on the newly synthesized strand. As shown in Figure 6, this process results in an exponential amplification of the area bracketed by the primers under isothermal conditions. The BDProbeTec (Becton, Dickinson and Company, Franklin Lakes, NJ) is an example of an automated platform utilizing this method. The assay has a sensitivity of 5 to 50 genome copies per ml and requires approximately one hour for completion.

#### Ligase Chain Reaction

The principle of this assay, illustrated in Figure 7, involves thermal cycling with the polymerase replaced by a thermostable ligase (102). The assay involves the ligation of a pair of primers complementary to the full length of the target sequence of each strand that hybridize at adjacent positions and are joined by the ligase. Increasing the temperature results in the dissociation of the primer-derived strands, to which new primers can anneal at reduced temperature, and allows the reaction to continue with the formation of the ligated primers as the end product. The assay has a sensitivity of 5 to 50 genome copies per ml and is reported to be minimally susceptible to inhibitors in the specimen.

#### Nucleic Acid Sequence-Based Amplification (NASBA)

This isothermal assay is based on the amplification of predominantly RNA genome targets using 2 primers, one of

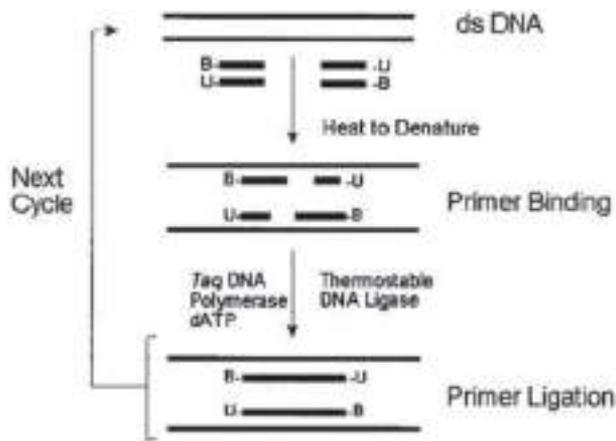

**FIGURE 6** Strand displacement amplification. This isothermal amplification assay is based on four requirements namely primers which include an upstream restriction endonuclease site (BsoB1), the cognate enzyme (BsoB1), a DNA polymerase lacking 5'-exonuclease activity and nucleotide triphosphates of which one has been modified to contain an alpha-thiol group (dCTP $\alpha$ S). In this reaction, the target DNA anneals with the primers and is converted to a double-stranded form by the polymerase. The restriction endonuclease introduces a cleavage in the primer sequence and the polymerase synthesizes a new strand from this site and displaces the existing strand. The restriction endonuclease is not able to cut the newly synthesized strands because of the modified nucleotides and can only introduce cuts in the sites present in the primers. Restriction site bearing primers are designed to anneal to sequences of both strands of the target DNA resulting in an exponential synthesis of displaced strands. (Reprinted from reference (185) with permission.)

which has a T7 promoter sequence at the 5'-end, a reverse transcriptase, a T7 DNA-dependent RNA polymerase, and RNase H along with the deoxynucleotide triphosphates (103). In the assay, the primer with the T7 promoter hybridizes to the RNA template and is extended by the reverse transcriptase. The RNA portion of the heteroduplex is digested by RNase H and the reverse primer hybridizes to the new DNA strand and is extended by the reverse transcriptase to produce a double-stranded DNA. The T7 polymerase copies multiple RNA strands off the DNA template in a primer-independent manner. Each of these can bind the primers and repeat the entire process. These reactions are illustrated in Figure 8. A closely related approach, transcription-mediated amplification (TMA), initially called self-sustained sequence replication, is very similar, differing only in that conditions are set so that the endogenous RNase H activity of the reverse transcriptase is able to substitute for the exogenously added RNase H (104). This platform has been adopted in kits such as those from Gen-Probe, Inc., San Diego, CA and BioMérieux SA, Marcy l'Etoile, France. The assay is reported to have a sensitivity of 5 to 50 genome copies per ml.

#### Recombinase Polymerase Amplification

An intriguing application of the recombinase polymerase reaction using phage T4 proteins UvsX and its cofactor UvsY allows for the primer-based amplification of DNA under isothermal conditions (105). This approach allows

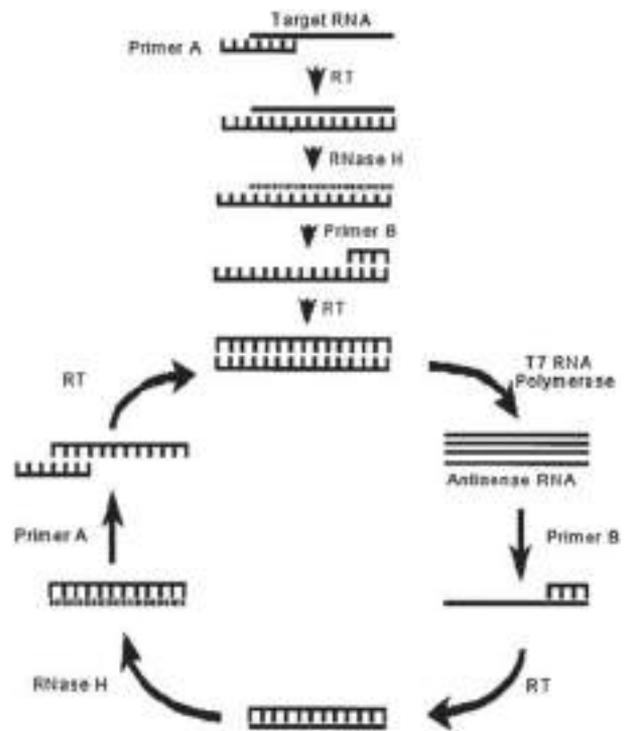

**FIGURE 7** Ligase chain reaction. This reaction includes two pairs of primers, each pair annealing to one strand of heat denatured target DNA with a gap of 2 to 7 nucleotides between. The primers are designed to bind so that the gap between them consists of a single nucleotide type. The reaction also contains the relevant nucleotide triphosphates, a thermostable DNA polymerase and a thermostable DNA ligase. Once the gap is filled by the polymerase, the ligase joins the last nucleotide to the downstream primer. The temperature is then raised to denature the product and then lowered to allow further primer binding. The cycle is repeated so additional primer pairs can be ligated. By having the upstream primer labeled at the 5'-end with biotin (B) and the downstream primer at the 3'-end with a fluorescent label, the products can be captured on a solid phase and tested for presence of the fluorescent label. (Reprinted from reference (185) with permission.)

for a rapid diagnosis of viruses under field conditions, as has been shown for dengue virus as well as for MERS-coronavirus and for other biothreat agents (106–108). The assay has been reported to be as sensitive as conventional RT-PCR, with results available in as little as 20 minutes.

#### Hybridization-Based Assays

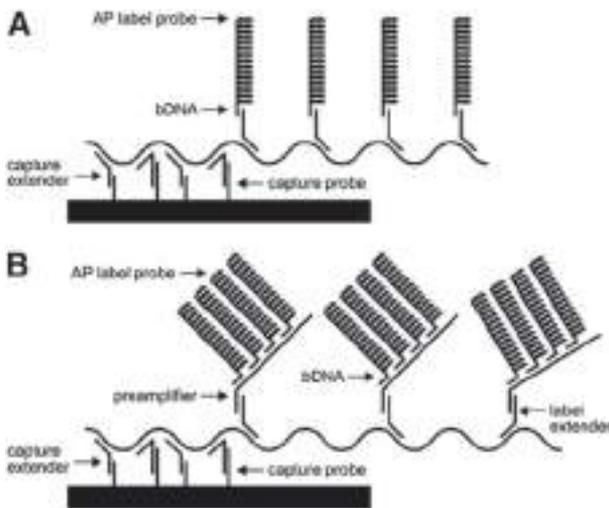

Hybridization with labeled probes has long been used for detection of viral genomes. This has been refined to a high sensitivity in the branched-chain DNA assay which is based on signal amplification (109). In this process, shown in Figure 9, the genome is hybridized to a primary probe of complementary sequence which is immobilized on a solid phase. The genome then further hybridizes to secondary probes, which then hybridize with an amplification multimer. The latter hybridizes further with labeled probes that allow for the detection of the branched chain structure. Branched DNA assays have a sensitivity of 50 to 500 genome copies per ml. An alternative approach, exemplified by the hybrid capture assay, involves hybridization in solution between a denatured DNA target and complementary RNA probes resulting in the formation of a DNA-RNA hybrid. This structure is recognized by an antibody which is then detected by an immunoassay detection system. Such an approach has been commercially applied in the Digene Corporation Hybrid Capture assays (Qiagen, Venlo, Netherlands). Hybridization assays, while not as sensitive as nucleic acid amplification (i.e., limit of detection of 500 to 1,000 genome copies per ml), have an ability to quantitate the amount of genome present in the specimen. These have been successfully adapted to the quantitation of hepatitis C virus (HCV) RNA (110).

**FIGURE 8** Nucleic acid sequence-based amplification (NASBA). This procedure is particularly well adapted to the detection of RNA. The reaction mixture consists of one primer which contains the sequence for the T7 RNA polymerase promoter at its 5'-end, a second primer at the downstream end of the sequence to be amplified, T7 RNA polymerase, reverse transcriptase, and RNase H as well as the ribo- and deoxyribonucleotide triphosphates. When the primer containing the T7 promoter anneals to the target RNA, the reverse transcriptase synthesizes the complementary DNA strand and the RNA portion of this duplex is digested by the RNase H. After the binding of the downstream primer, the reverse transcriptase synthesizes a double-stranded DNA with a T7 promoter at one end which serves as a template for the T7 RNA polymerase that synthesizes approximately 1,000 copies of antisense RNA in a promoter-dependent manner. This RNA can be further reverse transcribed to double-stranded DNA which can serve as a template on which the RNA polymerase can synthesize multiple antisense RNA copies. (Reprinted from reference (185) with permission.)

#### Quantitative Nucleic Acid Tests

Initially, quantitation by PCR assays was accomplished by performing the assay on serial dilutions of the specimen. Currently, quantitative PCR assays contain an internal standard target of defined concentration that serves as a reference on which the calculations of concentrations of the analyte nucleic acid are based. Due to inherent variability, most commercial assays claim an accuracy within 0.5 log<sub>10</sub>, or approximately 3-fold. These approaches are based on the assumption that the amplification efficiencies of the standard and the target are nearly equivalent. Quantitation can also be achieved by NASBA and branch chain DNA assays (111). The latter being a signal amplification assay is considered less variable but also less sensitive than target amplification assays. The NASBA and PCR assays have been optimized to detect the product in the log phase of the

**FIGURE 9** Branched chain DNA (bdDNA) assay of first (A) and third (B) generations. Target DNA hybridizes to capture probes linked to a solid phase. A short oligonucleotide called the label extender hybridizes with complementary sequences on the target DNA and with either the amplifier oligonucleotide shown in A or a longer oligonucleotide called the preamplifier that contains multiple repeat sequences shown in B. Amplifier oligonucleotides then hybridize to the alkaline phosphatase (AP)-linked probes shown in A as well as the preamplifier sites shown in B. Alkaline phosphatase is detected by standard reagents for the enzyme.

amplification rather than at the end, thereby increasing the dynamic range. To overcome some of the barriers associated with quantitative PCR such as the requirement for standard curves for absolute quantification, and the efficiency dependence of the polymerase reaction which can lead to data variability from sample contaminants, digital PCR (dPCR) was introduced (112). The technique is based on the partitioning of a single sample (containing DNA or RNA, primers, polymerase, and a fluorescent probe) into thousands of individual reaction vessels followed by amplification. Each reactor can then be sorted by fluorescent signal as positive or negative delineating the presence or absence of target (113).

### Controls

Controls are of critical importance in NAT assays, because the analytical sensitivity is high and because the amplicons generated in the PCR reactions are relatively stable and serve as a potential source of contamination. Efforts to overcome this problem include the use of assays that do not create DNA amplicons such as NASBA, branched DNA, and real-time PCR which does not involve the opening of the tube with amplified products. The addition of deoxyuridine triphosphate together with uracil DNA glycosylase to the PCR, which destroys the amplicon sequence at the end of the assay (114), is commonly used. Fastidious adherence to the design of the laboratories so that amplicon contamination is avoided by restriction of movement among clean and dirty rooms is essential. Amplicon contamination of the environment can be further reduced by wiping the surfaces with household bleach, exposing working surfaces to short ultraviolet light, and working in laminar flow biological safety cabinets with appropriate clothing and use of gloves.

NATs require numerous controls to ensure that the amplification reactions did occur and that they were free of any contamination. These include amplification controls or target-related oligonucleotides such as genomes of related viruses with sequences complementary to the same probes, genomes of other viruses for which probes are provided, and DNA of defined sequences in plasmid vectors or RNA produced by T7 polymerase from a recombinant DNA target with T7 promoter. It is particularly important to protect the RNA controls from endogenous RNases by inclusion of RNase inhibitors, or by encapsulating them into proteins such as that of MS1 phage as in the case of “armoured RNA” (115). Controls are also added to the specimen or aliquot thereof before extraction to serve as extraction controls. Water, free of any target, is an essential negative control. Finally, a sample quality control consisting of a common gene such as Beta-globin or RNase P helps to validate that the specimen contained adequate tissue for testing.

### Application of Nucleic Acid Testing in Virology

The very high sensitivity of NATs has greatly improved the ability to obtain an accurate viral diagnosis, but has also created a need for enhanced insight into the interpretation of the test results and the need to more thoroughly understand the pathogenesis of viral infections. Applications of NATs include detection of the virus in the patient specimen in acute and chronic infections, the potential to subtype the virus to the level of its genome sequence, to quantitate the concentration of the virus to determine the extent of the infection, the likelihood for transmission, and the response to antiviral therapy, and to monitor the development of strains resistant to antiviral agents.

### Routine Diagnosis of Virus Infection

Detection of most common viruses can be performed by NAT within comparable or superior turnaround times, and with substantially increased sensitivity, relative to conventional methods. Using real-time PCR, most of these viruses can be identified in patient specimens on a same-day to next-day basis, making the diagnosis relevant for patient management. In addition, the development of multiplex assays has allowed for an unprecedented breadth of testing for all known respiratory viruses in a patient specimen within a working day using a single test (93). Likewise, nucleic acid microarray technology is believed to have a similar potential (116).

Real-time PCR has been successfully applied to same-day testing for herpes simplex virus either as “in-house” or commercially marketed assays (117). The diagnosis of noroviruses and other gastrointestinal viruses by NAT is more efficient and reliable than ELISA or EM (118). While enteroviruses have conventionally been diagnosed by isolation in cell culture, NAT is substantially more sensitive, an important consideration in the diagnosis of neurotropic viruses (119). Accordingly, laboratories are becoming increasingly reliant on NAT for routine virus diagnosis, a trend that is likely to continue as the costs of these tests decrease with increased volumes of use, and the implementation of further automation.

### Diagnosis of Novel and Emerging Viral Infections

NAT is particularly suitable for the diagnosis of novel and emerging infections. The ones that stand out in recent times are the diagnosis of the Sin Nombre hantavirus in 1993, the diagnosis of SARS-coronavirus in 2003, and the diagnosis of MERS-coronavirus more recently (120–122). A major

advantage of NAT in the workup for novel agents of as yet unknown risk, or those associated with high morbidity and mortality, is that much of the investigation does not need to be performed under BSL-3 conditions. The risk of working with extracted nucleic acids is minimal under BSL-2 conditions. Group-specific PCR assays based on conserved sequences can provide evidence as to the identity of the virus at the family level, and the virus is further characterized by the sequencing of the amplicons. Similarly, amplicons from randomly primed PCR reactions can be characterized by shotgun sequencing. In implementing tests for pandemic influenza in 2009, NAT reagents were readily available, the primer sequences quickly identified and communicated to laboratories, the extraction and NAT assays were readily scaled up 10-fold, and testing was performed in BSL-2 laboratories with specimen extraction being the only risky step (123).

### Diagnosis of Chronic Viral Infections

Primary diagnosis of chronic viral infections such as HIV, HBV, and HCV is generally accomplished by serology, but NAT has an important role in the follow-up of these infections. With NAT, one can differentiate between a chronic HCV infection which is present in approximately 75% of seropositive patients, and successful resolution of the infection in the remainder (124). NAT is used to determine whether a child, born of an HIV seropositive mother, is infected or whether the antibody in his/her serum comes from passive maternal transfer (125). NAT can help resolve conundrums in HBV serology and establish or rule out infectivity. Likewise, NAT is used for testing blood donors to rule out the use of the very rare infected unit that cannot be identified by serology and other screening methods. Finally, NAT is often the only realistic test to use to investigate infection in immunocompromised patients unable to mount a humoral immune response.

NATs that can assess the concentration of the virus in the blood have proven valuable as the viral load correlates with the risk of transmission. Pregnant mothers with HIV are treated with antiviral drugs to suppress the viral load, which can be monitored (125). Likewise, the viral load correlates directly with the risk of transmission in HIV-discordant couples (126). Finally, for healthcare workers with chronic HBV infections, a high viral load can be used to exclude them from certain procedures.

### Viral Diagnosis in the Management of Immunocompromised Patients

Patients immunocompromised either through infection, malignancy, or iatrogenically, such as those having undergone transplants, are subject to many life-threatening viral infections. Infections of particular concern to such patients are those of the herpesviruses, EBV and CMV (127). Monitoring the viral load in the blood of transplant patients, especially those in the pediatric group, and either modulating immunosuppression or using antiviral drugs such as ganciclovir is critical for their survival. Likewise, monitoring the presence of adenoviruses and the human polyomavirus BK in the blood and urine are important in transplant patients and these are most commonly done by NAT (78, 128).

### Monitoring Response to Antiviral Therapy and Antiviral Drug Resistance

In HCV-infected individuals, the duration of antiviral therapy with interferon and ribavirin has been determined

by the genotype of the virus and the efficacy of the treatment on the viremia (129). The viral genotype is obtained by characterizing the amplified nontranslated 5'-region of the genome by either sequence analysis or by hybridization to probes immobilized as lines on a solid phase (Line blot). The response to treatment of specific genotypes is monitored by quantitative assays such as branched chain DNA and quantitative PCR. These are vital assays for HCV treatment, the utilization of which is dependent on a brisk fall in viremia and the absence of detectable virus at the end of treatment. Likewise, HBV viral load can be quantitated by branched chain DNA or PCR assays and used to monitor the response to antiviral drugs.

The capacity to accurately assess the viral load is essential in the management of HIV infections, where there is a relationship between viral load, the CD4 cell count, and disease progression (130). When patients are undergoing antiviral treatment, the goal is to maintain the viral load at levels below 50 genome copies per ml of plasma, the lower limit of detection of quantitative assays (131). In another application, an increased viral load in a patient receiving antiviral therapy may suggest the development of viral resistance, which can be confirmed by specific phenotypic or genotypic resistance assays.

### Nucleic Acid Sequencing

DNA sequencing has evolved from a research tool to become an expected part of diagnostic virology. It has proven its value by greatly simplifying the typing of enteroviruses and adenoviruses (132, 133). It allows for identifying specific genotypes of noroviruses and rotaviruses (118, 134) and for monitoring the drift of influenza A viruses at the nucleotide level over time (135). Newer sequencing technologies such as pyrosequencing and shotgun sequencing allow for even more effective application of sequencing to diagnostics, and are indicative of the future directions of these technologies in viral diagnosis (136). This includes more accurate determination of quasispecies of the virus present in a clinical specimen. Finally, high throughput sequencing allows for metagenomics analysis of the nucleic acids present in clinical specimens to comprehensively identify existing and potentially novel viruses (137, 138).

## SERODIAGNOSIS OF VIRAL DISEASES

Serologic assays for the detection of antibodies directed against viruses continue to play a major role in the clinical laboratory. For individual patients, these assays can be used for diagnosis of acute or chronic infections, determination of immune status (either as a result of natural infection or immunization), and for detection of individuals latently infected with certain viruses (e.g., *Herpesviridae*) (Table 7). Clinically, these assays are used for seroepidemiologic surveys, donor screening for prevention of transmission of blood-borne viruses (e.g., blood, organ, tissue, etc.) from donor to recipient, preemployment of healthcare workers and others, infection control purposes, prenatal screening of mothers for determining risk of vertical transmission and planning of preventive strategies (e.g., hepatitis B), and for managing risks associated with occupational or other exposures (e.g., needlestick injuries, etc.). In addition to preventing transmission of blood-borne viruses during transplantation or transfusion, knowing the serologic status of organ donors and recipients prior to transplantation for certain viruses such as CMV is important when considering the type of donor and blood products to be given, and in

**TABLE 7** Utility of serological determinations in clinical virology

Application	Most common virus(es) <sup>a</sup>
Diagnosis of recent or chronic infections	
Hepatitis	Hepatitis viruses A-E, CMV, EBV, HSV, VZV, HIV, coxsackievirus B, adenovirus, yellow fever virus
Central nervous system	HSV, CMV, VZV, EBV, HHV-6, enteroviruses, West Nile virus and other arboviruses, measles virus, mumps virus, rubella virus, rabies virus, HIV, LCV
Congenital/perinatal	CMV, HSV, VZV, rubella virus, HBV, HCV, parvovirus B19, LCV
Exanthems	Measles virus, rubella virus, parvovirus B19, HHV-6, HHV-7, arboviruses
Myocarditis/pericarditis	Coxsackievirus B types 1–5, influenza virus types A and B, CMV
Infectious mononucleosis	
Heterophile antibody positive	EBV
Heterophile antibody negative	EBV <sup>b</sup> , CMV, HIV, rubella virus, HHV-6
Nonspecific febrile illness	CMV, EBV, HHV-6, HHV-7, Parvovirus B19, HIV, dengue virus, Colorado tick fever virus
T-cell leukemia	HTLV-I/II
Hemorrhagic fever	Filoviruses, arenaviruses, flaviviruses, bunyaviruses
Hantavirus pulmonary syndrome	Sin Nombre virus, other hantaviruses
Screening for immune status <sup>c</sup>	
Preemployment	VZV, rubella virus, measles virus, HBV
Prenatal	Rubella virus, CMV, HSV, VZV, Parvovirus B19, HBV, HCV, HIV
Pretransplant	CMV, HSV, EBV, VZV, HBV, HCV, HIV
Blood donation	HIV, HBV, HCV, HTLV-I/II
Postexposure	HIV, HAV, HBV, HCV, VZV
Epidemiology and surveillance	All viruses
Verify response to vaccination	HAV, HBV, HPV, VZV, measles virus, mumps virus, rubella virus

<sup>a</sup>CMV, cytomegalovirus; EBV, Epstein-Barr virus; HSV, herpes simplex virus; VZV, varicella-zoster virus; HIV, human immunodeficiency virus; LCV, lymphocytic choriomeningitis virus; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV-6, human herpes virus-6; HHV-7, human herpes virus-7; HPV, human papillomavirus; HTLV-I/II, human T-lymphotropic virus I and II; WNV, West Nile virus.

<sup>b</sup>A comprehensive panel of EBV-specific serological tests should be performed for patients with heterophile-negative infectious mononucleosis, since only 60% of individuals will have heterophile antibodies by the second week of EBV mononucleosis and the test is usually negative in children  $\leq 4$  years of age. Commercial EIA and IFA EBV serological tests allow for the simultaneous titration of virus-specific antibodies to the viral capsid, early and nuclear antigens of the virus. Interpretation of the panel permits identification of current or recent primary infection, recurrent or chronic infection, or past infection with EBV.

<sup>c</sup>Determination of immune status either as a result of natural infection or immunization.

determining the treatment or prophylaxis to be used following transplantation.

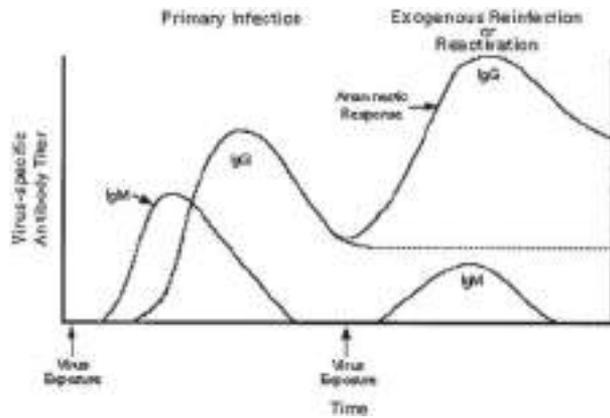

Detection of virus-specific antibodies in a patient's serum or plasma may also be the only means of making a viral diagnosis under certain circumstances. A number of viruses are impossible, difficult, or even hazardous to grow in culture, or difficult to detect by other methods. Proper specimens for culture or direct detection assays may be difficult to obtain or may not be obtained because viremia or virus replication and shedding have subsided to undetectable levels when symptoms occur. In these situations, serodiagnosis is often helpful in confirming a recent or past infection with a specific virus. Sometimes, the clinical significance of detecting a virus by means of a direct assay or by molecular techniques may be uncertain. In these situations, serology may assist in establishing a causal relationship (e.g., significant changes in antibody titre to the detected virus or presence of IgM antibodies to a specific virus). Serology is also an invaluable tool in the public health domain, whether to assess incidence and prevalence of viral diseases for epidemiological studies, surveillance systems, or evaluation of the efficacy of prevention and control programs.

Although traditional methods of viral serodiagnosis are still in use, automated technologies have now become the mainstream of serological testing in clinical laboratories. Use

of recombinant antigens and synthetic peptides representing immunodominant regions has improved test sensitivity and specificity for detecting and confirming virus-specific antibodies. At the same time, simple-to-use commercial tests or devices capable of rapidly analyzing single specimens, such as finger prick blood samples, have been introduced for rapid point-of-care testing.

### Antibody Response to Viral Infections

Immunoglobulins as markers of humoral response are more useful and reliable than cell-mediated immunity for diagnostic purposes. Antibodies can be detected and measured as they develop in response to an infecting virus or to immunization (Figure 10). Because of the transient nature of the IgM antibody response, its presence is generally indicative of current or recent viral infection. However, reactivation of latent or chronic viral infections (e.g., HSV, Hepatitis B, others) can result in detectable levels of IgM antibodies, making the distinction between acute infection and reactivation disease difficult. As well, certain viruses such as EBV can result in a polyclonal B-cell stimulation with elevated IgM antibodies to multiple different viruses. A significant (classically a 4-fold) rise in IgG antibody concentration between acute and convalescent serum samples collected 10 to 14 days apart is also accepted as evidence of an acute or

**FIGURE 10** Diagram depicting the typical IgM and IgG antibody responses following primary viral infection, reactivation or reinfection. During primary infection, IgM appears within several days after onset of symptoms, peaks at 7 to 10 days, and normally declines to undetectable levels within 1 to 3 months. Following natural viral infection or after successful immunization, IgG antibodies appear several days after the production of IgM, reaches higher levels than IgM, and can persist for years, even life-long, in lower quantities. During reactivation or exogenous reinfection, an anamnestic response in IgG antibodies will occur and an IgM response may or may not be observed.

recent infection. In some instances, measurement of antibody avidity may help in distinguishing a recent infection from a past infection with associated reactivation (139, 140). Avidity refers to the accumulated strength of multiple affinities between an antibody and antigen as a result of multiple antigen-binding sites simultaneously interacting with the target antigenic epitopes. As the antibody response to a viral infection matures over time, avidity of the antibody-antigen interaction increases. Hence, low avidity is likely to point to a recent primary infection (141). Avidity can only be measured in individuals with detectable IgG antibodies to the particular virus of interest. Avidity tests for rubella virus, measles virus, *Toxoplasma gondii*, CMV, VZV, HIV, hepatitis viruses, EBV, and others have been developed. Although maturation of the IgG antibody response generally occurs within 6 months following infection, in some individuals this may take longer resulting in a prolonged low or intermediate avidity value and a potentially misleading interpretation as evidence of a recent infection (142).

Avidity assays are generally based on direct ELISA methods in which the serum sample is tested in duplicate. In one well, the ELISA is performed as described above while in the other well, a chaotropic agent such as urea capable of breaking antibody-antigen bonds is added after the antigen-antibody reaction is allowed to occur, but before the detector antibody is added. A comparison is then made between the reading of the two wells and a result is generated which is reported as an avidity index (AI). A low AI suggests relatively recent infection, whereas a high AI is consistent with a mature or past infection. One of the most common areas where measurement of IgG avidity has been applied is in evaluating pregnant women for possible recent CMV, rubella, and VZV infection.

The role, onset, level, and duration of IgA, IgD, and IgE antibodies are less predictable than either IgM or IgG, and

serological tests for these isotypes are generally not performed routinely in diagnostic laboratories.

### Specimens for Serodiagnosis

Serum is the specimen of choice for most serological assays; plasma can be used in some instances but is not suitable for all antibody tests unless specified by the manufacturer of the assay. Although antibody tests can be applied to other specimen types (e.g., CSF and other body fluids), most assays have not been validated for use with these specimens and results must be interpreted with caution. In adults, 4 to 7 ml of blood obtained from venipuncture in a collection tube containing no additive or preservative is usually sufficient for most testing. The laboratory will accept smaller volumes of blood, particularly from infants and young children or when few tests are being requested. Whole blood collected and dried on filter paper has been studied as a practical and effective substitution to obtaining serum by venipuncture, especially when screening for antibody to HIV (143). A consumer-controlled home collection kit using whole blood has been licensed for HIV-1 testing. Dried blood specimens have also been used for HBV, HCV, measles, mumps, and rubella antibody screening either because phlebotomy was resisted by the patient or transport and long-term storage of serum and plasma specimens was logistically difficult (144, 145).

Whole blood should be allowed to clot for 30 to 60 minutes at room temperature. A centrifugation step allows separation of the serum from the remainder of the blood components. Collected whole blood should not be frozen as this may cause hemolysis rendering the specimen unusable for serologic testing. Icteric, lipemic, or heat-inactivated sera may also cause erroneous test results and should be avoided, if possible. Serum should be refrigerated at 4°C shortly after separation from the blood clot and during transport to the laboratory. If an extended delay in transport or testing of a specimen (beyond 5 to 7 days) is anticipated (e.g., holding an acute-phase serum until the convalescent-phase serum is collected), freezing the serum to at least -20°C is advised.

A single serum specimen is required to determine the immune status of an individual or to detect IgM-specific antibodies. With few exceptions (e.g., EBV mononucleosis), paired serum specimens, collected 10 to 14 days apart, are required for the diagnosis of acute or recent viral infections when specimens are tested for IgG antibodies alone. The acute-phase serum should be obtained as soon as possible during the course of the illness, and no later than 5 to 7 days after onset. The most useful results are obtained by testing acute- and convalescent-phase sera simultaneously in a single assay run. Evaluation of serum for antibodies to so-called TORCH (*Toxoplasma gondii*, rubella virus, CMV, and HSV) agents associated with congenital and peripartum infections requires that two serum specimens be submitted for testing: one from the mother and the other from her infant. To identify congenital infection, the newborn should be younger than 3 weeks when the specimen is obtained. IgG antibodies to a particular virus in the newborn's blood may reflect passive transfer of maternal antibodies *in utero* and may persist for months after birth, making diagnosis of congenital or perinatal infection based on detection of IgG antibodies alone difficult. However, because IgM antibodies do not cross the placenta, their presence in the newborn's blood is consistent with either congenital or perinatal transmission.

CSF may be tested for viral antibodies in patients with viral central nervous system (CNS) disease and may be

superior to NAT detection for some infections (e.g., West Nile virus). For members of the *Herpesviridae* family, and some respiratory viruses that may cause neurologic disease, both CSF and serum specimens should be collected and paired for accurate measurement of virus-specific intrathecal antibody synthesis (146). Simply finding virus-specific IgG antibodies to these agents in the CSF is not diagnostic of CNS infection, because of the expected passage of immunoglobulin (Ig) from blood to CSF. The normal ratio of Ig in blood to CSF is approximately 250:1.

Whole saliva, oral mucosal transudates rich in gingival crevicular fluid, and urine also have been evaluated as noninvasive alternatives to the collection of blood for the detection of antibodies to a number of different viruses (147). Particular attention has been paid to the value of oral fluids and urine for the diagnosis of infections with HIV (148–150). Accuracy of saliva for HIV antibody detection has been shown to be equivalent to serum for clinical usage as well as epidemiological surveillance (147). The sensitivity and specificity of urine tests are inferior to those of blood and oral fluid tests. FDA-approved HIV oral fluid and urine tests are commercially available. Accordingly, several commercial devices have been developed for the collection of oral mucosal transudate specimens. The devices provide a homogeneous specimen rich in plasma-derived IgG and IgM that is passively transferred to the mouth across the mucosa and through the gingival crevices (151). Lastly, vitreous humor has been used for the detection of antibodies to HSV or VZV in individuals with eye infections due to these agents (152, 153).

### Procedures for Detecting Viral Antibodies

A variety of methods are available for serodiagnosis of viral infections (reviewed in (67, 154, 155)). The more traditional assays include complement fixation (CF), hemagglutination inhibition (HI), neutralization (NT), immune adherence hemagglutination (IAHA), and indirect and anti-complement (ACIF) immunofluorescence (IFA). With the exception of some commercial IFA kits, these are in-house assays and are rarely performed outside of specialized reference or public health laboratories. Most clinical laboratories use commercially manufactured assays including SPIA, passive latex agglutination (PLA), immunoblotting (IB), and immunochromatographic (IC) tests. The selection of which test method(s) to perform will depend on the patient population and clinical situation, the number of specimens to be tested, turnaround time, ease of testing, and the resources and capabilities of the individual laboratory. Critical clinical information such as the date of onset of disease symptoms, recent travel history, immunization, or medical antecedents may also influence the choice of an adequate analytical strategy. Qualitative measurements of virus-induced antibody can be performed when it is useful to know simply that a specific antibody is present or absent. Quantitation is essential when it is important to know the amount of antibody present, particularly when measuring virus-specific IgG antibodies (e.g., immunity to hepatitis B and rubella viruses).

### Complement Fixation

Complement fixation can be used for measuring antibodies against virtually any cultivable virus and it has the distinct advantage of assessing significant rises in antibody levels during acute viral infections (156). The CF method uses the cytolytic property of the complement system as an indirect marker for the antigen–antibody reaction. When virus-specific antibody is present in a patient's serum, it will

complex with its corresponding antigen and fix guinea pig complement, thereby preventing lysis of sheep red blood cells (RBC) complexed with anti-erythrocyte antibodies. Conversely, absence of antibody results in activation of the complement cascade by the addition of the sensitized RBCs, thus resulting in their lysis. Although inexpensive in material and reagents, the method is technically demanding, requires rigid standardization and titration of reagents, has a long turnaround time, and acute and convalescent serum must be tested in the same assay run. The CF test is also less sensitive than other methods and cannot be used to determine immune status. Invalid results can occur with sera possessing anticomplementary activity due to nonspecific binding of serum components to the complement used in the assay. For these reasons, the CF test is rarely if ever used today in a routine clinical laboratory.

### Hemagglutination Inhibition

HI has been applied to the detection of antibodies to viruses possessing surface proteins that can agglutinate RBCs (157), particularly for the detection of antibodies to influenza, parainfluenza, measles, mumps, and rubella viruses and sometimes to the arboviruses, adenoviruses, and polyomaviruses. Antiviral antibodies in a patient's serum can inhibit the agglutination of RBCs by a viral antigen. The assay is prone to many of the same limitations as CF. In addition, nonspecific inhibitors and natural agglutinins need to be removed from some serum specimens before virus-specific antibodies can be detected. The specificity of HI also varies with the virus, being highly specific for influenza and parainfluenza viruses but less so for arboviruses. Detection of hemagglutinating antibodies is the current standard for assessing the immunogenicity of seasonal influenza vaccines and is often used for retrospective diagnosis of individual infections. The HI assay is also commonly used for subtyping and antigenic characterization of influenza virus isolates by reference laboratories.

The monospot test for the diagnosis of acute/recent EBV infection is a hemagglutination test that relies on the agglutination of horse RBCs by heterophile antibodies in the patient's serum (158). The test is specific for heterophile antibodies produced by the human immune system in response to EBV infection (159). In performing the monospot test, a drop of the patient's serum is mixed on a glass slide with a suspension of guinea-pig kidney stroma and a suspension of beef red cell stroma. A drop of horse RBC suspension is then added to each mixture. After approximately a minute, the slides are examined for the presence or absence of red cell agglutination. If agglutination is stronger with the guinea-pig kidney mixture, the test is positive. If it is stronger with the beef red cell mixture, then the test is negative. Commercial kits for performing the monospot test are available and continue to be widely used because of their relative ease to perform, rapid results, and low cost. The specificity of the test approaches 100% while the sensitivity ranges from 70 to 90%.

### Neutralization

Unlike SPIAs, which detect binding antibodies to viral antigens, NT assays detect functional virus-specific antibodies capable of neutralizing or blocking the infectivity and replication of a given virus within a cell culture system (160). The assay can be performed in microtitre plates containing cell monolayers infected with approximately 100 infectious units of virus and a serially diluted antiserum. For greater accuracy, it can also be performed as a Plaque

Reduction Neutralization Test (PRNT). Neutralization titer is usually expressed as the reciprocal of the highest serum dilution resulting in a 90% reduction in the number of infected foci or plaques produced by a virus on a cell monolayer. Detection of neutralizing antibodies is clinically important in establishing protective immunity in response to a viral infection or vaccination. However, the assay is cumbersome, expensive, time-consuming, and in the case of highly pathogenic viruses, needs to be performed under high biosafety conditions (e.g., BSL-3 for West Nile virus and avian influenza A [H5N1] virus). Similar to HI, the quantity of virus used in the system must be carefully determined to obtain accurate results. The NT assay remains the method of choice for the detection of antibodies to the enteroviruses and the most specific test for confirmation of West Nile virus and other arthropod-borne flaviviruses.

A variant of the PRNT is used for the measurement of neutralizing antibodies to rabies virus (161). The Rabies Fluorescent Focus Inhibition Test (RFFIT) remains the gold standard for detection of rabies neutralizing antibodies in a patient's serum. Rather than count plaques, immunofluorescence is used to assess changes in rabies virus replication in cell culture. RFFIT is not generally used for diagnosis of rabies infection. Its major use is for the measurement of rabies neutralizing antibodies in persons vaccinated with the rabies vaccine and whose antibody levels are being monitored routinely due to occupational exposure to rabies virus.

### Immune Adherence Hemagglutination

The IAHA method uses the hemagglutinating property of the C3b fragment of complement following attachment to C3b receptors on human type O RBCs as an indirect marker for the antigen-antibody reaction (162). Virus-specific antibodies in serum are detected when complement binds to antibody-antigen complexes that have formed rather than to RBCs, thus inhibiting hemagglutination. The assay is simple, and has a sensitivity and specificity that is better than CF, comparable to IFA, and only slightly less sensitive than SPIA. IAHA is reliable for immune status testing and quantitative measurements of antibody titers. IgM can be detected after fractionation from IgG antibodies. Special attention has to be given to finding an adequate supply of human type O erythrocytes, and to qualify commercial antigen preparations. A prozone effect may occur in the presence of excess virus-specific antibody in the serum sample. IAHA has been used for the detection of antibodies to many different viruses (e.g., rabies, hepatitis, and VZV). It is rarely used in clinical virology laboratories.

### Immunofluorescence Assays

IFA are very useful and inexpensive methods that offer the advantages of speed and simplicity for the qualitative and quantitative detection of both IgM or IgG antiviral antibodies in clinical specimens (163). Commercial kits or antigen-coated slides are readily available for many of the common viruses, and labeled secondary antibodies can be purchased separately. Antibody is usually detected by either an indirect IFA or ACIF. In the indirect IFA, dilutions of serum are incubated with virus-infected cells that have been fixed to a glass microscope slide; specific antibody-antigen complexes that form are then detected using an anti-human antibody conjugated with a fluorochrome, most often FITC. A variation of this procedure called monoclonal antibody-enhanced IFA (MIFA) has been designed to increase the sensitivity of the fluorescent signal. It is a three step procedure using an anti-human immunoglobulin mouse mono-

clonal antibody which is allowed to react with antibody-antigen complexes before an anti-mouse labeled antibody is used in the detection step (164). ACIF differs in that following incubation of test serum with virus-infected cells on a glass slide, fresh complement is added and bound by any specific antigen-antibody complexes that have formed. A fluorescein-labeled anticomplement antibody is then added and binds to the C3 component of complement. ACIF amplifies the fluorescence signal, allowing for the detection of small amounts of antibody or antibodies of low avidity. This method is routinely used to detect antibodies to the nuclear antigen of EBV.

The disadvantages of IFA are that it requires a fluorescence microscope and dark room for examining slides and extensive training and critical evaluation are needed to read and reliably interpret the test results. The number of positively fluorescing cells, as well as the quality and intensity of the fluorescence, must be carefully examined and compared to those of cells reacted with positive and negative control sera. Most manufacturers of commercial kits provide antigen slides in which only 20 to 40% of the cells express viral antigens. Therefore, nonspecific binding of antibodies to the cells is easily discerned since the staining produced by these antibodies involves all of the cells.

### Solid-Phase Immunoassays

The term SPIA encompasses a large variety of methods and platforms aimed at detecting immobilized antigen-antibody complexes by means of a reporter signal. They have become the methods of choice for the detection of many virus-specific antibodies because of their speed, convenience, relative simplicity, and excellent sensitivity and specificity. The assay format is quite versatile, has evolved from polypropylene test tubes to microscopic spheres, and is applicable to many viruses and large numbers of specimens at a relatively low cost. As noted earlier, ELISA and EIA are the most popular SPIA used in clinical virology laboratories; they offer the advantages of using highly standardized and stable immunoreagents, especially those using recombinant antigens and synthetic peptides. EIA kits that detect IgG or IgM antibodies to a number of different viruses are available from a variety of commercial sources. A newer generation of assays even provides simultaneous detection of antigen and antibody, thereby improving the early detection of HIV and HCV (165, 166).

As for the detection of viral antigens, both noncompetitive and competitive assays are available, and the results can be evaluated either qualitatively or quantitatively (67). The basic principle of the noncompetitive EIA for the detection of antibodies is similar to that for the detection of viral antigens, except that viral antigen is immobilized on a solid phase and is used to capture free virus-specific antibody in a clinical specimen. The captured antibodies are then detected with the addition of an enzyme-labeled anti-human antibody followed by the addition of a chromogenic substrate to produce a color change. The intensity of the color generated is measured in a spectrophotometer and is usually proportional to the amount of virus-specific antibody in the specimen. Quantification of antibody content can be calculated from a standard curve established from serial dilutions of a reference antibody. In addition to color production, other detector labels have been used including fluorochrome labels such as fluorescein, rhodamine, and Texas red, as well as chemiluminescent substrates.

In a competitive EIA, enzyme-labeled antiviral antibody is mixed with test serum, and the presence of virus-specific

antibodies in the specimen will compete with the labeled antibody for a limited number of viral antigen binding sites on the solid phase. The activity of labeled antibody activity is then measured as described above. The decrease in detectable labeled antibody is inversely proportional to the quantity of antibody present in the sample. Competitive antibody assays are often used to provide greater specificity than noncompetitive assays.

RIAs using radioactive iodine as a label were developed in the 1970s (167). RIAs are less appealing because of the precautions and regulations needed to work with radioisotopes and dispose of these hazardous materials. Consequently, RIA has been largely replaced by EIA.

Microbead-based liquid arrays combine SPIA with flow cytometry to allow simultaneous detection of multiple antibodies (168, 169). The system uses 5.6  $\mu\text{m}$  polystyrene microspheres, each containing a unique spectral address determined by varying the concentrations of red and infrared fluorochromes. Each bead, coated with carboxyl groups, is covalently linked to peptides or proteins. Antiviral antibodies are then allowed to bind to their respective target antigens labeled with a fluorescent reporter molecule. Detection is performed by means of a flow cytometer composed of a dual beam laser detection system. A microfluidic device drives the microspheres into the laser beams. A red laser classifies the bead based on its internal color corresponding to a given antigen. A green laser measures fluorescence intensity corresponding to the reaction of antibodies with the antigen-reporter molecule complex. Microsphere immunoassays can detect up to 100 different viral antigens in a single well in less than 30 s per well, and require only small sample volumes. They have been applied successfully to the detection of antibodies to HIV, respiratory viruses, arboviruses, EBV, and HPV (170–174).

A number of semi-automated and fully automated immunoassay analyzers for SPIA are now commercially available. These systems have found particular utility in the area of blood banking and clinical virology, where extensive test menus now exist for the automated performance of serological assays for antibodies to HIV, hepatitis viruses, viral agents causing congenital infection, and other viruses of clinical importance. The majority of the automated immunoassay analyzers provide random access, walk-away simplicity to perform assays from sample processing through interpretation of results.

### Passive Latex Agglutination Assays

PLA is an uncomplicated, convenient, and inexpensive method that is best suited for testing small numbers of specimens. A suspension of latex particles coated with viral antigens is mixed with a clinical specimen and allowed to incubate with rotation for a short time (175). The antigen-coated particles will clump and produce visible agglutination in the presence of virus-specific antibody, which can be visualized with the naked eye. The test can be completed within 10 min and requires limited equipment and technical ability. Both IgG and IgM antibodies are detected without differentiation, and the sensitivity and specificity of PLA are reported to be comparable to those observed for EIA and IFA. However, reading an agglutination reaction by PLA can be subjective, and the results may be difficult to interpret. Also, a prozone or reduction in the degree of agglutination can occur with sera that have high levels of specific antibody, resulting in the need to dilute negative specimens and repeat the assay. PLA is best suited for qualitative determinations of viral antibody, but quantitation is also pos-

sible. An automated particle counting technology has been developed which allows objective reading of the agglutination reaction (176). When RBCs are coated with viral antigen, the procedure described for PLA is termed passive hemagglutination.

### Immunoblot Assays

IB is a distinct type of SPIA using nitrocellulose or polyvinylidene fluoride membranes as the physical support for the detection of antibodies to specific viral antigens (177). The classical example is the Western blot, an assay widely used for confirmation of positive HIV antibody results obtained by a screening test. In the Western blot assay, whole virus lysates of inactivated and disrupted viral proteins are separated by electrophoresis according to their molecular weight or relative mobility as they migrate through a polyacrylamide gel in the presence of sodium dodecyl sulfate. The resolved protein bands are then transferred onto a membrane. The membrane is then cut into strips. Each strip can then be incubated with its respective serum. If virus-specific antibodies are present in the serum, binding of specific antibodies to some or all of the separated proteins on the strip will occur. The antibody-antigen complexes are visualized as bands on the strip by using an enzyme-labeled anti-human antibody followed by a chromogenic substrate. Each band corresponds to a unique set of antibodies directed against its respective viral protein. For years, the HIV Western Blot assay has been the gold standard assay for confirmation of HIV antibodies following initial screening with an ELISA (178).

Strip IB assays, also known as line immunoassays, are similar to Western blot except for the preparation of the membrane strip (155). They use the same general procedure for incubation and readout of a chromogenic enzymatic product at the site of binding of a virus-specific antibody. However, strip IB utilizes recombinantly derived proteins and synthetic peptides of a virus that are directly deposited and immobilized at predetermined positions on the membrane. These artificial antigens reduce the presence of contaminating material derived from whole virus lysates and cell culture which may interfere with the assay. Strip IB assays are used mainly as a confirmatory or supplemental test to help verify the specificity of positive results obtained from SPIA used to initially screen for virus-specific antibodies. Commercial kits are available for HSV-1 and HSV-2, HIV-1 and HIV-2, HCV, human T-lymphotropic virus type-I (HTLV-I), and -II (HTLV-II). These assays are less sensitive than EIA screening assays but more specific with fewer indeterminate results compared to Western blot. However, they are relatively expensive and the findings can be subject to interpretation.

### Immunochromatographic Assays

IC tests, also known as lateral-flow tests, are a combination of SPIA and immunoblot. In most assays, blood or diluted serum is deposited at the bottom of a membrane. Virus-specific antibodies bind to a solid phase composed of recombinant viral antigens or peptides and a detector reagent. As this solid phase migrates across the membrane by capillary flow, it interacts with antibody capture lines deposited across the membrane. A built-in control line confirms proper functioning of the device after addition of the patient's sample and adequate procedural application. The result is read visually. The advantages of these qualitative assays are that they are simple to use, do not usually require special instrumentation, allow quick turnaround time,

are easy to interpret, and are applicable to urgent, field, and point-of-care testing (179). Commercial devices have been developed in recent years notably for HIV with sensitivities comparable to those of conventional EIA.

### IgM Antibody Determination

Virus-specific IgM antibodies are most commonly detected using SPIA and IFA (180). The methods are similar as those used for detecting IgG antibodies, except that IgM bound to viral antigen on the solid phase is detected using secondary anti-human IgM antibodies labeled with suitable markers. Assays to detect virus-specific IgM have been developed for most human viruses, and commercial reagents and complete diagnostic kits are available for a number of the agents (Table 8). However, false-positive and false-negative reactions are major concerns when measuring virus-specific IgM antibodies (180). False-negative reactions are the result of high levels of specific IgG antibodies competitively blocking the binding of IgM to the viral antigen placed on the solid phase. False-positive reactions occur when sera contain unusually high levels of rheumatoid factor (RF) or other interfering substances. RF is an IgM class Ig that reacts with IgG and is produced in some rheumatologic, vasculitic, and viral diseases. In the presence of virus-specific IgG antibodies, RF will form a complex with the IgG molecules. The IgG can then bind to the viral antigen on the solid phase, carrying nonviral IgM antibody with it and resulting in a false-positive result. The incidence of these false-negative and false-positive results can be minimized by separation of IgG and IgM from sera before testing.

A variety of methods have been developed for the removal of interfering RF and IgG molecules from serum, resulting in more reliable IgM tests (181). IgG and IgM antibodies can be physically separated using gel filtration, ion exchange chromatography, affinity chromatography, or sucrose density gradient centrifugation. Although such techniques are effective for separation of IgG and IgM, they are not very practical for clinical use. More rapid and simple procedures have been used for the selective absorption and removal of the IgG fraction from serum using hyperimmune anti-human IgG, staphylococcal protein A, or recombinant protein G from group G streptococci. These pretreatment methods are readily available and are incorporated within most commercial IgM detection kits.

Reverse capture solid-phase IgM or  $\mu$ -capture assays have been developed as an alternative to the physical fractionation of serum. In this method, the solid phase is coated with an anti-human IgM antibody that is used to capture the virus-specific IgM from the serum specimen. This is followed by washing to remove competing IgG antibody and immune complexes that may interfere with the accuracy of the test. A specific viral antigen is then added and allowed to bind to

the captured IgM. The antigen-antibody complexes are detected by adding an enzyme-conjugated secondary antibody, followed by a chromogenic substrate. IgM capture assays are very sensitive and specific and are considered to be superior to other IgM assay formats. An additional background subtraction step can further reduce nonspecific reactivity from interfering substances in serum (182).

### Interpretation of Serology Test Results

Interpretation of results for virus-specific antibodies in clinical virology is summarized in Table 9. Demonstration of a seroconversion from a negative to a positive IgG antibody response, or detecting the presence of virus-specific IgM, can be diagnostic of primary viral infection. Differences in antibody titers between acute- and convalescent-phase sera may support a recent viral infection due to reactivation or reinfection, although such testing is retrospective and has a limited impact on patient care. A significant change is defined as a 4-fold or greater rise in IgG titre between acute and convalescent serum when tested in the same assay run. This only applies to methods (e.g., CF, HI, others) that yield results in serial dilution endpoints or international units. Interpretation of a significant difference must rely on objective criteria specified by the laboratory or manufacturer when results of assays such as SPIA are expressed in optical density, relative luminescence, or index values. In titer, 4-fold decreases are seldom observed early enough to be useful for laboratory diagnosis since antibody levels tend to decline slowly over several months after infection. Detection of virus-specific IgG in a single-serum specimen, or no change in antibody levels between acute- and convalescent-phase sera indicates exposure to a virus some time in the past. Negative serum antibody titers may exclude viral infection.

The identification of intrathecal virus-specific antibody production in CSF can confirm the diagnosis of viral CNS infection (146). Finding virus-specific IgM antibodies in CSF is strong evidence for CNS disease caused by arboviruses, LCV, measles, mumps, or rubella viruses. Similar to using serum, 4-fold rises in virus-specific CSF IgG titers can also be diagnostic for these agents, but are less practical because of the need for and delay in testing acute- and convalescent-phase CSF specimens. The detection of any virus-specific antibodies to rabies virus in the CSF is diagnostic of active infection.

When assessing a newborn for congenital viral infections, the presence of IgM in the infant strongly suggests infection since IgM antibodies do not cross the placenta. Seronegative results in both the mother and infant indicate that the suspected viral agent is very unlikely to have infected the infant. Comparison of virus-specific IgG antibody titers between the infant and the mother is essential; a lower titer in the infant most likely reflects passive transfer of maternal antibody, whereas higher antibody titers in the infant than the mother may reflect active antibody production and thus infection of the infant. If maternal and infant serum antibody titers are the same, additional serum from the infant should be obtained 1 to 2 months later and periodically thereafter for 6 to 9 months, to be tested and compared with the earlier antibody titer. These sera should show a decrease in virus-specific antibody relative to the first specimen, if the infant has not been congenitally or perinatally infected with the tested agent.

The results of serologic tests for the detection of virus-specific antibodies must be interpreted with caution, because measurements of an antibody response to viral infections can be complicated by a number of factors. There may be a lack

**TABLE 8** Examples of viruses for which IgM serological determinations are useful and commercial reagents and/or kits are available

Measles virus	Dengue virus
Mumps virus	Hantavirus
Rubella virus	CMV
Parvovirus B19	EBV
Hepatitis A virus	VZV
Hepatitis B virus	HHV-6 and -7
West Nile virus	HSV-1 and -2

**TABLE 9** Interpretation of results for virus-specific antibodies in clinical virology

Context	Result	Interpretation
Immune status	IgG present	Past exposure or immunization
	IgG absent	Past exposure unlikely
Diagnosis of acute infection	IgM present	Primary or recent viral infection likely
	IgG seroconversion	
	Fourfold rise in IgG titers	
	Absence of IgM or IgG	Excludes viral infection
CSF infection	IgG present, single or stable titer	Past exposure
	IgM present	Strong evidence of CNS infection
	IgG seroconversion	
Congenital infection	IgM in infant	Evidence of congenital infection
	Absence of IgM or IgG in mother and infant	Suspected infection unlikely
	IgG infant < IgG mother	Passive antibody transfer
	IgG infant = IgG mother	Retesting in 1 to 2 months required
	IgG infant > IgG mother	Suggests congenitally or perinatally acquired infection
Immunocompromised individual	IgM and/or IgG absent	Possible delay in production of serum antibodies

of or delay in production of serum IgM or IgG antibodies, particularly in newborns, the elderly, and immunocompromised hosts. IgM antibodies also may persist for extended periods after primary infection and can be present during reactivation of latent viral infections. IgM may be undetectable during acute disease for individuals that were previously immunized but unsuccessfully protected. Significant rises in IgG antibodies do not always occur as a result of recurrent infections or exogenous reinfection. Virus-specific IgG antibodies may be present in recipients of intravenous Ig, newborn infants possessing passively acquired maternal antibody, or patients who have received recent blood transfusions, making it difficult to interpret IgG tests. Rises in the titres of either IgM or IgG antibody to certain viruses also may be nonspecific and in response to recent infections with other viruses. Accordingly, the possibility of a false-positive IgM result should be considered when the incidence of the virus under investigation is low. Indeterminate results inherent to some immunoassays may require additional patient visits, venipuncture, and repeated serologic testing. Accuracy of antibody detection assays is critical when follow-up care decisions are based on test results. For this reason, serologic assays producing fewer inaccurate or indeterminate results than others are likely to be more cost-effective. Finally, failure to establish an accurate serological diagnosis frequently results from the inability to submit an adequate set of paired serum.

For neurological viral diseases, the appearance of virus-specific antibody in the CSF may be delayed for 2 to 4 weeks. Also, for certain viruses, the presence of virus-specific antibody in the CSF may represent the passive transfer of serum antibodies across a damaged blood-brain barrier. Methods must be performed to determine and compare the CSF/serum ratio of virus-specific antibody to the CSF/serum ratio of albumin, particularly for members of the *Herpesviridae* family (146). Since albumin is not synthesized in the CNS, its presence in high concentrations within the CSF reflects the presence of contaminating serum proteins and an interruption of the blood-brain barrier. Demonstration of an intact blood-brain barrier in the presence of high levels of detectable virus-specific CSF antibody represents intrathecal

production of antibody and is considered evidence of viral infection of the CNS.

In the diagnosis of an infant with suspected viral congenital disease, measuring IgG antibody titres to the common agents rarely results in a definitive diagnosis and is more useful for excluding infection. Detecting a single elevated titer of IgG antibody to a specific viral agent is not useful and testing for HSV-specific antibody is of limited value. Negative antibody titers in the mother and child also may be the result of the mother having a primary infection of recent onset without immediate production of virus-specific antibodies. Appropriate follow-up studies are essential. Because of the many caveats associated with serologic diagnoses of viral infections, antibody determinations should be confirmed by isolation of the virus in culture or by using direct methods of detecting viral antigens or nucleic acids. The results should also be interpreted with careful consideration of the patient's symptoms and history.

## QUALITY ASSURANCE AND QUALITY CONTROL

Quality management, assurance, control, and continuous improvement are key elements of a complete quality assessment system, ensuring that all steps from specimen collection to result reporting are performed correctly. The goal of maintaining a quality system in a diagnostic laboratory is that "the right test is performed on the right specimen, and that the right result and interpretation are delivered timely to the right individual."

### Quality Assurance

Quality assurance is a broad term used to describe administrative and technical procedures for monitoring quality in the laboratory. Licensed, certified, or accredited clinical virology laboratories must comply with specific requirements of comprehensive quality assurance programs that are issued by regulatory and accreditation agencies. In the U.S., some minimal requirements are supported by legislative measures. In other countries, their scope may vary depending on local or regional jurisdictions. Quality assurance requires active

participation by all members of the institution. Standard operating procedures specify how preanalytical, analytical, and postanalytical activities are to be performed. These procedures are revised periodically and updated when necessary. Internal audits performed at regular intervals monitor compliance. Record keeping, equipment calibration and preventive maintenance, personnel training and competence assessment, and internal and external proficiency testing are all part of a quality assurance program (183). Ultimately, quality assurance leads to improvement of all aspects of laboratory services so that patient healthcare will benefit.

### Quality Control

Quality control focuses on monitoring the testing process itself in order to ensure test system performance. Variables affecting the quality of results are adequacy of training of laboratory personnel, sample type and condition, assay reagents, equipment performance, testing procedure deviance, and interpretation, transcription, and reporting of test results. Key elements of quality control include a set of written procedures specifying the elements to verify prior, during, and after the testing process. Major issues to be considered in this regard are documenting instrument conditions (e.g., temperature); calibration and use; reagent labeling regarding receipt, storage, and use prior to expiration date; storage of materials; hazard materials labeling and use; comparison of new methods to prior standards; and satisfactory performance of kits. Initial qualification of new lots of kits and reagents using known standard panels and insertion of control samples on each test run ensure that the kit, device, or equipment is performing within specifications and that the results generated are correct. For in-house assays, performance characteristics must be established. These include repeatability and reproducibility, cutoffs for qualitative assays, and linearity including lower and upper limits of quantification for quantitative and semiquantitative assays.

Monitoring test performance may allow detection of factors affecting assay quality, and ultimately reliability of results. Analyzing data for trends can establish deviation in test results over time (e.g., drift in the performance of a manufactured diagnostic kit). Investigation of a faulty test or run is facilitated when ancillary information is documented, and thus traceable throughout the procedure. If a result is not obtained according to procedure, or a specific instrument or reagent has failed to meet prescribed criteria, a non-conformity to a test procedure should be documented as well as the corrective action that is put in place to remedy the problem. This compilation is essential as it can identify a weakness in assay performance that otherwise may go unnoticed.

Analyzers and robotic platforms interfaced with computers are more common now in the virology laboratory, especially for antigen, antibody, and nucleic acid detection assays. Bar coded clinical specimens and reagents limit errors and facilitate monitoring and documentation of tests parameters. Users have the responsibility to assess the performance of these automated instruments. As test results are required rapidly to ensure prompt medical decisions, the diagnostics industry has been responding with point-of-care devices or tests, such as for influenza, RSV, and HIV. These assays are aimed to be used outside of the strictly controlled laboratory realm and constitute a new challenge for quality control in clinical virology. Development of adequate built-in controls may help to ensure accuracy of the kit result. However, deficiencies regarding basic documentation,

training, conformity of testing to manufacturer's package insert, respect of expiration dates, and knowledge of the limits of the test may affect result quality and interpretation. The consequences of an inaccurate result may include inappropriate medical decisions, unnecessary interventions, and worry for the patient. Therefore, personnel performing point-of-care tests should comply with documented protocols for specimen collection, processing, and testing, including adherence to established guidelines for confirmatory testing. It may also be considered to retest negative samples with an alternative assay when point-of-care testing is used to support prophylactic decisions (e.g., HIV). Finally, users should initiate corrective action when deviations or non-conformities to established parameters are detected.

Practical aspects of quality assurance programs and quality control in the clinical laboratory can be found in several American Society for Microbiology documents including *Clinical Microbiology Procedures Handbook* and *Cumitechs* (<http://www.asm.org/>). The Clinical and Laboratory Standards Institute has also published guideline documents addressing quality assurance and quality control issues for viral culture, immunoassays, point-of-care testing, and molecular diagnostic methods (<http://www.clsi.org/>).

*This chapter is dedicated to the memory of Michel Couillard, our co-author in the third edition.*

# Immune Responses to Viral Infection

HENDRIK STREECK, TODD J. SUSCOVICH, AND GALIT ALTER

## 16

The concept of “immunity” dates back to ancient Greece, where as early as the fifth century BC, documented cases of “immune” individuals were described who were related to individuals who recovered from the plague (1). However, it was not until the 10th century that specific “interventions” were described that could induce immunity. In both China and the Middle East, a process known as “variolation,” consisting of purposefully exposing healthy individuals to the contents of dried variola lesions, was actively practiced to prevent severe infection with smallpox. In the early 18<sup>th</sup> century, the practice of variolation was brought to Great Britain, where the development of the first vaccine by Jenner catalyzed the creation of the field of immunology. Beginning in the late 19<sup>th</sup> century, major breakthroughs, including the establishment of the “germ theory” by Koch and Pasteur, which held that disease was caused by bacteria or pathogens; the discovery of phagocytic cells by Metchnikoff; the identification of immune proteins in serum by von Behring and Kitasato; the identification of B cells and their regulation by Ehrlich; the discovery of lymphocytes by Gowan; the identification of pattern recognition receptors and innate immune activity by Janeway; and the discovery of dendritic cells, which link the innate and adaptive immune system, by Steinman, collectively gave rise to modern immunology and our current appreciation for the host immune response. This response has evolved to contain, eliminate, and remember virtually any pathogen to which it is exposed. This chapter reviews the components of the immune system, focusing on the innate and adaptive immune response to viral infection and how these arms of the immune system collaborate to prevent and control viral disease.

### THE IMMUNE SYSTEM

The immune system consists of a network of highly specialized cells, tissues, and organs that work collectively to provide protection from infection. Immune protection can be broadly divided into three lines of defense: (1) **barrier immunity** that nonspecifically protects against the invasion of pathogens, (2) **innate immunity** that is comprised of specialized networks of cells that rapidly respond, in a non-antigen-specific manner, to control and clear the invading pathogen, and (3) **adaptive immunity** that is a slower cellular response that evolves during an infection to confer

antigen-specific memory against that pathogen for life. Importantly, these three lines of defense, discussed below, collaborate to effectively prevent, contain, and eliminate infection via cellular communication networks, where at each line of defense, a failure to contain the threat is communicated to the next line of defense to ensure that immunity develops rapidly to contain the invading pathogen. The importance of these immune networks is most evident in genetic defects that result in compromised immunity that are often associated with severe disease (Table 1). For example, more than 200 inherited genetic defects have been described that affect single points within the immune response, and only very few children can survive such abnormalities.

### Barrier Immunity

The human body contains over 100 trillion cells. However, only 1 in 10 of these cells is human; the rest of the cells are largely bacterial and fungal. While the vast majority of this microbiome is innocuous or even beneficial to the host, some of these microorganisms would be pathogenic if allowed to proliferate unfettered. Recently, a virome, consisting of the collection of uncontrolled/infectious, persistent/chronic, genomically integrated, and asymptomatic viruses, has been described that may play an equally important role in both shaping the bacterial microbiome (2) and modulating and supporting the immune system (3). Thus, the first line of defense includes physical and chemical barriers that cover the surfaces of the body exposed to the environment (Fig. 1). These barriers, consisting of specialized cells and molecules, create a physical barricade that viruses must traverse and include (1) the skin, (2) mucosal membranes that line organs exposed to the external environment, and (3) the microbiota present on these barrier surfaces. Together, these barriers create highly complex physical and chemical barricades to prevent infection with incoming pathogens.

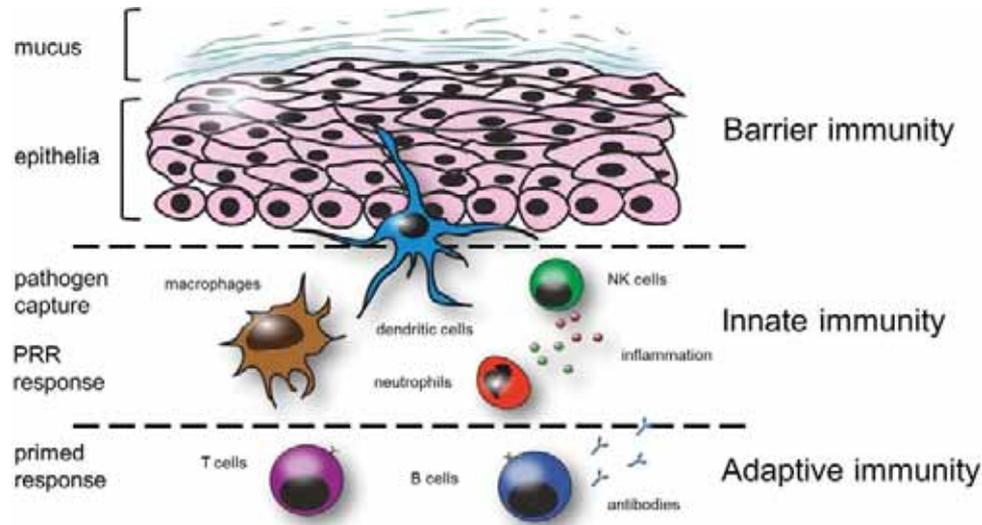

### The Skin

The skin is the body's largest organ, constituting a major component of our first line of defense against infection. Although there are many potential pathogens on the surface of the skin, the skin regularly repels these invaders and is rarely infected by direct inoculation of viruses with the exception of some poxviruses, human papilloma virus (HPV),

**TABLE 1** Clinical manifestations of genetic defects in different arms of the immune system

Immunological pathway	Defect	Immunodeficiency or syndrome	Mutated gene	Key clinical manifestations
<b>Defects in PRR</b>	Lack of TLR3, TLR7, TLR8, TL9 signaling	UNC93B deficiency	<i>UNC93B1/UNC93B1</i> protein	Impaired cellular responses to IFN- $\alpha/\beta$ and - $\lambda$ , increased infections with <b>HSV</b> and <b>CMV</b>
	Lack of TLR3, signaling	TLR3 deficiency	<i>TLR3/TLR3</i>	Impaired cellular responses to IFN- $\alpha/\beta$ and - $\lambda$ , increased infections with <b>HSV</b> and <b>CMV</b>
	Impaired signaling from TLRs except TLR3	MyD88 deficiency, IRAK4 deficiency	<i>MYD88, IRAK4</i>	Invasive and severe infection with <i>S. pneumoniae</i> , <i>S. aureus</i> , and <i>P. aeruginosa</i> , but normal response to other bacteria, viruses or parasites
	Impaired TLR3 signaling	TRAF3 adaptor molecule deficiency	<i>TRAF3/TRAF 3</i>	Impaired TLR3-dependent induction of type I IFN and IFN- $\lambda$ , increased <b>HSV</b> infections, otherwise healthy
	Lack of NF $\kappa$ B activity resulting in lack of TLR and other PRR signaling	NEMO defects	<i>NEMO</i>	Resulting in lack of intracellular signaling including TLR signaling, lethal
<b>Defects in phagocytes/ granulocytes</b>	Neutropenia	WHIM syndrome	<i>CXCR4/chemokine</i> receptor 4	Retention of neutrophils in the bone marrow, decreased IgGs, <b>HPV</b> infection
	Extreme neutrophilia	Leucocyte adhesion defect/ LAD	Integrin beta2	Skin infections and poor wound healing
	Absence of specific granules	Neutrophil-specific granule deficiency	CCAAT	Increased pyogenic infections
<b>Defects in NK and T cells</b>	Lack of SLAM-associated signaling (SAP)	XLP syndrome 1	<i>SH2D1A</i>	T and NK cell lymphoproliferative disorder, dysgammaglobulinemia; severe <b>EBV</b> infection
	Lack of SLAM-associated signaling (SAP)	XLP syndrome 2	<i>BIRC4/ X-linked</i> inhibitor of apoptosis	Reduced survival of NK cells, NK lymphopenia, increased apoptosis of T cells, hypogammaglobulinemia, severe <b>EBV</b> infection
	T-cell signaling transfection	EBV-associated lymphoproliferative syndrome	<i>Itk/interleukin-2</i> inducible T-cell kinase	Absent NK cells, severe <b>EBV</b> infection
	Defect in T-cell activity	Chronic active EBV infection	<i>PRF1/perforin</i> 1	Decreased cytotoxic T cell and NK cell activity, hypogammaglobulinemia, severe <b>EBV</b> infection
	Unknown/ zinc homeostatis	Epidermodyplasia verruciformis	<i>EVER1,EVER2/epidermodyplasia</i> verruciformis 1 and 2	Decreased T-cell responsiveness, fulminant <b>HPV</b> infection
	Overactive T cells with lack of T regulatory control	X-linked immune dysregulation with polyendocrinopathy (IPEX) Syndrome	FoxP3	Autoimmune diseases
	<b>Defects in humoral immunity</b>	Impaired CD4 B-cell interaction and AICDA activation	Hyper-IgM syndrome	Type 1: CD40L, Type 2: AICDA, Type 3: CD40, Type 4: downstream AICDA, Type 5: UNG
Defect in B-cell maturation		X-linked agammaglobulinemia	<i>BTK/Bruton's</i> tyrosine kinase	Hypogammaglobulinemia/Agammaglobulinemia, low B cell numbers, <b>Enterovirus</b> infections

NEMO=Nuclear factor-kappa B essential modulator; WHIM=Warts, Hypogammaglobulinemia, Immunodeficiency, and Myelokathexis; SLAM=signaling lymphocytic activation molecule; XLP=x-linked lymphoproliferative; AICDA=Activation-induced cytidine deaminase.

**FIGURE 1** Three layers of immunity: physical barrier immunity, innate immunity, and adaptive immunity. 1) Physical barriers, including the skin and mucosal membranes, represent the first level of protection against foreign invaders. Damage to this layer can lead to pathogen access to the underlying cells. Many viruses utilize vectors to breach this barrier. 2) Innate immunity represents the nonspecific rapid response arm of the immune system, and the first white blood cell responders help control, clear, and arm the immune response. C) Adaptive immunity consists of the antigen-specific response that evolves to specifically clear the pathogen and to confer long-lived immunity against the pathogen upon re-exposure.

herpes simplex virus (HSV), or polyoma viruses. While the skin functions largely as a physical barrier, it also dynamically participates in immune surveillance as it actively secretes a number of compounds with antimicrobial and inflammatory activity and is home to a multitude of effector cells of both the innate and adaptive immune systems.

The primary function of the skin is to protect the body from a range of environmental threats, including temperature, radiation, chemicals, and microorganisms (Fig. 1). It is composed of two main layers, the epidermis and the dermis, with the outer epidermis functioning as a passive barrier to infection. The epidermis is largely comprised of terminally differentiated keratinocytes, and by itself, the keratinized epidermis is an impenetrable barrier to most viruses. It is only upon injury to the skin that pathogens are able to penetrate and infect the underlying tissues, such as in the case of burns, which render this barrier remarkably vulnerable to pathogens. Thus, some viruses, such as Japanese encephalitis virus, dengue virus, and yellow fever virus, have evolved mechanisms to breach this barrier by entering the host via arthropods (e.g., mosquitoes) that deposit the pathogens directly into the underlying dermis.

The skin itself can also actively limit a potential infection via the production of a number of compounds with antimicrobial and inflammatory activity produced by a variety of skin-resident cells, including keratinocytes, sebocytes, eccrine glands, and mast cells, as well as cells that are recruited to the site of infection, such as neutrophils and natural killer cells (4). Although viral skin infections are a less common manifestation of primary immune deficiencies (PIDs), compared to bacterial infections, severe warts due to human papilloma virus (HPV) do emerge in some individuals with immune PIDs. For example, epidermodysplasia verruciformis (EV) is associated with uncontrolled HPV wart proliferation and eventually malignant transformation due to defects in genes involved in zinc metabolism (5). Additional gene defects in GATA-2 and serine threonine kinase 4 (STK4)

mutations have also been linked to disseminated facial warts due to HPV. Moreover, allergy-associated eczema and autoimmune psoriasis, both of which alter the integrity of the skin barrier, have been indirectly associated with a predisposition to viral infection.

Although the skin is home to a large number of distinct immune effector cells discussed in more detail below, including macrophages, natural killer cells, and mast cells, one of the most important skin-resident immune cells is the Langerhans cell (6). Langerhans cells are a class of antigen-presenting cells, or dendritic cells, that act as critical gatekeepers of the immune system and are responsible for capturing pathogens within skin, processing foreign antigens, and traveling to specialized immune organs (lymph nodes) to present these antigens and instruct cells of the adaptive immune system. The adaptive immune cells then travel back to the site of infection to contain and clear the infection. Ultimately, both skin-resident and recruited immune cells, as well as the local skin cells, collaborate to clear the pathogen and ensure that the integrity of the tissue is maintained.

#### Mucosal Barriers

Other tissues of the body are also directly accessible to the environment, including the gastrointestinal, respiratory, and urogenital tracts (7). Whereas the skin is covered with a thick keratinized layer, these other tissues typically require moisture to mediate their biological activities and thus are not coated with a water-impermeable keratin, like the skin is. Rather, these internal tissues are protected by a mucosal barrier, that is, thinner layers of epithelial tissue that are coated in a thick fluid known as mucus (8). However, because many microorganisms grow prodigiously on moist barriers, these surfaces are littered with symbionts and potential pathogens and are therefore often more susceptible to infection. Similar to the skin, mucosal surfaces possess an array of strategies aimed at protecting these vulnerable epithelial barriers, including chemical barriers, the production

of immunomodulatory proteins, and a large population of tissue-resident immune cells that are armed and ready to respond upon infection.

A thick layer of keratin protects the skin, and a thick layer of mucus protects mucosal membranes. Mucus is a viscous, acidic fluid that functions to both lubricate the tissue and protect the tissue from potential pathogens. It is produced from specialized cells found within the mucosal barrier (e.g., goblet cells in the intestinal mucosae) and largely consists of heavily glycosylated proteins (e.g., mucins), other glycoconjugates, and water. These components form interconnecting lattices within the mucus that protect the underlying epithelium via the formation of a thick (over 100  $\mu\text{m}$ ), dense network that pathogens must traverse to access the underlying epithelial border. Although small molecules can easily diffuse through the mucus, movement through this fluid is remarkably difficult for pathogens, including viruses that are trapped easily (9), as is evidenced by the lack of any microorganisms in the mucus adjacent to the epithelial barrier. Intriguingly, the epithelial-proximal mucus glycoproteins are often transmembrane proteins with large cytoplasmic tails containing multiple signaling motifs (10). Therefore, it is possible that some mucus proteins may function in two capacities, in limiting pathogen access to the underlying barrier and also as sensors that may signal into the underlying epithelium should a potential pathogen make it through the mucous layer. This may enable the epithelial border to secrete antimicrobial and inflammatory proteins and alert underlying immune cells to restrict any pathogens.

As injury to the mucosal epithelium can have grave infectious consequences, similar to injury to the skin, the mucosal epithelium secretes a large number of antimicrobial compounds that can directly kill invading pathogens or recruit and activate tissue-resident and circulating immune effector cells. These antimicrobial compounds are secreted by specialized cells in the epithelium (e.g., Paneth cells in the intestine) and can diffuse through the mucus, providing an additional layer of protection from infection. Furthermore, mucosal epithelia are lined with large numbers of both innate and adaptive immune cells, including T and B cells, dendritic cells, neutrophils, natural killer cells, and macrophages. These tissue-resident immune cells patrol for invading pathogens and evidence of stress due to an epithelial breach and form lymphoid aggregates that enable the rapid induction of mucosal-specific immune responses. Thus, even though mucosal surfaces are under constant exposure to external threats from the air, food, and commensal microbiota, a combination of structural, chemical, and cellular components protects these vulnerable sites from infection.

### Commensal Organisms

Although the body's barrier surfaces are designed to prevent infection with and control the commensal microbiota that colonize these surfaces, it has become increasingly apparent over the past decade that the commensal microbiota also provide protection against potentially pathogenic microorganisms (11, 12). Because the commensal microbiota significantly outnumber the cells in our body, these microorganisms also play a prominent role in preventing infection both directly via production of natural antimicrobials and indirectly via cross-talk with the underlying epithelium and immune effector cells that may render the barrier more resistant to viral infection (13). The critical nature of the commensal microbiome in providing protection from infection has been most clearly demonstrated in the setting of long-term antibiotic treatment, where dis-

ruption of the natural microbiome results in the overgrowth of pathogenic yeast and bacteria such as *Candida* spp. and *Clostridium difficile*. Moreover, it has also been demonstrated in some viral infections, such as influenza and HIV infection, that particular microbial flora are critical for the evolution of effective antiviral immunity (14, 15) and even in providing a more fertile ground for HIV transmission at the mucosal barrier (16). Furthermore, the use of probiotics or stool transplantation has been shown to reverse disease associated with pathogen colonization, clearly illustrating the critical nature of the microbiome itself as a barrier to infection.

Moreover, beyond the microbiome, an enormous and highly diverse population of viruses that shape immunity coexist with humans (17). This other "microbiome" includes viruses that cause symptomatic and nonsymptomatic infections that may infect the host and/or the microbiome, that may coexist or integrate into the host genome, and that can even be reactivated intermittently and cause *de novo* infections. Moreover, recently it was shown that the HIV infection-induced changes in the enteric virome, specifically related to the expansion of enteric adenoviruses, were associated with a loss of CD4<sup>+</sup> T-cell counts and therefore disease progression (18). Moreover, this altered virome was highly associated with dramatic alterations in microbial biodiversity, pointing for the first time to a role for the enteric virome in driving AIDS-associated enteropathy and disease progression.

### Innate Immunity

Intertwined with physical barrier immunity, the innate immune system provides an immediate response to infection and foreign antigens (Fig. 1). The innate immune system is a network of cells and molecules that is rapidly mobilized in response to danger signals generated following infection. Importantly, the innate immune system, composed of a network of distinct effector cells (Fig. 2), is armed and ready to respond without the need for prior antigen sensitization. Because the innate immune system is able to fight pathogens at the site of infection, it provides an immediate defense against any incoming pathogens.

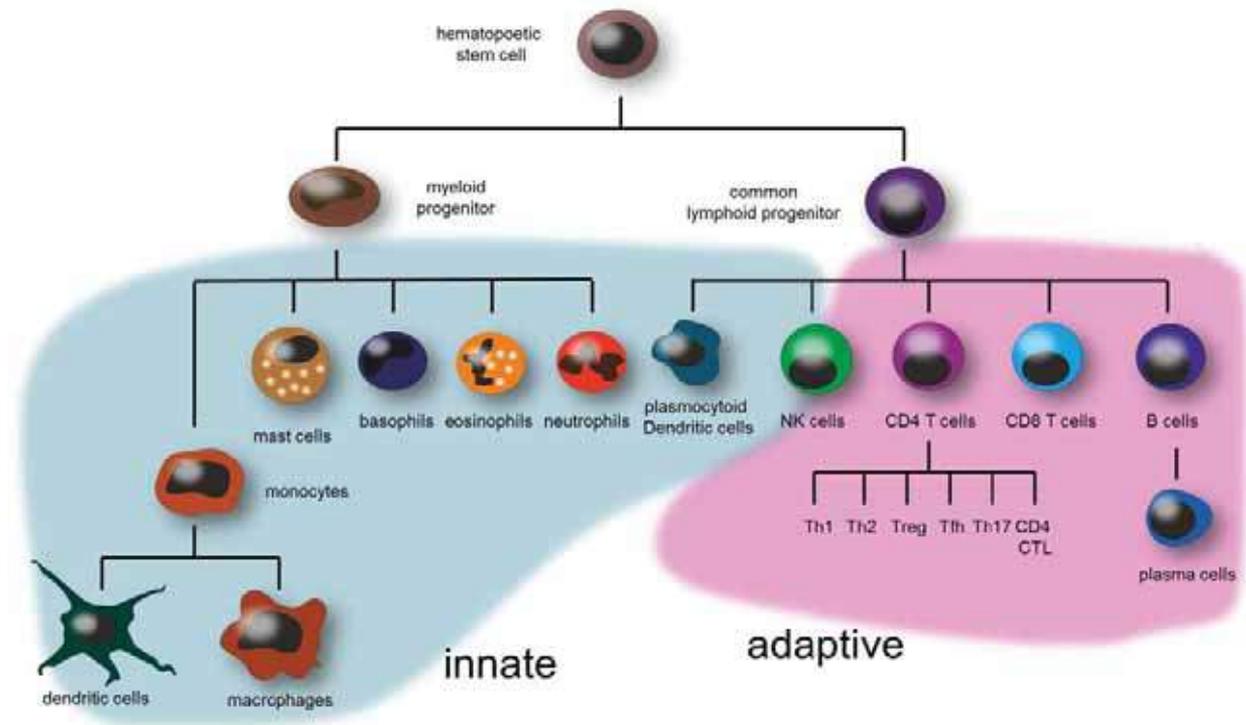

#### Effectors of Innate Immunity

The innate immune system is composed of five major classes of immune effectors that collectively aim both to contain the infection as well as to provide the infrastructure necessary for the generation of a long-lived adaptive immune response that can drive long-term memory against that pathogen: (1) phagocytes, (2) granulocytes, (3) innate lymphoid cells, (4) antigen-presenting cells, and (5) the complement system. These innate immune cell types and proteins, each with a highly specialized function, have evolved to rapidly recognize, contain, and eliminate invading pathogens.

#### Phagocytes

Tissue-resident phagocytes are typically the first line of defense against pathogens that have broken through protective barriers. Phagocytes are cells that protect the body through a process by which a cell internalizes a smaller cell, cell fragment, microorganism, or foreign particle (called phagocytosis). While many cell types possess phagocytic activity, the principal phagocytes in the body are macrophages, neutrophils, and dendritic cells (discussed further below).

**Macrophages** are mononuclear phagocytes that mature from blood monocytes that have left the circulation and migrated into the tissue (19). They are relatively long-lived,

**FIGURE 2** The two arms of the immune system. All immune cells develop from a common hematopoietic stem-cell progenitor that can differentiate into a myeloid or common lymphoid progenitor (CLP). The adaptive arm of the immune system is composed of four immune cell types, called lymphocytes, that share a CLP origin. The innate arm consists of an array of distinct cell types, most of which are derived from the myeloid progenitor, except NK cells and plasmacytoid dendritic cells that differentiate from a CLP.

with a lifespan of several months. Unlike other phagocytes, which are typically recruited to the site of infection, macrophages can be found in healthy, uninfamed tissue, making macrophages critical sentinels against infection and the first innate immune cells to respond to infections. Macrophages and other phagocytes recognize pathogens via the use of cell surface receptors (detailed below) that can discriminate pathogens from self. Upon recognition of the pathogen via these receptors the pathogen is actively engulfed and killed by the phagocyte.

In addition to their phagocytic activities, macrophages also play a critical role in inducing inflammation to recruit additional immune effector cells to the site of infection. Macrophages are constantly surveying their surroundings for pathogens. Upon infection of the host, the activation of macrophages leads to the rapid release of copious amounts of proinflammatory cytokines and chemokines that arm the immune system, recruit additional cells, and drive enhanced pathogen clearance. This inflammatory cascade triggers the rapid recruitment of additional waves of macrophages and neutrophils to the site of infection. The newly recruited macrophages are vital to the rapid clearance of dead and dying neutrophils, as well as to the clearance of pathogens or pathogen-infected cells, which can be rapidly processed and presented in lymph nodes for the induction of adaptive immune responses to promote long-lived adaptive immune memory.

Given their critical role in the initiation of the immune response, several viruses deliberately infect macrophages, including adenoviruses, alphaviruses, HIV, ebola virus, and dengue virus (20), and impair the immunological activity of

these cells from within. In the context of HIV infection, the virally encoded proteins directly interfere with the antigen-presenting activities of macrophages via the downregulation of major histocompatibility complex antigens (MHC) II and CD4. Despite this HIV-evasive activity, there is ongoing debate whether infection of macrophages represents a critical safety niche for HIV, because once infected, these macrophages can take up long-lived residence in tissues throughout the body, including immune-privileged sites such as the brain (21).

While macrophages are typically the first phagocyte to respond to an infection, **neutrophils** are the most abundant phagocyte in the body and first to invade sites of infection (22). Neutrophils are short-lived (a lifespan of approximately 5 days), polymorphonuclear cells that make up the majority of the white blood cells in the body, and their main function is to phagocytize and destroy invading pathogens. Unlike macrophages, however, neutrophils are not typically found in healthy, uninfamed tissue; rather, they are rapidly recruited to sites of infection en masse by chemokines secreted by macrophages and other cell types in response to infection. Upon recruitment, they are involved in the rapid phagocytic clearance of invading pathogens.

In addition to their role in the phagocytic elimination of pathogens, neutrophils are also armed with a number of cytoplasmic granules containing enzymes and antimicrobial peptides. Two different types of cytoplasmic granules can be found in neutrophils, depending on their maturation state. Immature neutrophils possess primary granules loaded with cationic proteins and enzymes involved in protein degradation (e.g., elastase and cathepsins) and pathogen destruction

(e.g., defensins, lysozyme, and myeloperoxidase). By contrast, more mature neutrophils are loaded with secondary granules that contain enzymes that are involved in generating reactive oxygen species. When stimulated by a pathogen, the contents of these granules are rapidly released into the extracellular environment, where they indiscriminately kill surrounding cells, a process known as degranulation. Because the uncontrolled degranulation of neutrophils can lead to extensive tissue damage, this process is tightly regulated.

While the ability of neutrophils to eliminate pathogens via phagocytosis and the degranulation-mediated release of antimicrobials has long been known, the third strategy employed by neutrophils to eliminate pathogens has only recently been discovered. Activated neutrophils can release a web-like DNA structure known as a neutrophil extracellular trap (NET). These traps are comprised of a web of chromatin and serine proteases that can snare and kill extracellular pathogens in the absence of phagocytosis. Furthermore, these traps can function as a physical barrier to limit the progression of the infection.

While neutrophils are critical for immune defense against bacteria and parasites, their role in antiviral immunity has only begun to be elucidated (23, 24). Multiple viruses, including influenza virus, herpes simplex virus, respiratory syncytial virus, and cytomegalovirus, have been shown to activate neutrophil phagocytosis, degranulation, and NET release. Furthermore, the depletion of neutrophils results in a compromised immunity against influenza virus (25). NET formation and release is critical for the early control and clearance of poxvirus infection in the liver, illustrating the role of neutrophils in distinct tissues and against diverse viruses. Importantly, neutrophils are not only involved in the direct antiviral response to infection but also critically contribute to shaping the adaptive immune response via their unique localization and activity in the lymph node where they are involved both in limiting antigen availability (26) and driving enhanced T-cell proliferation (27).

### Granulocytes

In addition to being a phagocyte, neutrophils are also a member of a larger family of cells known as granulocytes. Granulocytes are white blood cells that are characterized by the presence of numerous granules in their cytoplasm. These granules contain a number of antimicrobial and immunomodulatory compounds, and while granulocytes can have secondary functions in antigen presentation, the principle function of granulocytes is the release of these compounds into the extracellular space where they can directly kill potential pathogens, induce inflammatory cascades, and recruit other immune effectors. There are two additional types of granulocytes, eosinophils and basophils, and while not technically granulocytes, mast cells are very similar to basophils and are discussed here.

**Eosinophils** are highly granular, myeloid-derived white blood cells that are largely involved in the antiparasite immune response. Following activation, eosinophils are stimulated to release a number of cytotoxic cationic granule proteins, including proteins with RNase activity (28), antimicrobial reactive oxygen species, proinflammatory cytokines, and potent inflammatory mediators known as leukotrienes (29). While eosinophils are not classically considered critical antiviral mediators, increased eosinophil numbers have been implicated in enhanced clearance of respiratory syncytial virus (RSV) infection (30) accumulating in the lungs of RSV infected patients (31), where eosinophils appear to respond directly to the viral RNA.

However, the role of eosinophils in anti-RSV protection is not direct; instead, eosinophils dampen inflammation and reduce infection-associated immunopathology in the lung tissues following viral infection (32). Thus, while eosinophils likely contribute to antiviral immunity, their effects are likely largely mediated through their ability to protect the tissues where infections occur.

**Basophils** are the least frequent myeloid-derived granulocyte in the blood, and like eosinophils, when activated, basophils release a large number of granule proteins and enzymes (e.g., histamine and elastase) and inflammatory mediators (e.g., cytokines and leukotrienes) that promote vasodilation and inflammation. Although a direct role for basophils in the elimination of viral infections has not been described, basophils have several secondary roles that are important in the resolution of viral infections. First, basophils produce large amounts of the cytokine IL-4 in response to viral infection (33). IL-4 is a cytokine important for the development and activation of particular subsets of T cells, humoral immune responses, and innate lymphoid cells (34). Additionally, basophils can tune dendritic cell activity to promote specific adaptive immune responses (35) and have been implicated as the earliest recruiters of eosinophils into inflamed skin (36).

While not technically granulocytes, **mast cells** are large granular innate immune cells that are very similar to basophils (37). Mast cells leave the bone marrow in an immature form, and they remain immature until they enter the tissue, where they mature into highly granular cells, loaded with preformed stores of histamines and various enzymes that are critically involved in triggering inflammatory responses. Thus, within seconds of an infection, mast cells are able to release immunomodulatory compounds that rapidly initiate an inflammatory cascade to selectively kick start the antiviral immune response. In particular, mast cells contain large intracellular stores of histamine (2 to 5 pg/cell) that are rapidly released in response to activation. Histamine is a potent vasodilator that also increases vascular permeability, enabling the recruitment of large numbers of innate immune cells, such as neutrophils and macrophages, to enter infected tissues. In addition to their role in initiating inflammatory cascades, similar to neutrophils, mast cells are able to directly phagocytize pathogens or infected cells, release reactive oxygen species that can directly kill pathogens, and release extracellular traps (38). Thus, while mast cells are most classically known for their role in allergy, they have been implicated in respiratory virus triggered-asthma and are clearly critical for the early defense and arming of the innate immune response aimed at containing viral infections.

### Innate Lymphoid Cells

Unlike granulocytes, which are derived from a common myeloid precursor, innate lymphoid cells develop from a common lymphoid precursor cell that also gives rise to the cells of adaptive immune system (B cells and T cells) (Fig. 2). Innate lymphoid cells rapidly secrete immunoregulatory cytokines upon activation and have been broadly divided into three groups based on the cytokines they secrete. Group 1 innate lymphoid cells typically produce type 1 cytokines (e.g., IFN- $\gamma$  and TNF- $\alpha$ ) and include cytotoxic natural killer cells; Group 2 innate lymphoid cells typically produce type 2 cytokines (e.g., IL-4, IL-5, and IL-13); and Group 3 innate lymphoid cells produce IL-17A and/or IL-22. With the exception of natural killer cells, the role of the various subsets of innate lymphoid cells in infection has only recently begun to be elucidated (39); however, given their localization

within mucosal tissues and their ability to rapidly secrete a wide variety of immunoregulatory cytokines, they likely play an important role in the early immune response to infection.

**Natural Killer Cells.** Natural killer (NK) cells are the only innate immune lymphocytes that survey the periphery for stressed, malignant, or infected cells. These cells develop in the bone marrow, where they undergo a complex educational process on cells expressing self-antigens that select for NK cells that recognize self (major histocompatibility complex, MHC) through inhibitory NK cell receptors, and therefore can be turned off (40). Thus only NK cells that will not become auto-reactive are permitted to mature and gain cytolytic functions, in a process called “licensing” or “education.” Importantly, the critical nature of NK cells in antiviral immunity is most clearly illustrated in the case of children born with NK cell deficiencies who are highly susceptible to HSV infection (Table 1), despite the presence of normal adaptive immune responses (41). Moreover, NK cells have been centrally linked to spontaneous control of infection with hepatitis C virus (42) and control of HIV (43), highlighting the essential role of this innate immune cellular subset in antiviral immunity.

Importantly, NK cells are preloaded with cytolytic granules, and upon recognition of a stressed or infected cell, release these granules in a highly regulated and directed fashion. These granules contain perforins and granzymes that generate holes in the membrane of target cells, resulting in the lysis of or the induction of apoptosis of the target cell. Importantly, NK cells are capable of killing any aberrant cell without the need for antigen sensitization.

Because of their highly cytolytic nature, NK cell function is regulated through a complex network of inhibitory and activating receptors. Among the large array of receptors that can be expressed on NK cells, four major receptor families regulate NK cell function. The first family includes the killer immunoglobulin receptors (KIRs) that interact with MHC, expressed on all cells. The MHC proteins are involved in presenting random samples of small segments of self-proteins to the immune system to ensure that the cell is healthy. However, upon infection, viral proteins are rapidly synthesized, offering a novel array of peptides for presentation in MHC to circulating NK cells. Many viral infections, such as HIV (44) and CMV (45), downmodulate the expression of MHC class I, to reduce viral-peptide exposure. However, loss of MHC is sensed by circulating NK cells, signalling that the cell is stressed or infected, and activating NK cells via their KIR receptors. Moreover, emerging data also point to a role of viral peptides that alter the conformation of MHC as critical ligands for KIR. Thus the KIR family arms NK cell activation and cytolytic activity both through a loss of MHC sensing as well as through altered viral peptide conformational changes to MHC (46). The second class of receptors include the C-type lectin receptors (CLRs, described below) that are involved in sensing stress following the up-regulation of a class of MHC homologues (MICA/B or ULPB) that are rapidly expressed following genotoxic or viral infection related intracellular stress (47).

The third class of receptors includes the natural cytotoxicity receptors (NCRs) involved in the rapid activation of NK cells (e.g., by influenza) (48). Self-ligands have yet to be defined. The final class of receptors includes FcγRIIIA (CD16), which is involved in driving antibody-dependent cellular cytotoxicity following the opsonization of virally infected cells with antibodies. Thus, while additional acti-

vating and inhibitory receptors are expressed on NK cells, together this large array of germline-encoded receptors that are expressed stochastically on the surface of NK cells resulting in a highly heterogeneous network of NK cells (49) collectively regulate and rapidly deploy the antiviral activity of these cells following viral infection.

While NK cells play a critical role in the nonspecific response to infection, more recent data suggest that a novel subset of NK cells, termed memory NK cells, may also emerge following viral infections (e.g., lymphocytic choriomeningitis infection in mice) and result in long-lived innate memory (50). Moreover, these memory NK cells appear to also evolve following vaccination with distinct viral antigens (51) and can survive up to 5 years in non-human primates following vaccination with particular viral vectors (52). Thus, while the bulk of the NK cell response is involved in a rapid nonspecific cytolytic control of viral infection, a small subset of these innate lymphocytes may emerge following infection that are aimed at conferring long-lived memory and rapid responsiveness upon pathogen re-encounter, suggestive of adaptive-like activity within this unique innate lymphocyte cell subset.

**Antigen-Presenting Cells.** In addition to directly eliminating pathogens and pathogen-infected cells, the innate immune system plays a pivotal role in priming the adaptive immune system to induce long-lived immunity against pathogens. This is accomplished via the collection and display of foreign antigens to cells of the adaptive immune system by antigen-presenting cells. Antigen-presenting cells sample the extracellular environment either by phagocytosis or endocytosis and then display epitopes of the sampled proteins on their surface, where in combination with various co-stimulatory molecules, cells of the adaptive immune system can recognize them. While many innate immune cells have some ability to present antigen, professional antigen-presenting cells, in particular dendritic cells, are highly specialized to present antigen in a manner that can drive long-lived immunity (53).

**Dendritic cells (DC)** function as an important bridge between the innate and adaptive arms of the immune system (54). Their main function is to take up, process, and present foreign antigens on their surface to T cells of the adaptive immune system. DCs are generated in the bone marrow and enter into the circulation and tissues in an immature form. Immature DCs patrol the body or lie dormant in tissues awaiting an infection. Because immature DCs have high endocytic activity, these cells can rapidly engulf pathogens, infected cells, or apoptotic cell debris, rapidly degrade the material, and quickly present these antigens on their surface. The engulfment of foreign antigens (integration of the danger signal described below) results in the rapid maturation of the DC, which results in decreased endocytic activity, increased migratory activity, and increased immunostimulatory capacity. The latter is accomplished via an increase in the expression of several classes of costimulatory receptors on the cell surface that are required for priming effective T-cell immunity. Thus upon maturation, the DC migrates to the lymph node where it can present the foreign material to T cells (55). Two predominant types of dendritic cells have been described, myeloid dendritic cells and plasmacytoid dendritic cells, and both types play an important role in the generation of long-lived immune responses.

**Myeloid DCs (mDCs)** are the principal antigen-presenting cells in the body. While macrophages are more abundant and can also capture and present antigens, mDCs

are rarer, have greater T-cell activation potential, and exclusively function to activate naïve T cells (56, 57). Given their crucial role in the generation of an effective immune response, many viruses have evolved elaborate strategies to dampen mDC activity. Many viruses selectively infect these cells, including lymphocytic choriomeningitis virus, ebola virus, dengue virus, and HIV (58–60), to eliminate these cells or manipulate their ability to induce effective T-cell immunity, thereby evading the adaptive immune response. For example, although HIV infection of mDCs remains controversial, once inside, HIV expresses an infectivity factor, named Nef, that rapidly downregulates MHC expression, thereby preventing antigen presentation to CD8 T cells (61). In addition to directly modulating presentation of antigen on the surface of mDCs following infection, many viruses perturb the expression of costimulatory molecules on the surface of mDCs, further dampening the induction of robust T-cell immunity.

**Plasmacytoid DCs (pDCs)** are a tiny subset (<0.5% of circulating white blood cells) that are critical for the initiation of the immune response following infection. Unlike mDCs, pDCs selectively express receptors that recognize intracellular single-stranded RNA (TLR7) and DNA (TLR9), making them uniquely poised to recognize viral infections. Once activated, pDCs are the primary producer of the inflammatory cytokines, interferon- $\alpha$  and - $\beta$ , that denote a highly specialized antiviral immune response. A large array of viruses can trigger the production of interferon- $\alpha$  and - $\beta$  from pDCs including herpes simplex virus, HIV, influenza virus, newcastle disease virus, vesicular stomatitis virus, and sendai virus. However, in addition to interferon- $\alpha$  and - $\beta$ , pDCs also produce other pro-inflammatory cytokines and chemokines that further activate the immune response and recruit additional innate immune effector cells to the site of an infection. This early cytokine cascade is critical for not only potentiating the innate immune response to the virus but also triggering the release of B cell activating and survival factor (BAFF), a key cytokine that is required for the evolution of the B cell response and generation of antibody-secreting cells (62). Clinically, elevated pDCs have been associated with reduced severity of dengue virus infection. Conversely, pDC numbers are progressively depleted in HIV infection (63), likely contributing to the compromised immunity observed in HIV-infected subjects (64).

## The Complement System

In addition to innate cells, a crucial component of the innate immune response to infection is driven by a cell-free network of proteins known as the complement system. The complement system consists of a network of more than 30 proteins found in the blood that can induce the direct lysis of pathogens, the agglutination and phagocytosis of pathogens, and the chemotaxis of macrophages and neutrophils (65). Liver, monocytes, and macrophages synthesize the components of the complement system as inactive proteins that are rapidly cleaved and activated upon exposure to a pathogen. Upon activation via one of three pathways (classical, alternative, or lectin pathway), a complex cascade of cleavage events is initiated that ultimately result in the deposition of a complex of complement proteins (known as the membrane attack complex) on the surface of the target, which ultimately lead to destruction. Importantly, many of the cleaved by-products of this cascade are highly inflammatory and function to increase vascular permeability and recruit additional effector cells to the site of infection, further enhancing the innate inflammatory response.

The classical pathway is triggered by antibody binding to the target antigen. The binding of the first component of the complement cascade (C1, itself a heteropentameric complex of C1q, C1r, and C1s) to antigen-complexed antibody results in the activation of the protease activities of C1r and C1s. The active C1 can then initiate the cascade of cleavage and activation that ultimately results in the cleavage of C5 (C1 cleaves C2 and C4, which cleave C3, which cleaves C5) and the deposition of the membrane attack complex. Unlike the classical pathway, the alternative pathway does not depend on antibodies but rather is initiated after spontaneous C3 activation. Spontaneous cleavage and activation of C3 exposes a reactive thioester in C3 that allows its deposition directly onto the surface of a pathogen or cell. Upon binding to a cell, the C3 is then able to bind to additional components of the alternative pathway (including factor B and factor P), ultimately leading the cleavage of C5 and deposition of the membrane attack complex. Importantly, as the alternative pathway is initiated spontaneously, normal cells express a number of complement regulatory proteins (e.g., CD35, CD46, CD55, CD59) that can disarm the complement cascade that have been deposited on their surface, preventing unwanted pathology. However, because pathogens, including viruses, do not express these regulatory proteins and infected or dying cells have reduced expression of these molecules, the alternative pathway can rapidly eliminate infections before the production of antibodies, which are necessary to initiate the classical pathway. Finally, the lectin pathway is triggered in a manner similar to the classical pathway. However, rather than triggered by antibodies, the lectin pathway is triggered by proteins that recognize particular glycan structures (e.g., mannose-binding lectin). The binding of these proteins to the surface of cells or pathogens results in the activation of proteases similar to C1r and C1s, which in turn can activate the remainder of the cascade.

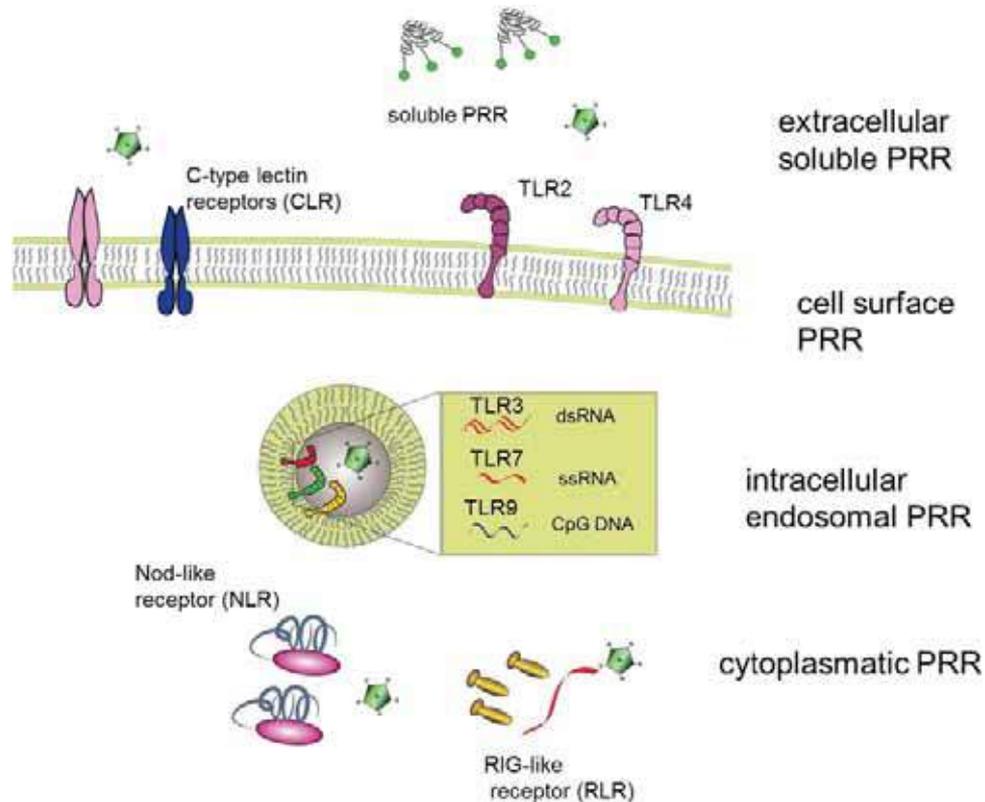

All three complement pathways have been implicated in the host immune response to many viruses, and deficiencies in complement activation have been associated with poor outcomes for many infections (66). For example, although antibody-mediated neutralization has been linked to vaccine efficacy for many clinically approved vaccines, recent data suggest that protective antibodies, like those induced by the smallpox vaccine, require the cooperative recruitment of complement to mediate their antiviral activity (67). Given the importance of complement in the control of viral infections, it is not surprising that many viruses have evolved elaborate mechanisms to evade the complement system. For example, HIV inactivates the complement system by capturing complement inhibitors (e.g., CD55 or factor H) on the virion surface, thereby protecting itself from destruction (68).

## Innate Immune Recognition of Viruses

Unlike the adaptive immune system, which recognizes pathogen-derived antigens in a highly sequence-specific manner, the innate immune system recognizes microbe-associated molecular patterns (MAMPs; also known as pathogen-associated molecular patterns, PAMPs) that are associated with particular groups of pathogens. These PAMPs typically play an essential role in the life cycle of the pathogen, such as single-stranded RNA or components of bacterial cell walls, and are recognized by groups of innate immune receptors, known as **pattern recognition receptors (PRRs)**.

### Innate Immune Receptors

PRRs detect classes of molecules including nucleic acids, proteins, lipids, and carbohydrates that are unique to

**FIGURE 3** Innate immune receptors. Four types of pattern recognition receptors exist that drive a rapid response to foreign pathogens including 1) extracellular secreted receptors such as mannose-binding lectin, 2) cell surface toll-like receptors or c-type lectin receptors, 3) endosomal TLRs, and 4) cytosolic pattern recognition receptors such as RIGI. The secreted and surface-bound PRRs recognize extracellular pathogens whereas the endosomal and cytosolic PRRs recognize pathogens that have entered into different cellular compartments within the cell.

particular classes of microbes. Thus, via the expression of distinct classes of PRRs, innate immune cells have the capacity to specialize in the recognition of specific classes of pathogens, contain them, and alert the immune system of infection. Importantly, many different classes of PRRs have been identified over the past two decades; these receptors not only specialize in the recognition of specific ligands but are also expressed in a highly specialized manner on and within particular immune cell subsets, greatly optimizing their function. Thus, PRRs can be located on the cell surface, within endocytic vesicles, and within the cytoplasm and can even be secreted to capture microbial products outside the cell (Fig. 3).

### Toll-Like Receptors

First discovered in *Drosophila*, toll-like receptors (TLRs) are a unique class of highly conserved, type I transmembrane proteins that recognize structurally conserved motifs, including PAMPs that are exclusively expressed by pathogens and damage-associated molecular patterns (DAMPs) that are expressed on damaged cells (69). PAMPs include the structural components of bacteria (e.g., lipopolysaccharides, peptidoglycans, flagellin), bacterial DNA, and viral RNA, while DAMPs include intracellular proteins such as heat shock proteins and protein fragments. While these receptors recognize an array of different ligands, all TLRs possess a characteristic leucine-rich repeat-containing extracellular domain and a conserved Toll/IL-1 receptor cytoplasmic do-

main that drives cellular activation and cytokine secretion upon ligation (70).

Twelve TLRs have been characterized to date in mice (TLR1–9 and TLR11–13), of which 10 are also expressed in humans (TLR1–10). TLR14 is only found in the Takifugu pufferfish. TLR2 recognizes PAMPs from Gram-positive bacteria, including lipoproteins, lipomannans, and lipoteichoic acids. TLR3 recognizes double-stranded RNA, which occurs during replication of some viruses, and TLR4 recognizes lipopolysaccharides. TLR5 recognizes bacterial flagellin, and TLR7 and TLR8 recognize single-stranded RNA. TLR9 recognizes unmethylated DNA motifs, which are frequently found in bacteria, and the agonist for TLR10 is unknown. Because TLRs are able to heterodimerize, they can extend their individual specificities to target additional PAMPs; for example, the heterodimer of TLR2/6 can further target diacylated lipoproteins and TLR2/1 can bind to triacylated lipoproteins. Moreover, the extended range of ligands that the heterodimers can recognize is coupled to enhanced cellular functionality via the increased number and diversity of intracellular adaptors and accessory molecules that interact with the heterodimers, resulting in a further tuning of innate functionality. The cellular localization of TLRs within the cell further aids in specializing TLR function. Specifically, TLR1, 2, 4, 5, 6, and 10 are expressed on the cell surface, whereas TLR3, 7, 8, and 9 are exclusively expressed in endocytic vesicles (Fig. 3). This unique cellular localization may aid in concentrating these innate sensors at

locations within cells where their respective ligands are most likely to be detected and where the TLRs themselves are least likely to drive immunopathology. For example, TLRs3, 7–9, which recognize nucleic acids associated with pathogens, are located within endocytic vesicles. This enables these TLRs to more effectively recognize viruses or bacteria that have already infected a cell. Thus, TLR3, 7/8 and 9 play a critical role in sensing viral infections and the initiation of the antiviral immune response.

While TLRs are critical for early nonspecific innate recognition, these receptors are expressed on cells of both the innate and adaptive immune system. On innate immune cells, TLRs rapidly program innate immune activity to drive a “pathogen-appropriate” immune response. Thus, depending on the TLR or combination of TLRs triggered, the innate immune system integrates this information to discern whether a bacterium-, parasite-, or virus-specific response would be most effective. Accordingly, fundamentally different immune cascades may be deployed for the containment of bacteria (largely extracellular organisms) compared to the purging of viruses (largely intracellular organisms). Moreover, these innate immune programs additionally also qualitatively tune the evolving adaptive immune response via the secretion of cytokines or the ligation of co-receptors that provide information regarding the type of invading pathogen aimed at promoting more effective immunity. However, adaptive immune cells themselves can also express TLRs, where they likely play two distinct roles: (1) tuning the primary immune response in a pathogen-specific manner and (2) rapidly promoting more effective reactivation of memory immune responses. Thus, in the adaptive immune system, TLRs synergize with the receptors of the adaptive immune system to adjust pathogen-appropriate responses.

### C-Type Lectin Receptors

Every organism is composed of four essential building blocks: protein, lipids, carbohydrates, and nucleic acids. Amino acids and nucleic acids are the most conserved across all organisms, but lipids and carbohydrates are more variable and vary wildly both in structure and composition across bacteria, parasites, viruses, and humans (71). Additionally, carbohydrates and lipids also vary extensively in human disease, such as cancer, resulting in the production of glycan-based antigens such as the carcinoembryonic/oncofetal type neoantigens (72). Thus, the immune system has evolved a unique set of innate immune receptors, known as C-type lectin receptors, that are able to specifically survey for carbohydrate-based antigenic variation. Because most pathogens are covered in unique glycans such as high levels of mannose on viruses and fungi and high levels of fucose on bacteria and helminths, C-type lectin receptors play a critical role in both host immune defense and in the clearance of aberrantly glycosylated material. Importantly, among the C-type lectin receptors, distinct cellular functions may be elicited, including endocytosis or signaling to drive distinct effector functions. This qualitative tuning is dictated by the signaling adaptors for each C-type lectin receptor and is driven by both the receptor itself as well as additional costimulatory signals that are received through other pattern recognition receptors (including TLRs). Two very broad families of C-type lectin receptors have been described, mannose receptors and asialoglycoprotein receptors.

### Mannose Receptors

Humans utilize mannose widely in protein glycosylation, but few glycoproteins within our bodies are decorated with

simple mannose structures or terminally mannosylated structures (73). In stark contrast, oligomannose structures decorate the surface of many viruses (HIV, hepatitis C, Ebola virus, etc.) and fungi. The mannose receptor family recognizes these terminal mannoses (as well as other glycan structures) on the surface of pathogens or infected cells, and is predominantly expressed by macrophages and dendritic cells. Surface mannose receptors recognize terminal mannose, N-acetylglucosamine, and fucose residues attached to proteins and induce phagocytosis of the pathogen. Similarly, the secreted mannose-binding lectin (MBL), which recognizes mannose and fucose, cooperates with members of the complement pathway to drive the rapid endocytosis and arming of innate immune cells for pathogen destruction and inflammatory activation. Moreover, studies during the severe acute respiratory syndrome coronavirus (SARS-CoV) outbreak revealed an association of enhanced SARS-CoV infection among individuals with a polymorphism resulting in low MBL expression, thus highlighting the importance of this PRR in the control and prevention of viral infection (74, 75).

### Asialoglycoprotein Receptors

Asialoglycoprotein receptors are a broad superfamily of C-type lectin receptors that are involved in the rapid clearance of glycoproteins that are not terminally sialylated (76). Receptors in this family include macrophage galactose-type lectin, DC-SIGN, langerin, dectins, and macrophage-inducible C-type lectin. These receptors collectively recognize unique glycan variants specific to distinct pathogens or improperly glycosylated host proteins, driving rapid clearance and immunological activation only in the setting of coligation with TLRs or other pattern recognition receptors.

### Cytoplasmic Sensors

Because some pathogens are able to invade host cells without activating extracellular or endocytic recognition pathways, additional pattern recognition receptors have evolved to sense infection within the cytoplasm. These intracellular cytoplasmic pattern recognition receptors are able to recognize PAMPs or DAMPs via the formation of oligomers that activate rapid degradation and intracellular signaling to arm the immune response against the invading pathogen. Two broad classes of cytoplasmic pattern recognition sensors have been identified: NOD-like receptors and RIG-I-like receptors.

### NOD-like Receptors

NOD-like receptors are a family of over 20 cytoplasmic pattern recognition receptors that can be broadly divided into four classes based on their N-terminal domain, NLR-A (Nod-like receptor A; “A” for acidic transactivating domain [e.g., CIITA]), NLR-B (“B” for baculovirus inhibitor of apoptosis protein repeat [e.g., NAIP]), NLR-C (“C” for caspase activation and recruitment domains (CARDs) [e.g., NOD1 and NOD2]), and NLR-P (“P” for pyrin domain [e.g., NALP1–14]) (77). NOD-like receptors recognize PAMPs and DAMPs, likely via their LRR domains, and ligand binding induces their oligomerization. These oligomers can then both activate inflammatory caspases like caspase 1, which is necessary for the maturation of proinflammatory cytokines like IL-1, and activate the signaling pathways necessary for the production of pro-inflammatory cytokines.

### NODs

NODs belong to the NRLC family of NOD-like receptors and recognize peptidoglycans from Gram-negative bacteria

(NOD1) or muramyl dipeptides found in both Gram-positive and Gram-negative bacteria (NOD2). In addition to the recognition of bacterial ligands, NOD2 has also been shown to respond to several viruses, including respiratory syncytial virus, parainfluenza virus, influenza virus, and vesicular stomatitis virus (78). The recognition of these ligands results in rapid oligomerization and signaling through recruited serine/threonine protein kinases (e.g., RIP2), which ultimately result in the production of proinflammatory cytokines.

### NALPs

NALPs belong to the NLRP family of NOD-like receptors, which are characterized by their N-terminal PYD domain. To date, 14 NALPs have been identified, and NALPs are activated in response to a wide range of ligands, including muramyl dipeptides (like NOD2), anthrax toxin, whole bacteria, bacterial RNA, and pore-forming toxins. Additionally, a number of viruses have been shown to activate specific NALPs, including Kaposi's sarcoma, herpesvirus, vaccinia virus, adenovirus, influenza virus, measles virus, hepatitis C virus, and HIV (78). Importantly, NALPs are necessary for the formation of several different types of inflammasomes, which are multiprotein complexes containing caspase 1 that plays an important role in the activation of the antiviral inflammatory cytokines IL-1 $\beta$  and IL-18.

### RIG-I-like Receptors

The RIG-I-like receptor family is composed of three proteins: RIG-I, MDA5, and LGP2 (79). This family represents a unique class of cytoplasmic RNA helicases that recognize intracellular double-stranded or single-stranded RNA, resulting both in the production of interferons  $\alpha$  and  $\beta$ , which functions to limit viral replication, induce the apoptosis of infected cells, recruit additional effector cells to the site of infection, and activate the inflammasome. A number of viruses have been shown to be recognized by RIG-I and/or MDA5, including Japanese encephalitis virus, hepatitis C virus, ebola virus, polio virus, and HIV (80). The critical nature of RIG-I-like receptors in antiviral immunity is highlighted by the evasion strategies developed by RNA viruses to subvert this potent antiviral activity. For example, two proteins encoded by hepatitis C virus (HCV) block a key step in the intracellular signaling cascade activated by RIG-I signaling. Similarly, the HIV-1 protease has been shown to degrade an important signaling node in the RIG-I-induced cascade.

### Induced Innate Immune Responses to Infection

Following activation of PRRs, a complex network of signals leads to both the immune-mediated clearance of the PAMP/DAMP-covered material and the rapid activation of the immune system via the induced release of cytokines and chemokines. Cytokines are small proteins that are released by various cells in the body in response to cellular activation (81). Over 40 cytokines have been identified to date, and these cytokines are often classified into families based on their structure or the receptor to which they bind. Importantly, each cytokine binds to a distinct cytokine receptor, differentially expressed on the surface of cells of the body, enabling a highly specialized responses to take place depending on the cytokine cascade. Along these lines, following immune recognition of a pathogen, networks of cytokines are rapidly released by infected cells and innate and adaptive immune cells present at the site of infection. These cytokines establish the "quality" of the inflammatory milieu and both provide instructions for the elimination of the

pathogen but also can signal for the recruitment of additional cell subsets that are required for enhanced pathogen clearance.

### Interferons

Among the first cytokines produced following viral infection are a family of cytokines known as interferons. The interferon family plays an essential role in the earliest host immune response to infection, particularly with viruses, by placing infected cells and neighboring uninfected cells in an anti-viral state. The sensing of double-stranded RNA, which is a common intermediate in the replication cycle of many viruses, induces interferon production by infected cells. Interferon signaling in neighboring uninfected cells triggers the expression of multiple defense mechanisms aimed at interfering with viral replication, increasing antigen presentation to aid in the adaptive immune elimination of infected cells, and activating recruited adaptive immune cells (82). Three families of interferons have been described, Type I, Type II, and Type III, and these families play distinct roles in the innate response to viral infection (83).

#### Type I IFNs

The Type I family of interferons includes IFN- $\alpha$  and IFN- $\beta$  (84). Type I interferons are among the first cytokines produced by an infected cell, as among others cytoplasmic nucleic acid stimulate their induction through the TBK1/STING/IRF3 pathway. While two types of IFN- $\beta$  ( $\beta_1$  and  $\beta_2$ ) exist, 13 subtypes of IFN- $\alpha$  with different activities have been identified in humans. Virtually any cell in the body can produce Type I interferons. Importantly, type I IFN signaling cascades induce the expression of a number of host restriction factors that rapidly recognize and restrict viral infections, including the enzyme oligoadenylate synthetase, protein kinase R (PKR), members of the tripartite motif-containing protein (TRIM) family, members of the apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like 3G (APOBEC) family, and tetherins. For example, oligoadenylate synthetase activates intracellular RNases, including RNase L, which degrades all RNA, both host and viral, within the cell. Similarly, activation of PKR inhibits protein translation within the cell, preventing further viral propagation. The TRIM family of proteins contains over 50 different members with distinct functions, including many with antiviral functions (85). For example, TRIM5 $\alpha$  recognizes motifs in retroviral capsid proteins and interferes with viral uncoating, while TRIM22 inhibits transcription from retroviral promoters and blocks the assembly and budding of newly formed virions. APOBEC proteins, a family of evolutionarily conserved cytidine deaminases, drive the attenuation of retroviruses by editing viral genomes present in nascent virions, inducing their rapid degradation (86). Tetherins function to prevent the release of viral particles from the surface of cells (87) and have been linked to the inhibition of HIV budding in the absence of Vpu (88). Furthermore, tetherin has been shown to play a role in lassa and Marburg virus infection (89).

#### Type II IFNs

IFN- $\gamma$  is the only member of the Type II family of interferons (90). While IFN- $\gamma$  is thought to be more of an adaptive cytokine, released by T cells, several classes of innate immune cells, including natural killer cells, monocytes, and dendritic cells, also produce IFN- $\gamma$ . IFN- $\gamma$  is highly pleiotropic, inducing very broad effects, including increasing the cytotoxic

activity of NK cells, improving antigen presentation to promote more effective killing by cytotoxic T cells, increasing nitric oxide synthesis in neutrophils, promoting more class switching to more potent antibody subclasses in B cells, promoting T-cell differentiation, activating phagolysosomes in macrophages after CD4 T-cell antigen recognition, and promoting cellular adhesion and extravasation that collectively restrict, control, and promote clearance of viral infection.

### Type III IFNs

The Type III family of interferons is relatively poorly characterized, although four family members have been identified, IFN- $\lambda$ 1–4 (91). Type III interferons are thought to play an important role in the innate response to viral infection. Many viruses have been shown to induce the expression of Type III interferons, including respiratory syncytial virus, influenza virus, Sendai virus, and HCV. While almost any cell type appears capable of expressing Type III interferons, dendritic cells, both myeloid and plasmacytoid, appear to produce the most. Unlike Type II interferons, Type III interferons induce a generalized antiviral state in cells exposed to them. This antiviral state is very similar to the state induced by Type I interferons, and in fact, many of the genes that are upregulated in response to Type I interferons are also upregulated in response to Type III interferons. One key difference, however, is that although the changes in gene expression following exposure to Type I interferons tend to be rapid and short lived, the gene expression changes following exposure to Type III interferons are slower but more prolonged. Intriguingly, receptors for Type III interferons are highly expressed in the liver, lung, and intestine, and polymorphisms in the interferon  $\lambda$  locus have been shown important in the response and clearance of HCV (92).

### Pyrogenic Cytokines

One of the important networks of cytokines that is released in response to viral infections is a group of cytokines that have fever-inducing, or pyrogenic, activity (93). During the initial days of infection a cytokine cascade, or storm, is initiated that drives rapid and general immune activation (94). The main cytokines with these effects are IL-1, IL-6, and TNF- $\alpha$ , which are all released by tissue macrophages rapidly after recognition of a pathogen. Collectively, these cytokines can act directly on the brain to raise the thermoregulatory set point in the hypothalamus. The increased temperature simultaneously restricts the replication of invading pathogens, because most pathogens grow better at lower temperatures, and increased temperatures also improve immune function, as cells of the adaptive immune response are more active at increased temperatures. These cytokines also have important secondary systemic effects as they can increase the activity of the complement cascade via the activation of the acute-phase liver response, increase neutrophil production and egress from the bone marrow, and induce the migration of dendritic cells to the lymph nodes where they can stimulate the adaptive immune response. In addition to these systemic effects, these cytokines also mediate local effects, including increasing vascular permeability, activating T cells, B cells, and NK cells, and increasing the cytotoxic activity of macrophages.

### Chemokines

Chemokines are cytokines that are centrally involved in driving cell movement or chemotaxis (95, 96). These proteins are structurally similar with four cysteine residues that

give these proteins their characteristic structure. They are involved in immune regulation at several levels, in the homeostatic control of cell migration, in tissue development, as well as in the rapid recruitment of immune cells during infection. Importantly, chemokines act by attracting cells to the source of the chemokine, trafficking through the body along a gradient. Thus, upon infection or immunological priming, innate and adaptive cells are instructed to express particular chemokine receptors that enable them to sense particular chemokine gradients located within target tissues. These cells then leave their resident tissues and patrol the body for the highest concentration of the particular chemokine, taking up residence where the cells may perform their designated function. Following recognition of a pathogen, infected cells or neighboring uninfected cells are therefore stimulated to produce a network of chemokines to recruit additional effector cells of the innate and adaptive immune system. For example, stimulation of dendritic cells by TLR3, TLR7, TLR8, or TLR9 has been shown to induce the expression of CCL4 (also known as MIP-1 $\beta$ ) and CCL5 (also known as RANTES). CCL4 and CCL5 recruit several players of the immune system including macrophages, NK cells and T cells. Therefore, the recognition of a pathogen can induce the expression of an elaborate network of chemokines, inducing the trafficking of a diverse range of immune cells to the site of infection, where they can mediate their protective activities.

## SUMMARY

Overall, the innate immune system composed of physical barriers, commensals, effector proteins, and an array of distinct immune cells collectively act with near instantaneous speed to protect us from infection. However, beyond its role as our first line of defense, the innate immune system is also poised to set the stage for the adaptive immune system that establishes long-lived memory that enables us to rapidly resist future infections with the same pathogens.

## Adaptive Immunity

The adaptive immune response is mediated by a network of lymphocytes that, following infection, acquire specificity through an evolutionarily unique set of antigen-specific receptors, providing protection from infection with the same or similar pathogen. This antigen-specific immune response is mediated by two major families of lymphocytes (T cells and B cells) that express a T-cell receptor (TCR) or B-cell receptor (BCR), respectively (Fig. 2). These adaptive immune responses are programmed through an elaborate process that begins with the generation of a large array of naïve TCR and BCR variants that then further mature, evolve, and gain enhanced specificity for pathogen-derived antigens in specialized secondary and tertiary lymphoid organs. With the influence of the innate immune response, qualitatively unique adaptive immune responses, able to provide the greatest level of pathogen-specific protection, are elicited.

## T-Cell-Mediated Immunity

### Introduction

T cells are lymphocytes that play a central role in cell-mediated antiviral immunity. T cells express a heterodimeric T-cell receptor (TCR; CD3) on their cell surface, which distinguishes them from other lymphocytes, including NK cells and B cells. Their name originates from the observation that a critical portion of T-cell maturation occurs in the

thymus, where T cells undergo an elaborate educational process that selects for highly effective, nonself-reactive T lymphocytes. Two major types of T cells exist, CD4 and CD8 T cells, each with distinct roles in the immune response to viral infections (Fig. 2). While CD4 T cells have been implicated as major orchestrators of the overall adaptive immune response through the release of cytokines that qualitatively tune immunity, CD8 T cells are generally regarded as the effectors of the immune system, poised to directly or indirectly eliminate infected cells.

The selection of effective CD4 or CD8 T-cell responses hinges on the “priming” process, whereby naïve T cells that recognize viral antigens on the surface of antigen-presenting cells (APCs). APCs present antigens to T cells via a unique class of cell-surface proteins known as the MHC (or Human Leucocyte Antigen (HLA) in humans) that present selected segments of digested proteins to TCRs. MHC class I generally presents cytosolic peptides to CD8 T cells, while MHC class II presents endosomal peptides to CD4 T cells. Thus, the processing, presentation, and recognition occurs through specialized machinery in distinct cellular compartments and ultimately lead to the activation and generation of highly specialized antigen-specific antiviral immune responses.

### T-Cell Development

T cells originate from hematopoietic stem cells (HSCs) present in the bone marrow that populate the thymus as lymphoid progenitors (97, 98). Once in the thymus, these thymic lymphoid progenitors (or thymocytes) pass through a series of distinct selection processes that collectively ensure that only functional, nonautoreactive T cells survive and exit as mature naïve T cells (99). Roughly 4% of thymocytes survive this positive selection process giving rise to equivalent numbers of CD4 and CD8 T cells.

At the start of the selection process, thymocytes do not express any typical T-cell markers and are CD3 negative, as well as CD4 and CD8 negative (called double-negative cells). The majority (95%) of the double-negative T cells acquire an  $\alpha\beta$  TCR (100), while the remainder of T cells develop to express a  $\gamma\delta$  TCR. Antigen-specific TCR generation occurs via a process known as VDJ recombination where two (for the TCR  $\alpha$  chain) or three (for the TCR  $\beta$  chain) gene segments are randomly recombined. For  $\alpha\beta$  TCRs, the process begins with recombination and expression of the TCR  $\beta$  chain (101, 102). Following successful rearrangement, the nascent TCR  $\beta$  chain can associate with a germline encoded, common pre-TCR  $\alpha$  chain, resulting in a survival signal. Cells that fail to successfully rearrange their  $\beta$ -chain are eliminated. The expression of the pre-TCR then signals developing thymocytes to halt  $\beta$ -chain rearrangement and to undergo a proliferative burst. This results in CD4 and CD8 receptor expression and initiates  $\alpha$ -chain rearrangement. At the end of this process a functional  $\alpha$  chain efficiently pairs with the  $\beta$  chain, and the thymocyte is ready to be “tested” as to whether it is suitable as a mature naïve T cell. Newly rearranged TCR-expressing T cells then undergo a positive and negative selection process aimed at selecting newly formed TCRs that are able to recognize self MHC molecules with foreign antigens (positive selection) but not self-antigens (negative selection). This process is critical to prevent the selection of self- or autoreactive T cells (103).

### Positive Selection

Immature thymocytes move into the thymus cortex where thymic cortical epithelial cells present self-antigen on MHC molecules. During this interaction, only thymocytes that

interact with MHC-I or MHC-II receive a “survival signal” (104, 105). Although thymocytes express both CD4 and CD8 receptors at this point, thymocytes that interact well with MHC class II molecules eventually become CD4+ T cells, whereas thymocytes that interact well with MHC class I molecules mature into CD8+ T cells (106). A T cell becomes a CD4+ cell by downregulating expression of its CD8 cell surface receptor. If the cell does not lose its MHC class II binding signal, it will continue downregulating CD8 and becomes a CD4+, single positive cell. But, if the signal is interrupted, the cell stops downregulating CD8 and switches over to downregulating CD4, and instead eventually becomes a CD8+, single positive cell. All other cells that bind either too weakly or too strongly die by “neglect” in the absence of a survival signal (107). Roughly, ~4% of thymocytes survive positive selection process giving rise to equivalent numbers of CD4 and CD8 T cells.

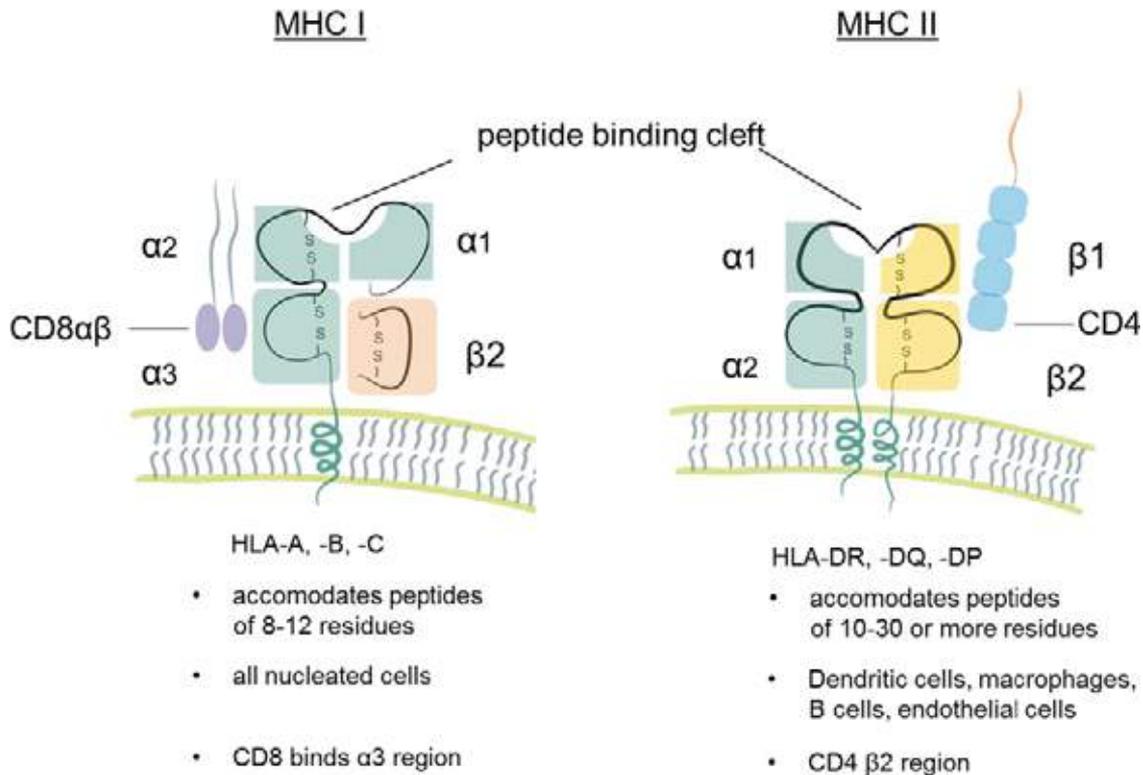

### Negative Selection

The surviving positively selected thymocytes migrate towards the boundary of the cortex and medulla in the thymus where medullary thymic epithelial cells (mTECs) express major “self” proteins (so called “tissue-specific self-antigens,” TSAs) (108). The expression of these “self” TSAs, from a wide selection of organ specific genes, is regulated by the autoimmune regulator (AIRE). Thymocytes that bind strongly to self-antigens rapidly undergo apoptosis (via negative selection). This overall process of selection against TSAs is critical to prevent autoimmunity, and thus the activity of AIRE reduces the threat of the occurrence of subsequent autoimmunity by allowing for the elimination of autoreactive T cells that bind antigens not traditionally found in the body (109). One exception is the development of thymically derived T regulatory cells (nTregs). While T cells that receive strong positive selection signals undergo apoptotic cell death and cells that receive low signals survive. T cells that receive intermediate signals become nTregs and upregulate the Treg transcription factor FoxP3 (110), which is epigenetically modified to maintain open FoxP3 gene expression. Overall only about 2% of all T cells survive the selection process and exit the thymus as mature naïve T cells.

### Triggering CD4 and CD8 T-Cell Immunity

Once naïve CD4 and CD8 T cells have completed their development in the thymus they recirculate between blood and peripheral lymphoid tissues until they encounter their specific antigen. A naïve CD4 T cell recognizes specific peptides in the groove of MHC class II by its TCR (Fig. 4). The CD4 receptor binds to the  $\beta_2$  domain of the MHC class II molecule D4, amplifying the signal generated by the TCR by recruiting the tyrosine kinase Lck, which is involved in the TCR signaling cascade (111). In contrast, naïve CD8 T cells recognize their specific antigen in the context of MHC class I through their TCR, while the CD8 receptor binds to the  $\alpha_3$  domain of the MHC class I molecule (112).

CD8 T cells play a more direct role in antiviral immunity via the recognition and lysis of virus-infected cells. Thus, MHC class I is ubiquitously expressed on all cell types, aimed at persistently sampling cytoplasmic proteins to monitor for viral infection. Conversely, while CD4 T cells can also contribute to direct cytotoxicity, these cells are often involved in orchestrating and shaping the adaptive immune response, qualitatively directing CD8 T-cell and B-cell immunity. Thus MHC class II is only expressed on a number of cells termed “professional” APCs that are poised to activate the

**FIGURE 4** Comparison of the structure of the major histocompatibility complexes (MHC) I and II. While class I molecules are composed of a polymorphic  $\alpha$  chain noncovalently attached to the nonpolymorphic  $\beta 2$  microglobulin, class II are composed of a polymorphic  $\alpha$  chain noncovalently attached to a polymorphic  $\beta 2$  microglobulin. While the peptide binding cleft of MHC I is closed, allowing only little sequence variation, the binding groove of MHC class II is open, even allowing tertiary structures.

master CD4 T-cell immune regulators. MHC class II preferentially presents antigens endocytosed from the extracellular matrix.

### Antigen Processing and Presentation

MHC class I and II genes, located on chromosome 6, are the most polymorphic genes of humans, providing an evolutionary advantage over many different diseases. MHC class I is composed of an  $\alpha$  chain that consists of three domains,  $\alpha 1$ ,  $\alpha 2$ , and  $\alpha 3$ . Structurally, the  $\alpha 1$  domain sits on a unit of the non-MHC molecule  $\beta 2$  microglobulin (Fig. 4). The transmembrane  $\alpha 3$  domain anchors MHC class I to the cell membrane, while the  $\alpha 1$  and  $\alpha 2$  domain form the peptide binding groove of the three major MHC class I genes (HLA-A, HLA-B and HLA-C), of which HLA-B is the most polymorphic allele. Each human possesses 2 sets of each of the 3 HLA class I alleles totaling up to 6 distinct HLA class I alleles that are able to present peptides to CD8 T cells.

Conversely, MHC class II is formed of two chains,  $\alpha$  and  $\beta$ , each with two domains ( $\alpha 1/\alpha 2$  and  $\beta 1/\beta 2$ ). Each domain possess independent transmembrane domains anchoring the MHC class II molecule to the cell membrane. The  $\alpha$  and  $\beta$  domains collectively form the peptide binding groove. There are three major MHC class II genes: HLA-DP ( $\alpha$ -chain HLA-DPA and  $\beta$ -chain HLA-DPB), HLA-DQ ( $\alpha$ -chain HLA-DQA and  $\beta$ -chain HLA-DQB) and HLA-DR ( $\alpha$ -chain HLA-DRA and four  $\beta$ -chains HLA-DRB1, DRB3, DRB4 and DRB5). However, because  $\alpha$  and  $\beta$  chains freely heterodimerize, heterozygous humans can have between 4 and 12 different MHC class II isoforms. Thus, there are over

10,000 potential combinations of HLA class II allele expression (113).

In addition to classical HLA alleles, a number of nonclassical MHC alleles also exist (HLA-DM and—DO) that are not exposed on the cell membrane but are involved in antigen presentation. In humans there are at least three additional nonclassical HLA class I alleles termed HLA-E, F, and G. The role of these nonclassical HLA class I alleles is less clear. HLA-E is by far less polymorphic than the other HLA class I alleles but is critically linked to NK cell recognition/activity. Yet, some virus-specific CD8 T-cell responses can also recognize HLA-E-restricted epitopes (114, 115) and have been recently linked to enhanced simian immunodeficiency virus (SIV) control and clearance in nonhuman primates vaccinated with a cytomegalovirus-based vaccine expressing SIV genes (116).

Unlike the other HLA class I alleles, HLA-F is located in the endoplasmic reticulum, and only a small amount appears on the cell surface. Interestingly, HLA-F often contains an immature oligosaccharide component and associates with at least two proteins involved in the MHC class I pathway, calreticulin and TAP. The third nonclassical HLA class I allele is HLA-G, which is thought to have an immunomodulatory role. Specifically, although HLA-G does not present peptides, HLA-G interacts with at least four different inhibitory receptors blocking the activity of NK cells, T cells, and B cells as well as some APCs. HLA-G plays an important role in pregnancy, where it inhibits the rejection of the fetal graft as a result of its expression on cytotrophoblast cells of the placenta.

In addition, homologues of MHC proteins exist, including the major histocompatibility complex class I-related chain (MIC) proteins, MICA, and MICB. Although these molecules do not bind peptides, they are selectively induced upon cellular stress, such as genotoxic stress, and serve as stress-inducible ligands for the NKG2D receptor on NK cells and on some T cells.

### MHC Class I

The MHC (HLA) class I molecule presents cell-derived peptides of specific dimensions within a tight groove with closed ends. Peptides that are able to bind must form critical bonds with invariant residues in the MHC class I binding groove. Both the MHC class I pocket shape and peptide bonds restrict peptide selection to peptides that are 8 to 12 amino acids in length that are not antagonized by groove residues. Additionally, two to three pockets exist at the bottom of the groove that act as anchor residues that accommodate a highly restricted set of amino acids. Thus stabilized peptides possess a select set of anchor amino acid residues, usually located at position 2 and position 9 (117).

The importance of MHC class I peptide selection is clearest in the setting of viral evolution and escape from T-cell recognition. For example, HIV viral escape at anchor residues is often associated with T-cell evasion via a loss of T-cell recognition of the evolved virus. However, MHC class I escape is often accompanied by compromised viral replicative fitness, which has been observed for HIV and HCV (118, 119), thus viruses struggle with both advantages and disadvantages of T-cell escape to maintain infection. However, the critical importance of MHC class I targeting of viruses is most clearly illustrated by the clinical effect of particular MHC class I alleles on disease progression. For example in HIV infection the MHC class I allele HLA-B\*57 has been associated with slow disease progression and control of HIV viremia via the presentation of highly conserved regions of the viral genome (120), while HLA-B\*35px has been associated with rapid disease progression and, therefore, poor prognosis due to enhanced peptide presentation from variable domains of the virus (121). Similar observations have been made for MHC class I alleles in association with clearance of HBV and HCV infection.

#### Loading Peptides into MHC Class I Alleles

By hijacking intracellular host machinery, viruses use infected cells to replicate and generate new virions. This process produces copious amounts of foreign peptides that are processed and presented by MHC class I or class II. Most viral peptides are derived from defective ribosomal products (DRiPs) (122, 123), which are rapidly degraded forms of newly synthesized proteins. In some instances the incoming virus also brings in sufficient quantities of viral proteins for antigen presentation. However, professional APCs can also, in some instances, transfer phagocytosed virions or viral proteins to the cytosol from their lysosomal compartments, to enable viral protein processing and presentation of “externally” derived material within the “internally” produced material that is typically presented in the MHC class I pathway. This process is called “cross-presentation.”

Degradation is largely mediated by a large multicatalytic protease complex called the proteasome (124, 125). The proteasome is composed of several units including a 20S protein and 2x 19S proteins on either side of the 20S that form a donut-shaped molecule with a hollow core in which proteins are degraded. The protein degradation by the proteasome is a multistep process: (1) ubiquitination and

targeting, (2) unfolding and translocation, and (3) proteolysis. In the first step a series of three enzymes (E1, E2, E3) facilitate the ubiquitination of the protein targeted for degradation. However, before it is recognized by the proteasome, the target protein must be labeled with at least four ubiquitin monomers in the form of a polyubiquitin. After a protein has been ubiquitinated it is recognized by the 19S protein of the proteasome and enters the 20S protein, where it contacts the proteolytic active site (step 2). Because the 20S protein is narrow the protein needs to be partially unfolded, a process called translocation, which occurs after deubiquitination. In the last step the  $\beta$ -subunits of the chamber of the 20S protein start the proteolysis.

Cellular chaperones (e.g., TCP-1 ring complex, TRiC) protect new peptides emerging from the immunoproteasome, preventing further cytoplasmic degradation of these peptides. Although proteasomes can generate the precise peptides presented by MHC class I molecules, many of the peptides may be longer than the MHC class I groove and are transported into the ER irrespective of groove-binding capacity. While the carboxy-terminal region of the peptides is defined by the catalytic activity of the proteasome in the cytosol, long peptides can be further trimmed by the aminopeptidases within the endoplasmic reticulum. Among the aminopeptidases, the *endoplasmic reticulum aminopeptidase associated with antigen processing* (ERAAP) has been identified as a key contributor to trimming long peptides within the ER (126, 127). Interestingly, many of the components involved in antigen processing within the immunoproteasome are rapidly upregulated by interferon (IFN). The immunoproteasome improves cleavage of polypeptides at hydrophobic residues (and decreases after acidic residues), which results in an increased binding in MHC class I residues and therefore more effective MHC presentation to alert the immune system of infection.

Peptides are continually transported from the cytosol into the ER by the transporter associated antigen processing-1 and -2 protein (TAP-1, TAP-2). In the ER newly synthesized MHC class I  $\alpha$  chains assemble with the membrane-bound chaperone protein calnexin to retain the MHC class I molecule in a partially folded state. Once  $\beta_2$  microglobulin binds to the  $\alpha$  chain, calnexin dissociates (128) enabling the MHC complex to bind to the peptide-loading complex (PLC) including the proteins tapasin, ERp57, and calreticulin. The PLC assists in this binding event, with the peptide and MHC class I complex. The binding of the peptide releases the PLC and MHC class I can now be presented on the cell surface.

### MHC Class II

While the MHC class I binding groove is closed, restricting peptide access, the MHC class II binding groove is open at both ends allowing for much greater heterogeneity in peptide length, permitting the association with peptides that hang loosely outside of the binding groove. The peptide segments that bind to MHC class II consist of about nine amino acids, which are termed the peptide binding register. The typical anchor residues of HLA class II alleles are at positions P1, P4, P6, and P9 of the peptide register and interact with residues in the pockets of the MHC molecule. Due to the variable length of the bound peptide, peptides can adopt different conformations and can even form tertiary structures on top of the HLA class II allele.

#### Loading peptides into MHC class II alleles

MHC class II-peptide complex assembly, peptide loading, and transport are different and slightly more complicated

than MHC class I peptide loading (129). MHC class II largely presents peptides generated in endocytic/lytic vesicles of macrophages, immature dendritic cells, B cells, or other antigen-presenting cells (APCs). Protein-derived peptides that are digested in vesicles, such as lysosomes, are transported into the ER. In the ER, premature MHC class II binding is prevented by the MHC class II-associated invariant chain (Ii or CD74) that binds and regulates MHC class II loading. Specifically, the Ii prevents peptide binding to the MHC class II molecule, and also diverts MHC class II molecules from the trans-Golgi network to an endolysosomal compartment. Here Ii is cleaved by cathepsins, in such a way that only a fragment called CLIP (class II invariant-chain peptide) remains in the MHC class II binding groove. CLIP loaded MHC class II molecules are then transported to a specialized antigen processing compartment, the class II containing compartment (MIIC). Here, the molecule HLA-DM stabilizes the empty class II molecule and prevents its aggregation, while it also catalyzes the release of the CLIP fragment, permitting the binding of other peptides to the MHC class II molecule (130, 131). It also catalyzes the removal of unstably or weakly bound peptides to allow other peptides to replace them. Within B cells, dendritic cells, and thymic epithelial cells another molecule, HLA-DO, is involved in the peptide loading of MHC class II molecules. HLA-DO serves as a negative inhibitory regulator of HLA-DM. It is unclear why HLA-DO is only found in selected cell subsets. Once MHC class II is associated with a peptide, the complex is transported to the cell surface for presentation to CD4 T cells.

Although MHC class II presents peptides from lysosomal compartments derived largely from extracellular antigens, there are exceptional circumstances when MHC class II can also present cytosolic peptides. For example, a significant number of self-peptides presented by HLA class II molecules are derived from cytosolic proteins. The most likely mechanism by which cytosolic peptides are processed for antigen presentation through the MHC class II pathway is during the natural uptake or removal of damaged organelles or proteins that are degraded in lysosomes. This process is called autophagy, the natural cellular catabolic process of degrading and recycling unnecessary or dysfunctional cellular proteins through lysosomes (132–134). However, because autophagy is increased during cellular stress, this permits cells to process more intracellular proteins, including cytosolic viral proteins present during viral infection, for MHC class II presentation to CD4 T cells. This process is critical during Epstein-Barr virus (EBV) infection of B cells, resulting in the induction of cytolytic CD4 T cells (135). Similarly, this process may also play a critical role in driving cytolytic CD4 T-cell responses against HIV-infected CD4 T cells, shown to associate with slower HIV disease progression (136). However, the fact that infected CD4 T cells can present to other CD4 T cells via MHC class II loading of viral peptides highlights a unique exception to the MHC class II-peptide presentation dogma, whereby activated CD4 or CD8 T cells can express HLA class II molecules in humans, which has not been observed in rodents. The biological significance of class II-restricted presentation by activated T cells in humans however is still unclear.

### Viral Evasion of MHC

Given the selective antiviral pressure mediated by T cells, many viruses have evolved approaches to evade immune recognition through MHC peptide presentation including mechanisms that modify the maturation, assembly, and ex-

port of MHC class I and II molecules. While the mechanisms are very different, the outcome of all these evasive strategies essentially achieves the same endpoint: the downregulation of MHC class I or II molecules on the surface of infected cells and thereby reduced antigen presentation of viral proteins. Herpes simplex virus 1 (HSV-1) and cytomegalovirus (CMV) both possess a protein that specifically blocks peptide entry into the ER (137). While the ICP47 molecule of HSV-1 blocks peptide binding to TAP, CMV encodes two proteins: the US6 molecule which directly inhibits TAP, and the US3, which blocks tapasin function of the peptide-loading complex (138, 139). Likewise, adenoviruses (AdV) have evolved an E19 protein that blocks the same proteins. Conversely, Nef, encoded by HIV, binds to MHC class I, driving rapid endocytosis and thereby evading CD8 T cell recognition. While many other evasion strategies have been exploited by viruses, the wide array of evasion strategies described here provide an example of the different strategies utilized by different viruses to avoid the antiviral pressure of T cells.

Similarly, many viruses have evolved a myriad of strategies to evade CD4 T-cell immunity. Viral mechanisms that interfere with MHC class II expression mainly affect MHC class II transcription or post-translational modification. Adenoviruses and CMV both affect the signaling cascade of MHC class II transcription. In contrast, the US2 protein of CMV translocates the DR $\alpha$  and the DM $\alpha$  chain into the cytosol, resulting in proteosomal degradation. Conversely, HPV influences MHC class II viral peptide expression by blocking acidification of Ii and thus altering vesicle traffic and endocytic machinery.

### Antigen Recognition

CD4 and CD8 T cells recognize their antigens through their T cell receptors (TCRs), which are the same molecules on both cell types. However, due to the differences in coreceptor (CD4 or CD8) utilization and function, T-cell subsets respond quite differently (Fig. 5). While the CD8- $\alpha$  interacts with the  $\alpha 3$  portion of the Class I MHC molecule, increasing the avidity of the TCR bond, CD4 binds to  $\beta 2$  of MHC II, increasing the TCR signaling via the activation of the Lck pathway.

The TCR is a disulfide-linked membrane-anchored heterodimeric protein in 95% of the T cells consisting of the highly variable  $\alpha$  and  $\beta$  chains, which is expressed as part of a complex with the invariant CD3 chain molecules. As mentioned above, a minority of T cells express a  $\gamma\delta$  TCR. Each of the  $\alpha$  and  $\beta$  chains are composed of two extracellular domains: variable (V) region and a constant (C) region (140). The constant region is proximal to the extracellular membrane, followed by a transmembrane region and a short cytoplasmic tail, while the variable region binds to the peptide/MHC complex. The variable domain of both the TCR  $\alpha$ -chain and  $\beta$ -chain each have three complementarity-determining regions (CDRs), whereas the variable region of the  $\beta$ -chain has an additional area of hypervariability (HV4) that does not normally contact antigen and therefore is not considered a CDR. As with antibodies, the variable region is linked to the constant region following genetic rearrangement, with additional combinatorial diversity generated in the CDR3 regions (as with antibodies, located at the junction of variable constant regions) by the insertion of one (for  $\alpha$  chains) or two (for  $\beta$  chains) additional small segments. Thus, as with antibodies, most of the diversity in the TCR occurs in the CDR3 region, which typically is in direct contact with the peptide bound by the MHC molecule. The other CDR regions contact the  $\alpha$ -helices that form the ridges

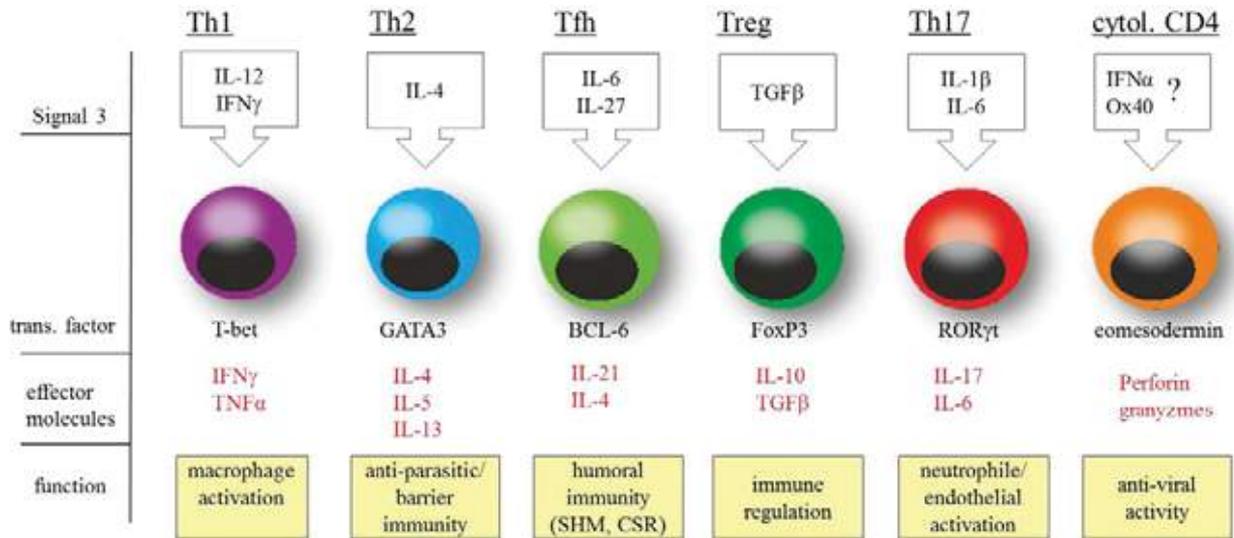

FIGURE 5 CD4 T-cell subsets. The various functional CD4 T-cell subsets are depicted, their associated main transcription factors, the cytokines they secrete, and their main effector functions.

of the MHC peptide-binding pocket. This provides the structural basis for the phenomenon of MHC restriction.

Unlike the BCR of B cells, T cells do not alter the constant region of the TCR. The TCR does not undergo somatic mutation during the course of an immune response. Thus, while the number of responding T cells increases during an immune response, the quality of the response can apparently be altered only via the recruitment of novel clonal T-cell populations (clonotypes).

### Generating a T-Cell Response

Naïve T cells recirculate between lymphoid tissue and peripheral blood. During this process they bind transiently to DCs, which enables them to survey the MHCs on DC in many different organs every day. Mature DCs bind naïve T cells efficiently through interactions with LFA-1 or CD2 on the T cell with several different adhesion molecules including ICAM-1, ICAM-2, and CD58. This transient binding and surveillance is crucial to provide T cells the time to sample several MHCs on the surface of any given DC. Once the T cell encounters its antigen presented as a peptide:MHC complex on a DC, it stops circulating and the T-cell response is initiated. The activation and differentiation of naïve T cells is termed “priming.” The priming of CD8 T cells usually generates cytotoxic CD8 T cells, while CD4 T cells can develop into effector CD4 T cells with a diverse array of functions. The recognition of the peptide leads to a conformational change in the LFA-1 molecule, which stabilizes the T-cell and DC interaction and the T cell forms an immunological synapse (IS) (141). The association of naïve T cells and DCs persist for several days, during which time the T cell differentiates into effector cells and proliferates. The DC feeds the naïve T cell with three distinct signals that drive T-cell activation, T-cell survival, and T-cell differentiation. The T-cell activation signal is the recognition of the appropriate peptide:MHC complex. The survival signal often comes through the ligation of CD28 with B7 molecules on the APC, which are necessary for the optimal clonal expansion of T cells. Antigen recognition and CD28 signaling triggers interleukin-2 (IL-2) cytokine secretion, which is the first step in the differentiation of T cells into

effector cells (142). Furthermore, CD28 signaling also leads to a stabilization of IL-2 mRNA, which would otherwise be rapidly degraded. IL-2 is a  $\gamma$ -chain cytokine like IL-4, IL-7, IL-9, IL-15, and IL-21, and combinations of other  $\gamma$ -chain cytokines can replace the IL-2 signal but confer slightly different biological functions. For example, under certain circumstances IL-15 can have similar effects as IL-2, which is secreted by monocytes and other immune cells. The resulting effect of IL-2 or IL-15 consecutively is not identical however, and the immune system uses them in a discriminating manner to optimize T-cell activation, apoptosis, Treg activity, and memory. This autostimulation drives T-cell proliferation and allows a single T-cell clone to expand to thousands of cells all bearing the same TCR. However, these T cells also become addicted to IL-2 because removal of IL-2 results in their death, which is a mechanism exploited by Tregs to control T-cell immune responses.

The key function of IL-2 in the induction of an immune response is has been utilized in several immunotherapies that aim to suppress T-cell immunity (e.g., cyclosporin A, tacrolimus). The activation and survival signals for T cells also drive the expression of additional proteins that can modify and fine-tune the immune response. These include CD28-related proteins such as inducible costimulatory (ICOS), cytotoxic T-lymphocyte associated factor-4 (CTLA-4), or TNF-receptor family proteins such as CD27, 4-1BB, CD40L, and Ox40 (143). ICOS binds to ICOS ligand which is critical for the induction of T follicular helper (Tfh) cell development, while also regulating the expression of other cytokines such as IL-4 and IL-21. Similarly, Tfh CD40L binding to DC or B cell CD40 provides a bidirectional signal that leads to rapid and enhanced T- and B-cell maturation. In the absence of costimulatory signals, T cells can enter a state of anergy, which is critical for the prevention of autoimmunity (144). Since the thymus cannot possibly present every self-peptide, T-cell recognition of a peptide in the absence of APC activation and upregulation of costimulatory receptors renders the T cell refractory to subsequent stimulation even by professional APCs. Like many of the costimulatory signals, the signals of this interaction are bidirectional, resulting in APC anergy. While all T cells

possess a common need for IL-2 survival signaling (signal 2), the additional differentiations (3) that are required to induce various T-cell populations are distinct and therefore described in the context of their respective function.

### Effector T-Cell Subsets

**Cytotoxic CD8 T cells.** While TCR/MHC recognition and costimulation of naïve CD8 T cells are crucial, these interactions alone do not determine the fate of specific CD8 T-cell clones. Additional signals such as the degree of antigenic activation, contact time with antigen-presenting cells, asymmetric division, and cytokine availability are forces that determine the development of CD8 T cells into phenotypically, functionally, anatomically distinct populations. Importantly, these qualitative features of the CD8/APC interaction also impact the long-term survival of the evolving CD8 T-cell response (145).

Among the key signals that drive strong CD8 T-cell responses, *in vitro* studies have shown that APC derived IL-12 can drive the proliferation and development of cytotoxic CD8 T cells. In addition, combined IL-12 and IFN $\alpha$  induce high levels of the cytolytic proteins, perforin and granule associated enzymes (granzymes: A-M), inside CD8 T cells that are required for *in vivo* antiviral activity. A specific set of transcription factors, called T-box transcription factors *tbet* and *eomesodermin*, are responsible for the cytolytic program of CD8 T cells (146, 147). Another transcription factor, Blimp-1, determines the effector function of CD8 T cells. Originally first identified in B cells, Blimp-1 is important in restricting and focusing the CD8 T-cell response. While more virus-specific CD8 T-cell responses are generated in the absence of Blimp-1 (148), the responses are less efficient in killing, have lower granzyme B levels, and are unable to fully differentiate into effector T cells.
