Parvoviruses have been isolated from a wide range of animals, including mammals, birds, insects, crustaceans, and reptiles. These viruses tend to be species-specific and can cause a variety of serious diseases in their host species (1). The first parvoviruses isolated from humans were adeno-associated parvoviruses, which have not yet been linked with disease. Until recently the only parvovirus associated with human disease was human parvovirus B19 (B19V), which was fortuitously identified in 1975 during an evaluation of tests for hepatitis B virus antigens (2). B19V has been associated with erythema infectiosum, transient aplastic crisis, chronic anemia in patients with impaired immune systems, hydrops fetalis, and purportedly a number of other conditions (3). Seven additional parvoviruses have recently been detected in humans by molecular screening for new sequences, including human bocavirus (HBoV)1–4, tetraparvovirus (PARV4), bufavirus (BuV), and tusavirus (TuV) (4–9). HBoV1 causes acute respiratory illness (10) and, as with HBoV2 and 3, possibly also encephalitis (11). The other recently discovered human parvoviruses are yet to be associated with human disease.

## VIROLOGY

### Classification and Genotypes

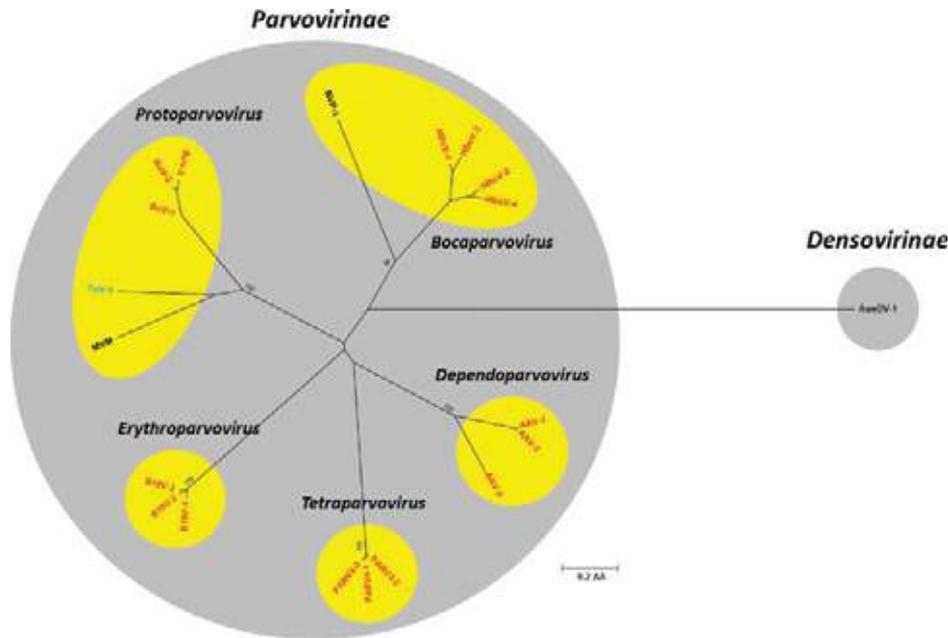

Parvoviruses are small, nonenveloped, single-stranded DNA viruses that infect a variety of animals, usually in a species-specific fashion. The family *Parvoviridae* is divided into two subfamilies: the *Densovirinae*, which infect arthropods, and the *Parvovirinae*, which infect vertebrates. The members of the *Parvovirinae* that infect humans will be the focus of this chapter. The subfamily *Parvovirinae* is divided into eight genera: *Protoparvovirus*, *Erythroparvovirus*, *Dependoparvovirus*, *Amdoparvovirus*, *Bocaparvovirus*, *Aveparvovirus*, *Copiparvovirus*, and *Tetraparvovirus* (1). The parvoviruses known to infect humans include B19V in the genus *Erythroparvovirus*, adenovirus-associated viruses (AAVs) in the genus *Dependoparvovirus*, HBoV1–4 in the genus *Bocaparvovirus*, PARV4 in the genus *Tetraparvovirus*, and BuV and potentially TuV in the genus *Protoparvovirus* (Fig. 1).

AAVs in the *Dependoparvovirus* genus require co-infection with another virus, usually an adenovirus or herpesvirus, to replicate. Multiple AAV genotypes have been identified to date, detected as co-infections of adenovirus

laboratory stocks or isolated from human or nonhuman primates (12). AAVs can establish a latent infection by integrating into the host-cell genome or being maintained in an extrachromosomal state. The ability of DNA of some AAVs to integrate into the human genome has made them a highly investigated vector for gene therapy (13). Latent AAV can be rescued by infection with a helper virus or *in vitro* by stressing the cell with ultraviolet or ionizing radiation. Members of the other genera in the subfamily *Parvovirinae* do not require a helper virus for efficient productive infection but do usually require actively dividing cells. B19V belongs to the species *Primate erythroparvovirus 1*, consisting of three genotypes, 1 to 3, which all belong to one serotype (1, 14–18). Among the three genotypes, genotype 1 is presently most commonly detected overall. Genotype 2 has been frequently detected within tissues of subjects born before 1972 (19) but very seldom in blood after the 1960s, and genotype 3 has been infrequently detected with the exception of a study in Ghana (20). The three genotypes appear to have similar biologic and antigenic properties (14). Sequence studies of PARV4 have also identified three genotypes; genotypes 1 and 2 (formerly PARV5) are found mainly among injecting drug users in Western countries, and genotype 3 has been detected only in sub-Saharan Africa (21–24), where it is endemic. PARV4 belongs to the species *Primate tetraparvovirus 1* (1). To date, sequence studies of HBoV isolates have identified 4 viruses, named HBoV1–4 (4, 5, 7, 25), of which HBoV1 is a respiratory virus, whereas the others seem to be enteric. HBoV1 and 3, as well as a gorilla bocavirus (26), belong to the species *Primate bocaparvovirus 1*, whereas HBoV2 and 4 belong to *Primate bocaparvovirus 2* (1). Of the more recently discovered bufavirus, there are three genotypes with yet unknown epidemiological, biological, or clinical differences, and they belong to the species *Primate protoparvovirus 1* (1, 8, 27).

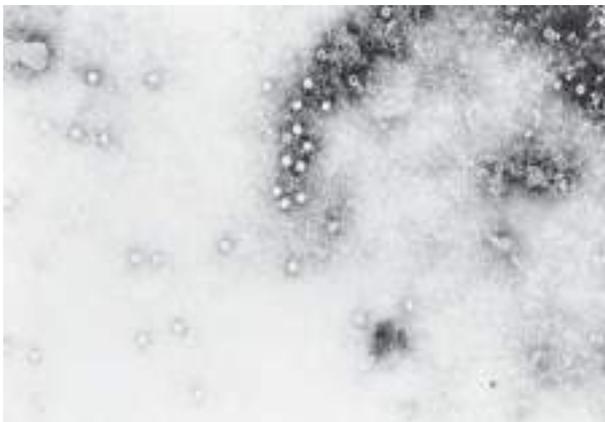

### Composition

Parvoviruses are icosahedral particles between 20 and 25 nm in diameter containing 60 copies of the structural proteins (Fig. 2). B19V and PARV4 capsids contain 2 proteins, termed VP1 and VP2, whereas AAV and HBoV capsids contain 3 proteins, designated VP1, VP2, and VP3 (28, 29). X-ray crystallography has been used to determine the structure for a number of parvoviruses including canine parvovirus (CPV); minute virus of mice (MVM); AAV2, 4, and 5; B19V;

**FIGURE 1** Neighbor joining phylogenetic tree derived from ORF1 (nonstructural protein) amino acid sequences obtained from GenBank and used by ICTV to classify parvoviruses (1). Subfamilies *Parvovirinae* and *Densovirinae* shown as gray circles. For simplicity, only one representative member of the *Densovirinae* is shown and only genera of the *Parvovirinae* with members known to infect humans are shown as yellow circles (*Copiparvovirus*, *Aviparvovirus*, and *Amdoparvovirus*, genera are therefore excluded). Representative human parvoviruses (in red), putative human viruses (in blue), and prototype viruses when not human (in black) are shown within each genus. AA, amino acid; AaeDV1, *Aedes aegypti* densovirus 1; AAV1, AAV2, AAV5, adeno-associated viruses 1, 2, 5; B19V1–3, parvovirus B19 genotypes 1–3; BPV1, bovine parvovirus 1; BuV1–3, bufavirus genotypes 1–3; HBoV1–4, human bocaviruses 1–4; MVM, minute virus of mice; PARV4 1–3, tetraparvovirus genotypes 1–3; TuV1, tusavirus genotype 1.

and HBoV1 (30). Common structural features among parvoviruses include one or more protrusions at the 3-fold axis, a depression at the 2-fold axis, and a channel at the 5-fold axis surrounded by a canyon. Depending on the extent of the 3-fold protrusion, the capsids appear either smooth, as for B19 and HBoV, or rough, as for AAV. Moreover, the 5-fold channel has been proposed to be a portal for genome packaging and externalization of VP1u; however, it seems to be closed in the B19V capsid. For some parvoviruses, the

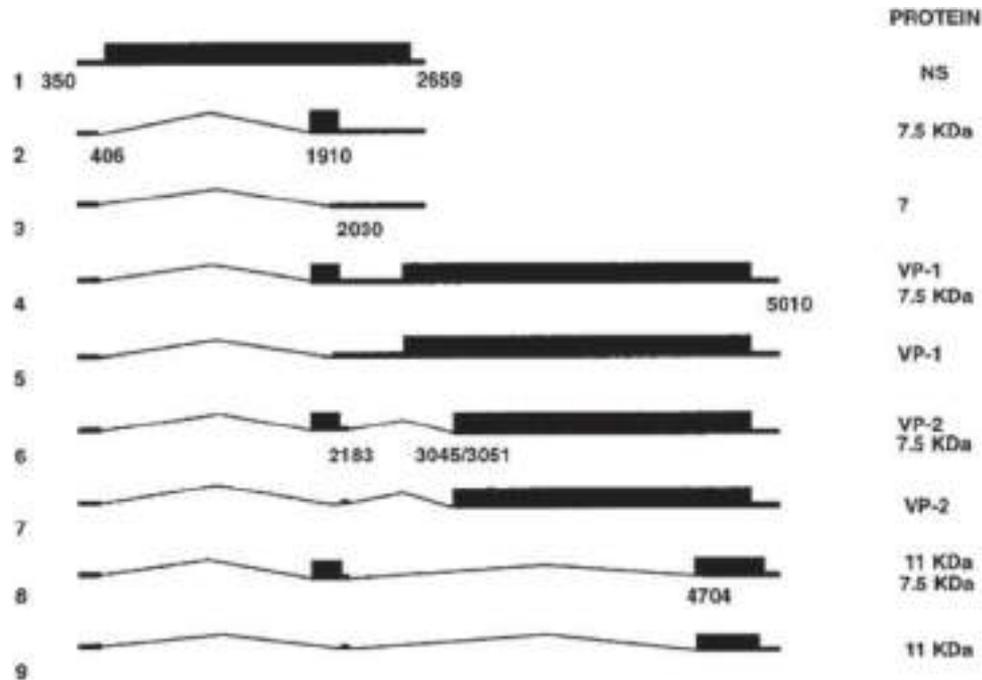

**FIGURE 2** Electron micrograph (X170,000) of B19V empty particles in a serum specimen from a patient with transient aplastic crisis. Courtesy of G. William Gary, CDC, Atlanta, GA.

locations of amino acids associated with cell receptor and antibody-binding sites have been determined.

The encapsidated single-stranded DNA genome varies from 4 to 6 kb in size, and each virion contains either the negative or positive strand in varying proportions. AAV and B19V, and presumably PARV4, virions contain equal numbers of positive- and negative-sense DNA strands, while HBoV encapsidates mostly the negative strand (21, 31–33). Parvovirus DNA contains palindromic inverted repeat sequences at each end that form terminal hairpin structures, which can be either semi-identical or different depending on the virus. These hairpin structures permit self-priming and are essential for replication. Parvovirus genomes contain generally two major open reading frames (ORFs), one that encodes nonstructural proteins in the left half of the genome and the other in the right half of the genome for the structural capsid proteins. HBoV, as with the other bocaviruses, has an additional minor open reading frame in the middle (4).

Multiple mRNA species are produced by splicing mechanisms. For example, the B19V genome encodes nine mRNA species from a single promoter (Fig. 3) (34). These 9 mRNAs translate at least 5 proteins, VP1, VP2, and at least 3 nonstructural (NS) proteins (Table 1) (35, 36, 37). The NS proteins play a key role in production of infectious virus, probably by regulating transcription, participating in replication, and assisting in encapsidation of virion DNA (38). The NS proteins can be toxic to cells, and this toxicity may contribute to cytopathology during infection. Similar to B19V, HBoV has only 1 promoter (39), whereas AAV has 3 (1).

**FIGURE 3** Schematic of B19 mRNA produced in erythroid progenitor cells. The thin line represents introns and the heavy line represents the nontranslated portion of exons. The filled box represents translated portions of exons. The numbers below the line indicate the start or end of the respective exon. All mRNAs are initiated at the same promoter (P6). The NS protein (first mRNA) is in one reading frame; the 7.5 kDa, VP1, and VP2 proteins are in a second reading frame (-1 relative to the NS protein); and the 11.0 kDa protein is in the third reading frame. Based on data from references 34 and 35.

VP2 or VP3 is the major component of the parvovirus virion. In the case of B19V, VP2 comprises about 95% of the virion and VP1, 5% (40). The VP2 proteins expressed in a Chinese hamster ovary-cell line or in a baculovirus system will self-assemble into empty capsids. VP1 can be incorporated into VP2 empty capsids, but VP1 alone does not self-assemble unless its unique amino terminus is truncated (41). VP1 contains the VP2 sequences plus an additional 227 amino acids unique to VP1 at its amino terminus termed VP1u. Empty capsids that include both VP1 and VP2 elicit neutralizing antibodies, while those containing only VP2 do not (42). Most parvoviruses, including all human parvoviruses, have a calcium-dependent phospholipase A2 (PLA2) motif in VP1u (43, 44). PLA2 is presumed to facilitate infection in cells by altering membranes of virion-containing endosomes.

### Receptors

B19V attaches to a specific cell-surface receptor, the glycosphingolipid ceramide globoside, also called blood group P antigen (45), where it undergoes endocytosis and migrates to the nucleus. Although globoside is necessary for infection, it

is not sufficient, and  $\alpha 5\beta 1$  integrin and KU80 autoantigen have been reported to act as coreceptors for B19V (46–48). VP1u also binds to cells and is important in determining tropism, although its receptor has not been identified to date (49). A variety of receptors have been identified for other parvoviruses, including transferrin receptors for some members of the genus *Protoparvovirus* and heparin sulfate proteoglycan, human fibroblast growth factor receptor 1, and integrin for AAVs (30, 43). The receptors for HBoVs, BuV, and PARV4 have not yet been identified.

### Replication Strategy

Efficient replication of parvoviruses requires cellular functions expressed only during the S phase of cell division and thus requires actively dividing cells. However, to ensure efficient replication, parvoviruses may utilize the cellular DNA damage response (DDR) and hypoxic conditions (50–54). Transcription of mRNA and replication of virion DNA occur in the nucleus. Replication of the single-stranded virion DNA is initiated at the terminal hairpins and produces dimer and dimer-duplex intermediate concatemeric replicative forms, involving rearrangement of the hairpins and cleavage to form single-stranded virion DNA in a process termed “rolling hairpin replication” (55). For B19V, PARV4, and AAV, the plus- and minus-sense single-stranded DNA genomes are encapsidated with equal frequency, but for bocaviruses the minus strand is favored in 85 to 95% of the capsids (21, 31–33, 56). Induction of cell apoptosis, exocytosis, or cytolysis results in virus release.

### Host Range

Parvoviruses are normally host specific, i.e., the human parvoviruses infect only humans, so there are no direct animal

**TABLE 1** Proteins of human parvovirus B19

Protein	Size (kDa)	No. of amino acids	Function
NS protein	77	671	Replication
VP1	83	781	Virus capsid
VP2	58	554	Virus capsid
7.5 kDa	7.5	72	Unknown
11 kDa	11	94	Unknown

models for these viruses. However, serologic tests have suggested that exposed animal handlers may have been infected with one of the simian erythroviruses (57). Close relatives of B19V, HBoV, PARV4, and BuVs have been detected in animals, besides nonhuman primates, and also in domestic animals, rodents, and bats (1, 26, 58, 59). Infection of other erythroviruses in their respective host species has been proposed as a model for B19V disease (60, 61).

### Growth in Cell Culture

Productive B19V propagation *in vitro* was first accomplished in late erythroid-precursor cells present in bone-marrow explant culture systems (62). Subsequently, several human leukemic cell lines, including UT-7/Epo, MB-02, JK-1, and KU812, have been shown to support low levels of B19V replication (63, 64), although CD36 cells from bone marrow remain the most efficient. As shown for several viruses, hypoxia can improve replication (65). Actively replicating cells are required for efficient replication, although B19V has also been shown to replicate in otherwise nonpermissive cells with the adenovirus providing helper functions (66).

With similar appropriate helper viruses, AAVs can replicate in a variety of tissue culture systems (67). If a helper virus is not present, AAV integrates into the host cell genomic DNA in a site-specific fashion. When cells containing integrated AAV are infected with helper virus or are subjected to certain chemical or physical treatments, AAV genes are expressed, the integrated DNA is released, and virions are produced. HBoV1 has been shown to replicate and produce progeny virions in polarized human-airway epithelial cells (HAE) (68, 69); however, it did not replicate in monolayer cultures of the same nondifferentiated cells. No tissue culture system has yet been shown to support PARV4, BuV, or TuV replication.

### Inactivation by Physical and Chemical Agents

Nonenveloped viruses like parvoviruses are stable under ordinary environmental conditions and are more difficult to inactivate on environmental surfaces. The choice and concentration of the inactivating agent, inactivation time, and presence of organic material all impact the effectiveness of inactivation. For surface inactivation, detergent and phenolic acid-based products are generally ineffective for nonenveloped viruses, whereas 5,000 ppm of free chlorine (e.g., 1/10 dilution of household bleach) and 70% aqueous alcohol solutions inactivate some nonenveloped viruses, and 2% glutaraldehyde solutions inactivate most (70). In transfusion medicine, inactivation of blood or blood products is problematic. Infection in persons receiving heat-treated clotting-factor concentrates indicates that the virus can withstand dry-heat treatment at 80°C for as long as 72 hours or at 100°C for 30 min (71). Based on *in vitro* studies, B19V is more sensitive to liquid heat treatment, and the level of sensitivity depends on the composition of the solution (72).

## EPIDEMIOLOGY

### Distribution and Geography

B19V infection is common throughout the world, although the percentage of persons positive for immunoglobulin G (IgG) antibody, as a measure of past infection, varies by location and timing of the last B19V epidemic (73–75). AAVs, HBoV, and PARV4 have been detected in multiple locations globally, whereas BuV has thus far been found only in a few countries in Africa, Asia, and Europe (8, 27, 76–78).

The seroprevalence of BuV is low, at least in Northern Europe (Väisänen, personal communication).

### Incidence and Prevalence

#### B19V

In most communities, the prevalence of B19V antibody increases from 2% to 15% among children 1 to 5 years of age, to 20% to 40% among children 6 to 9 years of age, and to 35% to 60% among children 11 to 19 years of age (79). Antibody prevalence continues to increase with age, reaching 75% to 90% in several studies among persons older than 50 years of age (Fig. 4). In most countries, the greatest rate of increase in IgG positivity occurs in school-age children, consistent with the observation that erythema infectiosum, the most commonly recognized manifestation of B19V infection, is most often diagnosed in this age group, and that children are the source of most infections (80).

The seroprevalence of B19V is significantly higher in some parts of the world, including parts of Africa and Papua New Guinea, with >80% of 10-year-olds having detectable B19V antibody (81, 82). In contrast, some parts of Asia, and among isolated tribes of Africa and South America, the seroprevalence can be significantly lower (83–85).

Subclinical infection is common, and most adults with B19V IgG antibody will not give a history suggestive of a B19V-associated illness. In outbreaks of B19V infection, 50% or more of infected persons may be asymptomatic or report a nonrash illness (86–88).

B19V infections are most often noted as outbreaks of erythema infectiosum in schools. Outbreaks in the United States and Europe usually occur in the winter and spring and often continue for months or until school recesses for the summer (86, 89). During school outbreaks, 25% to 50% of students have been reported to have clinical or serologic evidence of infection. Staff in schools are also commonly infected (80, 89–91); 20% of susceptible staff developed infection during one outbreak. Infections also occur endemically when no outbreak activity is noted in the community. Since recurrences of erythema infectiosum or transient aplastic crisis are rare, it is assumed that past infection, as indicated by presence of B19V IgG antibodies, confers long-term protection from disease. Experimental inoculation of one patient with low levels of B19V IgG antibody led to an asymptomatic infection, indicating that past infection may

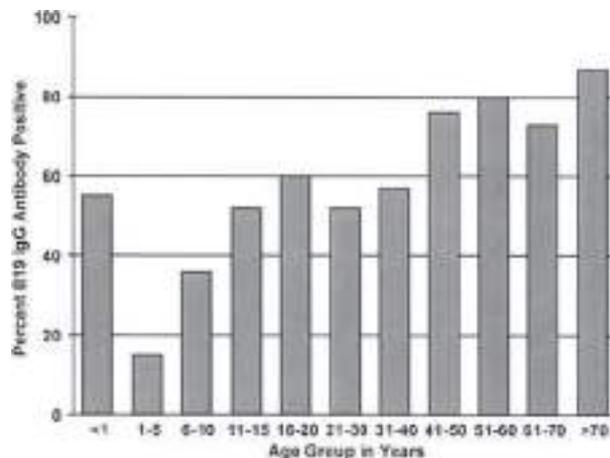

FIGURE 4 Rates of B19V IgG antibody positivity by age. Adapted from reference 73.

not always prevent re-infection but probably protects from disease (92).

### HBoV and Other Parvoviruses

HBoV infections are common, with respective seroprevalences of HBoV1–4 in 6-year-olds of 80%, 50%, 10%, and 0% (93). However, serologic studies of these four HBoVs is complicated by cross-reactivity and most likely by the immunological phenomenon known as “original antigenic sin,” leading to underestimates of the true prevalences (93–95). The majority of AAV data are for AAV2 for which 50% or more of persons 10 to 19 years of age have antibodies (96). Less is known about timing and extent of infection with PARV4. In European and North American populations, PARV4 infections are rare outside of persons with risk factors for blood-borne viruses, where seropositivity among the latter can exceed 90% (97–99). In contrast, studies in some sub-Saharan African and Asian countries have found a higher PARV4 seroprevalence in the absence of these risk factors (22, 24, 100, 101).

Bufavirus DNA has been detected in stools of children and adults having diarrhea, with low (0.2 to 4%) prevalence (8, 27, 78, 102) and tusavirus DNA in the diarrheal stool of one single child in Tunisia (9).

### Seasonality

In temperate climates in the Northern Hemisphere, B19V outbreaks most often occur during the late winter and spring (103). These outbreaks are cyclical, with increased B19V transmission occurring every 4 to 10 years in a given community (104, 105). Seasonal patterns of AAVs and PARV4 infections are not known, and those for HBoVs are yet to be clearly defined. HBoV1 can be detected throughout the year (106–112).

### Transmission

The primary route of B19V is through the respiratory tract because its DNA can transiently be found in secretions from the nose and throat (86, 87, 92). In volunteer studies, infection occurred in four of five exposed persons after intranasal inoculation (92, 113). Transmission also occurs by transfusion of contaminated blood (114, 115), from blood products including albumin and clotting factors (71, 116), from an infected mother to her fetus, and, potentially, even after tattooing (117). Depending on the community and antibody assay, between 40% and 60% of young adults will test positive for B19V IgG antibodies and thus presumably not be susceptible to infection.

The risk of B19V transmission from a single unit of blood is low, although high concentrations ( $>10^5$  IU) of B19V DNA were present per ml in 1/500 to 1/10,000 units in one study (118). The risk has been higher with use of many types of multi-unit blood products. B19V DNA has been detected in 25% to 100% of products, such as albumin and factor VIII concentrates, which may contain components from 5,000 or more units, and infection has often been associated with receipt of these products. The small size of the B19 virion and the resistance of the virus to inactivation have made it difficult to remove or inactivate during the preparation of these products, and, in Europe and USA, all plasma products are now required to be tested to ensure that the B19V viral load is  $<10^4$  IU/ml (119, 120).

Nosocomial transmission of B19V among staff and patients has been reported with infection rates as high as 50%, but it is often difficult to differentiate hospital-acquired from community-acquired infection in such outbreaks, except in

patients with very high virus loads, like those with transient aplastic crisis (121–125).

B19V is transmitted efficiently in households, with about 50% of susceptible exposed household members becoming infected (86, 87). Infection also occurs in about 20% of susceptible staff working in a school during an outbreak of erythema infectiosum (89, 91), in about 6% of susceptible residents of a community during one B19V outbreak (88), and in about 1% to 3% of women with no identifiable exposure during a year or a pregnancy (74, 126–128). In pregnant women living in communities with outbreaks of B19V disease, infection rates among susceptible persons have ranged from 4% to 14%. Risk factors for infection include working as a teacher or childcare worker or having children at home (74, 90, 91, 129).

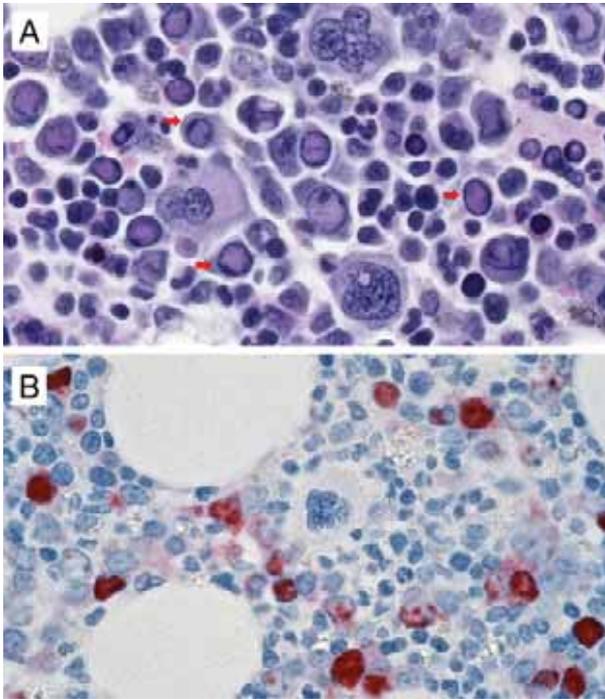

In a recent study of 3,710 pregnant mothers, a clear increased risk (adjusted hazard ratio, aHR=2.63; 95% CI: 1.27 to 5.46) of B19V infection among daycare employees was observed, compared with those of socioeconomically similar health care professionals (129). The difference in the infection risk was even more pronounced in the analysis of nulliparous women (aHR=5.59; 95% CI: 1.40 to 22.4), eliminating the effect of the women's own children. Vertical transmission from mother to fetus has been reported in 25% to 50% of infants of mothers infected during pregnancy (130–132).

The route of transmission for HBoV1 is the respiratory tract, but those for AAV, HBoV2–4, PARV4, BuV, and TuV are not well understood. The presence of HBoV2 and 3, as well as BuV and TuV, in feces suggests fecal-oral transmission, while HBoV4 is too rare for any conclusions (9, 78). The potential for maternal transmission of HBoV1 and PARV4 in newborns has also been documented (133, 134). The high prevalence of genotypes 1 and 2 of PARV4 in injecting drug users and persons infected with HIV, suggests that they are transmitted parenterally by contaminated needles or other blood contact (135). However, increasing evidence from regions in sub-Saharan Africa and Asia, with higher PARV4 seropositivity rates and demonstrable detection of PARV4 genotype 3 DNA in nasal and fecal specimens from children, also suggests a potential role for fecal-oral transmission (22, 24, 100, 136).

## PATHOGENESIS IN HUMANS

Nucleated erythroid-precursor cells are the primary cells and bone marrow the primary tissue for B19V replication (62, 137). Extramedullary hematopoiesis makes fetal liver an important site of fetal infection *in utero* (138). Giant pronormoblasts, erythroid cells with marginated chromatin and nuclear inclusions (Fig. 5), are typical of B19V infection and are found during active infection in bone marrow, circulating blood, liver, and other fetal tissues (139).

Globoside can also be found on other cell types apart from erythroid precursors (140). B19V can be detected in these nonerythroid tissues and cells (e.g., endothelial cells of the myocardium, epidermal cells, granulocyte precursors, megakaryocytes, and macrophages) and may persist in the joints, skin, heart, liver, and even in the brain for decades following the acute infection (138, 141–145). The mechanisms for B19 genome persistence in these diverse tissues are unknown. Studies have also demonstrated the presence of B19V-like particles or B19V DNA in fetal myocardial cells and macrophages of infected fetuses (132, 146). Although replication may occur in these cell types, it appears to be relatively inefficient.

**FIGURE 5** (A) Hematoxylin and eosin stain of bone marrow from patient with B19V infection. Note prominent intranuclear inclusions (arrows). (B) Immunostaining of B19V antigens in bone marrow (immunoalkaline phosphatase stain, naphthol fast red substrate with light hematoxylin counterstain). Original magnification of both images, X630. Panels courtesy of Wun-Ju Shieh, CDC, Atlanta, GA.

The course of erythema infectiosum, the most common manifestation of B19V infection, suggests disease is, in part, immune-mediated. The estimated incubation period to onset of rash is usually between 1 and 2 weeks but sometimes as long as 3 weeks (147). In experimental infection in humans, the first symptoms of fever, malaise, and myalgia occurred 1 to 2 weeks after inoculation of the virus. These symptoms developed during high viremia and were accompanied by a reticulocytopenia, drop in hemoglobin, and moderate, but clinically insignificant, lymphopenia, thrombocytopenia, and neutropenia (92). The viremia and reticulocytopenia resolved by days 11 to 16 as volunteers mounted an antibody response; the rash or arthralgias were noted at 15 to 17 days after inoculation (Fig. 6).

During the high level viremia, the bone marrow has a marked decrease in the number of erythroid cells but a relatively normal number of myeloid cells. The arrest of hematopoiesis during viremia is consistent with the expected impact of a lytic infection of red-cell precursor cells. On the other hand, the fact that onset of rash and arthritic symptoms occurs coincident with the host antibody response and decreasing levels of viremia suggests that the host immune response is important to the pathogenesis of these symptoms. The occurrence of rash in an immunocompromised patient after receiving immune globulin, and again after the patient mounted an antibody response, support this conclusion (148). B19V-antibody immune complexes have been detected in serum of experimentally infected adults by an immune adherence assay (92) and in serum of 31 of 38 B19V-infected patients by a C1q binding assay (122). The

finding of B19V antigens and viral particles in vascular endothelial cells from B19V-associated rash lesions suggests that infection of these cells might also contribute to the pathogenesis of the rash (145).

The pathogenesis of B19V-associated arthritis is less clear. B19V DNA has been detected by PCR assays in synovial tissue from the joints of patients with B19V-associated arthritis, other types of arthritis, and from control patients (149–151). However, there is no evidence that B19V replicates in synovial tissue. In B19V-associated arthritis, it is possible that virally expressed proteins are cytotoxic or contribute to joint inflammation. The PLA2 activity in VP1 can activate synoviocytes, induce mediators of inflammation, and, possibly, participate in B19V-associated arthritis (152).

Less is known about the tissue tropism and pathogenesis of the other human parvoviruses. HBoV2–4 have been found mostly in stool, whereas HBoV1 has been most often detected in respiratory specimens but also in stool and serum (10, 153), as well as in adenotonsillar tissues obtained from otherwise healthy children (154, 155).

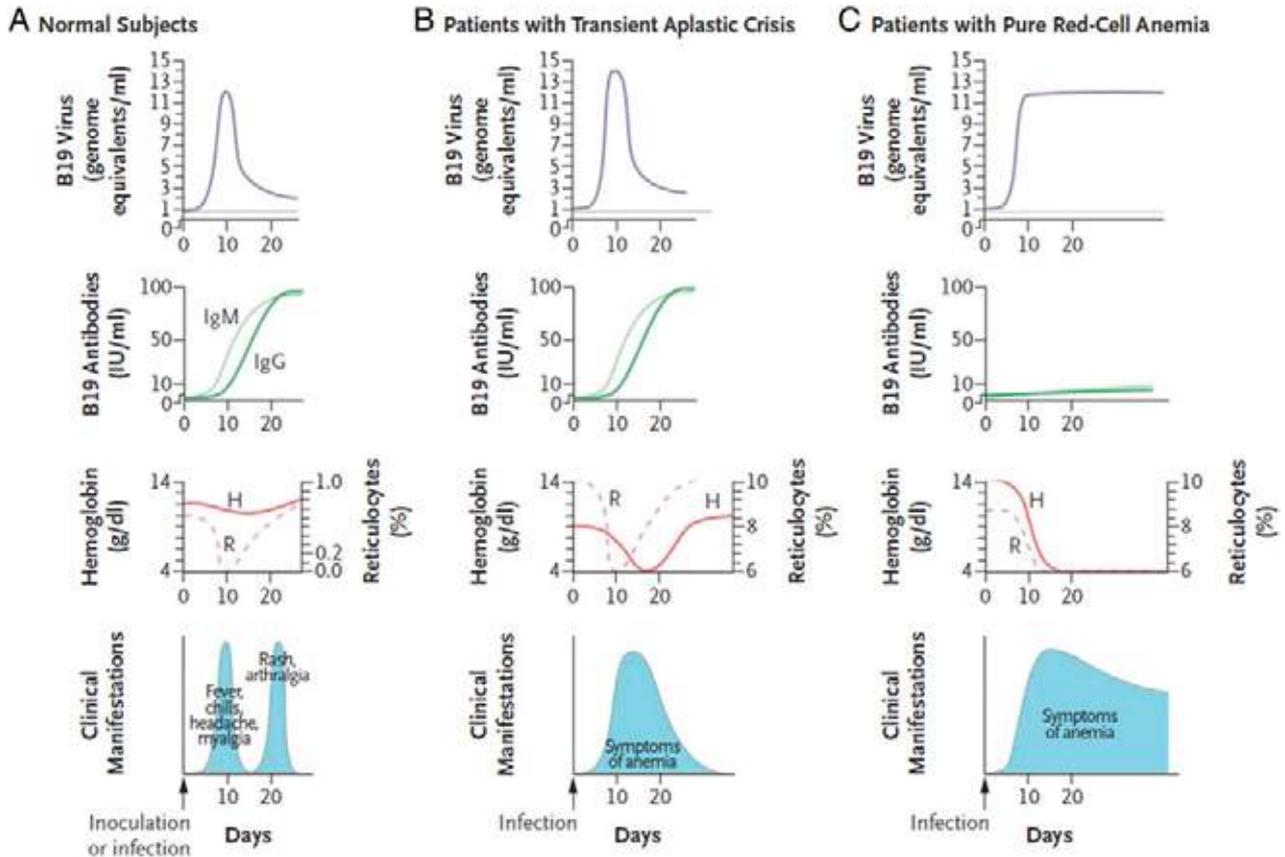

HBoV1 has been shown to infect and propagate in polarized human airway epithelial (HAE) cells in an air-liquid interface (ALI) culture (68, 69). Progeny virus particles were shown to be released from both the apical and basolateral surfaces of the HAE-ALI, while showing impaired epithelial integrity: i.e., thinning of the epithelium, decreased polarization, disruption of tight junctions, cell hypertrophy, and loss of cilia, all markers of respiratory tract injury (69). Persistent replication in these terminally differentiated cells was surprisingly observed for 50 days (156). The ability to replicate is thus not cell-cycle dependent as has generally been believed for parvoviruses. In these nondividing cells, it has been shown that HBoV1 utilizes the DNA-repair polymerases required, by the cellular DNA damage and repair (DDR) machinery, for its replication (54). Finally, by studying bronchoalveolar lavage samples of HBoV1-infected patients, an upregulation of various cytokines has been observed, similar to those seen in washes of HBoV1-infected HAE-ALI cell cultures (157). HBoV1 infection thus seems to trigger specific cytokines that may affect pathogenesis.

AAV has been most often detected in specimens from the genital tract, but it has also been detected in muscle, brain, and a variety of other tissues without causing any damage (12, 13, 142, 158). PARV4 has been detected in serum and blood specimens from otherwise healthy individuals and from autopsy bone marrow and lymphoid tissue specimens from human immunodeficiency virus–infected persons, likewise with nondefined pathology (21, 99, 106).

### Virus Replication Patterns

As noted above, the B19V-associated anemia correlates with viremia and is presumed to be related to the cytopathic effect of the virus on erythropoietic precursor cells. In immunocompetent persons, the immune response controls the infection within 7 to 10 days and before a significant anemia develops. In persons with borderline compensated hemoglobin levels, even the short cessation of red cell production can produce a self-limited, but serious, anemia (i.e., transient aplastic crisis). A variety of conditions, including sickle cell disease, hereditary spherocytosis, thalassemia, and acquired hemolytic anemias, have been associated with transient aplastic crisis.

Some patients with compromised immunity due to HIV infection, malignancies, chemotherapy, or organ transplantation are unable to control B19V replication and develop a

**FIGURE 6** Pathophysiology of parvovirus B19 infection. Inoculation of normal subjects and natural infection resulted in fifth disease (Panel A; study reported by Anderson et al. [92]). A two-phase illness was produced under control conditions; most subjects noted only the typical rash, joint symptoms, or both, corresponding to the appearance of specific antiviral antibodies. Reticulocytopenia occurs during viremia, but hemoglobin levels do not decline below normal values. H denotes hemoglobin, and R reticulocytes. Transient aplastic crisis occurs in patients with underlying hemolysis or erythroid stress who are infected with parvovirus B19 (Panel B; study reported by Saarinen et al. [200]). Cessation of erythropoiesis causes severe anemia, because of the higher demand for red cells. Chronic pure red-cell aplasia is due to persistent infection (Panel C; study reported by Kurtzman et al. [203]). Anemia persists because of the failure of the humoral immune response to clear parvovirus B19. Reprinted from reference 3.

chronic lytic infection of red cell precursors and an associated chronic reticulocytopenic anemia (3, 159–161). Patients with chronic infection often respond to treatment with intravenous immune globulin (IVIg) with a prompt reticulocytosis and clearing of viremia. Chronic infection with anemia has also been rarely noted in patients with presumed normal immune systems (3, 159–161). Persistence of low levels of B19V in blood, bone marrow, synovial tissue, heart, and liver in adults from infection many years earlier complicates the task of linking B19V to disease, based on its detection in these tissues (144, 151, 162–165).

The fetus is susceptible to severe B19V anemia because it has a need for increased red cell production and an immature immune system that is not always able to control the infection (3). B19V-associated myocarditis may also contribute to fetal disease. Transplacentally transferred maternal antibodies provide some protection to the fetus during the later stages of pregnancy.

Although the major cell type for productive B19V infection is the erythroid progenitor, a number of other cells have the P-antigen receptor (45, 140) and may be positive for B19V DNA or antigens (144–146, 166, 167). *In vitro*, macrophage and endothelial infection have been facilitated

by the presence of antibody, presumably through Fc receptor-mediated phagocytosis of virus-antibody complexes, or by the complement factor C1q receptor (168, 169). This may be the mechanism by which phagocytic cells in the bone marrow and synovial tissue and the endothelial cells in the heart may acquire B19 antigen and DNA. Further, B19V-infected bone marrow-derived circulating angiogenic cells may transport virus to diverse tissues where they could affect endothelial regeneration (e.g., resulting in cardiomyopathy) (170).

During respiratory tract infection, HBoV1 is often detected together with other respiratory pathogens. This, in large part, is due to nasopharyngeal persistence (or “shedding”) of HBoV1 for many months, or even up to a year (171–173), which can complicate the interpretation of positive PCR test results (10, 174, 175). It is therefore more accurate to speak about *co-detections* rather than *co-infections*. Based on detection of single-nucleotide polymorphisms (SNP) or sequencing of HBoV1 DNA in follow-up saliva or nasopharyngeal secretions, a few studies have suggested the existence of re-infections or reactivations of latent HBoV1 (173, 176). However, contaminations from other infants, not leading to true infections in the immune children, were

not ruled out. If reactivations would occur, one would expect the HBoV1 detection rate to be high in elderly individuals, which is not the case (177). More information regarding the possibility of reactivations and reinfections and the role of immunological cross-protection is needed (93, 178). Whatever the reasons for prolonged persistence, disease descriptions should not be based on mere PCR detection but should be confirmed by other means (see Laboratory Diagnosis). The presence of HBoV1 DNA in blood seems to be more short-lived and may thus be a better marker for acute infection (93, 112). Similar to the presence of HBoV1 in the airways, the occurrence of HBoV2–4 in stool is prolonged, as is the case with many other enteric viruses (93, 179).

### Immune Responses

IgM and IgG antibody responses (IgM and IgG) begin 10 to 14 days after infection (92) (Fig. 6) and correlate with reduction of the viral load in immunocompetent individuals. B19V IgG antibodies persist long-term and presumably confer protection from disease. The ability of IVIG to control and sometimes cure chronic infection in the immunodeficient patient clearly demonstrates the importance of antibodies in B19V immunity (160, 161). Various assays used to characterize the antibody response to B19V have identified differences in the temporal antibody response to epitopes on the capsid proteins: antibodies against linear epitopes on the VP2 protein are present during the acute phase but are lost in the late convalescent phase; VP1 linear and conformational epitopes are present during both the acute and the convalescent phases of infection (180, 181); neutralizing epitopes have been identified on both the VP1 unique and the VP1/VP2 shared regions of the structural proteins. An antibody response to the NS protein is detected in some patients (182–184). There is less information on the cellular immune response to B19V infection, although the evidence suggests that the low levels of B19V that can be detected in an individual following acute infection probably lead to persistent stimulation of the cellular response (185–191).

HBoV1 primary infections typically give rise to robust IgM and IgG responses with the latter persisting long-term at a relatively high level (112, 174, 192, 193). In contrast, HBoV2 and -3 IgM responses appear to be rare or short-lived in primary infections (93, 94). HBoV2 IgG responses also appear weaker and more prone to waning than those of HBoV1. This difference may reflect the frequency of systemic versus nonsystemic infections between these two virus types. In support of this notion, HBoV1 viremias coincide frequently with primary HBoV1 seroconversion, whereas corresponding HBoV2 viremias are infrequent.

Immune responses to HBoV1 infections are significantly weaker in individuals with preexisting HBoV2 antibodies and vice versa. A potential explanation is “original antigenic sin”: i.e., the propensity of the immune system to become primed by an antigen and subsequently to disregard, partially or completely, the novel epitopes of related subsequent antigens (93, 95). Alternatively, or possibly as a mechanism, the data might be explained by cross-protection, with preexisting immunity against one bocavirus limiting the propagation of another.

Little is known about the immune responses to natural infections with AAV, BuV, and TuV. Antibodies can be found in both natural AAV infections and after AAV vector-mediated gene therapy. As in B19V infection, the immune response does not eradicate the virus from the body. Preexisting antibodies can, however, affect the safety and effi-

cacy of AAV gene therapy by blocking transduction or directing the vector away from its target tissue (194, 195). Acute PARV4 infection does induce a specific antibody response, but due to the parental spread of the non-African genotypes of this virus, PARV4 IgG can mainly be observed among injecting drug users and hemophiliacs receiving clotting factors (99, 196). PARV4 infection may also elicit a strong T-cell response, which may be indicative of viral persistence (197).

## CLINICAL MANIFESTATIONS OF B19V

### Asymptomatic Infection

Asymptomatic infection or atypical illness is probably the most common manifestation of B19V infection. Among B19V-infected children in outbreaks (80, 86, 88), as many as 50% report no rash and 25% no symptoms.

### Erythema Infectiosum

Erythema infectiosum or fifth disease, the most commonly recognized clinical manifestation of B19V infection (87, 198), is a mild illness manifested by a malar erythematous rash (slapped cheek) (Fig. 7) and reticulated or lace-like rash on the trunk and extremities (147). Erythema infectiosum is most commonly diagnosed in school-age children. The child is usually afebrile but may experience a mild systemic illness 1 to 4 days before onset of rash. Various nonrash symptoms have been noted in some patients, including headache, sore throat, coryza, pruritus, gastrointestinal symptoms, and arthralgias or arthritis. In most patients, symptoms resolve over the course of a few weeks, but in some cases they last months and, rarely, even years. A typical feature of erythema infectiosum is the recrudescence of rash after a variety of nonspecific stimuli, such as change in temperature, exposure to sunlight, or emotional stress. Patients with erythema infectiosum usually do not undergo laboratory evaluation but may have reticulocytopenia and clinically insignificant anemia, lymphopenia, neutropenia, and thrombocytopenia before and possibly at the onset of rash.

### Transient Aplastic Crisis

Transient aplastic crisis (TAC) was the first illness associated with B19V infection (199). The lytic infection of the nucle-

FIGURE 7 Erythema infectiosum (fifth disease) associated with parvovirus B19.

ated red-cell precursors leads to cessation of hematopoiesis, which, in persons with a poorly compensated hematopoietic system, like sickle cell disease, may lead to severe, self-limited reticulocytopenic anemia, i.e., transient aplastic crisis. Patients present with symptoms of a severe anemia, i.e., pallor, weakness, and lethargy (200, 201), and sometimes also with nonspecific systemic symptoms and infrequently a rash. During the acute phase of the illness, patients have no reticulocytes and may have a drop in hemoglobin levels of 30% or more. The bone marrow has a hypoplastic or aplastic erythroid and normal myeloid series in the bone marrow. About 7 to 10 days after onset of illness, and coincident with development of an antibody response, reticulocytosis develops, and the hemoglobin begins to return to pre-infection levels.

### Pure Red-Cell Aplasia

In patients who cannot mount an immune response, B19V infection causes a potentially life-threatening illness (148, 202–204). Some patients with deficient immune systems develop a chronic B19V infection and associated chronic, severe reticulocytopenic anemia or pure red-cell aplasia (159, 160).

### Hydrops Fetalis and Fetal Death

Hydrops fetalis is a potential complication of B19V infection during pregnancy. The B19V parvovirus-infected fetus may not be able to control infection and develop a severe reticulocytopenic-anemia leading to high-output congestive heart failure, hydrops, and sometimes death (205, 206). B19V can also infect fetal myocardial cells, which may contribute to cardiac dysfunction and heart failure (3, 146). Although a few case reports have suggested that B19V might be teratogenic, most studies of children born of women infected with B19V during pregnancy have not demonstrated an increased risk of birth defects (74, 126, 132, 207–210). If B19V causes birth defects, it is likely an uncommon occurrence. B19V infection has, however, been detected in approximately 5% to 20% of autopsy cases of nonimmune hydrops fetalis (211, 212). Nevertheless, a hydropic fetus may also recover spontaneously or after intrauterine transfusion (see Treatment).

Approximately 30% to 50% of maternal B19V infections lead to fetal infection (130, 131). The risk of fetal death from an exposure can be defined by the following equation: rate of fetal death from an exposure = rate of susceptibility to B19V X expected rate of infection from the exposure X rate of fetal death with infection (213). The risk of fetal death with maternal infection during gestational weeks 9 to 20 is between 2% and 10% (74, 130–132, 211, 214–216), whereas the risk is negligible in >20 weeks of pregnancy (214). Maternal infection in the second half of pregnancy thereby presents much less risk to the fetus, possibly because transplacental transfer of maternal antibody and the maturity of the fetal immune response may occur and protect the fetus. Overall, the risk of fetal death in pregnancy can thus be estimated to be between 0.4 and 3.0% after exposure to B19V in the household and between 0.16 and 1.2% after exposures associated with working in a school or childcare setting with a B19V disease outbreak.

### Arthralgias and Arthritis

Arthralgias and arthritis associated with B19V infection have been described in children and adults but most commonly in adult females (74, 130, 131, 211). This condition

usually manifests as a symmetrical peripheral polyarthropathy commonly involving the hands, wrists, knees, and feet, although any joint can be affected. Joint symptoms may develop with or without other symptoms and before, during, or after the onset of rash and include tenderness and swelling. Symptoms usually resolve over the course of a few weeks but can persist for months and rarely for years. It is not a destructive arthritis. As with the rash of erythema infectiosum, joint symptoms can recur after a variety of stimuli.

The predisposition of B19V infection to cause joint disease has led to studies of B19V in patients with rheumatoid arthritis. While viral DNA is readily detected also in the joints of healthy individuals, there are suggestions of higher frequencies of DNA or B19V antibody in patients with rheumatoid arthritis, but these findings have been inconsistent (3, 151, 217). B19V is clearly not the cause of most forms of rheumatoid arthritis, although B19V-associated chronic arthritis may infrequently fulfill the classification criteria of rheumatoid arthritis, including induction of rheumatoid factor, but not anticitrullinated protein antibodies, and may similarly cause some cases of juvenile arthritis (218–221).

### Myocarditis and Hepatitis

There have been a number of case reports of both myocarditis and of hepatitis associated with B19V infection. In many of the case reports, the diagnosis of B19V as the cause is made simply on the detection of the B19V DNA genome, and, given the known persistence of B19V DNA in tissues and at low levels in blood of healthy subjects (144, 167), this diagnosis may be erroneous. However, there are clearly some cases of acute myocarditis in children and adults (222, 223), and it is clear that B19V infection causes myocarditis in the fetus (38, 224, 225). However, the role of B19V infection in the etiology of chronic heart disease is much more questionable (226, 227).

Similarly, the role of parvovirus B19 in both acute and chronic hepatitis remains unclear. Transient elevation of liver transaminases is not uncommon in B19V infection, and frank hepatitis associated with acute B19V infection has been reported (228–231) but more infrequently. The role of B19V infection as a significant cause of chronic or fulminant hepatitis is more questionable (167, 232, 233).

### Other Disease Associations

Other disease associations have been reported, but not established, for B19V infection. The list of possible B19V-associated conditions includes a wide range of cardiovascular, skin, endocrine, hematologic, neurologic, ocular, renal, respiratory, and rheumatic disorders (3, 234–236). Some of the purported associations are simply coincidental occurrences of a common infection and the disease. Others are probably instances in which B19V is one of several causes of the disease, and some represent instances in which false-positive laboratory results led to a spurious association. As with the persistence of B19V DNA in tissues mentioned above, false-positive results with B19V IgM antibody assays can be a substantial problem (144, 167, 237).

B19V infection may affect other lineages of the bone marrow, as well as the red cell precursors (98). There have been a number of reports of hemophagocytic syndrome associated with B19V infection in both healthy and immunosuppressed patients (238–240).

B19V infection has also been detected in patients with a wide range of rashes, including morbilliform, vesicular, and confluent ones, in addition to the slapped cheek and

reticular, lace-like rash on the trunk and extremities characteristic of erythema infectiosum. Other dermatologic illnesses reported with B19V infection include papular purpuric “gloves and socks” syndrome and papular acrodermatitis of childhood, Gianotti-Crosti syndrome, and livedo reticularis (241–243). Case reports of vascular purpura were first vasculitis-like findings associated with B19V infection (244). However, reports of B19V infection being associated with other vasculitides, including Henoch-Schönlein purpura, Wegener’s granulomatosis, polyarteritis nodosa, and Kawasaki disease, have not been substantiated (3).

B19V infection has been associated uncommonly with various neurologic abnormalities, including peripheral neuropathies, meningitis, and encephalopathy (245). B19V DNA has been detected in cerebrospinal fluid from several patients with encephalitis or meningitis during acute B19V infection (246), and B19V antigens and DNA have been detected in fetal brain tissue (247). These findings suggest that B19V infection may occasionally lead to neurologic disease.

### Clinical Illness Associated with the Human Bocaviruses

HBoV1 causes subclinical to life-threatening acute respiratory infections and has been implicated also in encephalitis (11, 248–250). HBoV1 is detected typically in 1 to 20% of respiratory specimens from children with acute respiratory illnesses (108, 109, 111, 174, 251, 252), whereas it seems to be much less common in adults and the elderly (10, 177, 253). The illness in HBoV1-positive patients is indistinguishable from that caused by other respiratory viruses and includes upper respiratory tract illness and a range of lower respiratory tract manifestations, such as pneumonia, bronchitis, bronchiolitis, and exacerbation of asthma (109, 110, 251, 254, 255). Typical symptoms often emphasized though are cough, wheezing, fever, acute otitis media, and diarrhea. The role the virus plays in the illness, however, has been confounded by detection of co-infecting viruses in as many as 90% of specimens, and presence of HBoV1 has also been detected in asymptomatic children. This, however, is due to the long-term persistence of this virus in the airways, which necessitates other diagnostic means than mere PCR in airway samples (10, 109, 171–175, 251, 256, 257) (see Laboratory Diagnosis). Particular pediatric symptoms that have been statistically associated with HBoV1 or confirmed by serodiagnosis are wheezing and pneumonia (109, 174, 250, 251, 258, 259). Positive correlations have been observed also between respiratory illnesses and high HBoV1 viral loads or HBoV1 sole infections (10, 174, 251, 260, 261). In a pediatric intensive care unit, seven children with severe acute respiratory tract illness (respiratory failure, bronchiolitis/asthma) were identified who had HBoV1 as the sole pathogen, as evidenced by next generation sequencing (NGS) (261). Longitudinal weekly saliva sampling and health data collection during the first two years of life have further provided evidence that HBoV1 infection was associated with new onset of upper respiratory symptoms (i.e., cough, rhinorrhea), as well as with health care visits (173). Despite the diagnostic challenges, accumulating evidence thus strongly suggests that HBoV is an important respiratory pathogen in children. Conversely, HBoV1 does not seem to be a major cause of gastroenteritis in constitutionally healthy children (262–264), even though one case report describes a life-threatening hypovolemic shock due to diarrhea associ-

ated with disseminated HBoV infection in an immunocompromised child (265).

HBoV1 has also occasionally been detected in adults with respiratory tract illnesses. Two adults with idiopathic pulmonary fibrosis (IPF) were shown to harbor HBoV1 in bronchoalveolar lavage (BAL), in one, as the sole pathogen, and in the other, codetected with cytomegalovirus (CMV) (266). In the latter patient, both viruses were also present in various postmortem tissues. Furthermore, an immunocompromised adult with rapidly progressing fatal pneumonia had HBoV1 as the sole pathogen in blood ( $1.5 \times 10^4$  copies/ml), and, as codetection with EBV, rhinovirus, and *Candida albicans*, very high HBoV1 loads in tracheal secretions ( $4.8 \times 10^{10}$  copies/ml) and sputum ( $4.3 \times 10^9$  copies/ml) (267), indicative of an acute infection at the time of death. Among both immunocompromised and immunocompetent adults, HBoV1-positive cases seem to be symptomatic (having mainly pneumonia or acute respiratory insufficiency), whereas nonsymptomatic controls tend to be HBoV1 negative (268, 269). This would suggest that in adults, HBoV1 does not occur as a bystander; instead it seems to be a real, but infrequent, cause of respiratory symptoms. Moreover, in HBoV1 infection of human airway epithelium, air-liquid interface cultures show hallmarks of respiratory tract injury, such as loss of cilia, epithelium thinning, and hypertrophy (69).

The enteric HBoV2 has been associated with gastroenteritis in one report but not in others (5). HBoV2, like HBoV1, occurs in 1 to 20% of stool specimens, and, occasionally, even in blood of children both with and without acute gastroenteritis (111, 262–264, 270, 271). HBoV2, as the single finding in various tissues, blood, or CSF, has been implicated in a fatal case of myocarditis and of encephalitis (248, 272); HBoV3–4 lack any known clinical role, although HBoV3 was found as a single agent in the CSF of a child with encephalitis (11).

### Clinical Illness Associated with Other Parvovirus Infections

AAVs, PARV4, BuV, and TuV have not yet been linked to human disease, although BuV has infrequently been detected in stools of patients with diarrhea (102, 273). In one recent study, the number of diarrheal stools per day in BuV-positive children was also significantly greater than in BuV-negative children, including norovirus- or rotavirus-positive children (102), suggesting a causative association. Only a few acute PARV4 infections have been recorded, mainly in injecting drug users or hemophiliacs, with no discernable PARV4-specific symptoms (99, 196). The apathogenicity of AAV is a valuable reason for its application as a tool for gene therapy (12).

## LABORATORY DIAGNOSIS

Serologic, antigen, and nucleic acid detection assays have been used for diagnosis of B19V infection. Acute infection in the healthy patient is most often demonstrated by detection of B19V IgM and past infection by detection of B19V IgG antibodies. Antibody assays are not reliable for diagnosing infection in immunocompromised patients, in whom detection of B19V DNA by PCR is required.

Detection of AAV, HBoV, PARV4, and BuV has been primarily accomplished with PCR-based assays. However, mere PCR-positivity in the airways, stool, or tissues is not a diagnostic marker of a primary infection. The diagnostic criteria for parvovirus primary infections in general are IgG seroconversion, IgM positivity, low-avidity IgG, and

detection of DNA in blood plasma (99, 174, 237, 274). Past infection has been determined using a variety of serologic assays for IgG antibodies (181, 237, 274, 275).

### Virus Isolation

Although erythroid precursor cells derived from human bone marrow, peripheral blood, and several continuous cell lines with erythroid precursor-like features support B19V infection, they do so inefficiently, and isolation has not been used to detect infection (55, 64). Isolation studies have been used to evaluate inactivation methods for blood or plasma products (72). HBoV1 can be cultured in a differential air-liquid interphase epithelial cell culture, which cannot be applied in a routine diagnostic laboratory (68, 69). There are no *in vitro* culture systems yet for PARV4, BuV, or TuV.

### Antigen Detection

Enzyme immunoassays have been developed for B19 parvovirus antigens, but they lack sufficient sensitivity to reliably diagnose acute infection, although they can be used for screening blood and blood products (276–278). Immunohistochemical techniques have proven useful for detecting B19V antigens in various tissues and cells, most commonly in fetal tissues and bone marrow specimens (139).

For detection of HBoV1 in nasopharyngeal samples, a less sensitive test, such as an antigen test, may be a better alternative than PCR. HBoV1 has recently been included in a multiplex point-of-care antigen test for respiratory tract infections, which is based on separation-free two-photon excitation fluorometry (279–281).

### Nucleic Acid Detection

Nucleic acid detection is an important part of B19V diagnostics for both detecting infection and screening blood products. Probe hybridization assays used in the past have been replaced by PCR assays, especially real-time qPCR assays that have the advantage of both speed and quantitation. A multitude of in-house and a few commercial PCR assays have been developed using a variety of primers and methods (282, 283). The sensitivity and specificity of PCR varies among assays and laboratories (284). It is critical that assays should be designed to detect all three B19V genotypes and be calibrated against the WHO B19V nucleic acid standard if quantitative results are desired (285). Due to the sensitivity of PCR, B19V DNA can remain detectable for months or even years at low levels, even following complete recovery, and thus quantitative PCR is required to distinguish recent infection (viral loads  $>10^6$  IU/ml) from past infections (237).

*In situ* hybridization studies have been successfully used to detect which cells and tissues harbor B19V DNA (139). Additional detection of viral mRNA can be useful for confirming the presence of replicating virus and active infection. Often this is achieved by amplification across a spliced junction to distinguish spliced RNA from viral DNA (286).

Most recent studies of HBoV1–4, AAV, and PARV4 have been based on a variety of PCR assays to detect the viral DNA (13, 23, 196, 254, 270, 287). Due to the prolonged nasopharyngeal persistence of HBoV1 for as long as a year, detecting the presence of HBoV1 by conventional PCR is not diagnostic (10, 172–174). Fortunately, other methods have been developed that more accurately indicate acute primary HBoV1 infection, such as serology (to show IgM

positivity, IgG seroconversion, and low IgG avidity), RT-PCR in airway samples (to demonstrate transcription activity of HBoV1, suggesting replication), qPCR (to separate high from waning lower viral loads in the nasopharynx), PCR in serum (revealing the typical brief viremic phase of an acute HBoV1 infection), and also antigen detection (174, 192, 193, 258, 281).

### Antibody Assays

B19V IgM antibody assays are the key to diagnosing most infections in immunocompetent individuals. A mu-capture antibody format as an enzyme immunoassay is the preferred format, with conformational epitopes as antigen (42, 181). Expressed proteins that do not form empty capsids may not include all the epitopes needed to detect a response in all patients, although they can be useful as antigens for timing when an infection occurred (181).

IgM antibody develops within 10 to 12 days after infection and is present in more than 90% of patients with erythema infectiosum at onset of rash and in about 80% of patients with TAC at the time of presentation (113, 276, 277, 288). IgM positivity increases to more than 90% in patients with transient aplastic crisis by 3 to 7 days after presentation. The IgM response begins to wane during the second month after infection. Indirect IgM antibody assays have been used but tend to be both less sensitive and less specific than the IgM capture format (289, 290). The capture assay method eliminates competition from IgG antibodies that can lead to false negative results and decreases the risk of rheumatoid factor or non-specific sticking of IgM antibodies that can lead to false positive results.

Other serologic indicators of acute or active B19V infection include low-IgG avidity (275, 291) and presence of antibodies against linear VP2 epitopes, i.e., epitope-type specificity (180, 181, 292). IgG antibodies appear at the same time as IgM antibodies and persist long-term. Unlike IgM antibody assays, the IgG indirect format should be as good as, or better than, the capture format.

As with B19V, HBoV antibody assays have been based mostly on empty virus-like particles (VLP) expressed in insect cells infected with recombinant baculoviruses (174, 192, 193, 259, 293–298). However, detection of HBoV1–4 immune responses is complicated by the structural similarity of these viruses, manifesting as serological cross-reactivity and “original antigenic sin” (93–95). This currently necessitates the use of antibody absorption assays to measure HBoV type-specific antibodies. Serological diagnosis of primary HBoV1 infections in individuals without preceding HBoV2–4 antibodies is considered highly specific and sensitive. Measurement of HBoV1 IgG-avidity is also helpful for confirming a primary infection (274). However, HBoV1 infections in individuals with preexisting HBoV2 IgG may be difficult to detect serologically, because HBoV1 antibody responses in these children are typically weak or even non-detectable. Primary HBoV2 antibody responses appear to be similarly affected by preexisting HBoV1 immunity. The sensitivity of serodiagnosis of HBoV2–4 primary infections is not well known because comparative data on the presence of HBoV2–4 DNA in stool and HBoV2–4 antibodies in blood are lacking.

A variety of serologic assays have been used to detect AAVs in a serotype-specific fashion (96, 194, 299). Serologic assays for PARV4 using recombinant VP2 capsids have been used for diagnosis of acute infection and for seroprevalence studies (97–99, 196).

## PREVENTION

Since B19V and HBoVs are probably most often transmitted via respiratory secretions during close contact, possibly by droplet or aerosol transmission, attention to good hygienic practices, like hand washing and not sharing food, may be effective in reducing the spread of both of these viruses. Although the effectiveness of such measures has not been studied, these public health interventions are straightforward and might reduce spread during outbreaks. For HBoV infections, as with any respiratory infection, distancing from persons with symptoms is also appropriate.

However, for B19V, respiratory symptoms are not a primary feature of infection, and, although nosocomial transmission has been reported after exposure to patients with TAC and chronic anemia due to B19V, once individuals have developed the rash the patient no longer has high viral loads and low levels or no virus in respiratory secretions (3, 113). Patients with TAC are probably a risk for transmitting B19V as long as a week after onset of illness and should be placed on droplet-isolation precautions for 7 days. The risk for transmission from immunodeficient patients is less well understood but may be prolonged, and immunodeficient patients with chronic infection should be placed on droplet precautions for the duration of their hospitalization (125).

Persons should be informed of potential exposures to B19V, and efforts to decrease the risk of exposures (e.g., avoiding the workplace or school environment) should be made on an individual basis after consultation with family members, health care providers, public health officials, and employers or school officials (213). Seronegative pregnant women should avoid contact with B19V-infected children (e.g., daycare centers experiencing outbreaks), at least during the first half of pregnancy (129, 214).

Although currently there are no vaccines available for B19V or any of the human parvoviruses, due to the ease of production and the neutralization efficiency of VLPs, prospects for a vaccine against B19V are favorable. A vaccine made from empty capsids produced in insect cells has been developed and evaluated (300); however, Phase 1 trials were halted due to unexpected cutaneous reactions in three patients (301). A second vaccine made in yeast is under development (302).

## TREATMENT

No viral-specific chemotherapy is available for B19V infection; however, most B19V illnesses, including erythema infectiosum, are mild and require no treatment. B19V-associated arthralgias or arthritis may benefit from nonsteroidal, anti-inflammatory medications. Patients with TAC often require hospitalization and transfusion therapy until the immune response controls the infection 1 to 10 days after presentation. In one study of 62 patients with sickle cell disease who developed TAC, 54 (87%) required blood transfusions (303). The death of one patient before transfusion therapy highlights the importance of prompt evaluation and treatment of patients with transient aplastic crisis (201).

Serum from blood donors, who have recovered from B19V infection, generally have high titers (1:200–1:2,500) of neutralizing antibody (286, 304), and immunocompromised patients with chronic infection and associated anemia should be treated with IVIG. Commercial IVIG, at a dosage of 400 mg/kg for 5 or 10 days or at a dosage of 1 g/kg for 3 days, has been used successfully (161, 203). Patients often respond to IVIG with a brisk reticulocytosis and resolution

of B19V-associated anemia and a drop of the viral load to <10 copies/ml. In some patients, the symptoms may resolve completely (although low-level B19V DNA can still be detected), whereas in others, high-level viremia and anemia may recur, resulting in the need for additional treatments with IVIG (305). Patients can be monitored with hemoglobin and reticulocyte counts, and if they develop a reticulocytopenic anemia and recurrent high B19 viral load, then retreatment with IVIG is indicated. IVIG treatment has not been shown to be effective for treatment of non-anemia manifestations of chronic infection (306).

Management and treatment of the fetus of a B19V-infected pregnant woman are problematic. Most studies have advocated monitoring the fetus with ultrasound to look for evidence of hydrops and treating hydropic fetuses with intrauterine blood transfusion. However, since the fetus can survive and be normal without treatment and intrauterine blood transfusion can cause fetal death, this approach to managing the hydropic fetus needs to be considered carefully. Intrauterine blood transfusion may be beneficial to an affected fetus, but the efficacy of this treatment is variable (205, 307–309). In one study, 9 of 12 fetuses treated with intrauterine blood transfusions survived and were normal at delivery compared to 13 of 26 untreated ones (307); analysis indicated a significant difference after adjusting for severity of ultrasound findings and gestational age. Although most B19V-infected transfused fetuses that survive are normal, one study of 24 transfused hydropic fetuses reported that some suffered long-term complications (208), including delayed psychomotor development in 5 of the 16 survivors (severe in 2). The available data suggest that intrauterine blood transfusions may be helpful and should be considered in the management of some fetuses with B19V-associated disease. Unfortunately, the data do not clearly indicate when the benefits of this procedure outweigh the risks.

# Anelloviridae

PETER SIMMONDS AND COLIN P. SHARP

## 31

The family *Anelloviridae* includes the human torque teno virus (TTV) and related small nonenveloped viruses with circular single-stranded DNA genomes. Viruses of this family frequently or ubiquitously infect humans and a range of other mammalian species. Infections are characterized by their lifelong persistence and great genetic variability. Despite the original claimed association between anellovirus infection and hepatitis in humans when first discovered in 1997, no evidence convincingly links infections with anelloviruses to clinical disease.

### VIROLOGY

#### Discovery

TTV was identified in the plasma of an individual who developed non-A to E hepatitis after blood transfusion, using representational different analysis (RDA). RDA provided the method for the specific amplification of nucleic acid sequences present in the plasma of the individual (initials "TT") during the period of his acute hepatitis but absent before transfusion (1). The cloning of the newly christened "TT" virus provided nucleotide sequences that allowed the development of methods for its detection by PCR. The original PCR method used primers from the "N22" region (a part of the gene encoding the TTV structural protein; see Composition) and were used to investigate other cases of posttransfusion hepatitis and other liver diseases of unexplained etiology (see Pathogenesis).

The cloning of the N22 region allowed the sequence of the rest of the TTV genome to be determined and its genome organization to be characterized (2, 3). The genome is comprised of single-stranded DNA with coding sequences on the antigenomic strand. The length of the genome of the originally described (prototype) isolate of TTV (TA278) was 3,853 bases in length, forming a covalently closed circle (2). This genomic configuration is most similar to that of the animal virus, the chicken anemia virus (CAV), with some similarities in its arrangement of coding sequences.

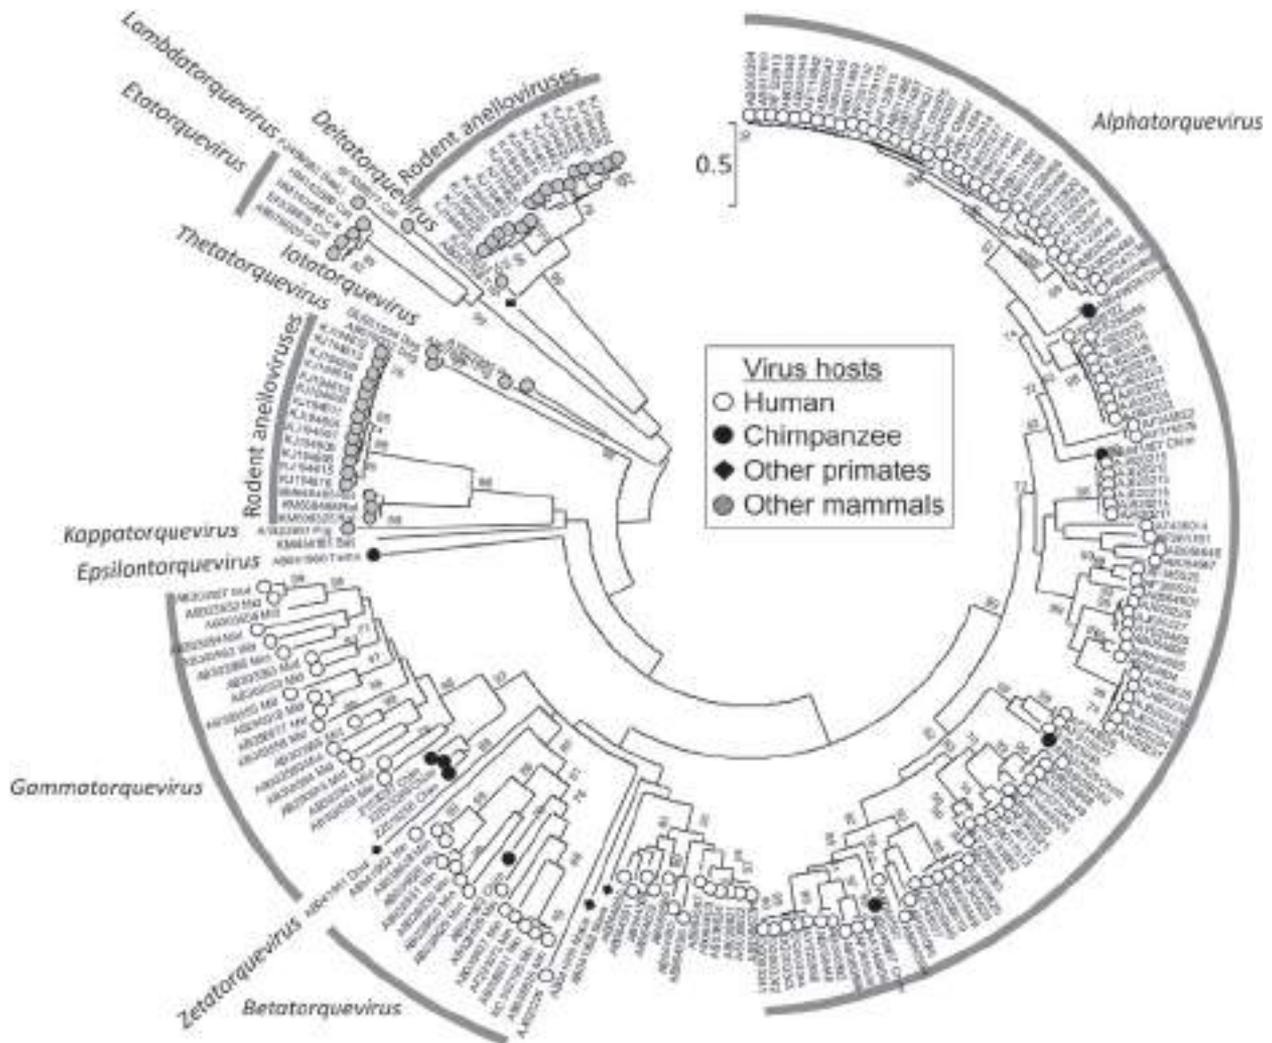

In the years following the discovery of TTV, further highly divergent groups of TTV-like viruses have been found in humans, in nonhuman primates, and in a variety of other mammalian species. Independently, a virus also having a claimed association with posttransfusion and other forms of hepatitis was discovered by RDA. Initially described as

SEN virus (SENV) after the initials of the infected patient (4), it became apparent that it represented a different genotype of TTV (see Genetic Variability). More divergent human viruses include the TTV-like minivirus (TTMV) and the TTV-like midivirus (TTMDV). TTMV was accidentally discovered by PCR of human plasma samples using TTV-specific primers that matched homologous sequences in TTMV but generated a noticeably shorter amplicon than expected for TTV (5). Its overall genome length was additionally much shorter than TTV (approximately 2.8 kilobases). Further TTV-like variants, initially described as small anellovirus types 1 and 2 (SAV-1 and SAV-2) because of their shorter genome lengths than TTV and TTMV, were cloned from a plasma sample of an individual at high risk for human immunodeficiency virus (HIV) infection (6). Subsequent findings indicated that the originally published SAV-1 and SAV-2 sequences were incomplete (7) and, given their finally determined sizes of 3.2 kilobases, these were renamed the TTMDVs.

A large number of anellovirus species have subsequently been reported in wild and domesticated animals, including pigs, wild boar, camels, cats, dogs, pine martens, badgers, sea lions, and a number of nonhuman primates (8–23). Many of the initial discoveries were made using PCR with highly conserved primers from the untranslated region, but novel species are increasingly being identified using sequence independent methods involving rolling circle amplification followed by random cloning or high throughput sequencing.

#### Classification

TTV and related viruses are currently classified in the recently created family *Anelloviridae* containing 11 officially recognized genera and 66 species (24, 25). The human viruses TTV, TTMV, and TTMDV (along with phylogenetically interspersed viruses of nonhuman primate origin) comprise the *Alphatorquevirus*, the *Betatorquevirus*, and the *Gammatorquevirus* genera, respectively. The remaining genera (*Deltatorquevirus*, *Epsilontorquevirus*, *Zetatorquevirus*, *Etatorquevirus*, *Thetatorquevirus*, *Lambdatorquevirus*, *Iotatorquevirus*, and *Kappatorquevirus*) contain viruses identified in tupaia, tamarins, douroucoulis, cats, dogs, sea lions, and two viral genera in pigs, respectively (Fig. 1). The highly diverse range of genome sizes of anelloviruses (from approximately 2

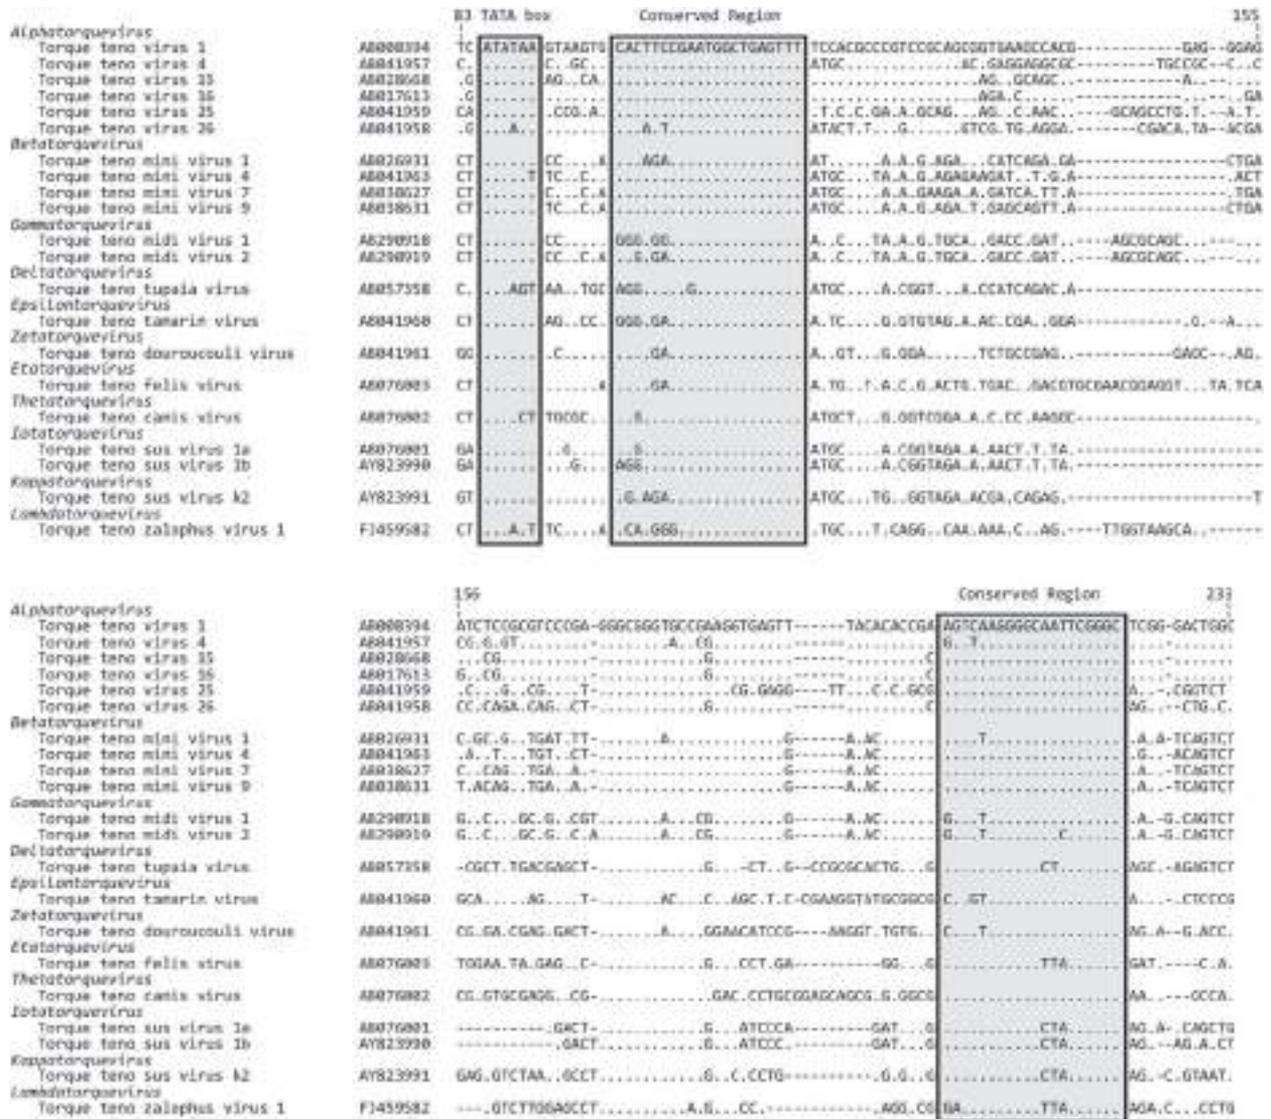

**FIGURE 1** Diversity of anelloviruses infecting humans, nonhuman primates, and other mammalian species. Sequence divergence of different anellovirus genera in the ORF1 protein-coding sequence. An alignment of ORF1-coding sequences between positions 1–862 (numbered from the start of the reading frame of the TA278 [NC\_002076] reference sequence) was created using MUSCLE, and a maximum likelihood phylogenetic tree was constructed using the optimal model (LG distances + F + G). The tree was bootstrap resampled to indicate robustness of groupings; values of greater than or equal to 70% are shown. Genera have been labelled according to the current International Committee on Taxonomy of Viruses (ICTV) classification, although several sequences currently classified as members of *Alphatorquevirus* do not cluster phylogenetically with other members of this genus (indicated by the dotted line). Sequences from nonhuman primates, such as the chimpanzee and monkey species (●, ◆), were frequently interspersed within the human-derived variants, while those from nonprimate mammalian species (e.g., pig, cat, dog, and rodent) formed separate groupings.

to approximately 4 kilobases) renders reliable taxonomic classification based on full-length sequences impossible, and classification is currently based on the analysis of the full-length ORF1 at the nucleotide level. Given the relatively high sequence variability in these viruses, the divergence cut-off value for genera is greater than 56%, and for species it is greater than 35%. With the rapid discovery of novel anellovirus or anellovirus-like sequences in a wide range of species, the number of officially recognized genera is likely to increase substantially in the future.

### Genetic Variability

Anelloviruses are characterized by extreme genetic diversity (Fig. 1). Not only does this create considerable problems for the classification of human TTV variants, but it also hampers the development of methods for anellovirus screening,

genetic characterization, and genotype identification. The situation has been made more complex by the discovery of TTMV and TTMDV that contain their own sets of genotypes and genetic groups and subsequently by the existence of a wide range of homologues of TTV and TTMV in nonhuman primates, as well as even more divergent viruses in other mammalian species (Fig. 1) (8, 11–23, 26, 27). Although the phylogenetic tree in Fig. 1 is based on the majority of publicly available complete anellovirus genome sequences, it likely only depicts a small subset of these viruses present in nature. The most conserved region of genome between all anelloviruses is in the untranslated region (UTR) (Fig. 2). PCR using primers from this region can amplify each of the five main genetic groups of human TTV, as well as TTMV, TTMDV variants, primate TTV-like viruses, and the majority of other related mammalian viruses.

**FIGURE 2** Alignment of sequences from the untranslated region of anelloviruses infecting humans and other species. Alignment of nucleotide sequences from the UTR of classified anelloviruses. Highly conserved regions are indicated in gray-shaded boxes, including the putative TATA box at position 85 in the prototype TTV sequence, TA278 (NC\_002076). Symbols: ".": sequence identity with prototype TTV sequence; "-": gap introduced to preserve alignment of homologous nucleotide sites.

Among nonhuman primates, TTV variants are species specific; for example, chimpanzees harbor a range of TTV genotypes distinct from those infecting humans, although they generally fall within the genetic groups of human viruses (Fig. 1). TTV sequences from primates more distantly related to humans such as macaques and the New World tamarins and owl monkeys are increasingly divergent from TTV variants infecting humans (Fig. 1) (22). TTMV infection has been detected in chimpanzees, with some reports showing genotypes interspersed with human genotypes (13, 16) and another finding phylogenetically distinct sequences (28). A complication of primate studies is the cross-species transmission of TTV genotypes; for example, it is known that human TTV variants can infect chimpanzees and macaques (29, 30). Cross-species transmission may occur in captivity or through the administration of human plasma-derived blood products containing infectious anelloviruses, which frequently occurs in experimental animals.

In the future, samples should ideally be collected from animals in the wild to investigate further their species specificity.

### Composition

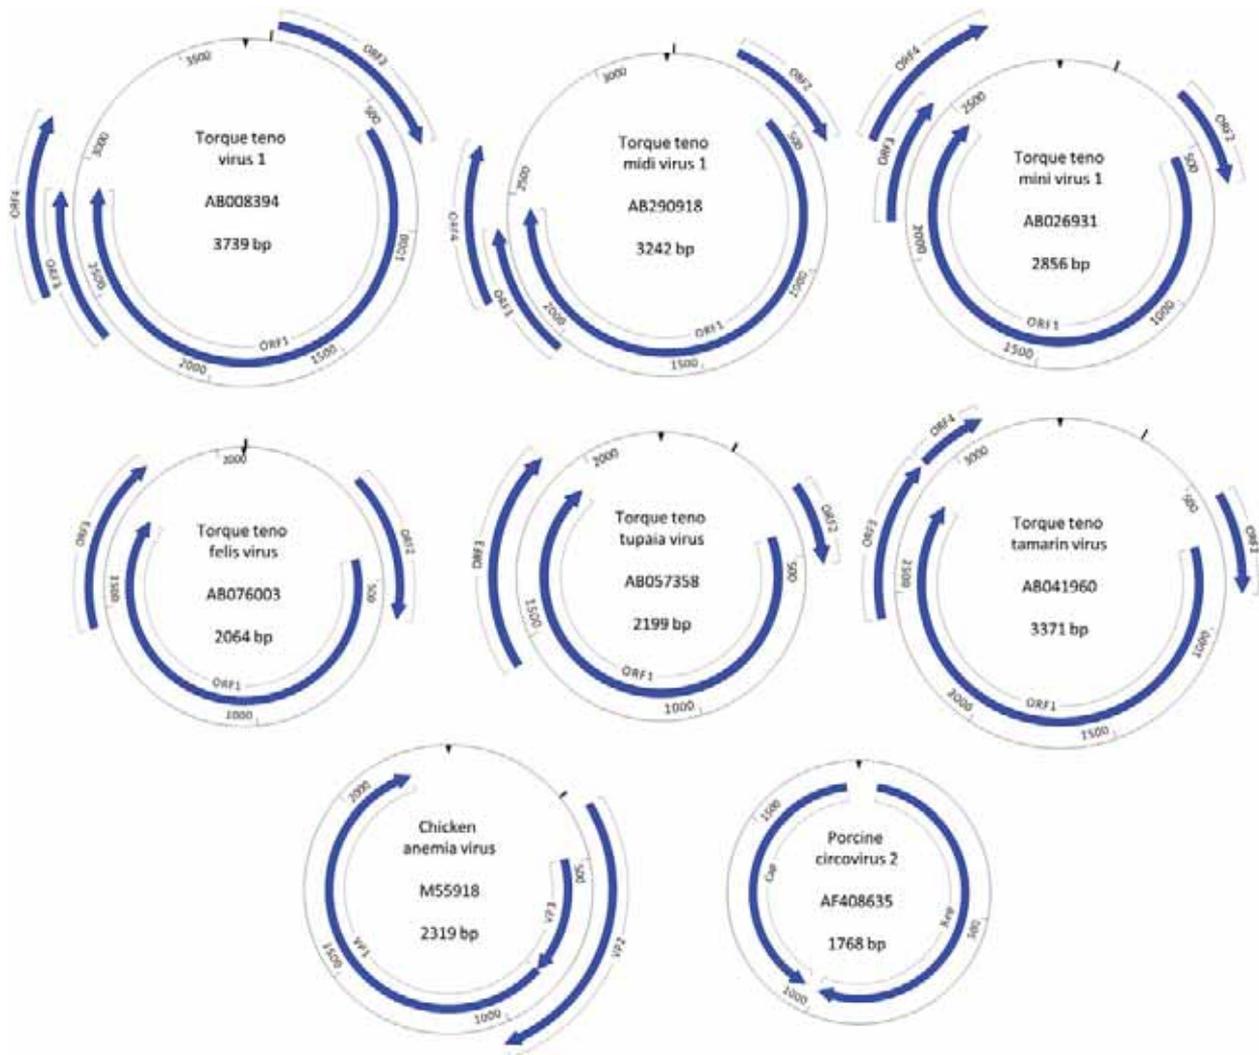

Anelloviruses are nonenveloped small viruses with a diameter measured by electron microscopy of 30 to 32 nanometers. The density of TTV in plasma on sucrose gradients ranged from 1.31 to 1.34 grams per cubic centimeter, although it was slightly higher for TTV virions excreted in feces (1.34 to 1.35 grams per cubic centimeter) (31). TTV purified from the plasma of infected individuals was found to be frequently immune complexed with IgG (31). The virion is likely composed of copies of only a single viral protein. TTV and related viruses are stable in the environment and can be detected following nanofiltration of blood products spiked with positive sera (32). Infectious TTV can be recovered from human feces (33), and frequent fecal shedding

even from healthy individuals has been reported (34). Based on the ubiquity of the virus in waste and its stability, the detection of anellovirus DNA has been proposed as a more appropriate biomarker for viral pathogen contamination of water sources (35, 36), hospital surfaces, and even air (37, 38) than currently used indicator systems based on the detection of coliform bacteria.

The genomes of anelloviruses contain several open reading frames (ORFs) that code for several putative viral proteins from either spliced or unspliced mRNA transcripts (Fig. 3). In the case of TTV, the antigenomic sequence ranges from 3,750 to 3,900 bases in length, in which a total of four gene sequences can be consistently identified among the different genetic groups. The largest open reading frame (ORF1) potentially encodes a protein of 770 amino acids in the TTV prototype strain TA278, while homologous proteins in related TTMV and TTMDV human viruses are shorter at 673 and 663 in prototype strains (Fig. 3). Based on an analogy with CAV, the ORF1 product is likely to form the replication-associated protein as well as the nucleocapsid

(39), with perhaps the amino terminus being responsible for binding, encapsidation, and nuclear targeting of genomic DNA. ORF2 sequences are also observed in all anelloviruses, and their translation is predicated to occur through the use of an initiating methionine upstream of ORF1.

The presence and nomenclature of other predicted ORFs in other anelloviruses is less conserved, and their translation requires the splicing of viral mRNAs. In the case of TTV, three main species of mRNA of sizes 2.8, 1.2, and 1 kilobases have been detected after *in vitro* transfection of TTV DNA (40) and in bone marrow and liver tissues *in vivo* (41). All mRNAs share common 5' and 3' ends (Fig. 3); for the large transcript, splicing removes an intron between positions 185 and 277, leaving the entire coding sequences of ORF1 and ORF2. For the shorter 1.3-kilobase mRNA, splicing removes the sequence between positions 771 and 2374 to join the coding sequence ORF2 with that of ORF4. The 1-kilobase transcript is generated by the removal of an intron from 771 to 2564 or 2567 to join ORF2 to ORF5. Each transcript can be translated from initiating methionines at positions 354 or

**FIGURE 3** Genome organization of anelloviruses. Genome organization of representative anelloviruses showing arrangement of genes on the antigenomic strand. Closed arrows represent the principal open reading frames in each virus. The genome organizations of two other small circular ssDNA viruses (chicken anemia virus and porcine circovirus 2) are shown for comparison.

581; thus, a total of six distinct proteins can be expressed during replication (42). TTMV and TTMDV show the same arrangement of ORFs as TTV, and it is therefore likely that nonstructural proteins comparable to those from ORF2/ORF4 and ORF2/ORF5 would be produced, as well as the structural protein from ORF1.

The UTR of the TTV genome contains conserved promoter sites, a TATA box, and cap sites consistent with the transcription of mRNAs from position 98 and termination around the polyadenylation signals at position 3073. The region contains a number of transcription promoters and regulatory elements responsible for transcriptional control (43). Although the nucleotide sequences of the UTRs of other anelloviruses are distinct, there are some restricted regions of sequence identity or close sequence similarity interspersed with more variable regions (Fig. 2). These regions of clear sequence homology are conserved between human TTV and the more divergent human and animal anelloviruses and can even be found in the otherwise dissimilar UTR of CAV. Apart from the TATA box, the functional constraints that have retained this sequence similarity are uncertain.

### Replication

Anelloviruses are likely to replicate in the nucleus of the infected cell, using host polymerases. The replication of small DNA viruses, such as the parvoviruses, is cell cycle dependent, and their replication is confined to rapidly dividing cells, such as those found in the bone marrow, the gut, and fetal tissue. It is unknown whether the replication of anelloviruses is restricted in a similar way or whether anelloviruses encode proteins with transforming activity, perhaps corresponding to the T antigens of the polyomaviruses that drive cells into division.

TTV can be cultured in the laboratory by the inoculation of plasma-derived virus onto Chang liver cells (44) or stimulated peripheral blood mononuclear cells (PBMCs) (45, 46). However, in contrast to the relative ease of virus culture of CAV and circoviruses, TTV replication *in vitro* occurs at low levels, and serial passage of virus is rarely achieved. Cloned TTV genomic DNA can also be replicated *in vitro* in cells engineered to express the SV40 large T antigen, but the ability of different isolates to propagate infection is highly variable (47). Replication in this system was also found to result in the production of replication-competent subviral genomes akin to those detected in sera from pregnant mothers whose children later developed childhood leukemia (48).

Anellovirus infections *in vivo* are characterized by persistent lifelong viremia, with circulating TTV levels typically ranging from  $10^4$  to  $10^6$  DNA copies per milliliter detected in humans and nonhuman primates (49, 50). Levels of viremia reflect the balance between virus production and clearance from the circulation by the immune-complex formation and the destruction of virus-infected cells; it has been estimated that a daily production rate greater than  $10^{10}$  virions per day is required to maintain observed levels of viremia (51).

The sites of this *in vivo* replication remain a debated topic. Initial investigations concentrated on the liver, given the originally described association of TTV infection with posttransfusion hepatitis, and *in situ* hybridization or quantitative PCR have provided evidence for replication of TTV in the liver (52–54), a conclusion corroborated by the detection of double-stranded replicative intermediates in this tissue (55) and high levels of TTV excreted in bile (33, 56, 57). The latter may be the main source of TTV in the gas-

trointestinal (GI) tract and its excretion in feces. TTV DNA has been detected in virtually all other tissues tested (58–60). Double-stranded, presumed replicative intermediates of DNA have been detected not only in liver but also in stimulated PBMCs, lung, lymph node, thyroid gland, spleen, pancreas, kidney, and bone marrow (46, 58, 61). Further supporting the role of other tissues as sites of viral replication, viral mRNA has been detected in bone marrow and PBMCs and lung, muscle, pancreas, kidney, colon, thyroid gland, gallbladder, omentum, and breast tissue (41, 46, 58, 60). Additionally, replication in the respiratory tract was suggested by the detection of high levels of TTV DNA in respiratory secretions (62–66).

In the lymphoid compartment, TTV shows a very broad cellular tropism as viral DNA can be detected in T and B lymphocytes, monocytes, and NK cells (45, 67–69). TTV tropism extends to granulocytes and other polymorphonuclear cells (45, 68). A recent study of the kinetics of TTV viremia following the administration of antilymphocyte immunosuppressive agents supports the hypothesis of T lymphocytes being the major site of replication (70).

## EPIDEMIOLOGY

### Distribution and Geography

Anelloviruses are widely distributed in both human and other mammalian populations throughout the world. The original surveys used detection methods based on primers that amplified the variable N22 region so that sequences similar to the prototype strain (TA278, genotype 1) are vastly overrepresented in the database of published sequences. Using primers based upon the conserved sequences in the UTR (Fig. 2), greater than 80% frequencies of viremia with TTV or related viruses have been found in virtually every population studied (49, 71–77). With the use of primers specific for individual genotypes or genogroups of TTV or those that differentiate TTV from TTMV sequences, high frequencies of coinfection with multiple variants of TTV have been described. In surveys of coinfections (78, 79), 84% to 89% of study populations (generally healthy adults) were viremic for TTV or TTMV, with coinfections of TTV and TTMV in 44% and frequencies of coinfection with multiple genotypes of TTV or TTMV of 40% to 70%. Infection with TTV-like viruses in pigs was similarly highly prevalent (33% to 100%) (10, 26, 27, 80–82).

Because of the near ubiquity of anelloviruses, the large number of genogroups and genotypes, and the difficulty in detecting coinfections, it is premature to conclude anything from previous investigations of possible geographical or risk group associations of genetic variants of these viruses.

### Transmission

The detection of greater than 80% frequencies of viremia in adult populations indicates a considerable incidence of infection early in life. Infection with TTV occurs in the perinatal period; samples collected at birth are generally PCR-negative, with a rapidly rising prevalence of infection over subsequent months (83–87). Recent work with broader spectrum PCR assays (74, 77) and high throughput sequencing (66) demonstrate increasing detection frequencies of all three genera of human viruses in the early months and years of life. However, there are also conflicting reports of the detection of TTV DNA in cord blood, implying *in utero* infection (88, 89), a route that has also been suggested for porcine anellovirus transmission (90). During close follow-

up of a newborn child (91), high levels of TTV DNA were detected in the saliva from days 4 to 9 after birth, a period that coincided with a mild rhinitis. The TTV variant infecting the neonate was genetically identical to that present in the maternal saliva during the neonatal period. Although anecdotal, these findings are consistent with findings from other studies indicating the rapid acquisition of TTV infections around the time of birth. Anelloviruses are present at high concentrations in saliva (62–64) and other respiratory specimens (66) and are even detectable in exhaled breath (92). They may therefore be transmissible by kissing or other close contact between the child and parents or siblings.

There are likely other sources of anellovirus infection. Viruses are present in peripheral blood and have been demonstrated to be transmissible by parenteral routes such as blood transfusion (1, 93). However, this route is probably insignificant when compared to the rapid acquisition of anelloviruses in the perinatal period. Infectious virus (33) can be recovered from feces, and persistent shedding from this route has been documented (34), providing an additional potential source of oral transmission. The likely great stability of anelloviruses may lead to general environmental contamination.

## PATHOGENESIS AND CLINICAL MANIFESTATIONS

### Pathology

No specific pathology has been attributed to the replication of human anelloviruses in bone marrow, liver, or lymphoid tissue. The current best evidence of any pathological changes following primary infection with an anellovirus has come from experimental infections of pigs with torque teno sus virus (TTSuV). The inoculation of gnotobiotic piglets with plasma containing TTSuV1 resulted in transient thymic atrophy, membranous glomerulonephropathy, modest lymphohistiocytic infiltrates in the liver, and mild interstitial pneumonia (94). Similar results were observed following the infection of specific pathogen-free piglets with TTSuV2-containing liver homogenates, where the predominant pathological changes were interstitial pneumonia, membranous glomerulonephropathy, and inflammatory cell infiltration in portal areas of the liver (95).

The importance of viral genotype in relation to disease is poorly understood, and it may be that certain genotypes or species possess a greater pathogenic potential. While there is no current evidence to support this hypothesis in human infections, studies in pigs (96, 97) have suggested that infection with members of the TTSuV2 (genus *Kappatorquevirus*) may be more readily associated with pathology and coinfections than TTSuV1 (genus *Lotatorquevirus*) infections. Comparable examples of differences in disease associations of anelloviruses in humans may emerge in the future.

### Immune Responses

Anellovirus infection is likely to be acquired around the time of birth (see Transmission), and this may lead to substantial immune tolerance as described for other viruses such as hepatitis B (HBV). Immunopathologic changes such as inflammation and lymphocyte infiltration are not observed in tissues where TTV replication occurs. The hypothesis that TTV and related viruses escape immunological detection is supported by the persistent nature of infection and the

presence of multiple circulating genetic variants in plasma (see Genetic Variability) that may represent repeated rounds of reinfection. However, antibody reactivity to whole virions (98) or recombinant proteins expressed from ORF1 (99, 100) is frequently found in viremic and nonviremic individuals, and virions purified from plasma are often immune complexed with IgG (31). Despite this, there is no evidence at present for an association with or presence of persistent anellovirus infection in immune-complex deposition diseases such as glomerulonephritis.

Elevated TTV viral loads are routinely detected in patients with chronic congenital, acquired, or iatrogenic immunosuppression, indicating a potential role of the immune system in controlling viral replication (70, 101–111). In subjects undergoing immunosuppressive treatment for idiopathic pulmonary fibrosis (101) or following solid organ transplant (70, 103, 105, 106), a significant correlation between the degree of immunosuppression and the serum TTV titers was observed. However, one study demonstrated that the administration of a single immunosuppressant medication was sufficient to increase the TTV load significantly, and the addition of other immunosuppressive drugs did not further significantly increase the TTV load (102). In patients coinfecting with HIV, viral loads of TTV (109–111) and TTMV (107) have been shown to have a significant negative correlation with CD4+ T-cell count despite the potential role of these cells as a major site of viral replication (70). Conversely, HIV-infected patients receiving highly active antiretroviral therapy (HAART) show a significant decrease in TTV viral loads following treatment (112, 113) as well as a decrease in the number of coinfecting TTV genogroups (114). Given this close correlation, the measurement of TTV viral load to be used as a clinical biomarker for immunosuppression has been suggested (115), although the clinical impact and usefulness of this approach remains to be determined.

Of great theoretical interest are the mechanisms of immune evasion that have evolved in TTV to establish persistent infection in immunocompetent individuals. One proposed mechanism of immune evasion is through the proinflammatory nuclear factor-kappaB (NF-kappaB) signaling pathway. Interactions between the ORF2 protein of a TTV isolate and subunits of the NF-kappaB signaling complex were shown to prevent nuclear entry of the p50 and p65 subunits, resulting in downstream inhibition of proinflammatory gene transcription (116). Predicted microRNAs (miRNAs) have been identified in a number of the available TTV sequences, although in none of the available TTMV or TTMDV genomes (117). Experimentally, the production of the miRNA encoded by the TTV-tth8 strain has been confirmed *in vitro*, and this has been shown to target the interferon-stimulated gene N-myc (and STAT) interactor (NMI), resulting in an inhibition of interferon signaling (117). Determining the function and targets of other anellovirus-encoded proteins and noncoding transcripts in the future could greatly enhance our current understanding of viral immune evasion and replication.

### Disease Associations

As anellovirus infections are almost universally present in human populations, it is unlikely that any of these viruses are pathogenic *per se*. Based on the initial discovery of TTV in a posttransfusion hepatitis patient, the potential pathogenic role of this virus has been most extensively studied in relation to hepatic diseases. While some early studies suggested that the presence or viral load of TTV is related to various

hepatic disorders (118–124), numerous reports have been unable to substantiate these findings (125–129). Studies on the association of TTV with hepatitis are often complicated by coinfection with known hepatitis viruses (commonly HBV and hepatitis C [HCV]) or HIV. In light of the aforementioned correlation between viremia and immunosuppression, it is likely that a large proportion of reported increases in TTV prevalence or viral titer are a consequence rather than a cause of disease, and the presence of concomitant TTV infection has been shown to have no effect on the response of HCV infection to interferon treatment (130). Following interferon therapy, decreased TTV and SENV detection frequencies have been reported (131), although others have found that the decreases seen in TTV and TTMV titers following interferon (132) or TTV detection following combined interferon-ribavirin treatment (133) were transient.

Other investigations have concentrated on the potential roles of anelloviruses in childhood respiratory disease. High levels of TTV DNA are found in respiratory secretions and saliva (62–66), and the respiratory tract may thus be a major site of TTV replication. Infection with TTV coincided with a mild rhinitis in a neonate (91), and children hospitalized with acute respiratory disease showed higher TTV viral loads than controls (65, 73). Higher TTV viral loads were associated with impairment of lung function among asthmatic children, although frequencies of detection and viral loads were comparable to those of children without asthma (134). TTV titers have also been studied in other chronic lung diseases and have been correlated with airflow limitation in children with bronchiectasis (135) as well as in idiopathic pulmonary fibrosis (IPF) with primary lung cancer, where titers greater than IPF of lung cancer alone were seen (136). Again, whether these increases in viral titer are a result of disease progression or treatment rather than causal remains to be determined.

High levels of TTV replication in bone marrow have been suggested as being responsible for an otherwise unexplained case of aplastic anemia (137). Interestingly, the infection of chickens with the related CAV is associated with anemia and lymphopenia that is generally only clinically apparent in association with other viral coinfections, such as the Marek's disease virus. Interactions between TTV and herpesviruses have also been suggested in humans. The presence of TTV DNA in the skin of people with Kaposi's sarcoma lesions but not controls (138) suggests that the virus may be a cofactor in Kaposi's sarcoma-associated herpesvirus infections. It has also been reported that TTV isolates show significantly enhanced replication in Epstein-Barr virus (EBV)-converted Burkitt's lymphoma cell lines compared to EBV-negative controls (139).

## LABORATORY DIAGNOSIS

PCR is the principal method used for the detection of anellovirus DNA in clinical specimens. Methods that use heminested or fully nested primers are capable of extremely high sensitivity and specificity. The UTR of TTV is much more conserved than coding regions and therefore more appropriate as a target sequence for PCR (60, 140, 141). PCR based on primers from regions around the transcription start site (Fig. 2) indicated that frequencies of anellovirus infections were close to universal, not only in humans but also in a range of nonhuman primates and other mammalian species (see Distribution and Epidemiology).

Because of the great genetic variability of anelloviruses, it has not been possible to date to develop effective genotyping assays for these viruses. A number of more recent methods employing rolling circle amplification have been reported. The use of these methods has allowed for greater sensitivity than PCR alone (142), and they have routinely been used for the generation of complete genome sequences in combination with random cloning or PCR using inverted primers designed within previously determined short sequences (12, 20, 143).

## PREVENTION AND TREATMENT

As anellovirus infection is ubiquitous and still not convincingly associated with any clinical manifestations, measures to prevent transmission are unwarranted. Similarly, there is no current indication to treat infected individuals, although the treatment of coinfecting HIV or HCV infections has been shown to have an effect on anellovirus titers 12–114, 130–132).

# Hepatitis B Virus

DARREN J. WONG, STEPHEN A. LOCARNINI, AND ALEXANDER J.V. THOMPSON

## 32

It has been over 40 years since the discovery of the hepatitis B virus (HBV), and yet the disease it causes remains a major public health challenge. Worldwide, over 240 million people have chronic hepatitis B (CHB), with the majority being in the Asia-Pacific region, and there are almost 800,000 deaths each year as a direct consequence of infection (2). HBV infection is the ninth leading cause of death worldwide. The main public health strategy to control hepatitis B infection for the last 30 years has been primary prevention through vaccination. According to WHO, as of 2013, more than 180 countries have now adopted a national policy of immunizing all infants with hepatitis B vaccine. However, a strategy of secondary prevention is clearly necessary to reduce the risk of long-term complications (cirrhosis, liver failure, and hepatocellular carcinoma) in those individuals who have CHB. The risk of these complications is strongly associated with persistent high-level HBV replication (3–5). Antiviral agents active against HBV are available. The long-term suppression of HBV replication has been shown to prevent progression to cirrhosis and reduce the risk of hepatocellular carcinoma (HCC) and liver-related deaths. However, currently available treatments fail to eradicate the virus in most of those treated, necessitating potentially lifelong treatment. WHO has set targets for both morbidity and mortality. A cure for CHB remains elusive, and a significant research effort is now being directed toward this goal.

## VIROLOGY

### Classification

The HBV is an enveloped 3.2-kb double-stranded DNA virus and prototypical member of the family *Hepadnaviridae*. HBV can be classified into ten major genotypes (A to J) based on nucleotide (nt) diversity of 8% or more over the entire genome (6–10). These genotypes show distinct geographical distributions (Table 1). As genotype designation is now based on the entire genomic sequence, it is a more reliable classification than the earlier serological subtype nomenclature (*adw*, *adr*, *ayw*, and *ayn*) used previously, which was based on the immunoreactivity of particular antibodies to a limited number of amino acids in the envelope protein. Particular HBV genotypes have unique insertions or deletions. For example, HBV genotype A varies from

the other genotypes by an insertion of six nucleotides at the C-terminus of the core gene (11). HBV genotype D has a 33-nt deletion at the N-terminus of the Pre-S1 region (11). HBV genotypes E and G have a 3-nt deletion also in the N-terminus of the Pre-S1 region. HBV genotype G also has a 36-nt insertion in the N-terminus of the core gene (8), and the precore/core region has two translational stop codons at positions 2 and 28 and results in a HBeAg-negative phenotype. A very large number of subgenotypes (of <8% but greater than 4% nt diversity) have been described in a number of these genotypes (A, B, C, D, and F), and recombination between two HBV genotypes has also been reported for genotypes B and C (12) and genotypes A and D (13), generating even more diversity.

Important pathogenic and therapeutic differences appear to exist among HBV genotypes (14, 15), including significant differences in intra- and extracellular expression of viral DNA and antigens (16). Genotype C is associated with more severe liver disease than is genotype B in Taiwan, while in India, genotype D is associated with more severe liver disease than is genotype A (17–20).

### Virus Structure: Virion and Subviral Particles

Three types of virus-associated particles are typically present in the blood of HBV-infected persons. The complete infectious virus is spherical with a diameter of 42 nm. Negative-staining electron microscopy usually reveals a double-shelled structure (Fig 1A). The outer shell, or envelope, is formed by hepatitis B surface antigen (HBsAg) proteins, while the inner shell with a diameter of 27 to 32 nm is the viral nucleocapsid or hepatitis B core antigen (HBcAg). The viral nucleocapsid encloses the viral DNA and endogenous DNA polymerase. The sera of viremic patients also contain large numbers of two types of noninfectious particles: spherical particles 17 to 25 nm in diameter and filamentous forms 20 nm in diameter with a variable length. Both types of subviral particles are composed of HBsAg and are not infectious.

### Genome Organization and Viral Proteins

The genome of HBV is a circular, partially double-stranded relaxed circular (21) (RC) DNA molecule. The two linear DNA strands are held in a circular configuration by a 226-base-pair (bp) cohesive overlap between the 5' ends of the

TABLE 1 Overview of the ten genotypes of HBV

Genotype	Subtype	Genome length (nt)	Frequency of mutation <sup>1</sup>		Global distribution
			PC	BCP	
A	A1	3221	Uncommon	Common	Africa, Asia
	A2				Northern Europe, North America
B	B1	3215	Common	Uncommon	Japan
	B2				Rest of Asia
	B3				Indonesia, China
	B4				Vietnam, Cambodia
C	C1	3215	Common	Common	Far East
	C2				Far East
	C3				Polynesia
	C4				Australian Indigenous Population
	C5				Philippines
D	D1	3182	Common	Common	Europe, Middle East, Egypt, India, Asia
	D2				Europe, Japan
	D3				Europe, Asia, South Africa, USA
	D4				Australia, Japan, Papua New Guinea
E		3212	ND	ND	Sub-Saharan Africa, UK, France
F	F1	3215	Uncommon	ND	Central and South America, Bolivia
	F2				Brazil, Venezuela, Nicaragua
	F3				Venezuela, Panama, Columbia
	F4				Argentina, Bolivia, France
G		3248	Very common	ND	USA, Germany, Japan, France
H		3215	ND	ND	USA, Japan, Nicaragua
I		3215	-	-	Vietnam, Cambodia
J		3182	-	-	Japan

Adapted from Locarnini et al. (650).

Note that genotype J has yet to be verified, as only one case has been isolated.

<sup>1</sup>PC, Precore mutations such as G1896A; BCP, basal core promoter mutations such as A1762T, G1764A; very common (most isolates); common (up to 50% of isolates); uncommon (less than 10% of isolates); ND, not described.

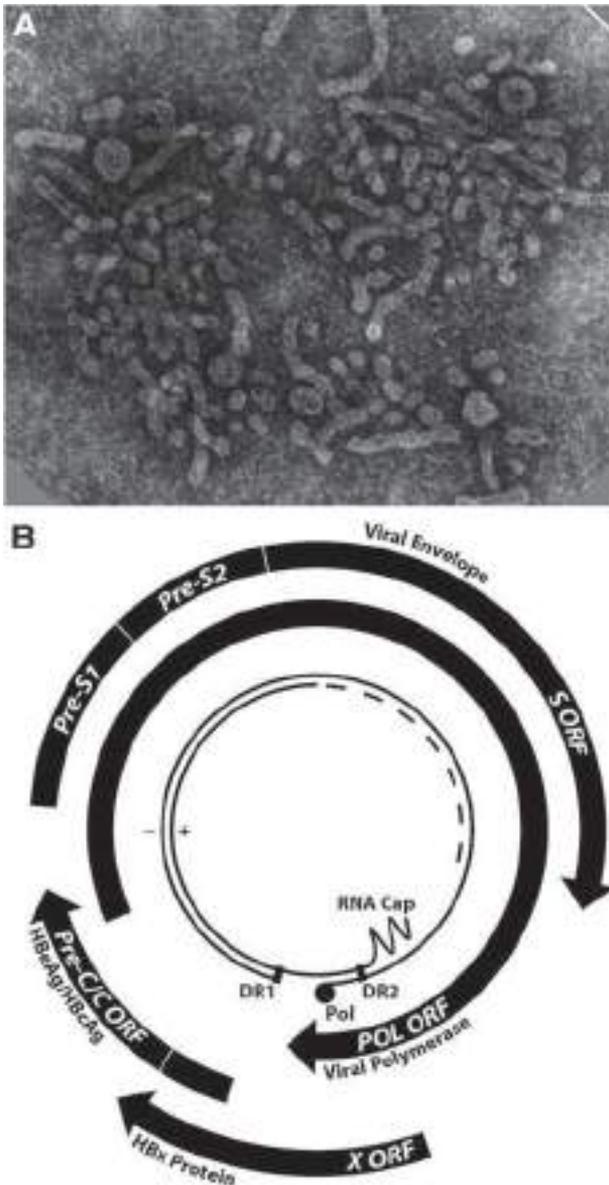

two DNA strands that contain 11-nt direct repeats called DR1 and DR2 (22). All known complete HBV genomes are gapped and circular (Fig 1B), comprising between 3181 and 3221 bases depending on the genotype (Table 1). The minus strand is not a closed circle and has a gap between its 3' and 5' ends. The viral polymerase is covalently bound to the 5' end of the minus strand. The 5' end of the plus strand contains an 18-base-long oligoribonucleotide, which is capped in the same manner as mRNA (23). The 3' end of the plus strand is not at a fixed position, so most viral genomes contain a single-stranded gap region of variable length ranging from 20 to 80% of genomic length that can be filled in by the endogenous viral DNA polymerase.

The minus strand encodes four open reading frames (ORF), the longest of which encodes the viral polymerase (Pol ORF) (Fig 1B). The envelope ORF (Pre-S1, Pre-S2, and S) is located within the Pol ORF while the precore/core (Pre-C/C) and the X ORFs overlap partially with it. The ORFs overlap in a frameshifted manner and so the virus strand is read one and one-half times. The transcriptional template of the virus is the covalently closed circular (ccc) DNA, which exists in the cell nucleus as a viral minichromosome. From this template four major RNA species, the 3.5-, 2.4-, 2.1-, and 0.7- kb viral RNA, are transcribed (Fig 2A). The enhancer II/basal core, large surface antigen (Pre-S1), major surface antigen (S), and enhancer I/X gene promoters direct the expression of these four transcripts, respectively (22).

### Pol ORF

The Pol gene is the longest ORF, spanning almost 80% of the genome and overlapping the other three ORFs. The Pol protein is translated from pregenomic RNA (Fig 2B). The 834 to 845 codons found in the Pol ORF have sequence homology to reverse transcriptases (22), and most parts of the ORF are essential for viral replication. The 90-kDa product of the Pol ORF is a multifunctional protein that has at least four domains (22) (Fig 2B). The N-terminal domain encodes the terminal protein that is covalently linked to the 5' end of the minus strand of virion DNA. This part of Pol ORF is necessary for priming of minus-strand synthesis. An intervening domain with no specific recognized function is referred to as the spacer or tether region. The third domain encodes the RNA- and DNA-dependent DNA polymerase activities; that is, the reverse transcriptase. The C-terminal domain encodes ribonuclease (RNase) H activity that cleaves the RNA in the RNA-DNA hybrids during reverse transcription.

The terminal protein's role in priming reverse transcription includes the provision of the substrate tyrosine at amino acid 63 of the HBV Pol for the formation of the covalent bond between the enzyme and the first nucleotide (G) of the minus-strand DNA (24). The DNA polymerase domain contains the sequence motif tyrosine-methionine-aspartate-aspartate (YMDD), which is essential for reverse transcriptase activity (25) (Fig 2B). The RNase H domain, besides degrading the RNA template, also plays a role in viral RNA

**FIGURE 1A** Electron micrograph of the various forms found in the blood of HBV-infected persons. The 42-nm virions, both full and empty, can be seen. Within the empty particles, the 27 to 32 nm core structure can be visualized. The excess 22 nm subviral particles and filamentous forms of HBsAg are also present.

**FIGURE 1B** The circular double-stranded DNA genome of HBV showing the four main open reading frames (ORFs). The minus (-) and plus (+) DNA strands are marked. The HBV Pol and capped mRNA oligomer at the 5' end of the (-) and (+) strands, respectively, as well as DR-1 and DR-2 are shown. The space between DR-1 and DR-2 is the "cohesive overlap region." The plus strand is typically incomplete.

packaging, in optimizing priming of minus-strand DNA synthesis and in elongation of the minus-strand viral DNA.

The Pol encodes at least two T-cell epitopes within its catalytic domains at amino acid residues 107 to 115 and 227 to 235 (26). Changes in these epitopes have been related to successful interferon- $\alpha$  therapy and viral clearance during acute infection (27).

### Pre-C/C ORF

The Pre-C/C ORF encodes the core protein P21, which is the major polypeptide of the nucleocapsid and expresses the HBcAg. The HBc protein is 183, 185, or 195 amino acids long, depending on the genotype of the virus (Table 1). ORF C is preceded by a short, upstream, in-phase ORF called the Pre-core region from which the soluble hepatitis B early antigen (HBeAg) is made (22).

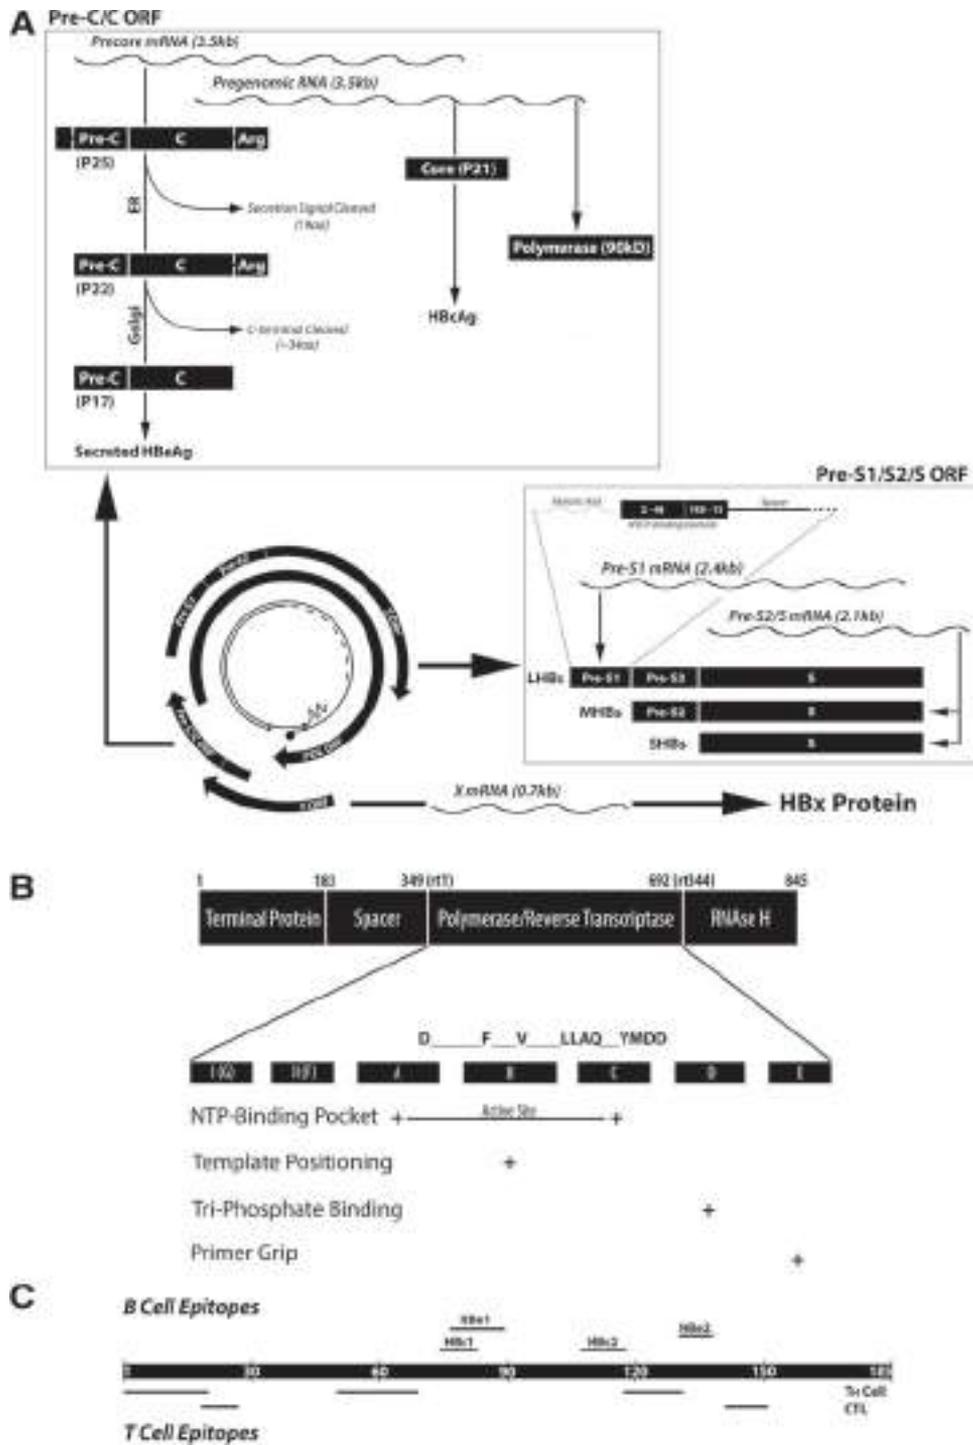

### HBc Protein

The HBc protein has two distinct domains with amino acid residues 1 to 144 required for the assembly of the 32-nm nucleocapsid, while the arginine-rich, C-terminal residues from around 140 onward form a protamine-like domain that mediates nucleic acid binding and is involved in viral encapsidation and DNA replication (22). This arginine-rich region contains four clusters and includes a potential nuclear localization sequence. The core protein contains many hydrophilic and charged amino acids, and, when expressed, it becomes phosphorylated (8). Phosphorylation of serine 170 to 172, between arginine clusters 3 and 4, appears to block nucleic acid binding and may negatively regulate nuclear localization of the core protein (8). The HBc protein is also translated from pregenomic RNA (Fig 2A) and carries the hepatitis B core antigen (HBcAg) epitopes, which are cross-reactive with the HBeAg epitopes (discussed below) (Fig 2C).

Aside from the function of HBcAg in the construction of the viral nucleocapsid, HBcAg may play an active role in regulating viral transcription. This was first suggested following experiments that demonstrated HBcAg aggregating in different cellular compartments depending on the phase of infection (28) (see Laboratory Diagnosis). The immunotolerant phase, in which high HBV-DNA levels are seen, is associated with a predominant nuclear distribution of HBcAg. In the immune clearance phase, HBcAg becomes predominantly cytoplasmic, in conjunction with decreasing viral load. HBcAg becomes undetectable in the immune control phase. HBcAg exhibits preferential binding for HBV-covalently closed circular DNA (cccDNA), modulating its transcription by altering nucleosomal packaging (29). These studies demonstrate the multifunctional nature of HBV proteins.

### HBe Protein

The HBeAg is essentially a soluble secretory form of the HBc protein and is considered an accessory protein of the virus. The Pre-C sequence is upstream of core, and translation initiating from the Precore initiation codon produces the Pre-core protein that contains the entire Core protein sequence plus an additional 29 amino acids at the N-terminal end (P25) (22). The Precore protein is translated from the Pre-C/C mRNA (Fig 2A). The first 19 amino acids of the Precore protein form a secretion signal that allows the translocation of the Precore protein into the lumen of the endoplasmic reticulum (ER). These 19 amino acids are cleaved by a host-cell signal peptidase, leaving the Precore protein derivative P22. The P22 is then secreted through the ER and Golgi apparatus and further modified by C-terminal cleavage of up to 34 amino acids, resulting in the secretion of a heterogeneous population of proteins of approximately 17 kDa, serologically defined as HBeAg (22) (Fig 2A). Thus, HBe protein differs in almost all aspects from HBc protein, although the primary sequences of these two molecules are almost identical. Some of the HBe protein does not reach

**FIGURE 2A** Biosynthesis of the precore/core, polymerase, envelope, and X proteins from the various HBV transcripts. The two major genomic 3.5-kb transcripts are the larger Precore mRNA, from which the Precore protein (HBeAg) is made, and the smaller pregenomic mRNA that encodes the core and polymerase and is the template for reverse transcription. The single 2.4-kb RNA makes LHBs, while the various 2.1-kb mRNAs translate MHBs and SHBs. The HBx protein is translated from the 0.7-kb mRNA.

**FIGURE 2B** The functional domains of the polymerase-reverse transcriptase of HBV. See Bartholomeusz et al. (475) for a more detailed discussion.

**FIGURE 2C** Linear, schematic representation of the core protein amino acid residues and the immunodominant B cell and T cell epitopes. See text for details.

the ER lumen and is not cleaved at all. The P25 HBe protein also expresses a nuclear transport signal (8). Thus, HBe proteins of variable length are found in practically all compartments of the cell, as well as being secreted.

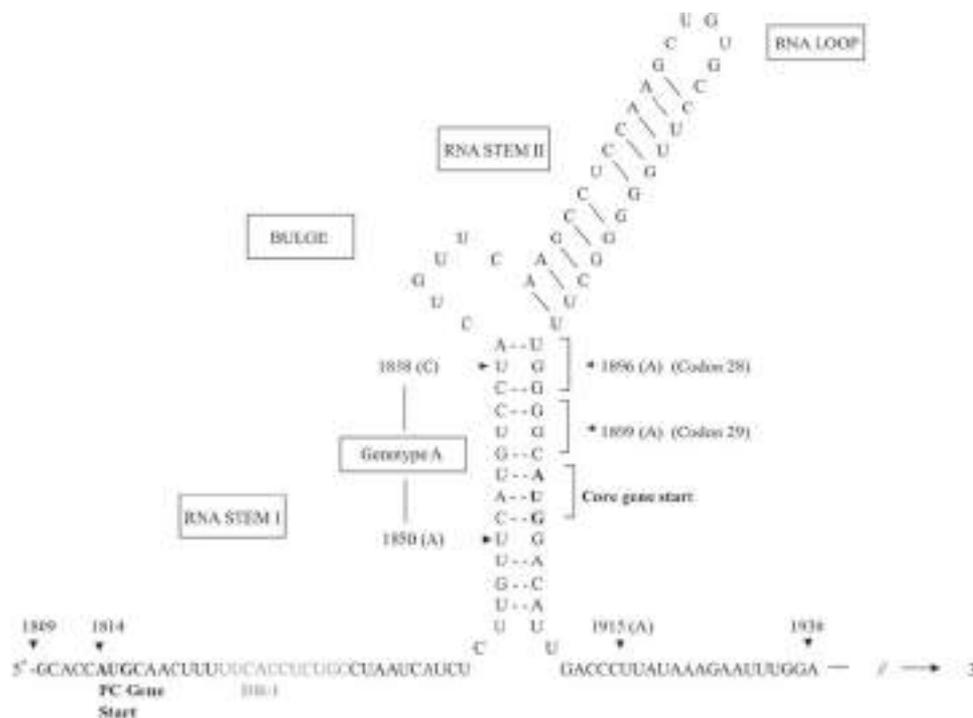

The HBe protein is essential for establishing persistent infection. Mutants of HBV without a functional Pre-C sequence and HBe protein are found commonly during chronic infection. An HBeAg-negative mutant of the woodchuck HBV is infectious for newborn woodchucks but is unable to establish persistent infection (30). Similar scenarios have been described for HBV (31), suggesting that the HBe protein may suppress the immune elimination of HBV-infected hepatocytes. It certainly can function as a tolerogen *in vivo* (32). HBeAg has been shown to slow HBV-DNA replication *in vitro* by reducing HBcAg dimerization, thereby reducing encapsidation of pgRNA (33). The HBeAg is not essential for HBV replication but is absolutely required for the establishment of persistent infection (34, 35). Expression of the precore protein has been shown to have anti-apoptotic properties *in vitro* (36), and *in vivo* it can act as an immune tolerogen (32). Thus, the HBeAg is an important accessory protein in the life cycle of HBV. Two major groups of mutations have been identified, which result in reduced or blocked HBeAg expression.

The first group of mutations affects the basal core promoter (BCP), typically at nt 1762 and nt 1764, resulting in a transcriptional reduction of the Pre-C/C mRNA (35). Mutations in the BCP, such as A1762T plus G1764A, may be found in isolation or in conjunction with precore mutations (see below), depending on the HBV genotype (Table 1). The double mutation of A1762T plus G1764A results in a significant decrease in HBeAg levels and has been associated with an increase in viral load. This pattern of mutation is

found in genotype A-infected individuals as the major cause of HBeAg loss (35) and typically in association with the precore mutations in the other HBV genotypes (37). Importantly, these BCP mutations do not affect the transcription of HBV pgRNA or the translation of the core or polymerase protein. Thus, by removing the inhibitory effect of the precore protein on HBV replication, the BCP mutations appear to enhance viral replication by suppressing Pre-C/C mRNA relative to pregenomic RNA (35).

The second group of mutations includes HBV mutants with a translational stop-codon mutation at nt position 1896 (codon 28: TGG; tryptophan) of the precore gene. The single base substitution (G-to-A) at nt 1896 gives rise to a translational stop codon (TGG to TAG; TAG = stop codon) in the second last codon (codon 28) of the precore gene located within the structure of pgRNA. The nt G1896 forms a base pair with nt 1858 at the base of the stem loop. In HBV genotypes B, D, E, G, and some strains of genotype C, the nt 1858 is thymidine (T). Thus, the stop codon mutation created by G1896A (T-A) stabilizes the structure based on conventional Watson-Crick pairing (Fig 3). In contrast, the precore stop codon mutation is rarely detected in HBV genotype A, F, and some strains of HBV genotype C, as the nt at position 1858 is cytidine (C), maintaining the preferred Watson-Crick (G-C) base pairing. Other mutations have been found within the precore transcript that block HBeAg production, including abolition of the methionine initiation codon (37), and the stop codons within the precore/core region of genotype G.

The HBeAg has two B cell epitopes, one of which is linear (HBe1) and the other (HBe2) conformational. The HBe1 epitope is found at core amino acid positions 76 to 89, and the HBe2 epitope is at positions 130 to 138 (38) (Fig 2C).

**FIGURE 3** Diagrammatic representation of the epsilon ( $\epsilon$ ) stem-loop structure of HBV. This is a highly conserved structure within the 10 genotypes of HBV, and the positions of base changes for genotype A2 are shown, as are the common translational precore mutations at G1896A (precore stop codon: UAG) and G1899A.

Two immunodominant core epitopes (HBc), localized between residues 74 and 83 (HBc1) (38), are colinear with HBc1 and to residues 107 to 118 (HBc2) (39). Not surprisingly, HBcAg and HBeAg are highly cross-reactive at the T cell level (26, 40) (Fig 2C). Two cytotoxic T lymphocyte (CTL) epitopes of HBc can be mapped to residues 18 to 27 (human leukocyte antigen HLA-A2 restricted) (41) and residues 141 to 151 (HLA-A31 and HLA-Aw68 restricted) (42). Three T-helper cell (T<sub>H</sub>) epitopes have been found on the core protein at amino acid residues 1 to 20, 50 to 69, and 117 to 131 (43).

#### Pre-S/S ORF

The HBsAg contains small (SHBs), medium (MHBs), and large (LHBs) proteins, all of which exist in two forms differing in the extent of glycosylation (Fig 2A). N-linked glycosylation and glucosidase processing are necessary for virion, but not subviral particle, secretion (8). The filaments consist of the same ratio of surface proteins as the virion envelope.

#### SHBs

The SHBs domain is 226 amino acids long and is the most abundant protein of all three HBV-associated particles. The SHBs is found in a glycosylated and a nonglycosylated form. It contains a high number of cysteine residues that cross-link with each other, forming a conformational loop that is the major antigenic determinant of HBsAg, the “a” determinant or antigenic loop (AGL) (44). The AGL is responsible for initiating viral entry to target hepatocytes by initially interacting with cell-surface heparan sulfate proteoglycans (HSPG) (45), which likely explains its presence on all known HBsAg isolates in a highly conserved fashion. The AGL has the subdeterminants “d” or “y” and “w” or “r.” Determinant d has a lysine at position 122, and y is represented by an arginine; likewise, determinant w has a lysine at position 160 and r has an arginine (46). These antigenic subtypes elicit cross-protecting anti-HBs following immunization. The “a” determinant has been renamed the major hydrophilic region (MHR), spanning amino acids 99 to 169, and is considered the major neutralization domain for anti-HBs.

#### MHBs

The MHBs Pre-S2 domain is a minor component of the virion or HBs particle and consists of the S and a 55-amino-acid N-terminal extension (22). It is either singly- or doubly-glycosylated but is not essential for virus assembly and release. The immunogenic epitopes are not conformationally dependent, as is the case for SHBs.

The central part of the Pre-S2 domain carries the major antigenic epitope, and the region between amino acids 3 and 16 has the ability to bind polymerized human serum albumin (8). The significance of this interaction is unknown, but many utilize albumin as an acting co-receptor or to mask the immunogenicity of this epitope (47). The MHBs is considerably more immunogenic than SHBs at the B cell level (48), and Pre-S2-containing HBs particles generated from animal cell lines have been used in some countries as a prophylactic vaccine (49).

#### LHBs

The LHBs contains a further N-terminal extension to the M protein of 108 or 119 amino acids (depending on the subtype/genotype) (Table 1) and is more prevalent than

MHBs in virions and filaments but less prevalent in HBs spheres. Thus, the LHBs contains three domains, Pre-S1, Pre-S2, and S, and is glycosylated. In mature virions and HBs particles, the Pre-S1 domains are exposed on the surface, and both the S domains and parts of the Pre-S2 sequence are covered by the Pre-S1 sequence of LHBs (8). In contrast to MHBs, the LHBs is essential for infection and viral morphogenesis, as the Pre-S1 region encodes the NTCP-binding domain (see Viral Attachment) (50, 51). The N-terminal end of the Pre-S1 domain is myristoylated at glycine 2, a function that is not required for virion formation and release but is essential for the ability of the virus particle to interact with the cellular plasma membrane (51). Amino acids 2 to 48 of the Pre-S1 sequence specifically interact with NTCP and contain a highly conserved motif [9-NPLGF(F/L)P-15] that is crucial for binding (Fig 2A). Residues 49 to 75 are also required for infection, but the precise function of this region is not known (51).

The LHBs has important antigenic sites for both B and T cells that appear to play critical roles in recovery from viral infection or protection from infection (52). The major immunogenic epitopes within the Pre-S1 coding region are at amino acids 27 to 35, 72 to 78, and 95 to 107. LHBs is also highly immunogenic for T cells in humans, at residues 21 to 48 as well as 81 to 108.

#### X ORF

The X ORF encodes a 154-amino-acid polypeptide (HBx) of 17 kDa (Fig 2A). This second accessory protein of HBV is conserved in a similar form across all the mammalian hepadnaviruses. The expression of full-length HBx protein is dispensable for virus replication *in vitro* but is a critical component of the infectivity process *in vivo* (53). HBx behaves as a transcriptional transactivator of a number of viral and cellular gene promoters through direct interaction with transcription factors, such as the RPB5 subunit of RNA polymerase II, TATA-binding protein, and the ATB domain, and is also involved in the activation of signal-transduction pathways, such as the Ras/Raf/MAP kinase cascade (8). HBx also increases the transcription of the cccDNA template by modifying its epigenetic regulation (54). In brief, epigenetic modification controls how tightly wound chromatin is to structural histone proteins. More tightly wound chromatin is not translated, whereas the converse is true; histone acetylation loosens chromatin but methylation tightens it. HBx recruits histone acetyltransferase and deacetylase enzymes in a fashion designed to prevent hypoacetylation (55). On the other hand, HBx *in vitro* inhibits protein arginine methyltransferase 1 (PRMT1), which functions to increase histone methylation (56).

Another important target of HBx is the ubiquitin-proteasome system (UPS), which is a conserved cellular pathway involved in protein ubiquitination and proteolysis (57). Many enzymes and proteins contribute to the function of this pathway, but of interest in the context of HBx is the damaged DNA binding protein-1 (DDB1) and the Cullin4 (CUL4) protein. HBx has been shown to bind DDB1, integrating itself into the DDB1-CUL4 complex, thus allowing regulation of its function (58). The importance of this interaction with regards to HBV replication has been demonstrated *in vitro* and in woodchuck hepatitis virus (WHV) models (59–61), but other consequences are as yet unknown.

The HBx protein also has a role as a cofactor in HBV-mediated carcinogenesis (62). The exact mechanism(s) whereby HBx contributes to the development of HCC is

unknown, although HBx-associated transactivation activity leads to alterations in cellular gene expression that contributes to transformation (63). Findings in support of this hypothesis include:

- HBx suppression of p53-mediated upregulation of microRNA pathways that enhance the growth and metastatic potential of tumors in a mouse HCC model (64).
- Studies of epigenetic changes show that HBx induces hypermethylation of genes with tumor suppressing activity (65).
- Disruption of signaling pathways critical to maintenance of cellular homeostasis (66).
- Abrogation of p53-dependent apoptosis and cell cycle checkpoint deregulation (67).
- HBx targeting of the 26S proteasome complex has also been implicated in hepatic carcinogenesis (57, 68, 69), suppressing viral antigen processing, and, consequently, presentation, thereby assisting evasion of immune detection (70).

### Viral Replication

The replication cycle of HBV revolves around two key processes:

1. Generation of HBV cccDNA from genomic RC DNA and its subsequent processing by host enzymes to produce viral RNA; and
2. Reverse transcription of the pregenomic (pg)RNA within the viral nucleocapsid to form RC DNA, completing the cycle (Fig 4). Earlier and later events are described below in the context of these two processes. The detailed molecular biology of HBV replication has been thoroughly detailed previously (71) and will not be repeated here.

### Attachment and Penetration

The first stage of infection is attachment to a susceptible hepatocyte and penetration of HBV into the cell cytoplasm following the binding of the HBV envelope to its specific cellular receptors. The “a” determinant region of the LHBs component of the HBsAg attaches to hepatocyte-associated heparan sulfate proteoglycans (HSPG) as the initial step in cellular entry (Fig 4) (72). This facilitates the next binding step of LHBs to the protein complex that forms the receptor for HBV, the sodium taurocholate cotransporting polypeptide (NTCP), which normally functions to maintain bile acid homeostasis via the enterohepatic circulation (50, 73). NTCP is encoded by the human *SLC10A1* gene, which is found on the long arm of chromosome 14. The pre-S1 domain of the HBV envelope protein contains two regions within the 75 amino acids at the N-terminal end, which are responsible for binding to NTCP (50). Myristoylation of these sequences is essential for virion infectivity (74, 75). Subsequent receptor-mediated endocytosis is responsible for the delivery of viral nucleocapsids into the cytoplasm. The possibility of utilizing drug therapy to block viral entry has been demonstrated *in vitro* using natural substrates of NTCP to inhibit viral infection of cell lines (50, 76, 77) (see Novel Therapeutic Strategies).

### Conversion of Genomic RC DNA into cccDNA and Transcription of the Viral Minichromosome

Intracellular viral nucleocapsids are transported to the nuclear membrane where they uncoat (78) and deliver their

genetic load into the nucleus. The genomic RC DNA is released and then converted into cccDNA using host cell enzymes resulting in the formation of the viral minichromosome, the template of HBV that is used for the transcription of all the viral mRNAs (79, 80) (Fig 4). The first step in this conversion, the release of the Pol protein from the 5′ end of the minus strand is achieved by utilizing the host DNA repair enzyme tyrosyl-DNA-phosphodiesterase 2 (TDP2) (81). The subsequent steps in cccDNA generation are yet to be elucidated.

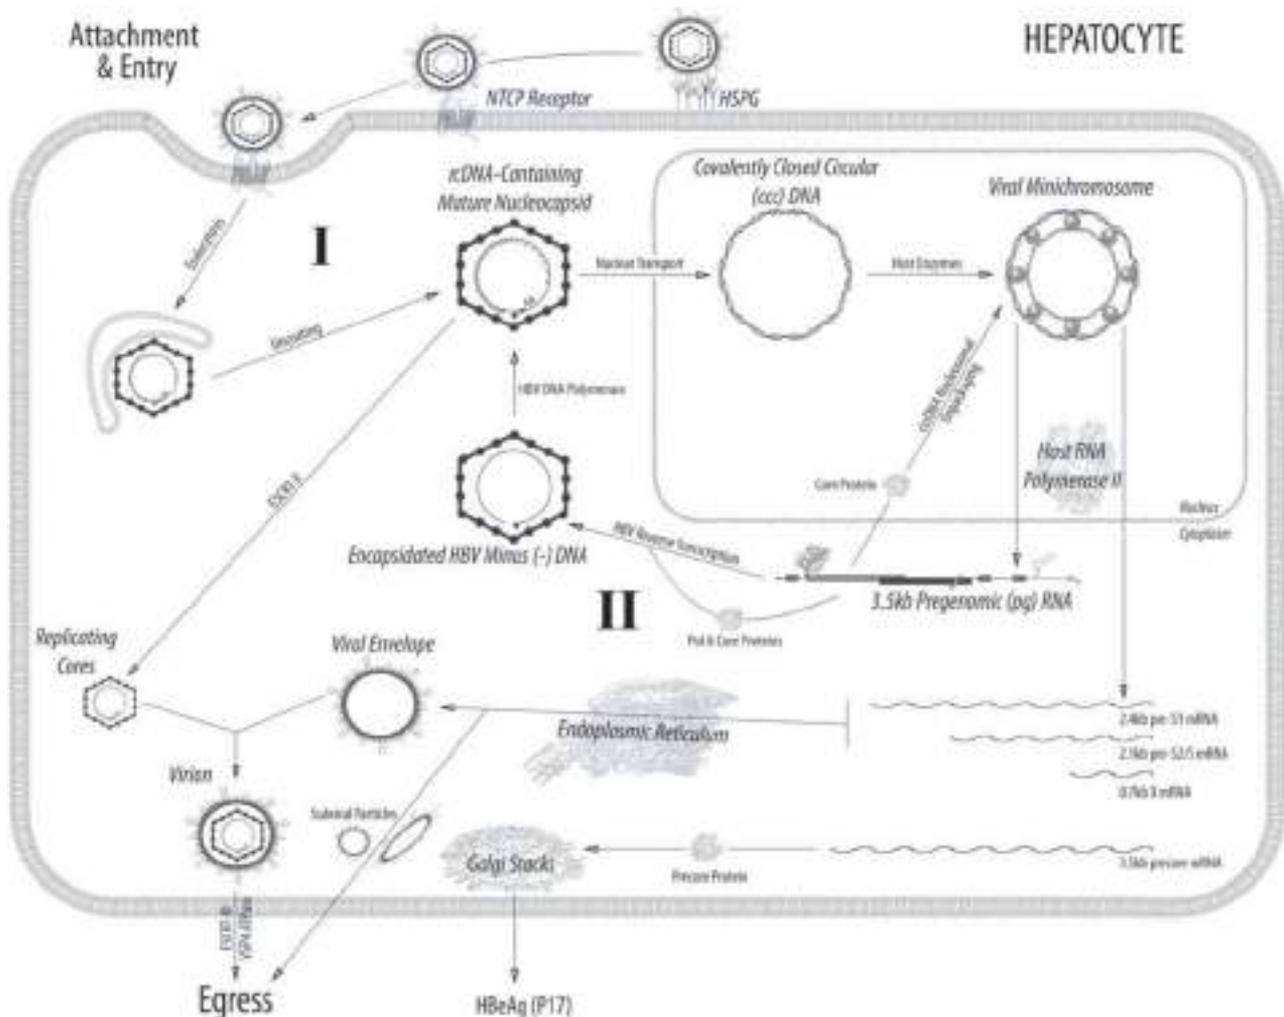

Two classes of transcripts are synthesized from the HBV minichromosome utilizing host cell RNA polymerase II, genomic length and subgenomic length (22). Both classes contain heterogeneous transcripts that are of positive orientation, are capped at the 5′ end, and polyadenylated at the 3′ end. The subgenomic transcripts function exclusively as mRNAs for translation of the envelope (Pre-S1, Pre-S2, and S proteins) and X proteins. The two genomic transcripts are longer than genomic length and encode the Pre-C, Core, and Pol ORF. Generation of the Pre-C/C mRNA is an early transcription/translation event and functions in translation of the precore protein, which is processed and then secreted as HBeAg (22). The Pre-C/C mRNA is not involved in reverse transcription. In contrast, the pregenomic RNA is multifunctional, serving as the template for reverse transcription into the viral (-) DNA strand and for translation of both HBeAg and HBV Pol.

### HBV Genomic Replication via Reverse Transcription

HBV genomic replication is initiated with packaging of the pgRNA and the newly translated viral polymerase/reverse transcriptase (HBV Pol) into subviral core particles, forming replication complexes. Reverse transcription occurs within the HBV nucleocapsid. As the HBV Pol is being translated off the same pgRNA molecule that will be packaged, the N-terminal region (terminal protein) specifically binds to the “bulge” region of a unique RNA stem loop structure, known as epsilon ( $\epsilon$ ), at 5′ end of the pgRNA (82) (Fig 3). This RNA structure also acts as the encapsidation signal around which cytoplasmic core protein dimers assemble into nucleocapsids. The HBV Pol undergoes a conformational change, which results in enzymatic activation, with the terminal protein domain priming DNA synthesis (24). This Pol-oligonucleotide (Pol-G-A-A) complex then translocates to the complementary sequences of a direct repeat (DR-1) region located at the 3′ end of the pgRNA. Minus (-) DNA strand synthesis then continues until it reaches the 5′ end of the pgRNA molecule (23), generating a short terminal redundancy of approximately 8 to 9 nt. While reverse transcription is proceeding, the pgRNA is degraded by the RNaseH activity of the HBV Pol, except for the 5′-capped terminal 18 nt fragment that contains the DR-1 sequence (22). This fragment includes a 6-nt homology to the direct repeat sequence, which allows circularization of the (-) DNA strand. The 18-nt capped RNA structure is then translocated to a second DR sequence (DR-2) on the 5′-end of the newly made (-) DNA strand, where it acts as primer for (+) strand synthesis, using the (-) strand as a template (23) (Fig 4). Synthesis of the (+) strand DNA continues until it reaches about 50 to 70% of the length of the (-) strand.

### Virion Assembly and Release

The viral envelope, the small particles, and filaments are synthesized and assembled at the ER membranes and then bud into its lumen. The HBe protein is synthesized in the

**FIGURE 4** Life cycle of HBV. Following attachment, penetration, and uncoating, the viral nucleocapsid is released into the cytosol and transported to the nuclear pore. The relaxed circular DNA is delivered into the nucleus where it is converted into cccDNA, and the viral minichromosome is generated. Transcription of the viral minichromosome produces the genomic and subgenomic HBV mRNA transcripts. Translation of the pregenomic RNA in the cytosol produces the Core and Pol proteins, and, in association with Hsp-60, all are selectively packaged into a replication complex. Within the nucleocapsid, reverse transcription begins. Synthesis of the (+) DNA strand proceeds from the RNA primer to the 5' end of the (-) DNA strand (23). The short terminal redundancy of the (-) DNA strand permits the transfer of the 3' end of the growing short (+) strand from the protein-linked 5' end to the 3' end of the minus strand, thereby circularizing the genome and allowing continuation of DNA synthesis, generating the genomic RC DNA molecule with the HBV Pol covalently attached to the 5' end of the (-) DNA strand. The envelope proteins Pre-S1, Pre-S2, and S are translated at the rough endoplasmic reticulum (ER) and then bud into the lumen of the intermediate compartment. Approximately 50% of the Pre-S1-enriched ER-membrane areas envelope core particles. The HBV virions and subviral particles are then secreted into the extracellular space by usurping the cellular ESCRT pathway. The nucleocapsids can also be transported to the nucleus via an intracellular conversion pathway, thereby increasing the number of nuclear cccDNA molecules.

cytosol and assembled independently of the envelope proteins (22). Immature nucleocapsids containing pgRNA-Pol can only commence envelopment once the nucleocapsid is phosphorylated. This latter process is coupled to the initiation of (-) strand synthesis (22). The assembled nucleocapsids containing genomic RC DNA are then selectively enveloped before exiting the cell (22). A further bias exists in favor of the export of genomes that have completed (-) strand DNA synthesis and at least started (+) strand synthesis (22). Correct assembly of replicating cores with the viral envelopes requires a critical relative molar ratio of Pre-S1 to S. Insufficient S or excessive Pre-S1 production results in abnormal assembly and release (22). As with many other

enveloped viruses, HBV usurps the endosomal sorting complex required for transport (ESCRT) network of proteins (Fig 4), which is a cellular network normally involved in the formation of multivesicular bodies and daughter cell cytokinesis (83–85). Various components of this system have important roles in the HBV replication cycle. In particular, the formation of mature nucleocapsids requires the ESCRT-II protein (83), and virion budding and egress require ESCRT-III and the VPS4 ATPase (85).

#### Variant Viruses

The replication strategy of HBV is essentially error prone. This poor fidelity is a result of two factors. First, there is a

lack of a proofreading or editing mechanism for the HBV Pol. Secondly, all reverse transcription processes have an intrinsic G-to-A hypermutation rate largely attributable to host APOBEC enzymes, and hepatitis B is no exception (86). Up to  $10^7$  base-pairing errors may occur each day (87). The rate of HBV virion production is approximately  $10^{11}$  virions per day. The error rate of the HBV Pol has been calculated as  $10^{-7}$  per nucleotide per day (88). Therefore, each day,  $10^{14}$  nucleotides ( $10^{11}$  virions  $\times 10^3$  nt) are replicated with potentially  $10^7$  base pairing errors (87). Thus there is the potential for every nucleotide in the genome to be substituted daily. Although mutations can occur randomly along the HBV genome, the overlapping open reading frames constrain the evolution rate, limiting the number and location of viable mutations. Because chronic HBV infection frequently persists for decades, many variants exist within the one host at any given time; HBV therefore exists as a quasispecies, with one variant typically dominating. There are three forms of variant HBV that are encountered commonly in clinical practice:

- Precore and basal-core promoter variants, which have an HBeAg-negative phenotype, typically emerge after HBeAg seroconversion and are the most common cause of HBeAg-negative CHB (discussed above).
- Envelope mutants that have been selected by hepatitis B immunoglobulin therapy in the posttransplantation setting or by vaccines following prophylactic immunization.
- Antiviral resistant polymerase mutants that emerge in the setting of nucleos(t)ide analogue (NA) therapy are responsible for virological breakthrough and treatment failure (discussed below).

#### Envelope Gene Mutations

Viral genomes that cannot synthesize Pre-S1 and Pre-S2 proteins have been found to occur frequently and are often the dominant virus populations in patients with CHB (89). Pre-S1 mutants are associated with intracellular retention of the

viral envelope proteins and the classical histological appearance of type I ground glass hepatocytes (GGH) (90). Type II GGH indicates the presence of Pre-S2 mutants. The Pre-S2 region overlaps the spacer region of the Pol protein, which is not essential for enzyme activity; thus both envelope mutants replicate in their infected host but with differing histopathological sequelae. Presence of GGH has been associated with increased hepatocarcinogenic potential, in part, attributable to a cellular growth advantage conferred by enhanced expression of vascular endothelial growth factor-A (91).

Current hepatitis B vaccine contains the major HBsAg. The subsequent anti-HBs response to the major hydrophilic region (MHR) of HBsAg between residues 137 and 148 induces protective immunity (51). Mutations within this epitope have been selected during prophylactic vaccination (44) and following treatment of liver transplant recipients with hepatitis B immune globulin (HBIG) prophylaxis (92). Most vaccine-HBIG escape isolates have a mutation from glycine to arginine at residue 145 of HBsAg (sG145R) or aspartate to alanine at residue 144 (sD144A). The sG145R mutation has been associated with vaccine failure (44) and has been transmitted, resulting in persistent infection and disease. Other important mutations have been found at a MHC class I-restricted T-cell epitope in HBsAg between codons 28 and 51 (93).

## EPIDEMIOLOGY

### Incidence/Prevalence

Approximately 240 million people have CHB (2). HBV is endemic in Asia, sub-Saharan Africa, Micronesia, and Polynesia, as well as in indigenous populations in Alaska, Northern Canada, Greenland, Australia, New Zealand, and within population groups in South America and the Middle East (94–96) (Fig 5). In developed countries, CHB is also seen in specific groups with percutaneous and sexual-transmission risk factors. These include injecting drug users, dialysis patients (3% to 10%), men who have sex with

**FIGURE 5** Global prevalence of HBsAg, WHO clarifies areas of high, medium, or low endemicity for HBV if the prevalence rates of HBsAg are  $\geq 8\%$ , 2 to 7%, or  $< 2\%$  respectively. (Adapted with permission from Ott et al. [649]).

men (6%), and people with multiple sexual partners. In low-prevalence countries, such as the USA, Canada, and Northern Europe, the prevalence of HBV infection is 0.1% to 2%. In intermediate prevalence countries (Mediterranean, Central and South America, Japan, and the Middle East) 3 to 5% of the population is infected and a 10-to-20% infection rate in high prevalence regions, such as Southeast Asia, Africa, China, and sub-Saharan Africa (95).

The prevalence of HBeAg-negative CHB is increasing worldwide. Rates of 50 to 80% in India and the Mediterranean area (Italy, Greece, and Israel) and 40 to 55% in East Asia (Hong Kong, Taiwan, and Japan) have been reported (34,97–102).

### Transmission

HBV antigens can be detected in almost all secretions (103–105), but only blood, saliva, and semen have been shown to be infectious (106, 107). The virus can be transmitted by perinatal, percutaneous, and sexual exposure or via close person-to-person contact in the presence of open cuts and sores (a common transmission method in children). However, the commonest route of transmission worldwide is perinatal infection (108).

The mode of transmission of HBV infection varies geographically. In high-prevalence areas, such as Southeast Asia and China, perinatal and early childhood horizontal transmission are the most common, resulting in high levels of chronicity (95% perinatal, 30% before 5 years). Perinatal transmission is likely to occur at birth or in the neonatal period; given the efficacy of neonatal vaccination, *in utero* infection is rare. The primary determinants of transmission are HBeAg status and HBV DNA level in the mother. The vertical transmission rate in HBeAg-positive women is 90% without intervention, compared to 32% for HBeAg-negative women (109). The failure rate of immunoprophylaxis in infants born to HBeAg-positive women approaches 10% when the HBV DNA level is  $> 10^8$  IU/ml ( $> 7 \log_{10}$  copies/ml) but is about 3% when the HBV DNA level is below this threshold (1).

In low prevalence areas, including the United States, Canada, Australia, and western Europe, sexual and percutaneous spread (primarily injecting drug use) is also seen. Limited data are available to describe risk per exposure; however, it has been observed that heterosexual partners of HBsAg positive individuals have a 25 to 59% seroprevalence rate (110). In the setting of needlestick injury sustained by healthcare workers, the occurrence of HBV transmission is rare since the implementation of universal vaccination in this special risk population (111).

In the setting of exposure during adulthood, HBV infection typically manifests as acute hepatitis (see below). The progression to chronic hepatitis is rare in the immunocompetent adult, occurring in  $< 1\%$  of individuals (112). Patients already infected with HIV, or immunosuppressed for other reasons, are at increased risk of chronicity after acute hepatitis B (113). The natural history of adult-acquired chronic infection differs from perinatal disease, with a higher rate of spontaneous and treatment-induced HBsAg seroconversion and lower rates of progression. However, the largest disease burden in most developed countries remains perinatal or childhood-acquired disease in immigrants from endemic areas (114).

### Uncommon Modes of Transmission

Transfusion-related hepatitis B is now uncommon in countries where blood is obtained from unpaid donors screened

for HBsAg and anti-HBc, with an estimated risk in the US of 1 per 3.2 million donors (115).

Nosocomial HBV transmission still occurs despite the availability of vaccination and postexposure prophylaxis, although HBV infection in healthcare workers (HCW) has declined dramatically in countries with HCW vaccination programs (111). Transmission from HCW to patient is rare but reported. The commonest situations are patient-to-patient or patient to HCW via needlestick injuries (syringe, suture needles) or scalpel. Nurses, dialysis staff, surgeons, dentists, and their assistants are at highest risk. Incomplete vaccination of staff, failure to apply universal precautions, and incorrect needle disposal technique are the commonest reasons for transmission. HBeAg positivity is associated with a higher risk of transmission, although transmission has been reported from HBeAg-negative individuals (116), confirming that HBV DNA levels are a better marker of infectivity.

Transmission from any organ donated by HBsAg positive donors is well recognized, and all donors are screened for HBsAg. Anti-HBc-positive liver donors can also transmit infection. This is less common in renal and other transplants (117).

### PATHOGENESIS

HBV is generally noncytopathic, and the liver inflammation and secondary fibrosis that complicate infection are primarily immune-mediated. The complex interplay that occurs between the host and pathogen in the setting of HBV infection is now starting to be unraveled (Fig 6). The experimental study of HBV immunopathogenesis has been limited by the absence of suitable animal models and *in vitro* cell lines permissive for HBV infection. HBV can infect chimpanzees but typically causes a self-limiting acute hepatitis, different in severity and outcome to human disease. This model is resource intensive and no longer ethically permitted. Surrogate small animal models include the infection of ducks with duck hepatitis B virus (DHBV) and the woodchuck with woodchuck hepatitis B virus (WHBV). These models have been useful for studies of molecular virology but less so for pathogenesis work. Transgenic mouse models have allowed for a better understanding of the role of cytokines and noncytolytic viral clearance in the pathogenesis of HBV but not the humoral immune response.

### Acute Infection

In contrast to hepatitis C virus, HBV does not start to replicate efficiently immediately post inoculation (118). Instead, experimental data, mainly from animal models, but also in humans, show that a “lag period” of 4 to 7 weeks is observed before HBV DNA and HBV antigens become detectable in the serum or liver. The explanation for this lag phase remains unclear. In acute HBV infection of chimpanzees, gene-array studies (119) found that no interferon-related genes were activated within the liver during the lag phase, despite a subsequent adaptive immune response then clearing HBV in all animals. While this work suggested that HBV might be a stealth virus that evades early innate immunity, increasing evidence suggests that HBV may be detected by the innate immune system almost immediately, which suppresses viral replication early after infection. This suppressive response includes the recruitment of NK/NKT cells (118), secretion of cytokines IFN $\gamma$  and TNF $\alpha$ , interleukin-6, -8, and -1 $\beta$  from Kupffer cells (120), and Toll-like receptor (TLR) signaling, especially within the hepatocyte, in early HBV infection (121–123). However, HBV

antibodies both pre- and postinfection with HBV demonstrated markedly prolonged incubation periods not present when anti-HBc alone was infused, suggesting a possible but undefined role for anti-HBe (135).

The integrated activation of both the cellular and humoral arms of the adaptive immune response is therefore required for clearance of acute HBV infection. HBV-specific antibodies, together with HBV-specific memory T cells, then provide protective immunity against future infections.

### Noncytolytic Clearance and the Transgenic Mouse Model

Important insights into the molecular mechanisms of noncytolytic clearance have been obtained from the HBV transgenic mouse model (70) (Fig 6). Key roles for the cytokines IFN $\gamma$ , TNF $\alpha$ , and IFN $\alpha/\beta$  have been revealed (70). HBV is inhibited by any stimulus that induces these cytokines in the liver, including injection of IL-12 (136), anti-CD40 mAb (137), IL-18 (138), IL-2 (139),  $\alpha$ -galactosylceramide (which activates NKT cells) (123), CD4+ T cells (140), other hepatotropic viral (adenovirus, LCMV, MCMV) (141), or parasitic infections (schistosomiasis, malaria) (142, 143). TLR signaling has also inhibited HBV replication in the transgenic mouse model via a type 1 IFN-mediated mechanism (122).

Adoptively transferred HBV-specific CTLs abolish HBV gene expression and replication in the liver of transgenic mice without killing the hepatocytes. This antiviral function is mediated by IFN $\gamma$  and TNF $\alpha$  secreted either by the CTL or by the antigen-nonspecific macrophages and T cells that they activate following antigen recognition (130). These cytokines activate two independent virocidal pathways. The first pathway eliminates HBV nucleocapsid particles and their cargo of replicating viral genomes by preventing replication-competent capsid assembly (136, 144) in a proteasome- (145) and kinase-dependent manner (146) (Fig 6). The second pathway destabilizes the viral RNA (130) by an SSB/La-dependent mechanism (147–149). The La autoantigen normally binds a predicted stem-loop structure of the 5' end of the posttranscriptional regulatory element of HBV RNA to protect several endoribonuclease cleavage sites from cellular RNases. IFN $\gamma$  and TNF $\alpha$  induce proteolytic cleavage of the La autoantigen, thereby allowing destabilization of HBV RNA (147) (Fig 6).

Type 1 IFNs (IFN $\alpha/\beta$ ) also inhibit HBV replication at both pre- and posttranscriptional levels. Transcription of the cccDNA minichromosome is inhibited via epigenetic modification, thus reducing pgRNA levels (150). IFN also activates hepatocellular mechanisms that prevent the formation of replication-competent HBV capsids (144). The molecular mechanism(s) that mediate this inhibition have not yet been defined, but the antiviral activities of double-stranded RNA-dependent protein kinase (PKR) and interferon-regulatory factor 1 (IRF-1) have been implicated (151).

The key role of TNF $\alpha$  was recently highlighted using a murine model of HBV infection with tail vein injection. The cellular inhibitor of apoptosis protein (cIAPs) was shown to attenuate TNF $\alpha$  signaling and restrict the death of infected hepatocytes, allowing viral persistence. Mice with a liver-specific cIAP1- and total cIAP2-deficiency efficiently controlled HBV infection compared with wild type mice. Pharmacological inhibitors of cIAPs were subsequently shown to promote the clearance of HBV infection in the mouse model, emulating the effect of experimentally induced cIAP deficiency (152). Birinapant, a cIAP inhibitor

developed for cancer therapeutics, has now entered phase I clinical development.

### Chronic Infection

The mechanism of HBV persistence is not fully understood but is likely multifactorial, including strategies of HBV-specific immune suppression and evasion, developmental-dependent and genetic host immunocompetence, and the persistence of stable forms of the HBV genome, such as cccDNA in the form of the minichromosome. Persistent infection is more likely to occur following perinatal transmission or after early horizontal transmission to children or immunocompromised adults. The dose and HBeAg phenotype of viral inoculum may also influence the outcome when a mature immune system is exposed (153).

The most important predictors of persistence appear to be 1) the maturity of the host immune system at the time of infection, as the majority of the world's CHB infections in endemic areas occur between the neonatal period and 5 years of age, and 2) the HBeAg phenotype of the HBV. However, unlike previously thought, the high rate of chronicity is not due to evasion of the immature immune system or induction of immune defects. The dogma that there is an absent or impaired immune response to HBV is at odds with the efficacy of HBV vaccination in infants born to mothers with HBV. The concept of "trained immunity" in infants born to HBV-infected mothers describes a phenomenon in which the functional maturation of neonatal immunity is modulated by extrinsic factors, such as live vaccination, which can subsequently protect newborns against unrelated pathogens by increasing the efficiency of innate immune function (154). One cohort of infants born to HBV-infected mothers, as compared to nonexposed controls, showed enhanced innate immune-cell maturation and Th1 development and *ex vivo* responses to unrelated pathogens (155). Rather than being defective, the immune system of a newborn, it appears, is less likely than that of an adult to trigger a pro-inflammatory reaction, which is possibly an evolutionary adaptation to avoid dangerous immune reactions in the developing fetus (156). Further challenging current "immune tolerant" models, chronically infected adolescents, considered to be in the traditional "immune tolerant" phase, do not exhibit a tolerogenic T-cell profile (157).

### Viral Mechanisms of Persistence

All of the major proteins produced by HBV have been implicated in the development of chronicity. The surges in viral load associated with disease flares have been correlated with elevations in IL-10, an immunosuppressive cytokine (158). Elevated IL-10 induces hyporesponsiveness in NK, CTLs, and T helper cells. Additionally, at levels of viremia  $>7 \log_{10}$  copies/ml, almost no circulating HBV-specific CTLs can be detected (159).

The continuous production of both HBsAg and HBeAg in concentrations at least 1000-fold higher than that of whole virions is associated with immunological alterations (160). HBeAg is not required for infection or replication, yet it is absolutely required for the development of chronicity. Viral mutants, defective for HBeAg production, may cause acute, even fulminant, hepatitis but not chronic hepatitis B. In murine models HBeAg has a "tolerizing effect" on CTL-mediated clearance of HBcAg-positive hepatocytes (32,161–163), and it likely contributes to the poor core-specific T-cell responses present in patients with HBeAg-positive CHB. HBeAg may generate this tolerance via modulation of various immune components:

- TLR2 expression is downregulated on peripheral monocytes, Kupffer cells and hepatocytes from patients with HBeAg-positive disease but upregulated in HBeAg-negative disease (121). When patient PBMCs are stimulated with the specific TLR2 ligand Pam-2-Cys, reduced TNF $\alpha$  induction is noted in the HBeAg-positive group, confirming functional significance.
- *In vitro* experiments have shown that HBeAg selectively and specifically binds several proteins involved in downstream TLR signaling pathways, thereby downregulating NF $\kappa$ B and IFN $\beta$  promoter activity (164, 165). This also suppresses NK cell secretion of IFN $\gamma$ , normally stimulated by IL-18 (166).
- HBeAg is also associated with downregulation of the costimulatory molecule CD28 on HBV-specific CTLs (167).

The excessive numbers of produced particles that are not infectious may act as a decoy for HBV-specific humoral immunity and also promote a state of T-cell anergy and deletion. In murine and cell line experiments, HBsAg may directly modulate innate immune-signaling pathways, namely NF $\kappa$ B and MAPK, suppressing inflammatory cytokines and interferon gene transcription normally upregulated by TLR signaling (165,168–170).

The HBx protein may contribute to establishing persistent infection by inhibiting proteasome-based degradation of viral protein to reduce HBV antigen presentation (70). Additionally, *in vitro* HBx binds the  $\beta$ -interferon-promoter stimulator-1 (IPS-1), enhancing its degradation (171), and also disrupting signaling pathways responsible for IFN $\beta$  gene transcription (172, 173). HBx has also been associated with alterations in the balance of pro- and anti-inflammatory cytokines, but the biologic significance of these alterations is yet to be defined in human infection (174, 175).

The HBV Pol protein suppresses the production of the MyD88 adaptor protein, which is central to TLR function (176), by downregulation of the STAT-1 nuclear transcription factor via 1) competitive binding of importin- $\alpha$ 5 (the nuclear entry transporter for STAT-1) by the RNaseH domain (177), and 2) inhibition of protein kinase C- $\delta$ , responsible for STAT-1 phosphorylation, by the TP-domain (177, 178). The biologic effect of this pathway has been demonstrated in murine models (179). Pol also blocks IRF-3 phosphorylation, which is part of the TLR-3 signaling pathway to produce IFN $\beta$  (173, 180).

Selection of mutations in the HBcAg by immune pressure may result in T-cell anergy. Analysis of HBcAg epitopes in chronically infected patients identified novel mutations that, when presented, resulted in antagonism of the T-cell receptor and functional inactivation (181). These mutations were HLA-A2 restricted and located in the major HBcAg epitope between residues 21 and 27. The significance of these mutants in a larger population has not been determined.

### Immune Defects in Chronic Infection

The immune dysfunction present in individuals with CHB manifests in the effector cells of both the innate and adaptive arms and may occur as a consequence of chronic immune stimulation. HBV-specific CD4+ and CD8+ T-cell responses are significantly diminished relative to individuals with resolved infection. The frequency and function of both intrahepatic and peripheral HBV-specific T cells are inversely proportional to the level of circulating HBV DNA in CHB (159), and, in animal models, the sustained presence of viral antigens may lead to progressive anergy and ulti-

mately deletion of T cells (182, 183). The mechanisms that may contribute to this are discussed below.

### Molecular Markers of Exhaustion

Exhaustion of immune effector cells is a known consequence of chronic viral infections; upregulation of molecules responsible for suppressing CTL function has been observed in both animal models and patients with CHB. The programmed death-1 receptor (PD-1) is overexpressed on HBV-specific CTLs in patients with CHB (184–186) with a corresponding increased expression of the PD-1 ligand on the surface of dendritic cells (DCs) in response to IFN $\alpha$  and IFN $\gamma$  (187). Activation of PD-1 by its ligand increases the sensitivity of a cell to apoptosis. Inhibition of PD-1 expression and signaling is now being evaluated as a possible therapeutic strategy to reverse the immune exhaustion associated with CHB.

T-cell immunoglobulin domain and mucin domain-containing molecule-3 (Tim-3) is also upregulated on the surface of both CD4+ and CD8+ T cells in CHB patients (188). Tim-3 activates cellular pathways responsible for functional inactivation and apoptosis. Consequently, Tim-3 upregulation results in impaired cellular proliferation and cytokine production (189). *In vitro* blockade of Tim-3 can restore cellular immune function (190). The natural ligand for Tim-3 has been shown to be galectin-9, levels of which are elevated in CHB patients (189). The source of galectin-9 has not been determined.

The exhaustion profile of both CD4+ and CD8+ HBV-specific T cells also includes overexpression of the NK cell receptor 2B4 (NK2B4) (191) and Bcl-2-interacting mediator (Bim) (192), which are involved in cytokine production and apoptosis, respectively. The inhibitory costimulatory molecule CTLA4 is also upregulated on CD8+ T cells (193), and the positive costimulatory ligand of CD40 is downregulated on CD4+ T cells (194). These changes result in suppression of signaling molecules associated with CD4+ cellular proliferation (195) and increased production of IL-10 (194).

### Innate Immune Dysfunction

The innate immune system is implicated in the pathogenesis of CHB. Type 1/3 IFN induction is triggered by TLR signaling in response to viral pathogen-associated molecular patterns (PAMPs), and TLR-7 ligands have now entered clinical development for HBV (see below). Dysregulation of TLR signaling contributes to immune evasion in CHB and impaired expression of TLR-3 and 9, as well as of TLR-2, and downstream signaling pathways have been described (196–198). More recently, miRNAs have been proposed to negatively regulate TLR signaling in the setting of CHB, specifically targeting TRAF6 and other key effectors of TLR signaling, including STAT-1 (199, 200). miR-146a is overexpressed by both CD4+ and CD8+ T cells in CHB patients, and *ex vivo* experiments reveal its overproduction in response to PBMC stimulation by HBV antigens, TNF $\alpha$ , and IFN $\alpha$  (200). Blockade of miR-146a *in vitro* restored HBV-specific CTL responses. miRNA may also directly regulate HBV replication and has been implicated in the pathogenesis of HBV-related HCC.

### Regulatory T Cells

The T-cell subset characterized by CD4+CD25+FoxP3+ expression, known as regulatory T cells, or Tregs, are known to modulate the immune system to maintain tolerance to self-antigens and to abrogate autoimmune disease. Some pathogens can manipulate Tregs to selectively immunosuppress

host immunity and promote persistence. Intrahepatic levels of Tregs are elevated in patients with chronic HBV (186,201–203), and their frequency correlates with both viral load and inflammatory activity (201, 204). *Ex vivo* experiments demonstrate the suppressive effect of Tregs on HBV-specific CD4+ and CD8+ T cells from patients with CHB (201, 205). Tregs may contribute to a proviral intrahepatic cytokine environment. Intrahepatic Tregs are increased in woodchucks chronically infected with WHV and have been associated with IL-12 nonresponse (202).

### Adaptive Immune Dysfunction

Chronic hepatitis B is characterized by a failure to mount an efficient adaptive immune response. In addition to cellular exhaustion detailed above,  $\gamma\delta$ -T cells ( $\gamma\delta$ TC), have been implicated in an immunosuppressive role in CHB. *In vitro* these cells from CHB patients can dampen the production of inflammatory cytokines by inhibiting their production from Th17 cells and CTLs (206, 207). The frequency of  $\gamma\delta$ TC production is increased in immune-tolerant patients (207). These cells also liberate cytokines that recruit intrahepatic myeloid-derived suppressor cells, which also lead to CTL suppression (208). In addition, the dying hepatocyte releases large quantities of arginase into the circulation. Arginase enzymatically degrades the amino acid L-arginine, which is essential for the function of the intracellular signaling zeta ( $\zeta$ ) domain of the T-cell receptor (TCR). The CTLs of CHB patients downregulate TCR $\zeta$ , with the functional consequence of impaired IL-2 secretion (209). Overall this results in reduced antiviral function (210).

### Humoral Immunity

B cells and humoral immunity play a critical role in CHB. HBV-vaccinated individuals have anti-HBs antibodies that are 95% protective against initial infection (211). Treatment with specific anti-B cell therapy (rituximab, ofatumumab) confers a 30 to 60% risk of viral reactivation. This risk persists even in those patients who have achieved HBsAg seroconversion and is much higher than if patients were treated with traditional immunosuppressive agents (212–215). Additionally, a new subset of B cells, called regulatory B cells, is characterized by the ability to secrete the potent immunosuppressive cytokine IL-10 (216). The full functions of this B cell subset, which is rare in the peripheral circulation, are yet to be elucidated, but their frequency increases in proportion to disease flares in CHB. This results in increased IL-10 secretion and subsequent CTL suppression (217).

### Host Genomic Factors

Genetic predisposition to the development of chronic HBV infection has not been studied extensively. A genome-wide association study in Japanese patients identified 11 single nucleotide polymorphisms associated with CHB risk that were localized to the HLA-DP locus, thus implicating MHC class II antigen presentation as a possible factor (218). Reinforcing the role of the HLA-DP locus, a separate study identified other polymorphisms that were associated with an increased chance of spontaneous HBsAg clearance at a younger age (219).

IL-28B genotyping, which is predictive of interferon-based treatment responses in chronic hepatitis C infection, may also influence the development of chronic hepatitis B infection, as well as the response to both IFN- and lamivudine (LMV)-based therapy (219–223). IL28B genotyping has been linked to rates of HBsAg loss following long-term IFN- $\alpha$  therapy (224).

## CLINICAL MANIFESTATIONS

### Acute Hepatitis B

The incubation period of acute hepatitis B varies from 1 to 4 months postinfection. Clinical presentation varies from asymptomatic infection in two-thirds of patients to frank icteric hepatitis and, rarely, fulminant liver failure. A serum sickness-like illness, characterized by fever, arthralgias, and rash, may develop in the prodromal period, followed by constitutional symptoms, anorexia, nausea, jaundice, and right upper-quadrant discomfort. Clinical symptoms coincide with the biochemical abnormalities that develop on liver function testing. The biochemical diagnosis of acute hepatitis is characterized by elevations in the concentration of serum ALT and bilirubin. ALT values in AH-B are usually greater than 500IU/ml, with ALT being higher than AST. Elevations in bilirubin are usually modest, 5 to 10 mg/dl (85 to 170  $\mu$ mol/l). The symptoms and jaundice generally disappear after 1 to 3 months, although fatigue may persist in some patients even after normalization of liver function tests.

### Fulminant Hepatic Failure

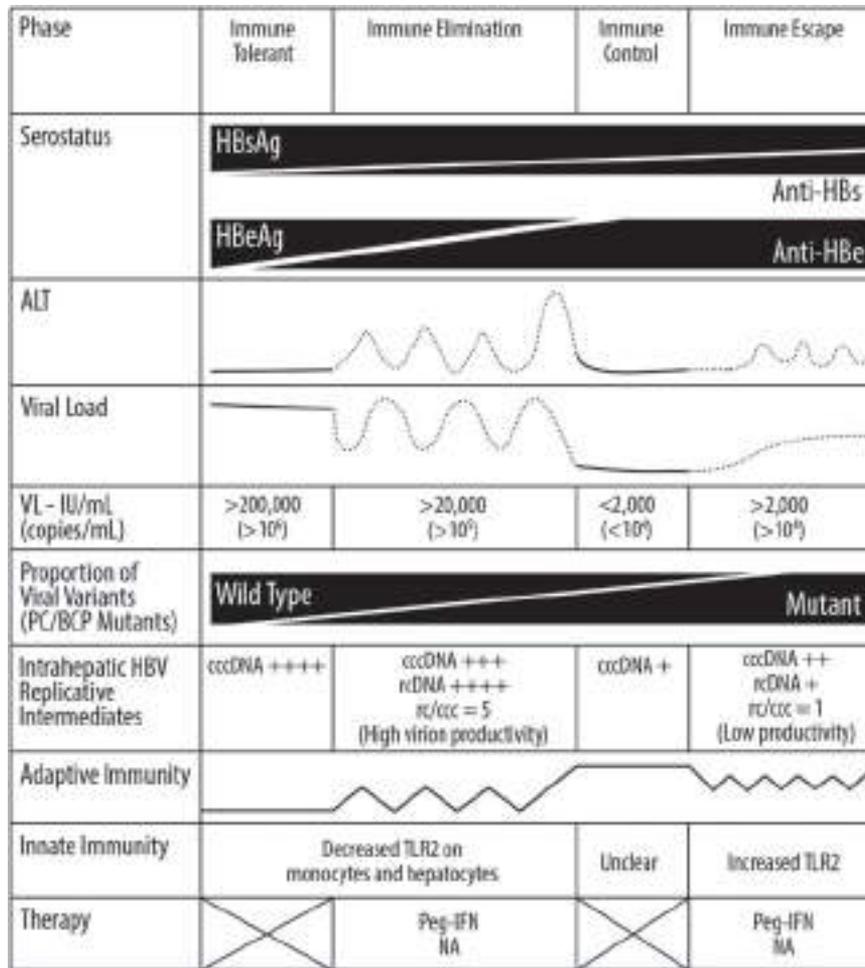

The most serious complication of HBV infection is fulminant hepatic failure (FHF). This is unusual, occurring in <0.5% of patients and is defined as the onset of hepatic encephalopathy within 8 weeks of the development of jaundice. The risk of FHF may be higher in patients acutely infected with basal core promoter or precore variants (225), coinfecting with other hepatitis viruses, or with underlying liver disease. The development of coagulopathy (marked by an international normalized ratio [INR] >1.6) should raise concern about the risk of development of FHF and warrants consultation with a liver transplant center as the prognosis is poor, carrying an 80% mortality rate, if left untreated. Prompt institution of nucleos(t)ide therapy to reduce viral load has reduced the mortality rate to 20% in some series (226).

### Chronic Hepatitis B

Most cases of CHB occur in endemic populations as the result of perinatal or early childhood horizontal transmission. The natural course of disease is determined by the interplay between virus replication and the host immune response and may be divided into four phases: 1) the immune tolerance phase; 2) the immune elimination phase; 3) the immune control phase; 4) HBeAg-negative CHB or immune escape phase (Fig 7).

The immune-tolerance phase is characterized by high levels of viral replication, with HBV viral load up to  $10^{12}$  IU/ml and HBeAg detectable, but no evidence of active liver disease as manifested by lack of symptoms, normal serum ALT measurement, and minimal changes on liver biopsy. HBV-specific T-cell responses are weak or undetectable in this phase (159, 227). The immune-tolerant phase usually lasts 10 to 30 years, during which time there is a very low rate of spontaneous HBeAg clearance, reported to be only 15% after 20 years of infection (228, 229).

Transition from the immune-tolerance to the immune-elimination phase typically occurs during the second and third decades of life. This transition is marked by increased HBV-specific T-cell immunity, falling HBV-DNA titers, increased serum ALT, and necro-inflammatory histological changes. Immune pressure drives an increase in viral quasi-species diversity. The immune-elimination phase may last for years, during which time disease activity fluctuates and progressive liver damage accumulates. The most important factor influencing prognosis appears to be prolonged viral

**FIGURE 7** The natural history of chronic hepatitis B, showing relationships between serology, biochemistry, molecular virology (serum and liver compartment), as well as immunological parameters of the innate and adaptive arms.

replication at levels >2000 IU/ml. In a small percentage of patients, severe ALT flares result in hepatic decompensation and, rarely, death from hepatic failure. Spontaneous HBeAg seroconversion, the serological marker of the end of the immune-elimination phase, increases to an annual rate of 10 to 20 percent during the immune-elimination phase (228, 229). HBeAg seroconversion correlates with a significant drop in viral load, often to undetectable levels, and histological arrest or improvement. HBV is not cleared from the liver, however, and the nuclear cccDNA reservoir persists.

Patients in the low or nonreplicative phase are HBeAg-negative and anti-HBe positive. A serum HBV-DNA threshold, below which HBV replication is not thought to be clinically significant, has been set at 2,000 IU/ml (230). In some patients, serum HBV DNA is no longer detectable. Liver disease remits as evidenced by normal serum ALT concentrations and resolution of necroinflammation in liver biopsies. HBV-specific T-cell reactivity is high and thought to maintain viral suppression (231). The remaining HBV population is genetically diverse, with positive selection of viral variants defective for HBeAg production that are able to persist but at the cost of a reduced replication phenotype (232, 233). The annual rate of delayed clearance of HBsAg has been estimated to be 0.5 to 2% in Western patients and much lower (0.1 to 0.8%) in Asian countries (234, 235).

HBsAg seroconversion is regarded as a functional “cure” and is associated with a good prognosis. However, it is unlikely that HBV DNA is ever completely cleared from the liver, and a small risk of reactivation persists in the setting of potent immune suppression (e.g., allogeneic bone marrow transplantation or B-cell depletion using therapeutic monoclonal antibodies).

A percentage of patients continue to have moderate levels of HBV replication and active liver disease (elevated serum ALT and chronic inflammation on liver biopsies) but remain HBeAg-negative. This typically occurs following the emergence of variants of HBV that are phenotypically HBeAg-negative and genotypically include PC or BCP mutants. It remains unclear whether this occurs as a smooth transition from the HBeAg-positive immune-elimination phase or as reactivation from the low-replicative phase.

In adult-acquired CHB, the immune-tolerance phase is typically absent, with disease progressing immediately to the immune-elimination phase. Some patients will be immunosuppressed, and, in this setting, the disease course may be more aggressive. HIV coinfection is associated with an increased risk of cirrhosis and liver-related morbidity (236).

CHB affects nearly 10% of HIV-infected patients. HIV directly impacts the outcome of HBV infection, complicating its natural history, diagnosis, and management. In the

setting of HIV and HBV coinfection, levels of serum HBV DNA tend to be higher, and spontaneous HBeAg seroconversion occurs at a lower rate. For reasons that remain unclear, liver damage, especially fibrosis, progresses at a higher rate than in HBV mono-infection, despite hepatic necroinflammation typically being less severe. With improved control of HIV disease with highly active antiretroviral therapy (HAART), liver disease has emerged as one of the leading causes of death in patients with HIV (236). Therefore, all patients with HIV should be screened for HBV infection. It is recommended that testing for both anti-HBc and HBsAg be performed, as patients with HIV can have occult HBV. Similarly, all HBV patients should undergo HIV testing (230).

### Complications of Chronic Hepatitis B

The major complications of CHB are cirrhosis, hepatic decompensation, and HCC. Between 15 and 40% of individuals with CHB will develop at least one of these sequelae during their lifetime, with the highest risk in men (237, 238). CHB has a variable natural history, and accurately predicting prognosis in an individual patient is difficult. A key role has, however, been identified for viral load  $10^4$  copies/ml ( $>2,000$  IU/ml), and age greater than 30 years, as risk factors for clinical progression to cirrhosis and HCC (3, 4).

#### Cirrhosis

The current challenge in CHB is to identify patients at risk for progressive liver disease so that therapy may be offered early to alter the natural history. The major risk factors for progression to cirrhosis are viral load, the presence of fibrosis on liver biopsy, and elevated serum ALT. Other factors that influence progression to cirrhosis include viral genotype, HBeAg positive disease, level of HBsAg, coinfection with other viruses, such as hepatitis D virus (HDV) and HIV, and alcohol consumption.

In patients with CHB, the strongest independent predictor of progression to cirrhosis is HBV viral load. In a prospective study of 3582 community-based HBsAg-positive Taiwanese nationals, followed for a mean of 11 years, the risk of cirrhosis increased significantly as baseline viral load increased (3). A critical-threshold viral load of  $10^4$  copies/ml (2,000 IU/ml) was identified (Table 2 and Fig 8A). The effect of viral load was independent of age, sex, cigarette smoking, alcohol consumption, HBeAg status, and alanine transaminase level. On multivariate analysis male sex, older age, HBeAg-positivity, and 45 IU/ml ALT at the time of study entry were also identified as independent predictors for cirrhosis. The annual incidence of cirrhosis was 0.9%, consistent with the 0.7% reported by a previous study of asymptomatic HBV carriers (239), but lower than the reported rate of 2 to 7% observed in tertiary referral-center populations (240–242). It is likely that the risk associated with absolute viral load at entry reflects duration of viremia and older age. High viral load in younger patients may not have the same prognostic implications, particularly for those still in the immunotolerant phase of disease. Whether the same risk applies to HBsAg carriers in Western countries with adult-acquired HBV infection also remains unclear.

A second prospective study conducted in mainland China has confirmed these data (243). A high baseline viral load ( $10^5$  copies/ml or 20,000 IU/ml) predicted severe liver disease and HCC 11 years later, in comparison to HBsAg-positive individuals with a baseline undetectable viral load. Furthermore, high viral load at baseline predicted liver-

**TABLE 2** Risk scores assigned to predictors of liver cirrhosis and HCC determined from a large, longitudinal Asian cohort of CHB patients, used in the developed risk nomograms shown in Figure 8

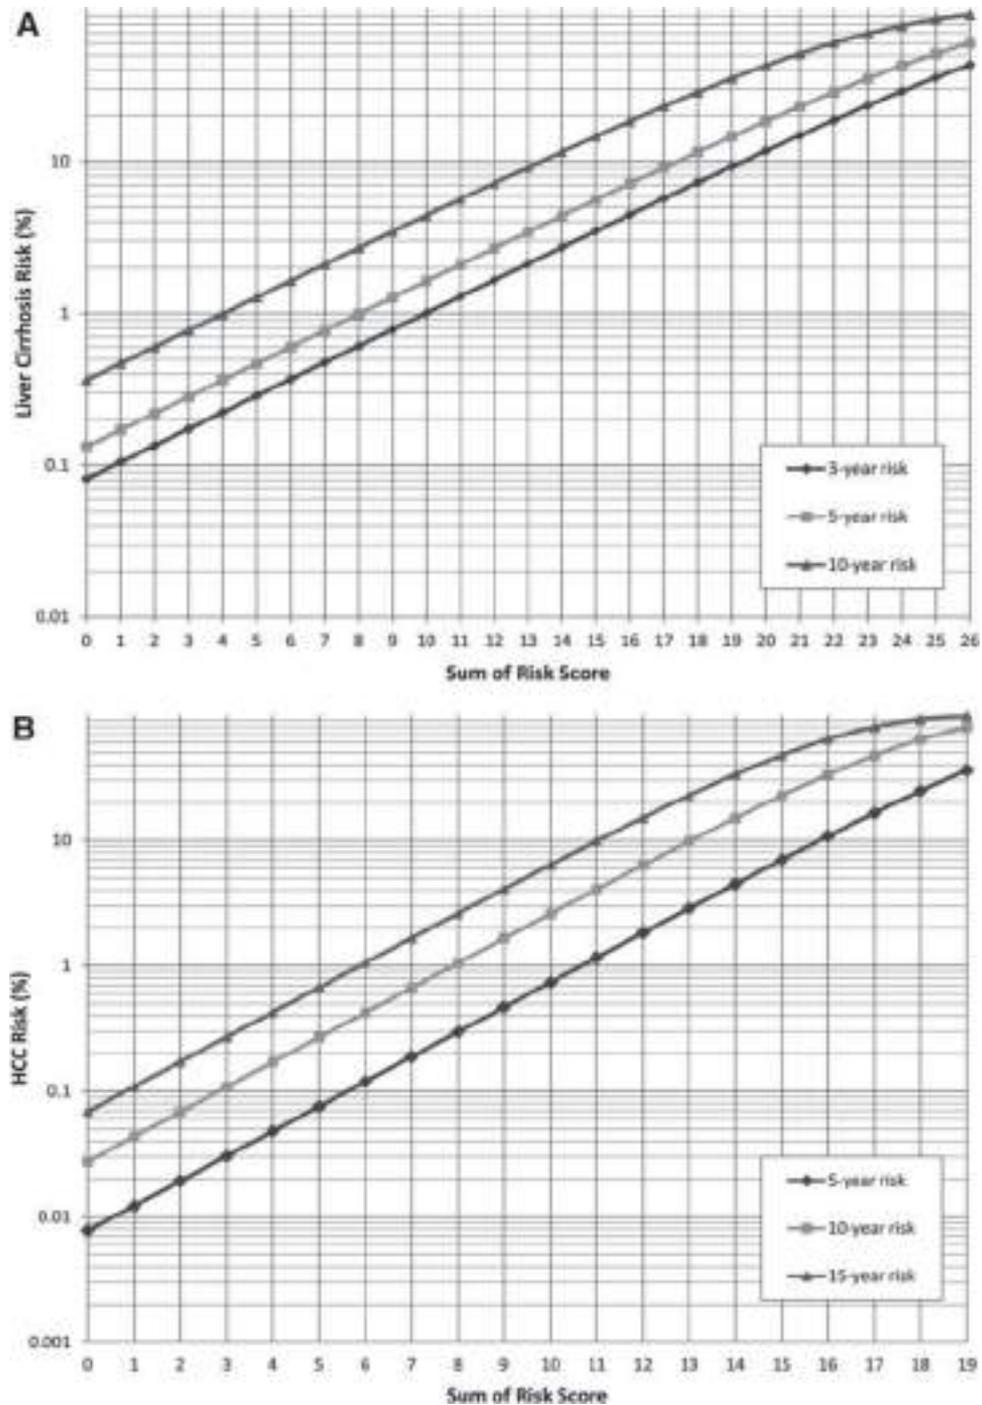

Baseline Predictor	Risk Score for Liver Cirrhosis	Risk Score for HCC
Age (each 5 years increment)	1	1

associated mortality. Mortality was substantial, with more than 20% of individuals with a high viral load at baseline dying of chronic liver disease or hepatocellular carcinoma by the end of follow-up. A more detailed stratification of viral load in this study was limited by sample size.

Although elevated serum ALT, especially frequent ALT flares, is a risk factor for progressive disease (241, 242, 244, 245), mild elevations of serum ALT are not necessarily reassuring. Hong Kong patients with serum ALT in the range of 1 to 2 times the upper limit of normal (ULN) have a greater risk of clinical complications than patients with serum ALT 2 times the ULN (246). Furthermore, serum ALT 0.5 to 1 times the ULN was associated with a greater risk of complications than a low-normal serum ALT ( $< 0.5 \times \text{ULN}$ ). Hence, patients with minimal enzyme elevations may have progressive disease. Studies that have considered ALT over time have suggested that progression of fibrosis in patients with normal ALT may be limited to those patients who subsequently develop ALT elevation (247).

Measurement of quantitative HBsAg levels is becoming more widespread and useful in cirrhosis risk prediction (248). Hazard ratios of 1.96 (CI: 1.32–2.90) and 3.60 (CI: 2.54–5.10) were found for HBsAg levels of 100 to 999 IU/ml, and  $\geq 1000$  IU/ml, respectively, in progression to cirrhosis.

**FIGURE 8** Nomograms for the predicted risk of (A) liver cirrhosis (low risk <11; moderate risk 11 to 16; high risk  $\geq 17$ ), and (B) HCC (low risk <9; moderate risk 9 to 12; high risk  $\geq 13$ ). These have been developed using identified virologic and host factors that increase risk of complications. The scoring system is outlined in Table 2. Reproduced with permission from Lee et al. (248).

Liver biopsy remains a useful clinical tool with prognostic significance. The probability of evolution to cirrhosis is significantly higher in patients with moderate-to-severe inflammatory changes, particularly if bridging hepatic necrosis is present (241, 242, 249–252). Advanced fibrosis (Scheuer score 2/3) is also a risk factor for the development of cirrhosis (244). The combination of aggressive inflammation and fibrosis has also been linked to survival (253). Liver histology

can also worsen rapidly in patients who have recurrent exacerbations or reactivations of hepatitis (230).

Viral factors, including both HBV genotype as well as common HBV variants, have been shown to influence the risk of disease progression. In Asian countries, where genotypes B and C predominate, more rapid and frequent progression to cirrhosis has been noted in patients with genotype-C disease (254–258). Much of this risk is

explained by the observation that genotype-C patients display more active hepatitis, and a later age of seroconversion, compared to genotype-B patients, confirming the critical role of prolonged viremia and inflammation in the development of clinical complications. Genotype A and D are more common in Western populations. Genotype-D infection has been associated with more advanced disease (259). There are no natural history studies that compare all 4 of the major genotypes. In one Japanese study, genotype A was associated with milder disease than genotypes B and C (260).

Among common viral mutants, the BCP mutation appears to be a risk factor for cirrhosis (261–265). The role of the PC variant, the most common variant associated with HBeAg-negative disease, remains unclear. Loss of HBeAg and emergence of the PC variant are now recognized to occur with increasing duration of disease, typically in the third or fourth decade. In treatment-naïve patients in France, advanced fibrosis tended to be higher in patients with PC mutant-positive and BCP mutant-negative infection (266). However, the advanced disease seen in patients in these selected cross-sectional studies may simply reflect persistent, long-standing viremia rather than a pathogenic role for precore mutants. Both genotype and BCP variants have also been linked to the development of HCC.

Several large Asian studies have demonstrated an increased risk of cirrhosis in CHB patients with comorbid metabolic syndrome or diabetes mellitus. One prospective study of 1466 CHB patients characterized their metabolic risk profile and liver fibrosis stage by transient elastography (TE), with a 10% subset undergoing formal liver biopsy, demonstrating good correlation between TE and histology. The presence of features of metabolic syndrome, including type II diabetes mellitus, hypertension, dyslipidemia, and central obesity, was associated with a higher risk of cirrhosis on multivariate analysis, independent of the traditional risk factors outlined above (267). A longitudinal follow-up study of this cohort identified an increased risk for liver fibrosis progression in patients with metabolic syndrome (odds ratio of 2.0 [CI: 1.1–3.5] for fibrosis progression, defined as an increase in liver transient elastography measurement of  $\geq 30\%$  [268]).

Other risk factors associated with increased rates of cirrhosis include habitual alcohol consumption and concurrent infection with HCV, HDV, or HIV (269, 270).

Although, intuitively, the conclusion that long-term viral suppression will prevent the development of cirrhosis remains unproven. However, two prospective studies of CHB patients achieving several years of sustained virologic suppression using either entecavir (ETV) or tenofovir have demonstrated regression of advanced fibrosis or cirrhosis (271, 272). Additionally, studies of the older antiviral drugs have shown improvement in histologic fibrosis scores (273).

### Hepatic Decompensation

Decompensated liver disease develops as a complication of cirrhosis. The estimated 5-year risk of progression in CHB to decompensation is 20 to 23% (274). Risk factors for decompensation include persistent viremia, age, and markers of impaired synthetic function (including low albumin, low platelets, high bilirubin, and ascites) (275–277). Once decompensation occurs, the estimated 5-year survival is 14 to 35%, compared to 80 to 85% for compensated patients. The advent of antiviral therapy has had a dramatic impact on this natural history, again emphasizing the critical role viral replication plays in disease progression.

### Hepatocellular Carcinoma

Seropositivity for HBsAg is one of the most important risk factors for the development of HCC. The relative risk of developing HCC, if HBsAg-positive, has been found to vary from 7-fold in Japan to 60- to 98-fold in Taiwan, likely varying with the population attributable risks of 10% and 94%, respectively (278, 279). More important for clinical practice is population stratification for individual patients with CHB.

HBV viral load has a profound impact on the development of HCC (Table 2 and Fig 8B), and a biological gradient of risk has been seen according to HBV viral load (4). The cumulative incidence of HCC over 13 years of follow-up was 1.3 versus 14.9 percent for baseline HBV DNA levels of  $< 300$  and  $> 10^6$  copies/ml ( $< 60$  and  $> 200,000$  IU/ml), respectively. The impact of persistent viremia was assessed by measuring viral load at last follow-up (the median time between samples was 10 years). Individuals were at highest risk if the viral load was  $> 10^5$  copies/ml ( $> 20,000$  IU/ml) both at baseline and follow-up. Conversely, a significant reduction in HCC risk was observed in those who had a high entry viral load at baseline, but in whom viral load was significantly reduced at follow-up. Of known covariates, cirrhosis at baseline, male sex, older age, alcohol consumption, and HBeAg-positivity were identified as independent risk factors. The presence of baseline cirrhosis was associated with the highest hazard ratio (HR) for development of HCC (HR 9.1, 95% CI 5.9–13.9).

The importance of viral load in hepatic carcinogenesis is further emphasized by the findings of an association between effective viral suppression using NA and reduced risk of HCC over time. Importantly, all studies have shown that the HCC risk is not completely eliminated, especially in cirrhosis, and lifelong surveillance for HCC continues to be recommended. It should be noted that the most robust data are available only for Asian populations. There are no comparative studies in Caucasian or African patients.

The risk of HCC has been independently associated with HBsAg levels in the Risk Evaluation of Viral Load Elevation and Associated Liver Disease/Cancer-Hepatitis B Virus (REVEAL) cohort, particularly at levels  $> 1000$  IU/ml (248). A separate study, also performed in a large population from Taiwan, demonstrated a 13-fold increase in risk associated with HBsAg  $> 1000$  IU/ml in HBeAg-negative patients classified as inactive carriers (i.e., HBV viral load  $< 2000$  IU/ml) (5). This suggests a clinical use for quantitative HBsAg measurement with regards to HCC risk stratification. The applicability of these results to Western populations is again uncertain.

Asian studies have identified viral factors that are associated with the development of HCC. Genotype C is associated with increased risk compared to genotype B (248, 280, 281) and genotypes A and D (282). Mutations in the viral genome have also been linked to hepatic carcinogenesis, in particular those located in the BCP and Pre-S regions (283). Of these, BCP mutations are the most strongly associated, conveying an almost 4-fold increase in HCC risk compared to wild type virus (17, 283). Interestingly, no increase in risk has been associated with precore mutant virus (283).

### Extrahepatic Manifestations

Chronic HBV infection is associated with several extrahepatic manifestations that are thought to be mediated by circulating immune complexes. These include the serum sickness-like prodrome of acute HBV infection, polyarteritis nodosa, HBV-associated glomerulonephritis, mixed essential cryoglobulinemia, and neurological manifestations (284).

A serum sickness-like prodrome precedes clinical hepatitis by 1 to 6 weeks in 10 to 30% of those acquiring acute HBV infection. Also known as the “arthritis-dermatitis” syndrome, it is characterized by a symmetrical generalized inflammatory arthritis, typically involving the small joints of the hands and feet, which may be indistinguishable from acute rheumatoid arthritis. The joint lesions are nondestructive, however. Skin manifestations are variable, occurring in more than 50% at the time of, or shortly after, the joint symptoms. Lesions described include maculopapular, petechial or purpuric rash, palpable purpura, Henoch-Schönlein-type purpura, erythema multiforme, toxic erythema, lichenoid dermatitis, and urticaria. Fever is common. Renal involvement with proteinuria or hematuria is much less common. Angioneurotic edema may rarely occur.

Polyarteritis nodosa (PAN) is a rare but serious complication of chronic HBV infection. The syndrome normally presents within 4 months of the clinical onset of HBV infection, with abdominal pain due to arteritis of medium-sized vessels causing ischemia of the intestine and gallbladder. The finding of microaneurysms of blood vessels in the renal, hepatic, or mesenteric circulations on angiography is virtually pathognomonic. Tissue biopsy of affected organs revealing inflammation of the medium-sized arteries confirms the diagnosis. Treatment involves antiviral therapy, immunosuppression, and plasma exchange. The prognosis is poor without treatment, with a mortality of up to 50%.

Glomerulonephritis (GN) is more commonly associated with CHB. The most common presentation is nephrotic syndrome. A number of patterns of glomerular injury have been described, including membranoproliferative GN, membranous GN, and rarely mesangial proliferative GN. In children the disease is usually self-limited; however, in adults, progression to renal failure has been described.

Other manifestations of HBV-related vasculitis include mononeuritis multiplex and polyneuropathy. Guillain-Barré syndrome has been reported. Associations with polymyalgia rheumatica, polymyositis, and HLA-B27-positive ankylosing spondylitis have also been reported, although a causative link remains controversial.

### Occult HBV Infection (OBI)

Of patients who have achieved HBsAg loss or seroconversion, following either acute or chronic HBV infection, an unknown proportion will have detectable HBV DNA in the liver. In this situation, viral DNA may or may not be detectable in the serum (285). When detectable, the serum viral load is low (often <200 IU/ml). This distinguishes true OBI from “false OBI” where the viral load is high but HBsAg is negative, an uncommon situation that is due to viral variants that produce an antigenically modified HBV S protein not detectable using commercial HBsAg assays, or carry mutations that inhibit S gene expression (286). Occult expression results from strong immune control of viral gene expression (287), and the molecular basis of OBI is related to long-lasting persistence of cccDNA within hepatocyte nuclei (288). The epidemiology of occult HBV remains poorly defined, but it has a worldwide incidence and appears to be more common in endemic areas, in the setting of coinfection with HCV and HIV, in patients with a history of injecting drug use, in hemophiliacs, and in patients on hemodialysis (286). It remains rare in developed countries.

Occult HBV carriers may be a source of HBV transmission in the case of blood donation (289), although the incidence of this has been reduced significantly due to the widespread adoption of nucleic acid testing of donations

rather than reliance on serologic markers (288). There is a risk of viral reactivation in OBI patients who are immunosuppressed (290, 291). OBI may be linked with the development of HCC. In one study of a cohort of 69 HCC patients, 75.5% of tumors from the OBI group (HBsAg negative, but HBV DNA detected in tumor tissue) had HBV DNA integrated into host chromosomes (292). This was comparable to the 80% of HBsAg positive groups and in contrast to 0% of the controls. A similar association was found in patients classified as having a cryptogenic cause of HCC (293). OBI might also be a cofactor in the development of HCV-related HCC (294).

### LABORATORY DIAGNOSIS

HBV infection is usually diagnosed by serological assays to detect specific antigens (HBsAg, HBcAg, and HBeAg) and corresponding antibodies (anti-HBs, anti-HBc, and anti-HBe). The assays for serum HBsAg and its resultant antibody are critically important because the persistence of HBsAg for longer than 6 months defines chronic infection, and the presence of anti-HBs indicates disease resolution or immunity after vaccination. Beyond diagnosis, novel quantitative assays for HBeAg and HBsAg and ultrasensitive assays for anti-HBe and anti-HBs are providing new insights into the dynamics of humoral immunity in the setting of CHB. The quantification of HBV DNA has recently become a primary tool in the management of CHB. Data are emerging on the relationship between the magnitude of HBV DNA load and the relative risk of developing liver disease (3, 4). Consequently, HBV DNA now plays a central role in defining antiviral treatment eligibility and efficacy. The development of resistance can also be identified by an increase in the level of HBV DNA, generally considered to be a greater than one log<sub>10</sub> increase from nadir in an adherent patient (295). Recent advances in molecular diagnostics allow analysis of intrahepatic HBV replicative intermediates, such that comparison of the peripheral serum compartment to the liver compartment is possible.

### Serological Markers of Infection

#### Acute Hepatitis B

Of the serological markers associated with acute infection (Table 3), HBsAg is typically the first to become detectable (296). It appears early, usually some 6 to 12 weeks after exposure, and is present before the onset of symptoms. HBeAg appears soon after HBsAg and is a useful marker of replication activity. As the antigen titers peak, the serum alanine aminotransferase (ALT) levels begin to rise and symptoms first become apparent. Antibodies to the antigens begin to appear during this symptomatic phase. The first antibody raised is IgM directed against the core antigen, anti-HBc IgM (296). In combination with the presence of HBsAg, anti-HBc IgM is the best indicator of acute infection. Anti-HBc IgM peaks in early convalescence before gradually declining over 3 to 12 months, irrespective of whether or not the disease becomes self-limiting or progresses to chronic disease. As the HBc IgM titer falls, a corresponding increase in titer of anti-HBc IgG occurs, which typically remains detectable for life (296). Anti-HBe is either detected concurrently with, or soon after, the appearance of anti-HBc IgM, and its appearance is associated with the rapid clearance of HBeAg. The seroconversion of HBeAg to anti-HBe coincides with a dramatic increase in ALT, reflecting the increased immune-mediated lysis of

**TABLE 3** Profile of the serological markers for hepatitis B virus infection

	Incubation Period	Acute Hepatitis	Recovery Period	Immunity	Vaccine Immunity	Chronic Infection	Occult Infection
HBsAg	±	+	±	-	-	+	-
Anti-HBs	-	-	-	+	+	-	±
HBeAg	±	-	-	-	-	±	-
Anti-HBe	-	+	+	+	-	±	±
Anti-HBc IgM	-	±	-	-	-	-	-
Anti-HBc total	-	±	+	+	-	+	±

infected hepatocytes (297). Often anti-HBe will persist for years, but in the absence of any active viral replication, the titer declines. Finally, anti-HBs appears, although it may not be detectable for 3 to 6 months. Anti-HBs is the neutralizing antibody and a marker of disease resolution. In some patients, there may be a “window period” when HBsAg cannot be detected and anti-HBs has not yet appeared; however, anti-HBc IgM is usually found at this time. Anti-HBs is also the marker for confirming successful vaccination, should be the only hepatitis B antibody found (Table 3), and provides protective immunity.

There is no major role for the detection of HBV DNA for the diagnosis of acute infection, as the “window period” is typically asymptomatic and patients will not present for clinical testing. The use of DNA amplification techniques, such as the polymerase chain reaction (PCR), allows detection of HBV DNA in the serum a few weeks after infection, but there is little advantage over the newer, more sensitive HBsAg detection assays (70, 298, 299).

### Chronic Hepatitis B

The persistence of high levels of HBsAg for >6 months following acute hepatitis indicates the development of chronic infection (Table 3) (211). The serological profile correlates with acute infection, but as the levels of ALT and anti-HBc IgM decline, HBsAg remains. In the early stages of chronic infection, ongoing replication is indicated by the presence of HBsAg, HBeAg, and HBV DNA. The antibody response consists mostly of anti-HBc IgG, measured as total anti-HBc, with minimal contribution from anti-HBc IgM. HBeAg titers may decline over time, with eventual seroconversion of HBeAg to anti-HBe. High levels of secreted HBe protein are found in the so-called tolerant phase of chronic infection and are associated with very high viral loads and near-normal liver histology. Hepatic flares, produced as a consequence of heightened immune reactivity to virus-infected hepatocytes, usually accompany elimination of HBeAg. The viral load drops significantly during these flares, presumably as a consequence of the antiviral activity of the host's immune response.

This HBeAg seroconversion occurs at a rate of 5 to 20% per year in adults, and the flare in disease activity at this time is known as the seroconversion illness. A number of abortive flares of active hepatitis may occur over several years before final anti-HBe seroconversion. In most cases, the loss of HBeAg is associated with a decrease in circulating levels of HBV DNA (which may become undetectable), normalization of ALT levels, and a significant clinical improvement despite the lasting presence of HBsAg. It is increasingly recognized, however, that HBV DNA may remain detectable, and disease progresses as HBeAg-negative CHB.

### Viral Load Assays

HBV DNA detection and quantification is a key prognostic marker and, as such, provides an important parameter for determining eligibility for antiviral therapy. Serial viral load measurements are now the standard of care for monitoring patients on therapy, both for efficacy and the development of drug resistance. Additionally, mathematical modeling of the kinetics of the decline in viral load has allowed the efficacy of antiviral drugs to be compared and the potential additive or synergistic effects of drug combinations to be examined (300, 301). Current commercial assays utilize real-time PCR, with wider dynamic ranges and lower limits of detection, that overcome problems with quality control, lack of standardization, and limitations in sensitivity of prior assays.

### Quantitative HBsAg Assays

First described in 2004, a number of commercially available ELISA assays are available for quantitative HBsAg titer (302–307). HBsAg assays detect virion-associated envelope protein as well as subviral particles. HBsAg levels may therefore reflect hepatocyte cccDNA level and cccDNA transcriptional activity, as well as integrated HBV sequence meaning that the clinical utility of measuring HBsAg levels may relate to a semi-quantitative measure of overall liver “HBV load” (308). During the natural history of hepatitis B, HBsAg level is highest during the immune-tolerant phase and declines through the immune-clearance and immune-control phases (309). In this context, HBsAg level has been evaluated as a biomarker for the natural history of disease, with a specific focus on risk of disease progression.

The level of HBsAg may differentiate the risk of immune escape among patients in the immune-control phase of CHB. In one cohort of 209 genotype-D patients with inactive hepatitis B (310), a combination of HBsAg less than 1000 IU/ml and HBV DNA less than 2000 IU/ml predicted maintenance of an inactive carrier state at 3 years with an 87.9% positive predictive value. This finding has been validated in a Taiwanese study of genotype-B and -C patients (311).

Low levels of HBsAg in the immune-control phase of CHB have also been linked to likelihood of HBsAg seroclearance. The Elucidation of Risk Factors for Disease Control or Advancement in Taiwanese Hepatitis B Carriers (ERADICATE-B) study identified HBsAg levels that strongly predicted HBsAg loss over time (312). Among 688 HBeAg-negative patients, with an HBV DNA less than 2000 IU/ml at baseline, HBsAg clearance occurred at a rate of 1.6% per year. An HBsAg level of less than 10 IU/ml was associated with an annual clearance rate of 7%, 13.2 times that of patients with a baseline HBsAg over 10,000 IU/ml.

HBsAg levels were more useful for predicting long-term HBsAg seroclearance than were HBV DNA levels.

HBsAg levels have been associated with risk of HCC development. Data from 3411 HBV carriers in the REVEAL study showed that both HBsAg and HBV-DNA levels were independent predictors of HCC development. The multivariate-adjusted hazards ratio for HCC development increased from 1.0 (reference) for serum levels of HBV-DNA/HBsAg of <2000/<100 IU/ml to 9.22 (95% CI: 4.34–19.58) for serum levels of HBV-DNA/HBsAg of  $\geq 2000/\geq 100$  IU/ml (313). Among 2688 noncirrhotic CHB individuals, followed for a mean of 14.7 years, the independent predictors of HCC risk were HBV DNA level (HR: 4.7; 95% CI: 2.2–10.0), increased quantitative HBsAg (HR: 7.2; 95% CI: 1.8–28.6), and elevated ALT level (HR: 6.6; 95% CI: 2.2–19.8) (311). HBsAg levels were most useful in patients with an HBV-DNA level <2000 IU/ml; the risk of HCC for individuals with HBV DNA <2000 IU/ml and HBsAg  $\geq 1000$  IU/ml was much higher than those with HBV-DNA <2000 IU/ml and HBsAg <1000 IU/ml (HR: 13.7; 95% CI: 4.8–39.3) (311).

HBsAg levels have also been proposed as a biomarker for responsiveness to peginterferon treatment (see the Treatment section). The value of HBsAg levels for decision-making in the context of peginterferon therapy has recently been acknowledged in clinical guidelines (314).

### Novel Diagnostic Tests

#### Quantitative HBeAg Assays

One of the drawbacks to measuring intrahepatic HBV intermediates is the requirement to use liver tissue. However, a correlation exists between the levels of circulating HBsAg and the levels of intrahepatic HBV cccDNA (315). Sensitive quantitative assays for HBsAg, as well as HBeAg, have been developed to study CHB patients (302,316–318), and much more relevant data can be obtained than is suggested by standard qualitative serology. The use of these assays may allow fine-tuning of treatment protocols, particularly with regard to interferon-based therapy (see below).

The therapeutic endpoint for HBeAg-positive CHB is HBeAg seroconversion. A potential role for quantitative HBeAg titer in guiding management algorithms is emerging. A large study using pegylated interferon- $\alpha$  for the treatment of HBeAg-positive CHB found that seroconversion was more likely to occur in the setting of a low HBeAg titer pretreatment, or if there was a rapid decline of HBeAg titer on therapy pretreatment (319). Conversely, the failure of HBeAg levels to fall on treatment predicted nonresponse. In this study the predictive power of HBeAg titer was greater than for HBV viral load, measured using a sensitive PCR assay. Beyond interferon-based therapy, there may be a particular application of HBeAg titer during nucleos(t)ide analogue (NA) therapy, both for predicting seroconversion early, as well as for monitoring patient response. NA therapy rapidly suppresses HBV viral load to undetectable levels, decreasing the utility of HBV DNA as a monitoring tool for HBeAg seroconversion. HBeAg titer has been shown to predict both seroconversion and nonresponse during LMV therapy (316, 317,320–324). In one study HBeAg titer was also observed to predict LMV resistance prior to virological breakthrough (322). The clinical utility of quantitative HBeAg measurements may be greatest when used in conjunction with virological sequencing of the HBV precore/basal core promoter region. Both basal core promoter and precore variants, which occur as quasispecies in HBeAg-

positive CHB, are associated with lower HBeAg titer, and stratification according to the dominant virus may be useful. Quantitative HBeAg serology remains a research tool, however, modeled after the method of Perrillo et al. (320), with the level expressed by establishing a standard curve using the Paul Ehrlich HBeAg reference standard.

#### Assays for Intrahepatic HBV Replicative Intermediates

Assays to quantify the various intrahepatic HBV replicative forms, in particular the HBV cccDNA, total intrahepatic HBV DNA (RC DNA), and pregenomic RNA (pgRNA), could provide insights into the natural history of HBV infection and therapeutic response.

Patients with HBeAg-negative CHB have lower levels of cccDNA than their HBeAg-positive counterparts (303, 304, 325, 326). Further, virion productivity, defined as the ratio of RC DNA to cccDNA, is reduced in HBeAg-negative CHB (Fig 7). This reduced replicative activity is associated with lower levels of pgRNA, implying transcriptional downregulation. In the context of antiviral therapy, preliminary data suggest that cccDNA level pretreatment may predict antiviral response and that significant decline of cccDNA to low end-of-treatment levels may predict durable off-treatment viral suppression, indicating clearance of infected cells (327, 328).

Eradication of HBV cccDNA may not be necessary to control chronic hepatitis B if its replicative activity, as measured by the pgRNA level, is low or quiescent. At present these assays remain in the research domain.

#### Hepatitis B Core-Related Antigens (HBcrAg)

In an effort to design a simple monitoring tool for patients on antiviral therapy for HBV, a sensitive enzyme immunoassay was developed to detect hepatitis B core-related antigens (HBcrAg) (329), defined as the protein products of precore/core transcription, namely HBeAg and HBcAg. The HBcrAg assay correlates with serum HBV viral load (329, 330). Using this investigative assay, the levels of HBcrAg correlate with viral intrahepatic replicative intermediates (331, 332). If further validated, the HBcrAg assay may provide a simple tool to monitor the level of viral replication in the liver without the need for a liver biopsy.

#### Ultrasensitive Immunoassays for Anti-HBs and Anti-HBe

The presence of large amounts of HBsAg and HBeAg in the serum may affect the ability to detect circulating antibodies and may obscure the onset of seroconversion. The available commercial assays usually detect anti-HBs and anti-HBe antibodies only after the respective antigens have been cleared from the serum. More sensitive immunoassays can detect antibody in the presence of excess serum antigen (333). Such approaches identified serological responses in the context of active viral replication. For example, all patients with “active” CHB and the majority of patients with immunotolerant CHB demonstrate ongoing humoral immune responses, including anti-HBe and anti-surface antibody (anti-HBs) production. In fact, anti-HBe seroconversion can occur many years (up to 6 years) before the actual loss of HBeAg or onset of liver injury. Similarly, anti-HBs may coexist with virions and subviral HBsAg particles for many years before viral clearance and loss of HBsAg. A small study utilizing a novel assay to detect HBsAg/anti-HBs complexes demonstrates this coexistence and a possible use

in predicting on-treatment response (334). The concept of a relatively nonoverlapping seroconversion from HBeAg-positive to anti-HBe positive status during CHB may need reconsideration (Fig 7).

### HBV RNA Assays

It has been known for some time that HBV RNA is found in the circulation of CHB patients (335). How RNA enters the serum compartment, and its biologic function, if any, is unknown. The utility of HBV-RNA measurement as a predictive tool for HBeAg seroconversion while the patient is on nucleos(t)ide therapy was recently examined by designing a specific real-time PCR assay, which used rapid amplification of complementary DNA techniques (336). Both full-length, polyadenylated RNA, as well as a truncated form, were detected. This study showed that reductions in RNA levels at 6 months on the order of  $1.8 \pm 1.4 \log_{10}$  copies/ml and  $3.1 \pm 1.7 \log_{10}$  copies/ml for the full-length and truncated forms, respectively, were predictive of HBeAg seroconversion after 24 months of NA treatment (336). While clearly in the preliminary stages of investigation and validation, this novel assay shows promise in identifying those who may achieve HBeAg seroconversion.

## PREVENTION

Effective strategies for the prevention of HBV infection include 1) the avoidance of high-risk behavior and the prevention of exposure to blood or bodily fluids; 2) active immunization with the hepatitis B vaccine; 3) active-passive immunization with vaccine and hepatitis B immunoglobulin after a suspected high-risk exposure; and 4) nucleos(t)ide therapy for expectant mothers to reduce perinatal transmission rates (discussed previously).

The global HIV epidemic has led to widespread education campaigns directed at decreasing the transmission of bloodborne viruses, including HBV, HCV, and HIV. Changes in sexual practice, the increased use of condoms, and needle-exchange programs all appear to have reduced the incidence of HBV infection. The screening of blood and blood products has led to a dramatic decline in transfusion-acquired HBV infection. The improved disposal of needles and other sharp objects in the hospital setting, as well as the advent of new devices designed to decrease inadvertent needlestick injury, have reduced occupational exposures. Unfortunately, such primary preventative measures are likely to be less effective in countries with a high prevalence of disease, where perinatal or early horizontal infection is common. In these areas, immunoprophylaxis, both passive and active, is the most effective strategy.

### Immunization

WHO has recommended that all countries provide universal HBV vaccination programs for infants and adolescents, with appropriate catch-up programs (211). In addition, persons at high risk should be targeted (including persons at occupational risk, institutionalized persons, dialysis patients, recipients of blood products, household members, and sexual partners of CHB patients, travelers to endemic areas, persons who have more than 1 sexual partner in a 6-month period, men who have sex with men, injecting drug users, and prisoners) (337). Prevacination testing is not cost-effective in low prevalence areas and is only useful in adults from endemic areas to identify those who are either infected or immune and therefore do not require vaccination.

Effective hepatitis B vaccines have been available since 1981. Multiple formulations are now licensed, as either a monovalent vaccine or in fixed combination with other vaccines (including hepatitis A, *Haemophilus influenzae*, diphtheria, tetanus, pertussis, and poliomyelitis). All licensed hepatitis B vaccines are recombinant and are typically made by incorporating the SHBs gene of HBV into the yeast expression vector *Saccharomyces cerevisiae* to generate recombinant HBsAg. They therefore contain the S epitope (the major antigenic determinant or “a” determinant), but not the Pre-S1 or Pre-S2 epitopes. Plasma-derived vaccines are no longer used or recommended. Third-generation recombinant vaccines containing 2 or 3 surface epitopes (S, Pre-S2 ± Pre-S1) have been generated from animal cell lines. They may provide enhanced immunogenicity and therefore a strategy in nonresponders to the standard recombinant yeast-derived vaccine (49, 338, 339). Currently licensed vaccines are, however, very effective at raising protective humoral immunity directed against the HBsAg (337). A new HBV vaccine utilizing a TLR-9 agonist as the adjuvant has been shown to have noninferiority to currently approved vaccine formulations with the requirement for fewer doses (340, 341). A larger phase III study is being conducted to satisfy USA FDA requirements for registration (NCT02117934).

The standard vaccination schedule consists of three doses of vaccine, given intramuscularly, of 10 to 20 µg in adults and 5 to 10 µg in children. The second dose is given 1 month after the first dose and the third, 6 months after the first dose. It is not necessary to restart the series if there have been prolonged intervals between doses. The complete vaccine series induces protective antibody levels in >95% of infants, children and adolescents (337). The efficacy of the vaccine is almost 100% in immunocompetent people who develop antibody levels of >10 IU/ml. The response declines with increasing age beyond 30 years; protection falls to 90% by the age of 40 years, and, by 60 years, protective antibody levels are achieved in only 65 to 75%. Risk factors for nonresponse include obesity and immunodeficiency.

Postvaccination testing is only recommended in the following groups: infants born to HBV-infected mothers, the immunocompromised (including dialysis and HIV patients), healthcare workers and other persons at occupational risk of exposure, and sexual partners of HBV-infected persons. Nonresponse is defined as the failure to mount an anti-HBs response >10 IU/ml 1 to 6 months after the third dose of vaccine. In nonresponders, 25 to 50% of immunocompetent adults will respond to one additional dose of vaccine. For individuals who remain seronegative after this booster dose, a second series (three additional doses) of the double-dose vaccine should be given; 50 to 60% will seroconvert (342). Those remaining seronegative are likely to be true nonresponders.

The duration of protection is at least 15 years (343, 344). Even if anti-HBs titers decline to become undetectable, anamnestic response appears to persist, providing protective immunity. A small number of high-risk individuals in whom protective antibody titers have been lost develop markers of HBV infection (anti-HBc). However, in most the infections were asymptomatic and detected by regular blood monitoring in the setting of clinical trials. Routine testing postvaccination and routine booster vaccination is therefore not recommended. Additional information is still needed to establish the need for a booster beyond 15 years after immunization in those who are at high risk for exposure (e.g., health care workers). Boosters may be considered to provide reassurance of protective immunity in these special groups (345).

The hepatitis B vaccine is very safe. Anaphylaxis is rare and is the only serious adverse effect that has been documented. There are no data to support a link with demyelinating disorders, Guillain-Barré syndrome, chronic fatigue syndrome, sudden infant death syndrome, lupus erythematosus, or other disorders (337).

### Impact of Vaccination on Transmission

Active-passive immunization was shown in the mid 1980s to prevent >95% of perinatal transmission (346, 347). Taiwan was the first country to introduce universal neonatal vaccination in 1986. Since the program began, the prevalence of HBsAg in children under 5 years of age has decreased from 9.3% in 1984 to 0.5% in 2004 (344). This suggests not only protection of those vaccinated but also prevention of horizontal transmission. Subsequently the incidence of both fulminant hepatitis (348) and HCC in children has declined sharply (349).

### Postexposure Prophylaxis

Passive immunization with hepatitis B immunoglobulin (HBIG) provides temporary immunity against HBV infection in those who are not immune. The most common indication for use is for postexposure prophylaxis. Postexposure prophylaxis is the standard of care for all nonvaccinated individuals exposed to infectious blood or bodily fluids, including infants born to HBsAg-positive mothers, and following percutaneous (e.g., needlestick), mucosal, or sexual exposure to HBV. The first dose of HBV vaccination is given within 12 hours of exposure, followed by second and third doses at 1 and 6 months respectively. HBIG (0.06 ml/kg intramuscular) should be administered with the first dose of vaccine and can be repeated at 1 month if there has been no response to the vaccine. Vaccinated individuals with documented response do not require prophylaxis.

## MANAGEMENT OF HBV INFECTION

### Acute Hepatitis B

Acute hepatitis B (AHB) is a spontaneously resolving infection in the majority of cases in immunocompetent adults. Antiviral therapy is not generally indicated unless fulminant disease is present. Care, in the absence of fulminant disease, is supportive, with the provision of adequate nutrition and hydration and the avoidance of hepatotoxic drugs, such as acetaminophen. However, there has been some interest in whether NA therapy would benefit patients with severe AHB. LMV use in patients presenting to a transplant center with severe AHB, defined by an INR >2.0, significantly improved mortality compared to a historical control; 14 of 17 patients (82.4%) survived with full recovery without liver transplantation compared to a historical cohort in which the survival without liver transplantation was 20% (4/20) (350). In contrast, a randomized controlled trial in India failed to demonstrate a benefit of LMV therapy in severe AHB defined by two of three criteria (hepatic encephalopathy; serum bilirubin  $\geq 10.0$  mg/dL [171  $\mu$ mol/l] and/or [4] INR  $\geq 1.6$ ) (351), although no patient in this study required liver transplantation. Given the limitations of current data, a trial of NA therapy may be reasonable in fulminant HBV with coagulopathy and elevated INR; the risk of resistance associated with long-term LMV would generally favor ETV or TDF. There have been case reports of lactic acidosis associated with ETV used for fulminant hepatitis B infection, but these reports do not prove causality (352).

## Chronic Hepatitis B

### Principles of Management

The aim of treatment for CHB is the prevention of clinical complications including decompensated liver disease and hepatocellular carcinoma. The prevention of these clinical end points may be achieved by durable suppression of HBV replication (353–358). As clinical end points may take years to eventuate, sustained virological response (SVR) has been adopted as the goal of therapy both in clinical trials and day-to-day practice (230, 359). SVR is defined as a decrease in serum HBV DNA to undetectable levels by PCR assays, with loss of HBeAg in patients who were initially HBeAg-positive (230). HBeAg seroconversion, in the context of HBeAg positive disease, has been shown to correlate with sustained viral suppression and clinical benefit, particularly in patients treated with pegIFN, and is therefore an end point for therapy (360). The end point for therapy in the setting of HBeAg-negative CHB is HBsAg loss (230, 314).

### Indications for Therapy

Candidates for antiviral therapy can be classified into three groups: HBeAg-positive CHB, HBeAg-negative CHB, and patients with advanced fibrosis/cirrhosis (who may be either HBeAg positive or negative). The clinical utility of this approach is based on the expected differences in the duration of therapy that will be required for these groups.

#### HBeAg-Positive CHB

The traditional clinical end point of therapy in HBeAg-positive CHB is HBeAg seroconversion. It is therefore reasonable to offer a trial of therapy to all patients with active disease, defined by a viral load >20,000 IU/ml and either raised ALT >2x the upper limit of normal (ULN) or moderate to severe inflammation on liver biopsy. In patients with an ALT <2x ULN, in the presence of viral replication, the decision whether to commence therapy is influenced by the severity of both inflammation and fibrosis on liver biopsy. Most professional bodies recommend a trial of observation for 3 to 6 months to allow for spontaneous seroconversion before initiating therapy (230, 314, 361). The options for therapy include interferon-based therapy or any of the recommended NA (Table 4A). HBeAg seroconversion is durable following peginterferon therapy, but it may be less durable following withdrawal of NA therapy (362). A period of consolidation therapy with NA for at least 12 months following seroconversion is recommended, and patients must be followed for reactivation.

#### HBeAg-Negative CHB

The only agreed end point of therapy for patients with HBeAg-negative CHB is HBsAg loss. Sustained virologic response may be achieved in a small percentage of patients using interferon-based therapy; however, it is likely that most patients will require prolonged therapy with a NA. Treatment decisions must therefore weigh the risk of future complications against the long-term financial costs and risk of antiviral resistance. Liver biopsy is useful in decision-making, as the presence of significant fibrosis should trigger consideration of therapy. Treatment is reasonable in patients with a viral load >2,000 IU/ml and evidence of moderate/severe inflammation or significant fibrosis (230). In patients with mild fibrosis and inflammation but ongoing replication, there are no data to determine whether the risk of long-term antiviral resistance outweighs the benefit of initial viral suppression (Table 4B).

**Cirrhosis**

Sustained viral suppression improves clinical outcomes in the setting of CHB and advanced liver disease, in particular, reducing the risk of HCC (353, 363). Long-term NA therapy would normally be recommended. It is critical that these patients be monitored closely both for initial virological response and, subsequently, for the development of antiviral resistance, to allow institution of salvage therapy before the serum ALT becomes elevated. Patients with compensated cirrhosis and HBeAg-positive CHB can be considered for pegylated-interferon with close monitoring for a hepatitis flare and long-term monitoring for virological relapse (364). Patients with decompensated liver disease should not receive interferon-based therapy because a hepatitis flare in

this setting is associated with a high chance of mortality; rather, long-term NA therapy and referral to a transplant center is indicated.

**Treatment of Special Populations**

**HIV-HBV Coinfection**

Since antiretroviral therapy is recommended for all HIV-infected patients, HBV-coinfected patients need to be identified and treated with a regimen effective for both viruses, with TDF and emtricitabine (FTC) being the favored combination (365). In the rare coinfecting patients declining antiretroviral therapy, HBV therapy should be based on agents that will not select for HIV drug resistance.

ETV is now recognized to have anti-HIV activity and is associated with the accumulation of HIV-type 1 variants with the LMV resistance mutation M184V (366). Therapeutic options therefore include adefovir dipivoxil (ADV) (10 mg) daily or pegIFN. Although Telbivudine (LdT) does not target HIV, its use as monotherapy is not recommended because of the risk of selection of the M204I mutation in the YMDD motif.

The hepatitis B vaccine should be given to all HIV-positive persons who are negative for HBV seromarkers. The vaccine should be given when CD4 cell counts are  $\geq 200$  cells/ $\mu$ l, as response is poor below this level. Persons with CD4 counts below 200 cells/ $\mu$ l should defer HBV vaccination until antiretroviral therapy has reconstituted CD4 counts above this threshold.

### Pregnancy

The introduction of active-passive immunization of infants born to HBV-infected mothers has significantly reduced the rate of perinatal transmission where this therapy is available (367). However, even with timely administration, highly viremic mothers ( $\geq 6 \log_{10}$  copies/ml) retain a  $> 10\%$  transmission rate to their newborns (368). Therefore, this group of patients will benefit from NA therapy to reduce viral load, in order to augment the efficacy of immunization. A meta-analysis of ten randomized, controlled trials of active-passive immunization, with or without LMV, examined outcomes for over 450 patients. Nine studies commenced therapy at 28 weeks of gestation, whereas one study commenced at 32 weeks. The pooled odds ratio (OR) for infant infection, as determined by HBsAg positivity at 9 to 12 months of age, was 0.31 (CI: 0.15–0.63) favoring LMV (369). A second meta-analysis of six studies examining the use of LdT in similar settings again strongly favored its use with a pooled OR of 0.11 (CI: 0.04–0.31) (370). A recent prospective, open-label, case-control study from China (371) on 362 LdT-treated pregnant women (either second or third trimester) found no cases of vertical transmission, as opposed to a 9.3% transmission rate in the 92 controls ( $P < 0.001$ ) (371). No obstetric complications or congenital malformations were reported.

TDF is the preferred agent in pregnancy and has been recommended in major society clinical practice guidelines to treat this population, given its high potency and ability to rapidly reduce viral load with a shorter duration of therapy (314, 361). To investigate this, a recent Australian “opt-in” prospective study examined the use of TDF as compared with LMV and placebo in pregnant patients with high viral load (372). The patients were predominantly of Asian ethnicity (88.5%), and those who elected to be treated commenced therapy in the third trimester. All infants received active-passive immunization at birth. Significantly more patients achieved a viral load  $< 6 \log_{10}$  copies/ml in the TDF group when compared to LMV (18% vs. 3%,  $P = 0.01$ ). Despite this difference, the rate of perinatal transmission was similar between the two groups (2% TDF vs. 0% LMV) but significantly better than the untreated group (20% transmission rate) (372). The USA FDA classifies both LdT and TDF as pregnancy category B drugs (no congenital risk in animal studies, but unknown data in humans), whereas LMV, ADV, and ETV are category C (teratogenic in animals, but unknown in humans). Therefore, either LdT or TDF are drugs of choice. However, more long-term data on the safety of TDF are currently available from its use in the HIV population. The Antiretroviral Pregnancy Registry has reported data on 2,330 live births having had TDF exposure

during the pregnancy. A congenital malformation rate of 2.3% was found in infants delivered to these mothers, which is equivalent to the baseline general population rate (373).

An issue that arises in patients who started antiviral therapy before parturition is when or if to stop treatment. Typically, given prescribing restrictions, these patients would not otherwise have been eligible for treatment and therefore are unlikely to qualify for ongoing prescription. A concern with ceasing therapy soon after delivery is the risk of a postpartum flare of hepatitis, due to a combination of increased viral replication and immune reconstitution in the puerperium. One small study has shown, however, that extending the duration of NA therapy beyond delivery does not abrogate the risk of flare (374). Further studies will be required to shed light on this area of management.

### Immunosuppression

Immunosuppression is a unique situation in which antiviral therapy is indicated for HBV. Reactivation of HBV replication with increase in ALT levels has been reported in 20 to 50% of HBsAg-positive patients undergoing immunosuppression or cancer chemotherapy (375–377). Such patients often have a complex quasispecies mix that harbors mutations in the major hydrophilic region, thus making immune escape more likely (378). The risk is especially high in patients undergoing hematopoietic stem cell or solid organ transplantation or with treatment with the anti-CD20 monoclonal antibody therapies rituximab and ofatumumab, particularly in nonHodgkin lymphoma patients (212, 379–381). There are also reports of reactivation following transarterial chemo-embolization for HCC and anti-TNF therapies for inflammatory bowel disease and rheumatoid arthritis (377, 382, 383). Although most cases are asymptomatic, icteric flares, hepatic decompensation, and death have all been reported. Patients with a high pretreatment viral load, defined by HBeAg-positivity or HBV DNA  $> 60,000$  IU/ml, are at higher risk of reactivation. The degree of risk can be estimated by combining the degree of immunosuppression expected from the treatment regimen with the patient’s serology (Table 5) (213). Therefore, all patients who are to undergo an immunosuppressive treatment regimen should have serology for HBV assessed, including a

**TABLE 5** Estimated risk of HBV reactivation based on serologic profile and type of therapeutic immunosuppression

	HBsAg-Positive	HBsAg-Negative/ Anti-HBc Positive
Anti-CD20	30–60%	$> 10\%$
Anthracyclines	15–30%	1–10%
Corticosteroids ( $\geq 4$ weeks & $\geq 10$ mg)	$> 10\%$	1–10%
TNF $\alpha$ inhibitors	1–10%	1%
Other cytokine/integrin inhibitors <sup>a</sup>	1–10%	1%
Tyrosine kinase inhibitors	1–10%	1%

<sup>a</sup>Abatacept, ustekinumab, natalizumab, vedolizumab.

<sup>b</sup>Azathioprine, 6-mercaptopurine, methotrexate. High risk group  $> 10\%$ ; moderate risk group 1–10%; low risk group  $< 1\%$ .

HBV DNA if HBsAg-negative/anti-HBc positive. All non-immune individuals should be vaccinated.

Prophylactic therapy with LMV reduces the rate of HBV reactivation, severity of associated hepatitis, and mortality (377,384–387). HBsAg-positive patients with baseline viral loads less than 2,000 IU/ml should be started on LMV at the onset of immunosuppression. Patients with baseline HBV DNA levels >2,000 IU/ml should continue antiviral therapy until a therapeutic end point is reached, as viral relapse has been reported after withdrawal (388). In this setting, where therapy may be prolonged, a high potency NA may be more appropriate.

Patients who are HBsAg-negative and anti-HBc ± anti-HBs-positive (i.e., occult hepatitis B) remain at risk of reactivation of HBV when profoundly immunosuppressed. This is due to persistence of the cccDNA template. Reactivation is infrequent but seen primarily with anti-CD20 therapies. Use of these agents mandates prophylactic treatment (214). In other situations, it may be reasonable to monitor patients closely (every 1 to 3 months) and to initiate treatment when serum HBV DNA level becomes detectable, ideally before a hepatitis flare is diagnosed.

Therapy should be continued for at least 12 months after completion of chemotherapy (230, 314, 361). Even after cessation of successful NA prophylaxis, patients treated with anti-CD20 therapy may require longer term regular monitoring in case of delayed reactivation (389).

## ANTIVIRAL THERAPY

As highlighted previously, there are two classes of therapy currently available for the management of CHB:

- 1) Nucleos(t)ide analogues (NA)
- 2) Pegylated interferon- $\alpha$

### Nucleos(t)ide Analogues

The development of potent oral NA that are safe, well tolerated, and have a low risk of antiviral resistance represent a major therapeutic advance (Tables 5A and 5B). There are five NA currently approved for the management of CHB—LMV, LdT, ADV, ETV, and TDF—which belong to three separate drug classes. It is useful to consider these drugs within their class due to overlapping resistance profiles. The use of a sixth agent, FTC, is approved, in combination with TDF, only for HIV infection, but FTC has some efficacy in treating HBV. ETV and TDF are now considered first line agents for CHB due to their high potency and high genetic barrier to resistance.

The advantages of NA are ease of administration, rapid viral suppression, and a good safety profile. If SVR is maintained, then long-term therapy results in improved clinical outcomes. The major disadvantage is the requirement for prolonged therapy in the majority of patients, the potential for drug resistance, and the absence of robust safety data for these agents during conception and pregnancy. The latter point is especially important for younger patients in whom prolonged therapy may be required. NA are also the only therapeutic option for patients with decompensated liver disease before liver transplantation.

The HBV cccDNA pool provides a difficult obstacle for antiviral therapy to overcome. As HBV replication does not employ a semiconservative mechanism, any nucleos(t)ide analogue-based therapy can only indirectly affect the pre-existing cccDNA template. The likely reason for relapse, seen after completion of antiviral therapy for hepatitis B

infection, is the persistence of the HBV cccDNA, which can re-establish pretreatment replication levels.

## L-Nucleoside Analogues

### Lamivudine (LMV)

Lamivudine is the (-) enantiomer of 2', 3' dideoxy-3'-thiacytidine. It inhibits DNA synthesis by the incorporation of its active triphosphate site into the growing DNA chain, resulting in chain termination, and was the first agent to be approved for the treatment of CHB. Unfortunately, the use of LMV is frequently complicated by the emergence of drug resistance (see below). As a result, LMV monotherapy is no longer recommended for treatment naïve patients. For economic reasons, however, it is likely that widespread use will continue in the developing world.

LMV is not a potent inhibitor of HBV replication. Treatment results in a mean decline of serum HBV DNA of 4- to 5-log<sub>10</sub> copies/ml by 48 weeks. In HBeAg-positive patients, HBV DNA levels became undetectable in 40 to 44% by 48 to 52 weeks, 41 to 75% normalized ALT, and histological improvement was noted in 49 to 56% (compared to 23 to 25% of placebo controls). HBeAg seroconversion has occurred in 16 to 18% (compared to 4% to 6% of controls, respectively) (390–394). HBeAg seroconversion increases with prolonged duration of therapy up to 50% by 5 years (393–396). Not surprisingly, pretreatment ALT is the strongest predictor of response in HBeAg-positive patients—seroconversion was greatest in patients with baseline ALT >5 x the upper limit of normal (ULN) in clinical trials and progressively less frequent in patients with ALT levels 2 to 5 x ULN, 1 to 2 x ULN and normal ALT (47%, 21%, 9%, and 2%, respectively) (397, 398).

Following treatment withdrawal, HBeAg seroconversion was demonstrated to be durable in 50 to 80% of patients in clinical trials, but real-world studies suggest that durability is much lower, with relapse eventually occurring in the majority of patients (362, 399, 400). If LMV is used, it is recommended that therapy be continued for at least 12 months after seroconversion to minimize the risk of viral reactivation following treatment withdrawal (401). LMV is also partially effective in HBeAg-negative patients (402–406); 1 year of therapy will suppress HBV DNA to undetectable levels in 60 to 70% of patients using sensitive PCR assays (404, 405, 407, 408). This is unlikely to reflect increased potency, as compared to HBeAg-positive cohorts, but rather a lower baseline viral load in the HBeAg-negative state. Despite apparent effective viral suppression, the vast majority of patients relapsed (90%) when treatment was stopped (403). Long-term therapy is therefore required for sustained viral suppression. Unfortunately, prolonged therapy is complicated by the progressive development of LMV resistance. In one large study of HBeAg-negative patients, virologic remission decreased from 73% at 12 months to 34% at 48 months, due to the emergence of LMV resistant mutants (Table 6) (354). These rates are even less encouraging in HIV coinfecting patients.

One seminal, double-blind, randomized, placebo-controlled trial of LMV therapy (353) in 651 Asian patients, who had evidence of active viral replication and bridging fibrosis and cirrhosis on liver biopsy, found a significant reduction in overall disease progression (as defined by an increase in the Child-Turcotte-Pugh score or hepatic decompensation) and HCC development (353). The clinical benefit was observed mainly in the 51% of patients who did not experience virologic breakthrough, emphasizing

**TABLE 6** Cumulative annual incidence of antiviral resistance in differing patient populations

Treated Population	Percentage of Patients Resistant after Years of Therapy					
	1	2	3	4	5	6
LAM	23	46	51	71	80	-
LdT HBeAg-Pos	4.4	21	-	-	-	-
LdT HBeAg-Neg	2.7	8.6	-	-	-	-
ADV HBeAg-Neg	0	3	6	18	29	-
ADV (LAM-resistant)	≤20%	-	-	-	-	-
TDF	0	0	0	0	0	0
ETV (naïve)	0.2	0.5	1.2	1.2	1.2	1.2
ETV (LAM-resistant)	6	15	36	46	51	57

(Adapted with permission from Zoulim and Locarnini [468]).

both the importance of sustained viral suppression and the problems associated with LMV resistance. Prospective data on clinical outcomes in patients with less advanced disease are lacking, although retrospective analyses suggest improvement in patients maintaining viral suppression after starting therapy with LMV (354, 355). Early on, LMV therapy demonstrated benefit in the management of patients with decompensated cirrhosis, but it has since been supplanted by newer agents (409–412). Clinical improvement takes 3 to 6 months, and the risk of HCC persists, so that treatment should be initiated early and surveillance for HCC continued. In the original LMV registrational study in patients with advanced fibrosis or cirrhosis, durable viral suppression decreased the cumulative incidence of HCC from 7.4% to 3.4% ( $P = 0.047$ ) by 32 months of therapy (353), despite the confounding effect of antiviral resistance emergence. More recently, ETV and TDF have been confirmed to reduce the risk of HCC, particularly in cirrhotic patients (413–416).

Overall, LMV is very well tolerated. Various mild adverse events have been reported in patients receiving LMV, but all were observed to occur at the same frequency among controls (230).

### Telbivudine (LdT)

Telbivudine is an L-nucleoside with a potent anti-HBV effect; 48 weeks of therapy will reduce HBV viral load by 6 log<sub>10</sub> copies/ml. In clinical trials, LdT has been shown to be more potent than LMV in suppressing HBV replication in both HBeAg-positive and negative CHB (417), which was sustained in those patients who experienced an early response (418). A HBV DNA reduction to less than 5 log<sub>10</sub> copies/ml, defined as the primary endpoint, was achieved by 75.3% versus 67.0% of patients receiving LdT as compared to those receiving LMV (417) and was associated with histologic improvement as well. Longer term follow-up studies of this phase III study cohort have shown an HBeAg seroconversion rate of 37% after 3 years of therapy (419). This study also showed that 84% of patients who stopped therapy had an undetectable viral load after 52 weeks. Data regarding durability of response are not available beyond this time point. Despite the potent antiviral effect, LdT is also associated with a high rate of resistance (25.1% and 10.8% at 2 years in HBeAg-positive and -negative, respectively), conferred by mutations in the YMDD motif (420). Therefore, LdT resistance mutations are cross-resistant with LMV. For this reason LdT monotherapy has a limited role in the treatment of HBV infection.

## Acyclic Nucleoside Phosphonates (Nucleotide Analogues)

### Adefovir Dipivoxil (ADV)

Adefovir dipivoxil is the orally bioavailable prodrug of ADV, a nucleotide analogue of adenosine monophosphate. Similar to other NAs, it inhibits HBV DNA polymerase by acting as a chain terminator. It can inhibit both reverse transcriptase and DNA polymerase activity. The degree of HBV suppression achieved is less than that with LMV therapy, with 48 weeks of therapy achieving a mean viral load decline of 3 to 3.5 log<sub>10</sub> copies/ml (421). Furthermore, approximately 30% of NA-naïve patients are primary non-responders (defined as a <2 log<sub>10</sub> drop in VL by 6 months of treatment) (422). ADV has activity against both wild type and LMV-resistant HBV *in vitro* and clinically.

In the phase III registrational trial of ADV monotherapy for HBeAg-positive CHB, 10 mg daily of ADV for 48 weeks was associated with significant benefits in mean HBV DNA reduction (3.5 log<sub>10</sub> copies/ml vs. 0.6,  $P < 0.001$ ), ALT normalization (48% vs. 16%,  $P < 0.001$ ) and histologic response (53% vs. 25%,  $P < 0.001$ ) compared to placebo (423). HBeAg seroconversion occurred in 12% at 48 weeks versus 6% in placebo ( $P < 0.049$ ), and was more common in patients having a higher baseline ALT. Cumulative seroconversion rates increased with continued therapy to 48% after 5 years (424). No difference in response was observed by racial background or viral genotype. At a dose of 30 mg per day for 48 weeks, ADV was associated with a superior clinical effect compared to the 10-mg dose but also with an 8% incidence of nephrotoxicity, including the rare development of Fanconi syndrome. The ADV dose approved for clinical use was consequently limited to 10 mg per day. Suboptimal dosage and pharmacogenomic factors may therefore be contributing to the primary nonresponse rate (425). HBeAg seroconversion appears to be durable, being maintained in 92% of 76 patients, who were followed for a median of 52 (5 to 152) weeks off treatment after a median 80 (30 to 139) weeks of therapy (230). Patients were treated for a median of 41 weeks postseroconversion, which may explain the high durability.

ADV is also effective in the management of HBeAg-negative CHB. In comparison to placebo, 48 weeks of ADV was associated with a higher rate of undetectable HBV DNA by sensitive PCR assay (51% vs. 0%,  $P < 0.001$ ), ALT normalization (72% vs. 29%,  $P < 0.001$ ), and histologic response (64% vs. 33%,  $P < 0.001$ ) (426). The rate of viral suppression increased with time to 67% after 240 weeks (427). Although the relapse rate is very high (92%) in patients with HBeAg-negative CHB if therapy is stopped after 48 weeks (428), it may be possible to withdraw therapy after long-term viral suppression. In a cohort of 33 patients, who maintained virological suppression on ADV for a median of 4 to 5 years, 67% maintained biochemical remission to a median follow-up of 18 months (range 15 to 20). Although all experienced SVR, HBV DNA levels remained at relatively low levels similar to the inactive HBsAg carrier state (<50,000 copies/ml) and, in most cases, declined over time. Persistent biochemical relapse was successfully treated by reinstatement of ADV in 3% of patients (427).

The risk of ADV nephrotoxicity and the observed primary nonresponse rate make ADV less suitable as a therapy for patients with advanced liver disease, either compensated or decompensated. While ADV has been shown to be effective as salvage therapy in decompensated CHB complicated by LMV resistance (429), TDF is the preferred agent in this setting.

Although less potent as an antiviral agent compared to LMV, ADV offers the benefit of a reduced incidence of drug resistance. Furthermore, as the main resistance profile of ADV differs from LMV, these two drugs do not suffer from cross-resistance (Table 7).

### Tenofovir Disoproxil Fumarate (TDF)

Tenofovir is one of the two first-line NAs recommended for the treatment of CHB. It is structurally similar to ADV, and these two drugs are equipotent *in vitro*. However, because TDF is associated with less nephrotoxicity, pharmacokinetic studies determined a safe dose 30 times greater (300 mg per day) than ADV. This explains the much greater potency seen in clinical trials (6 to 7 log<sub>10</sub> copies/ml reduction in viral load) (421). TDF has activity against both HIV and HBV. It is currently approved as both monotherapy and combination therapy with FTC for the management of HIV and HIV/HBV coinfection. TDF/FTC combination therapy is currently recommended as first-line therapy for HBV-HIV coinfection (430). It is not approved for the management of HBV mono-infection, although it does hold the promise of potent viral suppression and a high resistance barrier.

The superior efficacy of TDF, compared to ADV, in the management of CHB was established in two phase III studies, one examining HBeAg-positive and the other HBeAg-negative infection (431). Both studies treated patients for 48 weeks (200 mg daily TDF versus 10 mg daily ADV) with a primary endpoint of complete virologic response (HBV DNA <400 copies/ml) plus histologic response (two point reduction in Knodell inflammatory score). In the study of HBeAg-positive patients, which enrolled a predominantly Caucasian population (51.5% Caucasian; 36% Asian), with a relatively even distribution of the four major genotypes, 66% of TDF-treated patients reached the primary endpoint compared to 12% of placebo ( $P < 0.001$ ) (431). TDF was also superior with regards to ALT normalization (68% vs. 54%,  $P = 0.03$ ), HBsAg loss (3.2% vs. 0%,  $P = 0.02$ ), and HBV DNA suppression to <400 copies/ml on intention-to-treat analysis (76% vs. 13%,  $P < 0.001$ ). No statistically significant differences were seen in histologic improvement alone or HBeAg seroconversion (21% vs. 18%,  $P = 0.36$ ) (431).

The HBeAg-negative trial also had a predominantly Caucasian population (64.5% Caucasian; 24.5% Asian), with a preponderance of genotype D infection (63.5%). The primary endpoint was reached in 71% of TDF-treated compared to 49% of placebo-treated patients ( $P < 0.001$ ) (431). Similar to the HBeAg-positive group, this signifi-

cance was driven by complete viral suppression, attained in 93% vs. 63% ( $P < 0.001$ ) of patients without a significant difference in histologic response. There was no difference in ALT normalization (431).

Of the 641 initially randomized patients, 437 (68.2%) completed a further 7 years as part of a long-term treatment study (432). Complete viral suppression (HBV DNA <400 copies/ml) was maintained in 99.3% of the cohort. At enrollment into the long-term study, 154 patients were HBeAg-positive. At the end of follow-up, 54.5% had lost HBeAg, and 11.8% had lost HBsAg. Only one patient in the HBeAg-negative group lost HBsAg (0.3%) (432). No resistance to TDF was detected (433). Baseline and follow-up biopsies were available for 348 patients after 5 years of treatment. Regression of fibrosis (reduction of at least one point in Ishak fibrosis score) was seen in 51% of these patients (271). Additionally, while 96 of these patients were deemed cirrhotic on baseline biopsy, remarkably, 74% of these had regressed to noncirrhotic scores at follow-up (271).

Although generally well tolerated, TDF therapy may be associated with renal insufficiency, and there have been rare case reports of reversible Fanconi syndrome (434). No cases of Fanconi syndrome have been seen in long-term follow-up studies (432, 435), and elevations of serum creatinine  $\geq 0.5$  mg/dL were seen in only 1.7% of patients after 7 years (432). The risk of TDF-induced Fanconi syndrome may be related to rare variants in multiple genes involved in renal drug handling or renal cell homeostasis, but no biomarker has yet been determined (436). TDF has been associated with bone loss and osteomalacia in the HIV-treated population, for whom TDF has been available since 2001 (437). This has been postulated to result from hypophosphatemia induced by renal proximal tubular dysfunction, similar to the mechanism for Fanconi syndrome (438). In a study examining this issue, TDF was independently associated with a reduction in bone density in addition to traditional risk factors for osteoporosis (439). However, this was a modest reduction (OR 2.95 CI [1.14–7.45],  $P = 0.026$ ), and limited to the hip. The authors of this study concluded that classic risk factors were more important in risk-stratifying patients taking TDF (439). TDF is effective for the management of both LMV- and ADV-resistance (see below).

### Tenofovir Alafenamide (TAF)

Tenofovir alafenamide is the orally bioavailable phosphonamidate prodrug of tenofovir. In comparison with TDF, TAF enables enhanced delivery of the parent nucleotide and its active diphosphate metabolite into lymphoid cells and

**TABLE 7** Patterns and pathways of antiviral drug resistance in chronic hepatitis B in the context of cross-resistance

hepatocytes. Hydrolysis of TAF occurs by action of the enzyme carboxylesterase-1, which is predominantly expressed in HBV-infected hepatocytes (440). The TAF formulation lowers plasma exposure by 90% and has been designed to minimize the bone and renal toxicity associated with TDF (441). TAF is currently in phase III clinical trial development and is expected to be approved in Europe and North America in 2016 and Asia in 2017.

## D-Cyclopentanes

### Entecavir (ETV)

Entecavir is the second NA recommended as a first-line agent for the treatment of CHB. ETV is an analogue of 2'-deoxyguanosine. It inhibits HBV replication at three different steps: 1) priming of HBV DNA polymerase; 2) reverse transcription of minus-strand DNA; and 3) synthesis of plus-strand HBV DNA. ETV is more potent than LMV or ADV, reducing HBV DNA by 6- to 7-log<sub>10</sub> copies/ml after 48 weeks of treatment (421).

ETV was compared to LMV in the phase III registrational trial for the management of HBeAg-positive CHB (442). At week 48, 0.5 mg daily of ETV versus 100 mg daily of LMV was associated with superior rates of HBV DNA undetectability (67% versus 36% by sensitive PCR assay,  $P < 0.001$ ), normalization of ALT (68% vs. 60%,  $P = 0.02$ ), and histologic improvement (72% vs. 62%,  $P = 0.009$ ). HBeAg seroconversion was similar (21% vs. 18%,  $P = 0.33$ ) and was more common in patients having a higher baseline ALT. Rates of undetectable DNA and normal ALT continued to increase through to 96 weeks (443). In those patients who stopped therapy at this point, 5.1% vs. 2.8% had lost HBsAg 24 weeks after cessation in those taking ETV vs. LMV, respectively (444). Studies of long-term maintenance therapy have shown continued efficacy out to 5 years, with an additional 23% of patients achieving HBeAg seroconversion (445). No difference in response was observed by racial background or viral genotype.

In HBeAg-negative CHB, ETV was again associated with improved rates of undetectable HBV DNA, normalization of ALT, and histologic improvement compared to LMV (446). However, of 257 patients who had achieved undetectable HBV DNA and normal ALT levels after 48 weeks of treatment, 97% had detectable DNA within 24 weeks off-treatment, and 51% had elevated ALT levels (447). This reinforces the concept that long-term NA therapy is required for HBeAg-negative infection.

ETV-related viral suppression has a significant impact on regression of histologic fibrosis (272). A subset of 57 patients enrolled in the above studies (41 HBeAg-positive, 16 HBeAg-negative) had paired liver biopsies available for comparison. These were taken after 48 weeks of treatment and after at least 3 years of maintenance therapy (range 3 to 7 years). All patients had HBV DNA  $< 300$  copies/ml at the time of the second biopsy and 67% were Asian, hence genotypes B and C were most prevalent (60%). Ninety-six percent of this cohort had a significant reduction in necroinflammation, and 88% had improvements in their Ishak fibrosis score. All 10 patients with cirrhosis had regression and were considered no longer cirrhotic (272).

Concern regarding the safety of ETV in decompensated HBV-related cirrhosis was raised after a series of five patients developed severe lactic acidosis (448). All patients had end-stage liver disease (MELD) scores of  $> 20$ , indicating severely impaired liver function. One patient died, while treatment withdrawal resulted in resolution of the acidosis in

the remaining four. A prospective, randomized study examining the use of ETV, 1 mg, (twice the standard dose), or ADV 10 mg for up to 96 weeks in the decompensated cirrhotic population (449). Forty-nine percent of the ETV group had achieved a HBV DNA  $< 300$  copies/ml, compared to 16% in the ADV group at 24 weeks. This increased to 57% vs. 20% by week 48 ( $P < 0.0001$  for both time points) (449). Week 24 mortality was 12% in both groups. No cases of lactic acidosis were seen, although no patient had a MELD above 20, and overall safety profile was similar for the two drugs.

In general, ETV is very well tolerated, its safety profile being similar to that of LMV in the registrational trials (442, 446). Preclinical studies in rats, treated with doses 3 to 40 times the maximal human dose, found an increased risk of tumors in the lungs, brain, and liver. Similar events have not been observed in humans (445), where no difference in the incidence of any neoplasm has been observed with the use of ETV when compared to LMV.

ETV resistance is rare in NA-naïve patients and emerges slowly (450). ETV resistance is more common in the setting of prior LMV resistance, in spite of the increased 1-mg dose that is approved for this indication (see below).

## Other Direct Acting Antiviral Drugs

### Emtricitabine (FTC)

Emtricitabine (5'-fluorothiacytidine) is a fluorinated cytosine analogue that is structurally similar to LMV. It inhibits both HBV DNA polymerase and HIV reverse transcriptase. Forty-eight weeks of emtricitabine 200 mg daily reduced HBV DNA by 3 to 4 log<sub>10</sub> copies/ml and significantly improved liver histology (451). However, despite virologic, biochemical, and histologic improvement, this study of 248 patients (63% HBeAg positive) failed to show any benefit in HBeAg seroconversion compared to placebo—12% in the two groups (451). Furthermore, FTC-resistance mutations in the YMDD motif (rtM204V) were detected in 13% of patients at 48 weeks, the mutations being cross-resistant for LMV. Preliminary clinical results suggest that rtM204V/I mutations occur in 19 to 37% of patients after 2 years of treatment (452).

FTC has been approved for the management of HIV. FTC monotherapy is unlikely to have an important role in the management of HBV, given the frequency of primary drug resistance and the issue of cross-resistance with LMV, but does hold promise in combination with tenofovir (TDF) for NA-naïve mono-infected patients and is used routinely in HIV/HBV coinfecting patients.

### Clevudine

Clevudine (2'-fluoro-5-methyl-beta-L-arabinofuranosyluracil) is a 1-thymidine analogue with potent *in vitro* activity against HBV (453). It is a noncompetitive inhibitor of HBV Pol that inhibits viral (+)-(+)-strand synthesis without incorporating itself into viral DNA. A unique property of clevudine is that it appears to suppress HBV DNA for a prolonged period after cessation of therapy (454). Clevudine, at a dose of 30 mg for 24 weeks (455, 456), reduced viral load to undetectable levels in 59% of HBeAg-positive and 92% of HBeAg-negative patients (455, 456), and statistically significant differences in viral suppression remained 24 weeks after cessation of therapy.

The safety of clevudine has been called into question, as several studies have shown an incidence of myopathy in 3.4 to 13.6% of patients (457–460). Given these safety

concerns, enrollment into planned larger phase III studies was terminated, and clevudine is currently marketed only in the Philippines.

### Besifovir

Besifovir, formerly known as LB80380, is a novel nucleoside phosphonate analogue prodrug, similar in structure to ADV. It is, therefore, incorporated into the growing viral DNA strand causing termination and inhibition of replication. *In vitro* studies of efficacy demonstrated potent inhibition of HBV replication, leading to *in vivo* studies in the WHV model (461). Doses from 30 mg to 240 mg demonstrated significant reductions in HBV DNA without significant clinical or laboratory adverse effects (462). Besifovir also demonstrated efficacy in LMV-resistant infection (463). A phase IIb study, comparing besifovir at doses of 90 mg and 150 mg to ETV, 0.5 mg, showed equivalent degrees of viral DNA suppression between the three groups after 48 weeks of treatment (464). Increasing rates of viral suppression to approximately 80% undetectable have been seen after 2 years of maintenance therapy (465). Some concern has been raised over the decline in serum l-carnitine, seen in 94.1% of patients treated with besifovir, which required supplementation therapy. A similar effect was seen with high-dose ADV (466). Outcomes of a phase III study comparing besifovir 150 mg to tenofovir 300 mg for 48 weeks are awaited (NCT01937806).

### Nucleos(t)ide Analogue Resistance

Drug resistance is important because it is associated with the loss of virological, biochemical, and eventually histological therapeutic gain. In the setting of advanced liver disease, resistance may lead to hepatitis flares, hepatic decompensation, and death (353). Drug resistance mutations also appear to be archived in the nuclear cccDNA template (467).

Primary resistance mutations are those that directly alter drug binding and thus confer drug resistance. These mutations commonly result in reduced viral replicative ability when compared to wild-type virus (468). Secondary resistance mutations arise in selected variants that have acquired primary resistance mutations and have the effect of causing a compensatory increase in viral replication levels.

### Mutations Conferring Resistance

#### L-Nucleoside Analogue Resistance

Primary resistance to LMV and LdT has been mapped to mutations in the YMDD locus in the catalytic, or C, domain of HBV Pol (469). These occur primarily at rtM204I/V/S (Domain C),  $\pm$  rtL180M (Domain B) (469), and rtA181T/V (Domain B) (470). Only the latter mutation confers cross-resistance to ADV or TDF (471). There are multiple secondary resistance mutations that can be selected for in LMV-resistant strains, some of which contribute to ETV resistance. Individually, these mutations do not significantly impact the efficacy of ETV (472).

Mutations that confer LMV resistance decrease *in vitro* sensitivity to LMV from at least 100-fold to greater than 1000-fold. The rtM204I substitution has been detected in isolation, but rtM204V and rtM204S are found only in association with other changes in the B or A domains (473). The major patterns of mutation are: 1) rtM204I, 2) rtL180M + rtM204V, 3) rtL180M + rtM204I, 4) rtV173L + rtL180M + rtM204V, and 5) rtL80V/I  $\pm$  rtL180M + rtM204I. Genotype influences the dominance of a particular mutation sequence (474). The molecular mechanism of LMV resistance is steric

hindrance caused by the branched side group of valine or isoleucine amino acids colliding with the oxathiolane ring of l-nucleosides in the dNTP binding site (475).

LMV resistance increases progressively during treatment at rates between 14% and 32% annually (Table 6) (476). The rate of resistance observed with LdT therapy is lower than for LMV; however, it is substantial and increases exponentially after the first year of therapy. Genotypic resistance was observed at 1 and 2 years of therapy in 4.4%/2.7% and 21.6%/8.6% in HBeAg-positive and -negative patients, respectively (230).

#### Acyclic Nucleoside Phosphonate Resistance

Resistance to ADV was initially associated with mutations in the B (rtA181T/V/S) and D (rtN236T) domains of the Pol enzyme (Fig 2B and Table 7) (477). These ADV-associated mutations in HBV Pol result in only a modest (three- to eightfold) increase in IC<sub>50</sub> and are partially cross-resistant with TDF, probably because the molecular mechanism of resistance is similar in both, with indirect perturbation of the triphosphate binding site between the A and D domains (475). The rtN236T does not significantly affect sensitivity to LMV, LdT, or ETV, but it reduces the *in vitro* efficacy of TDF (477, 478). The rtA181T/V mutation is partially cross-resistant to LMV and LdT (471) and reduces sensitivity to TDF by approximately threefold (479). The rtA181S mutation appears to affect only ADV (480). Resistance to ADV occurs less frequently (around 2% after 2 years, 4% after 3 years, and 18% after 4 years) than resistance to l-nucleosides.

Resistance to TDF in patients with HIV-HBV coinfection is conferred by the rtA194T mutation in combination with rtL180M and rtM204V (481). *In vitro* the presence of rtA194T results in partial resistance to TDF but shows no cross-resistance with LdT or ETV. Additionally these virus strains had reduced replication efficiency compared to wild type, but this could be reversed by the introduction of either precore or BCP mutations (482). Clinical studies have not confirmed an *in vivo* effect of this mutation. Further *in vitro* studies have shown a 10-fold reduction in TDF sensitivity when the rtN236T and rtA181T/V mutations are found together.

#### D-Cyclopentane Resistance

Mutations in the viral polymerase associated with the emergence of ETV-resistance have been mapped to the B domain (rtI169T, rtS184G, and/or rtL180M), C domain (rtS202I and rtM204V), and E domain (rtM250V) (Fig 2B and Table 7). Thus, at least three mutations are required for resistance to develop. In the absence of the LMV mutations rtM204V/I and rtL180M, the rtM250V mutation causes a 10-fold increase in IC<sub>50</sub>, while mutations rtT184G+rtS202I have only modest effect (483–485). The molecular mechanism of resistance for the rtM250V change is exerted during RNA-directed DNA synthesis (485). The mutation reduces the dNTP-binding site by repositioning it, thus shifting the ETV binding pocket. The mechanism for the rtT184G/rtS202I combination is an allosteric change with altered geometry of the nucleotide binding pocket near the YMDD site (485). A newly recognized mutation at rtA186T confers primary ETV resistance in combination with LMV resistance mutations (486). The significance of this mutation will need confirmation in future studies.

Genotypic resistance to ETV is uncommon in NA treatment-naïve patients, seen in 1.2% of patients after 5 years of therapy (487). However, patients with LMV-resistance at commencement of ETV monotherapy develop

resistance rapidly (Table 6). This is because ETV resistance develops in a stepwise fashion, which means that a virus with YMDD mutations needs to develop fewer additional mutations to become resistant (472). Therefore ETV should not be used as monotherapy to treat LMV-resistant patients.

Importantly, ETV resistance-associated mutations are not cross-resistant with ADV or TDF.

### Multidrug Resistance

Multidrug-resistant (MDR) HBV occurs in patients who received sequential NA monotherapy (478, 483, 488–490). MDR strains have been shown to develop if an “add-on” therapeutic strategy to treat initial resistance to a single agent does not result in rapid and complete viral suppression (468).

The rtA181V/T mutation is a marker for multidrug resistance as it is responsible for reduced susceptibility to both the L-nucleosides and the acyclic phosphonate nucleosides (471, 491).

### Detection of Drug Resistance

Viral load assay is the principal clinical tool used to detect and confirm the development of drug resistance while on treatment. When a significant rise in viral load is seen ( $>1 \log_{10}$ ), patient compliance to therapy must be evaluated before ascribing the changes to resistance.

An analysis for genotypic resistance should be requested upon confirmation of viral breakthrough (defined above). Ideally, the nucleotide sequence of the HBV polymerase isolated from the patient during breakthrough should be compared with a sequence from a pretherapy sample from the same patient (492). In the absence of a paired sample, the sequence should be compared with published consensus sequences of the same HBV genotype (493). Determining which mutation/s are present will allow rational prescription of alternate therapy without cross-resistance (Table 7).

### Management

Factors that increase the risk of development of resistance include high pretherapy serum HBV DNA, high ALT levels, and high body mass index (476, 494, 495). Patients previously exposed to NA therapy are also at higher risk for developing resistance (496).

### Primary Nonresponse

Primary nonresponse is uncommon when using potent first-line agents, but is defined as a failure to achieve a 1  $\log_{10}$  reduction in viral load after 12 weeks of treatment (295). This has been shown to be related to pharmacogenomics factors and/or compliance issues in the case of ADV therapy, which is associated with the highest rate of primary nonresponse, occurring in 10 to 20% of patients (425). These patients should be quickly switched to either TDF or ETV therapy (497). Primary nonresponse to the other NA drugs is rare, and, in such situations, compliance must be carefully assessed (498). A compliant patient should then proceed to have genotypic resistance analysis (314).

### Partial Virologic Response

A partial virological response is defined as detectable HBV DNA after 6 months of treatment using current sensitive assays (314). A viral load of  $>3 \log_{10}$  copies/ml at this time-point has been shown to predict resistance after 2 years of therapy with LdT or LMV (420, 496). The effect of ADV on viral kinetics is slower than the other agents, so this threshold at 48 weeks of therapy can be used to predict resistance (428). This threshold/resistance effect is seen with all NA

used to treat CHB, but less so with TDF and ETV. It is again important to check compliance. If LMV, ADV, or LdT has been used, then switching to TDF or ETV can be done at week 24 in those who have had a partial response (468). A change in therapy is probably not necessary in those initially treated with TDF or ETV. In patients naïve to NA treatment and started on ETV, 21% had detectable HBV DNA at week 48. Despite this, 81% of this group proceeded to have a complete response by the end of the study at week 144 (499), and no resistance was seen. Similarly, studies in patients receiving TDF have shown continued virologic responses and no long-term resistance despite an up to 24% partial response rate at week 48 (431, 500).

### Virologic Breakthrough

Virologic breakthrough is defined as a  $>1 \log_{10}$  (10-fold) increase in serum HBV DNA from nadir, in two consecutive samples taken 1 month apart, in a compliant patient who had an initial virological response (295). Notably up to 40% of viral breakthrough is due to nonadherence to therapy (501), but in a patient adherent to therapy, virologic breakthrough is primarily due to viral resistance. Virologic breakthrough is usually followed by biochemical breakthrough but may occur months and sometimes years before biochemical breakthrough. Hence early detection and treatment is possible prior to the development of clinical complications. This is particularly important in the setting of advanced liver disease.

Ideally, resistance should be identified before ALT levels rise, and genotypic analysis should be performed in order to institute rescue therapy and avoid clinically significant consequences. The benefit of an early therapeutic adaptation has been shown in several studies (314, 502).

### Summary

Current recommendations suggest (314, 468):

- Lamivudine resistance: switch to TDF (or add ADV if TDF not available).
- Telbivudine resistance: switch to or add TDF (or add ADV if TDF not available).
- Entecavir resistance: switch to or add TDF (or add ADV if TDF not available).
- Adefovir resistance: if naïve before ADV, switch to either ETV or TDF (ETV preferred if high viral load). If rtN236T mutation present, add ETV or switch to TDF/FTC. If rtA181V/T mutation present, add ETV or switch to either ETV/TDF or TDF/FTC.
- Multidrug resistance: consider TDF/ETV combination therapy.

### L-Nucleoside Resistance

ADV is effective in the management of LMV resistant variants. However, despite early treatment response, following a switch to ADV monotherapy, rates of genotypic ADV resistance as high as 18% develop after 48 weeks (503). The optimal strategy for the use of ADV therapy in the setting of LMV-resistance is, therefore, to add-on ADV (504, 505). When used, ADV should be added on early (at the time of genotypic versus phenotypic resistance), when VL remains  $<200,000$  IU/ml ( $10^6$  copies/ml) to promote virological response (505, 506). Add-on therapy with ADV has also been successful when resistance to LdT monotherapy develops (507). This approach has a low rate of subsequent ADV resistance, occurring in 4% after 4 years of therapy (502).

Tenofovir (TDF) is also effective for the management of LMV-resistant HBV, resulting in a significant reduction in serum HBV DNA levels (508–511). It is more effective than ADV as primary salvage therapy and is also effective as secondary therapy following inadequate response to ADV salvage (508,512–514). A randomized study in patients with partial response to add-on ADV therapy after 6 months found complete virologic response in 96.4% of the TDF group versus 29.0% of those continuing LAM/ADV ( $P < 0.001$ ) (515), confirming that TDF is the preferred agent in the event of LMV-resistance.

In studies with follow-up limited to 48 weeks, ETV monotherapy at a dose of 1 mg per day appeared to be effective for the management of LMV resistance (higher than the 0.5 mg per day recommended for NA-naïve patients) (516). However, the M204V/I LMV mutations are required as the first “hit” in the two-hit process producing ETV resistance (483). Additionally, commencing ETV therapy in patients with genotypic LMV-resistance significantly impairs the rate of complete viral response as compared to treatment naïve patients (HR 0.14 [CI: 0.04–0.58],  $P = 0.007$ ) (517). Consequently, ETV resistance develops commonly with long-term therapy when used in patients with genotypic LMV-resistance, and ETV should not be used to treat genotypically proven l-nucleoside-resistant virus.

#### Adefovir Resistance

*In vitro* resistance profiles suggest that treatment options for ADV-resistance would include LMV, ETV, and TDF (Table 7) (518, 519). If used, LMV should be added on, especially in patients with a previous history of LMV-resistance, which has been reported to re-emerge rapidly following the re-introduction of LMV (488). Although the mutations are partially cross-resistant with TDF *in vitro*, the higher relative dose of TDF allows effective salvage therapy for ADV-resistance. In a randomized controlled trial of 105 ADV-treated patients with viral loads  $>1000$  copies/ml despite 24 weeks of treatment (520), patients received either TDF monotherapy or combination therapy with TDF/FTC. At baseline, 10% of the cohort had genotypic ADV resistance with rtN23T and/or A181V/T, and 12% had LMV resistance. After 168 weeks of follow-up,  $>80\%$  of patients in both arms had achieved DNA  $<400$  copies/ml, irrespective of the presence of genotypic ADV resistance (520). A second study of TDF versus TDF/ETV in genotypic ADV resistance showed similar results. There was a trend towards a slower reduction in viral load seen only in those with dual rt181V/T and rtN236T mutations (521).

#### Entecavir Resistance

There are few large studies investigating NA therapy for ETV-resistant infection. In essence, ETV-resistance can only be managed with acyclic phosphonate drugs or interferon, as l-nucleoside resistance mutations are a prerequisite for ETV-resistance to develop.

The utility of add-on ADV therapy in patients with genotypic ETV resistance was shown in two small studies (522, 523), one of which enrolled 67 patients and added ADV 10 mg to l-nucleoside therapy or ETV. Treatment for 24 months was associated with complete viral suppression in 47.4% of patients, with no difference between LMV/LdT or ETV groups ( $P = 0.23$ ) (522).

TDF has shown efficacy in ETV-resistant disease, both in combination with ETV and as monotherapy. A cohort of 57 heavily pretreated patients without complete virologic response included 24 (42%) who had ETV exposure (524).

After a median of 6 months [IQR: 4.6–7 months] of treatment with ETV/TDF, 89% had undetectable HBV DNA. Another study randomized 90 patients, all with genotypically proven ETV resistance (525), to receive 48 weeks of either TDF monotherapy or combination therapy with TDF 300 mg/ETV 1 mg, both daily. At the end of treatment, 71% in the monotherapy group and 73% in the combination group had achieved a HBV DNA level  $<15$  IU/ml ( $P = 0.81$ ). A small study also showed good efficacy of TDF monotherapy in patients with suboptimal responses to ETV rescue (515). Thus, on balance, TDF/ETV rescue should be considered a last resort.

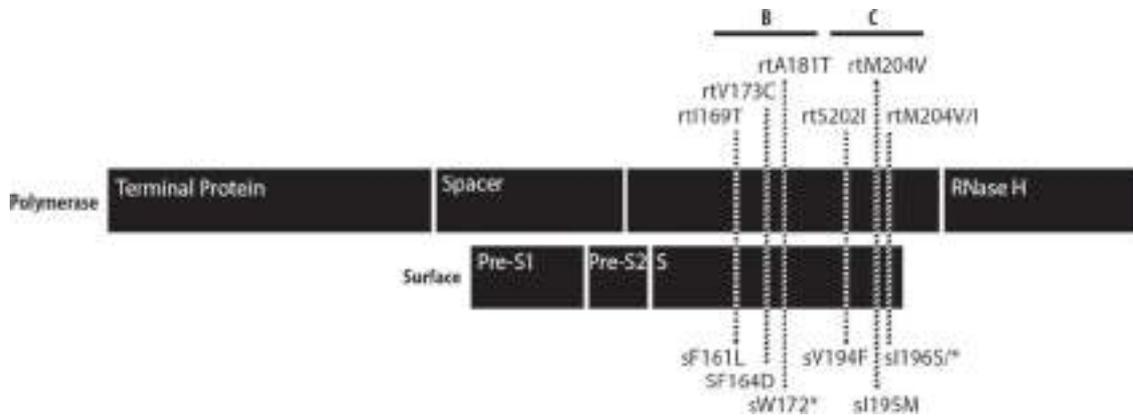

#### Prevention

Resistance will remain an important issue in the management of patients with CHB because long-term, and probably lifelong, therapy with NA will be required in the majority of patients. The use of high-potency, high-barrier-to-resistance first-line agents quickly reduce the viral load and quasi-species pool and reduce the risk of resistance. Adhering to best practice management and drug prescription can reduce the development of resistance. This includes avoidance of unnecessary drug use, continuous surveillance for resistance, prompt and appropriate rescue therapy if resistance emerges, and initial use of potent NA therapy with a high genetic barrier to resistance (TDF or ETV). Monitoring adherence to prescribed therapy, as well as on-treatment responses, should be performed using HBV DNA and ALT levels every 3 to 6 months for 2 years after commencing therapy. Polymerase gene sequencing upon the emergence of resistance should then be performed to determine the next therapeutic approach based on cross-resistance information.

#### Pol-HBsAg Mutations

The polymerase gene overlaps the envelope gene (Fig 9), and changes in the HBV Pol selected during antiviral resistance can therefore cause concomitant changes in the envelope gene. Thus, the major resistance mutations associated with NA failure also have the potential of altering the C-terminal region of HBsAg. For example, the rtM204V mutation associated with primary LMV and ETV resistance, results in a change at sI195M in the surface antigen, while the rtM204I change that is associated with LMV and LdT resistance is linked to three possible changes, sW196S, sW196L, or a termination codon (sW196\*). To date, only one published study has examined the effect of the main LMV resistance mutations on the altered antigenicity of HBsAg (526). One of the common HBV variants that is selected during LMV treatment is rtV173L + rtL180M + rtM204V, which results in changes in the HBsAg at sE164D + sI195M. Approximately 20% of HIV-HBV coinfecting individuals and 10% of mono-infected individuals carry this “triple Pol mutant” (527, 528). In binding assays, HBsAg-expressing triple-Pol mutants had reduced anti-HBs binding. This reduction was similar to the classical vaccine escape mutant, sG145R (44), and, subsequently, this virus successfully superinfected vaccinated chimpanzees (529).

The ADV-resistance mutation rtN236T does not affect the envelope gene and overlaps with the stop codon at the end of the envelope gene. The rtA181T mutation selected by ADV and/or LMV results in a stop-codon mutation at sW172stop (491). The ADV-resistance mutation at rtA181V results in a change at sL173F. HBV, with mutations that result in a stop codon in the envelope gene, requires the presence of a low percentage of wild type to enable viral assembly and release.

**FIGURE 9** HBV DNA genome showing the overlapping open reading frames (ORFs) of POL and S, and, in particular, how the polymerase-envelope overlap can affect each other during the emergence of NA resistance.

The ETV resistance-associated changes at rtI169T, rtS184G, and rtS202I also affect HBsAg and result in changes at sF161L, sL/V176G, and sV194F. The rtM250V is located after the end of HBsAg, and thus has no effect on it. The sF161L is located within the “a” determinant, or major hydrophilic region, which includes amino acids 90 to 170 of the HBsAg (530). This region is a highly conformational epitope, characterized by multiple disulphide bonds formed from sets of cysteines at residues 107 to 138, 137 to 149, and 139 to 147 (530). Accordingly, changes to HBsAg that are driven by NA resistance, such as sF161L, need further investigation in order to determine the effect on envelope structure and the subsequent affinity of anti-HBs binding. Proof of this concept is seen with distal substitutions, such as sE164D, which has already been shown to significantly affect anti-HBs binding (526).

In summary, because of the overlap between the Pol and S genes, the selection of drug-resistant HBV has important clinical, diagnostic, and public health implications. The significance of these changes warrants further investigation to determine what effect they have on the natural history of drug-resistant HBV and its transmissibility in the HBV-vaccinated community.

#### Transmission of Resistant Strains

Transmission of infection with LMV-resistant HBV to an HIV patient undergoing LMV treatment as part of antiretroviral therapy has been reported (531). Another report notes baseline YMDD mutations in two treatment-naïve patients with HBV-HIV coinfection (532) and also in two cases with acute HBV infection (533). In addition, LMV-resistance mutations were found in a cohort of dialysis patients with occult HBV (534). Therefore, it is important to recognize that both primary- and secondary-resistance mutations may result in associated changes to the viral envelope that could lead to vaccine and immune escape (529), resulting in substantial public health relevance.

#### Stopping NA Therapy

The defined end point for HBeAg-positive infection is attaining sustained HBeAg seroconversion with undetectable HBV DNA. Cessation of NA therapy can be considered following at least 6 to 12 months of consolidation therapy after achieving this goal (230, 314, 361, 535). Patients will require ongoing monitoring as a proportion fail to sustain their serological or virological responses (362, 399, 400, 536).

The majority of HBeAg-negative patients will relapse after discontinuing NA therapy, and the role of quantitative HBsAg testing in predicting those HBeAg-negative patients likely to have a sustained response is unsettled. In one study of 53 HBeAg-negative patients, who stopped LMV after 12 to 76 months of treatment after having achieved suppression of HBV DNA, all patients who achieved a quantitative HBsAg decline to below 100 IU/ml and a  $>1 \log_{10}$  decline continued to have suppressed HBV DNA at 12 months, whereas all who did not achieve these targets had virologic relapse (537). However, in a group of 184 patients, who had a minimum of 2 years of ETV therapy and at least 6 months of HBV DNA undetectability before cessation of therapy (538), the relapse rate was 91.4% after 48 weeks, which could not be predicted by baseline quantitative HBsAg or off-treatment quantitative HBsAg or viral load. Given these data, HBeAg-negative patients will require continuous NA therapy until HBsAg loss.

#### Immunomodulators

##### Interferon- $\alpha$

Standard IFN $\alpha$  (sIFN) is effective in suppressing HBV replication and was the first treatment approved for chronic HBV infection in most countries (Tables 5A and 5B). Its use has been largely supplanted in Western clinical practice by pegylated-IFN $\alpha$  (pegIFN) due to the more convenient dosing schedule and equivalent efficacy. The attachment of polyethylene glycol to a protein (pegylation) reduces its rate of absorption following subcutaneous injection, reduces renal and cellular clearance, and decreases the immunogenicity of the protein. All of these effects enhance the half-life of the pegylated- versus the native-protein. This allows pegIFN to be administered once weekly, while maintaining a more sustained viral suppression between doses. One phase II clinical study has suggested that the efficacy of pegIFN is similar to, or slightly superior to, sIFN (539). The advantages of interferon, as opposed to NA, include the finite course of treatment and the durability of HBeAg seroconversion. Interferon has also been shown to enhance degradation of cccDNA by upregulating cytidine deaminases (540) and by inducing epigenetic silencing of the mini-chromosome (150). The disadvantages are the side-effect profile, the lack of durable viral suppression in HBeAg-negative infection, and the overall poor sustained response. Response to interferon therapy is influenced by genotype, and current management and treatment guidelines do not

recommend a role for genotype determination unless interferon therapy is being considered.

### Standard Interferon- $\alpha$

Standard interferon- $\alpha$  (sIFN) was one of the first therapies investigated for CHB. A meta-analysis of 15 randomized controlled trials using sIFN for the treatment of HBeAg-positive disease concluded that viral suppression, normalization of ALT, and HBeAg seroconversion (33% vs. 12%) were significantly more common compared to untreated controls if patients received sIFN for 3 to 6 months and were followed for 6 to 12 months. The loss of HBsAg occurred in 7.8% of sIFN-treated patients compared to 1.8% controls ( $P = 0.001$ ). In long-term follow-up studies the durability of sIFN-induced seroconversion has been reported to be 80 to 90% at 4 to 8 years (356–358, 360, 541–544).

Clinical outcome studies comparing responders and nonresponders have found that HBeAg seroconversion predicted better long-term survival and survival free of hepatic decompensation (357, 358, 360, 364, 545). Only one prospective randomized controlled trial has compared clinical outcome following sIFN with placebo (356). This Taiwanese study found treated patients to have a lower incidence of HCC (1.5% vs. 12%,  $P = 0.04$ ) and improved survival (98% vs. 57%,  $P = 0.02$ ) after a median 8-year follow-up.

sIFN also has an antiviral effect in HBeAg-negative CHB. Four randomized controlled trials demonstrated an end-of-treatment response in 38 to 90% of patients compared to only 0 to 37% in controls (546–549). In comparison to HBeAg-positive CHB, relapse posttherapy is frequent, with sustained response rates of only 15 to 30% (550, 551). Late relapse has been noted out to 5 years.

The use of sIFN in the setting of cirrhosis is limited by the risk of hepatitis flare, which may precipitate hepatic decompensation. Approximately 20 to 40% of HBeAg-positive patients develop a flare of their ALT during treatment. In compensated cirrhosis the risk appears to be small, and less than 1% of cirrhotic patients included in HBeAg-positive cohorts developed hepatic decompensation (552, 553). Treatment response was comparable to precirrhotic patients. However, sIFN offers little virologic benefit once liver disease progresses to Childs class B or C and is complicated by significant toxicity and exacerbations of liver disease, even at low dose (554, 555). IFN is therefore contra-indicated in this setting, and NA therapy provides a safe and effective alternative.

sIFN therapy is associated with multiple adverse effects (see below).

### Pegylated Interferon- $\alpha$ (pegIFN)

pegIFN is useful for both HBeAg-positive and -negative CHB. In the largest phase III trial of over HBeAg-positive 800 patients, 48 weeks of pegIFN $\alpha$ -2a at a dose of 180  $\mu$ g/week was compared to the combination of pegylated IFN $\alpha$ -2a plus LMV 100 mg daily or LMV monotherapy (364). At the end of treatment, combination therapy achieved the most profound viral suppression but HBeAg seroconversion was similar (27%, 24%, and 20%, respectively). The HBeAg seroconversion rate was, however, significantly higher in the two groups that received pegIFN therapy at 24 weeks post-treatment being 32% and 27% vs. 19% ( $P < 0.02$ ). Sixteen patients receiving pegIFN (1.5%) experienced HBsAg seroconversion as compared with no patients in the LMV monotherapy group ( $P = 0.001$ ). The combination did not offer additional benefit. Similar results have been obtained in other studies using varying regimens of pegylated IFN $\alpha$ -2b

(556, 557). The standard regimen of 180  $\mu$ g/week of pegylated IFN-2a for 48 weeks has better efficacy than either lower dose, or shorter duration, regimens (558).

A number of baseline factors predict response to pegIFN in HBeAg-positive patients. HBeAg seroconversion is more likely in the setting of an ALT  $>2 \times$  ULN, low HBV DNA ( $< \log_{10} 9$  IU/ml), female gender, older age, and naïve to previous interferon-based therapy (559). Genotype also appears to be an important factor: genotype-A disease requires either elevated ALT or low DNA to predict SVR, whereas genotype D disease has a poor response regardless. Genotype B and C require both high ALT and low DNA to predict good response. This carries over to HBsAg seroconversion, which is more likely in the setting of genotype A disease, occurring in 14% after 52 weeks of therapy versus 2% in genotype D (560). These factors are associated with good long-term responses, with  $>80\%$  of patients maintaining HBeAg seroconversion out to 3 to 5 years (561, 562).

Fewer studies exist that examine the use of pegIFN for the treatment of HBeAg-negative CHB. The pivotal study used a design similar to the HBeAg-positive phase III trial above and compared pegIFN alone, or in combination with LMV, to LMV monotherapy (563). Sustained viral response, defined as undetectable HBV DNA ( $<400$  copies/ml), was 19% and 20% in the groups that received pegIFN, versus 7% in the LMV monotherapy group ( $P < 0.001$  for both comparisons). After 3 years, however, only 25% of patients achieving SVR maintained it (564). Predictive factors for SVR in HBeAg-negative infection have been found to be similar to HBeAg-positive patients (565).

HBeAg-negative genotype D patients are perhaps one of the most difficult groups to treat. A prospective, randomized study compared 180  $\mu$ g/week of pegIFN for 48 weeks to a group treated with 135  $\mu$ g/week of pegIFN for an additional 48 weeks (566). A higher proportion of the extended therapy group (28.8% vs. 11.8%,  $P = 0.03$ ) had a virologic response, defined as HBV DNA  $<2000$  IU/ml 48 weeks after treatment cessation, so that the prolonged regimen is standard of care for this patient population.

The limitation of all studies that have compared pegIFN to LMV is that both LMV and pegIFN were stopped simultaneously (in HBeAg-positive patients before the majority had achieved HBeAg seroconversion) (567). Primary end points were defined at 24 weeks posttreatment. In clinical practice, LMV would be continued until a clinical end point was achieved; it has been shown that virologic relapse is almost universal otherwise. In a study of pegIFN in 16 patients with LMV-resistant YMDD mutations, only two patients seroconverted and achieved sustained virologic suppression and biochemical normalization (567).

Like sIFN, pegIFN should be used with caution in patients with advanced liver disease, as a treatment-induced flare might precipitate hepatic decompensation. Although there are no data specifically addressing the use of pegIFN in cirrhotic patients, it is reasonable to extrapolate from the experience with sIFN. Thus, only patients with compensated cirrhosis should be considered for treatment. Further, in the two phase III trials approximately 15%/25% of the HBeAg-positive and -negative cohorts had advanced fibrosis/cirrhosis on liver biopsy, respectively, and no instances of hepatic decompensation were recorded (568). pegIFN should not be used for patients with Child-Pugh class B or C cirrhosis.

Both IFN preparations have similar side-effect profiles. Common symptoms include an initial flu-like illness, anorexia, weight loss, fatigue, mild alopecia, and skin rashes.

Significant neurocognitive effects are seen and commonly include emotional lability and poor concentration. Additionally, anxiety, irritability, depression, and even suicidal tendencies have been described. IFN is myelosuppressive, although profound neutropenia or thrombocytopenia is uncommon. Regular monitoring of blood counts is required during therapy. Autoimmune disease has been described, most commonly hyper- or hypothyroidism. Retinal changes and impaired vision occur rarely. A hepatitis flare is precipitated in 30 to 40% of patients undergoing IFN therapy for CHB. Although this is considered to be a marker of treatment response, indicating an increased likelihood of HBeAg seroconversion, it may precipitate hepatic decompensation, especially in the setting of cirrhosis.

### On-Treatment Predictors and Response-Guided Therapy

Given the side effects and cost of pegIFN-based regimens, interest has been directed towards delineating stopping rules for those patients who are unlikely to achieve a SVR. Much of this research has investigated the utility of quantitative HBsAg levels. Pretreatment quantitative HBsAg levels are not clinically useful (569, 570). However, on-treatment HBsAg levels at weeks 12/24 can be used to guide treatment decision-making. In HBeAg-positive patients infected with genotype B or C, week 12 HBsAg levels >20,000 IU/ml have a NPV of 92 to 98% for SVR. In genotype A or D patients, the absence of a quantitative HBsAg decline at week 12 has a negative predictive value of 97 to 100%. At week 24, HBsAg levels >20,000 IU/ml have a NPV 96 to 100%, irrespective of genotype (571). These thresholds therefore have utility as stopping rules, now acknowledged in clinical guidelines (314).

There is also a week-12 HBsAg futility rule for HBeAg-negative patients with genotype A or D CHB treated with pegIFN. At week 12, the combination of failure to achieve any quantitative HBsAg decline plus an HBV DNA reduction <2 log<sub>10</sub> IU/ml has a NPV of 95 to 100% (572, 573). Genotypes A to D were represented, although genotype D comprised about 55% of the population. This approach has since been found to be cost-effective in European populations (574). Validation in Asian populations is needed.

The utility of quantitative HBsAg in predicting longer term treatment response has been examined in HBeAg-negative patients in two studies. The first followed patients at 3 years and showed that an end-of-treatment quantitative HBsAg <10 IU/ml predicted a 52% chance of HBsAg seroconversion versus a 2% chance if this threshold was not reached (575). The second study demonstrated the importance of on-treatment quantitative HBsAg kinetics in predicting HBsAg seroconversion out to 5 years posttreatment. This was achieved by 23% of patients in whom quantitative HBsAg declined by at least 10% by week 12, compared to 7.5% in those whose levels declined by less than 10% (576).

Quantitative HBeAg levels have been less well studied as a prediction tool and would only be useful for HBeAg-positive infection. A *post hoc* analysis determined that an HBeAg level of >100 PEIU/ml at week 24 had a NPV of 96% for HBeAg seroconversion 6 months posttreatment (319).

### Thymosin- $\alpha$ -1

Thymosin- $\alpha$ -1 (T $\alpha$ -1) is a synthetic thymic extract. Thymosin derivatives regulate multiple aspects of T-cell function. *In vitro* studies have shown that T $\alpha$ -1 can influence T-cell production and maturation, stimulate production of

T-helper cell 1 (Th1) cytokines, such as interferon- $\gamma$  (IFN- $\gamma$ ) and interleukin-2 (IL-2), and activate natural killer cell-mediated cytotoxicity (568,577–586).

T $\alpha$ -1 is approved for the treatment of HBV in several countries, mainly in Asia. Treatment is usually well tolerated but antiviral efficacy remains controversial with a number of smaller clinical trials finding conflicting results (582, 584–586). A meta-analysis published in 2001, that included a total of 353 patients from five controlled trials, concluded that patients treated with T $\alpha$ -1 were significantly more likely than controls to have a virologic response, defined as loss of HBV DNA and HBeAg (578). The maximal rate of response was not seen until 12 months after discontinuing therapy (odds ratio 2.67, 95% CI 1.25–5.68). Another meta-analysis examined 583 HBeAg-positive patients across eight trials randomized to either LMV alone or combined LMV/T $\alpha$ -1 therapy. Superiority of combination therapy was shown for HBeAg seroconversion (45.1% vs. 15.2%,  $P < 0.00001$ ) (587). T $\alpha$ -1 offers the benefit of improved tolerability when compared to IFN therapy (582). Data on clinical efficacy are promising but confirmation in larger prospective randomized trials is required.

### Combination Therapy

*De novo* combination of two NA drugs in treatment-naïve patients has not, overall, been shown to improve responses or outcomes. In a randomized study of HBeAg-positive patients after 2 years of treatment, no greater viral suppression occurred with LMV/ADV over LMV monotherapy, although the incidence of new M204V/I resistance mutations was reduced (588). The combination of LMV/LdT also showed equivalent viral suppression when compared to LMV monotherapy after 52 weeks, and, concerningly, a trend towards increased LdT resistance was seen in the combination group (417). This confirms that drugs within the same class should not be used concurrently. In a study comparing the combination of TDF/ETV to ETV alone, there was no difference in the primary outcome measure of undetectable HBV DNA after 100 weeks of treatment (83.2% vs. 76.4% for ETV monotherapy,  $P = 0.088$ ) (589), although a *post hoc* analysis showed that the subset of patients, who were HBeAg-positive and with viral loads >7 log<sub>10</sub> copies/ml, had a higher rate of complete HBV DNA suppression with combination therapy. This finding needs confirmation in prospective trials.

Because a significant immune dysfunction occurs in the presence of high levels of viral antigen, there is a theoretical basis for the use of NA to reduce antigen levels, to restore immune function, and to optimize the immunomodulatory effect of subsequent pegIFN therapy. Multiple studies have compared combined pegIFN-NA therapy using either concomitant or staggered treatment schedules (590). Three large pivotal trials using pegIFN and LMV established the superiority of pegIFN over LMV in achieving HBeAg seroconversion after 1 year of treatment, but combination therapy with both agents was not shown to improve sustained response over pegIFN monotherapy, despite greater on-treatment viral suppression (364, 556, 557). A small study of pegIFN and LdT showed increased HBeAg seroconversion, but patients suffered a high rate of peripheral neuropathy (591). More promise has been shown using add-on pegIFN therapy than to viral suppression achieved with ETV. The first study started all patients on ETV, 0.5 mg, and randomized them to either pegIFN add-on therapy from week 24 to 48 or to continued ETV monotherapy (592). Although the primary outcome of HBeAg loss plus HBV

DNA <200 IU/ml at 48 weeks was equivalent between the two groups, add-on therapy resulted in a higher HBeAg loss at 96 weeks (26% vs. 13%,  $P = 0.036$ ). The second study selected patients treated with ETV who had achieved HBeAg <100 PEIU/ml and HBV DNA <1000 copies/ml. These patients were randomized to continued ETV therapy or to switch to 48 weeks of pegIFN. At end-of-treatment, those who switched had higher HBeAg seroconversion rates (14.9% vs. 6.1%,  $P = 0.047$ ) (593). Additionally, 8.5% of patients who switched also lost HBsAg.

In HBeAg-negative patients, the registrational trial showed no difference in virologic response or clinical outcomes between the pegIFN/LMV arm and the pegIFN monotherapy arm (563). Subsequent studies using either LMV or ADV have confirmed these findings (594, 595).

One large study including both HBeAg-positive and -negative patients, randomized them to one of three arms: TDF monotherapy, pegIFN monotherapy, or TDF/pegIFN combination therapy (596). After 48 weeks of treatment, 7.3% of patients in the combination arm achieved HBsAg loss versus 2.8% with pegIFN monotherapy and 0% with TDF monotherapy.

In summary, the weight of evidence for combination therapy has not definitively shown improved outcomes. Adding on or switching therapies in those with suppressed viral replication shows promise but needs replication in future studies, and data on individualizing therapeutic regimens for patients who will be most likely to benefit from such strategies requires further investigation.

### Novel Therapeutic Strategies

- 1) *Toll-Like Receptor Ligands*. In the transgenic HBV mouse model, TLR3, 4, 5, 7, and 9 ligands exerted an indirect antiviral effect via induction of type 1 IFN (122). Using the hydrodynamic-injection mouse model of HBV infection, TLR4 ligands have shown an antiviral effect (597). The TLR2 ligand Pam-2-Cys has been shown to have direct antiviral efficacy in a cell-culture model of HBV replication (121). An oral agonist of TLR7, known as GS-9620, showed promise in preclinical studies of HBV-infected chimpanzees (598). Viral load declined by a mean of 2.2 logs, and effects persisted for months after cessation of therapy. Use in the woodchuck model showed similar sustained responses after a short course of therapy (599). Despite these positive results, two phase Ib studies of GS-9620 demonstrated no change in quantitative HBsAg levels or HBV DNA (600). Although a transient, dose-dependent induction in peripheral interferon-stimulated gene (ISG)-15 expression was seen, no corresponding increase in IFN  $\alpha$  was detected. Seventy-five percent of patients were HBeAg-negative. The results of further studies in different populations are awaited (NCT02166047 and NCT01590654).
- 2) *Liver-Specific Drug Delivery*. Several experimental approaches have been taken: conjugation of antiviral agents to ligands that are selectively taken up by the liver, creation of prodrugs that require activation in the liver (601, 602), and use of a specific monoclonal antibody to recognize amino acids 183 to 191 of the envelope protein, as presented by the HLA-A201 MHC class I molecule. The monoclonal antibody therefore mimicked the specificity of the T cell receptor (603). This delivery system was used *in vitro* to selectively deliver IFN specifically to cells by conjugating the antibody to an interferon molecule (604). This may provide a future delivery platform for targeting HBV infected cells.
- 3) *RNA Interference*. *In vitro* and animal studies have suggested a potential therapeutic role for synthesized exogenous siRNA molecules targeted against HBV RNA transcripts (605–609). A delivery platform consisting of a hepatocyte-targeted endosome delivery system combined with a cholesterol-conjugated siRNA molecule targeted against HBV, known as ARC-520, has been developed and tested in mouse models (610). Subsequent phase I and IIb trials have been reported, showing a good safety profile and sustained quantitative HBsAg reductions in ETV-treated HBeAg-negative patients (611). Another phase II trial is ongoing, testing ARC-520 in combination with either TDF or ETV, in patients in the immune elimination phase (NCT02349126).
- 4) *Immunotherapy*. Therapeutic vaccine approaches have included a highly immunogenic pre-S1/pre-S2/S vaccine (339), DNA vaccines (612, 613), and T cell vaccines (614–616). Therapeutic vaccination has also been combined with PD-1 blockade (617) (see below) and NA therapy (618) to enhance the efficacy of the immunization in the functionally exhausted immune environment characterized by CHB infection. To date, despite promising results in animal models, this has not translated to durable responses in human infection (619–622). The *ex vivo* culture and priming of human dendritic cells with viral antigens, followed by autologous transfusion, is being explored as a form of immunotherapy (623–626).
- 5) *Reversal of Exhaustion*. As discussed previously, T cells of chronic HBV-infected patients exhibit immune exhaustion characterized by an increase in inhibitory surface molecules, such as PD-1. Experiments using CD8+ T cells from patients with CHB have revealed that *in vitro* blockade of PD-1 can restore HBV antigen-specific responses with regards to both proliferative capacity and cytokine production (627). *In vivo* blockade of PD-1 in the woodchuck model has shown similar results, with restoration of PBMC responses to HBcAg (617). Similarly, blockade of other mediators of immune paresis, such as Tim-3 and miR-146a, enhances T cell responses (200) (190).
- 6) *T-Cell Therapy*. Adoptive transfer of activated T-cell subsets, directed against HBV, into CHB patients may control replication (628). Other investigators have designed chimeric T-cell receptors directed against HBV surface proteins present on HBV-infected cells and used them to graft primary human T cells with antibody-like specificity via a retroviral transfection technique (629). The receptors were composed of a single-chain antibody fragment directed against HBV S or L protein fused to intracellular signaling domains of CD3 $\zeta$  and the costimulatory CD28 molecule. This method was shown to provide T cells with the ability to recognize HBsAg-expressing hepatocytes, lyse these cells, and liberate cytokines (629). Further studies of this chimeric antigen receptor therapy showed *in vivo* efficacy of viral suppression in the mouse model (630).
- 7) *Entry Inhibition*. These molecules would be useful in the settings of postexposure prophylaxis, organ transplantation, reactivation after immunosuppression, and

perinatal infection (51). Initial studies showed that acetylated peptides, derived from the large envelope protein, could prevent HBV infection in animal models (631). A specific molecule called Myrcludex-B has been developed, which is a synthetic lipopeptide derived from the pre-S1 domain of the HBV envelope protein (632). Preclinical studies in immunodeficient mice has demonstrated that Myrcludex-B not only prevents intrahepatic viral spread but also hinders the amplification of the cccDNA pool in initially infected hepatocytes (77). Early reports of a phase IIa clinical study in patients showed a dose-dependent decline in serum HBV DNA levels (633).

- 8) *Nucleocapsid Inhibition*. A high-throughput screening method identified isothiafludine, a novel molecule that inhibited the pgRNA encapsidation step of the HBV replication cycle (634). This inhibition occurred via blockade of the interaction between pgRNA and HBcAg and led to an accumulation of replication-incompetent capsids. Studies, both *in vitro* and using the duck HBV model of infection, found a dose-dependent reduction in HBV DNA replication with isothiafludine therapy (634). As both wild-type and drug-resistant strains were equally affected, further development of nucleocapsid inhibitors may lead to future therapies.
- 9) *cccDNA Inhibitors*. Clearly, these molecules would be key to eliminating the long-lived cccDNA pool responsible for occult and persistent infection. Lymphotoxin- $\beta$  receptor-specific activating antibodies have been shown to induce cccDNA degradation in a similar way to IFN. This occurs via induction of cytidine deaminases (specifically APOBEC3B) via IFN-independent pathways. This induction has also been shown to be safe, as well as more potent and durable than the response to IFN (540). The possibility of using epigenetic modification of cccDNA to reduce its transcription (635, 636) or harnessing specific endonucleases to target and cleave cccDNA without af-

fecting host DNA (637–640) are other strategies. Other therapeutic strategies are summarized in Table 8.

## LIVER TRANSPLANTATION FOR CHB

Liver transplantation for hepatitis B infection in the 1980s was associated with rapid viral recurrence, despite prophylactic HBIG, with resultant poor outcomes (641, 642). With the advent of the NA, in combination with high dose HBIG to prevent graft reinfection, transplantation with viral control became possible. However, HBIG is expensive, not readily available worldwide, and disease progression associated with drug resistance was common. Low-dose HBIG plus LMV provides safe and effective prophylaxis at significantly lower cost (643). The use of potent single agents has prevented reinfection and resistance, with equivalent outcomes irrespective of HBIG use (644, 645). NA therapy reduces the risk of clinical progression in patients with advanced fibrosis or cirrhosis (353, 413). Effective viral suppression has also allowed the salvage of many patients with decompensated cirrhosis, obviating or delaying the need for liver transplant (230, 646). Liver transplant outcomes for CHB are now equivalent to other liver diseases with a 5-year survival of 75% (647). Viral control can result in a dramatic improvement in liver function in the pretransplant patient, such that transplantation for decompensation is no longer required for some patients.

## CONCLUSION

Despite vast gains in our knowledge of the natural history and pathogenesis of this important human pathogen, it remains a significant global cause of morbidity and mortality. The increasing number of countries with national immunization programs and the use of newborn active-passive immunization will greatly reduce the number of incident cases in the coming decades. Unfortunately, the developing world is lagging behind, and new, more cost-effective methods of

**TABLE 8** Summary of potential novel therapeutic targets in chronic HBV, their mechanism of action, and current phase of study

Immune Modulation		
Mechanism	Examples	Phase/s of Study
Therapeutic vaccine	ABX-203, GS-4774, INO-1800	Phase I–III
TLR7 Agonist	GS-9620	Phase II
Immunotherapeutic	TG1050	Phase I
Immune modulator	CYT107	Phase I/IIa
Non-Nucleoside Antivirals		
Mechanism	Examples	Phase/s of Study
Entry inhibitor	Myrcludex B	Phase II
Capsid inhibitor	NVR-1221, Bay 41-4109	Phase I-IIa
RNAi gene silencer	ALN-HBV, ARC-520	Preclinical—Phase II/III
HBsAg release inhibitor	REP-9AC	Phase II
SMAC mimetic	Birinapant	Phase I/IIa
cccDNA inhibitor	BSBI-25	Preclinical
Small molecule nucleic acid hybrid	SB9200	Phase II
HBsAg inhibitor	TKM-HBV	Phase I
Cyclophilin inhibitor	NVPO18, CPI-432-32	Preclinical

preventing transmission are required. In order to address this deficit, WHO is developing a Global Health Sector Strategy on Viral Hepatitis (2016–2021), which will provide a platform of realistic goals to improve access to screening and treatment (648). In those who are identified as being chronically infected, the risk of complications of end-stage liver disease has been virtually negated in Western practice with the introduction of effective suppressive therapies and monitoring strategies. Despite this advance, a lasting cure for CHB remains elusive, with almost all patients being relegated to lifelong treatment. Future work is now focusing on the development of strategies and novel therapeutics to enhance functional and/or absolute cure, although a true solution is likely many years away from an introduction to routine clinical practice.

# Human Lymphotropic Viruses: HTLV-1 and HTLV-2

ROBERTA L. BRUHN, RENAUD MAHIEUX, AND EDWARD L. MURPHY

## 33

Human T-cell lymphotropic virus types 1 and 2 (HTLV-1 and HTLV-2) and the more recently recognized HTLV-3 and HTLV-4 are human retroviruses of the genus *Deltaretrovirus* originally derived from closely related simian viruses. Proviral DNA is integrated in the host genome and propagated by lymphocytic division with only a minimal production of infectious virus. A small viral genome encodes several structural and regulatory proteins that in concert with the host cellular immune response control the burden of infection, as measured by the proportion of lymphocytes harboring HTLV proviral DNA. Most chronically infected humans are asymptomatic, but 2% to 4% of HTLV-1 carriers develop a mature T-cell malignancy called adult T-cell lymphoma (ATL). HTLV-2 infection does not cause malignant disease. Another 1% to 2% of HTLV-1 and HTLV-2 carriers develop a spinal cord disease known as HTLV-associated myelopathy (HAM) characterized by a progressive weakness and spasticity of the lower extremities as well as a hyperactive bladder. Various inflammatory conditions have been associated with infection, and long-term mortality may be increased. HTLV-1 and HTLV-2 are transmitted from mother to child via breast-feeding, by sexual intercourse, and parenterally by the infusion of infected blood or injection drug use. From its presumed origins in Central Africa and Melanesia, HTLV-1 has spread globally along with human migrations and the historical slave trade. HTLV-2, endemic in Amerindian and African pygmy populations, has had a more limited geographic distribution except for hyperendemic spread among injection drug users (IDUs) in the United States and Europe.

### VIROLOGY

#### Classification

Within the taxa of DNA and RNA reverse-transcribing viruses, the HTLVs, along with bovine leukemia virus, are classified within the genus *Deltaretrovirus* in the family *Retroviridae* (1). HTLV-1 and HTLV-2 are RNA viruses that contain a diploid genome that replicates through a double-stranded DNA intermediary able to integrate into the host T-lymphocyte genome as a provirus. The integration process is essential to the ability of this class of virus to cause lifelong infection, evade immune clearance, and produce diseases of long latency such as leukemia/lymphoma and the inflam-

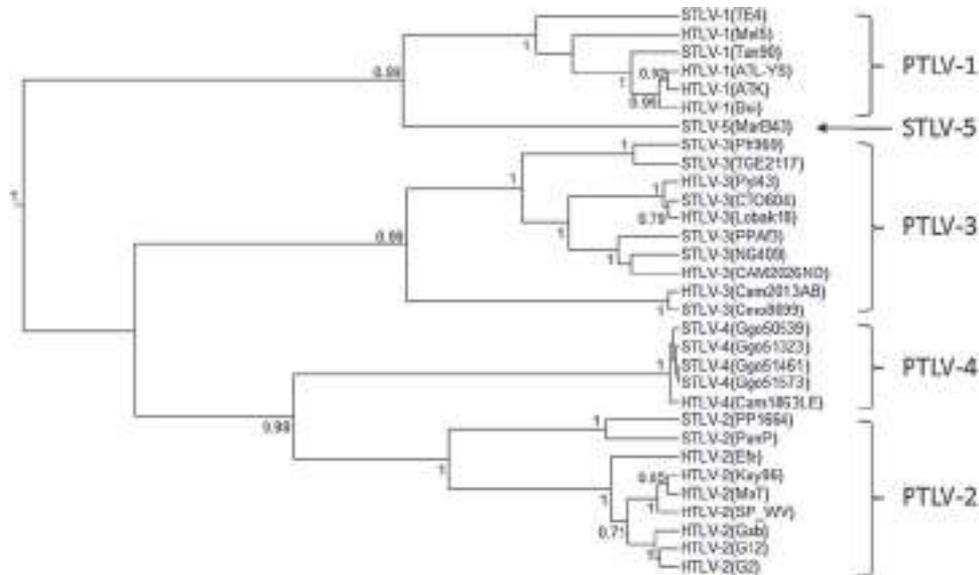

matory neurologic disease HAM. The high degree of sequence stability of the viral genome—despite hundreds of thousands of years of infecting humans—arose because HTLV-1 favors viral expansion through the proliferation of proviral DNA-harboring cells rather than the infection of new cells by cell-free virions like HIV (2). Therefore, the replicative machinery of the cell, rather than the error-prone viral reverse transcriptase, is responsible for maintaining viral genomic stability. The phylogeny of the HTLVs has become more complex as systematic studies of nonhuman primates and humans throughout the world have been carried out. A close relationship exists between the human and simian versions of these viruses. Figure 1 shows the phylogenetic relationship between the simian and human versions of the primate T-lymphotropic viruses. HTLV-3 is genetically equidistant (approximately 62% homology) from HTLV-1 and HTLV-2, which in turn are approximately 60% homologous (3, 4). HTLV-4 has only been reported in one individual from West Central Africa (5).

No serotypes for either HTLV-1 or HTLV-2 correspond to these genetically defined types. Serologically, there is significant cross-reactivity between HTLV-1 and HTLV-2, reflecting their approximate 65% sequence homology. There are limited data on seroreactivity for HTLV-3. The strongest antibody response to the major antigens of HTLV-1 and HTLV-2 occurs to the major capsid antigen p24, whereas the matrix protein p19 has approximately 50% homology and is less cross-reactive. No epidemiological data suggest that disease incidence or subtype is impacted by viral subtype for either HTLV-1 or HTLV-2.

#### Composition of the Virus

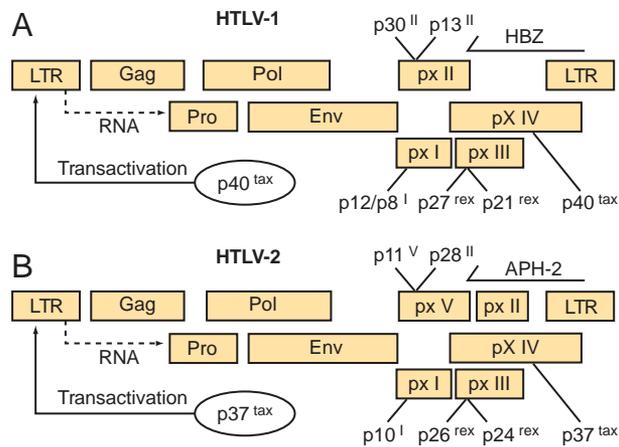

The HTLV-1 virion is approximately 100 nanometers in diameter, with a thin electron-dense outer envelope and an electron-dense, roughly spherical core. The total provirus genome consists of approximately 9,000 nucleotides, with identical sequences termed long terminal repeats (LTRs) at the 5' and 3' ends of the genome, which in the case of 5' LTR contain regulatory elements called Tax-responsive elements that control virus expression and virion production (Fig. 2). HTLV-3 has only two Tax-responsive elements in its LTR, while both HTLV-1 and HTLV-2 have three (6).

The major structural and regulatory proteins of HTLV-1 are summarized in Table 1. HTLV-1 shares with other

**FIGURE 1** Phylogenetic relationships of HTLV-1, HTLV-2, HTLV-3, and HTLV-4 inferred using Bayesian analysis and a relaxed molecular clock. Topology inferred using the first and second codon positions of concatenated *gag*, *pol*, and *env* sequences (3,490-bp). Posterior probabilities greater than 0.7 are provided at branch nodes. (We are grateful to Dr. William Switzer for his development of and permission to use this figure.)

replication-competent retroviruses the three main genomic regions of *gag* (group-specific antigen), *pol* (protease/polymerase/integrase), and *env* (envelope). Production of the Gag proteins occurs as a result of the translation of the full-length mRNA, which yields a large precursor polypeptide that is subsequently cleaved by the virally encoded protease. For the Pol proteins, production depends on translation made possible when the stop codon of the *gag* gene is bypassed, leading to a large polypeptide including

**FIGURE 2** Genomic structures of HTLV-1 and HTLV-2. A. HTLV-1. B. HTLV-2. LTR, long terminal repeat; *gag*, group-specific antigen whose products form the skeleton of the virion (matrix, capsid, nucleocapsid, nucleic acid binding protein); *pro*, gene for protease; *pol*, gene for reverse transcriptase and integrase; *env*, envelope gene; *rex*, viral regulatory gene involved in promoting genomic RNA production; *tax*, transactivator gene; HBZ, antisense transcribed HTLV-1 basic zipper gene involved in cell proliferation; and APH-2, antisense transcribed Antisense Protein of HTLV-2 gene involved in transcription regulation.

Gag- and Pol-related proteins, which are subsequently cleaved into functional proteins by the viral protease. Production of the Env surface and transmembrane proteins involves translation of spliced mRNA, which results in an envelope precursor that is cleaved into the subunits. The precursor proteins have characteristic molecular weights (MWs) that can be detected immunologically by Western blot analysis (Table 1). The Gag proteins function as structural proteins of the matrix, capsid, and nucleocapsid. The *pol* gene encodes several enzymes: a protease that cleaves Gag and Gag-Pol polypeptides, a reverse transcriptase that generates a double-stranded DNA from the RNA genome, and an integrase that integrates viral DNA into the host cell chromosomes. The *env* gene encodes the major components: the surface glycoprotein (gp46; MW, 46,000) and the transmembrane glycoprotein (gp21; MW, 21,000).

Unlike other vertebrate leukemia viruses, the deltaretroviruses have an additional region called pX that contains four open reading frames (ORFs). pX ORFs III and IV code for two transcription-regulatory proteins, the Tax and Rex proteins, whose functions are involved in the regulation of virus expression. pX ORFs I and II encode other regulatory genes whose functions are still a matter of research (7). Tax is responsible for the enhanced transcription of viral and cellular gene products and is essential for the transformation of human T lymphocytes (8); Rex (the regulator of expression of virion proteins for HTLV) promotes the export of non-spliced or singly spliced viral mRNA from the nucleus (9). As shown in Fig. 2, two overlapping reading frames are involved in the expression of both of these gene products, translated from a doubly spliced mRNA employing the initiation codon from *env* and the remaining sequences from the pX region. pX ORF I, also produced by this double-splicing mechanism, codes for a hydrophobic 12-kilodalton protein, p12<sup>I</sup>; in some HTLV-1 strains, p12 is cleaved, resulting in p8, which plays a role in viral transmission (10). pX ORF II results in the production of two nuclear proteins, p13<sup>II</sup> and p30<sup>II</sup> (11). Antisense RNA from the negative

**TABLE 1** Major structural and regulatory proteins of human T-lymphotropic virus type 1

Viral gene or region	Gene product (Protein size [kDa])	Function
5' LTR		Regulation of viral gene expression and regulation of viral expression
5' LTR & 3' LTR		Integration points for provirus into host genome
<i>hbz</i>	HBZ	<i>hbz</i> mRNA is found in ATL tumor tissue and is responsible for lymphocyte proliferation; HBZ RNA is also involved in cell cycle regulation as it increases G1/S transition; HBZ protein prevents/suppresses Tax-mediated viral transcription, suppresses the nuclear factor <i>κ</i> B (NF- <i>κ</i> B) pathway, impairs the production of Th1 cytokines, and enhances TGF- $\beta$ expression
<i>gag</i>	p15	Nucleocapsid (NC) is a small basic protein found in the virion in association with genomic RNA
<i>gag</i>	p19	Matrix (MA) protein is myristylated and anchored in the plasma membrane
<i>gag</i>	p24	Capsid (CA) protein forms the major internal structural feature of the core shell of the virion
<i>gag</i>	p53	Precursor protein for other Gag proteins
<i>pro</i>	Protease	Cleaves Gag precursor into CS, MA, NC, Pol precursor in RT and IN proteins
<i>pol</i>	Integrase	Integrates viral DNA into the host-cell genome
<i>pol</i>	Reverse transcriptase (95 kDa)	Reverse transcriptase generates a double-stranded DNA from the single-strand RNA genome
<i>env</i>	gp21 and gp46	Envelope transmembrane and surface glycoproteins
<i>pX</i>	Tax (p40)	Transactivator, enhances transcription of viral promoter and alters transcription from cellular gene promoters; recruits cyclic AMP response element binding proteins/activating transcription factors (CREB/ATF); activates signaling pathways including NF- <i>κ</i> B, activator protein-1 (AP-1), serum response factor (SRF), and nuclear factor of activated T cells (NFAT); Exogenous Tax causes a significant shift of cells from G <sub>0</sub> /G <sub>1</sub> to S and G <sub>2</sub> /M phases of the cell cycle; directly inhibits the function or the expression of tumor suppressor genes. DNA polymerase $\beta$ is downregulated by Tax, affecting both base excision repair and nucleotide excision repair. The telomerase reverse transcriptase (TERT) gene is activated by Tax, which also contributes to permanent cell proliferation and eventually transformation. Tax also induces defective mitotic spindle assembly checkpoint function, targets the RanBP1 protein, and causes abnormal amplification of cellular centrosomes, which causes chromosomal missegregation.
<i>pX</i>	Rex (p27)	Regulator of unspliced and singly spliced viral mRNA transport from the nucleus to the cytoplasm
<i>pX</i>	p12 <sup>I</sup>	Downregulation of major histocompatibility complex class I trafficking to the surface to evade CTLs; elevation of cytoplasmic calcium, increases T-cell activation. Increases NFAT activation, enhances LFA-1 mediated T-cell adhesion. Activation of STAT5b.
<i>pX</i>	p8	Cleavage product of p12; increases formation of intercellular conduits and viral transmission.
<i>pX</i>	p30 <sup>II</sup>	Interferes with TLR-4 signaling. Alters cell cycle and DNA repair. Promotes viral latency by interfering with <i>tax/rex</i> RNA export; stabilizes p53 and abrogates p53 suppressor cell function
<i>pX</i>	p13 <sup>II</sup>	Induces apoptosis; binds to and interferes with Tax transactivation; activates resting cells

ATL, adult T-cell lymphoma; CTL, cytotoxic T-lymphocyte; TLR, toll-like receptor.

strand of the pX region codes for the HTLV-1 bZip protein (HBZ) that downregulates viral transcription. Auxiliary proteins have been described in HTLV-2- and HTLV-3-infected cells (12, 13). HTLV-1 produces the HBZ (HTLV-1 basic leucine zipper [bZIP] factor) protein (14), while antisense transcription in HTLV-2 and the recently discovered HTLV-3 and HTLV-4 governs the production of a protein with some similarity in structure and function to HBZ, the Antisense Protein of HTLVs (APH), denoted APH-2, APH-3, and APH-4 for each virus, respectively (15–18). The HBZ protein is capable of inhibiting Tax-mediated activation of the HTLV-1 LTR, activating cellular transcription, and promoting T-lymphocyte proliferation (19, 20). The APH-2 and the APH-4 proteins localize in the nucleus of transfected cells, as does HBZ, while APH-3 localizes in both the nucleus and the cytoplasm. All APH proteins discovered thus far demonstrate the ability to repress Tax-mediated viral transcription (17, 18). While APH-2 is associated with a

higher proviral load (PVL), it does not promote cell proliferation nor cause lymphocytosis (15, 16).

### Biology

The replication strategy of the HTLVs involves a replication cycle typical of all members of the *Retroviridae* family, whereby the RNA genome undergoes reverse transcription into a DNA provirus that integrates into the host genome. Subsequently, new virions are produced via this integrated DNA template under the control of viral regulatory genes (Tax, Rex) (21).

### Receptors

HTLV-1 preferentially infects CD4 T-helper cells, whereas HTLV-2 has a preferential tropism for the CD8 cell type (12). Dendritic cells are also infected by HTLV-1. Additionally, HTLV-1 infects a wide range of cells *in vitro*, including endothelial cells, fibroblasts, and CD8 T cells (but at

a lower frequency based on studies of T cells from patients with HAM) (22). HTLV-1 is transmitted through a viral synapse or a viral biofilm (23) and enters target cells via interaction with molecules (Glut1, Neuropilin-1, and heparin sulfate proteoglycans [HSPGs]) that form the receptor complex (24, 25). HSPGs act as attachment factors, Neuropilin-1 as the binding receptor, and Glut1 as the fusion receptor.

HSPGs are also required for the efficient entry of HTLV-1 (26). Higher levels of HSPGs are found on activated primary CD4 T cells compared to CD8 T cells. Conversely, CD8 T cells, the primary target of HTLV-2, express GLUT1 at dramatically higher levels than CD4 T cells, thus explaining the preference of HTLV-2 for CD8 cells. HTLV-2 surface glycoprotein binding and viral entry are markedly higher for CD8 T cells, while HTLV-1 surface glycoprotein binding and viral entry are higher for CD4 T cells rich in HSPGs. The infection of CD4 cells by HTLV-2 can be increased if CD4 cells are made to overexpress GLUT1, whereas the HTLV-1 infection of CD8 cells can be increased by using transfection to increase CD8 cell HSPG expression (26). Studies employing chimeric HTLV-1 and HTLV-2 viruses in which envelope sequences are swapped demonstrate that cellular tropism is determined by type-specific envelope mapping to the C-terminal portion of gp21, indicating that *env* is a major viral determinant for HTLV T-cell tropism (12). Neuropilin-1, the receptor for semaphorin-3A and VEGF-A165 and a member of the immune synapse, is a physical and functional partner of HTLV-1 Env proteins in HTLV-1 cell entry (27). Thus, both cellular and viral envelope factors account for the complex tropism of the HTLVs. Interestingly, the HTLV-3 receptor complex is distinct from but overlaps with those of HTLV-1 and HTLV-2 (28).

HTLV is preferentially transmitted via direct contact between infected and targeted cells through a structure referred to as the virologic synapse, which is formed between the envelope glycoprotein of the virus and a cellular binding partner (29) or through the transmission of a viral biofilm (23). It is hypothesized that early during infection, most new HTLV-1-infected cells are produced via this cell-to-cell synapse, resulting in a polyclonal infection of both CD4 and CD8 T cells. This model is consistent with epidemiological data suggesting that cell-free biological fluids rarely transmit HTLV-1. In later stages of infection, when an equilibrium between viral replication and the immune response is established, HTLV-1 mainly multiplies through mitosis of the host cells (30).

### Replication

Once viral attachment takes place, the fusion of the virion with the cell membrane results in the uncoating of the diploid RNA genome of the virus. The virally encoded RNA-dependent DNA polymerase (reverse transcriptase) complexed to the genomic RNA of the virus transcribes viral RNA into double-stranded DNA. This double-stranded viral DNA is transported to the nucleus as a ribonucleoprotein complex where, through a complex process mediated by the viral integrase, insertion into the host genome occurs. The genomic integration of HTLV-1 establishes a lifelong infection and is integral to both the virus replication cycle and amplification through the expansion of HTLV-infected host cells (30).

Elements in the viral LTR are essential to integration and replication; they form the sites for covalent attachment of the provirus to cellular DNA and provide important regulatory components for transcription. Additional key regulatory elements of HTLV are *tax*, which activates transcription

of the viral genome, and *rex*, which modulates the processing of the viral RNA expressing unspliced forms of the viral mRNA. The HBZ leucine zipper protein encoded by the antisense pX gene inhibits CREB-2 binding to the viral promoter, thus modulating the viral replicating impact of Tax (19). When the DNA provirus is expressed (transcribed by a cellular RNAII polymerase complex), viral genomic RNA, mRNA, and subsequently viral proteins are made by the cell. Under the influence of Rex, new genomic full-length viral RNA is assembled and packaged for release (budding). During the budding process, the envelope incorporates some of the cell's lipid bilayer, producing an infectious virion of about 100 nanometers.

## EPIDEMIOLOGY

### Molecular Epidemiology

The four recognized HTLVs are closely related to simian counterparts and are approximately 60% homologous with each other (Fig. 1) (4). Based on the proviral DNA sequence, HTLV-1 is composed of seven subtypes—termed A through G, with up to 10% sequence variation (31, 32). It is postulated that most of these lineages arose from separate interspecies transmissions from simians to humans as long ago as 10,000 years (33, 34). All subtypes except A have examples of simian T-lymphotropic virus (STLV) isolates from the same geographic area of predominance, supporting that HTLV-1 variation is derived more from separate simian-to-human historical transmissions rather than the evolution of HTLV-1s within humans (35). The Cosmopolitan (A) subtype has the widest distribution worldwide and consists of four subgroups. Subgroup a (Transcontinental) is present in Japan, the Caribbean, Colombia, Chile, and India; subgroup b (Japanese) is found in Japan and India; subgroup c (West African) is found in the Caribbean and Africa, brought to the Caribbean through the slave trade (36); and subgroup d in North African samples was recently shown to be a recombinant virus (37).

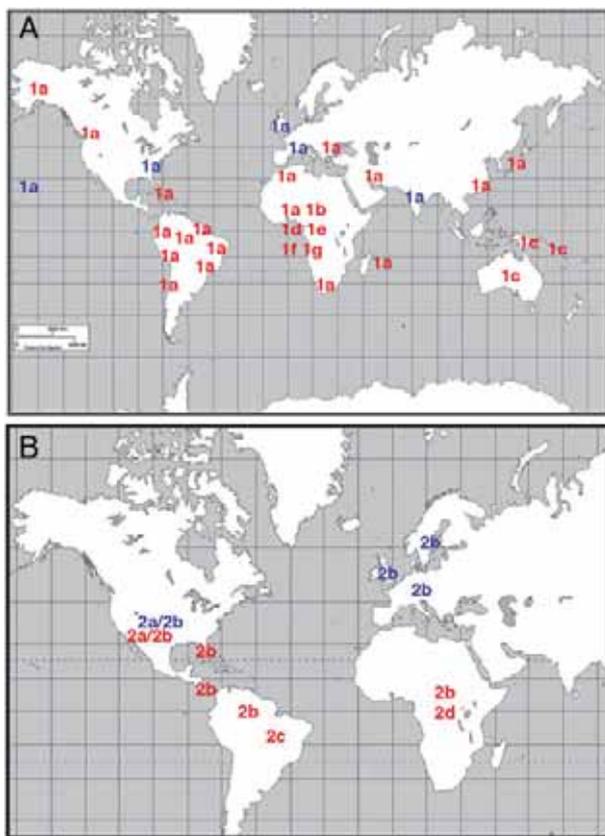

HTLV-2 consists of four types—A, B, C, and D—that are geographically distributed throughout the Americas and West Africa. Their prevalence is low in general populations but may be as high as 20% in Amerindian populations and drug user cohorts (38). Both HTLV-2 types A and B are found in West Africa and Cameroon. Between these subtypes, sequence differences of 2% to 4% are observed (39). In contrast to HTLV-1, HTLV-2 in humans appears to originate from simian-to-human transmission from a single simian species: bonobo apes (2).

More recently, HTLV-3 and HTLV-4 have been discovered in Central African pygmies (3,40–42). The full-length sequence of HTLV-3 suggests that it shares structural features that could make a pathogenic virus similar to HTLV-1, but no disease association has been made due to the limited number of infected humans (3, 4, 13,43–45).

### Distribution

#### HTLV-1

HTLV-1 is widely disseminated (Fig. 3), and 5 million to 10 million people are estimated worldwide to harbor the HTLV-1 infection (32). Over the lifetime of the infected carriers, 2% to 4% will develop the aggressive T-cell malignancy ATL, and another 1% to 2% will experience chronic inflammatory diseases, mainly HAM (46). In some areas of endemicity, over 70% of all lymphoid malignancies are attributable to HTLV-1 exposure (47).

**FIGURE 3** Geographic distributions of HTLV-1 (panel A) and HTLV-2 (panel B). Viral subtypes are indicated by lower case letters, red font indicates an endemic region for the virus, and blue font indicates imported or immigrant infections.

#### Japan and the Pacific

The distributions of both HTLV-1 and HTLV-2 infections vary by geographic region, race, ethnicity, and risk factors. HTLV-1 seropositivity or infection are present in endemic clusters in southern Japan, the islands of the Ryukyu chain (including Okinawa), and some isolated villages in the north of Japan among aboriginal Ainu populations; rates of infection among persons older than 40 years exceed 15% in these areas. However, most seropositive persons in urban northern Japan are immigrants from areas in the South where infections are endemic (48). China, Taiwan, Korea, and Vietnam are largely free of infection, suggesting that HTLV-1 was not carried by human migrations from these areas to Japan. High HTLV-1 prevalence (greater than 15%) in Melanesia and in Australian aborigines is attributed to the Melanesian virus type (49).

#### The Caribbean and the Americas

Another major endemic focus of HTLV-1 infection occurs in the Caribbean, where rates of seropositivity in Jamaica, Trinidad and Tobago, Martinique, Barbados, St. Lucia, Haiti, and the Dominican Republic range between 4% and 14% (50, 51). In Jamaica prevalence varies by geography, with the highest rates (10%) observed in the lowland high-rainfall areas (51). Seropositivity is found more frequently in persons of lower socioeconomic class and those who lack formal education (50). Men and women attending clinics for sexually transmitted diseases (STDs) have the highest rate of

seropositivity (about 6%) (52). The rate in blood donors is lower (1% to 5%) (53).

HTLV-1 is also prevalent in South and Central America, including large numbers in Brazil (greater than 15% in Bahia) and smaller numbers in Colombia, Venezuela, Guyana, Surinam, Panama, and Honduras (5% to 14%). With the exception of some foci among Native Americans, HTLV-1 is rare in the rest of Central and North America (54). A study of DNA from pre-Columbian mummies has suggested that the molecular characteristics of the Chilean HTLV-1 are closely related to the virus from Japan (55).

In the United States, large-scale screening of blood donors has documented low rates of HTLV-1 (prevalence, 5.1 cases per 100,000) and HTLV-2 (prevalence, 14.7 cases per 100,000) (56). In a significant proportion of HTLV-1-positive cases, the donor either has links to an area of endemic infection or has a history of risk-related behaviors, such as injecting drugs (57). Persons of African ancestry have higher rates of seropositivity (58). Similarly, migrant populations from Okinawa to Hawaii, from the Caribbean to the United States, and from the Caribbean to the United Kingdom are at increased risk of HTLV seropositivity, as are those exposed through sexual contact or blood transfusion in areas where the virus is endemic (59, 60).

#### Africa

In most African countries, HTLV-1 prevalence is poorly understood due to a lack of data and high rates of false-positive antibody screening tests, perhaps due to cross-reactivity with malaria antigens (61). Limited data from the Ivory Coast, Ghana, Nigeria, Zaire, Kenya, and Tanzania suggest a prevalence in the range of 5% of the general population (62). A recent study in South Africa found a prevalence of 0.16% in low-risk black blood donors, suggesting a prevalence in the general black population of almost 1% (63).

#### The Middle East and Europe

Surveys in the Middle East have not revealed HTLV-1, with the exception of northeastern Iran (Mashhad) and emigrants from that area now residing in Israel and New York (64). Surveys in southern India and Indonesia have identified some HTLV-1-positive cases; in the Seychelles in the Indian Ocean, HTLV-1 is highly endemic (greater than 15%). In Europe, occasional infections are detected among migrants from areas where such infections are endemic. In most western European countries, HTLV-1 is still uncommon except among immigrants from regions where it is endemic, sex workers, and IDUs (65).

#### HTLV-2

HTLV-2 has a more restricted distribution than HTLV-1 and occurs primarily in the Americas and parts of Africa. Amerindians residing in North, Central, and South America show various rates of positivity for HTLV-2 (5% to 30%). Pockets of infection are present among the Seminole in southern Florida and the Pueblo and the Navajo in New Mexico but not among various tribes in Alaska. In Central America, the Guaymi Indians residing in northeastern Panama near the Costa Rican border have high seropositivity rates (greater than 15%), but this does not hold true for the Guaymi living in southwestern Panama (66). At some time in the past, HTLV-2 was introduced into IDUs and amplified so that in the United States and southern Europe the prevalence ranges from 10% to 15% and higher (38, 67). From IDUs, HTLV-2 has infected members of the general US population via sexual transmission. The most frequent

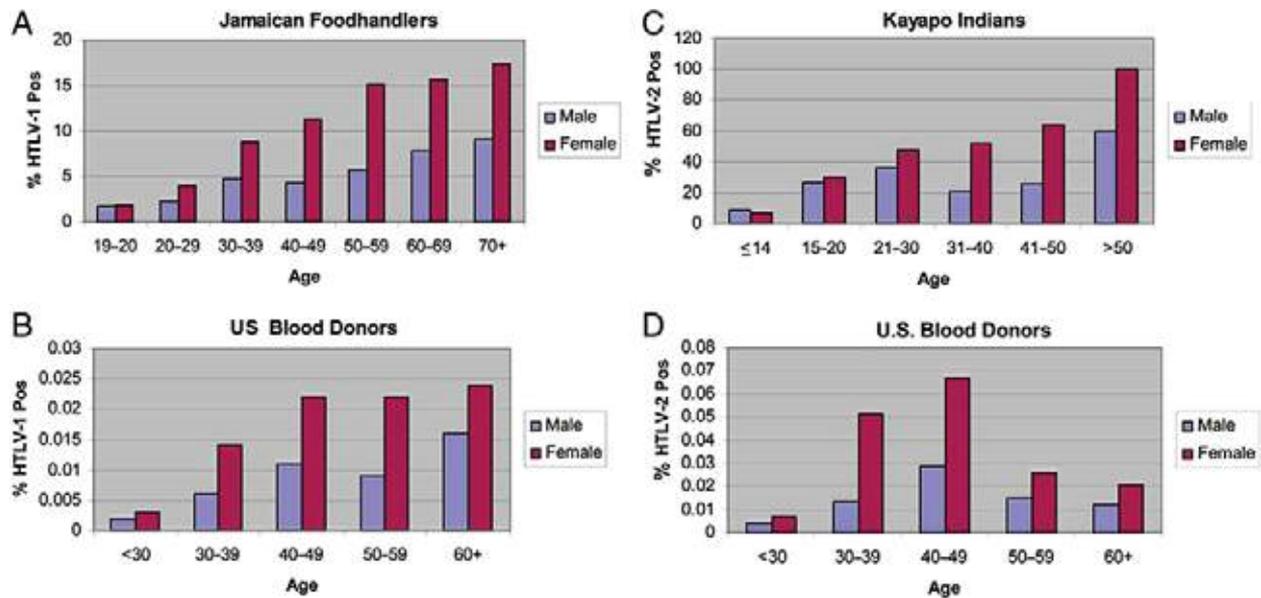

FIGURE 4 Seroprevalence of HTLV-1 (panels A and B) and HTLV-2 (panels C and D), illustrating age and sex dependence of HTLV-1 among endemic Jamaicans and US blood donors. For HTLV-2, a similar age and sex dependence is seen for endemic Kayapo Indians, but a likely birth-cohort effect is seen for US blood donors. (Adapted from references 51, 72, 214.)

risk factor for HTLV-2 in seropositive blood donors is previous sexual contact with an IDU (68).

## Incidence and Prevalence of Infection

### HTLV-1

HTLV-1 seroprevalence is characterized by an age-dependent increase that is observed in diverse geographic areas. The patterns of infection in Jamaica and in U.S. blood donors are similar despite orders of magnitude differences in seroprevalence (Fig. 4). The prevalence rate among children of both sexes is low (approximately 1%) and equal. During adolescence, coincident with the onset of sexual activity, the prevalence begins to rise, and a divergence in infection rates between males and females emerges, with female rates exceeding those of males. The reason for this female excess has been attributed to more efficient transmission from males to females. Part of this age-dependent rise, at least in Japan, has been attributed to a birth cohort effect whereby declining rates of infection in younger birth cohorts contribute to the observed age-dependent increase in prevalence (69). This pattern is observed in follow-up studies of Japanese emigrants to Hawaii, for whom rates of infection decline in successive generations (60). Possible explanations for this declining intergenerational prevalence include widespread condom use for contraception, changes in standards of living, improved nutrition, changes in breast-feeding patterns, the elimination of many coincident infectious diseases, and declines in other STDs. Nevertheless, Japanese and American couples discordant for HTLV-1 show evidence of ongoing person-to-person transmission (70, 71). There is no evidence to support the hypothesis that reactivation of immunosilent infection in seronegative persons accounts for this age-dependent increase in prevalence.

### HTLV-2

HTLV-2 also exhibits a characteristic age-dependent rise in seropositivity in populations that are endemic (Fig. 4).

Among populations of Amerindians in areas of endemic infection, prevalence increases with age similarly to HTLV-1; gender differences are less marked (72). Among IDUs, the sharing of injection equipment—a common practice before the wide availability of disposable syringes—explains the high rates of seropositivity in middle-aged and older persons compared to younger ones, again due to a birth cohort effect explained by high rates of drug use in the 1960s and the 1970s and fewer IDUs in subsequent decades. Again, there is little evidence of a virus-positive, antibody-negative state, although the HTLV-2 PVL is lower than that of HTLV-1.

## Transmission

Table 2 summarizes the routes, modes, and cofactors associated with HTLV-1 and HTLV-2 transmission. There are fewer studies of the HTLV-2 transmission risk than of the HTLV-1 risk. Data on HTLV-3 and HTLV-4 are not available due to the small number of isolates thus far.

## Routes

### Mother-to-Child Transmission

The mother-to-child transmission of HTLV-1 is the principal means of childhood infection and is associated with the greatest risk of ATL. The risk of infection in children of seropositive mothers correlates with the provirus load in breast milk, the concordance of human leukocyte antigen (HLA) class I type between mother and child, and the duration of breast-feeding (73, 74). Among children breast-fed for a prolonged period, the rate of infection ranged between 15% and 25% (75).

In Japanese prevention trials, breast-feeding accounts for most occurrences of perinatal transmission. Although 20% of breast-fed infants seroconvert to HTLV-1, only 1% to 2% of formula-fed infants of HTLV-1-positive mothers become infected (76). Children usually seroconvert in the first 2 years of life; the rates remain stable until the early teenage years, when new infections occur via sexual transmission. Maternal antibodies, present during the first 6 months of the

**TABLE 2** Transmission of HTLV-1 and HTLV-2

Mode of transmission or cofactor	HTLV-1	HTLV-2
Mode of transmission		
Mother to infant		
Transplacental	Low efficiency	Probable but not quantified
Breast milk	Very efficient	Probable but not quantified
Sexual		
Male to female	Very efficient	Yes but not quantified
Female to male	Efficient	Yes but not quantified
Male to male	Efficient	Not known
Parenteral		
Blood transfusion	Very efficient	Very efficient
Injection drug use	Efficient	Efficient
Cofactors		
Elevated virus load		
Mother to infant	Increased	Not known
Heterosexual	Increased	Increased
Sexually transmitted diseases	Increased	Not known
Cellular versus plasma transfusion products	Increased	Increased
Sharing of needles and paraphernalia	Increased	Increased
Cold storage of blood	Decreased	Decreased

child's life, appear to provide some protection for children exposed through breast milk, and infection rates increase as maternal antibody levels decline (77).

The viral load of the mother, as measured by antibody titer and viral antigen level in breast milk or blood, is the best predictor of the risk of mother-to-infant transmission (77), with the risk of transmission found to increase from 4.7 per 1,000 person-months when the provirus load in breast milk was less than 0.18% to 28.7 per 1,000 person-months when it was greater than 1.5% (74). The presence of antibodies to the Tax antigen and antibodies to certain envelope epitopes is associated with enhanced transmission. These antibodies are a surrogate for elevated maternal viral load, the major risk factor for transmission (77).

Limited studies of the mother-to-child transmission of HTLV-2 infection have been performed to date. The detection of HTLV-2 in breast milk, the 1% to 2% prevalence rate among preadolescent Guaymi Indians (a noninjecting drug use cohort from Panama at high risk for HTLV-2), and the finding that seropositive children had seropositive mothers support this route of infection (78).

### Sexual Transmission

HTLV-1 is present in the genital secretions of infected individuals and can be transmitted through sexual intercourse. A Japanese cohort of discordant couples followed for 10 years found that 27.3% of the initially seronegative women seroconverted, compared to 6.7% of the initially seronegative men, indicating that the risk of male-to-female transmission was 4.2 times higher (71). A similar study among former US blood donors found higher rates but similar gender patterns of HTLV-1 and HTLV-2 transmission from men

to women (1.2 transmissions per 100 person-years) as from women to men (0.4 transmissions per 100 person-years) (71).

Markers of sexual activity, such as an increased number of sexual partners and contact with female prostitutes, are associated with HTLV-1 transmission, as are STDs, such as syphilis and genital ulcer disease. The duration of a steady sexual relationship with a seropositive partner is also associated with seroconversion. Elevated HTLV-1 load, as measured by antibody titer or quantitative PCR of blood samples, correlates with a heightened risk of sexual transmission (79). The presence of anti-Tax antibody (perhaps a measure of *in vitro* proliferation) has also been associated with transmission (80).

The sexual transmission of HTLV-2 has been difficult to study because of the frequency of coincidental injection drug abuse among study populations (e.g., drug-addicted female prostitutes) (81). However, one prospective study of discordant couples found rates of HTLV-2 transmission (0.5 transmissions per 100 person-years) similar to those of HTLV-1 (0.9 transmissions per 100 person-years) (71). Among Amerindian populations the sexual transmission of HTLV-2 was documented in cross-sectional studies showing high concordance rates for seropositivity in couples (82).

### Parenteral Transmission

Parenteral transmission by transfusion, transplantation, or drug injection is an efficient means of acquiring HTLV infection. Although the probability of acquiring the infection through transfusion has been significantly reduced by blood donor selection and HTLV antibody screening, the transfusion of contaminated cellular components can result in seroconversion in more than 40% of recipients (53). The filter-based leukoreduction of blood products may reduce this risk substantially but not to zero (83). Among US blood donors who are confirmed to be HTLV positive, approximately half are HTLV-1 positive, and half are HTLV-2 positive, with regional differences. Their major risk factors for infection are sexual contact with an IDU, injection drug use, and birthplace in a region where HTLV-1 is endemic. The use of immunosuppressive drugs, such as corticosteroids, by the recipients of blood components may heighten susceptibility by blunting the cellular immune response to HTLV-1 following exposure. The transmission of HTLV-2 has been well documented for 50% of the recipients of known units of positive blood (84).

HTLV has been considered a contraindication to organ donation, but according to the United Network for Organ Sharing database, the prevalence of HTLV-1 or HTLV-2 infections in organ donors is 0.027% and 0.064%, respectively. In 2007 no reports of HTLV-related diseases in recipients were reported in a cohort at 1 year posttransplantation (85). The screening of deceased donors was discontinued in the United States in 2009. However, a recent report of HTLV-1 transmission and HAM following renal transplantation questions the wisdom of this decision (86). HTLV-1 transmission by organ transplantation has also been reported in Germany (87).

Parenteral drug abuse has been associated with the transmission of both HTLV-1 and HTLV-2, but most HTLV-positive drug abusers are infected with HTLV-2. This is likely due to epidemiological factors, namely historical transmission from Amerindians endemic for Native American HTLV-2 source and amplification by IDUs (88). Risk factors for seroconversion include the sharing of drug paraphernalia and blood exposure, which was more common before the wide availability of disposable syringes. Needle exchange

programs instituted to stem the HIV epidemic have likely contributed to a decrease in HTLV transmission among IDUs, although this has not been proven.

### Environmental and Socioeconomic Factors

There is no evidence of a seasonal variation in HTLV infection. Given the relative inefficiency of HTLV-1 transmission and its association with lymphoid cells, vector transmission is not thought to occur (51). The association of HTLV-1 with markers of lower socioeconomic status, such as poor housing, hygiene, and nutrition, are more likely due to behavior than environmental factors.

Occupational infection with HTLV appears to be rare. Documented cases include a health care worker who seroconverted to HTLV-1 after experiencing a “microtransfusion” when a syringe loaded with blood punctured his foot (89) and the transmission of HTLV-2 to a laboratory worker from a needlestick injury as she recapped a syringe after collecting material for an arterial blood gas analysis (90). In another study, an HTLV-2-infected blood donor admitted no risk factors except his work as a dentist (91). Casual contact does not seem to be sufficient for transmission.

### PATHOGENESIS

HTLV-1 is associated with two major categories of disease: (i) an aggressive CD4 T-cell leukemia/lymphoma called ATL and (ii) a chronic inflammatory neurologic disease, HAM, which is associated with inflammation and fibrosis of the long motor tracts of the spinal cord. In the case of ATL, HTLV-1 is monoclonally integrated into the leukemic cells, whereas in HAM, neurologic damage appears to result from an overexpression of virus and an altered immune response. Current research has demonstrated no specific genomic integration site associated with ATL (92). At the center of disease pathogenesis are the gene products of the pX reading frame (pX I to pX IV in Fig. 2 and Table 1), which not only engage in promoting viral replication but also impact cellular functions that favor viral replication. The most studied of these viral gene products coded for by pX IV is the p40 Tax viral regulatory protein, which, like its counterpart Tat from HIV-1, plays an important role in promoting viral growth and disease pathogenesis (93–95). More recently, HBZ has been recognized for its crucial role in the proliferation of ATL cells and the induction of T-cell lymphoma and systemic inflammation, mainly through the regulation of LTR transcription and the modulation of cellular signaling associated with cell growth, T-cell differentiation, and the immune response. The additional accessory proteins coded for by the pX region also play a role in pathogenesis (11).

### Viral Factors

#### Effects of Tax Protein

Tax is a posttranslationally modified protein (93) that shuttles from cytoplasm to nucleus and is responsible for the activation of virus transcription via *tax*-responsive elements. Tax alters cellular gene transcription and activates the proto-oncogenes *c-fos* and *c-erg*, as well as an array of early response genes, the human lymphotoxin gene, and the parathyroid hormone-related protein gene while it transrepresses the  $\beta$ -polymerase gene (96, 97). Tax alters the type I interferon (IFN-I) pathway (98), and the overproduction of interferon-gamma has been implicated in promoting the chronic inflammation that characterizes diseases such as HAM. Tax also affects regulators of the cell cycle, leading to uncon-

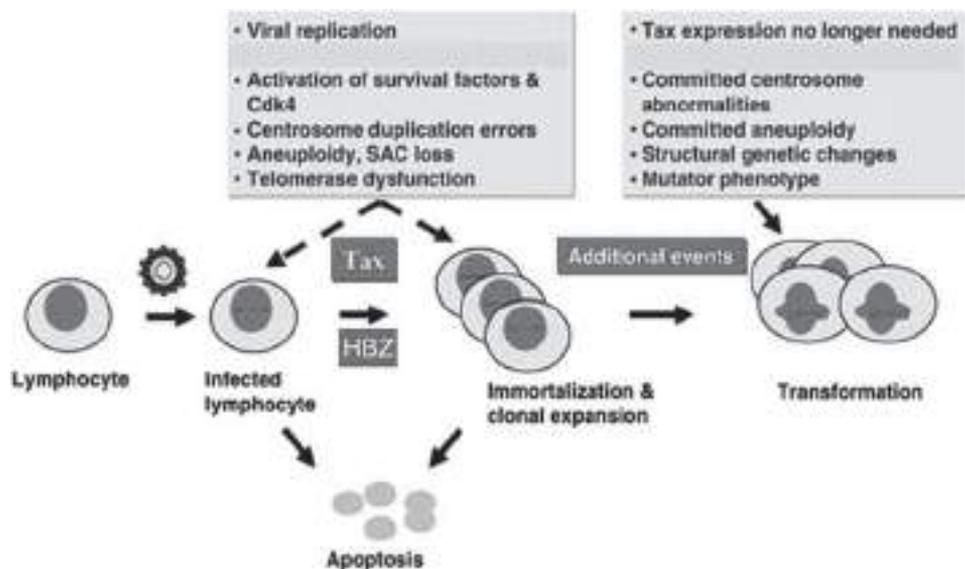

trolled cell proliferation that promotes the potential for oncogenic transformation and unregulated immune control and stimulates cell growth by directly inhibiting the function or the expression of tumor suppressor genes (99). Tax functions as an oncoprotein both to induce proliferation by the mechanisms summarized above and to inhibit apoptosis by activating the expression of BclXL and of Bfl1 (100, 101), as well as by direct transcriptional transactivation of cellular regulators of apoptosis (102, 103). Another strategy involves Tax making HTLV-infected cells resistant to various physical, chemical, and biological inducers of apoptosis, which may contribute to the risk of malignant transformation because such cells survive with damaged DNA following environmental carcinogenic exposures (104). Tax also induces structural DNA damage and alters chromosomal stability, resulting in harm to the cell's genomic integrity on the path to malignant transformation (Fig. 5). The high frequency of aneuploidy observed in ATL appears to result from Tax directly binding to mitotic arrest deficiency protein 1 (MAD1) and disturbing the segregation of chromosomes during mitosis (105). Given the high frequency of aneuploidy in ATL, the transition from oligoclonal expansion to malignant transformation is brought about by the impact of Tax on chromosomal stability (99, 106).

#### Effects of HBZ Protein

HBZ was initially identified as a binding protein that interacted with CREB/CREB-2 and inhibited HTLV-1 transcription (14, 107). HBZ promotes T-cell proliferation in its mRNA form, whereas it suppresses Tax-mediated viral transcription through the 5' LTR while in protein form (108). The HBZ binding protein, ATF3, is highly expressed in ATL cells, and its negative modulatory effects are curtailed by HBZ, allowing the proliferation of ATL cells via upregulation of CDC2 and cyclin E2 (109). HBZ enhances the transcription of telomerase reverse transcriptase, which in turn has been associated with the formation of malignant tumors, thus HBZ is implicated in ATL oncogenesis (110), and HBZ transgenic mice develop lymphoma (111). HBZ suppresses the NF- $\kappa$ B pathway and impairs cell-mediated immunity (112). It has been postulated that HTLV-1 might escape host immune attack through this mechanism (19). HBZ also allows HTLV-1 to convert infected T cells into Tregs by enhancing transforming growth factor  $\beta$  (TGF- $\beta$ ) expression. This is believed to be critical for virus persistence (19). Thus far, HBZ has been shown to inhibit Tax-mediated activation of the HTLV-1 LTR, activate cellular transcription, and promote T-lymphocyte proliferation, while all APH proteins have demonstrated the ability to repress Tax-mediated viral transcription (14, 15, 17, 18, 113). In HTLV-2, although APH-2 is associated with a higher PVL, it has not been shown to promote cell proliferation or lymphocytosis (15, 16).

#### Effects of pX I and II Proteins

pX I produces p12<sup>I</sup>, which is essential for establishing persistent infection (11). p12<sup>I</sup> targets cellular pathways involved in T-cell proliferation, thus contributing, along with Tax, to T-cell activation. p12<sup>I</sup> also interferes with the trafficking of the heavy chain of major histocompatibility complex (MHC) class I to the surface of T cells, thus contributing to the persistence of infected cells by blocking immune recognition. p12 can be cleaved into p8, which is involved in viral transmission (10). Efficient viral persistence and transmission requires both p12 and p8 (114). pX II produces p13<sup>II</sup> and p30<sup>II</sup>. p13 activates resting cells and

**FIGURE 5** HTLV lymphomagenesis: progression of T lymphocytes from immortalization and clonal expansion to transformation. Various changes in the cell during the different stages are listed in the shaded boxes. As shown, virus-infected cells can also go into apoptosis. (Adapted from reference (99) with permission of Macmillan Publishers Ltd.)

promotes apoptosis in transformed cells (115). p30<sup>II</sup> alters cell cycle and DNA repair mechanisms and promotes viral latency. Consequently, it decreases Tax expression and Tax-mediated viral transcription. The interaction between p30<sup>II</sup> and Rex appears to govern the switch between virus latency and replication (116).

### Proviral Load

Until molecular amplification tools became available, it was assumed that HTLV-1 had a low rate of expression because levels of plasma-associated virus were undetectable, and the variation in sequence diversity around the world was minimal. However, the cell-associated PVL of HTLV-1 is remarkably high compared to that of other retroviruses (117). Quantitative PCR shows that the median PVL among healthy carriers involves between 0.1% and 1.0% of peripheral blood mononuclear cells (PBMCs) (118). The number of infected cells present in the blood of a healthy carrier is generally relatively low; mean PVLs are 3.28 log<sup>10</sup> copies per million PBMCs (range, 0.5 to 5.3) for HTLV-1 and 2.60 log<sup>10</sup> copies per million PBMCs (range, 0.05 to 5.95) for HTLV-2 (119). In patients with HAM, between 5% and 10% of peripheral blood cells are infected, and in rare cases 30% of peripheral blood cells harbor the virus. Careful molecular analysis of HTLV-1 in various disease states has indicated that HTLV-1 infection is largely an oligoclonal rather than a polyclonal expansion. These observations are consistent with the hypothesis that most HTLV-1 replication and expansion occur via the proliferation of infected cells containing integrated provirus rather than through infection by cell-free virions. As a consequence, discussed below, cell-mediated immune responses are key for controlling viral infection (120). HTLV-2 genome-wide integration sites are similar to HTLV-1, but the expansion of HTLV-2-infected clones does not appear to have the same association with the genomic environment of the integrated provirus. Recent work has demonstrated that PVL in HTLV-2 is almost exclusively confined to CD8<sup>+</sup> T cells and is composed of a small number of highly expanded

clones, which suggests there are significant differences in the selection forces that control the clonal expansion of HTLV-1 and HTLV-2 during infection (120).

### Host Immune Responses

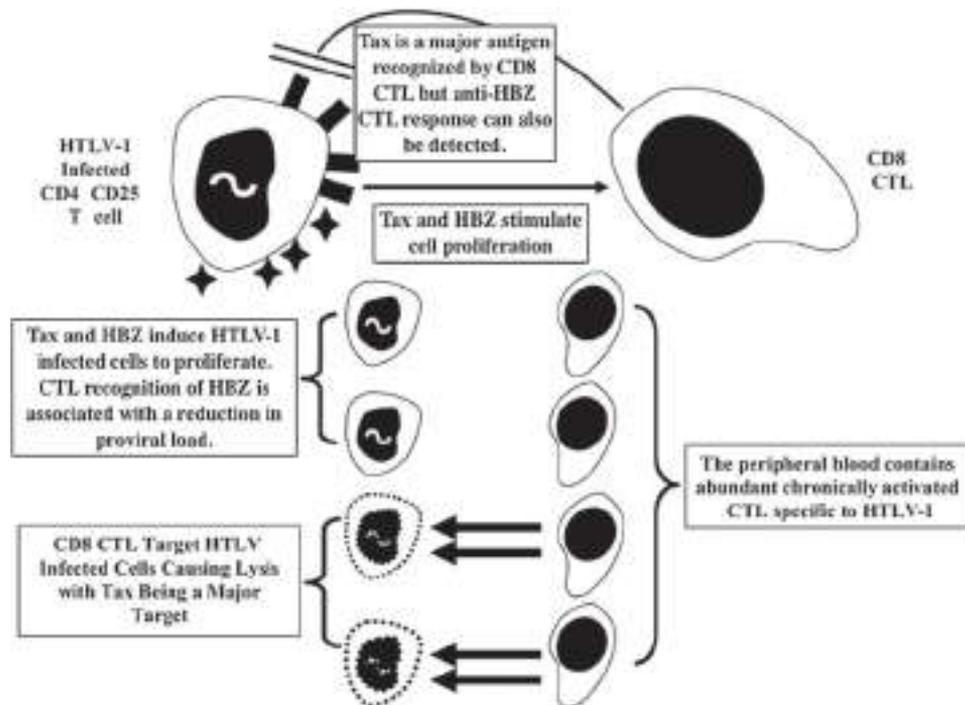

In the face of prodigious mechanisms for the expansion of viral infection, a robust and targeted cell-mediated immune response is mounted to control HTLV infection. In most cases this response is effective, given the relatively infrequent occurrence of disease among carriers, but at times the immune response may contribute to disease occurrence. A proposed model of this viral interaction with the host cell-mediated immune response is shown in Fig. 6.

#### Innate Immunity

The main *in vivo* cellular targets of HTLV-1 are cells from the adaptive immune system, for example, CD4 and C8 T cells. However, innate immune cells (monocytes, macrophages, and DCs) are permissive to the virus *in vitro* and/or are infected *in vivo* (94). The role of the innate immunity in HTLV-1 pathogenesis is not clear; however, HTLV-1-infected cells have been shown to alter IFN-1 signaling through the Tax protein, and the addition of IFN-1 efficiently suppresses HTLV-1 replication *in vitro* (98). However, even if it does not promote cell cycle arrest or cell death *in vitro*, the alpha interferon (IFN- $\alpha$ )-azidothymidine (AZT) combination is particularly efficient for treating leukemic, smoldering, and chronic ATL patients and significantly improves their survival.

#### Humoral Immune Responses

Antibodies to the various antigens of HTLV-1 occur at high levels in carriers and among patients with ATL and HAM. During primary HTLV infection, the first specific antibodies to emerge are directed against the Gag proteins. Subsequently, anti-Env antibodies appear, and about 50% of infected individuals develop detectable antibodies to p40 Tax protein (80). An older study found a median time to seroconversion of 51 days following transfusion-transmitted

**FIGURE 6** Model of CD8 CTL-mediated control of HTLV-1 infection. HTLV-1 infects CD4 T lymphocytes, with expansion of infection primarily via cell replication. As HTLV-1-specific antigens, particularly Tax, are expressed, a robust CD8 CTL response is generated that results in the killing of CD4-infected cells expressing Tax. Anti-HBZ CTL response is weak but associated with a reduction of PVL. The inability of some persons to control HTLV-1 expansion is thought to contribute to disease pathogenesis. In this model, the dynamic equilibrium between viral replication and immune destruction is mediated through Tax overexpression, causing CD4 target cell proliferation and a robust cell-mediated response to the antigen in particular, thereby leading to CTL-mediated lysis of these HTLV-1-infected CD4 cells. (Adapted from references (121, 123, 215, 216.) As a consequence of ongoing Tax and/or HBZ expression, there is a cell-associated expansion of HTLV-1 genome-containing CD4 cells and a compensatory expansion of CD8 CTL. As the number of CD4 cells containing integrated HTLV-1 provirus expands, HTLV-1 antigens are expressed on the cell surface and become targets for CD8-mediated cytotoxic killing.

infection, but time to seroconversion is likely to be shorter with newer, more sensitive antibody assays (53). Antibody titers vary from patient to patient, are significantly higher in patients with HAM and among those at risk for this disease, and correlate with the proviral burden (77, 118). This may explain the paradoxical finding of high antibody titers among women who transmit HTLV-1 to their infants through prolonged breast-feeding (75). The explanation for this paradox is that transplacental maternal antibodies appear to protect the infant from infection in the first months of life, but as passively acquired antibodies wane the infant becomes infected via maternal virus transmitted via breast milk, most likely by cell-associated infection. Other than this apparent protection afforded the baby through passive antibody transfer from an infected mother at birth, few data suggest that humoral immune responses play a role in protection from disease. The high titers observed in patients with HAM and ATL seem to reflect immune responses in the context of high viral burden observed in these conditions rather than as a direct correlate of disease risk.

### Cell-Mediated Immunity

Cytotoxic T lymphocytes (CTL) targeted at viral antigens expressed on infected cells play an essential role in the regulation of viral expression. Among chronic carriers, infected individuals mount a strong cell-mediated immune response to the virus, and up to 1% of CD8<sup>+</sup> CTL can recognize at least one epitope of HTLV. Freshly isolated cells

have substantial expression of activation markers, indicating that these cells have recently encountered the Tax antigen (121–123). Cell-mediated immune response to HTLV may also play a role in the pathogenesis of HAM.

In the case of HAM, there is an imbalance in immune response manifested by an overexpression of Tax, high levels of Tax-specific CTL, and the excessive elevation of HTLV viral load. For instance, CXCL10/IP-10, a T-helper type 1 (Th1)-associated chemokine, has been found to be significantly elevated in the cerebrospinal fluid (CSF) of HAM patients compared to healthy controls (124). Other cytokines in the Th1 pathway such as transcription factors T-beta, GATA-3, IL-12Rβ2, and suppressors of cytokine signaling are also markedly elevated in HAM patients (125). The role for CD8-mediated cell killing as the primary means of viral suppression may explain the epidemiological observation that recipients of infected blood products who are also receiving exogenous immunosuppressive medications are more susceptible to HTLV-1 infection due to the host's inability to clear the initial virus infection (54). CD4 CD25 T-cell subsets, the target of HTLV-1 infection (Fig. 6), stimulate and expand HTLV-I Tax-specific CD8 T cells, which may play an important role in the pathogenesis of HTLV-1-associated neurologic disease (126). The finding that Tax1A is more frequent in HAM than Tax1B may point to a viral motif in Tax1A that contributes to pathogenesis. Such a mechanism is consistent with the hypothesis that there is molecular mimicry between a viral and a cellular antigen. This

hypothesis is supported by the finding that HAM patients make antibodies to heterogeneous nuclear ribonuclear protein A1 (hnRNP A1), a neuron-specific autoantigen (127). Monoclonal antibodies to Tax cross-react with hnRNP A1, showing molecular mimicry between the two proteins and providing a pathogenic basis for autoimmune neurologic disease. Additionally, the finding of oligoclonal immunoglobulin bands in the CSF of HAM patients who react to HTLV-1 antigens supports this hypothesis (128).

### Impact of CD8 Lymphotropism of HTLV-2

In contrast to the predominant CD4 lymphotropism of HTLV-1, HTLV-2 provirus *in vivo* is integrated at the highest levels into CD8 lymphocytes but may also be demonstrated in CD4 cells (12, 129). The delayed hypersensitivity response is normal among HTLV-2-infected individuals, suggesting intact cell-mediated or Th1-type immunity (130). HTLV-2 infection is associated with chronic elevations in absolute lymphocyte and platelet counts (131). As noted above, there are differences in the clonal distribution of HTLV-1 and HTLV-2, and the PVL in HTLV-2 is almost exclusively confined to CD8<sup>+</sup> T cells and is composed of a small number of highly expanded clones (120). Total immunoglobulin G levels are higher in HTLV-2-infected persons (132), and HTLV-2 may induce the expression of gamma interferon, granulocyte macrophage colony-stimulating factor, and other cytokines (133, 134). Although HTLV-2 provirus has also been demonstrated in macrophages (135), whether such infection influences macrophage regulation or function to a clinically notable degree is not known. More intensive diagnostic evaluation and follow-up of HTLV-2-infected individuals is needed to confirm the relationship between HTLV-2 and recurrent pneumonia or asthma and other diseases (136).

### Pathogenesis of ATL

Following initial infection, there is a proliferation of infected cells that is downmodulated by CTL immune responses. Oligoclonal infection of mainly CD4 postthymic T cells manifests within months, and the infected cells resemble transformed but not malignant cells (79). In some instances, monoclonal infection of T cells is observed. Such oligoclonal and monoclonal expansions have been noted to appear and then sometimes disappear spontaneously.

The effect of Tax on ATL pathogenesis appears to be mediated via the transactivation of a variety of cellular growth (transcription) factors and bioactive cytokines, the interruption of cell cycle regulatory factors resulting in interruption of cell cycle arrest, the blocking of normal apoptotic pathways, and the interference with DNA repair (Fig. 5) (95). However, Tax expression is not necessary for maintenance of the malignant genotype because in most ATL cases, Tax is not expressed (108). Rather, evidence supports the HBZ protein encoded by the minus strand of HTLV provirus as being critical in the development of ATL (17). The *HBZ* gene remains intact and is consistently expressed in all ATL cases (19). HBZ promotes the proliferation of ATL cells and induces T-cell lymphoma and systemic inflammation, mainly through the regulation of LTR transcription and the modulation of cellular signaling associated with cell growth, T-cell differentiation, and the immune response. Interestingly, HBZ could be a target for immunotherapy (137, 138).

Thus, for ATL, the net effect of Tax, HBZ, and other ORF products is that the normal checks to transition be-

tween cell cycle phases are abrogated (Fig. 5), contributing to the potential for heightened mutation. Genetic damage that would normally be repaired accumulates, apoptotic cell death does not occur, and Tax induces aneuploidy directly—all in the path to malignancy. Subsequently, T cells can accumulate DNA mutations, resulting in transformation and the monoclonal outgrowth of a truly malignant cell. At the stage of malignancy, the *tax* gene is silent, and Tax is no longer expressed, as transformation of the malignant cell is complete.

### Pathogenesis of HAM

The pathogenesis of HAM appears to involve the dysregulation of immune function. This condition and other diseases with “autoimmune” manifestations of HTLV-1, coupled with the inability to downregulate HTLV-1 expression, appear to result from a failure of the cell-mediated immune response in HAM among carriers at risk. In the case of HAM, the major pathological manifestations appear to result from collateral damage to neurologic tissues as part of a cell-mediated immune assault on abundant CD4 HTLV-1-containing cells that infiltrate the central nervous system (CNS) (139). Elevated levels of lymphokines such as IL-6, tumor necrosis factor beta (TNF-β), and IL-2 are found in the CSF. However, attempts to document the presence of HTLV-1 in demyelinated lesions have not demonstrated a direct role for the virus in the target cell.

It is possible that HTLV-1 induces an autoimmune-like process through molecular mimicry or by indirect effects on immune function (see above). Autoantibodies against nuclear and perinuclear human brain proteins cross-reacting with different HTLV-1 epitopes have been found in the sera of HAM patients (140). Virus loads are high in HAM, suggesting a deficiency in the ability of the host to control viral proliferation. Furthermore, the pattern of oligoclonal expansion observed in healthy carriers is amplified in HAM. Up to one in five peripheral blood cells is infected with a high proportion of CD8<sup>+</sup> CTL targeting HTLV-1. Immunogenetic factors are associated with disease and possibly the overexpression of the virus (141).

The finding of HTLV-1 in CD8 cells and the coincidence of CD8 cells in spinal cord lesions raise the possibility that these cells may contribute to the induction of local spinal cord damage. Alternatively, because CTL against HTLV-1 account for a significant percentage of such lymphocytes, neuropathology has been hypothesized to result from collateral damage due to the local overproduction of harmful cytokines secreted by these cells. Thus, the tissue damage in the CNS in patients with HAM may be caused by lymphocytes chronically activated by the HTLV-1 Tax protein and secreting harmful cytokines and metalloproteinases (142, 143). The CD4 CD25 T-cell population is the main reservoir for HTLV-1 in HAM patients (144).

An association between class I HLA haplotypes and protection against HAM suggests that carriers of certain antigen-presenting motifs augment the efficient control of HTLV-1-containing cells. Thus, carriers of the HLA-A\*02 haplotype are less prone to developing HAM. Non-HLA-A\*02-positive carriers may be at increased risk of HAM because of an impaired cell-mediated immune response against HTLV-1-infected cells, resulting in the overexpression of HTLV (145, 146). Additionally, HLA-DRB1\*0101 doubles the odds of HAM in the absence of the protective effect of HLA-A\*02 (146). These data suggest that deficient immune recognition of Tax epitopes blunts a robust cell-mediated immune response.

### Pathogenesis of Other HTLV-Associated Conditions

For other HTLV-1-associated autoimmune diseases, such as uveitis and arthritis, HTLV-1-infected cells at the site of pathological changes and lymphokine and cytokine overexpression may account for the local pathological manifestations (147).

## LABORATORY DIAGNOSIS

### Virus Isolation

The isolation of HTLV by culture is used only in the context of research studies and is not a routine diagnostic procedure. The technique employs the cocultivation of patient cells with human PBMCs that have been stimulated *in vitro* with mitogens (e.g., phytohemagglutinin) and growth factors (e.g., IL-2). When peripheral blood from patients with ATL is cultured, the virus-positive cell that emerges has a normal karyotype, and the tumor cells themselves do not grow. The ability to isolate HTLV is dependent on the viral load, the immune status, and the stage of disease. Because HTLV-1 is so strongly cell associated, plasma antigenemia is not present at detectable levels. Antigen assays are used for detecting virus antigen in the supernatant of short-term cell cultures.

### Cellular Assays

In the research setting, the detection of cellular immune responses to HTLV-1 involves standard CTL assays using chromium release by either leukemic cells or transformed cells treated with HTLV-1 peptides or infected with recombinant virus. Flow cytometry-based assays adapting tetramer technology provide a much more precise measure of cell-specific CTL quantities. In these assays, PBMCs can be directly quantitated by the ability of MHC class I-restricted tetramers to bind Tax peptides (121).

### Nucleic Acid Detection

PCR assays previously employed in the research setting to confirm HTLV infection, distinguish HTLV type, and quantify the level of virus under various clinical conditions (148) are now available commercially to clinicians in practice. Refinements of the PCR assay resulted in a highly sensitive and reproducible detection system with limits of detection at 10 molecules of DNA in 1 milligram of human DNA (about 1 infected cell in 100,000 PBMCs) (117, 149). In the research setting, quantitative PVL measured by real-time PCR may be useful as a prognostic marker for disease progression in infected patients, and PCR following reverse transcription is used to detect viral mRNA in infected cells. Qualitative PCR detection of HTLV provirus is increasingly being applied in the clinical setting, for example, to distinguish a false-positive antibody test or to confirm infection in the context of transplantation. However, the tendency of PCR to yield false-positive results should dictate caution in its clinical use. For research applications, flow-based systems have allowed the detection of cell-specific viral antigen expression, usually Gag- or Tax-specific, in subsets of T lymphocytes (121).

### Serologic Assays

The primary test for HTLV-1 or HTLV-2 infection is detection of virus-specific antibody by a variety of techniques. Because HTLV infection is chronic, almost all HTLV-1 antibody-positive patients are also positive for HTLV proviral DNA. The most widely used assay for detection of

HTLV-1 antibodies in the United States is the enzyme immunoassay (EIA). In Japan a particle agglutination assay is used. These assays are highly sensitive and specific for virus infection (150), but the EIAs for HTLV-1 and HTLV-2 are cross-reactive. The virus subtype is distinguished by Western blot technology, which uses a combination of whole virus and recombinantly produced peptides. This assay is used to confirm that an EIA sample is truly positive and to distinguish between HTLV-1 and HTLV-2 types (151). The criterion for Western blot confirmation is the presence of antibody to the p24 *gag* gene product and one of the HTLV-1 *env* gene products, p21e (transmembrane), gp46 (external envelope), or gp61 (whole envelope). Sera with no reactivity to viral protein bands are considered negative; sera with partial reactivity are called indeterminate. Additional approaches such as the line immunoassay (LIA) or the recombinant immunoblot assay (RIBA) are supplanting the Western blot (Fig. 7). These assays contain both group-specific conserved antigen motifs from the transmembrane protein and type-specific antigen motifs from the external glycoproteins (recombinant gp46) of HTLV-1 and HTLV-2. The antigens are coated onto the strips and allow the simultaneous confirmation and differentiation of both HTLV-1 and HTLV-2 in 98% of cases (152). Confirmation by immunofluorescence assay (IFA) may be used but is labor-intensive, operator-dependent, and requires the maintenance of infected cell lines as reagents by reference laboratories. Titer determination to allow the quantification of antibody is possible with modifications to the EIA, the particle agglutination assay, and the IFA.

In tropical countries, particularly Africa, repeatedly reactive EIA samples exhibit a high frequency of indeterminate Western blot results. Typically, these sera show an HTLV Gag indeterminate profile, which may be related to endemic *Plasmodium falciparum* infection (61). To avoid overestimating the rate of HTLV-1 and HTLV-2 seroprevalence in these regions, PCR may be useful (124–126).

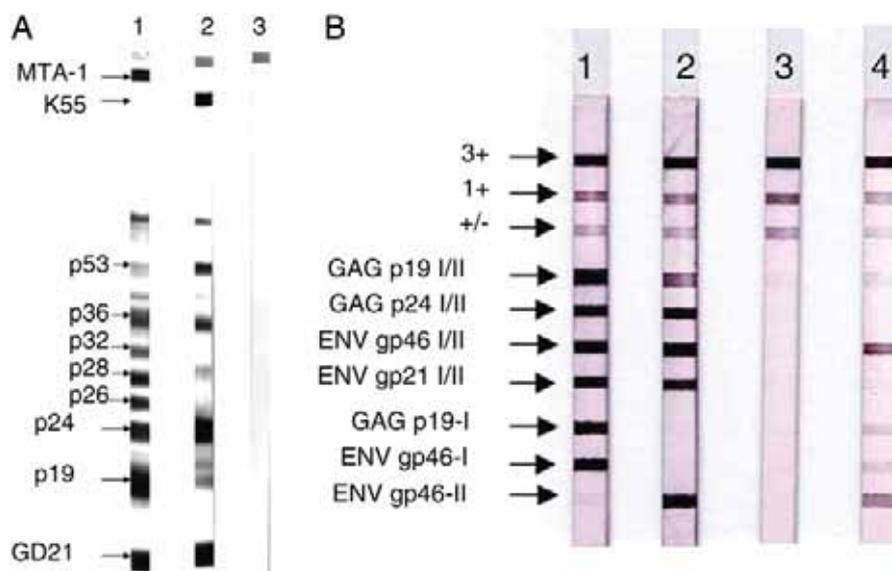

## CLINICAL MANIFESTATIONS

Acute seroconversion is associated with no recognized clinical syndrome. The median time from infection to seroconversion has been estimated at 51 days in a study of transfusion transmission, although this serologic window is likely shorter with more sensitive contemporary antibody assays (53). The time from seroconversion to disease can vary from 18 weeks with HAM to many decades with ATL. As summarized in Table 3, a wide range of clinical conditions are linked to HTLV-1, some of which result from virally induced cell transformation, as in ATL, while others appear to result from the indirect effects of virus-induced immunologic perturbation.

### ATL

Before the discovery and isolation of HTLV-1, ATL was characterized as an aggressive leukemia/lymphoma of mature T lymphocytes, with varied clinical manifestations: generalized lymphadenopathy, visceral involvement, hypercalcemia, cutaneous skin involvement, lytic bone lesions, and leukemia cells with pleomorphic features. Almost all patients with ATL present with lymphadenopathy, and 50% have hepatosplenomegaly (127).

The Lymphoma Study Group in Japan has classified ATL into four clinical types based on clinical features and cell morphology: acute, chronic, smoldering, and lymphoma/leukemia types (145). Figure 8 shows the characteristic

**FIGURE 7** Examples of assay results for HTLV-1 and HTLV-2. Lane 1 shows an HTLV-1-positive serum, lane 2 shows an HTLV-2-positive serum, and lane 3 shows a negative control serum. Modified from reference (217). (B) HTLV-1 and HTLV-2 line immunoassay, including type-specific HTLV-1 GAG p19, HTLV-1 ENV gp46, and HTLV-2 ENV gp46 antigens, in addition to shared GAG p19, GAG p24, ENV gp46, and ENV gp21 antigens. Lane 1 shows an HTLV-1-positive serum, lane 2 shows an HTLV-2-positive serum, lane 3 shows a negative control serum, and lane 4 shows an HTLV-3-positive serum from an African pygmy. (Modified from reference 42.)

morphological features of the leukemia cells and examples of the cutaneous manifestations that may be the first indication of disease. The prototypic acute ATL is distinguished by increased numbers of leukemic T cells with characteristic pleomorphic morphology (Fig. 8A), skin lesions (Fig. 8D), systemic lymphadenopathy, hepatosplenomegaly, and metabolic disorders, especially hypercalcemia.

Chronic ATL (Fig. 8B) resembles chronic T-lymphocytic leukemia; cells have a characteristic cleaved morphology called buttock cells, the white blood cell count is increased, and skin lesions are evident. Some patients manifest mild

lymphadenopathy and hepatosplenomegaly, and the serum lactate dehydrogenase level is sometimes elevated. Hypercalcemia and hyperbilirubinemia are not characteristic of this type of ATL.

Smoldering ATL (Fig. 8C) may clinically resemble mycosis fungoides/Sézary syndrome, with cutaneous involvement manifesting as erythema or as infiltrative plaques or tumors (Fig. 8D), and Pautrier's microabscesses characteristic of mycosis fungoides may be observed. This was the case in the first patient from whom the virus was isolated in the United States by Gallo and colleagues (146).

In patients with chronic or smoldering ATL, a long prodrome of symptoms or signs is usually noted before transformation to an acute ATL. Sometimes, ATL manifests as a non-Hodgkin's T-cell lymphoma with no other clinical features of ATL except monoclonal integration of HTLV-1 in the proviral DNA of the tumor cells. These cases are termed lymphoma-type ATL and are indistinguishable from peripheral T-cell lymphomas.

Between 50% and 60% of ATL patients have the acute type, 20% have the chronic and lymphoma type, and 5% have the smoldering type. Most patients with the acute and lymphoma types die within 6 months of diagnosis in the absence of therapy (Fig. 9), particularly if hypercalcemia is a presenting sign. In general, the smoldering type is the least aggressive; patients with the chronic type have a relatively poor prognosis, with death occurring within a few years of diagnosis. The cause of death is usually an explosive growth of tumor cells, hypercalcemia, bacterial sepsis, and other infections observed in patients with immunodeficiency.

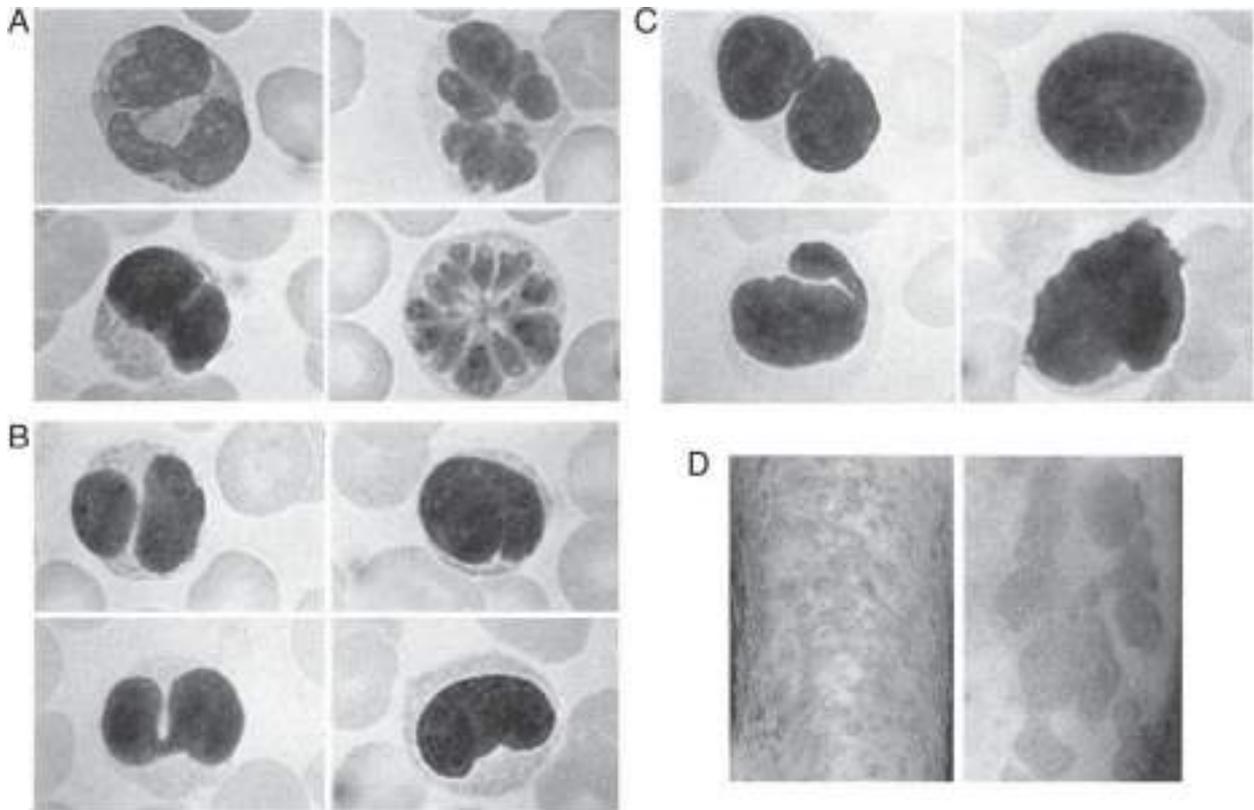

Opportunistic infections are often present and contribute to a rapid progression to death in patients with acute and lymphoma-type ATL. Immunocompromise is not due to the type of immune ablation observed for HIV-1, even though CD4 cells are infected by HTLV-1; rather, the

ATL, adult T-cell lymphoma.

**FIGURE 8** Photomicrographs of typical peripheral blood leukemic cells from patients with acute ATL (A), chronic ATL (B), smoldering ATL (C), and cutaneous manifestations (D). Details of the features are discussed in the text.

immunodeficiency is associated with rapidly proliferating malignancy, and the pattern of opportunistic infections is typical for those reported for patients with aggressive non-Hodgkin's lymphomas.

The diagnosis of ATL is based on the demonstration of monoclonal integration of HTLV-1 in tumor tissue, or if molecular diagnostics are not available, presumptive diag-

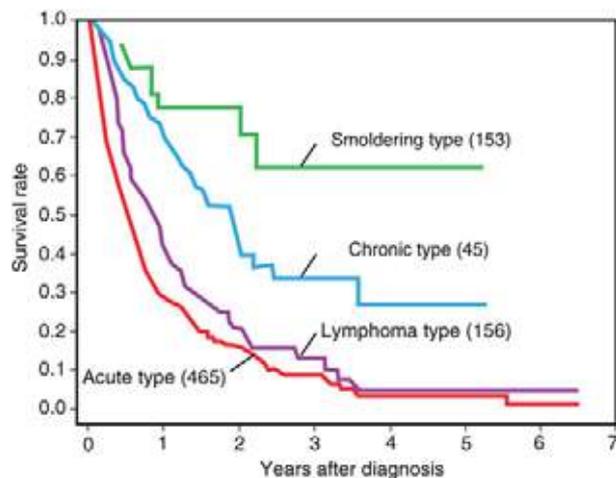

nosis can be based upon the presence of HTLV-1 antibodies in a patient with the characteristic clinical features of adult T-cell lymphoma. Proviral HTLV-1 can also be detected in the blood leukemia cells or in biopsy specimens from the patient, but such studies require a laboratory with specialized expertise. In some cases of ATL in patients from high-risk areas with typical clinical features, the HTLV-1 antibodies are absent, but a defective integrated virus with a retained *tax* function can be detected with sophisticated molecular probes.

### Other Cancers

HTLV-1 has been detected in isolated cases of other malignancies. In one case of small cell cancer of the lung, viral sequences were monoclonally integrated into the tumor cells (153). There is a statistically increased prevalence of HTLV-1 antibodies in patients with invasive carcinoma of the cervix, but this could result from shared sexual risk factors rather than a direct effect of HTLV-1 in carcinogenesis. Japanese patients with a variety of malignancies show elevated rates of HTLV-1 infections compared with healthy populations, but biases such as blood transfusion might have influenced the association. On the other hand, one study found that HTLV-1 infection was associated with the reduced risk of *H. pylori* carriage and reduced the incidence of stomach cancer (154).

### HAM

The onset of HAM is often subtle, and the full clinical picture is not usually seen at first presentation. A single symptom or physical sign may be the only evidence of early

**FIGURE 9** Survival patterns of patients with different ATL subtypes after polychemotherapy. Patients with acute and lymphoma-type ATL have the poorest prognosis after chemotherapy. (Adapted from reference 143.)

HAM. Symptoms often begin with urinary urgency and frequency and a stiff gait, progressing (usually slowly) to increasing spasticity and lower-extremity weakness, back pain, urinary incontinence, and impotence in men. Patients may complain of sensory symptoms such as tingling, pins and needles, and burning. The vibration sense is frequently impaired. Hyperreflexia of lower limbs, often with clonus and Babinski's sign, may be detected. Hyperreflexia of upper limbs, as well as positive Hoffmann's and Tromner's signs, are also frequent. Exaggerated jaw jerk is seen in some patients, and ataxia sometimes develops. Magnetic resonance imaging shows atrophy of the thoracic spinal cord but, in contrast to multiple sclerosis, only rarely shows cerebral lesions (155). The syndrome differs significantly from classic multiple sclerosis. HAM is usually chronically progressive, without the waxing and waning of symptoms characteristic of multiple sclerosis. Cognitive and cranial nerve findings are not present, and magnetic resonance imaging abnormalities are rare.

HAM patients characteristically have HTLV-1 antibodies or antigens in the blood and the CSF, and HTLV-1 provirus is found in the CSF (156). The CSF may also show a mild lymphocytic pleocytosis; lobulated lymphocytes with morphological similarity to ATL cells may also be present in the blood and the CSF. Mild-to-moderate increases in protein levels may be observed in the CSF, and oligoclonal bands with specific reactivity to HTLV-1 antigens are detected (122). The definite diagnosis of HAM requires a demonstration of HTLV-1 infection and the exclusion of other causes of myelopathy, such as spinal cord compression, paraneoplastic syndromes, parasitic myelopathy, vitamin B<sub>12</sub> and folate deficiency, multiple sclerosis, and amyotrophic lateral sclerosis, among others.

The link of HTLV-2 with HAM is now well established (157). Prospective follow-up of a cohort of former US blood donors found a cumulative incidence of HTLV-2 HAM of about 1%, lower than the incidence of HAM among HTLV-1 carriers in the same study (158). CSF lymphocytosis and the detection of HTLV-2 provirus in the CSF were less common than for HTLV-1 HAM, probably due to lower systemic PVLs (158). Earlier reports of HTLV-2 HAM had features reminiscent of the ataxic form of HAM found in Jamaica (159).

### Other Syndromes

In areas where the virus is endemic, cases of polymyositis have been associated with HTLV-1 seropositivity (160). A large-joint polyarthropathy has been reported in Japan among elderly patients (147, 161). A distinguishing feature of these cases is the presence of HTLV-1-producing cells in the synovial infiltrate. Another disease associated with HTLV-1 is uveitis. Patients with HTLV-1-positive uveitis complain of blurred, foggy vision or ocular floaters with an acute or subacute onset. Visual acuity is moderately affected. The most characteristic findings are vitreous opacities associated with mild iritis and mild retinal vasculitis. The clinical course is slowly progressive or persistent unless the condition is treated with corticosteroids. More than 90% of cases recur within 3 years, with a mean interval between episodes of 16 months (162).

Disseminated strongyloidiasis refractory to treatment has also been reported to occur in HTLV-1 carriers (163). An increased prevalence of HTLV-1 among tuberculosis patients and a high prevalence of tuberculosis among HTLV-1-infected individuals exist (164). A Japanese study reported a reduced delayed-type hypersensitivity response to *Mycobacterium tuberculosis* purified protein derivative, although a

similar study in US HTLV-1 and HTLV-2 carriers showed an intact response to recall antigens (165, 166). Therefore, immune deficits to bacteria and parasites, if they exist among healthy HTLV carriers, are likely to be limited to specific infections.

The association of infective dermatitis syndrome with HTLV-1 infection in children, originally described in Jamaica (167) but also found in other low- and middle-income areas including Brazil and Africa, appears to be an immunodeficiency syndrome induced by HTLV-1 and represents the first childhood HTLV-1 syndrome. These patients are born to HTLV-1-positive mothers and experience a syndrome of failure to thrive. They are prone to refractory generalized eczema with exudates and crusting on the scalp, ear, eyelid margins, paranasal skin, neck, axilla, and groin. Recurrent bacterial superinfections with beta-hemolytic streptococci, *Staphylococcus aureus*, or both are frequent but can be suppressed by chronic antibiotic therapy (168). This syndrome usually emerges in the first few years after birth and can persist into adulthood. Infrequent cases emerging in adolescence suggest that the induction of disease can occur following HTLV-1 infection of young adults. Some affected individuals go on to develop ATL or HAM.

Whether coinfection with HTLV-1 and HIV-1 results in a more rapid progression to AIDS is controversial. Given the effect of HTLV-1 Tax on cellular proliferation, a number of *in vitro* studies document the accelerated killing of HIV-1-infected cells that might predict an influence of HTLV infection on HIV-1-related AIDS progression. Epidemiological studies report varying effects of HTLV-1 infection on accelerating the clinical progression to AIDS, but other studies have not confirmed this observation (169); a recent review has concluded that there is little evidence that HTLV-1 hastens progression to AIDS in coinfecting patients (170). However, CD4 lymphocyte counts are elevated in HTLV-1 and HIV coinfection compared to HIV monoinfection, and this needs to be considered when managing the HIV disease.

### HTLV-2 Disease Associations

The original isolations of HTLV-2 came from patients diagnosed with T-cell hairy cell leukemia. In one of these cases, the tumor involved B cells, while the HTLV-2 was in the T cells (171). Several cases of large granulocytic cell leukemia (a non-T-cell malignancy with a similar pattern) have also been reported, although larger studies have failed to confirm an epidemiologic association between HTLV-2 and this malignancy (172–174). In addition to HTLV-2-associated HAM (described above), HTLV-2-infected individuals may show increased incidences of acute bronchitis, bladder or kidney infection, arthritis, and asthma and a higher incidence of pneumonia than HTLV-seronegative individuals (136). Finally, a prospective follow-up of the same cohort found increased overall mortality as well as cancer mortality (175). The biological basis for these clinic-epidemiologic findings has not been confirmed but may be due to chronic low-grade inflammation associated with HTLV-2 infection. HTLV-2 does not appear to alter the course of HIV disease in coinfecting patients (176).

### Disease Incidence

The incubation period between infection and disease onset ranges from months to years. Blood transfusion-associated cases of HAM have developed within a few months of transmission. For ATL, the incubation period appears to be

years to decades. For infective dermatitis, a childhood immunodeficiency condition, disease occurs within the first few months of life following infection at birth or via breast milk transmission.

#### ATL

In areas of endemicity, such as southern Japan and the Caribbean Islands, the annual incidence of virus-associated leukemia is approximately 3 per 100,000 per year and may account for one-half of all adult lymphoid malignancies (177). ATL occurs in 1 per 1,000 carriers per year, resulting in 2,500 to 3,000 cases per year worldwide (178, 179). ATL rarely occurs in the pediatric age group, but cases in 5- and 6-year-old children have been reported (180). Most ATL cases occur between the late 30s and the late 50s rather than in the older age groups, which is typical of B-cell lymphomas in developed countries. Before the age of 50, HTLV-1 is the major single cause of lymphoma in areas where infection is endemic. Compared to Japan, where the peak occurrence is between 50 and 60 years of age, cases in the West Indies and Brazil among persons of African descent peak approximately a decade earlier; immigrants from these regions to areas where infection is not endemic sustain this differential in the age-specific incidence (50). The male-to-female ratio for ATL cases is approximately 1, which contrasts with the excess of infections among females in adulthood. The decline in ATL incidence after age 50 suggests that early life exposure to HTLV-1 contributes substantially to a subsequent risk of lymphoid malignancy with a latency of decades.

#### HAM

The lifetime incidence of HAM in HTLV-1 carriers is estimated to be about 2% (range, 0.3% to 4%). The disease clusters geographically in regions of HTLV-1 endemicity. HAM appears to have a shorter latency than ATL and is associated with viral acquisition by sexual intercourse or blood transfusion rather than mother-to-child transmission. HAM cases may be more prevalent because of the long survival associated with this chronic degenerative neurologic condition. Females are approximately twice as likely to be affected with HAM as males; markers of sexual transmission have been associated with the disease in females (181, 182). Cases tend to peak in the 30- to 50-year age group, but cases have been reported for children as young as 3 years of age. HAM is considered uncommon in children, although case reports have increased in recent years (73, 183). In a report of seven children with infective dermatitis and HAM, the progression of neurologic symptoms was remarkably rapid (183). Infections during adult life are more likely to lead to HAM than to ATL.

### TREATMENT

Unlike for HIV-1, there is no proven antiviral therapy for HTLV-1. Hypothetically, some drugs that target HIV-1 reverse transcriptase might have effects against HTLV-1, as shown by *in vitro* studies showing the inhibition of viral growth. However, therapeutic effects have not been systematically evaluated in clinical trials, although anecdotal reports suggest some antitumor effects (see below). In ATL the role of active viral replication is far from clear because the tumor cell harbors many oncogenic mutations in cell regulatory genes, which may not be reversible by treating the virus. HAM, with its high viral load and substantial cell-mediated immune response to HTLV-1, would appear to be a better candidate for antiviral treatment, but therapy that

targets the immune response itself or a combination of antiviral and immunomodulator therapies may afford an equally attractive avenue for experimental treatment. An increased PVL is a prognostic marker for HTLV-1-associated disease development. A recent report demonstrated that associating histone deacetylase inhibitors with AZT in nonhuman primates naturally infected with HTLV-1 allows a very strong decrease in PVL. Thus, this approach could be envisioned in HTLV-1 patients at risk for developing disease. The opportunity exists to investigate the impact of antiviral therapy on persons coinfecting with HTLV-1 or HTLV-2 and HIV-1, and studies are needed to determine if, for example, the viral load of HTLV-1 or HTLV-2 is modulated by anti-HIV-1 therapy (184). However, one report indicated that a high viral load of HTLV-2 protected against HIV-1 disease progression. The mechanism appears to involve the heightened production of C-C chemokines in response to HTLV-2 infection, blocking HIV-1 infection (185). The HIV integrase inhibitor raltegravir also has *in vitro* activity against HTLV integration and may be useful in controlling PVL (186, 187). Further study of antiretroviral therapy in HTLV infection is warranted.

#### ATL

Despite advances in support and the development of novel treatment agents, the prognosis for patients with ATL remains poor. While response rates, even for the poorest risk categories, are over 50% and complete remissions are achieved in 20% of cases, these responses are short-lived, with relapses within weeks to months (58). Therapeutic approaches tested over the past 2 decades have been associated with modest improvements in response, but more recent strategies offer greater hope (188, 189). With a 70% 5-year survival rate with no therapy and because of complicating infections caused by bone marrow suppression, patients with chronic and smoldering ATL are not treated or are given prednisone with or without cyclophosphamide. The acute and lymphoma types of ATL are aggressive high-grade lymphomas with a generally poor prognosis and historically have 20% remission rates at best with a variety of traditional chemotherapy approaches, but remissions are short-lived, and the mortality rate is high.

Negative prognostic factors include poor performance status at diagnosis, age over 40 years, extensive disease, hypercalcemia, and a high serum lactate dehydrogenase level. Approximately 13% to 15% of patients with such aggressive cases experience a long-term survival (over 2 years), which has been associated with several factors: complete remission, longer time to remission, and total doxorubicin dose. Relapses in these long-term survivors often occur in the CNS and prove refractory to subsequent therapy.

A combination of AZT and interferon has been reported to induce remission and improve survival in cases of acute, chronic, and smoldering ATL; the lymphoma type is less responsive to this regimen (190). The mechanism of action of AZT and interferon is not well understood as HTLV replication is not active in most cases of ATL (143). Experimental approaches that use monoclonal antibodies to IL-2R linked with cell toxins selectively targeted to the leukemic cells are being tested, with some evidence of at least partial responses (191). A study of arsenic trioxide demonstrated responses in patients failing prior chemotherapy but involved a high level of toxicity (192). Newer agents like proteasome inhibitors, retinoids, and angiogenesis inhibitors, as well as cellular immunotherapy, are being evaluated (193, 194).

Combinations of doxorubicin and etoposide have resulted in complete remission rates of 40% (195). The current focus of therapy is the use of allogeneic hematopoietic stem-cell transplantation for patients with ATL following an initial complete or partial response to chemotherapy (196) (197). Mortality during transplant is high, but 5-year survival has exceeded 30% to 35%. One transplant patient showed a reappearance of cells harboring the integration of HTLV-1 previously observed in his leukemia cells, but the patient continues in clinical remission, suggesting a possible reversion to the preleukemic carrier state (198). Additionally, some patients have achieved a second complete remission, including by reduction or cessation of immunosuppression, suggesting a graft-versus-ATL effect (196).

### HAM

The treatment of HAM with corticosteroids benefits some patients, particularly when given early in the clinical course or in those with rapidly progressive disease, but side effects limit the chronic use of corticosteroids. Treatment with danazol, an androgenic steroid, has reversed urinary and fecal incontinence in some patients but not the spastic limb disease or the underlying neurologic deficit. Experimental studies with beta interferon (IFN- $\beta$ ) in doses comparable to those used for multiple sclerosis may be of value because the mechanism of immune pathogenesis may be shared between the two diseases (199). Treatment with IFN- $\alpha$  has shown to be of short-term benefit and appears to decrease provirus load (200). IFN- $\beta$ -1a interferon has also been reported to reduce the HTLV-1 mRNA load, but the provirus load remained unchanged, and there was only a slight improvement in motor function (201). However, toxicity limits the acceptance of interferon therapy by many patients.

Given the emerging picture of disease pathogenesis with an inability to control high viral expression, therapy with antiviral drugs would appear to be a promising avenue for research. The combination of two nucleoside analogs, zidovudine and lamivudine (AZT and 3TC), was evaluated in 16 patients with HAM (202), but after a year of follow-up, no significant changes in provirus load and no clinical improvements were observed. The HIV integrase inhibitor raltegravir also has activity against HTLV integration, and a current trial is assessing its effects on PVL and clinical course in HAM patients (203).

## PREVENTION

### Infection Control Measures

The transmission of HTLV is mediated by live cells and not via cell-free body fluids. For this reason, HTLV-1 is not an easily transmitted virus. Universal precautions like those recommended for HIV-1 are applicable for viral inactivation and protection from potentially infectious blood or bodily secretions. Guidelines for prevention and counseling have been developed for HTLV-1 and HTLV-2 by a Centers for Disease Control and Prevention working group (204). Standard prevention approaches address each of the major avenues of transmission and are similar for both viruses: screen blood, eliminate breast-feeding by known infected mothers (or, where not feasible, limit breast-feeding to the first 6 months of life), and advise the use of condoms by discordant couples.

The value of blood donor screening has been well documented in Japan, where up to 15% of HTLV-1 infections have been eliminated (205). In areas where the in-

fection is not endemic, such as the United States and Europe, the cost-effectiveness of screening has been questioned. Due to the low incidence of new HTLV infections, a strategy of antibody testing only first-time blood donors may be cost-effective. Filter-based leukoreduction has been shown to reduce the HTLV-1 PVL in blood units and reduce the risk of transmission, so some countries with low HTLV prevalence have used this approach without testing for virus (83). Reports on HTLV RNA detected in cell-free plasma have not been replicated (206).

Pregnant women in developed countries who are HTLV-1 positive should not breast-feed their infants. However, in developing countries, where safe alternatives to breast-feeding may not be available, limiting breast-feeding to the first 6 months may afford some protection via maternal antibodies (75).

The use of condoms is recommended for couples who are discordant for HTLV infection. Given the likely low frequency of sexual transmission for each sexual encounter, couples who desire a pregnancy could plan to have unprotected sex during periods of maximal fertility. Artificial insemination after washing semen to remove HTLV-infected lymphocytes has been performed. Such decisions require careful discussions between the physician and the patient; reproductive medicine guidelines include HTLV only in some states.

Counseling seropositive patients involves a clear discussion of the distinction of HTLV from HIV. In addition, the HTLV type should be defined by serologic methods, and the distinctions in disease associations of the two virus types should be emphasized. In areas where HTLV-1 is endemic, populations at risk for HIV are also at risk for HTLV-1 (e.g., persons at risk for STDs, persons with high rates of partner exchange, and commercial sex workers), and therefore HIV prevention guidelines will also benefit those at risk for HTLV-1. Prevention measures that promote using condoms, treating STDs, and decreasing high-risk exposures will also prevent HTLV-1 infection. Nosocomial infection has been reported only rarely (89–91), suggesting that HTLV-1 is unlikely to be transmitted in this setting.

There is no therapy for asymptomatic HTLV-1 infection and thus no chemoprophylaxis. Passive immunoprophylaxis is hypothetically effective, as noted below, in animal studies, but it has no practical clinical application given the low risk for transmission except through sexual, breast-feeding, and transfusion exposure, where other prevention methods are more applicable.

### Vaccines

While vaccines against HTLV-1 are theoretically feasible, there has been little impetus to develop or market an HTLV-1 vaccine because of the relatively low penetrance of illness and the “orphan disease” status of HTLV-1. Experimentally, vaccines containing whole virus and recombinant HTLV-1 envelope antigens successfully prevent HTLV-1 infection in monkey and rabbit models (207, 208). Protection is correlated with the presence of neutralizing antibodies, indicating that humoral immunity can be an effective barrier against infection, even when the challenge is cell associated. The HTLV-1 envelope is relatively highly conserved, and neutralizing antibody appears to protect against challenge with even major strain variants, consistent with the conclusion that a single serotype will protect against all variants (209). Therefore, a synthetic vaccine against one HTLV-1 isolate could protect against other HTLV-1 isolates. A vaccine that induces cell-mediated immune responses in

non-human-primate studies has also been shown to be effective (210). Therapeutic vaccines include one with Tax peptide-pulsed dendritic cells for adult T-cell leukemia/lymphoma (211) and another based upon Tax and HBZ sequences linked to a lentiviral vector. A preventive vaccine based upon HTLV structural peptides expressed in baculovirus is also being developed (212).

# Human Immunodeficiency Virus

JOHN C. GUATELLI, ROBERT F. SILICIANO, DANIEL R. KURITZKES,  
AND DOUGLAS D. RICHMAN

## 34

Infection with human immunodeficiency virus type 1 (HIV-1) is prevalent throughout the world and is characterized by a progressive deterioration of the immune system that is usually fatal if untreated. As of 2013, HIV-1 was estimated to infect 35 million people worldwide (<http://www.who.int/hiv/data/en/>). Over 95% of these infections are in low- and middle-income countries among young adults. The acquired immunodeficiency syndrome (AIDS) that results from chronic HIV-1 infection is the sixth leading cause of mortality worldwide; it was estimated to have caused 1.5 million deaths in 2013 (<http://www.who.int/hiv/data/en/>).

Although the first known human case of HIV infection dates to 1959 (1), AIDS was first recognized as a clinical entity in 1981. The syndrome was identified by clusters of unusual diseases including Kaposi's sarcoma and *Pneumocystis jirovecii* pneumonia in young homosexual men who had immunodeficiency due to depletion of CD4<sup>+</sup>, helper T cells (2–4). AIDS cases were subsequently reported in intravenous drug users (IVDU), hemophiliacs, and in infants born to mothers with AIDS, suggesting a blood-borne as well as sexually-transmitted pathogen. In 1983, HIV-1 was isolated (5), and this novel human retrovirus was proposed as the cause of AIDS. Within several years an antibody test was developed to detect infection, the nucleotide sequence of the genome of HIV-1 was determined (6–9), and the first antiretroviral drug—the nucleoside analogue zidovudine—was shown to have activity *in vitro* and in patients (10, 11). Since then, enormous progress in both basic and clinical research has provided the tools to suppress viral replication to a degree sufficient to prevent or reverse the immunological and clinical sequelae of HIV infection. Nevertheless, neither curative therapy for this disease nor a protective vaccine is available.

Each of the two types of HIV, HIV-1 and HIV-2, reflects the cross-species transmission of nonhuman primate lentiviruses to humans (12). Evidence for cross-species transmission emerged in 1985, when antibodies that were more highly reactive with proteins of simian immunodeficiency virus (SIV) than with those of HIV-1 were detected in West African prostitutes (13). This observation led to the discovery of HIV-2 (14), a virus closely related genetically to SIVsm strains isolated from sooty mangabeys (*Cercocebus atys*). Eight independent transmission events from sooty

mangabeys have yielded the HIV-2 genetic groups, A-H, and a ninth unrelated strain was recently identified in Côte d'Ivoire; however, this strain, as well as groups G and H, have been identified only in single individuals, suggesting that human-to-human transmission might sometimes be nonsustained (15, 16). In contrast to HIV-2, the zoonotic sources of HIV-1 are the chimpanzee subspecies *Pan troglodytes troglodytes* (*P.t.t.*), in which SIVcpz strains are endemic, and, to a lesser extent, gorillas, which harbor SIVgor (17–19). Based on genetic analyses, SIVcpz has been introduced into the human population from *P. t. t.* on two occasions to yield the HIV-1 groups M (main; the group responsible for the global pandemic) and N, whereas SIVgor is the source of HIV-1 groups O and P (19, 20). Each of the distinct cross-species transmission events that led to the appearance of the HIV-1 groups (M, N, O, and P) in humans appears to have occurred in southern Cameroon (19).

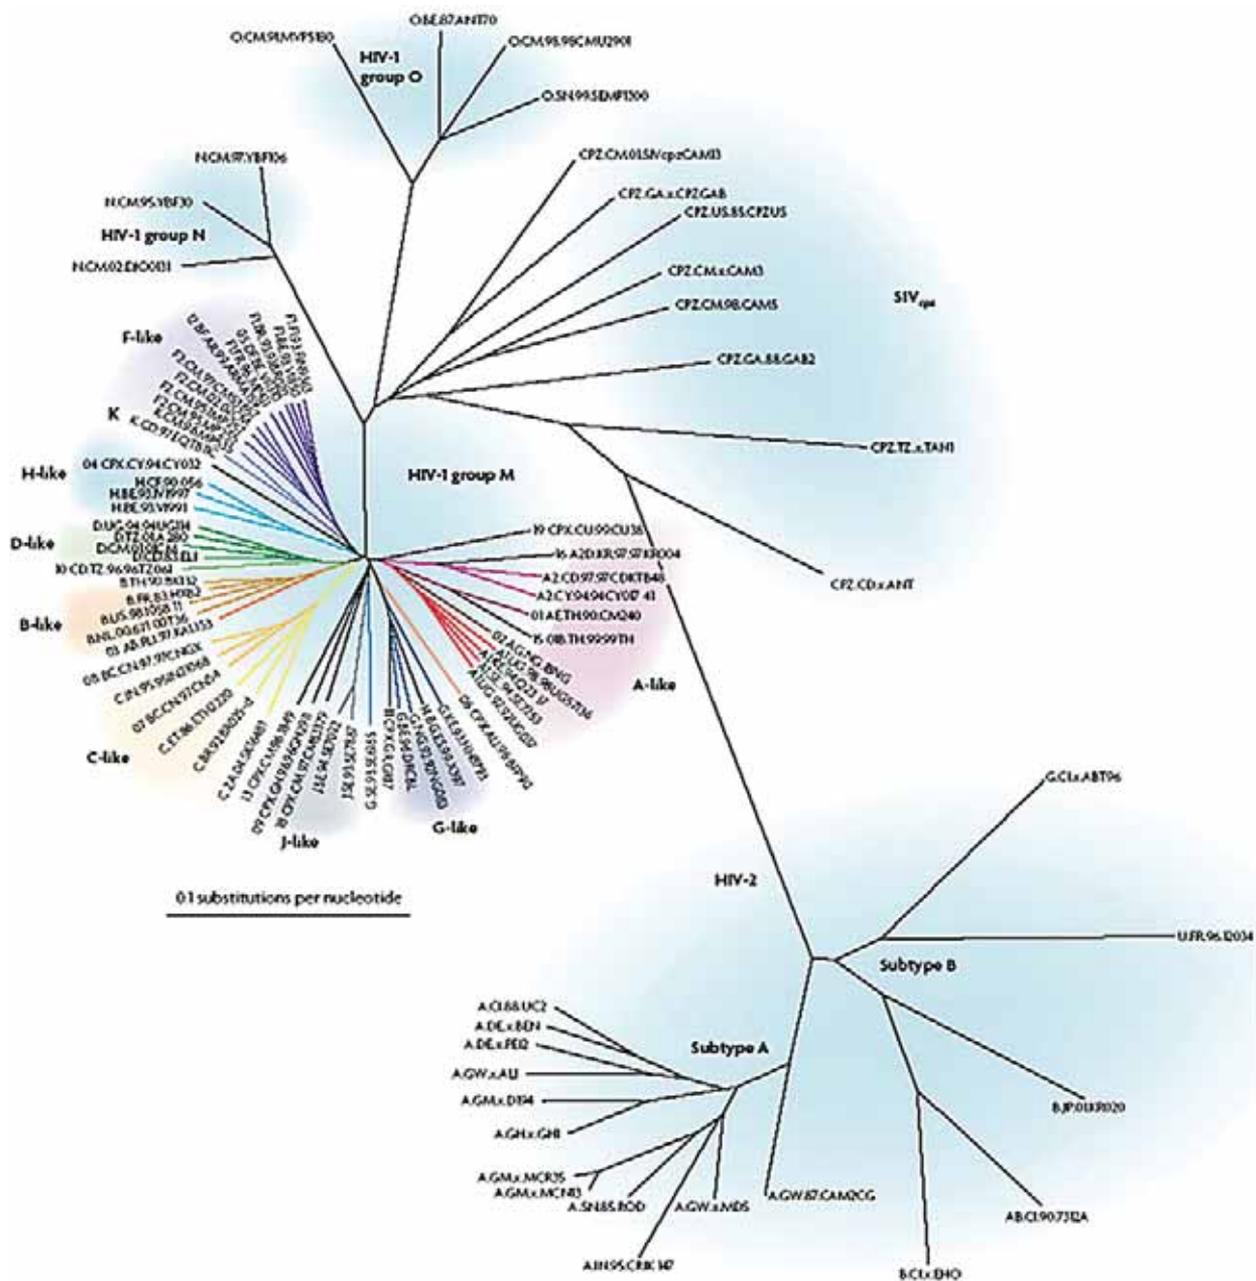

## VIROLOGY

### Classification

HIV-1 and HIV-2 are enveloped RNA viruses belonging to the family *Retroviridae*. These viruses reverse transcribe their genomes to form double-stranded DNA, which integrates into the host genomic DNA. HIV-1, HIV-2, and the SIVs are members of the lentivirus genus. Viruses in this genus are characterized by cytopathicity *in vitro*, lack of oncogenicity, the establishment of chronic infections, and relatively slow rates of pathogenesis. SIVs have been found in at least 26 species of nonhuman African primates, including African green monkeys (SIVagm) and sooty mangabeys (SIVsm) (12). In their natural hosts these viruses are generally not pathogenic. However, introduction of the African SIVsm or SIVagm into Asian rhesus macaques results in an AIDS-like illness, similar to that caused by the introduction of SIVcpz into humans (21).

### Genotypes, Serotypes, Antigenicity

Among the four genetic groups of HIV-1 (M, N, O, and P), group M viruses dominate the pandemic. This group is further divided into genetic subtypes or clades (A through D, F through H, J, and K) based on nucleotide sequence differences of more than 15% in *gag* and >20% in *env*

**FIGURE 1** The genetic relatedness of different HIV and simian immunodeficiency virus (SIV) strains. 87 human and simian lentiviruses were compared by aligning their full-genome sequences. Phylogenetic trees based on nucleotide distance were constructed by neighbor-joining methods. HIV-2 and HIV-1 share only 50 to 60% sequence identity and cluster at distinct locations on the phylogenetic tree, whereas SIV<sub>cpz</sub> branches out from the root of the HIV-1 groups. The origins of these HIV-1 groups in southern Cameroon indicate two probable jumps from chimpanzee (groups M and N) and gorilla (group O) species. HIV-1 M subtypes probably evolved from a discrete introduction into the human population and then diverged into different subtypes. The subtypes defined as “A-like” describe HIV-1 isolates with sequences that map phylogenetically more to subtype A than to any other subtype. For example, the recombinant form CRF02\_AG (such as 02 AG.NG.IBNG in the HIV-1 group M A-like cluster) has longer genomic segments that are more related to subtype A than to subtype G. M, main; N, new. (Modified with permission from [482]).

(Fig. 1). Subtype C is the most prevalent worldwide. Many viral isolates are recombinants containing sequences from more than one subtype. These are designated CRF for circulating recombinant form (22). For example, the former subtype E is believed to be a recombinant between subtypes A and E, and its current designation is CRF01-AE. Mosaic viruses that contain parts resembling four or more subtypes

are given the suffix cpx for complex; for example, the former subtype I has been given the designation CRF04-cpx to indicate that it is a complex circulating recombinant form. The designations of specific HIV-1 strains as CRFs versus parental subtypes are subject to change, since putative evolutionary relationships can be confounded by sampling history and high rates of recombination (23).

Both humoral and cellular immune responses have been detected to each of the proteins of HIV. Antibody reactivity to multiple proteins forms the basis for the confirmatory western blot assay. The primary structural proteins, Gag and Env, elicit the greatest antibody responses, which form the basis for the diagnostic ELISA assay. Neutralizing antibodies are directed to the envelope glycoproteins, gp120 and gp41, which are exposed on the surfaces of infected cells and virions. However, there are no clearly defined HIV-1 serotypes. The HIV-1 Env is composed of a surface domain (gp120) and a transmembrane domain (gp41), which are non-covalently associated and form trimeric spikes (Fig. 2). The peptide sequence of gp120 contains conserved (C) and variable (V) regions.

Several features of the envelope glycoprotein render the virus relatively resistant to humoral immunity (24, 25). Regions of gp120 that are involved in the binding interactions with cellular molecules required for infectivity are conserved but are poorly accessible to antibodies. For example, the binding site for CD4, the primary cellular receptor for the primate immunodeficiency viruses, is recessed and surrounded by variable, glycosylated regions (Fig. 2). In addition, the surface of gp120 is heavily glycosylated. This glycosylation reduces the antigenicity of Env, partly by allowing the molecule to appear to the immune system as “self.” Extensive glycosylation also provides a “shield” that appears to protect virions from neutralizing antibodies. Similarly, the binding site for the chemokine receptors, the so-called coreceptors for these viruses, is masked by the variable loops V2 and V3 (Fig. 2) (26).

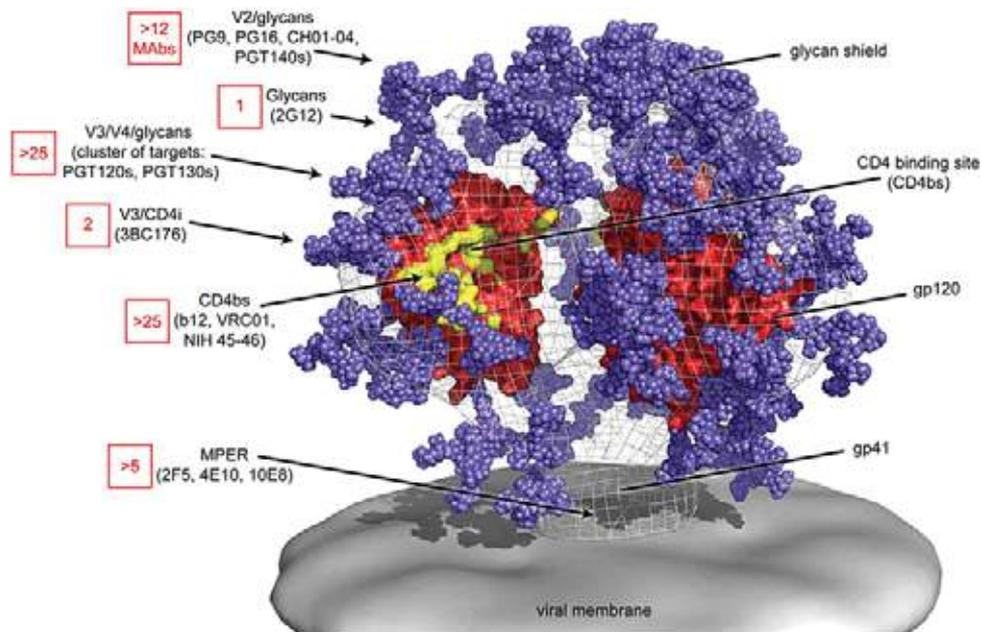

Antibodies to gp120 become detectable in the sera of HIV-infected individuals within 2 to 3 weeks after infection (27). However, these early antibodies are not neutralizing. They appear to recognize the interactive regions of gp120

and gp41, which, although immunogenic, are not exposed in the assembled, trimeric, glycoprotein complex (25). Subsequently, antibodies appear that may recognize the V3 or V2 loops and are neutralizing but usually restricted in activity to the infecting strain. Such antibodies appear to drive the selection of escape variants, so that patient serum can neutralize previous, but not contemporaneous autologous isolates (28). Finally, over time, antibodies appear that have more broadly neutralizing activity against a variety of isolates. Many of these interfere with the binding interaction between gp120 and CD4. These antibodies recognize key residues located within the binding pocket for CD4 on gp120 (the so-called CD4BS epitopes; Fig. 2). Other broadly neutralizing antibodies recognize epitopes that are near conserved residues involved in coreceptors binding (the so-called CD4i epitopes; Fig. 2). An unusual neutralization epitope is distant from the receptor binding sites on the outer domain of gp120. This epitope (2G12; Fig. 2) is carbohydrate-based and formed by a conserved cluster of oligomannoses (29). In addition to these epitopes on gp120, broadly cross-reactive neutralization epitopes are also located in the membrane proximal region of the ectodomain of gp41 (30). The last several years have witnessed the isolation of numerous human monoclonal antibodies that are broadly neutralizing; some of their locations on the envelope glycoprotein trimer are shown in Fig. 2.

### Composition of Virus

#### Virion Morphology, Structure, Size, Genomic Organization

By electron microscopy, the HIV-1 virion measures approximately 100 to 150 nm in diameter (Fig. 3). Mature viral particles are characterized by an electron-dense, conical

**FIGURE 2** Structure and antibody recognition of the HIV envelope spike. The molecule is a heterotrimer of composition (gp120)<sub>3</sub>(gp41)<sub>3</sub>. Gp41 is a transmembrane protein and gp120 is the receptor molecule for CD4 and CCR5 (or CXCR4). The model is adapted from a cryo-electron tomographic structure of the HIV trimer, with the crystal structure of the b12-antibody-bound monomeric gp120 core (red) fitted into the electron density map. Glycans are shown in purple. The CD4 binding site is shown in yellow. The approximate locations of the epitopes targeted by existing broadly-neutralizing monoclonal antibodies (bnMAbs) are indicated with arrows, and the number of MAbs targeting each epitope is shown in red boxes. A small selection of bnMAbs targeting each epitope is included. (Modified with permission from [483]).

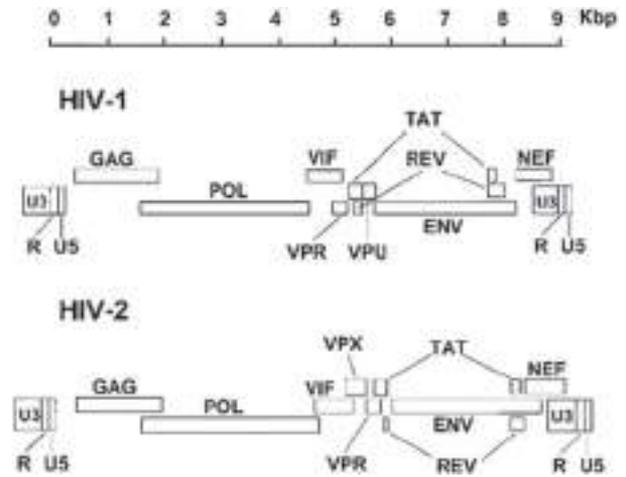

**FIGURE 3** Electron micrograph of an HIV-1 virion budding from an infected cell. The viral glycoprotein complexes are barely discernable on the surface of the virion membrane. The electron-dense material just beneath the viral lipid bilayer corresponds to the MA (p17) protein. The conical virion core is composed of the CA (p24) protein. Also with the core are the NC (p7) protein, which binds the genomic RNA, the p6 protein required for budding, the accessory protein Vpr, the reverse transcriptase, the integrase, and two copies of the genomic RNA. The accessory-protein Nef is also virion-associated. Micrograph courtesy of H. Gelderblom.

core. The core is surrounded by a lipid envelope that is acquired as the virion buds from the infected cell. The virion core contains two copies of single-stranded, positive sense, genomic RNA, each of which encodes the complete viral repertoire of structural, enzymatic, and regulatory proteins. The HIV genome is approximately 10kb in length and is organized similarly to other retroviruses (Fig. 4). The sequence is flanked by the two long-terminal repeats (LTRs). The 5' LTR contains the enhancer/promoter sequences for viral transcription, and the 3' LTR contains the polyadenylation signal. From 5' to 3' the viral genome contains the *gag* gene, which encodes the virion structural components; the *pol* gene, which encodes the viral enzymes; and the *env* gene, which encodes the envelope glycoproteins. The primate immunodeficiency viral genomes contain six additional genes: *vif*, *vpr*, *tat*, *rev*, *nef*, and *vpx* in the case of HIV-2 and SIV, or *vpu* in the case of HIV-1 (Fig. 4 and Table 1) (31). The products of these genes function via interactions with host cell proteins to optimize viral replication by a variety of mechanisms discussed below.

#### Major Structural and Regulatory Proteins

The major structural and core proteins of HIV are synthesized from *gag* as a large, myristoylated precursor polyprotein (pr55) that is subsequently cleaved by the viral protease to yield the matrix (MA; p17), capsid (CA; p24), and nucleocapsid proteins (NC; p7) (32, 33). The matrix protein is a peripheral membrane protein located along the inner leaflet of the viral lipid envelope, where it directs the incorporation

**FIGURE 4** Genomic organization of HIV-1 and HIV-2. The viral open reading frames (ORFs) are shown; the roles of their gene products are described in the text and in Table 1. The ORFs of the *tat* and *rev* genes are interrupted by an intron. The long terminal repeats (LTRs), found at each end of the fully reverse-transcribed viral DNA, are composed of U3, R, and U5 regions; the definitions of their boundaries are described in the text. The major genetic differences between these viruses are the lack of the Vpu ORF and the presence of the Vpx ORF in HIV-2; these features render HIV-2 more similar to most SIVs than to HIV-1.

of the envelope glycoproteins (Env) into the forming virion (34). The capsid protein (p24) assembles to form the conical core of the virion. The core structure follows the principles of a fullerene cone composed primarily of a curved array of hexameric CA subunits, with the inclusion of several pentameric subunits to allow closure of the cone (35). The nucleocapsid protein (p7) is an RNA binding protein required for packaging of the genomic RNA into the virion (36). Several smaller cleavage products, p1, p2, and p6, are also generated from the p55 precursor. The p6 protein contains the so-called “late” or “L” domain required for viral budding; these domains mediate interactions with cellular proteins of the ESCRT (endosomal sorting complexes required for transport) complex to mediate membrane scission during the budding process (37). The p6 protein also mediates the incorporation of the viral accessory protein Vpr into virions (38).

The viral enzymes are also produced by proteolytic cleavage from a large precursor polypeptide. During translation, a ribosomal frameshift occasionally occurs between the *gag* and *pol* ORFs, resulting in the synthesis of a *gag-pol* precursor protein (pr170) (39). The ratio of Gag-Pol to Gag produced in infected cells is approximately 1:20. Subsequent cleavage of pr170 yields the Gag protein products and the retroviral protease (p11), reverse transcriptase/ribonuclease H (p66/p51), and integrase (p32). The aspartyl protease p11 cleaves the structural and enzymatic proteins from the large polyprotein precursors. This enzyme is a symmetric dimer that is activated by dimerization during virion assembly (39, 40). Pharmacologic inhibition of the viral protease results in the formation of noninfectious particles. The reverse transcriptase enzyme is a heterodimer with 66 kDa- and 51 kDa-subunits. This enzyme provides both the reverse transcriptase activity, which allows RNA-dependent DNA polymerization, and the ribonuclease H activity, which specifically degrades RNA present in RNA/DNA heteroduplexes. The RNase H

TABLE 1 HIV genes and gene products

Gene	Protein	Size	Function
Structural			
<i>gag</i>	Matrix (MA)	p17	Structural protein (recruits envelope glycoprotein)
	Capsid (CA)	p24	Structural protein (forms conical core)
	Nucleocapsid (NC)	p7	Binds viral RNA to encapsidate genome
<i>pol</i>	p6	p6	Budding
	Protease (PR)	p12	Viral enzyme: cleavage of polyprotein precursors
	Reverse transcriptase (RT)	p66/p51	Viral enzyme: reverse transcription and RNase H activities
<i>env</i>	Integrase (IN)	p32	Viral enzyme: integration of viral cDNA into host chromosomes
	Surface glycoprotein (SU)	gp120	Viral envelope glycoprotein: receptor binding
	Transmembrane (TM)	gp41	Viral envelope glycoprotein: fusion
Regulatory/ Immune Evasion			
<i>tat</i>	Tat	p14	Transactivates viral transcription
<i>rev</i>	Rev	p19	Transports unspliced mRNA to cytoplasm
<i>vif</i>	Vif	p24	Promotes virion infectivity by degrading cellular cytidine deaminases in the APOBEC3 family
<i>nef</i>	Nef	p27	Down-regulates class I MHC and CD4; enhances viral infectivity; facilitates T-cell activation
<i>vpu</i> <sup>a</sup>	Vpu	p16	Promotes release of viral particles by counteracting BST2/tetherin; induces degradation of CD4
<i>vpr</i>	Vpr	p15	Arrests cell cycle in G <sub>2</sub> /M; facilitates viral replication in macrophages
<i>vpx</i> <sup>a</sup>	Vpx	p14	Facilitates viral replication in dendritic cells and macrophages by degrading the cellular enzyme SAMHD1

<sup>a</sup>*vpu* is found almost exclusively in HIV-1; *vpx* is found only in HIV-2 and SIV.

domain is present only in the larger of the two subunits (41). The integrase mediates insertion of the viral DNA into that of the chromosome of the host cell (42). To accomplish this, integrase comprises two activities: a DNA cleaving activity, which cuts the host DNA and processes the ends of the HIV-DNA, and a DNA strand-transfer activity which covalently attaches the viral DNA to that of the host, most frequently in transcriptionally-active ORFs (43).

The protein product of the *env* gene is synthesized in the endoplasmic reticulum as an 88 kDa polypeptide (44). This protein undergoes glycosylation in the endoplasmic reticulum and Golgi. The resulting molecule, gp160, contains N-linked, high-mannose sugars that account for approximately half of the final molecular weight of 160 kDa. Much of the newly-synthesized gp160 is retained in intracellular compartments and is eventually degraded; however, a fraction is cleaved by cellular serine proteases like furin to generate the transmembrane (gp41) and surface (gp120) subunits (44). This cleavage event is required for viral infectivity because it allows for subsequent exposure of a sequence within the ectodomain of gp41 that mediates fusion of the virion and target cell membranes (45). Following proteolytic cleavage, gp120 remains noncovalently associated with gp41 on the cell surface. The complex is incorporated into the envelope of budding virions via an interaction between the cytoplasmic domain of gp41 and the p17 matrix protein (34). The envelope glycoproteins are arranged as trimers in a spike-and-knob configuration (Fig. 2). As few as 8 to 14 Env trimers may be incorporated per virion (46, 47).

The primate immunodeficiency viruses encode several nonenzymatic and nonstructural gene products (31). Two of these genes, *tat* and *rev*, are essential for viral replication. Tat

is a 14-kDa *trans*-activating protein that markedly enhances the rate of transcription from the 5' LTR by recruiting cellular factors that enhance the processivity of the cellular RNA polymerase II complex (48–50). Tat recruits a cyclin-dependent protein kinase complex (Cdk9 plus cyclin T) to a structured region near the 5' end of the primary viral transcript (the transacting responsive region or TAR) (51, 52). Cdk9 hyperphosphorylates the C-terminal domain of RNA polymerase II, allowing efficient elongation of the nascent viral mRNA (53). In the absence of Tat, viral transcription is essentially stalled just after initiation.

The 18-kDa Rev protein mediates the transport of singly-spliced and unspliced viral RNAs from the nucleus to the cytoplasm. These RNAs encode the HIV-1 structural and enzymatic proteins and include the viral genomic RNA (54). Rev directly links these viral RNAs to a specific nuclear export pathway. The N-terminal region of Rev contains a basic domain that binds a structured region in the RNA (the Rev-response element or RRE, which overlaps the coding sequence of the gp41), while the C-terminal region contains a prototypical, leucine-rich, nuclear export signal that binds to the nuclear export protein CRM1, also known as exportin 1 (55–57). In the absence of Rev activity, viral mRNAs are inefficiently exported from the nucleus, and, as a consequence of prolonged nuclear retention, they undergo extensive splicing to yield subgenomic mRNAs encoding only a subset of viral proteins that includes Tat, Rev, and Nef.

The other nonenzymatic and nonstructural genes of HIV-1 and HIV-2 (*vif*, *vpr*, *vpx*, *vpu*, and *nef*) are not essential for viral replication under certain conditions *in vitro* and consequently have been termed “accessory genes.” Nevertheless,

these genes are highly conserved among primate lentiviruses, and their importance has been documented using the macaque/SIV and SHIV animal models of AIDS as well as by the use of relatively physiologic *in vitro* systems, such as primary cultures of T lymphocytes and macrophages (58–62). Moreover, the role of these gene products in providing evasion of host innate and adaptive defenses has become increasingly clear. The accessory gene products function by mediating interactions with cellular proteins to co-opt protein trafficking or degradation pathways. With the exception of Nef, each of these gene products modulates the substrate specificities of cellular ubiquitin-ligase complexes to cause the degradation of cellular proteins that are deleterious to the virus (63).

The 23-kDa Vif protein targets cellular cytidine deaminases, in particular APOBEC3F and APOBEC3G, for degradation by the proteasome via the cullin 5 ubiquitin ligase complex (64, 65). In the absence of Vif, APOBEC proteins are incorporated into virions, where they deaminate cytosine residues in the minus strand of the forming viral cDNA. The resulting uracil residues lead to inactivating hypermutation (G to A transitions in the plus strand) (66). Moreover, some APOBEC proteins inhibit reverse transcription directly (67). Thus, Vif is required for the production of infectious virions (68), and it is required for viral replication in primary cultures of T lymphocytes (58). APOBEC cytidine deaminases appear to provide an innate cellular defense not only against exogenous retroviruses such as HIV-1 but also endogenous retroelements (69).

The 14-kDa HIV-1 Vpr protein has at least two functions. First, Vpr arrests cells in the G2/M phase of the cell cycle (70). Cell-cycle arrest increases the yield of progeny virions due to enhanced viral transcription during the prolonged G2 phase (70), and it is associated with apoptosis (programmed cell death) (71). Second, Vpr facilitates efficient viral replication in macrophages, partly by stabilizing the envelope glycoprotein and enhancing its incorporation into virions (59, 72). These activities require the association of Vpr with a cullin 4-based ubiquitin ligase complex (73). This in turn, prematurely activates a host endonuclease complex, causing the arrest of the cell cycle and inhibiting the ability of the cell to “sense” viral DNA and respond by producing interferon (74). Vpr-activities can occur immediately after infection of the cell (75) because the protein is incorporated into virions by direct association with the p6 gag gene product (76).

The 14 kDa Vpx protein, not present in HIV-1, is found in HIV-2 and most SIVs. Vpx is genetically related to Vpr and probably arose from gene duplication. Like Vpr, its activity is mediated through the host cullin 4-based ubiquitin ligase complex. Vpx triggers degradation of the host enzyme, SAMHD1, a triphosphorylase and ribonuclease that restricts the replication of primate lentiviruses in myeloid cells, including dendritic cells and macrophages (77, 78). Thus, Vpx accounts for the differential ability of HIV-2, but not of HIV-1, to replicate efficiently in dendritic cells.

The 16 kDa Vpu protein is an integral membrane protein encoded by HIV-1 but not by HIV-2 or most SIVs (79). Vpu modulates cellular transmembrane proteins. It removes the host protein bone marrow stromal cell antigen 2 (BST2), also known as tetherin, from the plasma membrane. BST2 is an interferon-inducible protein that traps certain enveloped viruses, including HIV-1, on the surface of the infected cell just after budding (80–82). In the absence of Vpu, virions trapped by BST2 not only fail to contribute to cell-free infectivity, but they also increase the density of envelope

glycoprotein (Env) antigens on the cell surface and render infected cells more susceptible to killing by antibody-dependent cytotoxicity (ADCC) (83, 84). Vpu induces the degradation of CD4, the primary cellular receptor for the virus, by linking it, while still in the endoplasmic reticulum, to the proteosomal degradation machinery via the cellular protein  $\beta$ -TrCP and the cullin1 ubiquitin ligase complex (85). By degrading CD4, Vpu prevents the decreased infectivity of progeny virions that would otherwise occur due to the interaction of Env and CD4 (86). Moreover, this activity of Vpu prevents the exposure of CD4-induced epitopes within Env on the cell surface that are especially good targets for ADCC (87, 88). Vpu modulates several other cellular proteins, including NTB-A, a coactivator of natural killer (NK) cells; CD1d, a major histocompatibility complex (MHC)-like molecule involved in the presentation of lipid antigens; and CCR7, a receptor involved in chemotaxis (89–91). Overall, these activities support an overarching role of Vpu in immune evasion.

The 27-kDa Nef protein modulates both cellular signal transduction and membrane trafficking. Nef is a peripheral membrane protein that modulates T-cell activation via its interaction with cellular kinases (92). Nef also directly affects membrane trafficking by interacting with cellular proteins that coat transport vesicles and linking its targets to them (93–96). The consequences of this include the down-regulation of CD4 and class I MHC from the cell surface (97, 98). The down-regulation of class I MHC provides escape from immune surveillance by enabling infected cells to avoid destruction by cytotoxic T lymphocytes (CTL) (99). The down-regulation of CD4 by Nef provides optimal virion infectivity, and, like Vpu, it prevents the exposure of CD4-induced epitopes in Env on the cell surface (87, 88, 100). Nef also enhances virion infectivity in a manner potentially dependent on the stability of Env trimers; this results from antagonism of cellular transmembrane proteins in the serine family that specifically inhibit the activity of retroviral envelope glycoproteins (101–104).

## Biology

### Replication Strategy (Fig. 5)

The entire replication cycle of HIV-1, from the binding of virions to target cells to the release of infectious progeny, is completed in approximately 24 hours, *in vitro* and *in vivo* (105, 106). Replication is initiated by attachment of the virus to a target cell through the interaction of the viral envelope glycoprotein, gp120, with the cellular receptor molecule, CD4 (107–109). The binding of gp120 to CD4 induces conformational changes in gp120, which enable binding to the cellular coreceptor molecules (110). The two major coreceptor molecules for HIV-1 are CXCR4 and CCR5 (111–113), transmembrane proteins that function as receptors for chemoattractant cytokines (chemokines). The natural ligand for CXCR4 is the stromal cell-derived factor 1 (SDF-1), and the natural ligands for CCR5 are the  $\beta$ -chemokines CCL3, CCL4, and CCL5 (formerly known as MIP-1 $\alpha$ , MIP-1 $\beta$ , and RANTES, respectively). Binding of gp120 to these coreceptors is obligatory for the fusion of virus with the host cell, and natural or synthetic ligands for these molecules can block the infectivity of HIV-1. Some primary isolates of HIV-1 can utilize either CXCR4 or CCR5 as a coreceptor for entry, but many can utilize only CCR5. Binding of gp120 to the coreceptors allows exposure of a fusogenic motif in the amino-terminal ectodomain of gp41; which leads to fusion of the lipid bilayer of the virion with

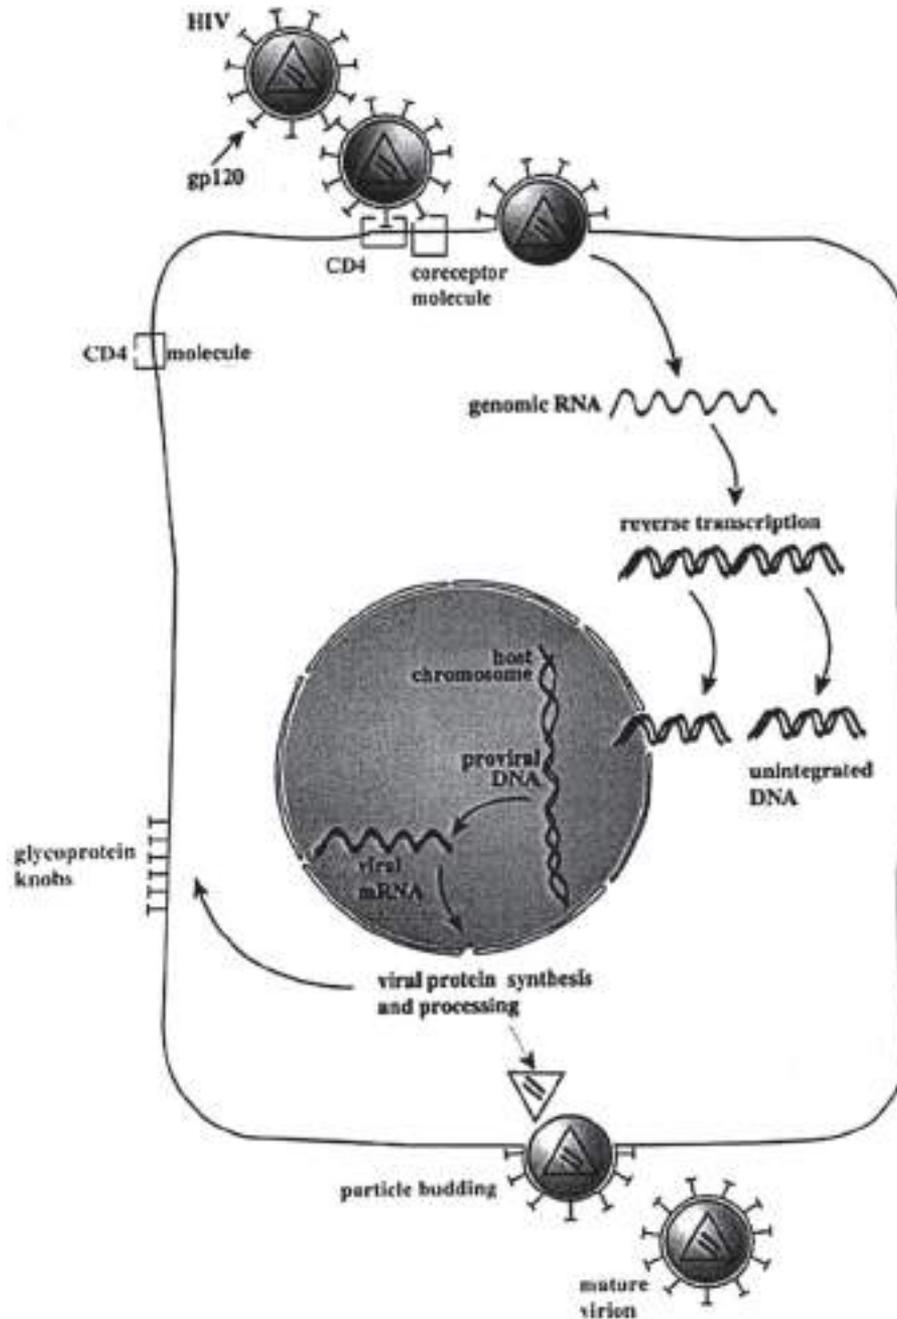

FIGURE 5 Replication cycle of HIV.

that of the host cell (114). The fusion-competent core of the gp41 forms a six-helix bundle analogous in structure to the low-pH (fusion-competent) conformation of the influenza A virus hemagglutinin (115). Formation of this so-called “hairpin” conformation is required for the viral and cellular membranes to reach sufficient proximity to fuse. Entry of HIV into the cell occurs from endosomal as well as plasma membranes, although unlike influenza virus, the process is acid-independent and is not blocked by weak bases or drugs that inhibit acidification of the endo-lysosomal system (116, 117).

Synthesis of the viral cDNA can begin in cell-free virions (118), but it is completed in the target-cell cytoplasm within

so-called reverse transcription complexes that include the viral capsid, which travels toward the cell nucleus along microtubules (119). The synthesis of the viral cDNA is discontinuous. The reverse transcriptase (RT) synthesizes the first complementary strand of DNA (the minus strand) using the viral genomic RNA as a template and a host tRNA-lys as a primer. The tRNA primer-binding site defines the 3′ end of the U5 region of the LTR. Viral ribonuclease H degrades the original RNA template. The reverse transcriptase (RT) then synthesizes the second strand of DNA (the plus strand), beginning at two polypurine tracks: one defines the 5′ end of the U3 region of the LTR, and the other is located near the center of the genome (120, 121). Strand-switching events

that utilize sequence complementarity at each end of the viral RNA occur during the synthesis of both minus- and plus-strand DNAs, generating the U3-R-U5 direct repeats (the LTRs) at each end of the complete, double-strand cDNA. These strand-transfer events lead to the utilization of both copies of the virion-associated genomic RNA as templates during reverse transcription, so that genetic recombination occurs when the two copies are dissimilar in sequence (122). Such recombination generates genetic variants following co-infection of the same target cell with genetically distinct viruses.

The reverse-transcribed viral genome remains associated with the capsid until transport into the nucleus, which occurs in nondividing cells through nuclear pores. The capsid itself contains binding sites for several cellular proteins that facilitate this process, including nuclear pore proteins (123). After entry into the nucleus, the double-stranded, linear DNA is integrated into the host-cell chromosome by the virally-encoded integrase in concert with host-cell DNA repair enzymes to form the provirus (124, 125). Covalently-closed DNA circles with either one- or two-LTR junctions are also formed by host enzymes in the nucleus, but these forms are dead-end products that cannot integrate into the target-cell DNA. Integration requires the cellular co-activator protein p75/LEDGF (126), which tethers the viral integrase enzyme to the host-cell chromatin. Chromosomal integration is required for viral replication. Integration also yields the form of the viral genome responsible for establishing a long-lived, latent reservoir in the host.

The activation of HIV transcription and gene expression from the integrated provirus is dependent on the activity of both cellular and viral factors. The virion-associated protein Vpr is a weak transactivator of transcription and may stimulate the initial expression of viral RNAs (75). Specific sites within the 5' LTR are recognized by cellular transcription factors including NF- $\kappa$ B, AP-1, SP1, and nuclear factor of activated T-cells (NFAT), several of which are induced during the activation of T cells (127). Transcription is initiated from a single site in the viral 5' LTR, the 5' boundary of the R region. The activity of the HIV promoter is repressed by chromatin structure; chromatin remodeling induced by histone acetylation can relieve this repression and activate transcription (128). The primary transcript is alternatively spliced to generate over 30 species of viral mRNAs. The early viral transcripts are extensively spliced to form a group of mRNAs that are 1.8 to 2.0 kb in size and which encode the proteins Tat, Rev, and Nef (129). Tat increases the level of viral transcription markedly by recruiting cellular factors to the nascent RNAs, facilitating their elongation as discussed above. Once Rev is synthesized, the incompletely spliced- (approximately 5 kb) and unspliced- (9 kb) viral mRNAs are exported from the nucleus (130). These RNAs encode the accessory gene products Vif, Vpr, and Vpu, all the structural and enzymatic proteins, and the genomic RNA. Thus, Rev mediates a transition from early gene expression (Tat, Rev, and Nef) to late gene expression (Gag, Pol, Env, Vif, Vpr, and Vpu) about six to eight hours after infection *in vitro* (105).

The assembly of virions occurs primarily at the plasma membrane (131). The Gag and Gag-Pol precursor polyproteins are synthesized in the cytoplasm and associate with the plasma membrane via N-terminal myristoylation and binding to specific membrane lipids (132). Dimerization of the Gag precursor activates the viral protease, which cleaves the precursor proteins to generate the individual structural and enzymatic polypeptides described above. In contrast to

Gag, the Env glycoproteins are synthesized in association with cellular membranes. Env is then recruited into the forming virion at the plasma membrane by association of the cytoplasmic domain of gp41 with p17 MA. The capsid protein p24 forms the core structure, and the nucleocapsid protein p7 binds the genomic RNA. The Gag polyprotein is sufficient for virion assembly and budding. Budding requires a specific domain (the "L-domain") in the p6 region of Gag, which binds endosomal proteins (the ESCRT complexes) involved in the biogenesis of multivesicular bodies (MVBs) (133, 134). MVBs are late endosomal structures that contain internal vesicles, and the viral budding process is topologically similar to the formation of the vesicles within MVBs. Virion assembly occurs selectively at the basal-lateral surfaces of polarized epithelial cells, at the uropod of T cells, and at regions of cell-cell contact that are enriched in cellular transmembrane proteins termed tetraspanins (135, 136). HIV-1, like measles and influenza virus, buds from specialized regions of the plasma membrane that are enriched in cholesterol and glycolipids (so-called "lipid rafts") (137). This modified lipid composition presumably facilitates budding and/or the fusion of the virions with target cells. In addition to the virally-encoded proteins, virions of HIV-1 incorporate a number of cellular proteins, including major histocompatibility antigens (138), adhesion molecules, such as intercellular adhesion molecule 1 (ICAM-1) (139), cyclophilin A (140), and several cytoskeletal and endosomal proteins (141). The roles of most of these virion-associated cellular proteins for the virus are not clear, although the incorporation of CD55 and CD59 protect virions from inactivation by complement (142).

#### Host Range, Tropism, CPE

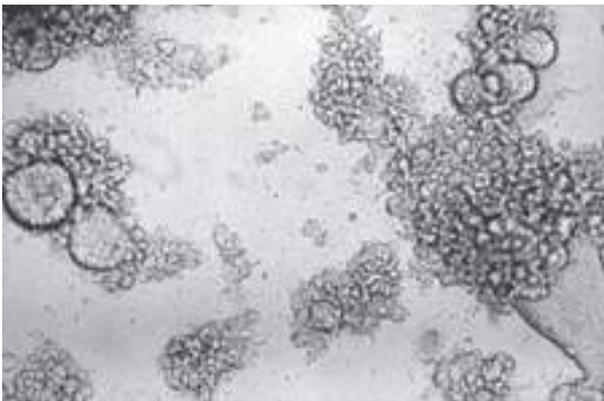

The natural host range of HIV-1 and HIV-2 is restricted to humans, although chimpanzees can be infected with HIV-1 under experimental conditions (143, 144), and cynomolgous monkeys and rhesus macaques have been infected with HIV-2 (145, 146). Unlike infection in humans, HIV-1 is generally nonpathogenic in chimpanzees, and virus replication declines over time.

Studies of the molecular determinants of the host range of primate lentiviruses have revealed novel, innate intracellular defense mechanisms that restrict infection. For example, Old World monkey cells cannot support infection with HIV-1 due to the species-specific activity of the host protein TRIM5 $\alpha$ , which targets the capsid protein of incoming virions to inhibit viral replication (147). Similarly, human BST2 presented a barrier to the cross-species transmission of SIVcpz to humans, which was overcome by evolution of the *vpu* gene (148).

The primary cellular targets for HIV-1 infection *in vivo* are CD4<sup>+</sup> T lymphocytes and macrophages. *In vitro*, HIV-1 replicates efficiently in primary cultures of CD4<sup>+</sup> T cells, while only a subset of isolates are capable of replication in immortalized CD4<sup>+</sup> T-cell lines. This cellular tropism is the result of the selective interaction of Env glycoproteins with specific coreceptor molecules (149). Many primary isolates (derived from patients by minimal passage in primary cultures of T cells) utilize CCR5 exclusively and fail to grow in T-cell lines, which typically express CXCR4 but not CCR5. Other primary isolates utilize both CCR5 and CXCR4, and consequently these isolates grow in both primary cells and T-cell lines. Exclusive use of CXCR4 is a feature of occasional clones from later-stage patients and laboratory strains of HIV-1 that have been adapted by extensive passage using CXCR4-expressing immortalized T cells. Macrophage-tropic

isolates utilize CCR5 as the cellular coreceptor. The basis of macrophage tropism remains incompletely understood because, although these cells express CXCR4, they are not permissive for the replication of viruses that use only this coreceptor. Within Env, the principal determinants of specific coreceptor usage and macrophage tropism map to the V3 loop, but other regions of gp120 are also important (150, 151). Macrophages have very low levels of CD4, and the ability of certain Env proteins to enable viral entry into cells expressing such low levels might be the key determinant of macrophage tropism (152). HIV enters dendritic and Langerhans cells via the interaction between gp120 and C-type lectins on the cell surface. Although these professional antigen-presenting cells do not support robust productive infection, they can retain infectious virions and transmit them to CD4<sup>+</sup> T cells (153, 154). This so-called transinfection may be an important part of the mechanism of transmission of HIV at mucosal surfaces and of its initial spread to regional lymphoid tissue.

*In vitro*, the fusion of infected and uninfected cells leads to a cytopathic effect characterized by the formation of multinucleated giant cells (syncytia) (Fig. 6). Not all primary isolates of HIV-1 induce syncytia in immortalized T-cell lines *in vitro*. Isolates derived early in the course of infection are usually nonsyncytium-inducing (NSI), while isolates from later stage patients often, but not always, have a syncytium-inducing (SI) phenotype (155, 156). The NSI phenotype is caused by exclusive use of CCR5 by the Env of the isolate, while the SI phenotype is caused by the additional ability to use CXCR4, allowing viral growth in T-cell lines. In longitudinal analyses of patient isolates, the acquisition of tropism for cells expressing only CXCR4 is associated with more rapid decline in CD4<sup>+</sup> T cells and clinical progression of disease (157, 158). The use of CXCR4 enables the virus to infect naïve CD4-positive T cells, whereas the use of CCR5 enables the virus to infect memory CD4-positive T cells (159). Thus, the additional use of CXCR4 as a coreceptor is a marker for expanded tropism including both naïve and memory CD4-positive T cells, potentially explaining the association of this phenotype with more rapidly progressive disease.

**FIGURE 6** Formation of syncytia during replication of HIV-1 in a culture of T lymphoblastoid cells. In immortalized T-cell lines, the interaction of the viral-glycoprotein complex with the cellular receptors CD4 and CXCR4 allows cell-cell fusion and the formation of multinucleated giant cells. The formation of syncytia begins with cell clustering, followed by cell-cell fusion and the ballooning of cell membranes.

### Inactivation by Physical and Chemical Agents

HIV is sensitive to a variety of chemical agents including glutaraldehyde, hypochlorite, quaternary ammonium compounds, phenolics, ethanol, and iodine (160). Cell-free virus is inactivated most readily; infectivity is decreased by at least 10<sup>6</sup>-fold after 1 minute of exposure of cell-free virus to 0.5% glutaraldehyde or 35% ethanol. Cell-associated virus is less susceptible to inactivation; exposure of cell-associated virus to 35% ethanol for five minutes is inadequate, but exposure to 75% ethanol for one minute is sufficient. Cell-associated virus suspended in blood is the most resistant to inactivation; glutaraldehyde (0.5%), hypochlorite (25,000 ppm), and 75% ethanol are effective after one minute, but quaternary ammonium compounds and phenolics are ineffective even after 10 minutes.

HIV is also sensitive to ultraviolet light (160). As in the case of chemical inactivation, cell-associated virus and virus in blood are more resistant to inactivation by ultraviolet light. A 10-minute exposure of cell-free virus to ultraviolet light in a typical biosafety cabinet is sufficient to inactivate HIV, but 30 minutes is required to inactivate cell-associated virus, and even 60 minutes fails to inactivate cell-associated virus suspended in blood. HIV-1 is inactivated by heating, which is useful not only for the safety of preparations of clotting factors but also for the safety of breast milk from HIV-infected mothers (161, 162).

## EPIDEMIOLOGY

### Distribution and Geography

The AIDS pandemic can be viewed as a composite of multiple epidemics, each occurring in specific geographic regions and populations. While HIV-2 has remained largely confined to West Africa, HIV-1 has spread throughout the world. Group M viruses are responsible for the vast majority of HIV-1 infections. Distinct subtypes or clades of Group M viruses have been isolated in geographically distinct regions of the world. In the United States, Europe, and Australia, the prevalence of subtype B illustrates a founder effect in which one or several viral variants were introduced and then disseminated through the population (163). Subtype B is found rarely in Africa, whereas subtype A predominates in West Africa, subtype A and D in East Africa, and subtype C in southern Africa. Variants of HIV-1 appear to quickly expand to become the major subtype when introduced into a specific population or geographic area. For example, in Thailand, subtype B viruses predominated among intravenous drug users in Bangkok, while CRF-01AE (formerly designated subtype E) recombinant viruses spread throughout the country by heterosexual contact (164).

The distribution of HIV-1 subtypes is complex, uneven, and probably reflects a stochastic dissemination. In regions like central Africa, Southeast Asia, and South America, where different subtypes are prevalent, the incidence of co-infection and subsequent recombination between subtypes may be high (165). Intersubtype recombination may be high in areas such as Africa and Southeast Asia, where multiple subtypes of HIV-1 are known to circulate simultaneously. For example, in Cameroon, mixed infections were observed in approximately 10% of cases and included co-infection with two subtypes within group M, co-infection with M and O viruses, and even co-infection with HIV-1 and HIV-2 (166). Recombination events have been described between all of the HIV-1 subtypes belonging to group M. Recombination has also been described between Group M and O viruses (167).

### Incidence and Prevalence of Infection

According to WHO estimates, approximately 30 million people are estimated to have died, while 35 million are living with HIV infection or AIDS. About 2.5 million new cases were estimated to occur globally during the year 2006. Approximately 95% of all HIV infections have occurred in the developing world and among young and middle-aged adults.

The prevalence and incidence rates of HIV infection vary considerably in different regions of the world and reflect the progress of local epidemics, fueled by distinct modes of transmission, socioeconomic environments, and behavioral factors (168). Sub-Saharan Africa accounts for over 60% of the current cases of HIV infection and for 75% of the world's HIV-infected women and children, although it contains only 10% of the world's population. The overall prevalence of disease in adults between 15 and 49 years of age in sub-Saharan Africa is approximately 6%, but many countries in this region have prevalences exceeding 10%. Although the prevalence of infection has stabilized in some regions of Africa, this reflects approximately equal rates of incidence and mortality. Africa continues to account for the majority of new cases in the world. Asia accounts for over 20% of the world's cases of HIV-1 infection, with over 6 million cases as of the 2006. The majority of these have occurred in India. Latin America accounts for over 4% of the world's cases of HIV infection, with 1.6 million cases. Although the adult prevalence in Europe is less than 1%, regions in Eastern Europe have experienced marked recent increases attributable to high rates of injection-drug use. Eastern Europe and Central Asia now account for 1.6 million cases. North America accounts for approximately 4% of the world's cases of HIV infection.

### Transmission

Transmission of HIV occurs through direct contact with infected body fluids, including blood and blood products (169), semen (169), vaginal and cervical secretions (170), amniotic fluid (171), and breast milk (172). Despite detection of HIV-1 RNA in saliva and tears (173, 174), there have been no documented cases of transmission via these body fluids. Transmission most commonly occurs during sexual contact with the exchange of semen, genital secretions, or blood from an infected individual to the uninfected partner. Unprotected receptive anal intercourse, with associated mucosal trauma, carries the highest risk of sexual transmission. In the majority of instances, heterosexual transmission occurs during vaginal intercourse, although cases have occurred after fellatio. Sexual transmission is facilitated by the presence of underlying sexually-transmitted diseases including chancroid, herpes genitalis, and syphilis, which disrupt the integrity of the skin or mucosal linings (175, 176).

Transmission is also more likely when the source partner is acutely infected and the concentration of virus in genital secretions is highest (177). The exact mechanism of sexual transmission is unclear. The form of the transmitted inoculum may be cell-associated virus or cell-free virions. How HIV breaches the mucosal barrier is also uncertain; the possibilities include facilitation at areas of disruption in the mucosa, as noted above, transcytosis of virions through epithelial cells with release into the lamina propria, or uptake of virions into Langerhans cells with transinfection of T cells as discussed above.

Infection also occurs through direct inoculation of infected blood, particularly re-use of contaminated needles,

transfusion of infected blood products, and transplantation of infected tissues. The risk of HIV-1 transmission, following occupational percutaneous exposure to infected blood via a contaminated needle, is approximately 0.3% (178, 179). The likelihood of transmission is influenced by many factors, including the type of needle (hollow versus solid bore), the depth of penetration, the volume of the inoculum, the amount of infectious virus in the inoculum, and the post-exposure use of antiretrovirals.

The third primary mode of transmission of HIV-1 is from an infected mother to her child during pregnancy, delivery, or breastfeeding. The risk of maternal-fetal transmission is 13 to 40% in the absence of antiretroviral therapy (180), but this can be significantly reduced by the prevention approaches discussed below.

### Patterns of Transmission

The primary modes of transmission vary in different regions and populations. The mode of transmission in sub-Saharan Africa is heterosexual in 90% of cases; almost 60% of the HIV-positive individuals in this region are women. This region also accounts for 87% of the world's total of HIV-infected children, in whom infection is acquired perinatally.

The pattern of spread of HIV in South and Southeast Asia is exemplified by the epidemic in Thailand, which began among injection-drug users and sex workers, then spread into the general population. Peak prevalences reached 10% among military recruits and 6.4% in prenatal clinics by 1993–1994, but they have declined subsequently due to control measures like condom use in commercial sex establishments (168). Heterosexual transmission plays a major role in the epidemics in Southeast Asia, as evidenced by the fact that 25% of the infected adults are women. In Latin America, the initial epidemic primarily involved men having sex with men. However, injection-drug use and heterosexual transmission have become significant modes of spread in this region.

The dramatic rise in incidence rates in Eastern Europe and Central Asia has been fueled by injection-drug use, primarily among men in the Ukraine and countries of the former Soviet Union (181). Eastern Europe has also been the site of nosocomial outbreaks of HIV infection caused by improper reuse of medical equipment. In Western and Northern Europe, the initial epidemic involved men having sex with men. More recently, the incidence of infection in other populations has increased, with heterosexual contact and injection-drug use accounting for an increasing number of cases.

In the United States, both the overall prevalence and incidence of new HIV infections remain greatest among homosexual and bisexual men, with disproportionate case numbers in African-Americans. The proportion of infections in women in the United States has progressively increased to a quarter of all cases, with higher rates in African American and Hispanic women. In contrast, the HIV infections diagnosed among infants declined dramatically from 907 cases in 1992 to 53 in 2011, attributable to the treatment of infected women, prenatal screening, and peripartum chemoprophylaxis.

## PATHOGENESIS

### Incubation Period

In classic terms, the incubation period is the interval between acquisition of the infection and onset of the illness.

For HIV-1 infection, the term is problematic in the sense that a symptomatic illness, called primary HIV-1 infection, develops in some infected individuals within one to four weeks after exposure, while clinical immunodeficiency (AIDS) typically appears after a prolonged asymptomatic period measured in years following primary infection. During this time, active viral replication and critical pathophysiologic changes occur. Patients with advanced HIV-1 infection show numerous immunologic abnormalities, the most prominent of which are severe quantitative and qualitative defects in the CD4<sup>+</sup> T lymphocyte compartment. Much of the decline in CD4<sup>+</sup> T-cell counts occurs during the asymptomatic period between initial infection and the development of clinically-apparent immunodeficiency. In adults, the average length of this asymptomatic period is 10 years. Opportunistic infections (OI) by organisms that do not cause disease in immunocompetent individuals herald the development of AIDS. These usually do not occur until the level of CD4<sup>+</sup> T cells has dropped from the normal levels of 600 to 1000 cells/ $\mu$ l to below 200 cells/ $\mu$ l. The degree of loss of CD4<sup>+</sup> T cells is an excellent predictor of progression to AIDS, and a CD4<sup>+</sup> T-cell count below 200 cells/ $\mu$ l is now considered to be an AIDS-defining condition. Susceptibility to particular opportunistic infections appears in a predictable way, such that some infections appear as the CD4 count falls below 200 cells/ $\mu$ l (*Pneumocystis jiroveci* pneumonia), while other infections are seen only in patients whose CD4 counts have fallen to below 100 cells/ $\mu$ l (*Mycobacterium avium* complex infection) or 50 cells/ $\mu$ l (cytomegalovirus [CMV] retinitis). These findings suggest that the loss of CD4<sup>+</sup> T cells is central to the development of clinical immunodeficiency.

Therefore, understanding the mechanism of CD4 depletion is the central problem in AIDS pathogenesis.

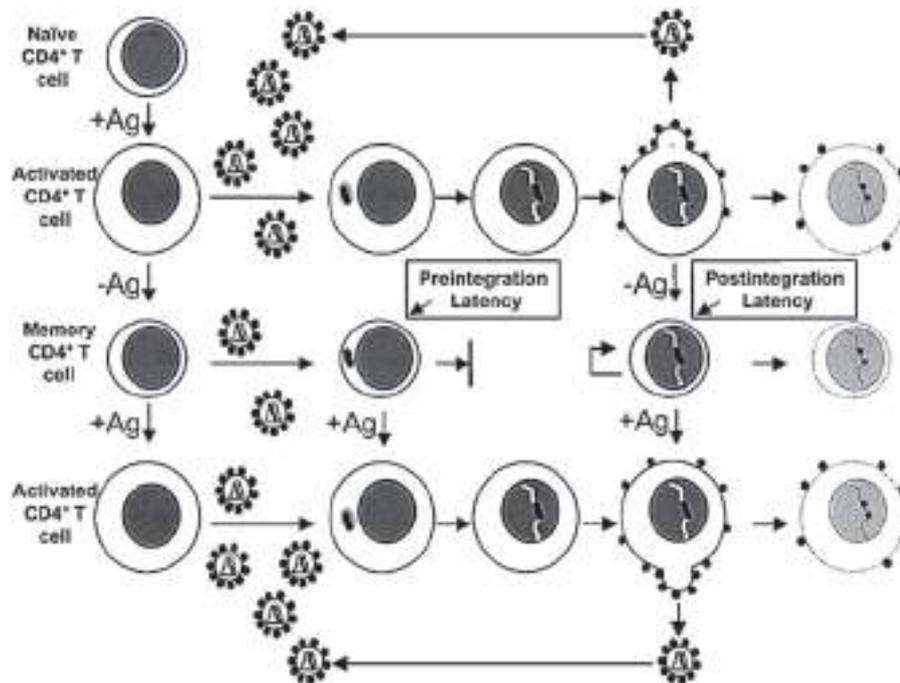

### Patterns of Virus Replication

#### Organ and Cell Specificity

In untreated individuals virus is detected in the blood throughout the course of HIV-1 infection, but virus replication occurs predominantly in the peripheral lymphoid organs, especially the spleen, lymph nodes, and gut-associated lymphoid tissue (182, 183). However, HIV-1 virions can infect CD4<sup>+</sup> cells in any tissue. Target cells include not only mature CD4<sup>+</sup> T cells in lymphoid tissues but potentially also developing T cells in the thymus and the ubiquitous tissue macrophages, which express low amounts of CD4. While fusion and entry occur if appropriate coreceptors are expressed, subsequent steps in the replication cycle depend upon the cell type (CD4<sup>+</sup> T cell versus macrophage) and the state of activation of the cell.

#### CD4<sup>+</sup> T Lymphocytes

The cellular dynamics of infection of CD4<sup>+</sup> T lymphocytes by HIV-1 are illustrated in Fig. 7. CD4<sup>+</sup> T cells are heterogeneous with respect to activation state (resting versus activated) and previous antigen exposure (naïve versus memory), and HIV-1 pathogenesis must be considered in the context of this heterogeneity. Normally, the majority of mature CD4<sup>+</sup> T lymphocytes are in a resting G<sub>0</sub> state. These resting T cells are among the most quiescent cells in the body and are simply waiting to encounter antigen. About half are memory cells, which have previously responded to some antigen, while the remainder are naïve T cells.

**FIGURE 7** Cellular dynamics of HIV-1 infection of CD4<sup>+</sup> T cells. Successive steps in the life cycle of the virus are indicated by horizontal arrows. Transitions between resting (small) and activated (large) CD4<sup>+</sup> T cells are illustrated by vertical arrows. HIV-1 can infect resting and activated CD4<sup>+</sup> T cells, but integration of the reverse-transcribed HIV-1 provirus, which is necessary for virus production, occurs only in antigen-activated T cells. Productive infection requires antigen-driven activation of recently infected resting CD4<sup>+</sup> cells or infection of antigen-activated CD4<sup>+</sup> T cells. Productively-infected cells generally die within a few days from cytopathic effects of the infection, but some survive long enough to go back to a resting state, thereby establishing a stable latent reservoir.

The frequently-transmitted CCR5-tropic (R5) forms of HIV-1 can bind to, and fuse with, activated CD4<sup>+</sup> T cells and a small subset of resting memory CD4<sup>+</sup> T cells (184). CXCR4-tropic (X4) viruses can enter essentially all CD4<sup>+</sup> T cells due to the broad expression of CXCR4 in CD4<sup>+</sup> T cells. Resting CD4<sup>+</sup> T cells do not generally support productive infection due to numerous blocks in the viral life cycle. SAMHD1, a host cell restriction factor, is a deoxynucleoside triphosphate (dNTP) hydrolase that restricts HIV-1 in nondividing cells by hydrolyzing dNTPs required for reverse transcription (77, 78, 185). Its action may account for the fact that reverse transcription occurs very slowly in resting CD4<sup>+</sup> T cells (186). As reverse transcription slowly proceeds in these cells, the resulting viral DNA can be sensed by a cytoplasmic DNA sensor, interferon- $\gamma$ -inducible protein 16 (IFI16), which triggers an innate immune response, leading to caspase-1 activation and pyroptosis, an inflammatory form of cell death (187–189). Even if reverse transcription is completed in resting CD4<sup>+</sup> T cells, entry of the preintegration complex containing the reverse transcribed HIV-1 DNA into the nucleus may not occur (190). Thus, in resting T cells, reverse-transcribed HIV-1 genomes reside in the cytoplasm for a finite period of time (days to weeks) before the preintegration complex becomes nonfunctional. If the T cell is activated by antigen before the preintegration complex becomes nonfunctional, then the subsequent replicative steps can occur. In this sense, resting T cells carrying unintegrated HIV-1 DNA represent a latent reservoir for the virus known as preintegration latency (191). In untreated, asymptomatic HIV-1-infected individuals, most of the viral DNA present in resting CD4<sup>+</sup> T cells is in this unintegrated form (192, 193). Because transcription of unintegrated viral DNA in the cytoplasm cannot occur, latently-infected cells carrying this form of viral DNA presumably escape detection by immunologic mechanisms. In addition, there are blocks at subsequent steps in the virus life cycle. For example, lack of key host-cell transcription factors NF $\kappa$ B and NFAT in the nucleus of resting CD4<sup>+</sup> T cells ensures that resting CD4<sup>+</sup> T cells probably do not become productively-infected without some form of activating stimulus.

Following encounter with antigen, resting CD4<sup>+</sup> T cells undergo blast transformation and enter a state in which they are highly susceptible to productive infection by HIV-1. In activated T cells, there is no block to nuclear import. Thus, the infection progresses rapidly to integration, viral gene expression, and virus production. Gene expression from the HIV-1 LTR is dependent upon host transcription factors, such as NF $\kappa$ B that are upregulated in activated T cells (194). This adaptation allows HIV-1 gene expression and virus production to be dramatically increased in activated CD4<sup>+</sup> T cells and largely shut off in resting CD4<sup>+</sup> T cells.

From this point, there are several possible fates for infected cells (Fig. 7). *In vitro* studies have shown HIV-1 infection can be highly cytopathic for activated CD4<sup>+</sup> T cells and can induce cell killing by mechanisms that are described below. Some of these cells can also be destroyed by immunologic mechanisms, including HIV-1-specific cytolytic T lymphocytes. The resulting half-life of productively-infected CD4<sup>+</sup> T cells is relatively short, generally 1.5 days. However, some of the productively-infected CD4<sup>+</sup> T cells escape both the viral cytopathic effects and immunologic effector mechanisms and revert to a resting memory state carrying integrated provirus (195). This is a reflection of the normal physiology of T-cell activation; a fraction of the T cells that respond to any given antigen survive and enter the long-lived pool of memory T cells. In a resting state, these memory

CD4<sup>+</sup> T cells are likely to have little or no virus gene expression and therefore go unrecognized by the immune system. Because the viral DNA is in an integrated state in these cells, it is highly stable. Thus these cells provide a long-term, stable latent reservoir for the virus, a phenomenon termed postintegration latency (193, 195). The distribution of HIV-1 in various subsets of T cells reflects the physiologic factors described above (196). Levels of HIV-1 infection are lowest in naïve CD4<sup>+</sup> T cells. Latent virus persists in resting memory CD4<sup>+</sup> T cells. The virus persists in various subsets of memory cells including central memory cells, effector memory cells, and transitional memory cells (197). These subpopulations have somewhat different trafficking patterns and proliferative potential. Importantly, they all harbor latent HIV but to different extents in different patients.

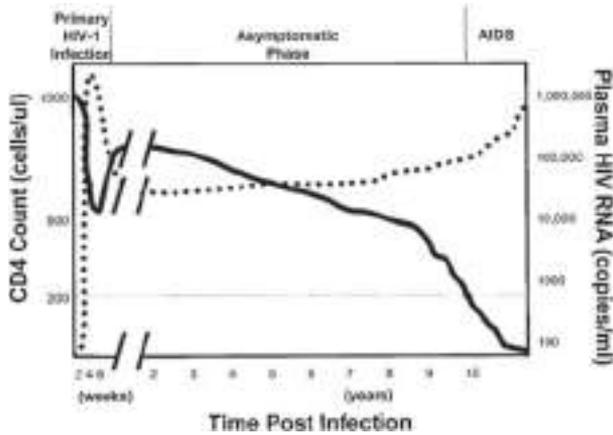

As discussed below, the pool of latently-infected cells represents a major barrier to curing HIV-1 infection. Upon subsequent exposure to antigen, these cells will become activated and release infectious virus. Thus, antigen plays a critical role in driving CD4<sup>+</sup> T cells into states in which they are susceptible to productive infection by HIV-1 and subsequent destruction by viral cytopathic effects or immune mechanisms (Fig. 7).

### Macrophages

The cellular dynamics of HIV-1 infection are different in macrophages as compared to CD4<sup>+</sup> T cells. HIV-1 can replicate in macrophages (198, 199), although integration and replication can occur only in dividing cells for most retroviruses. Specific amino acid sequences in the HIV-1 Gag, Vpr, and integrase proteins, and even a portion of the reverse-transcribed HIV-1 DNA, all have been reported to participate in targeting the viral preintegration complex for nuclear import, permitting integration and replication in nondividing cells, such as macrophages (59, 123, 200). Infection is not cytopathic in macrophages, and *in vitro* studies suggest that infected macrophages can continue to produce virus over long periods of time (198, 199). Infected macrophages may thus serve as a reservoir of virus *in vivo*; however, the role of macrophages as an obstacle to potential cure remains unresolved. The detection of viral DNA in macrophages from subjects appropriately treated with antiretroviral drugs may reflect phagocytosis of dead or dying infected CD4<sup>+</sup> T cells that are infected (201). Virus production by macrophages is particularly apparent late in the course of disease when few CD4<sup>+</sup> T cells remain and in the setting of opportunistic infections (202).

### Time Course of the Infection

The natural history of HIV-1 infection may be divided into three phases (Fig. 8). During the initial phase, known as primary or acute HIV-1 infection, virus replication produces a viremia that spreads the virus throughout the body. Viremia is eventually reduced by the emergence of CD8 T-cell responses. These events occur during the first several weeks following exposure to HIV-1. In the 50 to 70% of individuals who develop constitutional symptoms during primary infection, a transient illness resembling infectious mononucleosis appears two to three weeks after exposure (see below). During the acute illness, levels of genomic HIV-1 RNA in the plasma (a reflection of the free virion concentration) are usually greater than 10<sup>6</sup> copies/ml and can be as high as 10<sup>8</sup> copies/ml. Antibodies to HIV-1 are initially absent, and seroconversion usually occurs within a few weeks after onset of the acute illness.

**FIGURE 8** The three stages of disease in a hypothetical case of HIV-1 infection.

As the immune response to HIV-1 develops, there is a dramatic reduction in the level of viremia. Typically viremia falls to a lower plateau level (the “set point”). Set point values for plasma HIV-1 RNA are usually between  $10^3$  and  $10^5$  copies/ml. The CD4<sup>+</sup> T-cell count is typically reduced during symptomatic primary HIV-1 infection, reflecting both virus-induced depletion and sequestration of circulating CD4<sup>+</sup> T cells in lymphoid organs. After the acute illness resolves, peripheral CD4<sup>+</sup> T-cell counts generally rise again but usually not to preinfection levels.

During acute infection, there is rapid and dramatic depletion of CD4<sup>+</sup> T cells from the gut-associated lymphoid tissue (183, 203, 204). This early CD4 depletion in the gut is much more pronounced than CD4 depletion in other organs. The early loss of CD4<sup>+</sup> T cells from the gastrointestinal mucosa allows translocation of microbial products, which causes immune system activation and, in turn, contributes to CD4 depletion and end-organ disease (205).

Primary HIV-1 infection provides clues regarding the importance of various immune effector mechanisms in controlling HIV-1 infection. Virus-specific CTL appear early and likely represent a critical host factor in the control of acute HIV-1 infection (206, 207). In rhesus monkeys depleted of CD8<sup>+</sup> T cells, the viremia of primary SIV infection is not brought under control, and the animals progress quickly to AIDS (208). Thus it is very likely that, through the lysis of infected cells and perhaps also through the release of chemokines like MIP-1 $\alpha$ , MIP-1 $\beta$ , and RANTES that inhibit HIV-1 entry, CTL help to reduce the level of circulating virus to the lower levels that are characteristic of the asymptomatic phase of infection.

The initial seeding of the latent reservoir occurs during acute infection. In the SIV model of HIV-1 infection, a stable reservoir is established as early as day 3 postinfection, since prolonged administration of suppressive antiretroviral therapy beginning on day 3 postinfection is not curative and viral rebound occurs when treatment is stopped (209).

The second phase of HIV-1 infection is the long asymptomatic period between primary infection and the development of clinical immunodeficiency. The most important and characteristic pathophysiologic feature of the asymptomatic phase of HIV-1 infection is the gradual loss of CD4<sup>+</sup> T cells, although virus replicates continuously during this period. As primary infection resolves, plasma virus levels fall to a relatively stable steady-state level, which is different in different

patients and which determines the rate of disease progression (210). The higher the set point of plasma HIV-1 RNA (often referred to as the viral load), the more rapidly the patient will lose CD4<sup>+</sup> T cells and progress to AIDS. The plasma HIV-1 RNA level determines how rapidly CD4 cells will be lost, and the CD4 count reflects the degree of impairment of immunologic function and the risk of opportunistic infections.

There is tremendous individual variation in the length of the asymptomatic period in different infected individuals. Some individuals progress to AIDS within two years of infection, whereas others termed long-term nonprogressors (LTNP) have lived with HIV-1 infection for over 20 years without experiencing significant CD4 depletion. Many individuals in this category eventually do progress to AIDS in the absence of antiretroviral treatment. Nevertheless, a subset of LTNP, termed “elite controllers,” actually have no measurable viremia in the absence of treatment (211). Many of these individuals harbor forms of HIV-1 that appear to be replication competent, but it appears that the virus is held in check by immunologic mechanisms (212). These individuals frequently carry the class I MHC allele HLA B\*5701, suggesting a role for cytolytic T lymphocytes (213). It is likely that both virologic and host immunologic factors (discussed below) play a role in limiting HIV-1 replication and disease progression in elite controllers and LTNP. Some LTNP are infected with strains of HIV-1 that are defective in accessory genes like *nef* (214). Polymorphisms in structural and regulatory regions of other chemokine receptors or chemokine genes have subtle but significant effects on the rate of disease progression (215, 216).

Viral loads are, on the average, lower in women in the first five years after infection, although rates of disease progression are similar to those observed in men (217). Rates of disease progression may be influenced by environmental factors, particularly concurrent infections. Although a direct relationship between rate of progression and concurrent infections has not yet been clearly established, the activation of CD4<sup>+</sup> T cells in response to other infections provides the virus with an increased number of target cells, allowing transient spikes in viremia, which can also be observed after immunizations with recall antigens (218).

Another important factor in disease progression is the evolution of viral variants with substitutions in the envelope protein leading to a change in the pattern of chemokine receptor utilization, specifically from CCR5 to CXCR4. These so-called X4 viruses have a potentially wider host-cell range due to the broader distribution of CXCR4 and have been associated in some studies with more rapid replication rates and higher cytopathic potential. The appearance of X4 viruses is temporarily associated with more rapid CD4 cell decline (219). The rate of disease progression is thus influenced by the characteristics of the infecting virus, host genetic factors influencing virus entry and antiviral immune responses, and possibly environmental factors related to immune system activation.

### Factors in Disease Progression

Although rates of progression differ, the fundamental relationship between viral load and the rate of CD4 cell loss remains a central feature of AIDS pathogenesis, indicating that viral replication is the driving force for CD4 depletion. However, the exact mechanisms are still uncertain. For example, it is unclear whether the fraction of cells infected is high enough to account for the depletion of the entire CD4<sup>+</sup> T-cell compartment as a consequence of direct infection. At

any given time, only a small fraction of CD4<sup>+</sup> T cells are productively-infected. Thus, it is likely that additional mechanisms contribute to CD4<sup>+</sup> T-cell depletion. These include alterations lymphoid tissue microenvironments and chronic immune activation.

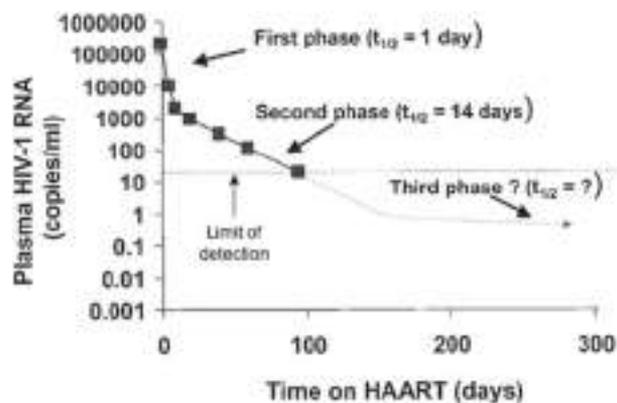

### Histopathologic Changes

During the asymptomatic phase of the infection, there are important changes in the structure and function of the peripheral lymphoid organs (182). Early in the asymptomatic period, the lymph nodes show characteristics of immune activation. Scattered productively-infected CD4<sup>+</sup> T cells are seen throughout the lymph nodes. The B-cell areas of the lymph nodes show a pattern of follicular hyperplasia indicative of intense B-cell stimulation. Virus particles are readily detected in the germinal centers where they are found associated with the network of follicular dendritic cells (FDC). These cells express Fc receptors and three types of complement receptors (CR1, CR2, and CR3) and, as a result, are capable of binding antigens that have bound antibody or activated complement. FDC may serve as filters that trap virus particles and thereby lower the level of infectious virus in the circulation. FDC are not susceptible to HIV infection; however, they play an important role in the activation of B lymphocytes in response to antigen. During the asymptomatic phase of HIV-1 infection, there is progressive disruption of the normal architecture of the lymph nodes, with loss of the FDC network and follicular involution (182). Fibrotic changes in the lymph node microenvironment may impair the homeostatic mechanisms that maintain T-cell populations (220). The loss of FDC may, in part, be responsible for the abnormal B-cell function observed in HIV-1-infected individuals. In contrast to FDC, blood-derived dendritic cells (DC), which have an important role in the presentation of antigens to T cells, can bind virus and transmit the virus to the CD4<sup>+</sup> T cells with which they interact during the course of an immune response (221). Following stimulation with inflammatory cytokines, immature tissue DC migrate to the lymph nodes where they present antigens taken up in the tissues to T cells in the lymph nodes. DC may carry virions bound via dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin (DC-SIGN) to the nodes where they mediate infection of CD4<sup>+</sup> T cells (154), but the importance of this pathway of infection remains unclear.

### Viral Dynamics

Analysis of changes in the level of viral RNA following the initiation of antiretroviral therapy has provided a striking picture of the very dynamic nature of the infection (222) (Fig. 9). All current antiretroviral drugs have the effect of blocking the new rounds of infection of susceptible cells without inhibiting release of virions by cells that are already infected. Following the initiation of therapy, plasma virus levels drop by approximately two logs within less than two weeks, indicating that the half-life of plasma virus is very short (now estimated to be on the order of minutes) and that the half-life of most productively-infected cells is also very short (1.5 days) (51, 223). Thus activated CD4<sup>+</sup> T cells that are only recently infected produce most of the plasma virus (224). Continuous new rounds of viral replication sustain the infection.

Because the rates of clearance and decay are largely independent of stage of disease and other factors, the level of viral RNA in the plasma reflects the rate of virus production. Because the half-life of free virus particles is extremely short,

**FIGURE 9** Hypothetical plot of plasma virus in a patient who is started on an effective regimen of drugs that block infection of new cells. Plasma virus titer drops rapidly in the first two weeks of treatment, reflecting the short plasma half-life of the virus and the short half-life of most of the productively-infected cells. These cells appear to be activated CD4<sup>+</sup> T cells. The decline in plasma virus shows a second, slower phase, which is due to turnover of cells infected before initiation of therapy. These may be persistently infected macrophages or CD4<sup>+</sup> T cells that are in a lower state of activation. Alternatively, this RNA could represent the clearance of virions that had accumulated in the germinal centers of lymphoid tissue. The second phase brings the viral load down to below the limit of detection, but the virus persists in reservoirs, including an extremely stable reservoir of latent virus in resting memory CD4<sup>+</sup> T cells. Reproduced from reference (484) with permission.

the steady-state level of viral RNA genomes in the blood reflects very recent virus production (106). The magnitude of the first phase of decay indicates that infected cells with longer half-lives, such as chronically infected macrophages, make a relatively minor contribution to plasma viremia in untreated individuals.

After the rapid initial phase of decay, there is a second slower phase of decay, reflecting either the clearance of virions that have accumulated in the germinal centers or the decay of a longer-lived population of virus producing cells (225), perhaps infected macrophages or infected CD4<sup>+</sup> T cells that are in a lower state of activation (224). The second phase of decay usually reduces plasma virus levels to below the limit of detection of current assays (50 copies or fewer of HIV-1 RNA/ml of plasma). The rapid drop in viremia initially raised hopes that eradication of the infection with antiretroviral therapy might be possible (225). Resting memory CD4<sup>+</sup> T cells in the postintegration state of latency (Fig. 7) persist; however, even in patients who have responded well to highly-active antiretroviral therapy (ART) and have had no detectable free virus in the blood for several years (226–228). These cells appear to represent the major barrier to curing the infection with antiretroviral drugs (229). The reservoir of resting memory CD4<sup>+</sup> T cells with integrated HIV-1 DNA is established early in primary infection (230) and shows minimal decay in infected adults (229) and children (231). Although early treatment usually leads to a smaller reservoir, recent studies indicate that the reservoir decay rate is nevertheless extremely slow (232).

Several hypotheses have been proposed to explain the extraordinary stability of the latent reservoir. The first is that the stability is simply a reflection of the fact that the virus has taken up residence in memory T cells, which, by nature, survive for prolonged periods of time. In this sense, the

mechanism of HIV-1 persistence resembles that of Epstein Barr virus (EBV), which establishes latent infection in memory B cells with viral persistence exploiting a fundamental feature of the immune system, the long-term survival of memory T cells. The stability of the memory T-cell response is due not only to the long half-life of individual memory T cells, but also to the process of homeostatic proliferation in which memory T cells occasionally enter the cell cycle and divide. The proliferation of latently-infected cells could contribute to the stability of the latent reservoir. Recent studies of HIV-1 integration sites have provided direct evidence for the proliferation of infected cells (233, 234). In some cases, the integration of HIV-1 into genes associated with cell proliferation may actually have driven the observed clonal expansions. What is not yet clear from these studies is whether the integrated proviruses are functional, as the overwhelming majority of proviruses in resting CD4<sup>+</sup> T cells are defective due to large internal deletions or APOBEC3G-mediated hypermutation (235).

A distinct, but not mutually exclusive hypothesis, is that the reservoir is continually reseeded by a low level of viral replication that may continue even in patients whose plasma virus levels are below the limit of detection (236–240). Even in patients who have suppression of viremia to below the limit of detection of ultrasensitive clinical assays (50 copies of HIV-1 RNA/ml), free virus particles are continuously present (236). Recent studies suggest that a new steady-state level of viremia is reached in patients on HAART, with average values of approximately 1 copy/ml (241). While all patients on HAART are continuously viremic, direct analysis of this residual viremia does not provide evidence for viral evolution (242, 243), and it is possible that the residual viremia simply reflects release of virus from latently-infected cells that become activated or from other stable reservoirs and not ongoing replication (244). If this is the case, then the use of even more intensive drug regimens would not accelerate the intrinsic decay rate of the latent reservoir, and, in fact, no study of treatment intensification to date has shown a decrease in residual viremia (245).

### T Cell Dynamics and Mechanisms of CD4 Depletion

In infected individuals, the rate of CD4<sup>+</sup> T-cell loss exceeds the rate at which CD4<sup>+</sup> T cells are produced by thymic differentiation and clonal expansion of peripheral CD4<sup>+</sup> T cells. CD4<sup>+</sup> T cells may be lost through a number of potential mechanisms, some operative for noninfected cells. In addition, the possibility that the production of CD4<sup>+</sup> T cells is decreased in HIV-1 infection needs consideration. HIV-1 infection accelerates the thymic involution that normally occurs with age. The decline in naive CD4<sup>+</sup> and CD8<sup>+</sup> T cells in the peripheral blood of infected individuals has been interpreted as indicating a defect in thymopoiesis (246), but it is difficult to measure directly the rate at which new T cells are produced in the thymus. To monitor ongoing thymic production of new T cells, studies have quantitated T-cell receptor excision circles (TRECs) produced as a by-product of the VDJ recombination reactions that occur in the thymus as new T cells are generated (247). These DNA circles are stable in cells after the gene rearrangements occur that produce functional T-cell receptors. Lower than normal TREC levels in peripheral blood CD4<sup>+</sup> and CD8<sup>+</sup> T cells have been observed in some HIV-1-infected adults, with partial reversal upon treatment. Analysis of TRECs generated by rearrangement of the  $\alpha$  and  $\beta$  chains of the T-cell

receptor has provided convincing evidence for a defect in thymocyte proliferation in HIV-1-infected individuals (248).

Accelerated CD4<sup>+</sup> T-cell loss is a critical factor in CD4<sup>+</sup> T-cell depletion. Under some experimental conditions, HIV-1 infection of susceptible cell types *in vitro* results in death of the infected cell. Syncytia (multinucleated giant cells) may form by the fusion of infected cells expressing Env protein and noninfected cells expressing CD4 (249). Inclusion of noninfected CD4<sup>+</sup> T cells in short-lived syncytia provides a potential mechanism for CD4<sup>+</sup> T-cell depletion. The extent to which syncytium formation contributes to CD4<sup>+</sup> T-cell depletion *in vivo* is unclear.

In addition, under some conditions, HIV-1-infected T cells appear to die from infection independent of any cell-cell fusion events (250, 251). Most potential mechanisms for HIV-1-induced single-cell killing involve the Env glycoprotein, which is poorly tolerated by many cell types. The fusogenic properties of the Env protein are an important determinant of the intrinsic toxicity of this protein for host cells (250). Other HIV-1 proteins, including Nef, Vif, and Vpr, have also been implicated in the death of infected cells (252, 253). Nonproductive or abortive infection of resting CD4<sup>+</sup> T cells may lead to their rapid death through the process of pyroptosis (187–189). In these cells, the viral DNA intermediates, generated during reverse transcription, appear to be sensed by innate immune sensors, resulting in the triggering of cell death pathways.

Another obvious mechanism for the loss of CD4<sup>+</sup> T cells involves the destruction of such cells by components of the immune system, particularly CD8<sup>+</sup> CTL. As is discussed below, the natural immune response to HIV-1 infection includes a strong CD8<sup>+</sup> CTL response, and it is quite likely that CD8<sup>+</sup> CTL mediate the destruction of infected cells *in vivo*. The destruction of productively-infected cells by CTL is beneficial to the host because it leads to a more rapid cessation of virus production from cells that are destined to die. CTL provide a strong selective force that leads to the rapid evolution of viral variants with mutations in key epitopes recognized by CTL (see below). Nevertheless, while CTL are clearly important in controlling viral replication *in vivo*, it has been difficult to demonstrate that they actually shorten the lifespan of productively-infected cells (254).

During HIV-1 infection several interesting reactions can potentially cause the loss of CD4<sup>+</sup> T cells that are not infected. As discussed above, disruption of the architecture of the lymph nodes may contribute to CD4 depletion. Fibrosis is commonly observed in the lymph nodes of patients with advanced infection, and it is likely that the disruption of the microenvironment where CD4<sup>+</sup> T cells reside contributed to CD4 depletion. HIV-1 infection is also associated with high levels of immune activation, and activated T cells are susceptible to apoptosis (255). *In situ* studies of lymph nodes from HIV-1-infected children and SIV-infected rhesus monkeys have shown that cells undergoing programmed cell death are distinct from cells productively-infected with virus, supporting the notion that indirect cell killing mechanisms may contribute to CD4 depletion (256). Rates of T-cell proliferation are increased several fold, and steady-state considerations suggest that this increased rate of CD4<sup>+</sup> T-cell proliferation must be more than balanced by an increased rate of destruction of T cells in the periphery (257, 258). The proximal cause of the immune hyperactivation seen in untreated HIV-1 infection remains unclear. One theory suggests that microbial translocation from the gastrointestinal tract contributes to the activation. Continuing

exposure to HIV and to other viruses, such as CMV are likely to also contribute to immune activation.

In addition to the depletion of CD4<sup>+</sup> T cells, qualitative defects in the function of the surviving CD4<sup>+</sup> T cells and on B-lymphocyte function. While normal absolute numbers of circulating B cells are found in HIV-1-infected individuals, circulating levels of immunoglobulins are high, reflecting polyclonal B-cell activation, but antibody responses to specific immunogens are very poor, particularly in patients with AIDS. Part of the B-cell defect may be intrinsic and not simply a consequence of defects in CD4<sup>+</sup> T cell help. However, the precise mechanisms remain obscure.

### Immune Responses

Immunodeficiency develops in HIV-1 infected individuals despite the presence of readily detectable B and T lymphocyte responses to HIV-1. Virtually all infected individuals develop antibody responses to several of the protein products of the HIV-1 genome. Even more striking is the finding that most infected individuals also have very high levels of virus-specific CTL. On the other hand, CD4<sup>+</sup> T-cell responses are generally reduced. Current research is focused on understanding which elements of the immune response are the most important in controlling viral replication and why the response as a whole is not more effective in eliminating the virus.

### Antibody Responses

All infected individuals develop readily measurable antibody response to HIV-1. Only antibodies to the extracellular portion of the Env glycoprotein can neutralize the virus. In general, levels of neutralizing antibodies are low even when high levels of anti-Env antibodies are present, indicating that many are not neutralizing. When neutralizing antibodies do arise, the virus can escape by accumulating mutations in the *env* gene. Of the viral proteins, the Env glycoprotein gp120 shows by far the most sequence variability. Neutralization-resistant variants have been selected *in vitro* in the presence of neutralizing antibody and arise readily when HIV-1 infection of human T cells is maintained in immunodeficient SCID mice (259). Antibodies present in patient sera can neutralize autologous virus isolates obtained at earlier time points, but generally cannot neutralize the contemporaneous isolate (28, 260), which results from the rapid and continuous evolution of the ectodomain of Env as a consequence of the selective pressure of the neutralizing antibody response (261). B-cell depletion studies in the SIV model have provided evidence that neutralizing antibodies contribute to the control of viral replication during chronic infection.

Antibodies to gp120 become detectable in the sera of HIV-infected individuals within two to three weeks after infection (27); however, these early antibodies are not neutralizing. They appear to be directed against disassembled envelope glycoproteins, and they recognize the interactive regions of gp120 and gp41, which, although immunogenic, are not exposed in the assembled, trimeric, glycoprotein complex (25). Subsequently, antibodies appear that are neutralizing but are usually restricted in activity to the infecting strain (28). Finally, antibodies appear that have more broadly neutralizing activity against a variety of isolates but in relatively low titers. A major recent advance has been the development of methods for cloning the antibody gene encoding these broadly neutralizing antibodies (bNAbs) (262, 263). Many of these bNAbs interfere with the binding interaction between gp120 and CD4. Such antibodies recognize discontinuous epitopes, the key residues of which are located within the binding pocket for CD4 on gp120 (the

so-called CD4BS epitopes). Other broadly neutralizing antibodies recognize epitopes that are near conserved structures involved in coreceptor binding (the so-called CD4i epitopes), membrane proximal epitopes, or epitope composed largely of gp120 oligosaccharides. A common feature of these bNAbs is that they have unusual structures, likely the result of a long period of co-evolution of the virus and the host immune response. Whether it will be possible to induce these antibodies in a vaccine setting is not yet clear.

### CTL Responses

HIV-1 specific CD8<sup>+</sup> CTL are readily detected in healthy seropositive individuals and are sometimes detected in patients with AIDS (264, 265). As discussed above, CTL appear early in response to acute HIV-1 infection and help to control the high-level viremia characteristic of this stage of infection by lysing productively-infected cells. CTL may also control viral replication through the release of chemokines (266). Vigorous HIV-1-specific CTL responses are observed in many long-term survivors of HIV-1 infection (267). The frequency of HIV-1-specific CTL appears to decline as disease progresses. In the SIV system, CD8<sup>+</sup> T cells help to control viremia in both acute and chronic infection (208, 268). MHC genotype influences the rate of disease progression (269), and particular class I-MHC alleles have been associated with slower disease progression, probably as a result of the capacity of the relevant alleles to present conserved epitopes in HIV-1 proteins to CTL. Certain MHC-class I alleles are overrepresented among patients who control viremia without antiretroviral drugs. The breadth of the CTL response is also important, and perhaps, as a consequence, heterogeneity at the class I loci is also associated with slower disease progression (270).

The HIV-1-specific CTL response can lead to the evolution of epitope escape variants, which accelerate AIDS pathogenesis (271, 272). Viral escape from CTL responses can involve mutations that diminish viral fitness, as evidenced by reversion of the mutations upon transmission of the virus to a new host with a different HLA genotype (273). While mutational escape provides one mechanism by which HIV-1 persists in the face of an ongoing CTL response, the functional capacity of HIV-1-specific CTLs is compromised in patients with progressive disease. HIV-1-specific CTLs express the inhibitory receptor PD-1, which is associated with clonal exhaustion (274–276). In contrast, the maintenance of “polyfunctional” CTLs has been associated with slower disease progression (277). Escape mutations may complicate HIV-1 eradication efforts because patients who start treatment in the chronic phase of the infection will have archived viruses with escape mutations in major CTL epitopes in the latent reservoir (278).

### Helper T-Cell Responses

The one component of the immune response that is not readily demonstrable in most infected people is the helper T-cell response to HIV-1 proteins. HIV-1-specific CD4<sup>+</sup> T cells are inactivated early in the course of the infection. They can be readily detected only in those rare individuals in whom the disease does not progress (long-term nonprogressors). Treatment of infected individuals with antiretroviral therapy early in primary HIV-1 infection facilitates this HIV-1-specific immune response to develop.

### Central Nervous System Disease

Neurological problems are common in HIV-1 infection (279). In addition to opportunistic infections and malignancies

affecting the central nervous system (CNS), there is a unique dementia syndrome, HIV-associated neurologic dysfunction dementia (HAND), that appears to result from direct effects of HIV-1 on the CNS. HAND appears late in the course of disease, roughly coincident with the development of clinical immunodeficiency, and is an AIDS-defining condition.

The pathogenesis of HAND is complex and poorly understood but involves interactions between various types of infected and uninfected cells in the CNS. HIV-1 probably gains access to the CNS from the blood stream, which requires a mechanism for crossing the blood-brain barrier. This may occur either by direct infection of capillary endothelial cells (280), or, more likely, by ingress of infected monocytes/macrophages (281). This “Trojan horse” mechanism resembles the mechanism by which other lentiviruses gain access to the CNS. Although CNS disease does not become apparent until late in the course of infection, entry of HIV-1 into the CNS may occur very early. Studies using an artificial blood-brain barrier demonstrated that upregulation of adhesion molecules and proinflammatory cytokines are critical for transendothelial migration. Heightened trafficking may occur with peripheral activation of monocytes in late-stage HIV-1 infection, which is generally when HAND occurs. Proinflammatory cytokines like TNF- $\alpha$  may also alter the permeability of the blood-brain barrier to free virus (282).

The principal cellular target cells for HIV-1 replication in the CNS are brain macrophages and microglial cells (283). Both cell types are derived from peripheral blood monocytes and are presumed to undergo gradual turnover. In some cases, syncytia composed of numerous infected macrophages and microglial cells can be observed in the vicinity of blood vessels in the CNS. No convincing evidence exists for HIV-1 DNA in neurons, endothelial cells, or oligodendrocytes (284, 285). Progress in the understanding of the extent of infection within the CNS has been hampered by the obvious difficulty in obtaining tissue and by uncertainties with regard to the relationship between level of virus in the cerebrospinal fluid (CSF) and levels of virus in the brain parenchyma.

The development of HAND is not universal in advanced AIDS, suggesting that there may be viral, as well as host, genetic determinants of heightened risk. Indeed, distinct strains of HIV-1 isolated from both peripheral blood and the nervous system of the same individual can have different biological characteristics and cellular tropisms. Brain isolates tend to be more macrophage-tropic with specifically conserved regions in a portion of the envelope, the V3 domain (286, 287). These observations suggest that certain strains of HIV-1, having an increased propensity to invade (neurotropism) and cause damage in the nervous system (neurovirulence), might lead to clinically significant CNS involvement (288, 289).

How viral infection of brain macrophages and microglial cells leads to CNS dysfunction is still unclear. The simplest hypothesis is that infected cells release soluble products that damage other cells in the CNS. The long list of potential mediators includes viral proteins like gp120, Tat, and Nef, as well as inflammatory mediators such as TNF- $\alpha$ , NO, and prostaglandins (283). Concern exists that the virus might persist in the CNS and produce disease even in treated patients who have no detectable plasma virus, in part because of the limited CNS penetration of certain protease inhibitors. Other important factors include the active efflux of antiretroviral drugs through transporters including p-glycoprotein (290). While case reports, describing patients who had undetectable or low plasma HIV RNA levels yet significantly

higher CSF HIV RNA levels, alerted clinicians to this possibility, there have been relatively few clinical examples of “CNS escape.” In fact, significant reductions in the incidence rates of HAND have been noted since 1996 (291). HAART regimes can actually improve neuropsychological performance and radiological abnormalities in those with HAND (292). Turnover of infected microglial cells over the course of weeks to months may result in replacement by uninfected monocytes from the blood. Thus, as is the case with HIV-1-induced immune deficiency, HAND appears to be driven by active viral replication.

## CLINICAL MANIFESTATIONS

The cardinal manifestation of HIV-1 infection is the progressive loss of CD4<sup>+</sup> T lymphocytes. The resulting defect in cellular immunity leads to development of the opportunistic infections and malignancies that characterize AIDS. In addition, certain organ-specific syndromes may be caused directly by the virus itself. A comprehensive discussion of the myriad complications of HIV-1 infection is beyond the scope of this chapter, and the reader is referred to the many excellent textbooks of infectious diseases and AIDS medicine for more detailed discussions of specific syndromes and opportunistic pathogens.

### Major Clinical Syndromes

#### Primary Infection

Symptomatic primary infection with HIV-1 occurs in approximately 30 to 70% of infected individuals (293). Symptoms begin around 14 days after exposure and peak virus titers occur a week later (294). The most frequent symptoms include fever, pharyngitis, headache, arthralgias, myalgias, and malaise (Table 2). A nonpruritic, maculopapular rash on the face and trunk is also commonly observed. Generalized lymphadenopathy is a frequent finding. Mucocutaneous ulceration occurs and helps to differentiate primary HIV-1 infection from other viral syndromes. Oral candidiasis occurs frequently, and candidal esophagitis is well-documented (293). Other gastrointestinal symptoms can include nausea, vomiting,

**TABLE 2** Frequency of signs and symptoms in patients with acute HIV-1 infection

Sign/symptom	Frequency (%)			
	Kinloch-de Loes <sup>a</sup> (n=31)	Daar <sup>b</sup> (n=40)	Sydney <sup>c</sup> (n=74)	Schacker <sup>d</sup> (n=41)
Fever	87	88	80	~95
Lethargy/fatigue	26	n/a	67	~90
Myalgia	42	60	63	~60
Rash	68	58	53	~30
Headache	39	55	51	~55
Sore throat/Pharyngitis	48	43	51	~70
Lymphadenopathy	6	38	43	~50
Arthralgia	29	28	26	n/a
Diarrhea	32	n/a	32	~45
Night sweats	n/a	50	n/a	~45
Oral ulcers	13	8	30	n/a

<sup>a</sup>From reference (479).

<sup>b</sup>From reference (350).

<sup>c</sup>Group 3 from reference (480).

<sup>d</sup>Estimated from Fig. 1 in reference (481).

and diarrhea. Aseptic meningoencephalitis is the most common neurological manifestation of primary HIV-1 infection. Acute peripheral neuropathy, myelopathy, and mononeuritis multiplex are less-frequently observed (293). In the majority of patients, symptoms resolve within a month. Persistence of symptoms beyond 8 to 12 weeks, along with a severely depressed CD4<sup>+</sup> lymphocyte count, may be clues to unusually rapid progression of HIV-1 disease.

The virologic and immunologic aspects of primary HIV-1 infection are discussed in the Pathogenesis section. The principal laboratory abnormality is a decrease in the absolute CD4<sup>+</sup> lymphocyte count. In most patients there is also an increase in reactive CD8<sup>+</sup> T lymphocytes. Hematologic abnormalities are uncommon except for mild thrombocytosis. Serum aspartate transaminase and alkaline phosphatase levels may be mildly elevated, but clinical hepatitis is an infrequent finding (293).

### Progression to AIDS

In most patients, a prolonged asymptomatic period follows the resolution of primary infection. In the absence of antiretroviral therapy, the median time from acquisition of HIV-1 infection to AIDS is approximately 8 to 10 years. Use of the term “clinical latency” to describe this interval is misleading, given the presence of continuous virus replication and CD4<sup>+</sup> lymphocyte depletion. On average, there is a loss of 30 to 60 CD4<sup>+</sup> cells/ $\mu$ l per year, although in many patients CD4<sup>+</sup> lymphocyte counts may remain stable for several years followed by a period of rapid decline. Progression to AIDS within one to two years of primary HIV-1 infection occurs in less than 5% of patients. Rapid progression often follows severe primary infection and may be associated with transmission of syncytium-inducing (CXCR4 utilizing) variants of HIV-1 (295).

In many patients, fatigue and lymphadenopathy continue to be noted during the otherwise asymptomatic phase of HIV-1 infection. The occurrence of minor clinical events, such as oral hairy leukoplakia (secondary to EBV), oral or vaginal candidiasis, herpes zoster, and a variety of other dermatologic disorders, may be early signs of progression. Worsening fatigue, night sweats, and weight loss become more common with advancing disease. The risk of serious, potentially life-threatening opportunistic infections increases significantly at CD4<sup>+</sup> cell counts below 200/ $\mu$ l. For this reason, a CD4 count of less than 200/ $\mu$ l was selected as a diagnostic criterion of AIDS according to the 1993 revised CDC case definition (296).

### Systemic and Organ-Specific Manifestations

Infection with HIV produces a variety of clinical manifestations affecting nearly every organ system. Improvement in most of these manifestations, following the institution of potent antiretroviral therapy, strongly implicates HIV replication or immune activation in their pathogenesis. Earlier initiation of antiretroviral therapy, as a result of changing treatment guidelines, has made these manifestations significantly less common in economically-advantaged countries, although examples are still seen among persons presenting with advanced disease and in resource-limited settings.

Dermatologic disorders, including pruritus and xerosis, are frequent symptoms in patients with early infection; a variety of noninfectious inflammatory conditions are commonly observed including seborrheic dermatitis, papular pruritic eruption, and eosinophilic folliculitis (297).

Neurologic manifestations of HIV infection include disorders of the central and peripheral nervous system, oppor-

tunistic infections, malignancies, vascular complications, and myopathies. The most frequently recognized “primary” neurologic manifestation of HIV infection is HAND, or the AIDS dementia complex, which occurs in up to 27% of patients with late-stage HIV disease (298). This syndrome involves progressive cognitive, motor, and behavioral deficits that usually begin in patients with moderately advanced HIV disease (CD4<sup>+</sup> cell counts below 200/ $\mu$ l). Computed tomography or magnetic resonance imaging studies of the brain usually show evidence for cortical atrophy, ventricular enlargement, and diffuse white matter abnormalities. Rapid clinical improvement in response to treatment argues for a central role of HIV in the pathogenesis of AIDS dementia (299).

Disorders of the peripheral nervous system can be classified as distal symmetric polyneuropathy, toxic neuropathy, inflammatory demyelinating polyneuropathy, progressive polyradiculopathy, and mononeuropathy multiplex (298). Up to 35% of patients with HIV infection develop signs or symptoms of distal symmetric polyneuropathy in later stages of disease (300). Symptoms begin as burning pain and numbness in the feet and may progress to the point that ambulation becomes impossible. Subjective complaints of distal polyneuropathy may precede objective findings on neurologic examination by several months. In more advanced cases there is diminished vibratory sensation and loss of ankle reflexes. Inflammatory demyelinating polyneuropathy is characterized by progressive weakness and areflexia resembling that of Guillain-Barré syndrome. This form of neuropathy, along with mononeuropathy multiplex, may occur during primary HIV-1 infection and is thought to have an autoimmune basis (298).

Nonspecific interstitial pneumonitis and lymphocytic interstitial pneumonitis (LIP) have been associated with HIV infection, as has primary pulmonary hypertension. The occurrence of LIP is most frequent in infants with mother-to-child transmission of HIV (see below). Clinical signs and symptoms of interstitial lung disease are similar to those in HIV-uninfected patients. Histological features include lymphocytic or mononuclear cell infiltration and the absence of known pulmonary pathogens (301).

Oral pathology attributable to HIV infection includes xerostomia, recurrent aphthous stomatitis, and gingivitis. Giant aphthous ulcers of the esophagus also occur but less frequently than aphthous stomatitis. Diarrheal illness is common in patients with advanced HIV disease and usually can be attributed to infection with specific enteric pathogens, such as cryptosporidium, microsporidia, or *M. avium* complex. Extensive HIV-1 infection occurs in gut-associated lymphoid tissue, suggesting a direct contribution of HIV-1 to intestinal dysfunction (302).

Endocrine dysfunction and metabolic disorders are well-described as complications of advanced HIV infection, including hypogonadism, loss of libido, and testicular atrophy. It is uncertain whether the primary abnormality is at the level of the hypothalamus or the testis. Fertility is decreased and the rate of fetal loss increased among women with advanced stages of disease (303).

Wasting syndrome in HIV infection is defined as the unintentional loss of more than 10% of body weight. When accompanied by constitutional symptoms for longer than 30 days, wasting, in the absence of opportunistic infection, or malignancy is sufficient to make a diagnosis of AIDS (296). In the developing world, the high prevalence of HIV-associated wasting has given AIDS the appellation “slim disease.” In developing countries, some degree of HIV-associated wasting

occurs in nearly a third of otherwise asymptomatic patients (in the absence of effective antiretroviral therapy) and in 60 to 90% of patients with AIDS (319). As in starvation and cancer, death from wasting in AIDS occurs at 66% of ideal body weight (304).

Anemia and neutropenia are the most frequent hematologic disorders in HIV-infected individuals. Although a large number of drugs used in the treatment of HIV infection and its complications can cause bone marrow suppression, HIV infection per se is clearly associated with anemia and neutropenia, particularly in late-stage disease. In untreated patients with AIDS, anemia has been noted in 4% and neutropenia in 11% (305). The anemia is normochromic and normocytic, and iron studies are suggestive of the anemia of chronic disease. Although the hypergammaglobulinemia associated with HIV infection may lead to a positive Coombs's test in 20% of patients, other evidence in support of hemolysis as a cause of anemia in HIV infection is rare (306). Similarly, antigranulocyte antibodies detected in many HIV-infected patients do not appear to play a major role in the development of HIV-associated neutropenia. Progenitor cells for myeloid, erythroid, and megakaryocyte lineages from HIV-infected individuals have a reduced capacity for growth *in vitro*. The mechanisms by which HIV reduces the proliferative capacity of these progenitor cells are poorly understood.

In contrast to anemia and neutropenia, thrombocytopenia in HIV infection is usually due to immune-mediated destruction of platelets. Platelet-associated antibodies are detected in the majority of patients with HIV-associated thrombocytopenia, and examination of the bone marrow reveals increased numbers of megakaryocytes, suggesting peripheral destruction of platelets. The incidence and severity of immune thrombocytopenia appears to increase with diminishing CD4<sup>+</sup> cell count. Some degree of thrombocytopenia is present in 5 to 10% of patients at earlier stages of HIV disease and in up to 30% of patients with AIDS (306).

A variety of rheumatologic syndromes have been described in HIV-infected individuals, including Reiter's syndrome, psoriatic arthritis, polymyositis, vasculitis, and sicca syndrome (307). Inappropriate immune activation and polyclonal B-cell activation leading to hypergammaglobulinemia and autoantibody production are implicated in the pathogenesis of these HIV-associated syndromes, but precise pathogenetic mechanisms have not been defined.

HIV infection is also associated with a rapidly progressive form of glomerulosclerosis (HIV-associated nephropathy) leading to nephrotic-range proteinuria and renal insufficiency. The incidence of HIV-associated nephropathy is highest among African Americans and injection-drug users. Renal biopsy reveals collapsing focal segmental sclerosis of involved glomeruli, as well as tubulointerstitial changes accompanied by an interstitial mononuclear cell infiltrate and the presence of HIV-1 RNA in tubular epithelial cells and glomerular podocytes (308). Effective antiretroviral therapy has been associated with resolution of histologic changes. Despite reductions in HIV-1 levels in the kidney, persistence of viral RNA transcripts suggest that the kidney may serve as a reservoir for HIV-1 infection.

## Complications

**1. Opportunistic infections.** The incidence and severity of opportunistic infections increases as cellular immunity wanes during the course of HIV-1 infection. The widespread use of potent antiretroviral therapy and chemoprophylaxis has markedly reduced the incidence of opportunistic infec-

tions in HIV-infected patients in the developed world. However, because of limited access or avoidance of care, patients continue to present, late in the course of HIV disease, with active opportunistic infections.

The CD4<sup>+</sup> cell count is the most useful marker for predicting the immediate risk of developing a particular opportunistic infection. Such complications are rare in patients with CD4 counts above 500 cells/ $\mu$ l. As the CD4 count drops below 500 cells/ $\mu$ l patients may begin to experience oral candidiasis, pneumococcal infections, and a host of cutaneous disorders including recurrent reactivation of herpes simplex virus, varicella zoster, dermatophyte infections, pityriasis, and onychomycosis. The risk of more serious opportunistic infections, such as *Pneumocystis* pneumonia, *Candida* esophagitis, reactivation of latent histoplasmosis and other systemic fungal infections, toxoplasma encephalitis, and cryptococcal meningitis, increases significantly as the CD4 count falls below 200 cells/ $\mu$ l. At CD4<sup>+</sup> cell counts under 50/ $\mu$ l, patients are at increased risk for the occurrence of disseminated infection with *Mycobacterium avium* complex, reactivation of cytomegalovirus infection, cryptosporidiosis, and progressive multifocal leukoencephalopathy (PML) due to John Cunningham (JC) virus infection.

Infection with HIV-1 significantly increases the risk of pulmonary and extrapulmonary tuberculosis. The HIV-1 pandemic has contributed to a 5- to 10-fold increase in the incidence of tuberculosis in resource-poor countries, where more than 80% of patients newly diagnosed with tuberculosis are co-infected with HIV (309). In contrast to other opportunistic infections, the risk of tuberculosis is increased even in patients with well-preserved CD4 cell counts. A study in South African gold miners found that the incidence of tuberculosis doubled within the first year of HIV infection (310). Numerous other opportunistic infections have been catalogued in patients with advanced HIV disease, but are beyond the scope of this chapter.

**2. Oncologic complications.** The oncologic manifestations of HIV infection arise as opportunistic malignancies in the setting of severe immune deficiency. NonHodgkin's lymphoma (often associated with high-level EBV replication), Kaposi's sarcoma (associated with human herpesvirus 8 infection) (311), and cervical cancer (due to oncogenic serotypes of human papillomavirus [HPV] infection) are recognized as AIDS-defining cancers when they occur in HIV-infected patients. Anal carcinoma, although not formally considered an AIDS-defining cancer, is also caused by HPV infection. Other malignancies, including Hodgkin's disease, liver cancer, and stomach cancer also occur more often among HIV-infected patients than in the general population (312). By contrast, rates of common epithelial malignancies, such as breast, prostate, and colorectal cancer, are not increased.

**3. Cardiovascular complications.** HIV-1-infected patients have increased risk of myocardial infarction, compared to control populations matched for traditional cardiovascular risk factors (313–316). More striking is the finding that interrupting antiretroviral therapy significantly increases the risk of cardiovascular events, independent of CD4 cell count (317, 318). This increased risk is correlated with an increase in plasma levels of soluble markers of inflammation and coagulation like interleukin-6 (IL-6), high-specificity C-reactive protein (hsCRP), and D-dimer (319–321). In addition, adverse changes in surrogate markers associated with cardiovascular risk, such as flow-mediated vasodilatation, carotid intimal-media thickness, and coronary artery

calcification, occur in patients with HIV-1 infection (26, 27). The extent to which these changes can be prevented or reversed by antiretroviral therapy, anti-inflammatory drugs, and/or statins is an active area of current research.

### HIV-1 Infection in Children

In the absence of preventive antiretroviral therapy, 15 to 30% of children born to HIV-infected mothers acquire HIV infection through mother-to-child transmission (322, 323). The course of HIV-1 infection is accelerated in children with vertically-acquired HIV-1 compared to HIV-infected adults. Because of the lymphocytosis of infancy, the absolute CD4<sup>+</sup> lymphocyte count may not accurately reflect functional immune status and must be adjusted for age. Without potent antiretroviral therapy, approximately 20% of infected infants develop AIDS in the first year of life, and 28% die before five years of age (324). In the developed world, the five-year survival rate for children who develop signs of HIV infection within the first five months of life is 45%, as compared to 74% for children with a later onset of disease (325). In lower socioeconomic countries, two-year mortality of HIV-infected children exceeds 50% (326). Lymphadenopathy, splenomegaly, and hepatomegaly are the most common signs of HIV infection in the first year of life. Growth failure and developmental delay are manifestations of HIV infection in children. Progressive encephalopathy is found in approximately 15% of infected children (327). Another unique manifestation is lymphoid interstitial pneumonitis, which occurs in 30 to 40% of children with HIV infection (327). Abnormalities in immunoglobulin synthesis predispose to recurrent pyogenic infections with organisms that are common causes of infection in young children, such as *S. pneumoniae*, *H. influenzae*, *Staphylococcus aureus*, and *Salmonella* sp. The most frequently-encountered opportunistic infections in children are *Pneumocystis pneumonia*, *Candida* esophagitis, disseminated CMV infection, cryptosporidiosis, and disseminated MAC infection (327).

### Clinical Diagnosis

Before the discovery of HIV-1, AIDS was defined, in part, by the occurrence of opportunistic infections suggestive of immunodeficiency in patients not receiving immunosuppressive therapy and without a history of congenital immunodeficiency. This definition remains useful in helping to identify patients with advanced HIV-1 disease. Thus, the occurrence of opportunistic infections, such as *Pneumocystis pneumonia*, *Candida* esophagitis, cryptococcal meningitis, toxoplasmosis, or chronic ulcerative herpes simplex, in the absence of a known cause of immunodeficiency, should raise the possibility of HIV-1 infection. Recurrent or disseminated zoster, pneumococcal infection in a young adult, oral or recurrent vulvovaginal candidiasis, disseminated papillomavirus infection, persistent fever, night sweats, lymphadenopathy, weight loss, and chronic diarrhea all may be evidence of infection with HIV-1. Similarly, a diagnosis of HIV-1 infection should be entertained in patients with unexplained lymphopenia, anemia, or neutropenia, and in cases of idiopathic thrombocytopenia. In such cases, information should be sought from the patient to determine if he or she is at risk for HIV infection (e.g., men who have sex with men, current or prior injection-drug use, female sexual partners of bisexual men or injection-drug users, a history of unprotected sex with a new or unknown partner, or a history of transfusion or occupational exposure).

It is a difficult challenge to identify individuals during the asymptomatic stages of infection. Early diagnosis is essential

in order to provide appropriate counseling and advice regarding modification of behaviors that may spread the virus to other individuals and to institute antiretroviral therapy prior to immune depletion. For this reason, the CDC recommends that HIV testing be performed as part of routine medical care at least once in all persons aged 13 to 64 years and annually in those at high risk of HIV infection (328). Presence of another sexually transmitted disease, infection with hepatitis B or C viruses, or active tuberculosis should prompt testing for HIV-1 infection.

The clinical diagnosis of primary HIV infection is particularly challenging due to the relatively nonspecific nature of the presenting signs and symptoms (Table 2), which may be confused with other viral infections including adenovirus or enterovirus infection, influenza, and CMV or EBV mononucleosis. This difficulty is further confounded by the observation that patients with acute HIV infection who seek medical attention usually do so in a primary care or emergency room setting, where clinicians may be less attuned to the possibility of primary HIV infection. In one study, approximately 1% of heterophile-negative sera from patients tested to exclude acute mononucleosis were found to be have high titers of HIV-1 RNA but negative results on HIV antibody testing, suggesting acute infection (329).

### LABORATORY DIAGNOSIS

A diagnosis of infection with HIV can be made by virologic, serologic, or nucleic acid tests. For the majority of patients with clinical symptoms suggestive of HIV infection, and for those at high risk for HIV infection, diagnosis is straightforward. The broad application of HIV diagnostic tests to persons at little or no risk of acquiring HIV infection, however, requires an understanding of the performance characteristics of these assays.

#### Virus Isolation

HIV-1 can be cultured from plasma or peripheral-blood mononuclear cells (PBMC) of infected individuals. A positive culture provides direct evidence of HIV-1 infection, but virus culture is rarely necessary to establish a diagnosis. The overall sensitivity of PBMC culture is 95% or more in patients with CD4<sup>+</sup> cell counts below 500/μl, but sensitivity is lower in patients with higher CD4 counts. Virus isolation is limited to research purposes.

#### Antigen Detection Assays

Circulating HIV-1 capsid (p24) antigen becomes detectable by immunoassay approximately 15 to 20 days after infection (Fig. 10). Detection of p24 antigen has been incorporated into HIV-1/2 antigen/antibody combination immunoassays to enhance detection of HIV-1 infection during acute infection, prior to the development of HIV-specific antibodies (see below). After seroconversion, p24 antigen is complexed with p24 antibodies and becomes undetectable in the majority of infected individuals. For this reason p24 antigen assays in isolation are not useful diagnostic tests in asymptomatic individuals at risk for HIV-1 infection.

#### Nucleic Acid Detection

##### Qualitative Assays for Proviral HIV-1 DNA

Evidence for HIV-1 infection can be established by demonstrating the presence of proviral DNA in PBMC. Assays for detecting proviral DNA employ the polymerase chain reaction (PCR) to amplify conserved sequences in the HIV-1 *gag* or *pol* gene, coupled to a detection step based on

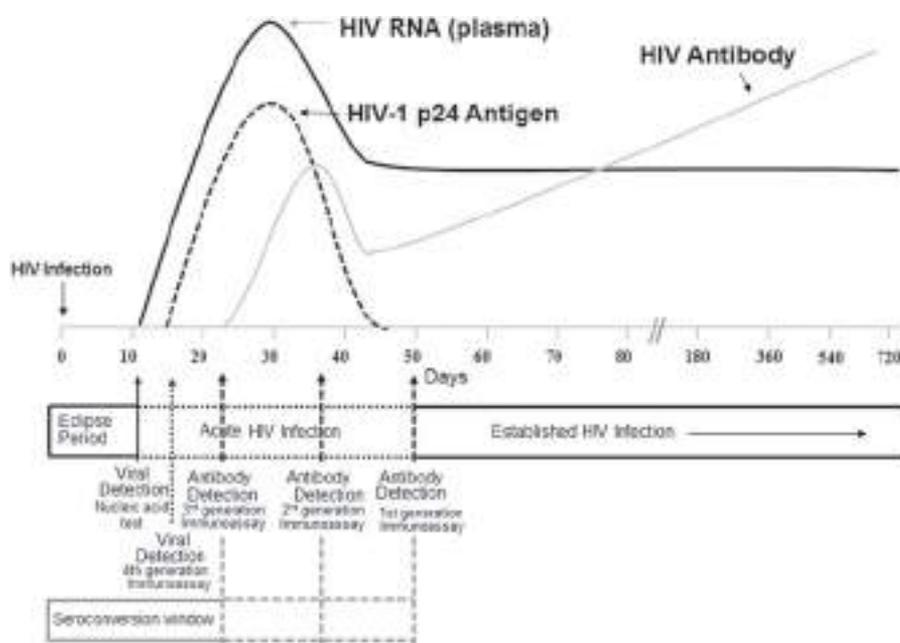

FIGURE 10 Order of appearance of laboratory markers of HIV-1 infection (228).

hybridization of a labeled oligonucleotide probe specific for the amplified gene sequences. With carefully standardized procedures and rigorous quality assurance and quality control, experienced laboratories can achieve 100% sensitivity and specificity.

Despite the excellent performance of these assays in proficiency panels, the sensitivity of HIV-1 DNA PCR assays in clinical practice is only 96 to 99%. As with virus culture and p24 antigen detection, sensitivity is lower in individuals with higher CD4<sup>+</sup> cell counts due to the lower titer of circulating infected PBMC. The greatest potential clinical utility of HIV-1 DNA PCR assays is in the early diagnosis of HIV-1 infection in neonates (see below). Clinical applications of these tests are relatively limited in adults, but occasionally DNA PCR testing may be helpful in persons with positive immunoassays but negative plasma HIV-1 RNA tests, as in elite controllers.

#### Assays for Quantifying Plasma HIV-1 RNA

Quantitative assay of HIV-1 RNA levels in plasma is used to monitor the course of disease and the response to antiretroviral therapy in patients already known to be HIV-1-infected. Several assays based on different methodologies have been approved by the FDA for clinical use.

Despite methodological differences, results of the commercially-available quantitative HIV-1 RNA assays are highly correlated (330, 331). The assays have a lower limit of quantification of 20 to 75 copies/ml, depending on the assay. The assay range can be extended by using larger volumes of plasma and pelleting virion particles prior to RNA extraction, but the precision with which plasma HIV-1 RNA can be quantified diminishes substantially at titers below 200 copies/ml. Serial testing of clinically stable patients not on antiretroviral therapy (or on a stable failing regimen) has shown the relative stability of plasma HIV-1 RNA levels over the short term (weeks to months), with a biological variation of approximately 0.3 to 0.4 log<sub>10</sub> copies/ml (332). Thus, changes of greater than 0.5 to 0.7 log<sub>10</sub> (3- to 5- fold) are likely to reflect significant changes in HIV-1 replication.

Whereas earlier versions of these assays were specific for HIV-1 belonging to Group M, newer real-time PCR assays (COBAS AmpliPrep/COBAS TaqMan version 2, Roche Diagnostics; RealTime HIV-1, Abbott Molecular; Aptima HIV-1 Quant, Hologic) can also quantify HIV-1 Groups N, O, and P; they do not detect HIV-2 (333–335).

#### Clinical Utility of Plasma HIV-1 RNA Monitoring

Numerous studies have demonstrated the correlation of plasma HIV-1 RNA levels with stage of disease. Patients with AIDS or symptomatic HIV infection have significantly higher titers of plasma HIV-1 RNA than do those with asymptomatic infection, although HIV-1 RNA level and CD4<sup>+</sup> cell count are weakly correlated. Individuals with plasma HIV-1 RNA levels greater than 100,000 copies/ml within six months of seroconversion are 10 times more likely to progress to AIDS within five years than patients with lower levels of plasma HIV-1 RNA (336). Although plasma HIV-1 RNA levels are strong predictors of the risk of disease progression, they are weak predictors of the rate of CD4 count decline (Table 3) (337). This seeming paradox may be explained by the large variance observed in CD4 slopes and

TABLE 3 Association of plasma HIV-1 RNA level with decline in CD4<sup>+</sup> cell count and risk of AIDS and death

Plasma HIV-1 RNA level (bDNA assay)	Change in CD4 <sup>+</sup> cell count per year (cells/μl)	Progression to AIDS within six years	Death from AIDS within six years
< 500 copies/ml	-36.3	5.4%	0.9%
501-3,000 copies/ml	-44/8	16.6%	6.3%
3,001-10,000 copies/ml	-55.2	31.7%	18.1%
10,001-30,000 copies/ml	-64.8	55.2%	34.9%
> 30,000 copies/ml	-76.5	80.0%	69.5%

Adapted from reference (210).

the weak association between CD4 slope and risk of disease progression (338).

In the absence of treatment, plasma HIV-1 RNA levels may provide prognostic information in late stages of disease (339) and in children with perinatally-acquired HIV-1 infection (340). However, the CD4 count may be a better predictor of disease progression than is plasma HIV-1 RNA in patients with very low CD4 counts (below 50 cells/ $\mu$ l) (341).

The dynamic response of plasma HIV-1 RNA to treatment makes it possible to assess the effectiveness of antiviral therapy within a matter of weeks. A decrease in plasma HIV-1 RNA confers a significant reduction in risk of disease progression, independent of baseline plasma HIV-1 RNA level and CD4 count, and independent of the increase in CD4 count due to treatment (342). A  $0.3\log_{10}$  (2-fold) reduction in plasma HIV-1 RNA levels confers a 30% reduction in the risk of progression to AIDS or death (343); a  $1\log_{10}$  (10-fold) reduction reduces the risk of disease progression by approximately two-thirds (344). Although initial studies suggested that HIV-1 RNA was a more significant predictor of response to antiretroviral therapy than the change in CD4 count, subsequent studies make clear the prognostic importance of improvement in both markers (345, 346).

### Sample Collection

Blood for plasma HIV-1 RNA testing should be collected into tubes containing EDTA as an anticoagulant and the plasma separated and stored frozen at  $-70^{\circ}$  C until testing. Studies show that HIV-1 RNA is stable for up to 48 hours at room temperature in the presence of EDTA, but samples ideally should be processed within six hours after collection. Events leading to immune activation, such as vaccination or acute infectious illness, can transiently raise the plasma HIV-1 RNA level (218). Therefore, plasma HIV-1 RNA testing should not be performed within four weeks of an intercurrent infection or immunization. Because of differences between assay formats and commercial laboratories, the same laboratory should be used for serial tests on an individual patient.

Current treatment guidelines recommend obtaining plasma HIV-1 RNA level as part of initial patient evaluation. Virus load testing also should be performed immediately before and within two to eight weeks after initiating treatment to assess the initial response to a regimen. A decline in plasma HIV-1 RNA level of approximately  $2.0\log_{10}$  is expected for treatment-naïve patients within eight weeks of starting an initial antiretroviral regimen, and plasma virus titers should fall to undetectable levels (below 50 copies/ml) by 16 weeks. However, more than 24 weeks may be required for plasma virus titers to fall below the limit of detection in patients with high levels of viremia (above 100,000 copies/ml). Declines of  $1\log_{10}$  or more within eight weeks should be expected following a change in regimen due to treatment failure. Subsequently, plasma HIV-1 RNA levels should be repeated every three to four months to monitor the success of antiretroviral therapy. The frequency of testing can be reduced to once every six months in adherent patients with consistently-suppressed plasma viremia (347).

### Plasma HIV-1 RNA Assays for Diagnosing Primary HIV-1 Infection

The earliest laboratory marker of HIV-1 infection is plasma HIV-1 RNA, which becomes detectable in plasma approximately 10 days after infection (348, 349). Quantitative

plasma HIV-1 RNA assays are frequently used for diagnosing primary HIV-1 infection, although they are not approved for this purpose. These assays are highly sensitive (100%), but occasional false positive tests result in a specificity of only 97.4% (350). However, HIV-1 RNA levels are less than 3,000 copies/ml in nearly all false-positive assays, whereas HIV-1 RNA levels exceed 10,000 copies/ml in the great majority of patients with primary HIV-1 infection (351). Thus, plasma HIV-1 RNA testing should be considered in cases in which a history of recent exposure and symptoms consistent with acute HIV-1 infection provide a high index of suspicion. Qualitative HIV-1 RNA assays have been approved for HIV-1 diagnosis (Aptima HIV-1 RNA Qualitative Assay, Hologic Gen-Probe; Procleix Ultrio, Novartis Diagnostics) and are recommended for use in this setting (352).

Nucleic acid amplification tests also are used to screen donated blood to exclude presence of HIV-1 (and hepatitis B and C virus) infection. To maximize efficiency, samples from many donors are pooled and individual samples tested only if the pool tests positive (352). Four out of 12.6 million donations, that were p24-antigen-negative and seronegative, were found to be positive by nucleic acid amplification testing (1/3,150,000) (353).

### Immunoassays

In most cases, infection is diagnosed by demonstrating the presence of antibodies specific for HIV-1 or HIV-2. Assays have been developed for detection of HIV antibodies in serum, whole blood, saliva, urine, and dried blood collected on filter paper. The appearance of IgM antibodies to HIV can be detected by 3rd and 4th generation HIV immunoassays approximately 25 days after infection (354, 355). The older 1st and 2nd generation assays, which detect only IgG antibodies, become reactive one to four weeks later (352). The time to serologic detection of HIV after initial infection can be reduced by seven days by the use of "4th generation" diagnostic tests, which combine detection of HIV antibodies and core (p24) antigen (Architect HIV Ab/Ab Combo, Abbott Laboratories; GS HIV Combo Ag/Ab EIA, Bio-Rad Laboratories) (356, 357). These assays have a sensitivity of 99.8 to 100% for HIV-1 and 100% for HIV-2 (358–360).

Serologic diagnosis is a two-stage process. Previously, sera that gave a positive reaction by an initial antibody screening assay (EIA, chemiluminometric, or rapid immunoassay) were retested to exclude the possibility of clerical or laboratory error, and repeatedly reactive sera were then tested by a confirmatory assay, such as a Western blot or immunofluorescence assay, to verify that reactive antibodies were directed against HIV antigens. Newer guidelines based on the availability of combination HIV-1/2 antibody/antigen detection assays have streamlined testing algorithms (Fig. 11). According to current guidelines, initial testing should be performed with an antigen/antibody combination immunoassay capable of detecting antibodies to HIV-1 and HIV-2, as well as HIV-1 p24 antigen (352). Such assays will detect infection in persons with established HIV-1 or HIV-2 infection, as well as with acute HIV-1 infection. Samples that test positive in this initial step should then be tested by an assay that can differentiate antibodies to HIV-1 from those directed against HIV-2 (Multispot HIV-1/HIV-2 Rapid Test; Bio-Rad Laboratories); samples that are nonreactive on the initial immunoassay do not require further testing and can be reported as negative (no evidence of HIV infection). Detection of antibodies specific for HIV-1 or HIV-2 is evidence of established infection with HIV-1, HIV-2, or both,

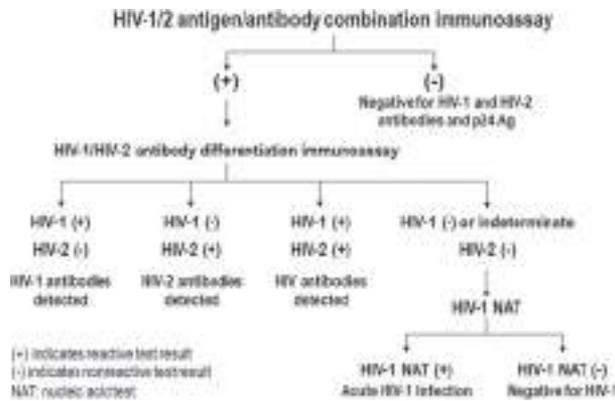

FIGURE 11 Testing algorithm for HIV diagnosis (228).

depending on the pattern of reactivity. Samples that yield negative or indeterminate results in the HIV-1/HIV-2 antibody differentiation assays should be tested by an HIV-1 nucleic acid test (i.e., plasma HIV-1 RNA assay). A positive HIV-1 RNA test, along with a negative or indeterminate test for HIV-1- or HIV-2-specific antibodies, is evidence of acute HIV-1 infection; a negative result indicates a false-positive reaction on the initial combination immunoassay. (There are currently no FDA-approved assays to diagnose acute HIV-2 infection.)

In addition to the standard HIV immunoassay, rapid diagnostic tests based on red cell or particle agglutination, as well as dot-blot assays, have been developed. The simplicity and wide range of operating temperature for some of these rapid tests make them particularly well-suited for point-of-care testing. Field testing of a rapid test approved for detection of HIV-1/2 antibodies in whole blood, plasma, and oral fluids (OraQuick Advance; OraSure Technologies) found a sensitivity of 99.7% in whole blood and 99.1% in oral fluid, with specificities of 99.9% and 99.6%, respectively (361). However, the occurrence of 16 false positives in one study resulted in a specificity of only 99.0%. For this reason, a positive result by a rapid HIV antibody test should be confirmed using the algorithm described above, beginning with an antigen/antibody combination immunoassay.

### Diagnosis of HIV-1 Infection in Neonates and Infants

Placental transfer of HIV-1 IgG antibodies from infected mothers to their fetuses poses special challenges to the early diagnosis of HIV-1 in infants and neonates. All infants born of HIV-1-infected mothers are initially HIV-1-seropositive (322, 323). Titers of maternal IgG decay over 12 to 15 months. Persistence of HIV-1 antibodies beyond 15 months is therefore considered diagnostic of infection in the infant. Infection with HIV-1 can reasonably be excluded by two or more negative HIV-1 serologies performed at least one month apart in infants older than six months of age.

Early identification of infected infants is essential to maximize the potential benefits of antiretroviral and prophylactic therapies, while minimizing exposure of uninfected infants to the potential toxicities of these therapies. Consequently, the diagnosis of HIV-1 infection in infants depends on virologic assays (e.g., virus culture or DNA or RNA PCR). Current guidelines recommend testing infants born to HIV-infected mothers at age 48 hours, at age one to two months, and at age three to six months. A positive test suggests the possibility of HIV-1 infection, which should be

confirmed by a second test as soon as possible. DNA-PCR testing is positive in approximately 40% of infected children by age 48 hours and in 93% of infected children by age 14 days (362). Virus culture has similar sensitivity and specificity as DNA-PCR tests. Plasma HIV-1 RNA testing detected infection in significantly more infected infants at birth and at six weeks of age than did either HIV-1 culture or DNA PCR (363). Serum p24 antigen assays are less sensitive than other virologic assays for diagnosis of HIV-1 infection in infants and have a high false-positive rate in infants younger than one month of age (364).

### HIV-1 Drug Resistance Testing

HIV-1 resistance to antiretroviral agents can be assessed by genotypic and phenotypic assays (365, 366) (see also Chapter 15). Advances in molecular diagnostic techniques have made these tests routinely available to clinicians. Genotypic assays determine the sequence of protease (PR), reverse transcriptase (RT), or integrase (IN) coding regions of the *pol* gene, whereas phenotypic assays determine susceptibility of a patient's virus to specific drugs in an infected cell culture system. The two kinds of assays provide complementary information. Each approach has distinct advantages and disadvantages, and both types of assays share certain limitations.

Resistance assays for HIV-1 depend upon initial amplification of the coding sequences of selected HIV genes targeted by drugs from plasma viral RNA by reverse transcription followed by PCR. For genotypic analysis, the amplicons are then subjected to automated DNA sequencing, probed by hybridization-based assays, or tested by point-mutation assay. Automated sequencing provides the most comprehensive data regarding genotypic changes associated with drug resistance. Phenotypic tests are performed by generating recombinant viruses or pseudoviruses using sequences from patient samples together with a molecular clone of HIV-1 deleted in the gene of interest. The resulting recombinant viruses (or pseudoviruses) share a common genetic backbone but express PR, RT, IN, or Env from the patient's virus. This approach eliminates many of the problems associated with older assays performed with primary virus isolates in peripheral-blood mononuclear cells, which had considerable interassay variation.

A limitation shared by currently available drug-resistance assays is their relative insensitivity to the presence of minority species in the virus population. Resistant variants of HIV-1 generally are not detected by most genotypic and phenotypic assays until they constitute more than 20 to 30% of the quasispecies. In addition, because of technical limitations in the RT-PCR step required to amplify viral sequences from plasma HIV-1 RNA, specimens with HIV-1 RNA levels less than 500 copies/ml may fail to generate a result.

Genotypic assays have the relative advantage of being faster and easier to perform, resulting in quicker turnaround times and lower cost than phenotypic assays. In addition, sentinel mutations may be detectable by genotypic assay before a shift in drug susceptibility becomes apparent. A major limitation of genotypic assays is the difficulty in predicting the consequences of mutational interactions on phenotype. Likewise, the extent of cross-resistance among drugs within a class (e.g., protease inhibitors) can be difficult to predict on the basis of genotype alone. The Stanford University HIV Drug Resistance Database (<http://hivdb.stanford.edu/>) offers useful guidance and a variety of tools for the interpretation of genotypic resistance tests. The

application of emerging “next-generation” sequencing technologies may provide the capacity to generate HIV-1 genotypes with higher throughput and at lower cost. These technologies may make detection of minority variants feasible in clinically useful tests.

Phenotypic assays have the advantage of providing susceptibility data in a format that is familiar to most clinicians (i.e., 50% inhibitory concentration [IC<sub>50</sub>] or fold-resistance), as well as the capacity to determine drug susceptibility, even if the genetic basis of resistance to a particular drug is uncertain, and the net effect of different mutations on drug susceptibility and cross-resistance.

Strong correlations exist between genotype or phenotype at the time of regimen switch and the subsequent virologic response to salvage therapy. One meta-analysis showed that the risk of virologic failure was reduced by 30 to 50% for each drug in the salvage regimen to which the virus was susceptible, as predicted by the resistance test employed (367). In randomized trials (368) selection of a salvage regimen with the assistance of resistance testing resulted in significantly greater decreases of plasma HIV-1 RNA or a greater proportion of patients achieving a plasma HIV-1 RNA level below the limit of detection, although follow-up in most studies was brief.

Resistance testing is recommended to help guide the choice of new regimens after treatment failure and in pregnant women (369). In addition, resistance testing should be performed prior to initiating therapy in treatment-naïve patients, particularly in areas with a high prevalence of drug resistance in recently transmitted viruses. Testing is also advisable in patients with primary HIV infection, but treatment should not be delayed while awaiting results. Because resistant variants can be replaced by wild-type virus within weeks of discontinuing treatment, resistance testing is most accurate when the sample is obtained while the patient is still on the failing antiretroviral regimen. If high-level resistance to a drug is detected, that drug is unlikely to be useful in a treatment regimen. Failure to detect resistance to a previously-used drug does not necessarily imply activity of that drug, however, for reasons cited above. Because sample mix-ups and PCR contamination can lead to reporting of erroneous results, clinicians should not hesitate to repeat a resistance test if the results are markedly discordant with the treatment history or results of viral load and CD4 testing.

## PREVENTION

### General

The mechanisms and risks for transmission of HIV are clearly defined. Virus in blood and genital secretions accounts for practically all infections. By excluding blood donors at risk for infection and by testing blood products for HIV, transmission by this route can be virtually eliminated. Unless and until an effective vaccine is available, the combined implementation of the other prevention strategies that have been proven to be effective remain the best opportunity to reduce expansion of the pandemic (370).

The major causes of adult transmission of HIV, sexual intercourse and injection-drug use, represent two extremely strong biologic drives. Transmission can be significantly diminished, if not avoided, by monogamous sex with a known uninfected partner, use of barrier contraceptives, and not sharing drug paraphernalia. Many individuals have successfully modified their risk behaviors to prevent infection. For example in the San Francisco homosexual men’s cohort,

HIV spread early and rapidly between 1978 and 1984. When the mechanism of its transmission was recognized and behavior changed as a result, new infections in this cohort diminished remarkably (371). Unfortunately, new generations of young men who have sex with men are often ignoring these stark lessons; this risk behavior also contributes significantly to transmission in developing countries (372). Educational programs regarding condom use have appeared to have dampened rates of transmission in some locales. Needle-exchange programs to reduce sharing of contaminated paraphernalia by intravenous drug users reduces HIV transmission, but in many places in the United States, former Soviet Republics, and Southeast Asia, socioeconomic or political considerations thwart implementation of this intervention (373, 374). One persisting obstacle to any effective intervention, whether treatment or prevention, is the substantial proportion of populations not yet identified as infected or at risk (375, 376).

### Preexposure Prophylaxis (PrEP)

The administration of antiretroviral drugs to uninfected individuals at risk of transmission to prevent acquisition of HIV has rapidly progressed from an intense area of investigation to an approved indication for the use of a fixed-dose combination of daily oral tenofovir disoproxil fumarate and emtricitabine (TDF/FTC). The efficacy of this combination or TDF alone has been demonstrated in clinical trials with MSM and transgender women (377), with serodiscordant heterosexual couples and young heterosexual men and women in Africa (378, 379), and with injecting drug users (380). Efficacy was not shown in two clinical trials with heterosexual women in Africa (381, 382). The prime determinant of reduced efficacy in the successful trials and the lack of efficacy in the unsuccessful trials appears to be poor adherence. Animal models have supported both the observations about efficacy and the requirement for adequate drug levels in blood and genital and rectal mucosal tissues. Injectable antiretroviral drugs with half-lives of weeks to months, such as cabotegravir and long-acting rilpivirine, confer prolonged protection in a macaque model and are undergoing human trials (383).

Many healthcare providers and subjects at risk have been reticent to implement PrEP more actively. Obstacles to uptake include drug cost, the stigma of taking antiretroviral drugs, discomfort with new approaches, poor appreciation by either subjects or providers of the level of risk for infection, and concern about encouraging risk compensation. Efforts to document increased behavioral disinhibition with any prevention strategy have not provided documentation for this concern. Drug resistance can develop if PrEP is administered shortly after transmission has occurred (377) or during periods of suboptimal drug levels resulting from poor adherence. Such situations have occurred, but not commonly (384). The search for additional drugs and the conduct of additional clinical studies remain intense areas of investigation.

One special type of PrEP is topical prevention for women with vaginal preparations. In many cultural and social situations, women who have limited choice regarding sexual encounters could utilize effective prophylaxis without the need of a partner’s consent. The initial high priority in this area was to develop a vaginal microbicide effective against HIV (385). Ideally the microbicide would be active against other sexually-transmitted infections as well, since they increase transmission rates of HIV by producing mucosal ulceration and local inflammation (175). Unfortunately the

similarity between the retroviral envelope and the host cell membrane provided a challenge to identify inactivating agents with selective activity. In phase 3 trials, the topical microbicides nonoxynol-9 and cellulose sulfate both increased transmission of HIV, presumably by disrupting the integrity of the natural mucosal barrier (386), while Carraguard fared no better than placebo. Consequently, the focus shifted to the use of safe and effective antiretroviral drugs. The self-administration of 1% tenofovir gel by South African women conferred protection against HIV (and herpes simplex virus), once again with the degree of success correlating with the level of adherence (387). One clinical trial with both an oral and a vaginal gel arm showed no efficacy, attributable to poor adherence (382). Additional drugs and formulations, including vaginal rings that slowly release maraviroc or a nonnucleoside reverse transcriptase inhibitor, daviropine, are being actively investigated. Similarly, formulations for gels to be used intrarectally for prophylaxis are being investigated. More thorough reviews of all aspects of PrEP are available (386, 388–390).

### Male Circumcision

Male circumcision has been shown in randomized controlled trials to reduce the transmission of HIV, herpes simplex virus, human papillomavirus, and genital ulcer disease in men, and to reduce human papillomavirus, genital ulcer disease, bacterial vaginosis, and trichomoniasis in their female partners (391). Randomized trials in uninfected men have shown a 50 to 60% protective effect of circumcision against heterosexually-acquired HIV (392–394). This intervention is less effective than condom use but does not require adherence with each sex act and presumably remains effective for life. Thus, its cost-effectiveness has prompted many implementation initiatives and has been supported by many low- and middle-income countries (395). These studies have consistently confirmed the benefits in heterosexual men with substantial cost-effectiveness. The benefits in men who have sex with men remain to be documented. The implementation efforts in Africa had provided circumcision to over six million males by 2015 with increasing implementation in many countries.

### Passive Immunoprophylaxis

With the identification of more potent and broadly-reactive neutralizing monoclonal antibodies, initiatives to assess these alone or in combination for prevention or treatment are in progress (396). One critical challenge has been the difficulty in eliciting potent broadly-neutralizing antibody by natural infection or candidate immunogens. The administration of monoclonal antibodies or polyclonal sera that provide neutralizing activity against the challenge virus can confer protection from infection in both murine and rhesus macaque models (397, 398). The administration of neutralizing monoclonal antibodies, alone or in combination, suppressed viremia in rhesus macaques and delayed the re-emergence of detectable viremia in humans after suppressive antiretroviral therapy was withdrawn (399–401). The viruses that emerged were neutralization-escape variants to the monoclonal antibody 2G12, indicating that the selective pressure conferred by that antibody contributed to the delayed emergence of replicating virus. The development of more promising antibodies (402) and insights into engineering monoclonal antibodies with better effector functions and longer half-lives (403, 404) have renewed the energy being put into the development of promising bio-

logicals to administer to humans and into clinical trials to apply these for prevention and treatment (405, 406).

### Prophylaxis

Postexposure prophylaxis has proven effective for those exposed either occupationally or during sexual activity (407). Approximately one in 300 healthcare providers becomes infected with HIV after percutaneous exposure with a needle used on a seropositive patient (178). With the inoculum size in such transmissions probably representing close to one human infectious dose, prompt administration of chemoprophylaxis may be beneficial. Because of the low rate of transmission, controlled randomized trials are not feasible, and decisions must be based on judgment, retrospective studies, and animal models. A retrospective analysis of the use of zidovudine for postexposure prophylaxis of healthcare workers after percutaneous exposure to infected blood suggested an 80% reduction in risk of seroconversion (408). Prevention of needlestick transmission is best accomplished by prevention of needlesticks. This requires care and attention by healthcare workers during injection and phlebotomy procedures, use of gloves, proper disposal of sharp instruments, and the use of needles with guards and other devices designed to minimize risk.

The issue of risk to patients from infected providers has raised much controversy. The mechanism of transmission in one outbreak associated with a Florida dentist remains unexplained (409). Nevertheless, routine healthcare provided by HIV-infected providers poses no measurable risk of transmission, and effective antiretroviral treatment virtually eliminates any risk.

Considerations similar to those for healthcare providers apply to postexposure prophylaxis following sexual exposure due to rape, broken condom, or other unprotected consensual or nonconsensual sex (410). The decisions regarding implementation and regimen significantly overlap with those described for occupational exposure.

Extrapolation from other applications of chemoprophylaxis for infections would argue that the earlier the administration and the more potent the regimen, the greater the likelihood that the prophylaxis will work. Because many HIV-infected subjects have been infected with transmitted drug-resistant virus or they have been treated with antiretrovirals and thus may harbor drug-resistant virus, guidelines recommend tenofovir disoproxil fumarate, either lamivudine or emtricitabine, and a third agent (efavirenz, a boosted protease inhibitor or an integrase inhibitor) (410). Because of drug tolerability, lack of drug interactions, and risks of drug resistance in the source subject, integrase inhibitors have become the preferred third component. The recommended 28-day duration of prophylaxis is also based on judgment and consensus rather than empirical data, although studies in the macaque model indicated equivalent benefit with shorter durations. Early initiation of prophylaxis, potent regimens, and adherence are almost certainly more important than duration of prophylaxis.

### Treatment as Prevention

The suppression of HIV in blood and genital secretions with antiretroviral therapy is associated with the reduction, if not the elimination, of the risk of transmissibility (411, 412). The approach, termed treatment-as-prevention, has been well documented in studies of heterosexual transmission among serodiscordant couples (411, 413) but likely applies to others at risk of transmitting, including MSM and injection-

drug users. On an epidemiologic basis, reductions in HIV-1 incidence correlate with relative saturation density of coverage of antiretroviral therapy (414–416). Certainly the recommendations to benefit individuals with universal treatment in resource-rich countries (347) and expanded treatment in low- and middle-income countries (417) is compatible with the public health benefits of diminishing HIV incidence with extensive treatment of populations. The challenge remains that both the individual and public health benefits of expanded treatment have been constrained by insufficient screening, access to care, and resources for healthcare and drugs.

### Mother-to-Child Transmission

Maternal-fetal transmission represents a unique opportunity for prevention because risks can be readily ascertained with reasonable lead times and effective interventions have been identified. By 2013, 3.2 million children were living with HIV infection with over 650 children newly infected daily, one-half of whom would die by their second birthday without treatment (418). These numbers reflect diminishing numbers of new infections because of prevention of mother to child transmission but increasing numbers of children living with HIV because of the survival benefits of antiretroviral treatment. Maternal-fetal transmission occurs antepartum by transplacental transmission, during delivery, and via breastfeeding (419). Thirteen to 40 percent of untreated HIV-infected pregnant women transmit infection to their newborn infants (419). Perinatal administration of zidovudine alone to treatment-naïve pregnant women with more than 200 CD4 cells/ $\mu$ l blood and to their newborns reduced transmission from 25.5% to 8.3% (157). With these perinatal interventions, the protection is primarily conferred as postexposure prophylaxis in the newborn (420). Implementation of strategies to prevent maternal-fetal transmission in low- and middle-income countries began with the very low-cost single-dose nevirapine, which led to high levels of resistance in both mother and child. This led to increasingly more effective combination perinatal regimens (421). The current strategy is to offer combination antiretroviral treatment to the pregnant mother at diagnosis of infection, regardless of CD4 cell count or clinical stage, and to maintain treatment for life. This last strategy, called option B+, is the WHO recommended approach (422), having the advantage of both providing the most effective (and cost-effective) (423) approach to preventing transmission to the newborn and maintaining the health of the mother. Treating the mother permits breastfeeding with greatly-diminished risk and results in survival and quality of life benefits for the mother and for both her infected and uninfected children. Challenges remain including the testing of mothers with unknown HIV status, adherence, and retention in care (421, 424). The expensive but potentially effective approach of prophylaxis with passively administered monoclonal neutralizing antibodies as discussed above has entered clinical trials (425).

### Vaccines

The prevention strategies described above can each reduce transmission; however, a relatively cost-effective intervention with the promise to have a major impact on incidence almost certainly requires a vaccine. The challenges are substantial, however (Table 4). Ideally an HIV vaccine would induce a sustained high level of broadly cross-reactive neutralizing antibodies, which is the primary correlate of protection of most effective viral vaccines (426). It is quite

**TABLE 4** Obstacles to an effective vaccine for HIV

1.	The immune responses conferring protection and mediating viral clearance and the viral antigens that elicit these responses are not defined.
2.	HIV displays great antigenic diversity among individuals.
3.	HIV mutates readily to generate escape mutants and genetic diversity within individuals.
4.	The HIV envelope glycoprotein is heavily glycosylated, which shields many potential epitopes.
5.	Mucosal immunity may be needed.
6.	Enhancing or blocking antibodies may exist.
7.	The viral genome integrates into the host cell chromosome.
8.	The major target organ of HIV is the immune system.
9.	No inexpensive, simple animal models exist.
10.	Most effective viral vaccine vectors are subject to pre-existing antivector immunity and elicit immunity that compromises re-use.
11.	High-titer, broadly-reactive neutralizing antibody responses do not occur within a year in any subject or over many years in most subjects with natural infection. Such antibodies require extensive affinity maturation.
12.	No immunogen has been designed that elicits neutralizing antibody that is not strain-specific or that has a high titer.

possible that other nonneutralizing activities of envelope-specific antibody (e.g., antibody-mediated cellular cytotoxicity) or CD8 CTL responses would contribute to vaccine efficacy (426–428). However, more than two decades of efforts to design an effective vaccine have only confirmed that approaches that have worked for so many effective vaccines are insufficient to address HIV.

Studies in macaques have indicated the protective value of passively-administered neutralizing antibody (398). However, naturally-occurring neutralizing antibody responses to infection are of low titer and of restricted cross-reactivity in humans, and most antibodies to the HIV envelope exhibit poor neutralizing activity. Neutralizing antibody develops within two to three months after infection; however, this antibody is strain-specific, and more broadly-reactive neutralizing-antibody responses develop only over years and only in a subset of individuals (28). Neutralizing-antibody responses to candidate vaccines have been weak and restricted to laboratory-adapted strains rather than primary isolates (397). Modified envelope-protein preparations have not yet been designed that elicit neutralizing antibody to heterologous strains. Thus, although neutralizing antibody comprises the basis of most protective viral vaccines (426), new basic insights will be needed to elicit protective humoral responses to HIV infection.

Extensive efforts have been employed to induce HIV-specific CTL. Historically this has been done using live, attenuated virus to express viral antigen in the context of autologous HLA-restricted presentation of epitopes. The use of live, attenuated HIV has been complicated by concerns over the balance between immunogenicity and attenuation (429), which may be unpredictable and highly variable in humans with their heterogeneous genetics, ages, health, and nutrition. Efforts to induce CTL have thus focused on the expression of HIV antigens either with “naked” DNA or with viral or bacterial vectors. Virtually every available vector has been studied as a candidate, but the most extensive studies with primate and human trials have utilized

poxviruses (vaccinia and avian) and adenoviruses. The literature in rhesus macaque models is replete with negative or borderline levels of protection. Substantial CTL responses after DNA priming with adenovirus or poxvirus boosting or after sequential vector immunizations have resulted in reductions in HIV RNA “set point” and rates of progression in rhesus macaque models of SIV or SHIV infection; however, the effect is limited in magnitude and duration and is usually overcome by viral immune-escape mutations (430, 431). Investigation of approaches to elicit effective cell-mediated immune responses are focusing on the design of viral vectors that are effective and resistant to pre-existing immunity in the population, as well as the design of expression construct that will elicit effective responses to protective epitopes. Since no T-cell-based vaccine has been shown to confer protection in humans, evidence is needed to show whether this approach can replace or enhance an antibody-based approach. One innovative strategy that appears to have a qualitatively superior level of protection in the rhesus macaque model is a vaccine construct in an attenuated CMV vector, which has been shown to elicit a range of T-cell responses not characteristic of the usual class I HLA cell-mediated immune responses (432).

Dozens of candidate HIV vaccines comprised of protein constructs and gene constructs delivered by naked DNA or an array of microbial vectors have been tested in phase I and II clinical trials (433). In general both neutralizing antibody and cell-mediated immune responses have been lower and more restricted in breadth than natural infection, which in itself is poorly protective against superinfection (434, 435). Larger randomized placebo-controlled trials have also provided limited encouragement. Gp120 glycoprotein vaccines elicited some neutralizing antibody against the vaccine strain, but did not elicit a broad response and conferred no protection compared to placebo (436–438). Three trials of vaccines based on adenovirus-5 vectors showed no efficacy (439–441) with the Step trial suggesting an increased risk of transmission in uncircumcised men with high-baseline antibody levels to adenovirus 5 (439). The large RV 144 trial used a canarypox vector expressing a CRF01\_AE *env* as a priming immunization, followed by a boost with bivalent B and E monovalent gp120 glycoproteins in alum adjuvant, and conferred a 31% rate of protection with up to 42 months of follow-up (442). The components of the vaccine that most contributed to this activity, to the durability of efficacy, and to the mechanism of this low level of protection remain important issues for future vaccine development. Analyses to find correlates of this low level of protection have suggested that antibody responses to V1/V2, IgG3 responses, and Fc function, possibly related to antibody-mediated cellular cytotoxicity, may have been related to protection (443). Variants of this approach have been designed for studies to attempt to confirm efficacy in other populations at risk for different subtypes of HIV-1.

The development of innovative approaches to the design of an effective HIV vaccine remains a high priority for a highly-effective prevention strategy. The identification of a series of neutralizing monoclonal antibodies that are much more potent and broadly reactive than previously recognized, as described above, has prompted investigations into the process immunoglobulin maturation in B cells from germ line to protective immunoglobulin responses (444). Antibodies are also being studied for efficacy mediated by activities conferred by nonneutralizing responses and via functions of the Fc portion of the molecule (404, 445). Efforts have intensified to design immunogens that can elicit

more than a strain-specific antibody response. A more innovative approach is to deliver antibodies or related constructs intramuscularly in an adeno-associated viral vector that can generate high levels of broadly neutralizing antibody constructs for years (446, 447).

## TREATMENT

The improvement in AIDS mortality statistics reflects the introduction of combination antiretroviral treatment regimens first in Western Europe and the Americas and later in low- and middle-income countries (Fig. 12) (448–450). Opportunistic disease has been reversed and prevented. Healthcare costs have diminished. Many ill and disabled patients have returned to normal and functional life styles. This dramatic impact does come with costs—the expense, inconvenience, and toxicity of antiretroviral therapy. These costs and the benefits of treatment initially created a tension in the decision-making process regarding when to initiate

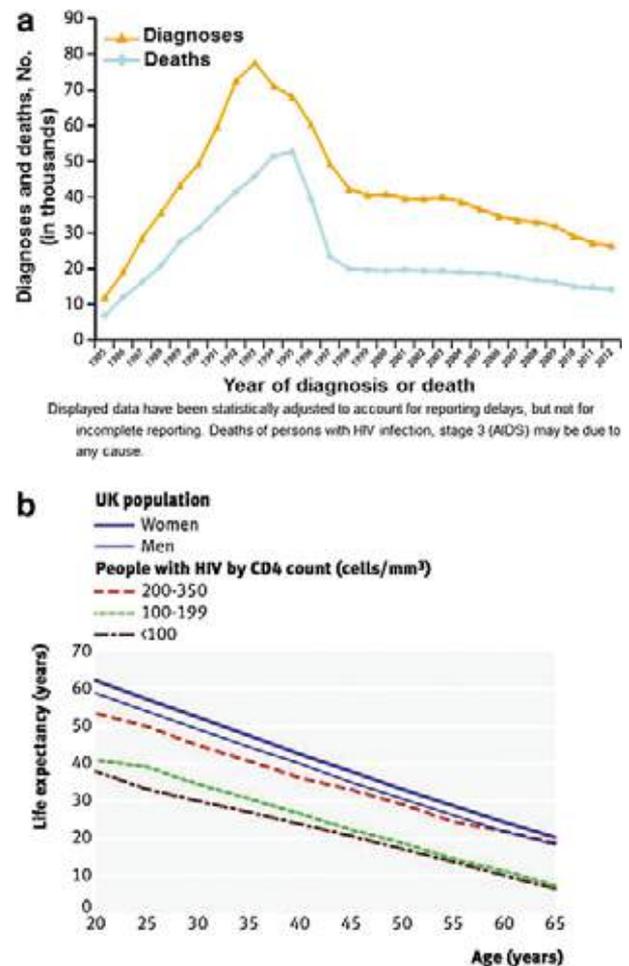

FIGURE 12 a) Estimated incidence of AIDS and deaths of adults/adolescents with AIDS in the United States during the period 1985–2005. Number of deaths is adjusted for reporting delays. b) Estimated proportion of persons surviving with AIDS in the US by year of diagnosis. (Both figures adapted from the CDC; <http://www.cdc.gov/hiv/>.) With new infections continuing unabated and with survival increasing as a result of improving treatment, one consequence is the progressive accumulation of persons living with HIV infection.

therapy. With the development of drugs that can be taken for decades with low toxicity, as well as fixed-dose combinations that require only one pill daily, the treatment guidelines have expanded to recommend treatment for all HIV-infected individuals in resource-rich countries (347, 451) and all individuals in low- and middle-income countries with CD4 cell counts below 500 cells or who are pregnant or have active tuberculosis, chronic hepatitis B, or a serodiscordant partner (417). Earlier initiation of treatment prevents complications and death, preserves immune function, reduces the size of the latent HIV reservoir, and prevents transmission.

Because of the rapid advances in treatment, for specifics regarding the use of antiretroviral drugs and the management of HIV infection, the reader is advised to refer to the updated versions of the guidelines referenced previously. This chapter, rather than provide a manual for chemotherapy, will summarize the principles and challenges of the treatment of HIV infection. The antiretroviral drugs, including their mechanisms of action, pharmacology, and toxicities are summarized in Chapter 11.

### Virologic and Immunologic Principles Underlying Antiretroviral Chemotherapy

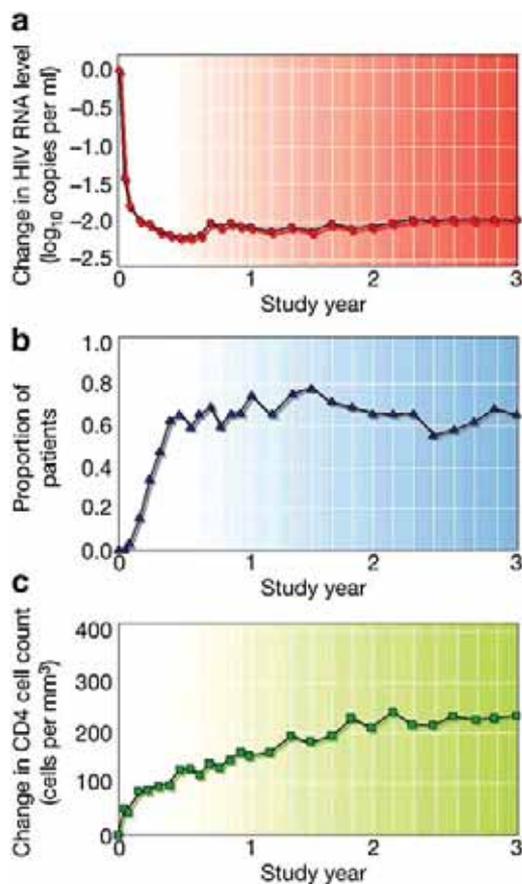

The primary goal in the management of antiviral therapy for the HIV-infected patient is to achieve prolonged suppression of viral replication. While a small subset of individuals, for reasons attributable to the genetic composition of the virus or immunologic responses, may survive years to decades without an increase in viral burden (452, 453), HIV infection in most individuals leads to increasing levels of HIV, decline in CD4 cells, and death.

As discussed in the Pathogenesis section, the turnover of virus particles in the body is tremendous, clearance of virus from the plasma is rapid (minutes to hours), and the clearance rate constant varies little among individuals and different stages of disease. The steady-state levels of HIV RNA in the blood are thus determined by the rate of virus production. These rates of production are a function of the number of infected lymphocytes in the lymphoid tissue (454, 455). The rate of decline of CD4 lymphocytes is thus directly related to the steady-state level of plasma HIV RNA. The higher the RNA levels, the faster the loss of CD4 cells, and the shorter the duration of HIV infection before death (210). Since the CD4 count determines the risk of disease and death, and the level of HIV RNA determines the rate of CD4 cell decline, these values are routinely used clinically to assess clinical status and response to chemotherapy.

When potent combination therapy is effectively administered, levels of HIV RNA in plasma and infected cells in lymphoid tissue rapidly decrease (Fig. 9 and Fig. 13a). Failure to reduce plasma HIV RNA levels to below the limits of detection of 20 to 50 copies/ml with the currently-available assays indicates inadequate suppression and a risk for the outgrowth of resistant virus. In patients sustaining suppression below this level (Fig. 13b), many will sustain steady-state levels of 1 to 40 copies HIV RNA/ml, which is not associated with clinical progression or with viral evolution (241). The relative contributions of smoldering replication, release of virions from activated latently-infected cells, and persistently-infected long-lived cells have not been well delineated.

### Compartments and Reservoirs

The treatment of HIV is complicated by the existence of tissue compartments and cellular reservoirs. Although there

**FIGURE 13** Three-year treatment with indinavir, zidovudine, and lamivudine. a. Median changes in serum HIV RNA level (Amplicor assay with quantification limit of 500 copies per milliliter) from baseline. b. Proportions of patients with serum HIV RNA levels less than 50 copies per milliliter (ultradirect assay). c. Median changes in CD4 cell count from baseline. The number for contributing patients in each trial and at each time point was between 30 and 33. Details regarding the study and analyses are published (464). Adapted from reference (484) with permission.

is trafficking between the blood and CNS, much virus in the CNS evolves independently (286,456–458). Similar observations have been made with virus in semen (459–461). Drug penetration into these compartments differs from the circulation and lymphoid tissue and varies with each drug. Latently-infected CD4 lymphocytes represent a small fraction of infected cells during active infection, but like immunological memory, persist for life (229). Such cells survive, archiving virus that can be drug-resistant, and re-emerge and propagate after the withdrawal of chemotherapy.

### Immunological Restoration with Antiretroviral Therapy

The immunologic consequences of suppressing virus replication are dramatic (Fig. 13c). The increase in CD4 lymphocyte numbers has two phases. In the first month or two the increase is often large (20 to 100 cells per  $\mu$ L blood) (462–465). The magnitude is proportional to the steady-state HIV RNA levels, which drive the level of generalized activation of the immune system. The normal distribution of

lymphocytes is 2% in the circulation and 98% in the lymphoid tissues. With the immune activation of HIV infection, the distribution shifts to 1% and 99% (454, 466). Therapy largely corrects this shift and results in redistribution of mostly CD45RO<sup>+</sup> memory T cells from the lymphoid tissue back to the circulation (465, 466). Production of new cells, mostly of the CD45RA-naive phenotype, is generated both by bone marrow and by restored thymic mass and function in younger individuals (247, 467).

It is the restoration of immune function that has transformed the natural history of AIDS. Both CD4 and CD8 T-cell responses to recall antigens are regenerated (462, 468). Persistent opportunistic infections are often resolved. Occasionally subclinical chronic infections, with mycobacterial or cytomegalovirus infections, for example, are manifested when a restored immune response produces a local inflammatory reaction, termed the Immune Reconstitution Inflammatory Syndrome (IRIS) (469, 470). Patient care has been transformed with the ability to withdraw prophylactic or suppressive chemotherapy for pneumocystis, toxoplasma, cytomegalovirus, *Mycobacterium avium* complex, Leishmania, cryptococcus, and candidal infections, which had previously been lifelong commitments.

### Drug Resistance in Antiretroviral Chemotherapy

Antiretroviral drugs select for the emergence of drug-resistant viral variants. These mutations, and their impact on phenotype and treatment, have been well-described (366, 369, 471), but it is important to note that the speed, magnitude, and clinical impact of the emergence of resistance differ among antiretrovirals. The likelihood that resistant mutants will emerge is a function of at least four factors: (1) the viral mutation frequency, (2) the intrinsic mutability of the viral target site with respect to a specific antiviral, (3) the selective pressure of the antiviral drug, and (4) the magnitude and rate of virus replication.

For single-stranded RNA viruses, whose genomic replication lacks a proofreading mechanism, the mutation frequencies are approximately  $10^{-5}$  per nucleotide per replication cycle or approximately 1 mutation for every progeny genome (472, 473). Some mutations at a single nucleotide will result in greater than 100-fold reductions in susceptibility, for example, to lamivudine or nonnucleoside reverse-transcriptase inhibitors (366). For many nucleosides and protease inhibitors, high-level resistance requires the cumulative acquisition of multiple mutations.

With regard to the selective pressure of the antiviral drug, one definition of an antiviral drug is a compound that confers sufficient selective pressure on virus replication to select for drug-resistant mutants. With increasing drug exposure, the selective pressure on the replicating virus population increases to promote the more rapid emergence of drug-resistant mutants. For example, higher doses of zidovudine or of ritonavir monotherapy tend to select for drug-resistant virus more readily than do lower doses (474, 475).

With current drug treatment, this relationship is most apparent when patients with suboptimal adherence develop resistance more readily than those with very poor adherence. Increasing selective pressure for resistant mutants increases the likelihood that such mutants will arise as long as significant levels of virus replication persist (Fig. 14). As antiviral drug activity increases still more, the amount of virus replication diminishes to the point where the likelihood of emergence of resistance begins to diminish, and becomes nil when virus replication is completely inhibited. No evolution of an HIV nucleotide sequence can be discerned for over a

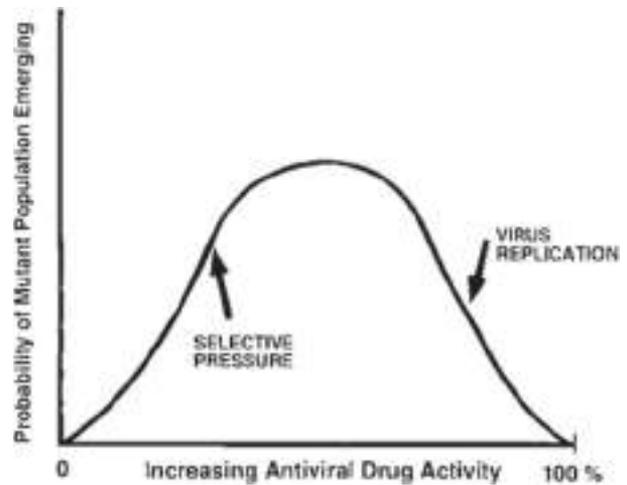

FIGURE 14 Hypothetical impact of antiviral drug activity upon the probability of the emergence of drug resistance. From reference (485) with permission.

decade of fully-suppressive antiretroviral therapy. Thus the ultimate goal of chemotherapy for HIV is to identify drug regimens that completely inhibit virus replication.

The magnitude and rate of replication of the virus population have major consequences on the likelihood of emergence of resistant mutants. Approximately 10 billion ( $10^{10}$ ) HIV-1 virions are generated daily (106), and approximately one mutation is generated for each new genome of 9200 nucleotides (473). Thus, genomes with each possible mutation, as well as many with double mutations, should be generated daily. Incompletely-suppressed viral replication, with drug regimens sufficient to exert selective pressure, drive the evolution and fixation of drug-resistant virus at a rate Darwin himself never imagined. Moreover, drug-resistant virus is readily archived in latently-infected cells to confound treatment modifications for the remainder of the patient's life (227, 228).

### Impact of Resistance on Treatment

As resistance mutations accumulate, drug susceptibility diminishes, progressively reducing the potency of components of combination antiretroviral regimens. Continued replication in the presence of drug selects for even greater levels of resistance to each administered drug and progressive cross-resistance to drugs of the same class. Thus, impotent regimens, suboptimal adherence, pharmacologic hurdles, and ineffectively-treated compartments permit the emergence of resistant virus. Its emergence drives a vicious cycle of treatment failure and yet more difficult treatment challenges. Regimens for patients failing treatment with resistant virus are constrained by more limited options but must still contend with the same obstacles of adherence, pharmacology, and tolerability that challenged the first regimen.

Resistant virus in genital secretions, blood, or milk can be transmitted during sexual activity, needle-sharing, childbirth, or nursing (294). With the more widespread use of nucleoside-only regimens and then early three-drug combination regimens in the 1990s, the rates of transmission of drug-resistant virus increased dramatically, with up to 20% of primary infections due to drug-resistant virus, many of which exhibited resistance to multiple classes of drugs (294, 476). Patients with such resistance are more likely to fail their first treatment regimen. With more effective and tolerable

regimens requiring one or a few pills, the rates of both acquired- and transmitted-resistance have plateaued or even diminished in resource-rich countries. In low- and middle-income countries, where the first decade of the rollout of antiretroviral drugs included thymidine analogues, the increasing rates of acquired- and transmitted-resistance recapitulated the earlier experience in more developed countries (477).

### Resistance Testing to Manage Patients

The accumulation of drug resistance due to treatment failure and transmission raises challenges to the effective treatment of individuals and to public health. As discussed above, the use of drug-resistance testing has been incorporated into standard HIV care (365, 366, 471). Drug-resistance assays can help determine which drugs will not work, thereby diminishing cost, toxicity, and inconvenience, and which drugs are most likely to be effective.

### Antiretroviral Drugs

As of 2015, 30 antiretroviral drugs had been approved for use in the United States, and several more were in various stages of clinical development (Chapter 11). Although any function in a genetically-efficient organism is a candidate for an inhibitory drug, the currently-approved drugs are directed against reverse transcriptase, protease, integrase, and viral entry, with the reverse transcriptase inhibitors being classified as nucleosides or nonnucleosides.

The use of these drugs in the management of HIV-infected patients has developed into a remarkably complex specialty. These drugs must be used in various combinations of three or more drugs for optimal efficacy. Each drug has a complicated pharmacology that often interacts with other components of the regimen or with nonantiretroviral drugs. Treatment success is related to rigorous adherence. Initial regimens have become increasingly effective, tolerable, and convenient, with many regimens taken once daily. Regimens for treatment failure become increasingly complex and are attended by higher rates of undesirable side effects.

### THE CHALLENGE OF CURING HIV

The latent HIV reservoir, which persists despite decades of effective antiretroviral therapy, represents an obstacle to cure. Antiretroviral therapy must be life-long, and withdrawal results in the resumption of high levels of virus replication within weeks. The “Berlin patient” underwent hematopoietic stem-cell transplantation with cells from a donor homozygous for the delta 32 deletion mutant of CCR5 (478). He has had no evidence of detectable virus or recrudescence of ongoing infection for more than seven years after discontinuing antiretroviral therapy; however, the relative contributions to this apparent cure of resistant donor cells, intensive chemotherapy for leukemia, and a vigorous graft versus host reaction cannot be dissected with a single anecdote.

The eradication of the latent HIV reservoir to achieve a cure has become an active area of investigation. Achieving a cure could relieve treatment fatigue, reduce drug costs, reduce drug toxicity, reduce drug resistance, reduce transmission, and reduce morbidity and mortality associated with viral persistence and immune activation (e.g., malignancies, cardiovascular disease, CNS impairment). The hurdles to success in achieving a cure include both the biology of latency and the current limitations in both knowledge and technology. The biological hurdles are several. One in a

million or so CD4 T cells is latently-infected with replication-competent virus so the target is a very rare event in a sample. Two, the majority of the latent reservoir is in extra-circulatory tissues, which are difficult to access. Three, the mechanisms for establishment and maintenance of latency are cellular functions, which means that drug interventions will need to target host, rather than viral, targets, thus imposing greater risk of toxicity. Four, enhancing immune function to assist in clearing these latently-infected cells must address the fact that the immune system has often selected for escape mutants-to-host responses (278).

Similarly, the limitations in our knowledge and technology are several. One, do cells other than CD4 T lymphocytes, such as macrophages and microglial cells, represent a latent reservoir? Two, are there pharmacologic sanctuaries for latency like the central nervous system? Three, what are the mechanisms for the establishment and maintenance of latency that provide targets for candidate drug interventions? Four, will enhancement of the immune system with a therapeutic vaccine of monoclonal antibodies contribute to clearance of the latent reservoir? Five, can practical gene therapy approaches contribute to curative strategies? Six, how do we measure the latent reservoir and reductions in it by candidate interventions when latency occurs infrequently in cells and at most 1 to 2% of the reservoir exists in the blood?

# Colorado Tick Fever and Other Arthropod Borne Reoviridae

STEVEN YUKL AND JOSEPH K. WONG

## 35

Among arthropod-borne viral infections, Colorado tick fever is second in incidence in North America only to West Nile fever (1). As with other viruses, evidence of infection by arthropod-borne reoviruses, including many newly identified viruses, as the cause of both human and veterinary disease continues to accumulate. This likely reflects advances in detection and diagnostic methods and perhaps also evolving demographic conditions that facilitate contact between human populations and the insect vectors that transmit these viral infections. The clinical importance of reoviruses will doubtless continue to change in the wake of the emergence of other arthropod borne infections such as Zika and dengue viruses.

### COLORADO TICK FEVER

The earliest accounts of what was most likely Colorado tick fever emerged in the 19th century from settlers and mountaineers in the Rocky Mountains of North America who termed it, along with other febrile illnesses, "mountain fever" (2). By the time the rickettsial disease Rocky Mountain spotted fever (RMSF) was identified as a distinct entity in the first decade of the 20th century, cases of RMSF without rash were also being described, and some of these cases were likely Colorado tick fever (2–7). In 1930, Becker described the clinical manifestations and gave them the name Colorado tick fever (8). The clinical features and epidemiology were further characterized by Topping in 1940 (9). In 1944, Florio and colleagues reported the experimental transmission of the disease to animals and adult volunteers, thus establishing the presumptive viral etiology (10).

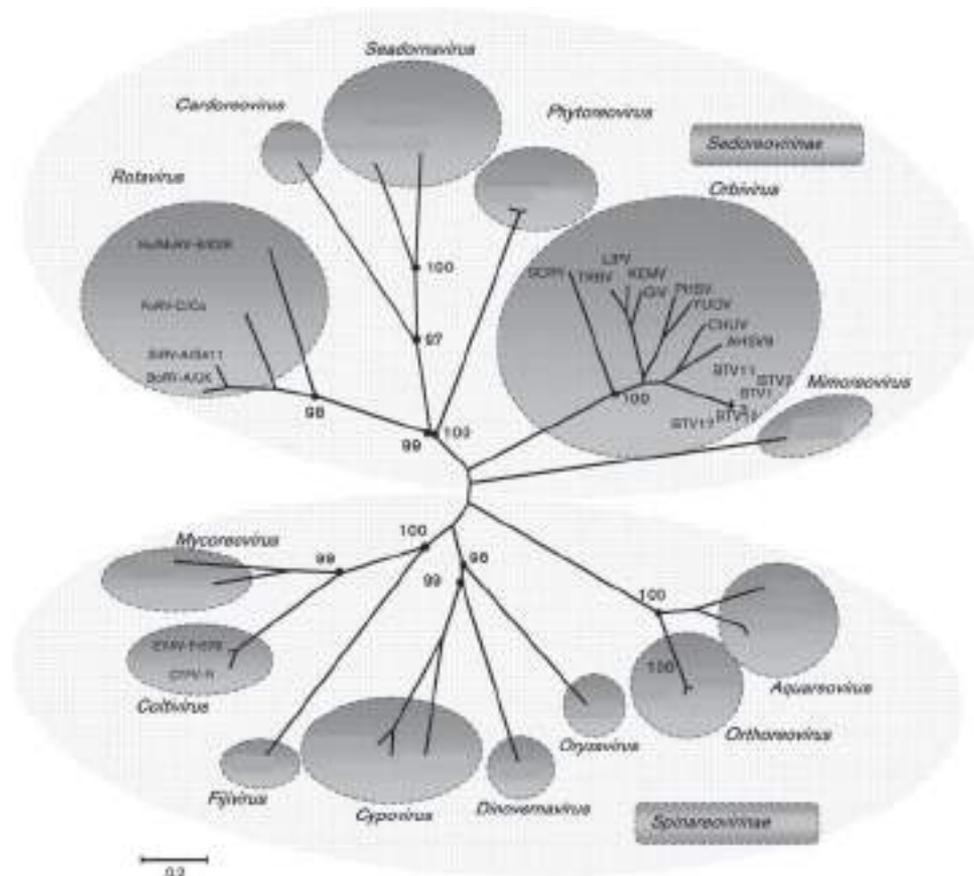

The development of viral cultures in chicken embryos and mice by Koprowski and Cox in the 1940s (11) and subsequent refinements in viral isolation and molecular biology permitted further characterization of Colorado tick fever virus (CTFV). Much is now known about its ecological niche and replication cycle in vertebrate and invertebrate hosts as well as the epidemiology, pathogenesis, and clinical course of infection in humans (5,12–17). A growing body of genetic sequence information has helped to delineate the relationship between CTFV and related viruses (18–24).

### VIROLOGY

#### Classification

Three genera of arthropod-transmitted viral agents of medical importance are recognized within the family *Reoviridae*: *Coltivirus*, *Orbivirus* and *Seadornavirus* (South East Asian Dodeca RNA virus). The former is further classified within the subfamily *Spinareovirinae* (spiked or turreted; spina, Latin for spiked) while the latter two are classified with the *Sedoreovirinae* (non-spiked; sedo, Latin for smooth), although there is overlap in the morphological appearance of these genera by electron microscopy (EM) (25). Recognition of the fundamental difference in their genome structure (10 double-stranded RNA [dsRNA] segments in orbiviruses versus 12 dsRNA segments in coltiviruses and seadornaviruses) and other genetic attributes are responsible for the current classification (25–28). Species designations of members of each genus have been based on analysis of electropherotypes, RNA cross-hybridization assays, RNA sequence analysis, serologic reactivity, and the ability to reassort and produce viable progeny in co-infection experiments (25, 29). Phylogenetic analyses now provide a more precise picture of the relationships between different viral species (30) (Fig. 1).

CTFV is the type species of the genus *Coltivirus* (after Colorado tick fever). A number of other coltiviruses have been isolated and partially characterized and identified to species level. Eyach virus (EYAV) has been isolated from *Ixodes ricinus* and *Ixodes ventralloi* ticks in central Europe (31, 32). In a serologic survey of patients with meningoencephalitis and polyradiculitis in the former Czechoslovakia, 10% and 20%, respectively, had demonstrable antibody to EYAV, but a definite causal relationship remains to be proven (33). A coltivirus isolated from *Lepus californicus* hares in an area of northern California (outside the territory of *Dermacentor andersoni*) has been designated CTFV-Ca (formerly S6-14-03 virus) (23, 28, 34). Although this isolate has not been proven to cause human disease, it has been postulated to be responsible for Colorado tick fever-like human infection in California (35). A coltivirus dubbed Salmon River tick fever virus was isolated from a patient in Idaho with an illness similar to Colorado tick fever (35, 36). Whether this represents an antigenic variant of CTFV or a unique virus remains

**FIGURE 1** Relationship between members of Coltivirus, Seadornavirus, and Orbivirus with other Reoviridae based on phylogenetic analysis of the viral polymerase sequence (VP1). Each forms a distinct sequence cluster. Seadornaviruses appear most closely related to rotaviruses. KDV, Kadipiro virus; BAV, Banna virus; SCR, St. Croix River virus; AHSV, African horse sickness virus; CHUV, Chuzan virus; BTV, Bluetongue virus; YUOV, Yunnan orbivirus; PHSV, Peruvian horse sickness virus; CTFV, Colorado tick fever virus; EYAV, Eyach virus; BoRV, Bovine rotavirus; SiRV, Simian rotavirus; PoRV, Porcine rotavirus; Hu/MuRV, Human/Murine rotavirus. Tree generated using MEGA 4 with a neighbor-joining method. Values at the nodes indicate bootstrap confidence. Bar, genetic distance or approximate number of substitutions per site. (Reprinted from reference 30 with permission of the publisher.)

to be determined. CTFV and EYAV have been fully sequenced. Nucleotide sequence homologies among CTFVs range from 90% to 100% for conserved segments such as genome segment 12, while homologies between CTFV and EYAV isolates range from 53% to 58% in this segment. These viruses constitute the *Coltivirus* genus (18–20, 23).

Previously grouped within the genus *Coltivirus*, the *Seadornavirus* genus comprises a distinct group of arthropod borne agents, principally found in East Asia (19, 20, 23, 29) (Fig. 1). The current taxonomy recognizes three distinct species: (i) the type-species, Banna virus (BAV); (ii) Kadipiro virus; and (iii) Liao Ning virus. The pathogenic potential of these viruses in humans remains to be determined, although associations of BAV infection with febrile illnesses and encephalitis are convincing. Seadornaviruses are serologically distinct from CTFV and EYAV, have a lower G+C content than coltivoruses (37% to 39% vs. 48% to 52%) and show genetic distances in the RNA-dependent RNA polymerase of more than 90% when compared to coltivoruses. Phylogenetic analysis based on sequences from the RNA-dependent RNA polymerase suggest that seadornaviruses are more closely related to rotaviruses than to other members of the *Reoviridae* (Fig. 1) (25, 30). Furthermore,

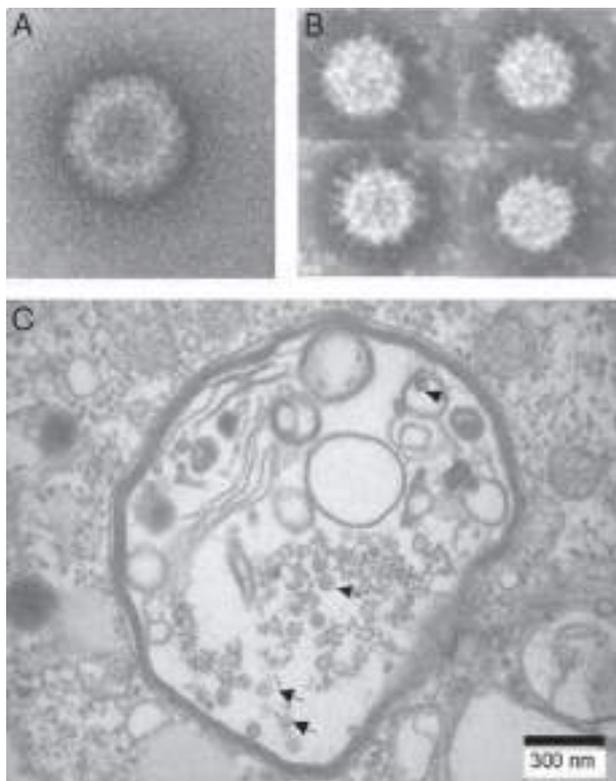

structural studies demonstrate similarities between BAV proteins and those of rotavirus. The BAV outer capsid viral protein 9 (VP9) has homology to the rotavirus receptor binding protein VP8, and there are additional similarities between BAV VP10 and the VP5 domain of rotavirus VP4 (37).

At present, there are over 20 recognized orbiviral species comprising over 200 identified serotypes, as well as a number of as yet unclassified viruses (25, 29, 38). The best-studied members of the genus *Orbivirus* are a number of veterinary pathogens, including the type-species bluetongue virus and African horse sickness virus, but several other groups within the genus (including Changuinola, Kemerovo, Lebombo, and Orungo) appear capable of infecting humans with or without causing disease. In the southwestern United States, orbiviral infection with an agent(s) related to the Kemerovo-Lipovnik serogroup of the Great Island virus species or the Six Gun City virus (Chenuda virus species) is suspected to be the cause of an acute febrile illness characterized by myalgia, abdominal pain, vomiting, and pancytopenia (7, 29, 35). It seems quite likely that additional members of each genera of arthropod-borne reoviruses will be identified in the future (36).

### Composition and Biology

CTFV particles consist of nonenveloped double-capsid structures with icosahedral symmetry and an outer capsid diameter of approximately 80 nm. While classified in the subfamily *spinareovirinae* based on sequence homology, CTFV spikes are not prominent and capsids appear smoother than is typically seen for either *seadornavirus* or *orbivirus* particles, with less prominent surface projections (23) (Fig. 2). BAV has a structure similar to that of rotaviruses, with protein fibers extending from the surface (37). Though CTFV does not acquire an envelope, electron microscopy studies frequently demonstrate association of viral particles with membrane (28,39–41).

The genome of all members of the *Reoviridae* consists of segmented dsRNA. Orbiviruses contain 10 segments, rotaviruses contain 11 segments, and coltivirus and seadornaviruses contain 12 segments ranging in approximate molecular mass from 0.24 to  $2.53 \times 10^6$  u (approximately 0.35 to 3.7 kbp). The 29 kB genome of CTFV is the longest of any *Reoviridae* characterized to date (18), while *Seadornavirus* genomes average 21 KB. Characteristic of the general genetic organization of the *Reoviridae*, each segment encodes a monocistronic message and gene product (22, 27, 28, 42–44). However, genome segment 9 of CTFV produces two different proteins through the use of a functionally “leaky” stop codon, allowing translation of both a truncated protein (VP9, a structural protein) and a longer, “read-through” protein (VP9’) (45).

**FIGURE 2** Negative contrast electron micrographs of (A) Colorado tick fever virus and (B) Banna virus (BAV). (C) Thin section of BAV-infected C6/36 cells showing viral particles (arrows) in vacuole-like structures. (Reprinted from reference 23 with permission of the publisher.)

Comparatively more is known about the gene products of orbiviruses and seadornaviruses than of CTFV. BAV (the prototype seadornavirus) has seven structural proteins. VP4 and VP9 form the outer capsid, while VP1, VP2, VP3, VP8, and VP10 form an inner core with a smoother surface (37). VP9 is involved in binding to the cell surface and may play a role in internalization (46). VP3 has guanylyltransferase activity (47). VP1 of CTFV has sequence homology to and includes signature motifs characteristic of the RNA-dependent RNA polymerases of other reoviruses (18). Putative functions of other CTFV genes and their orbiviral homologs have been described previously (Table 1) (22).

The natural segmentation of the genome of *Reoviridae* allows reassortment, as has been shown by comparative studies of CTFV isolates acquired from the same location at different times. The adaptive advantage of this ability to reassort presumably outweighs the inherent cost of maintaining this segmented organization, both by permitting the generation of a larger number of potentially advantageous variants (positive selection) and by allowing salvage of portions of genomes that have suffered deleterious mutations because of the inherent infidelity of RNA genome replication (purifying selection) (48, 49).

Some genetic variability has also been demonstrated by differential polyacrylamide gel electrophoresis mobility of some of the RNA segments from different isolates obtained simultaneously from one location (50). Antigenic variation of CTFV is demonstrable by serum cross-neutralization studies (51). However, there is relative conservation of CTFV sequences based on RNA-RNA hybridization under conditions that allow hybridization with as low as 74% homology (52). A more complete understanding of the degree and role of genetic heterogeneity in the biology of CTFV awaits further characterization of individual gene products and comparative sequence data.

Studies on bluetongue virus have shown that the endocytic pathway is important to viral entry of orbiviruses and that completion of the replication cycle necessitates exposure to relatively low pH conditions (53). It is not known whether coltivirus and seadornaviruses share similar entry requirements, but the observed similarities between the receptor binding proteins of BAV and bluetongue virus suggest that this may be the case (37).

Orbiviruses, coltivirus, and seadornaviruses are all rendered noninfectious at a pH of 3. Unlike the orbiviruses, coltivirus are relatively sensitive to treatment with deoxycholate, although with rare exception, members of each genus are relatively resistant to ether and other solvents (28, 54).

### EPIDEMIOLOGY AND ECOLOGY

The geographic distribution of Colorado tick fever, which is defined by the distribution of the arthropod and vertebrate hosts for CTFV, consists of mountainous and highland areas at altitudes between 4,000 and 10,000 ft (1,000 to 2,500 m) in the western United States and southwestern Canada (Fig. 3) (7, 17). Because reporting of cases is not required, the several hundred cases reported annually likely underestimate the true annual incidence by a factor of 10 or more (1, 6, 16, 36). As an example, the declassification of Colorado tick fever as a reportable disease in Colorado in the early 2000s resulted in an apparent but misleading decline in disease incidence in that state. In contrast, active surveillance in Sublette County in Wyoming in 2009 resulted in the highest number of cases reported to the Centers for Disease Control from any one county or state since 1998 (1, 55).

**TABLE 1** Coding organization of Coltivirus, Seadornavirus, and Orbivirus segments<sup>a,b</sup>

Coltivirus		Function	Seadornavirus		Orbivirus <sup>c</sup>		Function
CTFV	EYAV		BAV	KAV	BTV		
VP1	VP1	<b>RNA dep. RNA polymerase</b>	VP1	VP1	VP1	<b>RNA dep. RNA polymerase</b>	
VP2	VP2	<b>Capping enzyme-methyltransferase</b>	VP3	VP3	VP4	<b>Capping enzyme-guanylyltransferase</b>	
VP5	VP5	<i>Guanylyltransferase (NS)</i>	VP5	VP6			
VP3	VP3	RNA replication factors			VP3	Major subcore protein	
VP6	VP7	<b>Nucleotide binding, NTPase</b>	VP6, VP2	VP5, VP2			
VP7	VP6	<i>RNA replication factor (Protein kinase/NS)</i>	VP7	VP7	NS1	Tubule protein	
VP8	VP8	<i>Unknown (Core)</i>	VP8	VP9	VP7	Major core surface protein	
VP9	VP9	<i>Structural and non-structural (Core, stalk base)</i>	VP10	VP10	VP2, VP5	Outer capsid protein

VP11	VP11	<i>Unknown (Cell attachment)</i>	VP9	VP11	NS2	Viral inclusion protein	
VP12	VP12	<i>RNA replication Factor (NS)</i>	VP11	VP12	NS3	Virus budding viral release protein	

<sup>a</sup>Adapted from references 7, 8, 12, 55, 95.

<sup>b</sup>Coltivirus functions shared by homologous segment of Seadornavirus and/or Orbivirus are listed in **bold**. When putative function of a segment from Coltivirus does not coincide with function in Seadornavirus, function in Coltivirus is *italicized* and function in Seadornavirus is in parentheses (). Functions of Coltivirus and Seadornavirus genetic segments are shown in column 3; functions of Orbivirus genetic segments are shown in column 7. Colorado tick fever virus (CTFV); Eyach virus (EYAV); Banna virus (BAV); Kadipiro virus (KAV); bluetongue virus (BTV); viral protein (VP); non-structural (NS).

<sup>c</sup>Although Orbivirus contain only 10 segments, segment 9 encodes both VP6 and NS4.

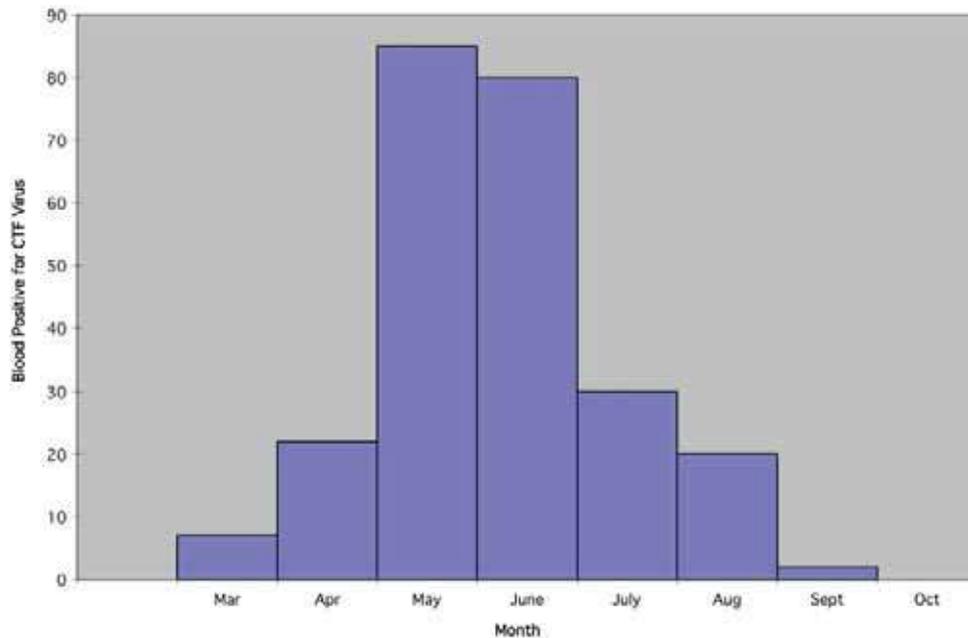

**FIGURE 3** Distribution of *Dermacentor andersoni* ticks (shaded area) and number of cases of Colorado tick fever from 1990 to 1996. (Modified from reference 7 with permission of the publisher.)

Cases occur between March and October, with 90% of cases occurring between May and September (Fig. 4) (1, 17, 56). This seasonal distribution probably reflects the heightened numbers and activity of the arthropod vector *Dermacentor andersoni* (wood tick) and its natural vertebrate hosts (including the golden-mantled ground squirrel, Columbian ground squirrel, yellow pine chipmunk, and least chipmunk), as well as the greater exposure of human hosts participating in occupational and recreational activities during the summer months. Ticks are particularly numerous in grassy and low-brush areas, on south-facing slopes, and near streams (7, 17, 57).

In past studies, a preponderance of males between the ages of 15 and 40 comprised reported cases of Colorado tick fever. This does not stem from increased susceptibility but rather reflects the greater likelihood of exposure of this population to the vector carrying CTFV. There is no difference in likelihood of infection based on age or sex in populations when normalized for exposure (10, 58). More recent studies demonstrate a shift towards higher incidence rates among those 51 to 70 years of age. This possibly reflects greater case ascertainment among older patients, although a change in rates of exposure has not been excluded (1, 55).

Although CTFV has been isolated from several tick species, *D. andersoni* has been the only species demonstrated to transmit disease to humans (5). It has been postulated that *Dermacentor variabilis* may transmit CTFV or CTFV-Ca in regions of California that lie outside the area of distribution of *D. andersoni* (35). The life span of *D. andersoni* has been reported to be as long as 3 years, and once this species is infected, it remains so for life. Acquisition of infection can occur in the larval, nymphal, or adult stage with transstadial persistence, but transovarial transmission does not occur. Hence, passage of CTFV between generations of ticks requires an intermediate reservoir provided by the small mammalian hosts. These natural mammalian hosts develop subclinical infections followed by persistent viremia lasting weeks to months. Hibernating animals appear to sustain viremia for longer periods; this may be one mechanism that allows CTFV to survive the winter and to initiate a new cycle of infection when fed upon by larval and nymphal ticks in the spring and summer. The virus titer in an infected adult

**FIGURE 4** Frequency distribution by month of confirmed illness due to Colorado tick fever virus in Colorado during 1973 and 1974. (Modified from reference 56 with permission of the publisher.)

tick of  $10^2$  to  $10^5$  mouse 50% lethal doses/ml (homogenized tissue) can be maintained for up to a year. Transmission to humans or animals occurs by transfer of virus in saliva during feeding. Mature adult ticks prefer blood meals from large animals such as deer, elk, porcupines, and occasionally, humans (5, 7, 16, 36). Human-to-human transmission can occur during the viremic phase of illness, and there has been at least one documented case of transfusion-related Colorado tick fever (59).

## PATHOGENESIS

### Organ and Cellular Pathology

EM studies of cultured cells following infection reveal viral particles in association with granular matrices within the cytoplasm (40, 41). Filamentous arrays are also seen lying in parallel bundles, both in the cytoplasm and in the nucleus (nuclear filaments are not seen with other reovirus infections). In late stages of infection, the matrices become larger and viral particles become more numerous, but the viral particles are still contained within cells. There is no evidence for release of virus until cells undergo dissolution. EM of neurons infected *in vivo* fail to demonstrate a comparable cytopathic effect (23,39–41).

The tropism of CTFV for hematopoietic cells is demonstrated by the ability to detect viral antigen within erythrocytes by various methods (virus isolation, histochemical staining, fluorescent-antibody [FA] staining, and EM) long after the acute phase of infection (56, 60, 61). Since CTFV antigens are intracellular and not found on the erythrocyte surface, the virus may be shielded from immune clearance by neutralizing antibody throughout the natural life span of the erythrocyte. CTFV is able to infect and replicate in human hematopoietic progenitor cell lines, thus providing not only an explanation for the intraerythrocytic persistence but also a possible explanation for the frequently encountered leukopenia and thrombocytopenia (62). This pathology could be due to either a direct cytopathic effect on

infected stem cells as they differentiate towards these cell lineages or a consequence of host immune clearance of those infected cells capable of displaying viral antigen. In patients infected with CTFV, mononuclear cells are also less able to produce colony-stimulating factors, and a circulating inhibitory factor (possibly lactoferrins or interferon) can be demonstrated in patient sera (63).

Only four deaths have been attributed to Colorado tick fever in the medical literature. Three were children and one was an 80-year-old man with underlying chronic lung and cardiac disease. Autopsies of two children, both of whom died from bleeding diatheses, reported purpura and cutaneous petechiae. Acute respiratory distress syndrome, encephalitis, and swollen endothelial cells were described in a 4-year-old boy. A 10-year-old girl had disseminated intravascular coagulation with focal necrosis involving the brain, liver, spleen, heart, and intestinal tract (4, 64). The adult patient presented with fever, diarrhea, and leukopenia and then developed disseminated intravascular coagulation and progressive respiratory failure. The patient developed immunoglobulin M (IgM) and immunoglobulin G (IgG) against CTFV; CTFV was recovered in tissue culture but equivocal IgM and positive IgG against hantavirus were also detected. Post-mortem findings in this lone published case of an adult death disclosed interstitial pneumonia (1). Studies on suckling mice and hamsters have disclosed histopathological findings similar to those described in these cases (65, 66).

### Immune Response

High plasma levels of type I interferon (IFN) can be detected in a majority of Colorado tick fever patients during the first 10 days of infection. These levels appear to correlate with fever but not with other clinical parameters (67). Although the events responsible for upregulation of interferon expression in CTFV have not been described, they have been investigated for other *Reoviridae*. Infection of epithelial cells with bluetongue virus (BTV) upregulates expression of type I

IFN and related cytokines in a manner dependent on sensing and signaling by the cytosolic pathogen pattern recognition receptors retinoic acid induced gene-1 (RIG-I) and melanoma differentiation associated gene 5 (MDA-5) (68). In contrast, exposure of plasmacytoid dendritic cells results in MyD88-dependent but toll-like receptor (TLR) 7/8 independent IFN production (69). Overexpression of either RIG-I or MDA-5 in a cell line model impedes BTV infection (68). One third of patients develop detectable neutralizing antibody titers within 10 days of onset of symptoms. By 30 days, more than 90% are antibody positive, but many patients continue to have detectable viremia by either indirect FA assays or viral culture (presumably due to intra-erythrocytic persistence) (56). Nearly 50% of patients are culture positive after 4 weeks and 5% to 17% are culture positive up to 12 weeks after onset of clinical symptoms. There is no apparent relationship between the persistence of viremia and the duration of symptoms. It is not known whether other immune mechanisms are involved in viral clearance.

Convalescence is accompanied by lasting immunity against reinfection. Only a single case has been reported of a patient experiencing either relapse or reinfection a year after the initial infection. Interestingly, the second episode was accompanied by loss of previously demonstrated neutralizing antibody titers (56). Experimental rechallenge of immune subjects with CTFV failed to produce clinical disease (with the exception of several hours of headache in some of the subjects) (10).

### CLINICAL MANIFESTATIONS

Individuals with Colorado tick fever typically have a history of tick attachment or exposure (>90%) and residence or travel within endemic areas. Following an incubation period of 3 to 5 days (range 1 to 14 days), fever is noted along with malaise, headache, myalgias, and gastrointestinal upset (Table 2). In approximately half of all cases a characteristic

“saddleback” fever pattern is seen. This consists of 2 to 3 days of fever, followed by an afebrile interval of up to several days, followed by return of fever for 2 to 3 days. Rarely, this can be followed by yet another febrile period. Thereafter, most patients recover without sequelae, although some have reported prolonged lassitude lasting weeks to months. Likely, mild or subclinical infection occurs but has been underrepresented in the literature (4, 5, 56).

Physical examination during the acute phase of disease can reveal altered sensorium, neck stiffness, photophobia, mild conjunctivitis, and occasionally lymphadenopathy and splenomegaly. Rash is seen in a minority of cases. When present, it appears as faint, fine macules or maculopapules on the trunk or, at times, the extremities (56). Hemorrhagic diatheses with attendant petechiae, particularly in those under age 10, have been attributed to thrombocytopenia and, in at least one case report, to frank disseminated intravascular coagulation (DIC) (4, 64). Central nervous system (CNS) involvement can range from self-limited meningitis to encephalitis with coma and death (6, 67). Other reported complications have included hepatitis, epididymo-orchitis, pericarditis, myocarditis, and pneumonitis (58, 59, 70–72). Rarely, deaths have been attributed to bleeding, pneumonitis, and CNS complications (1, 4, 6, 64).

There have been occasional reports of Colorado tick fever acquired by women during pregnancy, including one case of abortion 2 weeks after infection, one case of multiple congenital abnormalities in a mother infected in the first trimester (Colorado tick fever was thought not to be causal), and a case of apparent perinatal transmission with self-limited disease in the neonate (4, 73). No published reports describe the course of Colorado tick fever in human immunodeficiency virus-infected or other immunocompromised hosts, although one clinical review reports that immunocompromised individuals may be at risk for more severe disease (74).

### Laboratory Findings

The most characteristic routine laboratory feature is a moderate leukopenia of 2,000 to 4,000 leukocytes/mm<sup>3</sup> or less, with a relative lymphocytosis (approximately 60% of patients). Other findings can include a “left shift” (at times with the appearance of metamyelocytes and even myelocytes) and toxic granulation. Thrombocytopenia can occur with or without DIC. Anemia (usually mild) may be present, but hemolysis is not a typical feature in the absence of DIC. There can be mild elevations of hepatic transaminases and creatine phosphokinase (5, 16, 36, 43, 56).

Mild to moderate cerebrospinal fluid (CSF) pleocytosis can occur, usually with a lymphocyte predominance (typical range, 0 to 500 mm<sup>3</sup>), although there is a single case report of Colorado tick fever meningoencephalitis with a CSF leukocyte count of 1,578 and 89% neutrophils. CSF glucose has ranged from 40 mg/dl to normal and CSF protein has ranged from normal to 170 mg/dl in Colorado tick fever patients with meningoencephalitis (58).

### Differential Diagnosis

Consideration of a diagnosis of Colorado tick fever must depend largely on epidemiological features. Because ticks can transmit a number of other infectious diseases, the differential diagnosis includes tularemia, RMSF, ehrlichiosis, Lyme disease, and tick-borne relapsing fever. Although the vectors for relapsing fever (*Ornithodoros* sp.), ehrlichiosis (*Dermacentor variabilis*, *Amblyomma* sp., *Ixodes* sp.) and Lyme

**TABLE 2** Symptom frequency of 320 patients suspected of having Colorado tick fever in Colorado for the years 1973 and 1974 (222 Confirmed positive and 98 negative)

Symptom	Positive for	Negative

(Modified from reference 56 with permission of the publisher.)

disease (*Ixodes* sp.) are different than the principal vector transmitting CTFV to humans, this distinction is often not made by patients or health care providers (7, 17, 75). Colorado tick fever must also be distinguished from a number of other viral diseases, in particular, those caused by the enteroviruses (because of the similar seasonal association) and in those cases with prominent CNS features, with West Nile virus. Distinguishing Colorado tick fever from RMSF can be difficult early in the course of disease. However, the typical improvement after 2 to 3 days, the possible appearance of the relapsing-fever pattern, the relative leukopenia, and the failure of the rash to evolve to a purpuric/petechial nature (as is seen with the vasculitic process of RMSF) would all point away from the diagnosis of RMSF (3, 5, 7, 16, 17, 36, 75).

The distributions of human monocytotropic ehrlichiosis (HME), caused by *Ehrlichia chaffeensis*, and human granulocytic ehrlichiosis (HGE or anaplasmosis), caused by *Anaplasma phagocytophila*, overlap only marginally with that of Colorado tick fever (76–78). *E. chaffeensis* is concentrated in the southeastern and south central United States, with sporadic cases reported from the Rocky Mountain and western states, consistent with the distribution of *Amblyomma americanum* (the Lone Star tick) in the southeast and south central United States and *Dermacentor variabilis* in the western United States (79, 80). HGE has been predominantly described in the upper Midwest (Minnesota and Wisconsin), Northeast (New York and Massachusetts) and, more recently, northern California, conforming to the geographic distribution of the *Ixodes* tick vectors (80–84). Nevertheless, it seems prudent that these two tick-borne diseases should remain in the differential diagnosis of suspected Colorado tick fever patients, especially those with severe disease. In particular, the cytopenias seen with HGE and severe cases of HME might be confused with that of Colorado tick fever.

### LABORATORY DIAGNOSIS

Specific diagnosis of CTFV can be made by (i) viral isolation, (ii) demonstration of viral antigens, (iii) serology, or (iv) PCR-based detection of viral nucleic acids. Although CTFV can be cultured directly (in Vero or BHK-21 cells), the most sensitive method of isolation is intracerebral or intraperitoneal inoculation of blood clot suspensions or erythrocytes into suckling mice. The mice sicken and die 4 to 8 days after inoculation. Specific isolation is confirmed by FA staining of smears of mouse brain or blood or by cell culture. The blood clot intended for virus isolation should be stored refrigerated but not frozen. Typically, such procedures are available only through reference laboratories. When available, a source tick can be retained for species identification and virus isolation.

A more rapid, albeit less sensitive (60% to 70% compared with culture), approach to specific diagnosis is by direct immunofluorescence staining of blood smears for the presence of viral antigen (5, 7, 16, 17, 36, 43). Although diagnostic yield by either isolation or direct demonstration of antigen is greatest during the acute phase of disease, viremia is at times detectable well into the period of convalescence (56). Antigen is detectable in erythrocytes by direct FA assay in nearly 10% of patients as long as 20 weeks after onset of symptoms.

Paired acute- and convalescent-phase sera can be assayed for antibody titer in a variety of ways, including complement fixation (CF), indirect FA assay, enzyme-linked immunosorbent assay (ELISA), and an assay for neutralizing antibody measuring plaque reduction. CF antibodies may appear rela-

tively late, whereas neutralizing antibodies are typically detectable from 14 to 21 days after onset of symptoms. IgM detectable by ELISA appears at about or slightly before neutralizing antibody but declines abruptly after 6 weeks (5, 16, 17, 36, 43, 85, 86). A recent ELISA for IgM using synthetic antigens and a separate Western blot analysis may be more sensitive than earlier ELISA systems for diagnosis but will require validation (87). Different ELISAs are also available for EYAV (using VP6) and BAV (using VP9) (88, 89).

Molecular diagnosis based on reverse transcription-PCR (RT-PCR) of RNA isolated from cell-free plasma or erythrocytes has been investigated for Colorado tick fever (87, 90). These methods appear to be comparable to or slightly more sensitive than viral isolation in the first week following infection but have the important advantage of providing rapid results and do not require the highly specialized reagents needed for virus isolation and identification. They should be superior to serologic assays for diagnosis in acute infection. However, these methods have only been applied to a limited number of viral isolates and retrospectively collected clinical samples and have not been prospectively tested except on experimentally infected animals (87). Furthermore, assays vary in sensitivity depending on virus strain, presumably due to sequence variation (90), although recent RT-PCR assays appear to be capable of detecting a single genome and are at least 10 times more sensitive than standard plaque assays (87, 91). Notably, some RT-PCR assays for CTFV do not detect the related CTFV-Ca, Salmon River tick fever virus, or EYAV (91). The utility and validity of these assays should increase when more complete sequence data become available from additional clinical viral isolates, permitting further assay refinement. Such approaches that permit early diagnosis are needed because the most important diagnostic and therapeutic decisions are faced during acute infection when clinical distinction from RMSF and other potentially more serious tick-borne diseases is most challenging. Microarrays that have been developed to simultaneously screen for multiple viral pathogens currently include probes for *Coltivirus* and *Seadomavirus* (92). Metagenomic approaches, for example, “deep sequencing,” have been employed for pathogen diagnostics (93, 94) and discovery (95), including detecting other reoviruses (96). While there have been no reports of CTFV detection by these approaches to date, it seems likely in the future as assay methods improve and are more frequently used.

### PREVENTION

Individuals should be educated and encouraged to take preventive measures when outdoors in endemic areas during the late spring and summer months. Wearing long-sleeved shirts and light-colored clothing, frequent self-inspection for ticks, and use of repellents such as DEET (*N,N*-diethyl-*m*-toluamide) or permethrin (only for treatment of clothing or bedding) should be advised (5, 7, 17, 43).

Patients recovering from Colorado tick fever should not donate blood for a period of at least 6 months because of the intraerythrocytic persistence of virus.

In the 1960s, a Colorado tick fever vaccine was developed using formalinized infected murine brain extracts (97). This vaccine elicits a neutralizing antibody response, but because of the modest morbidity of natural infection, the vaccine development program has since been abandoned.

### TREATMENT

The typical, uncomplicated case of Colorado tick fever requires no specific therapy. Reassurance, analgesics, and

antipyretics can be given, with the caveat that aspirin and other nonsteroidal anti-inflammatory drugs with antiplatelet activities should be avoided (particularly in children) because of the occurrence of thrombocytopenia (5, 16, 17, 36, 43, 56).

*In vitro* activity against CTFV has been demonstrated for ribavirin, 3-deazaguanine, and to a lesser extent, 3-deazauridine (MICs of 3.2, 3.2, and 32 µg/ml, respectively, in MA-104 cells and MICs of 32, 3.2, and 10 to 100 µg/ml, respectively, in Vero cells). In mice inoculated intracerebrally with CTFV, intracerebral or intraperitoneal ribavirin triacetate (but not ribavirin) reduced the mortality, while intracerebral 3-deazaguanine increased the mean survival time (98, 99). However, no experience with humans has been published. At present, no specific antiviral therapy exists for Colorado tick fever (100, 101).

### SEADORNAVIRUSES

BAV (102, 103) was first isolated from the CSF and blood of patients with febrile syndromes and encephalitis (35, 104) as well as from mosquitoes (35, 102, 105) in southern and western China in 1987. Numerous additional isolates have since been reported from patients in China, including northern, more temperate regions, and Indonesia (106). Insect vectors for BAV include *Anopheles*, *Aedes*, and *Culex* mosquitoes. Viral sequences with similarity to BAV have also been found in cattle and pigs (107), suggesting a potential role for livestock as an animal reservoir. BAV is currently classified as a pathogen requiring biosafety level 3 laboratory containment and is the only species of the genus

to be isolated from humans (23). BAV is endemic in areas of tropical and subtropical Asia that overlap with Japanese encephalitis virus and dengue virus, so it is likely that infection with BAV may be underestimated. Indeed, recent retrospective surveys of sera from Chinese patients with suspected Japanese encephalitis and other encephalitic syndromes suggest BAV infection in 8% to 12% (107). No specific treatment exists for BAV infection.

Kadipiro virus and Liao Ning virus are serologically distinct seadornaviruses that have also been obtained from mosquitoes in Indonesia and China (35, 102, 105). Sequence comparisons of the viral polymerase gene show homology ranging from 24% to 42%. However, these viruses have not been isolated from humans. Liao Ning virus is the only species of *Seadornavirus* that is able to replicate in a variety of mammalian cell lines and is also able to establish pathogenic infection in adult mice (108). A serologic assay for antibody to VP9 antigen (the outer coat protein) of BAV has been developed (89), as have RT-PCR assays for BAV and Kadipiro.

More recently, a virus detected in the intestinal contents of fresh water carp in Hungary by metagenomic analysis and confirmed by RT-PCR detection, Balaton virus, appears phylogenetically related to BAV, suggesting that the geographic distribution of *Seadornavirus* extends at least to Eastern Europe (96).

### ORBIVIRUSES AND HUMAN DISEASE

The name *Orbivirus* derives from the appearance of virus particles as large, doughnut-shaped capsomeres by

TABLE 3 Orbiviruses that naturally infect humans<sup>a</sup>

Characteristic	Changuinola virus	Kemerovo virus <sup>b</sup>	Oklahoma tick fever virus <sup>c</sup>	Lebombo virus	Orungo virus
Geographic distribution	Panama	Russia and Eastern Europe	Oklahoma and Texas	Nigeria and South Africa	Western and central Africa
Insect vectors	Plebotamine flies	<i>Ixodes</i> ticks	Ticks (presumed)	<i>Aedes</i> and <i>Mansonia</i> mosquitoes	<i>Aedes</i> , <i>Anopheles</i> , and <i>Culex</i> mosquitoes
Reported clinical syndromes	Self-limited febrile illness in one adult	Fever, encephalitis, ? polyradiculitis	Fever, pancytopenia	Fever in one child	Fever, headache, myalgias, nausea, and vomiting (diarrhea, flaccid paralysis, seizures, normal routine CSF parameters in one child)
Specific diagnosis <sup>d</sup>	Rise in serologic titer; viral isolation in i.c. <sup>e</sup> -inoculated suckling mice, plaques in Vero and LLC-MK2 cell culture	Rise in serologic titer; viral isolation in i.c.-inoculated newborn mice, hamsters, chicken embryos; plaques in primary chicken embryo, Vero, and BHK-21 cell culture	Rise in serologic titer; viral isolation yet to be successful	Rise in serologic titer; viral isolation in i.c.-inoculated suckling mice, plaques in Vero and LLC-MK2 cell cultures	Rise in serologic titers; viral isolation in i.c.-inoculated suckling and weanling mice, plaques in Vero and BHK-21 cell cultures

<sup>a</sup>Data from references 110, 76, 55, 27, 30, 97, and 113.

<sup>b</sup>The Kemerovo strains include Kemerovo, Tribec, and Lipovnik viruses regarded as strains of the Great Island virus as well as at least 32 other strains that are not known to be pathogenic for humans.

<sup>c</sup>Serologically related to the Kemerovo strain of Great Island virus and the Six Gun City strain of Chenuda virus.

<sup>d</sup>Reagents to assay for various combinations of CF antibodies, neutralizing antibodies, IFA and direct nucleic acid testing are available at only a limited number of reference laboratories. Suspect cases can be referred to Division of Vector-Borne Infectious Diseases, CDC, Fort Collins, CO or to the U.S. Army Medical Research Institute for Infectious Diseases, Ft. Detrick,

<sup>e</sup>i.c., intracerebrally.

negative-contrast EM (orbi from Latin *orbis*, meaning “ring”). Although the most studied orbiviruses are agents of veterinary importance, a number of serogroups within the genus cause human disease (28, 43). They are predominantly transmitted by arthropod vectors (ticks, gnats, midges, and mosquitoes).

Changuinola virus was first isolated from a man in Panama experiencing a self-limited febrile illness. Serologic surveys in the area verify human exposure, but the frequency of clinical disease is unknown. The virus can be isolated from phlebotomine flies (43, 109). Four tick-borne viruses (Kemorovo, Tribec, Lipovnik, and Great Island) are currently classified as variants of the Great Island virus species (29, 30). Of these, Kemorovo has been implicated in febrile illness and CNS infection in Russia, and human seroreactivity to Kemorovo, Tribec, and Lipovnik viruses has been detected in parts of eastern Europe (33, 43, 110, 111). Serologic evidence of infection with a virus related to Lipovnik and Six Gun City viruses (a serotype of the Chenuda virus) was found in several patients from Texas and Oklahoma who were hospitalized with febrile illnesses associated with tick exposure and various degrees of transient leukopenia, thrombocytopenia and anemia. The etiologic agent(s) have not been successfully isolated (7, 112). The clinical syndrome has been given the name Oklahoma tick fever. Orungo virus has a wide geographic distribution in western and central Africa (43, 113). The principal vector is *Aedes* mosquitoes (though also isolated from *Anopheles* and *Culex*). The epidemiology of infection with Orungo virus therefore parallels that of yellow fever, and serologic surveys done during outbreaks of yellow fever demonstrate a high incidence of apparent coinfection with Orungo virus (114). In these studies, the contribution of Orungo virus to clinical illness was thought (understandably) to be small relative to that of yellow fever virus, but Orungo has been incriminated in febrile syndromes independent of yellow fever (115), and in at least one case it has been associated with CNS complications (43, 116). Lebombo virus has been isolated from a febrile Nigerian child and from *Aedes* and *Mansonia* mosquitoes in Nigeria and South Africa (43, 117). Lebombo and Orungo viruses are distinct serologically and by RNA-RNA hybridization and genetic reassortment studies (118).

Over several years in the 1980s, four laboratory workers in a South African veterinary vaccine packaging plant were apparently infected with neurotropic attenuated strains of African horse sickness virus (119, 120). Three of the four cases included frontotemporal encephalitis, and all four had evidence of uveochorioretinitis. The diagnosis was made based on specific serologic studies (CF, enzyme immunoassay, and neutralizing antibody) and the serologic exclusion of a battery of other viral and nonviral entities, including herpes simplex virus (though two of the four received 10-day courses of acyclovir) and Rift Valley fever virus. Several other laboratory workers demonstrated antibody to African horse sickness virus without overt clinical symptoms. The mode of acquisition was thought to be inhalation of lyophilized virus in laboratory accidents. Despite episodic outbreaks of African horse sickness virus and bluetongue virus around the world, natural human infection has not been reported.

Table 3 summarizes some of the clinical aspects of these naturally acquired human orbiviral diseases. As with coltivirus and seadornaviruses, we are likely to encounter more orbiviruses in the future that have the capacity to cause human disease.

# Rotaviruses

MANUEL A. FRANCO, JUANA ANGEL, AND HARRY B. GREENBERG

## 36

Acute infectious diarrhea is one of the two most frequent diseases of young children. Until the early 1970s, numerous unsuccessful attempts were made to grow viral agents responsible for acute infectious diarrhea of children. The etiologic agent of epizootic diarrhea of infant mice (EDIM) was identified by electron microscopy in 1963 (1). Nonetheless, it was only with the discovery of the virus responsible for calf scours (with this same approach) in 1969 by Mebus et al (2) and of the human Norwalk virus by Kapikian et al (3) in 1972 that the methodology for identification of the viruses responsible for severe diarrhea in children was established. Using electron microscopy, Bishop et al (4) identified the first human rotavirus in an intestinal biopsy from a child with diarrhea. At roughly the same time, other groups used immune electron microscopy to identify the enteric caliciviruses and astroviruses, viruses that were also difficult to grow *in vitro*, as additional causes of acute infectious diarrhea in children and adults. Shortly after the discovery of human rotaviruses, it was realized that the EDIM virus and the calf scours virus were morphologically and antigenically related, and all these strains were grouped in the genus rotavirus. In rapid order, rotaviruses were shown to be among the most important pathogens of acute diarrhea in the young of many animals, including humans.

Rotaviruses are responsible for a median of 39% (range 12% to 68%) of all hospitalizations in children under 5 years of age due to diarrhea worldwide, and it has been estimated that in 2008 (prior to the introduction of vaccines) they were responsible for the death of approximately 1,200 children daily (5) (Figure 1). In the Global Enteric Multicenter Study (GEMS study), conducted between 2007 and 2011 in countries with moderate-to-high mortality in children under age 5 in Africa and Asia, rotavirus was found to be the principal etiologic agent of moderate to severe diarrhea in children less than 59 months of age (6).

Rotaviruses do not account for a substantial number of deaths in developed countries, probably because of efficient and widespread access to rehydration and other supportive measures. Moreover, with the advent of rotavirus vaccines the impact of this pathogen has diminished in recent years in most developed countries. For example, in the United States detection of rotaviruses and costs for associated treatment have drastically diminished after vaccine introduction (7, 8). Although rotavirus was still identified in 12% of children

with acute gastroenteritis in 2009 and 2010, during the same period norovirus replaced rotavirus as the leading cause of medically attended acute gastroenteritis in U.S. children (9). A similar situation may be occurring in some developing countries, as exemplified in Nicaragua where the epidemiology of diarrhea is changing (10).

## VIROLOGY

### Classification

Rotaviruses belong to the *Reoviridae* family of icosahedral, nonenveloped, segmented double-stranded (ds) RNA viruses. Rotaviruses are classified into five groups (A through E) depending on the presence of cross-reactive antigenic epitopes primarily located on the internal structural protein VP6. Among these, Group A rotaviruses (RVA) are the most frequent pathogens of humans, and groups D and E have been found only in nonhuman animals. Unless otherwise noted, this chapter will address only RVA. Group B rotaviruses (RVB) are sporadic pathogens of animals but have been implicated in several large outbreaks of adult diarrhea in China in the 1980s and less frequently in the 1990s (11). More recently, they have been identified in children and adults with diarrhea in India and Bangladesh (12, 13). Group C rotaviruses (RVC) are primarily veterinary pathogens but have been reported to be sporadically associated with diarrhea in children. The seroprevalence of these rotaviruses is relatively high in humans, especially those living in rural areas, suggesting transmission from animals to humans (14). However, in some countries such as India, prevalence of antibodies against RVC is the same in urban and rural populations (15). Despite occasional studies implicating the importance of RVB or RVC in humans, RVA continues to be by far the most frequently identified pathogen.

RVA have been serologically classified into subgroups depending on the presence of epitopes localized on VP6 (11). Four subgroup specificities have been defined: subgroup I (most animal and a few human strains), subgroup II (most human and few animal strains), subgroup I + II, and nonsubgroup I/nonsubgroup II, with only rare human strains belonging to these last two categories. The subgroup classification was useful in early epidemiological studies but is less commonly used today.

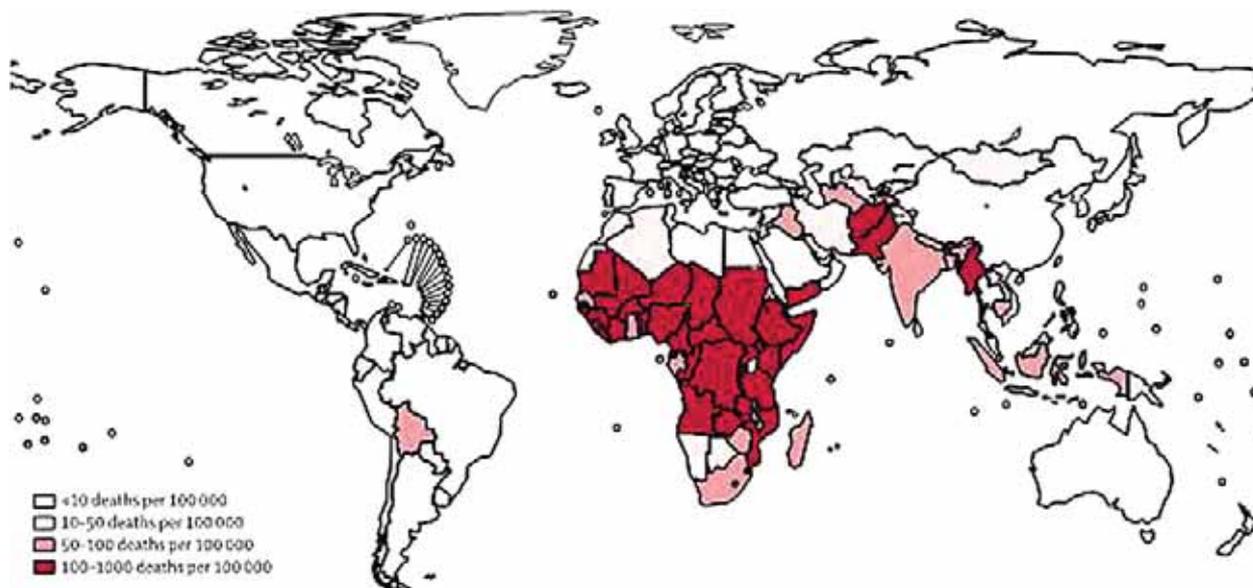

FIGURE 1 Map of the world showing rotavirus mortality in 2008, reproduced with permission from (5).

Antibodies that neutralize rotavirus *in vitro* are used to further classify the virus into serotypes. The two outer viral capsid proteins (VP7 and VP4) induce neutralizing antibodies and segregate independently, resulting in a binary serotyping system much like that of influenza. Antibodies against VP7 define the G (glycosylated protein) serotype and antibodies against VP4 the P (protease-sensitive protein) serotype. Historically, hyperimmune serum and later monoclonal antibodies (MAbs) against distinct rotavirus strains were used to classify viral serotypes.

The classification of G serotypes has been extensive and clear-cut because antibodies against VP7 generally predominate in hyperimmune sera, and serotype-specific MAbs to neutralizing epitopes on VP7 have been easy to isolate. The G protein has also been characterized based on its sequence analysis (genotype), and this classification correlates well with traditional serologic designations. In contrast, to obtain optimal P serotyping reagents it has been necessary to raise polyclonal antibodies against the different recombinant VP4 proteins (16) and these reagents have not been widely available. For this reason, many more distinct types of VP4 have been identified by comparison of gene sequence (genotype) than by serology. A significant but not absolute correlation exists between P serotypes and P genotypes. For example, the most common human P serotypes, 1A and 1B, correspond to genotypes [8] and [4], respectively, but genotypes [2] and [3] both can correspond to P serotype 5B (11). Worldwide, six G serotypes (G1- G4, G9, and G12) and three P (P[4], P[6] and P[8]) genotypes account for most human rotavirus infections (17). Human rotavirus strains belonging to G1, G3, G4, G9, and G12 serotypes are preferentially associated with P[8], while G2 serotype strains are most frequently associated with the P[4] genotype.

More recently, a complete genome classification system was developed for RVAs that assigns a specific genotype to each of the 11 rotavirus genome segments (18). The VP7-VP4-VP6-VP1-VP2-VP3-NSP1-NSP2-NSP3-NSP4-NSP5/6 genes of RVA strains are described using the abbreviations Gx-P[x]-Ix-Rx-Cx-Mx-Ax-Nx-Tx-Ex-Hx (x = Arabic numbers starting from 1), respectively. The current guidelines recommend that nomenclature for individual strains include

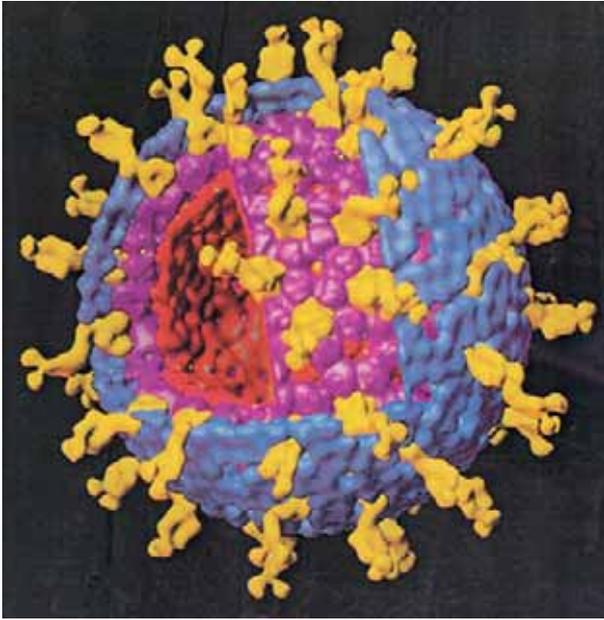

the following: rotavirus group/species of origin/country of identification/common name/year of identification/G and P-type (18). The prototype simian agent 11 (SA11) rotavirus strain is designated RVA/Simian-tc/ZAF/SA11-H96/1958/G3P5B[2] and the full genetic descriptor is indicated by G3-P[2]-I2-R2-C5-M5-A5-N5-T5-E2-H5 (18).

## Composition of Virus

### Virion Morphology

Rotaviruses, when studied with conventional electron microscopy (that does not permit clear identification of the VP4 spike protein), are 70-nm particles that have a multi-layered icosahedral structure. *In vitro* treatment of a complete virus or triple-layered particles (TLP) with calcium chelating agents removes the outer viral capsid (VP4 and VP7), producing double-layered particles (DLP) composed of VP6 on the surface. Within the double-layered particles is a third layer (composed of VP1, VP2, and VP3), called the core, which contains the viral dsRNA genome. Pioneering structural studies of rotavirus using electron cryomicroscopy (19, 20) obtained detailed functional and structural information about this relatively large and structurally complex virus (Figure 2). More recent studies have elaborated an atomic model of the infectious particle (21, 22). The diameter of the viral particle, including the spikes, is 1,000 Å. Both outer and inner capsids are constructed with T = 131 (levo) icosahedral lattice symmetry. The 60 spike structures that protrude from the surface of the viral particle have been shown to be formed by trimers of VP4 that interact at their base with both the outer layer (VP7) and middle layer proteins (VP6) (23, 24). The structural changes of VP4 that probably occur during cell penetration recall those of enveloped virus fusion proteins (23). The localization of neutralizing epitopes on VP7 has also been identified (25) and insights into the mechanism of viral penetration obtained (26).

The particle has three types of aqueous channels that connect the central core containing the genome with the viral surface. Depending on their location relative to the icosahedral symmetry, these channels have been classified

**FIGURE 2** Computer image reconstruction of a rotavirus triple-layered particle based on cryoelectron microscopy. VP4, the spike protein, and VP7 compose the outer viral layer, in the cutaway, the middle layer is composed of VP6 and inside this layer, the core (that contains VP1 and VP3 and the viral RNA not seen) formed by VP2 can be seen. into three types (I, II, and III) and are thought to be important in the entry of metabolites required for RNA transcription. Images of actively transcribing double-layered particles have been obtained (20) and the molecular localization of VP1 identified (27). The exit of nascent mRNA from the double-layered particles occurs via type I channels that do not differ in their structure from nontranscribing double-layered particles. Viral transcription may occur simultaneously from each of the 12 type I channels in the viral particle. Approximately one-fourth of the viral RNA is organized in an ordered dodecahedral structure localized near a VP1 (the viral polymerase), VP3 complex at the base of the type I channels (20). Further studies, in which actively transcribing particles have been incubated with MAbs that block transcription, have shown that the continuous translocation of nascent mRNA through the capsid is critical for efficient mRNA elongation and that blockage of translocation causes premature termination of transcription (28).

### Viral Genome

Rotavirus contains 11 segments of dsRNA that range in size from 0.6 to 3.3 kilobase pairs with a total genomic size of approximately 18 kilobases. These segments are numbered according to size from largest (segment 1) to smallest (segment 11) (11). With the exceptions of segments 9 and 11 (which are bicistronic at least in some viral strains), each RNA segment contains a single open reading frame (ORF) with relatively short 5' and 3' terminal conserved noncoding regions. These conserved noncoding terminal sequences differ between RVA, RVB, and RVC and could be one of the factors that restrict reassortment between different groups of rotavirus. Positive strands of the dsRNA are capped at their 5' ends but do not possess a polyadenylation tract at their 3' end (11).

The genomes of rotaviruses are highly diverse. In decreasing order of relative importance, three primary sources for this diversity have been proposed: point mutations, reassortment, and rearrangement of the viral genome (11). *In vitro* studies have revealed a mutation rate of  $<5 \times 10^{-5}$  mutations per nucleotide per viral replication cycle. This rate of mutation suggests that the average rotavirus genome differs from its parent genome by at least one mutation. Reassortment of gene segments also occurs at high frequency during mixed infections with two or more rotaviruses both *in vitro* and *in vivo*. In humans, the epidemiologic consequences of gene reassortment and the generation of serotypic diversity are much less dramatic than for influenza, although reassortment clearly occurs, especially in less developed countries (17).

Rearrangements (concatemerization, partial gene duplications, and deletions) of the viral genome segments have been observed, most frequently among rotaviruses recovered from chronically infected immunodeficient children (29). Rotaviruses with rearranged genome segments can also be generated *in vitro* following multiple passages at a high multiplicity of infection. Gene rearrangements generally involve the nonstructural proteins and VP6.

### Viral Structural and Nonstructural Proteins

In addition to six structural proteins (designated as VP followed by a number), rotaviruses encode six nonstructural proteins (designated as NSP followed by a number). The gene coding assignments for these proteins were initially established with prototypic rotavirus strains that were easily cultured *in vitro*, like the simian table 3 SA11 strain (Table 1). A few hours after viral entry, perinuclear non-membrane-bound, electron-dense cytoplasmic inclusions called viroplasm appear in infected cells, in which RNA replication, genome packaging, and the initial steps of assembly of double-layered particles take place.

VP1 binds the 3' end of the viral RNA, but its transcriptase activity is functional only in association with VP2 (22). The viral-like particles (VLPs) formed by VP1/2 are the minimal combination that supports RNA replication (11, 22). A conserved rotavirus specific motif present on the VP1 of RVA, RVB, and RVC is probably important for the structural or functional activity of the polymerase.

Baculovirus-expressed VP2 binds double-stranded RNA and DNA and assembles in the cytoplasm of infected cells in core-like particles 45 nanometers in diameter (11). The role of VP2 in the assembly of VP1 and VP3 and in replicase activity appears to be primarily structural and is linked to its ability to bind the mRNA template for minus-strand synthesis (11).

VP3 is found at the vertices of the inner core and it is a multifunctional capping enzyme because it has both guanylyltransferase and methyltransferase activities (30). Recently, VP3 was also found to contain a phosphodiesterase (PDE) motif and to have the capacity to inhibit RNase L-activation during the innate immune response (31).

VP4 trimers form spikes on the virion surface (24). VP4 has been shown to be the viral attachment protein both *in vivo* and *in vitro*, a determinant of viral growth *in vitro*, and a virulence factor *in vivo* (11, 32). Trypsin treatment of rotavirus cleaves VP4 into VP8\* (amino terminal) and VP5\* proteins and greatly enhances viral infectivity *in vitro* (11).

VP8\* contains the most sequence variation in VP4 and determines the viral P genotype (11). Antibodies against VP8\* neutralize the virus by inhibiting viral attachment. VP8\* has been shown to be responsible for the ability of

**TABLE 1** The dsRNA segments and encoded proteins of simian rotavirus SA11

dsRNA segment (Size bp)	Proteins (#: protein structure/function)	Protein size: no. of aa (kDa)	Protein copies/particle	Protein location	Functions
1 (3,302)	VP1 (Pol)	1,088 (125.005)	<25	inner capsid at 5 fold axis	RNA-dependent RNA polymerase, ssRNA binding, located at the 5-fold axis inside the inner capsid, part of minimal replication complex
2 (2,690)	VP2 (T1)	880 (102.431)	120	inner capsid shell	Inner capsid structural protein, sequence nonspecific RNA-binding activity, myristoylated, part of minimal replication complex
3 (2,591)	VP3 (Cap)	835 (98.120)	<25	inner capsid at 5 fold axis	Guanylyltransferase, methyltransferase, basic protein, part of virion transcription complex, phosphodiesterase (PDE), likely inhibits RNase L activation
4 (2,362)	VP4	776 (86.782)	120	outer capsid spike	Trimers form outer capsid spike, P-type neutralization antigen, haemagglutinin, cell attachment protein, involved in cell tropism and virulence. Cleavage by trypsin into VP5* and VP8* enhances infectivity
	VP5*	529 *247–776 (60.000)			VP5* permeabilizes membranes
	VP8*	247 *1–247 (28.000)			VP8* hemagglutinin, highly variable sequence, and determines P genotypes
5 (1,611)	NSP1	495 (58.654)	0	nonstructural	Associates with cytoskeleton, extensive sequence diversity between strains, two conserved cysteine-rich zinc-finger motifs, RNA binding, has a role in suppressing the host IFN response, nonessential for <i>in vitro</i> replication in some strains
6 (1,356)	VP6 (T13)	397 (44.816)	780	middle capsid	Major virion protein, middle capsid structural protein, homotrimeric structure, subgroup antigen, myristoylated, hydrophobic region required for transcription
7 (1,049)	NSP3	315 (34.600)	0	nonstructural	Homodimer, specifically binds 3' end of rotavirus mRNA, binds eIF4G1, involved in cellular translational regulation
8 (1,059)	NSP2 (Vip)	317 (36.700)	0	nonstructural: in viroplasms	Nonspecific ssRNA-binding, accumulates in viroplasm, involved in viroplasm formation, NTPase and helicase activity, homomultimer (4–8 subunits), binds NSP5 and VP1, regulates NSP5 autophosphorylation
9 (1,062)	VP7	326 (37.368)	780	Virion surface glyco-protein	Outer capsid structural glycoprotein, G-type neutralization antigen, N-linked high mannose glycosylation and trimming, RER transmembrane protein, cleaved signal sequence
10 (751)	NSP4	175 (20.290)	0	nonstructural	Enterotoxin, receptor for budding of double-layered particle through ER membrane, N-linked high mannose glycosylation, uncleaved signal sequence, RER transmembrane glycoprotein, putative Ca <sup>++</sup> /Sr <sup>++</sup> binding site, secreted cleavage product. NSP4 is a pore-forming protein (viroporin) that elicits the release of endoplasmic reticulum (ER) luminal calcium into the cytoplasm of the infected cell
11 (667)	NSP5	198 (21.725)	0	nonstructural: present in viral inclusion bodies	Interacts with NSP2 and NSP6, homomultimerizes, O-linked glycosylation, (hyper-) phosphorylated, autocatalytic kinase activity, binds ssRNA, component of viroplasm
	NSP6	92 (11.012)	0	nonstructural	Product of second out-of-frame ORF, interacts with NSP5, localizes to viroplasm, other functions unknown

#: Protein structure/function: RNA polymerase = (Pol); Inner virus structural protein with T = 1 symmetry = (T1); capping enzyme = (Cap); Inner virus structural protein with T = 13 symmetry = (T13); viral inclusion body or viroplasm matrix protein = (Vip). Other species of rotavirus within the genus may have proteins of different sizes.

\*These proteins are produced by the VP4 gene.

selected rotavirus strains to bind sialic acid and for the hemagglutinating activity present in many animal strains but absent in most human rotavirus strains. Structural analysis of the VP8\* protein shows that it belongs to the galectin family of lectins expressed in enterocytes (33).

VP5\* has been shown to function as an additional component of the rotavirus attachment complex (34). Also, VP5\* is a specific membrane-permeabilizing protein which likely plays a role in the cellular entry of rotavirus (35).

VP6 is the major structural protein of the inner viral capsid (middle viral layer). VP6 is the most immunogenic viral protein and carries group- and subgroup-specific epitopes. The VP6 domains necessary for binding to VP2 are conserved in different rotavirus serogroups and are necessary for double-layered particle formation (11). Although not required for *in vitro* replicase activity, VP6 is required for the transcriptase activity, but its exact role in this function is unknown (36).

VP7 can be coded by gene segments 7, 8, or 9 depending on the viral strain (11). It is the major constituent of the outer rotavirus layer and the target of type-specific as well as heterotypic neutralizing antibodies. VP7 is a glycoprotein with three potential sites for N-glycosylation that are used variably, depending on the viral strain. Glycosylation of VP7 can influence its antigenicity. The retention of VP7 in the endoplasmic reticulum (ER) is mediated by a signal peptide sequence and other unique residues of the protein (11). Two neutralizing antibody epitope binding regions have been structurally defined for VP7 (25, 37), and antibodies recognizing them inhibit uncoating of the virion outer layer.

The amino acid sequence of NSP1, reported to bind zinc and RNA, is the most variable of all the rotavirus proteins. NSP1 has been implicated in host range restriction in the mouse model, although not in swine (11, 32), and appears to be dispensable for growth in some cell culture systems. Depending on the strain and host, NSP1 is used by the virus to evade the IFN response by promoting degradation of IRF3 or NFκB and inhibiting interferon-mediated STAT1 activation (38).

NSP2 interacts with NSP5, has helicase activity, and is present at high concentrations in the viroplasm, where viral replication takes place. NSP2 functions as an octamer with multiple enzymatic activities and it is considered the principal regulator of viroplasm formation (39).

NSP3 is a sequence-specific RNA binding protein that binds the nonpolyadenylated 3' end of the rotavirus mRNAs (40). NSP3 also interacts with the cellular translation initiation factor eIF4GI and competes with cellular poly(A) binding protein (PABP) (40). The competition between NSP3 and PABP for eIF4G has been postulated to be responsible for the shut-off of host cell translation seen during rotavirus infection (11). However, recent data suggest that rotaviruses reduce host protein translation by blocking the nucleocytoplasmic transport of polyadenylated mRNAs, in which NSP3 seems to play a role (41). Moreover, other recent data also suggest that NSP3 is a translational surrogate of the PABP-poly(A) complex and therefore cannot by itself be responsible for inhibiting the translation of host poly(A)-tailed mRNAs upon rotavirus infection (42).

The capacity of NSP4 to bind double-layered particles and insert them into the ER plays an important role in viral morphogenesis, and it is also a viroporin (11). NSP4 was the first putative viral enterotoxin described (43). A fragment of NSP4 is secreted from infected cells via a raft-dependent pathway (44). NSP4 is associated with virulence in mice (45), virulence of a porcine rotavirus, and host-range restriction of a human rotavirus (46). However, in humans and

mice no clear association between virulence and specific NSP4 sequences has been identified (11).

NSP5 is a phosphoprotein with putative autocatalytic kinase activity localized to the viroplasm associated with NSP2, and it is a key protein during viral replication. NSP5 is present in infected cells as various isoforms, which vary according to different patterns of O-linked glycosylation (11).

NSP6 is the product of the second ORF of segment 11. It interacts with NSP5 and might have a regulatory role in the self-association of NSP5 and thus in viral replication (11).

## Biology

### Replication Strategy

Viral replication is understood mainly from *in vitro* studies (Figure 3). The process of viral attachment and entry is mediated by multiple interactions between rotavirus and the cell surface, and varies for different rotavirus strains (34, 47). Historically, RVA has been classified as sensitive to neuraminidase (NA) (most animal strains) or NA resistant (most human strains), depending on their susceptibility to the treatment of cells with NA and thus the presence or absence of sialic acid involvement in their attachment process (47, 48). However, NA-resistant rotavirus strains have been shown to bind to internal sialic acids that are not affected by NA (34). Moreover, P[8] and P[4] human rotavirus recognize H-type histo-blood group antigens (HBGA), whereas neonatal P[11] strains recognize the precursor of H-type 2 HBGA, referred to as type II glycans (47, 49, 50). Biochemical studies showing the involvement of N-glycoproteins, glycolipids, and cholesterol in rotavirus infection suggests that the integrins and other proteins involved in the attachment and entry process are likely to form part of lipid microdomains (rafts) in the cell membrane (34). However, inhibition of viral entry with agents specific for all the identified putative receptors/coreceptors decreases viral infectivity by less than 1 log, suggesting that more relevant entry factors are likely to be identified or that these known entry factors are redundant (34).

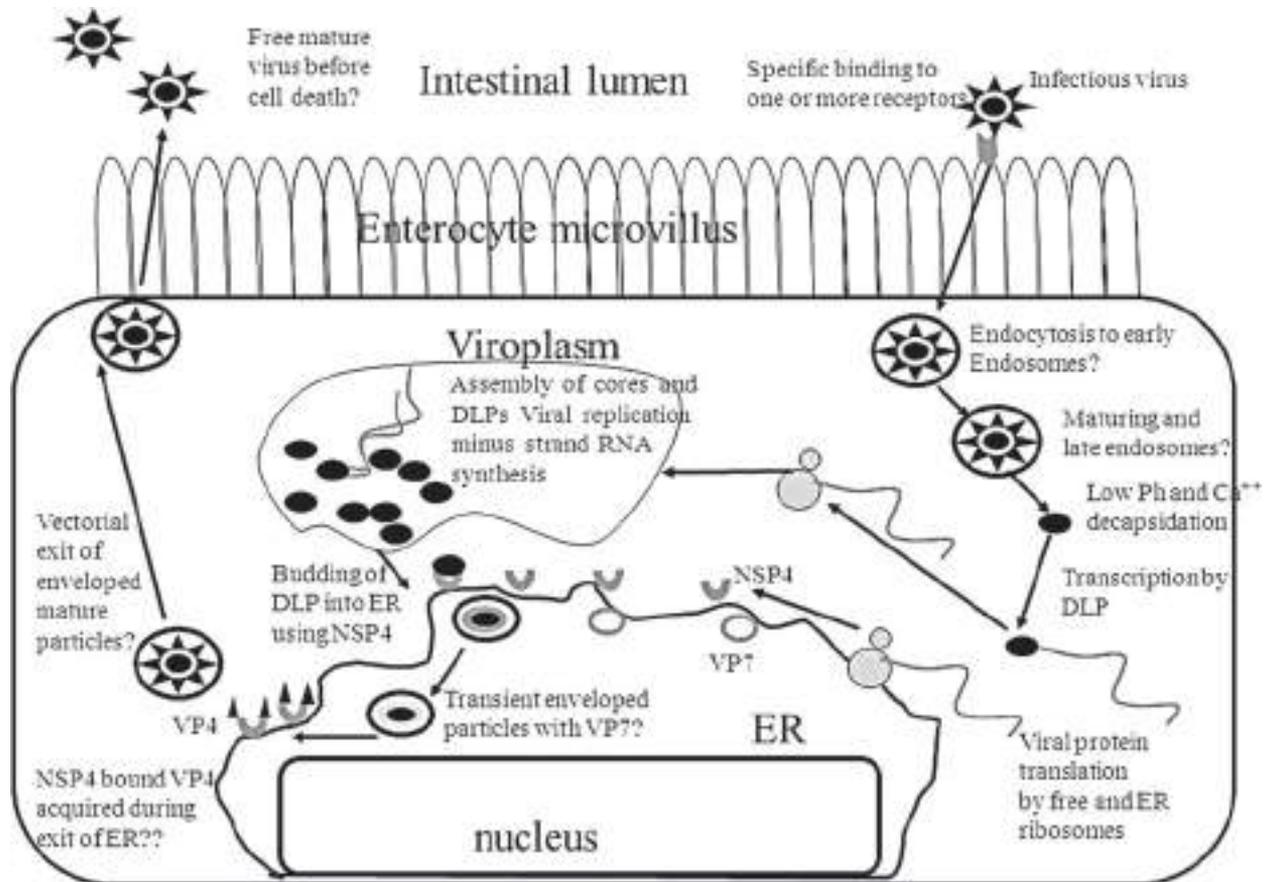

### Host Range

Animal and human RVA can reassort *in vitro* and *in vivo*; for human RVA, multiple reassortment and interspecies transmission events contribute to their diversity (51). Nevertheless, there is a significant restriction of growth of rotavirus from one host species in another (host-range restriction); this restriction formed the basis for the development of Jennerian rotavirus vaccines (see the Vaccine section).

### Growth in Cell Culture

Although initially growth of human rotavirus *in vitro* was very difficult, the discovery that trypsin treatment enhanced viral yield led to the cultivation of most isolates. Biochemical studies of rotavirus gene expression and function have been done both in the MA104 cell line (monkey kidney cells) and in polarized intestinal epithelial cell lines (52). The use of intestinal organoids (fragments of intestinal villi) has been recently proposed as a more physiological model to study rotavirus replication (53).

It is possible to construct infectious cDNA for many RNA viruses. However, transfection of purified rotavirus RNA or cDNA into permissive tissue culture cells, without helper viruses, has failed to yield infectious virus. Because of this, it has been impossible to efficiently use reverse genetics for rotaviruses, and researchers have been unable to manipulate the viral genome easily and to perform extensive functional studies of the viral genes. A reverse-genetics

**FIGURE 3** Schematic representation of the rotavirus replication cycle in intestinal polarized epithelial cells. The initial cell attachment step involves binding to cellular glycans and subsequent interactions with multiple receptors/coreceptors mediated by VP8\* and VP5\*, respectively (47). As a second step in entry, RVA have been proposed to interact with integrins  $\alpha 2\beta 1$ ,  $\alpha V\beta 3$ , and  $\alpha X\beta 2$  and with the heat shock cognate protein hsc70 (34). Although not completely established, most studies suggest that rotaviruses enter cells by endocytosis (34) and then lose VP7 and VP4 (11). In the cytoplasm, double-layered particles gain transcriptase activity and begin to synthesize viral mRNAs. Viral proteins accumulate in the cytoplasm in an electron-dense region called the viroplasm, where the viral genome is replicated and the assembly of progeny double-layered particles takes place (22). An initial stage in viral assembly that is incompletely understood involves the assortment of single-stranded positive RNA strands corresponding to each one of the 11 gene segments (216). A viral intermediate particle that consists of VP1, VP2, VP3, and probably all the nonstructural proteins, except NSP4, is then formed (11). This complex acquires VP6 and during this process the nonstructural proteins are lost. Subsequently, the double-layered particles via VP6 interact with NSP4 that has been synthesized by ER ribosomes (217). This interaction leads to budding of the double-layered particles (DLP) into the ER lumen. In this organelle the particles acquire a transient lipid membrane. Subsequently the viral particles acquire VP7 and VP4 and lose the transient enveloping membrane. The exit of the mature triple-layered viral particles from the ER and the cell has been incompletely elucidated and may involve a raft-dependent pathway before cell lysis occurs (218, 219) or may be a postlysis event. The mechanism of cell death induced by rotavirus (before or after viral exit) is incompletely understood but is dependent on cell apoptosis *in vitro* and *in vivo* in mice (220, 221).

method to create rotaviruses with complementary DNA (cDNA)-derived reassorted genes was developed but, since this method relies on helper virus functions, it has proven relatively inefficient (54). At least two additional reverse genetic methods that also use helper viruses have been described (55, 56) that may prove more useful. As an alternative approach to study the function of individual viral genes, inhibition of specific RNAs with small interfering RNA (siRNA) (57) has proven quite useful.

## EPIDEMIOLOGY

### Distribution

Rotavirus infection occurs worldwide; most children develop antirotavirus antibodies by the age of 2 years. The

incidence of rotavirus infection is comparable in developed and developing countries, implying that improvements in sanitation and hygiene will be ineffective for the control of this infection.

### Incidence and Prevalence of Infection

The estimated incidence of rotavirus diarrhea varies depending on the method used for detection and case definition and on the epidemiologic settings under study. The incidence of rotavirus diarrhea defined by prospective studies in developing countries has varied between 0.07 and 0.8 episodes per child per year (6, 11). Compared with diarrhea caused by other microorganisms, the diarrhea produced by rotavirus infection is particularly severe and frequently associated with dehydration. Rotavirus infections account for a low percentage (8%) of all cases of community-acquired diarrhea,

28% of diarrhea associated with outpatient or clinic visits, and 39% of hospitalizations for diarrhea among young children (11).

The incidence of various rotavirus serotypes/genotypes varies by geographic location and time (17, 58). Of the 35 P and 26 G genotypes described to date, P genotypes [4], [6], [8], [9], [10], [11], [14], and [25] and G genotypes 1–4, 9, and 12 are epidemiologically important for humans (11, 58). A review of rotavirus genotyping studies from 1996 to 2007 characterized changes in RVA strains in the prevaccine era (58). Five genotypes (G1-G4 and G9) accounted for 88% of all strains, with temporal variation being evident. The prevalence of G1 strains declined from 2000 onward, while G3 strains reemerged, and G9 and G12 strains emerged during the same period. Rotavirus genotyping studies have been extensively performed in the postvaccine era (2007 to 2012) to determine if vaccine administration influenced the genotypes of circulating strains (17). Similar to the prevaccine era, the six strains most commonly reported in people were found in approximately 73% of the samples (G1P[8], 31.2%; G2P[4], 13.0%; G3P[8], 10.7%; G9P[8], 10.2%; G4P[8], 5.0%; G12P[8], 2.7%). Following prevaccine trends, temporal geographic variations in strain distribution have been observed in the postvaccine era. For example, in South America G2[P4] strains, and not G1[P8], are the predominant strain. In Africa, prevalence of viruses with genotypes P[6] and G8 was greater than 1%, including G2P[6] (8.2%), G1P[6] (6%), G3P[6] (5.5%), G12P[6] (3.5%), G8P[6] (1.7%), G8P[4] (1.8%), and G1P[4] (1.1%). Moreover, evidence for genetic interaction between vaccine and wild-type strains was observed, and transient predominance of heterotypic strains (G2P[4]) was observed mainly in countries using the Rotarix™ vaccine (the human monovalent vaccine referred to as RV1, see below). However, this finding requires further monitoring, and a clear effect of vaccine introduction on long-term rotavirus strain epidemiology has not been established.

### Subclinical Infections

In a cohort of 200 Mexican children followed from birth to 2 years of age with weekly monitoring of rotavirus excretion in stool samples and regular serologic testing, approximately 50% of rotavirus infections were asymptomatic (59). The percentage of asymptomatic infections increased during the second, third, and subsequent infections, presumably as a result of the development of both homotypic and heterotypic immunity.

### Epidemic Patterns and Seasonality

In the temperate zones of the world (mostly developed countries), rotaviral infection occurs primarily during epidemic peaks in the cooler months of the year (60). This pattern is not seen in countries within 10 degrees of the equator, where infection occurs in an endemic fashion throughout the year (60). No clear explanation is available for the rotavirus winter epidemic peaks; higher airborne transmission (60), higher stability of rotavirus with low relative humidity, or indoor crowding have all been proposed. However, clear association between lower relative humidity and development of rotavirus infections has not been found in all settings where this variable was analyzed (11).

Before the introduction of rotavirus vaccination, a yearly wave of rotaviral illness spread across the United States (61) and Europe (62) following peculiar spatiotemporal patterns. In the United States this pattern of spread correlated with variation in birth rates, thereby suggesting that the number

of babies experiencing their first infection is one of the primary drivers of rotavirus epidemics (63). The high birth rates in developing countries may also influence the differential epidemiologic distribution of rotaviruses. The widespread use of rotavirus vaccine has greatly reduced or eliminated this spatiotemporal spread of rotavirus in the United States (64).

### Age-Specific Attack Rates

The peak incidence of rotaviral illness in children in developing countries is between 6 to 11 months of age. In contrast, in developed countries like the United States and Canada, the highest rates occur during the second year of life. This difference between developed and developing countries has been proposed as due to the seasonal pattern of rotavirus infection in the developed countries; a child born just after the rotavirus season in a developed country would have almost a year before being exposed to the next rotavirus season, whereas a child born in a rotavirus-endemic country could become exposed throughout the year. Rotaviral infection is frequently asymptomatic in neonates (65–67), and neonatal strains isolated have been reported to have a particular P type and also specific differences in their VP7 and NSP4 genes when compared to pathogenic strains of similar serotypes (67). For this reason, it has been suggested that some strains found in newborns are naturally attenuated and could serve as vaccine candidates (65, 67). However, it is likely the newborn host rather than the viral strain is primarily responsible for the avirulent phenotype in newborns (66). The relative resistance to rotavirus illness in infants less than 3 months old may be a result of antibodies acquired by placental transfer from the mother (66) and possibly a difference in the glycans available for viral binding in the neonatal intestine (50).

Rotaviral disease of adults is seen occasionally in the elderly and in people who take care of sick children. In a prospective study of families, almost 50% of the caretakers of children with rotavirus diarrhea become infected with rotavirus, and 50% of these infections were accompanied by mild symptoms (68). In challenge studies of adults with virulent rotavirus, low levels of preexisting serum antibodies were associated with symptoms (69). Given the importance of rotavirus disease in the elderly, trials of pediatric vaccines are being implemented in this population (70).

### Risk Factors and High-Risk Groups

Malnutrition, with its probable associated immunodeficiency, is a predisposing factor for severe life-threatening dehydration associated with rotavirus disease (71). In developed countries, low-birth-weight and premature infants appear to be at greater risk for hospitalization with rotavirus gastroenteritis (72). Interestingly, HIV has not proven to be a substantial risk factor for rotavirus illness (73), in contrast to severe combined immunodeficiency diseases (74). In the United States, although breast feeding was found to be protective, low-birth-weight infants, children in daycare, those covered by Medicaid or without insurance, and those having another child in the house had an increased risk of rotavirus hospitalization for rotavirus disease (75). African-American origin (76), maternal age, and maternal education less than high school may also increase the risk of hospitalization for rotavirus disease (75). On the other hand, in less developed countries breast feeding was not shown to protect against rotavirus illness (77). Thus, socioeconomic factors seem to be most important for increasing the risk of hospitalization with rotavirus gastroenteritis (75). Also,

three recent studies that implicate HBGA as RVA receptors have shown that the HBGA glycan can determine susceptibility to disease in a strain-specific manner (78–80); however, these results need to be confirmed.

### Reinfections

In the cohort of Mexican children mentioned above, rotavirus reinfections were very common. Of the children studied, 96%, 69%, 42%, 22%, and 13% were reinfected 1, 2, 3, 4, and 5 times, respectively, during their first 2 years of life (59). The severity of disease rapidly decreased after the first infection and, remarkably, no child experienced moderate or severe disease after the second infection. In a more recent study in India, 56% of children were infected by 6 months of age (81). As in the Mexican study, protection against moderate or severe disease increased with subsequent infections but was only 79% effective after three infections.

### Transmission

Rotaviruses are usually transmitted by the fecal-oral route, but some indirect evidence has suggested that they could also be transmitted by the respiratory droplet route (82). While nasal shedding of an attenuated human rotavirus strain in pigs has been reported, this phenomenon was less common when a virulent human rotavirus was examined in swine, suggesting that, if the pig model were relevant for study of human rotavirus transmission, then this mode of transmission might vary by viral strain (83). The origin of a rotavirus that infects a child who is not in contact with other children is unclear but may be due to subclinical infection in household adults (11). Although rotaviruses have been detected in both treated and untreated sewage water, waterborne outbreaks of rotavirus are probably rare because of the relative instability of rotavirus at high relative humidity (11). Foodborne outbreaks are also rare, although it has been reported that oyster and mussel samples can be heavily contaminated by rotavirus (84).

The efficient transmission of rotaviruses in the environment is assured, at least in part, because they are shed in the feces at a very high concentration (up to  $10^{11}$  particles per gram) and are very resistant to degradation at ambient temperatures.

Institutions, such as daycare centers, with high concentrations of young children have an increased risk of developing rotaviral disease outbreaks. Moist surfaces including water fountains and water-play tables are common sources of rotavirus contamination in daycare centers (85). Rotavirus infection also occurs frequently in neonatal nurseries and, although most of these infections seem to be asymptomatic, some are not (86). Nosocomial rotavirus infections, especially in newborn nurseries, can be caused by a predominant rotavirus strain that differs from the strain currently circulating outside of the hospital (86, 87).

## PATHOGENESIS IN HUMANS

### Incubation period

The incubation period for rotavirus infection has been estimated to be less than 48 hours, based on animal studies and experimental infection of adult volunteers. This very short incubation period, which permits substantial viral replication prior to the amplification of a memory immune response, may be one of the factors that explains why multiple reinfections (generally mild or asymptomatic) occur with rotavirus (88).

### Patterns of Virus Replication

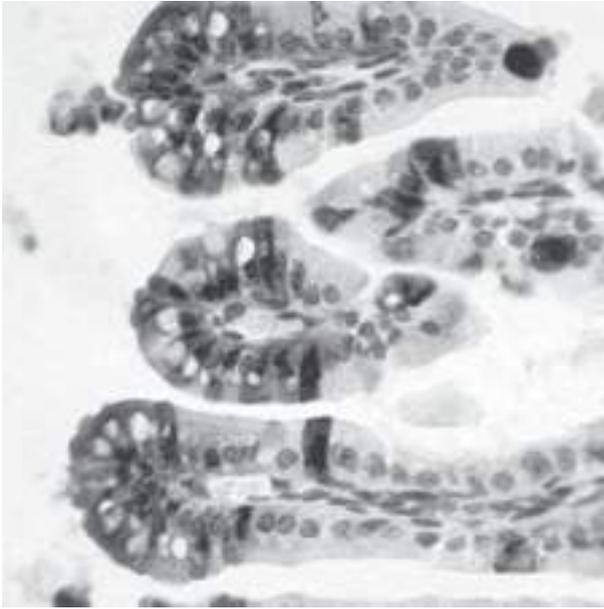

The duration of viral excretion in infected children, determined both by ELISA and a sensitive PCR method, ranges from 4 to 57 days after onset of diarrhea (89). In about 43% of the children viral excretion stops in 10 days and within 20 days in 70% of the children. Extended excretion (mainly with the primary infecting rotavirus), but at generally substantially diminished levels, is detected for 25 to 57 days in the remaining 30% of the children.

An important study in cattle showed that rotaviruses penetrate but do not replicate in the intestinal M cells of Peyer's patches, an observation suggesting that rotaviruses can come in contact with the immune system by means of these cells (90). Although it was once thought that in immunocompetent children rotavirus infection was restricted to the mature enterocytes on the tips of the small intestinal villi (11), studies in both normal humans and animals clearly showed that this paradigm is incorrect. Most rotavirus infections are associated with antigenemia (91), RNAemia (92), and some level of viremia (93) in the initial phase of rotavirus-induced diarrhea in animals and children. In mice, the level and location of extraintestinal replication varies among rotavirus strains, and viral replication seems to occur in several leukocyte subsets (94). However, the clinical relevance of the findings of extraintestinal spread and replication is unclear, and in children and animals the greatest rotavirus replication occurs in the mature villus tip cells of the small bowel. Immunostaining with antibodies directed against nonstructural rotavirus proteins in autopsy samples from liver and kidney from severely immunodeficient children with chronic rotavirus infection suggests that viral extraintestinal replication occurs under these circumstances (74).

### Pathology and Pathogenesis

The pathologic changes in the intestines of children infected with rotavirus include shortening and atrophy of the villi, mononuclear infiltration in the lamina propria, and distended cisternae of the ER (95). However, a direct relationship between the extent of histopathology and disease has not been demonstrated. For example, in a study of intestinal biopsies of children with rotavirus diarrhea, 95% of 40 patients did not have prominent histopathological changes despite symptoms (96). In the mouse model, rotavirus disease is associated with very modest histopathological findings, suggesting that the mechanism or mechanisms for the induction of rotavirus diarrhea could be similar in mice and humans. As noted above, the bulk of rotavirus infection appears to be restricted to the mature villus tip cells of the small bowel of all species (Figure 4), while low levels of viremia and extraintestinal replication probably take place in other organs. Using semiquantitative PCR, a correlation has been found between the levels of viral RNA in stool and the severity of diarrhea (97), suggesting that children with more severe diarrhea excrete more virus than children with less severe disease.

Study of the physiological basis of rotavirus-induced diarrhea in humans and in several animal models has yielded diverse and at times contradictory findings (95). In the pig model, rotavirus infection is associated with decreased intestinal lactase content, increased fecal lactose loss, and an increased fecal osmotic gap (95). These findings are consistent with the hypothesis that malabsorption of carbohydrates causes an osmotic diarrhea during rotaviral infection. In humans, a lactase deficiency has also been associated with

**FIGURE 4** Cross-section of the small bowel villi from a rotavirus-infected mouse immunostained for rotavirus antigen. Note the restriction of growth of rotavirus to the mature villus tip cells of the small bowel.

rotavirus gastroenteritis (98). The most common explanation for the malabsorption and lactase deficiency associated with rotavirus diarrhea is the direct destruction of the enterocyte during viral replication. An alternative explanation that is more congruent with cases of rotavirus disease not associated with substantial pathologic findings is that rotavirus affects the turnover of disaccharidases in the microvilli (99). In support of this theory, it has been shown that rotavirus reduces sucrase-isomaltase expression and activity in human intestinal epithelial tumor cell lines by disrupting protein targeting and the organization of the microvillar cytoskeleton before apparent cell destruction occurs (100). In children with rotavirus diarrhea, some (98, 101) but not all (102) studies have shown increased mucosal permeability. A possible explanation for these *in vivo* findings has been suggested by *in vitro* experiments that show that rotavirus induces structural and functional alterations in tight junctions of polarized intestinal Caco-2 cell monolayers without alterations in cell and monolayer integrity (103). A recent study in mice did not find evidence for increased permeability at the onset of disease (104). The heterologous SA11 recombinant NSP4 and a synthetic peptide derived from it have been shown to induce an age-dependent secretory diarrhea in mice (43). In these studies, mouse pups born to dams immunized with the NSP4 derived peptide were partially protected from the diarrhea induced by a heterologous rotavirus strain. The homologous mouse NSP4 has also been shown to induce diarrhea in mice.

Because cystic fibrosis transmembrane conductance regulator (CFTR)-knockout mice, which do not respond to any known intestinal secretagogues, have homologous rotavirus-induced diarrhea, and NSP4 and the NSP4-derived peptide also induce diarrhea in these mice, NSP4 may mediate its effect through a novel secretory (non-CFTR-dependent) pathway or by another nonsecretory mechanism (11). Rotavirus also induces intestinal fluid and electrolyte secretion by activation of the enteric nervous system in the intesti-

nal wall (105). In addition, rotavirus infection and NSP4 stimulate release of serotonin from intestinal sensory enterochromaffin cells *in vitro* and *ex vivo* (106). Mouse pups infected with rotavirus responded with central nervous system activation in brain structures associated with vomiting, providing an explanation for this symptom in rotavirus disease. Also in mice, rotavirus disease is associated with increased intestinal motility via activation of the myenteric nerve plexus (104). The fact that children with rotavirus gastroenteritis can be successfully treated with racecadotril, an enkephalinase inhibitor that can act on the enteric nervous system, also supports a role for this mechanism in rotavirus-induced diarrhea (107).

The three factors (malabsorption, NSP4, and enteric nervous system) proposed to explain rotavirus diarrhea could play different relative roles depending upon the animal species analyzed and, for a given species, could be operating together, with the relative importance of each mechanism varying depending upon the stage of infection. Determining the relative importance of each mechanism in human rotavirus-induced diarrhea might help in developing more effective vaccine strategies or new strategies to treat rotavirus diarrhea.

### Immune Responses

As discussed above, although symptomatic reinfection with rotaviruses can occur throughout life, the severity and number of rotavirus infections diminishes with increasing age, and, in most settings examined to date, severe infections seem to be primarily limited to the first or second infection (88). This pattern of infection strongly suggests that a protective immune response against rotavirus develops after primary infection but that the generation of complete immunity requires multiple infections (108). Chronic rotavirus replication, prolonged symptoms, and extraintestinal infection in children with severe combined T and/or B immunodeficiencies (29, 74) also argue for an important role of the adaptive immune system in immunity to rotavirus. As is the case with severely immunocompromised children, some, but not all, strains of T- and B-cell immunodeficient mice become chronically infected with murine rotavirus (88).

### Innate Immunity

Studies in mice have shown that rotaviruses are inactivated in the stomachs of adult but not newborn mice (109), which suggests that the development of gastric acid and pepsin secretion may be an important host defense factor against the virus. Lactadherin present in human milk specifically binds to rotavirus and inhibits its replication *in vitro* (110). Lactadherin levels in maternal milk are significantly higher in asymptomatic than symptomatic children with rotavirus infection, suggesting that this glycoprotein, rather than IgA, could be mediating an antiviral effect in milk.

The importance of innate immunity against rotaviruses has been indicated by experiments in which antibiotic treatment of mice reduces rotavirus infection in a toll-like receptor (TLR)-dependent fashion (111, 112). A potential mechanism of immune evasion is rotavirus stimulation of the secretion of TGF- $\beta$  in polarized Caco-2 cells, and this effect has been shown to inhibit the capacity of dendritic cells to activate Th1 T cells (113, 114). Rotavirus has developed multiple mechanisms to evade interferon (IFN) innate immunity: NSP1, in particular, induces the proteosomal degradation of interferon regulatory factors (IRF) 3, 5, and/or 7, depending on the strain (115). In addition, NSP1 has recently been shown to inhibit the amplification phase of the

innate response by inhibiting STAT1 activation (38). Mice lacking the receptor for type III IFN, and to a lesser degree the receptor for type I IFN, have been reported to be more susceptible to murine rotavirus infection (116). On the other hand, STAT1 knockout mice (deficient in types I, II, and III interferon signaling) have been shown to be only marginally more permissive for homologous murine rotavirus replication (38). Hence, the relative roles of the IFNs in suppressing homologous rotavirus replication are not completely clear. However, the vomiting associated with rotavirus disease has been correlated with the increased levels of serum IFN- $\alpha$  found in children with acute rotavirus infections (117). Interestingly, interleukin (IL)-22 has been shown to act synergistically with type III IFN to restrict rotavirus replication (118). Finally, the combined effect of IL-22 and IL-18 is able to prevent and cure rotavirus infection in mice through a TLR5/NLRC4 mechanism (119).

### Specific Humoral and Cell-Mediated Immune Responses

The immune response against rotavirus has been extensively studied in several animal models (88). Because rotavirus replication is primarily restricted to the enterocyte *in vivo*, the immune response against rotavirus originates in and exhibits its effector function directly at the intestinal mucosa. Intestinal T cells and neutralizing antibody responses are relatively weak in neonatal mice following homologous murine rotavirus infection (120, 121). Moreover, the presence of the integrin  $\alpha 4\beta 7$  (the intestinal homing receptor) has been shown to be required by B cells, but not CD8<sup>+</sup> T cells, for the migration of the lymphocytes to the intestine to provide immunity to rotavirus (88). The migration of the B cells to the intestine also depends on the presence of the CCR9 and CCR10 chemokine receptors (122). Although the studies in animal models have been enlightening, the immune response in humans may differ substantially. For example, while mice develop a primary lifelong protective intestinal IgA response against rotavirus, humans do not and can be reinfected multiple times.

A rotavirus-specific IgA coproantibody response occurs in 70% to 84% of children after a symptomatic infection (88). This IgA response has been reported to peak from 1 to 4 weeks after infection and then to decrease rapidly (108, 123). The relatively short duration of human intestinal antiviral IgA is probably one of the factors that contribute to multiple reinfections. During the acute phase of infection, IgM serum antibodies predominate and are subsequently replaced by IgG and, to a lesser extent, IgA (124). The IgG serum response is more durable than that of salivary or fecal IgA (125). During acute infection rotavirus-specific serum IgA has been shown to be directed principally against VP2 and VP6 and to broaden to include other structural and nonstructural proteins in the convalescent phase (126). Secondary infections will generally boost the fecal IgA response, and in many but not all children induce protective fecal antirotavirus IgA levels (108). Studies of human neutralizing antibody responses against rotavirus have shown that upon first exposures to rotavirus, children develop higher homotypic than heterotypic antibody levels (127). However, as the number of rotavirus infections increase, children develop more heterotypic antibodies.

To better understand rotavirus humoral immunity, specific B cells have been studied in both animals and children (128, 129). An important fraction of naïve human B cells bind rotavirus VP6 with low affinity (130), which highlights the importance of B cells as an innate component of im-

munity to rotaviruses. However, the Ig genes used by naïve rotavirus-specific B cells are different than those expressed by memory B cells, suggesting that the latter do not primarily develop from the former (131, 132). Moreover, rotavirus-specific B cells are enriched in CD27<sup>+</sup> memory B cells that express IgM (132, 133). Recently, using single-cell mass cytometry, intestinal and blood circulating rotavirus-specific B cells have been compared, and antibody secreting cells in the intestine and blood have been shown to be highly clonally related (134).

Based on ELISPOT and intracellular cytokine staining assays (135–138), healthy adults have circulating rotavirus-specific CD4 T cells that secrete IFN- $\gamma$  or IL-2, whereas cells producing IL-4, IL-13, IL-10, or IL-17 were below detection limits. The frequencies of rotavirus-specific CD4 T cells producing IFN- $\gamma$  in these subjects are comparable to those specific for other mucosal respiratory viruses (138). However, the majority of rotavirus-specific CD4 T cells were IFN- $\gamma$  single producers, followed by a low percentage of double IFN- $\gamma$ /IL-2 producers cells (138); they had the phenotype of terminally differentiated effector cells and were probably unable to provide long-term immunity (139). In agreement with their proposed intestinal origin, human rotavirus-specific CD4 T cells detected with a tetramer express both  $\alpha 4\beta 7$  and CCR9 (140).

### Correlates of Immune Protection

Studies in animal models and humans have shown that local intestinal antibody is probably the primary protective effector mechanism against rotavirus (127). In mice, other mechanisms, such as CD8<sup>+</sup> T cells induced by natural infection, can also mediate modest levels of short-term protection (88). Protective humoral immunity in several, but not all, animal models, is associated with the presence of neutralizing antibodies directed at VP4 and/or VP7 (88). In mice, non-neutralizing IgA antibodies directed against VP6 are able to protect against viral infection (141), probably by mediating intracellular viral inactivation during transcytosis through the enterocyte (141, 142). In addition, suckling pups nursed by dams vaccinated with an NSP4-derived peptide can be partially protected from heterologous rotavirus diarrhea (43). However, in pigs (the only animal model in which protection from disease and not viral infection is measured) NSP4 antibodies do not correlate with protection (143). Thus, immunity may vary according to the vaccine, the animal species, the route of vaccination, and age of the vaccinees (121).

In studies performed in daycare centers and orphanages, in which antibodies to rotavirus have been measured very shortly before a rotavirus outbreak, intestinal and serum antibodies have correlated with protection against natural rotavirus reinfection (88). Rotavirus-specific antibodies (stool IgA in particular) have also been correlated with protection in some (108) but not in other studies involving naturally infected as well as vaccinated children (88). In general, serum antibody levels have been better correlated with protection following natural infection than following vaccination (144). At present, we do not have a precise and reliable marker of protection induced by vaccination (127). This deficiency has been an impediment to the development of new rotavirus vaccines because the only way of determining whether a vaccine is effective is in large-scale field efficacy trials. Both serum-neutralizing antibodies and serum and stool G-type specific antibodies have been shown to correlate with protection in studies carried out in an orphanage and daycare center as mentioned above (123).

Nonetheless, neutralizing antibodies have not been shown to correlate with protection in other settings (88). Likewise, in vaccine studies, some investigators (145) but not others have found a correlation between the presence of neutralizing antibodies and protection (88). The age at which children receive their first dose of the human RV1 seems critical in inducing neutralizing antibodies, and the frequency of children developing these antibodies is significantly below the level of protection induced by the vaccine (146). Thus, although neutralizing antibodies seem to play a role in protection, it is possible that antibodies against other proteins (VP6 and NSP4) or other mechanisms can also play a role in immunity. Recently, IgA antibodies against rotavirus have been shown to correlate with protection induced by RV1 (147). In addition, titers of rotavirus-specific IgA correlated with mortality in children under age 5 for both RV1 and RotaTeq™ (the bovine pentavalent rotavirus based vaccine referred to as RV5) (148). Polymeric antibodies (IgA or IgM) that have been secreted into the intestinal lumen can, by an unknown mechanism, be retrotranscytosed and reach the blood (88). In a small trial of a precursor to RV1, both titers of rotavirus-specific serum IgA and secretory antibodies correlated with protection, but this result needs to be confirmed (149).

The relative importance of maternal antibodies acquired transplacentally and from milk in protection against rotaviruses is unclear. In the pig model, antibodies acquired transplacentally (simulated by the passive transfer of serum from rotavirus-infected animals) or by colostrum could reduce the severity of primary rotavirus disease (150). These antibodies also inhibited the development of an effective mucosal immune response, and animals that received these antibodies were more susceptible to viral reinfection than the ones that did not receive the antibodies (150). It has been postulated that the relative resistance of newborns to rotavirus diarrhea is due to transplacentally acquired serum antibodies (66). Children breastfed with milk that contains antirotavirus neutralizing antibodies develop diarrhea to a similar extent as nonbreastfed children or those breastfed with milk lacking the antibodies (151). Breastfed children and nonbreastfed children seem to develop symptomatic or asymptomatic rotavirus infections to the same extent (110). The concentrations of lactadherin, but not rotavirus-specific secretory milk IgA, are higher in children with asymptomatic infection than in children with diarrhea. Thus, breastfeeding probably confers some limited protection against rotavirus but this effect is relatively minor compared to the effect breastfeeding has against several bacteria-induced diarrheas. Although some studies have shown slightly decreased vaccine “take” rates with breastfeeding (151), withholding breastfeeding during vaccination does not improve vaccine immunogenicity (152).

#### Correlates of Disease Resolution

The mechanisms that mediate disease resolution are multiple and probably redundant. In mice, CD8 T cells are probably the first immune mechanism that mediates rotavirus clearance (88), but in their absence antibody or other mechanisms can also perform this function.

### Clinical Manifestations

#### Major Clinical Syndromes

The primary clinical syndrome caused by rotavirus infection is acute gastroenteritis. Typically, rotavirus-induced diarrhea is watery, lasts for approximately 5 days, is often preceded by

the sudden onset of vomiting usually lasting 1 to 2 days, and is frequently accompanied by several days of fever (37.9°C or greater) and dehydration (153). Respiratory symptoms, although common in children with rotavirus infection, have not been specifically linked to this virus. Severe diarrhea in an age-susceptible child during the cool months of the year in a country with a temperate climate strongly suggests the diagnosis of rotavirus infection. Nonetheless, the clinical characteristics of rotavirus illness are not distinct enough to permit diagnosis based solely on physical examination and history, and laboratory confirmation of the diagnosis is necessary. However, laboratory diagnosis is seldom needed for therapeutic purposes in children with mild or moderate gastroenteritis.

Laboratory abnormalities in children with rotavirus infection are related to the extent of vomiting and dehydration (high urine specific gravity and electrolyte alterations) and should be investigated depending on the severity of these findings. The presence of reducing sugars in stool samples should alert the clinician to probable associated lactose intolerance (154). Occult blood and fecal leukocytes are found in small proportions, less than 16% and 39%, respectively, of rotavirus-infected children, but these findings are present at higher frequencies in children with bacterial infections and may suggest the differential diagnosis (155). Overtly bloody stools, prolonged diarrhea, leukocytosis, and a raised erythrocyte sedimentation rate also suggest a bacterial etiology (153). Children with rotavirus gastroenteritis often have elevated alanine aminotransferase (ALT) and aspartate aminotransferase (AST), suggesting that some hepatic involvement may occur during natural rotavirus infection (156, 157).

Rotavirus infection can cause severe and prolonged disease in children with severe combined primary immunodeficiency disease, some of whom shed virus chronically and develop disseminated infection (74). Acquired immunodeficiency also predisposes to severe rotavirus disease, and the virus can be a particular threat to severely immunosuppressed children with bone marrow and liver transplants (158). The role of rotavirus-induced disease in immunosuppressed adults with HIV and adult transplant patients is much less important (73, 159), although in some series death of patients with transplants has been associated with rotavirus infection (160).

#### Complications

Rotaviruses are not a major cause of prolonged diarrhea. However, diarrhea of rotavirus origin, especially in developing countries, can be the initiating factor for malnutrition with its accompanying immunodeficiency, which in turn makes children susceptible to other infectious diseases (161). Thus, the effects of rotavirus disease may not be limited to the morbidity and mortality associated *per se* with an episode of acute diarrhea. Some (but not all) studies have not found an association between natural rotavirus infection and intussusception (162–164). In mice, rotavirus enhances lipopolysaccharide (LPS)-induced intussusception (165). Moreover, natural rotavirus infection thickens the intestinal wall and enlarges mesenteric lymph nodes (166), suggesting a potential mechanism by which infection could promote intussusception. Studies aimed at clarifying this potential association are of great relevance, because RotaShield, the first licensed rotavirus vaccine, was withdrawn from the market because of its temporal association with very rare cases of intestinal intussusception. These cases mostly occurred in the first week after administration of the first vaccine dose (167). Although studies have failed to identify the reasons

RotaShield induced intussusception, it is important to note (see section on rotavirus vaccines) that this complication occurred mostly (80%) in children older than 3 months of age (168). A relationship between rotavirus infection and the development of diabetes has been proposed but not supported by experiments in mice or observations to date in children (169, 170). A possible association between RVC and the development of biliary atresia has been proposed by some (171) but not other studies (172). However, in rodents certain strains of heterologous simian RVA induce a biliary obstructive disease (173), which may be autoimmune in nature, since adoptive transfer of T cells from mice with rotavirus-induced biliary atresia into naive syngeneic recipient mice with severe combined immune deficiency resulted in bile-duct-specific inflammation in the absence of detectable virus. Also, some preliminary evidence suggests a possible association with celiac disease (174, 175). Seizures have been reported during rotavirus illness and in association with mild gastroenteritis caused by other viruses (176). The casual relation between rotavirus and seizures has been supported by the detection of rotavirus by PCR in some cerebrospinal fluid samples (176) and by the fact that rotavirus vaccination protects against childhood seizures (177). Electrolyte abnormalities and fever associated with infection could also explain some of the seizures, so a firm conclusion concerning the mechanism of seizures cannot be drawn at present. Many other rare complications have been associated with rotavirus infection, but due to the high frequency of rotavirus infections these associations probably occurred by chance.

## Laboratory Diagnosis

### Virus Isolation

Cell culture: At present cultivation of human RVA is a relatively straightforward task although rarely done in clinical laboratories. In contrast, very few RVB and RVC have been grown *in vitro*. Best results for growing human RVA are obtained using fecal samples (rectal swabs are less efficient) (11). With pretreatment of virus with trypsin (5 to 10 µg/ml) and subsequent incorporation of trypsin (0.5 to 1 µg/ml) in the medium of infected MA104 cells in roller tubes, 75% of human rotaviruses can be grown *in vitro* (11). Primary simian kidney cells (178) and intestinally derived cell lines such as the human colon adenocarcinoma cell line CaCo-2 (179) are probably superior to MA104 cells for primary isolation of rotavirus.

### Antigen Detection

The first method available for making the diagnosis of rotavirus infection was electron microscopy. Although this method has generally been replaced by the more readily available and sensitive solid phase immunoassays, it can still be of use, for example, for detecting nongroup A rotavirus and mixed infections with other enteric viruses. Of the commercially available latex agglutination tests and ELISA kits for the detection of rotavirus in stool samples, the latter are more sensitive and are probably the most commonly used assay for making the diagnosis of rotavirus infection (180). The commercial ELISA kits available can have a sensitivity and specificity of up to 98% and 100%, respectively. Among the ELISA tests, those that employ specimen-specific negative controls (preimmune serums as capture antibodies) are superior in minimizing false-positive reactions (180). ELISA kits that use G- and P-serotype-specific MAbs are also available to type the most frequent rotavirus strains that infect humans.

### Nucleic Acid Detection

Because in the early rotavirus studies it was impossible to culture the different viral isolates, the characteristic migration patterns of RNA during polyacrylamide gel electrophoresis were an important laboratory and epidemiological tool. This method of differentiating rotavirus strains is called electropherotyping. Although this method is still useful to differentiate RVA from rotavirus of other groups, among group A strains the different electropherotypes do not correspond to specific serotypes and are of limited value (11).

PCR amplification of rotavirus nucleic acid from stool specimens is the most sensitive way to detect RVA, RVB, and RVC (181–183). With this method, in a case control study up to 29% of asymptomatic children less than 1 year of age were positive for rotavirus (183). Although it is not clear that the RNA detected reflects active viral replication, symptomatic children generally shed much more viral RNA than asymptomatic children. A correlation has been observed between the severity of rotavirus diarrhea and the quantity of RNA shed (97). G (184) and P genotyping by PCR (185) is more sensitive than serotyping using ELISA with specific serotype-specific MAbs.

### Serologic Assays

Detection of rotavirus-specific serum and stool antibodies is generally performed by ELISA and typically is restricted to epidemiological and vaccine studies. The most sensitive and rapid immunologic test to diagnose primary infection seems to be the detection of virus specific IgM in serum (124). A four-fold increase in convalescent as compared to acute serum titers of IgA and IgG can also be used to diagnose primary infections. An increase in IgA titer in convalescent stool samples is a more sensitive marker of rotavirus reinfection than is seroconversion (125). However, measurement of these antibodies in breastfed children is complicated by the fluctuation of these antibodies as a result of the presence of maternal milk IgA. Measurement of rotavirus-neutralizing antibodies is commonly performed by plaque reduction or focus reduction assay (146). Serotype-specific responses to defined epitopes of VP7 can be measured by an immunoassay that uses neutralizing MAbs to compete with the test serum as an alternative to traditional neutralization assays (186).

## Prevention

### General

Strict isolation of rotavirus-infected hospitalized patients is unnecessary, since the risk of nosocomial rotavirus infection is not enhanced by room contact with a rotavirus-infected patient or by the sharing of attending personnel. Precautions should be exercised in disinfection of surfaces thought to be contaminated with rotavirus, since these viruses have been shown to be highly resistant to many commonly used disinfectants. A spray composed of 0.1% o-phenyl phenol and 79% ethanol is highly effective in decontaminating surfaces with rotavirus (187). These measures, combined with careful hand washing, will limit the spread of infection in hospitals or other institutional settings. Nonetheless, the fact that the incidence of rotavirus infection is similar in developed and less developed countries suggests that these measures will not replace the need for an effective vaccine.

### Passive Immunoprophylaxis

The feasibility of passively protecting newborns by immunizing mothers with rotavirus has been demonstrated in animal models and human trials in which oral vaccination of

mothers increased virus-specific antibodies in breast milk (188); however, the protective efficiency of this strategy in humans has not been evaluated.

### Active Immunization

Because animal and human rotaviruses share antigens capable of inducing protective immunity (189), Jennerian vaccines (vaccination of humans with a naturally attenuated animal virus) have been the most extensively tested for rotavirus. A quadrivalent vaccine with the four most common human G serotypes was made by combining a Rhesus rotavirus (serotype 3) and three mono reassortants of this virus that possessed the gene for VP7 of human rotavirus serotypes 1, 2, and 4. The quadrivalent Rhesus vaccine (RotaShield, Wyeth/Lederle) was licensed for use in the United States but then withdrawn from the market because of its association with intussusception (167). However, the impact of this vaccine on the total attributable risk of intussusception was relatively small (estimated at 1/10,000) and age dependent (190).

Two live-attenuated rotavirus vaccines are currently licensed for use in many countries worldwide and are recommended by the WHO (191). The vaccine produced by Merck (RotaTeq<sup>TM</sup>, or RV5) contains five monoreassortants of a bovine virus with G1, G2, G3, G4, and P1A[8] human rotavirus genes given in a three-dose schedule (192). The vaccine produced by GlaxoSmithKline (GSK, Rotarix<sup>TM</sup>, or RV1) is an attenuated human G1P1A[8] virus given in a two-dose schedule (193). In trials that involved over 60,000 infants, both of these vaccines were shown to be safe and to provide protection against any and severe rotavirus diarrhea of over 70% and 98%, respectively. Importantly, both vaccines reduced the rates of all gastroenteritis related hospitalizations of any cause by over 40% (127). However, in developing countries in Africa and Asia these vaccines are less effective (194–196). The recommendation of the Advisory Committee on Immunization Practices (ACIP), which has been endorsed by the American Academy of Pediatrics, is that three doses of RV5 be given at 2, 4, and 6 months of age with an interval of at least 4 weeks between doses. Two doses of RV1 are recommended to be given at 2 and 4 months of age (197). Both vaccines are contraindicated for 1) infants with a history of severe allergic reaction (e.g., anaphylaxis) after a previous dose of rotavirus vaccine or exposure to a vaccine component, 2) infants diagnosed with severe combined immunodeficiency (SCID), and 3) infants with a history of intussusception (198). Both RV1 and RV5 can be coadministered with other childhood vaccines. Initially, for both vaccines the maximum age for dose 1 was 14 weeks and 6 days of age and for the last dose was 8 months of age, but recently WHO removed the age restriction for rotavirus vaccination after considering that benefits outnumber the potential excess vaccine-associated intussusception deaths (191). Nonetheless, early immunization is still favored (as soon as possible after 6 weeks of age), but each country establishes its own policy concerning age restrictions for vaccine administration, and rotavirus vaccination of children older than 24 months of age is not recommended.

Rotavirus vaccines have had a rapid impact on diarrhea induced by rotavirus and all other causes (199). After introduction of vaccines in the United States, rotavirus and all-causes diarrhea hospitalizations have declined 60% to 83% and 29% to 50%, respectively, in children less than 5 years of age (199). Indirect protection of older unvaccinated children and young adults has been detected in several de-

veloped countries, and more importantly, Mexico, Brazil, and Panama also detected declines in diarrhea mortality following vaccine introduction (199). Postlicensure monitoring of increased risk of intussusception has been conducted in some countries with similar results: e.g., 1 to 5 excess cases per 100,000 vaccinated children in U.S. studies. Also, both DNA from porcine circovirus types 1 and 2 were detected in rotavirus vaccines; however, these viruses are not known to cause human infection or disease and are very common in pigs. Again, WHO and regulatory authorities considered that benefits of vaccination greatly exceed these low risks and reaffirmed the global recommendation for use of rotavirus vaccines (199).

In addition to the newly licensed vaccines, several other live oral vaccines are being evaluated or in use (127): The Lanzhou lamb rotavirus strain, which was developed in China and used in the United States since 2000, induces only partial protection when given to children between 9 and 35 months old (200). A bovine reassortment vaccine developed in the United States by the National Institutes of Health has been shown to provide high levels of protection, and, in a new approach to vaccine development, this vaccine was licensed to seven companies in three developing countries, where it is currently under development and evaluation (201). This strategy may be useful to lower the price of rotavirus vaccines. Based on the observation that neonatal rotavirus infection protects against severe rotavirus gastroenteritis later in life (65), vaccines derived from neonatal rotavirus strains (the Indian 116E and the Australian RV3 P[6]G3) are also under evaluation (202, 203). The 116E candidate was recently shown to be safe and effective in a large Phase 3 trial in India (203) and is now licensed and being marketed in India under the trade name of Rotavac<sup>®</sup>. As a strategy to lower the risk of intussusception, some investigators are proposing neonatal administration of live oral vaccines, since at this young age intussusception is very rare (204). Also, to try to minimize this complication, strategies for future rotavirus vaccines include inactivated and several nonlive vaccines (e.g., recombinant viral antigens [VP6]), rotavirus-virus-like particles, DNA vaccination with selected rotavirus genes and vaccination with synthetic peptides (127). It is unknown if current rotavirus vaccines directed at RVA are cross-reactive with RVB or RVC, and vaccines against the latter agents have not been tested in humans.

### Treatment

Since rotavirus disease spontaneously resolves in a few days to 1 or 2 weeks without treatment, therapy is aimed at preventing dehydration, which is the main serious complication (205). The standard hydration solution in use was derived from the formula initially used to treat secretory cholera diarrhea and thus has a high sodium concentration and an osmolarity of 331 mmol/L. Rehydration formulas with reduced osmolarity (224 mmol/L) have been suggested to be superior for treatment of children with non-cholera-induced diarrhea, especially the subset of patients with the most severe persistent disease (191, 205).

Several studies have indicated that passive oral immunotherapy (antirrotavirus immunoglobulin from bovine colostrum, for example) can shorten the duration of rotavirus infection in animals and humans. The rationale for this type of treatment has been studied while treating immunocompromised children with chronic rotavirus diarrhea (206). More recently, a llama-derived, heavy-chain antibody fragment specific for rotavirus reduced stool output in male infants with severe rotavirus diarrhea (207). It is unclear,

however, whether these strategies will be economically feasible or logistically practical. In animal (208, 209) models and children (210), administration of some strains of *Lactobacilli* (the bacteria present in yogurt) can stimulate a stronger immune response to rotavirus and shorten the duration of diarrhea. These bacteria are considered to be safe, are currently recommended for use in Europe (211), and a clinical report by members of the American Academy of Pediatrics finds that there is evidence to support their use for the treatment of gastroenteritis, although more studies are necessary (212). Because of the associated side effects, such as ileus, the use of opiates and atropine are contraindicated for treatment of children with diarrhea. Several other compounds, such as racecadotril (an enkephalinase inhibitor with antisecretory and antidiarrheal actions) (107) and nitazoxanide (213) have been shown to be safe and effective in rotavirus-induced diarrhea but have been tested only in limited clinical studies (205). Zinc supplementation is effective in preventing and treating diarrhea in children in developing countries, but its use in developed countries needs further evaluation (191, 205).

Early refeeding after rehydration of children with diarrhea is recommended (214). A meta-analysis found that this practice does not prolong diarrhea and it may reduce the duration of diarrhea by approximately 0.5 day (214). Recommended foods include complex carbohydrates (rice, wheat, potatoes, bread, and cereals), lean meats, yogurt, fruits, and vegetables. Fatty foods and foods high in simple sugars (including juices and soft drinks) should be avoided. The American Academy of Pediatrics initially recommended gradual reintroduction of milk-based formulas or cow's milk in the management of acute diarrhea, beginning with diluted milk mixtures. Based on several studies (154), this recommendation was changed and at present the recommendation is that children with diarrhea can receive a regular age-appropriate diet, including undiluted milk but with active clinical monitoring to detect the few children who develop malabsorption and lactose intolerance (214). Lactose intolerance should be suspected if diarrheal disease severity worsens 3 to 4 days after the onset of diarrhea, and for those who are passing significant amounts of reducing sugars in their stool (154). In Thai and other Asian children with genetically determined low lactase levels, lactose-free diets seem to be better for recovery after rotavirus infection (215).

# Respiratory Syncytial Virus, Human Metapneumovirus, and Parainfluenza Viruses

JOHN V. WILLIAMS, PEDRO A. PIEDRA, AND JANET A. ENGLUND

## 37

Respiratory syncytial virus (RSV), human metapneumovirus (HMPV, MPV), and the parainfluenza viruses (PIVs) are the most important causes of lower respiratory tract illnesses in infants and children. RSV was first isolated from chimpanzees with coryza in 1956 (1) but was soon shown to be the major cause of bronchiolitis and pneumonia in infants (2). RSV was named after the cell fusion that is characteristic of its growth in some continuous cultured cell lines. PIV types 1, 2, and 3 were first recovered in 1956 (3, 4) and were recognized as the major causes of croup, or laryngotracheobronchitis, in children. PIV types 4A and 4B have been recovered from adults and children with upper respiratory illnesses but historically were difficult to isolate in cell culture (5). MPV was first discovered in the Netherlands in 2001 (6) and soon thereafter was documented to be an important cause of lower respiratory tract illness in children worldwide. In older children and adults, these three viruses cause frequent reinfections that are generally mild in healthy persons, but they may cause serious disease in the very young or elderly, immunocompromised patients, and persons with underlying cardiopulmonary diseases.

## VIROLOGY

### Classification

RSV, PIV, and MPV belong to the Paramyxoviridae family. RSV is a member of the genus pneumovirus; MPV is a member of the genus metapneumovirus, and the PIVs are members of the genus paramyxovirus. A number of related human and animal paramyxoviruses are important respiratory pathogens, including measles (Chapter 39) and mumps (Chapter 38) viruses (Table 1; see also Chapter 40 on Zoonotic Paramyxoviruses). RSV is comprised of two subgroups that are antigenically distinct, classified as RSV/A and RSV/B (7). The subgroups are further classified into genotypes based on the variability of the distal third of the G gene; amino acid variability is up to 20% within group A and 9% in group B (8). The major difference between the subgroups is the antigenic properties of the attachment (G) surface glycoprotein protein (8), while the F or fusion surface glycoprotein remains relatively conserved (Table 2) (8). Of the three surface proteins (small hydrophobic or SH, F, and G), only the F and G surface glycoproteins evoke antibody responses that are important for conferring protection against life-threatening RSV illness.

In contrast to RSV, PIVs have no clinically significant antigenic variants within each of the recognized 5 types (1, 2, 3, 4A, and 4B) (9). Immune responses to the two PIV surface glycoproteins hemagglutinin and neuraminidase (HN) and F appear to correlate with protection against infection.

Several MPV genes including F, G, and phosphoprotein (P) have been used for subtyping, and phylogenetic analysis of these sequences have defined two major genetic subgroups of MPV, A and B, each with two minor subgroups (10, 11). The two major MPV groups (A and B) show significant genetic variability in the G gene (50%–57% nucleotide identity with 30%–37% amino acid identity between MPV/A and MPV/B subgroups) and relative conservation in the F gene (84% nucleotide identity with 94%–97% amino acid identity between subgroups) (11). F protein induces neutralizing antibodies and appears to be the major protective antigen.

### Structure

The virions are pleomorphic, varying from almost spherical to filamentous in shape, and range in diameter from 150–300 nm (12). Large filamentous forms are often noninfectious because they may lack a nucleocapsid. All of these viruses have an envelope consisting of a lipid bilayer derived from the host cell with spike like membrane-anchored glycoproteins. The main elements of their structures are illustrated in Fig. 1. The lipid-containing envelope is lined by a matrix protein that surrounds the helical nucleocapsid. The diameter of the nucleocapsid of PIV is 18 nm whereas that of RSV is slightly smaller at 12 to 15 nm. The genomes are composed of single-stranded RNA with negative sense polarity but vary in size. The RSV genome consists of  $15.2 \times 10^3$  nucleotides, the PIV genome consists of  $15.5 \times 10^3$  nucleotides, and the MPV genome consists of  $13.3 \times 10^3$  nucleotides.

The organization of the genome differs for the three viruses (Fig. 2). Eleven proteins are encoded by the RSV genome, two of which are nonstructural. PIVs have at least six structural proteins and one or more nonstructural proteins. MPV encodes nine proteins analogous to those of RSV but lacks NS1 and NS2. The nucleocapsid comprises the RNA bound to the nucleoprotein (N) with the P protein, the transcription processivity factor M2-1, and large L proteins that have RNA-dependent RNA polymerase activity.

The compositions and major proteins of RSV, the PIVs, and MPV are compared in Table 2. RSV, PIV, and MPV all

**TABLE 1** Animal viruses related to human respiratory paramyxoviruses

Human strain	Related animal strain <sup>a</sup>	Animal host(s)	Disease
PIV type 1	Sendai virus	Rodents	Pneumonia
PIV type 2	Simian virus 5	Dogs	Canine croup
PIV type 3	Bovine PIV type 3	Cattle	Shipping fever
RSV	Bovine/ovine RSV	Cattle, sheep	Shipping fever
MPV	Avian metapneumovirus (formerly turkey rhinotracheitis virus)	Turkeys, chickens	Swollen head syndrome

<sup>a</sup>Sendai virus of rats is closely related to PIV type 1. Simian virus 5, a cause of canine croup, is related to PIV type 2. Bovine PIV type 3 contributes to the economically important shipping fever complex of cattle and is closely related to human PIV type 3.

have an F protein in the envelope, but each has a distinct second large surface glycoprotein. PIV has an HN protein with both hemagglutinating and neuraminidase activities, while RSV and MPV have a large glycoprotein, designated the G protein, that is important for attachment but lacks these activities. RSV and MPV have a relatively conserved SH protein in the envelope that appears to form a viroporin with undefined biological function (13).

### Replication

Infection is initiated by attachment of the virion to a susceptible cell by the HN, G, or F protein (14–17). The putative receptor for RSV G protein is heparin sulfate (18, 19), although recent work suggests CX3CR1 is a receptor for G on primary airway epithelial cells (20, 21), Nucleolin is a putative receptor for RSV F (22). PIV HN binds to cell surface sialic acid to initiate infection (5). MPV F binds to Arg-Gly-Asp (RGD)-binding integrins to mediate attachment and infection and is capable of entering cells by endocytosis (16, 17, 23), and viruses with mutations of the RGD motif are attenuated in rodents (24). MPV F and G proteins bind to heparan sulfate, which may serve as a receptor (15, 25). The F protein must be cleaved by cellular proteolytic enzymes to become activated and capable of fusion. The cleaved F proteins (F1 and F2) act to fuse the host cell membrane to the virus lipid envelope to allow the nucleocapsid to enter the cytoplasm. RSV, PIV, and MPV replicate solely in the cytoplasm with no requirements for

nuclear processing. The virion polymerases (P+C and L) transcribe the negative-strand RNA to mRNA for production of the viral proteins (Fig. 3). The negative-strand RNA also serves as a template for synthesis of the genomic intermediate positive-strand RNA. The virion-complementary RNA is then copied into progeny negative-strand RNA. The virion is assembled with the progeny negative-strand RNA and structural virus proteins, and then released by budding from the host cell membrane.

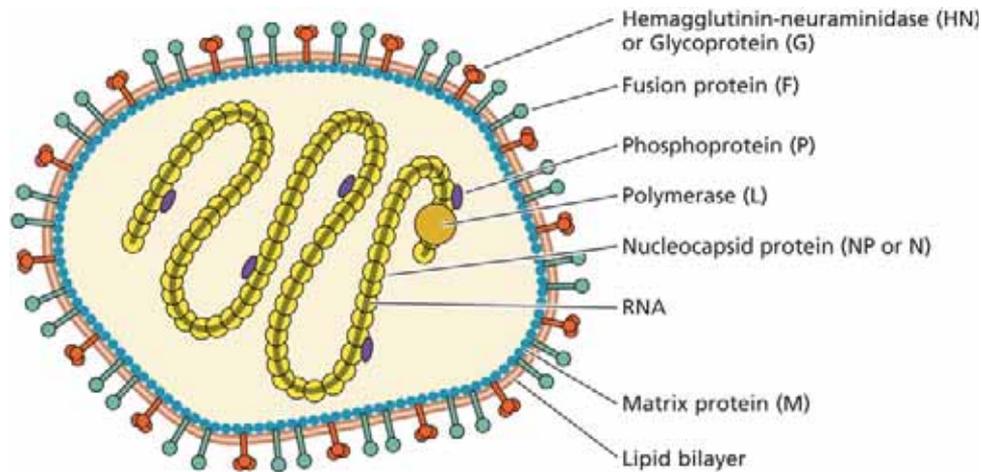

New understanding of viral entry mechanisms of RSV and PIV is being elucidated. HPIV infects its target cells by coordinated activity of the HN receptor-binding protein and the fusion envelope glycoprotein F (26). The prefusion F undergoes a structural transformation following binding of the HN and F, inserting itself into the target cell membrane, and then changing into a postfusion structure that mediates fusion of the viral and cell membranes (26). Fusion mechanisms and machinery differ in strains grown in human airway epithelia and those adapted for *in vitro* replication. Unlike most paramyxoviruses, RSV appears to enter the cell by macropinocytosis, followed by cleavage of the second furin site of the F protein in the endocytic compartment, with subsequent fusion and release of infectious nucleocapsid (27). MPV is also capable of entering cells to initiate infection via clathrin-mediated endocytosis, as well as fusion at the cell membrane (23).

### Host range

Human RSV infects nonhuman primates and, under experimental conditions, rodents, including cotton rats and mice (28–32). Disease manifestations due to RSV in primates and cotton rats have similarities to those in humans; RSV infection in mice is characterized by constitutional symptoms such as weight loss and fur ruffling with minimal pulmonary symptoms, despite histopathologic changes in the lungs. Viruses closely related to RSV cause symptomatic disease in cattle, sheep, and mice (33). Counterparts of the human PIVs are found in animals, and human PIV strains are also found in wild nonhuman primates (34) (Table 1). MPV is most closely related to avian metapneumovirus (formerly turkey rhinotracheitis virus) type C, which is an important pathogen in agricultural poultry. Although an initial report indicated MPV did not replicate in experimentally inoculated chickens and turkeys (6), another group reported that turkeys inoculated intranasally with MPV developed rhinitis associated with MPV RNA detection by RT-PCR but without confirmed productive MPV replication

**TABLE 2** Proteins of RSV, MPV, and PIV

RSV		MPV		PIV	
Gene	Protein	Gene	Protein	Gene	Protein
F	Fusion	F	Fusion	F	Fusion
G	Attachment	G	Attachment	HN	Hemagglutinin-neuraminidase
M	Matrix	M	Matrix	M	Matrix
N	Nucleoprotein	N	Nucleoprotein	NP	Nucleoprotein
P	Phosphoprotein	P	Phosphoprotein	P+C	Polymerase complex
L	Large polymerase complex	L	Large (RNA polymerase)	L	Large polymerase complex

(35). MPV is capable of infecting cotton rats, hamsters, ferrets, mice, and nonhuman primates under experimental conditions (36–40). MPV has also been reported to cause disease in wild chimpanzees and gorillas, likely transmitted from human tourists (41, 42, 43). Some experimental challenge studies suggest that the inoculum size is an important variable for achieving RSV and PIV infections in adults and possibly infants and children (44–46). A limitation of most animal models is that they require a large inoculum.

### Stability

Because of their lipid-containing envelopes, these respiratory viruses are sensitive to ether and other lipid solvents. RSV and the PIVs differ in their lability; RSV is relatively unstable, and isolation in cell culture is enhanced by immediate inoculation into sensitive cells without freezing the specimen. By contrast, PIV are relatively stable and remain viable in a virus-stabilizing medium for up to 5 days at 4° C (15). MPV is relatively stable to repeated freeze-thaw cycles, and infectious particles can persist on nonporous surfaces for up to 6 hours (47).

## EPIDEMIOLOGY

### Geographic Distribution

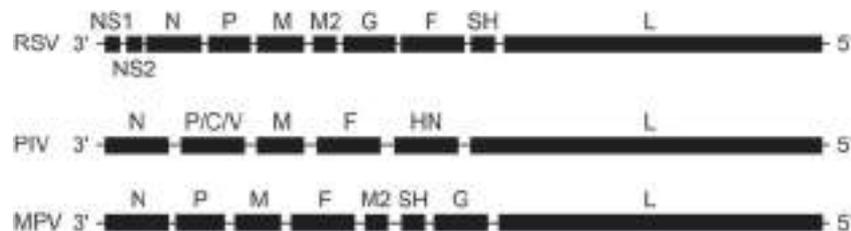

RSV, PIV, and MPV are recognized as causes of upper and lower respiratory tract disease across all age groups worldwide. These ubiquitous pathogens are especially important

causes of disease in young children. In particular, RSV infection in infants is associated with high morbidity and mortality (48, 49). Importantly, respiratory diseases remain the most important cause of mortality in young children worldwide, with an estimated 3 to 4 million deaths annually of children less than 5 years old (50).

### Age-specific infection rates

Infections with all three viruses are common during early childhood (51–53). Approximately two-thirds of infants are infected with RSV and PIV type 3 during the first year of life (Table 3). Most primary infections in children occur during the first 2 years of life and are symptomatic; RSV infections are more likely to involve the lower respiratory tract, while PIV type 3 infections are more likely to produce illnesses limited to the upper respiratory tract (Table 3). Infants and young children are also commonly infected with MPV, although the mean age of hospitalization with MPV infection is approximately 6 months older (54–65). Virtually all children are infected with RSV by 2 years of age and with MPV by 5 years of age. Infections with PIV types 1 and 2 occur at a lower rate; by age 5 years 74% and 59% of children have been infected with types 1 and 2, respectively (66). Hospitalization for RSV, PIV, or MPV illness is common in U.S. children (Table 4) and elsewhere.

Severe disease due to RSV infection in children without underlying chronic conditions is most common in infants younger than 6 months of age. After primary infection, the

**FIGURE 2** Schematic presentation of the RSV, PIV, and MPV genomes. incidence of RSV lower respiratory tract falls with increasing age (52, 67), until late adulthood, when increasing rates are again noted in the elderly (68). Immunity induced by primary infection has a limited effect on illness associated with the first reinfection, but the severity of illness is significantly reduced by the third RSV infection (52). Repeated infections in children and adults occur frequently, indicating that protection against reinfection is incomplete (52). Asymptomatic infection is more common in adults and may contribute to spread (69).

For PIVs, lower respiratory tract infection occurs most frequently in children younger than 4 years of age (51). Relatively few cases of severe disease in infants less than 4 months of age have been documented, although severe disease has been reported in premature infants or those hospitalized in neonatal intensive care units (70). Immunity elicited after infection appears to be very important in reducing the severity of disease following reinfection.

Hospitalization of children for MPV infection occurs primarily in the first year of life, although many studies report that the peak age of hospitalization for MPV is from 6 to 12 months of age and thus later than the peak age of hospitalization for RSV (54–65). MPV is rarely detected in asymptomatic children (65, 71, 72).

RSV and MPV are important causes of acute respiratory infections in adults, especially among older adults and high-risk adult populations (68, 73–80). RSV and MPV infections are more common in adults at high risk, such as those with chronic cardiopulmonary disease, immune compromise, or age greater than 65 (73, 74, 77, 78, 81–90). Medically significant PIV infections appear to be less common in adults,

although there are fewer published studies (91–94). Most PIV disease in adults occurs in high-risk populations (95–100).

### Reinfection

Reinfections with these viruses are common. Overall, 76% and 67% of children are reinfected with RSV and PIV type 3, respectively, during the second year of life (Table 5). Repeated infection is common but usually results in upper respiratory infection or inapparent infection, with markedly lower rates of lower respiratory tract disease (51). Only 3% of children less than 5 years old develop lower tract disease with PIV type 3 reinfection compared to 11% who have lower tract disease with RSV. Reinfection with MPV can cause upper or lower respiratory tract disease (53, 72, 101). Reinfections with these viruses also cause a sizable proportion of upper respiratory illnesses in healthy older children and adults. RSV, PIV, and MPV reinfections are common causes of hospitalization of adult patients with chronic lung conditions such as asthma and chronic obstructive pulmonary disease (86,102–104). RSV and MPV can cause serious lower respiratory tract infection among immunocompromised adults, residents of long-term care facilities, and the elderly who live in the community (73, 75, 77, 78, 94, 105–109). Of pneumonia hospitalizations and deaths in older adults, 2% to 9% are due to RSV, and 2% to 11% to MPV (76, 110).

### Clinical Attack Rates

RSV, PIV, and MPV are the most important causes of acute lower respiratory tract disease in children (111–113). Almost 30% of infants have a medically attended illness due to RSV in the first year of life that is usually diagnosed as bronchiolitis or pneumonia (114). RSV-related hospitalization rates for lower respiratory tract diseases are similar in developed and developing countries (115). At least 2% of all infants are hospitalized with RSV disease, with the peak occurrence in the second month of life, though hospitalization rates are higher in high-risk groups such as premature infants (116, 117). Infants from low-income households and many Native American or aboriginal populations have a much higher risk of hospitalization than those from upper- and middle-income groups (102). The frequency of RSV lower tract disease decreases gradually during the preschool years. In a classic Houston family study, about two-thirds of children were infected during each of the first 2 years of life, with the risk of illness at least 30 per 100 children per year (51). In a Chapel Hill daycare study, the age-specific attack rate for PIV3 lower respiratory tract disease paralleled that of RSV, with annual attack rates ranging from 7 to 15 per 1000 children per year for children less than 3 years old. Boys have a greater frequency of clinical croup (118).

RSV is associated with a substantial number of hospitalizations for acute respiratory infections in adults. A longitudinal cohort study over four seasons found that RSV was associated with approximately 11% of all hospitalizations for pneumonia, similar to the rate for influenza (74). The mortality of hospitalized adults with RSV (8%) was similar to the death rate for influenza (7%). Another study used a modeling approach to combine hospital discharge data with national respiratory virus surveillance data to estimate age-specific hospitalization rates for RSV and influenza (119). This study found a rate of 86/100,000 for RSV hospitalization in adults greater than age 65, less than the rate for influenza of 309/100,000. Other studies also found high rates of RSV among hospitalized older adults (79, 80, 120–124).

Rates of hospitalization, clinic visits, and emergency department visits for MPV disease are lower than that of RSV and similar to influenza (65, 79, 125). PIV type 3 infects children at an early age, but these infections are much less likely to involve the lower respiratory tract. The highest incidence of lower respiratory tract disease due to PIV types 1 and 2 occurs between 6 and 18 months of age (126). The total impact of the three PIVs combined, as reflected by admissions to the hospital, is about the same as that of RSV. Attack rates of PIV4 may be as high as those for PIV 1, but there are fewer data on PIV4 epidemiology (127). The PIVs have lower rates than does RSV in infants but higher rates than RSV in the 1-to-4-year age group (66).

The health and associated economic impacts of RSV infections are substantial and extend beyond the acute episode (128). In the United States approximately 2 million health care visits for RSV occur annually in children less than 5 years of age, of which 1.7 million are office visits and 580,000 emergency room visits, resulting in 60,000 to 144,000 hospitalizations with an average stay of 3.4 to 3.9 days (117). The annual direct medical cost is estimated to be \$1.15 billion dollars with another \$625 million due to lost income

and other expenses for caregivers (129). The annual combined cost for hospitalizations due to PIV types 1, 2, and 3 in the United States is \$259 million (130). Fewer data are available for MPV, but one study used the population-based burden of hospitalization for MPV (65) to estimate an annual cost for hospitalizations due to MPV at \$277 million (131).

### Epidemic occurrence and seasonality

Distinct seasonal patterns of infections occur for these agents in the temperate zones (51, 132). In temperate climates RSV produces annual midwinter epidemics that are characterized by bronchiolitis in infants, particularly in large urban centers, but some variations occur. For example, in the southern United States, the RSV season generally begins earlier than in other regions of the country. Epidemics that alternate between large midwinter epidemics followed by small early spring outbreaks in the following season have been reported in some countries. RSV outbreaks are less clearly delineated in tropical areas, where year-round infection is reported with or without epidemics (132). RSV/A infections usually predominate, but sometimes RSV/B infections are more prevalent, and in certain settings, RSV/B may alternate with RSV/A (7, 133). In recent years, the RSV/B/Buenos Aires genotype and the RSV/A/Ontario genotype have become the dominant RSV genotypes in circulation worldwide (134, 135). These genotypes are distinctive in that they have a 60- or 72-nucleotide insertion in the distal third of the G gene, possibly increasing viral fitness compared to other genotypes.

PIV type 1 causes croup epidemics every other year in the autumn (51). PIV type 2 infections usually follow the same pattern as PIV type 1, but the manifestations of PIV type 2 infections are milder. PIV type 3 circulation is the least predictable; infections occur in an endemic pattern most of the time but outbreaks do occur, usually in the spring, and disease is characterized by both upper and lower respiratory tract infections. PIV-3 remains the most common PIV type detected in both hospital-based and outpatient studies; either PIV-1 or PIV-4 may be the second most common PIV detected in children, depending on the year (136, 137). PIV type 4 may be detected year round (137), is associated with less severe respiratory symptoms compared with other PIVs, and is not associated with croup (127). Although PIV-4a has typically been more commonly reported, subtype 4b has been detected nearly as often in recent studies in China (138).

Different lineages of MPV frequently circulate in a community during the same winter season, although one subgroup may predominate in a given year (53, 139, 140). Viruses from each subgroup appear capable of causing severe lower respiratory tract disease; different subgroups have not been convincingly associated with varying severity of disease (141–144).

<sup>a</sup>Data from references 51 and 52.<sup>b</sup>LRD, lower respiratory tract disease.

Outbreaks of infections with these respiratory viruses are common in closed populations of young children, especially in pediatric hospital wards or large daycare centers (145). Reports of epidemic RSV disease in nursing homes (146) and homes for adolescents with developmental disabilities (147) have also been described. Similarly, numerous epidemics of PIV and MPV have been documented in pediatric wards, neonatal intensive care units, and hematology-oncology wards, as well as in long-term care facilities (70, 90, 148–153).

Epidemics of RSV or PIV can be recognized by clinical syndrome, for example, seasonal outbreaks of bronchiolitis in infants in the autumn and winter months or croup epidemics due to PIV types 1 and 2 in slightly older infants and toddlers in the autumn. PIV type 3 outbreaks tend to occur in late winter or spring. MPV generally follows the RSV season in the late winter or early spring. Many upper respiratory illnesses that occur in older children and adults during these periods are caused by reinfections with these viruses. However, in general, these viruses are not clinically distinguishable.

### Transmission

Most evidence indicates that these viruses are transmitted by respiratory secretions through direct contact or via fomites (154) or by large droplet spread (155). RSV has been recovered from environmental surfaces in infected patients' rooms for up to 6 hours (156) and MPV can remain viable on nonporous surfaces for 6 hours (47). Entry likely occurs through contact with nasal mucosa or eyes, in contrast to the less permissive oral route (46). Transmission by small particle aerosols of RSV has not been proven, and if it occurs, it is an infrequent route. Clinical observations suggest PIVs and MPV are transmitted similarly to RSV (157). Although PIV types 1 and 3 have been recovered from air samples collected in the vicinity of infected patients (158), direct contact and transmission via fomites are likely to be more important. The high initial and subsequent infection rates suggest that these viruses spread readily, that reinfected persons may be infectious, and that relatively small inocula are necessary to infect.

A preschool or school-age sibling is the most likely source of RSV and PIVs in the family, with approximately half of family members becoming infected once the virus is introduced (159). On average, the time between primary and secondary infections in family members is 5 to 6 days.

### Nosocomial infections

RSV, PIVs, and MPV are common causes of nosocomial infections, contributing to significant morbidity and mortality in pediatric wards, and can involve health care workers and patients both as sources and transmitters of disease (148, 160–164). PIV outbreaks may be more difficult to bring under control due to prolonged asymptomatic shedding, particularly in young children and immunocompromised hosts (165). Nosocomial RSV and PIV infections in adults with leukemia and bone marrow transplants are associated with a high mortality (83, 164, 166). The transmission of identical strains of RSV from the outpatient setting into the hospital has been documented, demonstrating the importance of infection control measures (162). Nosocomial transmission of MPV also occurs, with outbreaks in both inpatient and outpatient units. In one study, 15 patients were diagnosed with MPV within 7 weeks in a tertiary care cancer unit (163). Molecular subtyping revealed infection with genotype A2a virus, implicating nosocomial transmission. Four patients (26.6%) died from MPV-associated pneumonia and consequent multiorgan failure.

## PATHOGENESIS

### Virus replication patterns

Infants and young children shed infectious RSV in nasal secretions for a mean of 7 days, with a maximum of 3 weeks (167). Nearly all hospitalized infants shed RSV during the first 7 days of hospitalization, and the majority still shed virus at the time of discharge (168). High viral titers,  $10^5$  to  $10^7$  plaque-forming unit (PFU) per ml, can often be found in secretions from the upper and lower respiratory tract in young children (168, 169). In immunocompromised adults with uncomplicated infection, very low titers of RSV ( $\sim 35$  PFU/ml) are detected in the upper respiratory tract, making rapid antigen tests less sensitive in adults than in children (169). Another study using RT-PCR detection of RSV in nasal swab and sputum specimens found that outpatient and hospitalized adults with RSV illness had modest amounts of detectable virus ( $\sim 2\text{--}3 \log_{10}$  PFU equivalents/ml) for a mean of 10 days and a maximum of 13 days (170). Viral detection was more prolonged in adults age 65 or older, and hospitalized adults had higher viral loads than outpatients. Another study of hospitalized adults also found that viral load correlated with disease severity (171). Prolonged replication for weeks to months may occur in immunocompromised hosts (81, 169).

The duration of viral replication for PIVs is approximately a week, although this is variable and dependent on age, number of prior infections, and severity of infection (157). PIV type 3 may be shed for up to 4 weeks, and 17% of specimens from infected children are positive during the third week after illness onset (172). Some children may excrete PIV 6 days before the onset of illness, and prolonged PIV detection may occur in children with primary infection and adults with underlying chronic lung disease (172, 173). Prolonged viral shedding (mean=4 weeks) occurs in immunocompromised children and adults and is associated with malignancy, organ transplantation, congenital or acquired immunodeficiency, or prolonged steroid treatment (164). Persistent detection of PIV RNA in asymptomatic immunocompromised patients for several months has been noted using more sensitive molecular methods (165).

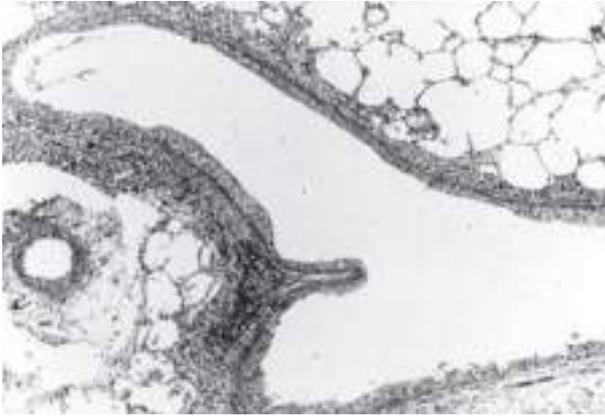

MPV replication in immunocompetent children and adults is limited to 1 to 2 weeks (174, 175), although it can be prolonged in immunocompromised persons (163, 174, 175).

### Organ specificity

In the immunocompetent host, RSV, MPV, and PIV replication is restricted to the respiratory epithelium. Viremia or isolation of RSV, PIV type 3, or MPV from cerebrospinal fluid has been reported rarely. All these viruses spread primarily from cell to cell in the upper respiratory tract and at times progress to the lower respiratory tract.

### Histopathology

The pulmonary histopathology of bronchiolitis has been described primarily from infants and young children who have succumbed acutely from RSV infection (176, 177). Limited data are available for PIVs and MPV, although the histopathology appears similar to that of RSV (177–180). The earliest lesion to develop within 24 hours of onset is necrosis of the bronchiolar epithelium with denudation of the ciliated epithelial cells. This is followed by migration of lymphocytes into affected tissues, resulting in peribronchiolar infiltration (Fig. 4). The submucosal and adventitial tissues become edematous and accompanied by increased secretions from mucus-producing cells. Plugs consisting of mucus, cellular debris, fibrin strands, and DNA-like

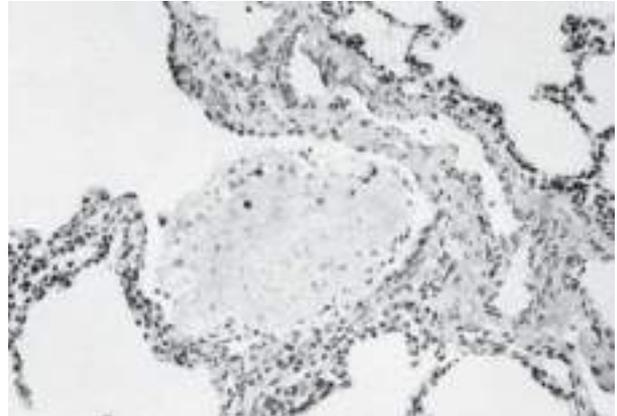

**FIGURE 4** Characteristic histopathologic changes of the airways of an infant with bronchiolitis due to RSV infection. Note the peribronchovascular interstitial inflammation, relatively normal alveoli, and focal ulceration on top with regenerative epithelial changes. Hematoxylin and eosin stain. Magnification, 45x.

materials occlude the smaller bronchioles. Activated neutrophils, a major cellular component in the airway lumen in bronchiolitis, release neutrophil extracellular traps, a network of DNA-containing antimicrobial proteins, that probably contribute to airway occlusion (181). However, polymorphonuclear cells are not common in the bronchial epithelium and parenchyma of the lung. Fatal RSV infection has been characterized by viral antigen detected primarily in cellular debris obstructing the lumen of the small airways and in multinucleated cells lining the bronchiolar lumen, near absence of CD-8 positive lymphocytes and natural killer cells, and enhanced expression of apoptosis markers (182, 183). The major pathologic features are air trapping with distension of some segments or obstruction with alveolar collapse in bronchiolitis and extension of necrosis into the parenchyma with interstitial pneumonia. Histologic recovery is slow, beginning with regeneration of the basal epithelial layer within 3 to 4 days and exuberant regeneration of the ciliated epithelial cells starting at the end of the second week (176). The plugs of cellular debris are eventually resorbed (Fig. 5).

Interstitial inflammation with mononuclear cell infiltration is the rule in RSV and PIV pneumonia (Fig. 6) (177, 184). The epithelial cells are flattened, with loss of cilia. The subepithelial tissues of bronchiolar and interalveolar walls are thickened due to mononuclear cell infiltration. Subsequently, significant epithelial necrosis, intense mononuclear inflammatory response extending from the smaller bronchioles into alveoli, hyaline membrane formation in alveolar spaces, and edema of interalveolar walls may occur. Histologic differences observed between bronchiolitis and pneumonia may represent a continuum of disease possibly related to the size of the viral inoculum, with higher concentrations of virus resulting in pneumonia (184).

MPV has been detected almost exclusively in respiratory tract specimens, suggesting that its replication is limited to respiratory epithelia. In lung transplant recipients infected with MPV, both acute and organizing lung injury occur, with diffuse alveolar damage and cytoplasmic inclusion bodies (185). Bronchoalveolar lavage fluid from immunocompromised patients contains sloughed, degenerated epithelial cells with eosinophilic cytoplasmic inclusions, multinucleated giant cells, and histiocytes (186). Because available histopathologic evidence comes from lung biopsies and

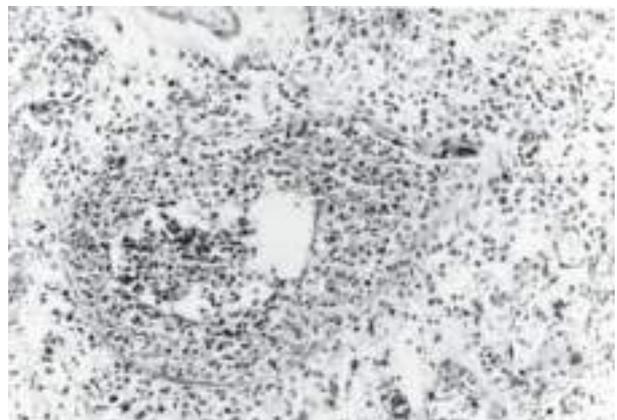

**FIGURE 5** Histopathologic features of resolving RSV bronchiolitis in an infant. Note the plug of mucus and cellular debris in a terminal respiratory bronchus. Hematoxylin and eosin stain. Magnification, 144x.

bronchoalveolar lavage specimens from patients with underlying immunodeficiency or malignancy, these findings may not reflect what occurs in otherwise healthy humans. The pathologic features of MPV infection in mice, cotton rats, and macaques include disruption of respiratory epithelial architecture, sloughing of epithelial cells, loss of ciliation, and inflammatory infiltrates (36, 37, 187). Histopathologic changes or evidence of infection was not detected in any other tissues. In macaques and cotton rats, viral antigen is localized almost exclusively at the apical surface of ciliated respiratory epithelial cells. The limited histologic data from human autopsies suggests that syncytia can be found *in vivo*, especially among immunocompromised persons, but are less common than in measles pneumonia (161, 178, 183, 188–190).

## IMMUNE RESPONSES

### Innate response: cytokines and inflammatory mediators

Upon virus infection of the respiratory epithelium, the innate immune response is the first line of host defense.

**FIGURE 6** Histopathology in an infant with congenital immune deficiency and RSV pneumonia. Note the plugging of a terminal bronchus by cellular debris and parenchymal infiltration with necrosis. Hematoxylin and eosin stain. Magnification, 72x.

Mannose-binding lectin, surfactant proteins, and other collectins act as opsonins with activity against RSV and likely MPV and PIVs. Signaling receptors such as Toll-like receptor 4, which recognizes the fusion protein of RSV, can activate the NF- $\kappa$ B signaling pathway, inducing the expression of cytokines and costimulatory molecules. Gene polymorphisms of pattern-recognition receptors (Toll-like receptor 4 and surfactant protein D) and of downstream-induced antiviral molecules (interleukin 4 [IL-4], IL-8, IL-10, and tumor necrosis factor alpha [TNF- $\alpha$ ]) and other innate immune genes have been associated with severe RSV infection (191–193). Cytokine production is depressed in infants and children compared with adults and may account for their less-than-optimal immune response (194).

Unlike several other respiratory viruses, RSV infection is notable for the induction of little or no local interferon (195, 196). The host interferon response to RSV is suppressed by RSV nonstructural proteins NS1 and NS2. *In vitro* studies of PIV3 have demonstrated the induction of interferon-gamma (IFN- $\gamma$ ) and RANTES (regulated on activation, normal T-cell expressed and secreted) protein in human nasal epithelial cells (197), correlating with human studies demonstrating detectable levels of interferon in 30% of children with PIV infection (196). Interferon induction following PIV infection has been hypothesized to be associated with diminished shedding of the virus (196). The P/C/V gene of PIV type 1 inhibits interferon response by inhibiting interferon regulatory factor-3 activation and subsequent interferon production (198, 199).

The clinical significance of the cytokine profiles associated with severity of RSV and other respiratory viruses is emerging. Although it was thought that the inflammatory response generated against RSV contributed substantially to the development of respiratory disease, recent data suggest that a robust early inflammatory response is critical in the control of viral replication and mitigation of respiratory disease (182, 198, 199). Each respiratory virus has a distinct cytokine profile, even though the clinical presentation of disease is similar (182, 198, 199).

IL-2 and IFN- $\gamma$  are the predominant RSV-stimulated cytokine responses of memory T cells from young children exposed to one RSV season, older children with one or more prior RSV infections, and adults (200, 201). Some children also develop an increase in IL-5 mRNA. RSV-specific-memory T cells appear to have a dominant TH1 response and are similar for different age groups. TNF- $\alpha$  and IL-8 are produced by RSV-infected alveolar macrophages. These cytokines attract neutrophils and macrophages to the site of infection (202). IL-6, a promoter of mucosal B lymphocytes and immunoglobulin A (IgA) production, and TNF- $\alpha$  are detected in the nasal secretions and tracheal aspirates of most infants and young children with acute primary RSV infection, although peak concentrations are not correlated with the peak of mucosal RSV-specific IgA responses (203). Elevated nasal levels of IL-6 and macrophage inflammatory protein 1 $\alpha$  (MIP-1 $\alpha$ ) are more common in hospitalized adults (170).

Various mediators of inflammation, in particular degranulation products of mucosal mast cells and eosinophils, have been associated with severity of involvement in bronchiolitis. Histamine and leukotrienes C4, D4, and E4 are the major mast cell mediators responsible for constriction of smooth muscle, increased mucus production, and increased vascular permeability. In infants with RSV and PIV type 3 bronchiolitis, elevated levels of histamine, leukotriene C4, and eosinophilic cationic protein have been de-

tected during the acute phase of the disease and have been associated with wheezing and hypoxemia in RSV-infected infants (204–207).

Increased levels of IL-8 and decreased levels of RANTES have been reported in nasal secretions of MPV-infected children compared with those of RSV-infected children (208). Children infected with MPV appear to have significantly lower levels of IL-1 $\beta$ , IL-6, IL-8, IL-12, and TNF- $\alpha$  as compared with infants infected with RSV or influenza virus (199). MPV-infected children have lower levels of nasal IFN- $\gamma$  and a reduced Th2 bias compared to children with influenza RSV (209). MPV infection of human dendritic cells (DCs) *ex vivo* (210) induces production of TNF- $\alpha$  and IL-6 in myeloid DCs and IFN- $\alpha$  in both myeloid and plasmacytoid dendritic cells.

### Humoral, cell-mediated, mucosal immune responses

Humoral immune responses of infants hospitalized following primary RSV infection consist of virus-specific IgM antibodies that may persist up to 10 weeks after illness and virus-specific IgG and IgA antibodies that are produced within the second week, peak by 3 to 4 weeks, and decline to low or nondetectable levels by the following RSV season. Re-infection with RSV results in a rapid increase in all three classes of antibody. Age-specific and preexisting virus-specific maternal antibodies appear to influence the development of serum antibodies to the F and G surface glycoproteins and serum neutralizing antibodies in infants undergoing primary RSV infection (211). Older infants develop stronger protein-specific and functionally active neutralizing antibody responses after primary RSV infection. However, the antibody response to primary infection appears to be low avidity regardless of age (212). Primary infection with RSV/A virus elicits antibodies that cross-react with RSV/B virus (213). In contrast, primary RSV/B infection induces cross-reactive antibodies to RSV/A virus less efficiently. IgG responses to F and G proteins after primary RSV infection are predominantly IgG1 and, less frequently, the IgG3 subclass, a finding consistent with the protein domain bearing the dominant antigenic sites (214). In contrast, adults respond to the heavily glycosylated G protein with IgG1 and IgG2 subclass antibodies, with a dominant IgG1 subclass response to the less glycosylated F protein (215). The dominant IgG antibody response induced by natural infection to the F protein appears to be directed to the pre-fusion conformational form rather than the post-fusion form (216). The pre-fusion and post-fusion F conformations have both unique and shared antigenic sites, including a shared antigenic site that is the target for palivizumab and motavizumab (217). The structure of MPV F protein demonstrates a novel antigenic site that has a likely analogue on RSV F (218).

Antibodies directed to the G protein most likely neutralize the virus by preventing attachment of virus to cells, while antibodies directed to the F surface glycoprotein neutralize the virus by preventing virus-cell fusion and inhibiting cell-to-cell spread (219, 220). Other effector mechanisms mediated by IgG1 and IgG3, such as complement-enhanced neutralization and antibody-dependent cell cytotoxicity, help clear virus and virus-infected cells; this function has been suggested for non-neutralizing antibodies directed to the SH surface protein (221). Since RSV is restricted to the mucosa, the antibodies present in the lower and upper respiratory tract are important for disease prevention. In adults, concentrations of both IgG1 and IgG2 in serum and the terminal airways are similar (48).

Infection with PIVs induces both humoral and cellular immune responses in infected humans, including local and systemic IgG and IgA responses, and specific T-cell responses. PIV primary infection does not confer durable immunity, although immunity is usually sufficient to restrict virus replication from the lower respiratory tract and prevent severe disease following reinfection. Mucosal IgA levels correlate with protection from replication of PIVs in adults (222). Neutralizing antibodies against the HN and F protein are critical for long-term protection (223). Cellular immune responses are thought to play an important role in clearing RSV and PIV infections and preventing lethal disease. As noted above, persons with deficient cellular immunity may shed virus for months (51, 83) and infection may progress to fatal lower-tract disease (89, 161, 224).

The role of the cytotoxic T lymphocytes (CTL) in RSV, PIV, and MPV lung disease has not been fully elucidated in humans. RSV-specific CTL responses occur in a minority of infants with RSV bronchiolitis, and the highest responses occur in children with mild lung disease (225). Infants who develop RSV-specific CTL responses after RSV lower respiratory tract illness in the first year of life appear less likely to develop a lower respiratory tract illness in the second year of life (201). RSV-specific CD8<sup>+</sup> cytotoxic activity *in vitro* correlates with RSV-induced INF- $\gamma$  and inversely with IL-4 production by CTL (201). In adults, RSV-specific CTL recognize the N (nucleoprotein) protein, the SH protein, the F protein, the M protein and, poorly, the M2 protein but not the G protein (226, 227). In elderly adults, development of severe RSV infection may be due to low numbers of RSV-specific CD8<sup>+</sup> memory T cells that maintain effector function (228). RSV-specific CTL appear to be important for recovery from infection, and their maintenance is critical for the control of subsequent RSV infections. Humans develop a CD8<sup>+</sup> T cell response to MPV, but the contribution of these cells to immunity and disease in humans is unknown (229). Mouse studies show that T cells are required to clear MPV infection and memory T cells contribute to protection against reinfection (230–232). The finding of lymphopenia as an additional risk factor for severe disease among immunocompromised hosts supports the importance of T cells in viral clearance (88, 90, 233, 234).

Impairment of T-cell function appears to be a common denominator in children with prolonged shedding due to RSV, MPV, and PIVs (161, 235). MPV and other respiratory viruses induce pulmonary CD8<sup>+</sup> T-cell functional impairment, mediated by the inhibitory receptor programmed cell death-1 (PD-1); this functional impairment contributes to delayed viral clearance and reinfection in animals and may facilitate reinfection in humans (40, 231).

Secretory antibodies found in the nasal secretions consist of IgA, IgM, IgG, and IgE classes and are directed to at least the major surface glycoproteins of these viruses (236, 237). The rate and magnitude of IgG and IgA secretory antibody responses to RSV are lower in younger than older infants. With primary infection, secretory IgG and IgM antibodies peak between 8 to 13 days, while secretory IgA peaks between 14 to 28 days after onset of illness. After 2 months, infants have low or nondetectable levels of virus-specific secretory antibodies of all three immunoglobulin classes. Primary infections with PIVs result in low, transient virus-specific IgA responses in secretions (238).

The production of virus-specific IgE antibody has been associated with RSV disease severity (205, 239). During primary RSV and PIV infections, secretory virus-specific IgE antibody has been detected primarily in infants with bron-

chiolitis. Virus-IgE complexes may induce mast cells to release mediators that are responsible for smooth muscle constriction, increased mucus production, and vascular permeability.

### Correlates of immune protection

Infants with high levels of maternally acquired RSV- and PIV type 3–specific antibodies are better protected against lower respiratory tract illness than those with lower levels (51, 52). The level of neutralizing antibody in cord blood directly correlates with age at which primary RSV infection occurs and is inversely related to the severity of illness. The risk of reinfection in children and adults is also inversely related to the level of serum neutralizing antibodies for RSV and MPV (51, 52, 240, 241).

Human challenge models have increased understanding of the kinetics of illness following virus exposure and of the immunologic factors relevant for protection (43, 46, 242). Experimental challenge studies in adult volunteers show that serum virus-neutralizing antibody and nasal IgA titers correlate with protection against infection, although in one study serum and nasal antibody were not correlated and thus may be independent correlates of protection (242). However, symptoms, peak virus titer, and duration of viral shedding do not correlate with preexisting antibody titers among adults who have been successfully infected (43, 46, 242).

Other humoral correlates of immunity against RSV and PIV infections are IgG antibodies directed to the F surface glycoprotein and to the homologous G (HN for PIV) surface glycoprotein of the infecting virus strain (240, 243–245). However, even in the presence of high levels of virus-specific antibodies, primary infection and reinfection can occur (51, 52). For PIVs, serum antibodies to both HN and F proteins confer protection (246, 247).

## CLINICAL MANIFESTATIONS

### Respiratory Syncytial Virus

Any respiratory virus may be associated with a wide spectrum of illness severity ranging from inapparent infection or mild afebrile upper respiratory illness to severe and fulminating pneumonia. However, RSV and PIVs produce distinct clinical syndromes that are hallmarks of infection with these viruses, especially during epidemics. These viruses may also be associated with severe illness in a variety of immunocompromised hosts (see below).

#### Children

The characteristic illness caused by RSV in infants is bronchiolitis manifested by expiratory wheezing, air trapping, nasal flaring, subcostal retractions and, sometimes, cyanosis (Table 6). RSV is the most common virus associated with bronchiolitis, detected in approximately 70% of children with bronchiolitis during disease epidemics (49). Fever is not a prominent finding; approximately 50% of infants with RSV disease seen at the hospital will have moderate or greater elevations in temperature. Coryza and cough are common presenting symptoms. Radiographic pneumonia is common with primary RSV infection, and infants may have signs and symptoms of both clinical conditions simultaneously. The clinical presentation may depend on the proportion of the small airways partially occluded by the inflammatory process. This results in expiratory wheezing and air trapping, whereas subsegmental atelectasis results

**TABLE 6** Clinical manifestations of RSV, PIV, and MPV infection at various ages

from complete occlusion of the small airways. Radiographic findings depend upon the same factors. Partial occlusion of the bronchioles results in hyperaeration and flattening of the diaphragms (Fig. 7), while complete occlusion results in atelectasis that may be lobar, usually involving the right middle or right upper lobe (Fig. 8).

Hypoxemia is a common finding in infants with lower respiratory tract disease (125). Apnea occurs in about 20% of hospitalized young infants with RSV illness (248) and may be the presenting sign of RSV in premature babies or infants less than 3 months old. Apnea occurs in approximately 5% of children hospitalized with bronchiolitis, generally within the first 2 days of hospitalization (249). Oxygen saturation is lower on average in infants with apnea, even if other signs of severe disease such as subcostal retractions are absent. Infants with apnea tend to be younger, to be born before 37 weeks' gestation, and to have a history of apnea of prematurity. Some deaths in infants who die unexpectedly at home may be a result of RSV infection accompanied by apnea. Interstitial pneumonitis is not commonly recognized

**FIGURE 7** Chest radiograph of an infant with bronchiolitis due to RSV. Peribronchovascular thickening with hyperaeration and flattened diaphragms bilaterally are evident. Reprinted from Reference 240 with permission.

**FIGURE 8** Posterior-anterior (A) and lateral (B) chest radiographs of an infant with bronchiolitis and pneumonia due to RSV. with RSV infection, but cases are overrepresented in autopsy series (177). Therefore, the recognition of interstitial involvement should alert the caregiver to the need for repeat clinical assessment.

Acute otitis media (AOM) is a frequent complication of RSV infection in children, with rates up to 60% in some studies. RSV is commonly detected with bacteria in middle ear fluid samples (250). Severity decreases with age and following repeated infections, such that mild upper respiratory tract disease is typical of RSV infection in school-age children (115).

#### Adults

The common clinical presentation of RSV infection in otherwise healthy adults is similar to that reported for older children. Initial symptoms commonly include upper respiratory tract complaints like nasal congestion, cough, sore throat or hoarseness, earache, and low-grade fever (Table 6). Adults may have minimal or no symptoms and still have RSV isolated from respiratory secretions, or they may be symptomatic with sore throat, bronchitis, or wheezing. In

adults with underlying pulmonary disease, RSV infection may manifest as increased dyspnea with or without hypoxia and may be accompanied by cough, fever, nasal congestion, and wheezing (68). The clinical presentation of disease and morbidity and mortality caused by RSV and MPV in the noninstitutionalized elderly population is similar to that observed with influenza A infection (73, 78, 80). In elderly persons, clinical features with RSV infection are often indistinguishable from those of influenza, with the possible exception of a lower frequency of high-grade fever and higher frequency of wheeze in RSV (75).

### Parainfluenza Virus

Prospective studies of children indicate that primary infection with PIV is usually symptomatic but often mild (51, 127). In children followed during the first two years of life, nearly one-third of primary infections result in lower respiratory tract disease, but only 5% of primary infections resulted in illnesses for which medical care was sought (127, 251). The classic syndrome for PIV in children is croup, or laryngotracheobronchitis. Croup is manifested by fever, hoarseness, and a barking cough in a child usually between 6 and 18 months of age. Severe narrowing of the subglottic area of the trachea may progress to cause inspiratory stridor (Fig. 9). Observation in the hospital may be required for children with severe stridor, so that the airway can be secured. PIV type 1 is the major cause of croup, though PIV type 2 also is associated (252). PIV type 3 causes sporadic croup but also causes bronchiolitis and pneumonia in young infants, at a lower frequency than RSV (Fig. 10). PIV type 4 disease is not associated with croup and typically presents with nonspecific respiratory symptoms that may progress to bronchiolitis, paroxysmal cough, or lower respiratory tract disease with hypoxia (253).

PIV disease in adults commonly presents as a relatively nonspecific upper respiratory tract illness, with rhinorrhea, nasal congestion, and hoarseness commonly noted. Reinfection with PIV is a common cause of serious morbidity in adults with chronic lung disease (102). In immunocompromised pediatric and adult patients, PIV infection typically presents with low-grade fever and upper respiratory tract symptoms that may persist or rapidly progress to lower respiratory tract disease with cough, wheezing, and hypoxia.

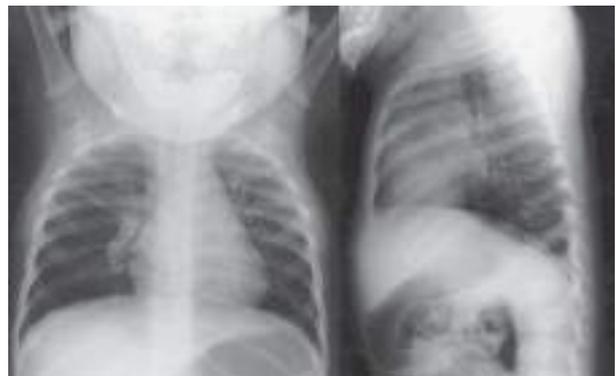

**FIGURE 9** Chest radiograph of a child with croup due to PIV type 1. Peribronchial thickening, scattered infiltrates, and marked narrowing of the superior portion of the trachea (arrow) are evident.

**FIGURE 10** Chest radiograph of an infant with pneumonia due to PIV type 3. Right upper lobe atelectasis and multilobar infiltrates are evident.

### Human Metapneumovirus

Children with MPV infection typically present with upper respiratory symptoms such as rhinorrhea, cough, and fever, similar to those with RSV and PIV (Table 6). Conjunctivitis, vomiting, diarrhea, or rash are occasionally reported but are not prominent in most studies. The lower respiratory tract syndromes most frequently associated with MPV are bronchiolitis, croup, pneumonia, and asthma exacerbation. These illnesses are neither clinically nor radiographically distinct from the same clinical syndromes caused by other common respiratory viruses (Fig. 11). Reinfections with MPV are more likely to be limited to the upper respiratory tract in otherwise healthy children (53, 72). MPV is associated with a substantial proportion of AOM in children, and viral RNA has been detected in middle ear fluid from patients with AOM (254, 255).

### Infections in Immunocompromised Patients

Immunocompromised children and adults are vulnerable to severe RSV, PIV, and MPV infections (81, 87–89, 105, 161, 165, 256, 257). RSV and PIV type 3 infections are especially devastating for infants with severe combined immunodeficiency syndrome (SCID) (208, 258) in whom persistent viral shedding and the development of progressive pneumonia occur. Children or adults who acquire RSV or MPV during or shortly after chemotherapy for malignancy also may have severe, life-threatening disease (81, 89). Children with human immunodeficiency virus (HIV) infection have a higher rate of pneumonia, decreased likelihood of wheezing, prolonged viral carriage with intermittent disease, and increased morbidity following infection by one of these viruses. Although the clinical course is generally not fulminant in HIV-positive patients when good supportive care and anti-retroviral therapy are available (235, 259), the overall mortality of these patients in developing countries is substantial, with significantly higher rates of lower respiratory tract disease and mortality (7.5% vs. 0%) in HIV+ versus HIV- children (257, 260).

Hematopoietic stem cell transplant (HCT) recipients of all ages may have a more fulminant course following RSV or PIV infection, particularly if infection occurs around the time of transplantation (82, 224, 261). Adults with leukemia (262), profound chemotherapy-induced myelosuppression (262, 263), and solid-organ transplant recipients, particularly lung and pediatric heart recipients, are also at risk of fatal outcome. Initial clinical symptoms related to RSV infection in these patients are similar to those in immunocompetent persons, but upper respiratory tract infection progresses more often to lower respiratory tract disease, with likelihood of progression related to immune status (83, 88, 100, 166, 264). Risk factors for disease progression include lack of engraftment, decreased lymphocyte count, and older age (265). Evidence of pulmonary infiltrates on chest radiograph may be delayed or absent in patients with severe neutropenia but may become apparent following immune reconstitution or on chest computed tomography or magnetic resonance imaging (266). Over 1 to 2 weeks, lower respiratory tract involvement may become evident by increasing respiratory distress, worsening hypoxia, and, frequently, the need for assisted ventilation. Recovery following assisted ventilation for RSV and MPV pneumonia occurs but remains uncommon despite advances in supportive care. Quantitative bronchoalveolar lavage (BAL) viral load has not been associated with mechanical ventilation or death for RSV, PIV, or MPV in adult patients following HCT; however, the detection of respiratory virus RNA in serum has been associated with fatal outcomes (267).

Many immunocompromised adults with PIV infection first present with symptoms of mild upper respiratory tract disease, but in contrast to RSV, influenza, and MPV infections, detection of PIV-1 and -3 in asymptomatic HCT recipients is relatively common, reported in 35% of 17 infected patients in one prospective study (165). Fewer than half of PIV-infected immunocompromised patients have a fever. In severely immunocompromised patients, such as allogeneic HCT recipients less than 100 days post-transplant, PIV type 3 is the most common PIV subtype detected, reported in 80% of 544 HCT recipients with PIV (100). In all PIV-infected transplant recipients, infection may progress to lower respiratory tract disease, with more serious disease linked to supplemental oxygen requirement, low monocyte counts, and high-dose (>2 mg/kg/day) steroid use. The

detection of PIV in BAL or other lower respiratory tract specimens is associated with decreased survival overall in HCT recipients (100). Higher pretransplant PIV-3 antibody levels are not protective against severe sequelae (268). Concomitant infections with other viruses or fungi or severe graft-versus-host disease are relatively common in adult patients with PIV pneumonitis (269, 270).

MPV also causes severe infections in immunocompromised hosts. Fatal infection attributed to MPV has been reported in cancer patients, and MPV is a relatively common cause of acute respiratory infection in children and adults with malignancy and HCTs or organ transplants (87, 88, 256). Risk factors for severe MPV infection include lymphopenia (88, 89, 163).

### Complications

AOM is the most common complication of RSV, PIV, and MPV infection (271). The virus infection causes dysfunction of the Eustachian tube resulting in negative pressure in the middle ear. Normal clearance mechanisms for bacteria that reside in the nasopharynx are disrupted, and purulent middle ear infection may result. Acute sinusitis may develop by the same pathogenetic process.

Bacterial pneumonia may complicate lower tract infections due to these viruses, although the risk following RSV infections is low, as determined by studies of hospitalized children in the United States and Europe (272, 273). Recent studies support an association of acute RSV infection enhancing the incidence of pneumococcal pneumonia and or invasive pneumococcal disease within the 30 days after RSV infection (274–276). Superinfection with pneumococci and staphylococci are more common after PIV infections (277). Higher rates of serious bacterial pneumonia have been seen in HIV+ children in prospective studies carried out in HIV-endemic areas in Africa (260). Outbreaks of bacterial tracheitis have been reported in the past with PIV type 1 epidemics (278).

PIV2 and PIV3 have been associated with parotitis by isolation of the virus from oral swabs, although in some of these cases convalescent sera demonstrated seroconversion to mumps virus (279–281).

PIV2, PIV3, PIV4, and MPV have been associated with aseptic meningitis and encephalitis, with detection of the virus in cerebrospinal fluid (280, 282–287). However, it appears that this is a rare manifestation of infection with these viruses.

### Asthma

The relationship between the development of reactive airway disease and RSV infections is intriguing (288, 289). Children with RSV bronchiolitis in infancy have a high risk of recurrent wheezing illness during the first decade of life. Longitudinal studies of pulmonary mechanics after RSV bronchiolitis show persistent abnormalities. Prophylactic use of palivizumab, a monoclonal antibody to prevent RSV hospitalization, in infants has been associated with a lower incidence of physician-diagnosed asthma and recurrent wheezing in the subsequent 2 years of life (290). Additional intervention trials have strengthened the potential causality of early virus infection and recurrent wheezing (291, 292), but establishing a causal relationship to childhood asthma will require longer studies. RSV, PIV, and MPV infections are frequently associated with asthma exacerbations in older children and adults, and prevention of these infections in

this high-risk group could significantly reduce morbidity (102, 104, 293).

A causal relationship between MPV infection and development or exacerbations of asthma is currently unproven. One study of outpatient children did not find an association between MPV and asthma exacerbations (294), while another found a highly significant association between MPV and the diagnosis of acute exacerbation of asthma (72). MPV infection has been detected in 8.9% of children hospitalized for wheezing and in 6.9% of adults hospitalized for asthma exacerbations (293, 295). One study reporting a strong association between infantile MPV bronchiolitis and asthma at age 5 years (296) requires confirmation, in part because of the difficulty of making the diagnosis of asthma during infancy, when acute wheezing frequently is associated with viral infections.

### Clinical diagnosis

Epidemiological and clinical features including age, season, and clinical findings are helpful in determining the etiology of disease, particularly during relatively discrete winter outbreaks. However, because the viral seasons and symptoms can overlap, laboratory testing is required to confirm the diagnosis. The clinical findings of RSV in immunocompetent adults are nonspecific, and definitive diagnosis requires laboratory testing. Moreover, infection with more than one virus may be present. Because clinical care in young children is generally supportive, routine viral testing for all children with bronchiolitis is not currently recommended (297). However, for severe disease caused by these viruses, high-risk hosts, or those who are hospitalized for respiratory symptoms, laboratory testing for a specific diagnosis may alter care.

The differential diagnosis of croup due to PIV infection includes upper airway obstruction due to foreign bodies or bacterial epiglottitis, an entity less commonly seen since the decline of *Haemophilus influenzae* type b infections.

## LABORATORY DIAGNOSIS

### Sample type and handling

The diagnosis of respiratory viral infections is critically dependent on the type and quality of the clinical specimen and proper handling of the specimen prior to laboratory studies (298). Adequate clinical specimens are needed to avoid false-negative diagnoses. The preferred specimen type for the diagnosis of RSV, PIV, and MPV in infants and young children is a nasal wash (299, 300), aspirate (301), or mid-turbinate swab. A nasal wash specimen is the classical sample used for viral diagnosis by culture and for obtaining samples for cytokines or antibodies. The amount of RSV present in nasal wash specimens from young children is very high, ranging from  $10^3$  to  $10^8$  PFU/ml (169, 302), or  $10^3$  to  $10^{11}$  genome copies/ml by RT-PCR (mean,  $7.6 \log_{10}$ ) (303).

Nasopharyngeal swabs and mid-turbinate swabs are not as sensitive as nasal washes for viral diagnosis by culture or direct fluorescent antigen detection; however, they have good diagnostic yields with molecular detection methods (299, 304). Specimens from adults are less sensitive than those from children as a result of decreased viral load. Other clinical specimens which have proven useful for the detection of RSV, PIV, and MPV in patients of all ages include endotracheal aspirates collected from intubated patients (305), bronchoalveolar lavage (BAL) (81, 89), nasal mucosal epithelium collected by scraping (157), sputum (306), and lung tissue obtained by biopsy or at autopsy (81, 89, 166).

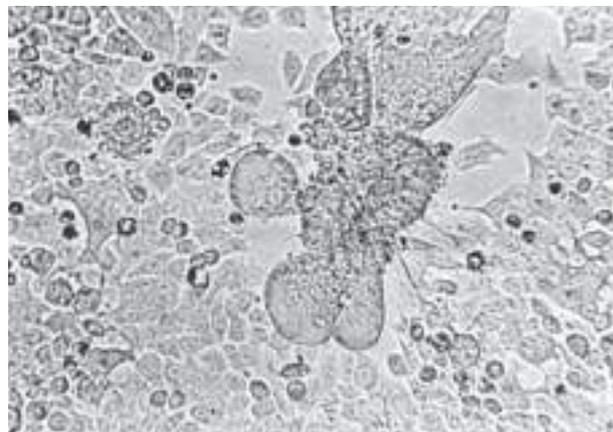

### Virus isolation

Virus isolation in cell culture is slow and labor intensive and is being replaced by sensitive and rapid nucleic acid amplification-based molecular diagnostic methods. Clinical specimens should be transported on ice and inoculated onto cell culture lines within 4 hours of collection, and those that are not immediately processed should be flash frozen using alcohol and dry-ice baths (298). Cell lines such as HEp-2, A549, or Vero cells are best used for the isolation of RSV. Mixed cell cultures containing two or more cell lines have also been used with or without centrifugation to enhance respiratory virus detection (307). RSV is identified by a characteristic syncytial pattern formed by the infected cells (Fig. 12). For PIV isolation, primary or continuous monkey kidney cells (e.g., LLC-MK2) with trypsin added in the medium are equally sensitive (308). PIV-3 can produce a recognizable cytopathic effect with syncytium formation in continuous cell lines (309), but cytopathic effect is generally not detected with other PIV types. PIV 4 has a restricted host range in cell culture, growing mainly in LLC-MK2 cells without syncytium formation or typical cytopathic effect, except for cell rounding that progresses to destruction of cell monolayers (310). MPV has been cultivated in a number of cell types, most commonly LLC-MK2 (47). The addition of trypsin is required for efficient growth of MPV in culture. Cytopathic effect caused by MPV consists of cell rounding and syncytia (Fig. 13) and is generally not seen for several weeks after inoculation. MPV does not hemadsorb, but fluorescent antibody detection has been reported (311).

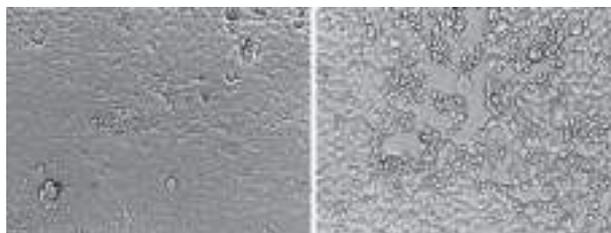

### Antigen detection

Rapid diagnosis of RSV and PIVs using direct or indirect immunofluorescence (IF) methods became widely used with the advent of commercially available reagents (312–314) and has been adapted to detect MPV (311). Advantages of IF methods include the direct examination of clinical sample for epithelial cells (permitting specimen quality control), rapid results, and low cost. The IF method has become less widely used because it is less sensitive than molecular diagnostics, is not suitable for large-scale testing, and requires trained technicians and specialized equipment.

The availability of point-of-care tests (rapid antigen detection test) for the detection of RSV, PIV, and MPV antigen

**FIGURE 12** Cytopathic effect of RSV in cell culture on a continuous human epithelial cell line (HEp-2 cells) after 1 week of incubation. Large syncytial cells are noted, with ballooning and coalescence of RSV-infected cells.

**FIGURE 13** Cytopathic effect of MPV in cell culture on a continuous monkey kidney epithelial cell line (LLC-MK2 cells) after 14 days of incubation. Rounding up and detachment of cells are noted, with developing syncytia.

in clinical specimens provides a quick, reliable, and relatively inexpensive diagnostic test. Currently available point-of-care tests for RSV in pediatric specimens have sensitivities and specificities ranging from 80% to 95% (133, 315). Rapid antigen tests for PIV or MPV are not yet available in the United States. Antigen detection tests with nasopharyngeal specimens obtained from adult patients have much lower sensitivity, most likely because of the substantially lower viral titer (often <100 PFU of RSV/ml in immunocompetent adults) (169). In general, point-of-care tests do not require expensive equipment or highly skilled personnel, take only 15 to 20 minutes from start to finish, and are suitable for single specimens or batch testing of many specimens. Disadvantages include the lack of sensitivity compared to molecular diagnostic methods, absence of evaluation of the quality of the clinical sample, and potential false positives when samples with blood or mucus are tested. Point-of-care tests are often waived by the Clinical Laboratory Improvement Amendments, have been successfully used in clinics, at the bedside, and by non-laboratory personnel (314).

### Nucleic Acid Detection

Molecular diagnostics, such as multiplex real-time PCR, have replaced cell culture, IF, and ELISA in many diagnostic laboratories because they can be automated, have high sensitivity and specificity, excellent quality control procedures, and detect a large battery of viral and bacterial pathogens rapidly in a single sample. The use of molecular diagnostics has significantly improved sensitivity compared to cell culture and IF, especially in adults (316). Reliable diagnosis of MPV currently depends on molecular techniques based on nucleic acid amplification assays. Several different RT-PCR methods are quite sensitive (303, 317, 318). Use of multiple simultaneous PCR reactions in clinical samples may be useful when PIVs and RSV are co-circulating (319). Numerous rapid multiplex PCR assays are now commercially available that can detect up to 18 or more viruses simultaneously (320, 321). More than a dozen single or multiplex molecular respiratory virus assays are FDA-cleared, with time to result ranging from less than 1 to 8 hours, but most (including all multiplexed assays) can currently be performed only in a clinical laboratory rather than at point-of-care. These assays are sensitive and specific and some can differentiate all four PIV subtypes (322). PCR sequencing assays have been applied to the molecular epidemiology of RSV, PIV, and MPV by analyzing a portion of the G or F protein gene (162, 323).

### Antibody Assays

Acute- and convalescent-phase sera are generally required for the serologic diagnosis of RSV, PIV, or MPV. A 4-fold

increase in antibody after at least 2 weeks, and preferably 3 to 4 weeks, or the appearance of specific IgM antibody is required for serologic confirmation of infection. Serologic assays have been useful in epidemiological and vaccine studies but less so clinically. Furthermore, young infants may not generate a reliable response to RSV or may have antibody responses obscured by maternal antibody. Immunocompromised patients or older persons who have had repeated infections may not demonstrate rises in antibody titer (298). Antibodies to RSV are sensitively measured by ELISA, neutralization, indirect IF, and plaque reduction (with or without complement enhancement) assays (305, 324, 325). RSV antibodies measured by the microneutralization test correlate best with protection from RSV disease in an animal model (326). Antibody to PIV in serum and respiratory secretions can be measured by complement fixation (CF), neutralization, or hemagglutination-inhibition (HI) techniques (309, 327). Careful interpretation of the CF or HI antibody results is required because heterologous cross-reactions are frequent among the paramyxovirus group, including mumps virus (309). Serologic evidence of previous MPV infection has been determined by measuring virus-neutralizing antibodies in plaque reduction assays (6) and by ELISA methods based on recombinant MPV proteins (328).

### PREVENTION

The international health impact and economic burden attributed to RSV, PIV, and MPV is becoming more appreciated and contributes to the urgency of developing safe and effective vaccines against these pathogens (115, 329, 330). Progress has been slow (331), in part because of the serious adverse events following the use of the formalin-inactivated RSV (FI-RSV) vaccine in young children (332), early failures with live-attenuated virus vaccines, and the ineffective immune response elicited by primary RSV infection. The identification of serum neutralizing antibody as a correlate of protection against serious RSV lower respiratory tract disease has been an important advance in this field. Candidate vaccines against PIV and MPV have been tested in preclinical models, with limited human studies (38, 39, 333–337).

### Management of nosocomial outbreaks

Nosocomial outbreaks characteristically occur from multiple introductions of community respiratory viral strains (338). For prevention of nosocomial transmission, contact isolation precautions are effective as long as compliance with the policy is maintained among personnel (339). The importance of isolation based on symptoms as opposed to viral-test positives has been shown, but prolonged shedding of respiratory viruses with even minimal symptoms may complicate efforts of infection control. Patients known or suspected to be infected with RSV, PIV, or MPV should be kept in contact isolation or cohorted together until symptoms have resolved and repeated sensitive diagnostic tests are negative (340).

Hospital personnel may play a role in the transmission of RSV to susceptible patients (162). Spread of RSV can be limited in these settings by aggregating infected and exposed individuals and adhering to strict hand-washing procedures, but hand washing is frequently neglected (341, 342). Use of gloves, masks, and goggles in the hospital setting will also limit spread (343). The use of masks and goggles can decrease nosocomial infections in hospitalized children and medical personnel by preventing viral infection of

**TABLE 7** Control measures for the prevention of nosocomial RSV, PIV, and MPV infections

Institute contact isolation precautions (strict adherence).
Pay strict attention to good hand washing and/or use of gloves.
Wear a gown to prevent exposure of clothing to contaminated secretions.
Screen hospitalized patients for RSV, PIV, and MPV infections.
Cohort infected patients.
Exclude visitors with respiratory infections.
Prevent staff with respiratory illness from caring for susceptible patients.
Consider the use of eye-nose goggles when caring for subjects at high risk for severe viral infections.

personnel, who then transmit virus to susceptible individuals (343, 344). Strict compliance with glove and gown isolation precautions can also significantly reduce nosocomial RSV infections (339, 342). Such strict measures are appropriate in high-risk settings such as pediatric intensive care units or bone marrow transplant wards. Restriction of visitors, particularly young children, in hospital wards at high risk for RSV infection may be necessary during community epidemic periods. Continued compliance through the respiratory virus season by all members of the health care team is critical to any successful infection control policy. The Committee on Infectious Diseases of the American Academy of Pediatrics has provided guidelines for the prevention of nosocomial infections attributed to RSV and PIVs, as illustrated in Table 7 (345).

## Prophylaxis

### Passive immunoprophylaxis

A humanized monoclonal antibody specific for antigenic site II of the F protein of RSV, palivizumab (Synagis®), has been approved for use in high-risk children since 1998. It is currently the only FDA-approved monoclonal antibody for prophylaxis in infants and young children at increased risk of hospitalization with RSV infection. It was approved for preterm infants less than 35 weeks' gestational age, for infants with chronic lung disease of prematurity (CLD), and hemodynamically significant congenital heart disease (CHD). The administration of 15 mg of palivizumab per kg intramuscularly at 4-week intervals during the RSV season has been shown to be safe and effective in reducing hospitalization due to RSV by 55% in preterm children, children with CLD, and children with CHD (346, 347). Motavizumab, a more efficacious monoclonal antibody in the prevention of RSV in high-risk infants, was not approved by the FDA because of safety concerns (348, 349). Next-generation RSV F protein monoclonal antibodies that target antigenic sites on the pre-fusion F form with enhanced neutralizing activity or contain novel mutations in the Fc-domain (YTE) that extend half-life 3- to 4-fold, allowing a single dose per season, are undergoing clinical evaluation (Clinical Trials. Gov ID: NCT02325791 and NCT02290340). Other antibodies in development are broadly neutralizing monoclonal antibodies against both RSV and MPV (350, 351) and recombinant human polyclonal antibodies against viral infections including RSV (352).

The 2014 Guidelines issued by the American Academy of Pediatrics added additional restrictions for palivizumab prophylaxis among high-risk infants and young children, in part, driven by its high cost (353). The revised guidelines

recommend that prophylaxis with palivizumab be considered for 1) preterm infants born before 29 weeks without CLD or CHD and who are younger than 12 months at the start of the RSV season; 2) preterm infants with CLD during the first year of life and whose CLD developed at less than 32 weeks' gestational age. A second year of prophylaxis may be considered for infants who continue to require medical support for CLD; and 3) infants 12 months old or younger with hemodynamically significant CHD during the first year of life, in particular, those with acyanotic heart disease who require medication for control of congestive heart failure or will require cardiac surgical procedures. Other high-risk groups to consider for prophylaxis are children during the first year of life with pulmonary abnormalities or neuromuscular disease and children younger than 24 months of age who are profoundly immunocompromised.

Passive immunoprophylaxis against PIV and MPV infection has not been studied.

### Active immunization

There are currently no approved RSV, PIV, or MPV vaccines. In the 1960s, field studies were conducted with FI-RSV and PIV vaccines (332, 354). The FI-RSV vaccine produced by Pfizer was a crude RSV-monkey kidney cell harvest precipitated with a high concentration of alum and concentrated 100-fold. The PIV vaccine was prepared similarly. In all four studies, some children, usually less than 2 years of age, who received the FI-RSV vaccine experienced more severe respiratory disease, including some deaths, on subsequent infection with RSV. Enhanced disease was not observed in the PIV vaccinees. FI-RSV vaccinees had a nearly 8-fold-increased risk of pneumonia and a 16-fold-increased risk of hospitalization compared to the controls (175). The enhanced respiratory disease described in children less than 2 years of age appeared similar to naturally occurring disease in infants less than 6 months of age who were hospitalized with RSV bronchiolitis/pneumonia. Importantly, the FI-RSV vaccine produced by Merck was not associated with enhanced disease in young children (355, 356), suggesting that variables other than the RSV vaccine may have been required for the development of vaccine-enhanced disease. The pathogenesis of vaccine-enhanced disease remains poorly defined. Advances in the development of new RSV vaccines have been hampered by the inability to identify the immune mechanism responsible for vaccine-enhanced disease and a satisfactory animal model.

With the technical advancements in molecular virology and vector development, a greater understanding of the structure-function relationship of RSV proteins, and an expanding appreciation of RSV-related morbidity and mortality among children and older adults worldwide, there has been an explosion of candidate RSV vaccines at the preclinical and clinical phases of development ([www.path.org/vaccinesresources](http://www.path.org/vaccinesresources)). A broad array of vaccine formulations is being evaluated in animal models. These include live attenuated, whole-virus inactivated, virus like-particles, subunits, DNA or RNA, and vector-based RSV vaccines. Most of the inactivated, DNA, and vector vaccines are composed solely of or include as a major component the F gene or F protein in the vaccine formulation. This is because the F protein is relatively well conserved among the RSV/A and RSV/B genotypes, and it contains conserved antigenic sites that induce neutralizing antibodies. Two major conformational forms of the F protein occur in RSV, the pre-fusion and postfusion conformations (217). Both the pre-fusion and postfusion conformational forms have unique

and shared antigenic sites. There is an ongoing debate as to which conformational form will lead to the better vaccine. Relevant to this discussion will be issues related to production, cost, antigen stability, safety, immunogenicity, and efficacy. A nanoparticle RSV-F vaccine currently leads the RSV vaccine field with two phase III trials started in the winter of 2015, one in older adults and a second in pregnant women. However, recently an RSV-F nanoparticle vaccine induced neutralizing antibodies and demonstrated 50% protection against RSV infection diagnosed by Western blot antibody assay in women of childbearing age (357). In a phase II trial in older adults, this RSV-F nanoparticle vaccine prevented 64% of moderate to severe RSV cases with 44% efficacy against symptomatic confirmed RSV cases (NCT02266628, [ClinicalTrials.gov](http://ClinicalTrials.gov)) (358). This is the first vaccine candidate to date that has been reported successful in preventing serologic and symptomatic RSV infection.

Live attenuated vaccines could potentially circumvent the issues related to the enhanced disease of FI-RSV vaccine and also take advantage of mucosal immunity. However, developing an attenuated, genetically stable, non-transmissible, and immunogenic live RSV vaccine for use in infants has proven difficult (331). Early attenuated cold-adapted temperature-sensitive phenotypes were found to require further attenuation by chemical mutagenesis (359, 360). Studies of genetically characterized live attenuated, temperature-sensitive RSV vaccines have been carried out in infants as young as 2 months of age (361). None of the infants and young children who received the live attenuated RSV vaccines developed enhanced disease on subsequent exposure to RSV (362). More recently, a live attenuated RSV vaccine with alterations in the M protein has shown enhanced immunogenicity in a small study conducted in seronegative children (363). Codon deoptimization is an alternative strategy being pursued to generate a stable, attenuated and immunogenic live attenuated RSV vaccine (364, 365).

Inactivated and live attenuated PIV vaccines have been studied. Two different strategies are currently under active development by the National Institute of Allergy and Infectious Diseases (NIAID) and industrial partners for PIV3 vaccines: candidates based on live-attenuated bovine parainfluenza type 3 (BPIV3) strains, and those based on a cold-adapted live attenuated PIV 3. BPIV3 vaccines have been tested in infants, children, and adults with good safety and immunogenicity (366–368). Evaluation of cold-adapted, live attenuated PIV type 3 vaccines in children has paralleled that of the live attenuated RSV vaccine (366). Newer live attenuated PIV vaccines have shown promise in clinical trials, with a cDNA-derived recombinant version of a PIV3 strain developed via repeated passages at low temperatures showing promise of safety and immunogenicity in young seronegative children (333). PIV subunit vaccines with proven efficacy in animal models have not been evaluated in clinical trials (369). The live attenuated bovine PIV-3 vaccine is also being studied as a vaccine vector (370, 371), using a chimeric construct expressing the PIV-3 F (fusion) and HN (hemagglutinin-neuraminidase) proteins and the RSV F protein. Such vaccines have been tested in seropositive and seronegative children and young infants (372).

Several approaches to MPV vaccines have been tested in animal models, including subunit proteins, chimeric virus vectors, T-cell epitope vaccines, virus like particles, and live attenuated virus (373). Recombinant F protein subunit vaccines for MPV have been demonstrated to be effective in rodents (39, 334). Peptide vaccines based on CD8<sup>+</sup> T-cell

epitopes reduced viral titers in mice (374). Recombinant chimeric PIV and alphavirus-vectored vaccines that expressed MPV F, or avian/human MPV chimeric vaccines, were immunogenic and protective against challenge with MPV in rodents (337, 375, 376). Virus like particles induced neutralizing antibodies and T-cell responses and protected against challenge in mice (232, 335, 377). Live attenuated MPV vaccines are under development using reverse genetics approaches (378). These include gene deletion (G and/or SH), temperature-sensitive mutations, mutations in M2-1 or L, mutations in the N-glycosylation sites of F protein, and mutation of the integrin-binding RGD motif in the F protein (24, 38, 336, 379–381).

### Maternal Immunization

RSV-specific serum neutralizing antibodies are efficiently transferred from the mother to the newborn (243, 382). High levels of neutralizing antibodies acquired transplacentally by the neonate protect against lower respiratory tract disease during the first few months of life. The decline of virus-specific immunity provided by maternal antibodies closely mirrors the half-life of IgG1, the principal IgG subclass antibody to RSV F and G glycoproteins that is transplacentally transferred in preterm and term neonates (382).

One strategy to protect infants younger than 6 months of age from RSV disease is to augment maternal antibody by administration of an RSV vaccine to the mother during pregnancy (383, 384). An RSV-F nanoparticle vaccine was shown to be well tolerated, safe for the mother and fetus, and immunogenic in a phase I randomized, placebo-controlled trial in pregnant women (NCT02247726, [ClinicalTrials.gov](http://ClinicalTrials.gov)) (385). A worldwide phase III trial of the RSV-F nanoparticle vaccine in pregnant women is ongoing (NCT02624947, [ClinicalTrials.gov](http://ClinicalTrials.gov)).

## TREATMENT

### Supportive Treatment

Previously healthy children and immunocompetent healthy adults infected with RSV generally require supportive treatment only. Antibiotic treatment is usually not necessary except for concomitant suspected bacterial AOM or sinusitis (272, 273). The potential hypoxemia, apnea, and poor oral intake resulting from infection in young infants require close medical management, and hospitalization may be required for children less than 1 year of age. Intravenous fluid replacement and oxygen therapy may be necessary. Secondary bacterial pneumonia is uncommon (272). Because the hypoxemia is related to unequal ventilation-to-perfusion ratios, infants will generally respond to inspired oxygen concentrations of 40% or greater (298). Corticosteroid therapy is not effective in the treatment of acute RSV and does not benefit pulmonary function during convalescence in young infants (386, 387). Thus, systemic or inhaled steroids are not recommended for treatment of RSV. Bronchodilator therapy is no longer recommended, based on studies that fail to show shortened hospital stay or improved outcomes (388). Supportive management in the care of lower respiratory tract disease due to RSV in the older child or high-risk adult may include oxygen therapy, close attention to fluid and electrolyte balance, and aerosolized bronchodilators. In patients with underlying pulmonary or heart disease, recovery from the effects of RSV infection may take weeks to months.

Treatment of croup, the most common clinical presentation of PIV infection, generally consists of reassurance of

the family and providing advice regarding the need for medical attention. Treatment of a child with croup in a mist tent has not been shown to be of benefit and is no longer recommended (389, 390). Systemic glucocorticoid therapy, including intramuscular dexamethasone, oral prednisolone, and nebulized budesonide is efficacious in mild to moderate and severe croup in the young child (391, 392). The decision to use and the route of administration—oral, injected, or aerosolized—should be based on the clinical assessment of the child, the ease of administration, cost, and duration of use. Epinephrine is used for symptomatic relief in patients with moderate to severe symptoms, but because the benefits of racemic epinephrine are short lived, such patients must be observed carefully after therapy to be sure that their clinical condition does not deteriorate after the effects of epinephrine have diminished. Children with airway obstruction or signs of hypoxia require admission to an intensive care setting for close monitoring and may benefit from treatment with intravenous dexamethasone; children with severe disease may require intubation. Antibiotic therapy is generally not beneficial except in cases of secondary bacterial infection, as suggested by persistent high fevers or purulent material noted at endotracheal intubation. Lower respiratory tract infections due to PIV in young children or immunocompromised hosts may require hospitalization and adjunct therapy, including intravenous fluids and oxygen support.

The majority of children infected with MPV can be managed at home with supportive care. For infants and children who require hospitalization, therapy is supportive, including supplementary oxygen and intravenous hydration. Bronchodilators and corticosteroids have been used empirically, but there are no controlled trials of these medications for MPV and no data to support or refute efficacy.

### Management of Severe Disease

Infants with respiratory failure require mechanical ventilation and may require pressor support. Severe RSV disease in very young infants can result in life-threatening damage to the lungs and secondary end-organ failure affecting the cardiac, renal, and hepatic systems. Some success with the use of other ventilatory support modalities such as high-frequency ventilation, mixtures of gases such as helium and oxygen or nitrous oxide, or extracorporeal membrane oxygenation (ECMO) to permit healing of the lung has been reported. Prolonged supportive therapy with ECMO for days to several weeks may be required for RSV infection (393).

Upper respiratory tract disease due to RSV in immunocompromised hosts (81) may progress to severe lower respiratory tract disease requiring ventilatory support. Underlying immunosuppression, high inspired oxygen concentrations, and the accompanying barotrauma may result in pulmonary hemorrhage or acute respiratory distress syndrome or both. The presence of pneumonia and associated respiratory failure in severely immunocompromised patients generally culminates in multi-organ system failure, with mortality in intubated patients approaching 80% to 90% (81, 83, 166, 224). Supportive care in these immunocompromised patients includes fluid and nutritional support, as well as aggressive therapy of secondary fungal, bacterial, or viral infections. Antiviral therapy is frequently used (discussed below).

PIV infection with lower respiratory tract disease in immunosuppressed patients, particularly very young patients or those in the immediate post-transplantation period, may result in a similar clinical picture (166, 394), although the overall mortality does not appear to be as high as with RSV (230, 268). Supportive and management measures are similar

to those used for RSV disease. Severe and fatal MPV infections have been reported in immunocompromised or other high-risk hosts, including very young children and the frail elderly (77, 78, 87–90, 153, 163, 257, 266). Mechanical ventilation and ECMO have been used to treat these patients.

### Antiviral Treatment

Ribavirin, a synthetic guanosine nucleoside, has been licensed as an aerosol formulation for treatment of RSV respiratory disease in children since 1986 and for the treatment of RSV disease in mechanically ventilated patients since 1993. Ribavirin is the only approved drug for lower respiratory tract disease due to RSV (395), but concerns regarding efficacy in children, cost, and drug administration issues have resulted in minimal current use of the drug, except in immunocompromised patients (396). Ribavirin is administered by small-particle aerosol from a solution containing the drug at a standard concentration of 20 mg/ml sterile water via aerosol for approximately 20 hours per day. Aerosol administration results in high levels of ribavirin in the secretions, with levels exceeding 1,000  $\mu\text{M}$  and little systemic absorption.

The duration of therapy in immunocompromised hosts with serious lower respiratory tract disease is generally greater than 5 days. Delayed antiviral treatment of RSV infections in markedly immunocompromised patients, such as bone marrow transplant recipients who receive antiviral therapy only after the initiation of mechanical ventilation, is not generally successful (264). Initiation of antiviral therapy at the stage of upper respiratory tract disease may decrease viral load and possibly reduce the risk of respiratory failure (397, 398). Intermittent therapy utilizing higher drug concentrations (60 mg of ribavirin/ml of water) administered over 2 hours three times daily to provide the same total amount of drug compared favorably with standard ribavirin therapy in one small clinical trial in children and in an uncontrolled trial in immunocompromised adults (398). This delivery method may improve patient access, improve compliance with therapy, and decrease environmental release of drug (399). A small randomized trial comparing short intermittent ribavirin in HCT patients with RSV upper respiratory tract disease demonstrated good tolerability and a trend of decreasing viral load over time compared to no treatment (400).

The potential environmental release of ribavirin has caused concern in hospital personnel because of the potential teratogenicity of ribavirin in the rodent model (401). Exposure is contraindicated in pregnant women because of its teratogenic potential. Administration of ribavirin via a ventilator, using a high-dose, short-duration method of drug delivery (399) or with a vacuum-exhausted treatment hood (402) results in minimal or no detectable ribavirin in the rooms of treated children.

Systemic antibody therapy (403), combined antibody therapy and ribavirin (264, 404), and aerosolized antibodies have been used for treating RSV disease (56). The combination of high-titer RSV immune globulin (RSVIG) and ribavirin has been associated with therapeutic success in uncontrolled studies in severely immunocompromised adults with RSV disease. Treatment studies with RSVIG (which is no longer available), palivizumab at 15 mg/kg, and motavizumab at 30 mg/kg have not proven efficacious in infants (405). Nanobodies, derived from the heavy-chain variable Ig domains that occur naturally in camels, administered by inhalation are being investigated for the treatment of RSV infection (406).

Two promising antiviral agents (GS-5806 and ALS-008176) have recently been shown to reduce viral load and clinical disease in an adult challenge model of RSV infection (407, 408). GS-5806 is a small molecule that inhibits virus entry by blocking viral fusion with cells in the respiratory epithelium, and ALS-008176 is an orally bioavailable prodrug of a nucleoside analogue that inhibits RSV replication by chain termination. Clinical treatment studies on these antiviral agents are ongoing.

There is no approved antiviral therapy for the treatment of PIV infections. Ribavirin inhibits PIV replication in cell culture and has been used for the treatment of lower respiratory tract disease in immunocompromised hosts (224). Case reports documenting decreased viral load and clinical improvement in children with severe combined immunodeficiency following multiple treatments with aerosolized ribavirin therapy have been published (99, 209). Ribavirin has also been utilized in bone marrow transplant recipients with upper and lower respiratory tract infection with PIV, without apparent benefit (224, 269). Intravenous ribavirin administered by intermittent dosing or constant infusion has been used in individual patients for the treatment of serious PIV infections (409), although retrospective studies of ribavirin in transplant recipients have not demonstrated convincing efficacy (270). A new potential antiviral therapy for PIV and other sialic acid-binding viruses targets the removal of lung epithelial sialic acid receptor for PIV, thereby preventing viral entry. A novel recombinant sialidase fusion inhibitor, DAS-181 (Ansun Biopharma, San Diego, CA), first developed as an antiviral agent for influenza, functions by cleaving sialic acids from the host cell surface, thereby inactivating the host cell receptor recognized by PIV (410). Successful use of this agent in pediatric and adult transplant recipients under compassionate use has been reported (411, 412), and a clinical trial in adult HCT recipients is ongoing.

Antiviral therapy for the treatment of severe MPV disease has not been studied in humans. One animal study suggested benefit with ribavirin and corticosteroid treatment of experimentally infected mice (413). Both ribavirin and polyclonal human immunoglobulin possessed *in vitro* virus inhibiting activity against MPV equivalent to their activity against RSV (414). A number of agents have shown efficacy *in vitro* or in animal models, including NMSO<sub>3</sub>, a sulfated sialyl lipid (415, 416); monoclonal antibodies (351, 417, 418); fusion inhibitor peptides (419, 420); and short interfering RNA (421, 422). There are numerous case reports of ribavirin and polyclonal intravenous immunoglobulin (IVIG) in severely immunocompromised patients (163, 423), but no controlled trials have been published for these interventions.

# Measles

WILLIAM J. MOSS AND DIANE E. GRIFFIN

## 38

Measles is a highly contagious disease caused by infection with measles virus (MeV), and it has caused millions of deaths since its spread within human populations thousands of years ago. Disease begins with fever, cough, coryza, and conjunctivitis followed by the appearance of a characteristic maculopapular rash. Genetically, MeV is most closely related to rinderpest virus, a pathogen of cattle that was recently eradicated. MeV was originally a zoonotic infection that adapted to humans 5,000 to 10,000 years ago when populations achieved sufficient size in Middle Eastern river valley civilizations to maintain a continuous chain of transmission among susceptible individuals. Subsequent introduction of MeV into naive populations resulted in high mortality. Millions died as a result of European exploration of the New World, largely due to the introduction of diseases such as smallpox and measles into native Amerindian populations (1).

Abu Becr, an Arab physician also known as Rhazes, first distinguished smallpox from measles in a 9th century treatise on the two diseases. Peter Panum, a Danish physician sent to the Faroe Islands in 1846 during a large measles epidemic, first described several of the basic epidemiological features of measles (2), including the highly contagious nature of MeV infection, the 14-day incubation period, and the lifelong immunity following infection. Following the practice of variolation to protect individuals from smallpox, Francis Home, a Scottish physician working in the 18th century, attempted to immunize children by inoculating their scarified skin with blood taken from infected individuals shortly after the rash appeared (3). Joseph Goldberger and John F. Anderson reproduced the disease in monkeys inoculated with filtered respiratory tract secretions from patients with measles, thus demonstrating that a virus was the cause of measles. MeV first was isolated from the blood and propagated in cell culture in 1954 by John Enders and Thomas Peebles, laying the foundation for the development of attenuated measles vaccines (4).

### VIROLOGY

#### Classification

MeV is a member of the genus *Morbillivirus* within the family *Paramyxoviridae*. Other members of the genus include canine distemper virus, which affects dogs and other mammalian

carnivores; rinderpest virus, which affects domestic cattle and swine; peste des petits ruminants virus, which affects sheep and goats; phocine distemper virus, which causes epizootic disease in seals; and porpoise and dolphin morbilliviruses, which cause epizootic disease in porpoises and dolphins, respectively. Morbilliviruses differ from other paramyxoviruses in lacking neuraminidase activity and in forming intranuclear inclusion bodies as a distinctive feature of their cytopathology.

#### Serotypes

Only one serotype of MeV exists, and recovery from measles confers lifelong immunity to reinfection. Although antigenic changes have been detected in the hemagglutinin surface protein, these variations have not reduced the protective immunity induced by wild-type MeV infection or measles vaccines. MeV remains a monotypic virus, likely because of functional constraints on the amino acid sequence and tertiary structure of the MeV surface proteins (5–7).

#### Genetic and Antigenic Variation

Despite the high degree of genetic variation expected of a single-stranded RNA virus, analysis of hemagglutinin (H), fusion (F), nucleoprotein (N), and phosphoprotein (P) gene sequences have shown that MeVs isolated during the 1950s and 1960s, including vaccine strains, were remarkably homogeneous and differed in sequence by no more than 0.5% to 0.6% at the nucleotide level. Sequence analysis of more recent wild-type MeVs has demonstrated some genetic variability relative to vaccine strains and these older wild-type viruses, particularly in the N and H proteins. One of the most variable regions of the MeV genome is the 450-nucleotide sequence at the carboxy-terminus of the N protein, with up to 12% variability between wild-type viruses that has been useful for genotyping. The World Health Organization (WHO) currently recognizes eight clades of MeV (designated A through H) and 24 genotypes. New genotypes may be identified with improved surveillance and molecular characterization. As measles control efforts intensify, molecular surveillance of circulating MeV strains can be used to document interruption of transmission and to identify the source and transmission pathways of MeV outbreaks (8, 9).

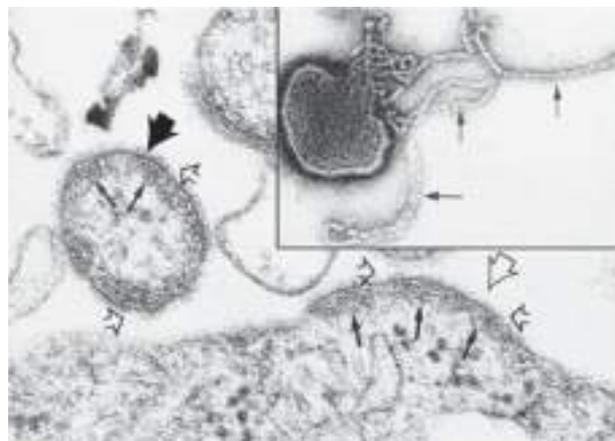

These genetic changes are accompanied by minor antigenic differences in the corresponding H, N, and matrix (M) proteins of some wild-type MeV isolates (10). Serum

specimens from vaccinated persons and from persons naturally infected during the 1950s and 1960s have comparable neutralization activity against vaccine viruses and recently isolated wild-type MeVs, although sera from persons infected in the 1990s have higher neutralization titers to the homologous wild-type virus (11). As an example of how genetic changes have failed to alter important antigenic epitopes, MeV isolates from a genotype circulating in the People's Republic of China during 1993 and 1994 differed from other wild-type viruses by as much as 6.9% in the H gene and 7% in the N gene. However, they did not differ significantly from other wild-type viruses in their anti-H monoclonal antibody binding patterns, and they were neutralized by human post-vaccination antiserum (12). Thus, neutralizing epitopes on the H protein are highly conserved among MeVs. Many centuries of selective pressure exerted by naturally acquired immunity and more recently by vaccine-induced immunity have not resulted in the selection of new antigenic types.

### Composition of the Virus

#### Virion Morphology

Measles virions are spherical, enveloped particles with a helical nucleocapsid and are morphologically indistinguishable from the virions of other paramyxoviruses (Fig. 1). Virion diameter averages 150 nm and varies between 100 and 250 nm. The envelope, a lipid bilayer derived from the plasma membrane of the infected host cell, carries surface projections composed of two transmembrane glycoproteins, the H and F proteins. On the inner surface of the envelope is the M protein, which interacts with the nucleocapsid and cytoplasmic tails of the H and F transmembrane glycoproteins to play a key role in virus maturation (Fig. 2). The helical nucleocapsid is packed within the envelope in the form of a symmetrical coil consisting of about 2,500 copies of

**FIGURE 1** Measles virus (MeV) in cell culture. An extracellular virion (large solid arrow) is coated with glycoprotein spikes (small open arrows) with the viral nucleocapsid (small solid arrows) positioned beneath the envelope. An infected cell has a region on the membrane (large open arrow) with viral glycoprotein spikes and subjacent viral nucleocapsids that is a site of MeV maturation and budding. Free paramyxovirus nucleocapsids (small solid arrows) from a disrupted virion are shown in the inset. (Courtesy of Cynthia Goldsmith, William Bellini, and Erskine Palmer of the Centers for Disease Control and Prevention, Atlanta, GA.) [Adapted from Oxman, 2nd edition of *Clinical Virology*.]

the N protein encapsidating the genomic RNA, together with small amounts of the P and the large polymerase (L) proteins.

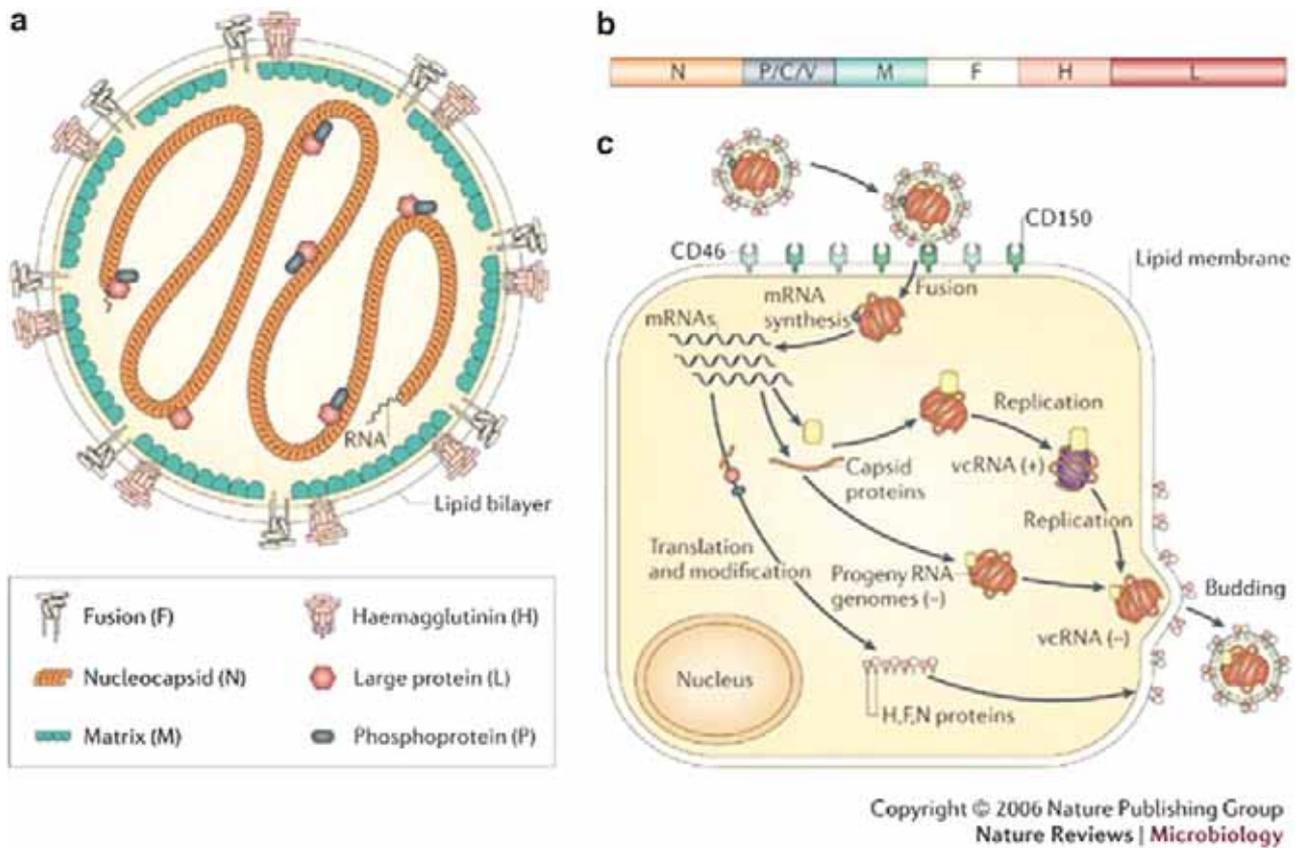

#### Genome

The MeV genome consists of linear, single-stranded, non-segmented RNA of negative polarity and contains about 16,000 nucleotides (Fig. 2), although the number of nucleotides can vary between virus strains (based on date and location of the measles virus isolate or sequence) and even between viruses of the same strain. At the 3' end of the genome, a 53-nucleotide leader sequence shows a high degree of complementarity to the extragenic 40 nucleotide trailer sequence at the 5' end, allowing the formation of a stable panhandle structure. The leader contains sequences that promote encapsidation of the nascent RNA by N protein and binding sites for the viral RNA polymerase. After the leader sequence are six consecutive non-overlapping genes that encode the N, P, M, F, H, and L proteins (Fig. 2). The P gene encodes two additional nonstructural proteins, C and V. The intergenic regions consist of a single trinucleotide, GAA, with a single variation between the H and L genes. In addition, there is an untranslated GC-rich region of about 1,000 nucleotides at the M-F gene boundary that spans the 5' end of the M gene and the 3' end of the F gene.

#### Structural and Regulatory Proteins

Six MeV gene products are structural proteins (Table 1). Three proteins, N, P, and L, are complexed with viral RNA to form the nucleocapsid, and three other proteins, M, H, and F, participate in the formation of the virus envelope (13). There is a transcriptional gradient from N to L for the mRNAs that encode these proteins, which determines their relative abundance. The N mRNA is transcribed first from the genome and thus is the most abundant. When expressed alone, N is an insoluble protein that migrates to the nucleus and self-assembles into helical nucleocapsid-like structures. When coexpressed with P in MeV-infected cells, N is retained in the cytoplasm as a soluble N-P complex. N binds both to RNA and to P, and it is required for transcription and replication. The N protein surrounds genomic and antigenomic RNAs that possess the leader sequence to form ribonucleocapsid structures that form the templates for both mRNA transcription and RNA replication. The conserved N-terminal portion of the N is required for self-assembly into nucleocapsids and for RNA binding (14). The variable C-terminal 125 residues form an intrinsically disordered region structurally similar to the acidic activation domains of cellular transcription factors (15). Sequence differences in the variable C-terminus of N provide the basis for the identification of different MeV genotypes.

The P protein is a polymerase cofactor activated by phosphorylation that forms tetramers and links L to N to form the replicase complex. The P protein modulates the assembly of functional MeV nucleocapsids after binding to individual molecules of N protein in the cytoplasm to form a soluble N-P complex that is required for RNA encapsidation. P also binds to the L protein to form an L-P complex involved in mRNA transcription and genome replication. The P gene of MeV, as in many members of the *Paramyxoviridae* family, encodes nonstructural proteins in addition to P. C is a basic protein translated using an alternate initiator methionine codon in an overlapping reading frame. V shares the P protein initiator methionine and the amino terminal 231 amino acids, but a non-templated guanosine residue is added through RNA editing, which shifts

**FIGURE 2** MeV structure, genome, and replication cycle. (a) MeV is a spherical, nonsegmented, single-stranded, negative-sense RNA virus. Of the six structural proteins, the phosphoprotein (P), large protein (L), and nucleoprotein (N) form the nucleocapsid that encloses the viral RNA. The hemagglutinin protein (H), fusion protein (F), and matrix protein (M), together with lipids from the host cell membrane, form the viral envelope. (b) The MeV RNA genome is comprised of approximately 16,000 nucleotides encoding eight proteins, two of which (V and C) are nonstructural proteins alternatively translated from the P gene. (c) The H protein interacts with F to mediate attachment and fusion of the viral envelope with the host cell membrane through specific receptors (CD46 and CD150) enabling viral entry into the cell. Remaining MeV proteins are involved in viral replication. The P protein regulates transcription, replication, and assembly of nucleocapsids. The M protein is critical for viral assembly. the reading frame to produce a different cysteine-rich C-terminus that has zinc-binding properties. Neither C nor V is necessary for MeV replication *in vitro* but both interact with cellular proteins to regulate the innate response to infection (16–18).

The L protein interacts with the P protein to form the MeV RNA-dependent RNA polymerase. Although P is required for polymerase activity, the L protein, which contains six regions that are highly conserved among the RNA polymerases of negative-stranded RNA viruses, has the catalytic activity for RNA synthesis.

H is the receptor-binding protein and an important determinant of cellular tropism. It is a type II transmembrane glycoprotein present on the surface of infected cells and virions as a disulfide-linked homodimer that self-associates to form tetramers (19). H has a 34 amino acid cytoplasmic tail preceding a single hydrophobic transmembrane region and a large C-terminal ectodomain with a propeller-like structure and 13 strongly conserved cysteines. The primary function of H is to bind to MeV receptors on the surface of host cells (19–21). The H protein is also responsible for the ability of measles virions to agglutinate simian erythrocytes by binding to a simian homologue of human CD46.

Antibodies that block hemagglutination generally also neutralize virus infectivity. A second essential function of H is to interact with the F protein to mediate fusion of the virion envelope with the host cell membrane for delivery of the ribonucleocapsid into the cell (19, 22).

F is a highly conserved type I transmembrane glycoprotein, synthesized as an inactive precursor  $F_0$  that is processed to the active disulfide-linked  $F_1$  and  $F_2$  that cooperate with H for fusion and entry. After synthesis and glycosylation in the endoplasmic reticulum,  $F_0$  is transported to the Golgi where it is cleaved by furin into  $F_1$  and  $F_2$  (Table 1). The  $F_1$  subunit, derived from the carboxy-terminus of  $F_0$ , is anchored in the viral envelope and has a cytoplasmic tail, the terminal 14 amino acids of which are highly conserved among morbilliviruses. At the amino terminus of  $F_1$  there is a 25 amino acid hydrophobic region, the fusion peptide, which interacts with the host cell membrane to induce fusion and is highly conserved among *Paramyxovirus* fusion proteins. Fully processed active  $F_{1,2}$  proteins are present as trimers on the surface of infected cells and virions. Although the function of F is to fuse the viral envelope with the host cell membrane, F alone is not sufficient to induce fusion and coexpression of H is required. The interaction of H with the

**TABLE 1** Major structural and regulatory proteins of MeV

Protein	Amino acids	Location within infected cell	Location within virion	Function and special features
Nucleoprotein (N)	525	Cytoplasm	Nucleocapsid	Most abundant of viral proteins. Closely associated with full-length and positive sense RNA to form nucleocapsids.
Phosphoprotein (P)	507	Cytoplasm	Nucleocapsid	More abundant in infected cells than in virions. Regulation of transcription and replication. Complex formation with N and L.
C	186	Cytoplasm and nucleus	Not present	Read from the same transcript as P, but in different reading frame. Regulates transcription and sensitivity to antiviral effects of interferon $\alpha/\beta$ .
V	298	Cytoplasm	Not present	Read from an "edited" transcript of P gene. Regulates transcription and sensitivity to antiviral effects of interferon $\alpha/\beta$ .
Matrix (M)	335	Inner leaflet of plasma membrane; cytoplasm in persistent infections	Inner surface of membrane	Virion assembly and budding.
Fusion (F)	553	Endoplasmic reticulum, Golgi and plasma membrane	Type I transmembrane surface protein	Glycosylated; membrane fusion, virus entry, and hemolysis activity in conjunction with H; active form cleaved from F <sub>0</sub> to F <sub>1</sub> and F <sub>2</sub> .
Hemagglutinin (H)	617	Endoplasmic reticulum, Golgi and plasma membrane	Type II transmembrane surface protein	Glycosylated. Receptor binding. Hemagglutination activity. Disulfide-linked dimer.
Large (L)	2213	Cytoplasm	Nucleocapsid	Catalytic component of viral polymerase. Least abundant protein. RNA transcription and replication. Complex formed with P.

Adapted from reference 26.

cellular receptor induces a conformational change in F that brings the fusion peptide region of the F<sub>1</sub> subunit trimer into a position to initiate fusion (22). Synthetic peptide analogs of the fusion peptide inhibit both cell fusion and virus penetration, but they do not prevent virus attachment.

M is a basic protein with several conserved hydrophilic domains and is the second most abundant viral protein. It forms a continuous layer on the inner surface of the envelope and interacts with progeny nucleocapsids and with the cytoplasmic tails of F and H to mediate virion maturation. Binding of M to nucleocapsids inhibits transcription of MeV mRNA (23, 24).

## Biology

### Receptors

Three cellular receptors for MeV have been identified: membrane cofactor protein or CD46 (25, 26), signaling lymphocyte activation molecule (SLAM) or CD150 (27), and poliovirus receptor-like protein-4 or nectin-4 (28, 29). CD46 is a widely distributed human complement regulatory protein expressed on all nucleated cells. It acts as a cofactor for the proteolytic inactivation of C3b/C4b by factor I, but also induces proliferation and differentiation of regulatory T cells (30). SLAM is an important costimulatory molecule expressed on activated cells of the immune system (31). The cytoplasmic domain has tyrosines and SH-2 domain-binding regions that constitute an immunoreceptor tyrosine-based switch motif that binds small SH-2 domain adaptor proteins important for cell signaling. Nectin-4 is an adherens junction protein of epithelial cells. Both vaccine and wild-type strains of MeV can use SLAM and nectin-4 as receptors.

Vaccine strains tend to use CD46 efficiently, while wild-type strains do not (32). The receptor binding regions for CD46 and SLAM on H are contiguous or overlapping and most H proteins can bind both receptors, but affinity and efficiency of entry differ (19, 21). In general, binding affinity for SLAM is higher than for CD46, and differences in the efficiency of receptor usage may involve interactions with F.

MeV probably uses additional receptors. The distributions of the known receptors in tissues do not account for the tropism and sites of MeV replication in acute infections, in which endothelial cells as well as immune system and epithelial cells are infected (33), or in chronic infections, in which cells of the central nervous system (CNS) are important targets for infection (34). Receptors used by attenuated vaccine strains adapted to growth in cells from nonsusceptible hosts, such as chickens, probably represent an additional category of MeV receptors that have not been identified.

### Replication

Infection is initiated when the MeV H on the virion envelope attaches to the receptor. The fusion peptide at the amino terminus of the F<sub>1</sub> subunit, which is physically associated with H, undergoes a conformational change that results in fusion of the envelope with the cell membrane and delivery of the viral nucleocapsid into the cell cytoplasm (22). The virion RNA-dependent RNA polymerase (L) is then activated and begins transcribing monocistronic mRNAs from the nucleocapsid template.

Transcription occurs sequentially following the gene order. The polymerase terminates synthesis at the end of each gene following polyadenylation and reinitiates at the

consensus sequence of the next gene, without transcribing the intergenic nucleotides. The viral mRNAs are capped and polyadenylated. The poly-A tails are synthesized by a slippage or stuttering mechanism in which the polymerase reiteratively copies the sequence of four to seven Us at the end of the gene. The polymerase sometimes fails to reinitiate and detaches from the nucleocapsid, resulting in the mRNA abundance gradient (35).

The envelope glycoproteins H and F are synthesized and glycosylated in the endoplasmic reticulum, further processed in the Golgi, and transported to the cytoplasmic membrane as oligomers to form the H and F peplomers. The other MeV proteins accumulate in the cytoplasm. The availability of N appears to regulate the transition from mRNA transcription to viral RNA replication because the synthesis of genome-length, positive- and negative-sense RNAs is coupled to their concomitant encapsidation by N. To initiate encapsidation, the RNA polymerase catalyzes the sequence-specific binding of N from soluble N-P complexes to nascent leader RNA, releasing P protein. The continuing encapsidation by N, which is coupled to further RNA synthesis, masks the consensus signals at each gene boundary, preventing termination and RNA processing and yielding the full-length nucleocapsid. Positive- and negative-sense RNAs are encapsidated, but the majority of the nucleocapsids contain negative-sense viral RNA. A small number of P-L polymerase complexes associate with each of the nucleocapsids.

Measles virions bud from the plasma membrane, with progeny nucleocapsids attaching to growing actin filaments. Growth of the actin filament transports the nucleocapsid from the cytoplasm to the plasma membrane, initiating the budding process. M binds to newly synthesized nucleocapsids and also associates with the inner surface of the cytoplasmic membrane, with the cytoplasmic tails of H and F. Association with other M proteins excludes cellular membrane proteins from patches of cytoplasmic membrane destined for virion budding (36, 37).

### Host Range

Because of the specificity of the host receptors and high infectivity of MeV, humans are the only natural host for the virus. Nonhuman primates can be infected experimentally and develop an illness similar to measles in humans, thus serving as models for measles pathogenesis and the evaluation of vaccines. However, native populations of nonhuman primates are not of sufficient size to maintain MeV transmission in the wild. Rodent-adapted strains of MeV have been developed by repeated intracerebral passage of virus in newborn animals. Although these strains do not produce an acute disease resembling measles in humans, they are used as models of MeV pathogenesis in the nervous system.

### Growth in Cell Culture

Primary cultures of human and monkey kidney cells have traditionally been used for isolating MeV. Problems with supply and the potential contamination of primary monkey cells with simian viruses led to the use of continuous monkey kidney cell lines (e.g., Vero cells) for propagation of tissue culture-adapted strains of MeV. Isolation and propagation of wild-type strains of MeV are most efficient in cells that express SLAM. Most commonly used are the Epstein-Barr virus-transformed marmoset B lymphocyte cell line B95-8 and Vero cells engineered to express human SLAM (38, 39).

The incorporation of MeV H and F proteins into the plasma membranes of infected cells causes them to fuse with adjacent infected and uninfected cells. Consequently, replication of wild-type MeV in permissive cells results in characteristic cytopathic effects that include the formation of multinucleated giant cells as well as the production of eosinophilic intranuclear and intracytoplasmic inclusion bodies. Eosinophilic Cowdry type A intranuclear inclusion bodies are characteristic of morbillivirus infection. The intranuclear inclusion bodies are composed of helical nucleocapsids that appear smooth by electron microscopy and contain only the N protein. In contrast, intracytoplasmic inclusions are composed of helical nucleocapsids that appear “fuzzy” by electron microscopy and contain P and M proteins in addition to N.

### Inactivation of MeV by Physical and Chemical Agents

MeV is inactivated by detergents and by lipid solvents such as ether or acetone. MeV is acid labile, losing infectivity below pH 4.5, and it is also inactivated by proteolytic enzymes, drying on surfaces, and exposure to sunlight. MeV is also thermolabile, with a half-life of 2 hours at 37°C, and it is completely inactivated in 30 minutes at 56°C. MeV may retain infectivity for a week at 0°C, and it can be stored for long periods at -70°C. MeV can be freeze-dried, and lyophilized virus is stable for prolonged periods at refrigerator temperatures (0°C to 8°C), a characteristic important for the storage and transportation of attenuated measles vaccines.

## EPIDEMIOLOGY

Measles continues to be an important global cause of child mortality. Deaths from measles are due largely to an increased susceptibility to secondary bacterial and viral infections, attributed to a prolonged state of immune suppression. The disease burden caused by measles has decreased substantially over the past decades because of a number of factors. Measles mortality declined in developed countries in association with economic development, improved nutritional status, and supportive care, particularly antibiotic therapy for secondary bacterial pneumonia. The introduction of measles vaccines beginning in the 1960s led to substantial reductions in measles incidence, morbidity, and mortality in both developed and developing countries. Overall global measles mortality in 2014 was estimated to be 114,900 deaths (uncertainty bounds 53,700 and 330,000 deaths), a 79% reduction since 2000 (40). Despite this enormous progress, measles remains a leading vaccine-preventable cause of childhood mortality and continues to cause outbreaks in communities with low vaccination coverage.

### Geographic Distribution

Measles can occur anywhere in the world, wherever MeV is circulating or introduced into susceptible populations. Small isolated populations, such as island populations, cannot sustain MeV transmission because of exhaustion of susceptible individuals and require the importation of MeV for outbreaks to occur. In the United States, the number of measles cases declined 99.9% by 2006 following the introduction of measles vaccine, but outbreaks in unvaccinated, susceptible populations continue to occur through importation of MeV (41–43). Persons in the United States who do not receive measles vaccine because of philosophical or

religious exemption are at particular risk of measles following importations (41, 44).

### **Incidence and Prevalence of Infection**

MeV is one of the most highly contagious, directly transmitted pathogens and outbreaks can occur in populations in which less than 5% to 10% of persons are susceptible. Chains of transmission commonly occur among household contacts, school-age children, and health care workers. The contagiousness of MeV is best expressed by the basic reproductive number  $R_0$ , which represents the average number of secondary cases that arise if an infectious agent is introduced into a completely susceptible population. In the 1951 measles epidemic in Greenland, the index case attended a community dance, which resulted in an  $R_0$  of 200 (45), an unusually high  $R_0$  that demonstrates the potential infectiousness of MeV. In more typical settings, the estimated  $R_0$  for MeV is 12 to 18, compared to only five to seven for smallpox and rubella viruses. The high infectivity of MeV implies that a high level of population immunity is required to interrupt MeV transmission.

There are no latent or epidemiologically significant persistent MeV infections and no animal reservoirs. Thus, MeV can only be maintained in human populations by an unbroken chain of acute infections and transmission events, requiring a continuous supply of susceptible individuals. Newborns become susceptible to measles when passively acquired, transplacental maternal antibodies are catabolized, providing the main source of new susceptible individuals. For births to provide a sufficient number of susceptible persons to maintain MeV transmission, a critical community size of 300,000 to 500,000 persons with 5,000 to 10,000 births per year is required (46). In smaller populations, episodic outbreaks are dependent upon the importation of MeV by infectious individuals.

Prior to the introduction of measles vaccine, more than 130 million cases of measles and 7 to 8 million deaths occurred globally each year, and almost everyone was infected during childhood or adolescence. In the United States, the prevalence of antibodies to MeV in 18-year-olds exceeded 98%, and the incidence of measles, as in almost every other country, was equal to the number of surviving newborns. The widespread use of attenuated measles vaccines significantly reduced the incidence of measles and lowered measles morbidity and mortality.

### **Epidemic Patterns**

When endemic, measles has a typical temporal pattern of incidence characterized by yearly seasonal epidemics superimposed upon longer epidemic cycles of 2 to 5 years or more. In temperate climates, annual measles outbreaks typically occur in the late winter and early spring. These annual outbreaks are likely the result of social networks facilitating transmission (e.g., congregation of children at school) and environmental factors (e.g., low humidity and ambient temperatures) favoring the infectivity and transmission of MeV (47). Measles cases continue to occur during the interepidemic period in large populations but at low incidence. The longer cycles occurring every several years result from the accumulation of susceptible persons over successive birth cohorts and the subsequent decline in the number of susceptible persons following an outbreak. The interval between epidemics is shorter in populations with high birth rates because the number of susceptible individuals reaches the epidemic threshold more quickly. Measles vaccination programs that achieve coverage rates in excess of 80% ex-

tend the interepidemic period to 4 to 8 years by reducing the number of susceptible individuals.

### **Age-Specific Attack Rates**

Secondary attack rates in susceptible household and institutional contacts generally exceed 90%. The average age of MeV infection depends upon the rate of contact with infected persons, the rate of decline of protective maternal antibodies, and the vaccine coverage rate. Infants in the first few months of life are protected by passively acquired maternal antibodies, and measles is rare in this age group. In densely populated urban settings with low vaccination coverage rates, measles is a disease of young children. The cumulative incidence can reach 50% by 1 year of age, with a significant proportion of children acquiring MeV infection before 9 months, the age of routine vaccination in many countries. As measles vaccine coverage increases, or population density decreases, the age distribution shifts toward older children. In such situations, measles cases predominate in school-age children. Infants and younger children, although susceptible if not protected by immunization, are not exposed to MeV at a rate sufficient to cause a large disease burden in this age group. As vaccination coverage increases further, the age distribution of cases may be shifted into adolescence and young adulthood, as seen in measles outbreaks in the Americas (48, 49), necessitating targeted measles vaccination programs for these older age groups. This shift in measles cases to older age groups has recently been observed in many countries as a consequence of moderately high measles vaccine coverage (e.g., 60% to 80%), allowing susceptible individuals to age into adolescence and young adulthood without being exposed to either wild-type MeV or measles vaccine.

As noted above, young infants in the first months of life are protected against measles by maternally acquired IgG antibodies. An active transport mechanism in the placenta is responsible for the transfer of IgG antibodies from the maternal circulation to the fetus starting at about 28 weeks of gestation and continuing until birth. Three factors determine the degree and duration of protection in the newborn: (i) the level of maternal anti-MeV antibodies; (ii) the efficiency of placental transfer; and (iii) the rate of catabolism in the child. Although providing passive immunity to young infants, maternally acquired antibodies can interfere with the immune responses to the attenuated measles vaccine by inhibiting replication of vaccine virus (50, 51). In general, maternally acquired antibodies are no longer present in the majority of children by 9 months of age (52), the time of routine measles vaccination in many countries. Women with vaccine-induced immunity tend to have lower anti-MeV antibody levels than women with naturally acquired immunity, and their children may be susceptible to measles at an earlier age. The half-life of anti-MeV antibodies has been estimated to be 48 days in the United States and Finland but is shorter in some developing countries. Infants born to human immunodeficiency virus (HIV)-infected women may have lower levels of protective maternal antibodies independent of their own HIV infection status and may thus be susceptible to measles at a younger age (53).

### **Subclinical Infection**

MeV infections in nonimmune individuals are almost always symptomatic. Subclinical measles is defined as a 4-fold rise in MeV-specific IgG antibodies following exposure to wild-type MeV in an asymptomatic individual. Subclinical infection

may be important in boosting protective antibody levels in children with waning immunity (54). Whether partially immune individuals with subclinical infection can sustain MeV transmission is unknown. However, MeV has been isolated from a naturally immune, asymptotically reinfected individual (55), and acquisition from a person with subclinical infection was implicated in at least one investigation.

Wild-type MeV infection induces lifelong immunity to disease, and reinfection is not required to maintain this protective immunity. On re-exposure, immune individuals may be reinfected and support limited virus replication, as evidenced by increases in their preexisting levels of humoral and cellular immunity to MeV. Such reinfections are almost always asymptomatic and rarely result in transmission of MeV to susceptible contacts (as with subclinical infections).

### Seasonality

In temperate climates the incidence of measles peaks in late winter and early spring and reaches a nadir in late summer and early autumn. These differences are less pronounced in tropical climates. Where widespread immunization has reduced MeV transmission, the temporal distribution of cases is determined by importations of MeV and outbreaks may occur at any time.

### Transmission

MeV is transmitted primarily by respiratory droplets over short distances and less commonly by small particle aerosols that remain suspended in the air for long periods of time or by direct contact with infected secretions. The symptoms induced during the prodrome, particularly sneezing and coughing, enhance transmission. Airborne transmission appears to be important in certain settings, including schools, physicians' offices, hospitals, and enclosed public gathering places (56). Direct contact with infected secretions can transmit MeV, but the virus does not survive long on fomites and is inactivated by heat and ultraviolet radiation. Transmission across the placenta can occur when measles occurs during pregnancy, but congenital measles is uncommon.

### Duration of Infectiousness

Persons with measles are infectious for several days before and after the onset of rash, when levels of MeV in blood and body fluids are highest and when the symptoms of cough, coryza, and sneezing are most severe. The fact that MeV is contagious before the onset of recognizable disease hinders the effectiveness of quarantine measures. MeV can be isolated from the urine as late as 1 week after rash onset. MeV shedding is prolonged in those with impaired cell-mediated immunity. Giant cells were detected in nasal secretions up to 28 days after the onset of rash in malnourished Kenyan children with severe measles (57), and MeV antigen was detected up to 13 days after rash onset in malnourished Nigerian children (58). Prolonged presence of MeV RNA has been associated with HIV infection (59, 60) and congenital measles (61). However, whether detection of MeV by these methods indicates prolonged contagiousness is unclear.

### Risk Factors for Transmission

The risk of MeV transmission is increased by more frequent, prolonged, and intimate contact between susceptible persons and infectious cases. The risk of transmission is substantially greater if contact occurs when the index case is in

the late prodromal stage with more pronounced coryza, cough, and sneezing rather than later when these symptoms have abated. Patterns of air circulation may determine the risk of transmission when airborne transmission is involved. In daycare centers and schools, the risk of transmission often exceeds 50% to susceptible contacts.

### Nosocomial Transmission

Medical settings are well-recognized sites of MeV transmission. Patients may present to health care facilities during the prodrome when the diagnosis is not obvious, although the patient is infectious and likely to infect susceptible contacts. Health care workers can acquire measles from infected patients and transmit MeV to others. Nosocomial transmission can be reduced by maintaining a high index of clinical suspicion and using airborne isolation precautions when measles is suspected, and it can be prevented by administering measles vaccine before exposure to susceptible patients and health care workers, as well as documenting immunity to measles (i.e., receipt of two doses of measles vaccine or detection of antibodies to MeV) in health care workers. If a health care provider without evidence of immunity is exposed to measles, measles vaccine should be given within 72 hours or immunoglobulin should be given within 6 days when available.

### Morbidity and Mortality

Measles case fatality ratios vary, depending upon the average age of infection, nutritional and immunological status of the population, measles vaccine coverage, and access to health care. In developed countries, fewer than 1 in 1,000 children with measles die. In areas of endemicity in sub-Saharan Africa, the measles case fatality proportion may be 5% or higher. Measles is a major cause of child deaths in refugee camps and in internally displaced populations. Measles case fatality proportions in children in humanitarian emergencies, such as refugees, have been as high as 20% to 30% (62). Consequently, a frequent, early response in humanitarian emergencies is to administer measles vaccine.

The measles case fatality ratio is highest at extremes of age. Exposure to an index case within the household may result in more severe disease, perhaps because of transmission of a larger inoculum of virus (63). Vaccinated children, should they develop disease after exposure, have less severe disease and significantly lower mortality rates. Vaccination programs, by increasing the average age of infection, shift the burden of disease out of the age group with the highest case fatality (infancy), further reducing measles mortality.

Measles and malnutrition have important bidirectional interactions. Measles is more severe in malnourished children. Children with severe malnutrition, such as those with marasmus or kwashiorkor, are at particular risk of death following measles. Measles can in turn exacerbate malnutrition by decreasing intake (particularly in children with mouth ulcers), increasing metabolic demands, and enhancing gastrointestinal loss of nutrients as a consequence of a protein-losing enteropathy. Measles in persons with vitamin A deficiency leads to severe keratitis, corneal scarring, and blindness (64).

Measles mortality may be higher in girls than boys (65), although older historical data and more recent surveillance data from the United States do not support this conclusion (66). Supporting the hypothesis of biologic differences in the response to MeV was the observation that girls were more likely than boys to have delayed mortality following receipt

of high-titer measles vaccine (67). The underlying mechanisms are likely differences in immune responses to MeV between girls and boys, although no cogent explanation has been developed.

In regions of high HIV prevalence and crowding, such as urban centers in sub-Saharan Africa, HIV-infected children may play a role in sustaining MeV transmission. Children born to HIV-infected mothers have lower levels of passively acquired maternal antibodies and are thus susceptible to measles at an earlier age than children born to uninfected mothers (53, 68). Protective antibody levels can wane within 2 to 3 years in vaccinated HIV-infected children (69). Children with defective cell-mediated immunity can develop measles without the characteristic rash (70). HIV-infected children have prolonged shedding of MeV RNA (59, 60), potentially increasing the period of infectivity. Counteracting the epidemiologic effects of increased susceptibility of HIV-infected children to measles is their high mortality rate, particularly in sub-Saharan Africa, such that these children do not live long enough for a sizeable pool of susceptible children to develop (71). However, increasing access to antiretroviral therapy increases survival without restoring measles immunity (72). The WHO recently recommended that HIV-infected children receiving antiretroviral therapy receive an additional dose of measles vaccine to protect the individual child and prevent the build-up of susceptible children (73).

## PATHOGENESIS IN HUMANS

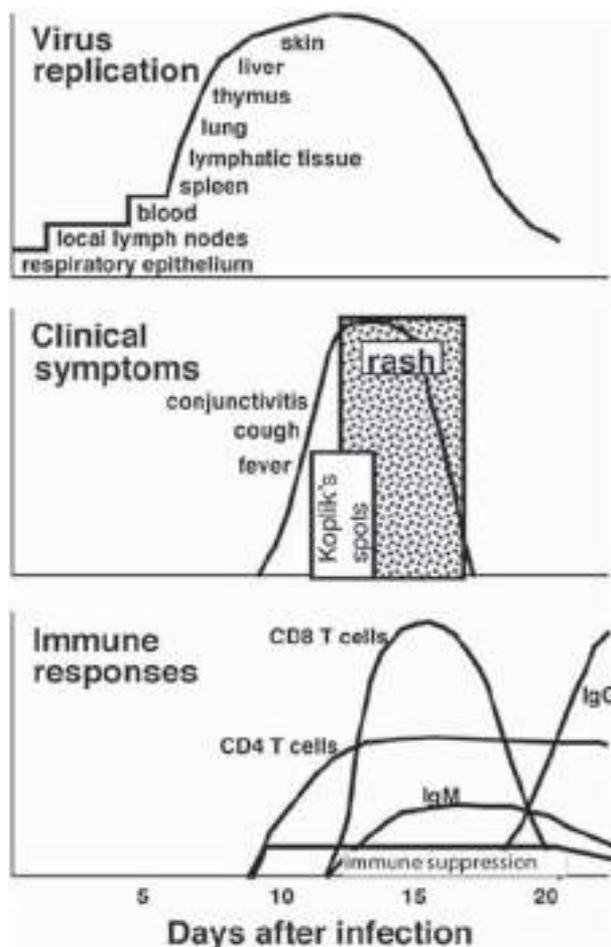

### Incubation Period

The incubation period for measles, the time from infection to clinical disease, is approximately 10 days to the onset of fever and 14 days to the onset of rash. A systematic review estimated the median incubation period from infection to the first onset of signs and symptoms to be 12.5 days (95% confidence interval, 11.8 to 13.2 days) based on 55 observations from eight studies (74). The incubation period may be shorter in infants or following a large inoculum of virus, and it may be longer (up to 3 weeks) in adults.

### Virus Replication

Infection is initiated when MeV reaches cells in the respiratory tract, oropharynx, or conjunctivae (Fig. 3). The lower respiratory tract is more susceptible than the nasopharynx, which is more susceptible than the oral mucosa. Direct observations pertaining to the early multiplication of MeV in humans are lacking, but experimental studies in monkeys and experimental and histopathological observations in humans suggest that during the first 2 to 4 days after infection, MeV proliferates locally in the respiratory mucosa and spreads, perhaps within infected pulmonary macrophages and dendritic cells (75), to draining lymph nodes where further replication occurs.

Virus then enters the bloodstream in infected leukocytes, primarily monocytes (76), producing the primary viremia that disseminates infection to sites throughout the reticuloendothelial system. When MeV is administered parenterally, bypassing the usual respiratory route, the incubation period is shortened by 2 to 4 days, suggesting that during natural measles the virus is initially confined to tissues at the portal of entry for this period. Lymphoid tissues throughout the body, including tonsils, adenoids, submucosal lymphoid tissue in the respiratory and gastrointestinal tracts, lymph nodes, thymus, spleen, appendix, and Peyer's patches, be-

**FIGURE 3** Basic pathogenesis of MeV infection. Panels summarize features of the pathogenesis of MeV infection. (a) The spread of the virus from the initial site of infection in the respiratory tract to the skin. Sites of infection are overlaid with virus titer. (b) The appearance of clinical signs and symptoms in relation to viral replication and the immune responses. (c) The immune responses to measles virus. The clinical manifestations arise coincident with the onset of the immune response. (From reference 127 with permission of the publisher.) Source: Moss WJ, Griffin DE. Global measles elimination. *Nat Rev Microbiol* 2006;4:900–908.

come major sites of virus replication. Though clinically inapparent, MeV replication at these sites is indicated by lymphoid hyperplasia and the formation of multinucleated giant cells. In the thymus, MeV infection of epithelial cells leads to apoptosis of uninfected thymocytes and a decrease in the size of the thymic cortex.

Further replication results in a secondary viremia that begins 5 to 7 days after infection and disseminates MeV to tissues throughout the body, including the skin, conjunctivae, CNS, oropharynx, respiratory mucosa, lungs, genital mucosa, kidneys, gastrointestinal tract, and liver (Fig. 3). Replication of MeV in these target organs, together with the host immune response, is responsible for the prodromal signs and symptoms that occur 8 to 12 days after infection and mark the end of the incubation period. The prodromal manifestations reflect involvement of epithelial surfaces in the oropharynx, respiratory tract, gastrointestinal tract, and conjunctivae. During this secondary viremia, virus is again

transported within monocytes and lymphocytes, of which more than 5% may be infected. In a rhesus macaque model, the predominant cell types infected by MeV are CD150<sup>+</sup> cells and dendritic cells (77).

Infection of vascular endothelial cells plays a central role in measles pathogenesis. Infection of the endothelial cells of small vessels in the lamina propria and dermis during the secondary viremia precedes infection of the overlying epithelium, and inflammatory changes in and around these vessels are an integral part of the local pathology and characteristic rash.

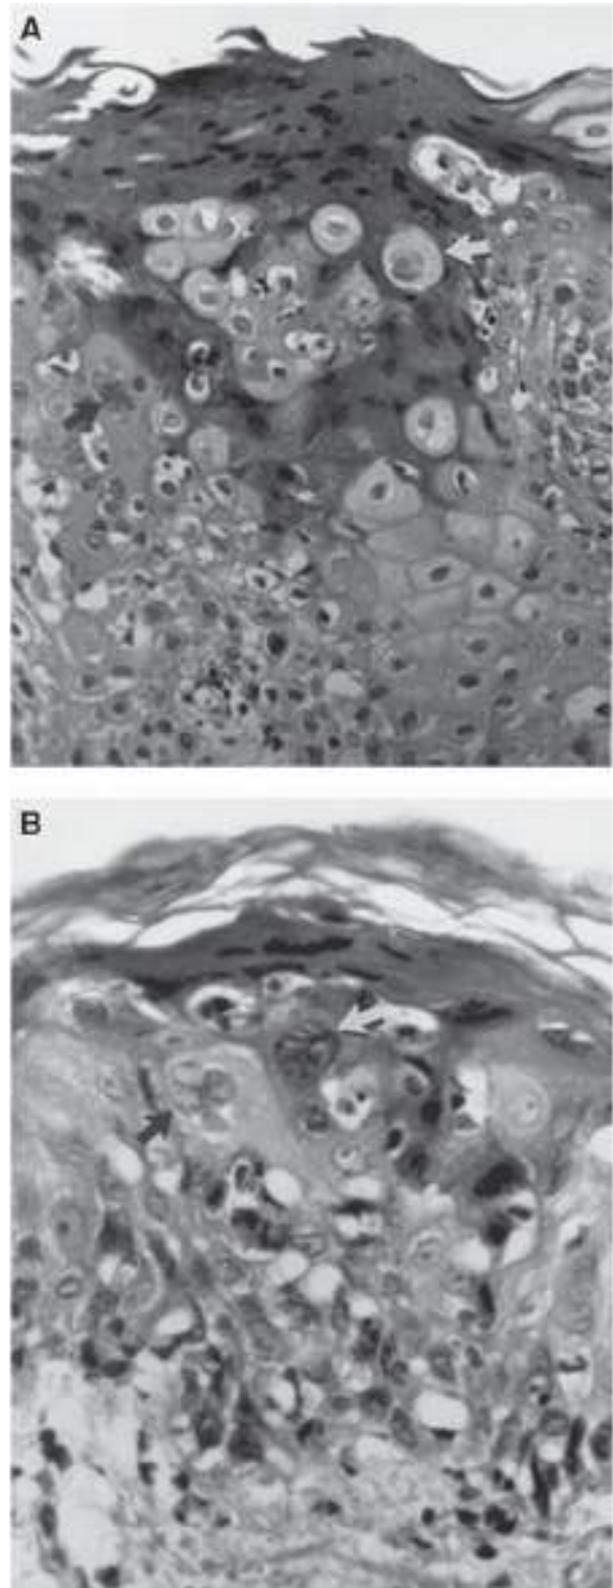

MeV may also enter respiratory epithelial cells from infected lymphocytes and monocytes through the basolateral surface (78). Virus then buds from the apical surface, allowing for respiratory transmission.

### Pathology

The most striking and consistent pathological feature of MeV infection is the formation of multinucleated giant cells that result from the fusion of infected cells with infected and uninfected neighboring cells (Fig. 4). Endothelial cells of small vessels show evidence of MeV infection, including inclusion bodies, MeV antigens, or MeV RNA, during the prodrome and the first days of rash. This is accompanied by vascular dilatation, perivascular infiltration with mononuclear cells, and increased vascular permeability. Changes in the skin, conjunctivae, and mucous membranes of the respiratory and gastrointestinal tracts are secondary to changes in the underlying small blood vessels. MeV antigen and RNA also have been detected in perifollicular histiocytes in lymph nodes and spleen, in epithelial cells of Hassall's corpuscles in the thymus, in biliary duct epithelial cells in the liver, in the epithelium of submucosal glands in the respiratory and gastrointestinal tracts, and in the cells lining hair follicles and sweat glands in the skin.

The rash and Koplik's spots of measles have similar pathogenesis and histopathology (Fig. 4). The initial event is infection of endothelial cells in superficial vessels in the dermis. The earliest histopathologic changes are mild hyperemia, edema, and lymphocytic infiltration of the dermis, with swelling and proliferation of endothelial cells in capillaries, precapillary vessels, and small veins. MeV antigens and viral nucleocapsids can be detected in these endothelial cells on the day before and on the first day of the rash (79). Infection of the overlying epidermis is due to the spread of virus from the infected vascular endothelial cells in the subjacent dermis and by infiltration of infected leukocytes. This leads to the formation of epithelial giant cells containing eosinophilic intracytoplasmic and intranuclear inclusion bodies. A lymphohistocytic infiltrate accumulates around the dilated dermal vessels, and the infected epithelial cells become necrotic. By the third day, this process results in the formation of a vesicle under the stratum corneum that undergoes desiccation and desquamation. In the mucous membranes of the mouth, the necrotic epithelial cells of Koplik's spot slough, leaving a tiny shallow ulcer.

During the secondary viremia, infection of capillary endothelial cells throughout the respiratory tract produces foci of peribroncheolar inflammation, dilated submucosal vessels, perivascular and interstitial mononuclear cell infiltrates, and epithelial hyperplasia. Epithelial giant cells develop in the mucosa from the trachea to the alveoli, and some are shed into the lumen. This pathologic process is well developed by the onset of the prodrome and accounts for the cough and coryza. The damage to the respiratory tract caused by MeV infection also predisposes it to secondary bacterial

**FIGURE 4** Histopathology of Koplik's spots (A) and the skin rash (B) of measles. The epidermal changes in both are characterized by multinucleated giant cells (arrows), focal parakeratosis, dyskeratosis and spongiosis, intracellular edema, and a sparse lymphocytic infiltrate. infections. In the normal host, virus replication and giant cell formation cease within 2 or 3 days after the onset of the rash, and measles giant cells disappear from the respiratory tract shortly thereafter. With more severe disease, multinucleated giant cells lining the alveoli constitute Hecht's giant cell pneumonia.

### Immune Responses

MeV-specific immune responses are essential for recovery from measles and for the establishment of long-term immunity to reinfection, but they also play a role in the pathogenesis of measles and its complications (80, 81). Immune responses to MeV are first apparent during the prodrome and are well developed by the onset of rash. Marked activation of the immune system is manifested by T- and B-cell activation, spontaneous proliferation of peripheral blood mononuclear cells, and increased levels of cytokines and soluble cell surface proteins in the circulation (Fig. 3). Immune suppression, evidenced by impaired delayed type hypersensitivity (DTH) skin test responses to recall antigens and by reduced humoral and cellular immune responses to new antigens, occurs at the same time, and susceptibility to secondary infections is increased. Immune activation and suppression persist for many weeks after recovery from measles.

### Innate Immune Responses

In contrast to many other acute virus infections, neither type I nor type III interferon (IFN) is induced as a part of the innate response to MeV infection (82–85). This is likely due to the combined effects of RNA encapsidation and efficient shutdown of IFN induction and response by the C and V nonstructural proteins (18, 86). Suppression of IFN responses may facilitate systemic spread of virus during the clinically silent incubation period.

### Humoral Immune Responses

The onset of clinically apparent disease coincides with the appearance of MeV-specific adaptive humoral and cellular immune responses (Fig. 3). Antibodies to MeV are detectable at the time of rash onset (87). The isotype is initially IgM followed by a switch to IgG3 and then, in the memory phase, to IgG1 and IgG4 (87). IgM antibodies generally decline to undetectable levels within 6 to 8 weeks. IgG titers rise rapidly, peak within 3 to 4 weeks, then gradually decline, but generally persist for life. IgG is initially of low avidity, but avidity increases steadily over several months (88). IgG1 is efficiently transported across the placenta, and levels of antibody to MeV are often higher in the newborn than in the mother. The role of mucosal immunity to MeV is unclear. IgA, IgM, and IgG antibodies to MeV are found in secretions, and sampling of saliva has provided a noninvasive method for determining immune status (89, 90).

The most abundant and most rapidly produced antibody is to N. Because of the abundance of anti-N antibody, absence of this antibody is a reliable indicator of seronegativity. The M protein elicits only small amounts of antibody, except in atypical measles. Antibodies to H are the primary antibodies measured by tests based on neutralization of virus infectivity (91). Human convalescent sera show reactivity to linear epitopes as well as to epitopes dependent on conformation and glycosylation. Major conformational and neutralizing epitopes have been localized to an exposed region of the protein without N-linked carbohydrates (7, 92, 93). Antibodies to F contribute to virus neutralization, probably

by preventing fusion of the virus membrane with the cell membrane at the time of virus entry (94).

Antibody can protect against MeV infection and may contribute to recovery from infection. Antibody is sufficient for protection because infants are protected by maternal antibody and the level of maternal antibody correlates with failure of the humoral response to vaccination (50). Furthermore, passive transfer of immune serum can partially protect children from measles after exposure. The best correlate of protection is the level of neutralizing antibody, with a plaque reduction neutralizing titer of 120 mIU/ml generally considered the level needed for protection from disease in outbreaks and 1,000 mIU/ml the level needed for protection from infection (95).

IgG antibodies to MeV are maintained for decades (96). MeV extensively replicates in lymphoid tissues during the acute phase of measles, and although infectious MeV is cleared at the time of the rash, MeV RNA persists in blood leukocytes and lymphoid tissues for months. Slow MeV clearance and prolonged immune stimulation by MeV proteins likely contribute to maturation and maintenance of memory immune responses after infection (60, 97).

Contributions of antibody to virus clearance are less clear, but mathematical modeling suggests that they are important (97). Furthermore, failure to mount an adequate antibody response carries a poor prognosis, and levels of antibody-dependent cellular cytotoxicity correlate with clearance of the cell-associated viremia (98). Antibody binding to infected cells alters intracellular virus replication and may contribute to control of infection (99). However, transient depletion of B cells does not affect virus clearance in infected monkeys (100), and children with congenital agammaglobulinemia, who produce no detectable antibody to the virus, recover from infection (101). Such evidence suggests that cell-mediated immunity is essential for MeV clearance.

### Cellular Immune Responses

A vigorous T-cell response is induced during MeV infection (97) (Fig. 3). MeV-specific and proliferating CD8<sup>+</sup> T cells with evidence of clonal expansion are detectable in blood at the time of the rash. Further, they can be detected in bronchoalveolar lavage fluid during pneumonitis (102). IFN- $\gamma$ , soluble CD8, and  $\beta$ 2 microglobulin are increased in plasma (103, 104), and CD8<sup>+</sup> T-cell memory is established after infection (102, 105, 106). Depletion of CD8<sup>+</sup> T cells in infected monkeys impairs control of virus replication (107). T-cell epitopes have been identified within all MeV proteins except V, although H contains the majority of epitopes recognized by HLA-A2-positive humans (105, 108).

CD4<sup>+</sup> T cells are also activated in response to MeV infection. CD4<sup>+</sup> T cells proliferate during the rash, and soluble CD4 is elevated in plasma during acute disease and remains so for several weeks after recovery (109). MeV-specific T-cell proliferation and the production of cytokines are stimulated during measles, and CD4<sup>+</sup> T-cell memory is established after recovery.

MeV-specific T cells are responsible for production of a variety of cytokines and soluble factors during disease and recovery. Plasma levels of IFN- $\gamma$ , neopterin (a product of IFN- $\gamma$ -activated macrophages), and soluble interleukin (IL)-2 receptor rise during the prodrome, prior to the appearance of the rash (82, 103). This is followed by increases in IL-2 at the time of the rash. As the rash fades, IL-4, IL-10, and IL-13 increase, and elevation of these cytokines persists in some individuals for weeks (104, 110). This pattern of cytokine

production suggests early activation of CD8<sup>+</sup> (IFN- $\gamma$ ) and type 1 CD4<sup>+</sup> (IFN- $\gamma$  and IL-2) T cells during the rash followed by activation of type 2 CD4<sup>+</sup> T cells (IL-4, IL-13) and then regulatory T cells (IL-10) during recovery. IFN- $\gamma$  can suppress MeV replication and likely has an important direct antiviral effect.

The cellular immune response is necessary for development of the characteristic measles rash. Biopsies show infiltration of CD4<sup>+</sup> and CD8<sup>+</sup> T cells and macrophages into areas of virus replication and individuals with deficiencies in cellular immunity may develop severe measles without a rash (111, 112).

### MeV-Induced Immunosuppression

The intense immune responses induced by MeV infection are paradoxically associated with depressed responses to unrelated (non-MeV) antigens, lasting for several weeks to months beyond resolution of the acute illness (113). This state of immune suppression enhances susceptibility to secondary bacterial and viral infections that cause pneumonia and diarrhea, and it is responsible for much measles-related morbidity and mortality. DTH responses to recall antigens, such as tuberculin, are suppressed (114), and cellular and humoral responses to new antigens are impaired. Reactivation of tuberculosis and remission of autoimmune diseases after measles have been attributed to this state of immune suppression.

Abnormalities of both the innate and adaptive immune responses have been described following MeV infection (Fig. 5) (115, 116). Transient lymphopenia affecting both CD4<sup>+</sup> and CD8<sup>+</sup> T lymphocytes occurs in children with measles (117). Functional abnormalities of immune cells are also detected, including decreased lymphocyte proliferative responses (118). The dominant type 2 cytokine response in children recovering from measles can inhibit type 1 responses and increase susceptibility to intracellular pathogens (109). The production of IL-12, important for the generation of type 1 immune responses, decreases following binding of the CD46 receptor (119) and is low for several

weeks in children with measles (120), potentially resulting in a limited type 1 immune response to other pathogens. Elevated plasma levels of IL-10, a cytokine capable of inhibiting immune responses, also suggest a role for immunomodulatory cytokines in the immune suppression following measles (68).

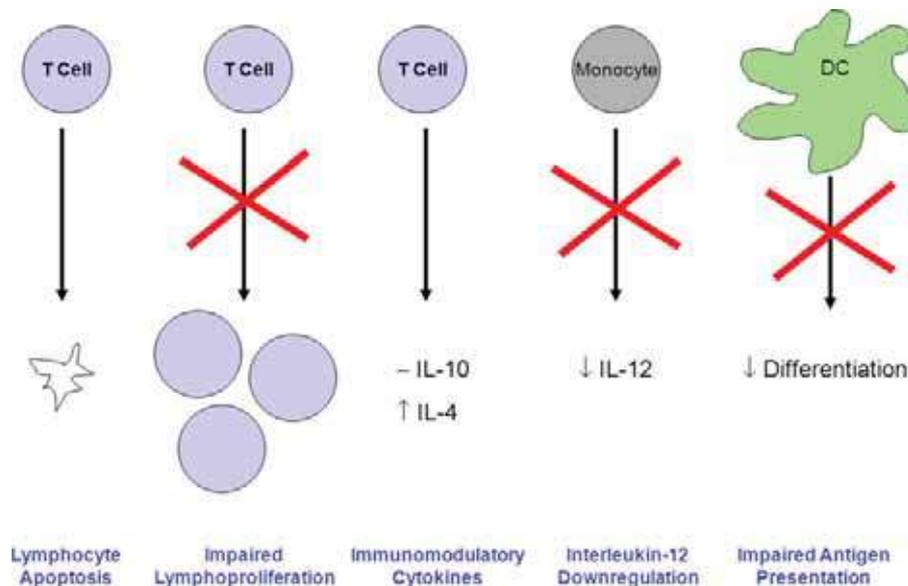

## CLINICAL MANIFESTATIONS

### Typical Measles

The prodromal phase of measles begins with fever, malaise, and anorexia followed by coryza, conjunctivitis, and cough. The catarrhal symptoms increase in intensity, as does the fever, reaching a peak at the height of the skin eruption on about the fifth day. Coryza can be intense, with a profuse mucopurulent nasal discharge. The cough can be severe with a brassy barking quality. Sore throat, eye pain, headache, and myalgia can occur, especially in adolescents and adults. Ocular findings include palpebral conjunctivitis with lacrimation, edema of the lids, photophobia, and punctate keratitis visible on slit lamp examination or with fluorescein staining.

Two to three days before the onset of the rash, Koplik's spots, the pathognomonic enanthem of measles, appear as small (1 mm) white lesions on the buccal mucosa that allow the astute clinician to diagnose measles prior to the onset of rash (Fig. 6). Initially, only a few are present opposite the second molars but these can increase to coat the entire buccal mucosa. Usually by the third day of rash the lesions slough, the erythema fades, and the mucosal membranes regain their normal appearance. Koplik's spots may not be recognized unless the buccal mucosa is examined carefully; they may also be seen on the conjunctivae and other mucosal surfaces, including the gastrointestinal tract.

The intense inflammation of lymphoid tissues during the prodrome can result in generalized lymphadenopathy and mild splenomegaly, with posterior auricular, cervical, and occipital lymph nodes typically enlarged and tender. Lymphoid inflammation is also responsible for the most frequent

abdominal complication of measles, acute nonsuppurative appendicitis, which can develop prior to the rash.

The rash begins 3 or 4 days after the onset of prodromal symptoms. The earliest lesions, consisting of 3- to 4-mm dull red blanching maculopapules, appear behind the ears, on the forehead at the hairline, and on the upper part of the neck. The rash then spreads downward over the face, neck, upper extremities, and trunk, and it continues downward until it reaches the feet by the third day. The rash is most profuse in the areas first affected. The lesions on the face and neck tend to become confluent, producing a blotchy appearance characteristic of measles (Fig. 7), whereas those on the abdomen and limbs tend to be more discrete. In severe cases, the rash may be associated with edema, especially of the face. The rash begins to fade by the third day in the order of its appearance, so that the rash may be fading on the face by the time it appears on the legs. The fading rash can leave a brownish discoloration of the skin, probably the result of

FIGURE 7 Measles rash. Note the characteristic blotchy appearance. (From reference 127 with permission of the publisher.) Source: Moss WJ, Griffin DE. Global measles elimination. *Nat Rev Microbiol* 2006;4:900–908.

capillary hemorrhage, which resolves during the next 10 days with fine desquamation that usually spares the hands and feet. In fair-skinned children the rash may become purpuric. This type of eruption is not related to severe hemorrhagic measles or the thrombocytopenic purpura that occasionally occurs after the rash has disappeared. Severely undernourished children and children infected with HIV may have a more severe, desquamating rash at the end of the acute illness. In uncomplicated measles, fever reaches a peak of 39° to 40°C at the height of the skin eruption with rapid defervescence on the third or fourth day of rash (Fig. 6).

Tracheobronchitis and peribronchial interstitial pneumonia are common features of uncomplicated measles. Pulmonary infiltrates may be seen on chest radiographs during the acute phase of measles. The illness typically reaches its climax between the second and third days of rash. The temperature then falls rapidly over the following 24 to 48 hours, the coryza and conjunctivitis clear, and the cough decreases in severity, although it may persist for a week or more. Most children in developed countries fully recover within a few days. Persistence or recurrence of fever beyond the third day of rash usually indicates a secondary bacterial infection. Although uncommon in children, hepatic dysfunction has been frequently documented in adults with measles (121). These abnormalities are generally subclinical and self-limited. Myositis, manifested by myalgia and elevated levels of creatine phosphokinase, is observed in 30% to 40% of adolescents and adults during the acute phase of measles, and one-third have hypocalcemia (122).

### Modified Measles

Modified measles occurs in partially immunized persons, including persons given immunoglobulin following exposure to MeV and infants with residual maternal antibody. Modified measles is usually a mild version of measles, although the incubation period may be prolonged up to 21 days. The prodrome is shortened or absent, fever is reduced, Koplik's spots are fewer, the rash is short-lived and markedly attenuated, and complications are extremely rare. Patients with modified measles rarely transmit MeV to others.

### Atypical Measles

A severe atypical measles syndrome was observed in recipients of formalin-inactivated measles vaccine (FIMV) who were subsequently exposed to wild-type MeV (123). An estimated 600,000 to 900,000 children were immunized with FIMV between 1963 and 1967. After exposure to wild-type MeV, vaccinated individuals were at risk of developing high fever, headache, myalgia, abdominal pain, anorexia, non-productive cough, and dyspnea followed by the development of an atypical rash that began on the palms and soles and spread centripetally to the proximal extremities and trunk, sparing the face. The rash was initially erythematous and maculopapular but frequently progressed to vesicular, petechial, or purpuric lesions. Most patients had pneumonitis with interstitial infiltrates and segmental pulmonary consolidation, and many had pleural effusions, hilar adenopathy, and nodular parenchymal lesions. Hepatocellular enzymes were often markedly elevated, and some patients had evidence of myositis and disseminated intravascular coagulation. Cases of atypical measles were reported many years after administration of FIMV, but the clinical characteristics in adults were more variable than in children. Despite its severity, atypical measles was self-limited, although pulmonary abnormalities persisted.

In rhesus macaques, the FIMV induces a poor cytotoxic T-cell response and antibody that does not undergo affinity maturation (124, 125). Low-avidity antibody can neutralize infection with viruses that use CD46 as a receptor *in vitro*, as routinely measured by plaque reduction neutralization assays in Vero cells, but cannot neutralize infection with wild-type viruses that primarily use CD150 (125). This difference in neutralization properties may be due to the higher affinity interaction between MeV and CD150 compared to MeV and CD46. Subsequent infection with MeV induces an anamnestic antibody response in both humans and macaques, but the antibody produced is also of low avidity and cannot neutralize wild-type virus. This leads to formation of complexes of nonneutralizing antibody and MeV resulting in immune complex deposition, vasculitis, and pneumonitis in rhesus macaques (124, 125). The exact nature of the defect in immune priming exhibited by FIMV has not yet been identified.

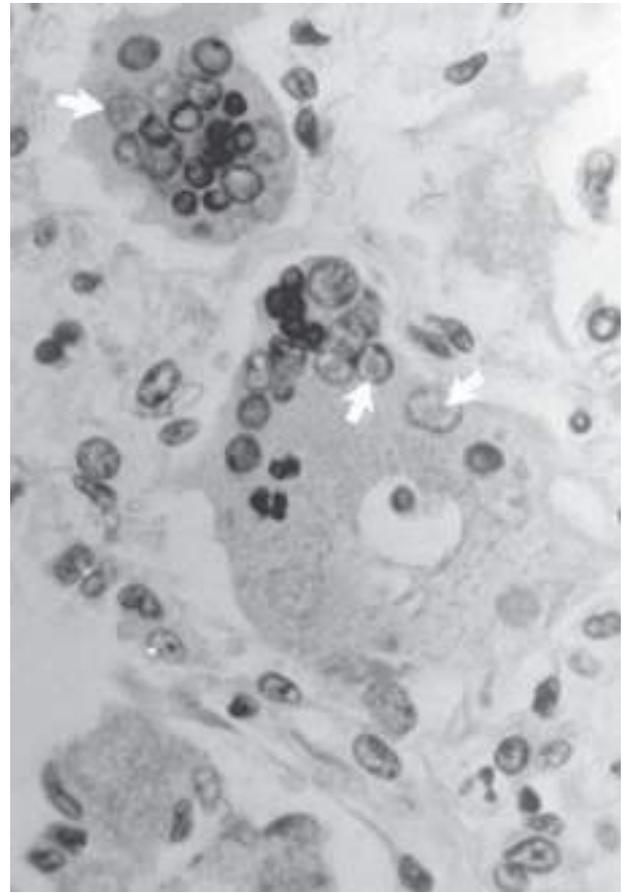

### Measles During Pregnancy and the Neonatal Period

Morbidity and mortality are increased in pregnant women with measles, due to an increased risk of MeV pneumonia during the third trimester and peripartum period. Measles during pregnancy has not been associated with congenital abnormalities in the fetus but is associated with an increased incidence of premature delivery and spontaneous abortion (126). Congenital measles, in which the rash is present at birth or appears during the first 10 days of life, varies from a mild illness to a rapidly fatal disease. In the absence of immunoglobulin prophylaxis, the overall mortality is about 30%. Mortality is higher in premature than in term infants and in infants who fail to develop rash (126). Postnatally, replication of wild-type MeV in permissive cells results in characteristic cytopathic effects that include the formation of multinucleated giant cells as well as the production of eosinophilic intranuclear and intracytoplasmic inclusion bodies. Eosinophilic Cowdry type A intranuclear inclusion bodies are characteristic of morbillivirus infection. Acquired measles in the neonate is rare because passively acquired maternal antibodies result in protection of most newborns. In the absence of protective maternal antibodies, however, measles in neonates is often severe.

### Measles in Immunocompromised Patients

Children and adults with deficient cell-mediated immunity may develop severe, progressive, and frequently fatal MeV infection, often in the absence of the typical rash and characteristic prodrome. The most frequent manifestation is giant cell pneumonia (Hecht pneumonia), characterized by increasing respiratory insufficiency, progressive interstitial pneumonia with multinucleated giant cells throughout the tracheobronchial and alveolar epithelium (Fig. 8), the presence of measles giant cells in pulmonary and nasopharyngeal secretions, and a chest radiograph showing diffuse interstitial and alveolar infiltrates resembling adult respiratory distress syndrome (70, 127). The case fatality ratio for MeV pneumonia was estimated to be about 70% in oncology patients and about 40% in HIV-infected patients in one early study (127). However, mortality in HIV-infected children was more recently estimated to be 10% to 15% (128).

The other frequent manifestation of progressive MeV infection in immunocompromised patients is measles inclusion body encephalitis (MIBE). MIBE may accompany or follow giant cell pneumonia, but it more often occurs as the

**FIGURE 8** Measles giant cell pneumonia. Two multinucleated epithelial giant cells are visible in alveolar spaces in the lung of an immunosuppressed child who died of giant cell pneumonia. Eosinophilic Cowdry type A inclusion bodies are visible in many nuclei (arrows). (From reference 56 with permission of the publisher.) [Adapted from Oxman, 2nd edition of *Clinical Virology*.]

sole clinical manifestation months after MeV infection (129). The disease usually presents with refractory focal myoclonic seizures and altered mental status and progresses to generalized seizures, coma, and death. Mortality exceeds 85%. Patients with MIBE are frequently afebrile and have normal cerebrospinal fluid (CSF) analysis and head computed tomography and magnetic resonance imaging scans. Electroencephalograms are abnormal but nonspecific. Progression is often rapid, with the majority of deaths occurring within 6 to 8 weeks of onset. Survivors have severe neurological sequelae. At autopsy or biopsy, the brain shows gliosis and focal necrosis, lymphocytic perivascular cuffing, and eosinophilic intranuclear and intracytoplasmic inclusions in glial cells and neurons. MeV antigens are detectable by immunofluorescent staining, and MeV RNA can be detected by reverse transcriptase-PCR (RT-PCR). Live attenuated measles vaccine may also cause MIBE in severely immunodeficient infants (130).

Measles also is severe in malnourished children, frequently resulting in secondary infections causing pneumonia and diarrhea, and with a case fatality ratio exceeding 10%. Many factors are likely to contribute to the increased morbidity and mortality, including early age of infection, rapid loss of maternal antibody, vitamin A deficiency, and prior

or concurrent infection with other pathogens. However, depressed cell-mediated immune responses secondary to malnutrition likely contribute significantly to high risk of morbidity and mortality.

### Complications

In developed countries, about 10% of measles cases are associated with complications, although the rate exceeded 20% during the 1989 to 1990 measles epidemic in the United States, primarily because of the high proportion of cases in young children and adults. The most common complications are otitis media (5% to 9%), diarrhea (5% to 9%), pneumonia (1% to 7%), and encephalitis (0.1%). Pneumonia is more common in young children, and encephalitis more common in adolescents and adults. In resource-poor countries, measles is a devastating disease with complication rates as high as 80% in many epidemics, and case fatality rates may exceed 10%. Diarrhea and pneumonia are frequently fatal. Keratitis in children with vitamin A deficiency can lead to corneal ulceration and blindness, and secondary bacterial infections cause otitis media, osteomyelitis, and other pyogenic complications.

### Respiratory Tract Complications

The most frequent complications of measles involve the respiratory tract. Coryza, mild laryngitis, and tracheobronchitis with cough are almost invariably present in uncomplicated measles. Only when they are unusually severe or prolonged are they considered complications. Pneumonia is the most frequent life-threatening complication of measles (131), and it may present clinically as bronchiolitis in infants or as bronchopneumonia or lobar pneumonia in infants and older children. Although the incidence in developed countries is less than 10%, pneumonia accounts for more than 60% of measles-associated deaths. In children, pneumonia is usually caused by secondary bacterial infection and occurs predominately in children younger than 5 years of age. Common bacterial pathogens are *Streptococcus pneumoniae* and *Haemophilus influenzae* type b (Hib) in unvaccinated children and *Staphylococcus aureus*. Widespread use of Hib and pneumococcal conjugate vaccines should decrease the incidence of these pathogens as causes of post-measles pneumonia. Secondary bacterial pneumonia should be suspected in any child with measles who develops respiratory distress in association with persistence or recurrence of fever.

Symptomatic pneumonia is observed in 5% to 15% of immunocompetent adults with measles. In contrast to pneumonia in children, pneumonia in adults is more commonly caused by MeV itself. Respiratory distress and hypoxemia develop in parallel with the rash, and there is evidence of prolonged and extensive MeV replication, including high and persistent fever, persistence of rash, per-

sistent viremia, and laboratory evidence of hepatitis and myositis (121). Pneumonia caused by bacterial superinfection develops later, usually 5 to 10 days after the onset of the rash. Typically, deteriorating clinical and pulmonary status, high fever, elevated white blood cell count, and purulent sputum develop in a patient whose rash is resolving. In MeV pneumonia, chest radiographs reveal bilateral diffuse reticulonodular interstitial infiltrates. Segmental pulmonary consolidation, parenchymal nodules, hilar adenopathy, and pleural effusions are rarely observed except in atypical measles. Measles pneumonia is frequently a severe illness in healthy young adults, but fatalities are rare.

Otitis media is usually signaled by increasing irritability and ear pulling in infants or earache in older children, together with persistence or recurrence of fever. In severe cases, the first sign of otitis media may be spontaneous perforation of the tympanic membrane with a purulent discharge from the middle ear. The incidence of otitis media is increased in infants.

Laryngotracheobronchitis (croup) due to MeV may occur in up to 20% of children with measles who are under 2 years of age, and it should be suspected when a child with measles develops inspiratory stridor, progressive hoarseness, a barking cough, and suprasternal retraction. Increased restlessness, dyspnea, anxiety, and tachycardia suggest increasing airway obstruction (obstructive laryngitis), which may require tracheostomy. Bronchiolitis may also complicate measles in infants and children younger than 2 years of age and is clinically indistinguishable from bronchiolitis caused by respiratory syncytial virus. Sinusitis occurs in 2% to 4% of patients with measles, primarily in adolescents and adults, and has been observed in 25% of young adults hospitalized with pneumonia.

### Neurological Complications (Table 2)

Uncomplicated measles is frequently accompanied by CSF pleocytosis and electroencephalographic abnormalities, but there is no evidence that the parenchyma of the brain is directly infected. Infection of vascular endothelial cells is a central feature of the pathogenesis of uncomplicated measles, and vascular endothelial cells in the brain are not spared (132). MeV infection of vascular endothelial cells in the CNS provides a route of entry for virus into the brain parenchyma in those rare patients who develop MIBE or subacute sclerosing panencephalitis (SSPE).

### Acute Postinfectious Measles Encephalomyelitis

Acute postinfectious measles encephalomyelitis is the most common neurological complication of measles. It is rare in children under 2 years of age, but it occurs in about one in 1,000 cases of measles in older children and somewhat more frequently in adults (133). The onset is usually during the first week after appearance of the rash, but it

TABLE 2 Neurologic complications of measles

Disease	Host	Typical age of measles	MeV in brain	Incidence	Pathology	Time course
Acute postinfectious measles encephalitis	Normal	>2 years	No	1:1,000 cases	Demyelination and perivascular inflammation	Monophasic course over weeks
Measles inclusion body encephalitis (MIBE)	Immune suppressed	Any	Yes	Unknown	Inclusion bodies in neurons and glial cells	Progressive course over months
Subacute sclerosing panencephalitis (SSPE)	Normal	<2 years	Yes	1:10,000 cases	Inclusion bodies and inflammation	Progressive course over years

Adapted from reference 26.

occasionally develops during the prodrome. Onset is typically abrupt, starting with resurgent fever, irritability, headache, vomiting, and confusion and progresses rapidly to obtundation and coma. These manifestations are frequently accompanied by seizures, and some patients develop focal neurological signs, including cerebellar ataxia, myelitis, optic neuritis, and retinopathy. There are usually signs of meningeal irritation, and the CSF shows a mild lymphocytic pleocytosis and a moderately elevated protein concentration. Mortality is 10% to 20%, and the majority of survivors have neurological sequelae.

Acute postinfectious measles encephalomyelitis appears to be an autoimmune disease. The neuropathology is similar to that of experimental autoimmune encephalomyelitis, with lymphocytic perivascular cuffing and perivenular demyelination (134). Neither MeV RNA nor viral antigens have been detected in the brain, and there is no intrathecal synthesis of MeV-specific antibody. However, antibodies to myelin basic protein are present in the CSF. The pathogenesis is unclear but possibilities include altered presentation of myelin antigens, activation and expansion of autoreactive lymphocytes as a result of the immune activation and dysregulation, and molecular mimicry. There are regions of homology between MeV proteins and myelin basic protein, but neither cross-reactive antibodies nor cross-reactive T cells have been identified (134).

#### Subacute Sclerosing Panencephalitis

A second form of measles encephalitis, SSPE, is a rare delayed complication of measles that occurs in approximately one in 10,000 cases (135). Typically, SSPE presents 6 to 8 years after measles that occurred in early childhood, generally before the age of 2 years (136). The onset is insidious, with symptoms of progressive loss of cortical function developing over months. In the early stages, subtle personality changes and declining school performance often indicate deteriorating intellectual capacity. There may also be awkwardness and stumbling followed by development of myoclonic jerks, seizures, and characteristic EEG changes consisting of periodic high-amplitude slow-wave complexes. Patients subsequently develop ataxia, progressive mental deterioration, and extrapyramidal dyskinesias, including choreoathetosis and dystonic posturing. Progressive loss of vision is caused by chorioretinitis, optic atrophy, or cortical blindness. Disease progression is variable and periods of remission are common, but in most cases death occurs within 1 to 3 years of onset (137).

Pathologic examination reveals diffuse encephalitis involving both white and gray matter with perivascular cuffing, diffuse lymphocytic infiltration, extensive microglial proliferation, and patchy demyelination. Neurons and glial cells contain typical nuclear and cytoplasmic inclusion bodies composed of MeV ribonucleocapsids, but multinucleated giant cells are not present. Although large amounts of viral RNA and N and P proteins are present, the MeV envelope proteins are usually markedly reduced, absent, or functionally defective, resulting in deficient virion assembly and budding (138). The defective MeVs in SSPE brains have mutations throughout the genome, especially within the M, H, and F genes, and infectious MeV cannot be recovered (139–141).

Patients with SSPE have exceptionally high titers of antibody to MeV in their plasma and CSF. Synthesis of antibody to MeV by plasma cells in the CNS results in elevated levels of MeV-specific CSF immunoglobulin. Because this antibody is of limited heterogeneity, electrophoretic

analysis of the CSF typically reveals oligoclonal bands of IgG (142).

The pathogenesis of SSPE is unclear, but sequence analysis of MeV RNA from various parts of the brain suggests that virus in the CNS is clonal. Neurons and glial cells are not fully permissive for MeV, down-regulate transcription, and increase the 3'-5' transcription gradient, resulting in a marked reduction in the synthesis of envelope glycoproteins. Infected cells produce MeV nucleocapsids and defective interfering particles, but little or no infectious virus. Antibodies to MeV may contribute to this process by further inhibiting transcription of MeV mRNA and removing MeV proteins from the cell membrane. The result is the establishment of a persistent infection that can slowly progress by cell-to-cell spread within the brain in the absence of giant cell formation. Immune lysis of cells expressing even small amounts of MeV envelope proteins may limit progression of the infection and could account for the prolonged latent period of SSPE. The diagnosis of SSPE is based on (i) the gradual and progressive onset of behavioral changes, myoclonus, dementia, visual disturbances, and pyramidal and extrapyramidal signs; (ii) characteristic periodic EEG discharges; and (iii) demonstration of antibodies to MeV in the CSF.

#### Measles Inclusion Body Encephalitis

The third form of measles encephalitis, MIBE, is a progressive, generally fatal infection of the brain that occurs in immunocompromised patients (see Measles in Immunocompromised Patients).

#### Gastrointestinal Complications

MeV infection of epithelial surfaces and lymphoid tissues throughout the gastrointestinal tract is responsible for the nausea, vomiting, diarrhea, and diffuse abdominal pain observed in 30% to 60% of children and adults with measles, as well as for rare cases of nonsuppurative appendicitis. Laboratory evidence of hepatitis occurs in the majority of adults with measles, but there is rarely symptomatic hepatitis or jaundice (121). In developed countries, these manifestations are self-limited and generally resolve as the rash disappears. In developing countries, severe and persistent diarrhea occurs in 20% to 70% of children with measles and is frequently associated with secondary bacterial or protozoal infection (143).

#### Cardiovascular Complications

Electrocardiographic evidence of myocarditis and pericarditis, including prolongation of the P-R interval, ST segment abnormalities, and T wave inversions, can be detected in 15% to 30% of children and adults during the acute phase of measles (144). These abnormalities are transient and rarely result in symptomatic disease. Prolongation of the Q-T interval also may be observed, presumably related to the transient hypocalcemia that can occur during the acute phase of measles.

#### Ocular Complications

Conjunctivitis and punctate keratitis are features of uncomplicated measles and resolve as the rash disappears. In malnourished children with vitamin A deficiency, these lesions frequently progress to corneal ulceration, which may be complicated by secondary bacterial infection. Consequently, before the widespread use of measles vaccine measles was an important cause of childhood blindness in developing countries where vitamin A deficiency was prevalent.

### Other Complications of Measles

Mild to moderate thrombocytopenia is common during the acute phase of uncomplicated measles, but it is asymptomatic and transient, resolving soon after the rash disappears. Rarely, thrombocytopenic purpura develops several weeks after uncomplicated measles. This complication resembles idiopathic thrombocytopenic purpura and has an excellent prognosis.

Severe hemorrhagic measles (black measles) is an extremely rare form characterized by the sudden onset of high fever, seizures, delirium, respiratory distress, and a confluent hemorrhagic eruption in the skin and mucous membranes. Bleeding from the nose, mouth, gastrointestinal tract, and genitourinary tract are frequently severe and uncontrollable, and mortality is high. The pathogenesis appears to involve disseminated intravascular coagulopathy associated with extensive MeV infection of vascular endothelium.

Tuberculosis may be exacerbated or reactivated by measles, presumably because of the prolonged suppression of cell-mediated immunity induced by MeV infection (114). This has not been observed after live attenuated MeV vaccine, although suppression of tuberculin skin test reactivity and *in vitro* lymphoproliferative responses occur after measles vaccination.

There are conflicting and inconclusive data suggesting that persistent MeV infection causes or contributes to the development of chronic diseases of unknown etiology, including multiple sclerosis, Paget's disease, inflammatory bowel disease, and otosclerosis (66). However, no causal association has been established between MeV or measles vaccines and these conditions.

### Clinical Diagnosis

Measles is readily diagnosed on clinical grounds. Koplik's spots are especially helpful because they appear early and are pathognomonic of measles. Clinical diagnosis is more difficult during the prodrome, when the illness and rash are attenuated by passively acquired MeV antibodies or prior immunization, or when the rash is absent in immunocompromised patients and severely undernourished children. Clinical diagnosis is also more difficult in regions where the incidence of measles is low because other pathogens are responsible for the majority of measles-like illnesses (fever and rash). The Centers for Disease Control and Prevention (CDC) case definition for measles requires (i) a generalized maculopapular rash of at least 3 days' duration; (ii) fever of at least 38.3°C (101°F); and (iii) either cough, coryza, or conjunctivitis. While the CDC case definition has a sensitivity of at least 90%, its specificity is only about 25% in the absence of endemic and epidemic measles.

The differential diagnosis of measles includes a number of conditions associated with fever and rash, including rubella, enterovirus infections, drug eruptions and other allergic rashes, scarlet fever, meningococemia, roseola infantum caused by human herpesvirus 6, erythema infectiosum caused by parvovirus B19, and dengue virus infection. Other diseases that may cause maculopapular rashes resembling measles include toxic shock syndrome, infectious mononucleosis caused by Epstein-Barr virus, toxoplasmosis, and Kawasaki's disease.

### Laboratory Diagnosis

#### Virus Isolation

Measles can be diagnosed by isolating virus in cell culture from respiratory secretions, nasopharyngeal and conjunctival swabs, peripheral blood mononuclear cells, or urine. Spin

amplification (shell vial) assays, with fluorescent antibody staining for MeV antigens, can improve the speed and sensitivity of culture diagnosis. Nevertheless, virus isolation remains technically difficult and unavailable in most clinical settings.

#### Cytologic Diagnosis and Antigen Detection

Direct detection of giant cells in respiratory secretions or urine; on accessible epithelial surfaces, such as the pharynx, nasal mucosa, buccal mucosa, or conjunctiva; or in tissue obtained by biopsy provides a rapid and practical means of diagnosis. Characteristic multinucleated giant cells containing eosinophilic intranuclear and intracytoplasmic inclusion bodies are ordinarily present during the prodrome and for the first 2 or 3 days of the rash. Multinucleated giant cells with eosinophilic intranuclear inclusion bodies are also produced by herpes simplex and varicella-zoster virus infections. Detection of MeV antigens by immunofluorescent or immunoenzyme staining increases sensitivity and specificity. These techniques can detect MeV antigens later in the disease when infectious virus can no longer be isolated. Polyclonal sera and monoclonal antibodies are both effective, but antibodies to the MeV N protein are most useful because this viral protein is the most abundant antigen.

#### Nucleic Acid Detection

Detection of MeV RNA by RT-PCR amplification of RNA extracted from clinical specimens or tissue can be accomplished using primers targeted to highly conserved regions of the MeV N, M, or F genes. Testing is frequently performed at WHO Regional or Global Network Laboratories, including the CDC. These techniques provide an extremely sensitive and specific means of diagnosis and are especially useful in CNS infections in which infectious virus cannot be readily isolated and in immunocompromised patients who may not be capable of antibody responses. RT-PCR assays can be applied to specimens obtained under field conditions and, when combined with nucleotide sequencing, permit the precise identification and characterization of MeV genotypes for molecular epidemiologic studies.

#### Serologic Diagnosis

Serology has been the mainstay of the laboratory diagnosis of measles. A 4-fold or greater increase in MeV-specific IgG antibody levels between acute and convalescent sera or the detection of MeV-specific IgM or low-avidity IgG antibodies in a single specimen of serum or saliva are considered diagnostic of acute MeV infection. The presence of IgG antibody to MeV in a single serum specimen is evidence of prior infection or immunization. In primary infection in the normal host, detectable antibodies to MeV generally appear in the serum within 1 to 3 days of rash onset and reach peak levels in 2 to 4 weeks. Because some patients will already have had a substantial rise in antibody titer if the initial serum is obtained 4 days or more after rash onset, acute serum should be obtained as soon as possible after the onset of symptoms. Convalescent serum should be obtained 2 to 4 weeks later, although an interval of 7 days is often sufficient to demonstrate a rising antibody level. MeV-specific IgM antibodies may not be detectable with some currently available assays until 4 to 5 days or more after rash onset, and MeV-specific IgM antibodies usually fall to undetectable levels within 4 to 8 weeks of rash onset (145).

A number of methods are available for measuring antibodies to MeV. Neutralization tests are sensitive and specific, the results are highly correlated with immunity to infection,

and they provide the most clinically relevant measure of response to immunization (146). However, they require propagation of MeV in cell culture and are thus expensive, laborious, and not widely available. The hemagglutination inhibition (HI) test results correlate well with those of conventional neutralization tests and the presence of HI antibody is indicative of immunity to measles. The complement fixation test is less sensitive than HI or neutralization tests and more difficult to perform, and it is now rarely used.

Enzyme immunoassays (EIAs) are now the most widely used means of serologic diagnosis. Employing antigens prepared from MeV-infected cells or recombinant MeV proteins, they can detect both IgM and IgG antibodies. With sensitive EIAs, it is possible to detect MeV-specific IgM antibodies in patients with secondary immune responses to MeV, albeit at lower IgM to IgG ratios than observed in patients with primary immune responses. Thus the presence of IgM antibody is not necessarily indicative of primary MeV infection. Recent MeV infection also can be distinguished from past infection by the presence of low-avidity antibody and IgG3 (147).

## PREVENTION

### General

Environmental disinfection has little impact on the spread of MeV because the virus is efficiently transmitted by respiratory routes and fomites do not play a significant role in transmission. Quarantine is generally futile because exposure often occurs during the prodrome and before the diagnosis is made. Airborne precautions are indicated for all hospitalized patients with measles until 4 days after the onset of the rash. These include use of an N95 respirator or a respirator with similar effectiveness in preventing airborne transmission and preferably placement in a single patient, airborne infection isolation room (see CDC recommendations for details: <http://www.cdc.gov/hicpac/>). Immunocompromised patients with measles may continue to shed virus and should be isolated for the duration of their illness. Susceptible medical personnel exposed to measles should be relieved from patient contact from the 5th through the 21st day after exposure, regardless of whether or not they receive postexposure immunization with vaccine or Ig. Personnel who become ill should be relieved from patient contact until 5 days after the onset of rash.

### Passive Immunoprophylaxis

Ig can prevent or modify measles in susceptible persons, but administration of measles vaccine is the preferred intervention. Attenuated measles vaccines may provide some protection to immunocompetent persons if administered within 72 hours of exposure and have the advantage of inducing long-term immunity. In immunocompetent persons, administration of Ig within 72 hours of exposure usually prevents MeV infection and almost always prevents clinical measles. Administered up to 6 days after exposure, Ig will still prevent or modify the disease. Prophylaxis with Ig is recommended for susceptible household and nosocomial contacts that are at risk of developing severe measles, particularly children younger than 1 year of age, immunocompromised persons (including HIV-infected persons previously immunized with attenuated measles vaccine), and pregnant women. Except for premature infants, children younger than 6 months of age will usually be partially or completely protected by passively acquired maternal anti-

body. If measles is diagnosed in a mother, all unimmunized children in the household should receive Ig. The recommended dose of Ig is 0.25 ml/kg of body weight given intramuscularly; immunocompromised persons should receive 0.5 ml/kg. The maximum total dose is 15 ml. Intravenous immunoglobulin (IgIV) contains antibodies to MeV and the usual dose of 100 to 400 mg/kg should provide adequate prophylaxis for measles exposures occurring as long as 3 weeks or more after IgIV administration.

In countries where the use of measles vaccine has been widespread for decades, most adults are immune as a consequence of vaccination rather than natural infection, and the reduction in indigenous MeV transmission has eliminated the immunologic “boosting” associated with re-exposure. Consequently, levels of antibody to MeV in adults are considerably lower than they were when wild-type MeV infection was prevalent, resulting in lower levels of passively acquired maternal antibody to MeV in newborns (148) and lower levels of antibody to MeV in current lots of immunoglobulin (149).

Susceptible persons who receive postexposure prophylaxis with Ig should be immunized with attenuated measles vaccine (if it is not contraindicated). Measles vaccine should be given 5 months after Ig if the dose was 0.25 mg/kg (standard dose) and 6 months after Ig if the dose was 0.5 mg/kg (for immunocompromised persons).

### Active Immunization

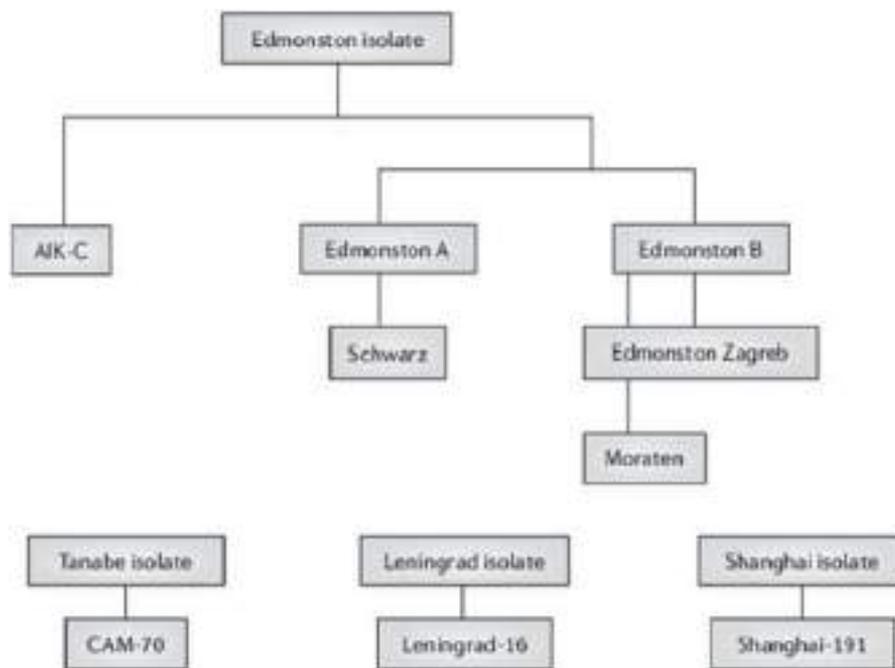

Remarkable progress in reducing measles incidence and mortality has been and continues to be made as a consequence of increasing routine measles vaccine coverage, provision of a second dose of measles vaccine through routine immunization services or supplementary immunization activities (SIAs), and increasing efforts by the WHO, the United Nations Children’s Fund (UNICEF), and their partners in the Measles and Rubella Initiative to achieve and sustain measles elimination. All six WHO regions have adopted measles elimination goals, with the latest date being 2020.

This achievement in reducing measles impact attests to the enormous public health significance of measles vaccination and was a key factor in achieving the Millennium Development Goal 4 to reduce overall child mortality. The most recent global measles goals were to achieve the following by 2015: (i) increase coverage with the first dose of measles vaccine to >90% nationally and >80% in every district; (ii) reduce global measles incidence to fewer than five cases per million population; and (iii) reduce global measles deaths by 95% compared to the estimated number of measles deaths in 2000 (40).

### Measles Vaccines

The process of adaptation of MeV grown in nonsusceptible host cells, such as the chick embryo and canine and bovine kidney cells, led successfully to the development of attenuated vaccine strains. The first attenuated measles vaccine was developed by passage of the Edmonston strain of MeV in chick embryo fibroblasts to produce the Edmonston B virus (Fig. 9) (150). Licensed in 1963, this vaccine was protective, but also reactogenic, inducing fever and rash in a large proportion of immunized children. Reactions were reduced when Ig that contained antibodies to MeV was given at the time of vaccination.

More extensive passage of the Edmonston B virus in chick embryo fibroblasts produced the more attenuated Schwarz vaccine that was licensed in 1965 and currently

**FIGURE 9** Measles virus vaccines. Most attenuated measles vaccines were developed from the Edmonston strain of measles virus. The Edmonston B vaccine was the first licensed measles vaccine but was associated with a high frequency of fever and rash. The further attenuated Schwarz and Edmonston-Zagreb vaccines are widely used throughout the world. The Moraten vaccine is the only measles vaccine used in the United States. [Origin: Markowitz LE. Measles control in the 1990s: immunization before 9 months of age. Document WHO/EPI/GEN/90.3. Geneva: World Health Organization, 1990. Reprinted in: Cutts FT. Measles. Module 7. The Immunological Basis for Immunization Series. Document WHO/EPI/GEN/93.17. Geneva: World Health Organization, 1993.] (From reference 127 with permission of the publisher.) Source: Moss WJ, Griffin DE. Global measles elimination. *Nat Rev Microbiol* 2006;4:900–908.

serves as the standard measles vaccine in much of the world (Fig. 9). The Moraten strain (licensed in 1968 and meaning “more attenuated Enders” strain) used in the United States is closely related to the Schwarz strain (Fig. 9) (151). Other Edmonston-derived vaccine strains (e.g., Zagreb, AIK-C) and attenuated strains developed independently (e.g., CAM, Leningrad-16, Shanghai-191) are also successful vaccines. Few antigenic differences have been described among MeV vaccine strains (all genotype A) regardless of the geographic origin of the parent virus. However, the Edmonston-Zagreb vaccine is produced in human diploid cells, rather than chick embryo fibroblasts, and may be more reactogenic and immunogenic in young infants and when delivered by the aerosol route (152).

The lyophilized attenuated vaccine virus is relatively stable, but the reconstituted vaccine rapidly loses infectivity. The attenuated virus is inactivated by light and heat, and after reconstitution loses about half of its potency at 20°C and almost all potency at 37°C within an hour. Therefore, a cold chain must be maintained prior to and after reconstitution. Attenuated vaccine viruses replicate less efficiently than wild-type MeV but induce both neutralizing antibody and cellular immune responses qualitatively similar to that induced by natural disease, although antibody titers are lower (153). Antibodies first appear 12 to 15 days after vaccination and peak at 1 to 3 months. In many countries, attenuated measles vaccine virus is combined with other live attenuated virus vaccines such as those for rubella (MR), mumps and rubella (MMR), and mumps, rubella, and varicella (MMRV). With increasing global emphasis on rubella elimination, more countries are using combined measles and rubella vaccines.

### Administration

The recommended age of vaccination with the first dose of measles-containing vaccine (MCV) varies from 6 to 15 months depending on region and is a balance between the optimum age for seroconversion and the probability of acquiring measles before that age. In areas where measles remains prevalent, measles vaccination is routinely performed at 9 months, whereas in areas with little measles, vaccination is often at 12 to 15 months. During epidemics and among HIV-infected infants, the measles vaccine may be administered at 6 months with another routine dose at 9 months of age.

Attenuated measles vaccine is administered subcutaneously or intramuscularly. However, there is substantial interest in alternate routes of delivery that would not require needles and syringes. Neither oral nor intranasal administration is effective, but delivery to the lower respiratory tract may be more promising. Aerosol administration was advocated by Albert Sabin in the early 1980s, is highly effective in boosting preexisting antibody titers, and may hold promise for use in older children. However, the primary immune response to aerosolized measles vaccine is lower than it is to subcutaneous administration of the same vaccine (154). The reasons for this are not known but may be related to dose or efficiency of delivery and infection. A promising approach is the use of microneedle patches to deliver lyophilized vaccine virus subcutaneously (155).

The proportions of immunized children who develop protective levels of antibody are approximately 85% at 9 months of age and 95% at 12 months of age (156), although these proportions vary by vaccine strain and host characteristics (157). Genetic background affects the likelihood of

seroconversion and antibody titers (158, 159). Common childhood illnesses at the time of vaccination may also reduce immune responses, although this is not frequent and should not be a reason for withholding vaccination (160). Any potential decrease in seroconversion must be balanced against the loss of the opportunity for vaccination and the consequent risk of the child acquiring measles. Similar compromises must be considered with respect to immunizing individuals infected with HIV. Overall, measles vaccine has been well tolerated and immunogenic in HIV-infected children and adults, although antibody levels may wane (69). Because of the potential severity of wild-type MeV infection in HIV-infected individuals (70), attenuated measles vaccine is recommended for routine administration to HIV-infected children, except those who are severely immunocompromised (73, 157). Attenuated measles vaccine is also contraindicated in individuals with other severe deficiencies of cellular immunity because of the possibility of disease due to progressive pulmonary or CNS infection.

The dose of MeV routinely used for immunization is between  $10^3$  and  $10^4$  plaque-forming units. When 10- to 100-fold higher doses were used, seroconversion in younger infants improved, and in 1990 the WHO Expanded Program for Immunization (EPI) recommended use of the high-titer Edmonston-Zagreb vaccine at 6 months of age in countries where measles before the age of 9 months was a significant cause of death. However, subsequent follow-up of children receiving high-titer vaccines in countries with high childhood mortality showed an increased mortality in girls over the subsequent 2 to 3 years, and this recommendation was withdrawn (67). Mortality was not due to measles, but rather to a relative increase in the deaths due to other infections. The pathogenesis of delayed increased mortality after the high titer vaccine is not understood but occurred primarily in those who developed a rash after vaccination and may be related to long-term suppression of immune responses similar to that induced by measles or alteration of immune responses associated with a change in the sequence of delivery of vaccines (161).

The duration of vaccine-induced immunity is variable. Secondary vaccine failure rates have been estimated to be approximately 5% at 10 to 15 years after immunization, but they are probably lower when vaccination is given after 12 months of age (162). Waning antibody levels occur within 2 to 3 years of measles vaccination of HIV-infected children in the absence of antiretroviral therapy (69). However, decreasing antibody titers do not necessarily imply a complete loss of protective immunity because a secondary immune response usually develops after re-exposure to MeV, with a rapid rise in antibody titers without overt clinical disease (163).

### Second Dose of Measles Vaccine

With increasing emphasis on regional measles elimination and the potential for global measles eradication (see Regional Elimination and Global Eradication), achieving high coverage with two doses of measles-containing vaccine (MCV2) is receiving increased attention. The herd immunity threshold ( $H$ ) is the level of population immunity necessary to interrupt MeV transmission and is estimated by the equation,  $H = 1 - 1/R_0$ . This equation is based on several simplifying assumptions, but it provides an approximation of the level of population immunity required to eliminate measles. For MeV, this value is 93% to 95%, a level of population immunity that cannot be achieved with a single dose of MCV at 9 months of age. Thus, a second dose

is required for measles elimination. This second dose can be administered through routine immunization services, often in the second year of life or prior to school at 4 to 6 years of age, or through mass vaccination campaigns called supplemental immunization activities (SIAs). In the United States, many colleges and universities require a second dose of measles vaccine because of the shift to older age groups in recent measles outbreaks. This second dose serves to immunize those children who failed to respond to the first dose or who missed it. The vast majority of children who do not develop protective antibodies after a first dose of measles vaccine will respond to the second dose, although there have been recent measles outbreaks that included a substantial proportion of cases who had received two doses of measles vaccine (164).

### Vaccine Side Effects

Standard doses of currently licensed measles vaccines are safe in immunocompetent children and adults. Fever to  $39.4^\circ\text{C}$  ( $103^\circ\text{F}$ ) occurs in 5% to 15% of seronegative vaccine recipients, which can induce seizures in children predisposed to febrile seizures, and 2% to 5% of vaccine recipients develop transient rash. Attenuated measles vaccine is not a recognized cause of SSPE, which has declined in incidence in parallel with the vaccine-induced decline in the incidence of measles. Mild transient thrombocytopenia has been reported with an incidence of approximately one in a million vaccine recipients (165).

Although assumed to be rare, the risk of disease caused by attenuated measles vaccine virus in HIV-infected persons is unknown. The only documented case of fatal disease induced by measles vaccine virus in an HIV-infected person was in a 20-year-old man who died with MeV giant cell pneumonitis 15 months after receiving his second dose of measles vaccine (166). He had a very low  $\text{CD4}^+$  T-lymphocyte cell count but no HIV-related symptoms at the time of vaccination. Fatal, disseminated infection with measles vaccine virus has been reported rarely in persons with other impairments of immune function, and MIBE caused by vaccine virus was reported in a child with an uncharacterized immune deficiency (130).

As with wild-type MeV infection, measles vaccine is associated with immunosuppression. However, this immune suppression is less than after wild-type MeV infection and resolves within weeks after vaccination (167). Manifestations include decreased lymphoproliferative responses to mitogens and antigens, altered patterns of cytokine production, and suppression of delayed-type hypersensitivity skin test responses. Tuberculin skin test reactivity may be abrogated for 4 to 6 weeks after immunization, but unlike wild-type MeV infection, measles vaccine does not exacerbate tuberculosis.

Much public attention has focused on a purported association between MMR vaccine and autism following publication of a report in 1998 hypothesizing that MMR vaccine may cause a syndrome of autism and intestinal inflammation (168). The events that followed and the public concerns over the safety of MMR vaccine led to diminished vaccine coverage in the United Kingdom and provided important lessons in the misinterpretation of epidemiologic evidence and the communication of scientific results to the public (169). The publication that incited the concern was a case series describing 12 children with a regressive developmental disorder and chronic enterocolitis. Nine of the children had autism. Onset of the developmental delay was associated by the parents with MMR vaccination in eight children. This

simple temporal association was misinterpreted and misrepresented as a possible causal relationship, first by the lead author of the study and then by the media and public. Subsequently, several comprehensive reviews and additional epidemiological studies rejected evidence of a causal relationship between MMR vaccination and autism (170), and the original paper was retracted because of ethical violations and misrepresentation of data.

### Contraindications

Contraindications to measles vaccination include pregnancy (a theoretical risk to the fetus); anaphylactic allergy to eggs, gelatin, or neomycin; severe immune suppression associated with HIV-infection defined as percentage of CD4<sup>+</sup> T lymphocytes <15%, other conditions associated with severe impairment of cellular immunity, and recent administration of Ig, IVIg, or other Ig-containing products.

### Investigational Approaches to Measles Vaccination

A new measles vaccine approach would be advantageous if it would allow vaccination of infants before 6 months of age. This would both close the “window of susceptibility” between decay of maternal antibody and vaccination and facilitate delivery by allowing measles vaccine to be given at the same time as other WHO EPI vaccines. Additional motivations for development of new vaccine approaches would be to increase thermostability, eliminate the use of needles and syringes for delivery, and provide a vaccine that would be safe for immunocompromised individuals (171).

A number of experimental vaccines have been developed, including individual MeV proteins (usually H and F) expressed in plants, by viral or bacterial vectors, from DNA, or as peptides or proteins. Delivery of viral genes into host cells for processing and antigen presentation without the need for virus infection, along with thermostability, inexpensive manufacture, and the potential for mucosal administration make DNA vaccines an attractive possibility for development. Studies in juvenile macaques indicated that DNA vaccines could protect from measles and were not associated with predisposition to atypical measles (94). Adjuvants improved responses and protection in macaques. In addition to DNA, several viruses and bacteria have been used to express MeV proteins and tested as experimental vaccines. These include alphavirus replicon vectors, shigella, salmonella, and Bacille-Calmette-Guerin, the mycobacteria used for neonatal immunization against tuberculosis (171–173). These vaccines have received limited testing in humans and are not currently being advanced.

Needleless respiratory delivery of the current attenuated measles vaccine has been extensively evaluated. It is postulated that this route of vaccination would be more natural, be easier to administer, generate less medical waste, and might also overcome the presence of maternal antibody to allow vaccination at an earlier age (174, 175). Reconstituted aerosolized liquid measles vaccine has been studied for more than three decades (176–178) and recently dry powder versions have also been developed. Both are safe and immunogenic in humans and macaques (179, 180). If employed for routine vaccine delivery, either the liquid nebulized or inhalable dry powder vaccine is projected to provide substantial cost savings for measles immunization through elimination of the need for waste management of used needles and improved vaccine coverage particularly during mass campaigns (181).

### Measles Vaccination Strategies

Different goals for measles control have been established, necessitating different vaccination strategies. Three broad goals can be defined: mortality reduction, regional elimination, and global eradication.

#### Mortality Reduction

Mortality reduction, the least demanding of the three goals, calls for a reduction in measles mortality from a predetermined level through reductions in incidence, case fatality, or both (182). Although a reduction in case fatality using appropriate case management is an important component, measles mortality reduction is achieved largely through a reduction in incidence. To reduce incidence, measles vaccine is administered as a single dose through routine immunization services in child health clinics, with the optimal age of immunization determined by the transmission intensity and rate of decline of maternal antibodies. If vaccination coverage is sufficiently high, substantial reductions in incidence and mortality occur, the interepidemic period lengthens, and the age distribution shifts toward older children, further contributing to a reduction in case fatality.

#### Regional Elimination

Measles elimination is the interruption of MeV transmission within a defined geographic area, such as country, continent, or region. Small outbreaks of primary and secondary cases may still occur following importation from outside the region, but sustained transmission does not occur. Because of the high infectivity of MeV and the fact that not all persons develop protective immunity following vaccination, a single dose of measles vaccine does not achieve a sufficient level of population immunity to eliminate measles. A second opportunity for measles immunization is necessary to eliminate measles by providing protective immunity to children who failed to respond to the first dose and to those who were not previously vaccinated. Two broad strategies to administer the second dose have been used. In countries with sufficient infrastructure, the second dose of measles vaccine is administered through routine immunization services, typically prior to the start of school (4 to 6 years of age) or during the second year of life. High coverage levels can be ensured by school entry requirements. A second approach, first developed by the Pan American Health Organization (PAHO) for South and Central America (183), involves mass immunization campaigns (called SIAs) to deliver the second dose of measles vaccine. This strategy was very successful in eliminating measles in South and Central America and subsequently resulted in a marked reduction in measles incidence and mortality in parts of sub-Saharan Africa. This strategy has been adopted by most countries (not the United States) but is difficult to sustain in the long term because of the financial and human resources required for these large campaigns.

The PAHO strategy consisted of four subprograms: catch-up, keep-up, follow-up, and mop-up. The catch-up phase is a onetime, mass immunization campaign that targets all children within a broad age group regardless of whether they have previously had wild-type MeV infection or measles vaccination. The goal is to rapidly achieve a high level of population immunity and interrupt MeV transmission. These campaigns are conducted over a short period of time, usually over several weeks, and during a low transmission season. Under the PAHO strategy, children 9 months to 14 years of age were targeted for vaccination. In many coun-

tries, this is a substantial proportion of the total population. The appropriate target age range depends upon the age distribution of measles seropositivity. In regions with endemic measles, the majority of older children are likely to be immune. Nevertheless, seroprevalence studies usually are not conducted prior to catch-up campaigns, and this broad age range first adopted by PAHO has been widely used in sub-Saharan Africa and Asia. These campaigns require large investments of financial resources and personnel; extensive logistical planning to transport and store vaccines, maintain cold chains, and dispose of syringes and needles; and community mobilization to ensure participation. But if successful, SIAs are cost effective and can abruptly interrupt MeV transmission with dramatic declines in incidence and mortality.

Keep-up refers to the need to maintain greater than 90% routine measles vaccine coverage through improved access to measles vaccination and a reduction in missed opportunities (e.g., because of false contraindications to vaccination). Follow-up refers to periodic mass campaigns to prevent the accumulation of susceptible children. Follow-up campaigns typically target children 1 to 4 years of age, a narrower age group than targeted in catch-up campaigns. Follow-up campaigns should be conducted when the estimated number of susceptible children reaches the size of one birth cohort, generally every 3 to 5 years after the catch-up campaign. Mop-up campaigns target difficult-to-reach children in sites of measles outbreaks or low vaccine coverage. Difficult-to-reach children include those living on the street or in areas of conflict.

### Global Eradication

The possibility of measles eradication has been discussed for almost 40 years (184). Serious discussion of measles eradication began in the late 1960s, when smallpox eradication was nearing completion and the effective, long-term immunity induced by measles vaccine became apparent. MeV meets many of the biologic criteria for disease eradication (185). MeV has no nonhuman reservoir and is accurately diagnosed, and measles vaccination is a highly effective intervention. Although MeV displays sufficient genetic variability to conduct molecular epidemiologic analyses, the antigenic epitopes against which protective antibodies develop have remained stable. Where MeV differs from smallpox and polioviruses is that it is more highly infectious, necessitating much higher levels of population immunity to interrupt transmission.

The vaccination strategy necessary for measles eradication is not different from that of regional elimination, only that the target population is global. The success of measles elimination in large geographic regions suggests that measles eradication is possible. Two doses of measles vaccine, administered through routine immunization services or via SIAs would need to be administered to the children of the world. Many believe this to be a realistic and morally imperative goal, but as polio eradication efforts have shown, the endgame may be full of challenges.

## TREATMENT

### Symptomatic and Supportive Therapy

Treatment of uncomplicated measles is symptomatic and includes bed rest, hydration, and antipyretics. Secondary bacterial infections require prompt treatment with antibiotics. Antibiotics are indicated for children with measles

who have clinical evidence of bacterial infection, including pneumonia, otitis media, skin infection, eye infection, or severe mouth ulcers. *Streptococcus pneumoniae* and *Haemophilus influenzae* type B were the most common causes of bacterial pneumonia following measles prior to widespread use of vaccines against these pathogens. More recent data on bacterial pathogens causing pneumonia in children with measles are lacking. Whether all children with measles or all hospitalized children with measles should be given prophylactic antibiotics remains controversial. Limited evidence suggests that antibiotics administered as prophylaxis to all children presenting with measles may reduce the incidence of pneumonia but not mortality (131). The potential benefits of antibiotic prophylaxis need to be weighed against the risks of adverse effects and accelerating antibiotic resistance.

### Vitamin A

Vitamin A is effective for the treatment of measles, and its administration results in marked reductions in morbidity and mortality in hospitalized children with measles treated with vitamin A. The WHO recommends administration of two daily doses of 200,000 IU of vitamin A to all children with measles 12 months of age or older. Lower doses (100,000 IU) are recommended for children less than 12 months of age. Overall, this regimen results in a 64% reduction in the risk of mortality (186). Pneumonia-specific mortality is reduced, and the impact is greatest in children younger than 2 years of age (186). The mechanisms by which vitamin A reduces measles morbidity and mortality are not known, but these effects are likely mediated through beneficial effects on epithelial cells and host immune responses.

While vitamin A deficiency is not a recognized problem in the United States, many children in the United States with measles have low serum vitamin A levels and these children have increased morbidity following measles. The Committee on Infectious Diseases of the American Academy of Pediatrics recommends the administration of two consecutive daily doses of vitamin A (200,000 IU orally for children 1 year and older; 100,000 IU for children 6 months to 1 year of age) be considered for children 6 to 24 months of age hospitalized for measles and its complications, as well as for children older than 6 months with measles who have immunodeficiency, ophthalmologic evidence of vitamin A deficiency, impaired intestinal absorption, moderate to severe malnutrition, or recent immigration from areas where high measles mortality rates have been observed.

Vitamin A has been widely distributed through polio and measles SIAs as well as through routine child health services and fortified foods. Prophylactic vitamin A supplementation of apparently healthy children has resulted in a 39% reduction in measles-associated mortality (187).

### Antiviral Therapy

There is no antiviral therapy of proven efficacy for measles. Ribavirin inhibits MeV replication in cell culture and has been reported to reduce the severity of measles in children and adults (188). Anecdotal reports have described previously healthy, pregnant, and immunocompromised patients with measles pneumonia and immunocompromised patients with subacute measles encephalitis who recovered following treatment with aerosolized and/or intravenous ribavirin (127, 129). However, the clinical benefits of ribavirin treatment have yet to be demonstrated as only a few

anecdotal cases have been reported, and its use in measles is investigational.

Numerous therapeutic agents have been used to treat SSPE, including IFN, ribavirin, amantadine, isoprinosine, inosiplex, and levamisole. Experience has been anecdotal and any benefits have been transient at best.

# Mumps Virus

JOHN W. GNANN, JR. AND DONALD R. LATNER

## 39

Mumps virus, a member of the paramyxovirus family, causes a distinctive and generally benign systemic infection that is clinically characterized by fever and parotitis. In older literature, mumps was often termed “epidemic parotitis.” Historically, mumps occurred commonly among school-aged children but dramatically declined following the introduction of routine vaccination. Significant mumps outbreaks continue to occur, however, among previously infected or vaccinated individuals for reasons that are not fully understood. These cases of reinfection or vaccine failure can sometimes be difficult to diagnose due to mild clinical presentations and can be difficult to confirm due to limitations of current laboratory testing.

### VIROLOGY

#### Classification

Mumps virus is a member of the order *Mononegavirales* (viruses with nonsegmented, negative-sense, single-stranded RNA genomes), family *Paramyxoviridae*, subfamily *Paramyxovirinae*, and genus *Rubulavirus*. Serologic testing by hemagglutination inhibition or by *in vitro* plaque reduction neutralization assays has identified only one serotype of mumps virus. However, strain-specific variation in cross-neutralizing antibody titers has been observed with individual sera, and minor antigenic differences among mumps virus isolates can be detected using panels of glycoprotein-specific monoclonal antibodies (1–4).

#### Virus Composition

Mumps virions are markedly pleomorphic, irregularly spherical particles that range from 50 to >300 nm in diameter (average about 200 nm) (5–7). An outer envelope derived from the host cell plasma membrane encloses a helically coiled ribonucleocapsid core (8). The envelope is about 10 nm thick and is composed of three layers: glycoprotein spikes that project 10 to 15 nm from the outer surface of the envelope, which consists of a lipid bilayer acquired from the host cell as the virus buds from the cytoplasmic membrane, and an inner structural matrix protein (Fig. 1) (9).

#### Genome

The mumps virus genome is a linear molecule of single-stranded, negative-sense RNA (approximately 15,384 bases)

that serves as a template for both transcription and replication by the virus-encoded RNA polymerase. Wild-type mumps virus genomes adhere to the “rule-of-six,” meaning that the total number of bases in the genome must be evenly divisible by six (10), although this requirement may not be absolute (11). The gene order is 3′-NP-V/P/I-M-F-SH-HN-L-5′ (Fig. 2). The letter designations are NP (nucleoprotein), P (phosphoprotein), V and I (no alternative names), F (fusion), SH (small hydrophobic protein), HN (hemagglutinin-neuraminidase), and L (large protein; catalytic RNA polymerase subunit). There are 3′-leader and 5′-trailer untranslated regions (UTR) at the ends of the genome that encode the genomic and antigenomic promoter sequences, and short intervening sequences between each gene that encode transcription control signals (12–14). The V, P, and I genes overlap and share 5′ mRNA coding sequence. The V gene mRNA is produced by faithful transcription of the genome, but the P and I gene transcripts contain additional nontemplated G residues that are inserted by the RNA polymerase during transcription and result in shifted open reading frames (15–17).

There are 12 known genotypes of mumps virus recognized by the World Health Organization that are distinguished by sequences of the SH and HN genes (18). The SH gene sequence is the most variable of all the mumps virus genes (up to 20% heterogeneity among genotypes). The genotypes are designated by letters A through N (excluding E and M). The global distribution and temporal circulation of mumps genotypes has been described (18), but improved molecular epidemiology is needed to strengthen surveillance efforts.

#### Viral Proteins

The nucleoprotein (NP) is a major viral structural protein. Monomers of NP assemble into a left-handed helical coil, forming a tubular structure that encapsidates the genomic RNA. This is referred to as the ribonucleocapsid, or ribonucleoprotein complex (RNP) (19–23). An 18-Å resolution structure of the mumps RNP has been reported based on cryoelectron microscopy (20). The RNP helps protect the genome against degradation and is essential for transcription to occur (21).

The mumps virus RNA-dependent RNA polymerase (RdRp) is composed of two subunits: the large protein (L) and the phosphoprotein (P). There are few published reports

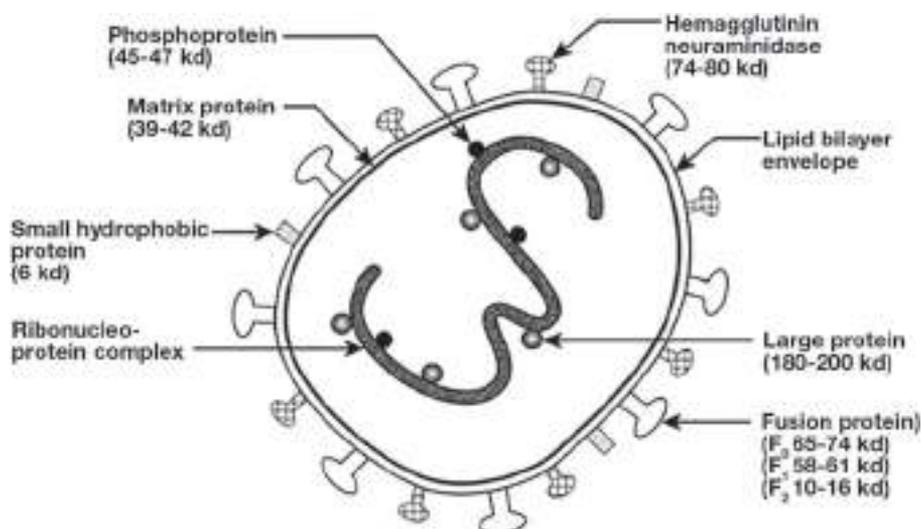

FIGURE 1 Structure of the mumps virion. Molecular weights of viral proteins as measured by gel electrophoresis are shown in parentheses. Data from Galinski and Wechsler (372).

that specifically describe the activities of mumps virus L subunit (14), but the L proteins of closely related paramyxoviruses provide catalytic activity for RNA polymerization, mRNA capping, and polyadenylation (24, 25). The phosphoprotein (P) is an essential cofactor for the polymerase that is required to uncoil the nucleocapsid to allow the L subunit access to the genomic RNA template (20, 26). Both the P and NP proteins are phosphorylated, which can alter the efficiency of RNA synthesis depending on the specific residues involved (21, 27). The kinases that phosphorylate mumps P and NP proteins are not known, and mumps virus does not encode any proteins with known kinase activity. However, based on studies of related paramyxoviruses, host cell kinases such as CKII, PKC- $\zeta$ , AKT, or PLK1 may be responsible (27-29).

The hemagglutinin-neuraminidase (HN) and fusion (F) membrane proteins have cooperative roles in virus attachment and entry into host cells (30-32). The HN protein is a type II glycoprotein; it is anchored in the plasma membrane at the N terminus, and it is glycosylated (33-35). Structurally, the HN protein forms a homo-tetramer that is characterized by a globular head sitting atop a stalk domain (36). The HN head binds to N-acetyl neuraminic (sialic) acid residues on host cells and attaches the virus particle to the cell prior to fusion (37). As a result of the sialic acid binding

property, the HN protein has the ability to agglutinate red blood cells (38). The HN globular head domain also has a neuraminidase activity that cleaves sialic acid, enabling release and preventing aggregation of virus particles as they bud from the host membrane (39).

The F membrane protein is a homo-trimer (40-42). It is synthesized as an inactive precursor (F<sub>0</sub>) that is cleaved into a biologically active form consisting of two fragments, (F<sub>1</sub>) and (F<sub>2</sub>), that are joined by a disulfide bond (43, 44). An irreversible change in the F protein conformation is triggered by direct interaction with the HN stalk domain. This change in structure is ATP independent and it brings F into a lower-energy state, resulting in fusion of the virus with host cell membranes (30, 36, 45-47). HN and F are essential not only for virus-cell membrane fusion, but also for cell-to-cell membrane fusion and virus spread (48). As a result, multinucleated giant cells (syncytia) can be observed in cultures of cells infected with mumps virus. However, due to variation in the activities of the HN and F proteins, the degree to which syncytia are formed is dependent on the specific virus strain (44, 48-50).

The matrix (M) protein is a membrane-associated molecular scaffold that is required along with the F and NP proteins for efficient virus particle formation and release (9, 32, 51, 52). Based on studies of related paramyxoviruses, the

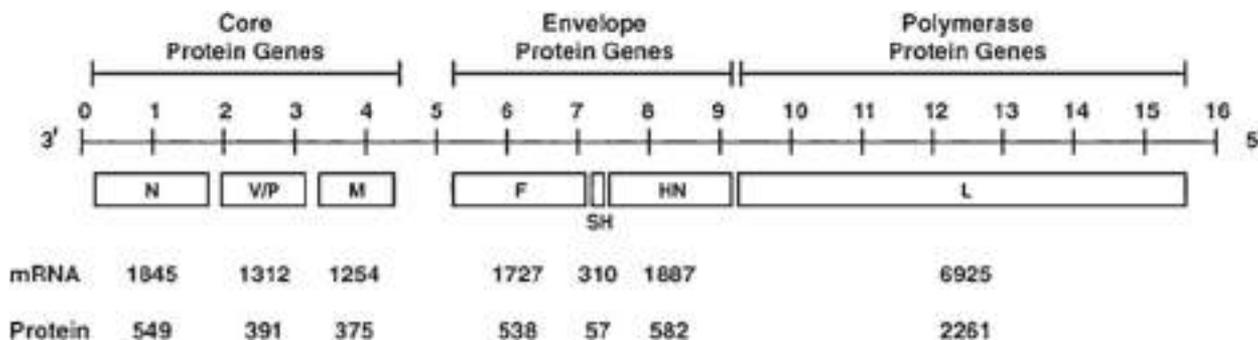

FIGURE 2 Genome organization of mumps virus. Number of nucleotides in messenger mRNA: and Protein: Amino acid residues in corresponding protein. Data from Pringle (373).

mumps M protein is thought to interact with the nucleoprotein and the tails of glycoproteins on the inside of the virion membrane to facilitate virus assembly and budding (9, 52). Mumps virus M protein also transits through the nucleus as the result of a bipartite nuclear localization sequence (NLS<sub>bp</sub>) and a leucine-rich nuclear export sequence (NES). The process of nuclear transit appears to be modulated by ubiquitination and may result in interactions with components of the nuclear pore complex (52). Additional evidence indicates that M protein interactions with class E host cell proteins of the ESCRT complex are essential for virus budding (51).

Both the mumps virus V and SH proteins have been implicated as modulators of the host immune response (53–55). The V protein inhibits the expression and signaling of type I interferon, and signaling by IL-6 by inducing ubiquitin-mediated degradation of host cell STAT1 and STAT3 proteins (56–59). In addition, the V protein has been reported to inhibit the double-stranded (ds)RNA pattern recognition receptor MDA5 (60). The SH protein is only 57 amino acids long and the C terminus of SH is integrated into the viral membrane (61). Although SH is nonessential for virus growth in tissue culture, SH interferes with tumor necrosis factor (TNF) $\alpha$ -mediated signaling and apoptosis by unknown mechanisms (53, 62, 63). The SH protein also binds cellular ubiquilins 1 and 4, which participate in the ubiquitin-mediated proteasome degradation pathway (64). There have been reports of a protein expressed from the I gene transcript, but additional information regarding I protein function is lacking (16, 17, 65).

### Replication Cycle

After binding to sialic acid on the cell surface and fusion of the virus and host membranes through cooperative interaction between the HN and F proteins, the RNP complex is released from the virus particle into the host cell cytoplasm (30). The RNP serves as a template for both transcription and replication by the viral RNA polymerase (L and P proteins) (12, 24). The polymerase engages the template at the promoter within the leader sequence at the 3' end of the genome. As the polymerase proceeds, it initiates mRNA synthesis and releases the transcripts in response to gene-start (gs) and gene-end (ge) sequences flanking each gene (12). The mRNA transcripts are capped and polyadenylated by the virus RNA polymerase (Fig. 3) (24). The likelihood that polymerase remains engaged with the template diminishes as it continues toward the 5' end of the genome, and termination occurs more frequently at the end of each successive gene. As a result, a gradient of mRNAs is produced, with NP and L mRNAs representing the highest and lowest abundance transcripts, respectively (24).

The molecular mechanism that determines if the RNA polymerase preferentially synthesizes monocistronic mRNA transcripts or full-length copies of the antigenome and genome is not clear. However, it is thought that the accumu-

lation of NP protein in the cytoplasm of the infected cell drives the switch from transcription to replication (12, 22). The polymerase is stabilized by the immediate binding of NP to the nascent, newly synthesized RNA as it emerges from the polymerase complex. As a result, the polymerase does not terminate in response to gene-end signal sequences and full-length antigenomic RNA is produced. The positive-sense antigenomic RNA then serves as a template for replication of the negative-sense genomic RNA. Synthesis of the genomic RNA is initiated by a promoter located within the trailer sequence juxtaposed to the L gene at the 3' end of the antigenome. Unlike viral mRNA, the full-length antigenomic and genomic RNA are not capped or polyadenylated (12). The mechanism that controls the relative abundance of full-length genomic and antigenomic transcripts is uncertain, but it has been suggested that binding of the V protein to L, or differential phosphorylation of the P protein might influence this process (12). The full-length negative-sense RNA copies may serve as templates for replication or as templates for secondary transcription, or they may be packaged into progeny virions (Fig. 3).

Assembly and budding of mumps virions from the host cell membrane is dependent upon the M, F, and NP proteins (9, 32, 51). The matrix protein orchestrates the assembly process through interactions with the ribonucleocapsid and the cytoplasmic tails of the glycoproteins along the inner surface of the cellular membrane. Evidence suggests that the functions of the M protein require ubiquitin-regulated trafficking through the nucleus and interactions with cellular class E proteins of the ESCRT complex (9, 32, 52). As the progeny virions are released from the cell by budding, they acquire a portion of the cellular cytoplasmic membrane, which becomes the virion envelope. As a result, the envelope may include some host cell membrane proteins, such as CD55 and CD46, which regulate the activity of complement (66).

### Host Range

Humans are the only known natural host for mumps virus; however, a virus with approximately 90% homology to mumps virus was recently isolated from bats, suggesting the potential of this host as a reservoir (67). Experimental mumps virus infection has been attempted in a variety of animal species, but no animal models consistently reproduce the full spectrum of clinical symptoms observed in humans. Rhesus macaques appear to be the best model for mumps disease in humans, although hamsters and mice have been the preferred models for studies of neuropathology induced by mumps virus infection (68).

### Cell Culture

Mumps virus can be propagated in embryonated chicken eggs (69) or in a wide variety of primate, human, and murine-derived cell lines. Vero cells (African Green Monkey kidney) are commonly used, but other cell lines that support mumps virus replication include CaCo2, PLC/PRF/5, NCI-H292, BSC-1, MCF-7, CV-1, A549, L-41, HEp2, HeLa, and CHO (66, 70–76). Although most of these cell lines have epithelial origins, there have been reports of mumps virus replication in cultures of human peripheral blood mononuclear cells, with preferential replication in T cells and T-cell-derived lymphoblastoid cell lines (77, 78). Mumps virus has rarely been isolated from blood of infected individuals, however, likely due to the development of neutralizing antibody during infection (79, 80). *In vitro* cytopathic effects may appear any time from 24 hours up to 1 week after

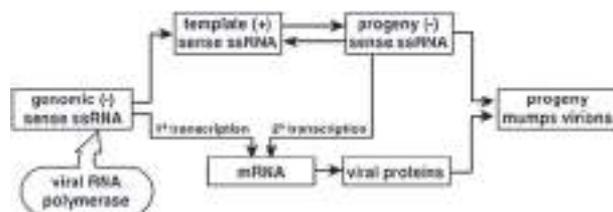

FIGURE 3 Replication strategy of mumps virus.

inoculation. A characteristic cytopathic effect of mumps infection is cell-to-cell fusion, resulting in giant multinucleated syncytia (Fig. 4). Varying degrees of fusion and plaque morphology can occur and are dependent on the virus strain and cell lines involved (81). However, the degree of virulence of mumps virus strains cannot be predicted by *in vitro* cytopathology. Persistent, generally noncytopathic mumps virus infection can be established in cultured cells, including Vero (82), L929 (83), BHK-21 (84), MCT (85), human HEp2, L-41, MCN, Lung-To cells (74, 86), and primary human cells derived from synovial membranes (87) and conjunctiva (88, 89).

### Stability and Inactivation

Infectivity of mumps virus can be maintained for months to years if stored at  $-70^{\circ}\text{C}$ , or if it is lyophilized and stored at  $4^{\circ}\text{C}$  (90, 91). The virus is stable within the pH range of 4.6 to 8.5 (69), but it can be inactivated by heating to  $\geq 56^{\circ}\text{C}$  or by exposure to formalin, organic solvents, detergents, or ultraviolet irradiation (92, 93).

## EPIDEMIOLOGY

### Transmission Patterns

Mumps has a worldwide distribution. In susceptible urban populations, it is primarily a disease of school-aged children, with over 50% of cases occurring between 5 and 9 years of age (94). In unvaccinated populations, over 90% of children have antibodies against mumps virus by age 15 (95). Infection is commonly acquired at school, with secondary spread to susceptible family members. Mumps is rare in children under 1 year of age, presumably due to the protective effect of passively acquired maternal antibody. Before the release of the mumps vaccine in the United States in 1967, mumps was an endemic disease with annual peak activity occurring between January and May. Localized epidemics of mumps in closed populations (isolated communities, boarding schools, military units, etc.) were also well recognized.

### Transmission

Mumps virus is spread by the respiratory route and can be transmitted by contact with respiratory secretions or saliva from infected individuals (96, 97). The incubation period between infection and symptom onset is approximately 18 days, but cases may occur from 12 to 25 days after exposure (97, 98). The virus can be isolated from and spread by infected individuals with no clinically apparent symptoms (97, 99). Many studies since the 1940s have estimated that 30% or more cases of mumps virus infection may be asymptomatic (100–107). Although mumps is easily spread, it is less contagious than measles (105, 108). The basic reproduction

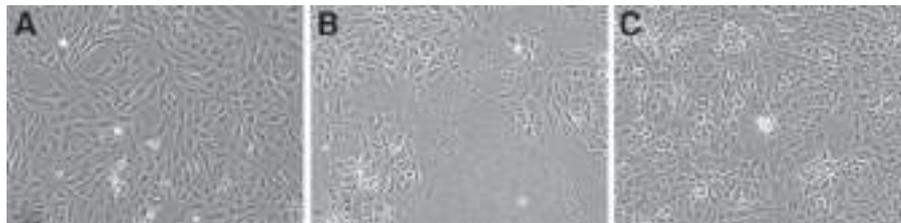

number ( $R_0$ , the estimated number of secondary cases expected to result from a single index case in a susceptible population) for mumps has been estimated as 10 to 12, while for measles it is 15 to 17 (109, 110).

### Incidence and Prevalence Epidemiology of Mumps in the United States

The largest number of mumps cases reported in the United States occurred in 1941 when the incidence was 250 cases per 100,000 persons (111). When the mumps vaccine first entered clinical usage in 1968, the incidence of mumps was 76 cases per 100,000 persons. Mumps vaccine was recommended for routine use in the United States in 1977. In 1985, only 2,982 cases of mumps were reported (1.1 cases per 100,000 population), which was a 98% reduction from the 185,691 cases reported in 1967 (112). Between 1985 and 1987, the incidence of mumps in the United States increased 5-fold to 5.2 cases per 100,000 population (111, 113). More than one-third of the cases reported during this interval occurred in adolescents, reflecting the failure to adequately vaccinate this cohort of children during the 1970s (114, 115).

In 1989, the Centers for Disease Control Advisory Committee on Immunization Practices (ACIP) issued a recommendation that all children receive a second dose of the measles-mumps-rubella (MMR) vaccine, primarily to ensure seroconversion to measles (112). Following this recommendation, the incidence of mumps in the United States also continued to decline and only 231 cases were reported in 2003 (116, 117). The importance of immunization of adolescents and young adults was further emphasized by a large outbreak (over 56,000 reported cases) of mumps in the United Kingdom in 2004 to 2005 (109, 118). Many of the cases occurred in university students who were too old to have been vaccinated, but too young to have been exposed to epidemic natural infection (119).

High two-dose MMR vaccination coverage in the United States led to the declared elimination of endemic sustained transmission of measles (120) and rubella (121) viruses in 2000 and 2004, respectively. It appeared that mumps would also soon follow suit. By testing sera from the 1999 to 2004 U.S. National Health and Nutrition Examination Survey (NHANES), the overall age-adjusted seroprevalence of IgG to mumps virus was shown to be 90% (122), a figure thought to be near the lower end of the level of seroprevalence required to achieve population immunity. In 2005 to 2006 a series of outbreaks in the United States and Canada demonstrated the potential for mumps virus to cause limited, localized outbreaks even among vaccinated populations (123, 124). In 2006, a total of 6,584 cases of mumps were reported in the United States, with a national incidence of 2.2 cases per 100,000 population (123). The American

**FIGURE 4** Cytopathic effect of mumps virus replication in tissue culture. Cell-to-cell fusion in Vero cells during the course of infection with mumps virus (10x magnification). (A) uninfected, and 48 hours post infection (m.o.i. = 0.01) with (B) Jeryl Lynn strain, and (C) wild-type virus (genotype G).

outbreak was centered in the Midwest and peaked in April 2006; 34% of the cases occurred in Iowa. Among the Iowa cases, 7% were unvaccinated; 14% had received one dose of MMR; 49% had received *two or more* doses of MMR; and 30% had unknown vaccine status. The highest age-specific rate was in persons aged 18 to 24 years (median age 22 years), many of whom were college students (125). Another relatively large mumps outbreak (>3,500 cases) occurred in 2009 to 2010 in New York and New Jersey, causing disease primarily among adolescent boys attending Orthodox Jewish schools (126). Mumps transmission in this highly vaccinated population was apparently facilitated by the close face-to-face interactions among the students (127, 128). Numerous other outbreaks among highly vaccinated populations have been reported from around the world (129–135).

### Mortality

Mumps is generally a benign disease; the case-fatality ratio from 1966 to 1975 was 1.0 to 3.4 per 10,000 cases, with most deaths resulting from encephalitis (136). This ratio is likely an overestimation due to underreporting of mild or asymptomatic cases. No deaths were reported during mumps outbreaks in the United States from 2006 to 2010 (137).

The basis for the recurrent mumps outbreaks among vaccinated individuals is not understood and may be multifactorial, but it is not completely unexpected since wild-type mumps virus infection does not necessarily confer lifelong immunity (138, 139). Although failure to vaccinate was a problem in past decades, the vaccine coverage rate for *one or more* doses of MMR was 91.9% for American children aged 19 to 35 months in 2013 (although MMR coverage was below 90% in 17 states) (140). Primary vaccine failure due either to reduced vaccine potency or host immune factors seems unlikely (141). Secondary vaccine failure (waning immunity over time) is certainly a concern but has been at least partially addressed by the addition of a mandatory second dose of MMR (142, 143). Some investigators have suggested the possibility of infection caused by variant wild-type mumps viruses and enabled by a genotype-specific neutralizing antibody response (144). Neutralization capacity of vaccine-induced antibodies may be reduced against more antigenically divergent mumps virus strains (3). However, other studies have demonstrated that sera from vaccinated children will effectively neutralize a spectrum of genotypically diverse wild-type mumps strains, arguing against the immune escape hypothesis (145). A combination of these factors could result in suboptimal population-level immunity in high-risk settings such as schools or college campuses (146).

Some have suggested the need for an improved mumps vaccine with a longer duration of protection (147). Alternatively, the propensity for mumps to spread among vaccinated adolescents in schools and communal living environments with high-intensity exposures raises the question of whether a revised vaccination schedule with a focus on young adults should be considered (123, 134, 148–150).

## PATHOGENESIS

### Viral Replication

Epithelial cells of the nasal and oral mucosa and the upper respiratory tract are assumed to be the initial sites of virus replication based on historic studies of experimental human inoculation (96, 97). Virus can be isolated from saliva for approximately 5 to 6 days before and following the onset of

symptoms (97, 151, 152), although the likelihood of detecting virus in the saliva rapidly diminishes by 3 days after the onset of symptom (153). As the infection progresses, the virus becomes disseminated systemically, but how this occurs is not clear since the virus has been rarely isolated from blood (79, 80, 96). Lymphocytes staining positively for the NP protein have been observed in the nasal mucosa, leptomeninges, and lungs in experimentally infected rhesus macaques (68). In addition, reports of *in vitro* infection and replication of mumps virus in human peripheral blood mononuclear cells suggest these cells may be important for spreading the virus to secondary sites of replication (77, 78). Difficulties with virus isolation from blood may be due to the development of neutralizing antibody around the time of symptom onset (79).

Based on autopsy reports, clinical observations, and experimental infection of animal models, the parotid gland, testes, kidney, and tissues of the central nervous system (CNS) are significant sites of disseminated virus replication (96, 154). Mumps virus has been detected in various human tissues and secretions depending on the timing of sample collection and severity of infection. These include the parotid gland (155), testes (156), semen (157), kidney (158), urine (159), thyroid (160), tears (161), brain (162), cerebrospinal fluid (CSF) (163, 164), myocardium (165), breast milk (166), and placenta (167). Mumps can be transmitted through the placenta to the fetus (96, 168, 169), and spontaneous abortion has been reported following maternal infection during the first trimester of pregnancy (170, 171). Although congenital malformation has been reported following mumps infection *in utero* (171), the rate of occurrence is statistically similar to uninfected controls (172).

### Pathology

Since mumps is rarely a fatal illness, few pathologic descriptions from autopsy series are available and usually involve patients who died of acute encephalitis (155, 162, 173–176). A hallmark manifestation of infection is swelling of the parotid salivary gland (parotitis), which occurs in 60% to 70% of individuals depending on age and immune status of population (101, 102). Parotid gland histopathology is characterized by diffuse periductal and interstitial edema with infiltration by lymphocytes and monocytes. The ductal epithelial cells degenerate and the ductal lumen becomes occluded with neutrophils and necrotic debris, but the glandular cells are generally not involved (155, 177).

Orchitis is a common complication of mumps virus infection in postpubertal men (approximately 30% of cases) (96, 102, 178, 179). Virus has been recovered from testicular biopsy material and semen, indicating that testicular tissue is directly infected (156, 157). Histopathology demonstrates severe and sometimes hemorrhagic interstitial edema with substantial infiltration of leukocytes and separation of the seminiferous tubules (174, 179–181). Swelling within the closed space bounded by the tunica albuginea causes severe pain and can produce vascular insufficiency and areas of infarction. Necrosis of the germinal epithelium and atrophy of the testicle along with scarring and fibrosis may also occur (179, 180). Temporary reduction in the levels of testosterone and inhibin B and elevations of luteinizing hormone have been observed along with negative effects on spermatogenesis (179, 182). Absolute infertility following mumps orchitis is rare, but impaired fertility has been estimated to occur in approximately 13% of patients (179).

Mumps virus frequently infects the kidney, resulting in viruria and microscopic hematuria, with abnormal renal

function evidenced by reduced creatinine clearance (159). Renal injury is usually minimal, but infection may rarely result in severe interstitial nephritis and acute renal failure with damage to the tubular epithelium, immune-complex-mediated glomerulonephritis, and edema with infiltration of mononuclear cells (158, 183–188). Pancreatitis has been reported in approximately 2% of cases (123, 189), but direct evidence for virus isolation from the pancreas in humans is lacking. A few reported severe cases of pancreatitis during acute infection have been accompanied by hemolytic anemia and renal failure (190–193). Pancreatitis associated with mumps infection can occur in the absence of parotitis (194). Infection may also result in thyroiditis. Mumps virus has been isolated from biopsy specimens of the thyroid; histology demonstrates infiltration of leukocytes around the follicles and giant cell formation with destruction of the acinar cells (160). Although cardiac complications resulting from infection are rare, mumps virus has been detected in the myocardium of several patients with endocardial fibroelastosis (165), and infection may result in interstitial fibrosis with hypertrophy and atrophy of heart muscle fibers (195).

In the prevaccine era, mumps infection was a common cause of deafness. Histopathologic changes of the inner ear in one individual who experienced hearing loss as a result of mumps prior to death (196, 197) were limited to the cochlear duct contents and the peripheral cochlear neuron. Degeneration of the organ of Corti and the stria vascularis was observed with complete atrophy of the basal coil and substantial damage to the tectorial and Reissner's membranes.

### Central Nervous System

Central nervous system involvement during mumps virus infection is common. Based on observed pleocytosis in CSF, asymptomatic meningitis has been reported in up to 55% of suspected mumps cases who have undergone lumbar puncture (198). Mumps virus has been isolated from CSF obtained from patients with meningitis without other clinical symptoms (164), and virus can be detected in CSF collected during the early phases of mumps meningoencephalitis in 30% to 50% of cases (199). Studies of infection in rodent models suggest that the virus enters the CNS via the choroid plexus and replicates in the choroidal and ependymal cells, resulting in the release of virus into the CSF (200, 201).

Brains of individuals who died with encephalitis as a result of infection have exhibited a range of neuropathologic findings including diffuse cerebral edema, meningeal infiltration with mononuclear leukocytes, perivascular cuffing with mononuclear cells, proliferation of glial cells, focal neuronal destruction, and localized demyelination (96, 173, 175, 176, 202, 203). Histologic changes indicate both direct viral cytopathic effect and demyelination suggestive of autoimmune postinfectious encephalopathy. In the suckling hamster model, mumps CNS infection is associated with the development of stenosis of the aqueduct of Sylvius and with granular ependymitis (204). These findings suggest a possible but unproven linkage between mumps CNS infections and aqueductal stenosis in children (205).

Mumps virus can establish persistent infection in neuronal cell lines (206) and chronic CNS infection in animal models (207), but it does not routinely cause chronic infections in humans. In patients with mumps meningitis, the persistence of leukocytes and mumps-specific immunoglobulins in the CSF for months after the acute infection suggests the possibility of ongoing antigenic stimulation from chronic mumps CNS infection (208). Anecdotal case reports of chronic

mumps encephalitis have appeared, but data are insufficient to confirm a role for mumps virus as a cause of chronic CNS infection in humans (209–213).

### Virulence Factors and Attenuation

Because mumps virus is highly neurotropic and infection can result in serious neurologic sequelae, substantial effort has been placed toward elucidating the roles of individual genes in neurovirulence and attenuation. Several reports have suggested that the HN gene may have an important role in neurovirulence (214–217), and the F, M, V, and SH genes also have been reported to influence attenuation (53, 59, 81, 217, 218). However, the precise roles of individual genes and their mutations in pathogenesis have been difficult to establish, in part because specific mutations only appear to have effects in a virus-strain-specific manner (96, 219, 220).

### Immune Responses

During the primary immune response to wild-type mumps virus infection (in unvaccinated individuals), virus-specific IgM is detectable in serum within the first few days following symptom onset. The amount of IgM in serum peaks by 7 to 10 days post onset and may persist for up to 6 months (221, 222). Similarly, virus-specific IgA is detectable in serum within days after the onset of symptoms, persists for up to 6 months (221), and can be detected in saliva for up to 5 weeks post onset (151, 223). The IgG antibody response is detectable within the first week of symptoms and continues to rise for approximately 1 month (222). While some studies indicate overall mumps antibody levels are maintained at a steady state throughout life (224), others indicate that neutralizing antibody levels wane over time (225). IgG1 is the dominant subclass of mumps-specific IgG (226). IgG specific for the nucleoprotein has been reported to appear first, followed by production of antihemagglutinin IgG (226). In addition, the nucleoprotein appears to be the immunodominant target and is nonneutralizing (226–228), while the HN and F proteins are neutralizing targets (229). Typical neutralizing antibody titers measured by *in vitro* plaque reduction tend to be low (230) and may wane over time (225). During a secondary immune response to mumps following acute infection, IgM may be present in up to 51% of previously vaccinated individuals (153), and rises in IgG titer and avidity have been observed (231–233). The frequency of mumps-specific memory B cells in circulation is low (234, 235). However, antibody-secreting B cells can be readily detected in the circulation during the course of acute infection (235), and mumps-specific long-lived plasma cells (CD19<sup>-</sup>, CD38<sup>hi</sup>, CD138<sup>+</sup>) have been isolated from the bone marrow more than 40 years after exposure (236).

The mumps-specific T-cell response has historically been characterized using antigen-induced proliferation assays (237, 238) and cytotoxicity assays (239), by detection of interferon production (240–242), and more recently by flow cytometry (243, 244). Virus-specific lymphoproliferative responses have been described following vaccination (245, 246) and can be detected up to 20 years post vaccination (243, 247). A correlation exists between histocompatibility leukocyte antigen (HLA) haplotypes and frequencies of virus-specific T cells, suggesting that the effectiveness of the immune response to mumps may be heritable (248–252). Virus-specific memory CD4<sup>+</sup> T cells have been detected in circulation at low frequency but with greater abundance in bone marrow (244). There is little or no correlation between the mumps-specific T-cell immune response and the virus-specific antibody response (239, 247, 253). Evidence of

mumps-specific T cells can be detected even in seronegative individuals, suggesting that this may be the most robust component of the mumps-specific immune response (247). Elevated frequencies of both gamma-delta T cells (254) and mumps-specific T cells with specific clonal TCR rearrangements have been described in the CSF of patients with meningitis (255–257). Recruitment of cytotoxic T lymphocytes into the CNS in patients with mumps may play a role in the immunopathologic changes observed in human brains after fatal mumps encephalitis (256).

Elevated levels of cytokines and immunoglobulins can be measured in CSF from patients with mumps meningitis. CSF interferon levels decline within a week in patients with self-limited mumps meningitis, but they remain elevated in the CSF of those patients who have more severe CNS involvement or persistent CSF pleocytosis (257). Intrathecal production of mumps-specific IgG and IgM is a common feature of mumps meningitis in children, although there is no apparent correlation between the severity of clinical meningoencephalitis and antibody titers in the CSF (258). A delayed hypersensitivity response to intradermally injected mumps antigen usually develops following clinical illness, but it is not a reliable indicator of mumps immune status (259).

Although humoral and cellular components of the immune response to infection can be measured for many years after vaccination or wild-type infection, it is not known what specific parameters of the immune response may constitute a protective level of immunity. Neutralizing antibody is assumed to be essential for protection, but no studies have been able to define a titer that reliably assures protection (178, 260). Although there is only one serotype of mumps virus (2, 145), infections have been documented in individuals who had been previously infected or vaccinated, and who (in many cases) had preexisting antibody (100, 138, 261–266).

## CLINICAL MANIFESTATIONS

### Primary Infection

The clinical manifestations described below refer to non-immune patients. Although breakthrough mumps virus infections occur in vaccinated individuals, the complication rates are lower and the symptoms are typically less severe (126). Following an incubation period of about 16 to 18 days (range 12 to 25 days), symptomatic mumps begins with a short, nonspecific prodromal phase characterized by fever, malaise, headache, and anorexia. Young children may initially complain of ear pain. Up to 50% of mumps virus infections may be associated with nonspecific or respiratory symptoms and 20% to 30% are asymptomatic (96, 103). Patients often develop characteristic parotid salivary gland pain and swelling (Table 1; Fig. 5). Parotitis occurs in 60% to 70% of patients, but the frequency may range from 50% to 95% depending on population characteristics such as age and immunity (178). Although parotitis is often unilateral at onset, it may progress to the contralateral side during the course of infection. Swelling of other salivary glands may also occur, but it usually does not occur without parotitis. Involvement of the submandibular glands may mimic anterior cervical adenopathy. Sublingual gland involvement is the least frequent symptom, but it may be associated with tongue swelling.

Presternal pitting edema occurs in about 5% of patients and may be secondary to lymphatic obstruction caused by

enlarged salivary glands (267). Painful parotid gland swelling progresses over 2 or 3 days, lifting the ear lobe outward and obscuring the angle of the mandible, which helps distinguish parotitis from cervical adenopathy. The orifice of Stensen’s duct is often erythematous and edematous. Patients complain of trismus, difficulty chewing, and difficulty speaking. Drinking citrus juice may exacerbate the parotid pain. Fever up to 40°C and parotid enlargement peak on the third day of illness, followed by defervescence and resolution of parotid pain and swelling within about 1 week. Long-term sequelae of parotitis are uncommon, although sialectasia and recurrent sialadenitis have been reported.

**FIGURE 5** Child with mumps displaying diffuse lymphedema of the neck due to parotitis. (Image courtesy of CDC Public Health Image Library.)

Routine laboratory findings in patients with mumps are generally nonspecific. The peripheral leukocyte count is slightly elevated (10,000 to 12,000 cells/mm<sup>3</sup>) with a mild lymphocytosis (30% to 40% lymphocytes). Approximately 30% of mumps patients will have an elevated serum amylase reflecting inflammation of the salivary glands or pancreas (268); these can be distinguished by isoenzyme analysis or by pancreatic lipase determination.

### Central Nervous System

CNS involvement is the most common extrasalivary manifestation of mumps and occurs with sufficient frequency (10% to 30% of mumps cases) that it should be considered a part of the natural history and not a complication (96, 198, 269). For reasons that remain unexplained, mumps CNS disease in unvaccinated individuals occurs 3 to 4 times more frequently among males than among females (176, 270, 271). In unvaccinated individuals, the spectrum of CNS diseases associated with mumps ranges from mild aseptic meningitis, which is very common, to fulminant and potentially fatal encephalitis, which is very rare, occurring in less than 0.1% of cases of acute mumps (270, 271). CSF pleocytosis is present in 40% to 60% of patients with acute mumps, although only 10% to 30% of mumps patients will have clinical evidence of meningeal irritation (Table 2). Thus, half of the mumps patients demonstrated to have CSF pleocytosis will not have CNS symptoms (176, 198).

CNS symptoms usually appear about 5 days after the onset of parotitis, although development of CNS findings before or simultaneously with parotitis is well recognized (270–272). Mumps CNS disease can also occur in patients without clinical evidence of parotitis; indeed 40% to 50% of patients with symptomatic mumps meningitis have no evidence of salivary gland enlargement. The diagnosis of mumps cannot be excluded in a patient with meningoencephalitis simply because the patient does not have clinically apparent salivary gland involvement.

Mumps CNS infection presents with high fever, vomiting, and headache that lasts for 48 to 96 hours (272–274) (Table 3). The majority of mumps patients with CNS involvement will have signs of meningeal irritation, but no evidence of cortical dysfunction. Defervescence is accompanied by overall clinical improvement; the total duration of illness in uncomplicated cases is 7 to 10 days. Mumps meningitis is a benign disease with essentially no risk of mortality or long-term morbidity.

The onset of seizures, altered level of consciousness, or focal neurologic abnormalities in a patient with mumps is indicative of encephalitis (270, 271). The mortality rate for patients with mumps encephalitis is less than 1.5% and permanent sequelae are rare. Even among patients who are profoundly encephalopathic, the probability of complete recovery is high; sustained seizures and focal neurologic deficits may indicate a less favorable prognosis (270).

<sup>a</sup>Compiled from 248 cases (199, 271–273). Modified from Gnann (269), with permission.

CSF pleocytosis (>5 white blood cells [WBCs]/mm<sup>3</sup>) occurs in 40% to 60% of unvaccinated patients with mumps parotitis and is a prominent feature of patients with mumps meningoencephalitis (275) (Table 2). Lumbar puncture in patients with mumps meningoencephalitis usually reveals a normal opening pressure and an elevated leukocyte count of 200 to 600 cells/mm<sup>3</sup> (ranging up to 2,000 cells/mm<sup>3</sup>) that is >80% lymphocytes (176, 271, 276). About 50% of patients will have a moderately elevated CSF protein and 10% to 20% will have moderate hypoglycorrhachia (CSF glucose 20 to 40 mg/dl) (276, 277). Depressed CSF glucose, an unusual finding in viral meningitis, has been reported most often with mumps virus, lymphocytic choriomeningitis virus, and herpes simplex virus infections. CSF pleocytosis often persists for weeks after resolution of clinical mumps disease (268). There is no definite correlation between the magnitude of the CSF abnormalities and the clinical course, although one study reported that higher CSF protein and lower CSF glucose levels were associated with longer durations of hospitalization (271, 278). Mumps virus can be isolated from about 33% of CSF specimens in which there is pleocytosis.

Numerous neurologic complications have been described in association with mumps encephalitis, including behavioral disturbances and personality changes (270, 279), seizure disorders (274), cranial nerve palsies (especially facial and ocular palsies) (280), muscular weakness (including hemiparesis), ataxia (270, 281), myelitis (282, 283), Guillain-Barré syndrome (284), and hydrocephalus (285–287).

Electroencephalograms recorded in patients with acute mumps encephalitis characteristically show moderate to severe slowing without spikes or lateralizing signs. Modern imaging techniques (computed tomography, magnetic resonance imaging, etc.) have not been systematically evaluated as diagnostic tools for patients with mumps CNS infection (288).

### Special Populations

Maternal mumps infection during the first trimester of pregnancy may result in an increased frequency of spontaneous abortion; infection during the second or third trimester is generally uncomplicated (289). Fetal wastage occurs as a result of infection of the placenta and/or fetus during the early viremic phase. Villous necrosis with intracytoplasmic inclusion bodies in decidual cells has been seen in placentas from spontaneous abortions following maternal mumps (169). In addition, mumps virus has been isolated from fetal tissue following a spontaneous first trimester abortion that occurred during acute maternal mumps (168).

A possible association between mumps occurring during the first trimester and low birth weight has been described. There is no clear connection between mumps occurring during pregnancy and congenital defects (172). Mumps virus is excreted in breast milk, but perinatal mumps infection is extremely rare.

There are few reports of wild-type mumps virus infection in individuals with congenital or acquired immunodeficiency. There are two case reports of mumps leading to fatal encephalomyelitis in individuals with severe combined immunodeficiency (290), and one renal transplant patient developed acute irreversible transplant failure due to interstitial nephritis caused by mumps (291). Reports of disease caused by wild-type mumps virus among HIV-infected individuals are lacking.

### Complications of Mumps

Mumps can result in a variety of complications, most of which have become much less common in the postvaccine era (137) (Table 1). Gonadal involvement can occur in both men and women with mumps (292). Epididymo-orchitis is rare in prepubertal boys with mumps, but was reported in 25% to 38% of men in the prevaccine era (293, 294). Orchitis can occur in vaccinated males who develop mumps but is less frequent and less severe (126, 295). Orchitis is usually unilateral; bilateral involvement occurs in 17% to 38% of cases. Orchitis typically develops within 4 to 10 days after the onset of parotitis, although it can develop prior to or even in the absence of parotitis (296, 297). Patients with mumps orchitis present with severe testicular pain and swelling accompanied by high fever (39°C to 41°C), nausea, vomiting, and headache (179). Physical examination demonstrates warmth and erythema of the scrotum with marked tenderness of the testis, which may be swollen to 3 or 4 times its normal size. Epididymitis is also present in 85% of cases (298, 299). The testicular swelling and constitutional symptoms resolve within 5 to 7 days, although residual testicular tenderness persists for several weeks in up to 20% of patients. Testicular atrophy may follow orchitis in 35% to 50% of cases, but impotence or sterility is uncommon even among patients with bilateral orchitis (300). A proposed association between mumps-related testicular atrophy and subsequent testicular malignancy is unsubstantiated (301).

Oophoritis occurs in 5% of postpubertal women with mumps. Women with mumps oophoritis typically report fever, nausea and vomiting, and adnexal pain. Sequelae are uncommon, although impaired fertility and premature menopause following mumps can occur. Fifteen percent of postpubertal women with mumps complain of breast swelling and tenderness consistent with mastitis.

Mumps-associated pancreatitis occurs in about 4% of cases and presents with fever, nausea, vomiting, and epigastric pain. Some epidemiologic data suggested an association between mumps pancreatitis and juvenile diabetes mellitus; however, the dramatic decline in the incidence of mumps has not been mirrored by a corresponding decline in the occurrence of juvenile-onset diabetes mellitus.

Migratory polyarthritis, or less frequently monoarticular arthritis, has been observed in mumps patients (302, 303). The pathogenesis of mumps-related arthritis is uncertain; virus has not been isolated from joint fluid, and there is no evidence of immune complex deposition. The arthritis may involve large and small joints and usually begins 10 to 14 days after the onset of parotitis. The joint symptoms may last 4 to 6 weeks, but usually resolve with no permanent joint damage.

Symptomatic mumps myocarditis is rare, although electrocardiographic (ECG) changes have been reported in 3% to 15% of patients (275). The most common ECG abnormalities are prolongation of the PR interval, flattening or inversion of T waves, and depression of ST segments. Rare cases of inflammatory myocarditis with lymphocytic infiltration in patients with mumps have been described. A proposed linkage of mumps with pediatric endocardial fibroelastosis remains unproven (165).

Sensorineural hearing loss is a well-recognized complication of mumps that occurs with a frequency of 0.5 to 5.0 episodes/100,000 mumps cases (304–307). In one series collected among military personnel, transient high frequency hearing loss occurred in 4.4% of cases (308). The onset of deafness may be either gradual or abrupt and may be accompanied by vertigo. Hearing changes result from direct damage to the cochlea by the mumps virus and may be either transient or permanent (309).

Other infrequent complications of mumps include thyroiditis, hepatitis, nephritis (184), and thrombocytopenia. Rare ocular complications of mumps include iritis, keratitis, and central retinal vein occlusion (310, 311). A mumps-virus-associated hemophagocytic syndrome has been described (312).

### Clinical Diagnosis of Mumps

The presentation of a febrile child with parotitis strongly suggests the diagnosis of mumps, particularly if the individual is known to be susceptible and has been exposed to mumps during the preceding 2 to 3 weeks (154). However, the etiology of aseptic meningitis may not be apparent if there is no concomitant salivary gland enlargement, and specific laboratory testing is required to establish the diagnosis.

A variety of other infectious and noninfectious disorders can cause parotid enlargement that may be confused with mumps (313, 314). Other viruses (including parainfluenza virus, coxsackievirus, adenovirus, EBV, HHV-6, and influenza A virus) can cause fever and parotid gland enlargement (315–317). Accurate diagnosis requires viral culture, molecular diagnostics, or specific serologic testing. Parotid gland enlargement has also been described in patients with AIDS, especially children (318, 319). Bacterial parotitis (usually caused by *Staphylococcus aureus* or Gram-negative bacilli) is most often unilateral and occurs in debilitated patients with poor oral intake, postoperative patients, and premature infants. Physical examination reveals erythematous skin overlying a hard, warm, and very tender parotid gland. Parotid massage expresses pus from Stenson's duct. Tumors, cysts, and duct obstruction due to salivary stones can also result in unilateral parotid swelling.

Drugs and systemic illness can result in parotid swelling, which is typically bilateral and nontender (320). Medications associated with salivary gland enlargement include iodides, phenothiazines, phenylbutazone, didanosine, and thiouracil. Chronic diseases in which parotitis can appear include cirrhosis, diabetes mellitus, malnutrition, chronic renal failure, sarcoidosis (uveoparotid fever), tuberculosis, lymphoma, amyloidosis, and Sjögren syndrome.

### LABORATORY DIAGNOSIS

The role of the laboratory in confirming clinically suspected cases of mumps infection is important because hallmark clinical symptoms like parotitis may not be present in all cases (321–324), vaccinated individuals may have mild or

modified symptoms (126), and parotitis can be caused by a number of other etiologies (316).

As described below, acute mumps infection can be confirmed by direct detection of virus in clinical samples by reverse transcription (RT)-PCR or culture and detection of virus-specific IgM in serum. These tests are available through some commercial diagnostic laboratories, many state public health laboratories, a network of regional reference laboratories designated by the Association of Public Health Laboratories, and through services offered by the federal Centers for Disease Control and Prevention. Among previously vaccinated persons, negative laboratory test results cannot be used to rule out the possibility of mumps virus infection, but positive results are useful for confirming clinically suspected cases of infection. Importantly, cases of mumps virus infection must be reported to local or state public health authorities as part of the National Notifiable Diseases Surveillance System. Additional information regarding laboratory testing, protocols, collection and transport of specimens, vaccination recommendations, answers to frequently asked questions, and further guidance for health care providers can be found at <http://www.cdc.gov/mumps/index.html>.

### Virus Isolation and Nucleic Acid Amplification

Detection of viral RNA in clinical samples by RT-PCR is a sensitive, definitive, and preferred diagnostic method. The SH and NP gene sequences are common amplification targets, although methods targeting the F, M, and HN genes have also been described (153, 325–330). Because the SH gene sequence has the most diversity among virus strains and is used for genotype determination, it is an important amplification target for enhancing epidemiologic investigation (18). However, the NP gene sequence provides somewhat greater sensitivity of detection (153).

Virus is shed into the saliva for up to 1 week following the onset of symptoms, but it rapidly diminishes around 3 days post onset (153). To increase the likelihood of detection, oral fluid samples should be collected as soon as symptoms appear. Following thorough massage (30 seconds or longer) of the affected parotid gland, samples of oral fluid should be collected by swabbing the area around Stenson's duct with a flocked swab made of synthetic material, such as polyester, but not cotton, which may interfere with nucleic acid amplification. To maintain viability, samples should be placed in 1 to 2 ml of viral transport medium such as Dulbecco's modified Eagle's medium, Hank's balanced salt solution, or phosphate-buffered saline containing a source of protein such as 2% fetal bovine serum, 1% bovine serum albumin, or 0.5% gelatin. Samples should be maintained at 4°C if testing is to be performed within 24 hours, or frozen at –70°C if testing is to be delayed. Although oral specimens are preferred, virus may also be isolated from urine for up to 2 weeks following infection (331) or from CSF (163, 164). If viral RNA cannot be amplified directly from a clinical specimen, the specimen may be used to inoculate a cultured cell line (typically Vero cells). Passage in cell culture may allow the virus to replicate to a level that can be detected by RT-PCR and confirmed by sequencing.

### Serologic Assays

Diagnosis of acute primary infection can also be reliably confirmed by the appearance of mumps-specific IgM in serum by ELISA (178, 222). In contrast, ≥50% of individuals with previous exposure to mumps virus either through wild-type infection or vaccination may not develop detectable

IgM (178). The most reliable method of IgM detection is capture ELISA. Indirect ELISA and immunofluorescence assays are less sensitive or have higher rates of false-positive results (153, 178, 332). The likelihood of obtaining an IgM-positive serum sample is lower at the time of symptom onset and increases up to the fifth day following onset (153). If an acute phase serum sample collected ≤3 days after the onset of parotitis is IgM negative, a second sample collected 5 to 7 days after symptom onset should also be tested since the IgM response may require more time to develop.

The presence of virus-specific IgG in the serum is evidence of a previous immune exposure and is routinely measured by commercially available ELISA or bead-based assays (333, 334). Avidity testing of IgG may be useful for distinguishing between cases of primary and secondary vaccine failure (232, 233). *In vitro* plaque reduction neutralization tests have been used as a measure of neutralizing antibody, but they are labor intensive (335). Other historical methods used to detect mumps virus or virus-specific antibody included hemagglutination-inhibition assays (336), complement fixation (337), and immunofluorescence (338). Although humoral immune responses to mumps infection or immunization can be measured by a variety of techniques, each is limited to some extent by antigenic cross-reactivity between mumps and other paramyxoviruses (339–341).

### PREVENTION

Current guidelines recommend the isolation of individuals with mumps for 5 days after the onset of parotitis, although it is recognized that viral shedding may also occur for a few days before the onset of symptoms (342, 343). Hospitalized patients with mumps should be isolated using standard and droplet isolation precautions for 5 days after onset of parotitis, the period of heaviest viral shedding (342).

### Vaccines

Mumps can be most efficiently prevented by use of an effective vaccine containing live attenuated virus. A formalin-inactivated mumps virus vaccine was also developed, but the duration of protection was shorter, so the killed virus vaccine is no longer used (178). The vaccine currently used in the United States contains replication competent genotype A mumps virus attenuated by serial passage in embryonated hens' eggs and chick embryo cell cultures. The "Jeryl Lynn" vaccine contains two virus strains JL5 and JL2, which differ by >400 nucleotides (344, 345).

The mumps vaccine is a component of the MMR vaccine and is given by subcutaneous injection in two doses. ACIP recommends that the first dose of MMR be given at 12 to 15 months of age and the second dose given at 4 to 6 years of age (346). A quadrivalent vaccine (MMR plus varicella [MMRV]) is approved for use in the United States (347). Because of a very small increased risk of febrile seizures associated with MMRV vaccine use in children aged 12 to 47 months, some authorities recommend that MMR and varicella vaccines be administered separately for the first dose; the MMRV vaccine is appropriate for the second dose (137).

Mumps-specific antibody appears within 2 weeks of immunization and is eventually detectable in about 94% of children vaccinated with Jeryl Lynn MMR (348). Although antibody titers decline over time, 74% to 95% of vaccine recipients followed for 12 years still had detectable antibody following two doses of vaccine (150, 225). Mumps-specific cell-mediated immune responses appear to persist even longer (253). While mumps-specific IgG is a simple measure

of vaccine response, it is not a definitive correlate of protection from mumps virus infection (349).

Early studies optimistically estimated that a single vaccine injection provided protective immunity to 97% of recipients (350). However, studies conducted during subsequent mumps virus outbreaks indicated an efficacy rate of 75% to 91% following a single dose (115, 351). The efficacy of at least one dose of Jeryl Lynn vaccine for preventing clinical mumps is estimated to be 69% to 81% (352); the median efficacy for two doses is higher at 86% to 88% (178, 353).

The two-dose MMR vaccination schedule was adopted in the United States in 1989 in response to increased rates of measles, but it also effectively addressed the problem of primary mumps vaccine failure seen with a single dose (112). Most states now require presumptive evidence of mumps immunity (documented age-appropriate vaccination, laboratory-demonstrated seropositivity, or laboratory confirmation of disease) before children are allowed to enroll in school. Health care workers without evidence of mumps antibody should also be immunized (137).

The Jeryl-Lynn-based mumps vaccine is safe, well tolerated, and cost-effective (354–356). In healthy children, immunization usually causes no symptoms other than localized injection site reactions. However, fever, febrile seizures, rash, and parotitis are occasionally reported (137, 357). Administration of MMR is contraindicated in pregnant women, but it can be safely administered to children who are household contacts of pregnant women. MMR is also contraindicated in (i) persons with primary or acquired humoral or cellular immunodeficiency syndromes; (ii) persons with lymphoproliferative malignancies; and (iii) persons receiving systemic immunosuppressive therapy (137). MMR is recommended for HIV-infected children without evidence of severe immunodeficiency, as determined by appropriate age-specific CD4 lymphocyte counts (137, 358).

Mumps vaccine is produced in chick embryo cell cultures and may contain trace amounts of neomycin, so immunization is not recommended for any person with a history of anaphylactic reactions to that antibiotic. Although MMR may contain trace amounts of egg protein, serious allergic reactions are extremely rare, even among children with a documented egg allergy. Therefore, history of egg allergy is not considered a contraindication to MMR administration (137).

Other strains of live attenuated mumps vaccine (including Urabe AM9 and Leningrad-3) have been associated with higher rates of vaccine-associated aseptic meningitis and are no longer widely used (359, 360). In some countries, the Urabe mumps vaccine strain was replaced by the highly attenuated Rubini strain, which provides unacceptably low levels of clinical protection (139, 361). An important advance has been the development of a rat-based neurovirulence assay to assess the safety of candidate mumps vaccine viruses (218, 362, 363).

### Postexposure Prophylaxis

Postexposure vaccination of mumps susceptible individuals may not provide protection or alter the course of the infection (137, 364). Mumps immune globulin is of no proven value in this setting and is not commercially available. The mumps antibody status of the exposed individual can be rapidly determined by ELISA, although it is generally safe to assume that adults born in the United States before 1957 have been naturally infected and are considered immune (112). Administration of a third dose of MMR as post-

exposure prophylaxis during a mumps outbreak appears safe, but the efficacy has not been established (355, 365, 366).

### TREATMENT

Therapy for uncomplicated mumps consists of conservative measures to provide symptomatic relief, such as analgesics, antipyretics, rest, and hydration. There is currently no established role for corticosteroids, antiviral chemotherapy, or passive immunotherapy in mumps. Case reports and small series have claimed that administration of interferon- $\alpha 2\beta$  is beneficial in men with mumps orchitis, but this treatment has not been adequately studied in a controlled fashion (179, 367, 368). Symptomatic measures to alleviate the pain and swelling of mumps orchitis include bed rest, scrotal support, opioid analgesics, and application of ice packs. Surgical decompression was frequently performed in the past for mumps orchitis, but is no longer recommended (369).

Patients with mumps and clinical evidence of encephalitis (e.g., altered mental status, seizures, or focal neurologic findings) should be hospitalized for observation. Supportive care for patients with mumps meningoencephalitis includes bed rest, fever control, hydration, antiemetics, and anti-convulsants as required. Lumbar puncture may temporarily relieve the headache in some patients with mumps meningitis. Corticosteroids have been used in the treatment of mumps encephalitis (274) and orchitis, but there are no data from controlled studies to support this approach, and corticosteroid use is not routinely recommended. Benefit from intravenous Ig infusion for mumps-related complications (e.g., transverse myelitis, immune thrombocytopenic purpura, acute disseminated encephalomyelitis) has been claimed in case reports, but this intervention has not been systematically evaluated and is not recommended (137, 154).

# Zoonotic Paramyxoviruses

DANIELLE E. ANDERSON AND LIN-FA WANG

## 40

This chapter focuses on emergent paramyxoviruses that are associated with zoonotic disease. Hendra virus (HeV), Nipah virus (NiV), Menangle virus (MenPV), and Sosuga virus (SosPV) are known to have caused severe zoonotic infections, and Tioman virus (TioPV), Achimota virus (AchPV), and Mojiang virus (MojPV) are also suspected of causing them. These viruses, which have emerged or been detected over the last two decades, are potential threats to both livestock animals and humans (Table 1). In particular, HeV and NiV have caused fatal diseases in animals and humans, and outbreaks of NiV continue to occur almost annually. Molecular biological studies have made substantial contributions to the characterization of emergent zoonotic paramyxoviruses. Sequencing studies provide an accurate picture of the relative taxonomic position of these viruses and provide rapid diagnostic capabilities. In the case of outbreaks of NiV in Malaysia, Bangladesh, and India, molecular biological data quickly identified the etiologic agent present, and reverse transcriptase PCR (RT-PCR) and serologic assays were used to rapidly confirm NiV infections in humans and animals (1–4).

Other paramyxoviruses that have been documented to cause rare human infections include MenPV (5–7) SosPV (8), and TioPV (9–11). Most of these viruses share a common reservoir in large fruit bats (in the genus *Pteropus*), also known as flying foxes (12). Because of their clear potential to cause severe disease in humans and animals, NiV and HeV have been designated class C select agents and have been the focus of intense study since their emergence (13–15). Although yet to be conclusively linked to zoonotic disease, bats are suspected to also play a role in the transmission of AchPV and MojPV to humans (16). MojPV is a novel henipa-like virus detected in rats (*Rattus flavipectus*) in a cave in Yunnan Province, China, in 2012 (17). Although isolated from rats, microbats (*Rhinolophus ferrumequinum*) also reside in this cave, so it is possible that the disease observed in the three humans may represent a spillover event from either rats or bats.

### VIROLOGY

#### Classification

HeV was originally named equine morbillivirus because initial sequencing and morphological studies conducted

following its emergence in 1994 led to the conclusion that HeV was most closely related to the morbilliviruses (18). However, subsequent studies showed that HeV is neither a morbillivirus nor an equine virus. Analysis of the sequences of the entire genomes of both HeV and NiV now groups these viruses together in the genus *Henipavirus*, within the subfamily *Paramyxovirinae* (Fig. 1) (15). HeV and NiV are related viruses that share 68 to 92% amino-acid-sequence identity in their protein coding regions and 40 to 67% nucleotide-sequence identity in the untranslated regions of their genomes (3, 19). Among the other seven genera within the *Paramyxovirinae*, the henipaviruses are more closely related to the respiroviruses and morbilliviruses.

Based on the genome structure and phylogenetic analysis, both MenPV and TioPV have been tentatively classified as members of the genus *Rubulavirus* (20). AchPV1 and 2 are distinct paramyxoviruses and, although not closely related, cluster with the other bat-borne rubula-like viruses (16). The genome organization of SosPV is typical of the rubulaviruses, and phylogenetic analysis clearly demonstrated that SosPV also clusters with the bat-borne rubula-like viruses (8).

Sequencing of a number of novel paramyxoviruses has substantially increased our appreciation of the diversity within this viral family (6, 8, 9, 16, 17, 18, 21, 22). Several of these viruses demonstrate a departure from the restricted host range that has been the norm for most members of the *Paramyxoviridae*. For example, viruses closely related to the morbillivirus canine distemper virus have been associated with disease outbreaks in harbor seals (23), striped dolphins (24), and Serengeti lions (25).

#### Genome Structure and Gene Function

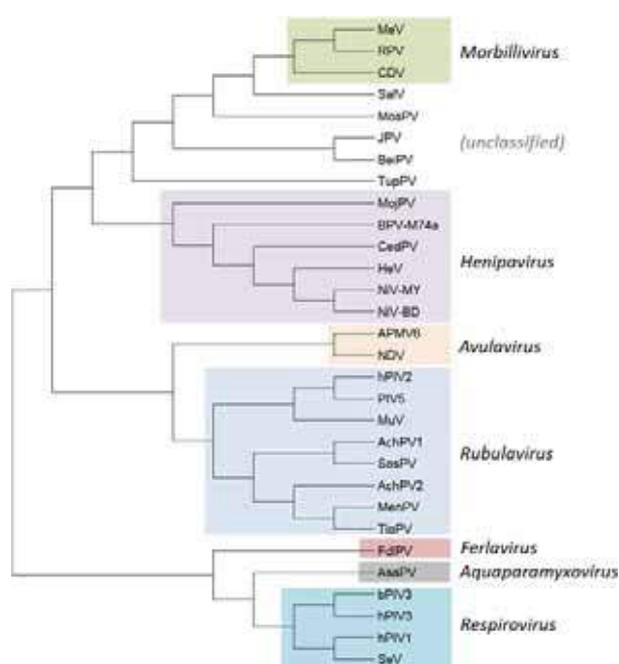

Paramyxoviruses contain a negative-sense, nonsegmented, single-stranded RNA genome ranging from 15,178 to 19,212 nucleotides in length. The genome structure is conserved with the nucleocapsid (N), phosphoprotein (P), matrix (M), fusion (F), attachment (HN/H/G), and large (L) genes present in all viruses (Fig. 2).

The genomes of HeV and NiV are 18,234 and 18,246 nucleotides in length, respectively, and, until the characterization of Beilong (26) and J viruses (27), these were the largest genomes among the paramyxoviruses. The newly characterized genome of henipa-like MojPV is also large, at 18,406 nucleotides. In contrast, the average genome size

**TABLE 1** Characteristics of zoonotic paramyxovirus infections of humans

Virus discovery and reservoir			Nonhuman species infected		Incidence and clinical disease in humans	
Virus	Year identified	Presumed Reservoir	Natural	Experimental	Human cases (fatal)	Clinical disease in humans
HeV	1994	Fruit bats	Horse, dog	Horse, cat, dog, guinea pig, ferret, bat	7 (4)	Influenza-like illness, pneumonia, encephalitis
MenPV	1997	Fruit bats	Pig	Pig	2 (0)	Febrile, rash illness
NiV	1999	Fruit bats	Pig, cat, dog, horse	Pig, cat, hamster, bat, guinea pig, squirrel monkey, ferret	557 (320) <sup>a</sup>	Pneumonia, encephalitis
SosPV	2012	Fruit bats	Unknown	Not done	1 (0)	Febrile, rash illness

<sup>a</sup>Includes one outbreak in Malaysia and Singapore (2), one outbreak in India (1), and outbreaks in Bangladesh, 2001 to 2005 (Institute of Epidemiology, Disease Control and Research Bangladesh situation reports: <http://www.idcr.org/>); not all cases were confirmed by laboratory testing.

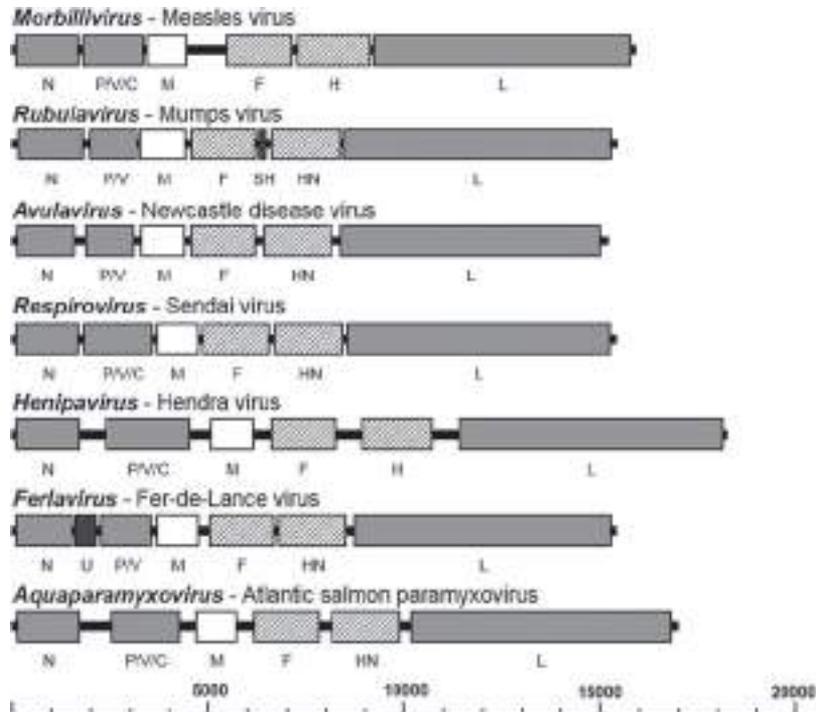

**FIGURE 1** Phylogenetic analysis of the sequences of the open reading frame of the N protein gene from selected viruses in the subfamily *Paramyxovirinae*. The genus name is on the right. Abbreviations of virus names and sequence accession numbers are as follows: Achimota virus 1 (AchPV1) JX051319; Achimota virus 2 (AchPV2) JX051320; Atlantic salmon paramyxovirus (AsaPV) EU156171; Avian paramyxovirus 6 (APMV6) AY029299; Bat paramyxovirus/Eid hel/GH-M74a/GHA/2009 (BPV-M74a) HQ660129; Beilong virus (BeiPV) DQ100461; Bovine parainfluenza virus 3 (bPIV3) AF178654; Canine distemper virus (CDV) AF014953; Cedar virus (CedPV) JQ001776; Fer-de-lance paramyxovirus (NDV) AF077761; Hendra virus (HeV) AF017149; Human parainfluenza virus 2 (hPIV2) AF533010; Human parainfluenza virus 3 (hPIV3) Z11575; J virus (JPV) AY900001; Menangle virus (MenPV) AF326114; Measles virus (MeV) AB016162; Mojiang virus (MojPV) KF278639; Mossman virus (MosPV) AY286409; Mumps virus (MuV) AB000388; Newcastle disease virus (NDV) AF077761; Nipah virus, Bangladesh strain (NiV-BD) AY988601; Nipah virus, Malaysian strain (NiV-MY) AJ627196; Parainfluenza virus 5 (PIV5) AF052755; Rinderpest virus (RPV) Z30697; Salem virus (SalPV), AF237881; Sendai virus (SeV) M19661; Sosuga virus (SosPV) KF774436; Tioman virus (TioPV) AF298895; Tupaia paramyxovirus (TupPV) AF079780.

for the other members of *Paramyxovirinae* is approximately 15,500 nucleotides. The genomes of the rubulaviruses MenPV (15,516), TioPV (15,522), SosPV (15,480), AchPV1 (15,624), and AchPV2 (15,504) are all typical in length. The larger size of the HeV and NiV genomes is mostly due to the unusually large sizes of the open reading frame (ORF) for the phosphoprotein (P protein) gene and the large 3' untranslated regions of several of the genes (3). The “rule of six” states that the total length of the genomic RNA of viruses within the subfamily *Paramyxovirinae* must be evenly divisible by six in order for the viruses to efficiently replicate (28). Studies with a minigenome replication assay confirmed that NiV and HeV conform to the rule of six (29).

The complete genome sequence of a horse isolate of HeV was published in 2000 (30, 31), and subsequent sequencing of other HeV isolates allowed for variants of HeV to be differentiated through analysis of the hypervariable region of the genome, despite the overall genome displaying genetic stability (32, 33). The complete genomic sequences of the NiV strains associated with the outbreaks in Malaysia in 1999 (NiV-MY) and Bangladesh in 2004 (NiV-BD) have been determined (4). The genome of NiV-BD is six nucleotides longer than that of NiV-MY, the prototype strain of NiV, and two nucleotides shorter than that of HeV. The additional six nucleotides map to the 5' untranslated region of the F protein gene. The gene order and sizes of all the open reading frames except V are conserved between NiV-BD and NiV-MY. The overall nucleotide homology between the genomes of NiV-BD and NiV-MY is 91.8%; the predicted amino acid homologies between the proteins expressed by NiV-MY and NiV-BD are all greater than 92% (4). The minor degrees of sequence variation among strains appear to be related to their geographic distribution. The N protein gene sequence of a bat isolate of NiV from Cambodia is more closely related to the sequence of NiV-MY than to the sequence of NiV-BD, while sequences obtained from samples from an outbreak in India were more closely related to NiV-BD (1). Full-genome sequence analysis of MojPV demonstrated that the closest relatives are the henipaviruses, but amino acid sequence identity only ranged from 38 to 63% compared to HeV and NiV (17).

The genomes of paramyxoviruses contain a number of conserved cis-acting signals that regulate gene expression and replication. The cis-acting signals include the gene transcription start sites, gene stop sites, RNA editing sites, genomic termini, and intergenic sequences (34). The 5' UTR contains a gene start (GS) sequence utilized for transcription initiation, and the 3' UTR contains a gene end (GE) region responsible for transcription termination. The GE sequence

**FIGURE 2** Schematic representation of the genomes of viruses in the subfamily *Paramyxovirinae*. Genomes are single-stranded, negative-sense RNA shown in the 3'-to-5' (left-to-right) orientation. Boxes indicate protein-coding regions, and solid lines indicate noncoding regions. The genome, coding regions, and untranslated regions are drawn to scale. The six conserved genes present in all paramyxovirus genomes are indicated as follows: light shaded = RNA polymerase and nucleocapsid genes (N, P and L); slanted = envelope membrane protein genes (F and attachment protein); white = matrix protein (M). The dark shaded boxes represent genes which are not commonly shared among members of the subfamily. The scale at the bottom represents genome size in nucleotides.

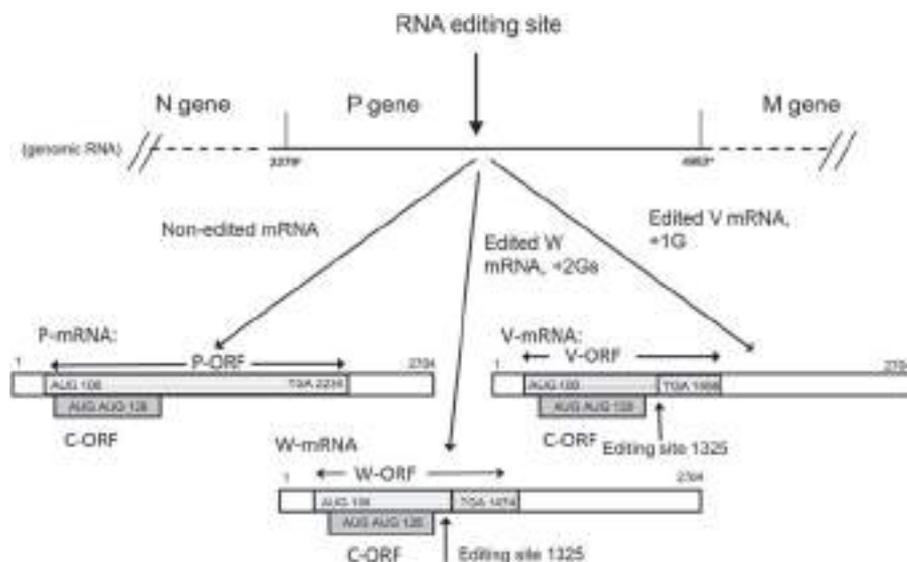

contains a stretch of four to seven uridine residues that act as a template for polyadenylation of the mRNA. The intergenic region is three nucleotides in length for most *Paramyxovirinae* members with the exception of rubulaviruses and avulaviruses, which can vary in length from 1 to 124 nucleotides (35, 36). However, HeV and NiV are the only paramyxoviruses in which the intergenic sequence, CTT, is conserved at every gene junction (3, 31).

### Proteins

The P protein is an essential component of the replication complex for all paramyxoviruses. The P protein of NiV contains binding domains for the N protein at both its amino and carboxyl termini (37). The coding strategy for the P protein gene of the henipaviruses, respiroviruses, and morbilliviruses is that a faithful transcript of the P protein gene codes for the P protein, while the transcript encoding the V protein is produced by RNA editing. RNA editing refers to the insertion of nontemplated guanosine (G) nucleotides into the mRNA of the P protein gene to permit access to additional ORFs (38). The V proteins of the respiroviruses, morbilliviruses, and henipaviruses share the N-terminus as their respective P proteins, which, at the editing site, are joined to a unique, C-terminal cysteine-rich domain encoded by a different ORF (Fig. 3). In contrast, faithful transcription of the rubulavirus P protein gene produces a V protein, while the P protein is produced by RNA editing. The P protein genes of the henipaviruses also code for a C protein, which is produced by internal ribosomal entry from an overlapping reading frame located near the 5' terminus of the P protein gene mRNA. As in the case of the

morbilliviruses, the translational start site for the C protein of HeV and NiV is located downstream of the start codon for the P/V protein (19, 30). The P protein genes of HeV and NiV also have the capacity to code for a protein that is analogous to the W protein described for Sendai virus (39). W protein is produced by the addition of two nontemplated G proteins at the RNA editing site. The P protein gene of HeV, but not NiV, also contains another short ORF that codes for a small basic protein (SB) with unknown function. While a similar coding region has been located in the P protein genes of vesicular stomatitis virus and Marburg virus, expression of SB has not been demonstrated for HeV (30).

The P gene products from viruses within the subfamily *Paramyxovirinae* have been demonstrated to inhibit both dsRNA signaling (40–43) and IFN production and signaling (44–46). The ability of viruses to inhibit IFN pathways is considered to be important determinants of virulence and host range. As for other paramyxoviruses, the C, V, and W proteins of NiV and HeV function as virulence factors that interfere with the innate immune system. NiV C, V, and W proteins can rescue growth of interferon (IFN)-sensitive viruses, and cells expressing both V and W of NiV block activation of an IFN-inducible promoter in primate cells (47). The V protein sequesters STAT1 and STAT2 in high-molecular-weight complexes, preventing both nuclear transportation and activation (48, 49), while W protein has been shown to sequester STAT1 in the nucleus (50, 51). The P protein also inhibits the nuclear translocation of STAT1 (50). The V and W proteins also block virus activation of the IFN- $\beta$  promoter and of an IFN regulatory factor 3-responsive, IFN-stimulated promoter (50). The ability to

**FIGURE 3** Schematic representation of the coding strategy found in the P protein gene of NiV. The predicted P protein mRNA is 2,704 nucleotides in length (nucleotides with asterisks indicate the location of the P protein gene sequence within the sequence with GenBank accession no. AF212302). The P protein is encoded by a faithful transcript of the viral genomic RNA from an opening reading frame beginning at nucleotide 106 of the mRNA. The RNA editing site is indicated by the vertical arrow. The addition of a nontemplated G nucleotide at the RNA editing site (nucleotide 1325) allows access to a different reading frame (–1 relative to P). The V protein contains the amino-terminal domain of the P protein (horizontal lines) joined to the cysteine-rich domain that is unique to the V protein (diagonal lines). The addition of two nontemplated G nucleotides at the RNA editing site produces the mRNA for the W protein in which the amino-terminal domain of P is joined to carboxyl-terminal domain unique for W (diagonal lines). The C protein (gray box) is expressed from an ORF that begins at nucleotide 128 (or 131) and overlaps P in the +1 frame.

block IFN signaling has been mapped to a single amino acid on the NiV V protein (52).

The N, P, and L proteins are necessary and sufficient for transcription and genome replication. The genes coding for the RNA-dependent RNA polymerase (L protein) of HeV and NiV have a linear domain structure that is conserved in all of the *Mononegavirales* (53). In domain III, all of the negative-strand RNA viruses have a predicted catalytic site with the amino acid sequence GDNQ. The sequence QDNE is found only in HeV, NiV, and Tupaia paramyxovirus (3, 31, 54). However, substitution of the E for Q did not affect the function of the L protein of NiV in a minigenome replication assay (55). Interestingly, the GDNE motif is not found in MojPV, Cedar virus (56), and other recently identified bat henipa-like viruses (57).

HeV and NiV have two membrane glycoproteins, the F protein and the attachment protein G, which perform the same functions as the membrane glycoproteins of the morbilliviruses and respiroviruses. As with the other paramyxoviruses, both the G and F proteins of HeV and NiV are required for cell fusion, and heterotypic mixtures of the G and F proteins of HeV and NiV are also fusion competent (58, 59). MenPV lacks detectable neuraminidase and erythrocyte binding activity, and the hemagglutinin-neuraminidases of MenPV and TioPV lack the hexapeptide, NRKSCS, that is proposed to be essential for neuraminidase activity (21). Compared to the other rubulaviruses, TioPV and MenPV also have some unique genetic features in their RNA start sites and intergenic regions (9, 60).

The F proteins of the *Paramyxovirinae* are type I membrane glycoproteins that facilitate the viral entry process by mediating fusion of the virion membrane with the plasma membrane of the host cell. F proteins are synthesized as inactive precursors, F<sub>0</sub>, that are converted to biologically

active subunits, F<sub>1</sub> and F<sub>2</sub>, following proteolytic cleavage by a host cell protease. The F peptide, located at the amino terminus of the F<sub>1</sub> protein, is highly conserved within the *Paramyxovirinae* (61). The F peptides of HeV and NiV are related to the F proteins of other paramyxoviruses, with the exception that HeV and NiV have leucine at the first position, while almost all of the other viruses have phenylalanine (19). However, substitution of phenylalanine for leucine in the F<sub>1</sub> subunit of NiV does not affect its ability to form syncytia (62).

Among the paramyxoviruses, the carboxyl terminus of the F<sub>2</sub> protein subunit contains either single-basic or multiple-basic amino acids that comprise the cleavage site between F<sub>1</sub> and F<sub>2</sub>. F proteins with multiple-basic amino acids are cleaved by furin-like protease during exocytosis from the host cell. F proteins of viruses with a single-basic amino acid are cleaved at the cell surface by trypsin-like proteases. These viruses usually require the addition of exogenous trypsin to replicate in cell culture. While HeV and NiV have a single-basic residue at the cleavage site, both produce productive infections in a variety of cell lines in the absence of exogenous trypsin. In addition, the cleavage site of the F proteins of NiV and HeV do not contain a furin-like protease consensus sequence (R-X-R/K-R) found in most morbilliviruses, rubulaviruses, and pneumoviruses (35, 61) and, in fact, the basic amino acids do not appear to be required for cleavage (62). Cleavage of the F protein of NiV and HeV occurs by a novel mechanism involving clathrin-mediated endocytosis via a tyrosine-dependent signal on the cytoplasmic tail (63–65). The F proteins of both HeV and NiV require the endosomal protease cathepsin L for proteolytic processing (66). N-glycans of the F protein of NiV are required for proper proteolytic processing, and these glycans may modulate access to neutralization epitopes (67, 68).

As for other paramyxoviruses, the NiV surface glycoproteins are the primary targets for neutralizing antibodies (59, 69, 70). Recombinant vaccinia viruses expressing NiV F and G proteins elicit neutralizing antibodies against NiV and protect Syrian hamsters and pigs against lethal NiV challenge (59, 70, 71). Antibodies to F or G protein also provided passive protection in the hamster challenge model (70, 72).

### Entry and Receptors

The attachment proteins of the *Paramyxoviridae* are type II membrane glycoproteins and are responsible for binding to receptors on host cells (34, 35). Paramyxovirus attachment proteins are designated HN, H, or G, depending on their hemagglutinin (H) and/or neuraminidase (N) activities (73). Unlike many other paramyxoviruses, neither of the henipaviruses has been shown to have erythrocyte binding or neuraminidase activities. The attachment proteins of the henipaviruses are most closely related to the hemagglutinin-neuraminidases of the respiroviruses (74). The conservation of most of the structurally important amino acids suggests that the attachment proteins of HeV and NiV would have structures that are very similar to the structure proposed for the attachment proteins of other paramyxoviruses (61). EphrinB2, the membrane-bound ligand for the EphB class of receptor tyrosine kinases, specifically binds to the attachment (G) glycoproteins of henipaviruses and is a functional receptor for HeV and NiV (75–77). While ephrinB3 has also been shown to be a functional receptor for both viruses, the binding of NiV to ephrinB3 is much more efficient than the binding of HeV (76, 78, 79), and the G protein of NiV has distinct binding regions for ephrinB2 and ephrinB3 (78). EphrinB3 but not ephrinB2 is expressed in the brain stem, so the difference in the abilities of HeV and NiV to bind to these cellular receptors is consistent with the neuroinvasiveness of NiV (76, 78, 79). NiV infection does not appear to down-regulate cell surface expression of ephrinB2 or ephrinB3 (80).

### Viral Replication

#### Cell Culture

Vero cell culture (African Green monkey kidney) supports the growth of HeV, NiV, and MenPV. Both HeV and NiV were first identified as syncytium-forming agents in Vero cell cultures, and electron microscopic studies revealed the presence of typical paramyxovirus “herringbone” nucleocapsid structures (2, 81). Vero cells are routinely utilized to attempt to propagate paramyxoviruses for virus isolation (9, 56, 82–84). In instances where a bat origin is suspected, cell lines such as PaKi (bat kidney) (56, 85, 86) are commonly used for virus isolation from various bat samples.

#### Virus Stability and Inactivation

Paramyxoviruses are susceptible to common soaps and disinfectants. Lipid solvents (alcohol and ether) and sodium hypochlorite solutions are used effectively in outbreaks for cleaning and disinfection. Paramyxoviruses are stable between pH 4.0 and 10.0 and inactivated by heating at 60°C for 60 minutes.

#### Animal Models

The development or characterization of animal models to study henipavirus infections has been critical for understanding their pathogenesis and for development of thera-

peutics or vaccines (87). Both cats and golden hamsters have been used as small animal models, and both develop fatal disease after challenge with NiV. In cats, virus is mostly present in the respiratory epithelium, while hamsters develop neurologic disease (70, 72, 88). NiV in pigs causes a febrile respiratory illness with or without neurologic signs (89, 90). Following infection of fruit bats with NiV, some bats seroconverted and intermittently excreted low levels of virus (91).

## EPIDEMIOLOGY

### Hendra Virus

#### Distribution and Geography

There have been multiple outbreaks of HeV among horses recognized between 1994 and 2014. The majority of the outbreaks have occurred in Queensland, Australia, and five have resulted in spillover to humans. The first incident occurred in September 1994 at a stable in Hendra, a suburb of Brisbane. An outbreak of acute respiratory disease resulted in 14 horse deaths (18, 92). Approximately 1 week after exposure to the index horse case, a pregnant mare recently moved to the stable, a stable hand and a horse trainer developed an influenza-like illness. The stable hand recovered completely after 6 weeks, but the horse trainer died on the seventh day of illness. The second incident, in October 1995, involved the death in Brisbane of a farmer from Mackay (93). The patient lived on a horse stud farm and often assisted a veterinary surgeon during treatment. In August 1994, the patient developed meningitis shortly after he cared for, and assisted in, the autopsies of two horses that died, one from acute respiratory distress and the other from rapid-onset neurologic symptoms. Both horses were retrospectively diagnosed with HeV (94). The patient recovered completely and remained symptom free for 13 months before his fatal illness, which is believed to have resulted from reactivation of virus that entered a putative latent phase following the initial disease. In the 20 years since the first two HeV outbreaks, there have been three additional outbreaks involving human cases, with two fatalities.

#### Transmission

Despite the potential for HeV to infect a wide variety of animals under experimental conditions (95–97), horses appear to be the primary source of human HeV infection. Each of the HeV-infected persons reported extensive contact with horses. In the first incident, both infected persons had close contact with a dying mare, particularly the horse trainer with fatal disease, who had abrasions on his hands and arms and was exposed to nasal discharge while trying to feed the incapacitated horse (98). The infected farmer from Mackay in the second incident cared for sick horses and assisted in their autopsies without using gloves, masks, or protective eyewear (93). No serologic evidence of infection was found in 22 other persons who reported feeding or nursing sick horses or participating in their autopsies or in more than 110 other persons associated with, or living near, the affected stables (98, 99). These data indicate that transmission of infection from horses to humans is inefficient and requires very close contact. The urine and saliva from infected horses are important in disease transmission (95), whereas respiratory spread is less likely. Human-to-human transmission of HeV has not been documented, either among domestic contacts or among health care workers (98, 99).

### Reservoir

No epidemiological connection could be found between the first two HeV incidents, which occurred within 1 month of each other at locations 1,100 km apart. No evidence of HeV infection was found among horses, other farm animals, or more than 40 species of wildlife in Queensland (100, 101). However, HeV antibodies were detected in several fruit bat species in Queensland, and the virus isolated from a fruit bat was indistinguishable from that isolated from horses and humans (102–104). The natural reservoir of HeV has been identified as flying foxes or fruit bats, with seroprevalence varying from 10 to 50% in different colonies (103, 105). HeV has also been isolated on several occasions from three different species of Australian pteropid bats: *Pteropus alecto*, *P. poliocephalus*, and *P. conspicillatus* (32, 103). It is postulated that transmission to horses may occur through the ingestion of pasture recently contaminated by the urine or infected fetal tissue of fruit bats (102, 106). In recent years HeV has also been reported to naturally infect dogs. On two separate occasions dogs have tested positive for infection, with these dogs being present on properties with known HeV infected horses. In 2011, a dog tested seropositive to HeV on a property where three horses were infected with HeV, and, in 2013, another dog tested positive to HeV by PCR (107).

### Nipah Virus

#### Distribution and Geography

The first known human infections with NiV occurred during an outbreak of severe encephalitis in 1998 to 1999, during which 265 patients (40% fatal) with viral encephalitis and 11 patients (1 fatal) with laboratory-confirmed NiV disease were reported in peninsular Malaysia and Singapore, respectively (2, 108, 109). This outbreak began in October 1998 in Malaysia near the city of Ipoh and then spread southward in conjunction with the movement of pigs, resulting in three other clusters of human disease in Malaysia. The largest, accounting for approximately 85% of all cases of outbreak-associated encephalitis, occurred in the Bukit Pelandok area of Negeri Sembilan state, a region with extensive pig farming activities. In Singapore, abattoir workers, who slaughtered pigs imported from outbreak-affected areas in Malaysia, were exclusively affected (110, 111). Adult males of Chinese or Indian ethnicity, who were primarily involved in pig farming activities, accounted for more than three-fourths of the cases. Infections were also documented among abattoir workers (110, 111), veterinary personnel and military personnel involved in pig-culling activities to control the outbreak. Since the 1998–1999 outbreak, Malaysia has reported no further cases of NiV infection; however, the virus continues to spill over and cause disease in other countries. Since 2001, human cases of NiV have occurred almost annually in Bangladesh and sporadically in neighboring India (1, 112, 113).

Sequence analyses suggest that there were at least two introductions of NiV into pigs prior to the outbreak in 1999. Only one of these variants was associated with the explosive spread within pig farms and subsequent transmission to humans, suggesting that a single spillover from the reservoir triggered the outbreak. In contrast, the sequence heterogeneity observed between samples obtained from the outbreak in Bangladesh in 2004 suggests multiple spillovers between the reservoir and humans (4).

#### Transmission

The transmission route of NiV differed between the outbreaks in Bangladesh and India, compared with Malaysia.

Human infections in Malaysia were almost exclusively associated with contact with infected pigs (114). In contrast, in Bangladesh, no intermediate animal host has been identified, and human-to-human transmission has been observed (1, 115). Mortality rates of outbreaks in India and Bangladesh have also been higher than the rate reported for Malaysia (116, 117). Direct, close contact with pigs was the primary source of human NiV infection during the initial outbreaks (47, 118). Activities involving close contact with pigs (e.g., medicating sick pigs and assisting in birthing) were associated with the greatest risk of human infection (119). In pigs, extensive infection of the upper and lower airways is seen with evidence of tracheitis and bronchial and interstitial pneumonia, and a harsh, nonproductive cough is a prominent clinical feature (2, 120). Vasculitis of small vessels in the kidney is also seen (2, 120), and viral antigen is detected by IHC studies as focal staining in renal tubular epithelium. Therefore, exposure to respiratory secretions and possibly the urine of infectious pigs likely results in transmission of virus among pigs and to humans.

Drinking fresh date palm sap was the most strongly associated risk factor among the exposures investigated during an outbreak of human NiV infection in Bangladesh in 2008 (121). To prevent NiV transmission, date palm sap should not be drunk fresh unless effective steps have been taken to prevent bat access to the sap during collection.

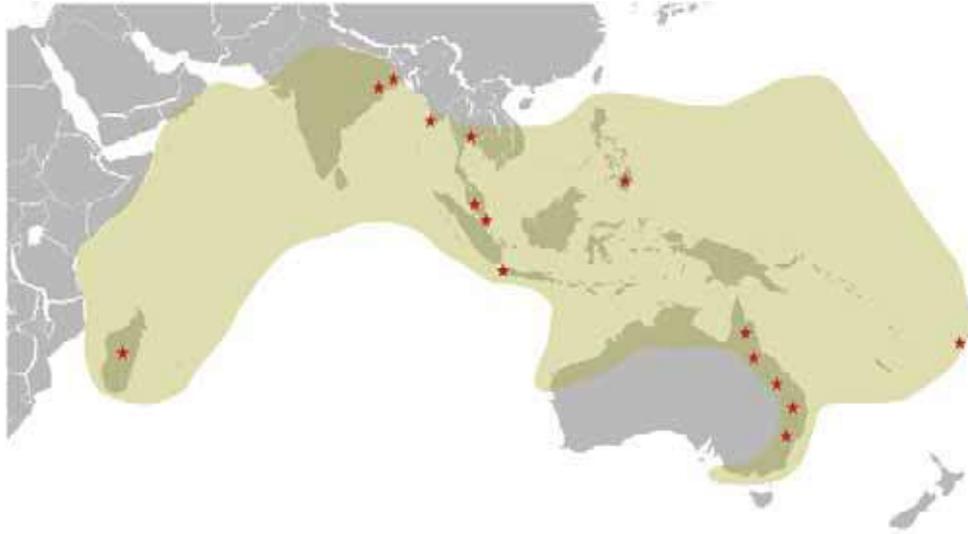

Serologic studies demonstrated evidence of infection among other species of animals, including dogs and cats (2, 120) on and near farms with NiV-infected pigs. As NiV can be found by IHC staining in renal glomeruli of infected dogs and cats and virus can be isolated from the urine of experimentally infected cats, virus may be transmitted by exposure to the urine of these two species. It is possible that humans are at risk from exposure to infected animals other than pigs, as some patients reported no direct contact with pigs and others reported contact with dogs that died of unknown causes (119, 122).

Although NiV is excreted in respiratory secretions and urine of patients (123), a survey of healthcare workers during the first outbreak initially demonstrated no evidence of human-to-human transmission (124). Human-to-human transmission has since been confirmed (125–127) and is a major pathway for human NiV infection (128).

### Reservoir

Knowing the similarities between NiV and HeV, surveillance for the natural reservoir for NiV focused on bats. Neutralizing antibodies to NiV were found in a total of 21 bats belonging to four fruit bat species and one insectivorous bat species in peninsular Malaysia (104). Attempts to detect the virus in sera from bats using both cell culture and amplification of RNA were unsuccessful. Bat colonies were noted proximal to pig farms near the city of Ipoh, where the outbreak in pigs was first noticed, supporting the hypothesis that transmission from bats to pigs initiated the outbreak (104).

Evidence of henipaviruses in several species of the genus *Pteropus* has suggested that the geographic range of the henipaviruses is significant and ranges from African coastal islands to the Western Pacific Islands (Fig. 4), including American Samoa, Thailand, Cambodia, Indonesia, Bangladesh, and Madagascar (112, 129–135). These findings primarily implicate species within the genus *Pteropus*, suggesting that this genus shares a coevolutionary relationship with the genus *Henipavirus*.

**FIGURE 4** Range of the genus *Pteropus* (shaded area). Locations where human infections of henipaviruses have occurred are designated by stars.

## Menangle Virus

### Distribution and Geography

From mid-April to early September 1997, at a piggery in New South Wales, Australia, a decline was noticed in the farrowing rate of sows, associated with an increase in the proportion of malformed, mummified, and stillborn piglets and occasional abortions (6, 7). Affected piglets had craniofacial and spinal abnormalities and degeneration of the brain and spinal cord. A new paramyxovirus, MenPV, was isolated from the brain, heart, and lung specimens of several affected piglets. No disease was seen in postnatal pigs of any age, but a high proportion of serum specimens (>95%) collected from these animals contained high titers of antibodies that neutralized the virus. Evidence of infection with MenPV was also detected in porcine sera from two other associated piggeries that received weaned pigs from the affected piggery but not in sera from several other piggeries throughout Australia (136).

A serologic survey of persons who came into contact with the affected piglets (5) detected a high titer of neutralizing antibodies in two workers, one at the affected piggery and one at an associated piggery. Both workers had an influenza-like illness concomitant with the outbreak in pigs, and no alternative cause was identified despite serologic testing. Thus, the illness was attributed to MenPV infection.

### Transmission

Close contact with infected piglets appears to be the primary mode of transmission of MenPV to humans. The worker reported splashes of amniotic fluid and blood to the face and the frequent occurrence of minor wounds on his hands and forearms (5). The other worker performed autopsies on pigs without gloves or protective eyewear. Of note, a large breeding colony of fruit bats roosted within 200 meters of the affected piggery, and sera from several bats had antibodies that neutralized MenPV (6). In addition, antibodies were found in sera collected in 1996 before the outbreak and from a colony of fruit bats 24 kilometers from the piggery. All other sera collected from a variety of wild and domestic animals (e.g., cattle, sheep, birds, rodents, feral cats, and a

dog) in the vicinity of the affected piggery tested seronegative for the virus.

In 2009, MenPV was isolated from a bat roost at Cedar Grove, South East Queensland, Australia (86). Black flying foxes were the predominant species in this colony at the time of sampling. The virus isolated was sequenced and demonstrated a 94% nucleotide sequence identity to the virus isolated from pigs in 1997, providing strong evidence supporting the original hypothesis that the outbreak of MenPV infection in pigs and humans in 1997 was probably the result of a spillover from bats roosting near the piggery.

## Sosuga Virus

### Distribution and Geography

In 2012, a wildlife biologist returned to the United States and developed a severe acute febrile illness after spending 6 weeks in South Sudan and Uganda collecting bats and rodents from remote rural areas for ecological research (8). During the field trip, the biologist manipulated animals in traps and mist nets, performed dissections, collected blood and tissues, and visited caves with large bat populations. Initial diagnostic evaluation excluded malaria, common bacterial pathogens, and viral hemorrhagic fever viruses like Ebola and Marburg. Next generation sequencing was performed on RNA extracted from blood and serum samples of the patient, and metagenomic analysis revealed a novel paramyxovirus (8) most closely related to ThkPV-3, a rubula-like virus isolated from *Rousettus leschenaultii* fruit bats in southern China (36). The novel paramyxovirus was provisionally named Sosuga virus (SosPV) in recognition of its probable geographic origin (South Sudan, Uganda). To date, there has only been a single recorded case of SosPV infection.

### Transmission

It is unclear how exactly the biologist became infected with SosPV. Interviews with the patient revealed that personal protective equipment (PPE) was used during animal capture and processing in Kibaale, Uganda, but inconsistent use of PPE occurred during the earlier South Sudan work (137).

Sequence similarity of SosPV with other bat-derived rubula-like viruses, in addition to the circumstances surrounding the biologist's illness is highly suggestive of a bat origin for this new paramyxovirus (8).

SosPV was detected in Egyptian fruit bats (*Rousettus aegyptiacus*), whereas Ethiopian epauletted fruit bats (*Epomophorus labiatus*), Angolan rousettes (*Lissonycteris angolensis*), and a roundleaf bat (*Hipposideros spp.*) caught in the same general vicinity were negative (137). Egyptian rousette populations in multiple locations across Uganda were shown to be actively infected with SosPV over a 3-year period (137). Given the biologist's exposure to bats in Uganda during the 3 weeks prior to onset of illness, these Egyptian rousettes were the probable source of the infection. The wide distribution and detection of the virus at multiple time points suggest the Egyptian rousette could be a reservoir species (137).

### Suspected Zoonotic Paramyxovirus Infections

Many novel paramyxoviruses have been detected across the world, including Ghana, Zambia, Democratic Republic of Congo, Gabon, Central African Republic, Comoros, Mauritius, Madagascar, Germany, Bulgaria, Romania, Thailand, Indonesia, Costa Rica, Panama, Brazil, and the Philippines (57, 83, 84, 138–143). These viruses belong to the genera *Henipavirus*, *Morbillivirus*, *Rubulavirus*, and *Pneumovirus*. Several of these novel paramyxoviruses are either implicated or suspected in causing zoonotic diseases.

Tioman virus (TioPV) was isolated from urine of the island flying fox (*Pteropus hypomelanus*) collected from Tioman Island off the eastern coast of peninsular Malaysia (9). TioPV is closely related to MenPV and has also been tentatively classified in the genus *Rubulavirus*. A serological survey of 169 Tioman Islanders demonstrated five individuals (1.8%) had neutralizing antibodies to TioPV, suggesting previous infection with TioPV or a similar virus (11). Successful experimental infection of pigs suggested that pigs could become naturally infected with TioPV and could facilitate virus transmission to humans following contact with oral secretions (10). However, there is currently no evidence of TioPV causing disease in humans or animals.

Mojiang virus (MojPV) is a novel henipa-like virus detected in rats (*Rattus flavipectus*) in Yunnan Province, China, in 2012 (17). This virus was detected in rectal swabs collected from rats in a cave, cohabitated by bats (*Rhinolophus ferrumequinum*). The detection resulted from part of an investigation of three fatal human cases among workers who had been involved in cleaning the cave, although no causative relationship can be established. Six months earlier, three humans visiting this cave had developed severe pneumonia. Although isolated from rats, it is not clear whether rats are the natural reservoir or a spillover host in this case. Genome sequence analysis of MojPV demonstrated that the closest relatives are the henipaviruses. If rats are the natural reservoir of this virus, it would suggest that henipaviruses have a broader natural reservoir range than just bats.

Achimota viruses (AchPV1 and 2) are two different paramyxoviruses, which have been isolated from urine samples collected from straw-colored fruit bat (*Eidolon helvum*), bats roosting in Accra, Ghana (16). These two viruses, although not closely related, cluster with the other bat-borne rubula-like viruses. Human sera collected in Ghana and Tanzania from both healthy and febrile humans were able to neutralize AchPV2 (16). This suggests that AchPV2 has zoonotic potential, with either AchPV2 or a closely-related virus having infected humans in the past. Whether

these viruses can cause disease in humans or animals is currently unknown.

During 2014, an outbreak of severe illness among humans and horses was reported in the villages Tinalon and Mid-tungok, province of Sultan Kudarat, island of Mindanao, Philippines (143). The outbreak encompassed fatal and nonfatal human infections, as well as concurrent neurologic disease (head tilting, circling, ataxia) and sudden deaths in several horses, which were subsequently consumed by villagers. A total of 17 human cases were identified during this outbreak. Of these cases, 7 people had participated in horse slaughtering and horse meat consumption, and 3 had only consumed horse meat. A further 5 people had been exposed to other infected humans, and, of these, 2 were healthcare workers without other known contacts (143). Among other domestic animals, 4 cats and 1 dog that had eaten horse meat died. Virus isolation was unsuccessful, but neutralizing antibodies and IgM against NiV and correspondingly lower neutralizing antibody titers against HeV were found for 3 patients (143). The pattern of neutralizing antibodies and IgM in paired serum samples was interpreted as evidence of recent exposure to a henipavirus. In addition, a serum sample from 1 of these patients was positive by real-time PCR for NiV, and a single-sequence read (71 bp) of the P gene of NiV was detected by next generation sequencing of the CSF from another of these patients. In addition to transmission to humans by direct exposure to infected horses, their contaminated body fluids or consumption of undercooked meat from infected horses, there is strong evidence for direct human-to-human virus transmission. Although the source of the horse infections is unclear, on the basis of the known ecology of henipaviruses, the most likely source of horse infection is fruit bats (143).

## PATHOGENESIS

### Hendra Virus

A total of seven human HeV infections have occurred to date, with four patients succumbing to their infections. All human infections have resulted from close physical contact with infected horses. Symptoms have varied between patients, with an estimated incubation period of 7 to 16 days. Initial disease signs are influenza-like, which progress to a fulminating encephalitis with multiorgan, failure (98, 144). The autopsy of the horse trainer who died in the first HeV incident showed a severe interstitial pneumonia. Both lungs were congested, hemorrhagic, and edematous. Histologic examination showed focal necrotizing alveolitis, with giant cells, syncytium formation, and viral inclusions. Postmortem lung, liver, kidney, and spleen samples were inoculated in cell culture, resulting in the appearance of prominent syncytia in cultures inoculated with kidney material (18, 98). The findings at autopsy of the farmer from Mackay, who died more than 1 year after initial infection with HeV (93), showed leptomeningitis with lymphocyte and prominent plasma cell infiltration, with discrete foci of necrosis in the neocortex, basal ganglia, brain stem, and cerebellum. Multinucleate endothelial cells were observed in the brain, liver, spleen, and lungs. Immunohistochemical (IHC) studies showed the presence of viral antigen in the cytoplasm of some cells, but most frequently scattered throughout the neurophils, although virus could not be isolated from the brain. These findings suggest that, following initial infection with the virus, possibly through the oral/respiratory route or through direct inoculation of cutaneous abrasions with

infectious secretions, viremia develops, resulting in spread to various organs, including the central nervous system. The pathogenesis of recurrence of fatal disease in the farmer from Mackay is unclear. The antibody profile during the fatal illness was indicative of an anamnestic response to viral antigens (93). This patient had abundant immunoglobulin M (IgM) antibodies suggestive of a reinfection, but no exposure to horses was documented prior to the recurrence. The failure to isolate virus from this patient's brain supports speculation that the pathogenesis may be similar to that of subacute sclerosing panencephalitis, as both diseases are caused by paramyxoviruses and are characterized by recurrence of fatal neurologic disease following complete recovery from an initial infection. However, the pathological findings and rapid course of this disease are strikingly different from those of subacute sclerosing panencephalitis.

### Nipah Virus

The incubation period for NiV infection has been estimated to be 1 to 2 weeks. During the initial outbreak, the period between the last contact with pigs and onset of illness ranged from several days to 2 months, but it was 2 weeks or less for 92% of patients (119). All available data on histopathological changes in humans infected with Nipah virus were obtained in a single study performed during the Nipah virus outbreak in Malaysia and Singapore (145). A multiorgan vasculitis associated with infection of endothelial cells is the hallmark pathological feature of Nipah disease (122). Occasionally, multinucleate giant cells characteristic of paramyxovirus infections are observed in the affected vascular endothelium. Infection is most pronounced in the central nervous system, where a diffuse vasculitis, characterized by segmental endothelial cell damage, mural necrosis, karyorrhexis, and infiltration with polymorphonuclear leukocytes and mononuclear cells, is noted. The lesions are primarily seen in the cerebral cortex and brain stem, with extension to parenchymal tissue, where extensive areas of rarefaction necrosis are seen. Eosinophilic, mainly intracytoplasmic, viral inclusions with a "melted-tallow" appearance are seen in the affected neurons and parenchymal cells. IHC studies with NiV antigen show intense staining of endothelial and parenchymal cells. Evidence of endothelial infection and vasculitis is also seen in other organs, including the lungs, heart, spleen, and kidneys. NiV has been isolated from CSF, tracheal secretions, throat and nasal swabs, and urine specimens from patients (119, 122).

The widespread distribution of vasculitis throughout the central nervous system and, to a lesser extent, in other organs, and the isolation of virus from a variety of clinical specimens, suggest that, following initial infection with the virus, possibly through the respiratory tract or direct inoculation of cutaneous abrasions with infectious secretions, viremia develops, resulting in systemic spread. Involvement of the uncus of the temporal lobe in some patients has led to speculation that virus may be spread along the olfactory tract to the uncus following inhalation and local replication (146). The nonspecific neurologic manifestations of Nipah disease probably reflect widespread vasculitis, but the distinctive features, such as segmental myoclonus and brain stem dysfunction, indicate a predilection of the virus for certain neurons.

Findings at autopsy of a patient, who died of encephalitis that developed 10 weeks following an initial asymptomatic infection, showed evidence of neuronal death, neuronophagia, parenchymal inflammation, and perivascular cuffing, suggestive of a primary viral encephalitis rather than a vas-

culitis or infarction (146). MRI showed patchy areas of confluent cortical involvement, mainly in the cerebral hemispheres. The distinctive pathology and the MRI features of patients with relapse suggest that the pathogenesis may differ from that of acute Nipah encephalitis.

### Immune Responses

Limited data are available regarding the human immune response to NiV infection and correlates of immune protection and disease resolution. A serum IgM response has been demonstrated shortly after onset of illness, and the presence of IgM antibody appears to reduce the rate of isolation of virus from throat and respiratory secretions (123). The presence of antibodies in the serum or CSF, however, does not appear to influence the rate of isolation of virus from CSF (81), suggesting that humoral immunity plays a minor role in recovery from neurologic disease.

The NiV nonstructural proteins C, V, and W have been shown to play a role in pathogenesis by antagonizing the interferon signaling response (147). Specifically, the C protein inhibits the early proinflammatory response at sites of infection, thereby preventing control of the infection by the immune system (148). NiV C regulates expression of proinflammatory cytokines, therefore providing a signal responsible for the coordination of leukocyte recruitment and the chemokine-induced immune response and controlling the lethal outcome of the infection. The role of innate immune signaling in NiV pathogenesis is further exemplified by the fact that NiV causes disease in IFNAR-KO mice lacking the type I interferon receptor, which are thus deficient in interferon signaling, but not in wild-type mice (149).

## CLINICAL MANIFESTATIONS

### Hendra Virus

The two patients in the first HeV incident had abrupt onset of an influenza-like illness, characterized by myalgia, headaches, lethargy, and vertigo (18, 92). One patient remained lethargic for 6 weeks but fully recovered. The other patient developed nausea and vomiting on the fourth day of illness and deteriorated rapidly in the next 2 days, requiring admission to an intensive care unit and mechanical ventilation. He died on the seventh day of illness. The fatal patient in the first HeV incident showed thrombocytopenia; increased levels of creatine phosphokinase, lactic dehydrogenase, aspartate aminotransferase, alanine aminotransferase and glutamyltransferase; and features of dehydration and acidosis (18). Chest radiographs showed diffuse alveolar shadowing. No laboratory abnormalities were detected in the patient who survived.

Unlike the first two patients, the affected farmer in the second HeV incident primarily had neurologic manifestations (93). He initially presented with features of meningitis, including headache, drowsiness, vomiting, and neck stiffness. Thirteen months following complete recovery, the patient presented again with a 2-week history of irritable mood and lower back pain, three episodes of focal seizures of the right arm, and an episode of generalized tonic-clonic seizures. In the following week, he continued to have a low-grade fever and focal and generalized seizures. By day 7, he developed dense right hemiplegia, signs of brain stem involvement, and depressed consciousness, requiring intubation. The patient remained unconscious and febrile until he died, 25 days after admission. Cerebrospinal fluid (CSF) examination showed an elevated protein level, normal glucose level, and mononuclear pleocytosis. Magnetic resonance imaging

(MRI) of the brain showed multifocal cortical lesions, sparing the subcortical white matter, that became more pronounced and widespread prior to death. The two patients infected during the 1998 outbreak also experienced initial influenza-like symptoms; however, after apparent clinical improvement, encephalitis developed in both patients. The MRI changes showed widespread cortical, subcortical and deep white matter involvement, similar to those described in a previous HeV encephalitis case (144).

### Nipah Virus

The initial symptoms of NiV are nonspecific and include headaches, fever, dizziness, and muscle pain. As the disease progresses, neurological symptoms become the dominant feature and, depending on the strain, respiratory involvement to various degrees. The onset of NiV disease is abrupt, usually with the development of fever. Often, patients deteriorate rapidly, requiring hospitalization 3 to 4 days after onset of symptoms. Severe encephalitis is the most prominent clinical manifestation. Fever (97%), headache (65%), dizziness (36%), vomiting (27%), and reduced level of consciousness (21%) are the most common features at presentation (122). Several other features of neurologic involvement, particularly signs of brain stem dysfunction, are noted in patients during the course of illness (Table 2). The disease in 3 of the 11 patients in the initial Singapore outbreak presented as an atypical pneumonia, with fever and infiltrates on chest radiography (111). NiV disease was fatal in up to one-third of hospitalized patients in Malaysia. The following are all associated with a poor prognosis: older age; evidence of brain stem involvement; the presence of segmental myoclonus, seizures, or areflexia; elevated hepatic enzyme levels or low platelet counts; and isolation of virus from the CSF (81, 122).

Survivors of NiV infection frequently experience long-term neurologic deficits (150). Late-onset or relapse encephalitis has been observed, and, in one case, this late-onset encephalitis occurred 11 years after the initial NiV infection (150, 151).

### Laboratory Abnormalities

Thrombocytopenia (30%), leukopenia (11%), and elevated levels of alanine aminotransferase (33%) and aspartate trans-

aminase (42%) are the most common hematologic abnormalities (122). CSF studies are frequently abnormal, with elevated white blood cell counts and/or protein levels (111, 122), but the presence of abnormal CSF findings does not correlate with severity of disease (81).

Computed tomography scans of the brain are generally unremarkable. On MRI, small, discrete lesions measuring 2 to 7 millimeters are seen in the subcortical and deep white matter of the cerebral hemispheres during both the acute and late phases of illness (111, 122, 146). These lesions possibly represent focal areas of ischemia and infarction resulting from the vasculitis. The pattern and extent of brain involvement on MRI do not appear to correlate with specific clinical features, severity of coma or outcome of disease (118). Electroencephalography (EEG) shows the following abnormalities: diffuse slow waves with focal sharp waves; continuous, diffuse, irregular slow waves; and intermittent, diffuse, slow waves (122, 146). Focal EEG abnormalities occur primarily in the temporal lobes.

### Complications

Residual neurologic deficits, including a vegetative state, cognitive impairments, and cerebellar disabilities, occur in 10 to 15% of patients (111, 122, 146). Recurrence of neurologic dysfunction is seen in some patients, including neurologic relapse with seizures and cognitive impairment or focal signs, such as isolated cranial nerve dysfunction.

Even without delayed progression to neurologic illness following Nipah fever, persistent fatigue and functional impairment are frequent (150). Neurologic sequelae were frequent following Nipah encephalitis. Neurologic dysfunction may persist for years after acute infection, and new neurologic dysfunction may develop after acute illness. Survivors of NiV infection may experience substantial long-term neurologic and functional morbidity.

### Clinical Diagnosis

Encephalitis can be diagnosed by the presence of fever, headache, reduced level of consciousness, and focal neurologic signs, as well as abnormalities on CSF examination and EEG studies. Clues to the NiV etiology are provided by the history of contact with pigs or bats, particularly in the context of an outbreak, the presence of segmental myoclonus and MRI findings of small, discrete lesions in the subcortical and deep white matter of the cerebral hemispheres. MRI findings are particularly useful in distinguishing encephalitis caused by NiV from that caused by Japanese encephalitis virus, the most common arboviral encephalitis worldwide, which is endemic in China, India, and other parts of Southeast Asia, and by herpes simplex virus, the most common sporadic form of encephalitis worldwide.

### Menangle Virus

The two MenPV-infected workers had similar illnesses, characterized by abrupt onset of fever, malaise, chills, drenching sweats, and severe headache (5). On the fourth day of illness, both developed a spotty, red, nonpruritic rash. Bilateral hypochondrial tenderness was present in one patient, and an abdominal ultrasound conducted 2 months after the illness showed splenomegaly and liver size at the upper limit of normal. Both patients recovered after approximately 10 days of illness.

### Sosuga Virus

Symptoms upon hospital admission included a 2-day history of fever, malaise, headache, generalized myalgia, and

**TABLE 2** Neurologic features in patients with laboratory-confirmed NiV disease, Malaysia, 1998 to 1999<sup>a</sup>

Feature	% of patients (n = 94)
Absent or reduced reflexes	56
Abnormal pupils	52
Tachycardia (heart rate >120/min)	39
Hypertension (blood pressure >160/90 mm Hg)	38
Abnormal doll's-eye reflex	38
Segmental myoclonus	32
Meningism	28
Seizures	23
Nystagmus	16
Cerebellar signs	9
Bilateral ptosis	4

arthralgia, neck stiffness, a metallic taste, and sore throat (8). A maculopapular rash on the trunk erupted on the second day after hospital admission, and several small ulcers appeared on her soft palate. The following day, fever, headache and myalgia persisted, and the patient experienced bloody emesis and mild diarrhea positive for occult blood but without frank hematochezia or melena. The rash became confluent. A bone marrow biopsy sample showed a mild increase in macrocytic hemophagocytosis and pancytopenia with a hypocellular marrow with myeloid hyperplasia and erythroid hypoplasia. The fever slowly but progressively decreased, and the last recorded fever was on the ninth day in hospital. The biologist was discharged from hospital after 2 weeks, but considerable sequelae (myalgia, arthralgia, headache, malaise, and fatigue) persisted for several months (8).

## LABORATORY DIAGNOSIS

### Virus Isolation

Traditional techniques of virus isolation in cell culture, electron microscopy, enzyme-linked immunosorbent assay-based serology, neutralization assays, and IHC techniques have been employed in the diagnosis of the zoonotic paramyxoviruses (2, 6, 152, 153). Virus replication, hence success of isolation, is cell-line dependent. NiV has been successfully isolated from human specimens, including nasal and throat swabs, as well as urine and CSF (122). The kidneys have been the only human source of HeV isolation from humans (18). In contrast, MenPV has not been isolated from human specimens, but virus isolations from the tissues of stillborn piglets were readily obtained (6).

NiV and HeV are internationally classified as biosafety level or biosecurity level 4 (BSL-4) agents; thus, clinical specimens suspected to be infected with these agents must be handled with caution. Propagation of viruses from clinical specimens known to be infected with henipaviruses is not recommended without appropriate containment facilities. The US Centers for Disease Control and Prevention, Atlanta, GA, and the Australian Animal Health Laboratory, Geelong, Australia, have adopted the approach that primary virus isolation from specimens of outbreaks, not already proven to be henipaviruses, take place at BSL-3 facilities. However, if the results of cell culture suggest the presence of these agents, cultures should be transferred to BSL-4 facilities to conform to biosafety guidelines (152).

### Antigen and RNA Detection

IHC is an excellent technique for the detection of the zoonotic paramyxoviruses (2, 94, 152, 153) in the absence of BSL-4 facilities. Tissue specimens can be formalin-fixed with minimal risk to the laboratory workers. Convalescent-phase human serum was initially used for antigen detection in the investigations of the first HeV outbreak, but subsequently, a wide variety of immunologic reagents became available from the Australian Animal Health Laboratory and US CDC, including polyvalent and monoclonal antibodies to both HeV and NiV. HeV and NiV are genetically closely related (2, 19); thus, the investigation of more current NiV outbreaks benefited greatly from the availability of immunologic reagents made to HeV.

Diagnostic specimens from suspected cases can be disrupted in chaotropic salts in preparation for RNA extraction and RT-PCR. The addition of the chaotropic agent (guanidinium isothiocyanate) almost immediately abrogates paramyxovirus infectivity, and it minimizes human exposure

to the infected tissues. RT-PCRs with conserved primer pairs (or families of degenerative primers), flanking the P protein gene-editing region (2, 38) of the subfamily *Paramyxovirinae*, were utilized in the investigation of the NiV outbreak in Malaysia and Singapore. Consensus primers targeting the conserved region of the L gene (154) have been successfully used in the identification and characterization of AchPV 1 and 2 (16), several henipaviruses in African bats (138, 155), and unclassified paramyxoviruses in Indonesia (141), Europe (57, 83), Africa (57, 139), and South America (57). This method can be used in conjunction with fresh or formalin-fixed tissues from a variety of sources, including brain, lung, and kidney, as well as CSF, for the detection of viral sequences.

Next-generation sequencing (NGS), otherwise known as massively parallel or deep sequencing, (156, 157) functions without knowledge about the target sequence, as opposed to conventional PCR. Targeted enrichment can greatly enhance the discovery rate of novel viruses (158–162). A combination of NGS and metagenomic analysis was used for the identification of SosPV (8), AchPV (16), and several other paramyxoviruses (163, 164).

### Serology

Enzyme-linked immunosorbent assays, using both indirect and antibody capture formats, have been configured for the detection of IgM and IgG antibodies to HeV and NiV (152). However, viral antigen preparation for the henipaviruses is expensive and must take place in a BSL-4 facility. While sufficient quantities were prepared and made available for the diagnostic needs of the HeV and NiV outbreaks, alternative approaches to viral antigen production from virus-infected cells are currently being explored. One alternative is the expression of individual viral proteins following the incorporation of the viral genes in baculovirus expression or similar expression systems. Measuring serum neutralization antibody titers against HeV and NiV is currently performed in Vero cell monolayers at BSL-4 facilities. In order to negate the requirement for BSL-4 containment, which is not widely available, pseudotyped virus particles provide an alternative diagnostic method that can be performed at BSL-2 conditions. VSV pseudotype particles displaying NiV F and G were used as a substitute for NiV virions (165, 166). Multiplexed microsphere assays for henipaviruses have also been used as a surrogate for virus neutralization (167). These tests are very specific and have been used in conjunction with enzyme immunoassays and radioimmunoprecipitation assays to confirm acute infection and previous exposure to the viruses. In addition, the neutralization assay has been used to detect neutralizing antibody to HeV and NiV in animal serum specimens, particularly bat serum, in attempts to identify possible reservoirs of these agents (56, 104, 105, 152, 168).

## PREVENTION

Currently, the only vaccine that exists for a bat paramyxovirus is Equivac HeV (Zoetis, Parkville, VIC., Australia), the HeV vaccine approved for use in horses. Equivac HeV was launched in 2012 and is the first vaccine licensed and commercially deployed against a BSL-4 agent (97). The HeV subunit vaccine consists of a recombinant soluble and oligomeric form of the G glycoprotein (169). Vaccine efficacy in immunized horses was assessed against the clinical, virologic, and pathologic features of HeV infection (97, 170). Studies using NiV in cats (88, 171) and monkeys (172) and HeV in ferrets (173) and nonhuman primates (174) provided strong evidence that the HeV glycoprotein subunit-based

vaccine could prevent not only disease but also infection in animals exposed to otherwise lethal doses of either HeV or NiV. The HeV vaccine has the potential for breaking the chain of HeV transmission from bats to horses to humans, thereby protecting both horse and human health.

Apart from vaccination, the principal means of preventing human infections are early recognition of animal disease and use of precautions to avoid exposure. As interruption of transmission to horses or pigs from the natural reservoir of these viruses is difficult, early identification of infected animals and use of appropriate personal protective measures to prevent transmission are keys to reducing the risk to humans. For example, persons handling horses in areas in which HeV may be endemic should be educated regarding the features of disease in horses and should use appropriate PPE (e.g., gloves, gowns, and face visors).

Pig farmers in areas in which NiV may be endemic should be educated regarding the features of Nipah encephalitis in pigs and to report any unusual disease. As transmission is possible without close contact with pigs, exposure to potentially infected animals should be completely avoided, if possible. Persons handling pigs or their excreta should wear PPE such as gloves, masks, gowns, and face visors.

Infection in piggeries with NiV or MenPV can be eradicated through a combination of quarantine, segregation, and culling. During the outbreak in Malaysia, a national swine testing and surveillance program was initiated in which a sample of adult sows from pig farms was tested for antibody to NiV. Farms with antibody-positive animals were considered infected, and pigs from these farms were culled. A similar program to identify infected farms by testing pigs entering abattoirs is also important.

During community outbreaks, additional control measures may be required, including the restriction of movement of animals between farms, the culling of pigs from infected farms and the temporary closure of abattoirs that slaughter pigs from farms in outbreak-affected areas. Disinfection of fruit and boiling of palm sap potentially contaminated by bats are warranted in areas where repeated NiV outbreaks have occurred (115, 175). In areas where large populations of fruit bats of the genus *Pteropus* congregate or frequent fruit or other agricultural products, means of reducing exposure of persons to potentially contaminated plants, areas and products and means of disinfection of fruits or commodities before consumption should be considered.

Person-to-person transmission of NiV occurred in Bangladesh and perhaps in India (1, 115, 126). Given the potential severity of illness, those in contact with patients, including healthcare workers, should use standard and droplet precautions (e.g., strict attention to good hand-washing practices and wearing a mask and gloves) during contact with secretions, excretions, and body fluids of patients.

## TREATMENT

Symptomatic therapy includes the use of antipyretic and antiepileptic drugs and mechanical ventilatory support for severely ill patients. Because of the histopathological features of vasculitis-induced thrombosis, aspirin and pentoxifylline were used empirically in some NiV patients (122).

No specific antiviral therapy for infection by henipaviruses has been proven effective to date. One HeV patient recovered completely without any specific treatment, and neither patient with fatal disease received antiviral therapy. *In vitro* ribavirin is inhibitory for HeV at a concentration of 10 to 50 micrograms per milliliter, and the drug also crosses

the blood-brain barrier with a mean CSF/plasma ratio of 0.7 (110, 176). In Malaysia, ribavirin was administered either orally or intravenously to 140 patients with suspected Nipah encephalitis; 54 patients who were managed prior to the availability of ribavirin or refused treatment were selected as controls (110). Of the 140 patients who received ribavirin, 128 received it orally (2 g on day 1, 1.2 g three times daily on days 2 to 4, 1.2 g twice daily on days 5 and 6, and 0.6 g twice daily for another 1 to 4 days), whereas 12 received ribavirin intravenously (loading dose of 30 mg/kg of body weight, followed by 16 mg/kg every 6 h for 4 days and 8 mg/kg every 8 h for 3 days). A total of 45 (32%) of the 140 treated patients died, compared with 29 (54%) of the 54 controls, representing an apparent 40% decline in the mortality rate in the treated group compared to historical and untreated controls. Because a small number of patients received intravenous ribavirin, its effectiveness could not be adequately compared with that of oral ribavirin. Despite the absence of any known published information on the *in vitro* effect of acyclovir on NiV infection or replication, acyclovir was empirically administered to all nine patients with encephalitis in Singapore. While only one of these patients died, several deteriorated before recovering. This may have been related to the quality of supportive care provided. The influence of acyclovir therapy on the course of disease is unknown.

Passive immunotherapy, with either polyclonal or monoclonal antibody specific for henipavirus envelope glycoproteins, has proved successful from initial proof-of-concept findings in animal models (70, 72, 177). Presently, the most promising postexposure therapy against Hendra or Nipah virus infection is a human monoclonal antibody (mAb) known as m102.4, which was isolated from a recombinant naïve human phage-displayed Fab library (178, 179). The m102.4 mAb has exceptionally potent neutralizing activity against both Nipah and Hendra viruses, and testing of m102.4 has confirmed its neutralization activity against different isolates of NiV-MY and NiV-BD (177). Effective postexposure efficacy with m102.4 has now been demonstrated in nonhuman primates (180). The cell line expressing the human m102.4 mAb was provided to the Queensland Government, Queensland Health, to allow health authorities to manufacture m102.4 for its potential use on a compassionate basis in future cases of high-risk human exposure. A phase I clinical trial will be conducted in Queensland.

Galectin-1, an endogenous lectin secreted by a variety of cell types, has pleiotropic immunomodulatory functions and also appears to have antiviral effects against NiV (181), although recently this lectin has been shown to also promote NiV infection of endothelial cells (182). A peptide based on the heptad repeats of the hPIV3 F protein was also able to inhibit HeV infection (183). A novel minigenome assay based on polymerase I-driven transcription has been used to screen a library of small molecules to identify potential lead compounds for further study (184).

# Rhabdoviruses

ALAN C. JACKSON

## 41

Rabies is an acute encephalomyelitis of humans and animals caused by infection with rabies virus. Rabies virus is usually transmitted by an animal bite. Worldwide, dogs are the most important rabies vector, whereas in North America wild animals, especially bats, are the main threat to humans. After a delay at the site of entry, rabies virus spreads through the nervous system within axons by fast axonal transport. Rabies can be very effectively prevented after a recognized animal exposure with wound cleansing and administration of rabies vaccine and rabies immune globulin. Rabies typically develops after an incubation period of 20 to 90 days following the exposure. There are both encephalitic and paralytic forms of rabies and the disease is virtually always fatal after clinical onset. Hydrophobia is a characteristic clinical feature of encephalitic rabies. Progressive weakness involving the limbs and face occurs in paralytic rabies, which often begins close to the site of the wound. Pathological changes in rabies include the presence of eosinophilic inclusions called Negri bodies in the cytoplasm of neurons and inflammatory changes. Imaging studies may be normal and do not show specific abnormalities. A laboratory diagnosis can be made antemortem with the detection of rabies virus antigen or RNA in tissues (e.g., skin) and/or body fluids (e.g., saliva) and with serological testing. There have been rare survivors of rabies, but there is no known effective therapy.

Rhabdoviruses in the family *Rhabdoviridae* contain many different virus species, but the most important is rabies virus in the *Lyssavirus* genus that causes the vast majority of cases of rabies. Rabies is an acute viral infection of the central nervous system (CNS) that is almost invariably fatal. Rabies is a zoonotic disease affecting mammals and is normally transmitted to humans by bites from infected animal vectors. Nonrabies virus lyssaviruses have also been recognized to rarely cause disease in humans and animals with identical clinical and pathological features to rabies. Rabies has typical clinical features, but they may not be recognized by physicians who are not familiar with the disease. Rabies can be very effectively prevented after recognized exposures if current recommendations are followed very closely. Vesicular stomatitis virus (VSV) is another rhabdovirus in the *Vesiculovirus* genus that causes vesiculation and ulceration in cattle, horses, and other animals, and causes a self-limited, mild, systemic illness in humans.

### HISTORY OF RABIES

Rabies is an ancient disease with references as far back as 2300 BC in the pre-Mosaic Eshnunna Code of Mesopotamia (1). In Greek and Roman times the works of Democritus (460–370 BC), Hippocrates (460–377 BC), Aristotle (384–322 BC), and Celsus (25 BC–50 AD) made reference to rabies in both humans and animals (2). Celsus described human rabies and used the term *hydrophobia*, which is derived from the Greek words meaning fear of water, and at that time he recognized that the saliva of the rabid animal contained the poisonous agent (2).

In 1769, the pathologist John Morgagni (1735–1789) wrote that rabies virus “does not seem to be carried through the veins, but by the nerves, up to their origins” (3), indicating his insight into a mechanism of neural spread by rabies virus at a very early time before experimental studies had been first performed. In the early 19th century Zinke (1771–1813) discovered that the infectious agent causing rabies was transmitted in the saliva by experimentally painting saliva from a rabid dog into incisions made in healthy animals (4). In 1879, Galtier (1846–1908), who was a professor at a veterinary school in Lyon, France, used rabbits in his experimental work on rabies and he found that using rabbits was technically much less difficult and dangerous than using dogs and cats (5). Subsequently, Louis Pasteur (1822–1895) also used this experimental rabbit model of rabies. Pasteur transmitted rabies virus by inoculating CNS tissues of rabies animals into the brains of other animals, and he observed that sequential brain passages led to attenuation of the agent after peripheral inoculation (6). In 1885, Pasteur successfully immunized a 9-year-old boy, Joseph Meister, who had been severely bitten by a rabid dog, with a series of inoculations of infected rabbit spinal cord tissues that he had partially inactivated by subjecting them to variable periods of desiccation (7). Joseph Meister did not develop rabies and subsequently many people with rabies exposures were immunized with nervous system vaccines in Paris and other locations throughout the world.

In 1903, Adelchi Negri (1876–1912) described eosinophilic cytoplasmic inclusions in infected neurons, which are now called Negri bodies (8). Negri bodies have proven to be useful in making a pathological diagnosis of rabies. In 1958, Goldwasser and Kissling (9) used fluorescent antibody staining in order to demonstrate rabies virus antigens in tissues, which proved to be much more sensitive for rabies diagnosis and also

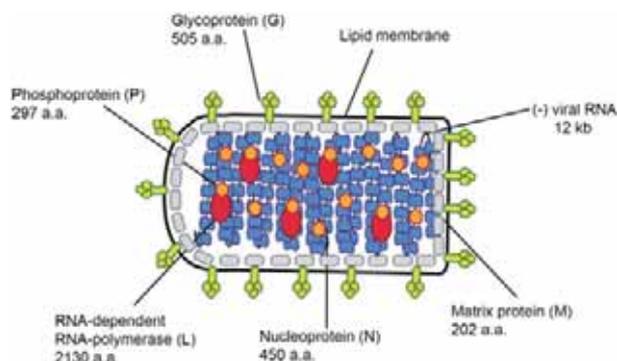

for the development of early rabies pathogenesis studies in animals, which were performed by Richard Johnson (10) and Frederick Murphy (11, 12) and their colleagues.

## VIROLOGY OF THE RHABDOVIRUSES

The *Rhabdoviridae* is a virus family (along with four others) in the viral order *Mononegavirales*, which are nonsegmented negative strand (anti-sense) RNA viruses. The *Rhabdoviridae* consist of both animal (vertebrates and invertebrates) and plant viruses in 11 different genera. The name rhabdovirus was derived from the Greek “rhabdos,” meaning rod. However, the viruses actually have a bullet-like morphology (13), which can be demonstrated by electron microscopy. The *Lyssavirus* genus contains 14 species, including rabies virus that causes infections in humans and other mammals. The *Vesiculovirus* genus has another well-known species, VSV (Alagoas, Indiana, and New Jersey) that causes infections in animals and only incidentally in humans after contact with infected animals. It has been recognized that rabies virus and VSV have many structural features in common. Rhabdoviruses are RNA viruses capable of rapid evolution because of the high error rate of their RNA polymerases with the lack of proofreading activity.

### Lyssaviruses

Rabies virus belongs to genotype 1 of lyssaviruses, which includes wild-type or street rabies virus strains and also laboratory-adapted strains, including vaccine strains. The sequence of rabies virus consists of 11,932 nucleotides that code for five viral proteins: nucleocapsid protein (N), matrix protein (M), phosphoprotein (P), glycoprotein (G), and large polymerase protein (L) (14) (Figure 1). A ribonucleoprotein (RNP) core of the virion is formed by helical genomic RNA associated with the N, P, and L proteins. The RNP serves as a functional template for viral transcription and replication. The G and M proteins are associated with a lipid-bilayer envelope surrounding the RNP core. The G protein forms spike-like projections on the surface of the viral envelope and serves as the major surface antigen of rabies virus and binds viral neutralizing antibodies and is important for stimulation of an immune response.

**FIGURE 1** Schematic representation of the rabies virus particle. Viral proteins: N for nucleoprotein, P for phosphoprotein, M for matrix protein, G for glycoprotein, and L for large protein; their length in amino acids are indicated. The viral membrane is covered by the glycoprotein G, whereas M is located beneath the membrane. N is bound to the genomic RNA and together with P and L forms the ribonucleoprotein, which constitutes the active viral replication unit. (Reproduced with permission from Albertini AAV et al.: Rabies virus transcription and replication, in *Research Advances in Rabies*, Alan C. Jackson (ed), *Advances in Virus Research* 79:1–22, 2011. Copyright Elsevier.)

In recent years, some of the nonrabies virus lyssaviruses have been recognized to very rarely cause human disease, which is clinically and pathologically indistinguishable from rabies, include Mokola virus (genotype 3), Duvenhage virus (genotype 3), European bat lyssavirus 1 (genotype 5), European bat lyssavirus 2 (genotype 6), Australian bat lyssavirus (genotype 7), and Irkut virus (genotype pending) (15).

### Vesiculoviruses

VSV is the prototype rhabdovirus and more research has been done on its molecular virology and biochemistry than any other member of the *Rhabdoviridae*. VSV has the same five genes (N, M, P, G, and L) as rabies virus in its genome organization and its virion structure, and the replication cycles are also similar and will not be addressed further. Two serotypes of VSV, New Jersey and Indiana (type 1), cause outbreaks in animals in the United States and there are additional VSV serotypes in Latin America (e.g., Alagoas, Cocal, and Piry).

## PATHOGENESIS

### Lyssavirus Infections

Except under unusual circumstances, rabies virus is transmitted to humans and animals in the saliva via an animal bite. However, a scratch or abrasion with salivary (or brain

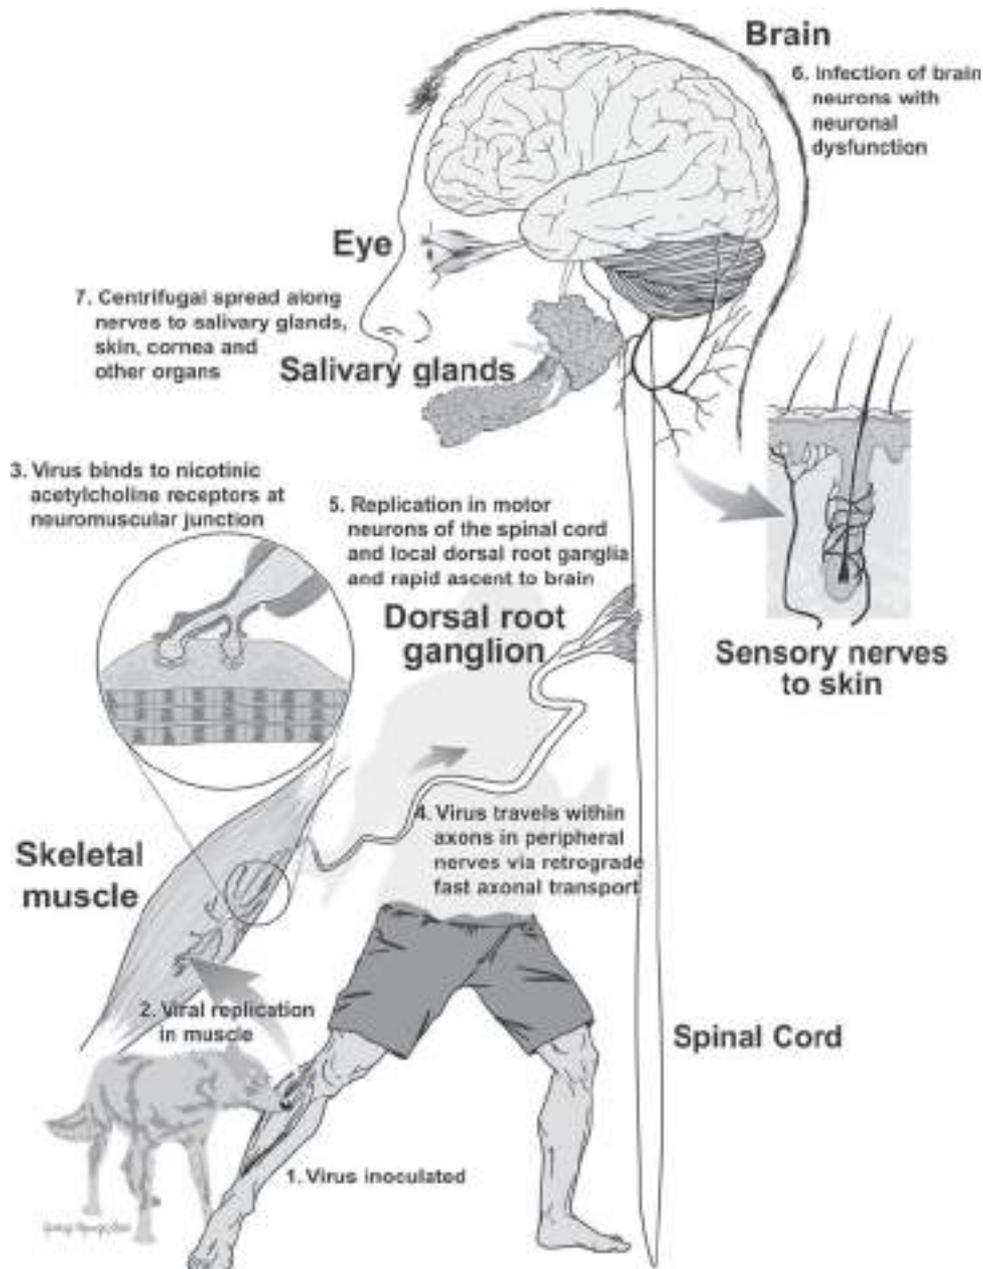

**TABLE 1** Cases of human rabies associated with organ transplantation in the USA (19–21), Germany (22), and Kuwait/Saudi Arabia (22a). or spinal cord tissue) contamination can also result in viral transmission. Aerosol transmission in laboratory accidents (16, 17) and in a cave containing millions of bats (18) have also been documented, but only occur very rarely. Organ (Table 1) and tissue (corneal and vascular conduit) transplantation are also well-documented causes of transmission of rabies virus in humans, which account for a total of 16 well-documented cases (19–22).

Experimental studies in animal models of rabies have provided much information about the events that occur in rabies pathogenesis (Figure 2). The incubation period is longer than many other infections and typically lasts approximately 20 to 90 days after the time of the exposure

(e.g., bite), although it may vary from just a few days to over a year or more. Based on animal studies, rabies virus is thought to remain close to the site of viral entry during most of this incubation period (24). After an exposure involving muscle, rabies virus is known to bind to nicotinic acetylcholine receptors (25) that are located in the postsynaptic membrane of the neuromuscular junction. After the virus crosses the synaptic cleft, it spreads centripetally towards the spinal cord in motor nerve fibers of peripheral nerves by retrograde fast axonal transport (26). Bats cause more superficial exposures than larger animals and their bites typically involve cutaneous and subcutaneous tissues, but experimental studies have not

**FIGURE 2** Schematic diagram showing the sequential steps in the pathogenesis of rabies after an animal bite/peripheral inoculation of rabies virus. (Reproduced with permission from Jackson AC, Fu ZF: Pathogenesis, in Rabies: scientific basis of the disease and its management, Third Edition, edited by AC Jackson, 2013, Elsevier Academic Press, Oxford, UK, pp 299–349. Copyright Elsevier.)

yet been performed to elucidate the detailed pathways of viral spread in animal hosts.

After infecting spinal cord neurons, rabies virus spreads widely within axons of the CNS by fast axonal transport along neuroanatomical connections. After CNS infection is established, there is centrifugal spread of rabies virus to multiple organs along sensory and/or autonomic nerves. In rabies vectors, viral spread to the salivary glands is important and saliva is secreted containing high titer infectious rabies virus, which is important for transmission to new hosts via bite exposures. Viral spread also occurs to multiple extraneural organs, including the heart (resulting in myocarditis in some cases), adrenal medulla, gastrointestinal tract, and skin (skin biopsy is used for antemortem rabies diagnosis in humans) (27).

### Vesiculovirus Infections

Relatively little is known about the pathogenesis of vesiculovirus infections. Intralingual inoculation of VSV into cattle or other animals results in vesicle formation at the site of inoculation (28), whereas intramuscular inoculation typically results in inapparent infection and immunity (29).

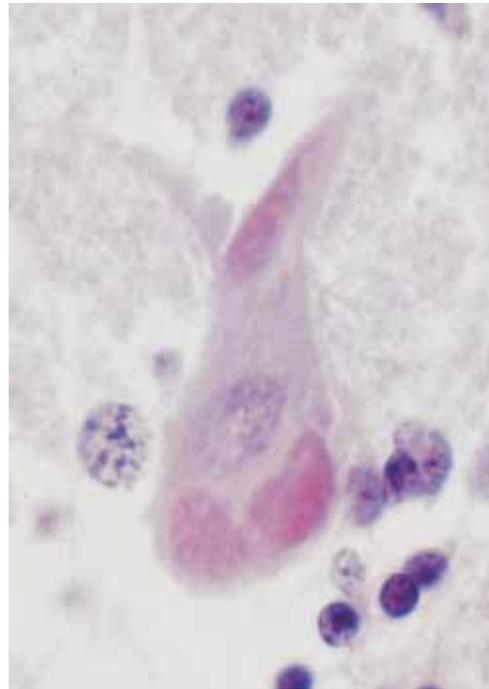

## PATHOLOGY OF RABIES

Despite the severe clinical disease in rabies, the neuropathological changes are relatively mild. Rabies virus prominently and predominantly infects neurons, although infection of glial cells has been recognized (30). There are mild inflammatory changes, but there are relatively few degenerative neuronal changes. Characteristic microscopic features of rabies encephalomyelitis include mild mononuclear inflammatory changes involving the leptomeninges, perivascular regions, and the CNS parenchyma. Microglial nodules described by Babes (31) are observed in the parenchyma and consist of activated microglia and monocytes, which are called Babes' nodules. Neuronophagia may be observed with accumulations of activated microglia/macrophages in the process of phagocytosing degenerating or dying neurons (32), but degeneration of numerous neurons is not a typical pathological feature of rabies. Negri bodies are characteristic eosinophilic inclusions that are observed in some infected neurons (Figure 3), which were described by and named after Adelchi Negri (8, 33). Electron microscopy has demonstrated that Negri bodies are composed of large aggregates of granulo-filamentous matrix material and variable numbers of viral particles (32). Both clinical and pathological findings in fatal human cases due to nonrabies lyssavirus infections are the same as in rabies due to rabies virus (genotype 1) infection.

## EPIDEMIOLOGY

### Lyssavirus Infections

About 99% of global human rabies cases are a consequence of transmission from dogs due to the presence of endemic dog rabies. There are approximately 59,000 human deaths per year related to endemic canine rabies (34) and the greatest burden of human disease occurs in Asia and Africa. The means of controlling endemic dog rabies are very well established (35). However, for a variety of complex economic, cultural, and political reasons, endemic dog rabies persists in many countries and is an ongoing threat to humans living or visiting these regions, who are at risk of transmission via dog bites. In other countries (e.g., North America) rabies is endemic in wildlife and this poses the main risk for transmission of rabies virus. Rabies virus variants can be identified with molecular techniques, including

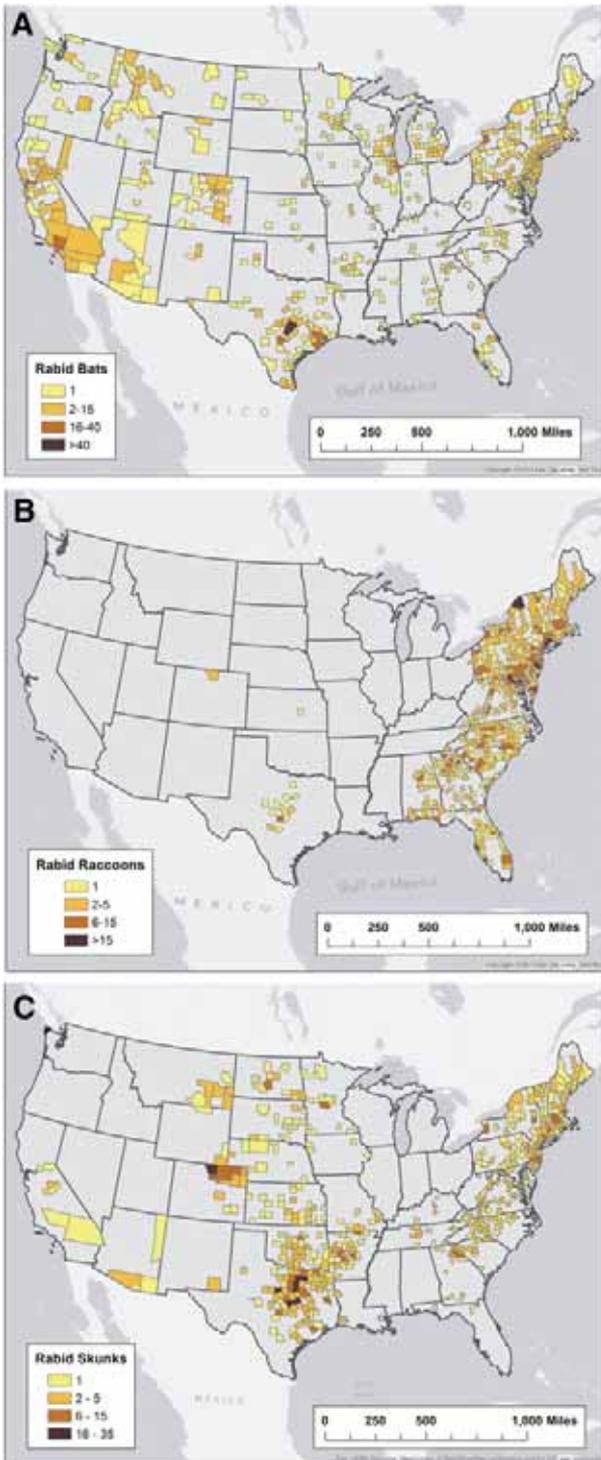

**FIGURE 3** Three large Negri bodies in the cytoplasm of a cerebellar Purkinje cell from an 8-year-old boy who died of rabies after being bitten by a rabid dog in Mexico. (Reproduced with permission from AC Jackson, E Lopez-Corella, *N Engl J Med* 335:568, 1996. Copyright Massachusetts Medical Society.)

monoclonal antibody characterization and reverse transcription polymerase chain reaction (RT-PCR) amplification with sequencing, which typically reveals the probable source of the infection when it is not readily apparent.

Because of their threat to human health, bats are the most important wildlife rabies vectors. In the United States, endemic bat rabies is present in every state except Hawaii (Figure 4A). Because of the small size of bats, their bites may not be readily recognized and, consequently, there is no opportunity for the initiation of highly effective preventive measures.

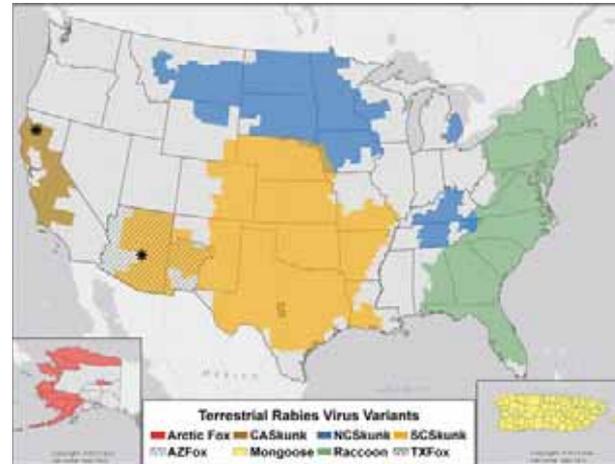

Patients infected by bat rabies virus variants via unrecognized bites may not even be aware that they have had contact with bats. A bat rabies virus variant associated with both silver-haired bats and tricolored bats is most frequently associated with human rabies in the United States and Canada. A variant associated with Brazilian (Mexican) free-tailed bats is the second most common bat variant associated with human rabies cases in the United States. Although big brown and little brown bats are often found in North American houses and are commonly found to be infected with rabies virus, the associated bat rabies virus variants are only infrequently responsible for human cases of disease.

Terrestrial animals that are vectors of rabies in North America include raccoons, skunks, and foxes (36) (Figure 5). Raccoon rabies is endemic along the entire eastern coast of the United States (Figure 4B). In the 1940s, raccoon rabies was initially present in Florida and over a period of decades it gradually spread north and the first incursion into Canada occurred in Ontario in 1999. There are only two documented cases of human rabies case due to raccoon rabies virus variants (21, 37), likely because raccoon exposures are usually recognized. Skunk rabies is present in the midwestern United States, the prairie provinces of Canada (Saskatch-

**FIGURE 4** Reported cases of rabies involving bats (A), raccoons (B), and skunks (C) by county, 2013. Adapted from JL Dyer et al., *J Am Vet Med Assoc* 245:1111–1123, 2014. (Centers for Disease Control and Prevention.)

ewan and Manitoba), and California (Figure 4C). Fox rabies is now uncommon in North America and it has been well controlled with oral vaccination programs in Ontario (red fox) and Texas (gray fox), and also in Europe. Companion animals, especially dogs and cats, are also at risk of devel-

oping rabies transmitted from wildlife vectors and, consequently, they may then pose a danger to humans.

### Vesiculovirus Infections

Mechanisms involved in VSV transmission are not well understood. VSV needs to penetrate the skin or mucous membranes via an injury or an insect vector (e.g., mosquitoes and sand flies). VSV is a viral disease of cattle, horses, pigs, and some wild mammals caused by VSV infection. VSV occurs in the Western hemisphere, especially in Latin America. Outbreaks in animals are usually seasonal, typically occur at the end of the rainy season in tropical regions and in late summer in temperate zones. Transmission to humans usually results from direct contact with infected animals, particularly cattle, and also occasionally from laboratory exposures.

## CLINICAL FEATURES

### Lyssavirus Infections

Typically, the incubation period from the time of the exposure (e.g., bite) until the time of the onset of clinical disease lasts between 20 and 90 days, but may be as short as only a few days or exceed a year or more. There is documentation of cases with incubation periods longer than a year, including one as long as 6 years (38). Prodromal symptoms in rabies are nonspecific and include fever, chills, malaise, fatigue, insomnia, anorexia, headache, anxiety, and irritability. They may last for up to 10 days prior to the onset of neurological symptoms. The earliest neurological symptoms of rabies include paresthesias, pain, and pruritus at or close to the site of exposure. They are likely due to infection and inflammatory changes involving local sensory ganglia (e.g., dorsal root ganglia or cranial sensory ganglia). The wound may have completely healed by the time these symptoms develop, or the site of exposure may be unknown (e.g., no recognized animal bite). There are two clinical forms of disease in rabies: encephalitic rabies (in 80% of cases) and paralytic rabies (in 20% of cases). It is likely that the main burden of the

infection in encephalitic rabies involves the brain, whereas in paralytic rabies the main burden likely involves the spinal cord, nerve roots, and peripheral nerves. Fever is present in most cases. In encephalitic rabies there may be episodes of generalized arousal or hyperexcitability, which are separated by lucid periods (39). Patients may have aggressive behavior, confusion, and hallucinations. Features of autonomic dysfunction, including hypersalivation, piloerection (gooseflesh), sweating, priapism, and cardiac arrhythmias, are common. Hydrophobia is a very characteristic clinical manifestation of encephalitic rabies, and occurs more frequently with infections due to rabies virus variants associated with dogs than with bats (40). Patients may initially have pain in the throat or have difficulty swallowing. When they attempt to swallow they experience contractions of the diaphragm and other inspiratory muscles, typically lasting for 5 to 15 seconds. Subsequently, this may become a conditioned reflex and the sight, sound, or even mention of water (or other liquids) may trigger the spasms. Aerophobia is the occurrence of these same spasms precipitated by a draft of air on the skin. As the disease progresses there is progressive neurological deterioration with worsening in the level of consciousness to coma and the development of paralysis.

In paralytic rabies there is early prominent weakness that usually initially involves the bitten extremity and progresses to involve the other extremities and facial muscles. Sphincter involvement, pain, and sensory disturbances also occur. Hydrophobia is unusual in paralytic rabies, although weakness of bulbar and respiratory muscles also develops. Patients with paralytic rabies later develop neurological deterioration with progression to coma, and they typically survive longer than patients with encephalitic rabies.

Medical complications are common in rabies patients treated aggressively in a critical care unit. Cardiac and respiratory complications are common. Cardiac disorders include heart failure, hypotension, a variety of arrhythmias, and cardiac arrest. Both cardiac ganglia and the myocardium may become infected with rabies virus, and in some cases there is an associated myocarditis (41–43). Respiratory complications include hyperventilation, hypoxemia, respiratory depression with apnea, atelectasis, and aspiration pneumonia (44). Hyperthermia or hypothermia may occur, likely secondary to hypothalamic infection. Endocrine complications include inappropriate secretion of antidiuretic hormone and diabetes insipidus (44, 45). Multiple organ failure commonly occurs in patients treated aggressively in critical care units.

### Vesiculovirus Infections

VSV in animals is associated with severe vesiculation and ulceration of oral tissues, teats, and feet. Most infections are subclinical. In humans, early conjunctivitis is followed by an acute influenza-like illness with fever, chills, nausea, vomiting, headache, retrobulbar pain, myalgias, substernal pain, malaise, pharyngitis, and lymphadenitis. Small vesicular lesions may be present on the buccal mucosa or on the fingers. Encephalitis is very rare. Typically, the illness usually lasts 3 to 6 days and there is complete recovery. Subclinical infections are common.

## DIFFERENTIAL DIAGNOSIS

### Lyssavirus Infections

The diagnosis of rabies may be difficult without a history of animal exposure, particularly in countries where rabies rarely

occurs, because physicians fail to consider the diagnosis due to a lack of familiarity with the disease, even in typical cases. Physicians may not ask about animal exposures and the patient may not recall an exposure or may not be able to provide this information at the time of presentation. In early phases, encephalitic rabies may be misdiagnosed as a psychiatric disorder, whereas paralytic rabies may be misdiagnosed as Guillain-Barré syndrome. Rabies hysteria is a conversion disorder (somatoform disorder) that may occur as a psychological response to the fear of developing rabies (46). It is characterized by a shorter incubation period than rabies, aggressive behavior (not common in humans), inability for the patient to communicate, and a long clinical course with recovery.

Other viral encephalitides may show behavioral changes with fluctuations in the level of consciousness. Hydrophobic spasms are not observed, and the presence of brainstem signs is unusual in conscious patients in most of the other viral encephalitides. Herpes simiae (B virus) encephalomyelitis, which is transmitted by monkey bites, is usually associated with a shorter incubation period and recovery may occur (47). Tetanus has a shorter incubation period (typically 3 to 21 days) than rabies and is characterized by sustained muscle rigidity involving paraspinal, abdominal, masseter (trismus), laryngeal, and respiratory muscles with superimposed brief recurrent muscle spasms (48). In tetanus, consciousness is preserved, there is no cerebrospinal (CSF) pleocytosis, and the prognosis is much better than in rabies. In Africa, rabies is commonly misdiagnosed as cerebral malaria (49). Anti-N-methyl-D-aspartate receptor (anti-NMDA) encephalitis occurs in young patients (especially females) and is characterized by behavioral changes, autonomic instability, hypoventilation, and seizures, and it has recently been recognized that this autoimmune disease rivals viral etiologies as a cause of encephalitis (50). Postvaccinal encephalomyelitis is an important differential diagnosis in patients immunized with a vaccine derived from neural tissues (e.g., Semple vaccine), which is currently used in only a few resource poor countries. Patients with paralytic rabies may resemble the Guillain-Barré syndrome and the pathological features may be also be similar (51). Local symptoms at the site of the bite, piloerection, early or persistent bladder dysfunction, and fever are all more suggestive of paralytic rabies.

### Vesiculovirus Infections

VSV in animals may be clinically indistinguishable from the more serious foot-and-mouth disease and vesicular exanthema. In humans, VSV infection presents as a nonspecific, mild, and self-limited systemic viral illness. The presence of vesicular lesions (buccal mucosa or fingers) and exposure to animals are important clinical clues to the etiology.

## INVESTIGATIONS

### Lyssavirus Infections

Routine blood tests and CT head scans are typically normal in rabies. MRI may be normal or show signal abnormalities in the brain, spinal cord, and/or nerve roots/plexuses, but these findings are not specific for rabies and the main usefulness of MRI is to exclude other diagnostic possibilities (52). CSF analysis usually shows a mononuclear pleocytosis with a cell count of less than 100 cells per  $\mu$ l. Serum neutralizing antirabies virus antibodies may develop in unvaccinated patients, but may not appear for a week or more during the clinical course of disease, and some patients never

develop antibodies prior to death. Neutralizing antirabies virus antibodies may also develop in the CSF, whereas CSF antibodies are not present in vaccinated patients who do not have rabies encephalitis. Specific laboratory tests for confirmation of a diagnosis of rabies include a full thickness skin biopsy taken from the posterior region of the neck at the hairline. Rabies virus antigen may be detected in nerve fibers around hair follicles with direct fluorescent antibody staining. Rabies virus RNA may be detected in fluids or tissues using RT-PCR amplification. Saliva is the most useful specimen for the detection of rabies virus RNA using RT-PCR. RT-PCR can also be used on skin biopsies (53) and CSF, but is much less sensitive on CSF. A negative laboratory test for rabies never excludes rabies unless performed on brain tissues, and the tests may need to be repeated for diagnostic confirmation of a rabies diagnosis. Brain tissues are only very rarely obtained by biopsy antemortem, but are routinely evaluated postmortem by direct fluorescent antibody staining and by culture techniques.

### Vesiculovirus Infections

A serologic diagnosis can be made on the basis of a rise in titer of either complement-fixing or neutralizing antibodies, RT-PCR for viral RNA has recently been described on clinical samples (54).

## RABIES PREVENTION

After recognized exposures, rabies can be very effectively prevented, whereas unrecognized exposures (e.g., bat bite) allow no opportunity for intervention. Detailed guidelines that are periodically updated are available from the Centers for Disease Control and Prevention (55) and from the World Health Organization (56) on the Morbidity and Mortality Weekly Report (<http://www.cdc.gov/mmwr/>) and World Health Organization (<http://www.who.int/en/>) websites, respectively. Algorithms have been developed concerning the decision-making process for initiation of postexposure rabies prophylaxis (57). The first step is to determine whether there is a real risk of rabies virus transmission. This depends on obtaining: the details of the exposure, the species of animal involved, and also on the local epidemiological situation. Advice from local public health officials can be very helpful in making a determination of whether postexposure rabies prophylaxis measures should be initiated. Laboratory testing on brain tissues from an animal is needed in order to make a definitive diagnosis of rabies, which is usually performed using an antigen detection method by the fluorescent antibody technique. If a dog, cat, or ferret remains healthy for a 10 day period after an exposure, then a conclusion can confidently be made that rabies virus transmission did not occur during the exposure because the brainstem infection associated with the salivary excretion of infectious virus did not progress to overt clinical signs within the period. Unwanted animals may be killed and the brains tested without an observation period. Other animal species must not be observed after an exposure because there is uncertainty about the period of time for clinical disease to develop and the period may be much greater than 10 days. If an animal escapes after an exposure, then the animal should be considered rabid unless information from public health officials indicates that this is unlikely. Current recommendations indicate that the physical presence of a bat may warrant postexposure prophylaxis when a person such as a small child or sleeping adult is unable to reliably report contact that could have resulted in a bite (55). In light of the low risks and high

costs, recommendations for bedroom exposures to a bat while sleeping and without known physical contact have been questioned (58) and require further expert consideration.

Postexposure rabies prophylaxis in previously unvaccinated persons includes wound cleansing and active immunization with rabies vaccine and passive immunization with human rabies immune globulin (HRIG). All animal bite wounds should be thoroughly cleaned with soap and water and, if available, a virucidal agent (e.g., povidine) should be used to irrigate the wounds. In the United States, four doses of rabies vaccine, which was recently reduced from five doses, are recommended on days 0, 3, 7, and 14 (59). Each 1.0 ml dose of vaccine should be given intramuscularly in the deltoid muscle. Two rabies vaccines are currently licensed in the United States and Canada: purified chicken embryo cell vaccine (PCECV) (RabAvert) and human diploid cell vaccine (Imovax). Pregnancy is not a contraindication for immunization. Local and mild systemic adverse effects are common. Local reactions include pain, erythema, edema, and pruritus; systemic reactions include fever, myalgias, headache, and nausea. Antiinflammatory medications and antipyretics may be used, but immunization should not be discontinued. The dose of HRIG is based on weight (20 IU per kg) and HRIG should be infiltrated into and around the wound and the remaining portion of the dose should be given intramuscularly in a different location (e.g., gluteal muscles) than where the vaccine is given. If there are multiple or extensive wounds and a large volume of HRIG is needed for infiltration, then HRIG may be diluted as required for satisfactory infiltration of all the wounds. HRIG should not be given later than 7 days after the first dose of rabies vaccine. Adverse effects of HRIG include local pain and low-grade fever. If HRIG is not available, then purified equine rabies immune globulin, which is much less expensive and more readily available in some rabies endemic countries (e.g., Thailand), may be used in the same manner at a dose of 40 IU/kg.

In persons at risk of rabies exposure, including laboratory workers, veterinarians, and travelers to places with endemic dog rabies (e.g., Asia and Africa), preexposure rabies immunization should be considered. Three doses of vaccine are given on days 0, 7, and 21. When prolonged protection is needed, booster doses of rabies vaccine can be given periodically as required, based on a serum neutralizing antirabies antibody titer. The perceived risk of exposure may determine the frequency of antibody testing (e.g., every six months to every two years). After a rabies exposure in preimmunized individuals, in addition to wound cleansing, two doses of rabies vaccine should be given on days 0 and 3; HRIG should not be given.

## MANAGEMENT OF HUMAN RABIES

Unfortunately, human rabies is virtually always fatal despite aggressive therapeutic attempts at therapy. Most survivors have received rabies vaccine prior to the onset of the clinical disease. The therapeutic options for consideration of an aggressive approach for a patient with rabies were evaluated by an expert group (60). Young and previously healthy patients with an early clinical diagnosis of rabies were felt to be the best potential candidates for aggressive therapy (60). Therapies that were suggested for consideration included rabies vaccine, human rabies immune globulin, monoclonal antibodies (for the future), ribavirin, interferon- $\alpha$ , and ketamine. It was felt that combination therapy might improve efficacy in situations in which specific therapies used

individually had failed in the past, similar to the situation for a variety of infectious (HIV and hepatitis C virus infections) and other noninfectious diseases (e.g., cancer).

A 15-year-old female survived rabies in 2004. She had been bitten on her finger by a bat and did not receive post-exposure prophylaxis therapy (61). About a month after the bite, she came to medical attention with typical clinical features of rabies encephalitis. On arrival to hospital in Milwaukee, Wisconsin neutralizing antirabies virus antibodies were present in both the serum and CSF (initially at titers of 1:102 and 1:47, respectively). Nuchal skin biopsies were negative for rabies virus antigen. Rabies virus RNA was not detected in saliva or in the skin biopsies using RT-PCR. She was intubated, and treated with a drug-induced coma, which included the noncompetitive *N*-methyl-D-aspartate

(NMDA) antagonist ketamine at 48 mg/kg/day as a continuous infusion, and intravenous midazolam for 7 days. She was maintained in a burst-suppression pattern on her electroencephalogram and given supplemental phenobarbital as needed. She was also treated with antiviral therapy, including intravenous ribavirin and amantadine 200 mg per day administered enterally. She improved and was subsequently discharged from hospital with neurologic deficits and later had further neurologic improvement (62).

This patient is the first documented rabies survivor who had not received any rabies vaccine prior to the onset of clinical rabies. However, it remains uncertain if therapy with one or more specific agents played any significant role in her favorable outcome (63). Since that time, there have been at least 31 cases in which the main components of this ap-

<sup>a</sup>Recovery of cases with atypical features of rabies without the development of rabies virus neutralizing antibodies have not been included because they are likely not cases of rabies (68, 123). A case reported by Rawat and Rao (124) was not sufficiently well-documented for inclusion.

<sup>b</sup>Patient died less than four years after developing rabies with marked neurological sequelae (L. Alvarez, personal communication).

<sup>c</sup>Patient died approximately two years after developing rabies with marked neurological sequelae (S. Mahusudana, personal communication).

proach (the “Milwaukee protocol”) were used with fatal outcomes (Table 2) (64). The induction of coma *per se* has no established benefit for the management of infectious diseases of the nervous system, and there is no evidence to date supporting this approach in rabies or other viral encephalitides. For this reason, therapeutic coma should not become a routine therapy for the management of rabies. Recent experimental evidence does not support a mechanism of excitotoxicity in a mouse model of rabies and also in rabies virus infection of cultured neurons, and there was also a lack of efficacy of ketamine therapy in cultured neurons and in the mouse model (65). Even in situations in which there is very strong experimental evidence of excitotoxicity in animal models, such as in stroke, numerous clinical trials in humans have failed to demonstrate efficacy of neuroprotective agents (66). This indicates that an effective neuroprotective effect of a therapy given to a single patient without a credible scientific rationale is highly doubtful. It is likely that this patient would have also recovered with only the supportive therapy.

Neutralizing antirabies virus antibodies are an important marker of an adaptive immune response that is essential for clearance of rabies virus and recovery (67). The presence of serum neutralizing antirabies virus antibodies early in a patient’s clinical course probably occurs in less than 20% of

patients with rabies and is likely an important factor contributing to a favorable outcome. There have been 11 survivors of rabies who received rabies vaccine prior to the onset of the disease, and only one without vaccine (Table 3). This observation suggests that an early immune response may be important for a positive outcome. Recovery of cases with atypical clinical features of rabies without the development of antirabies virus neutralizing antibodies (68, 69) were unlikely actual cases of rabies and these patients should not be considered survivors.

Bat rabies virus variants are probably less neurovirulent than canine virus variants or other variants that are responsible for most human cases of rabies (70), and there is less chance that human rabies due to canine rabies virus variants will have a favorable outcome than cases caused by bat rabies virus variants. The first well-documented survivor of rabies, who was also infected with a bat rabies virus variant, received rabies vaccine prior to the onset of disease and made an excellent neurological recovery (71). It is unknown if the causative bat rabies virus variant in the Milwaukee case was attenuated and had different biological properties than other isolated variants because no virus was isolated in this case. Diagnostic laboratory tests are usually negative for rabies virus antigen and RNA in fluids and tissues, and brain tissues are not normally tested in most survivors of rabies.

This may reflect effective viral clearance in which centrifugal spread of the infection to peripheral organ sites is reduced or very rapid clearance occurs through immune-mediated mechanisms.

Pathological data from a number of human rabies cases treated with the Milwaukee protocol have demonstrated that the therapy is not effective in clearing rabies virus infection from the brain and from preventing neuronal injury. A case from Edmonton (Canada) was treated with the Milwaukee protocol and after termination of the therapeutic coma, the patient remained in a brain death-like state for approximately four weeks (72). At autopsy, there was complete loss of neurons in the cerebral cortex and positive staining for rabies virus antigen was observed in both brainstem and cerebellar neurons, indicating a failure of clearance of the viral infection from the brain and also failure of protection against neuronal injury and loss (72). In Germany, lung and kidney/pancreas recipients from a rabies virus-infected donor developed rabies and were treated with major components of the Milwaukee protocol, including intravenous midazolam, ketamine, and phenobarbital (in one) (22). One patient died within 2 days, whereas the other survived 64 days after the onset of clinical rabies. At autopsy, the two patients had  $1.2 - 2.3 \times 10^9$  RNA copies/mg of CNS tissue, indicating ineffective viral clearance. The longer surviving patient showed viral clearance from systemic organs and peripheral nerves. Hence, the Milwaukee protocol therapy has proved ineffective in promoting viral clearance from the CNS in rabies. It now has become fairly clear that the Milwaukee protocol has no role at all in the management of human rabies. Unfortunately, promotion and repetition of this flawed therapy has likely already impeded progress in the development of new and effective therapies for rabies. A better understanding of basic mechanisms underlying rabies pathogenesis in humans and animals is needed, which may prove to be very helpful in the development of novel therapeutic approaches for the management of this dreaded disease.

## NONRABIES VIRUS LYSSAVIRUS INFECTIONS

Nonrabies virus lyssaviruses may cause fatal neurological illness that is clinically and pathologically indistinguishable from rabies. Mokola virus has been isolated from shrews, although the reservoir is unknown. In 1971, a 6-year-old girl died with Mokola virus infection (73); another case with mild illness was more likely due to cross-contamination of specimens in the laboratory (74). The index case of Duvenhage virus infection was transmitted by a bat and occurred in South Africa (75), and two additional cases were recently reported (76, 77). There have been two cases reported due to European bat lyssavirus 1 (78, 79) and another two cases due to European bat lyssavirus 2 (80, 81). In 1996 and 1998, cases due to Australian bat lyssavirus were likely transmitted by an insect-eating bat (82) and a fruit-eating bat (flying fox) (83), respectively, and there was another fatal case in 2013 (84). In 2007, a 20-year-old female died in the Primorye Territory, which is in the Russian Far East, due to Irkut virus, which had been previously isolated from a greater tubenosed bat (85).

## Vesiculovirus Infections

Therapy of VSV infection is symptomatic.

# Filoviruses

MIKE BRAY AND DANIEL S. CHERTOW

## 42

### INTRODUCTION

The filoviruses are nonsegmented, negative-sense RNA viruses in the family *Filoviridae*, order *Mononegavirales*. The genus *Marburgvirus* consists of a single species of related viruses, for which bats in Central Africa have recently been found to be a reservoir. The other genus, *Ebolavirus*, contains four species (Zaire, Sudan, Bundibugyo, and Ivory Coast) indigenous to Africa, and a fifth, Reston virus, found in the Philippines. It is likely that the African Ebola species are also maintained in bats, but attempts to recover infectious virus from captured animals have been unsuccessful. Except for the Reston agent, all filoviruses cause severe disease in humans, with fatality rates in outbreaks often exceeding 50%.

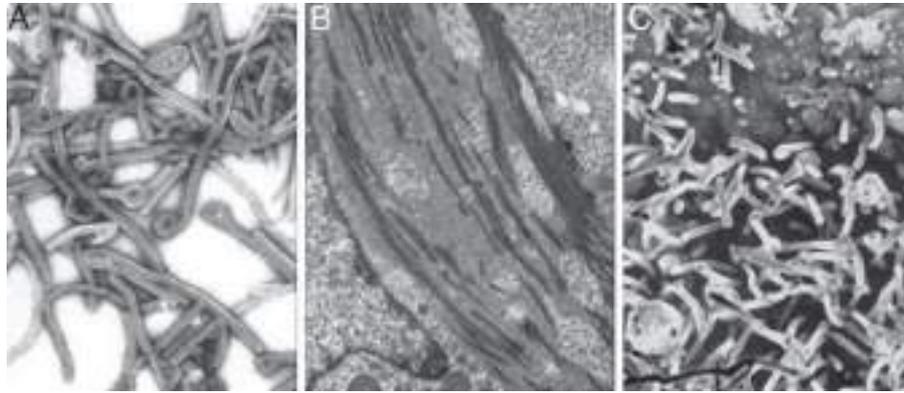

The first filovirus was recognized in 1967 when the inadvertent importation of infected monkeys from Uganda to a vaccine laboratory in Marburg, Germany led to an outbreak of fulminant illness in workers who came into contact with the animals or their tissues. The occurrence of fever and bleeding in many of the patients led to the classification of the new “Marburg virus” as an agent of viral hemorrhagic fever, a term first used by Russian scientists in the 1930s to designate certain zoonoses seen in the former Soviet Union. The unique filamentous morphology of the novel agent (Fig. 1) led to the designation of a new virus family. Extensive studies of animals trapped in Uganda failed to identify a natural reservoir.

In 1976, two almost simultaneous epidemics in Sudan and Zaire (the present Democratic Republic of the Congo) revealed the existence of the Ebola viruses. Over succeeding decades, some 25 outbreaks of Marburg or Ebola hemorrhagic fever, ranging in size from single infections to more than 400 cases, occurred sporadically across a region of Central Africa extending from the Sudan and Uganda to Gabon and Angola (Table 1, Fig. 2). Outbreaks were brought to an end through the combined efforts of local health care workers and international medical teams. Clinical and epidemiologic studies have found that the four African filovirus species cause similar syndromes, although mortality varies by species, and that person-to-person spread occurs only through direct contact with blood and other body fluids. In the absence of any vaccines or specific therapy, the medical response was based on identifying and isolating infected persons and their close contacts and providing basic supportive care while waiting for the outbreak to “burn out.”

In late 2013, the Zaire species of Ebola virus unexpectedly appeared in West Africa and was carried by chains of person-to-person transmission from a village in rural Guinea to the largest cities of Guinea, Liberia, and Sierra Leone. By mid-2014 the virus had killed more human beings than in all previous outbreaks combined. Efforts to halt the epidemic were hampered by the difficulty of recognizing Ebola patients against a background of malaria and other common febrile diseases and by the limited medical, public health, communications, and logistical resources in three of the world’s poorest countries. After a massive international response, including the construction and staffing of many dedicated treatment centers (Fig. 3), the epidemic began to decline. In mid-2015, new cases were still occurring, in several instances because of late sexual transmission from male survivors. WHO declared that Ebola transmission had ceased in all three affected countries by late December 2015, although enhanced vigilance for late-onset cases continued for 90 days (1).

The experience of the West African epidemic has brought about two significant changes in this chapter since the previous edition. The first is a major expansion of the sections devoted to the clinical syndrome and patient care. Before 2014, detailed descriptions of individual patients were limited to the 1967 Marburg outbreak, a few cases treated in South African hospitals, and some accidental laboratory infections, and reports of outbreaks contained only general summary data. The occurrence of more than 25,000 cases in the current epidemic, including more than 20 patients treated in the United States and Europe, has produced more detailed knowledge of the disease and approaches to its management that could scarcely have been imagined a year ago.

The second modification in this chapter since the last edition is a change in terminology: as clinicians in West Africa noted that significant bleeding is actually not a common finding in Ebola virus infection, the name of the syndrome has been changed from “Ebola hemorrhagic fever” to “Ebola virus disease.” This does not mean that the clinical syndrome differs from earlier outbreaks. Instead, the realization that coagulopathy is only part of the syndrome and that major hemorrhage is common only in the late stage of fatal cases has permitted clearer observation of other aspects of the disease, especially the profuse vomiting and diarrhea that frequently occur early in the course of illness that may

precipitate hypovolemic shock unless treated by prompt fluid replacement.

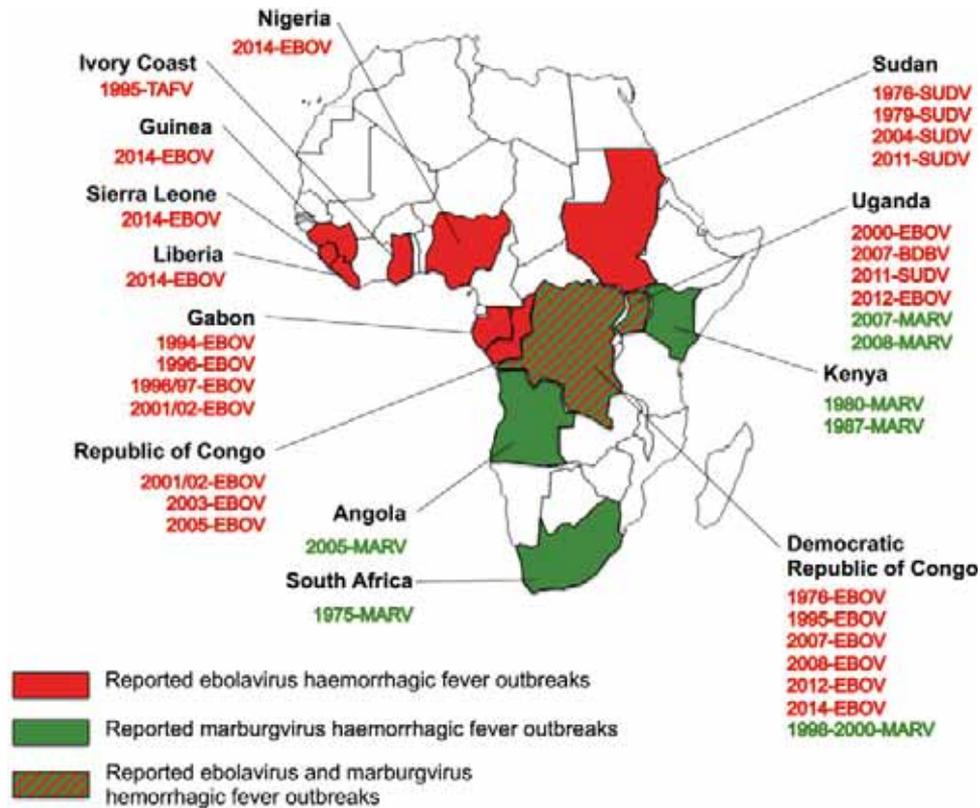

The West African epidemic also brought about the accelerated preclinical development and clinical testing of a number of drugs and vaccines, including the administration under emergency use protocols of a number of experimental

therapies, principally to accidentally infected Americans and Europeans evacuated to their home countries. Unfortunately, such advanced therapies did not arrive in time to prevent the deaths of nearly 1,000 African doctors and nurses who became infected while caring for patients. It can only be hoped that the experience of this devastating

**TABLE 1** Principal outbreaks and individual cases of filovirus disease and known cases and epidemics of filoviral hemorrhagic fever

Virus	Year	Location	Source of infection	Mode of person-to-person spread	No. of cases	CFR (%)

**FIGURE 2** Outbreaks of Marburg and Ebola virus disease in Africa, 1976–2014. All Marburg outbreaks have been caused by a single virus species. Most Ebola epidemics have been caused by the Zaire species (EBOV), with the Sudan virus (SUDV) responsible for a smaller number in East Africa. The Bundibugyo (BDBV) virus has been identified only in Uganda and the Ivory Coast virus in a single human infection in the Tai Forest in that country (TAFV). (Courtesy of Eric Leroy, CIRMF, Gabon. Reprinted with permission from Reference 180.)

epidemic will lead to the rebuilding and strengthening of the health care system in West Africa so that such a sacrifice will never be repeated.

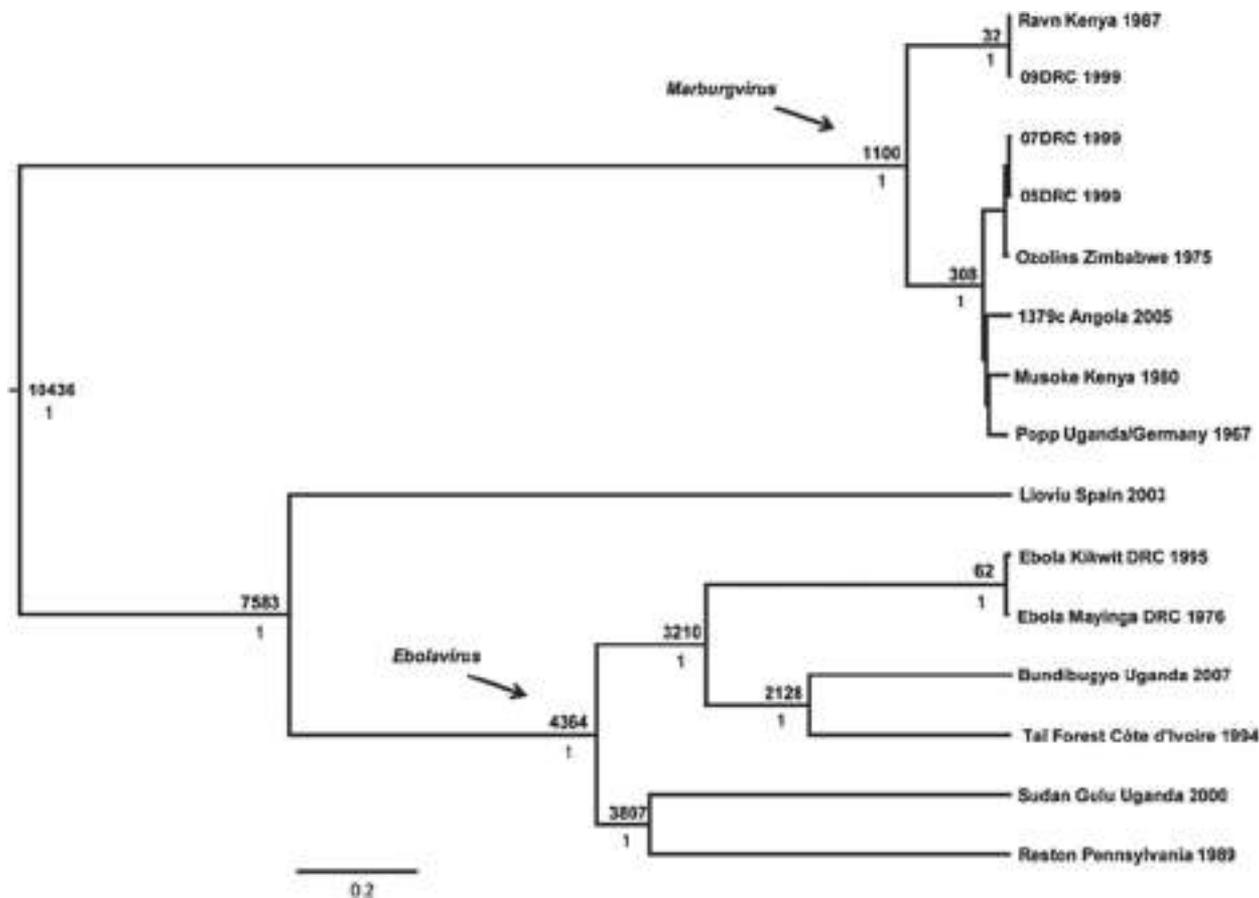

**FIGURE 3** The iconic figure of the West African Ebola epidemic: a health care worker in full personal protective equipment (PPE). The outbreak began in a rural village in Guinea in late 2013, then spread to the largest cities of Guinea, Sierra Leone, and Liberia. By January, 2016, more than 28,000 suspected, probable, and confirmed cases had been reported—more than 10 times the total of all previous Ebola epidemics combined—and 11,000 deaths (181) (Photo provided by Médecins Sans Frontières, used with permission.)

## VIROLOGY

### Phylogenetic Classification

The family *Filoviridae* contains three genera, *Marburgvirus*, *Ebolavirus*, and *Cuevavirus*, which are almost identical in genomic organization but differ extensively in nucleotide sequence. A recent phylogenetic analysis has placed the most recent common ancestor of the filoviruses some 10,000 years in the past (Fig. 4). The genus *Cuevavirus* is represented by a single species, *Lloviavirus*, which to date has been detected only as RNA sequences in the tissues of bats in Spain (2).

Although the Marburg viruses show some sequence divergence between the Ravn and Lake Victoria strains, they are still sufficiently closely related that only one species is recognized, and a recombinant vaccine based on the Musoke strain cross-protected macaques against the Angola and Ravn strains (3). In contrast, the genus *Ebolavirus* contains five species: Sudan, Bundibugyo, Reston, Côte d'Ivoire, and Zaire, now designated simply *Ebolavirus*. The earliest evolutionary divergence produced the ancestor of the Reston and Sudan species, while later pathways led to the more closely related Zaire, Bundibugyo, and Tai Forest viruses. The Makona strain of *Ebolavirus* responsible for the West African epidemic has an overall 97% sequence identity with

**FIGURE 4** Bayesian coalescent analysis of genomic sequences of the *Filoviridae*, based on representative viruses chosen from each *Ebolavirus* species and a diverse set of *Marburgvirus* isolates. Values at each node represent years since most recent common ancestor, prior to 2007. The tree indicates the early divergence of the genera *Marburgvirus*, *Cueavavirus*, and *Ebolavirus*. Although the Marburg Ravn and Musoke viruses have followed a separate evolutionary course for approximately 1,000 years, they are still more closely related to each other than any two species in the genus *Ebolavirus*. The Sudan and Reston viruses are the most distantly related to other Ebola viruses. (Reprinted from Reference 182 with permission.)

strains isolated earlier in the Democratic Republic of the Congo (DRC) and Gabon (4). The cellular replication mechanisms of Ebola and Marburg viruses differ only in the makeup of the replication complex and production of the surface glycoprotein (GP), as described below.

### Composition of Virus

Filoviral virions are long, filamentous structures that measure 80 nm in diameter but can range in length from 800 to more than 10,000 nm. Individual particles appear straight, branched, or U shaped when viewed by electron microscopy (Fig. 1). The outer surface of the virion is made up of a lipid bilayer derived from the host cell, in which trimeric spikes of the virion GP are embedded (Fig. 5A) (5). The central core is composed of a helical nucleocapsid, consisting of the genome and its encapsidating proteins, nucleoprotein (NP), VP35, and VP30. The nucleocapsid is linked to the inner surface of the envelope by the major matrix protein, VP40, and a minor protein, VP24. The RNA-dependent RNA polymerase, or L protein, is also carried within the virion.

### Genome

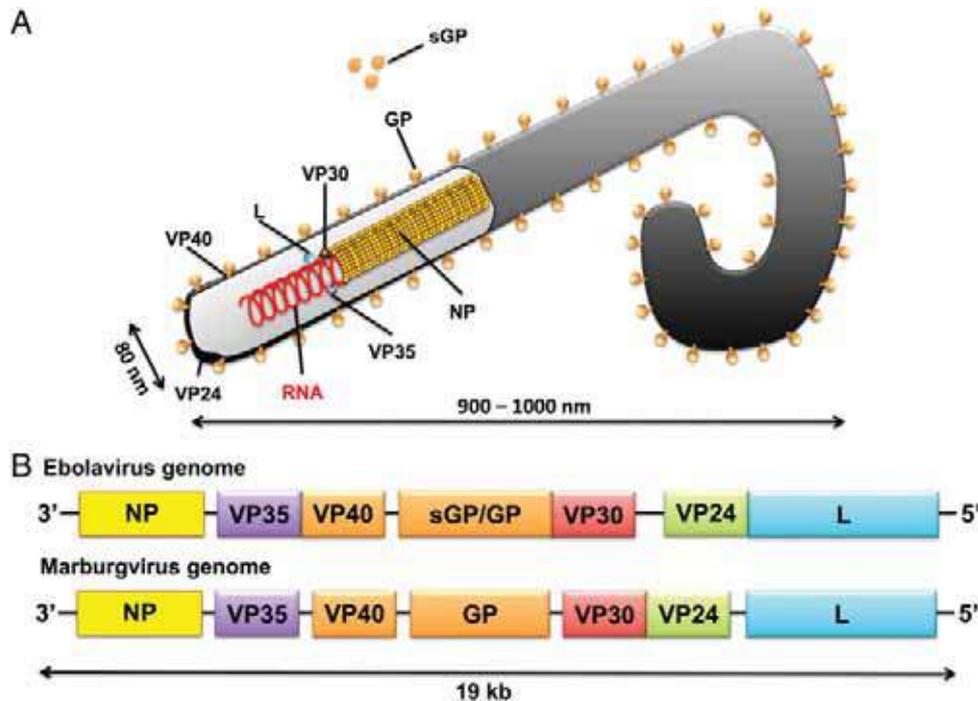

The filoviruses have the longest genomes of the *Mono-negavirales*, averaging just over 19 kb. The 3' and 5' ends

contain conserved, complementary sequences, which are involved in the initiation of transcription and genome replication. The order of the seven genes resembles that of the rhabdoviruses and paramyxoviruses (Fig. 5B). Most genes possess long noncoding regions at their 3' and 5' ends. A conserved UAAUU transcriptional signal is present at the 5' end of start sites and the 3' end of stop sites.

### Major Structural and Regulatory Proteins

#### Surface Glycoprotein

The surface of filoviral virions bears a single type of GP that is responsible for interactions with host cells and is the primary target for neutralizing antibodies (Fig. 5A). The Marburg virus GP is expressed from a single open reading frame. In contrast, all Ebola virus species encode their surface GPs in two contiguous reading frames, which are offset by a single nucleotide (5). The major product, encoded by the upstream reading frame, is a C-terminally truncated version of GP that lacks a hydrophobic membrane anchor and is secreted from infected cells (sGP). Full-length protein is expressed only when the RNA polymerase “stutters” while transcribing a series of seven U’s at a so-called “editing site” and inserts an additional adenosine. This site is absent from

**FIGURE 5** A. Structure of a filovirus virion, showing the RNA genome with its associated nucleocapsid proteins, enveloped in a lipid bilayer bearing glycoprotein spikes. NP and VP30 bind to virion RNA to make up the nucleocapsid, and VP35 and the RNA polymerase (L protein) join them in forming a replication complex. Matrix proteins VP24 and VP40 link the nucleocapsid to GP on the inner surface of the envelope. B. Schematic representation of the genomes of Marburg and Ebola viruses. The seven genes are drawn roughly to scale. (Courtesy of Eric Leroy, CIRMF, Gabon. Reprinted from Reference 180 with permission.)

the Marburg virus GP gene. Although it has been argued that sGP somehow contributes to the virulence of the Ebola viruses, its absence from the equally virulent Marburg virus argues against any significant role in pathogenesis.

Both sGP and the full-length molecule undergo extensive N- and O-linked glycosylation in the Golgi apparatus and are then cleaved by a furin-like enzyme into two segments that remain linked by a disulfide bond. The final membrane-bound product (GP<sub>1,2</sub>) is composed of the 140-kDa GP<sub>1</sub>, which is responsible for receptor binding and the 26-kDa membrane-anchored GP<sub>2</sub>, which contains a hydrophobic stretch of amino acids that fuses with the host cell membrane (6). GP<sub>1,2</sub> molecules aggregate into homotrimers on the virion surface. Some GP is cleaved by a cellular metalloprotease, tumor necrosis factor- $\alpha$  converting enzyme, and released into the circulation; this “shed GP” has been shown to bind to dendritic cells and macrophages, inducing the secretion of a range of pro- and antiinflammatory cytokines and the expression of cell-surface costimulatory molecules (7).

### Matrix Proteins

The matrix protein, VP40, is the most abundant protein in the virion and is the driving force behind the assembly and release of new viral particles from infected cells (6, 8). Like homologous proteins of other viruses, VP40 has evolved to resemble a host cell protein by acquiring a “late domain” sequence that is recognized by elements of the vesicular protein-sorting machinery, particularly Tsg101 and the ubiquitin ligase Nedd4, permitting interactions with microtubules that carry VP40 to the cell membrane. There it associates with cholesterol-rich lipid rafts, which serve as organizing centers for virion formation (9).

### Nucleocapsid

The filoviral nucleocapsid is a tubular structure 50 nm in diameter, with a central axial channel (Fig. 5A). Its principal component is the NP, a roughly 100-kDa phosphoprotein whose hydrophobic N-terminal segment binds to genomic RNA. When VP24 and VP35 are coexpressed, structures form that closely resemble nucleocapsids in virus-infected cells. In the presence of VP40, nucleocapsids move to the inner surface of the cell membrane, demonstrating the critical role of that protein in assembling structures required for virion budding.

### Nonstructural/Regulatory Proteins

Two filovirus nonstructural proteins make important contributions to virulence through the evasion of innate immune responses. VP35 inhibits cellular recognition of viral dsRNA, thus preventing the initiation of a type I interferon (IFN) response, while VP24 interferes with the transport of phosphorylated STAT1 into the nucleus, so that infected cells do not respond to exogenous type I IFN (10, 11).

### Biology

#### Replication Strategy

The mannose-rich oligosaccharides on the Ebola and Marburg virus surface GPs bind to widely distributed C-type lectins, including DC-SIGN and L-SIGN, but specific entry receptors have not been identified. Following internalization in a macropinosome, GP is “primed” for membrane fusion through cleavage by cathepsins B and L, which remove more than half of the molecule, including the mucin-like domain. Endosomal acidification then leads to triggering of membrane fusion, in a process that requires the Niemann-Pick

(NP) C1 protein; mice lacking NPC1 are solidly resistant to an otherwise lethal Ebola virus challenge (12, 13). Virions enter coated pits and are enveloped by endocytic vesicles; acidification then leads to a conformational change in GP<sub>2</sub>, exposing hydrophobic amino acids that carry out membrane fusion, resulting in release of virion contents into the cytoplasm.

Transcription of viral genes is performed in the case of Marburg virus by a replication complex consisting of NP, VP35, and the L protein (polymerase), while that of Ebola virus also includes VP30 (14). Transcription begins at the 3' end of the genome, producing a leader RNA and seven polyadenylated mRNAs. Production of virion proteins continues until the accumulation of a gene product, probably NP or VP30, triggers the synthesis of complementary copies of the viral genome that serve as templates for replication. As new genomes form, they become encapsidated by NP and other proteins to produce nucleocapsids, which form parallel aggregates in eosinophilic cytoplasmic inclusion bodies (Fig. 1B). Meanwhile, new GP<sub>1,2</sub> molecules emerging from the Golgi apparatus migrate to lipid rafts, where association with VP40 and nucleocapsids causes assembly and extrusion of new virions (Fig. 1C) (15).

### Host Range and Natural Reservoir

Although the first known filovirus outbreak resulted from the introduction of monkeys from Africa into Europe, and the use of virus-infected chimpanzees or gorillas as food by residents of Central Africa has triggered several small epidemics, it is clear that those animals (and in fact no primate species) can be a natural reservoir: Marburg and all five species of Ebola virus have caused severe disease in all primate species tested in the laboratory. However, a recent study found antibodies to Ebola virus in the feces of some 10% of wild apes in the Republic of the Congo, suggesting some animals might survive infection (16). Analysis of wild animal carcasses in Gabon and the Republic of the Congo found PCR evidence of Ebola virus infection in several gorillas and chimpanzees, and in a single duiker (17). It now appears most likely that the filoviruses are maintained in one or more species of small animals that are widely distributed in Central and West Africa, and that wild primates, like humans, become infected through contact with those animals.

Because many single cases and outbreaks over the years have been associated with exposure to bats, they have long been the leading candidates for the natural reservoir. A study following the 1995 Kikwit Ebola outbreak provided support for this hypothesis: inoculation of the causative agent produced persistent viremia but no visible illness in several species of fruit and insectivorous bats (18). More recently, Marburg virus was isolated directly from *Rousettus aegypticus* bats captured in caves in Uganda where human exposures had occurred (19). Studies of these bats in their natural cave environment have revealed periodic shedding of virus by juveniles during the birthing season (20). Captive bats inoculated with a low-passage bat-derived virus became viremic and shed infectious virus in oral secretions (21).

Parallel efforts to identify Ebola virus in bats trapped in a number of sites in Central Africa have detected circulating antibodies and viral RNA in body fluids and tissues but infectious virus has not been recovered (22, 23). People living in rural West Africa are frequently in contact with bats or their excretions, suggesting that the current epidemic arose through exposure of the index case to the body fluids of an infected bat (24). Studies in Gabon and the Republic of the Congo have found that dogs that consume the meat of

Ebola-infected animals become seropositive without becoming ill, suggesting they might be a source of human infection (25). There is no evidence of transmission of Ebola or Marburg virus by mosquitoes or other biting arthropods.

### Animal Models

Wild-type filoviruses do not cause disease in rabbits, rats, mice, hamsters, guinea pigs, or other common laboratory animals. However, sequential passage of Marburg virus in guinea pigs quickly resulted in the acquisition of lethal virulence for the animals. Ebola Zaire and Ebola Sudan viruses have been adapted to guinea pigs in similar fashion (26, 27). Similarly, a virus that is lethal for adult mice was obtained by serially passaging Ebola virus from the 1976 Zaire outbreak in progressively older suckling mice (28). This variant is more effective at suppressing murine type I interferon responses than wild-type virus; conversely, it appears to be attenuated for nonhuman primates (29). The mouse-adapted virus also causes severe illness in Syrian hamsters, with more features of coagulopathy than are observed in mice (30). Studies of filovirus replication, including antiviral drug testing, have also employed wild-type viruses and knockout mice deficient in type I interferon function, either through loss of the cell-surface IFN- $\alpha/\beta$  receptor or the cellular STAT1 protein (31, 32).

All filoviruses cause severe disease in captive nonhuman primates that resembles the illness in humans (33). Recent preclinical studies of the efficacy of vaccines, antivirals, and monoclonal antibodies have made use of rhesus and cynomolgus macaques (34–36). Infection of these animals with the Marburg virus or any of the species of Ebola virus produce a similar syndrome, with the onset of lassitude and inactivity 2 to 3 days after infection, followed by the progressive onset of shock. Minor evidence of coagulation defects, such as conjunctival bleeding, are common, but frank bleeding is rare. Changes in coagulation parameters, serum chemistry values, white blood cell and platelet numbers, and circulating cytokine levels resemble those observed in human patients.

### Growth in Cell Culture

All studies of live Ebola or Marburg virus replication in cell culture must be performed in Biosafety Level 4 containment. Filoviruses replicate to high titers in many types of cultured cells. Plaque assays for virus titration based on uptake of the vital dye, neutral red, are performed using the Vero E6 cell line. Ebola Zaire and some isolates of Marburg virus cause the death of these cells through necrosis, while the Sudan, Reston, and Ivory Coast strains of Ebola virus are less cytopathic. Syncytium formation is not observed.

### Inactivation by Physical and Chemical Agents

Filoviruses are relatively stable in aqueous suspensions and may remain infectious for at least several days in body fluids or when dried on surfaces, or for several weeks at a temperature of 4°C (37, 38). In a study focusing on the persistence of infectious virus in body fluids postmortem, infectious virus was detected in swabs of the oral mucosa of macaques fatally infected with the Zaire or West African Makona strain of Ebola virus for up to a week after death (39). Infectious virus was recovered from blood obtained one week postmortem, and viral RNA was detected for up to nine weeks.

Virus-containing material can be inactivated by treatment with standard bleach solutions, formaldehyde, or phenolic or quaternary ammonium disinfectants. In outbreak settings, bleach diluted in water is most commonly

used for disinfection. For example, in Ebola treatment units (ETUs) operated by Médecins Sans Frontières (MSF), 0.5% active chlorine is used to disinfect personal protective equipment and the environment, and 0.05% active chlorine is used to disinfect body surfaces. A list of EPA registered disinfectants that meet CDC criteria for use against Ebola viruses on hard nonporous surfaces is available (40).

## EPIDEMIOLOGY

Single cases or small clusters of filovirus disease have presumably occurred among residents of Central Africa for millennia, but large outbreaks apparently were not seen before the second half of the 20th century. Paradoxically, their appearance was in part a consequence of the construction of clinics and hospitals, which in the absence of proper infection control measures have facilitated person-to-person spread of virus. The vastly larger size of the current West African epidemic does not reflect a change in *Zaire ebolavirus* or its mode of transmission; instead, it has resulted from the introduction of the disease into urban settings in three extremely poor countries that lack the resources needed to control its spread.

### Distribution and Geography

Outbreaks of Marburg and Ebola virus disease have occurred over a region of Africa extending roughly 10° to either side of the equator (Table 1, Fig. 2). They have not been restricted to any one type of vegetation pattern or topography. The sporadic and unpredictable occurrence of the disease is consistent with the circulation of the virus among bats with a wide geographic range.

### Incidence and Prevalence of Infection

Table 1 lists principal outbreaks of Marburg and Ebola virus disease, beginning with the 1967 Marburg epidemic. Current evidence indicates that Marburg virus and the Zaire and Sudan subtypes of Ebola usually cause severe disease in humans, but mild or even asymptomatic infections may occur. Some serologic surveys beginning in the 1970s reported prevalences of antifilovirus antibodies exceeding 20% among residents of Central Africa, but the absence of any corresponding disease in the same areas suggested a lack of assay specificity (41). However, more recent serosurveys using more specific enzyme-linked immunosorbent assay methods (ELISA) detected IgG antibodies in some 10% of residents of villages in proximity to the 1995 *Zaire ebolavirus* outbreak in the Democratic Republic of the Congo and IgM antibodies to Ebola and Marburg viruses in the sera of 8% to 9% of patients in Sierra Leone being screened for Lassa fever (42). A 1996 study in Gabon found proinflammatory cytokines and specific antibody responses in a small number of family caregivers during an Ebola outbreak in 1996, in the absence of recognized illness (43). Taken together, these studies provide evidence for the occurrence of mild or asymptomatic infections in filovirus-endemic regions of Africa.

### Epidemic Patterns

Outbreaks of filovirus disease in humans have followed four different patterns. In the first, infection results from close contact with bats. As noted above, this source of infection has only been proven for Marburg virus, which has infected miners and tourists exposed to large populations of bats in caves in Uganda and the Democratic Republic of the Congo (44).

In the second pattern, which characterized both the original Marburg outbreak in Europe (45) and a number of

Ebola epidemics in the border region between Gabon and the Democratic Republic of the Congo, humans have acquired disease through direct contact with filovirus-infected nonhuman primates. Several outbreaks have resulted from the butchering and consumption of chimpanzees or gorillas found sick or dead in the forest, leading to a point-source epidemic (46, 47). The source of infection of great apes has not been proven, but it may result from exposure to infected fruit bats when the animals share food sources (22, 48).

In the third, hospital-based pattern, the disease is recognized when a sick individual is admitted to a hospital lacking basic infection control practices so that the disease spreads to doctors, nurses and other patients. As described below, this was first observed in the Ebola Zaire outbreak in 1976, when the reuse of contaminated syringes simultaneously infected all patients in a mission hospital, and in the 1995 Kikwit epidemic, when a surgical team operated on an unrecognized Ebola patient (49, 50).

In the fourth pattern, exemplified by the current West African epidemic, a filovirus is introduced by an index case infected from an unknown source, then spreads person-to-person within a community when family members and others care for a sick person, prepare a deceased individual for burial, or engage in risk behaviors during the burial process. Because such funeral practices may involve hands-on contact by many persons, they can lead to explosive epidemic spread.

### Marburg Virus Disease

The first recognized filovirus outbreak occurred in 1967, when *cercopithecus* macaques were imported from Uganda to Marburg and Frankfurt, Germany and to Belgrade, Yugoslavia as a source of primary kidney cells for polio vaccine production. Although the animals appeared well on arrival, 25 people who tended them or processed their tissues developed a severe hemorrhagic disease (45). Six doctors and nurses became infected; 7 of the 31 total cases were fatal. Follow-up studies in Uganda failed to reveal the source of the virus. During the next 31 years, only six Marburg virus infections were detected. The first was in a hitchhiker who arrived in South Africa from Rhodesia in 1975; infection also spread to his traveling companion and to a nurse where the two were treated (51). Cases also occurred in 1980 and 1987 in persons who had visited a cave in western Kenya inhabited by large numbers of bats.

The first known Marburg epidemic in Africa was detected in 1998 among men working in bat-infested mines in the Durba/Watsa area of eastern Democratic Republic of the Congo (44). Sequence analysis found that several strains of virus had been introduced on separate occasions into the affected community, suggesting repeated exposure to the virus-containing excreta of a mixed population of bats. In 2007, a cluster of cases occurred in Uganda in miners exposed to bats. In separate incidents in the following years, an American and a Dutch tourist who entered a bat-infested cave developed Marburg virus disease; one died of the disease, while the other recovered and was diagnosed retrospectively (52).

The largest epidemic of Marburg virus disease to date occurred in 2005 in Angola, when the agent was somehow introduced into the pediatric ward of Uige provincial hospital, causing a wave of lethal illness among the young patients, possibly through the use of contaminated transfusion equipment. The epidemic then spread to nurses, doctors, and family caregivers and into the surrounding community (53).

## Ebola Virus Disease

*Zaire ebolavirus*

The first recognized outbreak occurred in June, 1976 at a missionary hospital in Yambuku, close to the Ebola River in northern Zaire (the present Democratic Republic of the Congo) (49). It began when an infected person was admitted to the hospital, and rapid nosocomial spread took place through the reuse of unsterilized glass syringes. The epidemic was further amplified when doctors, nurses, and family members also became infected, but it eventually “burned out” without outside intervention. Another hospital-based outbreak in 1995 in Kikwit, Democratic Republic of the Congo began when an individual with abdominal pain and bloody diarrhea underwent surgery, spreading infection to the operating team (50). The causative agent proved to be almost identical in sequence to that which caused the 1976 epidemic. The epidemic spread as hospital staff and family members came into direct contact with patients; it ended when local and international health workers established an isolation center and instituted rigorous infection control measures.

Over the following decade, additional epidemics occurred in the border region of Gabon and the Democratic Republic of the Congo, when gorillas or chimpanzees sick or dead from Ebola virus infection were consumed as “bush meat” (47). Studies by primatologists have found evidence of drastic reductions in the local populations of these animals, suggesting extensive virus spread (54). Some additional outbreaks in the Democratic Republic of the Congo during the period 2000–2010 appeared to be linked to bat exposures (55); samples from captured bats yielded Ebola RNA sequences but no infectious virus. The case fatality rates of outbreaks caused by *Zaire ebolavirus* during the period 1976–2013 frequently exceeded 70%.

The largest Ebola epidemic in history began in December 2013 when an infant in the village of Gueckedou, Guinea became ill, presumably following exposure to an infected bat. The virus spread to his family members, then was carried by chains of person-to-person transmission to multiple sites within Guinea. In March 2014, the outbreak was recognized by the government and by an MSF unit working in the country (4). After initial control efforts by local and foreign responders, the outbreak appeared to have been halted, but it was then discovered that infected individuals had traveled to Liberia and Sierra Leone, carrying the disease with them. By the summer, Ebola virus was spreading rapidly through the largest cities of the three countries abetted by the lack of medical and public health resources in one of the world’s poorest regions. By fall, a massive international response helped create a large number of centers for the diagnosis and treatment of Ebola patients, staffed jointly by African and international medical workers (Figs. 6A, 6B).

A retrospective analysis found that the institution of treatment units has played a critical role in slowing the spread of the epidemic, preventing many thousands of cases (56). In addition to isolating patients and thereby reducing virus transmission, treatment units attempt to provide as much supportive care as possible. Although data on patient outcomes are limited, it appears that the overall case fatality rate for the epidemic is in the range of 30% to 40%, lower than what might have been expected based on previous experience in Central Africa (Table 1).

Several studies have examined the basic reproductive rate ( $R_0$ )—the number of persons to whom an infected individual is likely to transmit the disease—for Ebola Zaire

**FIGURE 6** The West African Ebola epidemic: patient care in a low-resource setting. A. Medical workers preparing to enter an Ebola treatment unit. ELWA-3, the largest Ebola treatment center ever constructed, built by Médecins Sans Frontières adjacent to the ELWA mission hospital in Monrovia, Liberia. The center is designed to isolate persons possibly incubating Ebola virus disease, treat those who have become ill, and prevent the further spread of infection. (Médecins Sans Frontières, used with permission.)

virus. A review of epidemiological parameters noted that estimates of  $R_0$  for past outbreaks had ranged from 1.4 to 4.7, while estimates for the West African epidemic had generally ranged from 1.2 to 2.5 (57). Traditional funerals have been a source of large numbers of infections, and the institution of safer practices is an important intervention to reduce transmission (58). The introduction of ETUs has both improved survival and reduced the spread of virus; in Liberia,  $R_0$  decreased from 1.7 early in the epidemic to 0.1 after isolation and treatment became available (59).

*Sudan ebolavirus*

In the 1976 epidemic in Sudan, the first cases were seen among workers in a cloth factory in Nzara, which harbored large numbers of bats. Once the first patients were hospitalized, the virus spread to medical staff and family members (60). The largest Ebola Sudan epidemic occurred in Uganda in 2000, with more than 400 cases. An initial chain of transmission went unrecognized until student nurses in Gulu hospital began to develop a severe hemorrhagic illness. Because of the approximately 50% case fatality rate and the availability of several serum samples on many patients, retrospective analysis has identified a number of biomarkers predictive of survival or death (61–64).

#### *Côte d'Ivoire ebolavirus*

In 1994, an ethologist studying chimpanzees in the Tai Forest of Côte d'Ivoire performed a necropsy on a recently dead animal, and 6 days later she became severely ill (65). The diagnosis of Ebola virus disease was made only after she had been evacuated to Switzerland; she survived, and no secondary transmission occurred. Despite its geographic origin, this virus is unrelated to the Zaire strain that caused the West African epidemic.

#### *Bundibugyo ebolavirus*

The fourth species of *ebolavirus* was identified in August 2007, when an outbreak of severe febrile disease occurred in western Uganda (66). The agent differed significantly from other Ebola species, but was distantly related to the Ivory Coast virus. The fatality rate of 25% among 149 confirmed cases was lower than that previously seen for the Zaire and Sudan viruses. Another outbreak occurred in eastern Democratic Republic of the Congo in late 2012, apparently originating from contact with bush meat; the case fatality rate was just over 50% (67).

#### *Reston ebolavirus*

The fifth Ebola species was recognized in 1989, when cynomolgus macaques imported from the Philippines to a quarantine facility in Reston, VA, developed a severe hemorrhagic illness, and electron microscopy examination of specimens unexpectedly revealed a filovirus (68). Several more outbreaks occurred over the following six years at other

laboratories supplied by the source in the Philippines, but they stopped once the latter ceased operations. No illness was seen in workers who had been exposed to sick animals, but several were later found to have antibodies to the agent, suggesting that they had asymptomatic infection. The Reston agent is a distinct species of Ebola virus, which may have been exported from Africa at some time in the past. In 2009, the virus was unexpectedly detected in Philippine pigs (69); a local survey found antibodies in a small percentage of farmers with no history of severe illness. In contrast to its lack of virulence for humans, the Reston virus is highly pathogenic for laboratory primates.

#### Age-Specific Attack Rates

Prior to 2014, nearly all patients in outbreaks of filovirus disease in Africa were adults, probably because children are relatively unlikely to participate in the two activities by which individuals are most likely to become infected: hands-on patient care and preparation of a cadaver for burial. In contrast, infections in young children have been more common in the West African Ebola epidemic, possibly reflecting the very large number of infected persons and the occurrence of virus transmission within families. Recent analyses suggest that children differ from adults in their susceptibility to fatal Ebola virus disease. Patients under the age of 21 years have had lower case fatality than individuals over the age of 45 years (70, 71). However, children under 5 years of age are more likely to die than older children, with case-fatality rates approaching 90% (72).

#### Routes of Transmission and Risk Groups

Bats are known to have been the source of infection in a number of single cases and outbreaks of Marburg virus disease; the same or related species have presumably played a similar role in initiating some Ebola epidemics, but this remains unproven. Many people in West Africa have frequent contact with bats, providing opportunities for virus transfer (24). Exposure of wild apes to bat excretions presumably lies behind outbreaks that have resulted from their consumption as bush meat.

Once a human case has occurred through direct or indirect exposure to an infected animal, secondary infections follow when family members or medical workers caring for patients become contaminated with virus-containing body fluids. Nurses and doctors have played the tragic role of "sentinels" in several large hospital-based outbreaks, when patients with unrecognized filovirus disease were treated in the absence of infection control measures. The lack of such precautions can be explained in part by the fact that the most common severe febrile syndromes in Central Africa, such as malaria and yellow fever, are not transmitted by direct contact.

#### Transmission Routes

Filoviruses replicate principally in macrophages and dendritic cells, which are present in large numbers in the dermis and submucosal tissues; all body fluids will therefore contain virus. In addition, the body surface of a sick individual is often contaminated with virus-containing blood, vomitus, or feces, and replication in sweat glands and other dermal structures may deliver more virus to the skin. Infection may therefore readily be acquired by touching a patient, whether living or deceased, followed by transfer of virus from the hands to the mouth or eyes. During the West African epidemic, numerous episodes have been reported in which the ritual preparation of a cadaver for funeral services and subsequent touching of

the skin by mourners resulted in extensive transmission. These “super-spreading” events may have played a major role in the explosive expansion of the outbreak.

There is no evidence that filovirus disease spreads from person to person by any route other than direct contact with infectious body fluids. Although virus is present in the saliva and pulmonary secretions of patients, airborne transmission has not been proven in humans. Experimental infection via small particle aerosols ( $\leq 5 \mu\text{m}$ ) has been demonstrated in the laboratory in rodents and nonhuman primates (73, 74). Secondary transmission of *Zaire ebolavirus* has been demonstrated between pigs and from pigs to nonhuman primates although these experiments did not distinguish between small versus larger ( $> 5 \mu\text{m}$ ) particle transmission (75, 76). Because blood and other body fluids can be aerosolized during medical procedures, all workers must use respiratory protection to avoid even a low risk of infection. The presence of virus in the breast milk of Ebola-infected mothers places infants at high risk of acquiring the disease (77).

### Nosocomial Infection

The occurrence of large hospital-based epidemics of filovirus disease in Central Africa, beginning in 1976, has illustrated the potentially catastrophic consequences of bringing large numbers of sick people into close proximity in the absence of basic infection control regimens. Nosocomial infections were also common in the early phase of the West African epidemic, when doctors and nurses were either unaware that they were caring for Ebola patients, attempted to care for colleagues or family members outside of ETUs, or lacked the personal protective equipment and training in appropriate use to protect themselves against virus transfer. Fortunately, the incidence of nosocomial infection has decreased, as health care personnel in West Africa have been provided with personal protective equipment and training in their use. Accidental infection of three critical-care nurses has occurred during the treatment of Ebola patients evacuated to the United States and Spain; all survived their disease (78, 79).

Interestingly, the experience of nosocomial infections with filoviruses prior to the West African epidemic showed that the admission of a patient with unrecognized filovirus disease to a hospital with good hygienic practices typically resulted in few secondary infections. Thus, even though the doctors and nurses who cared for patients in the 1967 Marburg outbreak knew nothing about the novel disease or its mode of spread, only six of them became infected, and no tertiary transmission occurred (45). Similarly, the admission of a Marburg virus-infected traveler to a South African hospital in 1975 led to only a single case in an attending nurse (51). Two decades later, a Gabonese physician with unrecognized Ebola virus disease was treated without special precautions in a South African hospital, and only one member of the medical staff became infected (80). These histories suggest that basic measures, such as the use of gloves and hand washing, are the most important factors in preventing filovirus infection.

Readers should refer to publications on the websites of the US Centers for Disease Control and Prevention (<http://www.cdc.gov/vhf/ebola/about.html>) and the World Health Organization (<http://www.who.int/csr/disease/ebola/en/>) for current recommendations during travel, hospital care, and convalescence.

### Duration of Infectiousness

In patients who survive filovirus disease, viremia tends to resolve by the end of the second week of illness, but some

excretion may continue in the urine, and infectious virus may persist for weeks to months in “immunologically privileged” sites such as the seminiferous tubules of the testes, the anterior chamber of the eyes, and the central nervous system (see below). Following the 1967 Marburg outbreak, a patient who had recovered sufficiently to leave the hospital infected his wife, apparently through sexual intercourse (45).

The potential for transmission of Ebola virus by convalescent patients, months after their release from hospital, has caused concern that new cases may recur in regions free of the disease. After the 1995 Kikwit outbreak, some vaginal, rectal, and conjunctival swabs from one female patient were positive by reverse-transcription polymerase chain reaction (RT-PCR) at day 33, and virus was recovered from the semen of a male patient 82 days after disease onset (81). Similar observations have been made during the current West African epidemic. The semen of one male survivor in Sierra Leone was positive by RT-PCR 284 days after symptom onset (82). One instance of transmission of Ebola infection from a convalescent male to a sexual partner was proven by sequencing of virus from both individuals (83); in other cases, sexual transmission has been suspected but not proven by molecular testing (84). The ability of specific antiviral therapy to speed the clearance of infectious virus has not been investigated.

### PATHOGENESIS IN HUMANS

The fulminant course and high case fatality rate of Ebola and Marburg virus diseases result from a combination of factors (85):

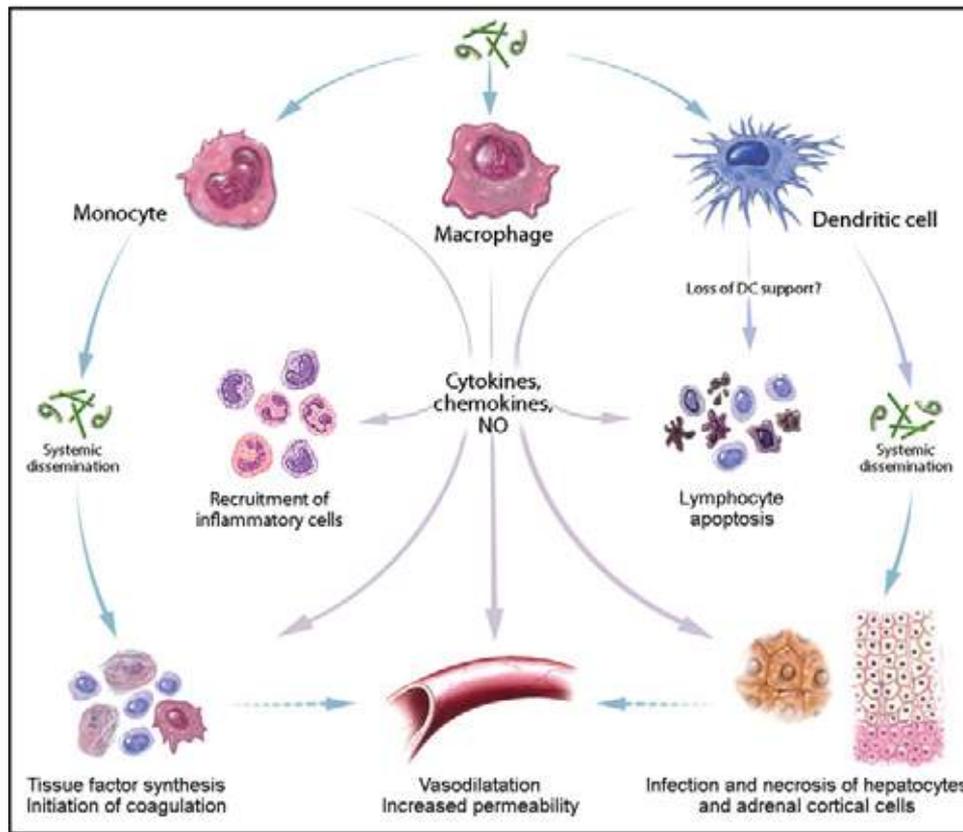

- The ability of filoviruses to suppress type I IFN responses and spread rapidly to macrophages, dendritic cells, and other cells throughout the body;
- The local and systemic effects of mediators released from infected cells, which may include acute gastrointestinal dysfunction;
- Fluid loss through vomiting and diarrhea, which may lead to hypovolemic shock;
- Extensive tissue damage caused by necrosis of infected cells;
- Impairment of adaptive immune responses, permitting uncontrolled viremia;
- Coagulation defects that accompany systemic inflammation and contribute to tissue ischemia.

Hemorrhage may occur, but bleeding is rarely the cause of death.

### Patterns of Virus Replication

Filoviruses use macrophages and dendritic cells as their principal sites of replication (Fig. 8). Rapid viral replication and systemic spread are facilitated by two viral proteins that suppress type I interferon responses: VP35 inhibits IFN production by the infected cell, while VP24 blocks the response to exogenous IFN (11, 86). Infected macrophages migrate to local lymph nodes, while free virions released into the lymph and bloodstream disseminate to fixed macrophages in the liver, spleen, and other tissues, from which infection then spreads to hepatocytes, fibroblasts, and other cell types.

Because laboratory animal models of filovirus infection are characterized by uniform lethality, information on the relationship between levels of virus replication and outcomes can be obtained only from studies in filovirus outbreaks. A retrospective study of the outbreak of *Sudan ebolavirus* infection in Gulu, Uganda found that patients

**FIGURE 8** Pathogenesis of filovirus disease. Monocytes, macrophages, and dendritic cells are the primary sites of replication. Suppression of type I interferon responses permits rapid virus dissemination via the bloodstream to the spleen and other lymphoid tissues and to hepatocytes and parenchymal cells of other organs, resulting in further productive infection and multifocal necrosis. The release of proinflammatory mediators, the production of cell-surface tissue factor, and endothelial dysfunction contribute to coagulopathy, organ-specific vascular leak (e.g. lungs), and eventual multi-organ failure. Lymphocytes remain uninfected but undergo apoptosis, contributing to the failure of adaptive immune responses. Note: observations in patients during the West African Ebola outbreak suggest that damage to renal parenchymal cells and injury within the central nervous system plays a significant role in pathogenesis.

who died had circulating virus titers (“viral load”) averaging 100-fold higher than those who survived (87). The positive correlation between the level of circulating virus and the likelihood of a fatal outcome has been confirmed in studies of cohorts of patients in the West African epidemic (70, 71). For example, a report from Sierra Leone based on 2,700 blood samples found that levels of viral RNA at the time of diagnosis were on average 100-fold lower in those who would survive their disease than in fatal cases (88). In another study, tracking of individual patients showed that survivors had significantly lower peak viremia levels than nonsurvivors and reached that level earlier (89). A decline from the peak level was observed in both groups, but it was more rapid in survivors. A third report stratified case fatality rates by the mean level of viremia during the first week of illness; for those with  $<10^4.4$  copies/mL, the CFR was 21%, but it was 81% for those with  $>10^5.2$  copies/mL (90). Because of the strong effect of circulating virus titer on disease outcome, future studies of novel therapies should be stratified by viremia level.

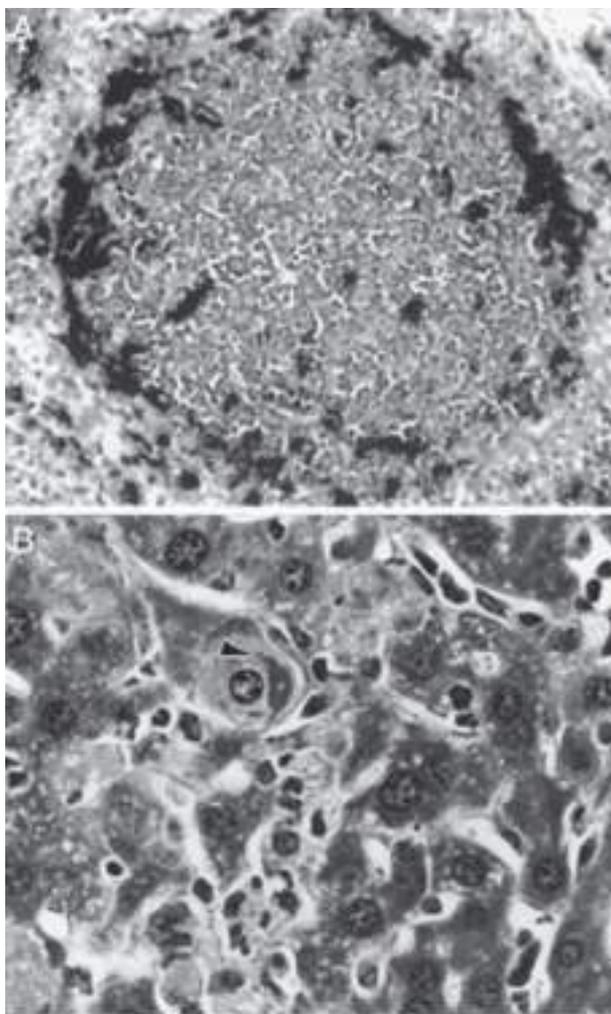

In addition to the widespread infection of macrophages and other cells and the systemic effects of circulating inflammatory mediators, the frequency of renal insufficiency and neurologic abnormalities in patients with Ebola virus disease suggests that these organs are also direct targets of

viral infection. Filoviruses apparently do not replicate in lymphocytes, but massive numbers undergo apoptosis during the course of illness (91). In infected macaques, this consists of the early loss of natural killer (NK) cells, followed by  $CD8^+$  and  $CD4^+$  T cells; similar changes occur in mice (92).

The increased vascular permeability seen in filovirus disease was at one time attributed to direct infection and injury of the endothelial lining of blood vessels, but experimental studies in nonhuman primates have found no evidence of viral replication in these cells until late in the disease course and that the endothelium remains relatively intact even at terminal stages of disease (93). Retrospective assessment of cases of Ebola Sudan virus infection found that elevated serum levels of cytokines and chemokines, including IL-6, IL-8, IL-10, and MIP-1 $\beta$ , and of molecules associated with coagulopathy and altered endothelial function, including D-dimers, thrombomodulin, sICAM, and sVCAM, are associated with a fatal outcome (61, 64, 94, 95). Similarly, because there is little evidence of viral injury of the mucosal epithelium or submucosal tissues of the gastrointestinal tract (85), it appears that the vomiting and profuse diarrhea seen in many Ebola patients are also induced indirectly through viral or host-derived mediators.

### Histopathological Features

Pathological changes in the tissues of filovirus-infected humans and animals can be divided into those caused directly by viral replication and those produced indirectly through host responses to infection (Fig. 8) (96). Among the former, the most prominent abnormality is the necrosis of virus-infected macrophages and dendritic cells in lymph nodes, thymus, spleen, liver, and other lymphoid organs, disrupting their normal architecture (Fig. 9A). Dissemination to parenchymal cells in the liver and other tissues also causes extensive injury. In the liver, virus spreads from Kupffer cells to hepatocytes, producing innumerable small foci of necrosis (Fig. 9B). Infected cells contain eosinophilic viral inclusion bodies, consisting of masses of viral nucleocapsids. Viral infection and necrosis of dermal cells and structures, including hair follicles and sweat glands, is apparently responsible for the extensive desquamation frequently seen in convalescent patients (97) (Fig. 10).

**FIGURE 9** Replication of mouse-adapted Ebola virus in a lethally infected mouse. A. *In situ* hybridization of viral RNA in a splenic follicle; all marginal-zone macrophages contain replicating virus, while lymphocytes remain uninfected. B. Multifocal necrosis in the liver. Some hepatocytes contain acidophilic inclusion bodies (arrow), corresponding to the nucleocapsid aggregates shown in Figure 2B. (Courtesy of Tammy Gibb and Kelly Davis, USAMRIID.)

**FIGURE 10** Extensive desquamation of the forearm and hand of a survivor of Ebola Sudan virus infection in Gulu, Uganda, 3 weeks after disease onset. (Courtesy of Dan Bausch, Tulane University.)

Histopathologic changes that result indirectly from filovirus infection can be separated into two categories. The first consists of manifestations of disseminated intravascular coagulation (DIC). Studies in laboratory primates have shown that the expression of cell-surface tissue factor causes infected macrophages to become encased in fibrin, most prominently in the spleen and other lymphoid tissues (98). Fibrin deposits are also seen in glomeruli and proximal tubules of the kidneys. The development of DIC also leads to perivascular and interstitial hemorrhage, most prominently in the bladder and in the lining of the gastrointestinal tract.

The second type of indirect injury in filovirus infection is the death of large numbers of uninfected lymphocytes in germinal centers of lymph nodes and lymphoid follicles of the spleen and thymus (91). Massive lymphocytolysis is a nonspecific accompaniment of septic shock and other types of severe infection, apparently induced by proapoptotic mediators and the disruption of normal physiological mechanisms that regulate lymphocyte populations (99). In combination with the destruction of dendritic cells and other antigen-presenting cells, lymphocyte apoptosis may prevent the generation of adaptive immune responses needed to eliminate viral infection.

### Immune Responses

#### Nonspecific Responses: Cytokines and Other Proinflammatory Mediators

Cultured human macrophages infected with *Zaire ebolavirus* release the proinflammatory cytokines and chemokines tumor necrosis factor alpha (TNF- $\alpha$ ), interleukin 6 (IL-6), macrophage inflammatory protein 1a (MIP-1 $\alpha$ ), MIP-1 $\beta$ , alpha interferon (IFN- $\alpha$ ), and RANTES into the growth medium (100). The same mediators, plus IFN- $\beta$ , IFN- $\gamma$ , and IL-18, and the potent vasodilator nitric oxide (NO) are present in the plasma of Ebola virus-infected nonhuman primates, and high levels of proinflammatory cytokines have also been detected in serum samples from acutely ill patients in African outbreaks (61, 101). NO levels were especially high in fatal cases in the 2000 Ebola Sudan outbreak (61).

The expression of cell-surface tissue factor by infected macrophages also plays a critical role in producing DIC by triggering the extrinsic coagulation pathway (98). Because tissue factor production begins with the first infected

macrophage, coagulopathy can be detected early in the disease course. In macaques, D-dimers are the first disease marker detected in the plasma, and they are extremely elevated in the plasma of patients dying from Ebola virus disease (94, 98).

### Specific Immune Responses

Most fatally infected Ebola patients have persistent high-level viremia, usually without a detectable antibody response. In contrast, patients who survive the disease develop virus-specific IgM and IgG responses, generally during the second week of illness (41, 87). These antibodies are evidently long-lasting, because a retrospective study of survivors of the 2000 Ebola Sudan epidemic observed neutralizing antibodies in some individuals up to 10 years after infection (102). Cell-mediated immunity also plays an important role in survival: sequential blood samples from four accidentally infected medical workers who were successfully treated at Emory University Hospital showed intense activation of both Ebola virus specific and nonspecific B and T cells, with large numbers of circulating plasmablasts and high percentages of activated CD4+ and CD8+ T cells, accompanied by production of virus-specific antibodies (103). These observations are consistent with our current understanding of pathogenesis, in which Ebola survivors are those who manage to mobilize an early adaptive immune response, while fatal cases fail to do so, at least in part from the destruction of infected dendritic cells and the loss of lymphocytes through apoptosis.

### Correlates of Disease Resolution

Efforts to identify features of filovirus disease and host responses that are predictive of survival have greatly expanded with the epidemic in West Africa. The principal finding has been that the ability of the patient's immune system to control viral replication is the fundamental determinant of survival: those who develop a virus-specific antibody response, typically in the second week of illness, will control and eliminate the agent, while patients lacking such a response will have continuous, high-level viremia until death (41, 61). Young patients who have a relatively low viral load at the time of presentation to a medical facility are most likely to survive; the development of severe diarrhea and markedly elevated serum creatinine values, indicative of renal failure, are principal predictors of a fatal outcome (70).

The roughly 50% survival rate in outbreak of Ebola Sudan virus infection in Gulu, Uganda made it possible to examine whether human genetic variation might influence the outcome of infection (61). Sequence-based HLA-B typing of isolated leukocytes showed that alleles B\*67 and B\*15 were linked to a fatal outcome, while B\*07 and B\*14 were more common in survivors. Such research has not yet been reported from the epidemic in West Africa, but the large number of patient samples and data on the course and outcome of illness should make such investigation possible.

## CLINICAL MANIFESTATIONS

Prior to 2014, detailed descriptions of filovirus disease could only be found in clinical reports from the 1967 Marburg outbreak, a few patients hospitalized in South Africa and a handful of accidental laboratory infections. In contrast, the West African epidemic has been accompanied by a large number of articles describing the clinical features of patients. Our comparison of early and recent reports has led us to the following conclusions:

- Marburg and the various species of Ebola virus cause similar clinical syndromes, differing principally in the case fatality rate.
- The disease that has occurred since late 2013 in West Africa resembles that observed in prior outbreaks in Central Africa.

As noted previously, Marburg and Ebola virus infections were classified by those who first studied them as types of "viral hemorrhagic fever," employing terminology introduced in the 1930s. Once filovirus disease had received that label, researchers studying laboratory animals and physicians caring for patients tended to focus on the development of coagulation defects and bleeding, even while recording that fatal hemorrhage was relatively rare. Other aspects of the filovirus syndrome, including the vomiting and profuse diarrhea seen in many patients in West Africa, were noted in clinical reports, but given relatively little attention.

Typical features of Ebola virus disease and associated abnormalities in laboratory tests are listed in Table 2. In contrast to earlier descriptions of "Ebola hemorrhagic fever," in which shock was attributed to diffuse vascular leak, clinicians now recognize that severe fluid loss from vomiting and diarrhea early in the course of illness may lead rapidly to shock, while the hemorrhage that was once assumed to be a major cause of death is relatively rare.

### Incubation Period

The incubation period of Ebola virus disease averages 6 to 12 days (range 2 to 21 days), followed by the onset of fever, generalized malaise, fatigue, and body aches. Although "asymptomatic" infections in persons in close contact with Ebola patients were described in a report from Gabon in 2000 (43), such cases have not been reported since. Findings described by organ system are noted below.

### Gastrointestinal

Large-volume watery diarrhea is a common feature of Ebola virus disease, often accompanied by episodes of severe nausea and vomiting, which may result in significant intravascular volume depletion (70, 104, 105). Diarrhea begins within 5 days of fever onset, and 5 or more liters of stool per day may be produced. Watery consistency of diarrhea and a large stool volume suggest a small-bowel, and possibly a whole-bowel, secretory process (106). Mild inflammation has been observed in the lamina propria of fatal cases, suggesting an inflammatory component, although confirmatory clinical studies evaluating for fecal leukocytes or lactoferrin have not been reported (85).

Oral ulcers, dysphagia, and odynophagia may contribute to decreased oral intake. Severe upper and/or lower gastrointestinal bleeding occurs in about 5% of patients, typically just before death. Reports of elevated serum amylase levels in the setting of abdominal pain suggest that pancreatitis may also complicate the disease (107).

### Neurologic

Patients with Ebola virus disease frequently develop profound neuromuscular weakness and pain, manifested by loss of energy and strength, beginning before or shortly after fever onset (108). Weakness develops acutely, is typically symmetrical, and is often progressive, involving both upper and lower extremities. Postural instability contributes to difficulty walking, and in severe cases respiratory muscle dysfunction results in ineffective ventilation. Myositis contributes to muscle pain and weakness with creatinine phosphokinase

**TABLE 2** Clinical and laboratory manifestations of Ebola virus disease

Stage of illness	Time post-onset	Clinical	Laboratory
Early febrile	Days 1–3	Fever, malaise, fatigue, body aches	Decreased WBC, lymphocyte and platelet counts Elevated AST, ALT, hemoglobin, and hematocrit
Gastro-intestinal	Days 3–10	Primary: Epigastric and abdominal pain, nausea, vomiting, diarrhea Associated: Persistent fever, asthenia, conjunctival injection, chest pain, dysphagia, odynophagia, arthralgia, myalgia, hiccups, delirium, rash	Leukocytosis (increased neutrophils and band cells) Persistently elevated AST/ALT, thrombocytopenia Increased BUN, creatinine, hypo or hyper kalemia, hypomagnesemia Hyponatremia, albuminemia Elevated PT/PTT/INR and fibrin split products
Shock, organ failure, and other complications	Days 7–12	Renal and/or respiratory failure (oliguria, anuria, tachypnea) Encephalopathy and/or meningoencephalitis, (diminished consciousness, agitation, stiff neck, seizures) Secondary bacterial infection GI hemorrhage	Findings may overlap with prior stages of illness. In addition to previous findings: Elevated lactate Decreased bicarbonate, Hb, HCT Hypoxemia
Recovery	Days 7–12	Resolution of abnormal signs and symptoms, increased oral intake, energy	Resolution of laboratory abnormalities
Convalescence	Up to six months	Arthralgia, myalgia, fatigue, abdominal pain, uveitis, hearing loss, neuro-cognitive abnormalities	

Abbreviations: WBC: white blood cell; AST: aspartate aminotransferase; ALT: alanine aminotransferase; BUN: blood urea nitrogen; PT: prothrombin time; PTT: partial thromboplastin time; INR: international normalizing ratio; Hb: hemoglobin; HCT: hematocrit.

elevations observed between 300 and 3,500 international units/L (71). More significant elevations, consistent with rhabdomyolysis, typically in the 10,000 to 25,000 IU/L range (109), have not been reported, suggesting that profound weakness cannot be attributed to myositis alone.

Delirium occurs during the peak of illness and may manifest as disorientation with difficulty arousing, confusion, or combativeness. Encephalopathy may be attributable to viral infection of the CNS, secondary host responses, or metabolic derangements, including high or low serum sodium levels, hypoglycemia, or uremia. Panencephalitis has been documented in Ebola-infected nonhuman primates (110) and in two fatal human cases of Marburg virus disease (85). Meningoencephalitis is manifested by headache, neck rigidity, delirium, and diminished consciousness typically during acute illness or early after initial recovery (105, 111, 112).

Seizures occur in approximately 5% of cases, typically as preterminal events (70). Intractable vomiting and occasionally hiccups are also observed. Despite the development of profound acute neurologic abnormalities, patients with EVD who receive adequate supportive care may achieve near-complete recovery (113).

### Ocular

Individuals may manifest signs and symptoms of uveitis (e.g., blurred vision, photophobia, blindness) during the acute illness (114). However, the etiology of these findings remains unclear, because detailed ophthalmologic examination including funduscopy, have not been reported.

### Cardiac

Ebola virus can infect the endocardium, and clinical pericarditis and myocardial dysfunction have been reported (115, 116). However, the contribution of viral infection to

structural or functional cardiac abnormalities has not been well characterized. Heart-rate responses in patients are frequently lower than would be expected in the setting of high fever and dehydration (107), which may result in an underestimation of intravascular volume depletion and diminished cardiac compensatory ability in the setting of shock. Peripheral edema may be observed in the setting of aggressive fluid resuscitation and low serum albumin levels, following renal failure, or in the setting of secondary bacterial sepsis resulting in vasodilatory shock.

Sudden death of uncertain etiology has occurred in West African Ebola patients who appeared to be recovering (105). Some of these deaths may be the result of low serum magnesium or potassium levels, which in combination with haloperidol, quinolone antibiotics, ondansetron, lumefantrine for malaria prophylaxis, and other drugs that prolong the QT interval, may predispose to the arrhythmia known as “torsade de pointes.”

### Respiratory

Probably because filoviruses do not induce upper respiratory tract symptoms and thorough assessment of the lungs is often not possible in low-resource settings, respiratory complications have largely gone unrecognized. However, the viruses are known to infect alveolar macrophages and pulmonary endothelial and interstitial cells (85). Lower respiratory tract complications, including multifactorial respiratory failure, have been observed in patients treated in high-resource settings (79, 116, 117).

Pulmonary injury results in noncardiogenic interstitial pulmonary edema and pleural effusions, which may be made worse by aggressive fluid resuscitation (79). Neuromuscular weakness predisposes to atelectasis, aspiration, and secondary bacterial pneumonia, as well as ineffective or dead-space ventilation, manifested by rapid, shallow breathing.

Multifactorial hypoxia and ineffective ventilation contribute to the development of respiratory failure (Fig. 7).

### Hepatic

Moderate to severe hepatitis typically begins early in the disease course, worsens progressively, and then improves with declining viral burden. Serum aspartate aminotransferase (AST) levels becomes elevated more than alanine aminotransferase (ALT) levels, typically in a 3:1 or greater ratio, suggesting some AST elevation may derive from sources other than liver (e.g., muscle) (70, 107). Multifocal necrosis with minimal inflammation is observed pathologically, with infection of hepatocytes, sinusoidal endothelial cells, and resident Kupffer cells (85). However, fulminant hepatitis with profound elevation in transaminases has not been reported. Elevated serum bilirubin may occur in the absence of jaundice, probably resulting from intrahepatic cholestasis following hepatocellular injury.

Hypoglycemia, hypoalbuminemia, and clotting abnormalities are observed in severe disease. This suggests hepatic synthetic dysfunction, but severe hypoglycemia is more likely the result of acute depletion of liver and muscle glycogen and increased metabolic demand in the setting of critical illness. Rather than being the result of diminished hepatic production, albumin may be lost in stool and urine, and clotting defects are more likely attributable to consumption of coagulation factors.

### Genitourinary

Renal insufficiency is common in Ebola virus disease, leading to renal failure in severe and fatal cases. The etiology of acute kidney injury is likely multifactorial. Autopsies have shown that the virus infects renal tubular and glomerular endothelial cells, with evidence of acute tubular necrosis (85), which might be induced through direct cytotoxic injury, hypoperfusion due to shock, and/or microvascular abnormalities. Another contributing factor might be myoglobin-induced renal tubular injury due to muscle breakdown.

### Hematologic

Leukopenia develops early, probably related to the indirect killing and depletion of lymphocytes in the spleen, lymph nodes, and other lymphoid tissues. White blood cell counts then recover, resulting in a neutrophil-predominant leukocytosis. Platelet counts decline early in the disease, with nadirs in the range of 30,000/mm<sup>3</sup>. Bone marrow evaluation in fatal cases has shown normal megakaryocyte numbers, suggesting that thrombocytopenia results from consumption rather than diminished production (85). Reactive thrombocytosis may be observed during recovery (78).

Increases in prothrombin time, partial thromboplastin time, international normalizing ratio, and fibrin split products, with low fibrinogen levels, also suggest the presence of consumptive coagulopathy in severe cases. Elevated hemoglobin and hematocrit may be observed early in the course of illness, suggesting hemoconcentration. Anemia typically follows, perhaps attributable to hemodilution in the setting of fluid resuscitation, gastrointestinal blood loss or increased peripheral destruction due to hemolysis.

### Endocrine

Based on studies in laboratory animals, it has been postulated that adrenal infection and necrosis may play an important role in pathogenesis (118). Patients show non-specific signs and symptoms observed during adrenal insufficiency (e.g., lethargy, fever, vomiting, hypoglycemia).

However, physiology of shock in EVD appears most consistent with hypovolemia and not vasodilatory (distributive) shock that is classically observed in adrenal crisis. Distributive shock has been described in patients with secondary Gram-negative bacterial sepsis (111), and adrenal insufficiency should be considered in refractory shock (117).

### Skin

Patients with Ebola or Marburg virus disease often develop an erythematous, nonpruritic maculopapular rash on the trunk and extremities during the first week of illness; it is typically more apparent in light-skinned individuals. The rash typically becomes confluent and may desquamate (Fig. 10) (107). In the setting of thrombocytopenia, a self-limited petechial rash may also be observed in areas where pressure is applied to the soft tissues. Patients are predisposed to skin breakdown and pressure necrosis because of immobilization, poor nutrition, and low serum albumin levels.

### Concurrent Infections

Patients with filovirus disease may develop bacterial coinfections, leading to bacterial sepsis (111). Infrequent access to microbiologic testing has limited knowledge of the actual frequency of concurrent infections in outbreak settings and their contribution to overall mortality (119). The degree to which malaria, tuberculosis, HIV, and other chronic infections common in West Africa have added to morbidity and mortality during the current epidemic is also not known.

### Pregnancy

EVD during pregnancy is associated with high risk of fetal and maternal death, typically associated with severe hemorrhage (120). Atypical presentation may occur in pregnancy because fatal EVD has been reported in the absence of either reported or detected fever (121). No data are available to suggest a benefit of caesarean versus vaginal delivery, although survival of the mother following vaginal delivery has been reported (122). Viral RNA has been detected in placenta and fetal blood up to 7 days after clearance from maternal blood (122).

Strict infection control is required in the care of pregnant women with potential EVD exposures and for those in labor even after EVD recovery. Live virus has been detected in breast milk of infected mothers up to 16 days after EVD onset (38). Consequently, breastfeeding of susceptible infants should be avoided until risk of transmission can be ruled out.

### Late Complications and Sequelae

Long-term sequelae include blurred vision, retroorbital pain, hearing loss, neurocognitive deficits, sleep difficulties, fatigue, and arthralgias (123). Multiple studies of survivor cohorts for these and other medical problems are in progress.

Well-documented late complications of EVD, attributable to the persistence of virus in immune protected sites, include uveitis and meningoencephalitis. Ophthalmic complications in survivors of Ebola virus disease were first described after the 1995 Kikwit outbreak (114). One month or more into convalescence, patients developed eye pain and loss of visual acuity, and physical examination revealed uveitis. Similar cases have occurred in the current West African epidemic, and testing has found live virus in samples of aqueous humor months after clearance from the bloodstream (124). One case of late-onset meningoencephalitis beginning 10 months after initial clinical recovery has recently been described in which virus RNA was detected in CSF and blood; full recovery was seen after experimental

antiviral therapy (see below) (125). As discussed above, the persistence of virus in the semen of an Ebola survivor for up to six months resulted in sexual transmission (83).

### LABORATORY DIAGNOSIS

Diagnostic tests for filovirus infection are based on the detection of viral RNA or antigens in patient samples, or occasionally of a virus-specific antibody response (126). Because all symptomatic patients are viremic, serum is the best specimen for testing. The need to collect and process many thousands of blood samples during the current Ebola epidemic in West Africa has resulted in the creation of guidelines for diagnostic testing by the U.S. Centers for Disease Control and Prevention (<http://www.cdc.gov/vhf/ebola/diagnosis/index.html>).

#### Virus Isolation

Filovirus isolation through growth in cell culture has long been considered the “gold standard” for diagnosis, but it is performed more often for research than diagnostic purposes. Any deliberate propagation of virus must be performed in a BSL-4 containment laboratory under adequate biosafety conditions. Vero cells (usually the E6 clone) are most widely used to culture virus from clinical samples.

#### Antigen Detection

Before the development of nucleic acid-based methods, filovirus detection in field settings was often based on detection of viral antigens by antigen-capture ELISA because it could be performed without a source of electricity (41). In response to the need for rapid point-of-care diagnosis in the West African epidemic, a novel antigen-based assay has been developed that employs a finger-stick blood sample and gives a result in 15 minutes (127). In contrast to RT-PCR, which requires electrical power and skilled technicians, the ReEBOV™ Antigen Rapid Test (Corgenix Medical Corp.) can be performed in the field by local health workers. A blinded comparison of the assay with a standard RT-PCR method found that the point-of-care test correctly identified 92% of patients and 85% of uninfected controls. Information on additional antigen-based diagnostic assays is available on the WHO website (128). A diagnosis of Ebola or Marburg hemorrhagic fever can also be made postmortem through immunohistopathological study of a formalin-fixed skin biopsy sample (97).

#### Nucleic Acid Detection

The most sensitive diagnostic assay, which has been performed many thousands of times during the current Ebola outbreak, employs RT-PCR, usually in the modified form of real-time (quantitative) RT-PCR, which can provide a diagnosis and measurement of viral load in an inactivated patient specimen within two hours. Real-time RT-PCR is being employed both to confirm Ebola virus disease before admitting a patient to a treatment center and to discharge survivors from a center, after two negative tests have been obtained over at least 48 hours. The use of sequence-based assays has been facilitated by the close genetic relationship of the West African virus to earlier Zaire isolates and the origin of all chains of transmission from a single source.

RT-PCR was first used to diagnose Ebola virus disease in 2000 in Gabon (129), and real-time RT-PCR was introduced two years later (130). The new methods were more sensitive than antigen-based tests for rapid diagnosis. In the Gulu epidemic, RT-PCR identified infected patients 24 to 48 hours earlier than an ELISA method (61). As discussed

elsewhere, the quantitation of circulating virus has prognostic significance because fatally infected patients have persistently higher circulating viral titers, which remain elevated through death. It will likely also prove important in therapeutic monitoring with respect to antiviral interventions.

#### Serologic Assays

The detection of filovirus-specific antibodies in serum has been used both to diagnose patients during outbreaks and to assess the prevalence of exposure to filoviruses among various population groups. In patients with Ebola or Marburg virus disease, the development of a virus-specific antibody response is an important prognostic marker because those who fail to produce an antibody response by the second week of illness are unlikely to survive (41). IgM disappears from the serum during convalescence, but specific IgG persists for at least several years.

Serosurveys carried out in Central Africa during the 1980s made use of immunofluorescence assays, which had a high background level of positivity, suggesting a high prevalence of filovirus infection in regions where the disease had never been observed. The method has since been abandoned in favor of IgG ELISA for population screening, but even this more specific test has given a positive signal in samples from persons outside of Africa. For the results of a serosurvey to be meaningful, the specificity of the assay must be proven by including numerous control samples from people outside the region of interest.

### PREVENTION

#### General

In Africa, primary filovirus infections of humans occur only as a result of direct or indirect contact with chronically infected bats or with sick or dead nonhuman primates. Prevention efforts in endemic areas focus on preventing such contact. Access to some abandoned mines and caves in Uganda and the Democratic Republic of the Congo inhabited by infected bats has been blocked and residents warned of the danger of bat exposure. In regions of Central Africa where Ebola virus disease is endemic, educational efforts have been initiated to warn local residents of the danger posed by gorillas, chimpanzees, and other animals found sick or dead in the forest.

#### Active Immunization

Studies in nonhuman primates have shown that exposure to the antigens of the two filoviral genera does not induce cross-protective immune responses: vaccines that protect macaques against Marburg virus are inactive against the Ebola viruses and vice-versa. Significant antigenic differences also exist among the various Ebola virus species. Because the Zaire and Sudan viruses have caused nearly all outbreaks, experimental vaccine formulations have contained antigens of one or both species.

Successful immunization of nonhuman primates against Ebola virus was first demonstrated in 2000, when macaques that had received three doses of a DNA vaccine encoding the Zaire *ebolavirus* surface GP, followed by one dose of a recombinant replication-deficient human adenovirus-5 encoding the same antigen, were protected against an otherwise lethal virus challenge (131). It was subsequently found that the Ad-5 vaccine given alone was sufficient to induce rapid protection (132). A few years later, recombinant vesicular stomatitis virus (VSV) vaccines encoding the

Marburg or Ebola virus GP were also shown to induce rapid protection in macaques (133–135). A number of other vaccine platforms have also been shown to protect nonhuman primates against Marburg or Ebola virus, but all of them have required more than one vaccine dose to elicit solid immunity. The current status of Ebola vaccine platforms can be determined from the latest update of the WHO report of research and development of drugs, vaccines, and diagnostics (136). However, because a fast-acting vaccine was clearly needed in response to the expanding Ebola epidemic in West Africa, the adenovirus- and VSV-vectored vaccines were given priority for development. The following discussion therefore focuses on these two approaches.

Few humans have been naturally exposed to VSV but adenovirus infections are common, and researchers have therefore been concerned that preexisting immunity to the vector might reduce the immunogenicity of a recombinant adenovirus vaccine. This proved to be the case in the first Phase I trial of an Ad5 Ebola vaccine, which detected significantly lower antibody responses to the Ebola Zaire GP in vaccinees whose serum contained antibodies to Ad5 (137). Because antibodies to Ad5 are common in all human populations and almost universal in Africa (138), developers evaluated two other human serotypes, Ad26 and Ad35, to which human populations show much lower antibody prevalence, as vectors for Ebola GP expression. However, an initial evaluation of an Ad26-vectored Ebola Zaire vaccine in macaques observed only partial protection in animals that had received a single vaccination, although full protection was achieved by boosting with the same antigen encoded by Ad35 (139).

In the meantime, other workers had found that adenoviruses isolated from chimpanzees were highly immunogenic (140); a chimpanzee adenovirus, ChAd3, as a vector for a *Zaire ebolavirus* vaccine provided rapid, uniform protection in macaques after a single immunization (141). Resistance to challenge waned after several months, but solid immunity was reestablished by boosting with a quadrivalent modified vaccinia Ankara (MVA) vector encoding the GP of the Zaire, Sudan, and Tai Forest Ebola species and of Marburg virus. No safety concerns were identified in dose-ranging Phase I studies in the United States and in West Africa (142); a dose of  $10^{11}$  viral particles elicited antibody responses expected to be protective in a field setting. Boosting with the tetravalent MVA vaccine was also well tolerated. Although such a prime-boost strategy could not be used to elicit rapid protection during an outbreak, it could provide durable, broad-spectrum immunity in laboratory researchers and medical workers who might respond to future epidemics.

As noted above, recombinant vesicular stomatitis virus (rVSV) vaccines encoding the Marburg or Ebola virus GP induce rapid protection in rodent and primates models (133–135). They are also able to prevent mortality or prolong the time to death of macaques when administered one week before virus challenge or soon after (< 1 hour for Ebola [143] but up to 48 hours for Marburg [144]), properties that are highly desirable in the setting of an epidemic. However, in contrast to vaccines based on replication-defective adenoviruses, rVSV vaccines employ a live, replication-competent virus that circulates in the bloodstream during the first few days postvaccination, potentially inducing illness and fever resembling the onset of filovirus infection. Phase I trials of a recombinant VSV Ebola vaccine observed transient viremia in most subjects and fever in about one third; at one study site, 22% of subjects developed transient arthritis in the second week, and some also developed lo-

calized skin vesicles; the vaccine virus was identified in vesicular fluid of two vaccinees and synovial fluid of one (145, 146). Disabling but self-limited systemic illness, fever, and viremia were also observed in a physician given a 5-fold higher dose of the rVSV vaccine as post-exposure prophylaxis (147).

Following a careful risk-benefit assessment, the rVSV Ebola vaccine was advanced to a controlled evaluation of efficacy in Guinea. Investigators employed a novel cluster-randomized “ring vaccination” strategy, in which the diagnosis of a new case of Ebola virus disease was followed by the immediate identification of the patient’s contacts and their contacts; adults within each such “cluster” were then randomized either to immediate rVSV vaccination or vaccination after 21 days (148). No cases of Ebola virus disease with onset 10 or more days after randomization were seen in the immediately vaccinated contacts compared to 16 cases in those who received delayed vaccination (direct vaccine efficacy 100%; 95% CI, 74.7%–100%), and there was some evidence for an indirect benefit for nonimmunized persons within clusters. This success led to early termination of the trial, and the vaccine is now being administered to all patient contacts.

The adenovirus and rVSV vaccine platforms differ in the mechanism of induced immunity. A study in nonhuman primates found that resistance to Ebola virus elicited by a recombinant adenovirus vaccine was based primarily on CD8+ T cells, and an antibody response was not required (149). Macaques immunized with the rVSV Ebola vaccine do not develop significant levels of neutralizing antibodies; instead, protection correlates with the titer of antigen-binding antibodies, as measured by ELISA (150). Its efficacy also does not require a cell-mediated immune response, as macaques depleted of CD8+ T cells were still protected (151).

Immunogenicity, including durability of responses, and safety data are being generated from other studies of ChAd3-, rVSV-, Ad26-, and MVA-vectored Ebola virus vaccines. MVA boosting of the ChAd3 vaccine provides a marked increase in antibody titers and is expected to significantly lengthen protective immunity (152). An NIH-sponsored large-scale, placebo-controlled trial of the ChAd3- and VSV-vectored vaccines (“PREVAIL”) began in Liberia in early 2015 (153). An unblinded, randomized trial of the VSV Ebola vaccine (“STRIVE”) was also initiated in Sierra Leone (154).

### Postexposure Prophylaxis

Antiviral drugs or antibodies that have shown therapeutic efficacy against filoviruses in laboratory animals might be used to prevent illness in persons who have suffered high-risk virus exposures. A UK report described four medical workers in the West African epidemic who had needle-stick injuries and were treated with the novel antiviral favipiravir, with or without a monoclonal antibody preparation; none became ill (155). Immediate postexposure treatment with favipiravir has been advocated in field settings but not subjected to rigorous testing (156).

Immunization with a fast-acting vaccine is also a potential means of postexposure prophylaxis. As noted above, an rVSV vaccine encoding the Marburg surface glycoprotein protected macaques when inoculated 30 minutes after an injection of Marburg virus and provided partial protection as late as 48 hours after an otherwise uniformly lethal virus exposure, while rVSV vaccines against Ebola viruses prevented death of 50% of animals when administered 20 to 30 minutes after Zaire or

Sudan virus challenge (135, 143, 145, 146, 157). The rVSV-Zaire ebolavirus vaccine has been given to several accidentally exposed medical workers in the West African epidemic. In one case, a physician was vaccinated 43 hours after an accidental needlestick and developed fever and malaise 12 hours later; testing of blood samples revealed circulating vaccine virus but no Ebola virus infection (147). In macaques, postexposure vaccination does not provide cross-protection between Marburg and Ebola viruses, indicating that it is not based on the induction of innate immunity but on the rapid development of antigen-specific responses.

### Management of Outbreaks

Because filoviruses spread from person to person only through direct physical contact with virus-containing body fluids, any outbreak can in principle be halted by traditional public health measures. These include finding, isolating, and treating all persons with a history of possible virus exposure; finding and monitoring everyone who has been in close contact with those persons; and continuing rigorous surveillance until no new cases have occurred during a time equal to twice the incubation period of the disease. In practice, as the epidemic in West Africa has demonstrated, ending a filovirus outbreak may be much more difficult. Simply establishing a diagnostic capability and constructing isolation and treatment units will be insufficient if members of the local population fail to understand the nature of the disease, distrust local and foreign medical workers, and see entry into a treatment center as a death sentence. Massive public education efforts may be needed to convince the public that cooperation with health authorities provides the best opportunity for survival.

Before an outbreak can be controlled, it must be recognized, so the initial challenge is for medical workers to suspect or diagnose the first cases of filovirus disease against the background of febrile illnesses common in Africa. Unfortunately, doctors and nurses have often acted as “sentinels” when caring for patients with unrecognized Ebola or Marburg virus infection, assuming that a patient has malaria or another condition that is not transferred through physical contact. Once a filovirus is known to be present and a response is under way, the establishment of a diagnostic laboratory and the testing of blood samples from sick individuals with an appropriate contact history can identify those who should be isolated.

Perhaps the most difficult aspect of controlling a filovirus outbreak is the establishment of trust between medical responders and those they are trying to help. The arrival in a village of aid workers clad from head to foot in protective gear and their attempts to convince patients and their contacts to enter a frightening isolation ward can cause sick persons to hide or flee and the general populace to resist the team’s efforts. Fear may be further heightened by rumors that the strangers are actually spreading the disease or are using it to conduct experiments on Africans. Such a reaction may be unavoidable as long as a diagnosis of filovirus infection is equivalent to a death sentence. To counteract it, medical workers must convince the local population that treatment in an isolation unit provides the best chance of survival; their success in doing so may be largely responsible for control of the West African epidemic.

## TREATMENT

### Supportive Care

The level of supportive care that can be provided to patients with Ebola virus disease influences survival and depends on

the setting and the available resources (Table 3). During the current Ebola epidemic, the vast majority of cases in West Africa have been managed in variably equipped field treatment centers, while a few have been transported to hospitals in Europe and the United States with advanced critical care capacity. In past outbreaks, case-fatality rates approached 90% in the absence of supportive care. In contrast, mortality in field centers in West Africa has generally ranged from 40% to 60% and have been 20% or less for patients treated in modern hospitals. The differences in overall mortality observed in these settings suggest that survival correlates with the availability of adequate medical staff, supplies, and equipment.

A basic factor in the quality of care is the frequency and duration of interactions between health care workers and their patients. In low-resource settings such as West Africa, the high ratio of Ebola patients to providers, combined with extreme heat exposure due to the tropical environment and restrictive personal protective equipment, severely limit bedside care. The resulting inability to control symptoms, limit, or replace fluid and electrolyte losses and address complications in a timely fashion predisposes to fatal outcomes. In contrast, the continuous bedside monitoring available in a high-resource setting permits improved recognition and management of clinical manifestations and complications. Peripherally inserted central catheters or standard central venous catheters allow for frequent laboratory testing and reliable administration of intravenous therapies (Fig. 7).

Management in the early phase of illness includes relief of fever, pain, and other symptoms. Paracetamol and acetaminophen have been used safely but may require dose adjustment in the setting of hepatic dysfunction. Nonsteroidal antiinflammatory drugs are not recommended, given the frequency of renal insufficiency. Salicylates are relatively contraindicated. Narcotics such as morphine may be used for severe pain, but diminished or altered mental status, contributing to delirium and inability for self-care, may limit dosage.

As noted above, agitated delirium is common in Ebola patients, predisposing them and their providers to harm. Antipsychotic medications such as haloperidol are effective but are associated with QT prolongation and should be used with caution. Benzodiazepines also reduce agitation but typically produce sedation that limits the patient’s ability for self-care, predisposing to dehydration, aspiration pneumonia, and other complications. In high-resource settings, close monitoring of neurologic function allows early recognition of complications, including encephalopathy and seizures. Intubation with continuous sedation and analgesia can be safely accomplished, if needed.

In the absence of supportive care the recurrent vomiting and large-volume watery diarrhea that typically develop within 5 days of fever onset may lead to hypovolemic shock and death (70, 104, 105). Even with close attention to fluid management, sequential organ dysfunction or failure may occur, necessitating advanced supportive care, including mechanical ventilation and renal replacement therapy, if available. Fluid losses may be limited with the use of antiemetic and antidiarrheal medications. Vomiting was effectively reduced in Ebola patients given metoclopramide (106), which carries a low risk of QT-interval prolongation, but dosage adjustment in renal insufficiency is recommended. Ondansetron has also been used, but there is a risk of QT prolongation. Promethazine is not recommended, given neurologic and cardiovascular risks.

**TABLE 3** Recommendations for management of filovirus disease in low- and high-resource settings

Clinical feature	Management recommendations	
	Low resource	High resource
General	Provide nursing care as the situation permits	Continuous bedside nursing with close clinical monitoring and management
	Place peripheral IV line for initial blood draw and IV therapy	Place PICC or central venous catheter for frequent blood draws and IV therapy
	Treat fever and moderate pain with paracetamol or acetaminophen	Treat fever and moderate pain with paracetamol or acetaminophen
Neurological	Administer benzodiazepines (e.g., valium) for agitation or seizures	Continuously sedate intubated patients (e.g., midazolam, dexmedetomidine)
	Administer narcotics (e.g., morphine) for severe pain	Administer narcotic drip (e.g., fentanyl) for pain in intubated patients
	Avoid over-sedation with benzodiazepines and narcotics	Maintain control of airway in heavily sedated patients
Cardiovascular	Assess for dehydration (e.g., mucous membranes, skin turgor)	Assess intravascular volume status and cardiac function by bedside ultrasound
	Prevent or treat hypovolemic shock with oral or IV fluid administration	Administer IV fluids and vasopressors for refractory shock
	Limit medications that prolong QT interval (e.g., Haldol, quinolones)	Continuous monitoring with advanced life support for reversible conditions
Respiratory	Monitor for respiratory distress (e.g., rapid shallow breathing)	Monitor for respiratory complications by pulse oximetry and chest x-ray
	Avoid worsening pulmonary vascular leak with excessive fluid replacement	Administer oxygen and/or invasive ventilation for respiratory failure
Gastrointestinal	Administer antiemetic and antidiarrheal therapy	Treat vomiting and diarrhea and quantify gastrointestinal losses
	Monitor for ileus by exam and/or abdominal girth measurement	Monitor for ileus by measuring abdominal girth; ultrasound or x-ray evaluation
	Provide oral nutrition to avoid hypoglycemia	Provide enteral or parenteral nutrition with close laboratory monitoring
Genitourinary	Assess for renal insufficiency by urine frequency, volume, and color	Quantify total intake and urine output hourly
	Monitor and replace magnesium and potassium orally or intravenously	Monitor renal function and electrolytes frequently and replace as needed
	Avoid nephrotoxic agents	Avoid nephrotoxic agents; administer RRT for renal failure
Hematologic	Monitor for hematemesis or bloody stools as situation permits	Perform clinical and laboratory monitoring for bleeding and coagulopathy
	Administer phytonadione for bleeding, blood if available	Administer phytonadione and blood products (e.g., platelets, FFP) for bleeding
	Encourage ambulation to prevent deep venous thrombosis	Administer prophylactic anticoagulation with resolution of coagulopathy
Concurrent infections	Test for or empirically treat malaria	Test for and treat malaria if present
	Consider preemptive or therapeutic antibiotics	Integrate laboratory and radiologic data to assess potential bacterial infection

Abbreviations: PICC: peripherally inserted central catheter; CVP: central venous pressure; IV: intravenous; RRT: renal replacement therapy; FFP: fresh frozen plasma.

Loperamide has antisecretory and antimotility effects and has been effective in the treatment of diarrhea in Ebola patients (105, 106). However, antidiarrheal agents should not be used in the setting of ileus, obstruction, or inflammatory diarrhea, as manifested by blood or mucous in the stool. Serial measurement of abdominal girth may be performed in both low- and high-resource settings as a means of detecting intestinal obstruction or ileus. In high-resource settings, point-of-care abdominal assessment may also employ measurement of bladder pressure and the use of abdominal ultrasound and radiography. Oral, enteral, or

parenteral nutrition may be required, depending on disease severity, associated complications (e.g., pancreatitis), and the care setting. Hypoglycemia must also be recognized and treated.

Intravascular volume depletion due to insensible losses from fever, limited oral intake, or vascular leak in the lungs or other organs may precede the onset of gastrointestinal symptoms, predisposing to renal insufficiency before the onset of shock. Dehydration should be recognized and managed early with oral or intravenous fluids. Oral rehydration solutions may be adequate in early or moderate

disease, assuming that vomiting can be controlled. Patients unable to drink fluids or those with evidence of shock require intravenous fluid replacement with isotonic solutions such as 0.9% normal saline. In high-resource settings, cardiac and intravascular volume status may be assessed by bedside ultrasound, and fluid-refractory shock can be managed with vasopressors. Close cardiac monitoring and periodic assessment of the QT interval is recommended, when possible. Advanced life support, including cardiopulmonary resuscitation for reversible conditions, should be considered in controlled settings with adequately trained staff.

An important aspect of fluid management is avoiding overly aggressive hydration, which may worsen pulmonary vascular leak and hypoxia. In clinical settings lacking access to oxygen or other types of supportive respiratory therapy, close monitoring for respiratory distress and careful fluid management are recommended. In high-resource settings, continuous monitoring of oxygen saturation and intermittent chest radiography facilitate the detection of pulmonary complications. Invasive mechanical ventilation may be required for multifactorial respiratory failure.

Renal function is also a critical aspect of Ebola virus disease, and careful monitoring of fluid intake and output are needed. Nephrotoxic agents, including nonsteroidal anti-inflammatory drugs and aminoglycoside antibiotics, should be avoided. In the early phase of illness or in moderately ill patients, electrolytes may be empirically replaced with oral solutions, but severe or ongoing loss requires frequent monitoring and replacement. Adequate magnesium replacement is required to achieve successful potassium supplementation. Renal-replacement therapy has been used in high-resource settings (158).

When conditions permit, clinically significant hemorrhage should be treated with phytonadione (vitamin K) and the administration of platelets, packed red cells, and fresh-frozen plasma, when available. Monitoring of coagulation parameters is recommended, and patients with severe disseminated intravascular coagulation with fibrinogen levels < 100 mg/dL should be given cryoprecipitate. Upon resolution of coagulopathy, pharmacologic prophylaxis of deep venous thrombosis with subcutaneous heparin or enoxaparin should be considered in nonambulatory patients.

Concurrent infections should be sought and treated. Given the high prevalence of malaria in settings where Ebola outbreaks occur, empiric treatment is recommended if malaria cannot reliably be ruled out. The choice of therapy should consider potential toxicities, including QT prolongation, the need for dosage adjustment with hepatic and renal dysfunction, and the ability to detect and treat toxicities in low-resource settings. Drugs used to treat chloroquine-resistant malaria that are associated with QT prolongation include quinine, quinidine, mefloquine, and artemether-lumefantrine. Secondary bacterial infections, including pneumonia and sepsis, often ascribed to gut translocation, are concerns in Ebola virus disease, but the optimal timing and choice of antibiotic therapy have not been established. In the absence of specific microbiologic testing capacity, preemptive antibiotic administration with coverage for enteric Gram-negative pathogens is reasonable.

### Antiviral Therapy

The West African epidemic has markedly accelerated the development of antiviral therapy for Ebola and Marburg virus disease. By early 2014, a number of different drugs had been shown to prevent illness and death of filovirus-infected mice, guinea pigs, and nonhuman primates, but none had

been administered to humans (159). As the outbreak expanded, several products were moved forward to Phase I trials and were also administered to accidentally infected medical workers from the United States or Europe under compassionate-use protocols. There were five types of these drugs: polyvalent antiserum, combinations of monoclonal antibodies (mabs), nucleoside/nucleotide analogues, interferons, and antisense molecules. Summaries of the current status of research and development efforts for Ebola therapies, vaccines, and diagnostic kits are available at the World Health Organization (136, 160).

Initial testing of polyvalent anti-Ebola serum produced in horses failed to achieve protection in macaques, and no evidence of a therapeutic benefit was found in macaques with convalescent whole blood (161–163). In contrast, a concentrated polyclonal IgG prepared from the pooled serum of macaques that had undergone vaccination and challenge with Marburg or Ebola virus was highly protective when administered to naïve macaques up to 3 days postexposure (164). Convalescent plasma has been administered to some patients in West Africa with uncertain effects (113) and one open-label study in patients in Guinea found no significant mortality benefit, compared to historical controls (165).

Initial testing of mab therapy of Ebola virus infection in laboratory animals did not appear promising; a single antibody targeting an epitope on the viral GP was protective in guinea pigs but not in macaques (166), but more recent evaluation of combinations of mabs targeting different epitopes on the virion surface GP has been very successful (167). A product containing three mabs, known as Zmapp®, was the first therapy to prevent the death of macaques when initiated after the development of illness (168). During the West African epidemic, Zmapp has been given under compassionate use to approximately 15 to 20 patients, mostly American or European health care workers, most of whom survived their infection (169). Whether these favorable outcomes were the result of mab therapy or simply reflect good supportive care in modern hospitals cannot be determined, especially as most patients received more than one experimental treatment. An open-label, randomized controlled trial comparing Zmapp therapy to supportive care is in progress (170).

Three nucleoside/nucleotide analogue antiviral drugs have also progressed from the laboratory to human use during the course of the West African epidemic. Favipiravir, a nucleoside analogue licensed in Japan for the treatment of novel influenza strains, was highly protective in Ebola virus-infected mice but only at dosage levels much higher than required for influenza therapy (32). Favipiravir has been administered therapeutically to several health care workers evacuated to the United States or Europe and in an open-label Phase 2 trial to a large cohort of African patients in Médecins Sans Frontières treatment centers in Guinea (136). Although the trial only compared treatment outcomes to previous patients who received no antiviral therapy, the findings suggested that favipiravir is beneficial if begun early in the course of illness in those with low viral loads (171). In contrast, no mortality benefit or antiviral effect was apparent in those with higher viral loads. A second nucleoside analog, BCX4430, which is highly potent in filovirus-infected macaques (35), has entered Phase I trials but has not yet been given to patients.

The third experimental product, GS-5734, a nucleotide analogue with a prodrug structure similar to that of the anti-hepatitis C compound sofosbuvir, is highly protective in

Ebola virus-infected macaques that had already developed signs of illness (172). It was used to treat a nurse who had recovered from Ebola virus disease but suffered a delayed recrudescence of infection in the central nervous system and also an infant in West Africa; both survived (125).

The broad antiviral activity of type I IFN suggests that it should inhibit filovirus infections, and limited therapeutic benefit has been observed in animal studies. Nonhuman primates treated daily with IFN- $\alpha$ 2b, beginning on the day of virus challenge, showed a prolongation in mean time to death, and a regimen employing IFN- $\beta$  had a similar outcome (162, 173). A clinical trial of IFN- $\beta$  was initiated in Guinea; outcomes have not been reported (160).

Antisense oligonucleotides that bind to specific sequences in Marburg or Ebola virus messenger RNA have proven beneficial in laboratory animals but to date have only been given to a few Ebola patients. The small interfering RNA molecule TKM-Ebola, which targets mRNA encoding the viral polymerase and VP35, was reengineered from its original *Zaire ebolavirus* sequence to match the West African Makona strain and, when delivered in a lipid nanoparticle formulation, proved protective in rhesus macaques when treatment was begun on day 3 postinfection (34). TKM-Ebola was administered together with convalescent plasma to two accidentally infected American physicians (113), but a trial in Sierra Leone was terminated by its Data Safety and Monitoring Board because of lack of efficacy. Phosphorodiamidate oligonucleotides targeting specific filovirus mRNA sequences are also highly active in infected laboratory animals (174) and have undergone dose-escalating safety and pharmacology studies in humans (175), but their use for PEP or therapy in Ebola patients has not been reported.

### Host-Directed Therapies

Efforts to develop effective treatments for filovirus disease have also focused on modification of damaging host responses to infection (160). One approach has been to prevent the initiation of DIC by blocking the binding of tissue factor to factor VIIa, using recombinant nematode anticoagulant protein C2 (rNAPC2) (176). When nine macaques were given daily injections of rNAPC2, beginning on the day of or the day after *Zaire ebolavirus* challenge, most showed a marked reduction in coagulopathy. Treatment also resulted in a striking decrease in peak serum levels of IL-6 and MCP-1 and a 100-fold drop in peak viremia in the three animals that survived infection. Treatment of Ebola virus-infected macaques with recombinant activated protein C also resulted in a survival benefit (177). Neither approach has been advanced to human trials. An attempt to treat Ebola patients in Sierra Leone with the host response modifier atorvastatin produced claims of therapeutic benefit that have not been documented (178).

### CONCLUSION

The filoviruses were long considered a local problem in Central Africa, with little global significance (179). The massive Ebola epidemic in West Africa has broken that pattern, but although its scale is much larger than any previous outbreak, the disease itself and its mode of transmission appear to be unchanged from earlier outbreaks. Extensive spread was made possible by difficulties in recognizing the disease against a background of malaria and other febrile illnesses, and the severely limited medical, logistic and communications resources in one of the world's poorest regions. Importantly, when the virus spread to countries with

more effective public health systems, such as Nigeria, chains of transmission were quickly detected and halted. Given the vastly increased awareness of Ebola virus disease, it is likely that future outbreaks will be recognized and contained quickly.

An important lesson from the current epidemic is that even in resource-limited settings, Ebola patients can receive meaningful treatment that reduces case fatalities. We have also learned that people infected with a deadly transmissible virus can be treated safely in modern hospitals in the United States and Europe, with a high likelihood of survival. The experience of managing large numbers of cases has reinforced the importance of early diagnosis so that fluid replacement can begin before the onset of shock. In severe cases, however, prevention of shock alone without adequate resources to diagnose and manage multiorgan failure may still result in death. Although a number of specific antiviral medications have been given to patients during the West Africa outbreak, their efficacy has not been established, and there is still a critical need for proven effective targeted therapies. Extensive experience has also been obtained with the recombinant adenovirus and VSV Ebola vaccines. The latter was shown effective in a ring vaccination trial, providing great promise as an emerging tool to protect medical personnel and control the spread of disease in future outbreaks.
