The major role of CD8 T cells is to rapidly and efficiently kill virally infected cells through lysis. Target cell lysis occurs in several steps, beginning with the recognition of a foreign peptide in the groove of an MHC class I molecule on the surface of a target cell. This interaction leads to a rapid arming of the T cells that is preceded by the ligation of coreceptors and adhesion molecules including LFA and ICAM-1, that collectively create a mature adhesive immunological synapse, also called the supramolecular activation complex (SMAC) (149). The SMAC importantly creates a tight seal around the interacting TCR/MHC complexes that allows for a reorientation of the cytoskeleton and the calcium-dependent release of cytotoxic granules into the target cell. Cytotoxic granules are loaded with perforin, granzymes, and granzymes within lysosomes coated with lysosomal-associated membrane protein (LAMP)-1/-2 (CD107a/b). Perforin acts as a delivery molecule, poking holes in the target cell, through which granzymes and granulins can enter. The granzymes trigger apoptosis in the target cells by activating caspase 3 involved in caspase proteolytic activity, leading to the activation of the caspase-activating deoxyribonuclease (CAD) (150). This nuclease acts as a DNase and degrades the target cell DNA. Furthermore granzymes also activate the BH3 interacting domain (BID) that disrupts the mitochondrial outer membrane, driving cellular apoptosis. Additionally, beyond direct cytolysis, a small fraction of CD8 T cells can also kill their targets via the induction of apoptosis through the interaction of Fas-ligand (Fas-L) on the CD8 T cells and Fas on the target cell.

In addition to their role in cytolysis, CD8 T cells also secrete several proinflammatory antiviral cytokines, includ-

ing IFN $\gamma$  and TNF $\alpha$ , which indirectly contribute to the antiviral host response. As mentioned above, IFN $\gamma$  can regulate MHC class I expression, activation of TAP, increase lysosomal activity, upregulate TRIM5 $\alpha$ , APOBEC, and tetherin. TNF $\alpha$  is also a chemoattractant and plays an important role in the activation of macrophages that may contribute to the clearance of apoptotic debris. However, TNF $\alpha$  can also bind to TNFR-I expressed on some target cells and thereby drive direct killing.

In addition to cytotoxic CD8 T cells, a small subset of CD8 T cells evolve with regulatory T-cell activity. Regulatory CD8 T cells are characterized by the expression of the transcription factor FoxP3 and express CD122 and are CD28 low. While these cells are largely involved in limiting autoimmune disease by the reduction of T-cell proliferation by secretion of IL-10, for example, they have also been implicated in limiting chronic immune activation in chronic viral infections caused by viruses such as HCV, HIV and EBV to prevent to immune-induced tissue damage (151, 152).

### CD4 T-Cell Help for CD8 T-Cell Immune Responses.

Although potent primary CD8 T-cell responses can be induced in the absence of CD4 T-cell responses, the establishment of long-lived, functionally robust memory CD8 T-cell activity requires the presence of CD4 T-cell help (153). Specifically, CD8 T-cell responses generated in the absence of CD4 T-cell help may remain in an effector-like state, associated with the constitutive expression of the transcription factor T-bet (154). These “unhelped” CD8 T cells develop a spectrum of functional defects such as compromised cytokine-producing capacity and diminished proliferative activity, often referred to as exhaustion (155). However, the precise pathway by which CD4 T cells help program CD8 T-cell memory is not fully understood. In addition, it has been shown that secretion of CCL3 and CCL4 by CD4 T cells can promote CD8 T-cell migration towards DCs (156). Moreover, CD4 T cells also appear to be essential in “licensing” DCs via CD40L-CD40 interactions to provide optimized signals to CD8 T cells during the priming process (157). Third, CD4 T cells also secrete IFN $\gamma$ , CXCL9, and CXCL10 required to direct CD8 T cells to the site of infection, which has been shown to play a role in HSV infection (158).

Furthermore, CD4 T cells also promote more effective CD8 T-cell activity directly via the secretion of both IL2 and IL21 (159, 160). While IL2 provides growth, survival, and differentiation signals to responding CD8 T cells, IL21 has been implicated in increasing the antiviral potency of CD8 T cells and increasing the production of granzyme and perforin. The importance of IL2 and IL21 signals in driving more effective T-cell immunity has been shown in many human viral infections, including HCV and HIV (161, 162). Indeed, in LCMV infection of mice, it has been demonstrated that CD8 T cells cannot control infection in the absence of IL21 secretion by CD4 T cells (159, 160).

**CD4 T Cells.** While the initial steps of antigen recognition by CD4 T cells through the TCR:MHC class II is similar to that of CD8 T cells, CD4 T-cell differentiation following activation is more complex because of the large array of distinct differentiation pathways that exist for this subset of T cells. Interestingly, CD4 T-cell differentiation is tightly linked to APC interactions. APCs not only present foreign antigens to CD4 T cell, but also produce cytokines and express costimulatory molecules that ultimately program CD4 T-cell differentiation, aimed at shaping CD4 help in a pathogen- and tissue-specific manner. Thus APCs that

integrate information through their innate immune receptors can then selectively skew the lineage commitment of CD4 T cells. There is evidence, however, that the commitment of CD4 T cells to one effector function is not necessarily set in stone and that under certain circumstances CD4 T cells can revert to a different CD4 T-cell effector function, suggesting that there is some plasticity in lineage development (163). Yet among the CD4 T-cell lineages, at least seven distinct T-cell subsets have been identified, each defined largely on the basis of the transcription factors that define their lineage and the cytokines that they secrete (Fig. 5).

**TH1 CELLS.** Th1 cells are induced in the presence of DC-derived IL-12 and DC or NK cell-derived IFN $\gamma$ . The signature cytokine of Th1 cells is IFN $\gamma$ , but they also secrete IL-2 and TNF $\alpha$ . Th1 driven-IFN $\gamma$  secretion further potentiates the Th1 profile, and autocrine IL-2 secretion promotes effective T-cell proliferation. Th1 cells are further characterized by the expression of the transcription factor t-bet (164). While Th1 cells are mainly involved in the control of intracellular/intravascular bacterial infections, almost all viral infections induce a strong Th1 CD4 T-cell response. Indeed, IFN $\gamma$  and TNF $\alpha$  secreted by CD4 Th1 cells potentiates CD8 T-cell immunity and contributes importantly to shaping the antiviral milieu. For example, it has been demonstrated that influenza virus infection is less severe in the presence of pre-existing Th1 CD4 T-cell response (165), and HCV and HIV disease outcomes are improved in the presence of broad virus-specific Th1 CD4 T cells (166, 167).

**TH2 AND TH9 CELLS.** The absence of IFN $\gamma$  signals and the presence of IL-4 drives Stat6 expression and the development of Th2 CD4 T cells. Stat6 specifically induces the expression of the main Th2 transcription factor GATA3, which is responsible for the activation and expression of Th2 cytokines including IL4, IL5, and IL13 (168). These cytokines further upregulate GATA3 expression and thus reinforce the Th2 lineage commitment bias. While the initial source of IL4, required to drive the initial lineage commitment is still unclear, basophils, eosinophils, and mast cells can all produce IL-4 and have all been implicated as potential catalysts if activated soon after infection. Critically, Th2 cells are important for the immune response against large extracellular pathogens and may play a role in the development of antibody responses against some viral infections. Similarly, Th9 cells are directed against large extracellular organisms and in particular against helminths. This newly described subset is induced in the presence of IL4 and IL9 and characterized by the expression of the transcription factor PU.1 and cytokine secretion of IL-9 (169). Th9 cells have no known role in antiviral activity.

**T FOLLICULAR HELPER CELLS.** An important component in the antiviral immune response is the humoral immune response, mediated by B cells. A specialized subset of CD4 T cells provide the help and instructions required to generate a robust B-cell response upon infection, the T-follicular helper (Tfh) cells. Tfh have a key role in the formation of germinal centers within lymph nodes, the affinity maturation of B-cell response, and the establishment of memory in the antibody responses (170). Tfh cells are the only subset of CD4 T cells that are defined based on their location within the B-cell follicle; although the cardinal cytokines produced by Tfh cells is IL-21.

The differentiation process of Tfh cells occurs in three phases: (a) initial differentiation towards the Tfh-lineage,

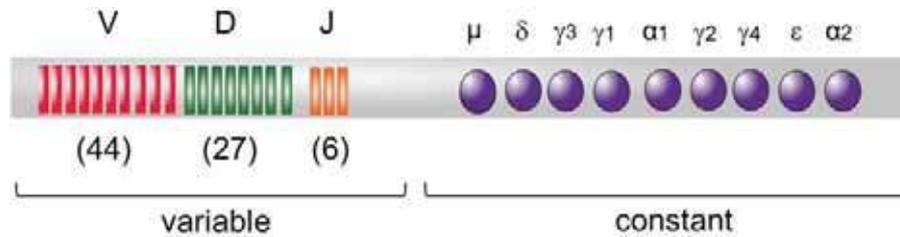

(b) migration into B-cell follicles where the cells interact with B cells, and finally (c) maturation within germinal centers. In the presence of DC-derived IL-6, IL-27, and IL-12 (in humans), naïve CD4 T cells upregulate the transcription factor BCL-6 and cMaf, which drive the expression of the chemokine receptors CXCR5, ICOS, and IL-21. Tfh cells now follow the chemokine gradient CXCL13 and reposition themselves at the B-cell/T-cell border of the B-cell follicle. Here, interaction with the cognate antigen presented on the B cell drives the further development of Tfh cells. Tfh cells and B cells engage in a bidirectional interaction involving an array of receptors including CD40-CD40L, ICOS-ICOSL, SLAM receptor family, PD1-PDL1, and others to tune B-cell activity. During this process Tfh cells further develop into germinal center (GC) Tfh cells that secrete IL21 and express the transcription factor Bcl-6.

Potent, long-lived, antigen-specific antibody responses hinge on the evolution of an effective GC reaction that enables the selection of high affinity B-cell responses to target foreign antigens. Within the GC, Tfh cells instruct B cells to undergo somatic hypermutation (SHM) that drives affinity maturation of the antibody response. CD40L and IL21 are required for B-cell survival, proliferation, class switching, and differentiation into memory B cells. Second, they activate the activation-induced deaminase (AID) enzyme that drives both SHM and class switch recombination (CSR).

**TH17 CELLS.** Under specific inflammatory conditions, a subset of IL17-producing CD4 T cells, Th17 cells, are induced that regulate neutrophils, epithelial, and endothelial cells (171). Th17 cells are induced in the presence of IL6, TGF $\beta$ , and IL1 $\beta$ , which drive the upregulation of the transcription factor RAR-related orphan receptor  $\gamma$  (ROR $\gamma$ ). Th17 cells play a critical role in the maintenance of the gastrointestinal tract microbial flora and control of bacterial infections, but their role in viral immunity has been disputed. However, while these cells may not contribute to antiviral immunity directly, Th17 CD4 T-cell responses play a critical role in dampening the immunopathology associated with HIV, CMV, HCV, and likely other viral infections. Specifically, following the extinction of nearly all mucosal CD4 T cells following acute HIV infection, elevated levels of Th17 cells are associated with enhanced gut epithelial integrity, reduced immunopathology, reduced microbial translocation, and therefore lower systemic immune activation. Additionally, Th17 cells may also contribute to antiviral immunity via the maintenance of the microbiome that indirectly shapes the immune response (172).

**T REGULATORY CELLS.** Regulatory T cells (Tregs) are a suppressive subset of CD4 cells important for the regulation of immune responses and a direct opponent of Th17 cells (173). Two types of Tregs have been described: (1) naturally occurring Tregs that are generated in the thymus (tTreg) with a TCR repertoire biased towards self-peptides, and (2) induced Tregs that emerge at later stages of infection (iTreg). Thymus-derived Tregs require CD28 costimulation, TCR engagement, and  $\gamma$ -chain cytokines, such as IL2, critical for the expression of FoxP3. However, IL-15, a second  $\gamma$ -chain cytokine, can also drive Treg generation. In contrast, iTregs are induced following the release of TGF $\beta$  and IL2.

Tregs are characterized by the demethylation of the Treg-specific demethylated region (TSDR) in the FOXP3 locus, high expression of the IL2 receptor (CD25), and low expression of the IL7 receptor (CD127). High IL2 receptor expression permits Tregs to soak up most of the IL2 in the

**FIGURE 6** The IgH locus. The human immunoglobulin locus consists of two regions that give rise to either 1) the variable domain (Fab) or the 2) the crystallizable/constant domain (Fc). The Fab is generated following the rearrangement and selection of a V, a D, and a J segment that are assembled and tethered to the Fc region, which is also selected following gene rearrangement and selection of a single constant gene segment. Gene rearrangement requires the cutting out of excess DNA and religation of DNA ends, generating irreversible changes in the IgH locus.

peripheral circulation, thereby competing with newly primed or memory T cells for survival factors. However in addition to this indirect regulatory activity, Tregs also secrete IL10, TGFβ, and IL33, which directly act to reduce inflammation and immune activation. Interestingly, while the role of Tregs in antiviral immunity is unique to each virus, Tregs play a key role in HSV infection in blocking virus-specific CD8 T-cell mediated immunopathology and directly blocking excessive tissue immunopathology.

**CYTOLYTIC CD4 T CELLS.** Despite the dogma that CD4 T cells are “helper” cells, a novel subset of CD4 T cells were recently described that mediate direct antiviral effects. The conditions under which CD4 T cells upregulate cytolytic functions are not fully understood. Yet in mice, it has been described that high levels of IFNα or the ligation of Ox40 and 41BB can drive the induction of a cytolytic CD4 T-cell program similar to that of CD8 T cells. Cytolytic CD4 T cells have a more terminally differentiated phenotype, with high expression of CD57 and KLRG1, but their profiles are distinct from Th1 cells (174). Cytolytic CD4 T cells seem to be less potent than CD8 T cells, but kill virally infected cells in a similar fashion as CD8 T cells. Importantly, cytolytic CD4 T cells have been implicated in protective immunity against several human viral infections including influenza, EBV, HCV, and HIV (175).

## Humoral Immunity

### Introduction

With the observation that immunity could be transferred using cell-free blood components the importance of antibodies discovered (176). It was postulated that the humoral immune system is able to generate an infinite number of antibodies with unique specificities that provide long-term protection from reinfection.

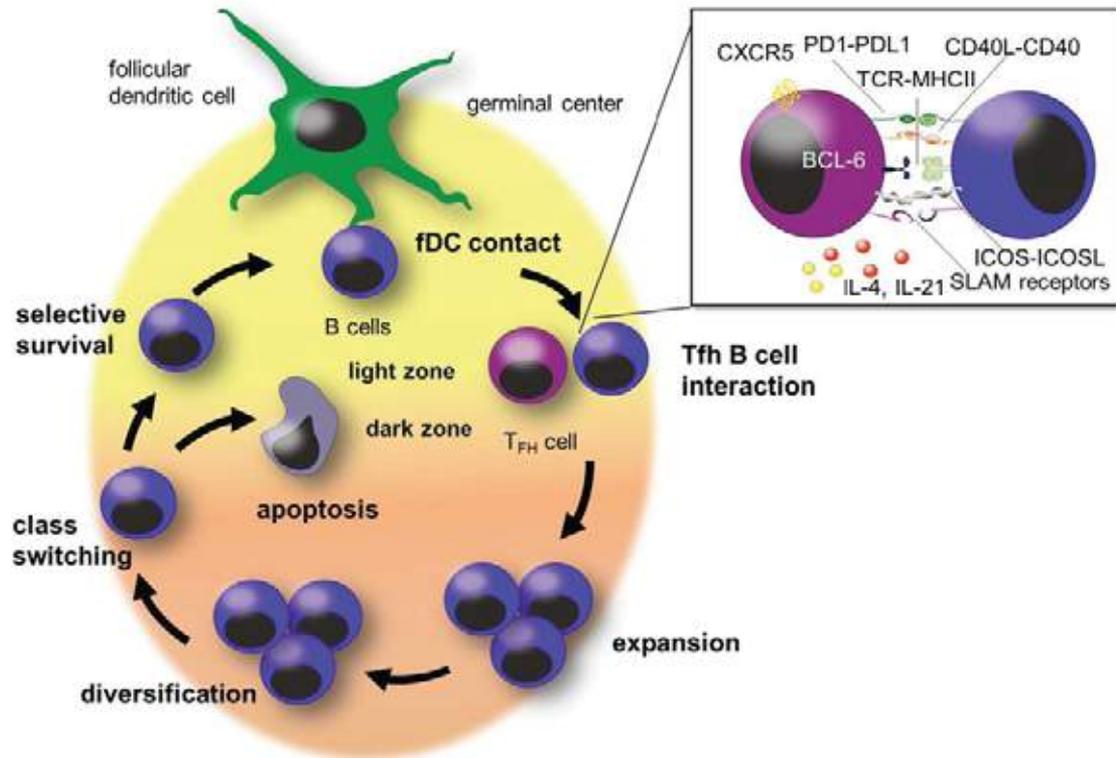

### B Cells

Cells are lymphocytes that develop in the bone marrow from a common lymphoid progenitor. While still in the bone marrow, the cells undergo VDJ recombination, resulting in the rapid rearrangement of a set of genes in the variable region of the immunoglobulin, encoded in the immunoglobulin heavy (chromosome 14) and light (κ-chain chromosome 2 or λ-chain on chromosome 22) chain loci (Fig. 7). During the rearrangement of the BCR, the heavy chains are rearranged to contain 1 of 44 different V-gene segments, 27 different D-gene segments (similar to TCR β chains, only the heavy chain contains D-gene segments), and 6 different J-gene segments. The random selection of distinct segments,

linked to the stochastic and random repair mechanisms that bring segments together, gives rise to an enormous diversity within the B-cell repertoire. Importantly, failure to select segments that produce a functional BCR or that generate autoreactive antibodies results in the death of the B cell. Conversely, successfully rearranged B cells can exit the bone marrow as pre-B cells once they begin to express their immunoglobulin as a transmembrane IgM receptor and IgD receptor.

Similar to T cells, B cells circulate through the blood in a resting inactive state, either as antigen-naïve B cells or antigen-experienced memory B cells. However, upon encountering their cognate free-floating or APC-presented antigen through their BCR, a unique transcriptional program is turned on in the B cell, driving B-cell survival, proliferation, maturation, and in some instances terminal differentiation into antibody-secreting cells, which occurs inside the GC. However, like T cells, BCRs collaborate with additional coreceptors to tune B-cell activation, including CD21, which tunes the activation threshold of the BCR.

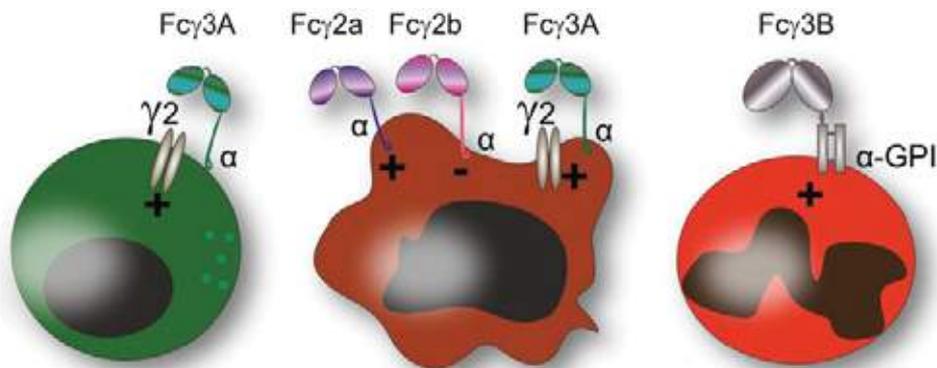

Both T-dependent and T-independent B-cell responses can be induced during an immune response. T-dependent antigens largely consist of protein antigens that are processed by B cells after they capture antigens with their BCRs from a specialized set of APCs, called follicular dendritic cells (FDCs). B cells process antigens and then present them on MHC class II to CD4 Tfh cells in the lymph nodes. Following Tfh recognition of peptide-MHC complexes on B cells, T cells deliver survival and activation signals to B cells by the ligation of coreceptors (CD40L) and the release of cytokines like IL-21 and IL-4, which further drive B-cell proliferation and survival. B cells that fail to present antigens recognized by CD4 Tfh perish due to a lack of survival signals. Activated B cells differentiate into activated memory B cells that cycle within the GC where they undergo extensive clonal expansion, class switch recombination, and affinity maturation to give rise to optimized BCRs that recognize and clear the pathogen with greater efficacy (Fig. 8). This extensive maturation process gives rise to hypermutated high-affinity antibodies that are thought to be critical in the evolution of neutralizing antibodies that prevent many viral infections. Additionally, through interactions with Tfh, successful memory B cells receive signals to exit the GC as long-lived memory B cells or bone-marrow destined plasma cells that secrete copious amounts of antibodies for life. In contrast, T-independent antigens are largely polysaccharides that induce B-cell responses in the absence of T cells through extensive BCR cross-linking (largely by repeating antigens on polysaccharide bacterial walls) and in conjunction with the activation of danger signals such as TLRs. While T-

**FIGURE 7** The germinal center reaction. The germinal center reaction begins with an initial contact between B cells and cognate Tfh cells through an array of different receptors such as PD1-PDL1, CD40-CD40L, ICOS-ICOS-L, and TCR-MHCII. This promotes extensive proliferation of antigen-primed B cells. The GC cycle is thought to form two microanatomically distinct regions: the T-cell zone-proximal dark zone (which contains proliferating centroblasts) and the T-cell zone-distal light zone (which contains centrocytes, follicular dendritic cell [DC] networks and antigen-specific gcTFH cells). The expansion of antigen-specific B cells in the dark zone is accompanied by B-cell receptor (BCR) diversification through somatic hypermutation and class switch recombination. Loss of binding through this process leads to apoptosis, and only the best “binders” receive positive signals and enter the cycle again until they leave the GC as plasmablasts or memory B cells.

independent responses are lower affinity and are associated with bacterial or parasitic pathogens, these responses are induced rapidly and may play a critical role in the early recognition and control of highly glycosylated viral glycoproteins, including HIV and Ebola virus envelope glycoproteins.

Importantly, antibodies circulating in the blood are produced by either long-lived plasma cells or short-lived plasmablasts (177). While long-lived plasma cells establish lifelong residence in the bone marrow, where they are able to secrete over 2,000 antibodies a second (178), short-lived plasmablasts are only generated immediately after B-cell

**FIGURE 8** Distinct Fc-receptor expression profiles on distinct innate immune cells. Differences in Fc receptor expression profiles on distinct innate immune cell subsets enable these cells to respond to antibody-opsonized material differently to promote control and clearance of pathogens. Specifically, while NK cells and neutrophils largely express a single Fc $\gamma$ -receptor, Fc $\gamma$ R3a, on NK cells and Fc $\gamma$ R3b on neutrophils, macrophages express nearly all Fc receptors including the two activating Fc $\gamma$ R2a and Fc $\gamma$ R3a receptors, as well as the sole inhibitory Fc $\gamma$ R2b receptor.

activation and differentiation and are aimed at rapidly generating large waves of antibodies to contain and/or clear the infecting pathogen.

### Antibodies

Antibodies consist of two antigen-binding domains (variable domains, Fv) and a constant domain (crystallizable domain, Fc). The presence of two identical variable domains ensures higher avidity binding to the antigen of interest, and the Fc domain provides instructions to the innate immune system on how the targeted antigen should be destroyed.

### Antibody Function

For most of the clinically approved vaccines, the generation of antibodies able to block, or neutralize, the pathogen are considered the correlate of protective immunity. This neutralizing antibody property is mediated by antibodies that can block key infectious units on the pathogen (i.e., viral envelope proteins) or opsonize the pathogen in such a way that infection may be sterically hindered. However, beyond neutralization, antibodies mediate a remarkably broad array of additional functions, including the classically defined recruitment of innate immune responses. These include antibody-dependent cellular cytotoxicity (ADCC) by the recruitment of NK cells, antibody-mediated cellular phagocytosis (ADCP) by the recruitment of macrophages or neutrophils, and complement-mediated killing by the recruitment of the classical complement pathway.

### Antibody Evolution

While the antibody that is produced early in the immune response functions to immediately protect cells from subsequent waves of infection and begin to eliminate the pathogen, B cells have the capacity to undergo additional genomic changes to produce antibodies with significantly higher affinity for pathogens. This **affinity maturation** occurs in the germinal center and results in the generation of waves of lineages of B cells that produce closely related antibodies with ever increasing affinities. Importantly, both the Fab and Fc domains of the antibodies can be independently optimized.

### Somatic Hypermutation

During affinity maturation of B-cell responses, the variable domain is diversified and optimized via a process known as **somatic hypermutation**. The GC is a site of rapid B-cell proliferation, and during this proliferation the immunoglobulin locus undergoes a high degree of mutation, typically at rates that are over a million times greater than the rates seen in other genes. Although the genes and regulatory signals involved in controlling somatic hypermutation have not been completely identified, several components, including the DNA editing enzyme activation induced cytidine deaminase (AID) and several DNA structural elements, have been shown to be necessary for efficient somatic hypermutation. Given the size of the variable region of the antibody and the mutational rates, somatic hypermutation typically results in the acquisition of a single amino acid change per cell division, while the B cell remains in the GC. Coupled with the rapid cell division that B cells undergo in the GC (dividing every 6 to 8 hours), this results in the rapid accumulation of additional mutations in GC B cells. Importantly, because antigen-loaded APCs are present in only limited numbers in the GC, each subsequent wave of somatically hypermutated B cells must compete for binding to antigen and the resulting stimulatory signals (Fig. 8). B cells

in which mutations that negatively impact antigen binding are rapidly eliminated via apoptosis because they can no longer compete with other B cells for antigen binding. Not surprisingly, GCs are sites of massive apoptosis, and these apoptotic B cells are cleared by lymph node-resident macrophages. However, when mutations that increase affinity for a target antigen are introduced, the resulting B cells are strongly positively selected, resulting in the outgrowth of progeny cells with increased affinity for the antigen of interest. These progeny cells can, in turn, undergo further somatic hypermutation, increasing the affinity for the antigen even further. Following multiple rounds of B-cell selection and somatic hypermutation, large clonal repertoires of B cells that target the pathogen with increased affinity are generated, and these cells can exit the GC to become antibody-secreting cells or memory B cells. Importantly, while affinity maturation is required for the development of all protective antibodies against all viral infections, neutralizing antibodies against HIV emerge only in a fraction of infected individuals because of the unusual characteristics of the antibodies that are able to protect against this rapidly evolving viral pathogen.

### Constant Domain (Fc) Diversification

While somatic hypermutation diversifies the variable domain of the antibody, increasing the affinity of the antibody for antigen, the constant (Fc) domain of the antibody can also undergo diversification. This constant domain diversification is achieved via two modifications to the antibody Fc domain: (1) selection of one of four distinct Fc isotypes (IgM, IgG, IgA, and IgE) or one of four IgG subclasses (IgG1, IgG2, IgG3, IgG4), and (2) variation in the glycosylation of the antibody in the Fc domain. These modifications alter the affinity of antibodies for various classes of innate immune receptors (e.g., Fc receptors on the surface of all innate immune cells or complement), thereby altering the bioactivity of the antibodies against the infecting pathogen.

### Class Switch Recombination

Although the variable and constant (Fc) domains of the antibody have distinct functional roles, their diversification is tightly regulated and coordinated through a common network of signals. For example, the enzyme, AID, is critically involved in somatic hypermutation of the variable domain, as mentioned above, but it is also critical in CSR that enables a B cell to select for different antibody isotypes and subclasses, with each isotype and subclass possessing different functional activities.

Upon B-cell activation, naïve B cells, which express an IgM/IgD BCR, can select a different subclass or isotype by the directed cleavage and recombination of constant region segments in the *IGH* locus (179). In the human *IGH* locus, the isotypes and subclasses are arranged in a particular sequence: IgM, IgD, IgG3, IgG1, IgA1, IgG2, IgG4, IgE, and IgA2 (Fig. 7). Each subclass and isotype gene segment is preceded by a unique switch region, which is the target of the recombination machinery during CSR. When a particular isotype or subclass is selected, the recombination machinery loops out and permanently deletes all of the intervening gene segments between the variable domain and the targeted constant domain sequence. For example, when the B cell transits from IgM/IgD to IgG2, all the gene segments encoding IgM/D/G3/G1 are all spliced out of the *IGH* locus in that specific B cell. In this example, while this particular B cell can never go back to produce an IgG3

antibody, it does still retain the capacity to further produce IgG4, IgE, or IgA2 antibodies.

CSR is a highly regulated process controlled by cytokines and helper signals (180). While the precise signals are unknown, IL-4 may selectively induce CSR to produce IgG4 and IgE (181, 182), whereas IL-10 induces CSR towards IgG1 and IgG3 (183, 184). Moreover, beyond cytokines alone, IgG subclass selection varies by infection and is related both to the inflammatory state induced by a pathogen and the location of the pathogen (e.g., intra- vs. extracellular) (185). Along these lines, HIV-specific IgG3 antibodies have been proposed as biomarkers of acute HIV infection, because of their enrichment during the first few weeks of infection (186). IgG3 antibody levels decline quickly over the first few weeks of infection and are rapidly followed by a robust wave of IgG1 responses that dominate the chronic phase of the disease (187). Most of the antibody responses to viral antigens appear to be dominated by IgG1 and IgG3 antibodies, and IgG3 has been shown to mediate most effective virus neutralization among the IgG subclasses (188), likely related to the long hinge region found in IgG3 antibodies (189). Moreover, the protective nature of IgG3 responses has been repeatedly observed against intracellular pathogens including malaria (185) and RSV (190). However, the importance of IgG3 in antiviral immunity was most clearly illustrated in the first moderately protective HIV vaccine trial, RV144 (191), which pointed to a critical role for IgG3 responses in reducing the risk of HIV acquisition (192, 193).

The order of the antibody subclass and isotypes is likely not coincidental but potentially evolutionarily programmed to allow for the selection of the most functional antibodies (e.g., IgG3 and IgG1) early in an immune response, followed by less inflammatory antibody subclasses in subsequent waves of the immune response (e.g., IgG2 and IgG4). For example, within the IgG antibodies, affinity for FCGRs, and therefore immune function, follows the same order as is encoded within the *IGH* locus with IgG3 harboring the highest affinity for FCGRs, then IgG1, then IgG2, and finally IgG4, which demonstrates negligible FCGR-mediated biological functionality. This enables new B cells to select the most functional antibody subclass earliest in an immune response and switch these out if they are ineffective.

**FC GLYCOSYLATION.** Although all antibody isotypes and subclasses are glycosylated, the functional consequences of IgG glycosylation have been the most well characterized. All IgG antibodies are glycosylated at a single asparagine residue (N297) within the CH2 domain of the Fc domain, and modulation of the antibody glycan rapidly and potently alters the inflammatory profile and effector functions of the antibody (194). This complex, N-linked glycan, consists of differing levels of four sugar moieties (galactose, sialic acid, fucose, and N-acetylglucosamine) attached to a biantennary core glycan structure. Particular glycan structures have been shown to differentially affect the binding of the antibody to various innate immune receptors, thereby modulating the functional activity of the antibody. For example, antibodies in which the glycan lacks additional galactose residues (known as G0 antibodies) have been associated with increased inflammation in HIV (195, 196) and chronic autoimmune conditions (197) and are known to drive enhanced complement binding and activation (198). In contrast, the presence of higher levels of galactose provides the scaffold for the addition of terminal sialic acid residues, which have been shown to have antiinflammatory activity

via binding to lectin-like receptors (199). Furthermore, changes in the fucose and N-acetylglucosamine content play a critical role in modulating antibody effector function, whereas a lack of fucose (200) or the addition of the N-acetylglucosamine (201) increases ADCC activity. Yet, beyond these well-characterized glycan structure: function relationships, over 30 different glycan structures have been identified in naturally produced antibodies, each with the theoretical capacity to drive distinct effector functional profiles.

### Fc Receptors

All innate immune cells express Fc receptors, which allow antibodies raised by the adaptive immune system to provide these cells with specificity to kill pathogens or infected cells. In humans, Fc receptors (FcRs) exist for individual antibody subclasses including Fc $\alpha$ R (IgA), Fc $\epsilon$ R (IgE), and Fc $\gamma$ R (IgG), with multiple family members belonging to each class of receptors. The broadest family of Fc receptors include the Fc $\gamma$ R family, with six different Fc $\gamma$ Rs identified in humans. These Fc $\gamma$ Rs having various affinities for IgG (high-affinity Fc $\gamma$ RI, and low-affinity Fc $\gamma$ RII and Fc $\gamma$ RIII), with several variants among the low-affinity receptors, including an activating Fc $\gamma$ RIIA, the inhibitory Fc $\gamma$ RIIIB, a rare activating Fc $\gamma$ RIIC, a transmembrane-activating Fc $\gamma$ RIIIA, and a GPI-anchored Fc $\gamma$ RIIIB protein. Moreover, within the activating Fc $\gamma$ RIIA and Fc $\gamma$ RIIIA receptors, polymorphisms exist that confer increased affinity to IgG molecules, including the 131H/R FCGRA variants (the H variant has higher affinity) and the 158F/V FCGR3A SNP (the V variant has higher affinity) recognized for their ability to affect the clinical efficacy of monoclonal therapeutic intervention strategies (202). Importantly, the expression of these receptors is relatively restricted among innate immune cell subsets, providing a level of regulation of the specific innate immune effector cells that are able to respond specifically to antibody targets. For example, Fc $\gamma$ RIIIA is expressed nearly exclusively on NK cells, whereas Fc $\gamma$ RIIIB is expressed predominantly on neutrophils. Conversely, monocytes, macrophages, and dendritic cells express Fc $\gamma$ RIIA and can upregulate Fc $\gamma$ RIIIA expression upon activation. The expression of Fc $\gamma$ RIIB is more restricted and is highly expressed on B cells and dendritic cells, aimed at regulating the activity of these cells.

Interestingly, in the context of infections, Fc $\gamma$ R polymorphisms have been linked to both susceptibility and resistance to several infectious diseases (203). Indeed, differences in Fc $\gamma$ RIIIA polymorphisms have also been linked to differential risk of infection following vaccination, including elevated risk of infection in the low-risk vaccine category in the HIV vaccine trial, VAX004, in which the 158VV Fc $\gamma$ RIIIA genotype was associated with enhanced risk of infection (204). Yet, despite the effects of these polymorphisms, Fc $\gamma$ R expression is tuned rapidly during an immune response to increase expression on innate immune cells (205). These rapid changes allow innate immune cells to respond instantaneously to pathogen-specific antibodies to drive rapid clearance and control of infection. Although neutralizing antibodies, able to block viral infection, are largely considered the correlate of protection against most viral infections, non-neutralizing, Fc-mediated antibody functionality also contributes to antibody-mediated control against West Nile virus (206), HIV (207), and ebola virus infections (207). In some instances, however, non-neutralizing antibody effector functions can also potentiate disease through the delivery of infectious particles to

macrophages via immune complex uptake through Fc-receptors, as has been shown for antibody dependent enhancement (ADE) in the setting of dengue virus infection. Thus antibody Fc-effector functions represent a double-edged sword that are critical for viral clearance but can also be hijacked by viruses to enhance their capacity to gain entry into the host. As we gain a deeper appreciation into the antibody Fc-functions that provide the greatest levels of protection, future vaccination strategies may be rationally designed to selectively drive protective functional antibody profiles that avoid any antibody-enhancing effects.

### Summary

The innate immune system composed of physical barriers, commensals, effector proteins, and an array of distinct immune cells collectively act with near instantaneous speed to protect against infection as well as set the stage for adaptive immune responses. The adaptive immune system, composed of T- and B-cell responses, represents an evolutionary marvel that permits the generation of nearly an infinite number of possible perpetually evolving, antigen-specific adaptive immune cells able to recognize, control, clear, and destroy any foreign antigen the immune system may encounter. However, the induction of this network of antigen-specific cells is heavily influenced by the innate immune system that clearly qualitatively shapes the functional activity of this arm of the immune system. Thus, the two arms of the immune system, the innate and adaptive arms, are intimately intertwined to ensure the evolution of the most effective immune response to ensure both the survival of the host following primary infection but also long-lived memory to rapidly clear and eliminate the pathogen upon reinfection.

### Conclusion

Over the course of human evolution, we have developed elaborate mechanisms to defend ourselves from the persistent threat of viruses. Although many of the primordial mechanisms evolved in humans still persist today as components of our innate immune response to viruses, we have developed more elaborate means to protect ourselves through the evolution of the adaptive immunity. Thus the collaboration of the innate and adaptive arms of the immune system provides life-long immunity against these opportunistic pathogens.

Immunity to viruses is still incompletely understood and new cellular responses, innate sensing, and host restriction factors are identified every year. However, several layers of the antiviral immune response have been identified and briefly summarized here:

1. The most superficial part of the antiviral defense system is a layer of commensal microbacteria followed by physical barriers that include keratinocytes of the skin, mucus on mucosal surfaces, and several layers of mucosal membranes that can sense invading pathogens through PRRs. These layers are categorized as **barrier immunity**.
2. Intertwined with the barrier immunity is the **innate immunity** that senses invading pathogens based on PAMPs that are unique to microbes. Several PRRs have been discovered, including TLRs, NLRs, RIG-Is, and CLRs, and it is likely that there are several more still undiscovered. The sensing of the PAMPs happens either extracellularly or intracellularly in phagocytes (mDCs, pDCs, neutrophils, macrophages, etc.). These cells respond to the respective PAMPs accordingly and

attract further cells of the innate and adaptive immune system or trigger the upregulation of host restriction factors such as TRIM5 $\alpha$ , APOBEC, or tetherin.

3. A subset of the innate immune response, the NK cells, can also recognize specific antigens of invading viruses and are on the border of the adaptive immune response, exhibiting memory.
4. The innate immune response shapes **adaptive immunity** that consists of CD4 T and CD8 T cells as well as B cells. The development of adaptive immunity is complex but the resulting immune responses are highly specific for the invading pathogen and can form memory that will protect against a secondary re-encounter of the pathogen.
5. CD8 T cells are the main cell subset involved in killing intracellular pathogens such as viruses, but CD4 T cells can also acquire this ability as well. However, CD4 T cells are largely involved in generating a host of different functions required for the overall orchestration of the immune response to any infection.
6. Simultaneously with the development of CD4 and CD8 T cells, virus-specific B-cell responses develop aimed at generating copious amounts of antibodies that can attack the incoming pathogen. The maturation and characteristics of these antibodies are dictated in the GC by Tfh cells, aimed at generating both high-affinity as well as functionally relevant antibodies.
7. Antibodies can have many different functions. Besides neutralizing the agent, they can also recruit cells of the innate and adaptive immune systems, via Fc-receptors, to drive rapid control and clearance of pathogens. The activity of antibodies is dictated by the constant region of the antibody and may be exploited by vaccination strategies.

Thus, with our evolving understanding of the immune response to viruses, the opportunities to rationally develop novel therapeutics and vaccine strategies to prevent infection and/or disease are endless. Thus biomedical research efforts must continue to dissect the remarkably rich complexity of our immune response to viral infections and to provide insights for the development of medical interventions to end morbidity and mortality caused by these pathogens.

# Immunization Against Viral Diseases

JULIE E. LEDGERWOOD AND BARNEY S. GRAHAM

## 17

Vaccines against viral infections are perhaps the greatest of all biomedical achievements for preventing disease and improving the public health. The most notable example is the success of smallpox vaccination. The practice of variolization (mechanical attenuation and intentional low-dose infection) to reduce the virulence of subsequent smallpox infection was started more than 1,000 years ago in India and China. However, smallpox vaccination was first performed by Jenner in 1796. This event marked the beginning of modern vaccine development and the first clinical test of vaccine efficacy. An expansive, sustained world health effort with global cooperation and leadership in combination with creative approaches, like the ring vaccination campaign, resulted in the 1980 WHO declaration that naturally occurring smallpox had been eradicated. Numerous other vaccines have had a significant impact on the severity and frequency of viral diseases, and many previously common viral illnesses are rarely encountered in modern clinical care (Table 1). In particular, vaccines against hepatitis A and B, poliovirus, measles, mumps, varicella, and rubella have markedly reduced the frequency of these infections in developed countries. Unfortunately, many of these infections remain major health problems, particularly in communities who choose to opt out of standard childhood immunizations (1) and in the developing world. A description of viral vaccines available for use in the United States is shown in Table 2.

Effective immunization safely induces a vaccine-specific host immune response capable of either preventing infection or attenuating illness. Historically, viral vaccine immunogens were created by either inactivating or attenuating whole virus and were tested empirically with a rudimentary understanding of basic viral pathogenesis or protective immune responses. Newer generations of viral vaccines often involve a detailed understanding of the virology and immunology specific to the pathogen and utilize molecular biology approaches to produce vaccine antigens. This chapter will review current viral vaccine practices and concepts and indicate future directions for vaccine research and development.

### GOALS OF VACCINATION

The goal of immunization against viruses is to improve both individual and public health by preventing or modifying virus-induced disease in a person and preventing or reducing

the spread of infection in a population. When individuals do not participate in vaccination efforts against epidemic diseases, there are potential consequences for the person but greater consequences for public health (2). Vaccination is one of the few opportunities for a personal health benefit to be amplified as a benefit to the greater population.

### Prevention of Infection or Disease

#### Active and Passive Immunization

Immunization is defined as induction of an antigen-specific host immune response by exposing the host to antigens representing, or comprised of those in, the wild-type pathogen. “Active immunization” to a virus can be induced by natural infection or by vaccination. The term implies an induction of immunological memory. “Passive immunization” refers to a transfer of temporary immunity to the host, which will not provide immunologic memory, but provides transient immune-mediated protection from infection or disease. The most common example of passive immunization is the transfer of disease-specific immunoglobulins into a host (3). In the cases of rabies and hepatitis B exposure, both passive (immunoglobulin) and active (vaccine) immunization are commonly used together to induce both rapid and long-lasting protection. Currently, there is only one monoclonal antibody (mAb) approved and in widespread use against an infectious disease. Palivizumab is used to prevent severe disease from respiratory syncytial virus (RSV) in premature infants. There are mAbs targeting HIV, West Nile virus, Ebola virus, and other infections in development and are likely to be used in future clinical practice for therapy or prevention of specific viral infections.

#### Prophylactic Vaccination

Most vaccines are designed to prevent virus infection in the individual. In most circumstances vaccine-induced immunity does not completely block infection but prevents disease by aborting or rapidly clearing infection through blocking transmission of virus to the target organ or preventing the indirect consequences of virus infections. Incomplete protection from infection has no clinical consequences for viruses that are typically self-limited and do not persist. For example, the inactivated polio (Salk) vaccine prevents dissemination of the virus to the anterior horn cells but does not prevent replication and shedding of poliovirus in the gut. The licensed hepatitis B virus (HBV) and human papillomavirus

**TABLE 1** Impact of licensed vaccines on annual prevalence of selected viral diseases reported in the United States

Viral disease	Peak year(s)	Peak prevalence	Modern prevalence	Percent reduction
Hepatitis A	1971	59,606	1,781 <sup>a,b</sup>	97
Hepatitis B	1985	26,654	3,050 <sup>a,b</sup>	88.6
Measles	1958–1962	503,282	187 <sup>a,b</sup>	>99.9
Mumps	1967	185,691	584 <sup>a,b</sup>	99.7
Polio	1951–1954	16,316	1 <sup>a,b</sup>	>99.9
Rubella	1966–1968	47,745	9 <sup>a,b</sup>	>99.9
Congenital rubella	1966–1968	823	1 <sup>a,b</sup>	99.9
Smallpox	1900–1904	48,164	0	100

(HPV) vaccines have a major goal of preventing a delayed clinical consequence of viral infection, liver cancer, or cervical, vulvar, vaginal, and anal cancers, respectively (4, 5). For viruses like HSV, HCV, or HIV that can become persistent or latent, vaccine-induced immunity to control or prevent virus infection needs to be more stringent and be achieved as soon after virus exposure as possible to prevent or minimize the viral reservoir. This is one of the great challenges in developing vaccines against these types of viruses.

#### Postexposure Vaccination

In some cases, vaccines can be effective even when administered after exposure to the pathogen, as for rabies and hepatitis B. Notably, individuals can be protected against a fatal outcome if vaccinia virus vaccine is administered up to four days after variola exposure, despite the relatively rapid progression of smallpox. For postexposure immunization to work, the vaccine must be highly immunogenic, and success is more likely when the pathogenesis involves a relatively long incubation period between infection and disease onset.

#### Vaccination to Control Viral Reactivation

Some vaccines can also be used therapeutically after long-term virus infection has become established in the host. This could be done to bolster immunity and prevent reactivation of latent infection or to induce additional immune effector functions in order to control persistent infection. The only licensed vaccine for postinfection prophylaxis is targeted against herpes zoster reactivation that may happen in persons with prior varicella infection as immunity wanes. Immunization of elderly adults with live-attenuated varicella-zoster virus (VZV) vaccine during latency reduces disease burden, the incidence of herpes zoster, and postherpetic neuralgia (6, 7). Diseases such as HSV-1, HSV-2, HCV, or HPV, which produce latent or persistent infection with periodic clinical flares or long-term clinical consequences, are candidates for therapeutic vaccine development, although achieving new responses to clear persistent virus in the setting of preexisting immunity is still an unproven concept. HIV-1 is also a target for therapeutic vaccine development, but the task will be more difficult for viruses like HIV that cause immunological impairment as a direct result of infection. Even for viruses like human papilloma virus (HPV), for which there is an effective prophylactic vaccine, the efficacy of therapeutic vaccination to either clear persistent virus or to treat cervical cancer will be difficult to achieve and will require a fundamentally different approach.

#### Herd Immunity

As an increasingly large fraction of a population is immunized against a particular pathogen, an indirect beneficial effect occurs that is greater than anticipated relative to vaccination rates. “Herd immunity” occurs as both transmitters of virus and susceptible persons are reduced in the population, and fewer incident cases of infection occur in the unprotected portion of the population. This results in a greater than expected decrease in the prevalence of infection and also means that if only a few individuals are not immunized, they will benefit from the immunity of those around them. This is an important consideration in the protection of individuals who have impaired immune systems and may not have the capacity to respond to vaccination. Rubella immunization is a practical example of herd immunity. The major goal is to prevent fetal abnormalities caused by intrauterine infection. Therefore, both males and females are immunized in the United States even though immunization has little direct benefit to males other than prevention of a relatively mild illness. Another type of herd immunity can occur when persons receiving live virus vaccines (e.g., oral poliovirus vaccine) transmit the attenuated vaccine strain to other susceptible contacts (8, 9). While this type of spread can improve vaccine coverage, depending on the stability of the attenuating mutations, if vaccine virus reverts to wild-type it could also have untoward consequences. Understanding the concept of the basic reproductive number ( $R_0$ ) of a pathogen in a population helps to explain the concept of herd immunity.  $R_0$  is the number of new infections that occur through transmission from a single individual. If  $R_0$  is  $> 1$ , then epidemics will expand, and if  $R_0$  is  $< 1$ , epidemics will contract. If vaccinees are protected from infection or if infected vaccinees have a shorter period of shedding, the number of transmission events from each infected person will drop. A rule of thumb to estimate the percentage of protected individuals in a population needed to achieve herd immunity is  $(1 - (1/R_0)) \times 100$ .

#### Disease Eradication by Vaccination

The ultimate goal of vaccination is to achieve disease eradication. This is theoretically possible for viruses (like variola) that have no animal reservoir, do not cause persistent or latent infection, do not undergo major antigenic change, and exhibit distinctive clinical signs of disease to enable reliable recognition. Polio and measles meet these criteria, and stuttering progress has been made in ongoing efforts to eradicate these diseases through vaccination. Beyond those two, there are no viral diseases that are immediate candidates for eradication. With the ever increasing

**TABLE 2** Vaccines licensed in the United States for use against viral diseases

Vaccine	Type	Route	Cell substrate	Trade name/sponsor	Comments <sup>b</sup>
Adenovirus	Live	Oral	Human diploid fibroblasts	Barr Labs Inc	Types 4 and 7 approved for military personnel 17 through 50 years of age and recommended by DoD for military recruits entering basic training
Hepatitis A	Inactivated	IM	Human diploid fibroblasts	Havrix/GSK VAQTA/Merck Twinrix (Hep A & B combination)/GSK	
Hepatitis B	Recombinant subunit virus-like particles	IM	Yeast	Recombivax HB/Merck Energix-B/GSK Twinrix (Hep A & B combination)/GSK	Booster: in specific circumstances (see ACIP guidelines)
Human papillomavirus	Recombinant, virus-like particles	IM	Yeast baculovirus	Gardasil/Merck Gardasil 9/Merck Cervarix/GSK	Types 6, 11, 16, 18 Types 6, 11, 16, 18, 31, 33, 45, 52, and 58 Types 16 and 18
Influenza A H1N1 2009 Monovalent Vaccine	Inactivated	IM	Embryonated chicken eggs	No trade name/CSL Limited No trade name/MedImmune LLC No trade name/ID Biomedical Corporation of Quebec No trade name/Novartis Vaccines and Diagnostics Limited No trade name/Sanofi Pasteur, Inc.	
Influenza A and B	Inactivated <sup>a</sup> or live	IM or intranasal	Embryonated hen eggs  Insect cells	FluLaval/ID Biomedical Corp of Quebec Fluarix/GSK Fluvirin, Agriflu, Flucelvax/Novartis Fluzone/Sanofi Flumist (live)/MedImmune Vaccines Flublok/Protein Sciences Corporation	Specific H3N2, H1N1, and B strains selected annually; trivalent and quadrivalent compounds
Influenza H5N1	Inactivated	IM	Embryonated hen eggs	No trade name/Sanofi	Based on the Vietnam Strain of H5N1; for National Stockpile only
Japanese encephalitis	Inactivated	SQ	Mouse brain	JE-Vax/Research Foundation for Microbial Diseases of Osaka University	Booster: one year or more from previous dose
Measles	Live	SQ	vero cell Chicken embryo fibroblasts	Ixiaro/Intercell Biomedical Attenuvax/Merck M-M-R II (measles, mumps, rubella combination)/Merck Proquad (measles, mumps, rubella, varicella combination)/Merck

capability in genome sequencing and molecular biology, even if a virus can be eradicated from nature, there will be full-length genome sequences (e.g., polio) and laboratory reservoirs (e.g., variola) that will remain.

### IMMUNOLOGIC BASIS OF VACCINATION AGAINST VIRAL DISEASES

Innate immune responses are an important component of the immune system and provide an early, rapid-onset defense against pathogens (see Chapter 16). These responses do not require previous exposure, are generally not antigen specific, and are not thought to confer immunologic memory. The innate immune system is universal, and all cells possess some inherent capacity for protection. In contrast, adaptive immunity is antigen specific and requires an activation and

amplification phase as it responds to a primary antigen exposure. This is accomplished primarily through specialized B and T lymphocytes and is characterized by immunologic memory with the capacity for rapid, specific effector responses upon reexposure to a previously recognized antigen. Many aspects of innate immunity intersect with elements of the adaptive immune response by providing mechanisms for recognizing threats, strengthening the engagement and activation of adaptive responses, and even sharing effector mechanisms.

Antiviral immunity is mediated by both innate and adaptive immune responses. However, vaccine-induced immunity depends on immunological memory, which is an inherent property of adaptive immune responses. Vaccination establishes preexisting antibody and memory populations of T and B cells that change the next encounter of a host with a

particular virus. Pre-existing antibody can reduce the initial number of infected cells and pace of viral replication, resulting in an attenuated disease course. An anamnestic response refers to the rapid increase in serum antibody that occurs after infection in a preimmune individual, indicating the presence of B cells that can rapidly expand as plasmablasts to produce antibody. A higher precursor frequency of virus-specific T cells can also attenuate disease through subtle changes in the timing and magnitude of responses. Vaccine design, formulation, and delivery will influence the specificity, quality, and location of T-cell responses and change the clinical expression of a subsequent virus infection. While it is the effector mechanisms of the adaptive immune response that are responsible for directly mediating vaccine-induced antiviral immunity, innate immune mechanisms are relevant to the pattern and quality of virus-specific responses that are predestined during the time immediately after vaccination.

### Innate Immunity

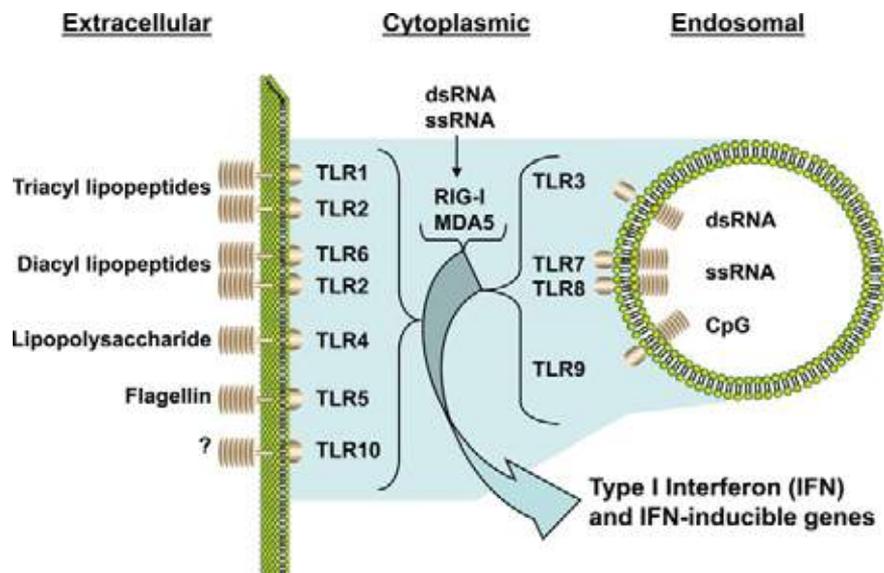

#### Pathogen Recognition

Janeway predicted that the immune system had mechanisms to recognize molecular patterns associated with pathogens and coined the term PAMPs (pathogen-associated molecular patterns) (10). That hypothesis has been validated through the discovery and description of toll-like receptors (TLRs) that recognize a variety of molecules typically associated with microbial pathogens (11) (Fig. 1). Some of these TLRs appear to have specifically evolved to recognize molecules within endosomes associated with viruses including double-stranded RNA (TLR-3) and single-stranded RNA (TLR-7 and TLR-8). Other pathogen recognition receptors (PRRs) have evolved to recognize dsRNA in the cytosol such as the RNA helicases, retinoic acid-inducible gene (RIG-I), and melanoma differentiation-associated (MDA) gene 5, or protein kinase receptor (PKR) (12). TLRs have also been noted to detect viral proteins such as the TLR-4 recognition of the RSV F glycoprotein (13). Triggering TLRs and other

PRRs leads to an integrated set of responses by antigen-presenting cells (APCs) through interferon regulatory factors (IRFs) and NF $\kappa$ B transcription factors that control the induction of genes involved in the antiviral response. The process of pathogen recognition is an important consideration when designing the adjuvant and delivery vehicles used in vaccine formulations (e.g., AS04 in Cervarix targeting HPV [14–16]). These activating stimuli prepare the immune system for recognizing specific antigenic sites on the virus that can be targeted by adaptive immune responses.

#### Antigen Presentation

The principle antigen-presenting cell for initiating adaptive immune responses are dendritic cells (DCs). The function of DCs varies as they progress through successive stages of maturation, the immature state generally being better for phagocytosis and the mature state better for antigen presentation. In addition, there are subpopulations of DCs that have distinct properties. In the future it may be possible to engage selected DC subpopulations and direct the patterns of immune activation. For example, plasmacytoid DCs (pDCs) express TLR9 and are a major source of Type I interferon (IFN) production. Activating pDCs during vaccination might be expected to induce strong CD8<sup>+</sup> T-cell responses because of the known association of IFN- $\alpha$  and memory CD8<sup>+</sup> T cells (17). It may be possible to augment pDC activation with CpGs, which are short palindromic sequences in bacterial DNA that serve as a ligand for TLR9. DCs usually first encounter antigen in tissue during an inflammatory event. After phagocytosis of the antigen or an apoptotic cell that contains antigen, they become mobile and traffic to regional lymph nodes. The mature DC in the lymph node presents processed antigen as peptides in the context of MHC class I or II molecules in combination with costimulatory molecules to activate epitope-specific CD8<sup>+</sup> and CD4<sup>+</sup> T cells, respectively. Therefore, DCs are important for the initial immunization event and are also

**FIGURE 1** Recognition of viral pathogens. Eukaryotes have evolved mechanisms to detect potential microbial pathogens as they encounter the plasma membrane or penetrate the endosomal or cytoplasmic compartments of the cell. The molecules that interact with microbe-derived ligands trigger signaling pathways that lead to inflammatory responses. Harnessing the coordinated regulation of immune responses elicited by TLRs and helicases is a major focus of new adjuvant development for vaccines.

important after exposure to a viral pathogen to rapidly carry the viral antigen to lymph nodes to activate and expand vaccine-induced memory T cells in response to infection.

### Immune Modulation

Immune modulation refers to altering the pattern of the immune response. This could involve the balance of response at various levels of specificity. For example, immune responses can be focused more on antibody or T-cell responses, CD4+ or CD8+ T cell responses, or Th1 or Th2 CD4+ T cell-responses. The patterns and characteristics of the immune response are often determined by the milieu of cytokines and chemokines and innate immune responses present at the time of initial antigen encounter (18). Therefore, vaccines are a powerful way to direct the pattern of subsequent immune responses to viral pathogens. For example, protein vaccines with alum adjuvants are more likely to induce Th2 CD4+ T cells that produce IL-4, products with oil-in-water adjuvant are more likely to strengthen antigen uptake and activate CD4 T cells (19), and gene-based vector vaccines are more likely to induce Th1 CD4+ T cells and CD8+ T cells that produce IFN- $\gamma$ . Similarly, combination adjuvant vaccines, i.e., TLR 7 adsorbed to alum, demonstrate immune activation with high antibody titers and Th1 induction (20–22).

### Adaptive Immunity

Adaptive immunity involves the capacity for immunological memory and for evolving improved antigen recognition and effector functions after subsequent exposures to antigen. The major cellular components of the adaptive immune response include B and T lymphocytes. The relative importance of these two arms of the immune response varies with the particular viral infection. In general, antibodies are the major mediator of resistance to reinfection with virus, and CD8+ T cells are the major mediator of clearing virus-infected cells. CD4+ T cells comprise diverse phenotypic subpopulations. They can produce distinct cytokine and chemokines critical for the induction of robust antibody responses and important for “helping” CD8+ T cell responses; they also have potential for direct antiviral effector functions.

### Antibody

Antibody is the key vaccine-induced effector mechanism for protecting against viral diseases. Antibodies are also a unique effector element of the adaptive immune response that can be maintained at protective levels prior to infection without causing harmful inflammation. The importance of antibody in protection against viral diseases has been demonstrated by the efficacy of passively administered antibody. Successful antibody prophylaxis has heralded subsequent vaccine development for polio, measles, varicella, hepatitis A, and hepatitis B. Passive antibody prophylaxis can also protect against some diseases for which no vaccine is available such as RSV and CMV, suggesting that active vaccination for these infections may also be possible.

Antibodies are generally thought to protect by “neutralizing” viral infectivity. Neutralization specifically refers to the property of reducing the number of infectious virus particles. Viruses are neutralized *in vitro* by antibodies using a wide variety of mechanisms. Antibodies can cause viral aggregation to effectively reduce the number of infectious units, inhibit virus attachment to cells, inhibit virus entry after attachment by inhibition of virus-cell fusion, or inhibit the release of newly formed virions from infected cells. Both

quantitative and qualitative features of antibodies affect neutralization potency. These include concentration, antibody-to-virus ratio, valency, state of polymerization, affinity, avidity, isotype, ability to bind the polyimmunoglobulin receptor (pIgR), ability to fix complement, and specificity for a particular antigenic site (23). Additionally, antibodies may control infection by mechanisms such as antibody-dependent cell-mediated cytotoxicity (ADCC) where an infected cell displaying viral antigen on the surface binds the antigen-specific Fab region of the antibody. This allows the Fc region of the antibody to bind to Fc receptors of ADCC effector cells, classically CD16 on natural killer cells, resulting in death of the infected cell. Supporting this, *in vivo* studies of neutralizing antibody protection against simian-human immunodeficiency virus (SHIV) suggest that the presence of the Fc receptor is needed for optimal virus neutralization and may be more important than complement binding (24).

Ideally, vaccine-induced protection will be mediated by antibody that has the right functional properties, magnitude, and specificity to completely neutralize virus and provide “sterilizing” immunity. Antibody is especially effective when the target organ for disease is distinct from the initial site of infection. For example, in measles, polio, hepatitis, or viral encephalitis, where viremia is required to cause significant clinical disease, vanishingly small amounts of preexisting antibody can protect. However, it is rarely possible to elicit sufficient antibody through vaccination to fully prevent viral infection. As an example, respiratory virus infections are not fully prevented through sterilizing immunity. Typically, responses to natural infection or vaccination limit infection to the upper airway and diminish disease severity but do not fully prevent infection. Therefore, vaccines that can induce both antibodies and virus-specific CD8+ T cell (cytotoxic T cells) to rapidly eliminate residual virus-infected cells provide an extra measure of certainty that virus-mediated disease will be attenuated.

Specific antigen bound to the B cell receptor triggers the B cell to proliferate and differentiate into antibody-producing plasma cells. Initially, about 5 to 7 days after antigen encounter, plasmablasts can be transiently found in blood. Some plasma cells take up residence in bone marrow where they can survive and maintain virus-specific antibody in serum for years (25). B cells can also undergo differentiation to become long-lived memory B cells. While these memory cells do not secrete significant amounts of antibody, they reside in the germinal centers of lymph nodes and express surface immunoglobulin that allows them to quickly respond to a subsequent encounter with a specific antigen. These subsequent encounters are responsible for initiation of affinity maturation of the antibody response accomplished through the process of somatic hypermutation.

Immunization can influence antibody-mediated immunity in many ways. First, by increasing the repertoire and the frequency of immunoglobulin receptors on memory B cells capable of recognizing a particular antigen, the kinetics of antibody production on subsequent exposure will be more rapid. Second, somatic hypermutation and B-cell selection in lymph node germinal centers results in antibody that has evolved from the original germline sequences. Therefore, repeated virus infections or immunization can lead to affinity maturation of antibodies. Consequently, multidose vaccine regimens or vaccination prior to primary infection can improve the affinity, magnitude, and duration of antibody persistence. Third, immunization with a vaccine formulation that promotes IFN- $\gamma$  production will increase the production

of IgG1 and IgG3 subclasses. Complement fixation is mediated by the CH2 region of the antibody Fc domain of IgM, IgG1, and IgG3, and complement binding can sometimes improve the neutralization potency of antibody. In contrast, IL-4 promotes IgE and IgG4 production, which are less desirable responses and are also associated with allergic reactions. Fourth, repeated immunization can improve the breadth of antibody responses to a particular virus by recruiting new responses to different antigenic regions. For example, there are five major antibody binding domains in influenza H3 hemagglutinin (HA) involved in virus neutralization, and repeated exposures to HA are generally needed to induce optimal antibody to all domains (26).

Some pathogens, particularly those with genetic variability, can misdirect the antibody response, including that to vaccines, as a mechanism of immune evasion. This has been characterized as “original antigenic sin” in the case of antibodies to the receptor-binding domain of influenza (HA) (27). B cells induced by past strains of influenza that recognize the rim of the sialic acid binding pocket can be preferentially expanded by new drifted strains because of their high precursor frequency, even though binding affinity and neutralizing capacity may be limited. This delays the induction of high-affinity antibodies that can neutralize the new strain and emphasizes the importance of the initial antigen priming event for the pattern and effectiveness of subsequent immunity. Immunodominance is another phenomenon that can prevent optimal antibody responses. There are examples of this in antibody responses to HIV env glycoprotein, gp160, associated with conformational states, where the most immunogenic sites are not neutralizing targets, and antibodies associated with broad neutralization are more difficult to achieve. Another example is influenza, in which antigenic sites in the head domain of HA are the most immunogenic but elicit antibodies that tend to be subtype specific. Responses to the HA head dominate responses to the HA stem domain, which has epitopes that are more conserved between subtypes and is associated with eliciting broadly reactive heterosubtypic antibodies (28–30). Therefore, identifying approaches that can induce more durable responses to subdominant stem epitopes may reveal strategies for developing a more “universal” influenza vaccine (31, 32).

### CD8+ T Cells

T-cell responses (cell-mediated immunity) are essential components of a successful immune response for many pathogens, especially for viruses. T cells express T-cell receptors (TCR), which recognize specific peptide epitopes bound to major histocompatibility complex (MHC) proteins on the surface of antigen-presenting cells (APCs). The cytotoxic lymphocyte (CTL) TCR recognizes a short 8 to 10 amino-acid peptide derived from an endogenously produced viral protein in the context of the MHC class I  $\beta$ 2-microglobulin heterodimer. Virtually all cells express MHC class I molecules and can be recognized by CTLs if they become infected by a virus. However, not all cells are equipped to effectively initiate a CTL response. For vaccine induction of virus-specific CD8+ T cells, the antigen containing the relevant epitopes must be present in the cytosolic compartment of a dendritic cell that can process the antigen, be liberated by proteolysis, and the peptide be transported into the endoplasmic reticulum where it can associate with the appropriate MHC class I molecule. Antigen presentation must then be accompanied by costimulatory signals that can activate T cells with relevant TCRs to proliferate and dif-

ferentiate into effector and memory cells. The process is facilitated by the cytokine milieu produced by the local inflammatory process and the APCs and can be attenuated by the influence of CD4+ FoxP3+ regulatory T cells (Tregs).

The importance of CTLs in recovery from viral infection is witnessed by the frequency of severe viral infections associated with cellular immune deficiencies, and by the diverse strategies viruses use to escape CTL killing (33). Herpesviruses, poxviruses, and lentiviruses in particular have evolved mechanisms for interfering with antigen presentation or effector molecules required for CTL activity. The influence of CD8+ CTL memory on the outcome of a subsequent virus exposure can be subtle and may depend on the absence or presence of other components of the immune response. The impact of the CTL response is critically dependent on the timing of response and the efficiency and specificity of cytolytic activity. The immune response gains advantage in cases where virus replication and spread is slower or when the immune response is accelerated. More targeted, rapid killing of virus-infected cells and less bystander killing will reduce immunopathology and generally improve the clinical outcome.

No vaccine based primarily on induction of CTL has been licensed, and this is generally a secondary goal to antibody induction in vaccine development. Advances in polychromatic flow cytometry (34, 35) and other technologies such as CyTof (36, 37), Fluidigm (38), single-cell evaluation by functional studies (39), and sequencing (40) have made it possible to define functional subsets of T cells with more precision (41) and may provide the necessary tools for effectively targeting CTL induction in the future. Preclinical studies and early-phase clinical trials have demonstrated the potential for effectively inducing T-cell memory with effector functions sufficient for protection against viruses such as simian immunodeficiency virus (SIV), hepatitis C virus, and Ebola (42–45). In addition to memory phenotype, TCR specificity, and avidity, there are other CD8 T-cell properties that may make them more likely to contribute to effective immunity. For example, some CD103+ CD8 T cells, termed tissue-resident memory cells, remain in barrier tissues at mucosal surfaces and are poised to rapidly recognize and clear virus-infected cells at the site of initial inoculation (46). Also, high magnitude CD8 T-cell effectors can be maintained against some epitopes in a process termed “memory inflation” when induced by cytomegalovirus (CMV) vectors that can become latent and sustain intermittent antigen expression (47). This provides a pool of effector T cells that can rapidly respond to new infections and could be exploited for vaccinating against pathogens that require T cell-mediated immunity (48).

### CD4+ T Cells

CD4+ T cells recognize peptide epitopes associated with the  $\alpha\beta$  heterodimeric MHC Class II molecules present on professional APCs. They have been categorized into an increasingly complex array of subpopulations based on which transcriptional regulator they express, the pattern of secreted cytokines, and other functional properties (49–52). These include not only traditional T-helper (T<sub>H</sub>) cells but also cells involved in regulating inflammatory cytokine responses (T<sub>H</sub>17 cells) and T-regulatory (Treg) cells that modulate the function of CD8 T cells. These subpopulations are important in molding the overall pattern of the subsequent immune response to viral infection and can be influenced by vaccine design and formulation. For example, T<sub>H</sub>1 cells are important for creating an interferon- $\gamma$  (IFN- $\gamma$ )-rich

environment that promotes better cytolytic activity in CTL and switching to more potent subclasses of antibody.  $T_H2$  cells produce IL-4, IL-5, IL-9, IL-10, and IL-13, which promote B-cell growth and differentiation but can also be associated with allergic inflammation. Another CD4 T-cell subpopulation critical for vaccine-induced antibody responses are follicular T-helper (TFH) cells. TFH are CCR5+ cells that produce IL-21 and express the transcription factor Bcl6. They are required for stimulating B-cell responses in lymph node germinal centers (53). Antigen specific  $T_H1$  and  $T_H2$  cells can be detected following vaccination (54, 55), as can antigen-specific  $T_{FH}$ . CD4 T cells can also provide direct antiviral activity *in vivo* (56–59), although the contribution is less than that of CD8 T cells, which is consistent with the limited distribution of MHC class II.

CD4+ T-cell epitopes are more numerous on viral proteins than CTL epitopes (60), and some responses can induce a protective immune response in the absence of B cells or CTLs (57). CD4+ T cells secrete IFN- $\gamma$ , TNF- $\alpha$ , and other soluble factors with direct antiviral activity. Interestingly, the processes involved in establishing CD4+ T-cell memory are distinct from those involved in CD8+ T-cell memory responses (61). Antigen processing and presentation, unlike CD8+ T cells, occur through the endocytic pathway, so induction can be achieved by killed virus vaccines or even purified proteins and does not require live virus or gene delivery approaches for cytosolic processing. CD4+ T cells do not proliferate to the same extent as CD8+ T cells during primary infection, and those producing IFN- $\gamma$  only do not survive as long-lived memory cells (62). In addition, inducing antigen-specific CD4+CD25+FoxP3+ Tregs may dampen other components of the adaptive immune response and diminish effector T-cell mechanism upon subsequent exposure to virus (63). The full impact of the complex role of regulatory T cells remains under investigation but the immune response to viral infection and vaccination is certainly affected by Treg activity (64–67). Therefore, the overall pattern and impact of CD4+ T cell induction is an important consideration in vaccine design.

### Mucosal Immunity

Mucosal immunity refers to the local adaptive immune response at mucosal surfaces, including oral, upper and lower respiratory tract, gastrointestinal tract, and vaginal mucosae. The mucosal surface is the primary portal of entry for most viruses, and antigen-specific humoral and cellular immune responses can be found at those surfaces. Theoretically, when antigen-specific immunity can be induced at a mucosal site at risk for future virus exposure, in addition to induction of systemic responses, overall protection should be improved (68). The live-attenuated nasally administered seasonal influenza vaccine is based on this principle (69). Poliovirus vaccines provide an example of how mucosal immunity influences wild-type virus replication patterns. The inactivated (Salk) poliovirus vaccine given parenterally produces antibody responses that block transmission of poliovirus from the gut via the circulation to anterior horn cells. This vaccine is highly efficacious for preventing paralysis but does not prevent infection and replication in the intestinal mucosa. In contrast, the live-attenuated (Sabin) poliovirus vaccine protects against infection and prevents wild-type virus shedding. The importance of measurable evidence of mucosal immunity for vaccine-induced protection against other viruses is controversial.

Traditionally, the hallmark of mucosal immunity has been considered to be the presence of IgA. Dimeric IgA present in

plasma or produced locally is transcytosed through mucosal epithelium and when associated with J chain protein binds the polymeric immunoglobulin receptor prior to secretion. IgA is thought to be particularly important for defense against pathogens limited to mucosal surfaces, and the primary immunodeficiency described as selective IgA deficiency may generally result in an increased risk of respiratory infections, diarrhea, and autoimmunity. However, IgA deficiency has not been associated with increased frequency or severity of specific viral infections. Therefore, the importance of specifically inducing IgA through vaccination is not known. IgG antibody present in the systemic circulation is also significantly involved in protection against mucosal pathogens if present at a protective titer. In general transudation of IgG occurs more easily in the lung than in the nasopharynx, and the intestinal tract is even more resistant. IgA can be present at high concentrations in mucosal fluid and is more resistant to proteolysis in that environment. The concept of a common mucosal immune system where mucosal immunity at one site confers protection at other mucosal sites has been suggested experimentally (70–72). However, in general, directly immunizing the mucosal surface at greatest risk of exposure will improve protection at that site. Although not well understood, this phenomenon may be related to observations that suggest some effector cells can remain in tissue for long periods of time at the site of a prior infection or antigen exposure (71, 73).

### FORMULATION, ANTIGEN CONTENT, DELIVERY OF VIRAL VACCINES

Most licensed and investigational viral vaccines fall into one of seven categories: live-attenuated vaccines or chimeric viruses, inactivated vaccines, subunit vaccines, virus-like particles, replication-competent or replication-defective vectors, or nucleic acid vaccines (Table 3). The type of vaccine used for a particular viral pathogen, its formulation or adjuvant properties, antigen selection, schedule, and route of administration will all have profound effects on the types of immunological effectors induced. Therefore, vaccine design should be informed by an understanding of the pathogenesis and the optimal form of immunity to a particular viral pathogen.

### Adjuvants

Adjuvants are used to improve the magnitude, composition, quality, and duration of vaccine-induced humoral and cellular immune responses to viral antigens. Adjuvants have typically been empirically derived from natural products with immunostimulating properties. For example, the classic Freund's adjuvant is a derivative of mycobacterial cell walls. Analysis of Freund's adjuvant, which is a mineral oil emulsion containing an undefined mixture of trehalose dymicolate, phospholipids, and lipopolysaccharides, led to more distilled products such as monophosphoryl lipid A (MPL) and MF59, oil-in-water emulsions. The active component in ISCOMS (immune stimulating complexes) derived from extracts of the soap bark tree (*Quillaja saponaria* Molina) was found in the 21st HPLC peak of the bark extract, hence the designation QS21.

The underlying mechanism of adjuvants has not been well understood. Traditional adjuvant concepts suggesting the importance of particulate antigen complexes, creation of antigen depots to prolong antigen persistence, or induction of nonspecific inflammation have given way to a more

**TABLE 3** Platform technologies used to deliver viral vaccine antigens<sup>a</sup>

Vaccine type	Prototypes	Induction of protective antibody	Induction of CD8+ T cell responses	Potential for mucosal delivery
Live-attenuated virus	Sabin polio vaccine (OPV), Flumist influenza vaccine, rotavirus vaccines	+++	++	+++
Chimeric live virus <sup>b</sup>	Recombinant parainfluenza, measles, or vesicular stomatitis virus	+++	++	+++
Whole killed or inactivated virus	Salk polio vaccine (IPV) or conventional influenza vaccine	+++	+/-	+
Viral protein(s), virus-like particles	HBsAg—Recombivax HB, Energix-B, Twinrix, HPV—Gardasil	+++	+/-	+
Subunit proteins	FluBlok rHA influenza vaccine, VZV gE <sup>b</sup>	+++	-	+
Replication-defective vectors <sup>b</sup>	Recombinant poxvirus or adenovirus vectors	++	+++	+++
Nucleic acid <sup>b</sup>	DNA or mRNA	+	++	+

<sup>a</sup>This table focuses on antigen delivery approaches and does not attempt to include all the licensed (alum, AS03, AS04, MF59) or unlicensed (AS01b, ISCOMS, TLR agonists) adjuvants that could be used to modify the formulations and properties of the vaccines.

<sup>b</sup>Investigational status in humans although licensed veterinary vaccines utilize some of these platform technologies.

precise understanding of how the innate and adaptive immune responses are linked. The discovery of TLRs and their importance in pathogen recognition and immune activation has led to new options for vaccine formulations based on specific TLR engagement. TLR ligands trigger signaling pathways that change the functional state of antigen-presenting cells and thereby control the pattern and timing of cytokine production, mobility, and expression of costimulatory molecules. Selecting individual cytokines or costimulatory molecules as vaccine adjuvants underestimates the complexity of the milieu and importance of timing involved in nascent immune responses. Using TLR ligands as vaccine adjuvants may avoid the unanticipated problems that arise when using individual molecular adjuvants in isolation (74) and provides a more authentic stimulus for generating primary immune responses. Many empirically discovered adjuvants are now understood to be TLR ligands. For example, muramyl dipeptide derivatives and monophosphoryl lipid A stimulate TLR-2 and TLR-4, respectively. Imidazoquinoline compounds such as imiquimod and resiquimod have been found to be agonists for TLR-7 and TLR-8 that are designed to recognize single-stranded RNA. Palindromic CpG sequences found in bacterial DNA are recognized by TLR-9. Using TLR ligands as adjuvants (75) or conjugates (76) will be an important thrust of future vaccine development (22).

### Antigen Targets

The antigenic content in the vaccine confers specificity to the immune responses. For antibody-mediated protection, the surface glycoproteins and capsid proteins of viruses are the primary antigens to target in a vaccine-induced immune response. These are the proteins associated with tissue tropism, attachment, and entry. Most neutralizing antibodies recognize conformational epitopes, so generally it is important to mimic the native structure as much as possible. When possible, displaying antigens as virus-like particles or in ordered arrays will tend to improve antibody responses (77). In some cases (e.g., HIV-1) induction of broadly neutralizing antibodies to viral glycoproteins is extremely challenging because of the need for oligomeric structures, conformational evasion, variable glycosylation patterns, genetic variation, and highly antigenic regions that are func-

tionally unimportant but divert the recognition of functionally important epitopes (78–80). There is usually more than one antigenic site associated with neutralization on a virus attachment protein, and to reduce the risk of immune evasion, antibodies should be elicited to multiple sites. Recent advances in human monoclonal antibody identification and structural characterization of viral surface glycoproteins and viral particles have significantly improved the options for atomic-level design of vaccine antigens for the elicitation of neutralizing antibodies (81). The best example of this comes from the fusion glycoprotein (F) of respiratory syncytial virus (RSV). Solving the crystal structure of neutralizing epitopes on the prefusion and postfusion conformations of trimeric F (82) guided the molecular stabilization of the pre-F conformation that displays multiple neutralization-sensitive epitopes not present on the post-F surfaces (83). In addition, the structural information provided the basis for designing a single scaffolded epitope that was able to elicit RSV-specific neutralizing activity (84), establishing a proof-of-principle for structure-based vaccine design.

Antigen selection for inducing CD8+ T-cell responses involves a different set of considerations. Since CTLs recognize processed peptide epitopes in MHC class I molecules, all viral proteins (surface proteins, internal structural proteins, and regulatory proteins) can serve as antigens because they are all produced in the cytoplasm and are susceptible to proteasomal degradation. Including a large portion of the viral antigenic content allows the APC to select the appropriate epitopes for association with the host MHC class I. Theoretically, another approach would be to build designer proteins with a high density of CTL epitopes separated by flanking sequences susceptible to processing. There are also theoretical advantages to using antigens that are produced in high abundance and early in the virus replication cycle. This might allow earlier recognition of the virus-infected cell and more rapid clearance. In addition, there may also be advantages to using internal viral proteins because they are typically more conserved in viruses capable of genetic variation. The principles for developing vaccines based on CTL-mediated protection are not well established at this time, and no vaccine has ever been licensed based purely on its ability to induce a T-cell response.

### Vaccine Delivery

The location and durability of vaccine-induced immune responses are affected by route and schedule of vaccine delivery. Currently licensed live-virus vaccines are given on mucosal surfaces orally (rotavirus and polio), by intranasal spray (influenza), by needle and syringe (measles-mumps-rubella and varicella), or bifurcated needle in the case of vaccinia. Delivery of vaccines by needle and syringe intradermally (ID) may provide dose sparing (85–87). This finding has been demonstrated with the licensed hepatitis B vaccine. Large-scale safety and immunogenicity studies were conducted by the U.S. Army to evaluate the dose-sparing potential of intradermal delivery for the licensed HBV vaccine. ID delivery of the HBV vaccine was safe and induced humoral immunogenicity at a lower magnitude (approximately 50% reduction) and a slightly lower frequency of immune response than traditional intramuscular (IM) delivery (88). As new vaccine technologies emerge, new delivery approaches may include microneedles (89) or for DNA vaccines, needle-free injection systems such as Biojector® or Powderject®, or electroporation devices that have been reported to improve antigen expression and immunogenicity (90, 91).

Delivery vehicles can provide mechanisms to codeliver mixtures of antigens and adjuvant, protect antigens from a harsh environment, control the timing of antigen release, or carry antigens into subcellular compartments. A number of carriers for delivery of vaccine antigens are in development. For example, virus-derived proteins inserted into liposomal membranes are referred to as virosomes. Virosomes containing the hemagglutinin of influenza are used in licensed products (outside the United States) to deliver vaccine antigens for influenza and hepatitis A (41). ISCOMs are 40 nm cage-like structures composed of lipids and saponins that can deliver viral antigens to the cytoplasmic compartment for processing and CTL activation (92). Microparticles or nanoparticles produced from synthetic polymers can be formulated with viral antigens or gene-based vectors for controlled release or delivery to selected cells (93, 94). Conjugates with carrier proteins also allow access to the cytoplasmic compartment of the APC.

### Schedule of Immunization

The schedule of vaccine delivery and concept of boosting is critical for establishing durable immunologic memory for many vaccines. In general, inactivated vaccines require at least two doses in a naïve host to establish a significant immune response. Even live viral vaccines benefit from booster doses (e.g., measles booster in adolescents). Boosting prolongs the duration of the memory immune response and it may alter the character or breadth of the response by expanding the repertoire of antigens that stimulate an immune response (54,95–98). The classic indication of memory induction of the humoral immune response is isotype switching from antigen-specific IgM to IgG production, detected in the serum. Antigen-specific memory T cells may be present even in the absence of detectable antibody response as in the case of hepatitis B vaccine nonresponders (those with a negative hepatitis B titer following the last vaccination in the series) (99).

Homologous boosting with the same vaccine is used for most licensed vaccines (e.g., hepatitis A or B). Heterologous boosting or the concept of using one vaccine approach for priming and an alternative vaccine approach for boosting (prime-boost) may be important in the development of

vector-based vaccines (100, 101) or for focusing the immune response on a particular antigenic site (102). Empirically it has been observed that as the interval between priming and boosting increases, the magnitude of the immune response improves (103). More recently, the importance of the length of time between the prime and boost has been clearly demonstrated (104–106). Considerations must be balanced between lengthening the vaccination schedule for potentially improved efficacy, and shortening the schedule for efficiency, compliance, and earlier protection. Some insight into the value of lengthening the prime-boost interval has been gained by understanding the basic biology of T-cell memory. After immune stimulation, lymphocytes evolve through an activation phase in which cells are highly functional but susceptible to apoptosis from excessive stimulation. As the acute phase of the response resolves, a population of memory lymphocytes is established with the capacity for rapid expansion rather than apoptosis after antigen stimulation (107). As the tools for immune assessment improve, the rules for prime-boost interval may be better tailored for each vaccine modality and be supported by a stronger scientific basis.

### LICENSED VACCINES FOR VIRAL DISEASES

There are now licensed vaccines for preventing disease caused by 15 viral pathogens and over 27 viral subtypes in the United States (Table 2). They can be divided by live viral vaccines and nonreplicating viral vaccines. The following sections discuss their general properties. The reader should also consult the pathogen-specific chapters for details on their use.

#### Live Viral Vaccines

Viral vaccines that contain live or replication-competent forms of the targeted viral agent are referred to as “live virus vaccines.” In live virus vaccines, the infectious virus is attenuated genetically, by host range characteristics, or by route of delivery to reduce virulence. Attenuated viruses are sometimes derived from naturally occurring isolates found to have low virulence or altered tropism (e.g., poliovirus 2). In most cases they are generated by performing serial passages of the virus in cell lines from an unnatural host. The underlying mechanism responsible for attenuating a pathogen during serial passage is due to spontaneous mutations that are selected by adaptation to the conditions of repeated passage in embryonated eggs or cell culture. Some of these mutations are associated with diminished pathogenicity in humans. Another source of live attenuated vaccine viruses comes from the “Jennerian” approach. Related viruses that have another species as a natural host are often highly attenuated in human hosts (e.g., rhesus or bovine rotavirus vaccines). In the case of adenovirus, the wild-type virus with natural tropism for the respiratory tract is delivered through the gastrointestinal tract, thereby attenuating virulence by avoiding the preferred tropism.

Live virus vaccines induce immune responses that closely mimic those of the wild-type virus, including the display of surface glycoproteins in their native conformation, the primary target of neutralizing antibodies. Live viral vaccines typically activate all components of the immune response. Both antibody responses and virus-specific T-cell responses (including CD8+ T-cell responses) are induced to the potentially protective antigens contained in the virus. The entire antigenic content of the pathogen is delivered by the live virus vaccine approach, and the antigen load is ampli-

fed by replication. Another advantage of live virus vaccines is that they can often be delivered to susceptible mucosal surfaces and elicit mucosal immune responses. Live viral vaccines are also associated with more durable immune responses and generally require fewer and less frequent booster vaccinations (108, 109). While there may be immunologic and protective advantages to the live virus vaccine approach, live vaccines may also have increased potential for adverse events. In rare cases, live vaccines may induce a mild or attenuated form of disease. Live virus vaccines are generally contraindicated in immunocompromised patients and pregnant women or in patients in close contact with immunocompromised individuals due to the risk of viral shedding and transmission in the postvaccination period (110). While many live virus vaccines are generally easy to manufacture, the production in mammalian cell substrates could introduce unexpected contaminants, virulence properties can change, and they are more susceptible to adverse storage conditions.

### Nonreplicating Viral Vaccines

Many killed or inactivated and subunit viral vaccines have also been licensed for the prevention of viral diseases (Table 2). These vaccines generally require at least two doses to invoke the optimal immune response and are generally safe and well tolerated. The major advantage of properly inactivated vaccines is that there is no risk of infection in the vaccinated patient or transmission of live virus to potentially immunocompromised close contacts of vaccinees. A disadvantage of inactivated or killed vaccines is that they typically require multiple booster injections in the primary series or later in life to maintain a protective immune response in the majority of individuals. Inactivated influenza vaccines grown in eggs have been used since the 1940s. Hepatitis A vaccine is an example of an inactivated virus vaccine where formulations are produced by infecting human diploid fibroblast cells lines (MRC-5) with hepatitis A virus strains that are attenuated in humans. Virus from the infected cell line is formalin-inactivated to produce a non-live vaccine product (111). Hepatitis B vaccine represents a nonlive, subunit vaccine formulation. Subunit HBsAg vaccine is produced in yeast by recombinant DNA technology (112). The vaccine is noninfectious but can induce transient serum HBsAg positivity (113). The vaccine is given in a three-dose schedule to infants, adolescents, or adults and results in seroconversion in >90% of patients who receive the three-dose regimen (5). Vaccines for both HPV and hepatitis B viruses have also been licensed utilizing virus-like particle (VLP) technology (Engerix-B and Cervarix, GlaxoSmithKline; Recombivax-HB and Gardasil 9, Merck & Co.). VLPs mimic viral structure but lack genetic material needed to allow for replication, yielding noninfectious and efficient antigen presentation (114). A VLP-based vaccine for hepatitis E virus has been licensed in China (115–117) and additional research on VLPs for a broad array of viral targets including alphaviruses is ongoing (118).

### Substrates and Additives in Vaccine Manufacturing

In the United States viral vaccines are regulated by the U.S. Food and Drug Administration Center for Biologics Evaluation and Research (CBER). Most viral vaccines are produced in cell substrates that involve mammalian, avian, insect, or bacterial cell culture. Good manufacturing practice (GMP) requires rigorous record keeping and validated standard operating procedures that minimize the risk of

contaminants or adventitious agents (119). Vaccine preparations are produced in bulk and stored or formulated with diluents, adjuvants, and preservatives before packaging. Each step in the process in highly regulated biological products is complex and raises many theoretical issues that may require clinical consideration and must be balanced for each individual against the personal and public health benefits of vaccination. For example, the preservative thimerosal is an organomercurial compound used in trace or small amounts in only a few vaccine preparations (120). Thimerosal is metabolized to ethylmercury and has been controversial because of the neurotoxicity associated with methylmercury. Ethylmercury is more rapidly excreted than methylmercury, and thimerosal has been given to animals and humans at doses well above 1 mg/kg without evidence of toxicity. The highest ethylmercury content in a 0.5 ml dose of any currently licensed vaccine is approximately 25 µg, and extensive clinical studies have not shown a causal relationship between thimerosal and neurological events (121). However, because of ongoing unsubstantiated public perception that it may be associated with neurocognitive or neurotoxic events and diseases such as autism, and ongoing efforts to improve vaccine safety and confidence, thimerosal has been removed from most licensed viral vaccines, especially childhood vaccines (120).

## CLINICAL MANAGEMENT OF VACCINATION

### Vaccination Schedules

The childhood and adult viral vaccine dosing schedules are routinely updated and listed in complete form by the US Centers for Disease Control and Prevention at <http://www.cdc.gov/vaccines/schedules/index.html> and by the World Health Organization at <http://www.who.int/topics/immunization/en/index.html>.

When a vaccine regimen is given as a series of doses, the question may arise about what to do in the case of missed or delayed doses. In general, it is not recommended or immunologically necessary to repeat or restart a vaccination regimen or schedule. The vaccine schedule should be continued where it was left off, regardless of the duration of time since prior vaccination. If there is concern regarding compliance and immune response following the last dose of vaccine in a series, an antigen-specific antibody titer can be measured in patient serum to determine if the patient has developed an appropriate immune response. For example, in the case of the licensed hepatitis B vaccine, an anti-HBs antibody titer of  $\geq 10$  mIU/mL, determined by commercially available immunoassay, correlates with protection from infection.

Live and killed viral vaccines can be administered simultaneously as recommended in published vaccination schedules (<http://www.cdc.gov/vaccines/schedules/index.html>). The general recommendation for administering multiple live vaccines is to administer them on the same day, or if that is not possible, to separate live vaccines by at least four weeks to allow for an optimal immune response to each vaccine. The recommendation is based on the premise that in the acute period of immune response to a live vaccine, additional immune responses to other live vaccines could be diminished because of innate immunity. Combination vaccines, with multiple vaccines coformulated and therefore coadministered have become increasingly common, both for ease of administration and improved compliance. Only licensed combination vaccine products that have been

rigorously tested for safety, stability, and immunogenicity in combination with other vaccine(s) should be coadministered in a single syringe. Health care providers should follow manufacturers' guidance and label information and should not prepare off-label formulations or combinations of vaccines by combining separate vaccines into a single syringe at the time of vaccination. The formulations of different vaccine products may be incompatible or antagonistic and significantly alter the chemical and antigenic properties of the vaccine products. This type of off-label practice could potentially lead to adverse events or reduction of the vaccine-induced immune response.

It is important to review the recommended vaccine schedule on a routine basis. The recommendations change periodically in response to outbreaks of disease or newly available vaccine products. For example, after several years of fewer than 300 reported cases of mumps per year, there was a multistate outbreak in 2006 with 6,339 cases reported. These were primarily in college age students with a median age of 21 (122). The surge in U.S. mumps cases was preceded by a large increase in mumps in the United Kingdom in 2005. Many of the infected persons had been vaccinated, but it is likely that waning immunity, particularly in persons who had not received at least two doses of MMR vaccine, was in part responsible. Adolescents should receive a booster dose of MMR vaccine, especially if they plan to attend college or live in settings such as dormitories where crowding may exist. Vaccine-induced immunity is not as long lasting as immunity induced by natural infection, and as infection dynamics evolve, vaccination schedules and clinicians will need to adapt. For example, although the United States declared measles eliminated in 2000, there was a multistate outbreak in 2014 with 668 cases from 27 states reported and 178 cases reported in the first half of 2015 (123). The surge in measles cases in the United States has been linked to transmission among unvaccinated communities and was preceded by a large increase in measles in the Philippines in 2014.

An important consideration in the resurgence of these vaccine-preventable diseases has been the opting out of recommended vaccination schedules. Whether based on fears concerning autism links (124, 125), waning belief for the need for vaccines in the face of declining incidence rates, or general antivaccine sentiments, complacency and skepticism have driven diminished protection (126–128). Outbreaks of HiB, varicella, measles, and pertussis have resulted from the popularity of nonmedical exemptions for vaccines granted in many states (129–132). In response, and to protect infants, adolescents, and immunocompromised populations, some US states have enacted restrictions to personal belief exemptions in order to achieve immunization specifically against childhood diseases.

### Contraindications to Vaccination

Prior to each vaccination the health care provider should assess the patient for possible contraindications to vaccination, including a history of adverse or allergic reactions to a previous vaccination, underlying illness, or allergy. For live vaccine administration the provider should assess the possibility of immunodeficiency or the potential for patient contact with an immunocompromised individual. Vaccination is contraindicated if there is a known hypersensitivity to the vaccine or to any of the vaccine components. Egg and gelatin allergies are important considerations because of the potential for reactions to vaccines that contain them and the prevalence of sensitivity of those components. Allergy consultation may be recommended if vaccination is neces-

sary and there is concern about a potential vaccine or vaccine component allergy.

### Vaccination of Immunocompromised Individuals

The issue of which viral vaccines should be administered to immunocompromised individuals is complex. Factors that affect the decision include the degree and type of immunosuppression, the overall state of health of the patient, and the type of vaccine to be administered. In general, the most effective way of protecting people with immunodeficiencies from vaccine-preventable diseases is to make sure the people around them are well vaccinated and are not transmitters of infection. If immunization is necessary, the focus should be on nonreplicating vaccines. Schedules for vaccinating selected subgroups of immunocompromised individuals can be found on the second page of the Recommended Adult Immunization Schedule Table at the CDC web site <http://www.cdc.gov/vaccines> by following the link to "immunization schedules."

Live viral vaccines are generally contraindicated in immunocompromised patients and in some cases if the patient has close contact with an immunocompromised person (i.e., smallpox vaccine). Patients undergoing chemotherapy or radiation treatment should avoid live viral vaccines, but in some cases (i.e., varicella) their close contacts should be vaccinated to protect the immunocompromised patient. Measles and varicella vaccine can be administered following cessation of chemotherapy (> 3 months or later for measles), if no other contraindication exists. Live viral vaccines, such as varicella or smallpox vaccine, are contraindicated in severely immunosuppressed individuals because there is a risk of disseminated infection with the vaccine virus that can be severe in these patients. Disorders associated with T-cell immunodeficiency are associated with severe disease more often than immunoglobulin disorders. An exception to this is severe enterovirus infection (including poliovirus) in persons with immunoglobulin deficiency.

Nonreplicating viral vaccines do not pose an increased risk to immunocompromised individuals, although the response to a vaccine may be diminished or absent depending on the ability of the adaptive immune system to recognize and respond to the vaccine antigens. For example, immune response to influenza vaccine has been shown to be reduced in some children with malignancy (133). Persons with renal failure on dialysis often do not make a sufficient antibody to hepatitis B vaccines that are otherwise extremely immunogenic (134). As noted, it is best to vaccinate when host responses are intact and to otherwise follow the national guidance for immunization of persons with selected immunodeficiencies.

In the case of pregnant women, guidelines suggest specific vaccinations before, during, and after pregnancy. Tetanus, diphtheria, and pertussis (Tdap) and influenza vaccination are approved and specifically suggested during pregnancy, and additional inactivated vaccines can be administered although discussion with health care providers is recommended (135).

### Adverse Effects of Vaccination

#### Expected Adverse Events

Vaccines are an important public health measure and provide a safe and effective method to prevent infectious disease. Occasionally, vaccines have been linked to adverse events. Vaccine-related adverse events may be expected with systemic or local reactogenicity, as manifested by mild fever, myalgia, malaise, or vaccination site pain, tenderness,

and erythema. These reactogenicity symptoms are transient and in most cases, antibiotics, antiinflammatory agents, and topical medications are not required.

### Allergic Reactions

In rare cases, unexpected adverse events may occur, including anaphylaxis resulting from an allergy to a vaccine component. Potential causes of vaccine-related anaphylaxis include reactions to residual egg or chicken protein in vaccines grown in chick embryo fibroblasts, or reactions to gelatin, which is a preservative in many vaccine formulations. Viral vaccines, which may contain trace amounts of egg or chicken protein and therefore are contraindicated in egg-allergic patients, include yellow fever vaccine and one formulation of the rabies vaccine. Although produced in a chick embryo fibroblast cell substrate, MMR vaccine is not contraindicated in egg-allergic patients due to a lack of egg or chicken residual proteins in the final vaccine product.

Measles, mumps, rubella, varicella, Japanese encephalitis, yellow fever, and smallpox vaccines contain gelatin as a preservative and are contraindicated in individuals with a history of gelatin allergy. Once a patient has had an allergic reaction to a vaccine, or combination of vaccines, further vaccination with those vaccines or with vaccines containing the same components should be avoided and only reconsidered after a careful allergy evaluation is performed. Consultation with an allergist is indicated if allergy to a vaccine or to vaccine components is suspected.

### Severe Rare or Idiosyncratic Adverse Events Related to Vaccination

The National Childhood Vaccine Injury Act of 1986 and The Vaccine Injury Compensation Program (VICP) (established 1988) were established by the U.S. Congress as a “no fault” alternative to financially compensate patients or the families of patients who suffer from vaccine-related injuries. Viral vaccines covered by the VICP include hepatitis A, hepatitis B, HPV, seasonal influenza, measles, mumps, rubella, polio, rotavirus, and varicella. The VICP Vaccine Injury Table details the covered adverse events and time intervals from vaccination for each of the vaccines (136). Adverse events included in the table are anaphylaxis for most vaccines, encephalitis for MMR, chronic arthritis for rubella vaccine, and thrombocytopenic purpura for measles vaccine. While rare, if these adverse events occur within a specified time period after vaccination, and no other cause for the event can be identified, the patient may have a claim.

Prior to vaccination, health care providers should provide the patient or their guardian with a Centers for Disease Control and Prevention (CDC) Vaccine Information Statement (VIS) (137). This is required under U.S. federal law for all vaccines covered by the VICP. It is strongly recommended for all other vaccines. The CDC routinely updates current VIS forms on the CDC website to be printed by providers and their staff. The provider should document the date and version of the VIS form and note that the VIS was provided in the medical record for each vaccination.

Severe vaccine-related adverse effects are uncommon, but the following section highlights several examples and the mechanisms implicated.

#### Smallpox

Routine smallpox vaccinations in the U.S. civilian population were discontinued in 1972 but were continued in the

U.S. military until 1990. Due to concerns about the possible risks of bioterrorism attacks, the U.S. military and a portion of the U.S. civilian population began to receive smallpox vaccination again in the winter of 2002–2003. Although individuals at increased risk for predictable vaccine-related adverse events were excluded, an unexpected adverse event, myopericarditis, was seen in approximately 1 in 12,000 primary vaccinees (usually within 30 days) following Dryvax vaccination (138). This finding, along with previously documented risks of adverse events, has led to multiple contraindications for prophylactic smallpox vaccination, including past or present atopic dermatitis, compromised immune system (HIV/AIDS, autoimmune disease, most malignancies, immunosuppressive medications), known or possible coronary artery disease, cerebral vascular disease, pregnancy, and breastfeeding. In the event of a smallpox outbreak or exposure, these contraindications would likely be disregarded and public health officials would make revised recommendations at that time.

#### Respiratory Syncytial Virus (RSV)

A formalin-inactivated whole virus RSV vaccine (FI-RSV) was studied in infants and children in the 1960s, when Tween-ether and formalin-inactivated measles virus was still being used. The RSV vaccine did not prevent infection and was associated with enhanced disease that was particularly severe in the youngest age group <6 months (139, 140). Both FI-RSV enhanced illness and atypical measles, an aberrant illness caused by infection several years after vaccination with inactivated measles vaccine when neutralizing antibody activity had waned, are thought to be the consequence of a similar combination of immunological events. First, enhanced illness occurred when vaccine-induced antibody did not have significant neutralizing or fusion-inhibiting activity and did not prevent infection (141). Second, vaccine-induced antibody had complement-fixing properties, and immune complex deposition could be demonstrated in affected tissue (142). Third, there was an exaggerated CD4+ T-cell response associated with eosinophilia (139, 143). Animal models of FI-RSV and measles suggest this was caused by a Th2 (142) biased responses, with production of IL-4, IL-5, IL-13, and eosinophilia (144).

#### Rotavirus

An oral tetravalent rotavirus vaccine (Rotashield®) was licensed for use in the United States in 1998 but was withdrawn from use due to a possible link to intussusception (145). The vaccine was associated with an increased rate of intussusception of up to 1 per 2,500 vaccinees, primarily following the first dose of vaccine (146). Subsequent epidemiologic studies led to a significant decrease in the estimates and suggested that the early period of increase in intussusception seen after the first dose was compensated by lower rates after subsequent doses, resulting in no net overall increase in the number of cases in vaccinees less than one year of age (146). The cases occurred predominantly when the vaccine was started in children three months of age or older rather than in children who received the recommended schedule (two, four, and six months of age) (23, 147, 148).

#### Influenza

Adverse events (local and systemic reactogenicity) related to seasonal influenza vaccines are generally mild, including localized redness, swelling or mild fever, and muscle

aches. Intranasal live-attenuated influenza vaccine can also be associated with mild rhinitis-like symptoms, headache, muscle aches, and fever. There have been rare moderate to severe, unexpected adverse events associated with influenza vaccines. In 1976 the influenza vaccine (swine flu vaccine) was associated with Guillain-Barré syndrome (GBS) at a very low rate (approximately 1 to 10 per one million persons vaccinated). A causal relationship between influenza vaccine and GBS was not clearly identified, but due to the historical association it is recommended that people with a history of GBS speak to their physician before influenza vaccination.

### Yellow Fever

Yellow fever virus (YFV) vaccine is generally considered one of the safest live virus vaccines and may be associated with mild reactogenicity in 25% of recipients. More serious conditions have been associated with YFV vaccine at very low frequencies. YFV vaccine-associated neurotropic disease has been reported in <1 in 8,000,000 persons receiving the vaccine. This condition is generally transient and rarely fatal. A second severe, possibly fatal, but very rare adverse event associated with YFV vaccine is yellow fever vaccine-associated viscerotropic disease which is seen in one in 400,000 initial doses. This condition mimics fulminant yellow fever infection caused by wild-type yellow fever virus. This rare condition has been reported only following initial vaccinations and has not been reported to occur following booster vaccinations with YFV vaccine (149).

### Reporting Vaccine-Related Adverse Events

Following licensure of a vaccine, adverse events that are clinically significant or unexpected as well as events listed in The Reportable Events Table (150) and in the manufacturers package insert should be reported to the Vaccine Adverse Event Reporting System (VAERS) (<http://vaers.hhs.gov/>). VAERS is a passive surveillance cooperative program between the CDC and the FDA. Any possibly related or temporally related vaccine side effects may be reported by any health care provider, patient, or patient guardian or representative. The VAERS system is public and represents unverified reports of possible vaccine-related adverse events. The VAERS system allows public health experts to detect rare adverse events that may not be discovered during vaccine clinical trials because of their low rates of occurrence (151). Potential vaccine-related concerns in the VAERS database are further investigated and/or verified by the CDC, Vaccine Safety Datalink Project (VSD) (152). Vaccine research and development would benefit from better-defined rates of unusual or severe conditions or illnesses in the general population so that occurrences that are temporally related to vaccine can be more clearly compared to the general population rate (unrelated to vaccine) (153).

## LICENSED PRODUCTS FOR PASSIVE IMMUNIZATION

When active immunization is not possible, transient protection from disease or infection can be passively acquired by administration of human polyclonal immunoglobulin known to have a high titer of antibody against a specific viral pathogen or virus-specific humanized monoclonal antibodies. Like vaccines, licensed immunoglobulin products for use in humans are regulated by the U.S. Food and Drug Administration Center for Biologics Evaluation and Re-

search (CBER). Human immunoglobulins are licensed for use in the United States against cytomegalovirus (CMV), respiratory syncytial virus (RSV), vaccinia, varicella zoster, rabies, and hepatitis B virus.

### Preexposure Prophylaxis

In the past, prophylactic immunoglobulin was used for protecting travelers against hepatitis A but has been replaced by an effective vaccine. Currently, the only passive antibody prophylaxis in widespread use is for RSV. RSV immune globulin (RespiGam®) was indicated for the prevention of serious respiratory disease from RSV infection in high-risk children <2 years of age but is no longer in use. A humanized monoclonal antibody against the F glycoprotein of RSV (palivizumab, trade name Synagis®) is indicated for the prevention of serious respiratory disease from RSV infection in high-risk children <2 years of age. Risk factors for severe respiratory disease from RSV include bronchopulmonary dysplasia, premature birth ( $\leq 35$  weeks), and hemodynamically significant congenital heart disease.

### Postexposure Prophylaxis

Rabies immune globulin is given to nonimmune individuals in conjunction with active rabies vaccination following potential or confirmed rabies exposure, such as in the case of animal bites. The wound should be infiltrated with immune globulin at the time of or within eight days of the first dose of rabies vaccine. Hepatitis B immune globulin is administered to nonimmune individuals exposed to hepatitis B as post-exposure prophylaxis and in that setting is usually given in association with hepatitis B vaccination. It should be administered within 24 hours of exposure to hepatitis B by needle stick, ocular, or mucosal exposure or within 14 days of a potential sexual exposure. Hepatitis B immune globulin is given to newborns of infected mothers (HBsAg positive) within 12 hours of birth and again at three months of age. Hepatitis B immune globulin is indicated only for prophylaxis and not for the treatment of hepatitis B (active or chronic). Vaccinia immune globulin is indicated for the treatment of smallpox vaccine-related complications, including eczema vaccinatum, progressive vaccinia, and severe generalized vaccinia. Varicella zoster immune globulin (VariZIG), approved in 2012 for the prevention of varicella infection in immunocompromised individuals exposed to varicella zoster virus and for those for whom varicella vaccine is contraindicated.

### Adverse Effects and Contraindications to Passive Antibody

Human immunoglobulin products may contain trace amounts of human IgA. IgA deficiency is the most common cause of primary immunodeficiency diseases, affecting approximately one in 500 people, and is often undiagnosed. In rare cases, individuals with IgA deficiency can develop IgE against IgA and experience anaphylaxis upon exposure to human blood products containing IgA, including immune globulins. IgA deficiency is a relative contraindication to receipt of human immune globulin products and this should be considered prior to administration.

Immunoglobulin can inhibit the immune response induced by some live viral vaccines. This may occur because the presence of virus specific serum antibody binds to and inhibits live virus vaccine replication and therefore prevents

the intended immune response. Varicella vaccination can be inhibited up to five months following administration of human immune globulin containing antiviral antibodies and rubella vaccination can be affected up to three months following immune globulin administration. Ideally, vaccination with varicella and rubella vaccines should be delayed by five and three months, respectively, following the administration of immune globulin. In cases where immune globulin is administered to a patient within three weeks after MMR or varicella vaccination, the immune response to those live vaccines may be blunted. In that situation, revaccination after three to five months is recommended if there are no other contraindications. Hepatitis B vaccine can be administered at the same time as hepatitis B immune globulin or  $\geq 1$  month following the administration of immune globulin. The immune response to yellow fever vaccine does not appear to be inhibited by the presence of immune globulin at the time of or following vaccination.

## VACCINE DEVELOPMENT AND FUTURE DIRECTIONS

Vaccine development in the 21st century promises new paradigms for design, manufacturing, immune response evaluation, and timelines. While empiricism will always contribute to scientific advances, vaccine development is now more dependent on rational design and a deeper understanding of the underlying molecular pathogenesis of disease. One example of this is adjuvant development based on new discoveries and understanding of TLRs. Sequencing technology, advances in molecular virology, ease of isolating and characterizing human monoclonal antibodies, and improvements in the technologies and speed of solving antigen structures will support rapid identification of new pathogens and atomic level guidance for vaccine antigen design. In addition to the traditional platforms of live attenuated, whole virion-inactivated, and virus-like particle vaccines, there are new options for structure-guided vaccine antigen development, and a variety of gene-based delivery approaches using DNA, RNA, or microbial vectors that will become part of the repertoire of licensed vaccines. Vector-based and nucleic acid vaccines using gene delivery of vaccine antigens have already been approved for veterinary use for several viral diseases.

Structure-based vaccine development utilizes specific knowledge of how human mAbs interact with viral surface proteins and neutralize virus (82, 83, 154) and the process is iterative. Improved vaccine antigens can be used as probes to select B cells with specified properties for cloning antibody genes for improved monoclonal antibodies that can be used to better characterize vaccine antigens. In addition, an expanding number of technologies have allowed the evaluation T-cell responses at the single-cell level and has prompted the development and evaluation of T-cell based vaccine concepts in addition to the traditional concepts of immunity based on antibody responses. Even the way antibody function is evaluated has evolved from ELISA and basic neutralization assays to measurements of epitope-specific binding and functional assays (155), multiple approaches to assess Fc-mediated functions (156, 157), and the impact of glycoforms on antibody function (158). Rapid advances in human genetics have created the possibility of designer vaccines that can take advantage of certain host polymorphisms to improve immunity and avoid others to reduce side effects. New sequencing technologies will impact

surveillance and virus discovery, better characterize genetic diversity and viral escape mechanisms, and the analysis of immune response ontogenies. They will also influence vaccine safety by application to the evaluation of biologics (159).

Significant biological hurdles still exist for developing effective vaccines to prevent viral infections with large disease burdens such as HIV-1, HCV, and HSV, as well as influenza where a more durable and broader “universal” influenza vaccine is needed. There is great effort to find effective vaccines for these viruses using a variety of new technologies to better understand pathogenesis and immunity and to design novel immunization approaches. For viral infections with the potential for sporadic epidemics or intentional release and high disease severity such as orthopox viruses, zoonotic influenza viruses, filoviruses, and flaviviruses, the challenges are both biological and strategic. The same is true for emerging pathogens with the uncertain potential for pandemic spread like Middle East respiratory syndrome (MERS) coronavirus. One approach for addressing the strategic issues involving emerging infections and biodefense has been to establish a stockpile of available vaccines and other prophylactic and therapeutic agents (160). To be effective, this concept will require a level of anticipation and significant political commitment to preparedness as illustrated by the West African Ebola crisis in 2014. Additional research and development is needed to establish platform vaccine technologies that can be rapidly adapted and deployed against new viral pathogens that will inevitably emerge. Innovative public and private partnerships will be needed to overcome the biological and logistical hurdles of vaccine development for emerging infections.

Solving the political and social obstacles that restrict the distribution and delivery of existing vaccines to regions of the world where they are not widely utilized would dramatically improve public health. GAVI, the Vaccine Alliance, has significantly improved global health by distributing new and underused vaccines to low- and middle-income countries (LMIC) and drives innovative vaccine-financing mechanisms. The vaccine manufacturing landscape is changing in part because of new technologies that promote more disposable and modular equipment for good manufacturing practice (GMP) and in part because of expanding global capacity for vaccine development. For example, Zhu and colleagues brought a hepatitis E vaccine to market following a large-scale efficacy study in a general population at risk of infection in China. The purified recombinant hepatitis E antigen vaccine, HEV 239, trademarked as Hecolin, received approval by China’s SFDA in December 2011 and is manufactured by Xiamen Innovax Biotech Co. (116, 117). More recently, a vaccine targeting rotavirus developed and manufactured in India received licensure in 2014 and was subsequently introduced into the country’s national immunization program. The live-attenuated monovalent human-bovine (116E) vaccine was assessed in a large scale efficacy study of over 6,799 Indian infants and proved efficacious and serves as an example of efficient viral vaccine development (161). In addition, Brazil is playing a large role in manufacturing and advanced evaluation of a dengue virus vaccine, providing another example of the changing paradigm. Even as manufacturing and distribution options improve in LMICs, additional investigation is needed to understand the biological basis for why vaccine immunogenicity is often diminished in developing country settings.

# Chronic Fatigue and Postinfective Fatigue Syndromes

ANDREW R. LLOYD

## 18

Chronic fatigue syndrome (CFS) is the label most commonly applied to a symptom complex characterized by unexplained, persistent, and disabling fatigue, when no clear implication of an infective or other cause for the prolonged illness can be inferred (1). Constitutional symptoms, including myalgia, arthralgia, sore throat, headache, and tender lymph nodes, are also common. In addition, complaints of unrefreshing sleep, irritability, and neurocognitive abnormalities, like short-term memory impairment and concentration difficulty, are typical (1). CFS is also commonly termed myalgic encephalomyelitis, particularly in the United Kingdom, based on a premise of inflammation within the central nervous system—although this remains unproven (2). The US Institute of Medicine recently proposed that the condition be renamed “systemic exertion intolerance disease” to reflect a phenomenon characteristic of the illness, which is an exacerbation of fatigue and other symptoms after exercise or activity, termed “postexertional malaise” (3). However, only the name CFS has been accepted in common use internationally.

Fatigue is a subjective and nonspecific symptom, present in at least 15 to 30% of patients in primary care settings (4, 5), where it is predominantly associated with minor psychiatric morbidity and transient infective illnesses (6). The relationships and boundaries between the ubiquitous symptom of fatigue in the community, the broadly inclusive symptom complex designated as CFS, and the more discrete entity of postinfective fatigue syndrome, are often blurred. Patients with postinfective fatigue represent a subset of those with CFS, although the size of this subgroup is uncertain as many acute infections are subclinical, are not investigated, and the causative agent for an apparent infective trigger for a fatigue syndrome is often not identified. In addition, the international case definition for CFS stipulates six months or more of disabling illness (1). Although many postinfective fatigue states are comparable in both symptom profile and functional impairment to CFS, the majority of episodes are of shorter duration (7).

Individuals suffering from acute infective illnesses typically develop a constellation of systemic symptoms, including feverishness, myalgia, arthralgia, and headache, as well as fatigue (8). In both humans and animals, infections are also accompanied by increased slow-wave sleep and stereotyped behavioral responses, including reduced motor activity,

social withdrawal, and anorexia (8). These characteristic physical and behavioral correlates of infection result primarily from the host response to the pathogen, as they are reproduced in infections resulting from a wide range of microbiologic agents (9). In a minority of cases, selected symptom domains from the acute phase of the illness persist and cause protracted ill health, marked by fatigue and disability. Prospective evaluation of such symptoms following serologically documented Epstein-Barr virus (EBV) infection indicates that illness extending over several months, marked by fatigue, is common (Fig. 1) (10–13).

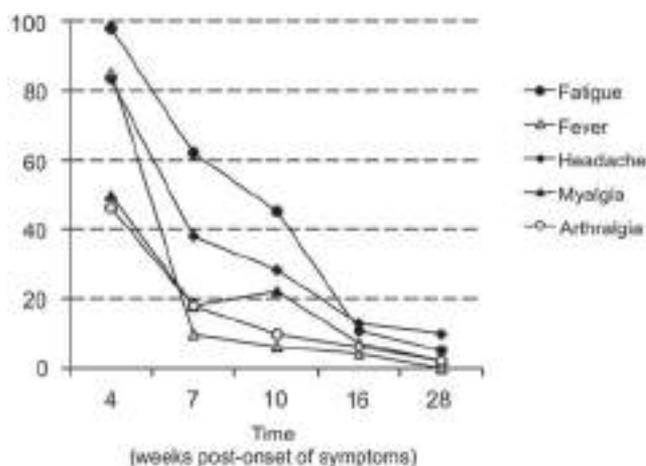

Over several decades, both CFS and postinfective fatigue syndrome have remained a focus of considerable research interest, including epidemiological studies, investigations of microbiologic, immunologic, neuroendocrine, metabolic, and psychologic hypotheses of etiology, and treatment interventions (reviewed in 14–18).

### HISTORICAL PERSPECTIVE

A review of the history of the modern day phenomenon of CFS indicates that the disorder is unlikely to be new (19). Perhaps the earliest description comes from Sir Richard Manningham in 1750, who described “febricula,” or little fever, as “listlessness with great lassitude and weariness all over the body . . .” (20). Other features included fleeting muscle and joint pains, as well as neurocognitive disturbance: “sometimes the patient is a little delirious and forgetful” (20).

The most widely known predecessor to the current label of CFS is the disorder termed “neurasthenia,” which was first delineated by George Beard, an American neurologist, in 1869 (21). This disorder was best described by Cobb in 1920: “Neurasthenia is a condition of nervous exhaustion, characterized by undue fatigue on slightest exertion, both physical and mental, with which are associated symptoms of abnormal functioning, mainly referable to disorders of the vegetative nervous system. The chief complaints are headache, gastrointestinal disturbances, and subjective sensations of all kinds” (22).

Despite these vivid historical references, precise parallels cannot be drawn with any confidence between the current label of CFS (which requires systematic clinical and laboratory evaluations to exclude alternative diagnoses), to

**FIGURE 1** Time to resolution of symptoms in 50 patients monitored prospectively from the time of diagnosis of serologically documented acute EBV infection. The vertical axis indicates the percentage of the group reporting the symptom. (Used with permission by A.R. Lloyd, unpublished.)

disorders such as the *febricula* or *neurasthenia* of earlier centuries. The term *neurasthenia*, for instance, was used in a variety of different contexts, including as a synonym for general nervousness and evolving psychosis as the male equivalent of hysteria in women; as an alternative label for minor depression; and as a diagnosis of fatigue states in patients who were not apparently depressed (19).

Although even the first descriptions of *neurasthenia* included a link with febrile illness, the observation that specific infectious diseases precipitated a subsequent fatigue state came with the microbiologic revolution of the late 19th and early 20th centuries. Notable among the infections linked to postinfective fatigue were influenza (23), brucella (24), and EBV (25) (Table 1). This association of a largely subjective syndrome of chronic fatigue with discrete infections, like influenza and brucellosis, sparked considerable controversy. Studies conducted in the 1950s provided evidence that much of the continued morbidity was attributable to psychological factors. Retrospective studies following up patients after acute brucellosis failed to find bacteriological evidence of chronic infection (26). However, sensitive detection techniques, such as polymerase chain reaction (PCR), to identify low levels of persistent nucleic acids of the microorganisms, or immunoassays to identify microbial antigens, were not available. The critical issue of whether the fatiguing illness led to psychological disorder or, conversely, whether such disorder resulted from chronic ill health, was studied in a prospective evaluation of military personnel before the Asian influenza epidemic of 1957 (23). This study pointed to premonitory psychological vulnerability as an important determinant of protracted recovery after infection, although it should be noted that the number of cases available for this analysis was very small.

These controversies of microbiologic versus psychological determinants of postinfective fatigue have continued to the present. The first prospective evaluation of patients followed from mononucleosis illnesses suggested that both concepts are valid (10, 27, 28). In this study, 245 patients were enrolled with either infectious mononucleosis (77%) or upper respiratory tract infection (23%). Of these, 101 (41%) had a fatigue syndrome associated with significant functional

impairment at the time of enrollment. The fatigue state persisted for one month or more in 71 individuals from this group (73%), for two months or more in 43 (43%), and for six months or more in nine (9%). The fatigue syndrome was most prevalent in those with mononucleosis documented to be due to EBV infection and was shown to be essentially independent of psychiatric diagnoses (10). By contrast, a well-controlled longitudinal study in general practice found that patients presenting with minor symptomatic infections, such as gastroenteritis, were not more likely to subsequently report chronic fatigue than patients presenting for other noninfective reasons (29). A prospective cohort study following individuals from the time of onset of serologically documented acute infection with three different pathogens identified a stereotyped postinfective fatigue syndrome (7). This study enrolled individuals after onset of infection with EBV, a herpesvirus with recognized latency; Ross River virus (RRV), a small, mosquito-borne RNA virus causing acute illness with arthritis; and *Coxiella burnetii*, the intracellular bacterium causing Q fever (7). The study documented that of 253 subjects enrolled, 29 (12%) experienced a prolonged illness characterized by fatigue, musculoskeletal pain, neurocognitive difficulties, and mood disturbance lasting six months or more and 28 (11%) met the diagnostic criteria for CFS after systematic assessment to exclude alternative medical and psychiatric explanations for the ongoing illness. The advent of a postinfective fatigue syndrome was predicted largely by the severity of the acute illness and not by demographic, psychological, or individual microbiologic factors. The fatigue state was present from the time of onset of symptoms of the acute infection and was stable in character over time, suggesting that the genesis of the postinfective fatigue syndrome is intrinsically linked to the host-pathogen interactions in the acute infection phase (7).

## EPIDEMIOLOGY AND NATURAL HISTORY

CFS is a relatively common condition in the community. The disorder predominantly affects young adults with a peak age of onset of 20 to 40 years, often following a documented, or an apparent, infectious illness (30–33). CFS does not preferentially affect individuals from upper socioeconomic groups (contrary to the notion of “yuppie flu”), rather, studies in both adolescents and adults suggest that fatigue syndromes are more common in people from more socially disadvantaged groups (31, 34–36). Estimates of the prevalence of CFS in the general population (7, 30, 31, 33, 37) and studies in primary care settings (which record the cases only among those attending medical practice and are therefore subject to selection bias) suggest prevalence rates ranging between 0.04 to 2.6% (31, 34, 37, 38). These differences in prevalence result from differences in the method of ascertainment (e.g., self-report or physician report), and, in the case definitions used for the syndrome, notably in the extent of the assessments undertaken to exclude alternative medical and psychiatric diagnoses (39). Preliminary estimates of the incidence of CFS suggest annual rates of approximately 0.1 to 0.3% (33, 37, 40, 41).

The long-term outcome of patients with CFS has been evaluated predominantly in tertiary referral settings, where the patient populations are intrinsically biased toward chronicity and disability. In one such study, 65 of 103 patients (63%), who had long-standing symptoms and who had been enrolled in treatment trials, reported improvement in symptoms and functional capacity at follow-up approximately three years later (42). No alternative medical diagnoses became evident over this period. Complete recovery was uncommon (6%). By contrast, spontaneous recovery in cases of fatigue of shorter duration in primary care appears to be high (43–45). Prospective, community-based studies suggest that the prognosis for recovery is high when the illness is abrupt in onset (potentially indicating an infective trigger) and of short duration (6 to 12 months), but declines substantially when the illness has been present for several years (46–49). Similarly, the prognosis for recovery in postinfective fatigue syndrome is high, even after six months of illness have passed, especially in adolescents (7, 16). Even in those with long-standing illness, the natural history is predominantly of stable or slowly improving status, rather than deterioration (50, 51).

## DIAGNOSTIC CRITERIA

The modern era of research in relation to CFS has been marked by the formulation of diagnostic criteria. Initially, Australian (52), American (53), and British (54) researchers separately developed consensus criteria sets for the case definition of the disorder. In 1992 the CDC (55) then proposed the term “chronic fatigue syndrome” to replace numerous previous eponyms, in particular, because this name removed the presumption of a postinfective or any other inflammatory etiology (as was implied in the earlier British nomenclature “myalgic encephalomyelitis”). In 1994, the CDC convened an international study group to formulate the most widely accepted diagnostic criteria (1) (Table 2). These criteria define persons with CFS as presenting with unexplained, persistent, or relapsing fatigue of at least six months’ duration, that is not relieved by rest, results in disability, and is accompanied by at least four of eight core symptoms (postexertional fatigue, impaired memory or concentration, unrefreshing sleep, headaches,

**TABLE 2** Diagnostic criteria for chronic fatigue syndrome (1)

<p><b>A.</b> Clinically evaluated, unexplained, persistent, or relapsing fatigue that is of new or definite onset; is not the result of ongoing exertion; is not substantially alleviated by rest; and results in substantial reduction in previous levels of occupational, educational, social, or personal activities;</p> <p><b>and</b></p> <p><b>B.</b> Four or more of the following concurrent and persistent symptoms:</p> <ul style="list-style-type: none"> <li>• Impaired short-term memory or concentration</li> <li>• Sore throat</li> <li>• Tender cervical or axillary lymph nodes</li> <li>• Muscle pain</li> <li>• Multijoint pain without arthritis</li> <li>• Headaches of a new type, pattern, or severity</li> <li>• Unrefreshing sleep</li> <li>• Postexertional malaise lasting more than 24 hours</li> </ul>
---

muscle pain, multijoint pain, sore throat, and tender cervical/axillary lymph nodes). With these criteria an epidemiologic perspective was provided for research into fatigue states. This perspective recognized that although prolonged fatigue syndromes are common and are associated with increased healthcare utilization, such syndromes are likely to be heterogeneous with regard to etiology, and possibly also to pathophysiology (56, 57). These criteria are consistent with symptom constructs described in both population-based samples and clinic studies (56, 58–60). A total of 20 sets of diagnostic criteria for CFS have been published including from the US Institute of Medicine, but it is not clear whether any offer a significant advance over the international consensus criteria, as none has been adequately tested to determine how well they differentiate patients with CFS from patients with other fatigue-related conditions (3, 61). As the symptom set of CFS is intrinsically subjective, an important milestone in improving the diagnostic criteria was the development of instruments to standardize assessment with validated self-report questionnaires, which was recommended by the reconvened international study group in 2003 (62). In addition, a semistructured clinical interview has recently been developed and validated with good sensitivity and specificity in assessing fatigue-related conditions (CFS, acute infection, post-cancer fatigue, major depression) and healthy subjects (63). Interestingly, in this study the symptom domains of fatigue and neurocognitive difficulties were shared across medical and psychiatric boundaries, whereas the key symptoms of major depression, such as anhedonia, were distinguishing.

## PROPOSED ETIOLOGIES

The leading hypotheses for the pathophysiological basis of CFS include a unique pattern of infection with a recognized or novel pathogen; an abnormal immune response to a recognized pathogen; a psychologically determined response to infection or other stimulus occurring in “vulnerable” individuals; a metabolic or neuroendocrine disturbance initiated by an unknown trigger; and a neuro-immune disturbance triggered by acute infection (reviewed in 14, 15, 64). Interactions and overlaps between these alternatives are also possible. In addition, a myriad less-extensively evaluated hypotheses exist.

## Infection

The potential role of infectious agents in producing chronic fatigue is the proposal that has been most closely examined. This notion arose naturally from the historical observations linking specific infections, such as brucellosis, to a subsequent fatigue state. Further support for this possibility comes from the anecdotal histories that patients with CFS give. These recollections typically describe a “flu-like” illness demarcating the patient’s prior good health from the subsequent chronic fatigue state. Unfortunately, these associations are frequently retrospective attributions with uncertain validity, as the expected incidence of symptomatic viral infections in the general population is approximately four annually (65), making chance associations likely. In addition, many reported case series are confounded by the selection bias of referral to specialty clinics *because* of the history of an infective illness (66). Nevertheless, the prospective studies following patients from the onset of acute EBV and other infections provide clear support for the hypothesis that a discrete postinfective fatigue syndrome can be precipitated by specific pathogens (7, 10, 27, 28). Several other viral, and some nonviral, agents have been implicated as apparent triggers for a postinfective fatigue syndrome (Table 1). A noteworthy inclusion in this list is the so-called “post-Lyme borreliosis syndrome” or “chronic Lyme disease,” which features fatigue, musculoskeletal pain, and neurocognitive difficulties lasting months or years after primary infection (67), and is unresponsive to prolonged antibiotic therapy (68–70).

Hypothetically, abnormal persistence of the triggering pathogen may underpin postinfective fatigue syndromes. Several early studies examined this possibility in patients with CFS without consideration of the (likely) heterogeneous nature of the triggering agents in such patient groups. Although initial reports suggested “elevated” titers of antibodies directed against organisms like EBV and human herpesvirus-6 (HHV-6) (perhaps implying persistent antigenic stimulation), these findings were refuted in suitably designed case-control studies and discordant twin studies (reviewed in 14, 15).

However, the notion of persistence of the microorganism as a key component of the pathogenesis of postinfective fatigue has been supported by the report of persistent microbial nucleic acids and antigenic, but nonviable, cell residues in patients with postinfective fatigue following serologically documented and appropriately treated Q fever (71, 72). By contrast, attempted PCR amplification of spirochetal DNA from the blood of 1800 patients with post-Lyme borreliosis syndrome was uniformly negative (73). Although, EBV persists naturally in all subjects following primary infection, by establishment of latency in B lymphocytes, the possibility of alterations in viral titer during or following the acute illness was examined in a case-control series of subjects with infectious mononucleosis who developed a postinfective fatigue syndrome in comparison to those who recovered promptly—no difference in cell-associated viral load in the peripheral blood was detected at any time point (74). Thus, there is a growing body of evidence against the role of ongoing, active infection with the triggering pathogen in postinfective fatigue syndrome.

In relation to CFS, the possibility of reactivation of latent HHV-6 infection as a driver for an ongoing immune response, and hence ongoing symptoms, has been examined in several studies, with inconclusive results (75–78). The initial positive report based on viral cultures, augmented by

immunofluorescence and PCR detection, demonstrated the presence of HHV-6 in peripheral blood mononuclear cells in a substantially greater proportion of patients than control subjects. However, other case-control studies using both serologic and PCR techniques have yielded conflicting evidence for HHV-6 reactivation (including specific examination of HHV-6A and B) in patients with CFS. Similarly, an association between persistent detection of the enteroviral antigen, VP1, and of enteroviral RNA in muscle biopsies of a subset of patients with CFS (79, 80) was refuted in subsequent reports, including one from the same research group (81–83).

Similarly, searches for a novel pathogen, including retroviruses (84–87) and Borna virus (88, 89), in patients with CFS have been fruitless, with initial positive findings failing to pass the subsequent hurdle of independent confirmation. The most recent example of this novel-pathogen hypothesis was initiated by a report describing the detection of sequences of Xenotropic Murine Leukemia Virus-related Virus (XMRV), a gamma retrovirus, as well as putative infectious virus, in the blood of a majority of patients with CFS (67%), compared to a small proportion (3.7%) of healthy individuals (90). Multiple subsequent studies failed to replicate the finding (91–94), which was ultimately shown to be a chimeric retrovirus generated by passage of human tissue in mice (95).

Given the diversity of specific infections now clearly linked temporally with the onset of CFS, and the essentially negative findings for occult pathogens to date, it is highly unlikely that any single infectious agent will be identified as the cause of CFS.

## Immunologic disturbance

The clinical course of most acute infections ranges from asymptomatic, to severe, incapacitating illness. This spectrum of disease is at least partially due to the magnitude of the immune response induced to control the invading organism, rather than to a direct effect of microbial replication. Cytokines, such as the interleukins (IL)-1, IL-6, tumor necrosis factor (TNF)-alpha, and the interferons, are released in a cascade of cellular activation induced by microbial antigens (see Chapter 14). In the context of acute infection, the classical sign of this host response, that is fever, has been shown to be induced by the action of pro-inflammatory cytokines on receptors within the brain (8). Similarly, the severity of the neurobehavioral manifestations of the acute sickness response, including fatigue, musculoskeletal pain, anorexia, somnolence, and mood disturbance, was shown to correlate with production of pro-inflammatory cytokines (96).

Accordingly, the immunologic hypothesis for postinfective fatigue syndrome has proposed that an aberrant and persistent cellular immune response to precipitating infectious agents results in chronic cytokine production, which may directly mediate protracted symptoms (97). Studies of cellular immunity in patients with CFS have produced widely varied results (reviewed in 98). The most consistent findings are of alterations in T-cell responses and reduced natural-killer-cell activity, but these changes have rarely correlated with the clinical condition. Given the diversity of infective and other triggers for the onset and persistence of CFS, these inconclusive findings may reflect underlying heterogeneity in the condition (56, 57). A comprehensive examination of antigen-specific immune responses against the pathogen documented to trigger the onset of the

postinfective fatigue syndrome was undertaken in a longitudinal case-control series of subjects followed from acute EBV infection either into a postinfective fatigue syndrome or to prompt resolution of clinical illness. Although minor differences in the kinetics of both humoral and T-cell responses against latent EBV antigens were documented, these changes did not correlate with the course of illness (74).

Numerous studies of cytokine production have been conducted in patients with CFS, with no consistent alteration detected in serum or cerebrospinal fluid cytokine levels (99–104, reviewed in 105). The possibility of aberrant, exercise-induced cytokine production has also been evaluated with negative findings (105–107). The opportunity to examine cytokine production in response to antigens, derived from the microbe believed to have precipitated the postinfective fatigue syndrome, has been provided by the recognition of a post-Q fever fatigue syndrome. The initial report suggested that increased production of IL-6 was evident in samples from subjects with post-Q fever fatigue when compared to samples from subjects who recovered uneventfully from acute Q fever (108). However, more comprehensive examinations of serum levels and *ex vivo* production of cytokines, in patients with postinfective fatigue syndrome and matched control subjects who recovered promptly after EBV, Ross River virus, or Q fever, did not reveal any significant alterations in cytokine production in those with postinfective fatigue (109, 110).

In summary, although there is evidence of minor immunologic alterations in patients with CFS, the changes are generally inconsistent, do not correlate with disease severity or course, and are not associated with clinically significant consequences, such as infection or malignancy. Cytokine levels do correlate with the acute-phase illness manifestations, including fatigue, but there is no evidence for ongoing cytokine production in the circulation in patients with postinfective fatigue. The possibility of an immunologic disturbance restricted to the central nervous system triggered by the insult of acute infection has not been formally examined.

Given these findings, there is no current role for immunologic testing as a diagnostic tool in the assessment of patients with CFS (1), other than for the detection of alternative medical diagnoses (Fig. 2 and Table 3).

### Psychological Disturbance

Approximately 30 to 70% of patients with CFS also meet criteria for the diagnosis of major depression (111–113 and reviewed in 14, 15). This high degree of comorbidity with depression is, in part, an artifact of overlapping symptoms (both disorders list fatigue, sleep disturbance, psychomotor change, cognitive impairment, and mood change as characteristic features). Furthermore, major depression is a common accompaniment of most chronic, disabling medical disorders. Some characteristic clinical features of major depression do help differentiate from CFS (if present), including weight loss, feelings of guilt and suicidal ideation, and observable psychomotor slowing. The mood disturbance described by patients with CFS tends to be irritability and transient depression rather than the profound loss of interest in, and pleasure from, daily activities (i.e., persistent anhedonia), which is the hallmark of a primary major depression (63).

The presence of concurrent mood disturbance does not demonstrate that depression is the cause of CFS. Studies have therefore sought to determine the rate of premorbid psychiatric disorder and also compared patients with CFS

with subjects suffering from other relevant psychiatric, neurologic, and chronic medical illnesses (114). Patients with CFS appear to occupy an intermediate status, having more premorbid and current psychopathology than patients with medical illnesses, but less than patients with overt psychiatric disorders.

The most contentious area of psychiatric comorbidity concerns “somatoform disorders” (i.e., psychological disturbances presenting with physical complaints). Patients with typical somatization disorder complain of a wide range of nonspecific medical symptoms, demonstrate a lifelong pattern of excessive medical treatment, and reject psychological interpretations of their illness. It is clear that analyses of the symptoms presented by patients with CFS in tertiary-referral and primary care settings suggest that a significant minority (up to 32%) of patients have a form of somatization (56, 57, 115, 116).

In relation to postinfective fatigue syndrome, the prospective cohort studies have not found a premorbid (i.e., pre-infection) history of depression to be a risk factor for a subsequent fatigue syndrome (10, 11). In addition, formal psychiatric assessment of patients with postinfective fatigue at six months after onset of infection revealed comorbid depression to be rare (11). In combination with the studies of CFS, these data suggest that there may be more than one pathway into the CFS—one via infection and another potentially via mood disorder. Whether the biological processes underlying these proposed pathways are shared or divergent is unknown.

### Metabolic or Neuroendocrine Disturbances

Hypotheses of several other pathophysiological disturbances have been explored in CFS, including impaired hypothalamic-pituitary-adrenal (HPA) axis activation (117–121), primary sleep disorder (122–125), and autonomic dysfunction (126–129). In the most exhaustive neuroendocrine study (118), lower mean urinary-free cortisol and reduced-basal evening glucocorticoid levels were found in patients with CFS in comparison to healthy control subjects. In addition, the patients were shown to have an increased adrenocortical sensitivity to administered ACTH, but a blunted response to CRH, consistent with a mild hypothalamic defect in the regulation of adrenal function. Other studies have shown generally concordant findings (reviewed in 130). The alterations in HPA axis performance were shown to differ from those in patients with major depression (in whom relative hypercortisolism and resistance to dexamethasone suppression are evident) (117). The available evidence suggests that these changes in patients with CFS are a consequence of the chronic illness, rather than the cause, as they are absent early in the course of illness and improve following unrelated treatment interventions, such as cognitive-behavioral therapy (see below) (130).

The complaint of unrefreshing sleep is a universal one in patients with CFS, often associated with either hypersomnia or insomnia. Accordingly, exclusion of the prevalent primary sleep pathologies, such as obstructive sleep apnea, is clearly important before applying the label of CFS (122, 131, 132). In the absence of such diagnoses, disturbances of sleep maintenance (i.e., frequent awakenings) are prevalent, and circadian rhythm may also be disturbed (133). The early report of a characteristic sleep abnormality, with the intrusion of high-amplitude alpha waves into the delta pattern of stage III–IV non-REM sleep, has not been reliably demonstrated, nor is it specific for CFS (134, 135). It remains plausible that alterations in sleep-stage transitions and

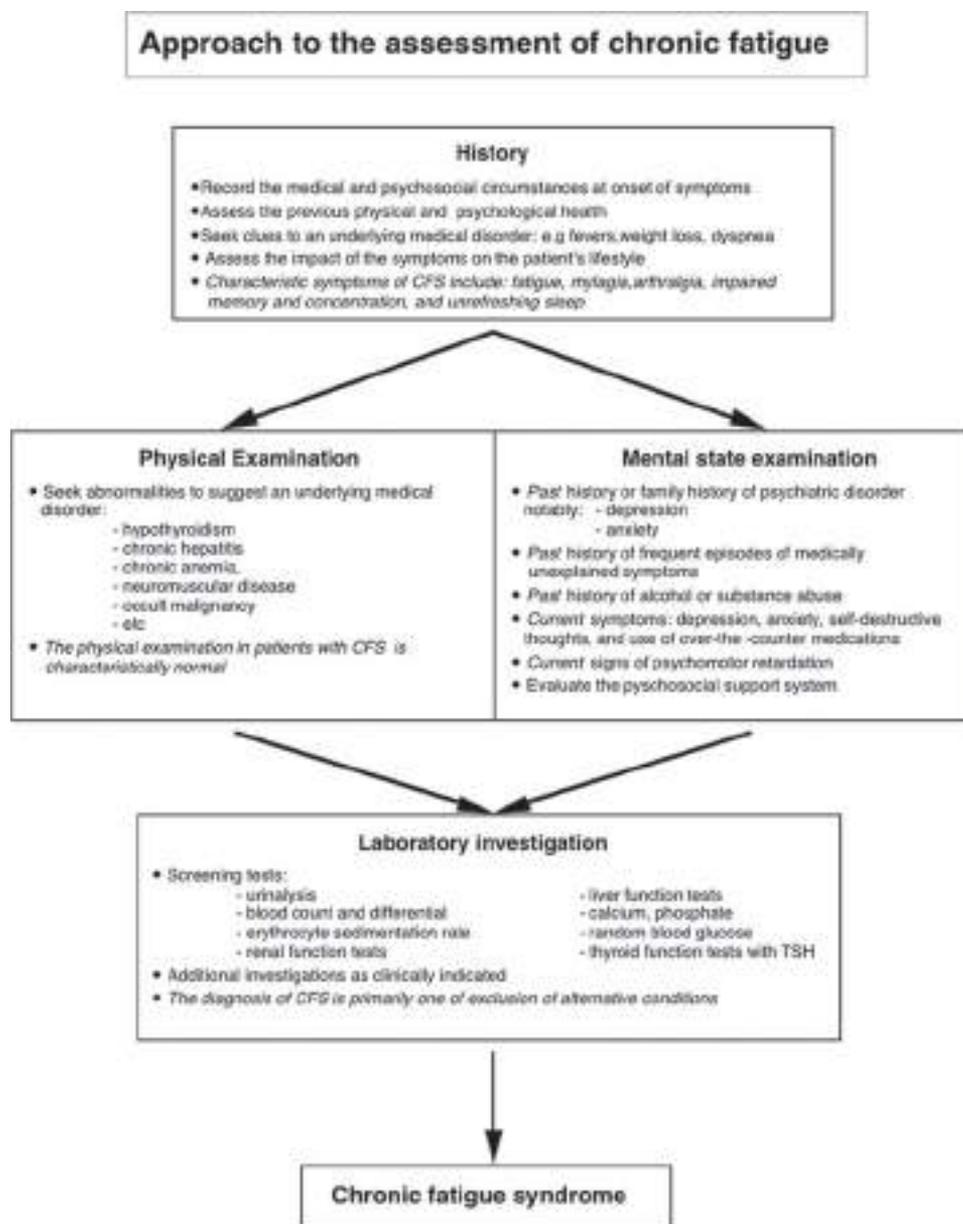

FIGURE 2 Approach to the clinical and laboratory assessment of patients with chronic fatigue. Adapted from reference (157)

associated physiological mechanisms, such as heart rate variability, may be relevant to pathogenesis (136–138 and reviewed in 139, 140, 141).

The potential role of altered autonomic function as a correlate or causative factor in CFS has been explored in several studies. The initial focus was on clinically apparent, neurally mediated hypotension and/or postural tachycardia (126–129). In the initial report, patients were evaluated using a three-stage tilt-table test with the administration of isoproterenol. An abnormal response was documented in 22 of 23 patients (96%) in comparison to 4 of 14 healthy control subjects (29%). Subsequent studies have generally confirmed that a subset of patients with CFS also display features of autonomic instability (142, 143). However, it is unlikely that this phenomenon is causative in CFS, as studies in identical twin pairs, discordant for the illness, have revealed comparable evidence for altered regulation of vasomotor control in the

unaffected siblings (126). In addition, appropriate treatment for this condition, in the form of mineralocorticoid supplementation with fludrocortisone to promote salt and water retention, is ineffective in resolving the major symptoms of the disorder (see below) (144). Nevertheless, several case-control studies have revealed reduced heart rate variability in patients with CFS, reflecting reduced parasympathetic (vagal) activity (136, 137, 141, 145, 146, and reviewed in 147). These observations have led to the hypothesis that sensitization within the central nervous system results in abnormally heightened perception of physiological signals from the body in conjunction with autonomic hyper-reactivity (reviewed in 148, 149) underpins CFS.

### Genetic Predisposition

Family studies of patients with CFS have demonstrated a higher prevalence in relatives, indicating a possible genetic

**TABLE 3** Causes of chronic fatigue

<b>Physiologic</b>	<b>Endocrine disorders</b>

Myeloproliferative disorders	<b>Syndromes of uncertain etiology</b>
<b>Occult malignancy</b>	Chronic fatigue syndrome
<b>Sleep disorders</b>	Fibromyalgia (fibrositis)

(or shared environmental) component to the disorder (150). Twin studies also indicate a likely heritable component (151, 152). A genealogical resource from Utah, linking family data and medical diagnoses, revealed a higher relative risk of development of CFS in those with a family history, which was evident between both first-degree (relative risk 2.7) and second-degree relationships (relative risk 2.34) (153).

Genetic polymorphisms confer variations in responsiveness of immunological and neurobehavioral responses (154, 155). During acute infective illnesses, the severity of the key symptoms, including fatigue, has been correlated with the level of production of pro-inflammatory cytokines, including interleukin (IL)-1 $\beta$  and IL-6 (153). Additionally, the severity of mood disturbance in this context was found to be more strongly associated with IL-6 production, whereas fatigue and pain were more closely related to the production of IL-1 $\beta$  (153). These associations suggested that individual cytokines could influence the various aspects of the symptom complex in the acute sickness response to infection. In the postinfective fatigue syndrome, both the severity of the acute illness and the duration of postinfective symptoms

(i.e., beyond the initial febrile period) have been associated with functional polymorphisms in the pro-inflammatory cytokine, interferon (IFN)- $\gamma$  and the anti-inflammatory, IL-10, genes (154). In particular, the high-producing allele of the IFN- $\gamma$  gene and the low-producing allele of the IL-10 gene were associated with more severe and more prolonged illness. A subsequent study, in which the symptom complex of the acute infective illness and the subsequent post-infective illness was divided into coherent symptom domains, or "endophenotypes," was undertaken to investigate the possibility of individual genetic associations of each symptom domain (155). In this analysis the high-producing allele of the IFN- $\gamma$  gene was specifically associated with the fatigue domain, whereas the low-producing allele of the IL-10 gene was associated with increased mood disturbance and neurocognitive difficulties. In addition, carriers of the high-producing allele of IL-6 also had increased mood disturbance (155). These findings await confirmation but suggest the genetic predisposition to patterns of pro- and anti-inflammatory cytokine production in the acute illness may partially underpin the susceptibility to a subsequent postinfective fatigue illness and its phenotypic characteristics.

There have been multiple candidate gene-association studies in case-control series of patients with CFS, including investigation of the human leukocyte antigen (HLA) complex, cytokine genes, as well as neurotransmitter pathways, but all of these studies have been underpowered, and none have passed the critical initial benchmark of independent replication (reviewed in 156). Large-scale genetic-association studies of carefully phenotyped patients with CFS may be warranted.

## CLINICAL AND LABORATORY ASSESSMENTS

Until a reliable biological marker for the syndrome is available, the key to evaluation of patients presenting with chronic fatigue will continue to include a thorough medical history, physical examination, and detailed assessment of psychological factors (Fig. 2) (157, 158). The medical interview should specifically determine i) whether the fatigue is of recent and discrete onset; ii) the medical and psychosocial circumstances at onset; and iii) the presence of symptoms suggestive of an underlying medical condition to explain the fatigue and related symptoms (e.g., documented fever suggesting infection, weight loss suggesting malignancy, or objective arthritis suggesting autoimmune disease) (1). It is also important to distinguish the characteristics of the phenomenon of fatigue to verify that the primary complaint is not muscle weakness, somnolence, or motivational loss. Patients with CFS characteristically describe profound fatigue, which is precipitated by physical tasks previously achieved with ease and is associated with a protracted recovery period extending over hours or even days.

The physical examination should similarly be directed at detection of signs of unrecognized medical disorders (e.g., goiter, stigmata of chronic liver disease, and neurologic signs of myopathy or multiple sclerosis). The physical examination in patients with CFS should be normal. The psychological evaluation should directly assess current mood, cognitive function, and illness attitudes. Particular attention should be directed towards the identification of serious and treatable anxiety or depressive disorders. Other important historical features include a past or family history of psychiatric disorder, previous episodes of medically unexplained symptoms and excessive healthcare utilization (suggesting a diagnosis of somatization disorder), and excessive use of alcohol or other substances of abuse.

Medical causes of chronic fatigue that should be ruled out include hypothyroidism, chronic hepatitis, anemia, sleep apnea, and side effects of prescribed medications, although many other causes are possible (Table 3). Patients diagnosed with “fibromyalgia” have essentially a synonymous disorder to CFS, differing principally in the prevalence and severity of musculoskeletal pain (159). Psychiatric disorders that commonly present with chronic fatigue include major depression, somatoform disorders, panic and other anxiety disorders, alcohol and substance abuse, and eating disorders.

Despite the wide range of hematologic, immunologic, virologic, psychometric, and neuroimaging investigations that have been conducted, no specific diagnostic test for CFS has emerged. In fact, the clinical heterogeneity of patients diagnosed with CFS makes it highly unlikely that any specific test could emerge (56, 57). Examples of specific tests that do not confirm or exclude the diagnosis of CFS include serological tests for Epstein-Barr virus, human herpesvirus 6, enteroviruses, and *Candida albicans*; detection of nucleic acids of *Mycoplasma sp.* or other microorganisms by PCR;

tests of immunity, including T-cell or natural-killer-cell phenotype and functional assays; and neuro-imaging studies, including cerebral magnetic resonance imaging scans or radionuclide studies.

The limited number of screening laboratory tests, which are recommended, are intended for the detection of alternative medical conditions (Table 3) (1). These screening tests should be uniformly negative or normal. If alternative diagnoses are suggested by the clinical history, examination, or screening investigations (e.g., anemia, sleep apnea, or multiple sclerosis), then additional directed investigations (e.g., iron studies, overnight sleep study, or magnetic resonance imaging, respectively) may be warranted. Similarly, if the mental status examination raises the issue of psychiatric disorder, then referral for specialist psychiatric opinion should be sought.

## TREATMENT

A wide range of antimicrobial, immunoregulatory, neuroendocrine, metabolic, and antidepressant therapies have been evaluated in randomized, placebo-controlled trials (reviewed in 14, 15, 144, 157, 160–181). While some positive outcomes have been reported, to date, no pharmacologic agent has consistently demonstrated efficacy in repeated, well-designed studies. Several trials have compared an immunologic therapy to placebo and have failed to show reproducible evidence of benefit, including with intravenous immunoglobulin and transfer factor (163, 164, 166, 182), with the possible exception of the Toll-like-receptor 3 agonist, rintatolimod [Poly I: C(12)U], for which limited benefit was evident only in those with severe disease (167, 183). Antiviral drug trials, including with aciclovir and valganciclovir, have failed to show benefit above placebo, although subjects with postinfective fatigue, which had been triggered by well-documented EBV or other herpesvirus infection, were not specifically included (160, 184). Antimicrobial therapy for post-Lyme borreliosis also did not show benefit (68–70). Preliminary findings of benefit in an uncontrolled pilot study of monocycline treatment for chronic fatigue after Q-fever infection (185), await replication in an ongoing randomized controlled trial (186). Similarly, the positive effects of the B-lymphocyte depleting agent, rituximab, await independent confirmation (187, 188).

Four placebo-controlled trials have evaluated a pharmacologic therapy directed at the HPA-axis disturbance by administration of corticosteroids—fludrocortisone and hydrocortisone (172, 189–191). The two trials using low-dose glucocorticoids suggested that this therapy may improve subjective fatigue or the sense of wellness, but at the risk of potentially harmful suppression of adrenal function and risk of other long-term adverse effects (172, 190). The two trials of mineralocorticoids, including one specifically limited to patients with CFS, which was associated with documented neurally mediated hypotension (191), showed no benefit in improving symptoms or functional outcomes (189).

Although antidepressant therapies are commonly suggested for the treatment of CFS, the empirical evidence for their utility is very limited. None of five placebo-controlled trials of antidepressant therapy in patients with CFS have demonstrated a substantive or sustained benefit from the agents studied, which included the monoamine oxidase inhibitors, phenelzine, selegiline, and moclobemide, as well as the serotonin reuptake inhibitor, fluoxetine (168–170, 175, 178).

Studies in patients with the overlapping clinical syndrome of fibromyalgia have demonstrated the benefit of a combination of a low-dose tricyclic antidepressant and a nonsteroidal anti-inflammatory agent, where effects on muscle pain and sleep disturbance are notable (192), arguing for a similar therapeutic trial in patients with CFS in whom pain and sleep disturbance are prominent. Reviews of the evidence-base for management of fibromyalgia endorse the use of pharmacologic agents for pain (antidepressants and centrally active agents, such as gabapentin) and nonpharmacologic interventions (graded exercise, heated pool), consistent with the principles of management of CFS (193–195).

Patient cohorts in such drug treatment trials are likely to be heterogeneous, as a simple consequence of the subjective, prevalent, and nonspecific symptom criteria used to make the diagnosis of CFS. Consequently, any treatment that claims to cure the majority of patients with CFS is likely to be acting via a nonspecific mechanism. As is true in other chronic medical conditions, at least 30% of patients with CFS generally demonstrate improvement in the nonspecific treatment arm of controlled trials (196).

By contrast, numerous randomized controlled trials have established the effectiveness of cognitive-behavioral (197–208) and graded-physical exercise (203, 206, 207, 209–212) in patients with CFS (reviewed in 180, 208, 213, 214). These management approaches link the principles of good clinical care with varying degrees of psychological intervention and functional rehabilitation via graded physical and cognitive activity. The outcomes of such multidisciplinary interventions are best described as improvement in both symptom severity and functional capacity but not cure (215).

Given the likelihood of spontaneous improvement in patients with chronic fatigue, controlled-treatment trials are essential for all proposed therapeutic modalities. Prevention of secondary medical and psychological morbidity due to prolonged rest and social isolation should be emphasized. Nonspecific aspects of good clinical management are effective and include careful medical and psychological evaluation, judicious use of investigations and specialist referral, consistent and empathic interactions with the patient over the course of the illness, and the encouragement of a rehabilitation approach. Irrespective of attitudes to etiology, the patient should be encouraged to incorporate the widest possible view of the role of medical, psychosocial, and rehabilitative strategies to promote recovery.

## 19

Smallpox has long been known as a severe human disease (1, 2) and was already endemic in India 2,000 years ago before spreading to China and Japan in the east and Europe and North Africa in the West by about 700 A.D. It was introduced to the Caribbean with the African slave trade in 1518 and thence to Mexico in 1520, taking a terrible toll on the totally nonimmune Amerindians. Repeated introductions from Europe and, to a lesser extent, from Africa, into North America occurred from 1617 onward. With the discovery of vaccination by Jenner in the latter part of the 18th century (3), the disease was brought under control first by local initiatives, which became national, and finally global. Following the last identified case in 1977, the world was certified free of smallpox by the World Health Assembly in May 1980 (2). The subsequent drawdown of vaccine stockpiles and cessation of childhood vaccination programs have increased the vulnerability of the human population to a devastating smallpox epidemic and increased the threat of variola virus (VARV) as a bioweapon. This unintended consequence of the most successful vaccination program in history was exploited by the former Soviet Union, which weaponized VARV in contradiction to the 1972 Biological and Toxin Weapons Convention (4, 5). This occurrence raised concerns that other rogue nations or terrorist groups could also develop VARV or monkeypox virus (MPXV) as a bioweapon.

Monkeypox is a disease that is clinically almost identical to smallpox. The monkeypox virus (MPXV) was discovered as a disease-causing agent of laboratory primates in Copenhagen, Denmark, in 1958 (6), and it caused several other outbreaks in captive primates before it was recognized as the cause of a smallpox-like zoonotic disease in West and central Africa in 1970. The incidence of monkeypox is on the rise in central Africa (7) and caused an outbreak in the United States. It is important to note that the names of many of the orthopoxviruses were based on the species where disease was initially seen and thus are not a species-specific disease. For example, monkeypox virus and cowpox virus obtained their names because the pox infection was first observed in monkeys and cows, respectively.

### VIROLOGY

#### Classification

The poxviruses (family *Poxviridae*) are one of the largest and most complex of all viruses (8, 9). The subfamily *Chordo-*

*poxvirinae* (poxviruses of vertebrates) contains eleven genera (10). Human infections have been caused by 13 poxvirus species belonging to four genera, the majority of which cause zoonotic infections (Table 1). The orthopoxvirus pathogens are the best studied, and variola virus (VARV) is the most important species, as it caused a severe human disease known as smallpox. While variola major caused severe disease and death, a second type, called variola minor, caused much lower mortality. Comparisons between the variola major and variola minor genomes show that these viruses have >95% identity of most of the genes (one-third of the genome is 100% identical) (11). It is speculated that the difference in virulence is due to nucleotide additions and deletions resulting in alterations of gene expression and protein truncations.

Vaccinia virus (VACV) and cowpox virus (CPXV) are related but distinct orthopoxviruses that cause human infections. CPXV is the agent that Jenner used to prove the efficacy of vaccination against smallpox; however, VACV was subsequently used for at least the last 100 years to vaccinate against smallpox. Human CPXV infections are rare and are usually acquired from the domestic cat. A VACV ancestor may originally have been maintained in nature in horses, as a comparative genome-sequencing study placed a poxvirus, isolated in 1976 from a diseased Mongolian horse, as a member of the VACV clade of orthopoxviruses (12) with recombination events leading to the virus we call VACV (13). In addition to vaccination and its complications, human infections with VACV result from contact with vaccinees or domestic animals persistently infected with VACV as a result of the smallpox eradication programs (cantalago and buffalopox viruses) (14–17). VACV and two members of the genus *Avipoxvirus* (fowlpox virus and canarypox virus) have been used as vectors for the production of novel vaccines and as oncolytics for cancer therapy (18–20). Recently, a newly discovered orthopoxvirus (GCP2013) was identified in the country of Georgia in a cow herder who developed chronic painful skin lesions (21).

The remaining human poxvirus pathogens belong to three genera: five in *Parapoxvirus*, two in *Yatapoxvirus*, and one in *Molluscipoxvirus* (Table 1). Orf virus (ORFV) causes orf (synonyms: contagious pustular dermatitis, contagious ecthyma, and scabby mouth), a disease of sheep. Pseudocowpox (PCPV; synonyms: milker's nodule and paravaccinia) and bovine pustular stomatitis (BPSV) viruses

**TABLE 1** Poxviruses that can cause disease in humans

Genus	Species	Distribution	Reservoir	Disease in humans
<i>Orthopoxvirus</i>	Variola virus	Was worldwide	Humans (before 1977)	Smallpox, specifically human, generalized disease
	Monkeypox virus	Central and West Africa	Squirrels, monkeys	Smallpox-like disease; a zoonosis
	Vaccinia virus	Worldwide	Laboratory virus	Used for smallpox vaccination, localized lesions
	Buffalopox virus, variant of vaccinia virus	India (Egypt, Indonesia)	Buffaloes, rodents	Localized pustular skin lesions
	Cantagalo virus, variant of vaccinia virus	Brazil	Cattle	Localized pustular skin lesions
	Cowpox virus	Europe, western Asia	Wild rodents	Localized pustular skin lesions; a rare zoonosis
	Novel orthopoxvirus (Georgia)	Country of Georgia	Not yet defined	Localized pustular skin lesions; a very rare zoonosis
<i>Parapoxvirus</i>	Orf virus	Worldwide	Sheep	Localized nodular skin lesions; a rare zoonosis
	Bovine papular stomatitis virus	Worldwide	Cattle	Localized nodular skin lesions; a rare zoonosis
	Pseudocowpox virus	Worldwide	Cows	Localized nodular skin lesions; a rare zoonosis
	Sealpox virus	Worldwide	Seals	Localized nodular skin lesions; a rare zoonosis
	Novel parapoxvirus (United States)	Tennessee and Tanzania (?)	Unknown	Localized nodular skin lesions; presumed zoonosis
<i>Yatapoxvirus</i>	Tanapoxvirus	Tropical Africa	Unknown	Localized nodular skin lesions; a rare zoonosis
	Yaba monkey tumor virus	West Africa	Unknown, possibly monkeys	Localized nodular skin lesions; rare accidental infections
<i>Molluscipoxvirus</i>	Molluscum contagiosum virus	Worldwide	Humans	Few or many nodular lesions; worse in immunodeficiency

cause diseases of cattle (22). Very rarely, humans may be infected with seal parapoxvirus (23). Recently, a newly discovered parapox-like virus (2013\_13 and 2013\_37) was identified as causing an infection in an immunocompromised patient who lived in Tennessee and an immunocompetent patient who had traveled to Tanzania (24). While both had contact with animals, the origin of the virus is unknown but is presumed to be a zoonosis. Tanapox virus (TANV) and Yaba monkey tumor poxvirus (YMTV) are rare causes of zoonotic diseases mainly in Africa. Molluscum contagiosum virus (MCV) causes a common cosmopolitan human disease and is the only poxvirus currently maintained in the human population without a zoonotic host (25).

### Structure of Virus

Poxvirus virions appear to be oval or brick-shaped structures of about 200 to 400 nm in length with axial ratios of 1.2 to 1.7. The structure of VACV (Fig. 1A and D) is characteristic of that of all the poxviruses that infect humans, except those belonging to the genus *Parapoxvirus* (Fig. 1B and E). The outer membrane of orthopoxviruses consists of tubular lipoprotein subunits arranged rather irregularly, whereas parapoxviruses have a regular spiral structure. The membrane encloses a dumbbell-shaped core and two “lateral bodies.” The core contains the viral DNA and associated proteins.

The double-stranded DNA poxvirus genome is 130 to 375 kbp in length and codes for 150 to 300 proteins, depending on the species (see Table 2 for examples of types of proteins

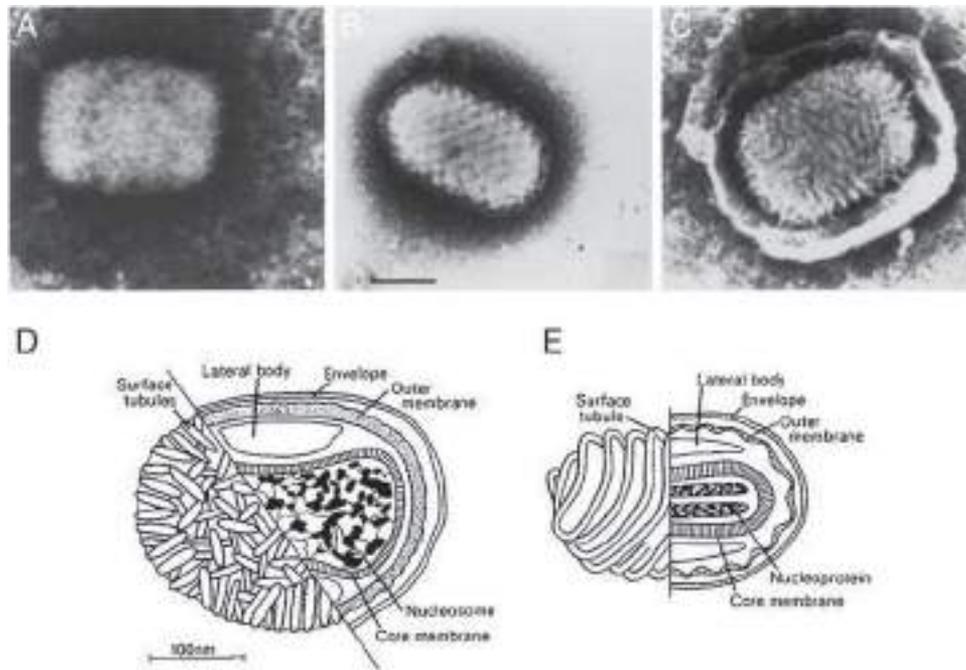

encoded by orthopoxviruses). The genomes of a large number of poxvirus species, including 51 isolates of VARV, have been completely sequenced (<http://www.viprbrc.org>). The genomic organization of the prototypic orthopoxvirus, VACV, is displayed in Figure 2. Orthopoxvirus virions contain a hemagglutinin (A56R, Table 2), and estimates of virus phylogeny based on hemagglutinin and A-type inclusion body protein gene sequences agree well with those based on restriction endonuclease maps, permitting the use of PCR analyses of these genes as the assay of choice for identifying orthopoxvirus species (28–30). Assignment of a poxvirus to a particular taxonomic group is based on extensive analyses of virus genomic sequences. The DNA sequence of strains of an orthopoxvirus species vary by no more than 2%. The orthopoxvirus species vary among themselves by 2 and 13%. The species of the orthopoxvirus genus differ from species of other genera by between 25 and 54%.

There is broad cross-neutralization and cross-protection between viruses belonging to the same genus but little to none between viruses of different genera; in laboratory experiments genetic recombination occurs readily between viruses of the same genus but rarely between those of different genera (31).

### Biology

#### Replication Strategy

Poxviruses are enveloped viruses and thus require the viral envelope to fuse with host cell membranes to gain entry into

**FIGURE 1** Structure of virions of poxviruses that cause human infections. Shown are negatively stained preparations of orthopoxvirus virions (cowpox, monkeypox, vaccinia, and variola viruses) (A), parapoxvirus virions (ORFV, BPSV, PCPV, and sealpox viruses) (B), and yatapoxvirus virions (TANV and YMTV) (C). The virions of orthopoxviruses and yatapoxviruses have similar morphologies, but those of yatapoxviruses always have two membranes. Virions of the parapoxviruses are smaller and have a distinctive regular-surface structure. (D) Diagram of the structure of the virion of VACV. The viral DNA and several proteins within the core are organized as a nucleosome. The core has a 9-nm-thick shell with a regular subunit structure. Within the virion, the core assumes the shape of a dumbbell because of the large lateral bodies, which are, in turn, enclosed within a protein shell about 12 nm thick—the first membrane, the surface of which appears to consist of irregularly arranged surface tubules, which, in turn, consist of small globular subunits. Mature virus released by exocytosis (extracellular virus) is enclosed within a second membrane (envelope) acquired from the Golgi. This membrane contains host-cell lipids and several unique virus-specific polypeptides not found in the intracellular mature virus outer membrane. Most virions remain cell-associated and are released by cellular disruption, without the second membrane. (E) Diagram of the structure of the virion of ORFV. The first membrane consists of a single long tubule that appears to be wound around the particle. In negatively stained preparations (B) both sides are visible, giving a characteristic criss-cross appearance. The second membrane is usually closely applied to the surface of the first membrane. Bar = 100 nm. Reprinted from reference (26) with permission.

the cell. While a number of cellular attachment factors have been identified, a specific cell receptor(s) that initiates the fusion event has not been identified. Many of the viral proteins involved in attachment and entry are targets of neutralizing antibodies. Viral membrane fusion is dependent on a membrane fusion complex that is made up of 11 to 12 viral proteins (32). Entry can occur at the plasma membrane or within endosomes after micropinocytosis. After entry, the replication of poxviruses occurs in the cytoplasm, and poxviruses encode dozens of enzymes required for transcription and replication of the viral genome, several of which [including DNA-dependent RNA polymerase, poly (A) polymerase, capping enzyme, methylating enzymes, and transcription factor] are carried in the virion itself (Fig. 3) (8). The viral core is released into the cytoplasm after fusion of the virion with the plasma or endosomal membrane. Transcription is initiated by the viral transcriptase, and functional capped and polyadenylated mRNAs are produced minutes after infection. The polypeptides produced by translation of these mRNAs complete the uncoating of the core, and transcription of about 100 early genes, distributed throughout the genome, occurs before viral DNA synthesis begins. Early proteins include DNA polymerase, thymidine kinase, and several other enzymes required for replication of the genome.

With the onset of viral DNA replication there is a dramatic shift in gene expression. Transcription of intermediate and late genes is controlled by binding of specific viral proteins to characteristic promoter sequences. Virion assembly occurs in circumscribed areas of the cytoplasm, where spherical immature particles assembling on cellular membranes can be visualized by electron microscopy. The immature particle incorporates DNA and additional proteins during morphogenesis to the mature virus. Most mature virus remains in the cytoplasm and is released on cell death; however, some moves to the Golgi complex, where it is wrapped in a double membrane, transported to the plasma membrane, and released by exocytosis with the loss of one of the Golgi acquired membranes to produce extracellular virus (that has an additional viral membrane) (Fig. 3). Both mature virus and extracellular virus particles are infectious, but extracellular virus particles appear to be important in virus spread through the body.

Poxviruses encode a large number of proteins that enhance the ability of the virus to replicate efficiently and spread within the animal host (8). A number of these gene products are important for optimal replication in differentiated and nondividing cell types, and some are involved in the blockade of cellular apoptosis pathways (33). Others are immunosubversive proteins that are secreted mimics of host

**TABLE 2** Examples of genes/proteins encoded by Orthopoxviruses

Gene name <sup>1</sup> in VACV strain WR	Gene name <sup>2</sup> in VACV strain Copenhagen	Description of encoded protein <sup>3</sup>
<b>Involved in viral DNA replication</b>		
VACWR138	A18R	DNA helicase; effects elongation and termination of postreplicative viral transcription
VACWR141	A20R	DNA polymerase processivity factor that interacts with D4
VACWR142	A22R	a late protein essential for concatemer resolution. An E. coli RuvC-like protein with Holliday junction resolvase activity
VACWR155	A32L	putative ATPase involved in DNA packaging
VACWR174	A48R	thymidylate kinase
VACWR176	A50R	ATP-dependent DNA ligase
VACWR115	D10R	contains mutT-like motif of NTP-phosphohydrolase for DNA repair
VACWR109	D4R	uracil glycosylase that also acts as a DNA polymerase processivity factor that interacts with A20
VACWR110	D5R	DNA-independent NTPase essential for DNA replication
VACWR114	D9R	contains mutT-like motif of NTP-phosphohydrolase for DNA repair
VACWR065	E9L	viral DNA polymerase
VACWR056	F17R	putative DNA-binding phosphoprotein in virus core
VACWR041	F2L	dUTPase, expressed early, nonessential in tissue culture, involved in nucleotide metabolism
VACWR043	F4L	ribonucleotide reductase small subunit
VACWR104	H6R	topoisomerase type IB
VACWR070	I1L	DNA-binding core protein
VACWR072	I3L	ssDNA-binding phosphoprotein
VACWR073	I4L	ribonucleotide reductase large subunit
VACWR094	J2R	thymidine kinase; common site to insert foreign genes by homologous recombination
<b>Involved in viral RNA transcription</b>		
VACWR119	A1L	viral late gene transcription factor (VLTF)-2
VACWR143	A23R	45kDa large subunit of viral intermediate gene transcription factor (VITF)-3
VACWR144	A24R	DNA-dependent RNA polymerase subunit (rpo132)
VACWR152	A29L	DNA-dependent RNA polymerase (rpo35)
VACWR120	A2L	viral late gene transcription factor (VLTF)-3
VACWR124	A5R	DNA-dependent RNA polymerase subunit (rpo19)
VACWR126	A7L	82kDa large subunit of viral early gene transcription factor (VETF)
VACWR127	A8R	32kDa small subunit of viral intermediate gene transcription factor (VITF)-3 used for intermediate gene expression
VACWR116	D11L	ATPase, nucleoside triphosphate phosphohydrolase-I, NPH-I; transcription elongation, termination, release factor
VACWR117	D12L	small subunit of mRNA capping enzyme; viral transcription termination factor (VTF)
VACWR106	D1R	large subunit of mRNA capping enzyme; transcription termination factor (VTF)
VACWR111	D6R	70kDa small subunit of viral early gene transcription factor (VETF)
VACWR112	D7R	DNA-dependent RNA polymerase subunit (rpo18)
VACWR057	E1L	poly-A polymerase catalytic subunit (VP55)
VACWR059	E3L	double-stranded RNA binding protein; inhibits antiviral activities of interferon; host-range determinant; host defense modulator
VACWR060	E4L	DNA-dependent RNA polymerase subunit (rpo30), viral intermediate-gene transcription factor (VITF)-1
VACWR080	G2R	late transcription elongation factor
VACWR083	G5.5R	DNA-dependent RNA polymerase subunit (rpo7)
VACWR086	G8R	viral late gene transcription (VLTF)-1
VACWR099	H1L	tyr/ser protein phosphatase VH1, is essential for viral transcription in vivo and in vitro
VACWR102	H4L	tightly associated with DNA-dependent RNA polymerase, aids early-stage transcription preinitiation and termination (RAP94)

(Continued)

**TABLE 2** Examples of genes/proteins encoded by Orthopoxviruses (*Continued*)

Gene name <sup>1</sup> in VACV strain WR	Gene name <sup>2</sup> in VACV strain Copenhagen	Description of encoded protein <sup>3</sup>
VACWR103	H5R	viral late gene transcription factor (VLTF)-4; substrate of B1R kinase
VACWR077	I8R	an encapsidated 72kDa protein, with NTPase and RNA helicase activity, essential for early transcription
VACWR095	J3R	multifunctional poly-A polymerase subunit, cap methyltransferase, and transcription elongation factor
VACWR096	J4R	DNA-dependent RNA polymerase subunit (rpo22)
VACWR098	J6R	DNA-dependent RNA polymerase subunit (rpo147)
VACWR091	L4R	ssDNA/ssRNA binding protein involved in early mRNA regulation
<b>Involved in viral cytoplasmic disulfide bond formation</b>		
VACWR121	A2.5L	S-S bond formation pathway; CxxxC links SH-oxidase E10R and thioredoxin G4L
VACWR066	E10R	S-S bond formation pathway; sulfhydryl oxidase, substrates L1R/F9L
VACWR081	G4L	S-S bond formation pathway; thioredoxin-like
<b>Involved in formation and/or part of mature virus (MV)</b>		
VACWR129	A10L	precursor p4a of core protein 4a, complexes with A4L
VACWR131	A12L	core protein
VACWR132	A13L	MV membrane protein; target of neutralizing antibody
VACWR134	A14.5L	nonessential hydrophobic IV and MV membrane protein; deletion attenuates virus virulence
VACWR133	A14L	repression of 90 aa A14 membrane phosphoprotein arrests virion assembly prior to/at crescent formation; interacts with A17; F10 and H1 substrate
VACWR136	A16L	component of the poxvirus multiprotein EFC, soluble myristylprotein
VACWR137	A17L	MV membrane protein required for morphogenesis
VACWR140	A21L	component of the poxvirus multiprotein EFC
VACWR149	A26L	MV protein required for incorporating MV into A-type inclusion body; involved in MV attachment to cell surface
VACWR150	A27L	MV surface protein; roles in MV-cell attachment, fusion, and microtubule transport; target of anti-MV neutralization
VACWR151	A28L	component of the poxvirus multiprotein EFC, target of neutralizing antibody
VACWR153	A30L	vaccinia core protein component of the seven protein complex required for virosomal uptake by viral crescents
VACWR122	A3L	p4b precursor of core protein 4b
VACWR123	A4L	39kDa core protein complexes with core protein p4a/4a
VACWR128	A9L	MV membrane protein required for morphogenesis
VACWR107	D2L	virion core protein
VACWR108	D3R	virion core protein
VACWR113	D8L	MV membrane protein binds cell surface chondroitin; may effect viral entry
VACWR118	D13L	rifampicin target associates with inner surface immature virus membrane
VACWR044	F5L	membrane protein that has a role in plaque morphology in a subset of cell lines
VACWR048	F9L	peripheral partner of EFC, S-S bond formation pathway; thiol substrate
VACWR079	G3L	component of the poxvirus multiprotein EFC
VACWR087	G9R	component of the poxvirus multiprotein EFC, myristylprotein
VACWR100	H2R	component of the poxvirus multiprotein EFC
VACWR101	H3L	MV heparin binding surface protein involved in MV maturation; neutralizing antibody target
VACWR071	I2L	component of the poxvirus multiprotein EFC
VACWR076	I7L	viral core cysteine proteinase
VACWR097	J5L	component of the poxvirus multiprotein EFC
VACWR088	L1R	MV membrane protein target of neutralizing antibody; S-S bond formation pathway thiol substrate; myristylprotein
VACWR092	L5R	component of the poxvirus multiprotein EFC

**TABLE 2** Examples of genes/proteins encoded by Orthopoxviruses (*Continued*)

Gene name <sup>1</sup> in VACV strain WR	Gene name <sup>2</sup> in VACV strain Copenhagen	Description of encoded protein <sup>3</sup>
<b>Involved in formation and/or part of extracellular virus (EV)</b>		
VACWR156	A33R	EV membrane phosphoglycoprotein associates with A36R; involved in CEV-cell adherence and actin tail formation
VACWR157	A34R	EV glycoprotein involved in CEV cell adherence and actin tail formation
VACWR159	A36R	transmembrane phosphoprotein that is required for EV formation, but not incorporated into EV membrane
VACWR181	A56R	EV type-I membrane glycoprotein; inhibits cell fusion and viral superinfection; also named hemagglutinin
VACWR187	B5R	EV type-I membrane glycoprotein; required for trans-Golgi/endosomal membrane-wrapping of MV
VACWR051	F12L	involved in plaque and EV formation; on IEV, not CEV, IV, or MV
VACWR052	F13L	palmytilated EV membrane protein; phospholipase motif, required for IEV formation; target of the anti-poxvirus drug ST-246
VACWR033	K2L	serine protease inhibitor-like (SPI-3); prevents cell-cell fusion; host range determinant; host defense modulator
<b>Host range genes</b>		
no ortholog	B23R	host range polypeptide
no ortholog	B24R	host range protein
no ortholog	C18L	host range protein
VACWR021	C7L	host range protein for growth in cell culture; possible host defense modulator
VACWR032	K1L	host range gene needed for viral replication in rabbit cells and is capable of complementing for C7L function in human cells
<b>Viral immune evasion or proteins that interact with host proteins</b>		
VACWR158	A35R	inhibits MHC class II antigen presentation
VACWR165	A40R	C-type lectin-like type-II membrane protein; deletion attenuates intradermal lesion in Vac-mouse model; host defense modulator
VACWR166	A41L	secreted glycoprotein; deletion causes more severe lesion and enhanced viral clearance in VAC-mouse skin model; host defense modulator
VACWR170	A44L	hydroxysteroid dehydrogenase; deletion attenuates intradermal lesion in VAC-mouse model; host defense modulator
VACWR172	A46R	Toll/IL1-receptor [TIR]-like; suppresses TIR-dependent signal transduction; host defense modulator
VACWR178	A52R	Toll/IL1-receptor [TIR]-like; suppresses TIR-dependent signal transduction; host defense modulator
VACWR179	A53R	gene fragment, secreted TNF-receptor-like protein; CrmC, intact in some Vac strains; host defense modulator
VACWR195	B13R	serine protease inhibitor-like (SPI-2, CrmA); inhibits Fas-mediated apoptosis, IL-1 convertase, lipoxygenase pathway
VACWR197	B16R	interleukin-1-beta-inhibitor; prevents febrile response in Vac-mouse intranasal model; host defense modulator
VACWR199	B18R	Interferon-alpha/beta-receptor-like secreted glycoprotein; host defense modulator
VACWR183	B1R	B1 is an early ser/thr kinase needed for ongoing viral DNA replication capable of phosphorylating the viral H5 and cellular ribosomal proteins
VACWR218	B29R	chemokine-binding protein; host defense modulator [found in the ITR]
VACWR190	B8R	soluble interferon-gamma receptor-like; host defense modulator
VACWR009	C11R	secreted epidermal growth factor-like; binds EGF receptor [found in the ITR]
VACWR205	C12L	serine protease inhibitor-like SPI-1; host defense modulator
VACWR001	C23L	chemokine-binding protein; host defense modulator [found in the ITR]
VACWR025	C3L	secreted complement binding protein; host defense modulator
VACWR034	K3L	interferon resistance; host defense modulator
VACWR028	N1L	virokine; host defense modulator

*(Continued)*

TABLE 2 Examples of genes/proteins encoded by Orthopoxviruses (*Continued*)

Gene name <sup>1</sup> in VACV strain WR	Gene name <sup>2</sup> in VACV strain Copenhagen	Description of encoded protein <sup>3</sup>
VACWR013	no ortholog	interleukin-18-binding protein; host defense modulator
VACWR210	no ortholog	secreted epidermal growth factor–like; binds EGF receptor [found in the ITR]
<b>Miscellaneous</b>		
VACWR162	A38L	CD47-like putative membrane protein
VACWR167	A42R	profilin-like
VACWR168	A43R	Conserved in all orthopoxviruses, but dispensable type-I membrane glycoprotein and not part of EV formation
VACWR171	A45R	inactive Cu-Zn superoxide dismutase–like in virion
VACWR194	B12R	ser/thr protein kinase–like
VACWR049	F10L	ser/thr kinase that phosphorylates viral proteins

<sup>1</sup>Gene names in VACV strain WR are named sequentially from left side of the genome to the right side (1 to 218).

VACV strain Copenhagen was the first VACV genome completely sequenced (193). The gene names are based on the HindIII restriction that digests the ~200 Kbp genome into 15 fragments. The largest fragment is A, next largest is B, etc. Gene names are then numbered within each HindIII fragment and are denoted with an L or an R if the gene is facing to the left or the right.

<sup>2</sup>Description of protein function adapted from [poxvirus.org](http://poxvirus.org).

<sup>3</sup>CEV, cell-associated extracellular virus; Crm, cytokine response modifier; EV, extracellular virus; IEV, intracellular extra-enveloped virus; ITR, inverted terminal repeat; IV, immature virus; MV, mature virus.

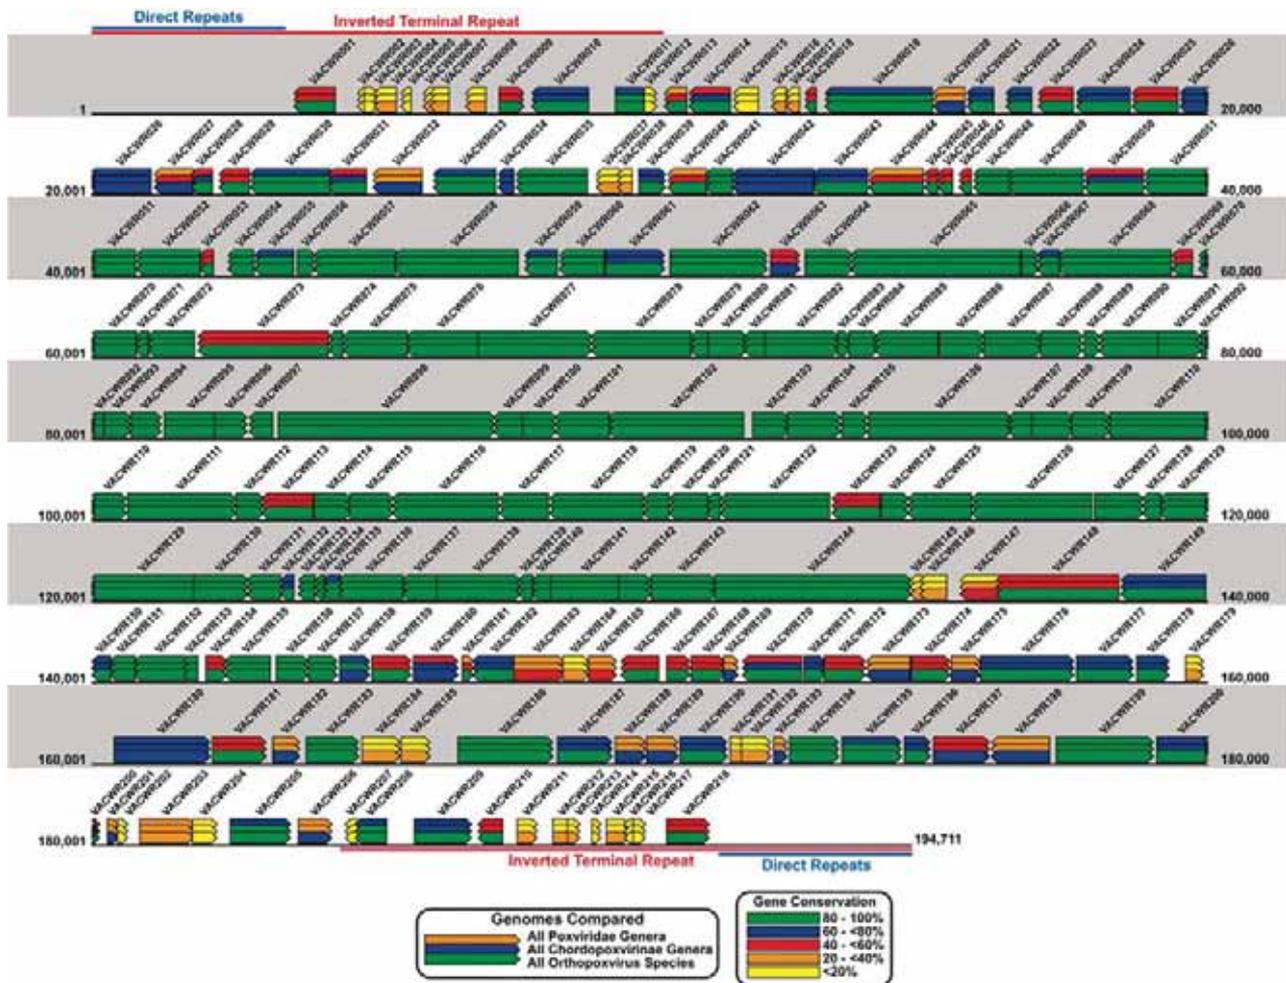

FIGURE 2 Schematic representation of the genome of the WR strain of VACV. The genome is a linear double-stranded molecule with terminal hairpins, inverted terminal repeats, and a series of direct repeats within the inverted repeats. Each overlapping bar indicates gene conservation between the WR strain and all poxviruses, vertebrate poxviruses, and orthopoxviruses. The bars are color-coded according to the percentage of gene conservation across the indicated taxa.

ligands, regulators, or receptors. These include homologs of epidermal growth factor and binding proteins for complement regulatory proteins C3 and C4, interleukin 1, interleukin 18, tumor necrosis factors alpha and beta, and type I and type II interferons (34–36).

#### Host Range

The animal host range of poxviruses that infect humans is narrow for VARV and MCV and relatively broad for VACV, CPXV, and MPXV. VARV has not been shown to cause significant disease in immunocompetent animal models except in nonhuman primates, in which lethal infections occur under conditions not characteristic of natural infection (37, 38). Aerosol challenge of cynomolgus macaques with up to  $10^{8.5}$  PFU of VARV results in an inapparent infection (37), whereas intravenous challenge with  $10^8$  PFU of VARV results in replication and the development of skin lesions, but is usually not lethal. Lethal disease is achieved 3 to 6 days following intravenous administration of  $10^9$  PFU. While these models do not recapitulate the natural pathogenesis of human VARV, which is initiated by deposition of a small number of virions on the respiratory mucosa, followed by the appearance of rash (10 to 12 days later), and death (20 to 22 days later) or recovery, they provide ability to test vaccines and therapeutics against variola virus in an animal model (39).

The ecology of MPXV is still not completely understood with respect to reservoir and incidental hosts (40, 41). Seroprevalence studies suggest that there may be several animal species serving as MPXV reservoirs in nature. For example, two genera and six species of squirrels and five genera and nine species of nonhuman primates have MPXV-specific antibodies. Virus has been isolated from an animal in nature only once, and the source was a diseased squirrel of the species *Funisciurus anerythrus* (42). However, cell culture

and PCR assays demonstrated MPXV in two *Funisciurus* spp. (rope squirrel), one *Cricetomys* sp. (giant pouched rat), and three *Graphiurus* spp. (African dormouse) from a 2003 shipment of African rodents to the United States (43). These observations suggest the natural ecology of MPXV to be a complex interaction of reservoir hosts and incidental species. This broad host range is a cause for concern, as it may facilitate the adaptation of MPXV to new hosts in new regions. Laboratory studies have demonstrated that cynomolgus macaques (44), prairie dogs (45), and ground squirrels (46) can serve as experimental hosts.

CPXV has a very broad host range in nature. The virus is maintained in wild rodents in western Eurasia, in particular, voles and wood mice. Short-tailed field voles have been proven to be the reservoir host in Great Britain (47). Cows are merely incidental hosts, as are rats, dogs, zoo animals (elephants, lions, cheetahs, pumas, panthers, and jaguars), and domestic cats (48, 49). The domestic cat is the frequent liaison host of human infections (50). In the laboratory, the mouse model is most often used to study CPXV.

VACV infects domesticated livestock species, possibly as a result of the smallpox vaccination campaign in which various animals were purposely used for vaccine production or inadvertently infected by contact with vaccinees (51). In Holland in 1963, 8 out of 36 outbreaks of “cowpox” in milking cows were found to be caused by VACV, and the rest were caused by authentic CPXV (52). In 1985, VACV was isolated from scabs taken from pox lesions on buffaloes in five different districts of Maharashtra State, India (53), and was also observed in Egypt and Indonesia, where water buffaloes (*Bubalus bubalis*) are used as domestic animals (54). Buffalopox outbreaks continued through 1996, with human infections and possible subclinical disease in areas of endemicity (54). There have been ongoing outbreaks of VACV in cattle and dairy workers based in Minas Gerais State, Brazil (55).

Similarly, in 1932, VACV appeared to adapt to a rabbit host, causing a new disease that was highly lethal and transmissible to contact rabbits by airborne infection (56). The isolated agent was named rabbitpox virus, and sequencing of its genome confirmed it as a strain of VACV (57). VACV replicates to various degrees in most tested animal models.

MCV has the narrowest host range of any poxvirus and has similarities in this regard to human papillomavirus (see Chapter 29): no experimental animals have been shown to support its growth.

### Growth in Cell Culture

Although the host range of human poxvirus pathogens can be quite narrow, all the orthopoxviruses replicate in a broad range of fibroblast or epithelial cell lines, including HeLa, BS-C-1, and Vero cells. Infection causes the cell to round and detach from the substrate, which is the basis for the plaque assay used to measure virus infectivity. Cytoplasmic inclusion bodies can be detected with appropriate histologic stains. MCV appears to replicate only in the human keratinocyte and has yet to be cultivated in cultured cells. MCV from skin lesions has been propagated in human foreskin xenografts (58, 59).

### Inactivation by Physical and Chemical Agents

Poxvirus infectivity is relatively stable in the environment compared to other enveloped viruses, and stability is measured in days or weeks, although not years (2). Since all poxvirus species likely share similar sensitivities to physical and chemical agents, data acquired with one poxvirus species can be applied to another. VACV infectiousness is adversely affected by both high temperatures and high humidity. VACV ( $10^7$  pock-forming units on chorioallantoic membrane/ml) sprayed in aerosols at room temperature (21 to 23°C) maintained 46 and 24% of the initial infectivity in low (18 to 19%) and high (82 to 84%) relative humidity, respectively, over a 4-h period (60). Higher temperatures (31.5 to 33.5°C) do not reduce infectivity further at low humidity, whereas infectivity dropped from 24 to 6% at high relative humidity. While virus on nonporous surfaces can remain infectious for months, the same trends of decreased viability are seen at high humidity (61). Infectious virus is present in scab material (62) and thus a person is considered infectious until all scabs fall off.

Since orthopoxviruses are highly infectious, and it takes only a small number of virions to initiate infection (40), the physical environment occupied by a person with poxvirus disease must be appropriately decontaminated. There are a number of disinfectants that inactivate poxviruses. Using the orthopoxvirus ectromelia virus, White and Fenner examined a range of chemical treatments for surface decontamination (63). For example, a 10-min treatment with 2% phenol or 40% alcohol was sufficient to destroy virus infectivity completely. Sterilization of surfaces can be achieved with formaldehyde gas or a range of commercially available contact sterilants, including fresh solutions of 10% bleach, Spor-Klenz, or Enviroid. Sunlight can also inactivate the virus (64).

## EPIDEMIOLOGY

### Distribution

Smallpox is no longer known to exist outside of two WHO-designated high containment laboratories.

Monkeypox is now the most frequent human orthopoxvirus causing serious infections (40). Because monkeypox

is clinically difficult to distinguish from smallpox, it was not identified as a distinct disease until smallpox was no longer endemic. Monkeypox is found mainly among the inhabitants of small villages in the tropical rain forests of West and central Africa (65), with occasional outbreaks elsewhere (31, 66–68). In 2003 and 2005 there were outbreaks in the United States and Sudan, respectively (69, 70). The US importation was traced to a shipment of animals from Ghana destined for the pet trade (69). Human cowpox is restricted to a region bounded by Norway, northern Russia, Turkmenistan, France, and Great Britain because of the limited ability to remain enzootic except in particular species of rodents. Zoonotic VACV infections are currently confined to Brazil and India, and contact infections from people receiving the smallpox vaccine are limited to countries that vaccinate their military or first responders to infectious disease outbreaks. Some rare human infections have occurred from contact with a recombinant VACV-based rabies vaccine that is used in bait to vaccinate wild animals (71, 72).

Of the remaining human poxvirus infections, ORFV has worldwide distribution. PCPV and BPSV are maintained in dairy herds derived from European herds in all parts of the world. In Great Britain, PCPV infection is enzootic in cattle and, in contrast to CPXV, persists in relatively small herds (73). Tanapox was first observed as an acute febrile illness associated with localized skin lesions, occurring in epidemics in 1957 and 1962 among people living in the flood plain of the Tana River in Kenya (74). It is endemic in this area, in the Democratic Republic of Congo (DRC, former Zaire), and probably elsewhere in tropical Africa (75). Molluscum contagiosum has a worldwide distribution and is very common in certain areas.

## Incidence and Prevalence

### Subclinical Infection Rate

Subclinical VARV infections among vaccinated subjects were documented in the smallpox eradication program, which, perhaps, is not surprising (2), but their occurrence in naïve subjects is unclear. Studies of human monkeypox in Zaire between 1981 and 1986, after cessation of smallpox vaccination, found that 136 (18%) of 774 unvaccinated contacts of monkeypox patients had serologic evidence of infection; 20% of these persons gave no history of illness, residual skin lesions, or other changes suggestive of monkeypox, and therefore were classified as having subclinical infections (66). More recent studies also provide evidence that subclinical monkeypox infections are likely occurring (76). A serosurvey done in 2003 of 109 children in 3 villages in Ghana who had never received smallpox vaccination and did not report prior monkeypox infection showed that 40 (37%) had antibodies detected against an orthopoxvirus. These villages were studied because the rodents that were imported into the US that caused prairie dog and human monkeypox infections were collected in these locations. Subclinical infections are probably universal for poxviruses, as multiple strains of mice can be infected subclinically with ectromelia virus and act as “silent” reservoirs of infectious virus for contact mice (77).

### Patterns of Infection

#### Variola

Except for VARV and MPXV infections, in which case fatality rates range from 1 to 30%, poxvirus infections of healthy individuals do not result in death.

Transmission of VARV typically occurred within household contacts. For example, an investigation in Pakistan (78) revealed a secondary attack rate of 77% of unvaccinated contacts (and ~5% in previously vaccinated contacts). From such data, the basic reproductive number ( $R_0$ , the number of new cases that one case will generate) for smallpox has been estimated to be between 3 and 10 (79–81). Overall mortality from smallpox was estimated to be 30%. However, in the nonimmune, severe disease and/or death were higher at the extremes of age. For example, in the early 1900s in Liverpool, England, infants <2 years old and unvaccinated adults >40 years old had death rates closer to 50 to 60% (82). In this same study, those previously vaccinated had nearly no death from smallpox. Even those who were vaccinated decades earlier showed death rates at <10%.

### Monkeypox

In 1981, the seroprevalence of hemagglutinin-inhibiting (orthopoxvirus) antibodies was 13% of West African children (Ivory Coast and Sierra Leone) and 19% of central African children (DRC) among 10,300 unvaccinated children. A less sensitive but more specific radioimmunoassay adsorption test for MPXV antibodies indicated that 17% of the sera positive for hemagglutinin inhibition contained MPXV-specific antibodies (66, 67). A less specific assay reported similar results, with 1.7% of 994 specimens positive for orthopoxvirus immunoglobulin M in the Likouala region of the DRC (83).

In Africa, over 400 cases of monkeypox were diagnosed between 1970 and 1986, the great majority in parts of Zaire where intensive surveillance supported by the WHO was in operation from 1980 to 1986. The case fatality rate was about 10%. Person-to-person transmission was uncommon but accounted for about 30% of the observed cases. Additional outbreaks were reported in the DRC between 1996 and 1998, but there were concurrent outbreaks of chickenpox, and investigations were hampered by an ongoing civil war (84). In a review by the WHO in 1999, however, it was estimated that about half of the 800 suspected cases in the Kasai Oriental were monkeypox (85). Cases appeared to be no more severe than in the 1980s, but the numbers of index cases and the proportion of secondary cases have increased in recent years (40). From November 2005 to November 2007 (7) surveillance in the DRC identified 760 laboratory confirmed cases in 9 independent health zones, which represented an increase incidence from 0.72 to 14.41 cases/10,000 (~20-fold increase). Ninety-two percent of cases occurred in people born after mass vaccinations ended in the 1980s. People who were previously vaccinated for smallpox had a 5-fold lower risk of MPXV as compared to unvaccinated (0.78 vs. 4.05 per 10,000), indicating a vaccine efficacy of ~81% decades after prior vaccination. This increase in human monkeypox infections in the post-vaccination era raises concerns about the emergence of a virus capable of more efficient spread in humans.

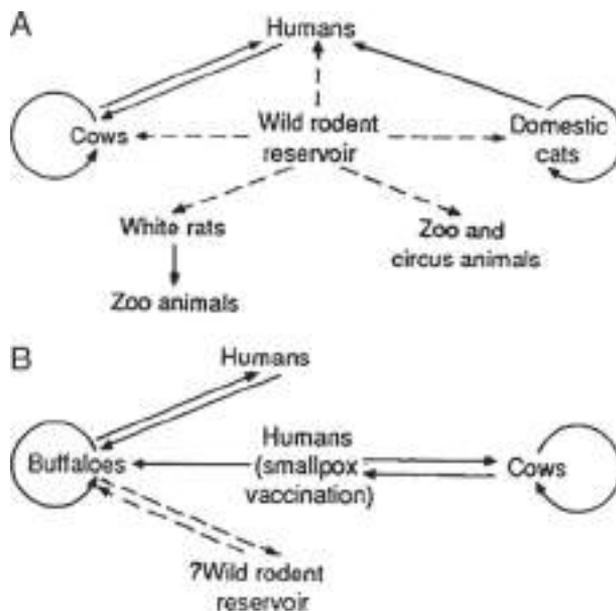

In 2003 in the Midwest of the United States, a MPXV infections occurred in prairie dogs housed in a distribution center in close proximity to MPXV-infected African rodents; the prairie dogs acted as an amplifying host for the documented human infections. Based on the case definition at the time, there were 35 confirmed cases and 36 probable cases (86), although other testing techniques identified additional cases (87). A majority of the confirmed infections (19 of 34, 56%) occurred after close contact with MPXV-infected prairie dogs (88), but a number of cases appeared to

result from indirect exposure to the virus through fomites or aerosols.

### Other Orthopoxviruses

The incidence of other orthopoxvirus infections is far less than that of human monkeypox, with approximately 54 cases of cowpox reported in Europe from 1969 to 1993 (50). Cowpox has been known in Europe for hundreds of years as a disease of cows, manifesting as ulcers on the teats (31). Occasionally, contact with such lesions produced pustular lesions on the hands of milkers. The cow is an accidental and occasional host of CPXV, but cows, cats, and zoo animals can be infected from a rodent reservoir host. Humans may be infected by contact with a wildlife source or with infected animals of several species, especially domestic cats (Fig. 4).

Natural infections with VACV result from epizootics based on virus reservoirs in buffalo and cattle. Buffalopox virus has persisted in India since the cessation of human vaccination (16) and is characterized by pustular lesions on

**FIGURE 4** Diagram illustrating the epidemiology of cowpox and buffalopox. Solid lines represent known paths of transmission; broken lines represent presumed or possible paths of transmission. (A) Identified wild-rodent reservoir hosts of cowpox include bank voles, wood mice, and short-tailed voles in Great Britain and probably elsewhere in Europe; lemmings in Norway; and susliks and gerbils in Turkmenistan. The traditional liaison hosts from which humans were infected were cows, but currently the most common liaison hosts are domestic cats. White rats, the source of disastrous outbreaks in animals in the Moscow Zoo in 1973 and 1974 (48), probably acquired infection from wild-rodent-contaminated straw or other bedding material. (B) In India, Egypt, and Indonesia, in the days of smallpox vaccination, buffaloes were sometimes infected with vaccinia virus from recently vaccinated humans, causing what was called buffalopox. Buffalopox seems to have disappeared in Indonesia and Egypt but is still a problem in several states of India. Since the cessation of vaccination, infected buffaloes constitute a source of infection of humans. It is possible that the virus can be maintained by serial transmission in buffaloes, but on the analogy of cowpox in Europe, it is possible that there is an unknown rodent reservoir. Reprinted from reference (63) with permission.

the teats and udders of milking buffaloes; occasionally a generalized disease is seen, especially in calves. Sometimes humans in contact with diseased buffaloes are infected (Fig. 4); thus, lesions may occur on the hands and face of milkers. Most strains have restriction maps somewhat different from those of the VACV strains used in India in the days of smallpox vaccination (53). In Brazil, a strain of VACV maintained in cattle is similarly causing zoonotic infections (89).

Recently, a previously unknown orthopoxvirus was identified in a herder in a very rural part of the country of Georgia (21). While only a single case was identified and a field investigation did not show evidence of other people or animals that had been infected with this novel virus, a patient in 2010 in an entirely different part of the country was infected with the same virus.

### Parapoxviruses

Human infections with parapoxviruses are an occupational hazard. ORFV, PCPV, and BPSV cause the so-called “barnyard” poxvirus infections, with ORFV infections being the most common. The papules and vesicles on the skin of the lips (scabby mouth) and sometimes around the nostrils and eyes of infected animals serve as a source for human infection. Persistence of the virus in flocks is due in large part to the persistent infectivity of virions in scabs that fall on pasture plants or the soil.

TANV infects both sexes and all age groups and occurs most frequently among persons who work or play close to the Tana River (75). There has been one case of human-to-human transmission reported in the United States (90). The same virus, described variously as Yaba-like disease virus, Yaba-related disease virus, and Oregon “1211” poxvirus, gave rise to epizootics in macaque monkeys in three primate centers in the United States in 1966, in which some of the animal handlers were infected (91). YMTV was first recovered from subcutaneous tumors that occurred in a colony of rhesus (Asian) monkeys in Nigeria (92). Infections of humans with YMTV have not been found in the field in Africa.

Molluscum contagiosum is endemic throughout the world to various degrees. Based on restriction enzyme digests of isolates, there are four subtypes (93). While detailed sequencing of all subtypes has not been done, cross-hybridization revealed that all had similar nucleotide sequences. All subtypes produce similar clinical disease. In the United States, 98% of cases are caused by MCV genotype 1 (25). Molluscum contagiosum is very common in Fiji, where 4.5% of a village population bore lesions (94), and in Papua New Guinea (95). In the Netherlands the cumulative incidence of childhood molluscum contagiosum is about 17% in persons 15 years of age (96). In Australia the seroprevalence was 23% in a representative cross-section of the population (96).

### Age-Specific Attack Rates

Information on age-specific clinical attack rates of unvaccinated contacts is available for smallpox, monkeypox, and molluscum contagiosum. For smallpox, while all nonimmune people are susceptible, when smallpox was an endemic infection, the contacts < 15 years of age showed the greatest risk of infection; this risk probably reflects the intimacy of physical contact, which is highest among the youngest siblings in a family. For monkeypox in Africa, the primary attack rate reflects the probability of developing the disease after exposure to an animal source. For molluscum con-

tagiosum, studies in New Guinea, Japan, the Netherlands, and the United States found the peak incidence to be in individuals < 10 years of age (96, 97).

### Risk Factors and High-Risk Groups

Persons of all ages were susceptible to VARV, but the mortality rates were highest in the very young, the elderly, pregnant women, and immunosuppressed individuals. A similar pattern is likely to exist for monkeypox.

Severely immunosuppressed patients have more severe disease with all poxvirus infections, and this has been documented for MCV (98) and ORFV (99). Individuals with atopic dermatitis are probably predisposed to poxvirus diseases of greater severity, especially at the sites of dermatitis. This has been documented for infections with VACV, ORFV, and MCV (96, 100, 101). In the case of molluscum contagiosum, 24% of patients were diagnosed with atopic dermatitis (96). At least two fatal cases of cowpox have been documented in persons suffering from atopic dermatitis (102).

Reported sex differences in smallpox and monkeypox susceptibility more likely reflect risk of exposure and do not represent an intrinsic susceptibility to infection or difference in disease severity. The lack of vaccination immunity is by far the most important risk factor for severe disease in smallpox and monkeypox. The risk of human cowpox increases with ownership of a cat that has access to infected rodent populations. The risk of parapoxvirus infection is occupational.

### Reinfections

Recovery from VARV, MPXV, and VACV confers long-lived to lifelong protection from severe disease following reinfection, whereas the generated immunity to CPXV is shorter-lived or is unable to block reinfection with CPXV (3). During the months of an active MCV infection, it is common for the virus to spread to other sites on the skin. However, once all lesions have disappeared, it is unclear if a patient can be reinfected.

### Seasonality

In the tropics, smallpox was most prevalent in the cool, dry season. Monkeypox in Africa shows no clear evidence of a seasonal pattern (66).

### Transmission

#### Routes and Risk Factors

Human poxvirus infections can be acquired through multiple routes. VARV is spread by the respiratory route, usually requiring close (household) contact. MPXV infection from the zoonotic host probably occurs through puncture wounds or microbreaks in the skin. MPXV human-to-human transmission is likely to occur via the respiratory route or through mucosal surfaces (65). CPXV and parapoxvirus infections are the consequence of the introduction of virus either directly or indirectly into breaks in the skin. MCV is spread by fomites or close contact among children and can be sexually transmitted among adults.

The transmission risks of MPXV infection are multifactorial. Primary MPXV infection is associated with adult male activities such as hunting and carcass preparation, whereas female caregivers are at greater risk for human-to-human transmission.

Parapoxvirus infections occur through occupational exposure. For example, marine mammal technicians are at risk for sealpox through bites from seals or sea lions (103).

Sexual activity is a risk factor for molluscum contagiosum in adults. Genital molluscum has become a much more common infection in the last two decades and can be an epidemiological marker for sexually transmitted diseases. The disease can be a troublesome complication of AIDS in Western countries, especially in homosexual men (104). For children, there is an association between swimming pools and MCV (97).

#### Nosocomial Infection

VARV and MPXV, which can be transmitted by respiratory droplets, can cause nosocomial infections. In 1970, a smallpox patient maintained in an isolation ward in a general hospital in Meschede, Germany, infected 17 patients that were in rooms that were one to two floors above the index patient (105). While face-to-face contact is the most common route of spread, it was thought that the spread in the hospital occurred because the index patient had a severe persistent cough and that strong air currents and low humidity in the hospital allowed airborne transmission. In 2003, extended interhuman transmission of MPXV was documented on the grounds of a community hospital in the DRC (106).

#### Duration of Infectiousness

The ability of human poxvirus infections to transmit infectious virus is dependent on the generation of a lesion in the cornified or mucosal epithelium that ulcerates, releasing virus into the environment. For VACV, CPXV, parapoxviruses, and MCV, the lesions are usually in the cornified epithelium and are likely infectious until scab formation or reabsorption. For smallpox and probably monkeypox acquired from human index cases, the mucosal lesions of the respiratory tract are a greater source of infectious virus than lesions of the cornified skin and are more important in the natural transmission cycle of the virus. VARV is detected 2 to 4 days following the onset of fever and reaches the highest level on the third and fourth days of disease (i.e., just after rash appearance) in oropharyngeal secretions of smallpox patients. The level of virus was greatest and persisted the longest in cases that had confluent ordinary-type (lesions on face or extremities are confluent) or flat-type smallpox. High levels of virus in secretions correlated with infectiousness of the patient, a period that usually lasted for the first week of the rash.

## PATHOGENESIS IN HUMANS

### Incubation Period

The incubation period for human poxvirus infections has been thoroughly documented only for smallpox, for which it was 10 to 14 days (2). A limited number of case studies of human-to-human transmission of MPXV suggest a similar incubation period (66).

### Patterns of Virus Replication and Spread

Our understanding of the pathogenesis of smallpox is based on animal models: namely, ectromelia virus in mice [(107, 108); Fig. 5] and MPXV in monkeys (109). Based on these models and epidemiologic observations of smallpox, infection with VARV usually occurs by the inhalation of virus released from oropharyngeal lesions into the saliva and respiratory secretions during the first week of the rash. After infection of cells in the upper and lower respiratory tract of contacts, macrophages became infected and entered the lymphatics. Infected white blood cells sometimes entered

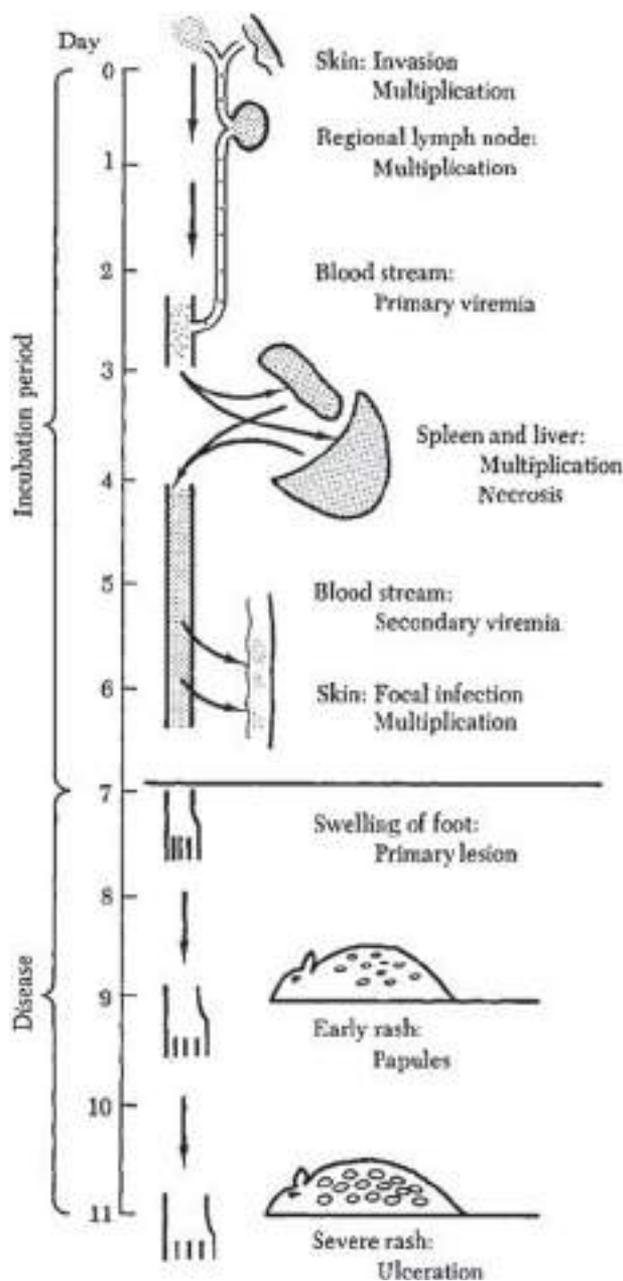

FIGURE 5 Diagrammatic representation of the mode of spread of ectromelia virus through the body in mousepox. Reprinted from reference (107) with permission.

the bloodstream at this stage, or in any case by about the fourth day. Lymphoid tissue and internal organs were infected following this primary viremia. The initial stages of infection produced neither symptoms nor a local lesion, and patients were not infectious during the incubation period. Approximately 8 to 10 days following infection, virus produced from infected internal organs (secondary viremia) localized in small vessels of the dermis and led to infection of the underlying dermis of the mucosal and cornified epithelium. The rash was detected approximately 10 days after infection, evolved through a number of distinct stages, and resolved with scab separation ~32 days following infection. Virus was difficult to detect in blood from cases of ordinary-type

<sup>c</sup>Data from reference (139).

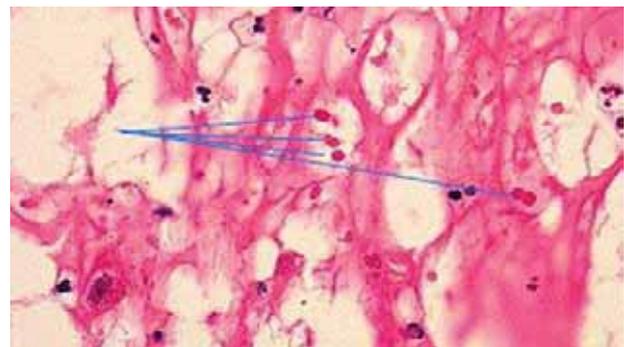

smallpox at all times during disease; however, this was not the case with hemorrhagic-type smallpox, in which high titers were readily detectable in blood of all cases. The outcome of the infection was either death, which was said to be usually due to “toxemia,” or recovery, with complete elimination of the virus but sometimes with sequelae. The most common sequelae were pockmarks, which could occur all over the body but were usually most profuse on the face (110). Blindness was an important but rare complication. Recovery was accompanied by prolonged immunity to reinfection.

The pathogenesis of monkeypox probably follows at least two distinct courses dependent on the route of transmission. Inhalation of MPXV, which is likely the mechanism of infection between an index case and contacts, has a pathogenesis very similar to that of the smallpox virus. Infections from an animal source may occur through additional exposure routes including puncture wounds or small lesions on the skin or the oropharynx. Infections through the skin likely have a distinct pattern of pathogenesis compared to that following a respiratory infection. This supposition is based on the fact that the smallpox case fatality rate was 20 to 30% following inhalation but was dramatically lower, at 0.5 to 2%, if virus was introduced into the cornified epithelium (variola; see below).

Except for VARV and MPXV, poxvirus infections of humans are most often through the cornified epithelium. The introduction of CPXV, VACV, or parapoxviruses into the skin causes localized distinct pustular lesions at the site of introduction that have species-specific distinctions. In immunocompetent individuals, systemic infections occur at a low frequency following VACV infection (Table 3, generalized vaccinia) and are extremely rare for CPXV or other human zoonotic poxvirus infections. The primary lesions heal over in 3 to 6 weeks following infection.

### Disease Production and Pathologic Features

The secondary skin lesions of smallpox develop through a series of characteristic stages that presumably begin with a virus-infected cell entering into the dermis through diapedesis, which is followed by local replication. The focus of infection becomes mildly inflamed due to the local release of cytokines and chemokines, which attract circulating inflammatory cells. Virus replication spreads from the dermis into the epidermis. Cells in the epidermis become swollen and vacuolated and stain for the characteristic B-type (Guarnieri) inclusion bodies (Fig. 6). The rupturing cells contribute to early vesicle formation. Lesions evolve from macules to papules and into pustules through the migration of polymorphonuclear leukocytes from the subpapillary vessels into the epidermal lesion. The pustule umbilicates, and with the development of an effective immune response,

**FIGURE 6** Intracellular inclusions (Guarnieri bodies) in a biopsy from a patient from Somalia prior to smallpox eradication. Courtesy of Dr. Dirk Elston.

the healing process commences and results in regeneration of the epidermis and the start of scab formation at ~16 days postinfection. Autopsies of people who died from smallpox showed enlarged and engorged organs. Histology showed ballooning of endothelial cells and an inflammatory infiltrate that was mainly mononuclear cells (111). High titers of virus can be found in internal organs, including liver, spleen, lymph nodes, and bone marrow (2).

The earliest histologic changes observed in VACV lesions following vaccination are cytoplasmic and perinuclear vacuolation in the epithelium, which are accompanied by coagulation necrosis, intercellular edema, and vesicle formation (2). By 48 h postvaccination, a cup-shaped vesicle traversed by an eosinophilic reticular network appears with the roof and floor formed by the stratum corneum and dermis, respectively. The region is characterized by edema, free erythrocytes, and a progressive infiltration of mononuclear and polymorphonuclear cells, which with time formed a dense, homogeneous, deeply staining reticulum that formed the crust beneath which epithelial outgrowth occurred.

In contrast to lesions of smallpox and monkeypox, parapoxvirus lesions are markedly proliferative (112). Changes that occur early in the proliferating keratinocytes include nucleolar enlargement and focal lysis of keratin fibrils. Extreme swelling of the cells results in ballooning degeneration, which, when accompanied by B-type cytoplasmic inclusion bodies and nuclear shrinkage, is pathognomonic of ORFV lesions. Dermal infiltration with monocytes and lymphoid cells is prominent around hyperemic capillaries and venules, and infection of the endothelial cells may produce endothelial proliferation.

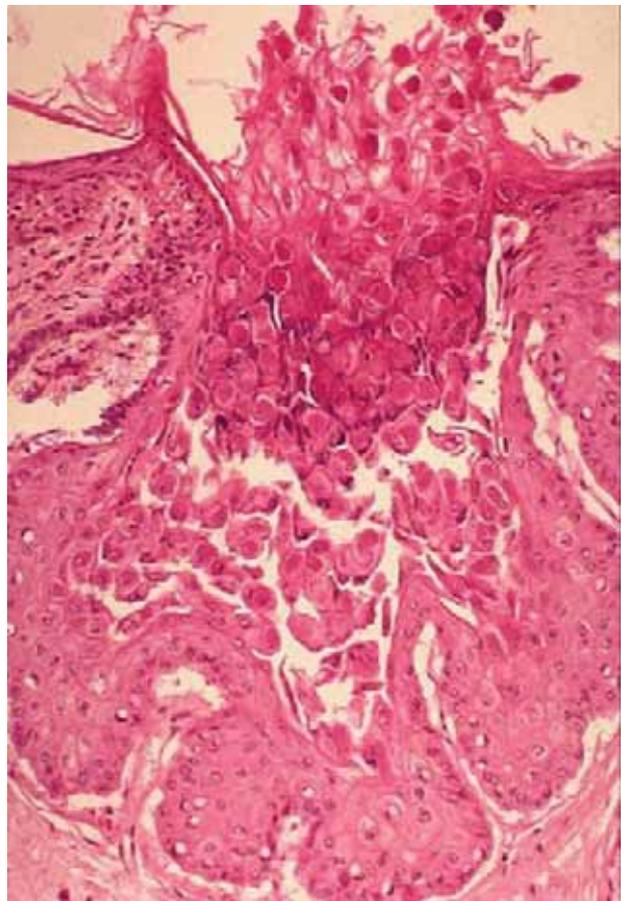

Tanapox lesions histologically show some typical features of an orthopoxvirus skin lesion, i.e., marked thickening of the epidermis with extensive ballooning degeneration of the prickle cell layer. The cytoplasm of swollen epidermal cells is filled with large, pleomorphic, granular, eosinophilic, B-type inclusion bodies. YMTV produces tumors in monkeys and humans after subcutaneous or intradermal inoculation. These are composed of masses of histiocytes, which are later infiltrated with lymphocytes and polymorphonuclear cells. No true neoplastic proliferation occurs, and the lesions regress as the immune response develops (113).

The typical molluscum contagiosum lesion consists of a localized mass of hypertrophied and hyperplastic epidermis extending down into the underlying dermis and projecting above the adjacent skin as a visible tumor. Each infected keratinocyte is many times larger than normal, and the cytoplasm is filled with a large hyaline acidophilic granular mass known as the molluscum body (Fig. 7), which pushes the nucleus to the edge of the cell. The core of the lesion consists of degenerating epidermal cells with inclusion bodies and keratin, which uninfected cells continue to produce. Unlike with orthopoxvirus lesions, there is no vesicle formation or inflammatory reaction unless secondary bacterial infection has occurred. The lack of inflammation is due to the restricted replication of the virus to the keratinocyte of the epidermis, the release of little antigenic material or virus from infected cells, and the expression of immunosuppressive proteins (36).

## Immune Responses

### Innate Responses

Innate responses have not been studied in human poxvirus infections but can be inferred from our knowledge of ex-

**FIGURE 7** Section of a skin lesion of molluscum contagiosum. Courtesy of CDC/ Dr. Edwin P. Ewing, Jr., Public Image Library ID# 860.

perimental mousepox (108). Infection with necrosis initiates a cascade of cytokines and chemokines and cellular activation. The cascade is further amplified by the autocrine and paracrine proinflammatory activities of the resident and infiltrating cells (monocytes, granulocytes, and natural killer cells) as well as the vascular endothelial cells. In MCV this process is absent or transient in nature.

### Adaptive Immunity

The adaptive response is characterized by the production of cytotoxic and cytokine-secreting T cells and antibody-secreting B cells. The cytotoxic T cells kill infected cells prior to the completion of the virus replication cycle by recognizing viral peptides in the context of antigens from the HLA complex. In animal models the humoral response plays a major role along with T cells in recovery from primary infection and is critical for protection from reinfection (114–116). The most important targets of neutralizing antibodies are unique proteins found on the surface of mature virus and extracellular virus (117).

The 2003 importation of animals from Africa infected with monkeypox virus provided an opportunity to study the immune response in infected humans. Antibody responses (IgG and IgM) could be detected within the first week after rash onset, often within the first day or two (118). T-cell responses were measured in people infected with monkeypox (87, 119), but samples from acutely infected patients were

not obtained. The severity of illness did not appear to be associated with the magnitude of the T-cell response (119).

The acute viral infections with VARV, CPXV, and VACV produce lasting long-term immunity. The more chronic infection by MCV initially provokes little immunity, and in individual patients the lesions may persist for as little as 2 weeks or as long as 2 years, without any sign of inflammation. The lesions are noteworthy for the absence of reactive cells. Virus-specific antibodies are demonstrable in about 70% of patients (120).

#### Correlates of Disease Resolution and Protection

In human poxvirus infections, scab separation of the last active lesion indicates disease resolution. In smallpox, this separation occurred at ~32 days following infection. The presence of scars from VARV, MPXV, or VACV lesions is considered a correlate of immune protection.

## CLINICAL MANIFESTATIONS

### Major Clinical Syndromes

#### Variola and Monkeypox

The prodrome of smallpox or classic monkeypox includes a spiking fever, malaise, and possibly headache followed by the development of a rash (2, 66). There are two clinical types of smallpox due to two viral variants, variola major and variola minor (alastrim) (2). Variola major had an overall case fatality rate of 20 to 30% in unvaccinated persons with mortality rates much higher at the extremes of age. Variola minor had a case fatality rate of about 1%. The onset was acute, with fever, malaise, headache, and backache. Three or four days after the onset of symptoms the characteristic rash appeared, first on the buccal and pharyngeal mucosa and then on the face, forearms, and hands. The lesions began as macules, which soon became firm papules and then vesicles,

which quickly became opaque and pustular. About 8 or 9 days after the onset, the pustules became umbilicated and dried up. The distribution of the rash, as well as its evolution, was highly characteristic, being usually most profuse on the face and more abundant on the forearms than the upper arms and the lower legs than the thighs, and relatively sparse on the trunk, especially the abdomen (Fig. 8, left panel).

The clinical features of monkeypox are indistinguishable from those of ordinary-type smallpox, except that enlargement of cervical, and often the inguinal, lymph nodes is much more pronounced than in smallpox (Fig. 8, middle and right panels). The evolution of the rash in monkeypox in central Africa is similar to that of smallpox. The rash is most severe on the extremities, and the lesions evolve as a group. This is in contrast to the disease observed in the 2003 US outbreak, in which distinct differences were noted in the morphology, evolution, and absolute numbers of skin lesions. In the US outbreak the lesion morphology varied from case to case and even within a family, and the lesions healed with a distinctive and prominent hemorrhagic crust (122).

Although like smallpox, monkeypox is clinically distinct from chickenpox, misdiagnosis of monkeypox for chickenpox and chickenpox for monkeypox is quite common (123). In general, Africans may be more susceptible to severe disease due to poor nutrition or coinfections with other pathogens. Two reports have documented coinfections of MPXV and varicella-zoster virus, with one fatal outcome (84, 124). AIDS increases the morbidity and mortality of humans when they are concurrently infected with *Mycobacterium tuberculosis* (125, 126), and a similar effect would be expected following coinfection with MPXV.

At least two distinct clades of MPXV exist, one found in West Africa and the other in central Africa (122, 127). Epidemiological studies and experimental inoculation of nonhuman primates suggest that the West African isolates

are less virulent than those from central Africa. The lesion character in the 2003 US outbreak was distinct from that of classic African monkeypox, and infected patients had, on average, fewer lesions (122). Patients also presented with a broad range of nonspecific signs and symptoms, with and without rash (88, 128). Interestingly, no deaths were reported, perhaps due to the fact that the virus was the less virulent West African strain (69).

### Vaccinia and Cowpox

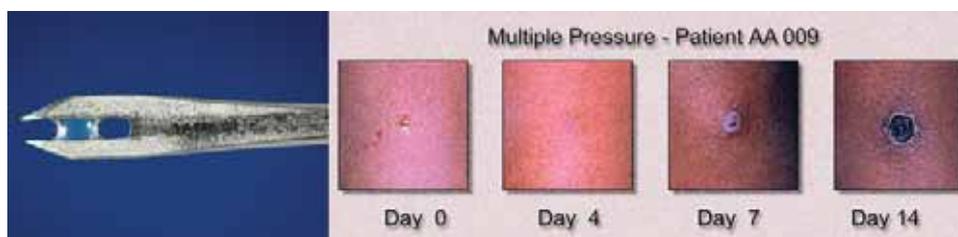

The prodrome of cowpox may include fever and myalgia but with less severity compared to that of smallpox and monkeypox. CPXV lesions are often found on the thumbs, the first interdigital cleft, and the forefinger. The lesions are quite distinctive (Fig. 9A); CPXV causes pustular lesions like those of VACV, and the parapoxviruses produce non-ulcerating nodules. The CPXV lesions pass through stages of vesicle and pustule before a deep-seated, hard black eschar forms 2 weeks later. Cowpox was traditionally associated with the milking of cows, but many cases involve no such history, and domestic cats now constitute a more important source of human infection.

In the first 6 days following vaccination with VACV (Dryvax), fever, headache, muscle aches, chills, nausea, and fatigue are reported in 3%, 44%, 39%, 13.5%, 19%, and 53% of 665 subjects, respectively (129). The current

smallpox vaccine (ACAM 2000) has similar clinical findings (130). In tanapox the first signs of infection are mild fever, headache, and myalgia. The primary response to VACV vaccination evolves through a characteristic series of lesions (Fig. 10). VACV infection via vaccination causes a papule to appear at the vaccination site 4 to 5 days after vaccination; 2 to 3 days later, this becomes vesicular and constitutes the umbilicated and multilocular "Jennerian vesicle." The contents rapidly become turbid because of the infiltration of inflammatory cells with the central lesion surrounded by erythema and induration, which reaches maximum diameter on the 9th or 10th day. At this time the draining lymph nodes in the axilla are enlarged and tender, and many patients have mild fever. The pustule dries from the center outward, and the brown scab falls off after about 3 weeks, leaving a scar by which previous vaccination can be recognized for many years.

### Parapox Viruses

There are few, if any, signs or symptoms of parapoxvirus infection except occasional fever before development of the primary lesion. Orf and milker's nodules are acquired by contact with infected sheep and cows, respectively, and the localized lesions are usually found on the hands. The lesions of orf are rather large nodules that may be multiple, and the surrounding skin is inflamed (Fig. 9C). Orf lesions are rather

painful and may be accompanied by low-grade fever and swelling of the draining lymph nodes. The lesions of milker's nodule (Fig. 9B) are hemispherical, highly vascular papules that appear 5 to 7 days after exposure and gradually enlarge into purple nodules up to 2 cm in diameter. They are relatively painless but may itch, and they do not ulcerate. The granulation tissue that makes up the mass of the nodule gradually becomes absorbed, and the lesions disappear after 4 to 6 weeks. The only evidence of systemic infection is occasional slight swelling of the draining lymph nodes. Human infections with BPSV are less common than with the other two parapoxviruses that infect humans, probably because contact between animal handlers and lesions of BPSV are less common than those of shearers with orf and milkers with milker's nodules (131, 132). The BPSV lesions appear as circumscribed wart-like nodules that gradually enlarge until they are 3 to 8 mm in diameter.

The first symptoms following a TANV infection are a mild preeruptive fever, sometimes accompanied by severe headache, backache, and myalgia, often with itching at the site where the skin lesion develops (75, 133, 134). Two to four days following onset of fever, a usually solitary erythematous macule appears on the skin. Initially there is a small nodule, which soon becomes papular and reaches a maximum diameter of about 15 mm by the end of the second week. The appearance of the skin lesion of tanapox is illustrated in Fig. 9D. The nodule is surrounded by an edematous zone and a large erythematous areola. The draining lymph nodes are enlarged and tender from about the fifth day. The skin lesion usually ulcerates during the third week and then gradually heals within 5 to 6 weeks, leaving a scar. In Kenya, the lesions are almost always solitary and on the upper arm, face, neck, and trunk (74), but in the DRC, 22% of patients have had multiple lesions (75). YMTV produces large protuberant tumors in monkeys, which are histiocytes containing poxvirus particles (113, 135). Rarely, similar lesions may be produced in humans by accidental contact with infected monkeys or after inoculation.

### Molluscum contagiosum

Molluscum contagiosum is characterized by multiple, small, noninflamed nodules in the skin scattered over the body or, in adults, usually in the thighs, genital or anal region (25). The lesions of molluscum contagiosum are pearly, flesh-colored, raised, umbilicated nodules in the epidermal layer of the skin, usually 2 to 5 mm in diameter (Fig. 11, left).

Rarely, lesions will present as a large lesion called giant molluscum (>5 mm in diameter). The incubation period varies from 14 to 50 days. The nodules are painless, and at the top of each there is often an opening through which a small white core can be seen. The lesions often persist for months but ultimately resolve spontaneously or following trauma or bacterial infection. More severe disease can be seen in immunocompromised hosts (Fig. 11, right).

### Age-Related Differences

In smallpox and monkeypox the young were more likely to be infected than the old, and the disease was most severe in the young and old. The exception was the 2003 US monkeypox outbreak, in which the majority of the cases were in adults (88); however, the pediatric patients were more likely to be hospitalized in an intensive care unit. Cowpox in children was usually more severe than vaccination with vaccinia virus (47, 50).

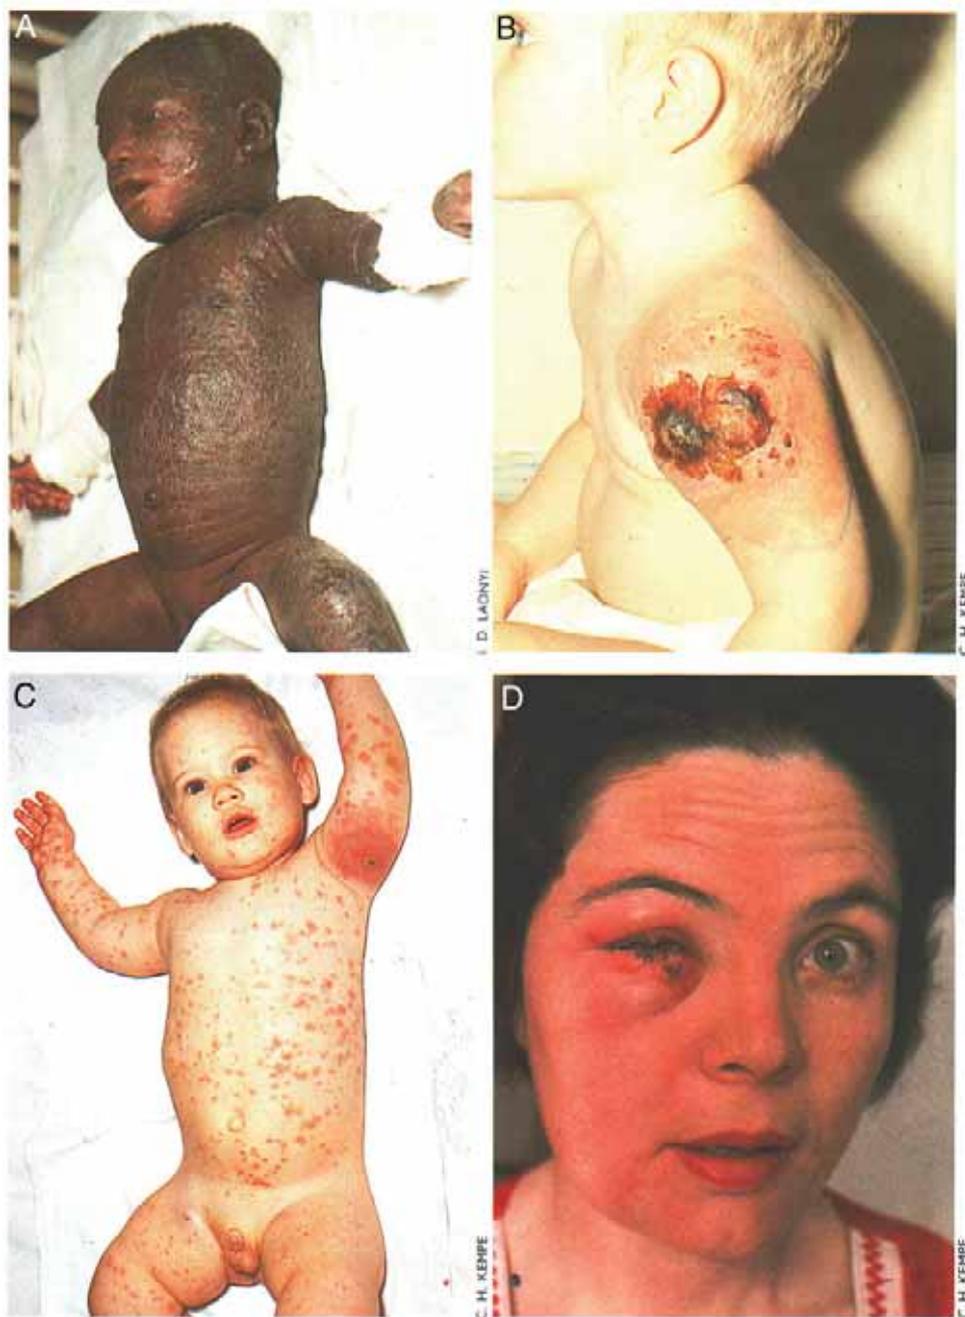

### Complications

#### Smallpox

Three other clinical presentations of smallpox were recognized. The rare hemorrhagic-type smallpox, most common in pregnant women, was associated with petechiae in the skin and bleeding from the conjunctiva and mucous membranes, very severe toxemia, and early death. Flat-type smallpox was characterized by intense toxemia and slow evolution of the skin lesions, which were usually flat and soft; most such cases were fatal. Modified-type smallpox was seen in persons who had been vaccinated, usually many years earlier; the disease was mild and the skin lesions evolved quickly and were often sparse.

#### Vaccinia

Smallpox immunizations with VACV results in occasional serious complications (Fig. 12; Table 3) (138–140). Vaccination against smallpox is undoubtedly associated with both increased reactogenicity and more complications than any other of the commonly used vaccines (141). Progressive vaccinia (Fig. 12B) occurs only in persons with deficiencies of the cell-mediated immune system. Vaccinated subjects with agammaglobulinemia but a normal cell-mediated response recover normally (142, 143). Eczema vaccinatum (Fig. 12A) occurs in persons with eczema or atopic dermatitis, which affects over 10% of the United States population. However, not every person with this skin condition develops eczema vaccinatum and thus it is not known what

**FIGURE 12** Severe complications of vaccination. (A) Eczema vaccinatum in an unvaccinated sibling of a vaccinated individual. (B) Progressive vaccinia (*vaccinia gangrenosum*), which was fatal in a child with a congenital defect in cell-mediated immunity. (C) Generalized vaccinia, 10 days after primary vaccination; benign course, no scarring. (D) Ocular vaccinia after autoinoculation. Reprinted from reference (2) with permission.

factors are involved in those who develop this severe complication (144). In those who do develop this complication, it can be life threatening if recognized late in the course of disease (145). Treatment with VIG (and other experimental anti-poxvirus agents) can lead to viral control and clearing of the lesions. Because vaccinia replicates preferentially in immature keratinocytes, other inflammatory dermatologic conditions or cutaneous injury sites can be accidentally infected by VACV. Generalized vaccinia comprises a generalized vaccinal rash, sometimes covering the whole body

(Fig. 12C) and occurring 6 to 9 days after vaccination. It is not associated with immunodeficiency, and the prognosis is good. Postvaccinal encephalitis is an unpredictable complication (146). In children less than 2 years old there is very occasionally a general encephalopathy associated with demonstrable viremia that occurs 6 to 10 days after immunization and is characterized often by convulsion, hemiplegia, and aphasia (147). In subjects older than 2 years, the complication occurs about 11 to 15 days after immunization. The onset of disease is marked by fever, vomiting, and other

symptoms of cerebral involvement. The pathological findings resemble those of other postinfectious encephalitis, and the case fatality rate is approximately 45% (146). Perivascular inflammation and demyelination are the principal lesions. Accidental infection of some part of the body distant from the inoculation site is the most common complication. From 1963 to 1968, ocular vaccinia (Fig. 12D) was found to have occurred in 348 persons (including 259 vaccinees and 66 contacts) (148). The cornea was involved in 22 of these cases, and 11 persons had residual visual defects.

### Clinical Diagnosis

When smallpox was endemic, the diagnosis of most cases could be made clinically according to the distribution and evolution of the rash. In regions where disease was not expected, modified-type variola major and variola minor were often confused with chickenpox, but the evolution and distribution of the rash in the two diseases were usually distinctive. In smallpox, lesions developed simultaneously all over the body, most obviously on the face and limbs rather than the trunk, whereas, the skin lesions of chickenpox were more superficial and appeared in “crops,” more apparent on the trunk than on the face and extremities.

The diagnosis of zoonotic poxvirus infections facilitated by the geographic location and epidemiological features of cases can be of help in the differential diagnosis, unless the disease appears in a nonzoonotic region, as in the case of importation of MPXV into the United States in 2003. Like smallpox, monkeypox can be misdiagnosed as chickenpox. Poxvirus infections acquired from contact with cows must be differentiated from among CPXV, PCPV, and BPSV. If the infection is acquired from sheep, it is likely ORFV. Tanapox is known to occur in animal attendants in contact with monkeys infected with TANV or YMTV or wild animals in regions of Africa where these viruses are endemic.

Diagnosis of a VACV infection can be problematic in subjects infected by contact with a vaccinee. The history of contact with a recently vaccinated person or with a laboratory source of VACV, or with a buffalo with buffalopox or cattle infected with cantagalo virus, should arouse suspicion; the diagnosis can be confirmed by recovery and characterization of the virus.

Molluscum contagiosum is endemic in most human populations. The diagnosis can be made clinically from the appearance of the lesions and their chronic nature. Occasionally, solitary lesions on the face or neck may be misdiagnosed as basal cell carcinoma. Cutaneous cryptococcosis can mimic molluscum lesions in patients with AIDS.

## LABORATORY DIAGNOSIS

Historically, the major diagnostic criteria for poxvirus infections are the size and morphology of the poxvirus virion in negatively stained preparations viewed with an electron microscope (Fig. 1). This approach is giving way to detection by PCR.

### Virus Isolation

#### Specimen Types

Specimens are usually fluid from primary or secondary vesicles or scabs (or corneal swabs), all of which contain sufficient viral material to be used for PCR identification.

#### Cell Culture

Historically, species diagnosis was made by observation of the characteristic pocks on the chorioallantoic membrane of

the developing chicken embryo. In combination with growth ceiling temperature, the careful diagnostic technician could use the observation of pocks to differentiate CPXV, VACV, MPXV, and VARV. In more recent times, cell culture in combination with antigen staining has been used as a confirmatory assay for electron microscopy. Orthopoxviruses produce cytopathic effect in Vero cells. Parapoxviruses from human lesions grow in primary bovine or ovine embryo kidney or testis cells or in primary human amnion cells. Once isolated, they grow well in human embryonic fibroblasts and LLC-MK2 cells. Yatapoxviruses grow in human thyroid cells, vervet monkey and patas monkey kidney cells, and WI-38, HEp-2, and Vero cells, producing focal lesions characterized by intense granularity followed by rounding up of the cells (74).

### Antigen Detection

Historically, antigen detection protocols rarely could differentiate poxviruses at the species level. Thus, VACV could not be discriminated from MPXV or VARV. This approach is rarely used since the development of PCR.

### Histology

Molluscum contagiosum can be diagnosed solely on clinical grounds based on the gross appearance of lesions and their chronic nature; however, giant molluscum can be confused with other disorders. The differential diagnosis is readily confirmed by hematoxylin and eosin staining of biopsy material, and the presence of “molluscum” or Henderson-Patterson bodies is pathognomonic for disease. Electron microscopy and PCR can also be used for diagnosis, but these are usually not warranted (149).

### Nucleic Acid Detection

The requirement for specific banks of tissue culture cells for poxvirus isolation and the long time to generate assay endpoints spurred the development of the PCR assay as the mainstay diagnostic method. PCR has become the method of choice to distinguish 11 species of *Orthopoxvirus* from each other and variola major virus from variola minor virus (30), four species of *Parapoxvirus* (150), MCV (149), and three species of *Yatapoxvirus* (134, 151). Testing for poxviruses is not routinely done by clinical microbiology labs, and thus testing is done through local public health labs in conjunction with the CDC.

### Serologic Assays

Presently, there are no sensitive, specific, and reliable serologic assays that retrospectively differentiate among orthopoxvirus infections. Also, following ORFV, PCPV, and MCV infections, antibodies have not always been detected or persist only transiently. An immunoglobulin M-capture enzyme-linked immunosorbent assay (ELISA) using VACV antigen has been developed as an epidemiological tool; however, this assay cannot directly differentiate among antibodies induced by orthopoxvirus species (118). The lack of a single species-specific ELISA for orthopoxvirus infections can be overcome by the use of an ELISA based on antigens of the orthopoxvirus species that need to be differentiated and comparison of titers in serum using these antigens along with known serologic standards (87). For example, in the 2003 monkeypox outbreak, the serologic assay needed to discriminate between an acute MPXV infection, residual immunity from smallpox vaccination in an uninfected subject, and MPXV infection of an individual with residual vaccine immunity.

## PREVENTION

### General

Environmental surroundings can be contaminated from lesional sources of poxvirus. For VARV and possibly other orthopoxviruses, this contamination is not usually of epidemiological significance, as the virions are locked in inspissated, pustular fluid that is difficult to resuspend in the air in a respirable form. In contrast, transmission of MCV and parapoxvirus infections have been documented with a large number of fomites (22, 152). Thus, environmental surfaces potentially exposed to poxviruses must be thoroughly disinfected. Of the human poxvirus infections, only adults with MCV have a behavioral component. The majority of adult MCV infections are the result of close skin-to-skin contact with an infected site that occurs during interactions such as sexual intercourse (153).

### Isolation of Infected Persons

Historically, the quarantine of communities and the isolation of infected individuals or their contacts were implemented for smallpox, and, to a certain extent, for human monkeypox because the infection can be transmitted by respiratory droplets. For those with smallpox disease, isolation was for 2 to 3 weeks, which represented the time for lesions to heal and scabs to fall off. Contacts of a case of smallpox would be quarantined for 2 to 3 weeks, which represented the asymptomatic incubation period. Vaccinees are counseled to avoid contact with the extremely young (<1 year old), with pregnant women, and with persons with atopic dermatitis or on immunosuppression.

### Passive Immunoprophylaxis

Historically, intramuscular administration of vaccinia immunoglobulin (VIG), a product derived from the pooled plasma of vaccinated individuals, was used to treat progressive vaccinia (vaccinia necrosum), eczema vaccinatum, and certain autoinoculations, although efficacy has not been demonstrated through controlled clinical trials (154). VIG was reported to halt formation of new lesions and to cause rapid clinical improvement in cases of generalized vaccinia and eczema vaccinatum (110). One large study suggested that postexposure treatment of contacts of patients with smallpox with vaccination and VIG appeared to be more efficacious than vaccination alone. Smallpox developed in 5 of 326 contacts who received VIG, compared to 21 of 379 controls, for a relative efficacy of 70% in preventing smallpox (155, 156). In 2005, the Food and Drug Administration (FDA) approved new stocks of VIG by DynPort Vaccine Company, LLC for intravenous use (VIG-IV). It is used at a dose of 6,000 units/kg to treat complications of vaccinia virus vaccination. Repeat dosing has been used in severe cases. VIG is part of the US Strategic National Stockpile, and its use should be performed with the help of CDC's Smallpox Vaccine Adverse Events Clinical Consultation Team (phone: 404-639-3670). Prior use of VIG to treat smallpox did not always provide reproducible and clear-cut benefit. A highly potent cocktail of monoclonal antibodies generated against key neutralizing epitopes on surface proteins of intracellular mature virus and extracellular enveloped virus has shown promise in nonhuman primate and mouse models (157, 158).

### Active Immunization

Vaccination has a long history for the prevention of poxvirus infections. As early as the 10th century in Asia, the inocu-

lation of pustule fluid or scab material into the skin ("inoculation" or "variolation") was shown to protect against "natural" smallpox, with case fatality rates of 0.5 to 2% instead of 20 to 30%. Variolation was introduced into Europe early in the 18th century, and in some countries, notably England, it was practiced on a large scale.

In 1796 Edward Jenner showed that persons who had been inoculated with a related orthopoxvirus, CPXV, were completely resistant to smallpox (3). Vaccination (named from *vaca*, Spanish for "cow") led to a great decline in the incidence of smallpox in many countries. By the early 1950s many of the industrialized countries had eliminated endemic smallpox, and in 1958 the World Health Assembly accepted the concept of global eradication of smallpox. Realization of this goal faltered for several years, but in 1967 a Smallpox Eradication Unit was established at WHO headquarters, and the goal of global eradication within a decade was pursued with vigor and enthusiasm. Helped by the availability of adequate amounts of potent and stable freeze-dried vaccine, a change in strategy from reliance on mass vaccination alone to ring vaccination supported by surveillance and containment, and a new and simple inoculation device (the bifurcated needle, see Figure 10), the WHO program achieved its target in October 1977, and the world was certified free of smallpox by the World Health Assembly in May 1980 (2, 159).

The traditional smallpox vaccine could be given as late as 4 days postinfection (160) and still modify the disease course. When the vaccine was administered optimally, nearly complete protection against smallpox was maintained for about 5 years, and various degrees of protection were maintained thereafter (88% at 10 years and 50% at 20 years after vaccination). This vaccine was estimated to be ~85% effective against severe monkeypox disease (66). As with smallpox, individuals who had been vaccinated as children were still infected with MPXV during the 2003 US outbreak, but they presented with mild or no disease (87, 119). The smallpox vaccine is likely efficacious to various degrees against other orthopoxviruses but not against poxviruses from other genera.

Due to the threat of bioterrorism, the United States developed a new smallpox vaccine, ACAM2000, as a replacement for the limited and aging stocks of Dryvax. ACAM2000 was FDA approved in 2007 and is the smallpox vaccine stockpiled in the United States (161). This vaccine was developed from Dryvax and is administered by bifurcated needle. In three phase I clinical trials, ACAM2000 produced major cutaneous reactions, evoked neutralizing antibody and cell-mediated responses, and had a reactogenicity profile similar to that of Dryvax (162). Similarly, phase II randomized, double-blinded, controlled trials found ACAM2000 to be equivalent to Dryvax in terms of cutaneous response rate, antibody responses, and safety (163). In phase III clinical trials, five cases of myo/pericarditis were observed in 873 subjects getting ACAM2000 for the first time, although this was not unexpected, because several cases of myo/pericarditis were identified after smallpox vaccination in three Dryvax and one ACAM2000 phase II clinical trial held in 2003 (164).

A significant proportion of the American population has contraindications for prophylactic vaccination with ACAM2000, because they are immunosuppressed, have significant underlying heart disease, or have a history or presence of atopic dermatitis. Consequently, a more attenuated live vaccinia virus vaccine, called modified Ankara virus (MVA) vaccine, is under evaluation. Since 1968 MVA has been safely used in more than 100,000 humans without

documentation of the adverse reactions associated with other VACV vaccines. Following prophylactic intramuscular or subcutaneous MVA immunization, mice and cynomolgus monkeys are protected from intranasal VACV (165, 166) and intravenous MPXV (165, 167) challenges, respectively. IMVAMUNE, an MVA vaccine (strain BN; Bavarian Nordic GmbH), has been tested for safety and immunogenicity in adult volunteers (168, 169), and may become a next generation smallpox vaccine approved by the FDA. Because the MVA virus does not produce infectious progeny virus in human cells, one or two vaccine doses containing approximately 100 times more MVA virus than ACAM2000 may be required to induce equivalent immune responses and protection.

Dryvax, ACAM2000, and MVA induce cell-mediated and antibody responses against many poxviral antigens (170). Animal models suggest that antibodies targeting a limited number of antigens on the surface of intracellular mature virus and extracellular enveloped virus may be sufficient for protection from disease on challenge because they protect against dissemination of virions through the body (171–173).

Currently, vaccination is recommended for laboratory workers who directly handle cultures or animals infected with VACV or recombinant VACV or other orthopoxviruses that infect humans (174; <http://www.bt.cdc.gov/>). Stocks of VACV vaccine for immunization of laboratory personnel are available from the Centers for Disease Control and Prevention in Atlanta, GA. To prevent accidental infection of unvaccinated contacts, especially those who are immunosuppressed or suffering from atopic dermatitis, the scarified area is “sealed” with an occlusive bandage.

### Management of Outbreaks

The approach to control a human orthopoxvirus that infects via respiratory droplets would depend to a large extent on the size of the initial focus and the reproduction rate of the agent (i.e., the average number of secondary cases generated by a typical primary case in a susceptible population). Although the transmission chains are becoming longer, MPXV still cannot maintain itself in the human population without constant reintroduction from zoonotic hosts. A natural outbreak, or bioterrorist release, of MPXV could be adequately contained with the traditional tracing and vaccination of contacts (“ring vaccination”) and the isolation of symptomatic cases. The response to a bioterrorist release of VARV could also be a ring vaccination or the vaccination of large segments of the population and the restriction of civil liberties, depending on the initial burden of cases and the reproduction rate.

## TREATMENT

### Supportive and Local Care

For nonsystemic zoonotic poxvirus infections, supportive care is provided on an outpatient basis. Invasive treatment procedures are applicable only to MCV. For MCV, the umbilicated core can be removed surgically by curettage, or the lesions may be treated by cryotherapy. This often leads to their resolution and halts the spread to other areas of the skin. These approaches are not appropriate for large numbers of lesions. Cantharidin and topical imiquimod are also commonly utilized agents, although efficacy has not been demonstrated in randomized double-blinded clinical trials (96). Lesions in children can continue to spread to new areas

but will ultimately disappear as the children grow older. In immunosuppressed patients, lesions can become more numerous and persist for long periods of time.

A variety of investigational therapies, usually delivered topically, have been used for VACV keratitis, which is estimated to complicate about 30% of ocular vaccinia cases. In a rabbit model of VACV keratitis, intravenous VIG did not affect the course of the disease, whereas topical trifluridine had an antiviral and beneficial clinical effect (175). Topical corticosteroids were associated with rebound in viral replication in this model and should probably be avoided. Thus off-label use of 1% trifluridine is recommended to treat VACV keratitis.

Systemic disease, such as monkeypox, requires hospitalization in severe cases. In the 2003 US outbreak, 9 of 34 patients with laboratory-confirmed monkeypox and no preexisting medical conditions were hospitalized as inpatients. Two were managed in the intensive care unit with respiratory complications (88).

### Antiviral Treatment

During the smallpox eradication program, a number of compounds were shown to have efficacy against orthopoxvirus infections in cell culture, but few were actually tested in field conditions. Thiosemicarbazone and metisazone were administered prophylactically in a series of trials in India and showed some protective effect, although their use was often associated with severe nausea and vomiting (2). Cytosine arabinoside and adenine arabinoside were also used to treat variola major and variola minor, but the drugs failed to affect the case mortality rate or the clinical progression of disease. Rifampin showed antiviral activity against VACV in a mouse model but was never tested clinically against VARV.

Cidofovir (CDV), a DNA polymerase inhibitor currently used to treat cytomegalovirus retinitis in AIDS patients, has been approved to treat complications from VACV vaccination under an investigational new-drug protocol; however, it must be given intravenously and has nephrotoxicity (<http://www.bt.cdc.gov/>) (see Chapter 12). This drug has been used off-license (176) to treat ORFV (99) and MCV (177) in immunocompromised patients.

Two orally administered antivirals, although not yet licensed, are part of the United States Strategic National Stockpile. Chimerix and SIGA, Inc., have received investigational new-drug status for the compounds brincidofovir (formerly CMX001) and tecovirimat (formerly ST-246), respectively. Brincidofovir is a hexadecyloxypropyl (HDP)-CDV salt synthesized by covalently coupling CDV to an alkoxyalkanol to form a prodrug of CDV (178). Brincidofovir (200 mg once weekly or 100 mg twice a week) is 80% bioavailable, distributed to tissues without significant concentration in the kidneys, and has lacked nephrotoxicity in clinical studies to date (see Chapter 12). Most importantly, CDV and brincidofovir have broad-spectrum activity against viruses that encode DNA polymerases, including all poxviruses known to infect humans, adenoviruses, and many herpesviruses (179), and brincidofovir has been tested in clinical trials against non-poxvirus viruses (180–182).

Tecovirimat (400 mg per day) is active against multiple species of orthopoxviruses, including two strains of VARV (39, 183). Resistance-mapping studies indicate that it targets the VACV F13L gene, which is conserved in orthopoxviruses. The F13L gene encodes a major envelope protein, p37, which is required for production of extracellular, but not intracellular, virus. Thus, tecovirimat does not affect the actual production of infectious virus; it affects only its

efficient egress from cells. Because brincidofovir and tecovirimat target different stages in the virus replication cycle, they show potent synergy in standard mouse orthopoxvirus infection models (184).

Both of these antivirals will likely treat all human orthopoxvirus infections, and brincidofovir might be effective against the remaining poxviruses, because the DNA polymerase is highly conserved. Consistent with this, CDV diphosphate, which is the active metabolite for both CDV and HDP-CDV, was shown to have activity against MCV DNA polymerase (185). The effectiveness of the egress inhibitor tecovirimat against poxviruses of other genera will depend on the importance of the cell-to-cell spread of virus in the disease process and the presence of the viral target.

While these new drugs have been used to treat a number of serious complications from vaccinia virus vaccine, the drugs and VIG-IV were most intensively studied in a patient who developed progressive vaccinia after developing, and being treated for, acute myelogenous leukemia (186, 187). While acutely ill, this patient required 30 times more VIG-IV than what was estimated to be needed to treat a person with a complication from smallpox vaccination. This may indicate that VIG may not be very effective at treating progressive vaccinia. This patient also required 3 times the dose of tecovirimat than had been used in healthy volunteers in whom pharmacokinetics had been defined. This may indicate that the drug doses may need to be monitored and adjusted in acutely ill patients, especially if ever used to treat someone with smallpox.

### Emergence of Resistance and Its Implications

Data available on the emergence of resistance to antiviral treatment mainly come from cell culture and animal models. Resistance to CDV in VACV can be generated after successive tissue culture passage in the presence of a drug or through the introduction of mutations through recombinant DNA technology (188–190). The mutations necessary to make the poxvirus polymerase resistant to CDV in tissue culture appear to reduce the virulence of the virus in tested animal models (189, 191). Resistance to tecovirimat occurs due to mutations in F13L gene (183, 192). While there appears to be a high barrier to the generation of virus resistant to brincidofovir's parental drug, CDV, this is not the case with tecovirimat. Cowpox virus mutants that are resistant to tecovirimat exist in laboratory stocks of virus without the need for drug selection. Mutant virus can be isolated by plaquing the virus in the presence of 10  $\mu$ M (200 times the EC<sub>50</sub>) of tecovirimat (183), although other selection conditions took longer to detect resistant virus (192). These trends were seen in the patient being treated for progressive vaccinia (187). In this critically ill patient, resistance to tecovirimat was seen in virus sequentially grown from the vaccination site. Thus, caution is needed when using tecovirimat as monotherapy, especially in a severely ill patient where drug levels may be suboptimal (187).

# Herpes Simplex Viruses

RICHARD J. WHITLEY AND BERNARD ROIZMAN

## 20

“A system. . . is exactly the opposite of a machine in which the structure of the product depends crucially on strictly predefined operations of the parts. In the system the structure of the whole determines the operation of the parts; in the machine the operation of the parts determines the outcome.”

Paul Alfred Weiss, in A. Koestler, V. R. Smithies eds., *Beyond Reductionism*, 1968.

London Hutchinson

Herpes simplex virus (HSV) infections of humans have been documented since the advent of writing. Genital herpes was described in Sumerian literature (1). Greek scholars, particularly Hippocrates, used the word “herpes,” meaning to creep or crawl, to describe the spreading nature of skin lesions (2). Herodotus associated mouth ulcers and lip vesicles with fever and called it “herpes febrilis.” Many of these original observations likely emanated from Galen’s deduction that the appearance of lesions was an attempt by the body to rid itself of evil humors, leading to the description “herpes excretins.”

As noted by Wildy (2), Shakespeare wrote of recurrent HSV labial lesions. In *Romeo and Juliet*, Queen Mab, the midwife of the fairies, stated: “O’er ladies lips, who straight on kisses dream, which oft the angry Mab with blisters plagues, because their breaths with sweetmeats tainted are.” In the 18th century, Jean Astruc, physician to King Louis XIV, associated herpetic lesions with genital infection. By the early 19th century, the vesicular nature of lesions associated with herpetic infections was well characterized. However, it was not until 1893 that Jean Baptiste Émile Vidal specifically recognized person-to-person transmission of HSV infections (2).

By the beginning of the 20th century, histopathologic studies described multinucleated giant cells associated with infection, and the infectivity of HSV was established by transmission of virus from humans to the cornea of the rabbit, resulting in keratitis. Reports through the 1950s focused on the biologic manifestations of HSV infection and the natural history of human disease. The host range of HSV was expanded to include a variety of laboratory animals, chick embryos, and cell culture systems. Expanded animal studies demonstrated that transmission of human virus could occur not only to the rabbit, as noted above, but also could lead to infections of the skin or the central nervous system (3, 4).

Host immune responses to HSV were defined by the presence of neutralizing antibodies to HSV in the serum of

newly and previously infected children and adults (5). Subsequently, some seropositive individuals developed recurrent labial lesions, albeit less severe than those associated with the initial episode. These observations, contrary to all known interactions of humans with infectious agents, led Robert Doerr, a leading virologist of the past century, to postulate that “All of these observations converge to indicate that the agent of herpes is no infectious agent which is conserved in the site of infection, but that it originates in the human organism, that is, endogenously” (6).

HSV has the distinctive property of establishing a silent or “latent” infection and reactivating in the presence of humoral and cell-mediated immune responses. In the course of these studies, the spectrum of disease was expanded to include primary and recurrent infections of mucous membranes (e.g., gingivostomatitis, herpes labialis, genital HSV infections, etc.), keratoconjunctivitis, neonatal HSV infection, visceral HSV infections of the immunocompromised host, HSV encephalitis, Kaposi’s varicella-like eruption, and an association with erythema multiforme.

Among many important laboratory advances of the past century was the detection of antigenic differences between HSV types (7). Historically, HSV-1 was more frequently associated with nongenital infection (infection above the waist), whereas HSV-2 was associated with genital disease (infection below the waist). This knowledge provided a foundation for many of the studies performed during the latter part of the 20th century. Over the past two decades, both HSV-1 and HSV-2 can be found in the mouth and in the genital tract, with HSV-1 becoming a more common resident of the genital tract.

The replication cycle of HSV in humans consists of three phases: the replication phase, in which HSV actively replicates and spreads from cell to cell; the latency phase, in which with few exceptions viral genes are silent, or at best, randomly transcribed at a very low frequency; and the reactivation phase in which the virus recurs from dormancy, replicates,

and is transported anterogradely to a site at or near the initial infection to reinitiate the replication phase (8).

The characterization of an infectious agent as a pathogen must take into account that the mission of all viruses is to spread and multiply. The task facing HSV is formidable: Spread from person to person is by voluntary contact between infected mucous membranes of one individual with those of an uninfected individual. Deceased individuals and people without obviously grotesque lesions do not transmit, as reviewed (9). Notwithstanding these limitations, HSV is one of the most successful human pathogens. In most societies, its penetration is 100% of the population, and it persists in a human for life. Numerous studies carried out in recent years suggest that it accomplishes its mission by tightly regulating its growth and resultant morbidity.

## VIROLOGY

### Classification

Herpes simplex viruses belong to the family Herpesviridae (10). The >100 known members of this family share the structure of their virions, general features of their reproductive cycle, and the capacity to remain latent. They differ, however, in many respects, and have been classified into three subfamilies (alpha, beta, gamma) with respect to the details of their replication, the cells in which they remain latent, gene content, and gene organization. HSV types 1 and 2 belong to the subfamily Alphaherpesviridae (11).

### Virion Structure

The HSV virion consists of four concentric components. From the center out, these are: (1) an electron-dense core containing viral DNA and polyamines, (2) an icosahedral capsid consisting of capsomeres (12), (3) an amorphous layer of proteins, designated tegument, surrounding the capsid, and (4) an envelope containing lipids and studded with at least 10 viral glycoproteins and several nonglycosylated membrane proteins.

Herpes simplex viruses have genomes that consist of a single double-stranded DNA molecule (12, 13), which is in excess of 152 kbp (the exact size depends on the number of terminal repeats). The G+C content of HSV-1 DNA is 68% and 69% for HSV-2 DNA. The HSV-1 and HSV-2 genomes encode at least 84 different polypeptides (12, 14). The DNAs consist of two covalently linked components, Large and Small (L and S), each consisting of stretches of unique sequences designated  $U_L$  and  $U_S$  that are flanked by the inverted repeats *ab* and *ca*, respectively. The two components invert relative to each other to yield four populations of molecules differing solely in the relative orientation of  $U_S$  and  $U_L$  (15). Although they differ with respect to nucleotide sequence and restriction endonuclease cleavage sites, and in apparent sizes of many viral proteins they encode, the HSV-1 and HSV-2 genomes are collinear and readily form intertypic recombinants in the laboratory (15).

### Proteins

HSV encodes at least 100 transcripts, of which 84 are translated into unique proteins. Of this number, 46 are dispensable for viral replication in at least some cultivated cells. The function of many of these “dispensable” genes is to render viral replication and spread more efficiently or to block host responses to infection (12, 16). Importantly, these genes are not truly dispensable, as viruses lacking these genes have not been isolated from humans. Viruses from which

these genes have been deleted by genetic engineering frequently exhibit a reduced capacity to multiply and spread in experimental animals (12, 16). Indeed, the observation that many HSV genes are dispensable and can be replaced by non-HSV genes sustains the expectation that HSV can be designed to perform different functions, such as to serve as vectors for foreign gene expression, live attenuated vaccines, or for selective destruction of cancer cells.

Because viral proteins studied to date have been found to perform multiple functions, it is likely that HSV encodes several hundred functions expressed by adjacent or overlapping amino acid blocks. Each function is performed at a designated time during replication and at an intracellular location that may be determined by posttranslational modifications and by protein partners that interact selectively with these posttranslationally modified viral proteins. Modifications include phosphorylation by cellular (e.g., cdc2) or viral ( $U_L13$ ,  $U_S3$ ) protein kinases, nucleotidylation by casein kinase 2, poly(ADP)-ribosylation, among others.  $U_L13$ , a key viral protein kinase, is homologous to the  $U_L97$  protein kinase of human cytomegalovirus (CMV) and a key component of antiviral chemotherapy (10).

### Replication

In recent years, it has become apparent that the replication of HSV is defined in part by both intrinsic mechanisms encoded by the virus and host innate immune responses. It is convenient and to some extent necessary to describe these processes in parallel (10).

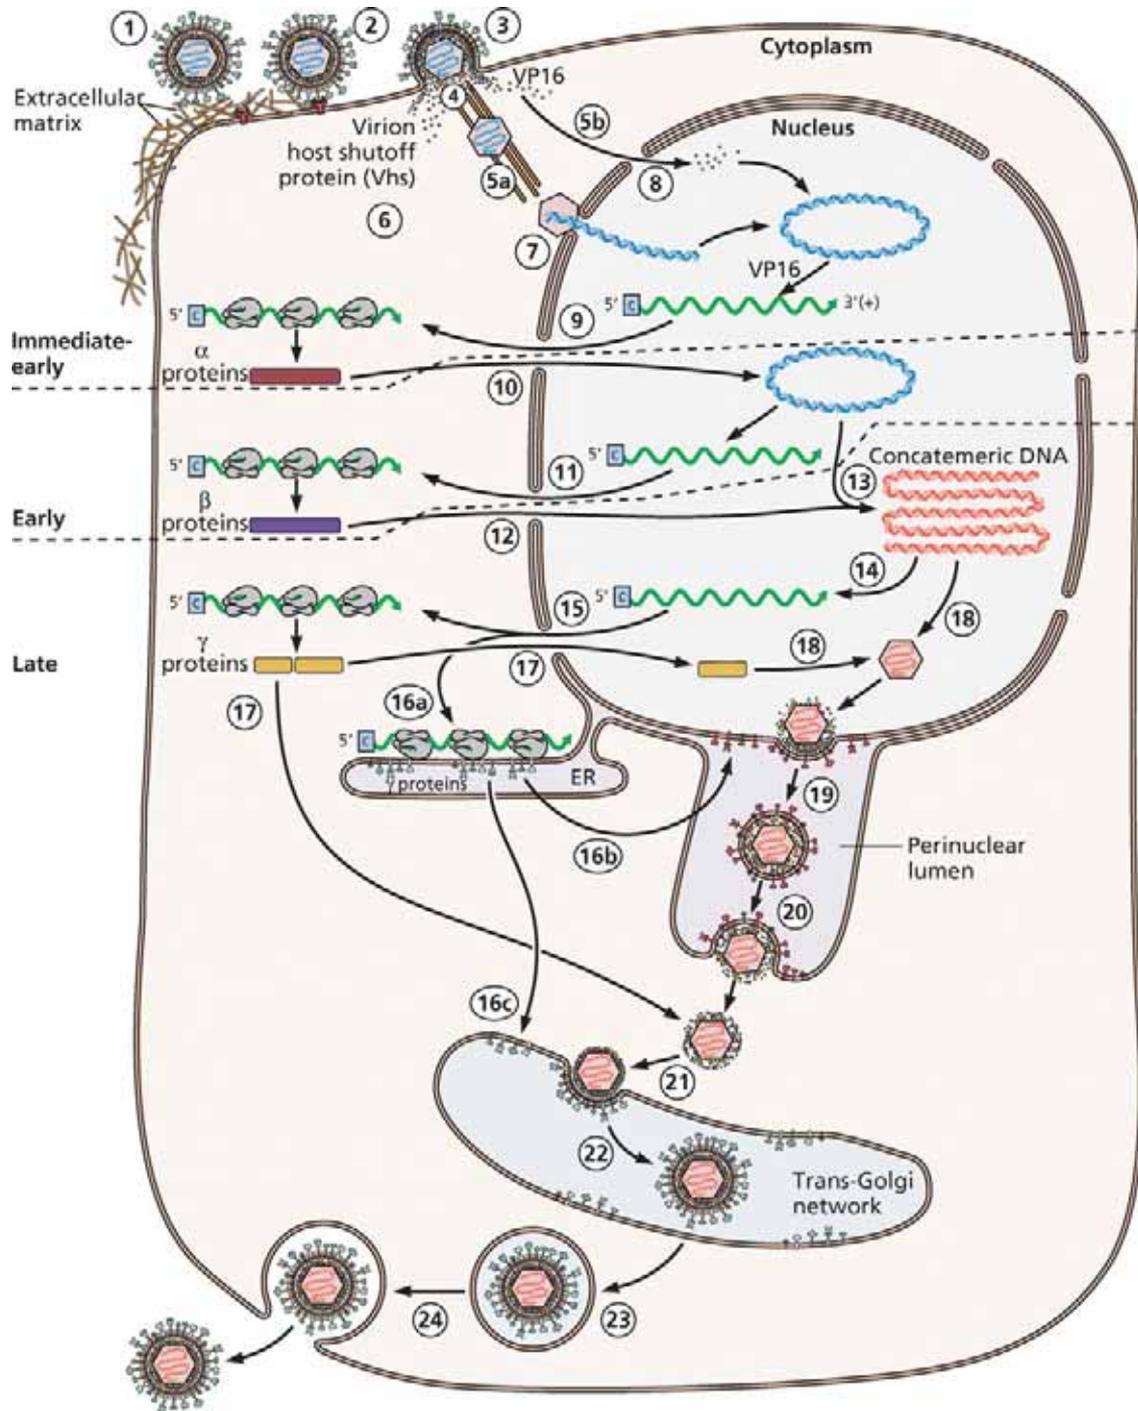

#### Initiation of Replication

To initiate infection, HSV must attach to cell-surface receptors and fuse its envelope with the plasma membrane or the membrane of the endocytic vesicle (Fig. 1). Viral surface glycoproteins mediate attachment and penetration of the virus into cells. They also elicit a “protective” host immune response to the virus. Of the 12 viral glycoproteins (*g*) designated *gB*, *gC*, *gD*, *gE*, *gG*, *gH*, *gI*, *gJ*, *gK*, *gL*, *gM*, and *gN*, five are involved in the entry process. In brief, *gB* and *gC* enable virions to attach to heparin-sulfated proteoglycans that stud the cell surface. In the next step, *gD* interacts with its receptor and triggers the fusogenic functions of *gB* and *gH/gL*. The consequence of the fusion of the envelope with the cellular membranes is the release of the capsid and approximately 20 tegument proteins into the cytoplasm. The capsid is transported to the nuclear pore, where the DNA is released from the capsid into the nucleoplasm. At least some tegument proteins are also transported into the nucleus. Little is known of the function of viral glycoproteins other than *gC*, *gB*, *gD*, and *gH/gL*. *gE* and *gI* form a potent Fc receptor that binds immunoglobulins at the cell surface.

To date, three cellular receptors have been described. These are: (1) HveA, a member of the tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) receptor family; (2) Nectin1, a member of the extended immunoglobulin family; and (3) a modified heparin sulfated proteoglycan. Of the three, Nectin 1 is the major receptor enabling infection of human cells with HSV (10).

#### Postentry Events

It is convenient to define three distinct phases of postentry events: immediate early, early, and late (Fig. 1). First, a complex of nuclear proteins aggregate at the entering viral DNA and form a complex designated ND10. The organizer of this complex is promyelocytic leukemia (PML) protein. Concurrently, viral DNA is silenced by deacetylated histones and methylation. Among the structures bound to the

**FIGURE 1** Schematic representation of the replication of herpes simplex viruses (HSV) in susceptible cells. 1. The virus initiates infection by the fusion of the viral envelope with the plasma membrane following attachment to the cell surface. 2. Fusion of the membranes releases two proteins from the virion. Virus host shutoff (VHS) shuts off protein synthesis (broken RNA in open polyribosomes). The  $\alpha$  gene trans-inducing factor ( $\alpha$ -TIF) is transported to the nucleus. 3. The capsid is transported to the nuclear pore where viral DNA is released into the nucleus and immediately circularizes. 4. The transcription of  $\alpha$  genes by cellular enzymes is induced by  $\alpha$ -TIF. 5. The 5'  $\alpha$ mRNAs are transported into the cytoplasm and translated (filled polyribosome); the proteins are transported into the nucleus. 6. A new round of transcription results in the synthesis of  $\beta$  proteins. 7. At this stage in the infection the chromatin (c) is degraded and displaced toward the nuclear membrane, whereas the nucleoli (round hatched structures) become disaggregated. 8. Viral DNA is replicated by a rolling circle mechanism, which yields head-to-tail concatemers of unit length viral DNA. 9. A new round of transcription/translation yields the  $\gamma$  proteins consisting primarily of structural proteins of the virus. 10. The capsid proteins form empty capsids. 11. Unit-length viral DNA is cleaved from concatemers and packaged into the preformed capsids. 12. Capsids containing viral DNA acquire a new protein. 13. Viral glycoproteins and tegument proteins accumulate and form patches in cellular membranes. The capsids containing DNA and the additional protein attach to the underside of the membrane patches containing viral proteins and are enveloped. 14. The enveloped proteins accumulate in the endoplasmic reticulum and are transported into the extracellular space. Reprinted with permission from (192).

viral DNA is the histone deacetylase 1 (HDAC-1) or HDAC-2 CoREST/ LSD1/REST repressor complex. This complex silences neuronal genes in nonneuronal cells. By extension, nonneuronal cells perceive HSV genes as neuronal. To express its function, viral DNA must be derepressed (17, 18).

Three key proteins are among the tegument components entering the nucleus. These are VP16, the virion host shutoff RNase (VHS-RNase) and pU<sub>L</sub>47. To initiate replication, VP16 recruits several transcriptional factors, including octamer binding protein 1 (Oct1), host cell factor 1 (HCF1), and lysine-specific demethylase 1 (LSD1) to the promoters of  $\alpha$  [immediate early (IE) genes] (19). The six IE or  $\alpha$  proteins [infected cell protein (ICP) 0, 4, 22, 27, 47 and US1.5] are expressed first. Next, ICP0 performs several functions. The functions important at this stage are 2-fold. First, ICP0 binds to CoREST and dislodges HDAC1. In consequence, the HDAC1 or 2/CoREST/LSD1/REST repressor complex falls apart and is translocated to the cytoplasm (20–22). This enables the early or  $\beta$  genes to be transcribed. Second, ICP0 recruits to the transcriptional machinery key cellular proteins (e.g., CLOCK, etc.) essential for efficient transcription of viral genes (23). The  $\alpha$  proteins have two key functions. Foremost, they disable, largely by preemptive actions, host responses to intrusion of foreign DNA and proteins into the infected cells. Equally important, they insure efficient expression of viral genes through subversion and recruitment of host proteins (8).

The key function of  $\beta$  gene products is to replicate viral DNA. HSV expresses at least seven proteins known to play a role in viral DNA synthesis, but additional host proteins may also be involved. The proteins involved in viral DNA synthesis are the targets of anti-HSV drugs (10). Once replication of viral DNA begins, the late or  $\gamma$  genes are expressed. Most  $\gamma$  proteins are structural components of the virion.

Assembly of the capsid and insertion of the viral DNA into the preformed capsid takes place in the nucleus. Envelopment takes place at the inner nuclear membrane and in the multivesicular bodies in the cytoplasm. Precisely how capsids reach the multivesicular bodies is the subject of much debate. One theory suggests that virions formed at the inner nuclear membrane become de-enveloped at the outer nuclear membrane or in vesicles formed by the outer membrane. The opposing view is that capsids are transported out of the nucleus through the nuclear pores, which fluctuate in size depending on the size of the transient cargo. Virions are transported to the cell surface in vesicles derived either from the outer nuclear membrane or the multivesicular bodies (10).

### HSV Replicative Functions and the Host Innate Immune Responses

In parallel with viral gene expression, a multifaceted interplay takes place between viral gene products and the host, one result of which is degradation of mRNAs encoding host response gene products. Cell sensors detect entry of virus into cells and induce the transcription of several hundred genes encoding stress response mRNAs that characteristically contain one to several AU-rich elements (AUUUUA) in their 3'-untranslated region (3'-UTR) and have a relatively short half-life. Thus, in uninfected cells, the stress response mRNAs are ultimately bound at the AU-rich elements by a protein (e.g., tristetraprolin) and are degraded in p-bodies or sequestered in exosomes. In HSV wild-type virus-infected cells, three series of events take place (24, 25).

First, VHS-RNase, a tegument protein, binds to the Cap structure of preformed cellular mRNAs and cleaves them at or near the Cap structure. The Cap-less mRNA is rapidly degraded 5' to 3' by cellular enzymes. Second, VHS-RNase and pU<sub>L</sub>47, another tegument protein, bind to the Cap structure of mRNAs made after infection. These mRNAs, of both cellular and viral origin, are not degraded except for the stress response mRNAs. The exception is the stress response mRNAs, in this instance among the host proteins induced after infection is tristetraprolin (26). Third, tristetraprolin forms a complex with VHS-RNase, binds to the AU-rich elements of the stress response mRNAs, and cleaves the 3'-UTR (27). The cleaved 5' portion, which contains the open reading frame, persists in the cytoplasm for many hours. Notably, the VHS-RNase-tristetraprolin complex does not degrade all stress response mRNAs. Among the mRNAs spared are those that encode tristetraprolin and ATF3.

HSV infection also causes degradation of PML and blockade of interferon (IFN) sensitivity. A key function of ICP0 is that of an ubiquitin ligase. In conjunction with UbcH5A ubiquitin conjugating enzyme, ICP0 mediates the degradation of the PML protein and SP100—two key components of ND10 (28–30). A key consequence of the degradation of PML is the loss of sensitivity to IFN (31). Thus, formation of ND10 bodies associated with viral DNA has the objective of turning off the viral transcriptome (17). HSV takes advantage of the association with ND10 to recruit ICP0 to PML ultimately rendering the infected cell insensitive to IFN. It also serves as a locus for assembly of transcriptional factors that ultimately enable the synthesis and assembly of viral particles (19). ICP0 E3 ligase activity has been reported to be responsible for the degradation of other proteins, notably that of IFI16, a nuclear host DNA sensor (32).

The presentation of antigenic peptides is inhibited at the cell surface. ICP47, an  $\alpha$  protein, binds Tap1/Tap1 and blocks the transport and presentation of antigenic peptides on the surface of infected cells. In essence, the infected cell is invisible to the cellular adaptive immune system until late in infection (10).

### Dephosphorylation of Eukaryotic Initiation Factor 2 $\alpha$ by ICP34.5

Beginning with the synthesis of  $\gamma$  proteins, there is an increase in the accumulation of complementary transcripts capable of forming double-stranded (ds) RNA. The presence of dsRNA activates protein kinase R (PKR), which, in turn phosphorylates the translation initiation factor eukaryotic initiation factor 2 $\alpha$  (eIF-2 $\alpha$ ). In turn, eIF-2 $\alpha$ -p shuts off protein synthesis, leading to cell death. To overcome this block, ICP34.5 encoded by the  $\gamma_1$ 34.5 gene recruits cellular protein phosphatase-1 $\alpha$  to dephosphorylate eIF-2 $\alpha$ -p and enable the synthesis of late viral proteins (33).

### The Latency Phase (10, 18, 34, 35)

The most common sites of latent infections are sensory or dorsal root neurons, although latent infections may also be established in autonomic neurons. The key property of these neurons is that they are shrouded by satellite cells. The affected neurons are anchored at one end in the mucous membranes, namely sites of initial HSV infection, and at the other by communicating neurons of the autonomic or central nervous system. HSV accesses sensory neurons by infection of nerve endings at the site of replication. The capsids containing viral DNA are then transported retrogradely in axons to the nuclear pore. The sequence of events

is known mostly from studies of murine models. In mice infected by the corneal scarification, the virus can be detected in trigeminal ganglia in less than 24 hours. The sequence of events is highly reproducible. HSV replicates in neurons, and infectious virus can be detected for at least 2 weeks. By week 3, infectious virus begins to disappear. What remains are neurons harboring latent virus. Infectious virus readily appears (reactivates) on excision of the ganglia and cultivation of the neurons *ex vivo*.

Several aspects of HSV infection that lead to latency are different from those that lead to replication. Foremost, latent infections cannot be established in cell culture or in tissues at the peripheral sites of viral replication. One hypothesis that could explain the restricted repertoire of cells capable of maintaining HSV in the latent state is that HCF1 in neurons is in the cytoplasm and that both VP16 and HCF are either not transported to the nucleus of the infected neurons or the transport is retarded (36, 37). As is the case of cells infected at the peripheral sites, on entry into the nucleus, viral DNA is coated by repressive proteins and essentially silenced (17). The only domain of HSV expressed at high levels consists of a 9-kb DNA stretch expressing a noncoding RNA that is processed by splicing into a stable intron designated the latency-associated transcript or LAT (38, 39).

The domain encoding the LAT precursor is enclosed by DNA sequences that insulate it from the remainder of the viral genome (40). The remainder of the DNA is transcribed randomly at very low levels. In essence, during the latency period, viral DNA is in the form of heterochromatin whose state is in a dynamic equilibrium defined by numerous factors. Stimulation of the neuron by injury [e.g., ultraviolet (UV) light], cytokines [e.g., interleukin-6 (IL6)] and other factors induce a stress response that can lead to apoptosis. Maintaining the viability of the neuron and at the same time silencing viral DNA are LAT, nerve growth factor (NGF), histone deacetylases, signal transducer and activator of transcription 3 (STAT3), the phosphatidylinositol 3-kinase/AKT (PI3K-AKT) pathway, and stress response factors (41, 42). LAT plays an important role in the viability of the neurons harboring latent virus and at the same time maintains the virus in latent state. Reactivation results from stimulations that lead to apoptosis and which cannot be blocked (43).

### The Reactivation Phase

The most common causes of reactivation of HSV are exposure to UV light, fever, emotional or physical stress, and menstruation, as discussed below. Experimentally, reactivation may also be induced by neuronal injury, deprivation of NGF or proapoptotic drugs (23, 42). A key question is the mechanism by which viral DNA is derepressed to enable its transcription in the absence of VP16 and ICP0. Recent studies show that nerve injury induces a proapoptotic response, but also concurrently activates the STAT3 and PI3K-AKT pathway to induce a stress response that suppresses apoptosis and blocks reactivation (42). A strong proapoptotic stimulus triggers total derepression of viral DNA. In essence, all viral genes, including regulatory proteins, viral DNA, and structural proteins, are synthesized simultaneously. The consequences are that the virus yields in reactivating neurons are quite small—enough to be transported anterogradely to peripheral tissues but not enough to pose a major threat to the host (23).

The frequency of reactivation, namely a higher number, has been linked to a specific chromosomal locus for labial herpes. This locus is on chromosome 21 and is known as the

Cold Sore Susceptibility Gene (CSSG-1) (44). There are, however, no known links between the chromosomal locus and the events taking place in neurons harboring latent virus.

### Control of Replication, Latency, and Reactivation

The ability of HSV to replicate and cause extensive lesions with primary infection, to establish latent infections, and then reactivate and again cause lesions in the presence of adaptive immunity, along with the high rate of penetration in the human population, are at first glance the properties of a successful pathogen. A central question then is how does the virus control its replication?

Recent studies suggest that HSV evolved novel functions that limit growth and cell-to-cell spread of virus. The findings that support this hypothesis are:

(1) Activation of PKR leads to induction of nuclear factor-kappaB (NF-kappaB) and ultimately to activation of IFN-stimulated genes. In infected cells, PKR is blocked primarily by dephosphorylation of eIF-2 $\alpha$ -p (33). Direct suppression of PKR does not take place, notably by U<sub>5</sub>11, until relatively late in infection (45). At the same time deletion of NF-kappaB p60 or p55 or both p60 and p55 components results in significantly lower yields following infection with wild-type virus (46).

(2) Activation of the stimulator of IFN genes (STING) by nuclear or cytoplasmic DNA sensors leads to synthesis of IFN and of IFN-stimulated genes. Curiously, STING is effectively stabilized in wild-type virus-infected cells and is exported in exosomes from infected to uninfected cells (47).

(3) To date, 30 virally encoded microRNAs (miRNAs) have been detected in productively infected cells, in ganglia harboring latent virus, and in ganglia in which HSV was induced to reactivate from its latent state. With few exceptions, miRNAs made during productive infection also accumulate in ganglia harboring latent virus, but not in ganglia in which HSV is in the process of reactivation. In contrast, the miRNAs accumulating in ganglia in which HSV is reactivating do not accumulate in productively infected cells and are absent from ganglia harboring latent virus. One hypothesis that could explain this paradox is that miRNAs suppress viral replication in ganglia in which the virus replicates and suppress some aspect of innate immunity, perhaps proapoptotic functions, in productively infected cells and ganglia harboring latent virus. Thus, two of the miRNAs accumulating in trigeminal ganglia harboring reactivating virus accumulate very late in the course of productive infection, i.e., at the time when the bulk of infectious virus had already been made. Studies in progress indicate that they have a significant inhibitory effect on viral gene expression when expressed before infection. Consistent with a role in controlling viral replication and spread, some of the miRNAs are exported in exosomes from infected to uninfected cells (9, 48).

(4) Last, the HDAC-1 or HDAC-2/CoREST/LSD1/REST repressor complex acts by binding of REST to RE1 response elements in viral DNA. Insertion into viral DNA of a dominant negative REST that binds RE1, but cannot bind the other components of the repressor complex, enabled the recombinant virus to replicate to higher levels and be more virulent in mice than the wild-type parent virus (49).

The examples cited above suggest that HSV has evolved mechanisms to replicate to higher levels and to spread more efficiently from infected to uninfected cells by eliminating its dependence on active NF-kappaB, eliminating RE1 sites and blocking export of STING and miRNAs from infected to

uninfected cells. A necessary conclusion of these observations is that HSV has evolved mechanisms to control its replication and spread to sustain a high level of person-to-person transmission.

### Pathogenic Correlates of Viral Replication

HSV-1 and HSV-2 exhibit two unique biologic properties that influence human disease. Both viruses have the capacity to invade and replicate in the central nervous system (CNS) and, as noted above, the ability to establish a latent infection (13).

The term *neurovirulence* encompasses both the ability of HSV to invade the CNS from peripheral sites and to replicate in neuronal cells. When paired isolates (brain and lip) from patients with HSV encephalitis are evaluated by plaque-forming unit/median lethal dose (PFU/LD<sub>50</sub>) ratios following direct intracerebral inoculation in mice, encephalitis isolates have lower PFU/LD<sub>50</sub> ratios than isolates from lip lesions, ergo are more neurovirulent. Neurovirulence appears to be the function of numerous genes (12). In fact, deletion of virtually any of the genes dispensable for viral replication in cell culture reduces the capacity of the virus to invade and replicate in CNS. Mutations affecting neuro-invasiveness have also been mapped in genes encoding glycoproteins. Access to neuronal cells from usual portals of entry into the body requires postsynaptic transmission of virus, and therefore a particularly vigorous capacity to multiply and to direct the virions to appropriate membranes. In addition, because neuronal cells are terminally differentiated and do not make cellular DNA, they lack the precursors for viral DNA synthesis that are also encoded by the viral genes dispensable for growth in cell culture. Of particular interest, however, is the role of the  $\gamma_134.5$  gene in neurovirulence (50–53). Although  $\gamma_134.5$  deletion mutants multiply well in a variety of cells in culture, they are among the most avirulent mutants identified to date when inoculated directly into the brain of susceptible animals.

Latency has been recognized biologically since the beginning of the century (54–57). Latent virus can be retrieved from the trigeminal, sacral, and vagal ganglia of humans either unilaterally or bilaterally (55). The recovery of virus by *in vitro* cultivation of trigeminal ganglia helps explain the observation of vesicles that recur at the same site in humans, usually the vermilion border of the lip. Patients treated for trigeminal neuralgia by sectioning a branch of that nerve develop herpetic lesions along the innervated areas of the sectioned branch (58–61). Reactivation of latent virus appears dependent upon an intact anterior nerve route and peripheral nerve pathways. Recurrences occur in the presence of both cell-mediated and humoral immunity. Recurrences are spontaneous, but there is an association with physical or emotional stress, fever, exposure to UV light, tissue damage, and immune suppression. Recurrent herpes labialis is three times more frequent in febrile patients than in nonfebrile controls (54, 56, 62, 63).

## EPIDEMIOLOGY

### Oral HSV Infections

#### Prevalence

Although HSV-1 and HSV-2 are usually transmitted by different routes and may involve different body sites, there is a great deal of overlap between their epidemiology and clinical manifestations. These viruses are distributed worldwide and occur in both developed and underdeveloped

countries, including remote Brazilian tribes (64). Animal vectors for human HSV infections have not been described; therefore, humans remain the sole reservoir for transmission to other humans. Virus is transmitted from infected to susceptible individuals during close personal contact. There is no seasonal variation in the incidence of infection. Because infection is rarely fatal and HSV becomes latent, over one-third of the world's population has recurrent HSV infections, and, therefore, the capability of transmitting HSV during episodes of productive infection.

Geographic location, socioeconomic status, and age influence the prevalence of HSV-1 infection (5, 65). In developing countries and societies, infection, indicated by seroconversion, occurs early in life. Among Brazilian Indians and children in New Orleans, HSV antibodies develop in over 95% of children by the age of 15 (66). In lower socioeconomic populations, approximately one-third of children seroconvert by 5 years of age; this frequency increases to 70–80% by early adolescence. Middle-class individuals in industrialized societies acquire antibodies later in life, such that seroconversion over the first 5 years occurs in 20% of children, followed by no significant increase until the second and third decades of life, during which the prevalence of antibodies increases to 40% and 60%, respectively (67). Seroconversion of susceptible university students occurs at an annual frequency of approximately 5–10% (67).

In the United States, the seroprevalence of HSV-1 and HSV-2 infections varies by age, sex, and race (Fig. 2) (68, 69). Through childhood and adolescence, African Americans have approximately a 2-fold higher prevalence of antibodies to HSV-1 than Caucasians, and females a slightly higher prevalence of HSV-1 antibodies than males. By the age of 40, both African Americans and Caucasians have a similar prevalence of antibodies. A recent global assessment indicated that the point prevalence of HSV-1 infection by age 49 years is 67%, a finding consistent with earlier studies (70). The high prevalence of antibodies appearing later in life may be the consequence of a cohort effect, namely these individuals had a higher rate of acquisition of HSV-1 earlier in life.

Seroprevalence worldwide shows geographic variation. An HSV-1 antibody prevalence less than 70% is found in populations residing in Pittsburgh, Pennsylvania; Birmingham, Alabama; Atlanta, Georgia; Japan; Lyon, France; Sweden and Caucasian Americans [U.S. National Health and Nutrition Examination Survey (NHANES) participants], whereas it exceeds 95% in Spain, Italy, Rwanda, Zaire, Senegal, China, Taiwan, Haiti, Jamaica, and Costa Rica for adults between the ages of 20 and 40.

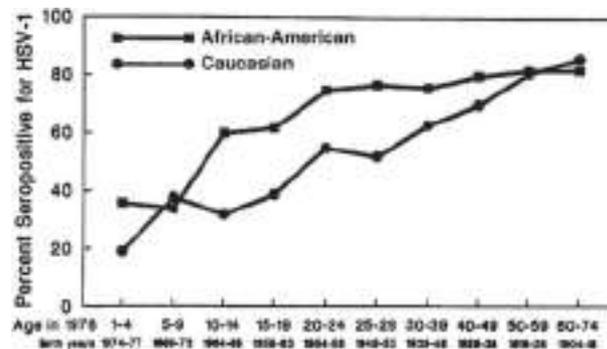

FIGURE 2 Seroprevalence of herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) by age.

Virus can be isolated from the saliva of approximately 20% of asymptomatic children between 7 months to 2 years of age (146). Virus shedding in children less than 6 months of age is uncommon. In older children, 3–14 years of age, presumed asymptomatic shedding has been documented in 18%. Virus recovery decreases with advancing age; over 15 years of age, the frequency of excretion is 2.7%, similar to contemporary cross-sectional surveys, which range from 2% to 5% (135,147–149).

### Virologic and Clinical Recurrences

The largest reservoir of HSV infections in the community is recurrent herpes labialis. A positive history of recurrent herpes labialis was noted in 38% of 1800 graduate students in Philadelphia (71). New lesions occurred at a frequency of one per month in 5% of the students and at intervals of 2–11 months in 34% of the students. Recurrences of one per year or less often were found in 61%. Over the past several years, HSV-2 infections of the oropharynx have been recognized both in immune competent and immunocompromised hosts (72).

### Outbreaks of HSV-1

Clustered human outbreaks of HSV infections have been reported (65), but there is no indication from either clinical or molecular epidemiologic studies that HSV causes epidemics in the general population. Most of the studies involve families in which several individuals suffer from HSV infection at approximately the same time, perhaps through exposure to recurrent labial lesions of one family member. Outbreaks in healthcare settings have occurred, but no common source can be determined. An outbreak of eczema herpeticum was reported in a large group of hospitalized patients within an 8-day period; in this case, the lack of attention to infection control procedures (e.g., hand-washing) was incriminated as being responsible for virus transmission. Outbreaks of herpetic stomatitis have been reported in dental offices and within orphanages (73), where attack rates for apparent infection were approximately 75% of susceptible children. Increased transmission of HSV in day care centers has not yet been reported (74).

### Genital HSV Infections

#### Prevalence and Incidence

Because genital HSV infections are usually acquired through sexual contact, antibodies to HSV-2, at least, are rarely found before the age of onset of sexual activity (75). Although most recurrent genital HSV infections are caused by HSV-2, an ever-increasing proportion of primary infection is attributable to HSV-1 (76), now accounting for nearly 50% of new cases (77). The differentiation in virus type is significant, because genital HSV-1 infections are usually both less severe clinically and significantly less prone to recur (76, 78). The number of new cases of genital HSV infections has been conservatively estimated to be approximately 500,000 individuals annually. Predicated upon newer serologic methods for detection of prior HSV-2 infection, a range of 40–60 million Americans are infected with HSV-2 (79).

Seroprevalence of HSV-2 increases from 5.6% between 12 and 19 years of age to 24.3% by the age of 60. For the aforementioned age groups, 4.5% and 8.7% of Caucasians, respectively, and 18.2% and 76.8% of African Americans, respectively, have HSV-2 antibodies. Factors found to influence acquisition of HSV-2 include sex (women greater than men), race (African Americans more than Cauca-

sians), marital status (divorced more than single or married), and place of residence (city greater than suburb) (80). In the United States, a 20% increase in seroprevalence, indicative of infection, occurred between NAHNES II (1976–1980) and NAHNES III (1988) (Fig. 3). However, the most recent study (NAHNES IV) indicates slightly lower HSV-2 seroprevalence rates (81). Seroprevalence studies indicated the highest prevalence of antibodies to HSV-2 in the United States is in female prostitutes (75%), and is virtually identical to that of prostitutes in Tokyo (69,82–84). Seropositivity amongst female prostitutes in Dakar, Senegal, was even higher—95.7% in 1985. Homosexual men have seroprevalence rates to HSV-2 varying from a high of 83.1% in San Francisco (1985–1986) to low of 21.6% in Seville, Spain (1985–1986), Tokyo, Japan 24.2% (1988), and Amsterdam, The Netherlands of 50.0% (1986). Although these seroprevalence rates account for HSV-2, they cannot discern the contribution of HSV-1 to genital infection.

Prospective studies of the incidence of HSV-2 infection indicate that among low-risk individuals, namely college students, the rate of acquisition was approximately 2% per year over 4 years as compared to 4% per year for homosexual men in San Francisco (69). The incidence of HSV-2 infection during pregnancy is about 2.5% per gestation, but may be as low as 0.58%. Acquisition of HSV-2 infection between monogamous sexual partners with discordant infection status is 10 to 15% yearly (97).

As noted, the number of different sexual partners, irrespective of sexual preference, correlates directly with acquisition of HSV-2 (Fig. 4) (69, 85). For heterosexual women living in the United States with one partner, the probability of acquisition of HSV-2 is less than 10%, but increases to 40%, 62%, and greater than 80% as the number of lifetime sexual partners increases to 2–10, 11–50, or greater than 50, respectively. For heterosexual men, similar data are 0% for one lifetime sexual partner, and 20%, 35%, and 70% for each of the three risk groups, respectively. In contrast, for homosexual men, seroprevalence increases from greater than 60–90% for those with 11–50 and greater than 50 partners. Thus, multiple sexual partners, irrespective of sexual preference, correlates directly with acquisition of HSV-2 infection (69, 85).

### Virologic and Clinical Recurrences

As with HSV-1 infections of the mouth, HSV-2 is excreted more frequently in the absence of symptoms at the time of primary, initial, or recurrent infection (86–88), providing a silent reservoir for transmission. The frequency of clinical

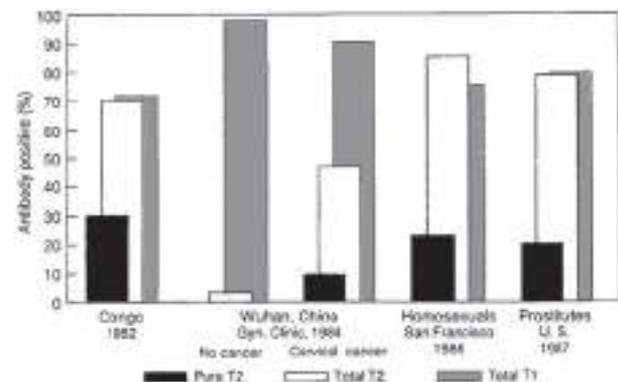

FIGURE 3 Seroprevalence of herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) by selected country.

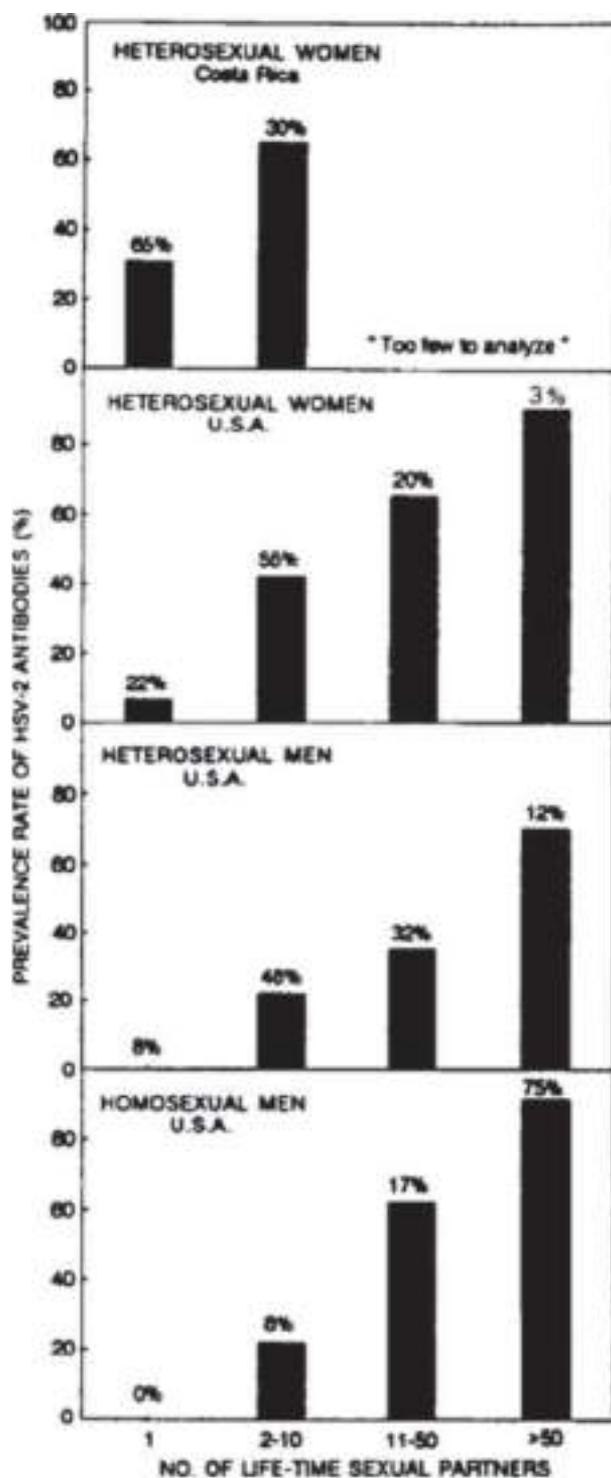

FIGURE 4 Seroprevalence of herpes simplex virus type 2 (HSV-2) as a function of the number of sexual partners.

recurrences varies somewhat between males and females, with rates of 2.7 and 1.9 per 100 days, respectively (76), figures much lower than recurrences detected by laboratory tests, as noted in the following paragraphs. Recurrences are most frequent in the year immediately following acquisition and tend to decrease somewhat over subsequent years. Several studies have implicated a frequency of clinical re-

currences as high as 60%. Genital infections by HSV-1 recur less frequently than those caused by HSV-2 (78, 89). Following the first episode of genital herpes, asymptomatic shedding was detected in approximately 12%, 18%, and 23% of women with primary HSV-1, primary HSV-2, and non-primary HSV-2 infection, respectively (90). For women with established genital HSV-2 infection, asymptomatic shedding was detected on 1% of all days cultures were obtained (88, 91). More contemporary studies indicate that only 20–25% of women who are HSV-2 seropositive have symptoms of genital herpes (92, 93). With the application of the polymerase chain reaction (PCR) to the serial evaluation of genital swabs from women with genital infection, the frequency of shedding of HSV DNA is even higher, suggesting that HSV is a chronic infection rather than an intermittent one (94). Indeed, HSV DNA can be detected in up to 20% of all days for women with HSV-2 infection. Interestingly, shedding can occur for a mere few hours on any given day and multiple sites, as reviewed (95, 96). Similar shedding data will be found for HSV-1 oropharyngeal infection (72).

#### HIV Coinfection

HSV-2 infection, by the nature of being an ulcerative disease, is associated with acquisition of human immunodeficiency virus type 1 (HIV-1). Most case-control studies performed in the United States and Central Africa indicate increased relative risk of HIV acquisition by 1.5- to over 2-fold (69,98–100). Furthermore, concomitant infection is associated with higher HIV RNA plasma levels that can be decreased with HSV therapy (101, 102). The association between acquisition of HIV and HSV-2 was also documented in heterosexual populations (99).

#### Pregnancy

Genital HSV infection in pregnant women is not uncommon, but it must be considered separately from nonpregnant populations because of the risk to the fetus and newborn. Recurrent infection is the most common form of infection during pregnancy. Transmission of infection to the fetus is related to shedding of virus at the time of delivery. The prevalence of viral excretion at delivery, as determined by culture, is 0.01–0.39% for all women, irrespective of past history (87), with rates as high as 0.6% (103). In a predominantly white, middle-class population, documented recurrent infection occurs in 84% of pregnant women with a history of recurrent disease. Asymptomatic viral shedding occurred in at least 12% of the recurrent episodes. Viral shedding from the cervix has occurred in 0.56% of symptomatic infections versus 0.66% of asymptomatic infections (87). The prevalence of cervical shedding in pregnant women with asymptomatic HSV infection averages approximately 3%. However, the observed rate for these women varies more than that among nonpregnant women (from 0.2% to 7.4%), depending upon the study population and trial design (87, 104).

## PATHOGENESIS

### Pathology

The histopathologic characteristics of a primary and recurrent HSV infection (Fig. 5) reflect virus-mediated cellular death with an associated inflammatory response. Viral infection induces ballooning of cells with condensed chromatin within the nuclei of cells, followed by nuclear degeneration, generally within parabasal and intermediate

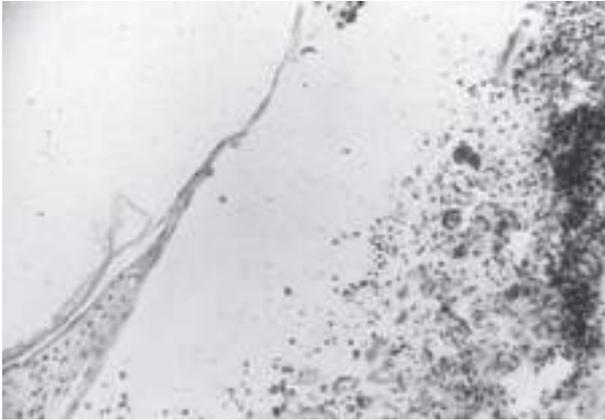

FIGURE 5 Histopathology of herpes simplex virus infection.

cells of the epithelium. Cells lose intact plasma membranes and form multinucleated giant cells. With cell lysis, a clear (referred to as vesicular) fluid containing virus appears between the epidermis and dermal layer. The vesicular fluid contains cell debris, inflammatory cells, and often multinucleated giant cells. In dermal substructures, there is an intense inflammatory response, usually in the corium of the skin, more so with primary infection than with recurrent infection. With healing, the vesicular fluid becomes pustular with the recruitment of inflammatory cells and scabs. Scarring is uncommon. When mucous membranes are involved, vesicles are replaced by shallow ulcers.

### Pathogenesis

The transmission of human infection is dependent upon intimate, personal contact between a susceptible seronegative

individual with someone excreting HSV. Virus must come in contact with mucosal surfaces or abraded skin for infection to be initiated. Following viral replication at the site of infection, either an intact virion, or more simply, the capsid is transported retrogradely by neurons to the dorsal root ganglia where, after another round of viral replication, latency is established (Fig. 6). The more severe the primary infection, as reflected by the size, number, and extent of lesions, the more likely it is that recurrences will ensue. Although replication sometimes leads to disease and infrequently results in life-threatening infection (e.g., encephalitis), the host–virus interaction leading to latency predominates, as noted above. After latency is established, a provocative stimulus causes reactivation; virus becomes detectable at mucocutaneous sites, appearing as skin vesicles or mucosal ulcers (Fig. 7).

Infection with HSV-1 generally occurs in the oropharyngeal mucosa. The trigeminal ganglion becomes colonized and harbors latent virus. Acquisition of HSV-2 infection is usually the consequence of transmission by genital contact; however, genital–oral spread is increasingly common and results in alternative modes of transmission from mucous membrane to mucous membrane for both viruses. Virus replicates in the genital, perigenital, or anal skin sites with seeding of the sacral ganglia (Fig. 8).

Operative definitions of the nature of the infection are of pathogenic relevance. Susceptible individuals (namely, those without preexisting HSV antibodies) develop primary infection after the first exposure to either HSV-1 or HSV-2. A recurrence of HSV is known as recurrent infection. Initial infection is when an individual with preexisting antibodies to one type of HSV (namely, HSV-1 or HSV-2) can experience a first infection with the opposite virus type (namely, HSV-2 or HSV-1, respectively). Reinfection with a different strain of HSV can occur, although it is extremely uncommon in the normal host, and is called *exogenous reinfection*.

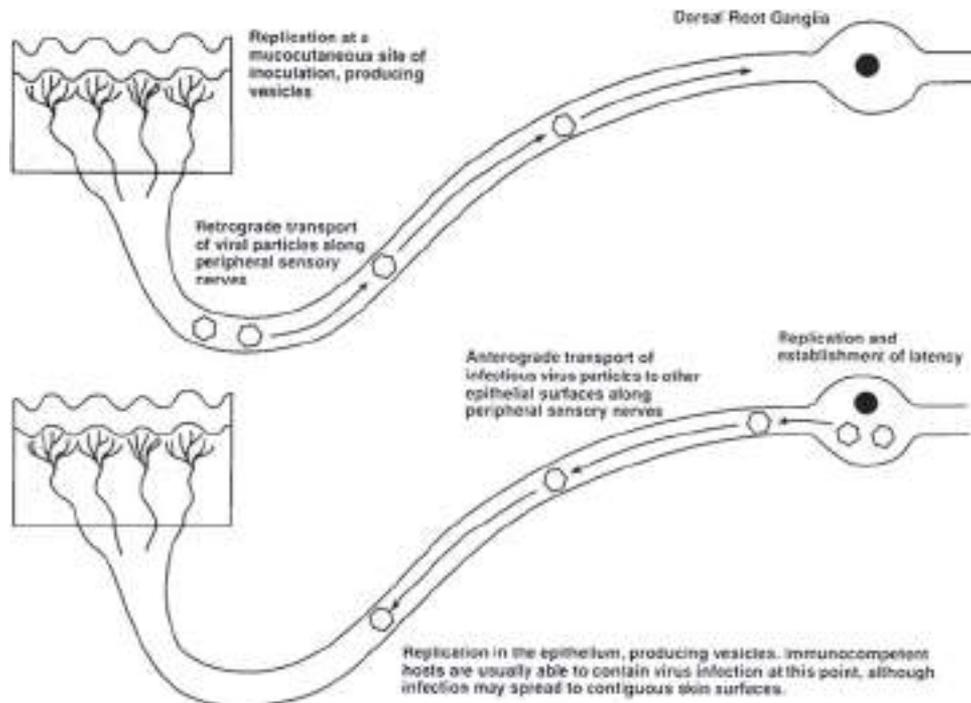

FIGURE 6 Schematic diagram of herpes simplex virus (HSV) infection.

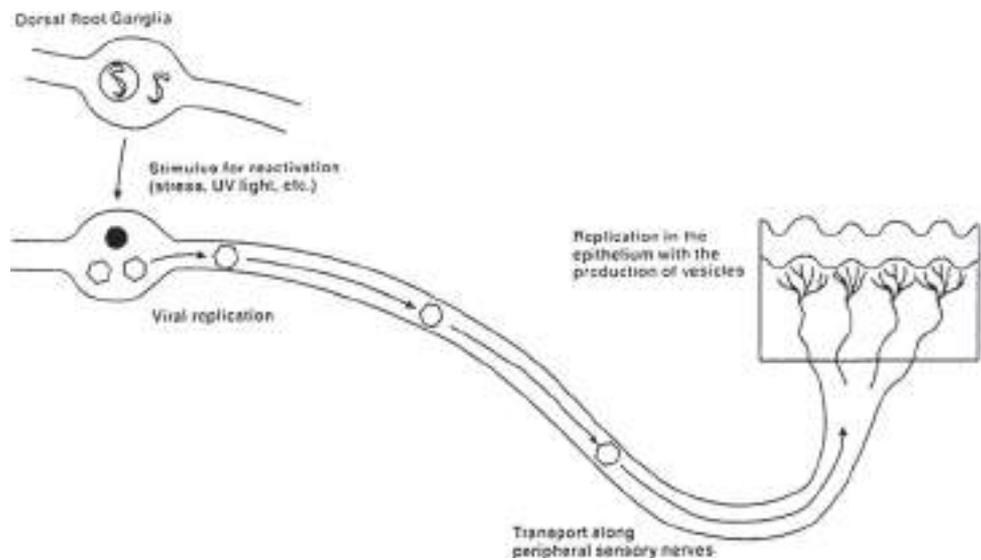

FIGURE 7 Schematic diagram of latency and reactivation.

Cleavage of HSV DNA by restriction endonuclease enzymes yields a characteristic pattern of subgenomic products. Analyses of numerous HSV-1 and HSV-2 isolates from a variety of clinical situations and widely divergent geographic area demonstrate that epidemiologically unrelated strains yield distinct HSV DNA fragment patterns. In contrast, fragments of HSV DNA derived from the same individual obtained years apart, from monogamous sexual partners, or following short and long passages *in vitro*, have identical fragments after restriction endonuclease cleavage (105). Utilizing endonuclease technology, exogenous reinfection is exceedingly low in the immune competent host.

**Immune Responses**

**Primary HSV Infection**

The host immune response to HSV infection has been recently reviewed (106). Following primary HSV infection, the initial, local immunological responses involve both

nonspecific defense mechanisms, namely IFN- $\alpha$  and IFN- $\beta$ , activated natural killer (NK) cells and macrophages, as well as HSV-specific responses, such as cytotoxic T cells (CTLs) (107) (see Chapter 16). The initial cellular response is synthesis and secretion of type I IFNs ( $\alpha$  and  $\beta$ ), leading to IFN-mediated activation of cellular enzymes such as 2'-5'-oligoadenylate synthetase (2'-5' AS) and dsRNA-dependent protein kinase, as well as intracellular signaling molecules through the activation of the Janus kinase (JAK)/STAT pathway. Relevant to HSV infection, IFN- $\alpha$  appears to inhibit IE gene expression (108). Thus, the antiviral mechanism directly affects transactivation of the IE responsive element necessary for synthesis of viral proteins.

IFNs also mediate macrophage and NK cell activation, activate CTLs, and induce major histocompatibility complex (MHC) class I and MHC class II antigens. In addition, cytokine secretion is stimulated, resulting in local inflammation. The role of IFN- $\gamma$  is less clear, although  $\gamma\delta$  T cells, NK cells, CD4<sup>+</sup> T cells, and possibly neurons produce IFN- $\gamma$

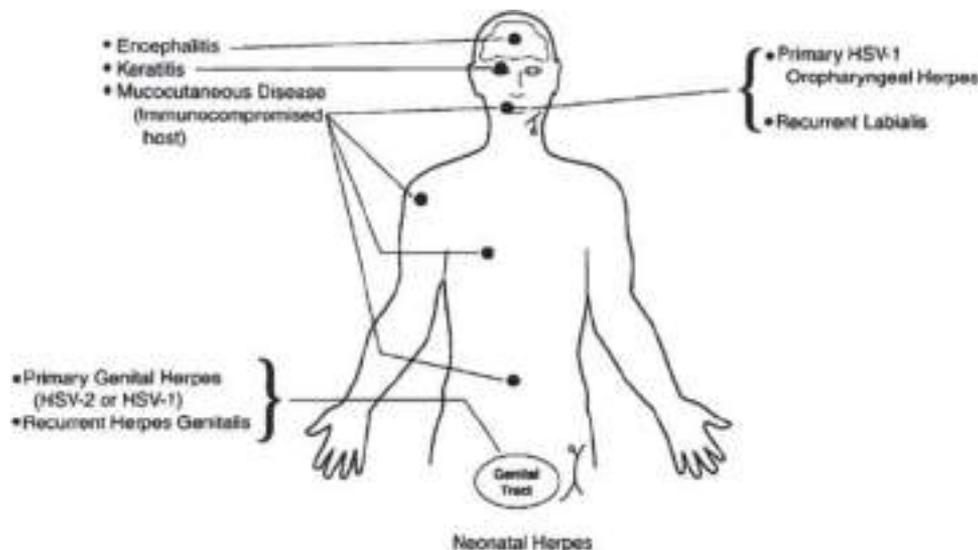

FIGURE 8 Sites of herpes simplex virus (HSV) infection and disease.

and TNF- $\alpha$  in response to HSV infection. IFN- $\gamma$  down-regulates priming of CD4<sup>+</sup> Th2 cells, which are responsible for inducing immunoglobulin (Ig) isotype B cell switching from IgA to IgG, thereby effecting humoral immune responses (109).

*In vitro* and *in vivo* experiments have demonstrated that NK cells protect from HSV challenge in a murine model (110). Severe herpetic disease has been correlated with low *in vitro* NK activity in newborns, as well as in a patient lacking NK cells (111). Other mononuclear cells, such as macrophages, are recruited to the site of infection, and upon activation, release immune cell mediators such as TNF and interleukins. Macrophages play a major role in mediating antibody-dependent cellular toxicity for viral clearance and antigen presentation (112).

As reviewed (106), an important aspect of immune responses to HSV infections is the maturation of dendritic cells (DCs) at the site of infection. Mobile DCs travel from mucosal or skin areas of infection and prime antigen-specific, naïve T-cells in draining lymph nodes (DLNs). In HSV-1 footpad infection of mice, fractionation of DC subpopulations in the DLN shows that classic CD8 $\alpha$ <sup>+</sup> dermal DCs, rather than specialized epidermal Langerhan's cells (LCs), prime naïve CD8<sup>+</sup> T cells (113). In the case of vaginal HSV-2 infection, dermal DCs rather than LCs again seem to be the physiologically active cell population in a similar DLN model (114). LCs are certainly able to present HSV antigens to memory HSV-specific T cells and may participate in primary or recurrent immune reactions. Plasmacytoid DCs (pDCs) react to HSV and produce IFN- $\alpha$  (115). pDCs are recruited to sites of infection, participate in viral clearance, and express relevant Toll-like receptors (TLRs), including TLR 7, 8, and 9, all of which recognize HSV (116, 117). Of interest, a low number pDCs or poor pDC reactivity is associated with severe human HSV infection (118, 119).

As infection progresses, virus-specific immune responses are detected. On days 4 and 5 postinfection, HSV-specific CD4<sup>+</sup> Th1 lymphocytes are detected in genital lymph nodes and in smaller numbers in the peripheral blood; they can subsequently be found in the genital mucosa (120). CD8 responses also occur quite quickly in the mouse (121); relevant human studies have not yet been reported.

Humoral immune responses rapidly follow initial HSV infection (106). The predominant mucosal antibodies are of the IgA isotype, which can be detected as early as day 3 following infection, peaking within the first 6 weeks after disease onset, and are followed by appearance of IgG1 and IgG3 subclasses of antibodies. HSV-specific IgA antibodies are present for at least 6 weeks, gradually decreasing to undetectable levels. IgM-secreting B cells have also been detected in secretions of the female genital mucosa (122). Shorter periods of viral shedding in women with primary genital herpes have been positively correlated with presence of secretory IgA in vaginal secretions (110).

### Recurrent Infections

Although immunosuppression enhances the frequency of reactivation, there is no proof that the immune system exerts any influence on reactivation at the level of the ganglia (123). Immunosuppression enhances the detection of HSV reactivation in the periphery. It is not clear if this is due to increased ganglionic reactivation or failure of control mechanisms in the skin to contain virus being delivered down the axon. HSV-specific CD8 and CD4 T cells persistently infiltrate latently infected trigeminal ganglia in mice and humans (124, 125). These cells appear to act via IFN- $\gamma$

(126). They have cytolytic activity, but neuron loss is not seen clinically, and inhibitory receptor-ligand pairings can be documented in the ganglia that may modulate their cytotoxic activity (127). In the periphery, HSV-2-specific CD4 and CD8 T cells localize to sites of recurrent HSV-2 infection and to the cervix (128, 129). Using *in situ* staining, HSV-2-specific CD8 CTLs have been shown to persist at the epidermal/dermal junction adjacent to sensory nerve endings (130). Damage to these cell populations in immunocompromised persons may lead to increased HSV replication either centrally or peripherally (112). Repeated subclinical episodes of HSV excretion may be a source of antigenic stimulation, leading to long-term HSV-specific immune memory (112). With recurrent HSV-2 infections, NK and HSV-specific CD4<sup>+</sup> cells are detected earlier than CD8<sup>+</sup> cells in genital lesions (109). CD4<sup>+</sup> T cells and, more recently, CD8<sup>+</sup> T cells have been highlighted as major mediators of viral clearance from mucocutaneous lesions in recurrent episodes (107, 128). Low IFN- $\gamma$  titers in vesicular fluid have been associated with a shorter time to the next recurrence in patients with frequent recurrences. T-cell proliferation is decreased in these patients in comparison to patients with less frequent recurrences (112). Inasmuch as the involvement of cytokines has been studied, IFN- $\gamma$  has been reported to have a role in viral clearance from mucocutaneous sites, whereas altered cytokine production appears to correlate with recurrence (131).

As with primary HSV infection, a shorter duration of viral shedding occurs in women with recurrent genital herpes who have detectable secretory IgA in vaginal secretions (110). IgA, IgG1, and IgG3 antibodies have been found in the sera of all patients with recurrent HSV-2 episodes, whereas IgM and IgG4 antibodies were detected in 70–80% of these patients. However, there does not appear to be clear correlation between humoral immune responses and disease prognosis (132).

### Newborn Infections

Host response of the newborn to HSV must be defined separately from that of older individuals, in part because of the immaturity of their host defense mechanisms. Other factors in defining host response of the newborn include the mode of transmission of the agent (viremia versus mucocutaneous infection without bloodborne spread), time of acquisition of infection, and the potential of increased virulence of certain strains, although this last point remains purely speculative. Two broad issues are of particular relevance in newborns. First, transplacentally acquired neutralizing antibodies and those mediating antibody-dependent cell-mediated cytotoxicity (ADCC) can either prevent or ameliorate infection in exposed newborns (133–135). Importantly, preexisting antibodies, indicative of prior infection, significantly decrease the transmission of infection from pregnant women to their offspring (57), contributing to the rationale for the development of a HSV vaccine.

Humoral IgG and IgM responses have been well characterized. Infected newborns produce IgM antibodies specific for HSV, as detected by immunofluorescence, within the first 3 weeks of infection. These antibodies increase rapidly in titer during the first 2–3 months, and they may be detectable for as long as 1 year after infection. The most reactive immunodeterminants are the surface viral glycoproteins, particularly gD. Humoral antibody responses have been studied using contemporary immunoblot technology, and the patterns of response are similar to those encountered in adults with primary infection (71, 136). The quantity of

neutralizing antibodies is lower in babies with disseminated infection (71, 136).

Second is the nature of immune responses mounted by HSV-infected newborns. The T-lymphocyte proliferative response to HSV infections is delayed in newborns compared to older individuals (71). Most infants have no detectable T-lymphocyte responses to HSV 2–4 weeks after the onset of clinical symptoms (71, 74, 137). The correlation between these delayed responses may be of significance in evaluating outcome to neonatal HSV infection. Specifically, if the response to T-lymphocyte antigens in children who have disease localized to the skin, eye, or mouth at the onset of disease is significantly delayed, disease progression may occur at a much higher frequency than in babies with a more appropriate response (71, 138).

Infected newborns have decreased production of IFN- $\alpha$  in response to HSV compared to adults with primary HSV infection (71). The importance of the IFN generation on the maturation of host responses, particularly the elicitation of NK cell responses, remains to be defined (139, 140). Lymphocytes from infected babies have decreased responses to IFN- $\gamma$  during the first month of life (71, 140, 141). These data taken together would indicate that the newborn has a poorer immune response than older children and adults. Antibodies plus complement and antibodies mixed with killer lymphocytes, monocytes, macrophages, or polymorphonuclear leukocytes will lyse HSV infected cells *in vitro* (94). ADCC is an important component of the development of host immunity to infection (88). However, the total population of killer lymphocytes of the newborn seems to be lower than that found in older individuals, and monocytes and macrophages of newborns are not as active as those of adults (3,142–145).

## CLINICAL MANIFESTATIONS

### Oropharyngeal Disease

#### Primary Infections

Great variability exists in the symptoms of primary HSV-1 infections. Asymptomatic infection is the rule rather than the exception and occurs twice as often as symptomatic infection. Manifestations of disease range from totally asymptomatic to combinations of fever, sore throat, ulcerative and vesicular lesions, gingivostomatitis, edema, localized lymphadenopathy, anorexia, and malaise. The incubation period ranges from 2 to 12 days with a mean of approximately 4 days. In a study of 70 children with serologically documented primary infection, only six (less than 10%) had clinical symptoms associated with infection (147). In an Australian study, 67.4% of seronegative children (29 of 43) developed HSV antibodies over a period of 1 year; 69% had asymptomatic infection. Importantly, asymptomatic infection occurs twice as often as symptomatic disease.

Primary HSV-1 infection results in oral shedding of virus in mouth for as long as 23 days (average of 7–10 days). The natural history of HSV-2 infection of the oropharynx is not well characterized. Neutralizing antibodies appear between days 4 and 7 after onset of disease and peak in approximately 3 weeks (5, 6).

Symptomatic disease in children is characterized by involvement of the buccal and gingival mucosa (Fig. 9). The duration of illness is 2–3 weeks, with fever ranging between 101°F and 104°F. Often, children with symptomatic primary infection are unable to take liquids orally because of the associated pain. Lesions within the mouth evolve from

FIGURE 9 Herpes simplex gingivostomatitis.

vesicles to shallow ulcerations on an erythematous base before healing. Submandibular lymphadenopathy is common with primary gingivostomatitis but rare with recurrent infections. Other findings include sore throat and mouth, malaise, tender cervical lymphadenopathy, and an inability to eat. A clinical distinction should be drawn between intraoral gingival lesions and lip lesions indicative of presumed primary and recurrent infections, respectively.

Primary HSV infections of adolescents and adults cause both pharyngitis and a mononucleosis syndrome (67). The differential diagnosis of both primary HSV gingivostomatitis and pharyngitis includes herpangina (usually caused by the coxsackieviruses), candidal infections of the mouth, Epstein-Barr virus-induced mononucleosis, lesions induced by chemotherapy or radiation therapy, and Stevens-Johnson syndrome.

#### Recurrent Infections

Recurrent infection may be asymptomatic, occurring in about 1% in children and 1–5% in immunocompetent adults (67, 147, 148, 150, 151). Nearly 1% of pregnant women and nursery personnel excrete HSV at any time (151), being a source of virus for transmission to the newborn. Asymptomatic excretion of virus is not limited to the healthy adult, as excretion of HSV in renal transplant recipients without signs or symptoms of disease occurs in nearly one-third of seropositive patients (152).

The onset of recurrent orolabial lesions is heralded by a prodrome of pain, burning, tingling, or itching, which generally lasts for 6 hours followed by the appearance of vesicles (149, 153). Vesicles appear most commonly at the vermilion border of the lip and persist for only 48 hours on the average (Fig. 10). Vesicles generally number three to five. The total area of involvement usually is localized, and lesions progress to the pustular or ulcerative and crusting stage within 72–96 hours. Pain is most severe at the outset and resolves quickly over 96–120 hours. Similarly, the loss of virus from lesions decreases with progressive healing over 2–3 days (66, 153). Healing is rapid, generally being complete in 8–10 days. The frequency of recurrences varies among individuals (153).

### Genital Disease

#### Primary and Initial Infections

Primary genital herpes manifests with macules and papules, followed by vesicles, pustules, and ulcers. Lesions persist

FIGURE 10 Recurrent herpes simplex labialis.

about 3 weeks (76, 154, 155). Primary infection is associated with larger quantities of virus replicating in the genital tract ( $>10^6$  viral particles/0.2 ml of inoculum) and a period of viral excretion, which may persist for 3 weeks. Systemic complications in the male are relatively uncommon; however, aseptic meningitis can develop. Paresthesias and dysesthesias which involve the lower extremities and perineum can result from genital herpetic infection.

Primary infections are usually associated with fever, dysuria, localized inguinal adenopathy, and malaise in both men and women. The severity of primary infection and its association with complications are statistically higher in women than in men (76, 156). Systemic complaints are common in both sexes, approaching 70% of all cases. The most common complications include aseptic meningitis and extragenital lesions.

In women with primary infection, lesions appear on the vulva and are usually bilateral, as shown in Fig. 11, with the cervix invariably involved. The actual frequency of primary cervical infection in the absence of vulvar infection is unknown. Lesions usually are excruciatingly painful, associated with inguinal adenopathy and dysuria, and may involve the vulva, perineum, buttocks, cervix, and vagina. A urinary retention syndrome occurs in 10–15% of female patients, and as many as 25% of women will develop aseptic meningitis.

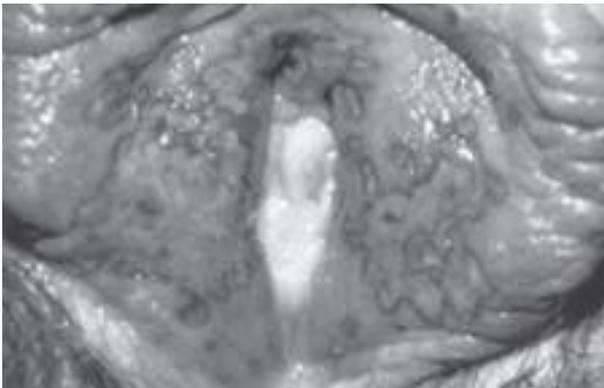

FIGURE 11 Genital herpes simplex virus infection (female).

In males, primary genital HSV infections are most often associated with vesicular lesions superimposed upon an erythematous base, usually appearing on the glans penis or the penile shaft, as shown in Fig. 12. The total number of lesions can vary significantly from 6 to 10 to many more. Extragenital lesions of the thigh, buttocks, and perineum can occur.

Complications following primary genital herpetic infection have included sacral radioculomyelitis, which can lead to urinary retention, neuralgias, and meningoencephalitis. Paresthesias and dysesthesias, which involve the lower extremities and perineum, may occur. Primary perianal and anal HSV-2 infections, as well as associated proctitis, are more common in male homosexuals. As with HSV-1 infections, as many as two-thirds of HSV-2 infections are subclinical, involving the mouth (73) or the uterine cervix (75, 92, 93). Nonprimary initial genital infection is less severe symptomatically, and heals more rapidly. The duration of infection is usually 2 weeks. The number of lesions, severity of pain, and likelihood of complications are significantly decreased. Preexisting antibodies to HSV-1 have an ameliorative effect on disease severity of HSV-2 (89).

### Recurrent Infections

With recurrent genital herpetic infection, a limited number of vesicles, usually three to five, appear on the shaft of the penis of the male or as simply a vulvar irritation in the female. The duration of disease parallels that encountered with recurrent HSV labialis, being approximately 7–10 days. Neurologic or systemic complications are uncommon with recurrent disease; however, paresthesias and dysesthesias occur. Virus is shed for an average of 2–5 days and at lower concentrations (approximately  $10^2$ – $10^3$ /0.2 ml of inoculum in tissue culture systems) in women with recurrent genital infection. Recurrent genital herpetic infection in both men and women is characterized by prodrome, which is a useful marker for therapeutic trials and by localized irritation.

The frequency of recurrences varies from one individual to the next. Recurrences are more frequent in the first year after primary infection, and the severity of primary infection appears to correlate positively with the likelihood and

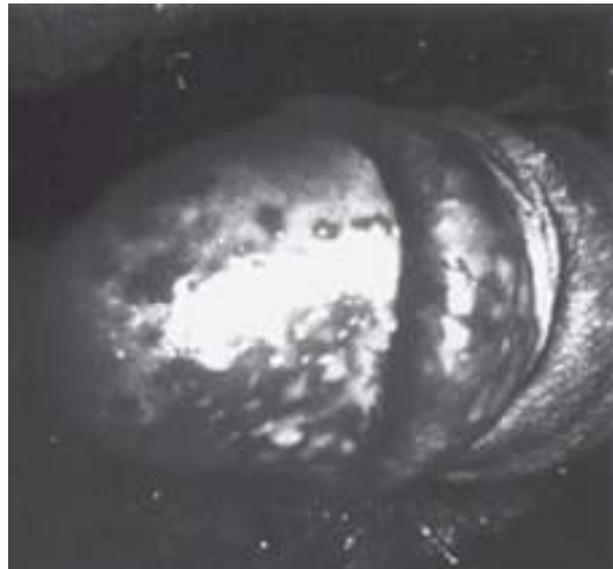

FIGURE 12 Genital herpes simplex virus infection (male).

frequency of symptomatic recurrences. One-third of infected individuals are estimated to have clinical recurrences in excess of eight or nine per year, one-third will have two to three per year, and the remaining one-third will have between four and seven (76). Individuals can transmit infection to sexual partners with symptomatic or, more commonly, asymptomatic recurrences. A high frequency of HSV DNA is detected by PCR in genital secretions between clinical recurrences (157). Many virologic recurrences may only be hours in duration (158). The implications of these data require the education of patients, including behavioral interventions and use of condoms to prevent transmission of infection.

### Pregnancy and Neonatal Infection

An uncommon problem encountered with HSV infections during pregnancy is that of widely disseminated disease in the mother (159), involving multiple visceral sites and sometimes cutaneous dissemination. Dissemination after primary oropharyngeal or genital infection has led to necrotizing hepatitis with or without thrombocytopenia, disseminated intravascular coagulopathy, and encephalitis. The mortality rate among affected pregnant women is reported to be greater than 50%. Fetal deaths have also occurred in more than 50% of cases, although mortality did not necessarily correlate with the death of the mother. Factors associated with pregnancy may place both mother and fetus at increased risk for severe infection, possibly because of altered cell-mediated immunity.

The major risk to the fetus is primary or initial genital HSV infection of the mother during the third trimester of gestation (93, 103). Thus, identification of the woman at risk for primary infection is of paramount importance. Serologic discordance averages 15–20% such that the mother is HSV-2 seronegative and her partner is HSV-2 seropositive. The associated risk for transmission from the father is 10–15% during the pregnancy.

Maternal primary infection prior to 20 weeks gestation in some women has been associated with spontaneous abortion (160) in about 20% of pregnancies. The contribution of primary maternal genital infection to spontaneous abortion must be weighed above that of a routine rate of fetal loss of approximately 20%. Infection that develops later in gestation has not been associated with the termination of pregnancy, but infection of the fetus during maternal primary infection may result in manifestations of neonatal HSV disease, severe intrauterine growth retardation, or premature termination of gestation (161).

### Neonatal Disease

The estimated incidence of neonatal HSV is approximately one in 2000 to one in 5000 live births annually in the United States. An increase in the number of cases of neonatal HSV infection has been noted in some areas, with rates approaching one in 1500 deliveries. Four factors influence the risk of HSV transmission of infection from mother to fetus. First the risk of transmission is 30–50% with maternal primary or initial infection as compared to 3% or less with recurrent infection (76, 103, 154). Second, paralleling the type of maternal infection, the mother's antibody status before delivery influences both the severity of infection and the likelihood of transmission. Transplacental maternal neutralizing and ADCC-mediating antibodies have at least an ameliorative effect on acquisition of infection for babies inadvertently exposed to virus at delivery (162). Third, prolonged rupture of membranes (greater than 6 hours) increases the risk of HSV acquisition as a consequence of as-

ending infection from the cervix. Fourth, fetal scalp monitors can be a site of inoculation of virus. Such devices should be relatively contraindicated in women with a history of recurrent genital HSV infection.

Infection of the newborn can be acquired at one of three times, and in all cases, the mother is the most common source of infection. First, *in utero* infection is rare and requires (163) stringent diagnostic criteria (namely, identification of infected babies within the first 48 hours of life who have virologic confirmation of infection). The second route of infection is that of intrapartum contact of the fetus with infected maternal genital secretions. Approximately 75–80% of babies acquire HSV infection by this route. The third route of transmission is postnatal acquisition. Although HSV-1 is associated with genital lesions, postnatal transmission of HSV-1 is increasingly suggested, with 15–20% of neonatal HSV infections caused by this type (3). Relatives and hospital personnel with orolabial herpes can be a reservoir for HSV infection of the newborn. The documentation of postnatal transmission of HSV has focused attention on such sources of virus for neonatal infection (164). Identical isolates, as demonstrated by restriction endonuclease technology, from babies born to different mothers in a nursery is rare. Postnatal transmission from mother to child has been documented as a consequence of nursing on an infected breast. Father-to-baby transmission has been documented from lesions of herpes labialis.

### Clinical Presentation

Neonatal HSV infection is almost invariably symptomatic and frequently lethal. Babies with congenital infection should be identified within 48 hours following birth. Those babies who are infected intrapartum or postnatally with HSV infection can be divided into three categories—those with (118) disease localized to the skin, eye, and mouth (SEM) (165); encephalitis with or without skin involvement (40); and disseminated infection that involves multiple organs, including CNS, lung, liver, adrenals, skin, eye, and/or mouth (166).

### Intrauterine Infection

Intrauterine infection is apparent at birth and is characterized by the triad of skin vesicles or skin scarring, eye disease, and the far more severe manifestations of microcephaly or hydranencephaly. Often, retinitis alone or in combination with other eye findings, such as keratoconjunctivitis, is a component of the clinical presentation. The frequency of occurrence of these manifestations is estimated to be one in 200,000 deliveries.

### Disseminated Infection

Babies with the highest mortality present for therapy between 9 and 11 days of age. However, signs of infection usually begin on an average of 4–5 days earlier. With the early introduction of antiviral therapy, about 23% of babies with neonatal HSV infection have disseminated disease. The principal organs involved are the liver, lungs, and adrenals, but other involved organs include the larynx, trachea, esophagus, stomach, gastrointestinal tract, spleen, kidneys, pancreas, and heart. Constitutional signs and symptoms include irritability, seizures, respiratory distress, jaundice, bleeding diatheses, shock, and, frequently, the characteristic vesicular exanthem, which is often considered pathognomonic for infection. Encephalitis appears to be a common component of disseminated infection, occurring in about 60–75% of children. The vesicular rash, as described

below, is particularly important in the diagnosis of HSV infection. However, over 20% of these children do not develop skin vesicles during the course of illness (3, 167). Mortality in the absence of therapy exceeds 80%; all but a few survivors are impaired. The most common cause of death in babies with disseminated disease is either HSV pneumonitis or disseminated intravascular coagulopathy.

### Encephalitis

Nearly one-third of all babies with neonatal HSV infection have encephalitis. Babies with infection of the CNS alone or in combination with disseminated disease present with the findings indicative of encephalitis in the newborn. Brain infection occurs either as a component of multiorgan disseminated infection or only as encephalitis with or without SEM involvement. The pathogenesis of these two forms of brain infection is likely different. Babies with disseminated infection probably seed the brain by a bloodborne route, resulting in multiple areas of cortical hemorrhagic necrosis. In contrast, babies who present with only encephalitis likely develop brain disease as a consequence of retrograde axonal transport of virus to the CNS. Two pieces of data support this contention. Babies with disseminated disease have documented viremia and are hospitalized earlier in life than those with only encephalitis, 9–10 days versus 16–17 days, respectively. Babies with encephalitis alone are more likely to receive transplacental neutralizing antibodies from their mothers, which may prevent viremia, allowing for only intraneuronal transmission of virus to the brain.

Clinical manifestations of either encephalitis (alone or in association with disseminated disease) include seizures (both focal and generalized), lethargy, irritability, tremors, poor feeding, temperature instability, bulging fontanelle, and pyramidal tract signs. Children with encephalitis without disseminated disease have skin vesicles in approximately 60% of cases at any time during the disease course (3, 167). Virus can be cultured from cerebrospinal fluid (CSF) in 25–40% of all cases. CSF findings usually include pleocytosis and proteinosis (as high as 500–1000 mg/dl), although a few babies with CNS infection have no CSF abnormalities. Death occurs in 50% of babies with CNS disease who are not treated and is usually related to brain stem involvement.

With rare exceptions, survivors are left with severe neurologic impairment. The long-term prognosis following either disseminated infection or encephalitis is poor. As many as 50% of surviving children have some degree of psychomotor retardation, often in association with microcephaly, hydranencephaly, porencephalic cysts, spasticity, blindness, retinitis, or learning disabilities.

The diagnosis of encephalitis can be challenging. For children with disease localized to the CNS, skin vesicles, the classic sign of disease, may not be present in as many as 40% of babies. Thus, for the baby with CSF pleocytosis and protein elevation at 2–3 weeks of life, other diagnostic clues, such as skin vesicles, may not be present. For the neonate with CSF findings indicative of infection, HSV must be considered along with other bacterial pathogens (e.g., group B streptococcus, *Escherichia coli*, etc.). A reasonable diagnostic approach, if all antigen and Gram stain studies are negative, would be serial CSF examinations to document progression in protein and mononuclear cell counts.

### Skin, Eye, and/or Mouth Infection

Infection localized to the SEM is associated with morbidity and not mortality. Vesicles occur in 90% of children with SEM infection. When infection is localized to the skin, the presence of discrete vesicles remains the hallmark of disease. Clusters of vesicles often appear initially on the part of the body that was in direct contact with the virus during birth. With time, the rash progresses to involve other areas of the body as well, particularly if viremia occurs. Vesicles occur in 90% of children with SEM infection. Children with disease localized to the SEM generally present at about 10–11 days of life. Babies with skin lesions invariably will suffer from recurrences over the first 6 months (and longer) of life, regardless of whether therapy was administered. Approximately 30% of these children eventually develop evidence of neurologic impairment in the absence of therapy (4). The skin vesicles (Fig. 13) usually erupt from an erythematous base and are usually 1–2 mm in diameter. Other manifestations of skin lesions include a zosteriform eruption. Infections involving the eye manifest as keratoconjunctivitis, or later, as retinitis. The eye can be the only site of HSV involvement in the newborn.

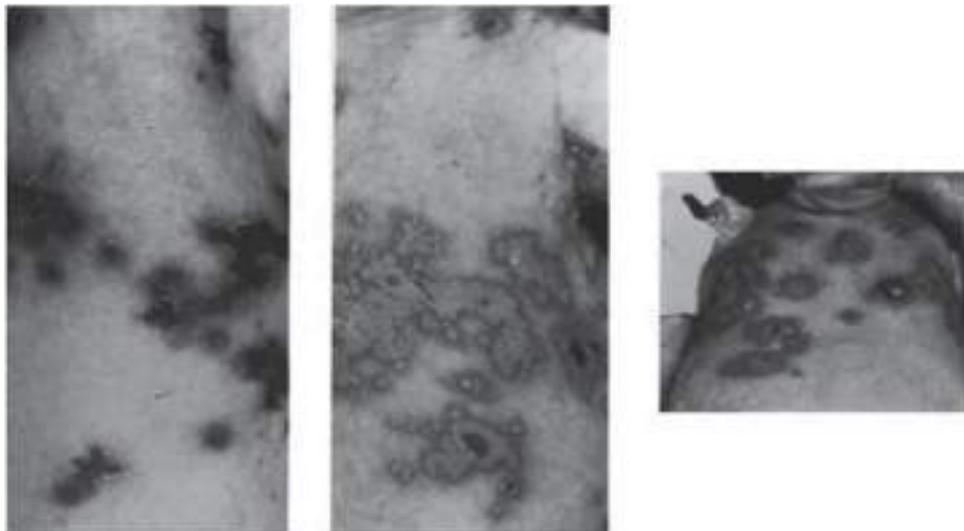

FIGURE 13 Vesicular rash of neonatal herpes simplex virus infection.

Long-term neurologic impairment may develop in children whose disease appears localized to the SEM. The significant findings include spastic quadriplegia, microcephaly, and blindness. Despite normal clinical examinations in these children, neurologic impairment has become apparent between 6 months and 1 year of life.

#### Prognostic Factors

Babies with the most severe disease have worse outcomes, as identified by disease classification (145). Level of consciousness also predicts a poor prognosis, as does the development of HSV pneumonia or disseminated intravascular coagulopathy. With encephalitis, prematurity and seizures predict a poor outcome. Finally, for babies with SEM disease, frequently recurrent HSV-2 cutaneous lesions define a group at risk for a poor neurologic outcome.

Application of PCR technology to CSF evaluation at the time of presentation SEM disease has identified a subgroup of babies with detectable HSV DNA. This group of children has asymptomatic infection of the CNS and accounts for those who develop neurologic impairment (168).

#### Herpes Simplex Keratoconjunctivitis

Viral infections of the eye beyond the newborn age are usually caused by HSV-1 (169). Approximately 300,000 cases of HSV infections of the eye are diagnosed annually in the United States where these infections are second only to trauma as the cause of corneal blindness. Herpetic keratoconjunctivitis is associated with either unilateral or bilateral conjunctivitis, which can be follicular in nature, followed soon thereafter by preauricular adenopathy. Eye infection is also associated with photophobia, tearing, eyelid edema, and chemosis, accompanied by the pathognomonic findings of branching dendritic lesions. Less commonly, with advanced disease, the infection is associated with a geographic ulcer of the cornea. Healing of the cornea can take as long as 1 month, even with appropriate antiviral therapy.

Recurrence frequency is similar to that for herpes labialis. Most frequently, lesions are unilateral in involvement, but a small percentage of cases involve both eyes. Characteristically, either dendritic ulceration or stromal involvement occurs. Visual acuity is decreased in the presence of the ulcers; and with progressive stromal involvement, opacification of the cornea may occur. Progressive disease can result in visual loss and even rupture of the globe.

#### Skin Infections

Infections of the digits, known as herpetic whitlow, are particularly common among medical and dental personnel. The estimated incidence is 2.4 cases per 100,000 population per year, being caused by HSV-1 or HSV-2. An increasing incidence of HSV-2 herpetic whitlow has been reported (170).

The prevalence of HSV skin infections in Skaraborg, Sweden, has been assessed among approximately 7500 individuals over 7 years of age and was found to be about 1% in those aged 7 years and older. In another Swedish study performed in dermatology clinics, 2% of men and 1.5% of women had evidence of herpetic skin infections over a 6-year period. In addition to individuals with atopic disease, patients with skin abrasions or burns appear particularly susceptible to HSV-1 and HSV-2 infections, and some develop disseminated infection (171).

Skin infections caused by HSV generally manifest as eczema herpeticum in patients with underlying atopic dermatitis, as reviewed in Chapter 8. Lesions can either be localized, resembling herpes zoster, or disseminated, as occurs

with Kaposi's varicella-like eruption. Disseminated HSV infections have been reported among wrestlers (herpes gladiatorum) (143). Burn patients are also at increased risk of severe skin infections, especially at sites of active epithelial regeneration. Other skin disorders associated with extensive cutaneous lesions include Darier's disease and Sezary's syndrome. As would be predicted, localized recurrences followed by a second episode of dissemination were observed. HSV infections of either type can trigger erythema multiforme (142). The detection of HSV DNA in skin lesions of erythema multiforme is as high as 80%.

#### Infections of the Immunocompromised Host

Patients compromised by immune therapy, underlying disease, or malnutrition are at increased risk for severe HSV infections. Renal, hepatic, bone marrow, and cardiac transplant recipients are all at high risk for increased severity of HSV infection (172) (Fig. 14). In organ transplant recipients, the presence of antibodies to HSV before treatment predicts the individual at greatest risk for recurrence (152). These patients may develop progressive disease involving the respiratory tract, esophagus, or even the gastrointestinal tract. The severe nature of progressive disease in these patients appears to be directly related to the degree of immunosuppressive therapy employed. Esophagitis is a common occurrence in the immunocompromised host and can be caused by HSV, CMV, or *Candida albicans*. Notably, acyclovir-resistant HSV disease can develop in treated immunocompromised hosts and be progressive. Reactivation of latent HSV infections in these patients can occur at multiple sites, and healing occurs over an average of 6 weeks (173).

Since the first reports of acquired immunodeficiency syndrome (AIDS), the increased frequency and severity of HSV clinical disease in these severely immunocompromised hosts was evident (174), especially in those with low CD4 counts. Because of persistent and high-level viral replication, resistance to antiviral therapy can develop. Asymptomatic excretion of HSV can occur even in the immunocompromised host. Parenthetically, acquisition of HSV infection from a transplanted organ (kidney) has been reported (175).

#### Infections of the CNS

Herpes simplex encephalitis is the most devastating of all HSV infections (Fig. 15) and is considered the most common

FIGURE 14 Cutaneous dissemination of herpes simplex virus infection in an immunosuppressed host.

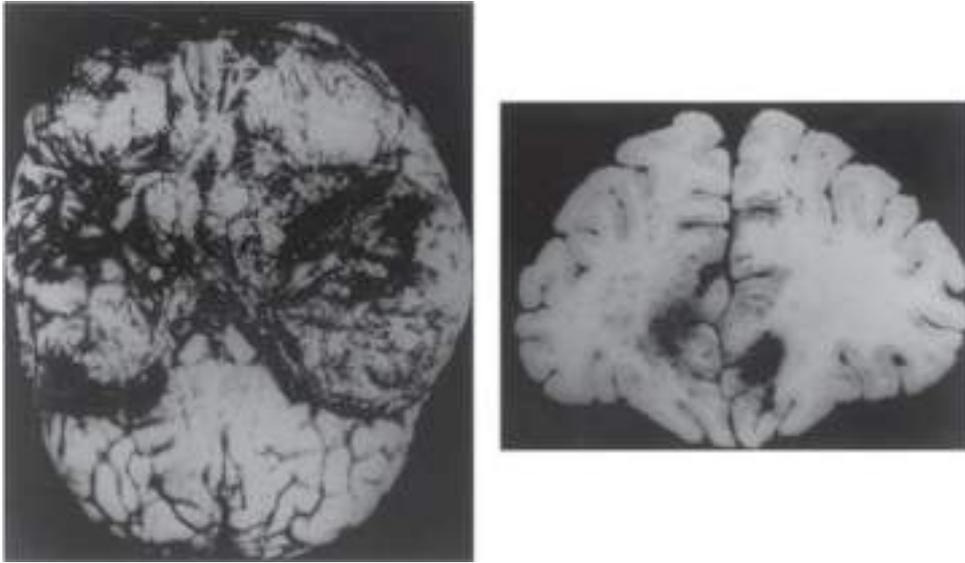

FIGURE 15 Coronal section of brain from patient with herpes simplex encephalitis.

cause of sporadic, fatal encephalitis (176). The incidence of severe hemorrhagic focal encephalitis is approximately one in 200,000 individuals per year, for a national annualized rate of approximately 1250 cases in the United States.

The manifestations of HSV encephalitis in the older child and adult are indicative of the areas of the brain affected, classically localized temporal lobe disease (166, 177). These include primarily focal encephalitis associated with fever, altered consciousness, bizarre behavior, disordered mentation, and localized neurologic findings. Clinical signs and symptoms reflect localized temporal lobe disease (166, 177). No signs are pathognomonic for HSV, but progressively deteriorating level of consciousness, expressive aphasia, bizarre behavior, fever, an abnormal CSF formula, and focal neurologic findings in the absence of other causes should make this disease highly suspect. Diagnostic evaluations should be initiated immediately, as other treatable diseases mimic HSV encephalitis. Mortality in untreated patients is in excess of 70%, and only 2.5% of untreated patients return to normal neurologic functions.

Standard neurodiagnostic procedures include CSF examination, electroencephalogram, and preferably a magnetic resonance image. Characteristic CSF abnormalities include pleocytosis (usually mononuclear) and elevated protein. Red blood cells are found in most (but not all) CSFs obtained from patients with HSV encephalitis. Upon serial examination, CSF protein levels and cell counts rise dramatically. The electroencephalogram generally localizes spike and slow-wave activity to the temporal lobe. A burst suppression pattern is characteristic of HSV encephalitis. Imaging will allow for localization of disease to the temporal lobe. Early after onset, only evidence of edema is detectable, if at all. This finding is followed by evidence of hemorrhage and midline shift in the cortical structures. Specific diagnostic assays are delineated below.

### Other Neurologic Syndromes

In addition to encephalitis, HSV can involve virtually all anatomic areas of the nervous system, causing meningitis, myelitis, radiculitis, and other syndromes. Aseptic meningitis is a common occurrence in individuals with primary genital HSV infections.

### Other Forms of Infection

HSV has been isolated from the respiratory tract of adults with adult respiratory distress syndrome and acute onset bronchospasm (139). Both were associated with increased mortality and morbidity.

### Genetic Susceptibility

Genetic susceptibility to HSV infections is attracting increasing attention, as noted above with the CSSG-1. A growing body of evidence has defined a polymorphism resulting in an IFN- $\gamma$  defect that has been reported in children with recurrent herpes encephalitis (178).

Furthermore, numerous reports have incriminated or refuted human leukocyte antigen (HLA) associations with human HSV infections. For recurrent fever blisters, these studies have included HLA-A1, HLA-A2, HLA-A9, HLA-BW16, and HLA-CW2. Recurrent ocular HSV infections have been associated with HLA-A1, HLA-A2, HLA-A9, and HLA-DR3 (44).

## LABORATORY DIAGNOSIS

### Polymerase Chain Reaction

The use of PCR is the diagnostic method of choice for HSV infections of the CNS (179, 180) and is rapidly replacing culture for routine skin and mucosal site infections because of its sensitivity. The sensitivity of PCR exceeds culture for detection of infection in genital and labial herpes (182).

Primers from an HSV DNA sequence common to both HSV-1 and HSV-2 (either the glycoprotein B domain or HSV DNA polymerase) can identify HSV DNA in CSF. The evaluation of CSF specimens obtained from patients with biopsy proven herpes simplex encephalitis (HSE) and those with proven other diseases indicates a sensitivity >95% at the time of clinical presentation and a specificity that approaches 100% (179, 181). False-negative assessments can be found when there is hemoglobin contamination in the CSF or the presence of inhibitors, such as heparin. Likely, PCR analyses of CSF specimens continue to reinforce the focal presentation of HSV infections of the CNS. Importantly, PCR evaluation of CSF can be used to

follow therapeutic outcome in patients with HSE. Persistence of HSV DNA in the CSF of newborns with suspected HSE requires continued therapy. The sensitivity of PCR exceeds culture for detection of infection in genital and labial herpes (182).

### Cell Culture

Virus isolation remains an important diagnostic tool, especially if resistance is suspected. If skin lesions are present, a scraping of skin vesicles should be made and transferred in appropriate virus transport medium to a diagnostic virology laboratory. Clinical specimens should be shipped on ice for inoculation onto cell cultures (e.g., human foreskin fibroblasts, Vero cells, etc.), which are susceptible to cytopathic effects characteristic of HSV replication. Cytopathic effect usually develops within 24–48 hours after inoculation of specimens containing infectious virus, thus the shipping and processing of specimens should be expedited. In addition to skin vesicles, other sites from which virus may be isolated include the CSF, stool, urine, throat, nasopharynx, and conjunctivae. Duodenal aspirates from infants with hepatitis or other gastrointestinal abnormalities are useful for HSV isolation. Because outcome with treatment does not appear to be related to the virus type, identification is only of epidemiologic and pathogenetic importance, and, therefore, not usually necessary.

### Cytologic Evaluation

Cytologic examination of cells from the maternal cervix or from the infant's skin, mouth, conjunctivae, or corneal lesions is of low sensitivity, being approximately 60–70%, and is not recommended (85). Cellular material obtained by scraping the periphery of the base of lesions should be smeared on a glass slide and fixed promptly in cold ethanol. The slide can be stained according to the methods of Papanicolaou, Giemsa, or Wright before examination by a trained cytologist. Giemsa or Tzanck smears likely will not demonstrate the presence of intranuclear inclusions. The presence of intranuclear inclusions and multinucleated giant cells are indicative, but not diagnostic, of HSV infection, as varicella-zoster virus induces the same histopathology. Electron microscopy assays are available but impractical.

### Serologic Assessment

Serologic diagnosis of HSV infection is of little clinical value for purposes of therapeutic intervention but can assist in counseling sexually active individuals. Serologic assays that distinguish HSV-1 from HSV-2 are commercially available, being type specific. These tests are predicated on the use of gG-1 and gG-2 antigens and can assist physicians counseling individuals, i.e., discordant serologic status between sexual partners. The use of enzyme-linked immunoassay (ELISA) antibody assays only allows definition of past infection or recent seroconversion, but cannot distinguish HSV-1 from HSV-2. Other commonly used tests for measurement of HSV antibodies are complement fixation, passive hemagglutination, neutralization, and immunofluorescence.

## PREVENTION

### Education

Because of the increasing incidence of genital herpes and neonatal herpes and its association with acquisition of HIV, every effort should be made to prevent HSV-2 infections. Until a vaccine is proven effective, educational efforts must

be developed for adolescents and adults at greatest risk. The use of condoms should be promoted.

### Neonatal HSV Infection

The detection of type-specific antibodies to gG-2 will be of value in identifying those women at greatest risk. Documentation of discordant serologic status between sexual partners may assist in prevention of maternal primary infection. Clearly, male partners who are seropositive should be educated regarding HSV transmission.

Surgical abdominal delivery will decrease transmission of infection when membranes are ruptured less than 4 hours, but cesarean section has not been proven efficacious when membranes are ruptured for longer periods of time. Nevertheless, cesarean section is recommended when membranes are ruptured up to 24 hours in the presence of active lesions. Although the recommendation seems logical, no data exist to support it.

For women with a past history of genital HSV infection, a careful vaginal examination at presentation to the delivery suite is of paramount importance. Visualization of the cervix is often difficult, but speculum examination for documentation of recurrent lesions is important and should be attempted in all women. A culture for HSV obtained at the time of delivery can be of value in establishing whether excretion can lead to transmission of infection to the fetus. Clearly, identifying women who excrete HSV at delivery and then using either antiviral prophylaxis in the neonate with safe and acceptable antivirals or delivery by cesarean section remains the optimal management of genital infection at delivery.

For babies born to women with known primary infections during the third trimester, routine prophylaxis of the newborn with acyclovir is recommended by the American Academy of Pediatrics (183). On the other hand if the child is born in the presence of lesions, surface cultures are indicated and therapy initiated. If cultures are negative, treatment can be discontinued (183). An algorithm for managing these babies has been developed (184).

### Nosocomial Transmission

At many institutions, a policy that requires transfer or provision of medical leave for nursery personnel who have a labial HSV infection is impractical and causes an excessive burden in those attempting to provide adequate care. Temporary removal of personnel who have cold sores has been suggested. Individuals with herpetic whitlows also shed virus, and these individuals should be removed from the care of newborns at risk for acquiring neonatal HSV infection because even gloves may not prevent transmission of infection. Education regarding the risks of transmission of virus and the importance of hand washing when lesions are present should be repeatedly emphasized to healthcare workers. In addition, hospital personnel should wear masks when active lesions are present.

## VACCINE DEVELOPMENT

Development of an HSV vaccine has been attempted for over a century, but remains investigational at present. Two approaches have attracted the most attention, as reviewed (68, 106). The first is based on either microorganisms or cell lines producing gB or gD2 for use as subunit vaccines in combination with an adjuvant. The second is based on genetically engineering the virus to yield either a live, attenuated vaccine from which putative neurovirulence and immune evasion sequences have been removed or to produce a vaccine virus that is only capable of a single round of

replication. Each of these approaches has been evaluated extensively in animal models and to varying extents in human investigations. Extrapolating protection from animal model systems to humans has not been possible because there are no validated markers of protection comparable to neutralizing antibodies for other viral diseases (165,185–191). Initial HSV vaccines were oriented toward the prevention of recurrent infections and thus considered therapeutic vaccines, whereas more recent efforts have been devoted to the prevention of HSV infection or disease following exposure to an infected partner.

### Subunit Vaccines

A history of HSV vaccines and basis for failure appears elsewhere (106, 192), and we will focus here on the current approaches. Subunit vaccines have been studied extensively, evolving from attempts to avoid viral DNA. In addition, these vaccines eliminate the potential for cellular transformation, enhance antigenic concentration, and induce stronger immunity as well as exclude any possibility of residual live virus contamination (193). Current subunit vaccines have been prepared by a variety of methods combining antigen extraction from infected cell lysates by detergent and subsequent purification; immunogenicity of vaccines derived from all of the envelope glycoproteins, free of viral DNA, has been demonstrated in animals (194–197). However, vaccination with envelope glycoproteins does not protect uninfected sexual partners against genital HSV infection (198, 199).

Specific subunit vaccines have been developed by cloning selected glycoproteins in either yeast or Chinese hamster ovary cell systems (186, 200, 201), as well as by other methods (202–204). When studied in a variety of animal models (205, 206), neutralizing antibodies can be detected in vaccinated animals, and in some systems, binding antibodies as well (207). In these systems the quantity of neutralizing antibody correlates with the degree of protection upon challenge. Because each of these models utilized different routes of challenge and different viral inocula, interpretation of these results is extremely difficult. In general, the subunit vaccines elicit a degree of protection, as evidenced by amelioration of morbidity and reduction in mortality in immunized animals. Several injections and an appropriate adjuvant are required to induce protection (208, 209). Notably, protection in the rodent is significantly easier than in primate species. This may be especially the case because the HSV is not indigenous to rodent species, and thus protection studies may be totally irrelevant when evaluating human responses. Vaccination of primates, specifically rhesus monkeys (205), chimpanzees (194, 205), and rhesus monkeys (210), induces neutralizing antibodies, leading to an amnestic response following subsequent immunization months later. The significance of the protection in these animals remains unclear for human prophylaxis.

Clinical trials have evaluated gB2 plus gD2 and gD2 alone subunit vaccines in humans. One of the earliest human vaccine studies was with a glycoprotein envelope subunit vaccine (198, 199, 210, 211). In sexual partners of patients known to have genital herpes, the number of individuals developing herpetic infection was nearly equal between placebo and vaccine recipients; thus, vaccination failed to provide any benefit at all. However, vaccine immunogenicity was poor because it induced ELISA antibody titers to HSV-2 glycoproteins D (gD2) and B (gB2) that were only 10% and 5%, respectively, of titers found in persons with recurrent genital HSV-2 infection (196).

Subsequent gB2 plus gD2 and gD2 alone subunit vaccines incorporated unique adjuvants, namely MF59, potent for Th-2 responses, and AS04 (50 µg of 3-O-desacyl-4'-monophosphoryl lipid A (212) and 500 µg of aluminum hydroxide). Both afforded a high level of protection from HSV disease in animal models (208, 213), and notably elicited higher neutralizing antibody and the total HSV antibody titer (as measured by ELISA) titers than following infection by wild-type virus. Furthermore, these antibody titers correlated with protection from disease (214, 215).

In Phase III studies, the combined antigen vaccine-induced antibody titers exceeded those found in individuals who had HSV-2 infection. However, the vaccine failed to provide significant long-term prevention of infection in susceptible sexual partners, although 50% reduction in the rate of infection among HSV seronegative women was present for the first 5 months (216). The overall efficacy of the vaccine for 1 year following a 6-month vaccination period was 9%. The vaccine had no apparent effect on the frequency of recurrences amongst vaccine recipients who became infected (217).

The monovalent gD2 vaccine (134) is a potent inducer of Th1 responses (218) and the vaccine induces robust humoral and cellular immune responses in vaccinees. The vaccine-induced titers of HSV gD-specific antibody are higher than those observed in patients who had sexually acquired genital HSV-2 infection (219). In controlled studies, women who were seronegative for both HSV-1 and HSV-2 were significantly protected from disease (72% efficacy;  $p=0.01-0.02$ ), and there was a trend toward protection against infection (43% efficacy;  $p=0.06-0.07$ ). However, in individuals seropositive for HSV-1, irrespective of sex, and seronegative men, no significant clinical benefit could be demonstrated. A Phase III study sponsored by the National Institutes of Health failed to protect against HSV-2 but did impact HSV-1. Likely the changing epidemiology of genital herpes, namely an increase in genital HSV-1 infection, influenced these results.

### Live-Attenuated Vaccines

Live vaccines, in general, are considered more immunogenic, but have increased safety concerns compared to killed or subunit vaccines. Several approaches to live virus vaccines have been attempted: HSV mutants, heterologous herpesviruses, antigens expressed in non-HSV viral vectors, and genetically engineered viruses.

Numerous constructs have been tested in animal models, but none have advanced to Phase II or III trials (106, 192). The most promising are genetically engineered attenuated (220–223) HSVs. The construction of these viruses was based on the use of an HSV-1 [HSV-1(F)] as a backbone. The genome was deleted in the domain of the viral thymidine kinase (TK) gene and in the junction region between the unique long and short sequences to excise some of the genetic loci responsible for neurovirulence and to create convenient sites and space within the genome for insertion of other genes. Last, an HSV-2 DNA fragment encoding the HSV-2 glycoproteins D, G, and I was inserted in place of the internal inverted repeat. The purpose of type 2 genes was to broaden the spectrum of the immune response a chimeric pattern of antibody specificities as a serological marker of vaccination. Because TK is expressed, it is susceptible to antiviral chemotherapy with acyclovir. When evaluated in rodent models, pathogenicity was attenuated and the ability to establish latency diminished; however, protective immunity was not induced.

Similar results were found in owl monkeys (*Aotus trivirgatus*) (224). While 100 PFU of wild-type viruses administered by peripheral routes were fatal to the monkeys, recombinants given by various routes in amounts at least  $10^5$ -fold greater were innocuous or produced mild infections, even in the presence of immunosuppression by total lymphoid irradiation (221).

Human studies with this vaccine were disappointing, as the maximum dose of vaccine administered ( $10^5$  PFU) elicited only mild immunogenicity, even with the administration of two doses (224). The ability to pursue higher doses of vaccine was limited because of an inability to produce satisfactory concentrations of vaccine.

Another replication-impaired deletion mutant is soon approaching clinical trials, having shown promise in animal model systems (225, 226). This HSV vaccine is using replication-defective viruses, as reviewed (227). While first studied over a decade ago (228, 229), a current construct deletes  $U_L5$  and  $U_L29$  in HSV-2 to generate the dl5-29 vaccine candidate. Importantly, this vaccine candidate was compared to a gD2 subunit vaccine in Freund's adjuvant. Significant protection was induced along with high titers of neutralizing antibodies and CD8<sup>+</sup> T cells (230–232).

## GENE THERAPY

The use of HSV for gene therapy has been reviewed (233). Genetically engineered HSV has undergone extensive pre-clinical studies and, recently, led to the licensure of one product for the treatment of nonsurgically resectable melanoma. Predicated upon the demonstration that viruses lacking the  $\gamma_134.5$  gene are incapable of replicating in postmitotic cells, such as the brain, an important degree of safety is incorporated; yet these viruses kill cancer cells. Furthermore, they can serve as a vector for foreign expression, particularly proinflammatory genes.

### Melanoma

Indeed, an HSV deleted in  $\gamma_134.5$  and expressing granulocyte-macrophage colony-stimulating factor (GM-CSF), talimogene laherparepvec [IMLYGIC<sup>R</sup> (Amgen)], was recently licensed in the United States and Europe for the treatment of stage IIIB, IIIC, and IV melanoma. The virus is derived from the pathogenic clinical isolate JS-1 (234). Attenuations in this vector include replacement of both  $\gamma_134.5$  genes with the gene encoding human GM-CSF and deletion of the  $\alpha 47$  coding sequence such that the US11 gene is expressed from the IE  $\alpha 47$  promoter. This virus is “armed,” meaning it expresses a transgene hypothesized to enhance antitumor effects by complementing the lytic mechanism of tumor clearance. In this case, the additional mechanism is immune stimulation through the cytokine GM-CSF, a hematopoietic growth factor that promotes the maturation and development of DCs as well as eliciting the formation of Th1 skewed immune responses.

### Glioblastoma Multiforme

Genetically engineered HSV has been assessed for the treatment of human glioblastoma multiforme. These constructs have included mutations in the viral genes TK, DNA polymerase, ribonucleotide reductase, and  $\gamma_134$  (235–241) and have been identified as HF10, HSV1716, NV1020, G207, G47 $\Delta$ , OncoVEX<sup>GM-CSF</sup>, rRp450, M032, and C134 (224, 234, 242–245). While virtually any alteration of HSV ameliorates neurovirulence, only the deletions in the  $\gamma_134.5$  gene consistently demonstrate safety and efficacy in animal

models. Tumoricidal effects are demonstrable *in vitro* and *in vivo* in multiple glioma models (mouse, rat, and human glioma cell lines, human glioma explants). *In vivo* models include tumor reduction in subrenal capsule and flank subcutaneous implants, but more importantly, increased survival and some tumor cures in intracranial implant models. These effects are reproducible *in vivo* for both immune-deficient animals (nude, *scid* mice) (236, 239–241) as well as immune-competent models (rats and mice) (237, 238, 241, 246). Three approaches to the experimental therapy of glioblastoma are in human investigations.

### G207

G207, derived from the HSV-1 (F) strain, is deleted for both  $\gamma_134.5$  genes and is further attenuated by insertion of the *lacZ* gene into the UL39 locus, preventing expression of ribonucleotide reductase. G207 was demonstrated to be safe following direct intracranial injection in both mice and in highly susceptible *Aotus nancymae* primates (247, 248).

The first Phase I safety trial with G207 evaluated direct intratumoral injection of virus in escalating doses ranging from  $1 \times 10^6$  to  $3 \times 10^9$  PFU. A total of 21 patients with recurrent grade III–IV malignant glioma were enrolled in the trial (249). Even at the highest dose ( $3 \times 10^9$  PFU), no significant adverse events related to G207 administration were reported. Importantly, no evidence of encephalitis was apparent in any biopsy samples taken to monitor tumor progression or at postmortem.

Additional Phase Ib studies in patients with recurrent glioblastoma multiforme have employed a variety of designs to define safety upon injection into a resected tumor bed, the ability of the virus to replicate in tumors, the effect of multiple administrations, and the definition of the contribution of radiation to improved outcome (250). At total doses of  $1.15 \times 10^9$  PFU of G207, the results continue to define safety, evidence of virus replication at the highest doses, radiographic improvement, and some long-term survivors.

### HSV1716

HSV1716 is one of two conditionally replication-competent, engineered HSVs directly injected into malignant glioma with demonstrated safety and the absence of neurovirulence. HSV1716 has been clinically studied for the treatment of malignant glioma in the United Kingdom. A series of Phase I studies of direct intratumoral and surrounding normal parenchyma administration of HSV1716 at doses ranging from  $1 \times 10^3$  to  $1 \times 10^5$  PFU proved safety and, subsequently, viral replication in the tumor (212, 251, 252).

HSV1716 has also been assessed as a therapy of oral squamous cell carcinoma ( $1 \times 10^5$  PFU of virus intratumorally) and melanoma with evidence of safety but no documentation of viral replication (253, 254).

### M032, C134

The engineered HSV recombinants M032 and C134 are similar in that both were originally derived from the wild-type HSV-1 (F) strain. They share identical deletions of the  $\gamma_134.5$  gene, but differ with regard to the inserted genes replacing  $\gamma_134.5$ . M032 expresses the human immunostimulatory cytokine IL-12. IL-12 promotes the activation of IFN- $\gamma$  secretion and Th1 polarization of CD8<sup>+</sup> T lymphocytes and also has antiangiogenic effects. Preliminary studies of a murine IL-12-expressing virus M002 demonstrate increased survival in intracranial tumor-bearing mice treated with M002 and increased infiltration of innate and adaptive immune cells into tumors (255). An Investigational New

Drug (IND) application has been submitted to evaluate the safety of M032 in patients with recurrent glioblastoma and is currently awaiting FDA approval.

C134 expresses the CMV PKR evasion and IFN- $\gamma$  resistance molecule IRS1 (256). IRS1 has equivalent functions as the  $\gamma_1$ 34.5 gene product ICP34.5 in terms of PKR evasion, but unlike ICP34.5 it does not contribute to neurovirulence. Cells infected with C134 do not undergo PKR-mediated host protein shutoff. This has been found to occur in neuroblastoma cell lines, prompting the submission of an IND application for a Phase I clinical trial of C134 in pediatric patients with neuroblastoma (242). A recent review summarizes these data (257).

## TREATMENT

Acyclovir has become the standard of systemic therapy of HSV infections. Acyclovir (9-[2-hydroxyethoxymethyl]guanine), its prodrug valacyclovir (Valtrex), and other antiherpes agents are described in detail in Chapter 12. When valacyclovir is administered at 1 gram every 8 hours, resulting plasma levels are similar to 5 mg/kg of acyclovir given intravenously. Famciclovir (Famvir), the prodrug of penciclovir, and valacyclovir are both available as generic drugs and provide enhanced oral bioavailability compared to acyclovir (81, 258, 259).

### Genital Herpes

In initial genital HSV infection, topical application of acyclovir reduces the duration of viral shedding and the length of time before all lesions become crusted, but it is less effective than oral or intravenous therapy (260). Indeed, topical therapy is not recommended. Intravenous acyclovir is the most effective treatment for first-episode genital herpes and results in a significant reduction in the median duration of viral shedding, pain, and length of time to complete healing (8 versus 14 days) (261). Intravenous acyclovir therapy usually requires hospitalization, thus it should be reserved for patients with severe local disease or systemic complications. Oral acyclovir therapy (200 mg 5 times daily or 400 mg t.i.d.) is nearly as effective as intravenous acyclovir for initial genital herpes (156, 262), and was the first licensed approach. Because of ease of administration and improved pharmacodynamics, valacyclovir and famciclovir have replaced acyclovir at most institutions. Neither intravenous nor oral treatment of acute HSV infection reduces the frequency of recurrences (258, 261, 262).

Recurrent genital herpes is less severe and resolves more rapidly than primary infection; thus, there is less time to introduce antiviral chemotherapy successfully. Oral acyclovir therapy shortens both the duration of viral shedding and the length of time to healing (6 versus 7 days) when initiated early (within 24 hours of onset), but the duration of symptoms and length of time to recurrence are not affected (263, 264). Valacyclovir and famciclovir provide added benefit, particularly with short-course therapy as described in Chapter 12 (81, 258, 265, 266).

Long-term oral administration of acyclovir, valacyclovir, and famciclovir all effectively suppress genital herpes in patients who have frequent recurrences (137, 267, 268). Daily administration of acyclovir reduces the frequency of recurrences by up to 80%, and 25–30% of patients have no further recurrences while taking acyclovir (268). Successful suppression for as long as 10 years has been reported, with no evidence of significant adverse effects. Titration of the dose of acyclovir (400 mg twice daily or 200 mg two to five times

daily) may be required to establish the minimal dose that is most effective and economical. The emergence of acyclovir-resistant strains of HSV appears to be infrequent in immunologically normal individuals (269). Importantly, asymptomatic shedding of virus can continue despite clinically effective suppression with acyclovir, so that the possibility of person-to-person transmission persists (136).

Valacyclovir and famciclovir are also efficacious in the treatment of recurrent genital herpes or for suppression. Valacyclovir for treatment is administered at a dosage of 500 mg b.i.d. for 5–7 days and for suppression 500 mg or 1 gram daily. Famciclovir is administered at 250 mg t.i.d. for treatment and suppression. Valacyclovir was proven to decrease person-to-person transmission when administered to the seropositive partner (270).

Tenofovir topical gel has been shown to impact viral shedding but remains experimental at this time and may prove useful in the developing world because of its activity for preventing HIV transmission as well.

### Herpes Labialis

Topical therapy is of no value. Orally administered acyclovir (200 mg 5 times or 400 mg t.i.d. daily for 5 days) reduces the length of time to the loss of crusts by approximately 1 day (7 versus 8 days), but does not alter the duration of pain or the length of time to complete healing (271). If the dose is increased to 400 mg 5 times daily for 5 days, treatment started during the prodromal or erythematous stages of infection reduces the duration of pain by 36% and the length of time to the loss of crusts by 27% (272). Thus, oral acyclovir has modest clinical benefit only if initiated very early after recurrence. Both valacyclovir and famciclovir can be administered for short courses, 3 days or 1 day, respectively, with similar results.

Oral administration of acyclovir can alter the severity of sun-induced labial reactivation of labial HSV infections. The administration of 200 mg five times daily to skiers did not decrease the frequency of recurrent labial infections as compared with placebo, but significantly fewer lesions formed on days 5–7 among acyclovir recipients. Short-term prophylactic therapy with acyclovir may benefit some patients with recurrent herpes labialis who anticipate engaging in a high-risk activity (e.g., intense exposure to sunlight). The intermittent administration of acyclovir does not alter the frequency of subsequent recurrences. No data support the use of long-term treatment with acyclovir for the prevention of herpes labialis.

### Mucocutaneous HSV Infections in Immunocompromised Patients

HSV infections of the lip, mouth, skin, perianal area, or genitals may be much more severe in immunocompromised patients than in normal hosts. In the former, the lesions tend to be more invasive, slower to heal, and associated with prolonged viral shedding. Intravenous acyclovir therapy is beneficial in such patients (141). Immunocompromised patients receiving acyclovir had a shorter duration of viral shedding and more rapid healing of lesions than patients receiving placebo (273). Oral therapy with valacyclovir and famciclovir are also very effective in immunocompromised patients (274).

Antiviral prophylaxis of HSV infections is of clinical value in severely immunocompromised patients, especially those undergoing induction chemotherapy or transplantation. Intravenous or oral administration of any of the three drugs reduces the incidence of symptomatic

**TABLE 1** Indications for acyclovir therapy

Type of infection	Route and dosage*	Comments
<b>Genital HSV</b>		
Initial episode	200 mg p.o. 5 x/day for 7–10 days	
Acyclovir	5 mg/kg intravenously every 8 hours for 5–7 days	Preferred route in normal host
Valacyclovir	400 mg p.o. t.i.d.	Reserved for severe cases
Famciclovir	1 gram p.o. b.i.d. x 7–10 days	
Recurrent episode		
Acyclovir	250 mg p.o. t.i.d. x 5–10 days	Limited clinical benefit
Valacyclovir	400 mg p.o. b.i.d. x 5 days	
Famciclovir	500 mg p.o. b.i.d. x 5 days	
Suppression	125–250 mg p.o. b.i.d. x 5 days	
Acyclovir	400 mg p.o. b.i.d.	Titrate dose as required
Valacyclovir	500 or 1000 mg p.o. 1 x/day	
Famciclovir	250 mg p.o. b.i.d.	
<b>Mucocutaneous HSV in an immunocompromised patient</b>		
Acyclovir	200–400 mg orally 5 x/day for 10 days	For minor lesions only
Valacyclovir	5 mg/kg intravenously every 8 hours for 7–14 days	
Famciclovir	400 mg p.o. 5 x/day for 7–14 days	
Famciclovir	500 mg b.i.d. p.o.	
Famciclovir	250 mg t.i.d. p.o.	
<b>HSV encephalitis</b>		
Acyclovir	10–15 mg/kg intravenously every 8 hours for 14–21 days	
<b>Neonatal HSV<sup>§</sup></b>		
Acyclovir	20 mg/kg intravenously every 8 hours for 14–21 days	

\*The dose are for adults with normal renal function unless otherwise noted.

<sup>§</sup>Not currently approved by the FDA.

HSV, herpes simplex virus.

HSV infection from about 70% to 5–20% (275). A sequential regimen of intravenous acyclovir followed by oral acyclovir, valacyclovir, or famciclovir for 3–6 months can virtually eliminate symptomatic HSV infections in organ transplant recipients. A variety of oral dosing regimens (acyclovir 200 mg t.i.d. to 800 mg b.i.d.; valacyclovir 500 mg or 1 gram q.d. or b.i.d.; famciclovir 500 mg t.i.d.) have been used successfully. Among bone marrow transplant recipients and patients with poorly controlled HIV infection, acyclovir-resistant HSV isolates have been identified more frequently after therapeutic acyclovir administration than during prophylaxis.

### Herpes Simplex Encephalitis

HSE is associated with substantial morbidity and mortality despite the use of antiviral therapy (144, 276). The administration of acyclovir at a dose of 10 mg/kg every 8 hours for 10–14 days reduced mortality at 3 months to 19%, compared with approximately 50% among patients treated with vidarabine (144). Furthermore, 38% of the patients treated with acyclovir regained normal function. Patients with a Glasgow coma score of less than 6, those over 30 years of age, and those with encephalitis longer than 4 days had a poor outcome. For the most favorable outcome, therapy must be instituted before semicoma or coma develops. Current recommendations utilize a 21-day regimen. Of note there is no benefit of long-term suppressive valacyclovir therapy (277), in contrast to that observed in neonatal infection.

### Neonatal HSV Infections

Babies with CNS or disseminated disease when treated with 20 mg/kg every 8 hours for 21 days have mortality rates of 5% and 25% compared historically to 10% and 55%, respectively. Among those survivors, 35% and 80% of babies develop normally, respectively (278–280). No baby with disease localized to SEM died. Of note, PCR assessment of the CSF should be used to classify extent of disease (i.e., CNS involvement) as well as to identify SEM babies who have asymptomatic CNS involvement. Furthermore, assessment at the end of therapy should be performed on the CSF, because some newborns will require longer therapy. Chronic suppressive therapy (300 mg/m<sup>2</sup> t.i.d.) for 6 months has been proven effective in improving neurologic outcome as defined by higher Bayley Developmental Score (280).

### Other HSV Infections

Case reports have described the successful use of acyclovir, valacyclovir, and famciclovir in the treatment of other HSV infections, such as hepatitis, pulmonary infections, herpetic esophagitis, proctitis, eczema herpeticum, erythema multiform, and herpetic whitlow (Table 1). Topical therapy with acyclovir for HSV ocular infections is effective, but probably not superior to trifluridine (281, 282) (Table 2).

### Antiviral Resistance

HSV can develop resistance to acyclovir through mutations in the viral gene encoding TK, through the generation of TK-deficient mutants, or through the selection of mutants

**TABLE 2** Investigation uses of acyclovir

Herpes labialis (prophylaxis)
HSV keratitis
Suppression of HSV infections in immunocompromised patients
Disseminated or visceral HSV infections (e.g., hepatitis)
HSV, herpes simplex virus.

possessing a TK that is unable to phosphorylate acyclovir (see Chapter 12) (283). Clinical isolates resistant to acyclovir are almost uniformly deficient in TK, although isolates with an altered DNA polymerase have been recovered from HSV-infected patients. Drug resistance was considered rare, and resistant isolates were thought to be less pathogenic until a series of acyclovir-resistant HSV isolates from patients with the AIDS were characterized (284). Although sensitive to vidarabine, cidofovir, and foscarnet *in vitro*, only foscarnet and cidofovir have been shown effective in the treatment of acyclovir resistant HSV. Acyclovir-resistant HSV isolates have been identified as the cause of pneumonia, encephalitis, esophagitis, and mucocutaneous infections in immunocompromised patients.

### Toxicity

Acyclovir, valacyclovir, and famciclovir therapy is associated with very few adverse effects. Renal dysfunction has been reported, especially in patients given large doses of acyclovir by rapid intravenous infusion, but appears to be uncommon and is usually reversible. The risk of nephrotoxicity can be minimized by administering acyclovir by slow infusion and ensuring adequate hydration. Oral acyclovir therapy at doses of 800 mg five times daily and valacyclovir at doses of 2 grams b.i.d. have not been associated with renal dysfunction (285). A few reports have linked intravenous administration of acyclovir with disturbances of the CNS, including agitation, hallucinations, disorientation, tremors, and myoclonus (140).

The Acyclovir in Pregnancy Registry has gathered data on prenatal exposure to acyclovir. No increase in the risk to the mother or fetus has been documented, but the total number of monitored pregnancies is too small to detect any low-frequency events (286). Because acyclovir crosses the placenta and is concentrated in amniotic fluid, there is concern about the potential for fetal nephrotoxicity, although none has been observed.

### New Therapies

There is a paucity of new drugs in development for the treatment of HSV infections. Only one, Pritelivir, a helicase-primase inhibitor, has been shown to have clinical and virologic value in a controlled clinical trial (287). However, because of concerns of toxicity in nonhuman primates, the FDA has put the drug on “clinical hold” (288).

# Cercopithecine Herpesvirus 1 (B Virus)

RICHARD J. WHITLEY

## 21

B virus, endemic in macaque monkeys, has the unique distinction of being the only one of nearly 35 identified non-human primate herpesviruses that is highly pathogenic for humans. Infection has resulted in over 50 cases, with a mortality in excess of 80% in the absence of therapy. The actual number of cases worldwide is unknown. The unique biology of B virus includes its neurotrophism and neurovirulence. Because untreated B-virus infections are associated with high mortality in humans, individuals handling macaques or macaque cells and tissues are at risk for infection. Human infection is associated with a breach of skin or mucosa and subsequent virus infection. Fomites and contaminated particulates or surfaces can serve as a source of virus infection. Since the early 1980s, 80% of infected individuals given antiviral treatment have survived. Timely antiviral intervention is the only effective means of reducing B-virus-associated morbidity and preventing a fatal outcome.

### HISTORY

In 1932, a young physician Dr. William Brebner was bitten by a monkey and later developed localized erythema at the site of the animal bite. This apparent localized infection was followed by lymphangitis, lymphadenitis, and, ultimately, a transverse myelitis with demise ascribed to respiratory failure. Autopsy tissue specimens from WB were obtained for laboratory investigation by Frederick P. Gay and Margaret Holden, who reported that an ultrafilterable agent recovered from neurologic tissues caused a cytopathic effect in tissue culture similar to herpes simplex virus (HSV) (1). The isolate was initially designated as "W" virus. Gay and Holden noted that it caused a similar disease in rabbits infected by either intradermal or intracranial routes of infection. Importantly, a rhesus macaque exposed to this virus showed no evidence of illness but developed antibodies, indicating asymptomatic infection.

Within a year of this first report, Albert B. Sabin independently also found an ultrafilterable agent in the tissue of this same index patient. He identified this as "B" virus (2), naming the virus by the initial of the patient's last name. Thus, the virus subsequently has been called Herpesvirus simiae, Cercopithecine herpesvirus 1, or more simply, B virus. Sabin also described the lethality of B-virus infection in rabbits, in which infectivity was independent of route of

inoculation. Experimentally infected dogs, mice, and guinea pigs showed no susceptibility to infection, regardless of the route of inoculation (2). Both groups observed that B virus induced immunologic responses in an infected host similar to HSV (3). The virus was also noted to share similarity with pseudorabies, among other viruses, including SA8 and two additional more recently described nonhuman primate alphaherpesviruses, human papillomavirus 2 (HPV-2) and Langur herpesvirus (3–8).

By 1959, B virus had resulted in 12 cumulative fatalities with 5 recognized survivors (9–11), suggesting that this infection was not always fatal. Although B-virus antibodies were detected in a number of individuals who had no clinical symptoms but a history of working with macaques (12), the early serologic assays could not distinguish between HSV and B-virus infection. Once differentiation of humoral immune responses to these viruses was possible, a high-risk group of 325 subjects exposed to rhesus macaques rarely, if ever, had antibodies in the absence of clinical symptoms.

During the decades since the initial reports of B-virus infection, investigators have defined the molecular biology of this virus and the resultant illness in humans and non-human primates, including its natural host, the macaque monkey. Because of neurovirulence in a foreign host, B virus is considered by some to be one of the most dangerous occupational hazards for those who work directly with macaques or their tissues or with monkeys who have been in contact with macaques.

### VIROLOGY

#### Isolation and Growth Properties

According to the CDC guidance, isolation of the virus is recommended in a Biosafety Level 3 (BSL-3) laboratory, whereas propagation should be strictly confined to a BSL-4 facility (39). The initial isolation of B virus was achieved using rabbits for passage of the virus (1, 2, 40); shortly thereafter, the virus was also grown on chorioallantoic membranes of embryonated eggs (4).

In 1954, B virus was isolated from rhesus kidney tissue that was used for preparation of poliomyelitis vaccines (41) and from rhesus central nervous system (CNS) tissue (42). Subsequently, cultured cells derived from monkey kidney and chick embryo were found to support the replication of B

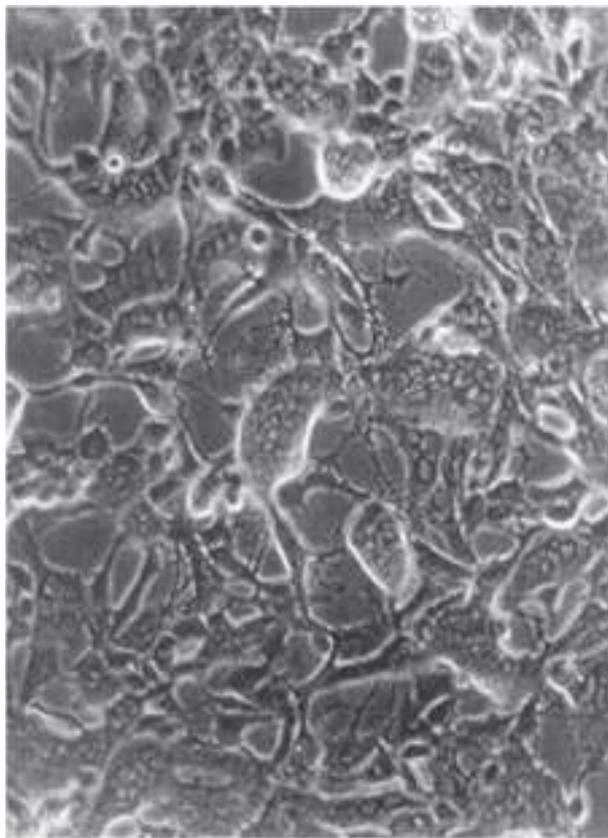

FIGURE 1 Vero cell monolayer infected with B virus.

virus (43, 44). The virus is stable in cell culture media stored at 4°C and can be maintained for years at –80°C but not at –20°C.

Replication kinetics of B virus follows a time course similar to HSV *in vitro*, with Vero cells being the best system for propagation (3, 4, 7, 8, 45, 46). Host cell machinery ceases once virus enters the cell in a fashion similar to HSV (47). Notably, glycoprotein D (gD) is functional, but dispensable, for virus entry into macaque and human cells, varying slightly from HSV (48). An eclipse of cell and viral activities is noted during the first 2 to 3 hours after infection, followed by synthesis of polypeptides early during infection. By 4 hours after infection, DNA synthesis increases dramatically and in parallel with the synthesis of viral polypeptides. Morphogenesis is also similar to HSV, as shown by

studies using electron microscopy (49). Infectious virus is detectable within 6 to 10 hours after infection, and both extracellular and intracellular virus levels plateau about 24 to 28 hours after infection, declining thereafter (44, 50). B virus, like HSV, has been observed to express sequential classes of proteins, that is, immediate early, early, and late proteins (50), and to possess glycoproteins and other structural proteins that were studied in detail with respect to their antigenic relatedness to HSV and later to other nonhuman primate alphaherpesviruses (51–54).

B virus replicates to high titer in cell lines of Old World monkeys, particularly in Vero, African green monkey, and vervet kidney cell lines, as well as rabbit kidney, BSC-1, and LLC-RK cells (31, 55). Although B-virus replication in cultured cells usually results in syncytium formation (Fig. 1), some primary isolates produce only cell rounding. Generally, cells balloon, fusing into polykaryocytes that expand outwardly as more cells become infected. In this manner, virus infection spreads through the entire cell monolayer, destroying cells. Eosinophilic intranuclear inclusions (Cowdry type A) can be detected after fixation and staining infected cell monolayers; however, these inclusions are not observed either in infected animals or in some humans with zoonotic infection (56, 57). Thus, the presence of characteristic intranuclear inclusion bodies is not a reliable diagnostic marker of infection.

### The B-Virus Genome

B virus contains a double-stranded DNA genome of about 162 kb. One strain of virus originating from a cynomolgus monkey has been mapped and subcloned (58, 59). The genome contains two unique regions—unique long (UL) and unique short (US)—flanked by a pair of inverted repeats, two of which are at the termini and two located internally, an arrangement that results in four sequence-orientated isomeric forms, as occurs with HSV. Figure 2 shows the comparative genomic organization of B virus and HSV-1, as established by using HSV-1 genes to identify and locate specific B-virus homologs (58). The overall size of the genome is slightly larger than HSV-1 (152 kb) and HSV-2 (155 kb). The guanosine and cytosine (G+C) content of the DNA has been calculated to be 75% on the basis of the buoyant density of viral DNA (60). The location of genes within the UL regions of HSV and B virus is co-linear (58). Homologs of HSV *US9* and *US10* genes are located upstream of the US glycoprotein gene cluster. This is in contrast to the downstream location of these genes in the HSV *US* region (58). Sequence analysis of the prototype strain (E2490), which originated from a rhesus macaque, however,

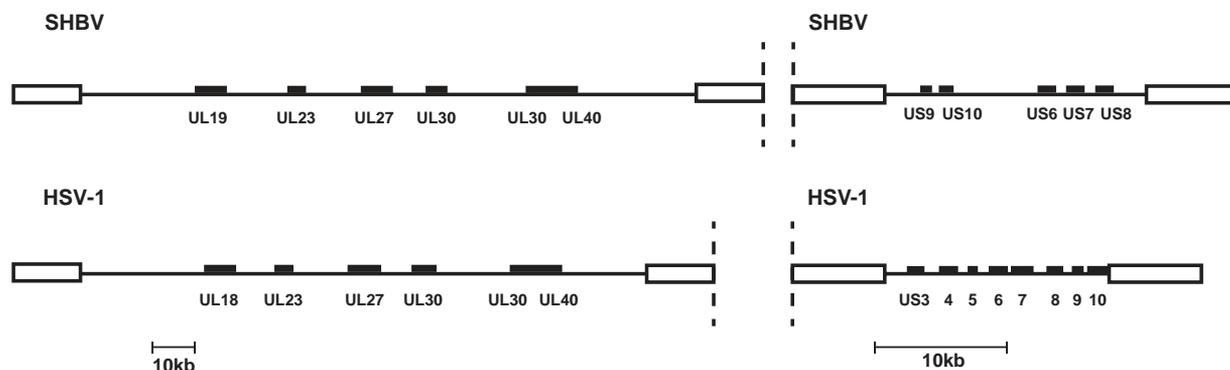

FIGURE 2 Physical map of B virus as proposed by Harrington and colleagues (58).

showed that B-virus DNA is colinear in these same regions with the HSV-1 genomic arrangement.

To date, sequences for only a few B-virus genes have been submitted to GenBank—homologs of gB, gD, gC, gG, gI, and gL—largely covering the sequence of the US region (61–63), although an entire genome sequence is available (59, 60). Each of the glycoproteins for which sequence information is available, except gG, has about 50% identity with HSV, slightly higher for HSV-2 than HSV-1. B-virus gG is a homolog of HSV-2 gG and is closer in size to gG-2 (699 kb) than gG-1 (238 kb) (63). Glycoprotein sequences demonstrate that all cysteines are conserved, as are most glycosylation sites. This conservation suggests that B-virus glycoproteins have similar secondary structure to that of HSV. Sequence analyses also suggest that B virus and HSV types 1 and 2 probably diverged from a common ancestor during the evolution of these pathogens.

Restriction-length polymorphisms (RFLPs) analysis indicates that intrastrain variation, commonly seen in HSV, exists among both human and nonhuman primate-derived isolates, although the significance of this remains to be defined (64–66). The existence of three distinct B-virus genotypes raises the possibility that these may vary with respect to pathogenicity for nonmacaque species (67). These genotypes were identified when collected data were analyzed phylogenetically; however, this postulate must be studied in a suitable animal model. Published case summaries that implicate other macaque species, and in one case a baboon, are difficult, if not impossible, to confirm (24).

### Viral Proteins

More than 50 polypeptides ranging from about 10,000 to 250,000 daltons have been identified by immunoblot analysis of infected cells. Each has been assigned an infected cell polypeptide number as an initial reference point (50). This number may be an underestimate of the total synthesized, but it serves as a basis for comparison in ongoing studies. More than 75% of the expected coding capacity of the viral DNA is accounted for by these infected cell polypeptides. Many of these glycoproteins have been cloned and sequenced (61, 67, 68). The proteins encoded were mapped to genes in the US region, which was largely colinear with the HSV glycoproteins gD, gI, gJ, and gG, as previously described. Sequence analysis of selected genes showed that B

virus is most closely related to herpesvirus papio 2 (HVP-2) (69). There are protein homologs in herpesviruses of New World monkeys. Very little, if any, cross-reactivity exists between B virus and the New World monkey herpesviruses.

The kinetics of protein and glycoprotein synthesis in infected cell cultures are similar to that observed for HSV, although infectious virus is detected earlier, appearing 6 hours after infection. Both host cell DNA and protein synthetic activities appeared curtailed during the first 4 hours after infection. The polypeptides of B-virus-infected cells, summarized in Table 1, may represent an overestimate of the primary gene products of the virus; however, this summary should serve as a fairly complete listing of B-virus-induced polypeptides for future reference. As for glycoproteins, only glucosamine and some mannoses are incorporated during the infection *in vitro*. B-virus polypeptides and glycoproteins can be grouped into classes that differ in their relative rates of synthesis at different times throughout the virus replication cycle, as is characteristic of alphaherpesviruses (50).

## EPIDEMIOLOGY

### Distribution

B virus is endemic in macaques, one of the Old World monkeys widely distributed throughout Asia. All species of macaques tested thus far serve as natural hosts. The virus can infect other nonhuman primates, but in such cases, the infected animal is not considered a natural host, and infection generally results in death within a relatively short time. Transmission of virus occurs by direct contact between members of the *Macaca* genus, from infected animal to human, from virus-contaminated surfaces, or, in one case, from human to human, as reviewed (13–26).

B-virus infection in the macaques rarely causes disease, and if so, it is mild ulcerative lesions. Infection in macaques is seldom associated with death, unless conditions prevail that facilitate generalized systemic infections (30).

### Natural Hosts

#### Macaques

Most adult wild macaques are seropositive for B virus (28). Prevalence estimates of B-virus infection, using different serologic methods and sampling approaches in both wild and

captive macaque colonies, indicate wide variability (27). Spread of infection in the colony correlates with onset of sexual activity, which facilitates transmission of the virus among animals (28, 29). Crowding of animals during transportation also accelerates the spread of infection (28).

Colonies of macaques that have been found to be predominantly seronegative do exist in the wild. More recently, such colonies have been established, apart from original natural habitats, to meet escalating needs for seronegative animals by the scientific community. These efforts have proven difficult (102). The seroprevalence in wild macaques, in addition to the noted high infectivity (27) and low morbidity within captive colonies (4), has confirmed the macaque as the natural host.

Macaques belonging to captive breeding colonies also have a high seroprevalence, in fact, one that increases after the onset of puberty (27, 101). Increasing seroprevalence appears to be associated with sexual transmission within the colony (89, 101). Infants and juveniles have a very low incidence of infection, judged by low prevalence of specific B-virus antibodies (27). There is evidence of transplacental antibody transmission. Importantly, all age groups have been found to be virus positive, indicating that routes of transmission other than sexual activity exist (76).

No particular species of macaque appears to be excluded as a natural host for B-virus infection, although there are minimal or no data available from certain species. While detection of antibodies has been confirmed in most macaque species, there has been speculation that virus isolated from certain species is less neurovirulent or less neurotropic than virus shed by rhesus macaques (103).

Virus shedding during either primary or recurrent infections has been noted to occur. In general, macaques shed virus for a longer duration during primary infection and, for short periods, even hours with recurrent infections. Levels of virus, as measured from mucosal swabs, range from  $10^2$  to  $10^3$  plaque-forming units (PFU). Asymptomatic excretion of virus occurs in slightly more than 2% of antibody-positive animals from mucosal sites and the eye. These observations suggest that reactivation is only transient (27–2931–38).

## Humans

B virus is an infection that humans rarely contract, but when they do, 80% of untreated cases result in death. B virus is usually acquired through zoonotic transmission from either a macaque or infected cells or tissues from the animal. In one case, human-to-human transmission was attributed to a shared tube of antiviral medication that was applied to treat the patient's bite wound. Later, the same patient auto-inoculated an eye, supporting the assumption that B virus can be transmitted in a fashion similar to HSV. A fatal case resulted from exposure of ocular membranes to virus from a monkey in the process of being transported. This tragedy has refocused attention on an earlier report implicating this type of transmission in the epidemiologic analysis of zoonotic transmission of the virus (43).

Interestingly, current case analyses suggest that categorization of risk levels with regard to the severity of injury is not useful. The low incidence of B-virus infection in humans makes it difficult to reach firm conclusions, but analyses of cases occurring during the 1990s support the observation that immediate medical attention ameliorates, if not prevents, disease. Only minimal disruption of the protective skin layer or instillation directly to a mucosal membrane can result in initiation of infection. The level of virus required to initiate infection in humans remains unknown. Rhesus

macaques have been most frequently implicated as the source of infectious virus in the known human cases, but alone, this is insufficient to conclude that rhesus-derived virus is uniquely important in the establishment of zoonotic infections. Other species of macaques, including baboons, have been linked to fatal zoonotic infections (24).

The incidence of zoonotic infections has been correlated retrospectively with periods of increased usage of macaques for biomedical research. Evaluation of past cases underscores that transmission of the virus is often associated with no more than a superficial scratch or puncture, suggesting that once virus gains entry into a host, the ability to initiate disease is perhaps dose independent, at least in some cases.

## PATHOLOGY AND PATHOGENESIS

During the course of B-virus infection, several observations are common to the natural host, the experimentally infected host, and infected humans. First, pathogenetic outcome varies according to the infected host. The route of inoculation predicts differences in the time course of infection, development, and spread through the CNS and visceral organs (e.g., spleen, adrenal, kidney, and, in some cases, even heart). These routes of infection are unique to the mode of infection—natural, experimentally infected, and human zoonotic infections. For example, venereal transmission of the virus is common in macaque hosts, whereas an intranasal route of virus delivery defines the experimental rabbit model, or, in the case of human zoonotic exposure, accidental aerosolization of virus. However, these routes share one common feature: All require exposure of mucosal membranes to infectious virus.

The cells that come into contact with the virus initially are also important to the permissiveness of infection. For example, nasal mucosa is a less ideal site for virus replication than lung (10,70–73). Another important consideration in B-virus infection is the quantity of the virus introduced initially into a host. For example, a far greater quantity of virus is required to infect rabbits by aerosolization than by an intradermal route of inoculation, although practically, whether these routes and doses influence human or non-human primate infection is unconfirmed. Another common feature of natural, experimental, or zoonotic infection is that B virus can be found in the CNS shortly after the onset of acute infection. But the distribution of virus and its consequences differs widely in natural infection as compared with infection failure of susceptible foreign hosts.

## The Natural Host

The macaque suffers little or no morbidity as a consequence of infection. Exceptions occur rarely and appear to involve specific accompanying factors, such as immunosuppression or stress (30, 74, 75). Infection is self-limiting (22, 23, 29,76–78). Virus replicates at the site of inoculation and induces localized erythema. Limited focal infection of liver and kidney may occur in some macaques (22, 23). Virus travels through the peripheral nerves from the site of inoculation to the representative sensory ganglia. Latent infection is established in the ganglia with intermittent reactivation of the virus throughout the life of the macaque (17, 27, 32, 36, 45, 79, 80). In rare cases, viremia has been observed (74, 81, 82). Virus has also been recovered from urine as well as multiple organs of animals. Reactivation from latency occurs in the natural host as judged by increasing antibody titers, recovery of virus by cocultivation of

sensory ganglia, and isolation of virus in the absence of detectable lesions (30, 35, 83).

During active B-virus replication, isolation of virus is readily accomplished from buccal, conjunctival, or genital mucosa sites (76, 84). The frequency of active infection among seropositive macaques is low, with relatively short time periods for successful virus recovery from mucosal sites (27, 29).

Mucosal ulcers, if present, extend down to the papillary layer of the dermis. Two distinct zones have been described, namely a central area of necrosis and a surrounding zone of ballooning degeneration. "Normal" epithelium exists around the lesion. An eosinophilic polymorphonuclear infiltration characterizes the histopathology of the lesion. Postmortem histopathologic examination of monkey tissues from animals euthanized at the time of active virus shedding reveals perivascular lymphocytic cuffing in sections of spinal cord. Examinations of latently infected but healthy animals failed to detect virus excretion routinely from peripheral sites, but virus can still be recovered from sensory ganglia (79).

### Experimental Infections

Rabbits, mice, rats, guinea pigs, and chickens have been studied as B-virus models, as previously mentioned (3, 40, 45). Disease is not a uniform consequence following B-virus inoculation of mice and guinea pigs; however, several strains of B virus that have increased virulence for the mouse have been identified. One strain, identified as E2490, was avirulent for rats and chickens; nonetheless, antibody developed after infection (19). Cotton rats infected by intraperitoneal, subcutaneous, or intracerebral routes succumbed to infection with selected strains. Rats had typical hind leg paralysis secondary to transverse myelitis similar to symptoms in the rabbit. Serially passaged human B-virus strains are capable of infecting mice, hamsters, and white chicks (85, 86). With respect to experimental infections, the rabbit is the most useful small animal model because virus replicates to high titers, making it a particularly good model for testing antiviral agents.

Using the rabbit or the mouse model, viral dose is important, depending on the route of inoculation, for establishment of infection. Experimentally infected animals inoculated intradermally with low doses of virus developed only erythema that resolved within a few days and was not associated with further apparent symptoms. In contrast, animals receiving a larger dose developed a necrotic lesion that was generally followed by CNS invasion (87, 88). B virus subsequently appeared in the regional lymph nodes late after infection. These nodes drained the area of initial infection, and, with time, necrosis of the infected nodes occurred, as seen upon postmortem examination. In the CNS, focal lesions are evident in pons, medulla, and spinal cord. Although virus spread through peripheral nerves is most common, in rare cases a hematogenous route of spread in experimentally or inadvertently infected hosts occurs (8, 30, 87–89).

The cervical spinal cord and medulla oblongata are the primary sites of postmortem virus recovery. With time after infection, virus is also found in olfactory regions of the brain that may be the consequence of movement of the virus centripetally through the nerves innervating nasal mucosa. Perivascular cuffing and glial infiltration are characteristic histopathologic findings upon examination of brain tissue. Hepatic congestion is accompanied by infiltration of polymorphonuclear and mononuclear cells seen in the periportal areas of the liver. Scattered foci of necrosis can be found

throughout the lobes of the liver. The presence of inclusions is detected mainly in the regions of inflammation around pyknotic or karyorrhetic hepatocytes. When lesions are present on skin, the depth of the involved tissue is significantly greater than that of mucous membranes, perhaps explaining the reason B virus can be recovered weeks or months later from these sites (56, 57, 90).

### Human Infection

Human B-virus infection generally occurs through occupational exposure to a macaque shedding virus at a site that comes into contact with broken skin or mucosal membranes of the susceptible human. Several human cases in which monkey contact had not occurred in years suggest that virus can infect and subsequently be reactivated.

The most striking characteristic of human B-virus infection is the involvement of the CNS, specifically the upper spinal cord and brainstem. These areas are the principal sites for virus replication. Initially, the infected individual experiences an influenza-like syndrome followed by numbness or paresthesia around the site of inoculation. An ascending transverse myelitis occurs during the final stages of the infection in humans, resulting ultimately in respiratory failure. Virus can be recovered at skin sites of inoculation for extended periods of time, and viral DNA can be detected generally in cerebrospinal fluid (CSF) by the time neurologic symptoms are experienced; CSF antibodies can also be detected. Cutaneous vesicular lesions are a source of virus isolation, even late in infection (91). Edema and degeneration of motor neurons are prominent. Even with advanced disease, Cowdry type A eosinophilic intranuclear inclusions can be found in only a few cases and certainly not uniformly. Gliosis and astrocytosis are late histopathologic findings; thus, there can be evidence of myelitis, encephalomyelitis, or encephalitis, or combinations of each of these conditions (24).

In several reports, ocular disease has been reported (95, 96). Histopathologic examination of the eye revealed a multifocal necrotizing retinitis associated with a vitritis, optic neuritis, and prominent panuveitis. Herpes-like viral particles were identified in the involved retina by electron microscopy in one case. Postmortem vitreous cultures taken from both eyes and retinal cultures taken from the right eye in the later case were positive for B virus. Thus, B virus can infect and destroy retinal tissue similarly to other herpesviruses. Ophthalmic zoster-like symptoms have been reported as well (33), and in one case, reactivation of latent infection was postulated.

To summarize human pathogenesis, the tissues and organs that become infected by B virus vary, likely according to the route of inoculation. If skin is the primary site of infection, the virus usually, but not always, replicates in the skin, resulting in localized erythema. Knowledge of the site of initial replication is useful for the development of guidelines for disease prevention and also for retrieval of a virus isolate that then allows unequivocal diagnosis. Subsequently, lymphangitis and lymph node involvement are observed. Although viremia has been documented in rabbits and monkeys, it has not been proven in humans, although with the application of more sensitive assays (e.g., polymerase chain reaction [PCR]), more details of infection can be uncovered. Certainly, with lymphatic involvement, virus can spread, particularly to abdominal viscera, where it has been isolated. Nevertheless, spread through neuronal routes is the fundamental route of transmission of the virus, as it is with HSV, given the involvement of the spinal cord and

CNS. Visceral organs, including heart, liver, spleen, lungs, kidneys, and adrenals, demonstrate congestion and focal necrosis with variations in the extent of involvement from patient to patient. Recent human cases failed to demonstrate necrosis, but virus was isolated from adrenal, kidney, lung, and liver tissue collected at autopsy (56, 57). In cases in which B-virus infection is suspected, medical personnel should follow published guidelines at the time of injury or observation of symptoms of possible infection (97–100).

### Immune Responses

B-virus antibodies have been studied in both natural and foreign hosts by a variety of methods, including serum neutralization with or without complement, competitive radioimmunoassay (RIA), multiple types of enzyme-linked immunosorbent assay (ELISA) including competition ELISA, and Western blot. Relatively consistent antibody responses are induced in both hosts (104–109). The natural history of antibody development has been measured in wild macaques, captive colony populations, individually imported animals, experimentally infected macaques, zoonotically infected humans, and even vaccine trial recipients. The ELISA methodologies provide a rapid diagnostic tool with increased sensitivities of detection and with enhanced specificity when competition protocols are used. Host humoral response to B-virus infections both in humans and nonhuman primates neutralize HSV-1 and HSV-2 as well as nonhuman primate alphaherpesviruses. Interestingly, HSV antibodies do not neutralize B virus, indicating the presence of virus-specific antigens unique to B virus (110, 111). Sequence data have been useful in confirming the existence of B-virus-specific epitopes (61–63).

The humoral immune response to B-virus infection has a characteristic pattern (56, 90, 112). The glycoproteins induce antibodies early in the course of infection. Antibodies begin to appear within 7 to 10 days after the infection and consist of immunoglobulin M (IgM). Within 14 to 21 days after the onset of acute infection, IgG antibodies are present. In rare cases, the infected host remains persistently antibody negative despite virus isolation. The pattern of the immune response is somewhat altered in the cases of humans who have had a previous infection with HSV-1 or HSV-2, because viral antigens that are shared among the three viruses induce an anamnestic response toward shared protein or glycoprotein sequences. Neutralizing antibodies develop in both the natural and foreign hosts, but at significantly lower levels in the foreign host. The nature and specificity of the humoral responses make it possible to design enhanced serologic testing strategies to identify detectable antibodies rapidly and to provide the basis for future diagnostic strategies.

### Latency

A characteristic of all herpesviruses is the ability to establish latency and to reactivate when provoked by the proper stimulus. B virus is no exception. Reactivation has been described in both wild macaques and established captive colonies (25, 27, 29, 35, 101). Unequivocal evidence of latent B-virus infection in macaques came with studies on frequency of recovery of virus in monkey kidney cell culture systems. At least 1% of macaque kidneys harbor latent virus that can be reactivated in cell culture (41). Virus has been isolated from rhesus tissues (32, 79) as well as by cocultivation from a variety of neuronal tissues, including gasserian ganglia, trigeminal ganglia, dorsal route ganglia, and spinal cord (38). Latent virus has been isolated by cocultivation of

tissues from experimentally infected rabbits (38), further supporting the rabbit as a potentially acceptable animal model for B-virus infections. Latency likely occurs after human infection.

As with human HSV infections, a prominent factor associated with reactivation of B virus in macaque monkeys appears to be stress, particularly that associated with the capture and shipment of animals from the wild to captivity. Shedding of virus after reactivation also occurs with illness and during the breeding season of the natural host. No information is yet available on the state of the viral DNA during latency or on the molecular or biochemical events associated with the establishment and reactivation of latent virus.

## CLINICAL MANIFESTATIONS

Observations of the clinical pattern of disease are important for rapid diagnosis of B-virus infection in both macaques and humans.

Humans exposed to B virus demonstrate clinically variable signs of disease. Surviving cases have varying degrees of morbidity, ranging from little or no neurologic impairment to more extensive CNS involvement (9,92–94). Some survivors experience slow neurologic decline, whereas others report few if any long-term effects. Several infected individuals have subsequently given birth to healthy children with no ill effects in either mother or infant. Monitoring of the vaginal canal for virus shedding in these individuals before delivery has produced negative results. Most often, illness is apparent within days to weeks, but in some cases, there appears to be a delay in development of acute disease. The reasons for this delay are unknown, and, although rare, delays may even range from months to years, making diagnosis difficult. Once symptoms appear, the clinical progression is associated with relatively consistent symptoms, including influenza-like illness, lymphadenitis, fever, headache, vomiting, myalgia, cramping, meningeal irritation, stiff neck, limb paresthesias, and urinary retention with an ascending paralysis culminating in respiratory failure requiring ventilatory support. Cranial nerve signs, such as nystagmus and diplopia, are common in most published cases. Sinusitis and conjunctivitis have been observed in some (56, 90). The array of symptoms may be related to the dose of virus with which the individual was infected or the route of inoculation. A summary of descriptions of human cases can be found in two comprehensive reviews (24, 25).

The highest percentage of deaths occurs within a few weeks after onset of disease. In some cases, however, life has been prolonged artificially for months or years. Incubation times from identifiable exposures to onset of clinical symptoms ranges from days to years, but most cases occur within days to months. Virus has been recovered from throat, buccal, and conjunctival sites as well as from lesions, vesicles, or injury sites as late as weeks to months after infection. Most clinical cases are associated with bites (50%), fomites, (8%) saliva (<5%), and aerosols (10%).

## DIAGNOSIS

### Nonhuman Primates

#### Macaques

B-virus infection in macaque monkeys is identified by virus isolation, the presence of specific antibodies, or both (65, 113, 114). The neutralization antibody test was the

predominant diagnostic tool in macaques and humans for many decades, but the time required for obtaining results was a drawback. Thus, dot blot, RIA, ELISA, and Western blots were developed (115–121); the results of these tests can be acquired in less than 1 day. Three of these techniques (dot blot, ELISA, and Western blot) rely on the use of monoclonal antibodies. These tests are available through commercial laboratories as well as through a national resource laboratory subsidized through the NIH National Center for Research Resources. All of these assays use B-virus-infected cells for antibody detection, making such tests more effective than other types of assays that rely on HSV-1 (122). This is a particularly important point with respect to diagnostic tools used to identify signs of infection for the establishment of B-virus-free colonies. Tests dependent on monoclonal antibodies or recombinant reagents have defined sensitivity and specificity for each macaque species to be tested. Finally, evaluation of a macaque is only optimal when analysis is performed on multiple samples at different dates, especially in cases in which antibody titer is low (less than 1:50). A constellation of different tests for deployment at varying time points after infection may be necessary in some cases to determine the status of an animal with a very low antibody titer correctly, particularly when such an animal is housed in a B-virus-free colony (123).

While virus isolation is the gold standard for diagnosis of infected macaques, it is not a particularly sensitive diagnostic tool and has the possibility of many false-negative results. Nonetheless, standard cell culture for virus isolation remains a valuable tool for the colony manager and for the veterinarian. Virus-positive cultures can be easily recognized by their unique cytopathic effect, but unequivocal confirmation requires either electrophoretic analysis of infected cell polypeptides or restriction-endonuclease-digested DNA. Several PCR tests have been described that can be used to verify the identity of the virus; however, this diagnostic tool for colony management is costly. Nonetheless, when a possible zoonotic infection must be confirmed, PCR may be beneficial for identification of B virus in macaques.

### Nonmacaques

Other species of monkeys infrequently become infected with B virus. These are usually animals that have been cohoused or housed in close proximity to B-virus-infected macaques at some time. Because many, if not all, nonhuman primates harbor indigenous alphaherpesviruses, the important diagnostic point is to differentiate specific antibodies from cross-reactive ones. Euthanasia is generally advised in the case of a B-virus infection in a nonmacaque monkey because it is likely that the animal will succumb, and, in the meantime, would pose a great risk to anyone attempting to treat the infection. B virus has been identified in the patas monkey and colobus monkey (124–126). In each case, there is a major concern for the people responsible for care of the animal, particularly because these animals often have severe morbidity and are shedding virus. Currently, the most effective assay for diagnosis of B virus in a nonmacaque monkey is a competition ELISA to facilitate discrimination between specific and cross-reactive antibodies similar to the challenge faced when diagnosing infection in humans.

### Humans

Both serologic and virologic techniques are available for diagnosis of B-virus infection in humans. Clinical symptoms in association with detection of specific antibody or virus positivity are the gold standard for diagnosis of B-virus in-

fection in an exposed individual. The CDC has published specific guidelines for recognition and treatment of such infections (57). In the case of a suspected infection, several emergency resources are available. Contact with the CDC or laboratories recommended by the CDC (see CDC guidelines) can expedite laboratory assistance for the clinician suspecting B-virus infection.

Generally, a rise in B-virus-specific antibodies over several days during acute infection substantiates B virus as the etiologic agent. However, in other cases, data are equivocal, and decisions with regard to patient management must be based on a complex decision table collectively using all diagnostic tools, including clinical symptoms. Serologic diagnosis of B virus in humans is a complex task when an individual with a suspect infection has detectable antibodies as a result of a previous HSV infection (127). As discussed previously, significant cross-reactivity of host response exists among these viruses. In the absence of these cross-reactive antibodies, diagnosis is rapid and straightforward, with confirmation using the neutralization assay, Western blot, or both. This was not the case before the development of rapid diagnostic competitive ELISAs and RIAs (119, 120). The diagnostic tests for humans are performed currently by only a few facilities that have been licensed and have access to BL-4 containment laboratories for the preparation of B-virus antigen.

Virus isolation remains the gold standard for diagnosis but is frequently not possible, even under the best of circumstances. Virus identification can be accomplished by isolation using conventional cell culture and, in clinical emergencies, by PCR (128). The identity of isolates should be confirmed by electrophoretic analysis of infected cell polypeptides or restriction-endonuclease-digested DNA (50). The application of PCR is most helpful in the symptomatic patient if virus cannot be recovered. PCR is also a useful tool for monitoring the efficacy of antiviral interventions.

## PREVENTION

Guidelines for treatment and prevention of B-virus infection can be accessed rapidly either through the CDC or the diagnostic resource using the URL [www.gsu.edu/bvirus](http://www.gsu.edu/bvirus). Because of the risk of human disease, precautionary methods must be followed in the workplace. Proper attention to the details of housing, management, and handling of macaque monkeys and organized exposure response measures using the CDC guidelines can minimize B-virus zoonotic infections.

### Exposure Risk Reduction

Multiple levels of prevention are used to prevent B-virus infection in both humans and nonhuman primates, ranging from attempts to eliminate virus-positive animals from colonies to designing methods to work safely in environments where there is increased risk for contracting this agent. Recognition of early infection allows removal of infected monkeys from captive colonies that are being established as B virus free. In B-virus-free colonies, it is important to remove seropositive animals and isolate animals with equivocal results to prevent infection of other colony members, or in seropositive colonies to minimize risk to humans who handle them. Macaques are not treated with antivirals because the high prevalence of infection makes it cost prohibitive.

In cases in which B-virus infection is suspected, medical personnel should follow published guidelines at the time of injury or observation of symptoms of possible infection

(97–100). The CDC has published detailed guidelines for maximizing protection of individuals working with macaque monkeys (97, 99). Furthermore, the NIH National Center for Research Resources has funded the development of B-virus-free colonies for NIH-funded research involving these animals in an attempt to eliminate this virus from colonies used for biomedical research. Nonetheless, B-virus-infected monkeys are plentiful and require handling that can be done safely if strict guidelines are followed, including barrier precautions.

When B virus is detected, decontamination can be accomplished with either heat or formaldehyde (11). Other virus inactivators include detergents and bleach, but individuals who are working in a decontaminated area should still be alert for injury prevention. Minimizing fomites decreases worker risk and reduces virus spread among animals. One B-virus infection in a human was acquired from a cage after the person sustained a scratch (57), underscoring that surface decontamination can play an important role in infection control.

### Vaccines

As early as the 1930s, attempts were made to identify an effective vaccine for protection of individuals who could be exposed to this virus while working with macaques or their cells or tissues. Limited vaccine trials have been performed in volunteers (108, 109), and, although short-term antibodies were induced, they waned quickly. Thus, the vaccine was not pursued further. Recently, a recombinant vaccine was tested and found to induce antibodies in macaques, but the duration of antibody persistence and efficacy remain to be assessed (68).

### Exposure Management

With respect to prevention, the value of first aid after a potential exposure due to a bite, scratch, splash, or other suspicious injury is very important. Guidelines for wound cleaning are described in detail by the CDC. Every institution working with macaques should have an injury protocol with immediate availability of first aid, a secondary care plan, and last, but not least, an infectious disease specialist who is a member of the institution's prevention and care response team.

### Chemoprophylaxis

Antiviral therapy is recognized as an effective prevention prophylactic of infection in human and animal trials when administered early after exposure (56, 57, 129–131). Acyclovir and the related family of nucleoside analogs were noted to be effective when given in high doses (90), for example, acyclovir at 10 mg/kg intravenously three times daily for 14 to 21 days. Antivirals are used by an increasing number of facilities for postinjury prophylaxis or after laboratory results indicate an animal may have been actively infected around the time of the exposure. Postinjury prophylaxis has been performed with famciclovir or valaciclovir, and both have demonstrated efficacy *in vitro*.

### TREATMENT

Antiviral therapy is uniformly used in humans with clinical disease. Efficacy of therapy in cases of infection in humans has been monitored by inhibition of peripheral virus shedding in some cases and by reduction in cerebrospinal fluid antibodies or viral DNA load in others (56, 57, 132). Some physicians follow intravenous therapy with long-term oral

suppression (acyclovir, valaciclovir, or famciclovir). Ganciclovir has a greater efficacy *in vitro* and thus has been used in a few cases since 1989 with success. Interestingly, before 1987, in at least five retrospectively analyzed cases, individuals fared well in the absence of antiviral therapy, but the use of one of these nucleoside analogs is recommended by CDC.

# Varicella-Zoster Virus

ANNE A. GERSHON AND MICHAEL D. GERSHON

## 22

Varicella-zoster virus (VZV) is the etiologic agent of two diseases, varicella (chickenpox) and zoster (shingles). Varicella, which occurs after the initial encounter with VZV, is a disease manifested by a pruritic rash accompanied by fever and other systemic signs and symptoms that are usually mild to moderate in nature. Most often, but not always, varicella is a self-limited infection of childhood. Live attenuated varicella vaccine was licensed for routine use in the United States in 1995 and after more than 20 years of use has changed the epidemiology of the disease, as the incidences of varicella and its complications have now significantly declined (1–3).

Zoster is mainly a disease of adults. A prerequisite for developing zoster is a prior episode of varicella, which on occasion may have been subclinical or following varicella vaccination. During primary infection, VZV establishes a latent infection in sensory, cranial, and enteric neurons; this infection may result from invasion of nerves by VZV in skin vesicles or from a viremia with VZV (or both) (3). During latency the neurons do not show obvious effects from the virus. Zoster results when the latent virus reactivates into an infectious form and travels down the nerve (retrograde transport) to infect the skin. Most often VZV reactivates when the host is relatively immunologically compromised, particularly in cell-mediated immunity (CMI), as occurs with aging and following disease or various treatments such as steroids, cancer chemotherapy, transplantation, and irradiation (3, 4).

Varicella was distinguished clinically from smallpox in the mid-18th century. The origin of the name chickenpox is uncertain, but it may have been derived from the French *pois chiche* (chick pea), or from the domestic fowl (in Old English *cicen* and Middle High German *kuchen*). Herpes is derived from the Greek word meaning to creep; zoster comes from the Greek word for belt, and the word shingles is derived from the Latin word (*cingulus*) for girdle (3).

The delineation of the link between varicella and zoster is of virologic, medical, and historical interest. In 1888 Bokay recognized that cases of varicella often occurred following an exposure to patients with zoster and postulated that there was a relationship between the two diseases (3). In early attempts to develop a vaccine against varicella, medical investigators inoculated vesicular fluid from zoster patients into varicella-susceptible children, who subsequently de-

veloped chickenpox (3). Weller and Stoddard performed the first successful *in vitro* studies and showed that viruses isolated from patients with varicella and zoster are immunologically similar (5). In the mid-1940s a possible analogy with herpes simplex virus (HSV) infection was recognized, and it was proposed that zoster was resulted from reactivation of latent VZV (6). Hope-Simpson was the first to recognize the importance of the immune system in controlling manifestations of zoster; he postulated that zoster resulted from waning immunity to VZV in the years following varicella, permitting the latent virus to emerge (7). More recently the importance of declining cellular immunity to VZV was recognized in the pathogenesis of zoster (3). Using molecular techniques for DNA analysis, it was demonstrated that latent VZV is present in sensory neurons of individuals with a history of varicella (8). VZV DNA from zoster isolates was shown to be similar to the DNA of the virus that caused the primary VZV infection or the DNA of the virus used for vaccination, proving that zoster results from reactivation of latent VZV (3). It is widely accepted that zoster is not acquired from contact with patients with chickenpox. In a placebo-controlled study of vaccination to prevent zoster in the elderly with live attenuated VZV, the vaccinees were not predisposed to develop early zoster as compared to controls (4).

## VIROLOGY

### Classification

There is only one serotype of VZV; no differences in antigenicity among virus isolates have been identified. There are minor differences in DNA sequence among VZV isolates, and seven genotypes have now been identified, which on the basis of single nucleotide polymorphisms are classified as European, Japanese, or Mosaics (9). Analysis of 130 circulating VZV strains from the United States in 2001 and 2002 indicated that 81.5%, 3%, and 15.5% were of the European, Japanese, and Mosaics genotypes, respectively (10). The Oka vaccine strain has not been demonstrated to circulate.

The genomes of the parental (wild-type) and vaccine Oka strains have been fully sequenced; there are numerous differences between the parent and vaccine strains, especially within open reading frame (ORF) 62 (3). Fifteen of 42

(36%) base differences between vaccine and wild-type VZV were present in ORF 62 (11).

The wild-type VZV DNA sequence is readily distinguished from that of vaccine virus by restriction enzyme analysis of DNA from cultured virus and/or by PCR. In countries other than Japan, a useful marker for the vaccine strain is the absence of a PstI restriction site in ORF 38 (3); however, this assay may become less useful should there be significant circulation of Japanese wild-type VZV in the United States. The presence of SmaI and NaeI restriction sites in ORF 62 clearly discriminates between the Oka vaccine strain and all wild-type strains, including Japanese wild-type virus (3). Using DNA sequence analysis of a single nucleotide polymorphism at 106262 in ORF 62, it is possible to distinguish rapidly between vaccine and wild-type VZVs (12). Molecular assays are useful for identification of adverse events temporally associated with varicella vaccine (3, 13) (3)

### Composition of the Virus

Enveloped virions are 150 to 200 nm in diameter, with a central DNA core. The inner viral nucleocapsid has an approximate diameter of 100 nm, consisting of 162 hexagonal capsomeres with central axial hollows organized as an icosahedron with 5:3:2 axial symmetry (3). Consistent with the morphological structure of other herpesvirus virions, a biologically important coat, the tegument, surrounds the nucleocapsid, which is in turn surrounded by an envelope derived in part from cellular membranes.

The genome of VZV is composed of approximately 125,000 bp. It contains 74 ORFs, which account for 71 different gene products (3). The linear double-stranded DNA consists of a long unique segment of approximately 100 kilobase pairs (kbp) and a short unique sequence of approximately 5.4 kbp, flanked by internal and terminal repeats of 6.8 kbp (Color Plate 30) (14). It exists in four isomers; the predominant ones account for 95% of the VZV population (3).

By analogy with HSV, VZV is thought to replicate via a temporally regulated cascade of gene expression, consisting in general of synthesis of immediate-early (IE), early (E), and late (L) genes. Expression of L genes culminates in lytic, productive viral infection. Interruption of the cascade, particularly at the IE/E stages, can result in failure to synthesize infectious virus and may result in latent infection (15). IE genes are for the most part regulatory, E genes may be regulatory or structural, and L genes encode structural elements of the virion. Some of the IE regulatory gene products that also encode structural elements of the virion, such as the regulatory ORFs 62, 4, and 63, are also found in purified virions (16) (Table 1). Gene products of ORFs 21 and 29 are lytic-cycle genes expressed early in infection. The ORF 62 protein acts as a transcriptional activator or as a repressor and is required for further latent or lytic viral synthesis because IE gene 62 is thought to initiate the cascade of gene expression of VZV (15). Gene 61 is a transcriptional repressor (15) that encodes regulatory proteins; however, unlike the ORF 62 protein, the ORF 61 protein is not present in the virion (16).

The functions and biochemical characteristics of most VZV proteins are still unknown. Many are nonstructural proteins involved in different aspects of viral replication. About 30 polypeptides have been detected in VZV, at least 9 of which are glycosylated (17). The virus-encoded glycoproteins are named alphabetically, corresponding to those of HSV, as follows: gB, gC, gE, gH, gI, gK, gL, gM, and gN. There is no VZV equivalent of gD, importantly, which is the

**TABLE 1** Summary of genetic information on VZV

Protein	ORF(s)	Comments on likely importance
gB	31	Fusion, entry, egress
gC	14	Adhesion, cell entry
gE	68	Most abundant; essential for replication, envelopment, spread
gH	37	Fusion, entry, egress
gI	67	Travels with gE; needed for proper envelopment
gK	5	Essential
gL	60	Travels with gH
gM	50	
Nucleocapsid	20, 40	
	10	Tegument, transactivator
	61	Transcriptional repressor
	28	DNA polymerase
Latency associated IE		
	63	Major protein; down-regulates transcription of IE gene 62; tegument
	4	Tegument, transcriptional activator
	62	Tegument, transcriptional activator or repressor
E		
	21	Nucleocapsid protein
	29	DNA binding protein
	66	Protein kinase

major glycoprotein of HSV. Some of these are essential to viral synthesis (such as gE) and others less so (such as gC). Some glycoproteins contain amino acid signal sequences or acid-rich patches in their cytoplasmic tails that are trafficking motifs that direct their movement, required for envelopment, to structures such as the *trans*-Golgi network and the plasma membrane (18–21).

The most abundant glycoprotein of VZV is gE; encoded by ORF 68, it is essential for production of infectious virus (22). This glycoprotein exists as several glycopeptides in different maturational stages with molecular masses ranging from 60 to 98 kDa (23). It is highly immunogenic; it is a phosphorylated high-mannose O-linked and N-linked complex-type glycan which, in concert with gI, binds to the Fc fragment of human immunoglobulin G (IgG) (23, 24). Glycoproteins gE and gI are covalently linked and act as an Fc receptor on infected cells. They play an important role in cell-to-cell spread of virus and are also essential for envelopment (19, 25). They play roles in viral maturation, transportation of other glycoproteins to the cell surface, and virulence (19, 22, 26). Glycoprotein gE contains trafficking sequences that mediate assembly of viral proteins and envelopment in the *trans*-Golgi network (20, 21). It also (along with gI) acts as a navigator, directing additional glycoproteins to the cell surface and back to the *trans*-Golgi network, where final envelopment of virions occurs (19). A variant VZV with a mutated gE has been isolated from five individuals (27, 28). These viruses are thought to be escape mutants, and their biological significance needs further study.

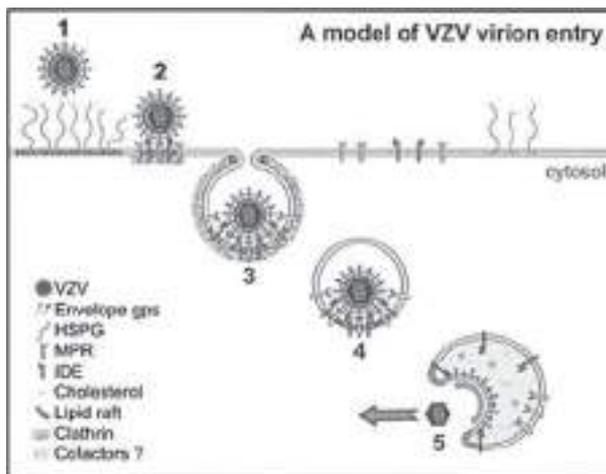

The second most abundant glycoprotein is gB, a heterodimeric glycopeptide linked by disulfide bonds. It too plays important roles in viral entry, envelopment, and egress from cells (29). This glycoprotein is thought to have an important role in virus entry, egress, and cell-to-cell spread in VZV infection (30). It exists as a single-species glycopeptide with a molecular mass of 118 kDa (31); it is a high-mannose N-linked glycopeptide which does not contain O-linked oligosaccharides. Glycoprotein gI is a 60-kDa glycopeptide with both N-linked and O-linked oligosaccharides; it is nonessential for growth of VZV in fibroblasts, but mutants lacking it replicate poorly in cell culture (31). Glycoprotein gC is a heterogeneous 95- to 105-kDa glycopeptide that contains N-linked oligosaccharides and possibly O-linked oligosaccharides (32). Antibodies to gE, gI, gB, and gH have neutralizing activity and are therefore hypothesized to be critical for viral spread, particularly viral attachment and penetration (30–35).

## Biology

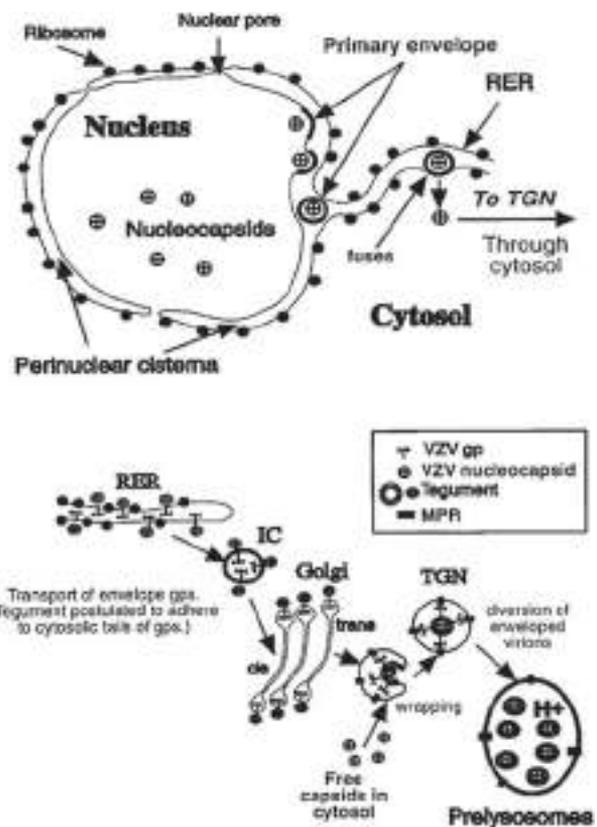

Entry of cell-free VZV particles appears to be dependent upon several factors. These include cell surface heparan sulfate proteoglycan (36), calcium-independent mannose 6-phosphate receptors (MPR<sup>ci</sup>) (36, 37), and the cellular insulin-degrading enzyme, which is a receptor for gE and is critical for cell-to-cell spread of VZV (38–40). Entry of cell-free enveloped virions into cells is highly cholesterol dependent and occurs mainly by clathrin-mediated endocytosis (Figure 1) (41).

After VZV DNA reaches the nucleus, VZV commences replication, synthesizing its DNA core and capsid. The capsid receives a temporary envelope from the inner lamella of the nuclear membrane; in order for it to receive a tegument it is de-enveloped by passing through the rough

endoplasmic reticulum into the cytoplasm as a naked nucleocapsid (42). Nucleocapsids and glycoproteins are transferred independently to the *trans*-Golgi network, where the tegument is added and final envelopment occurs (Figure 2). Additionally, because of the presence of mannose 6-phosphate in VZV glycoproteins, there is an interaction between MPR<sup>ci</sup> and VZV that results in the inclusion of virions into late endosomes, where they are exposed to lysosomal enzymes and an acid environment, and the infectivity of the virions thus becomes compromised (37). Most VZV synthesis occurs in this manner, *in vitro* and *in vivo*. In cell cultures, infectious VZV is not released into media. In contrast, in human skin, during the natural maturation of superficial epidermal cells, MPR<sup>ci</sup>s are lost, along with the lysosomal pathway. In patients infected with VZV, free virions are produced in these cells and are released into skin vesicles during acute varicella

**FIGURE 1** A suggested mechanism of VZV virion entry. (1) The incoming virion initially attaches to cellular heparan sulfate proteoglycan (HSPG), facilitating specific interaction with cellular receptor, e.g., MPR<sup>ci</sup> (2). This leads to receptor-mediated (clathrin-dependent) endocytosis (3) and delivery to an endosomal compartment (4). Within this structure, the virion is exposed to cofactors for membrane fusion, possibly including the insulin-degrading enzyme (IDE) and/or altered pH. (5) Following triggered membrane fusion, the VZV nucleocapsid is delivered to the cytoplasm. Cholesterol may play a role at each stage. (Reprinted from reference 41 with permission.)

**FIGURE 2** Putative route of intracellular transport and maturation of VZV in human embryonic lung fibroblasts. Structures are not drawn to scale. (Top) Nucleocapsids assemble in the nuclei of infected cells and bud through the nuclear envelope to reach the perinuclear cisterna-rough endoplasmic reticulum (RER). A temporary, primary viral envelope is acquired from the inner nuclear membrane. This envelope fuses with the RER, delivering unenveloped nucleocapsids to the cytosol. The nucleocapsids move through the cytosol to reach the *trans*-Golgi network (TGN). (Bottom) The glycoproteins (gps) of the viral envelope are synthesized in the RER independently of the nucleocapsids and are integral membrane proteins. Tegument proteins are probably synthesized by free ribosomes and are transported to the Golgi stack, as are the gps. Virions receive their final envelope by wrapping the TGN-derived sac and are delivered to acidic structures, identified as prelysosomes. (Reprinted from reference 152 with permission.)

and zoster. These 200-nm particles probably play roles in airborne transmission of VZV and establishment of latent infection in neurons (37, 43). If this hypothesis regarding MPR<sup>ct</sup>s is correct, it may explain why infectious virions are not released into supernatant media in cell cultures and *in vivo* in cells where MPRs are abundant. In contrast, *in vivo* in the superficial epidermis, the lysosomal pathway is circumvented and infectious, cell-free VZV is released into human skin lesions, accounting for the high degree of infectivity of varicella and establishment of latent infection by infection of neurons, with axons present in the area of the epidermis where the cell-free virions are present (37).

VZV appears to spread, therefore, in two ways (43). It can spread from one infected cell to another cell by fusion of the two cells; fusion is mediated in all probability by gE, gI, gH, and gB on the membrane of the infected cell. This form of spread does not require envelopment of virions. In mutant VZVs lacking gI, cell-to-cell spread takes place, although proper viral envelopment does not occur (19). Cell-to-cell spread is thought to be the major means of spread of VZV in the body and would explain the importance of cellular immunity rather than antibodies in host defense against this virus. The other form of spread, described above in the discussion of viral entry, is by cell-free virus. It is hypothesized that synthesis of cell-free VZV occurs only in skin vesicles, because MPRs are not formed in the superficial epidermis, and therefore infectious enveloped virions are not exposed to the acid environment of endosomes, so they are released from infected epidermal cells in an infectious form (37). Cell-free VZV in skin vesicles can be aerosolized and thus spread to persons susceptible to varicella. Cell-free virions are also able to establish latent VZV infection in an *in vitro* neuronal animal model (43).

Latency of VZV differs from latency of HSV. While early information suggested that latency might occur in various cells, it is now widely accepted that latent VZV infection occurs exclusively in neurons (44–46). At least six VZV genes have been shown to be expressed during latent VZV infection in a number of studies; these are mostly IE genes (ORFs 4, 62, and 63). The IE ORF 61, however, is not expressed in latent infection. ORF 63 protein, the predominant latency protein, in some studies interestingly inhibits apoptosis of neurons infected with VZV *in vitro* (47). Some E genes are also expressed in latent infection (ORFs 21, 29, and 66), but L genes are not; their expression indicates lytic rather than latent infection (15, 43, 48–52). All of the VZV latency genes have HSV type 1 counterparts; however, none of these genes is expressed in HSV latency. In contrast to VZV, during HSV latency only one region of the genome, termed latency-associated transcript, is expressed (53). During VZV latency, it is hypothesized that the cascade of viral synthesis is interrupted and that there is a block in the synthetic cascade, perhaps at the level of expression of ORF 61 (15). VZV latency-associated proteins are present only in the cytoplasm. The mechanism responsible for this aberrant cell localization is poorly understood. At least one latency-associated protein, ORF 29 protein, however, can be made to enter the nuclei of latently infected neurons in response to inhibition of the proteasome or ectopic expression of ORF 61p (54). Dephosphorylation of ORF 62 protein causes this cytoplasmic protein to translocate to the nucleus (55).

While there are considerable data to indicate that during VZV latency there is some gene expression, exactly what is occurring is not fully understood. There are currently two general hypotheses concerning how latent infection is established. One is that neurons are infected by VZV and that

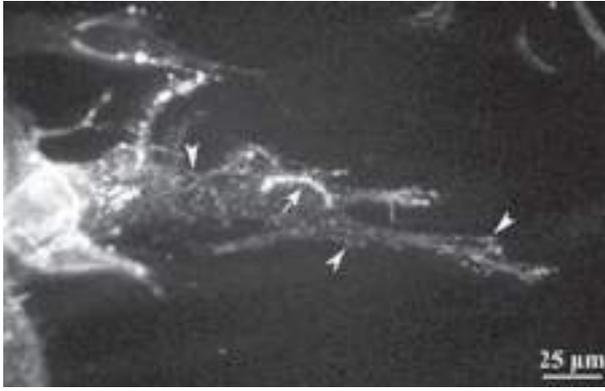

a certain level of viral multiplication takes place prior to the virus becoming latent (56). The other posits that cell-free virions are transported to a neuron, and latency is established but multiplication does not occur. HSV is thought to establish latency without viral replication (57), although this model fails to account for the rather high number of genomes that are present in each latently infected cell. In an experimental *in vitro* model of VZV latency in guinea pig enteric neurons, following infection with cell-free VZV the virus does not replicate, latency results, and the neuron survives *in vitro* for weeks. Infection of neurons with cell-associated VZV, in contrast, results in replication with rapid neuronal death, despite the presence of ORF 63 protein, which becomes nuclear (43). Reactivation with production of infectious VZV and rapid neuronal death was demonstrated in an *in vitro* guinea pig neuronal model of latency, induced by infection with an adenovirus vector carrying VZV ORF 61 (43).

Whether VZV proteins are produced during latent infection has recently been questioned (58, 59); however, there seems to be agreement that RNA transcripts are produced (53). Several cytoplasmic VZV proteins have been demonstrated in the guinea pig neuronal model (43). In patients undergoing gastrointestinal surgery, VZV transcripts of IE and E genes have been found in the enteric nervous system (ENS) in ~90% of those who either had a history of varicella or had been vaccinated, but they were not found in infants who had never been infected with VZV (60, 61). Further research on latency of VZV hopefully will clarify the participation of VZV transcripts and proteins during latent infection.

Other important observations with regard to VZV latency include the following. Patients with impaired CMI to VZV have an increased incidence of herpes zoster, which is consistent with the hypothesis that at least some aspects of suppression of VZV infectivity are under immunologic control (4). Various rodent animal models of VZV latency have been developed, but reactivation of the virus has not been demonstrated (3, 62). A recent exception is latent infection in guinea pigs, in which VZV has been shown to reactivate (63). See below.

VZV has an extremely limited host range, infecting mostly primates. Hairless guinea pigs may be infected with VZV that has been adapted in tissue culture to cells from this species. The primary illness produced is extremely mild and latent infection occurs only infrequently, but specific immune responses can be demonstrated (3). When guinea pigs are infected with VZV by intravenous injection of T lymphocytes infected with VZV, a latent infection occurs. Animals with latent infection appear asymptomatic. When they are treated with tacrolimus and cortisone-stimulating hormone, however, the latent VZV reactivates to cause a disseminated form of VZV infection in which the animals develop marked weight loss and rashes (63). It is hoped that in the future these animal models will provide information on VZV pathogenesis and that they may be used for testing various therapies and vaccines.

*In vitro*, VZV spreads rather slowly, from one cell to another. After inoculation of diploid human cell cultures such as human embryonic lung fibroblasts, a focal cytopathic effect (CPE) is not observed until at least 48 h after infection (Figure 3). VZV is best propagated at 32°C (3). The CPE of VZV in cell culture is characteristically focal, the result of cell-to-cell spread. Characteristic CPEs consist of foci of swollen refractile cells in a spindle-shaped configuration. Foci of infected cells enlarge and may slowly involve much

**FIGURE 3** VZV propagated in human embryonic lung fibroblasts after several days in culture. The specimen was stained with fluorescein-tagged monoclonal antibodies to gE of VZV. The arrow indicates gE in the *trans*-Golgi network, and the arrowheads indicate gE at the cell surface.

of the monolayer, but infectious virions are not released from cells. Diploid human cell cultures are the most convenient host system for virus isolation; primary and heteroploid cell lines such as MeWo cells can also be used (64).

There is little available information on the stability of VZV, but it is usually classified as a rather labile agent. Virus obtained from vesicular fluid is stable for years when frozen in sterile fat-free milk at  $-70^{\circ}\text{C}$ . Cell-free VZV obtained by sonication of infected cells can be stored at  $-70^{\circ}\text{C}$  in tissue culture medium containing fetal bovine serum with sorbitol at a final concentration of 10%. Infected cells can be preserved at  $-70^{\circ}\text{C}$  or in liquid nitrogen in medium containing 10% fetal bovine serum and 10% dimethyl sulfoxide.

## EPIDEMIOLOGY

### Distribution, Geography, and Seasonality

VZV infections occur worldwide. The virus spreads less readily in countries with tropical climates than in those with temperate climates (3), resulting in a higher rate of susceptibility to varicella in adults in tropical countries than in countries with cooler climates. It is possible that spread of VZV is inhibited at high temperatures because the virus is labile. In the prevaccine era, about 4 million cases of chickenpox—an entire annual birth cohort—were estimated to occur yearly in the United States. The disease affects males and females equally. Varicella is most common in the winter and early spring. In contrast, zoster occurs at equal rates during all seasons of the year (3).

### Incidence and Prevalence of Varicella

Varicella is one of the most contagious of infectious diseases (65). Reported secondary attack rates of varicella following household exposure of susceptible contacts range from 61% to 100% (3, 65). Secondary varicella cases in a family are usually more severe than primary cases (65), presumably because the intensity of exposure in that setting results in a higher viral inoculum. The first child developing varicella in a family thus usually has a milder infection than subsequent family members who become ill (3).

About three fourths of U.S. adults with no history of varicella have detectable antibodies to VZV (66), indicating that subclinical varicella can occur. From an epidemiological

study in which parents with no history of varicella were exposed to their children with chickenpox and did not contract it themselves, it was estimated that the incidence of subclinical varicella is approximately 5% (65).

In countries with temperate climates where vaccine is not used universally, varicella is a disease of childhood; most cases occur in children before they are 10 years old, with 8% to 9% of children annually developing disease between the ages of 1 and 9 years (3). These data were representative of children in the United States before many began to attend daycare facilities; it is possible that exposures to VZV in the daycare setting lead to an earlier acquisition of disease. The effect of daycare, however, on the epidemiology of varicella may never be fully known because live attenuated varicella vaccine was licensed for use in all varicella-susceptible children in 1995 in the United States.

Second attacks of varicella are uncommon but have been reported (67). Second attacks may be more frequent in immunocompromised hosts than in healthy individuals. One hypothesis that has been proposed for incomplete protection against varicella in some individuals is that VZV antibodies have lower avidity in patients with recurrent cases (68). An absence of antibodies directed at gE, gB, and gH does not account for reinfections (69). There is considerable boost in humoral immunity to VZV upon exposure of varicella-immune subjects to patients with VZV infections (3). In one study, 32% of parents exposed to their children with varicella manifested either transient IgM antibodies or an increase in antibody titer or both (70). Whether a boost in CMI also occurs after an exposure is not known, but boosting of CMI by immunization years following natural infection has been demonstrated (4). Hope-Simpson hypothesized over 50 years ago that immunologic boosting is important for long-term maintenance of immunity to VZV and may result from either endogenous (asymptomatic reactivation of latent virus) or exogenous exposure to VZV (7). It has been demonstrated that endogenous boosting of immunity to VZV occurs (71–76).

### Nosocomial Varicella

Nosocomial varicella can be a serious and expensive problem in hospitals, where both patients and employees may be susceptible to chickenpox (3). With the availability of varicella vaccine for adults and children since 1995, nosocomial varicella appears to be less of a problem in the United States than it was formerly. Because varicella-susceptible hospital employees may serve as vectors for spread of VZV to susceptible patients, it is now common to test employees for immunity to chickenpox serologically and to offer vaccine to those who are susceptible. Passive immunization (with preformed antibodies) is not useful to terminate potential nosocomial varicella outbreaks, but it is useful to protect varicella-susceptible immunocompromised patients who have been exposed to VZV (see below).

The risk of horizontal transmission of VZV in maternity wards or the newborn nursery after a hospital exposure to an adult or child is extremely low, which has been attributed to several factors (77). Many hospitalized newborn infants are placed in isolettes, and most hospital employees and mothers and their newborn infants have antibodies to VZV and are at reduced risk of developing clinical illness. Because IgG antibodies to VZV cross the placenta, newborns of immune mothers are at least partially protected. Even in low-birth-weight infants, serum antibodies to VZV are usually detectable. Nevertheless, a few episodes of transmission of varicella in the newborn nursery have been reported.

Many more instances of an absence of transmission following exposures in this setting, however, have been recorded (77).

### Incidence and Prevalence of Zoster

Zoster is traditionally a disease of adults. Patients who have zoster usually have a history of a previous attack of varicella or vaccination (3, 7). Zoster is rare in childhood, but there is an increased incidence in young children who had varicella either in utero or before reaching their second birthday (77). Chickenpox in the first year of life increases the risk of childhood zoster by a relative factor between roughly 3 and 21 (3), possibly as a result of immaturity of the immune response to VZV in young infants. Latent infection is also extremely common in infants with congenital varicella syndrome; zoster may occur in over 20% of affected infants (77).

Over a lifetime, zoster occurs in approximately 30% of individuals (4). The incidence of zoster in a population begins to increase sharply at about the age of 50 years; the incidence during the sixth decade, approximately 5 per 1,000 person-years annually, is almost double that of the previous decade (7, 78). During the eighth decade the incidence more than doubles again, to 14 per 1,000 person-years annually (7). The increased incidence of zoster with advancing age is attributed to a relative loss of CMI to VZV that occurs naturally with aging (3).

Zoster occurs with increased frequency in immunocompromised patients; those who are severely immunocompromised may also develop disseminated VZV infection with viremia (79). Zoster may be particularly frequent and severe following bone marrow transplantation, after which as many as 35% of patients develop it within a year (3). Spinal trauma, irradiation, and corticosteroid therapy may also be precipitating factors. The distribution of lesions in chickenpox, which primarily involves the trunk and head, is reflected in a proportionately greater representation of these regions in the dermatomal lesions of zoster (3). Zoster may recur, either in the same dermatome or in a different dermatome; however, the chance of developing recurrent zoster seems to be lower in healthy individuals than the chances of recurrent HSV (7). The reported incidence of zoster in various groups is shown in Table 2.

### Mortality

The mortality for varicella and zoster are low, but the rates increase with advancing age, pregnancy, and decreasing immunocompetence. For varicella, the reported case fatality rate is lowest in children aged 1 to 14 years (0.75 per 100,000). The reported case fatality rate in infants less than 1 year old is 6.23 per 100,000, in those aged 15 to 19 it is 2.7 per 100,000, and in those 30 to 49 years old it is 25.2 per 100,000 (80). In the prevaccine era 100 to 150 deaths were reported in the United States annually (3). Pregnancy, particularly when varicella occurs in the third trimester, may increase morbidity and mortality (3, 77, 81, 82). In a report of 44 consecutive cases of varicella during pregnancy, varicella pneumonia occurred in 9% of women, with one fatality (2.4%) (82). In a more recent collaborative study, however, involving 347 pregnant women who were consecutively monitored, there were no fatalities, although 5% developed varicella pneumonia (81). The mortality for varicella in children with leukemia receiving chemotherapy is reported as 1,000 times higher than that in healthy children (3). A fatality rate of 7% was reported for children with leukemia and chickenpox in the preantiviral drug era (79). Epidemiologic data from the 1990s suggest that the incidence of

severe varicella in healthy hosts was underestimated by a factor of 5 (83). Mortality related to zoster is due primarily to pneumonia; the overall risk of fatal infection is lower than that for varicella in immunocompromised patients, less than 1% (84). Zoster also has a lower mortality than varicella in otherwise healthy middle-aged or elderly adults (3).

### Transmission

Varicella is a highly contagious disease, particularly in the early stages of the illness; VZV is spread by the airborne route (77). It was long thought that the source of transmitted virus was the respiratory tract of infected individuals. Spread of VZV in closed communities that were attributed to exposure to an index case prior to development of rash has been occasionally reported, suggesting that respiratory transmission occurs (85). It is possible, however, that an early insignificant rash went unnoticed in such patients. Studies utilizing PCR identified VZV DNA in the nasopharynx of children during preeruptive and early varicella, although the rates have been inconsistent (3). The presence of VZV DNA, however, does not necessarily indicate the presence of infectious virus. For example, VZV DNA was recovered from room dust 2 weeks after a patient was discharged, long after the virus could remain infectious (3).

Evidence suggests that cell-free virions in vesicular skin lesions of patients with VZV are the major source of infectious virus (37). Secondary to the loss of MPRs in the superficial epidermis, high concentrations of cell-free, 200-nm particles of VZV develop in skin vesicles; these may be aerosolized and thus transmit the virus to others by the airborne route (37). Presumably airborne virus infects the respiratory tract of varicella-susceptible individuals. Clinical studies of transmission of VZV in leukemic vaccinees (86) and immunocompetent children (87, 88) have also implicated skin lesions as the source of infectious virus. There was a direct relationship between the number of skin lesions and viral transmission (87, 88). In a recent study from China, an outbreak among schoolchildren became controlled only after children with rash were excluded from school attendance (87). There is one report of transmission of VZV to others during an autopsy of a patient with varicella; obviously the virus was not spread from the respiratory tract (89).

Studies of isolation of VZV from patients with varicella also implicate the skin as the source of infectious virus rather than the respiratory tract. VZV is readily isolated in cell culture from skin lesions, but it is extremely difficult to isolate the virus from the respiratory tract. Searches for infectious VZV in throat secretions of immunocompetent patients during the incubation period of varicella have

proved largely negative (90–92). There is, however, one report of isolation of VZV from nasal swabs from 3 of 23 (13%) children and from pharyngeal swabs from 2 of 22 (9%) children on days 2 and 3 after the onset of rash (92). It is possible that there may have been vesicles on the mucous membranes in these children, and also it is not clear whether any of them were immunocompromised. In contrast, VZV can readily be cultured from vesicular lesions in patients with clinical varicella. Isolation of VZV was successful in 23 of 25 (92%) cases when vesicle fluid was cultured within 3 days after the onset of rash in one study (90) and in 12 of 17 (71%) cases in another study (92). Vesicular fluid specimens collected from 4 to 8 days after onset, however, yielded VZV in only one of seven instances (90). Infectious VZV may persist longer in vesicles of zoster patients (3). In general it may be conservatively presumed that varicella is transmissible to others from 1 to 2 days prior to the onset of rash and during the first few days of rash. Skin lesions in either varicella or zoster are unlikely to harbor infectious virus once they are dry. Taken together, these observations suggest that VZV spreads predominately from skin lesions and that within several days after the onset of rash, patients with varicella are no longer contagious to others. In contrast, zoster may be infectious for a somewhat longer period especially when vesicles in older patients are slow to heal.

Zoster is not transmissible to others as such, but the vesicular lesions contain infectious VZV and are therefore potentially contagious to others as varicella is (3). Even patients with localized zoster may transmit VZV to varicella-susceptible individuals, and therefore these patients should be isolated when hospitalized. Whether VZV is spread from the respiratory tract in zoster is unknown, but it seems unlikely. Based on scant information regarding household transmission of VZV from zoster patients to varicella-

susceptible contacts, zoster was estimated to be only about half as contagious as varicella (3).

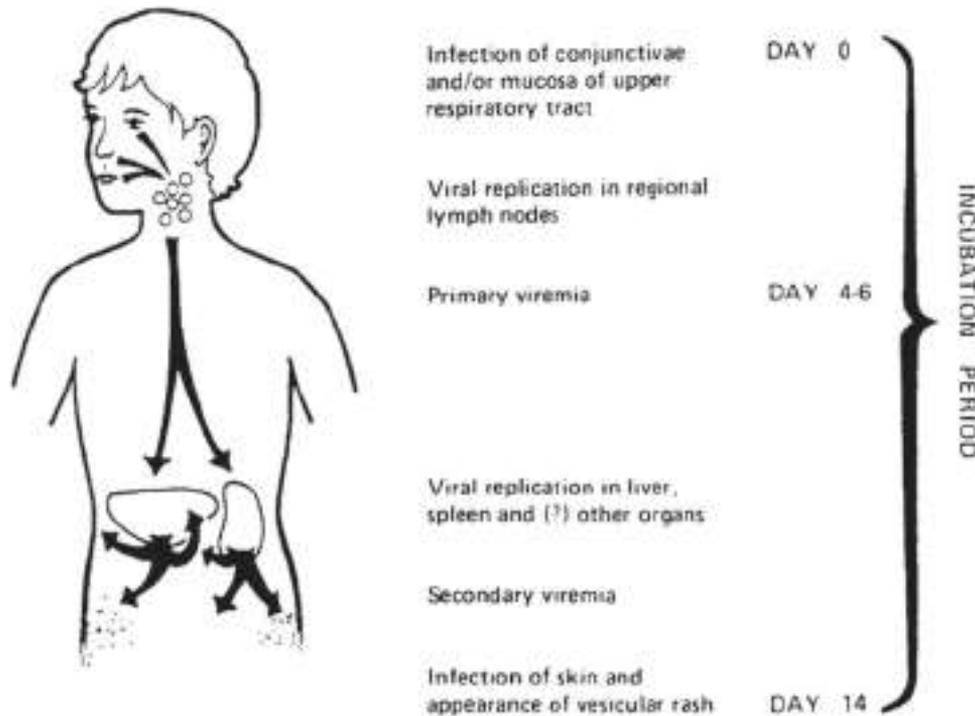

## PATHOGENESIS IN HUMANS

### Incubation Period, Patterns of Virus Replication, and Factors in Disease Production

The incubation period of varicella ranges from 10 to 23 days, with an average of 14 days (3). During the incubation period, VZV is thought to spread to regional lymph nodes, undergo multiplication, and cause a primary low-grade viremia about 5 days later (93) (Figure 4).

In varicella, two viremic phases have been hypothesized to occur, based on studies with the virus that causes mumps (93). Following a putative early viremia that spreads the virus to the reticuloendothelial system, there is local replication of VZV. This results in the second and greater viremia, which delivers the virus to the skin; there it causes the characteristic skin rash, in which “crops” of lesions develop, possibly reflecting several viremic episodes (93) (Figure 4).

A somewhat alternative proposal for varicella pathogenesis is based in part on studies of mice with severe combined immunodeficiency disease engrafted with various human tissues (SCID hu mouse model) infected with VZV (94). Following exposure of susceptible contacts, VZV infects tonsillar T cells as cell-free virus and multiplies in the respiratory mucosa, where T lymphocytes are infected. In VZV-infected SCID hu mice, these T cells deliver VZV promptly to implanted skin. In infected individuals, only limited viral multiplication in the skin is thought to take place at first, as a result of the innate immune response. Innate immunity is eventually overcome as the incubation

**FIGURE 4** Diagram showing proposed pathogenesis of varicella regarding events during the incubation period. (Reprinted from reference 93 with permission.)

period of the disease comes to an end. Because of circulation of infected T cells, there is a low-grade viremia for a week or so after infection, but as more T cells and keratinocytes are infected, the viremia increases, innate immunity is overcome, and the rash develops. At that time adaptive immunity develops, and within a week or so the pathogen is controlled and the patient recovers. VZV has been isolated from blood cultures either a few days before onset of rash or within 1 to 2 days after rash onset in immunocompetent children (95). VZV has also been isolated from blood obtained from immunocompromised patients with varicella or zoster (3). Experiments in SCID hu mice and human skin cellular implants indicate that human CD4 and CD8 lymphocytes are infected with VZV (96).

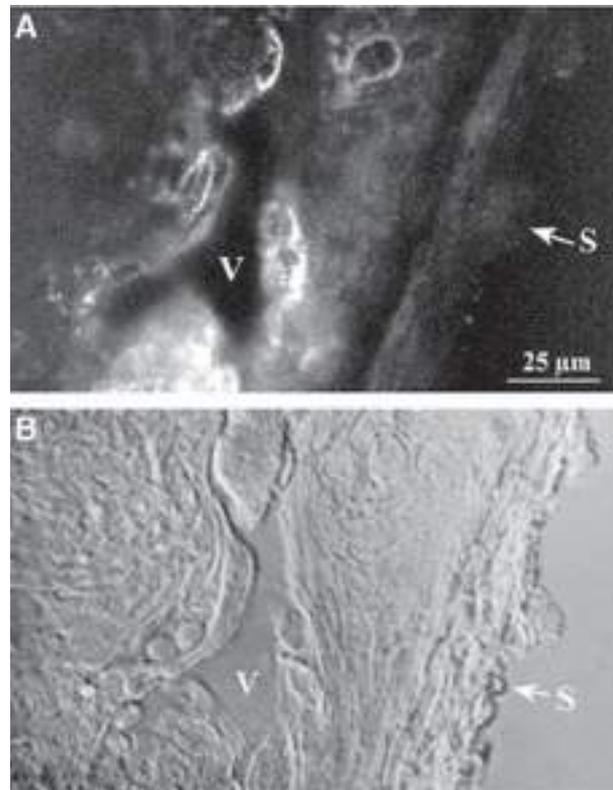

A number of strategies for immune evasion of VZV by host cells that facilitate VZV multiplication have been described, some unique to this herpesvirus (97–100). For example, in infected fibroblasts, VZV down-regulates major histocompatibility complex (MHC) class I antigens and thereby interferes with antigen presentation to cytotoxic T cells. Additionally, MHC class II expression can be blocked by VZV gene products, resulting in a decreased gamma interferon response. Immune evasion is thought to play an important role, particularly in viral multiplication that occurs during the incubation period of varicella.

The skin lesions of varicella begin as macules and progress rapidly to papules, vesicles, pustules, and scabs. Vesicles are located in the superficial epidermis. With time, the fluid changes from clear to cloudy, as polymorphonuclear leukocytes (PMNs) reach the site. Interferon is present in vesicular fluid, reflecting the adaptive cell-mediated immune response of the host (101). The predominant cell in vesicular lesions is the PMN, which may play a role in generating interferon in vesicular lesions and play a role in recovery (3). *In vitro* data also suggest that the PMNs are involved in host defense against VZV, possibly by mediating antibody-dependent cellular cytotoxicity (ADCC) (3). Natural killer (NK) cells also play a role in host defense against VZV (8). Cytotoxic CD4 and CD8 lymphocytes, however, represent the major host response that controls VZV infection (3).

Histologic changes in the skin vesicles are similar for chickenpox and zoster. The hallmarks of each are multinucleated giant cells and intranuclear inclusions. In varicella these are primarily localized in the epidermis, where ballooning degeneration of cells in the deeper layers is accompanied by intercellular edema. As edema progresses, the cornified layers and basal layers separate to form a thin-roofed vesicle. An exudate of mononuclear cells is seen in the dermis without characteristic nuclear changes of epithelial cells in this region (Figure 5) (102).

In zoster, in addition to skin lesions that resemble those of varicella, the dorsal root ganglion of the affected dermatome exhibits a mononuclear inflammatory infiltrate. There may also be necrosis of ganglion cells and demyelination of the corresponding axon (103).

Latent VZV is present in human sensory dorsal root and cranial nerve ganglia in human autopsy specimens in persons who have had varicella. Prior to development of zoster, VZV reactivates in the neuron, resulting in lytic infection, and then it travels down the affected sensory nerves to the skin, causing a characteristic unilateral vesicular rash (Figure 6). Zoster may last for several weeks, particularly in immunocompromised patients, who not only are at increased risk of developing this disease as a result of low levels of CMI to VZV but also may require long times to recover for the same reason.

(B) Same specimen as in panel A, viewed by Nomarski interference contrast microscopy. V, vesicular space; S, outer surface of epidermis.

### Immune Responses

Both humoral and cell-mediated adaptive immune responses to VZV develop within a few days after onset of varicella. Peak antibody levels are attained after 4 to 8 weeks, remain high for about 6 months, and then decline. IgG antibody to VZV is detected in healthy adults for decades after varicella (3). After active immunization against varicella, antibody titers are lower than after natural infection but may persist for periods of 20 years or more (104). Because doses of varicella vaccine used in different countries and made by different companies vary in composition and dosage, persistence of antibodies after vaccination may vary in different locations. Serum IgG, IgA, and IgM develop after both varicella and zoster. Zoster occurs in the face of high levels of specific antibodies, but significantly higher titers develop during convalescence, reflecting the anamnestic response to this reactivated infection (3).

CMI plays the major role in host defense against VZV, probably because the virus spreads almost entirely in the body as an intracellular pathogen. CMI can be demonstrated by stimulation of lymphocytes *in vitro* with VZV antigens (105, 106), by an intradermal skin test (66), and by specific lysis of histocompatible target cells by cytotoxic T cells (107). Natural killer (NK) cells and antibody-dependent cell-mediated cytotoxicity (ADCC) against VZV have also been described (108). CMI reactions can be detected for years after varicella, although this response may wane in many individuals after age 50 (109).

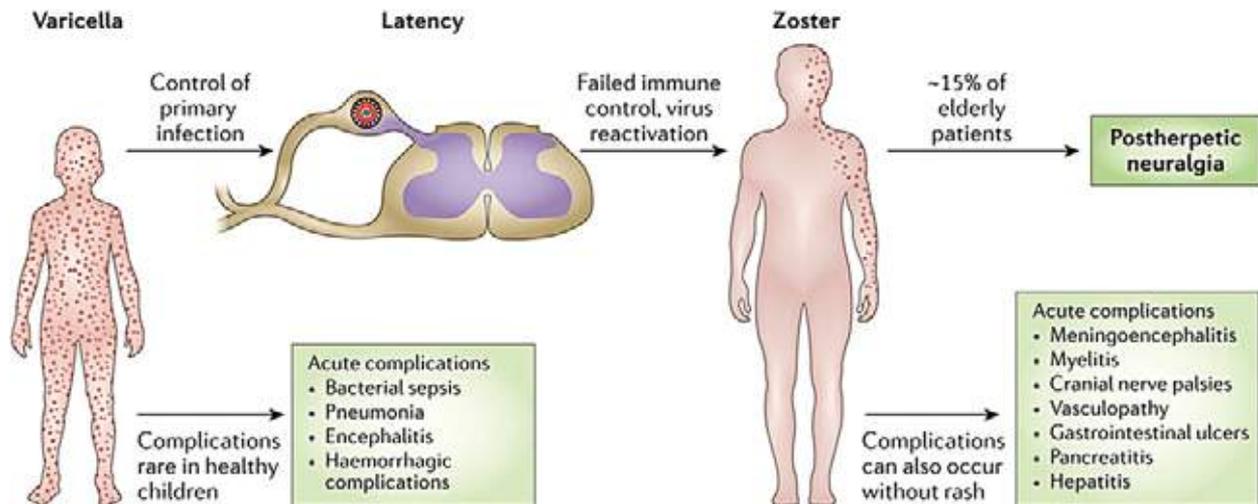

FIGURE 6 Proposed pathogenesis of zoster. (Reprinted from reference 180 with permission.)

Exactly how immunity to varicella and zoster is mediated, however, is still unclear. It is generally agreed that CMI, in the form of T-cell cytotoxicity, is more important than humoral immunity in recovery from infection. For example, children with isolated agammaglobulinemia are not at increased risk of developing severe varicella. CMI is probably crucial during chickenpox because spread of VZV within the body is almost exclusively by the intracellular route, rather than by release of cell-free virus, as occurs in vesicular fluid.

The response that prevents clinical illness after reinfection with VZV is not known for certain, although it is presumed to be some form of CMI, perhaps at times in concert with antibodies. Patients with agammaglobulinemia are not subject to recurrent varicella. On the other hand, elderly adults, who often have low CMI or an absence of CMI to VZV, are not particularly subject to second attacks of varicella; presumably, their antibodies protect them from recurrent chickenpox. Specific antibodies may play a role in immunity because passive immunization can be used to prevent or modify varicella in exposed susceptible individuals. It may be that antibodies are particularly effective right after infection occurs because of a brief period of multiplication in tonsils in which cell-free VZV, which can be neutralized, is produced. It is thus possible that passive immunization lowers the initial viral load, resulting in modified or asymptomatic infection. Certain antibodies, particularly those to gH, moreover, may impede cell-to-cell spread of the virus (30). Young infants, however, can develop varicella after exposure despite detectable transplacental antibody titers, but usually the illness is attenuated (77). Vaccinated leukemic children have developed modified cases of breakthrough varicella despite detectable VZV antibodies or positive CMI responses as measured by lymphocyte stimulation at exposure to VZV, but they do not have normal immune systems (3). They are, however, highly likely to be protected if they have both humoral and cellular immunity to VZV at exposure (110). Healthy individuals with detectable humoral immunity at exposure to VZV are far less likely to develop clinical illness than those lacking these responses (111). Both antibodies and CMI seem to participate in various aspects of protection against VZV, suggesting that redundancy in the adaptive immune response may provide the best strategy against the virus for the host.

## VARICELLA

### Clinical Manifestations

Varicella is a highly contagious, usually self-limited systemic infection, characterized by fever and a generalized pruritic rash, lasting about 5 days (Figure 7). A prodromal phase in children is unusual, but it is not uncommon for adults to experience a prodrome of malaise and fever for 1 to 2 days prior to onset of the rash (3). The rash is characteristically more concentrated on the trunk and head than on the extremities, and it typically evolves as a series of “crops” over 1 to 2 days in healthy hosts. Most children with varicella develop from 250 to 500 skin lesions, many of which are vesicular (65). In many cases a few lesions may develop in the mouth or conjunctiva or on other mucosal sites. Rarely, the skin lesions may be bullous or hemorrhagic. Residual scarring is exceptional, but depigmented areas of skin may result and be persistent. Constitutional symptoms may be mild despite an extensive exanthem, but usually the extent of rash reflects the severity of the illness. It is not uncommon to observe a transient increase in hepatic aminotransferase levels without jaundice during varicella, but this is not considered a complication of the disease (3). Adults are more likely to develop severe varicella than children, presumably because of lower CMI responses to VZV than in children (3). Newborn infants who acquire varicella from their mothers in the few days prior to delivery are also at risk of developing severe varicella, presumably because of the immature CMI response in very young babies in the absence of specific maternal antibodies (3, 77). Patients with various immunodeficiencies affecting the CMI response to VZV (T lymphocytes and NK cells) (112) and those receiving high doses of steroids for any reason are at risk to develop severe varicella (3, 8).

### Clinical Diagnosis

It is usually not difficult to make a clinical diagnosis of varicella because the vesicular pruritic rash is so characteristic. In questionable cases, epidemiologic information may be useful, such as a history of recent exposure to varicella or zoster and subsequent transmission of varicella to another person. The differential diagnosis of varicella includes generalized HSV infection, rickettsial pox, impetigo, allergic reactions (including Stevens-Johnson syndrome), poison

**FIGURE 7** Varicella on day 5 in an otherwise healthy 2-year-old boy, showing the typical distribution of skin lesions.

ivy, and insect bites. In locations where vaccine is being used, laboratory confirmation of mild breakthrough varicella in an immunized child (see below) may be required.

### Complications

The most frequent complication of varicella in healthy hosts is bacterial superinfection of the skin, lungs, or bones. Severe morbidity and even mortality involving group A beta-hemolytic streptococcal superinfections have been reported (113). Central nervous system complications that may precede or follow varicella in healthy hosts include transient cerebellar ataxia, a severe form of cerebral encephalitis, aseptic meningitis, transverse myelitis, and stroke. Because aspirin is no longer recommended for children with varicella, encephalopathy due to Reye syndrome has become rare. Meningoencephalitis and cerebellar ataxia, which usually occur between 2 and 6 days after onset of the rash, may also occur during the incubation period (3, 114). With these complications, the cerebrospinal fluid (CSF) may be normal or may exhibit a mild lymphocytic pleocytosis (<100 cells/ml), a moderate elevation of protein (<200 mg), and normal glucose. VZV encephalitis can be life threatening; symptoms may reverse rapidly or gradually improve. Chronic neurologic or developmental sequelae may occur (115). Cerebellar ataxia may persist for days to weeks but is almost invariably self-limited. Strokes after varicella are unusual, have only recently been recognized as a complication of the infection, and are hypothesized to be secondary to vasculitis provoked by VZV (116). Varicella may rarely

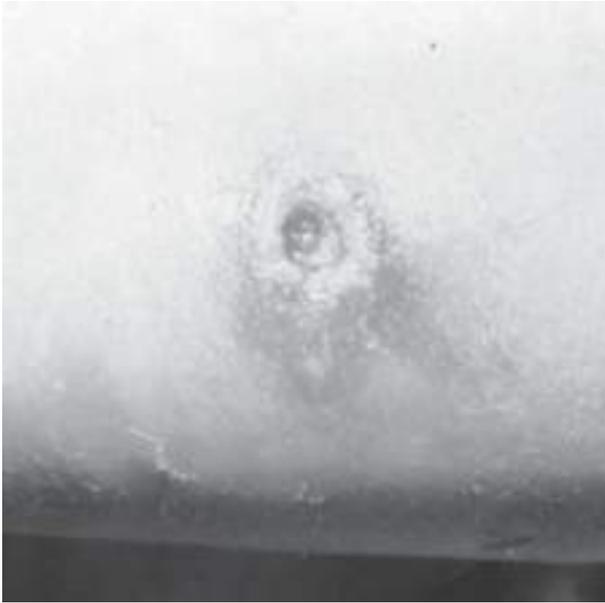

**FIGURE 8** Hemorrhagic fatal varicella in a child with underlying lymphoma.

cause neutropenia and thrombocytopenia with hemorrhagic complications 1 to 2 weeks after the initial infection (117). Arthritis is an infrequent, transient complication; VZV has on occasion been isolated from joint fluid. Vesicular lesions that involve the eyelids and conjunctivae rarely cause serious ocular complications (118). Other rare complications of varicella include renal failure, myocarditis, pericarditis, pancreatitis, orchitis, and purpura fulminans (3, 102, 119).

Varicella may be severe and even fatal in immunocompromised patients. These include persons with an underlying malignancy; congenital or acquired deficits in CMI, such as those who have undergone organ transplantation or have underlying human immunodeficiency virus (HIV) infection; and individuals receiving high doses of corticosteroids for any reason (3). Patients with deficiencies in CMI may manifest progressive varicella, with continuing fever and development of new vesicular lesions for as long as 2 weeks (Figure 8). Their characteristic skin lesions are often large, umbilicated, and hemorrhagic; primary varicella pneumonia is a frequent complication. Alternatively, some immunocompromised patients develop an acute form of varicella with disseminated intravascular coagulation that is rapidly fatal (3). A visceral disease rate of 30% and a fatality rate of 7% were reported for leukemic children who developed chickenpox prior to the availability of antiviral drugs (120). Severe varicella has been observed in children with underlying infection with HIV, especially those who have clinical evidence of AIDS, but most HIV-infected children develop mild to moderate forms of varicella. The illness in this population is not potentially as severe as in children with leukemia (121). However, because it is difficult to predict in advance whether a child with HIV infection will develop severe varicella, most physicians routinely elect to treat them at onset with antiviral drugs. Varicella does not seem to be a cofactor for clinical progression of HIV infection to AIDS, but chronic infections with wart-like hyperkeratotic lesions with occasional virus dissemination may develop in these patients (122) (Figure 9). These lesions appear to be a persistent form of VZV infection rather than classic zoster.

Primary varicella pneumonia accounts for many of the fatalities ascribed to varicella (Figure 10). It most commonly occurs in immunocompromised patients, adults, and neonates with chickenpox (3). In a chest X ray study of military recruits with varicella, radiographic evidence of pneumonia was found in 16%, although only one quarter of these

**FIGURE 9** Chronic VZV skin lesion in a child with underlying HIV infection.

patients had pulmonary symptoms (123). Pneumonia usually occurs within several days after the onset of rash, but sometimes this interval may be longer. Symptoms include fever and cough in almost all cases and dyspnea in more than 70%. Other common symptoms and signs include cyanosis, rales, hemoptysis, and chest pain. The chest X ray typically reveals a diffuse nodular or miliary pattern, most pronounced in the perihilar regions (124). The availability of antiviral chemotherapy has greatly improved the outcome of varicella pneumonia.

## ZOSTER

### Clinical Manifestations

Zoster usually begins as a localized skin eruption involving one to three dermatomal segments. The characteristic distribution of the unilateral rash reflects its pathogenesis, reactivation of latent VZV from dorsal root or cranial nerve ganglia (Figure 11). The skin lesions resemble those of varicella but tend more toward confluence. Zoster usually

**FIGURE 10** Chest radiograph of a patient with primary varicella pneumonia. (Courtesy of Walter Berdon.)

develops in patients who are at least somewhat immunodeficient, as a result of disease, chemotherapy, radiotherapy or normal aging. Healthy young adults who are not immunocompromised may develop zoster, presumably resulting from a transient decrease in CMI to VZV as a response to a stimulus such as another viral infection or stress. Because many immunocompromised persons do not develop zoster, however, deficiency of CMI to VZV is thought to be a necessary but not sufficient to develop this illness. It is likely that reactivation of VZV first occurs and that clinical zoster then results when the CMI response is deficient.

There is a spectrum of clinical manifestations of zoster. Zoster with no rash but with dermatomal pain has been described (zoster sine herpete) (125, 126), as has visceral zoster without skin rash (125). Increases in VZV antibody titer in the absence of an exposure to the virus have been ascribed to silent reactivation of VZV (3). Subclinical viremia in patients after bone marrow transplantation has been demonstrated by PCR (75). Shedding and transmission of infectious VZV from asymptomatic individuals has not been documented as it has for HSV. Asymptomatic reactivation of VZV following extreme stress has been detected (127, 128).

### Clinical Diagnosis

It is usually not difficult to make a clinical diagnosis of zoster because the unilateral dermatomal rash is so characteristic. In one study, however, 13% of cases clinically diagnosed as zoster were proven by culture to be due to HSV infection (129). HSV in particular should be considered in the differential diagnosis when the rash has a trigeminal/maxillary, breast (T4), or sacral distribution, and especially if the rash is recurrent. The unilateral rash of zoster most often involves the thoracic and cervical areas, followed by the face. Laboratory verification is becoming of greater importance in the vaccine era, when it may be of clinical interest to determine if a zosteriform rash is due to VZV and if it is wild or vaccine type.

Self-limited meningitis indicated by abnormalities of the CSF, including pleocytosis (predominantly of mononuclear cells) and elevated protein, may develop in many patients with zoster (3). Complete healing of the rash usually occurs within 2 weeks but may require 4 to 6 weeks, especially in immunocompromised patients. Segmental pain and/or itching are common symptoms in zoster. These sensations may precede the onset of rash. Other causes of acute segmental pain such as myocardial infarction, acute abdomen,

**FIGURE 11** Zoster in a 10-year-old boy with underlying leukemia, showing the unilateral lumbar distribution of the skin lesions.

and pleurisy may need to be excluded in patients with pre-eruptive zoster pain or zoster sine herpette.

### Complications

From 25% to 50% of persons over the age of 50 who develop zoster may develop protracted pain, or postherpetic neuralgia (PHN), following healing of the rash. Treatment with antiviral drugs has not led to a decrease in the incidence of PHN, although therapy may decrease the duration of pain (3). Pain may persist for months to years and is described as aching, jabbing, or burning. Abnormal sensations may also occur, such as pain after a minimal nonpainful stimulus (allodynia) and severe pain after a mild pain stimulus (hyperalgesia). The precise cause is unknown. Hypotheses include an aberrant immune response to the virus in the neuron, pain resulting from repair of neuronal damage, and continuing low-level multiplication of virus in the ganglion, with nerve damage from inflammation and hemorrhage. Evidence against the last hypothesis is the observed usual failure of antiviral therapy to relieve PHN. Both the incidence and duration of PHN are directly related to increasing age (4, 130).

Zoster can also involve various cranial nerves. Zoster in the ophthalmic branch of the trigeminal (fifth) nerve may cause dendritic keratitis, anterior uveitis, iridocyclitis with secondary glaucoma, and panophthalmitis (131). Retinitis from VZV is a particular problem for HIV-infected persons (132). Reactivation of VZV involving the maxillary branch results in oral lesions. Motor nerve deficits may also be associated with zoster of the trigeminal nerve. Reactivation in the geniculate ganglion of the seventh (facial) cranial nerve and the eighth (auditory) cranial nerve, termed the Ramsay Hunt syndrome, is associated with facial palsy.

Motor deficits occur in approximately 1% of zoster cases (133). Bladder dysfunction or ileus with intestinal obstruction is an unusual complication of lumbosacral zoster. Partial paralysis of an extremity can also occur after zoster. The prognosis for recovery from these motor deficits is good, although residua may follow in as many as 15% of patients (133). Transverse myelitis is an extremely rare complication with a high mortality (130).

Zoster is complicated by clinical encephalitis in an estimated 0.2% to 0.5% of cases. Risk factors include advancing age and cranial nerve involvement. Symptoms, which often occur about a week after onset, include altered state of consciousness, headache, photophobia, and meningismus. The average duration of encephalitic symptoms is about 2 weeks (130, 133). Neurologic sequelae may follow recovery.

Granulomatous angiitis resulting in signs and symptoms resembling those of a cerebrovascular hemorrhage or thrombosis (stroke) is an unusual complication of zoster that occurs particularly in the elderly (130). The central nervous system symptoms characteristically occur on the side opposite the rash, and they may develop months after onset of the rash. There is a high mortality, and at autopsy, vascular inflammation with thrombosis and microinfarcts are seen in the temporal and other arteries (130, 134–136).

A syndrome of zoster accompanied by inappropriate secretion of antidiuretic hormone has been described to occur in immunocompromised patients. It may be associated with severe abdominal pain and is associated with a poor prognosis (137, 138).

Visceral zoster with predominant abdominal symptoms, such as pain and even gastrointestinal obstruction, has been described, particularly for immunocompromised patients.

Pain may precede the rash by several days, and in some cases no rash develops (139). Latent VZV in the enteric nervous system of humans has been described, and its consequences (such as causing gastric ulcers resulting from reactivation of VZV in the absence of rash) are being identified (43, 123).

### CONGENITAL VARICELLA SYNDROME

Congenital varicella syndrome has a characteristic constellation of developmental abnormalities and was first described in case reports of infants born to mothers who had varicella in early pregnancy. In 1947, LaForet and Lynch described an infant with multiple congenital anomalies after maternal chickenpox during the 8th week of pregnancy (140). The infant had hypoplasia of the right lower extremity with clubfoot and an absence of deep tendon reflexes, cerebral cortical atrophy, cerebellar aplasia, chorioretinitis, torticollis, insufficiency of the anal and vesical sphincters, and scarred cutaneous lesions of the left lower extremity. While initially it was thought that the syndrome occurred after maternal VZV infection in the first trimester of pregnancy, an equal number of reported cases have occurred following maternal varicella in the second trimester. Over 100 affected infants have now been reported (77). Almost all of these cases have followed maternal varicella; a few cases following maternal zoster have been described but rarely substantiated (3). If a woman develops varicella in the first or second trimester of pregnancy, it is estimated that there is a 2% chance that her baby will be affected by this syndrome. In the prevaccine era it was estimated that about 40 infants were born annually in the United States with this syndrome (38). Scars of the skin, usually described as cicatricial, are the most prominent stigmata, reported in 70% of cases (Table 3) (77). Other frequent abnormalities include those involving the eyes, such as chorioretinitis, microphthalmia, Horner syndrome, cataract, and nystagmus. Hypoplastic limbs, cortical atrophy and/or mental retardation, and early death are also commonly observed.

**TABLE 3** Clinical data on over 100 reported infants with developmental defects whose mothers had VZV infections (over 95% with varicella) during the first or second trimester of pregnancy between 1947 and 2002<sup>a</sup>

Defect	% of infants with defect
Skin scars	70 <sup>b</sup>
Eye abnormalities (chorioretinitis, Horner syndrome/anisocoria, (microphthalmia, cataract, nystagmus)	60
Neurologic abnormalities (retardation, seizures, paralysis)	60

<sup>b</sup>Cicatricial in over 60%.

<sup>c</sup>Of infants with hypoplastic limb 50% had mental retardation.

## LABORATORY DIAGNOSIS

The diagnosis of VZV infection can usually be made clinically, but laboratory diagnosis may be necessary in unusual cases, particularly for vaccinated individuals who develop either possible varicella or zoster. Laboratory diagnosis of active VZV infection is facilitated by the presence of VZV in superficial skin lesions, where it is accessible for testing. Diagnosis is best made by demonstration of VZV DNA or specific viral antigens in vesicular skin lesions. PCR has supplanted viral culture as a diagnostic tool; it has been successfully employed for diagnosis of VZV utilizing skin scrapings, vesicular fluid, respiratory secretions, and CSF (64). PCR can also be used to differentiate between vaccine and wild-type VZV (13) and to demonstrate susceptibility to antiviral drugs (141). VZV antigen may be demonstrated by immunofluorescence (IF), using a commercially available monoclonal antibody to gE of VZV that is conjugated to fluorescein (64). This is a highly sensitive and rapid diagnostic method that can be completed within about an hour and is therefore clinically useful.

The presence of VZV by IF or culture in clinical material obtained from skin or other lesions, or autopsy tissue, is diagnostic of an active infection (142) because unlike for HSV, there is no known infectious carrier state in asymptomatic individuals. The presence of VZV DNA in specimens such as nervous tissue, however, suggests but does not prove latent VZV infection.

If a culture is to be successfully performed, vesicular fluid should be obtained as early in the course of illness as possible to facilitate isolation of VZV. Within several days after onset of varicella, vesicular fluid is no longer likely to be infectious, although viable VZV may be present in zoster lesions for a longer period, especially in immunocompromised patients. Isolation of VZV is a relatively slow method, since it takes at least 48 hours before the first signs of viral CPE are seen. It is also less sensitive than IF staining, since infectious virus persists for a shorter length of time in vesicles and is more labile than viral antigens. PCR is the most sensitive technique (143). VZV is rarely isolated from CSF, throat, pharyngeal, and conjunctival specimens. Human lung fibroblasts such as WI-38 cells are most frequently utilized to isolate VZV in tissue culture. The Tzanck test provides only nonspecific information; it has been replaced by more sensitive and specific methods mentioned previously.

A number of sensitive serologic tests are available to measure antibodies to VZV. These include the fluorescent antibody to membrane antigen (FAMA) method, latex agglutination, and enzyme-linked immunosorbent assay (64). Antibody to VZV develops within a few days after onset of varicella, persists for many years, and is present before the onset of zoster. VZV infections may be documented by a  $\geq 4$ -fold rise in VZV antibody titer in acute- and convalescent-phase serum specimens. The presence of specific IgM in one serum specimen suggests but does not necessarily prove recent VZV infection, either varicella or zoster (64). Persistence of VZV antibody in infants beyond 8 months of age is highly suggestive of intrauterine varicella (144). Immunity to varicella is highly likely to be present if a positive titer of antibody (measured by a reliable assay) to VZV is demonstrated with a single serum sample from a child or an adult with no history of disease. Serologic methods, however, particularly commercial enzyme-linked immunosorbent assays, may fail to identify many individuals who have been immunized with live attenuated varicella vaccine (64).

While the FAMA assay is the most sensitive test for this purpose, it is not generally available.

The value of serologic procedures for diagnosis of zoster is limited, since heterologous increases in titer of antibody to VZV may occur in patients with HSV infections who have previously had varicella. This phenomenon has been ascribed to antigens common to the two viruses (64).

## PREVENTION

VZV is such an infectious agent that general measures are not very useful for prevention of varicella in susceptible individuals. Some protection for hospitalized patients, however, can be accomplished by isolation of patients with moist VZV skin lesions, particularly if they are placed in rooms with negative-pressure ventilation. Hospitalized patients with active VZV infections should be admitted to a private room, and hospital personnel and visitors should wash their hands before and after entering the room and wear masks, gowns, and gloves while in it. Spread of VZV by fomites does not occur. Children with obvious varicella should be excluded from school until the skin lesions are dry. Vaccinated children who develop a few skin vesicles between 2 and 6 weeks after vaccination are unlikely to spread VZV and can attend school if they are otherwise well. Vaccinees with rash 1 to 14 days after immunization are likely to be infected with wild-type VZV. In recently vaccinated patients the development of more than 50 vesicles is highly suggestive of wild-type infection, which unlike the Oka strain, is highly transmissible. These patients, therefore, should be excluded from school and if hospitalized should be isolated from other patients.

Prevention of varicella may be accomplished with either active or passive immunization. Varicella-susceptible children at high risk of developing severe chickenpox should be passively immunized if they are closely exposed to someone with either varicella or zoster. Passive immunization usually modifies varicella but may prevent it. Passive immunization may be a life-saving measure for a high-risk susceptible child.

### Passive Immunization against Varicella

Varicella-zoster immunoglobulin (VZIG) was approved by the Food and Drug Administration (FDA) for use in 1981. Because the demand for this product decreased sharply after licensure of varicella vaccine in 1995, it is no longer being produced in the United States. It was shown to be most effective when administered up to 3 days after exposure and perhaps helpful for as long as up to 5 days. VZIG was replaced by a new varicella immunoglobulin product (VarizIG), manufactured in Canada (telephone numbers for information are 800-843-7477 and 800-746-6273). The dose is 1.25 ml (one vial or 125 U) for each 10 kg of body weight, with a maximum dose of 6 ml (five vials or 625 U) intramuscularly.

The major use of passive immunization is for prevention of severe varicella in people (usually children) who have been closely exposed to varicella or zoster and are at high risk of developing severe or fatal chickenpox. This includes immunocompromised patients and also newborn infants whose mothers have active varicella at the time of delivery. Passive immunization is customarily readministered to high-risk susceptible persons who are closely reexposed to varicella or zoster 3 weeks following a first exposure for which passive immunization was given.

Infants and children who are listed in the high-risk groups should be considered to be susceptible to varicella if they have no history of having had chickenpox. It is potentially hazardous to withhold passive immunization in an immunocompromised child who based on a positive antibody titer has no history of previous clinical varicella because of the possibility of a false-positive antibody test. Only about 25% of adults with no history of varicella are truly susceptible; therefore, passive immunization should generally be administered to VZV-exposed adults only if they are serologically proven to be susceptible to chickenpox. Presumably, passive immunization is useful for adults, but in contrast to use in children, for whom efficacy has been established, no efficacy studies have been performed in adults. An alternative for healthy varicella-susceptible adults with a known exposure to VZV would be to institute oral antiviral therapy at the very first sign of clinical varicella. The latter approach is considerably less expensive than passive immunization. Susceptible adults who do not develop varicella after a close exposure should be strongly considered for active immunization against varicella (see below).

Patients with HIV infection, especially those with AIDS, are at increased risk of developing severe varicella (3, 77). Their management should be similar to that of other varicella-susceptible immunocompromised children and adults.

Infants whose mothers have active varicella at delivery should receive passive immunization; specifically, this includes infants whose mothers have onset of chickenpox 5 days or less prior to delivery or within 48 hours after delivery. The transplacental route of infection and the immaturity of the immune system probably account for the severity of varicella in these infants (77). The dose of VZIG or VariZIG for newborn infants is 125 U intramuscularly. Attack rates for varicella of up to 50% in infants exposed to mothers who have varicella have been reported, despite administration of VZIG (77). Usually varicella is mild in passively immunized infants; severe varicella after timely administration of VZIG is rare (3). Passively immunized infants should be monitored carefully, but usually these infants can be managed on an outpatient basis even if they develop varicella. They may be given therapeutic oral acyclovir (ACV). The rare passively immunized exposed infant with varicella who develops an extensive skin rash (more than 100 vesicles) or possible pneumonia should be hospitalized and treated with intravenous ACV.

It is unnecessary to passively immunize full-term infants who are exposed to VZV after they are 48 hours old. Passive immunization is optional for newborn infants (under 1 week old) if their siblings at home have active varicella, particularly if the mother has no history of chickenpox or if the mother develops varicella. Infants whose mothers have previously had varicella and who are exposed to siblings or others with chickenpox are unlikely to develop severe varicella because they are at least partially protected by transplacental maternal antibody. Infants exposed to mothers with zoster do not require passive immunization because they and their mothers have high titers of antibodies to VZV. Some low-birth-weight infants may have undetectable VZV antibody titers at birth; therefore, it is recommended that newborn infants weighing less than 1,000 g or who are of less than 28 weeks' gestation who are exposed to VZV be passively immunized, even if their mothers had varicella.

Zoster occurs despite humoral immunity to VZV, and patients with zoster have very rapid rises in VZV antibodies; passive immunization is thus not useful to treat or prevent zoster. It is not known whether passive immunization of

pregnant varicella-susceptible women who have been closely exposed to VZV will protect the fetus against the congenital varicella syndrome. Passive immunization is potentially useful to prevent severe varicella in varicella-susceptible pregnant women who are exposed to VZV.

Alternatives to VariZIG include intravenous immunoglobulin, 400 mg/kg, and zoster immune plasma (3).

### Active Immunization against Varicella

Active immunization against varicella can be successfully accomplished with live attenuated varicella vaccine. This vaccine was developed in Japan in 1974 (145) and was approved by the FDA in the United States in March 1995 for universal administration to healthy children and adults who are susceptible to varicella (146). The vaccine is well tolerated and safe (3). The major complication following vaccination of healthy persons is a vaccine-associated rash, which occurs in 5% of vaccinees about 1 month later (3). These rashes are usually extremely mild in healthy vaccinees, with an average of five skin lesions that are generalized and/or at the injection site. The risk of transmission of Oka vaccine virus to others is present only while the vaccinee has rash, is exceedingly rare (1 transmission per 10 million vaccinees), and is much lower than the rate of transmission after exposure to wild-type VZV (3). The risk to anyone from wild-type VZV is greater than the risk from vaccine-type VZV. Therefore, it is recommended to immunize hospital workers and individuals whose family members are immunocompromised or pregnant, especially if they are susceptible to varicella (146). Highly immunocompromised individuals inadvertently closely exposed to a vaccinee with rash can be passively immunized if they are susceptible to varicella, although this is not considered mandatory.

Vaccinated individuals who develop a rash within 2 to 3 weeks after immunization may have been exposed to wild-type VZV prior to being vaccinated and are likely to have a rash caused by the wild-type virus (44). This should especially be suspected if many lesions occur and are accompanied by systemic symptoms, which are unlikely to be caused by the vaccine-type virus. It is extremely helpful in trying to evaluate such a situation to utilize PCR to differentiate between wild-type and vaccine-type VZV (3).

Live attenuated varicella vaccine is highly protective against chickenpox in healthy and immunocompromised children and in healthy adults. Not all vaccinees, however, are completely protected, particularly after one dose of vaccine (3). Roughly 15% of children may manifest a modified illness, referred to as breakthrough varicella, months to years after receipt of one dose. Varicella vaccine has, however, been over 95% effective in preventing severe varicella (3). Varicella vaccine is less effective in adults than in children; even after two doses of vaccine, only 70% of adults achieve complete protection from varicella following a close exposure to VZV, although the remainder usually have partial protection (147). In contrast, 85% of immunized healthy children are protected after only one dose of vaccine (3, 143, 148). Breakthrough varicella is almost always a modified illness, with fewer than 50 skin lesions and minimal systemic signs. In one study, about two thirds of cases of breakthrough varicella were classified as mild (< 50 skin lesions) (148).

In order to improve protection against breakthrough varicella in healthy child vaccinees, a second routine dose of vaccine was recommended by the Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics in June 2006 (146). The second dose may

be administered at any time after 1 month following the first dose, but an interval of at least 3 months is preferred. Varicella vaccine for children may be given either as monovalent vaccine or as measles-mumps-rubella-varicella (MMRV) vaccine. In a case control efficacy study of monovalent vaccine, two doses of varicella vaccine were significantly more protective against breakthrough chickenpox than one dose (149). Anamnestic humoral and cellular immune responses to VZV after two doses of vaccine given months or years apart have been reported in several studies (3).

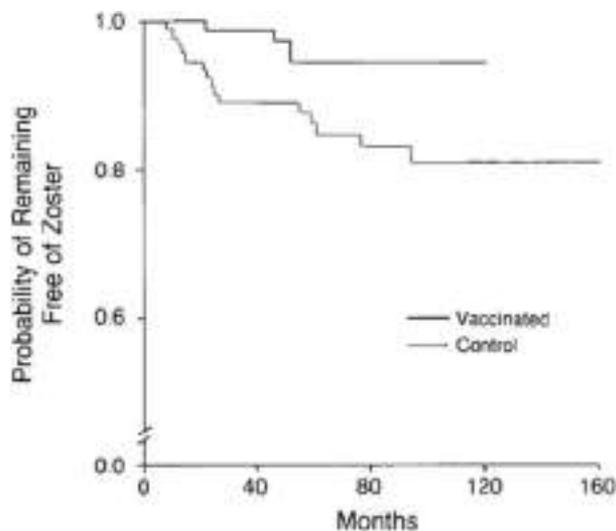

The observation of breakthrough varicella in about 15% of children following one dose of vaccine prompted analyses of whether this phenomenon could be due to primary or secondary immune failure. A result of either or both could be an accumulation of young adults who are susceptible to varicella a decade or so after vaccination. A study of 148 children indicated that the rate of primary vaccine failure was 24%, based on FAMA testing for VZV antibodies in the first 4 months after vaccination (111). An epidemiological study of children in Antelope Valley, CA, indicated that there was an increase in breakthrough varicella with time (over a 9-year period), with increasing severity of breakthrough cases (150). These data were interpreted to represent immunity's waning with time (secondary vaccine failure). In contrast, however, a case control study did not reveal any decrease in immunity in years 2 to 8 after immunization (143). The issue of whether waning immunity occurs after receipt of one dose of vaccine is therefore controversial but seems unlikely based on recent information (151). In any case, a recommended second dose of vaccine for all children addresses the possibility of both primary and secondary vaccine failure following one dose.

Varicella vaccine has been used effectively to protect immunocompromised children. It is no longer recommended that children with leukemia be vaccinated because of the development of vaccine-associated rash in roughly 50% that often requires treatment with acyclovir (ACV) (152). In contrast, children with HIV infection whose immune function remains relatively intact (more than 15% CD4 lymphocytes) have tolerated varicella vaccine as well as healthy children have (153, 154). Two doses at least 1 month apart are recommended for HIV-infected children. Vaccination against varicella protects HIV-infected children from both varicella and zoster (155). Vaccination of children prior to renal transplantation has also been highly successful in preventing severe varicella and also zoster (3). Small studies suggest that vaccination after liver transplantation may be safely accomplished (156).

Vaccinated individuals are at risk of developing zoster, but the incidence appears to be lower after vaccination than after natural infection (Figure 12) (157). Possibly this is because after vaccination the viral latency load is lower than after natural infection. A small study of healthy adult vaccinees also suggests similar protection against zoster (158). One third of the reported zoster cases in vaccinees are caused by the wild type virus (159).

Significant progress has been made in development of a vaccine to prevent zoster in the elderly. Interest in this approach was generated by the recognition of immunologic boosting that accompanies reexposure to VZV and the loss of VZV CMI prior to developing zoster. In this case, the rationale behind prevention of zoster with vaccination is to minimize reactivation by increasing CMI to VZV in persons who have latent infection.

Zoster can be prevented by immunizing elderly individuals with VZV latent infection due to a prior attack of

**FIGURE 12** Kaplan-Meier product limit analysis of the probability of remaining free of zoster in 96 children with leukemia who had naturally acquired varicella before or after the diagnosis of leukemia. varicella. This was shown in a double-blind placebo-controlled study involving 38,546 healthy adults over the age of 60 years, which was conducted from 1999 to 2004 (4). The dose of vaccine used, marketed as Zostavax (Merck and Co.), contains about 14 times the dose of live virus that is present in monovalent varicella vaccine (Varivax) in the United States (not less than 19,400 PFU per 0.65-ml dose). The vaccine proved to be extremely safe; adverse events were similar in vaccinees and placebo recipients, with the exception of transient reactions such as rash or redness at the injection site in 43% of vaccinees, compared to 17% in controls. Although the development of zoster was not the original primary endpoint of this study, a decrease in incidence of zoster of 51% was found in vaccinees compared to placebo recipients. There was better protective efficacy against zoster in vaccinees aged 60 to 69 years (64%) than in vaccinees aged 70 to 79 years (41%). In the original analysis, when development of significant pain, not zoster itself, was the primary endpoint, there was a 61% reduction of significant pain in vaccinees (some vaccinees had mild zoster with only minor or no pain). Vaccination was also highly effective in prevention of PHN, especially in patients aged 70 to 79 years (55% effectiveness). Efficacy persisted for ~8 years after vaccination (160).

A subunit (glycoprotein E) well-tolerated vaccine mixed with the adjuvant As01<sub>B</sub> (called HZ/su) was recently reported to have over 97% efficacy in elderly individuals (50 to >70 years of age) who were followed for ~3 years. In a double-blind placebo-controlled study of 15,411 subjects in 18 countries, the incidence of HZ was 0.3 in vaccinees and 9.1 in placebo recipients per 1000 person-years of observation (161). This vaccine has not yet been licensed for use, but rapid licensure seems likely.

These vaccines against zoster are important clinical advances, although many questions remain, such as the best age at which to immunize, the duration of the effectiveness of the vaccine, and whether booster doses are necessary.

### Drug Prophylaxis

The antiviral drug ACV has been examined for prevention of varicella in exposed persons (162). Despite apparent prevention of clinical varicella in almost all cases in such studies, the approach is not recommended in countries where passive and active immunization is available. Whether there is long-term maintenance of immunity after prophylactic ACV is not known. The CDC recommends postexposure vaccination for healthy nonpregnant varicella-susceptible individuals who have been exposed to VZV (2). Long-term ACV therapy (1 year) as a preventive against development of zoster in patients who have undergone bone marrow transplantation appears to be useful, as well as in patients who have undergone stem cell transplantation (163, 164).

### Treatment

Specific antiviral therapy became available in the mid-1970s. The first drugs used were relatively ineffectual and also toxic. The modern age arrived with the introduction of ACV, which as its triphosphate is an inhibitor of DNA polymerase and a DNA chain terminator that is highly effective against VZV (165). Current recommendations for antiviral therapy for VZV are summarized below. For additional details the reader is referred to chapter 12.

ACV is extremely useful for therapy of VZV infections. Patients with severe or potentially severe infections should be treated with the intravenous formulation at dosages of 30 mg/kg/day for adults and adolescents and 1,500 mg/m<sup>2</sup>/day for children (both given in three divided doses). Orally administered ACV is less reliable for immunocompromised patients because only about 20% of this formulation is absorbed from the gastrointestinal tract. ACV is excreted by the kidneys; patients with creatinine clearances of less than 50 ml/min/1.73 m<sup>2</sup> should receive one-half to one-third of this dosage. Intravenous ACV is infused over at least 1 h, with maintenance fluids given both before and during the infusion. Adequate hydration is important to prevent precipitation of the drug in the renal tubules, which can result in increases in serum creatinine levels. This complication of

ACV has also been associated with bolus administration. Other adverse effects of ACV include phlebitis, rash, nausea, and neurologic manifestations such as headache and tremor. In general, however, ACV is extremely well tolerated.

Because ACV has little associated toxicity, and therapy within 2 to 3 days of onset has been associated with the best outcomes, it is recommended that early therapy be instituted for patients at high risk of developing severe VZV infections, such as children with leukemia, in order to prevent dissemination of the virus, as well as patients with ophthalmic zoster (166, 167). Therapy with ACV not only is potentially lifesaving in immunocompromised patients with VZV infections but also it prevents considerable morbidity. In zoster patients, use of intravenous ACV is associated with more rapid healing of skin lesions and resolution of acute pain than if no specific treatment is given (Table 4) (166, 167).

Orally administered ACV may be used for treatment of varicella and zoster in otherwise healthy adults and children, although most of these infections are self-limited. Dosages used are 4 grams per day (in five divided doses) for adults and 80 milligrams per kilogram per day (in four divided doses) for children. Double-blind placebo-controlled studies with healthy children and adolescents given 80 milligrams of ACV or placebo per kilogram a day for 5 days, beginning within 24 hours of onset of the varicella rash, revealed that the number of chickenpox skin lesions was reduced by ACV therapy. There was, however, only about 1 less day of fever, and children who were treated with ACV did not return to school any more rapidly than those who received placebo, reflecting a modest benefit conferred by ACV therapy. Therapy with oral ACV did not prevent complications or prevent spread of VZV (168). The therapeutic effect of oral ACV is no more pronounced in adults with varicella than in children (169). Because of the possibility of a therapeutic effect with the use of a very safe drug, however, it has become customary to treat most immunocompetent adolescents and adults who develop varicella with ACV or a related compound.

For zoster, drug efficacy has been shown even if 3 days have elapsed since onset, but the earlier ACV is begun, the

**TABLE 4** Drugs for treatment of VZV infections<sup>a</sup>

Drug	Dosage for treatment		Comments
	Varicella	Zoster	
Acyclovir	20 mg/kg q.i.d. p.o. <sup>b</sup> for 5 days, 500 mg/m <sup>2</sup> every 8 hr i.v.	800 mg 5 times/day p.o. (adult dose) for 7–10 days, 10 mg/kg every 8 h i.v.	i.v. drug of choice for immunocompromised patients; p.o. administration shortens course of varicella by ca. 1 day in children and decreases acute pain of zoster
Valacyclovir (p.o.)	20 mg/kg t.i.d. p.o. for 5 days, age 2–18 yrs	1 g t.i.d. for 7 days (adult dosage) p.o.	High oral bioavailability; decreases ZAP duration; 0.5% of immunocompromised patients develop hemolytic-uremic-like syndrome
Famciclovir (p.o.)	NI	500 mg t.i.d. for 7 days (adult dosage)	High oral availability; decreases ZAP duration
Foscarnet	Dosage for children not established	120 mg/kg/day divided TID (adjust for renal function) i.v. up to 3 weeks	For ACV-resistant VZV infection i.v.

<sup>a</sup>q.i.d., four times a day; t.i.d., three times a day; p.o., orally; i.v., intravenously; NI, not indicated because of lack of supporting data; ZAP, zoster-associated pain (includes PHN).

<sup>b</sup>Maximum per day, 800 mg.

greater the therapeutic effect. There is some indication that early ACV therapy may decrease acute pain associated with zoster (170). Therefore, it is recommended that elderly patients with early zoster be given prompt antiviral therapy because the older the patient with this disease, the more likely it is that pain will be a future problem. One study showed no difference in outcome in older patients with zoster whether they were treated with ACV for 7 or 21 days (171). In this study, recovery was no more rapid, nor was PHN less likely to occur, if a 3-week course of tapering prednisolone (beginning at milligrams per day) were given along with ACV.

Famciclovir (FCV), is a prodrug of the antiviral penciclovir, to which it is rapidly converted in the body after oral administration. Penciclovir has an antiviral action similar to that of ACV. FCV was approved by the FDA in 1994 for oral therapy of zoster in adults. An advantage of FCV over ACV is that FCV is given three times a day (500 milligrams per dose) rather than five times a day, which may lead to better patient compliance. One study suggests that FCV given to elderly patients with zoster early in the course of infection decreases the duration of PHN but not its incidence (172). There are no data as to whether varicella may be successfully treated with FCV, nor are there any published data on use of FCV in immunocompromised patients or in children.

The prodrug of ACV, valacyclovir, which is also given orally, reaches levels in blood that are about four times higher than ACV levels after oral administration. Valacyclovir is approved for use in the United States, and one study suggested that it may be superior to ACV in immunocompetent patients with zoster (173). Valacyclovir may not be as effective as intravenous ACV, however, in highly immunocompromised adults, particularly those with AIDS with severe VZV infections (174). The dosage of valacyclovir for immunocompetent adolescents and adults with zoster is 1 gram three times a day, orally. As for all antivirals, early therapy (within 3 days of onset of rash) is required for effective results.

Foscarnet is useful for treating VZV infections caused by viruses that are resistant to ACV and FCV and was approved by the FDA for this purpose. Foscarnet acts by directly inhibiting the DNA polymerase of VZV (175). Intravenous foscarnet has been used for adults at a dosage of 120 milligrams per kilogram per day (in three divided doses) for VZV infections that are resistant to ACV. The dosage for children is not established. Its main toxicity is renal.

VZV retinitis is a potentially very serious but fortunately rare form of infection. Some forms require treatment with combination antiviral therapy including foscarnet and ganciclovir; consultation with an experienced ophthalmologist is strongly recommended for these patients.

Of concern about the potential widespread use of ACV is that drug resistance may develop and that resistant VZV may spread to others. At present, resistance is less a problem with VZV than with HSV. As for HSV, however, VZV resistant to ACV has been reported, most commonly for patients with underlying AIDS (176, 177). Rarely, the Oka vaccine strain of VZV has developed resistance to ACV (142, 178, 179).

# Cytomegalovirus

PAUL DAVID GRIFFITHS AND MATTHEW REEVES

## 23

Human cytomegalovirus (HCMV) was first isolated in the mid-1950s, when the new technology of cell culture became available. It was isolated independently by three different investigators and named because of its cytopathic effect (CPE), which produced large, swollen, refractile cells causing "cytomegaly." The virus is ubiquitous, having infected most individuals by early adulthood in developing countries and by late adulthood in developed countries. Most individuals show no symptoms as a result of primary infection, reactivation, or reinfection, indicating that the virus is well adapted to its normal host, which commits substantial immune resources to controlling HCMV. However, in individuals whose immune system is either immature (as in the fetus) or compromised by immunosuppressive therapy or human immunodeficiency virus (HIV) infection, HCMV can cause serious end-organ disease (EOD). Furthermore, accumulation of HCMV-specific T cells over decades contributes to immunosenescence. Thus, HCMV acts as an opportunist, damaging the very young and the very old as well as adults and children whose immune systems are impaired.

The pathogenesis of HCMV disease is complex, involving contributions from the host as well as from the virus. Increasing knowledge about the genetic composition of the virus can help to illuminate this complex series of relationships and provide a rational basis for therapeutic intervention and prevention of disease.

## VIROLOGY

### Classification

HCMV is a member of the *Betaherpesvirinae* subfamily of the *Herpesviridae*. This classification was originally based on its slow growth *in vitro* and strict species specificity but is now based on genetic sequence homologies among the *Alpha*-, *Beta*-, and *Gammaherpesvirinae* subfamilies. Based on restriction enzyme analysis of virion DNA, there are multiple genetic variants, termed strains. These genetic differences do not allow classification into distinct genotypes.

Likewise, the corresponding differences in antigenic constitution do not allow distinct serotypes to be defined. Strains are still best characterized as having an antigenic mosaic, which is recognized broadly by the host cellular and humoral immune responses. Individuals infected with one strain of HCMV thus have cross-reactive immunity against

all strains, although the extent to which this provides cross-protection from disease remains to be defined.

The International HCMV Workshop in 1993 agreed upon a nomenclature for the description of HCMV proteins, which is used in this chapter (1). The system designates p for protein, gp for glycoprotein, or pp for phosphoprotein, followed by the genetic locus and any preferred trivial name in parentheses. For example, gpUL55 (gB) is the glycoprotein encoded by the 55th open reading frame (ORF) in the unique long (UL) region, known as glycoprotein B (gB).

### Composition

Purified HCMV virions contain about 60 virus-encoded proteins and more than 70 host proteins (1). In common with all herpesviruses, the HCMV virion has three basic structural units.

### Capsid

The HCMV capsid has a diameter of 125 nm and, by cryoelectron microscopic (cryo-EM) reconstruction, is made up of 162 capsomeres arranged as an icosahedral lattice with a triangulation number of 16. There are 150 hexons, which comprise 6 copies of the major capsid protein (MCP, encoded by the UL86 gene), 11 pentons (5 copies of the MCP), and, by analogy with herpes simplex virus (HSV), 1 penton that is structurally distinct and acts as the portal for DNA packaging. In HSV, the portal is a dodecamer of the UL6 protein; the HCMV homolog of this is UL104. The capsid provides the architecture to contain the viral genome, a double-stranded DNA molecule.

### Tegument

Historically, the tegument has been described as an amorphous layer. Cryo-EM reconstructions of HSV have revealed a more structured protein layer (2), and it seems likely that the HCMV tegument has a broadly similar appearance. Structurally, the tegument is a link between capsid and envelope and may play a pivotal role in particle assembly. Functionally, the tegument contains key regulatory proteins, pp65 and pp71, that are delivered in significant amounts to the host cell.

### pp65

Protein pp65 (ppUL83), the most abundant virion protein, accounts for about 15% of the total. It is the antigen that is detected in the diagnostic antigenemia assay and is also the

major component of dense bodies (accounting for an excess of 90% of total virion proteins). The latter are noninfectious particles comprising a core of tegument proteins enclosed in a lipid envelope, which are formed during HCMV infection. Protein pp65 is trafficked to the nucleus very early in the infection via an unusual bipartite nuclear localization signal. The pp65 is a multifunctional protein that is required for various immunomodulatory roles: affecting presentation of immediate-early (IE) peptides (3), down-regulation of human leukocyte antigen-antigen D related (HLA-DR) (4), inhibiting natural killer (NK) cell responses (5), and antagonizing aspects of interferon response (6) known to be activated during viral infection (7). The protein also binds another tegument component, the viral protein kinase UL97 (8). Immunologically, pp65 is a significant target for CD4 and CD8 T-cell responses (9). Remarkably, a virus mutant lacking pp65 has no growth defect *in vitro*—except that no dense bodies are formed (10)—which would be consistent with the premise that pp65 is required for the evasion of host immune responses *in vivo*.

### pp71

Protein pp71 (ppUL82) is rapidly translocated to the nucleus after virus entry. It is a transcriptional transactivator, recognizing promoters with AP1 or activating transcription factor (ATF) sites in their regulatory regions, particularly the major IE promoter (MIEP) (11). This transactivation is enhanced by an interaction with another tegument protein, ppUL35. As a potent transactivator, pp71 is analogous to the VP16 virion transactivator protein of HSV. In addition, pp71 overcomes hDaxx-mediated suppression of HCMV replication and is thus essential for the onset of productive replication (12). Another key binding partner of pp71 is the retinoblastoma protein (13), an interaction that provides sensitive regulation of a key cellular protein that is also required for efficient viral replication (14).

### pp150

The basic phosphoprotein ppUL32 (pp150) accumulates late in infection at the putative sites of virus assembly, and a UL32-negative virus fails to complete the cytoplasmic stages of egress, consistent with a role in envelopment (15). The tight physical association of pp150 with capsids (16) emphasizes the presumed structural role of tegument in linking capsid with envelope and perhaps in driving virus assembly. Protein pp150 is an immunodominant B-cell target.

### Envelope

The viral envelope is a host-derived lipid bilayer that contains viral glycoproteins. Envelopment is thought to occur in the endoplasmic reticulum (ER)-Golgi intermediate compartment (17), and the envelope is thus most likely derived from membranes in this region of the cell (see below). The HCMV genome codes for over 50 predicted glycoproteins, 19 of which are detected in mass spectrometric analysis of purified virions (18). The envelope glycoproteins represent the main point of contact between intact virus and host, and as such they are important inducers of neutralizing antibodies.

An important subset of envelope glycoproteins mediates virus entry (Table 1). The entry glycoproteins fall into two groups: those that are conserved throughout herpesviruses, i.e., gpUL55 (gB), gH, gL, gM, and gN, and those limited to Betaherpesviruses, i.e., gO, gUL128, gpUL130, and gpUL131. The precise role of these proteins remains debated although the conserved glycoproteins appear important for

**TABLE 1** HCMV envelope glycoproteins

Complex in envelope	Constituent protein(s)	Mapped ORF

gB-dependent fusion in all cell types whereas the pentameric complex (including UL128/130/131) may act through a distinct mechanism (19) that is an important determinant of tropism for endothelial/epithelial cells (20).

The HCMV envelope glycoproteins appear to exist in three distinct complexes: gCI, gCII, and gCIII (21). The gCI is made up of oligomers of gB, which are thought to have a role in attachment, fusion, and receptor binding (see below). The gB monomer (Fig. 1) comprises two subunits, gp116 and gp55, derived by furin cleavage of a precursor. This cleavage is not essential for virus infectivity *in vitro* (22). The protein subsequently undergoes further processing and oligomerization (23). Studies of the crystal structure of HSV gB have shown a homotrimer, and HCMV gB probably shares this overall structure (24).

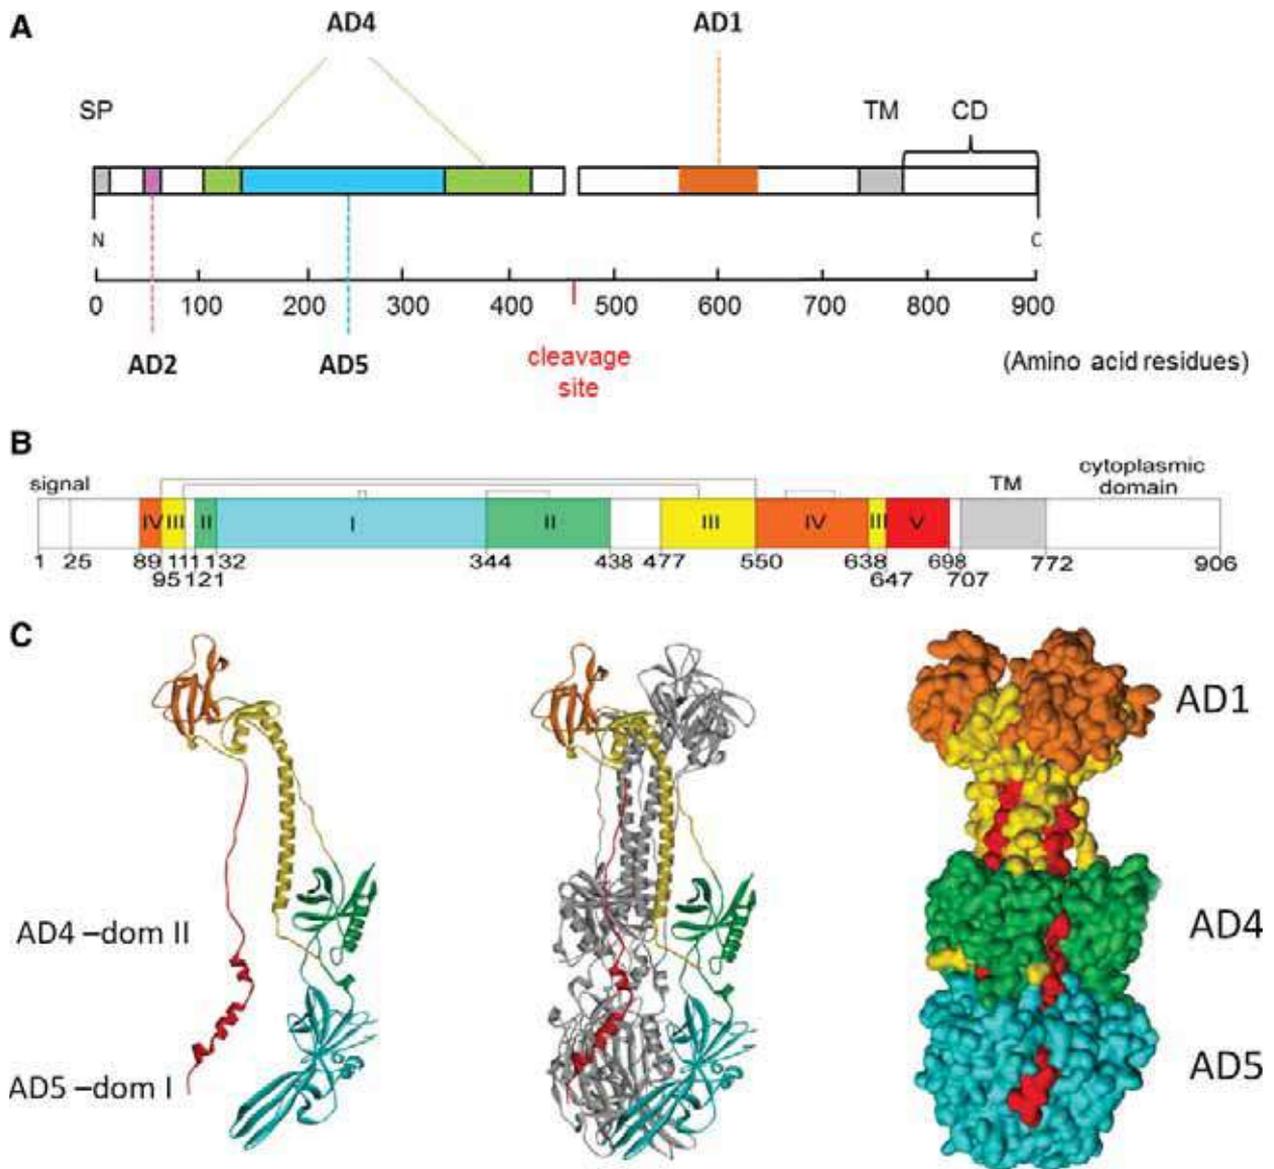

The gCII comprises heterodimers of gM (UL100) and gN (UL73). This complex plays a role in virus attachment via the host cell proteoglycan-binding activity of gN. Both components also have roles in assembly (25).

The gCIII is based on the disulfide-linked heterodimer of gH (UL75) and gL (UL115). This in turn interacts with gO (UL74) or with gpUL128, gpUL130, and gpUL131A, forming two or more distinct complexes (26). Virus-free fusion assays have implicated gH/gL alone as a fusogenic complex (27).

A number of other envelope glycoproteins have been recognized. gpUL4 is a glycoprotein of unknown function that is expressed with early kinetics. HCMV encodes four chemokine receptor homologs, US27, US28, UL33, and UL78. Two (UL33 and US27) are known to be in the virion (28). In contrast to most host receptors, the viral CCR homologs are constitutively activated. Those in the virion are theoretically able to signal as soon as they become incorporated into host membranes following virus entry. US28 induces migration of smooth muscle cells (29), and this is perhaps significant in terms of an association of HCMV with vascular disease.

### Genome

The most accurate representation of the HCMV genome has come from comparisons of the complete genomic sequence of a minimally passaged strain, Merlin, with partial sequences from other strains, including some obtained directly from clinical material (30). HCMV genomic analyses have

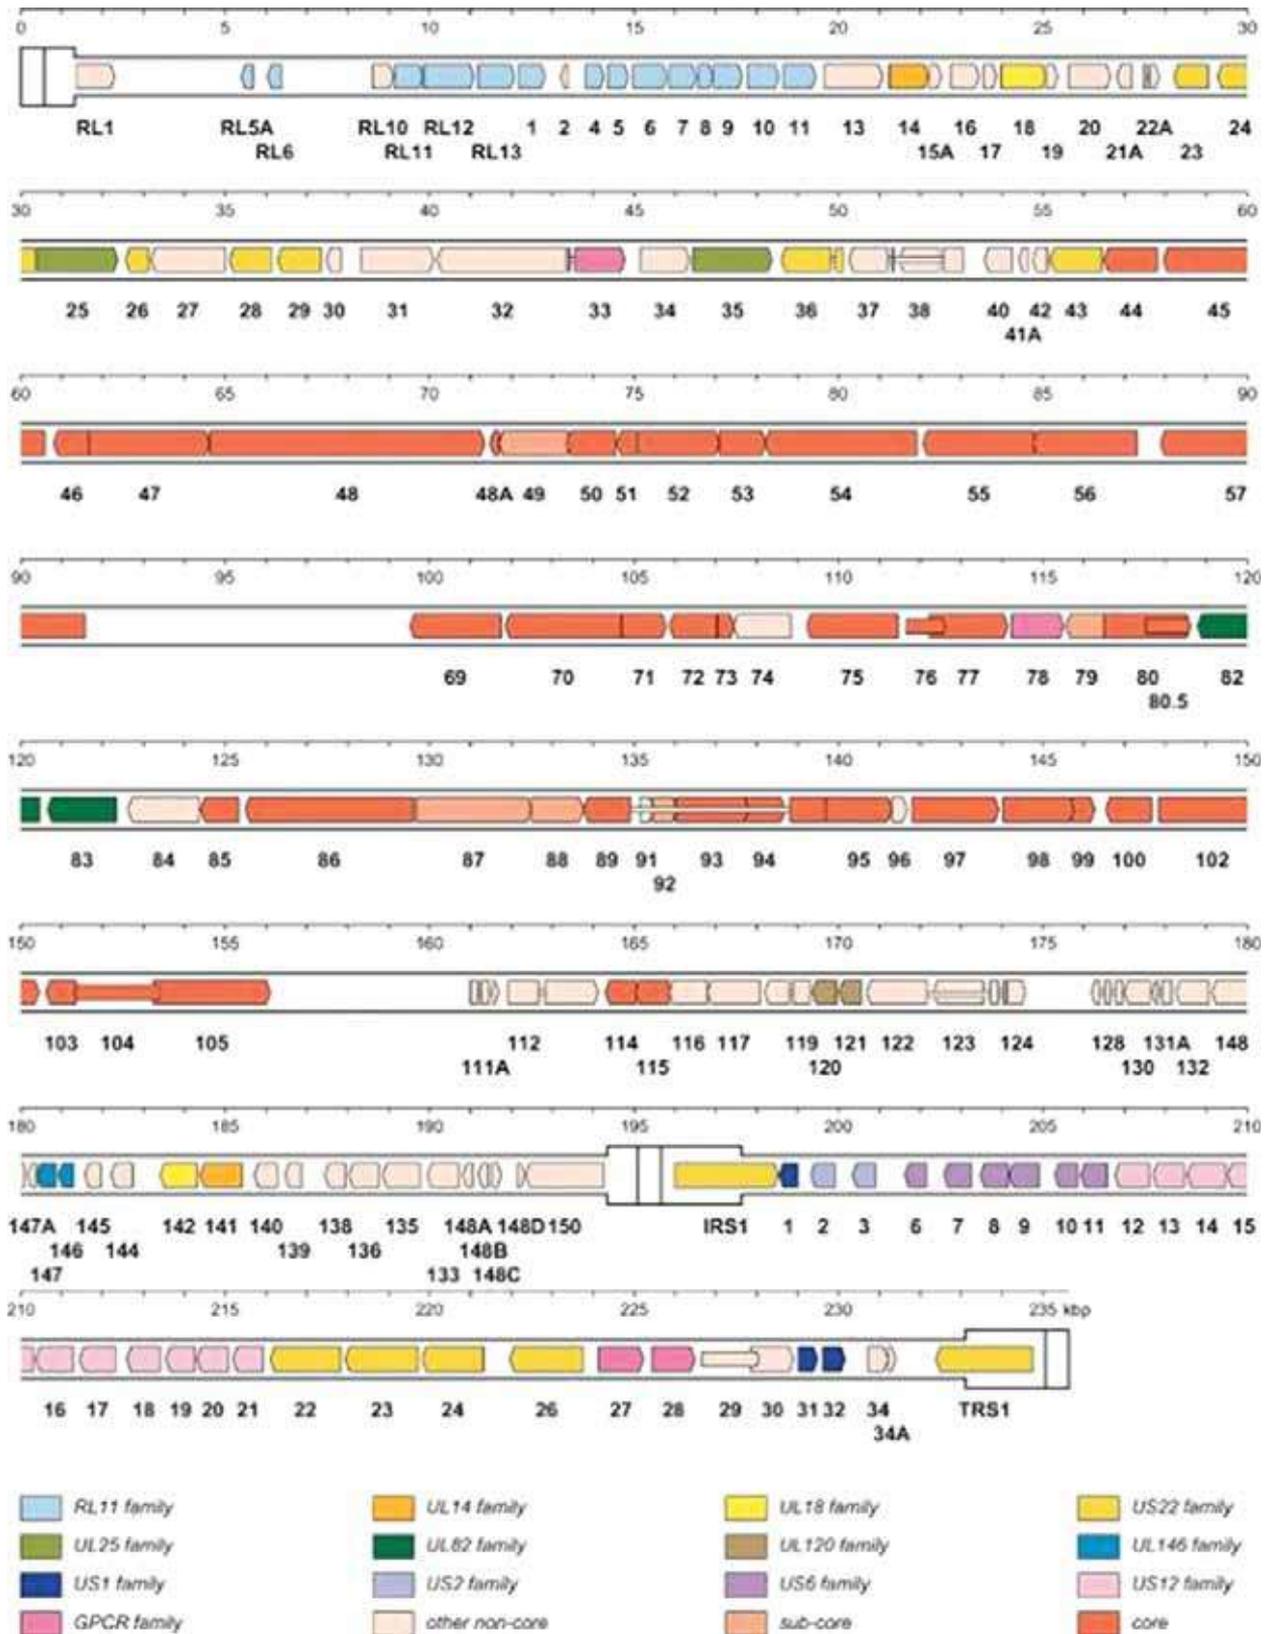

**FIGURE 1** Schematic representation of glycoprotein B from HCMV. **A:** The locations of the known antigenic domains (AD) mapped onto gB. **B:** Linear representation of domain architecture. **C:** gB monomer, trimer, and three-dimensional representation showing domains. AD1 is a linear, immunodominant epitope, AD2 a linear epitope, AD3 a linear epitope located where the transmembrane portion of gB abuts the cytoplasmic portion, AD4 a discontinuous epitope, and AD5 a discontinuous epitope. SP, signal peptide; TM, transmembrane domain; CD, cytoplasmic domain; dom, domain. Adapted from Potzch *et al.*, (2011) *PLOS Pathogens* vol 7, issue 8; e1002172.

been complicated by the tendency of the virus to lose a 22-kilobase (kb) segment of the genome, termed ULb', rapidly upon isolation and passage in fibroblasts (31). The ULb' segment contains genes that are not essential for replication *in vitro* but ones that play key roles in immune evasion and in determining cell tropism.

The HCMV Merlin genome is a 235,645-base pair (bp) linear double-stranded DNA molecule with a coding capacity of 165 genes (30). It is the largest genome among the human herpesviruses. The genome comprises two unique regions, termed UL and unique short (US), flanked by repeated sequences. Inversions of the unique regions give rise to four isomeric forms of virion DNA present in equimolar amounts. No pathological significance has been attributed to these isomers.

The Merlin genome (Fig. 2) has a central section that contains the core genes, approximately 40 genes that are conserved throughout the *Alpha*-, *Beta*-, and *Gammaherpesvirinae*. Many of the other genes are grouped into families of related genes (Fig. 2) thought to have evolved by duplication events. There are numerous spliced genes. MicroRNAs have been detected across the genome encoded by both strands (32–34). A functional RNA is encoded that regulates mitochondrial-induced cell death (35). The UL36–38 gene region encodes potent inhibitors of apoptosis which inhibit activation of caspase 8 (UL36), mitochondrial activation (UL37) exon 1 and apoptosis following endoplasmic reticulum stress (UL38; UL37).

Sequence variation occurs across the genome but appears to be highest at either end of the UL segment. A number of

**FIGURE 2** Consensus genetic map of wild-type HCMV based on the Merlin genome. RL and RS (which contain the *a* sequence as a direct repeat at the genome termini and as an inverted repeat internally) are shown in a thicker format than UL and US. Protein coding regions are indicated by colored arrows grouped according to the key, with gene nomenclature shown below. Introns are shown as narrow white bars. Genes corresponding to those in AD169 RL and RS are given their full nomenclature, but the UL and US prefixes have been omitted from UL1–UL150 (12 to 194 kbp) and US1–US34A (199 to 231 kbp). Colors differentiate between genes on the basis of conservation across the *Alpha*-, *Beta*-, and *Gammaherpesvirinae* (core genes) or between the *Beta*- and *Gammaherpesvirinae* (sub core genes), with subsets of the remaining noncore genes grouped into gene families. GPCR, G protein coupled receptor. (Reprinted from reference 30 with permission).

genes, notably UL146, which encodes a functional alpha chemokine, as well as UL73, UL74, and UL144, show a remarkable level of sequence variation (36). The functional significance of this variation is not known. “Next generation” sequencing techniques revealed extensive genetic diversity on an order of magnitude greater than previously identified (37). It remains possible that these techniques accurately document genetic variation in transcription but that most changes are deleterious to infectivity so that the CMV virion produces a genetic bottleneck containing a relatively conserved genome. Ribosomal profiling revealed that genetic information was being translated from regions of the genome that were not recognized as distinct ORFs (38). Indeed, proteins may be produced from 700 distinct regions of the genome rather than from the 165 named ORFs, although confirmation of these findings is needed.

## Replication Cycle

### Virus Entry

Like other herpesviruses, primary attachment of HCMV is mediated by interactions between virion glycoproteins and sulfated proteoglycans on the host cell surface (39). This primary attachment serves to bring the virus into close association with the target cell to allow receptor binding. HCMV entry can occur by direct fusion between the virion envelope and the plasma membrane or via endocytosis followed by fusion from within the endosome (40, 41). The cellular and viral factors contributing to the choice of pathway are not known. Three glycoproteins—gB, gH, and gL—constitute the core herpesvirus entry machinery. The roles played by each protein in the entry process remain unknown.

The crystal structure of HSV gB shows convincing similarities to the G protein of vesicular stomatitis virus, a known fusion protein (42). HCMV gB appears to be fusogenic when stably expressed in U373 cells, although fusion assays have shown that HCMV gH/gL alone can mediate fusion (27), and HSV gH/gL has certain characteristics that resemble fusion proteins. These proteins cooperate closely to mediate fusion, and coimmunoprecipitation studies show that HCMV gB and gH interact transiently during virus entry (43).

The gH/gL heterodimer is found in at least two distinct complexes (Table 1), one with gO and one with glycoproteins encoded by members of the genes from UL128 to UL131. The latter have been shown to have a role in mediating entry to endothelial cell types, but not fibroblasts (44), and blocking studies with soluble UL128 protein suggest that this may bind a receptor on endothelial cells (43). The use of different forms of gH/gL complex as a means of regulating host cell tropism is an emerging theme in the Beta- and Gammaherpesviruses (45), although recent data challenge this view (19) and instead argue that gH/gL/gO is required for gB-mediated fusion in all cell types and that the pentameric complex defines endothelial cell tropism through an additional undefined mechanism.

The virus cell contacts that are a precursor to entry induce a range of signaling events, but their role in the context of virus entry is not clear. Various candidate receptors for gB and gH/gL have been proposed, but there is as yet no consensus as to their role in entry.

### Transport to the Nucleus

After entry, the tegument and capsid are released into the cytoplasm. Transport of the capsid to the nucleus occurs in a

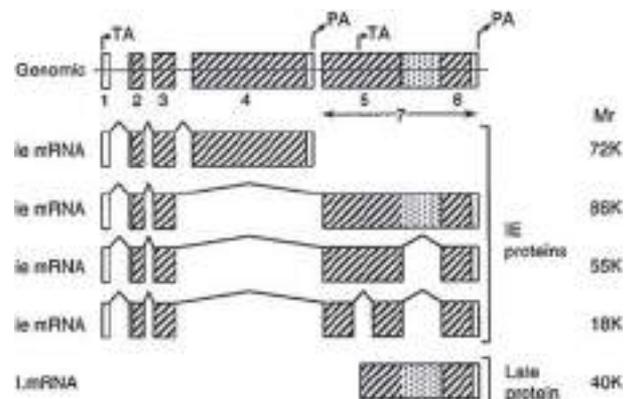

microtubule-dependent manner, and capsids appear to retain some tegument throughout this process (46). The viral genome is released from capsids when they reach the nuclear pores. The mechanism underlying localization and release of the genome is unknown, although recent data implicate the UL47 tegument protein in this process (47).

## Transcription and Gene Expression

HCMV gene expression, in common with other herpesviruses, occurs in three phases, termed immediate early (IE), early (E), and late (L). In general, IE genes encode regulatory proteins, E genes encode replication proteins, and L genes encode structural proteins. The IE genes are the first to be transcribed in the replication cycle. A defining characteristic is that they are transcribed in the absence of viral protein synthesis. There are five IE transcription loci in the genome: UL36-37, UL122/123, UL119-115, US3, and TRS1. The most abundant, and by far the best studied, transcripts are those arising from the major IE locus: UL122/123. Expression of these genes is controlled by the MIEP, well known from its widespread use in expression plasmids. The MIEP is complex, with multiple transcription factor binding sites in the upstream enhancer element. This combination of sites may well play a role in allowing IE gene expression to occur in a diverse array of cell types, perhaps containing a varied repertoire of transcription factors. Broadly speaking, the MIEP is active in differentiated cell types and is repressed in undifferentiated cell types. This differential activity appears to be a significant regulator of latency and reactivation.

Though numerous gene products are produced through intricate patterns of splicing, the two major products are the IE1 and IE2 proteins (Fig. 3). These two proteins have a common N-terminal region, corresponding to exons 2 and 3 of the gene locus; they differ in the C-terminal region, IE1 corresponding to exon 4 and IE2 corresponding to exon 5.

MIEP-driven transcription is favored by events that occur concurrently with virus entry. Cell surface binding by gB and gH induces NF- $\kappa$ B and Sp1 expression (51), which could favor MIEP activation due to the presence of binding sites for both these transcription factors. A more important aspect is the delivery of the virion transactivator, pp71, which is released as soon as incoming virions are uncoated (11) and targets a number of antiviral host factors to drive MIE viral gene expression. The detailed functions of the IE1 and IE2

**FIGURE 3** The major IE region of HCMV showing the splicing events that produce distinct proteins. TA, transcriptional activation; PA, polyadenylation; LmRNA, late mRNA.

proteins have been reviewed (52). IE1 binds PML and disrupts ND10 (53). An IE1-negative virus fails to replicate at a low multiplicity of infection. This deficit can be overcome by histone deacetylase (HDAC) inhibitors (54), highlighting the importance of these molecules in the regulation of MIEP activity (see below). Binding of IE1 to HDAC3 promotes transcription by antagonizing histone deacetylation through sequestration away from target viral promoters. This drives acetylation of histones bound to viral promoters driving viral gene expression (54). IE1 is also capable of direct transactivation (55).

IE2 is essential for virus replication. It has dual roles in regulating expression of viral and cellular genes and negatively autoregulating the MIEP via an upstream *cis*-acting repressive sequence (Fig. 4). IE2 also binds HDAC3, potentially resulting in an effect similar to that of IE1 (54) although this could also contribute to repression of MIEP seen at late times of infection (56). IE2 localizes to ND10-like structures in association with the viral genome. These foci develop into replication compartments, consistent with a role for IE2 in the early stages of genome replication (57). Indeed, IE2 binds a promoter in the lytic origin of replication in complex with the E protein UL84 (see below).

Both IE1 and IE2 activate E and L gene expression. E genes are defined as those genes that (i) require prior expression of the IE genes for transcription and (ii) can be expressed in the presence of inhibitors of DNA replication, such as ganciclovir and foscarnet.

#### DNA Replication, Capsid Assembly, and DNA Packaging

In contrast to transcription, for which the virus relies on cellular machinery, the virus encodes its own DNA replication apparatus. Thus, viral DNA replication is a key target for the development of antiviral drugs. HCMV also stimulates progression of the host cell cycle toward S phase yet suppresses host DNA synthesis, thus ensuring a cellular environment suitable for viral DNA replication (58). Upon delivery to the nucleus, genomes are deposited at ND10 sites, where transcription and DNA replication both occur (59).

The input genome is thought to be circularized independently of viral gene expression. Circularization is con-

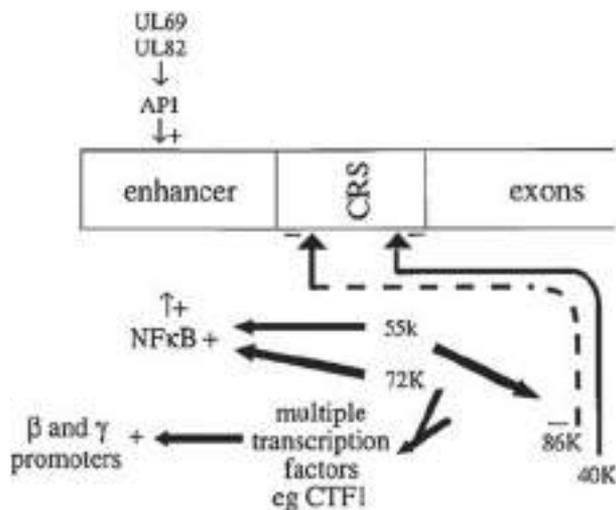

FIGURE 4 Regulation of the major IE region of HCMV. CRS, *cis* repression sequence.

sistent with a rolling-circle mode of replication, but this has not been proven for HCMV. Indeed, HCMV genome replication intermediates are more complex than would be produced by this method (60).

Eleven loci (Table 2) are required for HCMV genome replication (61). The core replication proteins corresponding to UL54 (DNA polymerase), UL44 (DNA polymerase accessory protein), UL57 (single-stranded DNA binding protein), UL105 (helicase), UL70 (primase), and UL102 (primase-associated factor), which are present in all herpesviruses, provide the basic DNA replication machinery. However, the details of their function and interactions are unknown (62).

The origin of replication, *oriLyt*, is adjacent to the UL57 gene, essential for virus replication, and distinct from other viral origins (63). It is structurally complex and contains numerous short repeated sequences, including transcription factor binding sites, and has an overall asymmetry of nucleotide distribution, being AT rich on the left side but GC rich on the other (64). Transcripts are produced within *oriLyt* (65), and two viral RNAs are present as RNA/DNA hybrids within the region in packaged genomes (66). Given the absence of an obvious origin binding protein in HCMV, it seems likely that these are in some way involved in initiation of replication (66); indeed, the UL84 protein, which is required for genome replication, binds stably to this region of *oriLyt* (62). The initiation of L gene expression, which is, presumably, in some way regulated by the onset of DNA replication, is not understood.

#### Capsid Assembly

Based on their structural similarities, assembly of HCMV capsids is likely to resemble that of HSV capsids. The MCPs are conserved throughout the herpesviruses.

A transient internal scaffold coordinates assembly of the nascent capsid (67). This scaffold contains two major components encoded by the UL80 gene region: the protease precursor (UL80) and the assembly protein, pAP (UL80.5), which comprises the C-terminal half of the protease. The first steps in capsid assembly occur in the cytoplasm, where pAP interacts with itself and with the MCP and causes the translocation of these capsid protomers to the nucleus (68). Once in the nucleus, pAP associates with the protease precursor and other capsid components are recruited to the protomers, giving rise to procapsids. Autoproteolysis of the protease then liberates the scaffold components from the nascent capsid (69).

Capsid maturation is coupled to DNA packaging. Based on data from HSV, DNA is packaged through a unique vertex containing the portal protein (UL6 in HSV). The HCMV portal homolog, UL104, forms high-molecular-weight complexes and binds DNA in a sequence-independent manner (70). HSV UL6 is thought to act as a nucleation factor for capsid assembly, explaining its asymmetric localization in the capsid.

DNA packaging requires *pac* signals located at the genome termini. These are recognized by the viral terminase complex, made up of UL56 and UL89 (71), which likely interacts with the portal protein.

### Egress

The broadly accepted model for HCMV egress is the envelopment–de-envelopment–re-envelopment model. Mature capsids bud through the inner nuclear membrane (INM), acquiring a primary envelope. The resulting perinuclear enveloped virions then fuse with the outer nuclear membrane, liberating capsids to the cytoplasm. These traffic to the site of envelopment, where they acquire tegument and the final envelope. Mature virions are released from the cell by exocytosis or lysis. However, much of this pathway is inferred from studies of other herpesviruses, and some aspects of the pathway remain controversial.

The earliest step is recruitment of capsids to the INM. For HSV, the UL31 and UL34 proteins play a role in this recruitment. The HCMV homologs of these proteins, UL53 and UL50, are thought to have a similar function, and UL53 colocalizes with lamin B at the INM, consistent with a role in nuclear egress (72). Primary envelopment likely occurs by budding into large infoldings of the INM. It is not clear whether all of the tegument proteins are present in these particles. Cryo-EM tomogram images of perinuclear enveloped HSV show that the tegument is distinct from that in mature virions, suggesting that a subset of tegument proteins may be included in these particles, although not all HCMV tegument proteins have been detected in the nucleus. The primary envelope is then lost by fusion between the primary enveloped virion and the outer nuclear membrane, giving rise to naked cytoplasmic capsids.

Based on confocal microscopic analysis, the site of final assembly has been defined as a secretory vacuolar structure that expresses Rab 3, TGN 46, and mannosidase II (49). Data also support a role for endocytic compartments in assembly and final envelopment. A fluid phase marker colocalizes with sites of virus budding, and cell surface biotinylation of infected cells leads to incorporation of biotinylated gB into virions (73).

Some tegument proteins may play roles in driving the last stages of virus assembly, including the secondary envelopment step. A pp28-negative virus has cytoplasmic accumulations of nonenveloped tegumented capsids (74); accumulation of other viral proteins in the Golgi-associated assembly region is not affected. Additionally, both gM and gN (which form a heterodimer in the virion) have roles in assembly.

During the later stages of virus assembly, an interaction between phosphorylated gB and the host trafficking protein PACS-1 is involved in recruitment of gB to the site of assembly, although blocking of PACS-1 function has a modest effect on progeny titers (75). EM studies have shown an association of HCMV glycoproteins and budding particles with cytoplasmic multivesicular bodies, and depletion of endosomal sorting protein VPS4 using small interfering RNA technology leads to enhanced release of HCMV par-

ticles and implicates the multivesicular bodies as components in viral degradation (76).

## BIOLOGY

### Latency and Reactivation

A defining characteristic of herpesviruses is the establishment and maintenance of a latent state from which the virus can periodically reactivate to undergo productive replication. Peripheral blood monocytes are a major site of carriage of HCMV DNA in healthy individuals (77). Monocytes arise from bone marrow resident pluripotent CD34<sup>+</sup> stem cells, and this cell population appears to be a site of HCMV latency, although it is not clear if this is the only one. CD34<sup>+</sup> precursor cells are a self-renewing population, but it is not clear whether successive generations of cells are reinfected by virus produced from infected bone marrow stromal cells or circulating infected endothelial cells or whether the HCMV genome is maintained in this population by some form of replication (78), perhaps analogous to the maintenance of the latent Epstein-Barr virus (EBV) genome in replicating B cells (79). The HCMV genome in CD14<sup>+</sup> peripheral blood mononuclear cells is in a circular plasmid form (80), but there is no conclusive evidence of a latent origin of replication or of genes homologous to those required for EBV genome maintenance (79). UL84 may be involved in the replication of latent genomes (78).

CD34<sup>+</sup> monocytic precursors spend a relatively short time in the bone marrow before differentiating and moving to the peripheral blood. The regulation and initiation of reactivation appear to be governed largely by differentiation-dependent chromatin remodeling around the MIEP. Studies of the MIEP in latently infected CD34<sup>+</sup> cells and monocytes from healthy donors show that it is associated with heterochromatin protein 1 (HP-1) and non-acetylated histones, both markers of transcriptional repression. Differentiation of these cells led to loss of HP-1 and histone acetylation, providing an environment consistent with transcriptional activation. This was correlated with recovery of infectious virus, showing that HCMV reactivation is associated directly with the chromatin remodeling that occurs with differentiation (81).

Various viral transcripts have been associated with latent infection, including those from the MIE region, the viral interleukin 10 (IL-10) gene (UL111.5A), UL138, UL144, US28, and an antisense transcript from the UL81-UL82 locus containing a 133-amino-acid ORF product. The role of these transcripts in latency, and of any proteins encoded by the transcripts, is currently unknown although recent evidence points toward vIL-10 playing a key role in immune evasion (82).

### HLA Modulation

HCMV has evolved to contain a series of genes that are capable of interfering with the immune response (see Chapter 14). Most of these are proteins, but one is a microRNA, and HCMV also recruits some cellular proteins, in the form of complement control proteins, to help avoid innate immune responses (Table 3). The presence of these multiple genes presumably allows HCMV to persist in multiple sanctuary sites throughout the body.

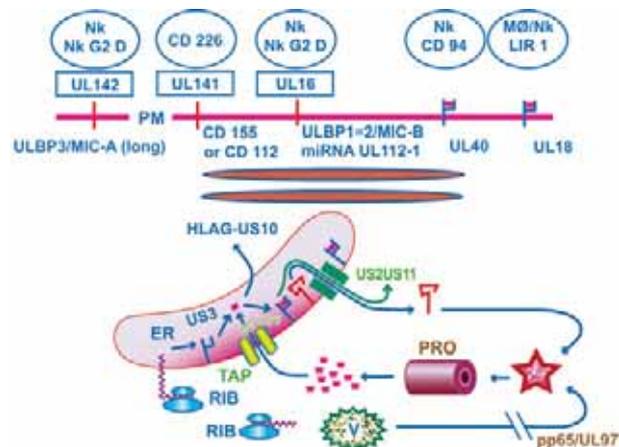

Several proteins are responsible for down-regulating the cell surface display of mature class I complexes (Fig. 5). At IE times, pUS3 binds to HLA heavy chains in the lumen of the ER and sequesters them. At E times, pUS6 blocks TAP, the

transporter associated with antigen presentation. At E times also, pUS2 and pUS11 re-export mature complexes back from the ER to the cytosol, where they are degraded in the proteasome. The coordinated action of these proteins produces a dramatic down-regulation of mature class I HLA complexes, blocking the ability of cytotoxic T lymphocytes (CTLs) to recognize the virus-infected cell. However, the cell would then be susceptible to lysis by NK cells, which recognize the absence of negative signals provided by non-antigen-specific HLA molecules. Accordingly, HCMV encodes two other proteins able to mimic these negative signals: gpUL18 and gpUL40 (Fig. 5). The latter protein encodes a canonical ligand within its leader sequence for HLA-E that is identical to the HLA-Cw03 signal sequence peptide. Expression of gpUL40 in HLA-E-positive cells confers resistance to NK cell lysis via the CD94/NKG2A receptor. The generation of the gpUL40 peptide ligand does not require the TAP system, and the mature gpUL40 can up-regulate expression of HLA-E.

HCMV also contains other genes that interfere with the stress response of the cell, which would normally activate NK cells to destroy the cell (Fig. 5). These include the proteins encoded by UL16, UL141, and UL142, which inhibit the action of the “UL binding proteins,” CD155, and an unknown stimulatory molecule. In addition, a microRNA also blocks one of the UL binding proteins (83).

**EPIDEMIOLOGY**

**Prevalence and Incidence**

HCMV infection is distributed worldwide, with geographic differences explained by socioeconomic differences of exposure (50). HCMV infects both vertically and horizontally and can be transmitted by either route during primary infection, reinfection, or reactivation. Frequent shedding in saliva, semen, and cervico-vaginal secretions in the absence of symptoms enables inapparent transmission to others. Between 2 and 10% of infants are infected by the age of 12 months in all parts of the world. In later childhood, close contact facilitates transmission, so family groups, particularly those crowded together in unhygienic circumstances, have a high prevalence of infection.

In populations with upper socioeconomic circumstances, approximately 40% of adolescents are seropositive, and this figure thereafter increases by approximately 1% annually (84) (Fig. 6). Approximately 70% of adults of upper socioeconomic conditions and 90% under poorer conditions eventually become infected with HCMV.

Following primary infection, HCMV persists either in a true latent form or in a state of low-level replication made possible by the immune evasion genes described above. Thus, individual cells could exhibit HCMV latency, while particular organs could always have some cells producing virus particles. Occasional reactivations of HCMV are almost always asymptomatic but presumably allow HCMV to spread horizontally. Reactivations also transmit vertically, so congenital HCMV infection is found most frequently in the poorest communities in the world (85).

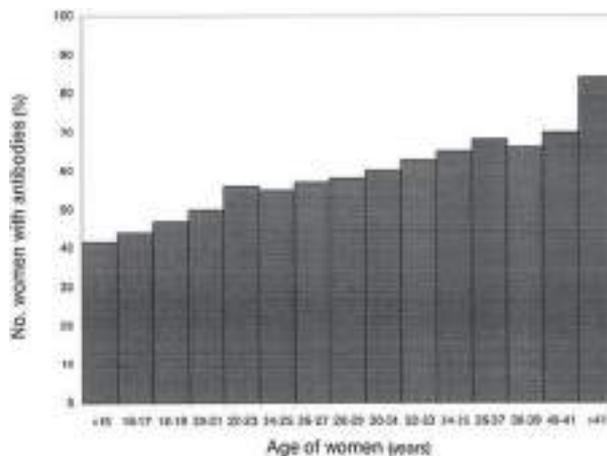

Reinfection with another, or possibly the same, strain of HCMV can also occur; comparison of virion DNA samples by restriction enzyme analysis or by sequencing can differentiate between strains. The term recurrent infection is often used when infection is non-primary but it has not been possible to differentiate reactivation from reinfection. No seasonal patterns are recognized.

**Transmission**

**Routes of Primary Infection**

**Intrauterine**

The greatest risk to the fetus follows primary maternal infection during pregnancy. Intrauterine infection presum-

**FIGURE 6** Age-specific prevalence of IgG antibodies against HCMV.

ably follows maternal viremia and associated placental infection. Intrauterine transmission of HCMV occurs in approximately 32% of pregnant women with primary infection (86). CMV-specific cell-mediated and neutralizing antibody levels would be expected to develop more rapidly in non-transmitters than transmitters, but the significance of detecting early host immune responses in pregnancy is confounded by gestational stage (87). Approximately 1% of seropositive women transmit HCMV in utero, but at present there are no laboratory markers to identify those at greatest risk. Although they have a low risk as individuals, the abundance of seropositive women in the community means that most babies with congenital CMV infection are born to women who were “immune” before conception (88).

### Perinatal

Perinatal infection can be acquired from infected maternal genital secretions or breast milk. Milk is a plausible source of HCMV, because perinatal infection has occurred only when breast-feeding has taken place, not when infected women gave bottle feeds to the infants.

### Postnatal

The asymptomatic nature of most postnatal HCMV infections precludes identification of the routes of transmission, but exposure to saliva or genital secretions during sexual contact is suspected, because these contain infectious virus. HCMV transmission occurs from child to child in day care centers, most commonly among young children and especially if one is known to be excreting HCMV. Transmission via fomites, such as toys contaminated by saliva, has been implicated. Infection in children is usually asymptomatic, but infectious toddlers may transmit virus to adult staff or to mothers (89–91).

HCMV seroprevalence is 90 to 100% among patients attending clinics for sexually transmitted disease and among male homosexuals. Individuals linked epidemiologically by sexual contact have been shown to excrete strains of HCMV on the cervix and in semen that are indistinguishable by restriction enzyme typing. While these findings are consistent with the sexual transmission of HCMV, formal studies have not quantified the risk of acquiring HCMV by seronegative or seropositive contacts from particular sexual practices. Individuals can be infected with more than one strain of HCMV (92).

### Blood Transfusion

The introduction of extracorporeal blood perfusion in the 1960s led to a syndrome of leukopenia, pyrexia, and atypical leukocytosis, termed post-perfusion syndrome, caused by primary HCMV infection. The failure to isolate HCMV from blood from healthy donors suggests that the virus exists in a latent state, presumably within leukocytes, and is reactivated when cells encounter an allogeneic stimulus. Allogeneic stimulation of macrophages containing latent HCMV reactivates virus, which can subsequently infect and replicate in fibroblasts (93).

Although HCMV can be transmitted by blood transfusion, this is an uncommon event, occurring in only 1 to 5% of seronegative recipients exposed to seropositive blood. The risk is reduced to zero where filters are used routinely to remove leukocytes. No laboratory tests have been shown to identify donors at high risk of transmitting HCMV.

### Organ Transplantation

Seronegative patients undergoing solid-organ transplantation are at no risk of primary infection from seronegative

donors, whereas a seropositive organ transmits the virus in 60 to 80% of donations. Both kidneys from a single donor are usually concordant for transmission; however, it is not clear whether parenchymal cells of the organ or infiltrating leukocytes are the source of the infectious virus. Reinfection also occurs with transmission from a seropositive donor to a seropositive recipient. In contrast, typing of strains by restriction enzyme analysis of DNA demonstrates that the virus causing disease after bone marrow transplantation is derived from the seropositive recipient (94). Indeed, seropositive donors may be chosen preferentially for seropositive recipients because they can adoptively transfer some immunity into the recipient (95).

### Sperm Donation

Organizations that recruit and organize sperm donors often reject CMV seropositive individuals. They collect sperm from CMV seronegative individuals and store it frozen. Three months later the same donor produces sperm and serum; if the latter shows him to still be CMV seronegative, then the earlier frozen sample is retrieved and used clinically. This system has the potential to keep CMV infection at a low rate, but has the disadvantage of rejecting the majority of men volunteering to be donors.

## PATHOGENESIS

HCMV replication occurs widely in multiple tissues, as illustrated by isolation from autopsy material from AIDS patients (Table 4). During life, biopsy samples of lung, liver, esophagus, colon, and kidney are frequently found to contain HCMV. Replication has been demonstrated in polymorphonuclear leukocytes, monocytes, T lymphocytes (CD4<sup>+</sup> and CD8<sup>+</sup>), and B lymphocytes (96). Thus, HCMV is a systemic infection. As described above, this ability to replicate in multiple tissues is consistent with the presence of many isoforms of transactivating proteins potentially able to function in many cell types. However, it is not consistent with the restricted range of cell types that can be infected *in vitro*. The latter finding is probably an artifact resulting from the inability to propagate and maintain in the

laboratory the fully differentiated cells preferred by HCMV. An incubation period of 4 to 8 weeks can be estimated from four distinct informative clinical settings. They are perinatal infection, transmission by organ allograft, transmission by blood transfusion, and intrauterine transmission following primary infection in the mother.

## Factors in Disease Production

### Primary Infection

Immunocompetent infants, children, and adults usually get no symptoms from primary infection. Infection in an immunologically unprimed individual represents the greatest risk of disease in the fetuses of pregnant women (97) and recipients of solid-organ transplants (98), but this effect is not absolute. Some patients with primary infection do not have disease, whereas some with reinfection get disease. HCMV reinfection of seropositive renal transplant recipients represents more of a risk for disease than reactivation of latent virus (98). In contrast to the case with solid-organ recipients, reactivation represents the major source of HCMV disease in bone marrow transplant patients (94). Likewise, HIV-positive patients rarely experience primary HCMV infection; their disease results from either reactivation of latent infection or reinfection.

### Viremia

Imbalance between the rate of production of HCMV at sites of infection and its effective rate of immune clearance may produce viremia. Subsequently, viremia seeds target organs, which may or may not have sufficient local defenses to prevent disease. The quantity of HCMV required to cause disease is predicted to vary considerably, depending on the precise details of the pathogenic mechanisms. Thus, immunopathology may be triggered at low viral loads but remain present at high loads. Moderate loads may cause disease through cell lysis secondary to viral replication. Finally, very high viral loads might damage target cells when HCMV binds to them, a process we term direct toxicity. This hypothetical scenario will become increasingly susceptible to investigation using measures of viral dynamics. Because HCMV DNA can also be detected in the plasma of patients (99), it will be important to determine if plasma viremia marks a distinct phase of pathogenesis.

In recipients of solid-organ transplants or bone marrow, the detection of active infection in saliva or urine using conventional cell culture or PCR has a relative risk of approximately 2 for future HCMV disease (100). In contrast, the detection of HCMV in the blood has a relative risk of 5 to 7, irrespective of methods of detection employed (100). This provides the scientific basis for administering antiviral drugs to patients with active HCMV infection before they develop symptoms. For patients with viremia, the term preemptive therapy is used, whereas the term suppression has been used for those with viruria. Viremia is not an absolute marker of disease but has a strong positive predictive value (Table 5). Presumably, viremia indicates that innate immune responses at local sites of infection have been inadequate. Viremia allows HCMV to seed multiple organs, but some transplant patients can presumably mount adequate regional innate or adaptive responses to prevent HCMV disease. This high risk for HCMV disease indicates that preemptive therapy should be considered in patients with viremia (101). Note that in the special case of HCMV pneumonitis in transplant patients, especially bone marrow transplant patients, the HCMV immune response may contribute to disease (i.e., HCMV pneumonitis may be an immunopath-

ological condition that, once initiated, does not respond well to effective anti-HCMV therapy) (102). Nevertheless, the incidence of such disease can be reduced significantly if antiviral therapy is given as suppression (103), preemptively (104), or as prophylaxis (105). This emphasizes the importance of targeting of antiviral drugs at the earliest possible stage of infection, rather than when the patient has disease.

### Virus Replication

HCMV replication patterns range widely depending on the type of infection and host population. In 1975, Stagno and colleagues (90) showed that among neonates with congenital HCMV, the titer of viruria was significantly increased among those with disease or those destined to develop disease (Fig. 7). The kidney is not a target organ for HCMV disease in neonates, so the quantity of viruria presumably reflects systemic infection in which viral production in the kidney acts as a marker for replication in the target organs, which are less clinically accessible (brain and inner ear) (106). In the case of the neonate, this observation is even more remarkable, given that the urine is sampled after birth, yet infection may have occurred months earlier in utero (97). Nevertheless, by 3 months of age, the significant difference between viral loads in the two groups of neonates is no longer present (90), presumably reflecting the ability of the neonate's immune response to control active replication.

The advent of PCR enabled greater sensitivity of detection of HCMV to be achieved, and quantification by real-time PCR can be used to determine HCMV load and thereby gain insight into HCMV pathogenesis in transplant

**FIGURE 7** CMV load in the urine of neonates. TCID<sub>50</sub>, 50% tissue culture infective dose. Symbols: ○, symptomatic congenital infection; ●, asymptomatic; ■, natal infection. Error bars indicate standard errors of the means.

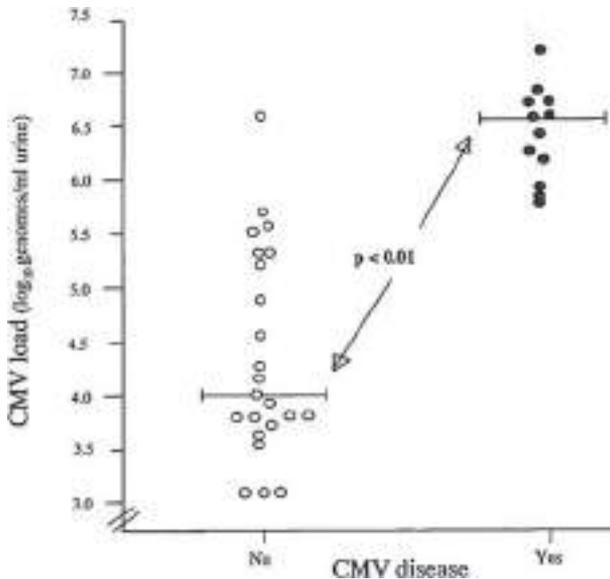

FIGURE 8 CMV load in the urine of renal transplant recipients.

patients (107). For example, in renal transplant patients, the peak level of viremia and risk of HCMV disease are clearly related ( $P < 0.01$ ) (Fig. 8). The difference between the median values in those with and without disease is approximately 2 logs, very similar to the difference found in the neonates using cell culture methods (90). Among three factors associated with HCMV disease (i.e., high viral load, viremia, and recipient serostatus), only viral load remains a significant independent risk factor in a multivariate model (Table 6). Furthermore, a plot of peak viral load against the probability of HCMV disease has a sigmoidal shape (Fig. 9), showing that HCMV infection is well tolerated clinically until very high levels are reached. Viral load measurements in stored neonatal dried blood spots from children who subsequently developed hearing loss have also confirmed the threshold relationship (108). This sigmoidal relationship suggests that antiviral interventions and vaccination strategies should be designed to prevent viral loads rising into the critical high range of  $>10^3$  to  $10^4$  genomes/ml of whole blood (or  $10^2$  genomes/semicircle of dried blood spot). Furthermore, the shape of the curve implies that a marked effect on HCMV disease could be achieved with a modest reduction in peak viral load. In AIDS Clinical Trials Group protocol 204, in which 1,227 AIDS patients were randomized to receive valgacyclovir at 2 g daily or one of two doses of acy-

TABLE 6 Univariate and multivariate assessment of prognostic factors for HCMV disease in renal allograft recipients<sup>a</sup>

Parameter	Univariate <sup>a</sup> factor			Multivariate <sup>a</sup> factor		
	OR	95% CI	P	OR	95% CI	P
Viral load (per 0.25 log)	2.79	1.22–6.39	0.02	2.77	1.07–7.18	0.04
Viremia	23.75	3.69–153	0.0009	34.54	0.75–1599	0.07
R <sup>+</sup> serostatus	0.22	0.05–0.95	0.05	0.92	0.002–446	0.98

The results demonstrate that virus load is a major determinant of disease and that viremia and recipient serostatus are markers of disease because of their statistical association with high viral load.

<sup>a</sup>OR, odds ratio; CI, confidence interval.

clovir, the higher of which had been shown to be ineffective in controlling HCMV disease, it was found that valgacyclovir significantly reduced HCMV disease despite a relatively modest reduction in HCMV load from baseline (median, 1.3 logs) (109). The serial measures of virus load in blood have also revealed the dynamic process of HCMV replication in its host, with an average doubling time (viral load increasing) or half-life (viral load decreasing) of approximately 1 day (110). Furthermore, serial measures of viral load can provide estimates of the efficacy of antiviral drugs, such as ganciclovir, required to bring HCMV replication under control (111).

### Differences Among Groups of Immunocompromised Patients

Table 7 provides an overview of the relative importance of HCMV disease in different patient groups. The phrase “HCMV infection in the immunocompromised host” obscures the great diversity among the various patient groups. The pathogenesis of bone marrow failure after bone marrow transplantation is thought to follow HCMV infection of stromal cells releasing cytokines and so producing a milieu unfavorable for hematopoiesis (112).

### CMV Pneumonitis

HCMV pneumonitis after bone marrow transplantation may be immunopathologically mediated (102). This hypothesis explains the timing of pneumonitis, because it occurs only after patients have engrafted their bone marrow, arguing that a host immune response is required for disease. It also explains why AIDS patients do not appear to suffer from HCMV pneumonitis, although HCMV is frequently found in their lungs. Presumably they cannot mount the immunopathological response required to cause disease. Patients with HIV seroconversion illness may, however, get HCMV pneumonitis, presumably because their cell-mediated immune response has not been sufficiently abrogated at this stage (113). The precise nature of the immunopathological response has not been identified, although the histologic appearance (Fig. 10) suggests that it is probably mediated by cytokines attracting leukocytes to the lung interstitium and so increasing the distance required for gas diffusion from alveoli to blood. If so, it is perhaps surprising that cases of HCMV pneumonitis have not been seen in patients given highly active antiretroviral therapy (HAART), in whom the regenerating immune system could recognize HCMV-infected target cells and trigger immunopathology. Perhaps HAART provides protective cell-mediated immune responses able to control HCMV replication in the lungs.

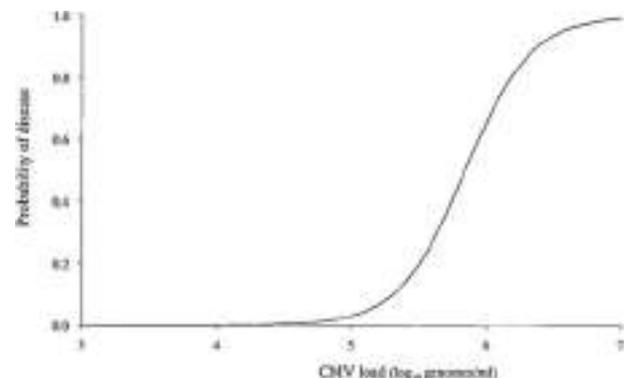

FIGURE 9 Threshold concept of CMV pathogenesis.

### CMV Retinitis

The dramatically increased proportion of HCMV retinitis found in AIDS patients compared to transplant patients remains unexplained but may result from prolonged exposure to high levels of viremia. Another new disease has occurred in AIDS patients given HAART that has all the hallmarks of immunopathology. Patients with a history of HCMV retinitis, which is typically now clinically silent, can nevertheless develop an inflammatory vitritis due to the infiltration of CD8<sup>+</sup> T cells specific for HCMV.

### CMV Encephalitis

In AIDS patients, viremia can disseminate HCMV to the brain in two distinct ways. The first seeds virus to the brain endothelial cells, allowing HCMV to spread to contiguous astrocytes and then to neurons. The histopathologic correlates of this route of infection include endothelial cell infection/inflammation, with or without thrombosis, and

**FIGURE 10** Histologic section of a lung sample from a patient with HCMV pneumonitis following bone marrow transplantation. Arrows show alveolar macrophages bearing the typical intranuclear inclusions of HCMV. An interstitial mononuclear cell infiltrate is seen.

multiple areas of glial nodular encephalitis (114). The second seeds virus to the choroid plexus epithelial cells and thence to the cerebrospinal fluid (CSF). Transmission to ependymal surfaces produces necrotizing ventricular encephalitis.

### CMV Polyradiculopathy

Viremic dissemination seeds CMV to peripheral nerves and the cauda equina.

### Gastrointestinal Involvement

Viremic dissemination leads to focal ulceration anywhere in the gastrointestinal tract but often in the esophagus or colon. In patients with inflammatory bowel disease, extensive ulceration may mimic relapse of the underlying disease and be exacerbated by steroid administration. This is consistent with inflammation providing an environment that supports CMV replication.

### Other Syndromes

In addition to these end-organ diseases (EODs), HCMV is associated with a variety of conditions collectively called indirect effects (115). Although HCMV has been shown for many years to be associated with these conditions, it is only recently that the results of controlled clinical trials have demonstrated that the associations are causal. The precise mechanisms whereby HCMV causes these effects have not been demonstrated, although there are several candidates, not least of which is the possibility that HCMV perturbs normal immune functions. In addition, in the case of graft rejection, HCMV may act like a minor transplantation antigen, may up-regulate cellular class I molecules bearing donor epitopes in adjacent non-infected cells, or may express the UL18 class I homolog. Fungal superinfection may reflect HCMV-induced immunosuppression, although there is no immunologic marker of the same. Finally, HCMV may trigger post-cardiac allograft coronary atherosclerosis because (i) pUS28 confers chemotactic mobility on smooth muscle cells; (ii) IE72 binds p53 in the same cells, preventing their apoptosis; or (iii) HCMV activates cyclooxygenase, so producing reactive lipoprotein peroxides.

In AIDS patients, clinically silent HCMV infection may similarly interact in multiple ways with HIV to increase its pathogenicity (i.e., act as a cofactor for progression of HIV disease) (116). This subject is controversial but is supported by data showing that HCMV can transactivate the HIV long terminal repeat *in vitro* and can provide an alternative receptor for HIV by inducing an Fc receptor (117). HCMV is widely disseminated at autopsy and is found in most tissues (Table 4). HCMV-HIV coinfection of individual cells or organs has also been described. The risk of AIDS is increased among male homosexuals with persistent HCMV excretion in semen, even after allowing for differences in baseline CD4 counts (118). Cohorts of patients develop AIDS more rapidly if they are coinfecting with HCMV. Furthermore, high levels of HCMV viremia are significantly associated with the death of AIDS patients (119). This effect is stronger than the association of HIV viral load with death (120) and persists in the era of HAART (121). Patients given intravitreal treatment for HCMV retinitis had a survival benefit if they were also given systemic treatment (122). Overall, it is difficult to avoid the conclusion that HCMV adversely affects the outcome in AIDS patients but that this effect is clinically inapparent and can only be documented by appropriate laboratory studies. Overall, these results are consistent with the possibility that HCMV may play a cofactor

role, but extensive controlled investigations would be required to establish this conclusively.

### Immune Responses

Herpesviruses persist by hiding from immune responses rather than by blocking their induction. Thus, all of the proteins encoded by HCMV are recognized by the host, so the human immune system commits more resources to controlling HCMV than to controlling any other virus (9). The major targets for CD8 T cells against HCMV are ppUL83 (pp65) and the IE2 protein, and the frequency of responding CD8 T cells against HCMV is very high. For example, using class I HLA tetramers in immunocompetent and immunocompromised patients with or without active replication, frequencies of CD8 T cells against epitopes within pp65 are approximately 1% in healthy seropositive individuals and up to 10% in patients experiencing active HCMV replication (123).

Prior exposure to HCMV can ameliorate the pathological potential of HCMV in some, but not all, patients. In pregnant women, the risk of damage to the fetus and the severity of that damage are clearly decreased in women who were “immune” before they became pregnant (124), suggesting that prior immunity in the mother can reduce the extent of HCMV exposure to the fetus. In women experiencing primary infection during pregnancy, an increased titer of neutralizing antibody and its avidity correlate with reduced risk of disease in the neonate (87).

The results for bone marrow transplant patients are distinct because reactivation of the recipient virus represents the source of HCMV-causing disease. Nevertheless, among seropositive recipients, those receiving marrow from immune donors have a reduced risk of disease (95). Direct evidence for adoptive transfer of immunity from the donor into the recipient was found by immunizing donors or recipients (or both, or neither) with tetanus toxoid (125). Although cell-mediated immunity is clearly the major response capable of containing HCMV infection, the possibility that HCMV disease may be controlled by other responses such as humoral immunity has been incompletely investigated. Humoral immunity could reduce the level of HCMV replication and reduce disease without being able to eliminate infection entirely. Humoral immune responses are directed against multiple CMV proteins, including surface glycoproteins, phosphoproteins of the tegument, and structural proteins of the capsid. Much of the antibody that neutralizes infectivity *in vitro* can be absorbed from sera with recombinant soluble gB, showing that this is the major target of the neutralizing response, but additional neutralizing epitopes are also found on gH, gL, and gN.

## CLINICAL MANIFESTATIONS

### Congenital Infection

Based on a systematic review of published prospective case series (85) 12.7% of congenitally infected babies are born with “cytomegalic inclusion disease” (Table 8). The remaining 87.3% appear to be normal at birth, but a proportion develop sequelae on follow-up, as described below.

In those symptomatic at birth, most of the noncentral nervous system (non-CNS) disease is self-limiting, although severe thrombocytopenic purpura, hepatitis, pneumonitis, and myocarditis may occasionally be life threatening (Table 8). A total of 0.5% of these patients die during infancy, and 50% of the survivors have permanent serious abnormalities. Brain

Retinitis

damage may present as microcephaly, mental retardation, spastic diplegia or seizures, and perceptual organ damage such as optic atrophy, blindness, or deafness. These abnormalities may occur alone or in combination.

Among those asymptomatic at birth, approximately 13.5% will develop hearing defects or impaired intellectual performance (Table 9). Twice as many children who come from the group who appear to be normal at birth are ultimately damaged by congenital HCMV, compared to those born with classical symptoms. This helps to explain why the burden of disease is underestimated for this infection.

A plausible pathogenesis for progressive hearing loss is apparent from the histologic examination of inner ear structures from a patient with a fatal case of congenital HCMV infection (Fig. 11). The virus spreads by the cell-to-cell route to produce a focus of infection surrounded by inflammation. This may represent stages of the infectious process in the inner ear, explaining how progressive damage to the organ of Corti could occur.

### Perinatal Infection

Neonates acquiring perinatal infection can start to excrete CMV in the urine from 3 weeks of age onwards. Most perinatally infected infants do not develop acute symptoms, although occasional cases of infantile pneumonitis develop, making HCMV a frequent pathogen in those few children presenting with an appearance of sepsis in the first 3 months of life (126). Perinatal infection may be severe in premature neonates because they do not benefit from transplacental passage of maternal immunoglobulin G (IgG) antibodies.

### Postnatal Infection

Primary infection in the immunocompetent child or adult is almost always asymptomatic, except for occasional cases of infectious mononucleosis. The patient presents with a fever with few localizing symptoms; pharyngitis, lymphadenopathy, and splenomegaly are less common than in EBV

**TABLE 9** Disease outcome in 1,000 infants born with congenital HCMV infection<sup>a</sup>

mononucleosis. Laboratory tests reveal biochemical hepatitis, with moderately raised transaminases, lymphocytosis with atypical mononuclear cells, and a negative heterophile agglutinin test. The condition resolves spontaneously, with a mean of 19 days' fever in one large study (127). Guillain-Barré syndrome has been described as a complication of postnatal primary HCMV infection. Rare cases of CMV EOD have been described among patients who are immunocompetent, including hepatitis, gastrointestinal ulceration with or without hemorrhage, and pneumonitis. Presumably these individuals have received a larger-than-average inoculum of CMV to explain their severe outcome.

### Immunocompromised Patients

Active HCMV infection causes a wide spectrum of disease, ranging from life threatening to asymptomatic and involving specific organs or causing constitutional disturbances.

Fever is a common component of all HCMV diseases in all immunocompromised hosts. Typically, this follows a spiking pattern, with temperatures in the range of 38 to 40°C, followed by precipitous declines below 37°C. During the fever, the patient complains of malaise and lethargy and may develop myalgia or arthralgia. This systemic phase of HCMV with leukopenia and elevated liver transaminases may resolve spontaneously or may herald particular clinical syndromes (EOD due to viremic dissemination of virus) that vary in incidence according to the underlying cause of the immunocompromised state (Table 7). The most common clinical presentations for each patient group are illustrated in Table 7, but any can occur in any patient group. HCMV disease typically manifests when the patient is most profoundly immunocompromised, that is, in the first and second months post-transplantation or, in AIDS patients, once the CD4 count has declined below 50 cells/ $\mu$ l. Indeed, successful institution of HAART reverses these changes and leads to immune-mediated control of HCMV viremia and prevention of EOD.

### Recipients of Solid-Organ Allografts

Leukopenia is common and may be profound. If leukopenia persists, it is associated with the development of secondary fungal and bacterial infections (128). Biochemical evidence of hepatitis is often found, with transaminase levels raised

two to three times the upper limit of normal. Thrombocytopenia may occur, with serial daily platelet counts below 100,000. All of these features usually respond to antiviral therapy.

Pneumonitis with interstitial infiltrates may occur, especially in recipients of lung (or heart-lung) transplants. Despite prolonged treatment, obliterative bronchiolitis may supervene (129), showing that HCMV plays an important role in the etiology of this chronic rejection process. Likewise, HCMV has been implicated in the development of accelerated atherosclerosis after cardiac transplantation (130) or graft rejection and graft atherosclerosis (131, 132). These conditions present as dysfunction of the transplanted organ with no clinical symptoms or signs to reveal the underlying contribution from HCMV. Yet, approximately 50% of acute biopsy-proven renal allograft rejections can be prevented by anti-HCMV prophylaxis with valganciclovir (133). Thus, the conventional diagnostic conundrum in the febrile allograft recipient of "rejection or HCMV" should be replaced with "rejection and HCMV."

### Recipients of Bone Marrow Grafts

Pneumonitis is the major life-threatening presentation of HCMV, occurring in 10% to 20% of bone marrow allograft patients before the availability of antiviral drugs. The patient presents with fever and hypoxia associated with pulmonary interstitial infiltrates. This complication is much less common (less than 5%) after an autograft, consistent with a postulated immunopathological disease process. HCMV infection may delay marrow engraftment (112) by replicating in bone marrow stromal supporting cells. An important clinical feature is that HCMV disease, especially pneumonitis, is statistically associated with GVHD (134). It is not clear whether HCMV infection can precipitate GVHD or whether the immunosuppressive nature of GVHD, or the treatment required for its suppression, facilitates HCMV reactivation.

### Patients with AIDS

In the pre-HAART era, at least 25% of AIDS patients developed disease attributable to HCMV. The vast majority (85%) of cases had retinitis, a clinical manifestation that is rare in transplant patients, followed by gastrointestinal involvement, encephalitis, and polyradiculopathy.

A patient with CMV retinitis may complain of "floaters" or loss of visual acuity. Alternatively, a typical focus of retinitis may be recognized at routine follow-up visits. Early lesions may be white due to edema, necrosis, or both (see figures in Chapter 10). Without treatment, the focus of infection spreads to neighboring cells (135), leaving white necrosis at the advancing border. There is hemorrhage, often flame shaped, surrounding blood vessels, with or without perivascular sheathing. It may be accompanied by anterior uveitis, retinal edema, or retinal detachment (136).

HCMV may also involve the gastrointestinal tract by causing ulcers deep in the submucosal layers. Clinical features vary with the anatomic site involved. Odynophagia is a common presentation of HCMV esophagitis, whereas abdominal pain and hematochezia frequently occur with HCMV colitis. Ulceration at these sites may cause perforation or hemorrhage.

HCMV causes encephalitis of two types in AIDS patients that mirror the pathology described above. The first is difficult to differentiate clinically from HIV dementia and manifests as subacute or chronic symptoms of confusion and disorientation attributable to cortical involvement. Focal

signs can be attributed to lesions in the brain stem. The second manifests as defects in cranial nerves, nystagmus, and increasing ventricular size (137), which progress rapidly to a fatal outcome.

HCMV also causes polyradiculopathy. Patients subacutely present with weakness of legs and numbness, progressing to flacid paraparesis, often with pain in the legs and perineum, bladder dysfunction, or both. The CSF shows a remarkable preponderance of polymorphonuclear leukocytes.

In the HAART era, most of these HCMV diseases have become uncommon (136). Nevertheless, HAART-induced immune recovery can produce vitritis and cystoid macular edema. These both profoundly affect vision, as does retinal detachment, which occurs when an HCMV-infected retina loses its substratum attachment to the underlying choroid layer (136).

### The Apparently Healthy Elderly

Immunosenescence, defined as a reduced T-cell CD4/CD8 ratio, is a major underlying contributor to morbidity and mortality (reviewed in reference 138). Immunosenescence is significantly increased in HCMV seropositive elderly persons compared to seronegative controls, although there are no differentiating clinical features between the two groups. However, HCMV seropositivity represents a significant risk factor for imminent death in the elderly (138). Immunosenescence is characterized by an excess of clones of differentiated T cells, detected by their restricted V $\beta$  repertoire, which have a reduced ability to respond to new antigens. (139, 140). Many clones of differentiated cells are HCMV specific, have an activated phenotype, and so may contribute to chronic inflammatory conditions, including atherosclerosis. Direct evidence for the adverse functional consequences of HCMV-associated immunosenescence include 2 possibilities; a decrease in naive T cells required to respond to new infections and vaccines; an increase in activated T cells that could contribute to chronic inflammation (140). T cells with the phenotypic markers of immunosenescence are found also in patients with chronic HIV infection where a randomized controlled trial showed that valganciclovir significantly reduced their abundance (141). To date, there are no randomized controlled trials of antiviral drugs or of immunotherapeutic vaccines in the elderly.

## LABORATORY DIAGNOSIS

### Detection of Virus

The characteristics of the assays used frequently in the identification of active HCMV infection vary widely among laboratories (Table 10). While the precise methodological details vary, all diagnostic virology laboratories should offer a service for rapid HCMV detection. The clinician should inquire about the positive and negative predictive values of

particular tests, understand their interpretation, and review whether day-to-day results have been audited to ensure that appropriate targets are achieved.

### Specimen Selection

Urine or saliva samples are usually collected to diagnose congenital or perinatal infection. If lumbar puncture or liver biopsy is indicated clinically, then samples can be processed, but the detection of HCMV at these sites does not have prognostic value for these children.

For adults with mononucleosis or hepatitis, urine and blood are the best samples. HCMV viremia might be coincidental, but the detection of viremia strongly supports the diagnosis. Pregnant women with symptoms should be investigated as for other adults. The screening of asymptomatic women has not been shown to identify those who will have newborns with congenital infection and so is not recommended.

Transplant patients should have surveillance samples of blood taken at least weekly from the time of transplantation. In the past, urine and saliva samples were also collected, but this has been superseded by assays using blood. Whole blood is the most sensitive for PCR (142). HCMV excretion from urine and saliva is very common but only doubles the relative risk for future disease. In contrast, viremia is detected less frequently in allograft patients but increases the relative risk to about 6 (Table 5). These different risks are used to define distinct treatment strategies discussed below.

The basic principles of HCMV natural history in patients who are HIV positive are the same as in the pre-HAART era, and these principles may become relevant again as individuals exhaust the salvage antiretroviral options in the post-HAART era. Individual AIDS patients with suspected CMV infection can be investigated for CMV viremia and by examining CSF by PCR when encephalitis or polyradiculopathy is suspected.

### Laboratory Assays

#### Assays to Detect HCMV in the Blood

Real-time PCR has become the new "gold standard" for detection of HCMV, in part because cell culture results can be misleading (Table 11). Because HCMV persists for the lifetime of infected individuals, a very sensitive technique such as nested PCR could potentially detect latent HCMV or virus that was replicating at such a low level that it had no clinical consequences. Four approaches have been taken to avoid this disadvantage.

#### Minimization of Latent Viral DNA Detection

A non-nested PCR method with high sensitivity but using only a small quantity of sample nucleic acid for analysis (i.e., 5  $\mu$ l of urine or 30 ng of DNA from peripheral whole

Strains of HCMV resistant to ganciclovir occur infrequently in immunocompromised patients	Resistance is more common; cell cultures select against detection of resistant strains	111

blood) has correlated well with conventional cell culture and provided useful prognostic information (Table 5) (143).

### Plasma PCR

Because the latent DNA of HCMV persists in the cellular fraction of blood, the detection of HCMV DNA in plasma should reflect active infection, although in practice some viral DNA is released from leukocytes prior to separation of the serum (99). An FDA-approved commercial assay is available (Roche Amplicor).

### RT-PCR and NASBA

Reverse transcription-PCR (RT-PCR) should detect only cells in which HCMV is replicating, since the target is mRNA. A nucleic acid sequence-based amplification (NASBA) assay for the detection of a late gene transcript (pp67) appears to be sensitive and specific and is available commercially (Biomerieux Nuclisens). However, there is no evidence that this assay offers any advantages over standard PCR.

### Real-Time PCR

Quantitative assessments of HCMV load are possible in real time. While such assays usually do not incorporate quantitative-competitive formats to identify possible inhibitors of PCR in the clinical sample, the results represent an important contribution toward controlling HCMV disease. The viral load found in the first available sample correlates with the peak viral load (144). The rate of increase in viral load can be estimated by back-projecting from the initial load to the last available PCR-negative sample from that patient. In multivariate models, the parameters of initial viral load and rate of increase are independent of each other, so both parameters can be used in combination to estimate an individual's risk of future HCMV disease (144). Serial

results from real-time PCR are frequently used to decide when to initiate preemptive therapy and to monitor the response to this treatment. In addition to testing blood, PCR has become invaluable for the investigation of CNS involvement in AIDS patients.

### Antigenemia

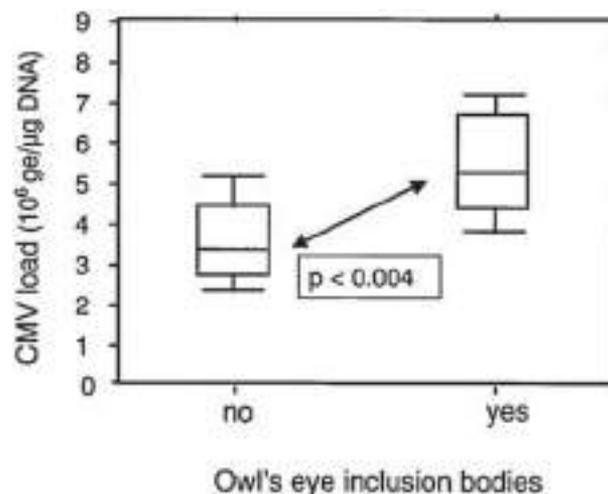

Monoclonal antibodies can be used to detect HCMV antigens directly in leukocytes from the blood of immunocompromised patients. The monoclonal antibodies react with pp65, the product of UL83. These monoclonal antibodies stain polymorphonuclear cells, monocytes, and endothelial cells from the peripheral circulation. The advantages of this technique are that it takes only a few hours and does not require facilities for cell culture or for PCR. The disadvantages are that it is subjective and samples can deteriorate rapidly. The antigenemia assay is therefore used by laboratories situated close to clinical facilities. It is possible to count the stained cells to provide a semiquantitative assessment of viral load. In general, antigenemia has been replaced by real-time PCR in most laboratories.

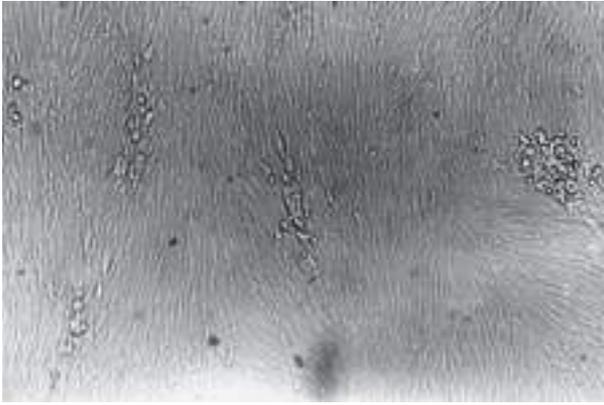

### Histopathology

Biopsies are often taken to confirm organ involvement. HCMV is recognized by its characteristic intranuclear "owl's eye" inclusions, which have a surrounding halo and marginated chromatin. They occur in kidney tubules, bile ducts, lung and liver parenchyma, and the gastrointestinal tract, inner ear, and salivary gland but are less prominent in brain tissue (Figs. 10 and 11). Cytoplasmic inclusions can also be seen in infected cells, particularly when stained with CMV-specific monoclonal antibodies. Histopathology provides a specific diagnosis that is insensitive (Fig. 12) compared to viral load measurements made by PCR in the same organs (145).

### Virus Isolation

Human fibroblasts (typically from foreskins or embryo lungs) are used to support HCMV replication *in vitro*. For the detection of viremia, buffy coat or unseparated heparinized blood can be inoculated into cell cultures. If toxicity is observed, denuded areas of the monolayer can be repaired by the addition of fresh fibroblasts.

**FIGURE 12** Correlation between high HCMV load and detection of intranuclear inclusions. ge, genomes.

**FIGURE 13** Photograph of human embryonic lung fibroblasts showing the focal CPE of HCMV. (Figure prepared by J. A. Bishop.)

All cultures should be observed at least twice weekly for the typical focal CPE of HCMV (Fig. 13). Occasionally, urine samples from patients with congenital infection produce widespread CPE within 24 to 48 hours that resembles that of HSV. More usually, the CPE evolves only slowly, typically becoming apparent at 14 to 16 days, so the cultures must be maintained for a minimum of 21 days before being reported as negative.

Monoclonal antibodies against the major IE and other E proteins of HCMV provide reagents useful in detecting the virus in cell cultures within 48 h before CPE had become apparent. Two techniques, (146) the shell vial assay (after the name of the container), and the (147) DEAFF test (detection of early antigen fluorescent foci) were a great improvement in their day due to the rapid availability of results. They have now been replaced by real-time PCR (see above) for testing surveillance samples but are still used to diagnose congenital infection (148, 149).

## Serologic Assays

### IgG Antibody

Many assays can detect HCMV IgG antibodies. The presence of IgG antibodies against HCMV is indicative of infection sometime in the past. Because the seropositive individual is liable to experience reactivations of his or her latent infection, the presence of IgG antibodies against HCMV is a marker of potential infectivity and immunologic responses do not imply complete protection from endogenous or exogenous infection.

IgG antibody detection can also be used as a marker of recent infection in populations, such as pregnant women, in whom the availability of avidity assays offers a practical way of detecting asymptomatic primary HCMV infections. Typically, it takes 16 to 20 weeks for IgG avidity to mature to high levels, and the reproducibility and specificity of the commercial assays appear to be superior to those of IgM assays. For pregnant women found on routine screening to be IgM positive, avidity assays can be used to triage them into groups with primary infection or recurrent infection and so reduce the number of terminations of pregnancy that might be undertaken based on the results of IgM testing alone (150). These tests are best performed in specialist laboratories with access to a range of commercial and in-house assays (150).

To detect serologic responses due to native virus infection after immunization with candidate vaccines, sera can be

preabsorbed with the immunogen to ensure that responses to this component of the vaccine are not mistaken for seroconversion (151).

Immunocompromised patients most at risk of HCMV disease may be those least able to mount prompt immune responses. In addition, false-positive *interpretations* are frequently seen when patients receive blood or blood products. Note that these are not false-positive *reactions*, as the patients do truly have HCMV IgG antibodies in their blood but these have come from an exogenous source. Thus, serial serologic testing is not recommended for monitoring individual immunocompromised patients.

### IgM Antibody

HCMV-specific IgM antibodies can also be used to detect current infection in immunocompetent patients such as those with HCMV mononucleosis. However, the specificity is poor for screening pregnant women for primary infection. The serologic approach is not recommended for the immunocompromised individual, in whom rapid detection of CMV is preferred.

## Detection of Antiviral Resistance

The protein kinase enzyme encoded by UL97 phosphorylates ganciclovir to its monophosphate. Cellular enzymes then convert this to the active triphosphate which is an inhibitor of the virus- encoded DNA polymerase UL54. HCMV can become resistant to ganciclovir through mutations in UL97 or, more rarely, UL54. Polymorphisms also occur in both genes, so a genetic change from that expected cannot, on its own, be taken as evidence of resistance. Instead, mutations should be transferred to a laboratory strain and shown to confer resistance *in vitro*.

Genetic changes in UL97 proven by site-directed mutagenesis to confer resistance when introduced back into a laboratory-adapted strain are shown in Fig. 16. These changes are detected by PCR amplification from clinical samples followed by sequencing. Many changes are clustered within specific regions of the gene so that small sections can be amplified by PCR to provide results rapidly. Changes in UL97 do not confer cross-resistance to any currently available anti-CMV drug. Unlike the situation with UL97, a number of mutations have been detected throughout the UL54 ORF following *in vitro* passage in the presence of antiviral drugs and in strains derived from patients undergoing drug therapy. Sequence analysis of the entire ORF is thus required to allow the detection of drug resistance at this locus in a clinical setting. Some changes in UL54 selected through use of ganciclovir confer cross-resistance to cidofovir (and brincidofovir) while rare changes are cross-resistant to foscarnet. None of these changes confers cross-resistance to maribavir or letermovir.

## PREVENTION

Because of the risk of fetal damage in pregnant women, especially when seronegative, changes in child-rearing practices could affect the incidence of disease attributable to congenital HCMV. Typically, middle-class seronegative women are at potential risk when they send their children to child care centers with young children excreting HCMV (90). Considerable anxiety may be induced in both mothers and day care workers because HCMV infection is usually asymptomatic and excretion is prolonged. Because professionally trained nursing staff are not at increased risk of acquiring HCMV infection from patients (91), routine

precautions such as hand washing must be sufficient to protect against transmission. Consequently, day care centers should be advised to review and improve their general hygiene standards. The same advice should be given to female staff, irrespective of their serologic status; humoral immunity in these women cannot guarantee that the fetus will be protected from infection, although it should reduce the chance of disease.

HCMV infection can be prevented in some patients by screening of blood products. Blood from donors who are seronegative should ideally be used for intrauterine transfusion, for pregnant women, and for immunocompromised patients, irrespective of whether the recipients are CMV seronegative or seropositive. Because such blood is in short supply, an alternative is to pass the blood through in-line filters capable of retaining leukocytes (152).

In the solid-organ transplantation setting, HCMV disease could be potentially reduced by matching donors and recipients, so that organs from seropositive donors are not given to seronegative recipients. However, in practice, this would reduce the likelihood of achieving the best available HLA match and would delay transplants for many recipients whose medical condition may deteriorate while they wait for a seronegative donor. Furthermore, because donor organs are in such short supply, there is pressure not to reject donations unless absolutely necessary. As a result, donor-recipient matching is generally required only by some centers where the risk for HCMV disease is considered especially high, such as for seropositive donors of lungs destined for seronegative recipients. In the remaining patients, various antiviral strategies can be employed to reduce HCMV disease.

### Active Immunization

No approved HCMV vaccine is currently available. A summary of HCMV vaccine candidates is shown in Table 12, and a list of possible volunteers for immunogenicity and phase III protection studies is shown in Table 13.

Pioneering work with live-attenuated vaccine strains by Plotkin and colleagues showed in volunteers that the Towne strain was truly attenuated compared to the virulent Toledo strain (153). A controlled trial in dialysis patients showed no reduction in the proportion of patients who became infected or ill due to CMV after subsequent renal transplantation, but the trial demonstrated a significant reduction in the severity of disease (154). The Towne vaccine did not provide protection against primary infection in parents of children attending day care centers. Overall, the effects seen were not sufficiently encouraging to allow further development of this

vaccine but provided a useful framework for the evaluation of future preparations.

Phase I studies are under way to administer Towne vaccine together with IL-12 as a way of improving immunogenicity. The Towne strain of HCMV lacks 19 genes found in the Toledo strain (31), and it is possible that some of these genes could provide protection against wild-type HCMV if they were incorporated into a vaccine. Accordingly, recombinants between Towne and Toledo have been prepared that include all 19 genes incorporated into the Towne attenuated background. Vaccine candidates containing all 19 genes have shown safety and immunogenicity in a phase I study.

Recombinant vaccines based upon gB have been developed, because gB can adsorb most of the neutralizing antibody from sera and also contains T-helper epitopes. The gB also possesses T-helper epitopes, although humans with particular HLA types have been shown to be low responders. Cells infected with a vaccinia virus gB recombinant adsorb between 40% and 88% of the total serum neutralizing activity in individuals who are either naturally immune or vaccinated with the Towne vaccine strain of HCMV. Purified and recombinant preparations of gB induce humoral immunity in experimental animals and can reduce the fetal loss and congenital infection that result from inoculation of guinea pig HCMV.

A canarypox virus vector that incorporates the ppUL83 (pp65) gene, which is the major target for cell-mediated T-cytotoxic responses, was immunogenic in phase I studies, although no humoral immunity was induced. Phase I trials of a DNA vaccine for HCMV in humans provide evidence of priming of the immune system. An alphavirus recombinant expressing gB has been shown to be well tolerated and immunogenic in a phase I study (Table 12).

Most clinical experience to date has been with a truncated form of gB expressed in mammalian cells and used to immunize volunteers in phase I and phase II studies. This prototype vaccine was immunogenic in seronegative healthy volunteers and induced neutralizing antibody titers greater than those found in seropositive persons (155). The novel adjuvant MF59 gave antibody titers superior to those obtained with the conventional adjuvant, alum, and the optimum immunization schedule was to give vaccine at 0, 1, and 6 months (155). Although antibody levels declined with time after this primary course of three vaccine doses, a prompt anamnestic response to a booster dose given at 12 months was seen (155). This vaccine produced very high neutralizing titers when given to seronegative toddlers and also boosted the titer of neutralizing antibodies when given to seropositive individuals. This gB/MF59 vaccine underwent 3 phase II studies. A controlled study in postpartum seronegative women determined that the rate of primary maternal infection was decreased by approximately 50% (156). Seronegative adolescents and seronegative or seropositive recipients of a kidney or a liver transplant also had evidence of reduced CMV infection when exposed to virus (157).

A summary of HCMV vaccine candidates is shown in Table 12, and a list of possible volunteers for immunogenicity and phase III protection studies is shown in Table 13. One theoretical concern that has been raised about widespread introduction of an HCMV vaccine is that alterations in herd immunity could delay infections so that more women acquire primary infection during pregnancy. This was also a concern during the development of rubella vaccine and is relevant because all vaccines increase the average

TABLE 12 Vaccine candidates studied clinically

Preparation	Type	Status
Towne	Live attenuated	Phase II
gB	Soluble recombinant	Phase II; 3 trials

age at which unvaccinated individuals acquire natural infection. Mathematical modeling shows that such a phenomenon will not produce a problem for HCMV vaccinees in a typical developed country because the average age of infection is already greater than the average age at which pregnancies occur (Fig. 14) (158). Modeling indicates that the basic reproductive number of HCMV in such a population is similar to that of smallpox, so by reducing the number of infectious individuals in a society, herd immunity could reduce the incidence of reinfections as well as primary infections (Fig. 15). Because reinfections are a more important cause of disease than reactivations in transplant patients (98) and probably in pregnant women as well (88,159), this prediction provides encouragement for the ultimate elimination of HCMV infection, although several generations of people would need to be immunized and eradication would take longer in communities where HCMV is acquired earlier in life. Nevertheless, we continue to hypothesize that control of initial HCMV infection could impair its ability to establish sanctuary sites protected by its

immune evasion genes, so that individuals become less contagious to others. This optimistic scenario has already been proven true for other infections that persist in humans (hepatitis B virus, varicella-zoster virus, and human papillomavirus), so hopefully one or more of the current HCMV vaccine candidates will demonstrate the modest degree of protection required to allow this hypothesis to be tested.

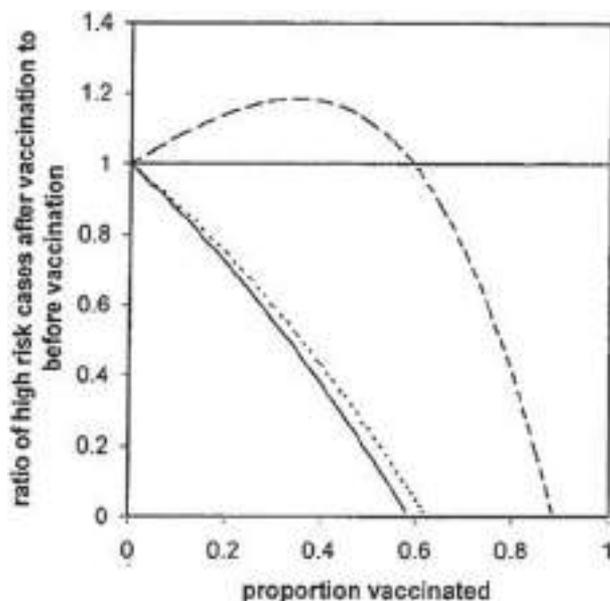

Passive immunoprophylaxis has been evaluated in three randomized controlled trials. Two were conducted in solid organ transplant patients, the largest of which reported significantly reduced CMV syndrome in liver transplant patients. The third trial was in pregnant women with primary HCMV infection in whom no significant reduction in intrauterine transmission of virus was seen, whereas an excess of complications of pregnancy was apparent (160). Thus, despite claims based on uncontrolled observations, hyperimmune immunoglobulin should not be offered to pregnant women in clinical practice.

## TREATMENT

### Transplant Patients

Before antiviral drugs became available, an important therapeutic decision in transplant patients with active HCMV infection was to reduce the dose of immunosuppressive drugs. This should remain a component of the management of HCMV infection, supported by the administration of specific antiviral drugs. In transplant patients, the availability of surveillance samples allows early treatment options in addition to those of prophylaxis and treatment of established disease. One key point is that lessons learned from one patient group cannot be applied directly to others.

Drugs with activity against HCMV could potentially be used in four main ways, depending in part on their toxicity profiles (Table 14). Sixteen double-blind, placebo-controlled, randomized trials conducted for HCMV are summarized in Table 15 according to four main criteria of success: prevention of HCMV infection, prevention of HCMV disease, reduction in mortality, and decreased indirect adverse effects (Table 15). In addition to ganciclovir and valganciclovir, several agents, including acyclovir, alpha interferon, and valacyclovir, have activity against HCMV *in vivo* (Table 15). In contrast to their relatively low potency when tested against HCMV *in vitro*, all of these treatments significantly reduced HCMV excretion, except immunoglobulin (Table 15). Quantitative virologic assessments were

**FIGURE 14** Herd immunity for HCMV or rubella —, CMV study 1; ·····, CMV study 2; - - - - -, rubella.

not done, but this suggests that any beneficial effect observed from the use of immunoglobulin is not necessarily mediated through a reduction in HCMV infection.

Only some of the studies have shown that control of HCMV infection leads to a reduction in HCMV disease (Table 15). The most consistent results come from the trials of ganciclovir, which clearly can markedly reduce HCMV disease in some groups (like stem-cell transplant patients) but inconsistently in others (an effect was seen in heart transplant patients for reactivation but not for primary HCMV infection in one study, whereas the converse was true in a second study). The apparent discrepancies among clinical trials (no significant effect for ganciclovir in one of two bone marrow transplant studies, an effect of acyclovir in renal transplant but not bone marrow transplant patients, and benefit in only two of the three alpha-interferon trials), can be explained by relatively small sample sizes. Each trial showed trends in favor of a reduction in HCMV disease.

When the parameter of clinical benefit was survival, only three studies showed a positive result (Table 15). Ganciclovir given to patients already excreting HCMV was life-saving, but the same was not true in either of two studies that evaluated prophylactic ganciclovir in bone marrow transplant recipients. These studies showed that the bone marrow toxicity of ganciclovir, manifested as neutropenia, was as-

sociated with bacterial superinfection (94, 161). Because all patients in this prophylaxis study were exposed to potentially fatal side effects but only some benefited from a reduced mortality associated with HCMV, these two effects cancelled each other out. In contrast, when ganciclovir was used in the suppressive mode, a major benefit was achieved while exposure to drug toxicity was minimized. Acyclovir use in the same patient population provides an interesting contrast. Although this drug is less potent than ganciclovir, patients showed a survival benefit overall because there was no serious toxicity to offset its moderate efficacy (105).

When the parameter assessed is the ability to control the indirect effects of HCMV, both ganciclovir and valacyclovir show significant benefits. The original study by Merigan et al. (162) of heart transplant recipients utilized a regimen of intravenous ganciclovir suboptimal in terms of both dose and duration. Indeed, the trial reported that HCMV disease was reduced among seropositive but not seronegative recipients, who we now know have high viral loads. Nevertheless, this suboptimal regimen produced significantly reduced risks of fungal superinfections and accelerated atherosclerosis during long-term follow-up (163). In renal allograft patients randomly allocated valacyclovir, 2 g four times daily for 90 days, or matching placebo, seronegative recipients showed a 50% reduced risk of biopsy-proven acute

**FIGURE 16** Schematic representation of the UL97 gene showing mutations at particular codons that have been proven to cause resistance to ganciclovir *in vivo* or that are associated with maribavir resistance *in vitro*. Bold letters indicate mutations confirmed by site-directed mutagenesis. Mutations 460 to 607 refer to ganciclovir; mutations 353 to 411 refer to maribavir. (Data from reference 189.)

graft rejections (133). Taken together, these results strongly implicate HCMV as a cause of the indirect effects listed in Table 7.

Meyers et al. (164) were the first to study acyclovir prophylaxis in bone marrow transplant patients. Among HCMV-seropositive patients, those who were also HSV seropositive and received high-dose intravenous acyclovir showed a marked reduction in HCMV disease and mortality rate. However, these encouraging results were not widely accepted, probably because at that time, acyclovir was not thought to have useful anti-HCMV activity. However, it is now known that the product of gene UL97 can phosphorylate acyclovir in addition to ganciclovir. A subsequent trial (105) based upon the protocol used by Meyers et al. (164) confirmed that acyclovir reduces the mortality in this patient group.

Among bone marrow transplant patients, Schmidt et al. (104) performed routine bronchoalveolar lavage on day 35 in asymptomatic patients and used the shell vial technique to detect HCMV infection. HCMV-infected patients randomized to receive ganciclovir had a marked reduction in HCMV pneumonitis following ganciclovir therapy, which contrasts with the failure of ganciclovir to improve survival once HCMV pneumonitis was established in these patients. This apparent contradiction is consistent with the hypothesis that HCMV pneumonitis is an immunopathological condition (102), presumably prevented by preemptive therapy (104). Bronchoalveolar lavage has now been replaced by routine detection of viremia as a less invasive way of identifying patients in need of preemptive therapy. Meanwhile, open studies of a combination of ganciclovir plus immunoglobulin suggest that better, but not excellent,

**TABLE 14** Strategies for chemotherapy of HCMV

Term used	Time when drug is given	Risk of disease	Acceptable toxicity	Agent responsible for treatment decision
True prophylaxis	Before active infection	Low	None	Clinician
Delayed prophylaxis	When there is increased risk, but before active infection and after rejection	Medium	Low	Clinician
Suppression	After peripheral detection of virus	Medium	Low	Laboratory
Preemptive therapy	After systemic detection of virus	High	Medium	Laboratory
Treatment	Once disease is apparent	Established	High	Clinician and laboratory

control of established HCMV pneumonitis can be achieved in this patient group (165, 166). Presumably, the immunoglobulin component has an immunomodulatory effect on HCMV immunopathological pneumonitis, whereas ganciclovir reduces the chance that neighboring lung cells will be recruited by HCMV to stimulate further immunopathology. It seems likely that an immunomodulatory effect of immunoglobulin would be nonspecific, and there is support for this from a rat experimental model (167). Thus, there is little evidence that immunoglobulin prepared from HCMV-positive donors has any advantage over immunoglobulin from unselected donors, but a comparative trial to test this formally would seem worthwhile. Foscarnet was equipotent with ganciclovir when used for preemptive therapy in bone marrow transplant patients (168). The combination of foscarnet plus ganciclovir (each at half dose) can be used to reduce toxicity without evidence of synergy (169).

In a controlled trial, low-dose intravenous ganciclovir prophylaxis was superior to high-dose oral acyclovir in liver transplant patients (170). In contrast to the case with bone marrow transplant patients, ganciclovir prophylaxis can be used safely in liver transplant patients, partly because of the lower dose chosen and partly because bone marrow toxicity may be a particular problem in bone marrow transplant patients.

Following the widespread introduction of antiviral prophylaxis in transplant patients, late-onset disease has emerged as a clinical problem that develops once patients stop their antiviral prophylaxis. Some patients develop disease due to ganciclovir-resistant mutants, and there have been serious cases of EOD, including death. Such late-onset disease is rarely seen in centers that use preemptive therapy (171). One plausible explanation is that low-level antigen presentation as part of preemptive therapy may stimulate the immune system to control long-term HCMV infection, analogous to “endogenous immunization.” Alternatively, ganciclovir may interfere with the division of T cells, thus impairing their ability to form the most potent clonal de-

rivatives. An important question for the field is whether prophylaxis per se selects for this immunologic problem or whether it is an adverse outcome of using ganciclovir prophylaxis. The results with newer drugs used for prophylaxis are therefore awaited with interest.

Both prophylaxis and preemptive therapy are effective strategies for preventing HCMV disease in transplant recipients. In addition, seven randomized clinical trials have directly compared prophylaxis and preemptive therapy in solid-organ transplant patients (172, 173, 176). A meta-analysis of these studies reported no significant differences in the incidence of HCMV disease, graft rejection, or death. Thus, while the relative merits of both strategies are hotly debated (171, 174), clinicians can use whichever strategy they find convenient for their transplant center.

Having managed patients for more than 20 years with ganciclovir plus occasional use of the other drugs mentioned, three new drugs have recently become available for clinical trials. They have all been evaluated in phase II studies, giving the drugs prophylactically to bone marrow transplant patients and recording whether the need for preemptive therapy with ganciclovir is reduced. All three placebo-controlled clinical trials were successful (175).

Maribavir is an inhibitor of UL97. Although strongly protein bound, sufficient drug can be administered to allow the free compound to inhibit HCMV replication. Maribavir is active against UL97 mutants and also against UL54 mutants resistant to ganciclovir, foscarnet, or cidofovir. However, because of its inhibition of UL97, maribavir results in a 13-fold increase in the 50% inhibitory concentration for ganciclovir, and consequently combination therapy with maribavir and ganciclovir will not be possible. The genetic changes in UL97 that confer resistance *in vitro* are summarized in figure 16.

Brincidofovir is a lipid prodrug of cidofovir. It lacks the renal toxicity of its parent compound and is distributed to all tissues in the body. It has significant activity against other viruses with double-stranded DNA, such as EBV, BK virus,

and adenoviruses. In a phase II study, prophylaxis with brincidofovir significantly reduced the need for preemptive therapy in stem cell transplant patients, but at the cost of dose-limiting gastrointestinal toxicity (176).

The CMV terminase complex cleaves concatemeric DNA into unit-length molecules as packaging proceeds by a “head-full” mechanism. Letermovir inhibits this complex and has activity against CMV only. In a phase II study, letermovir prophylaxis was more likely to prevent the need for preemptive therapy in stem cell transplant patients than was placebo (190).

All three of these new drugs have entered phase III clinical trials for prophylaxis in stem-cell transplant recipients. For the first (maribavir), the primary endpoint of CMV EOD was chosen, despite the fact that all patients were allowed preemptive therapy if maribavir or placebo failed to suppress viremia. In addition, a low dose of maribavir was chosen (191) In combination, these study design features led maribavir to fail its phase III evaluation (192). The lesson is clear; the effectiveness of prophylaxis should be determined by the ability of a drug to reduce the need for preemptive therapy.

None of the three new drugs has bone marrow toxicity. This means that if one or more of them become licensed, it could be given from the time of transplant onwards, as soon as patients can tolerate oral medication, rather than waiting for bone marrow engraftment to occur, as is the case with ganciclovir. The current delay in initiating antiviral prophylaxis with ganciclovir is undesirable, because better antiviral potency is obtained when treatment is begun before the patient has detectable levels of viremia.

### AIDS Patients

In contrast to the logical approach to treatment described above for transplant patients, drug evaluation in HIV-positive patients has been largely empirical. Studies have focused on the clinical problem of established HCMV retinitis rather than targeting HCMV itself based upon knowledge of the natural history of infection.

The trial of the Studies of Ocular Complications of AIDS Research Group recruited patients with first-episode HCMV retinitis and randomly allocated them to receive either ganciclovir for induction and maintenance or foscarnet for induction and maintenance (177). Both were equally effective at delaying the time to recurrence of HCMV retinitis, but survival was significantly improved with foscarnet, despite the fact that treatment toxicity necessitating a switch to the alternate treatment was more common in those receiving foscarnet. The possible reason for the survival difference may relate to foscarnet’s activity against HIV.

Two double-blind, controlled, randomized trials were conducted with HCMV-infected AIDS patients without EOD. These trials of oral ganciclovir (178) and oral valganciclovir (179) showed benefit in preventing disease. The strategy has been termed prophylaxis, but this refers to prophylaxis for disease and is not synonymous with prophylaxis of infection described above for transplant patients. Indeed, virologic assessment at entry shows that 50% of patients had HCMV infection detectable by PCR in urine, blood, or both. HCMV infection in HIV-positive patients occurs far earlier than has been appreciated by observing HCMV retinitis in AIDS patients. After 12 months, oral ganciclovir reduced HCMV retinitis from 30% in the placebo arm to 16%, whereas the valganciclovir trial reduced HCMV retinitis from 18% in the combined two-dose acyclovir arms to 12%. Ganciclovir showed significant benefit

only in the subset who were PCR negative at baseline (i.e., true prophylaxis), whereas valganciclovir showed significant benefit for both preemptive therapy and prophylaxis (109, 180). This difference probably relates to the doses of the drugs administered rather than to their inherent potencies. Despite its known toxicity, ganciclovir was fairly well tolerated in these patients, partly because poor oral bioavailability may have limited the potential for toxicity. Valganciclovir at the high dosage chosen, 8 g/day, was poorly tolerated by AIDS patients, many of whom stopped therapy prematurely. Thus, the efficacy figures given above for the intention-to-treat analyses should be reviewed with the knowledge that many patients stopped treatment during the trial.

The results from these two trials are encouraging, but there remains much room for improvement. Drugs can now be targeted to reduce HCMV infection and decrease the chance of seeding the retina. One possible approach would be to monitor HIV-positive patients for evidence of HCMV infection by PCR and then start preemptive therapy. However, ACTG protocol A5030, in which patients whose plasma PCR was positive on a single occasion were given valganciclovir or placebo, found no significant benefit, but the study was seriously underpowered because of the difficulties of identifying individuals positive for HCMV as determined by PCR in the era of HAART (181).

The main strategy to prevent HCMV retinitis in AIDS patients is treatment with HAART regimens that maintain the CD4 count above 100. Indeed, patients who present with HCMV retinitis can have valganciclovir maintenance therapy stopped if their CD4 count rises above 100 and persists at that level for at least 3 months, showing that recovery of preexisting HCMV-specific immunity is sufficient to control progression of this EOD. In patients with lower CD4 counts, there is no consensus about whether to monitor for CMV viremia and what treatment to offer if CMV DNA is detected.

### Neonates

A randomized trial in neonates with congenital HCMV and CNS symptoms or signs conducted by the Collaborative Antiviral Study Group (CASG), demonstrated significant control over progressive hearing loss from ganciclovir at 6 mg/kg twice daily given intravenously for 6 weeks (182). This benefit is consistent both with the increased viral load found in such neonates (90) and with the clinical observation that much of the hearing loss is acquired progressively after birth. Six weeks of treatment with intravenous ganciclovir became established as the standard of care for neonates born with CNS symptoms of congenital HCMV infection (182). Of note, ganciclovir has important toxicity (acute neutropenia and thrombocytopenia plus carcinogenicity in rodents at less than the human anticipated exposure), so evaluation of this drug should proceed with caution. Valganciclovir has been shown to be bioavailable orally in neonates (183), and a new CASG trial randomized congenitally infected neonates with symptoms at birth (not necessarily CNS symptoms) to receive 6 weeks versus 6 months of valganciclovir therapy (184). The longer duration of therapy provided significantly better control of hearing loss and effects on developmental milestones, although the incremental benefits seen were not as great as the fourfold increase in drug exposure, exactly as predicted by the threshold concept. This is now the new standard of care for babies born with symptoms affecting the CNS. Some pediatricians are reluctant to prescribe valganciclovir for 6

months if the symptoms at birth were mild, such as isolated thrombocytopenia, but no consensus has emerged on exactly which clinical criteria should guide treatment initiation.

### Therapeutic Drug Monitoring

Therapeutic drug monitoring is only rarely required, especially when preemptive therapy is used and the patient's viral load can be monitored until it declines below the level of detection. If this expected pattern is not seen, there are two possibilities, poor absorption of drug or antiviral resistance. The first is usually addressed by giving ganciclovir intravenously, with declining viral loads often attributed to poor patient compliance with oral medication rather than poor absorption of valganciclovir. Therapeutic drug monitoring can be useful in occasional patients receiving hemofiltration whose viral load is static despite intravenous ganciclovir.

### Resistance

Strains of HCMV resistant to ganciclovir have been found in AIDS patients receiving maintenance therapy for retinitis. Approximately 8% of urine samples contained resistant virus once patients had been treated for at least 3 months (185), which is probably an underestimate of the true situation *in vivo* because the long time taken to propagate HCMV in cell cultures allows the wild type to outcompete the resistant strain *in vitro* (111).

Most HCMV strains acquire resistance through mutations in the UL97 gene, although occasional mutations in DNA polymerase have been described. A range of mutations have been identified in UL54 that give rise to resistance to the antiviral drugs ganciclovir, foscarnet, and cidofovir. Some of these mutations, such as D301N, give rise to cross-resistance to all of the aforementioned nucleoside analogs. In a cohort of AIDS patients receiving oral ganciclovir maintenance therapy, 22% had resistance detected *in vivo* by genotyping (186, 187). None of the patients with resistance responded to reintroduction of ganciclovir, arguing that the laboratory results are clinically relevant. Knowledge of the rapid dynamics of HCMV replication *in vivo* has been used to explain and predict the development of resistance in AIDS patients (111). At present, resistance is not a major clinical problem because HCMV is controlled indirectly by HAART, but we anticipate further cases in the post-HAART era, and the principles discussed above should be reapplied. Specifically, patients who had genotypically resistant HCMV in the past may present again with HCMV disease poorly responsive to ganciclovir.

Increasing cases of ganciclovir resistance have been reported as antiviral prophylaxis has been used frequently in transplant patients. Mutations identical to those seen in AIDS patients develop. Late-onset HCMV disease, occurring after antiviral prophylaxis has been stopped, has emerged as a major clinical problem and is frequently caused by resistant strains. Alternative drugs to consider include foscarnet, letermovir, or brincidofovir, guided by the results of sequencing and the possibility of cross-resistance.

### Novel Antiviral Targets

Fomivirsen is a licensed treatment for HCMV retinitis, although it is no longer marketed because of the diminishing number of cases of HCMV retinitis. It is an antisense oligonucleotide containing modified bases to reduce nuclease susceptibility. The drug interferes with the IE86 transactivator (Fig. 3) and has to be given by intravitreal injection.

The HCMV protease is an attractive target, especially since this class of inhibitor has been successfully developed

for HIV. However, despite the availability of a three-dimensional structure since 1997, the search for inhibitors has been slow. This is partly compounded by the complexity of the enzyme and partly because the substrate binding groove is shallow, reducing the opportunities for small molecules to bind with high affinity.

### ACKNOWLEDGMENTS

We thank Dr J. McLoughlin for preparing Figure 10 from a patient under the care of Dr. H. G. Prentice. We also thank J. Bishop for Figure 13 and I. Baraniak for Figure 1.

# Human Herpesvirus 6 and Human Herpesvirus 7

KOICHI YAMANISHI AND YASUKO MORI

## 24

Human herpesvirus 6 (HHV-6) was first isolated from patients with lymphoproliferative disorders in 1986 and was initially named "human B-lymphotropic virus (HBLV)" (1). It was found to mainly infect and replicate in lymphocytes of T-cell lineage (2). Subsequently, several reports described the isolation of similar viruses mainly from patients with HIV/AIDS. The characterization of HHV-6 indicated that the virus was antigenically and genetically distinct from the other five known human herpesviruses (1, 3). HHV-6 isolates are classified into two closely related groups that have been named variants A (HHV-6A) and B (HHV-6B). Primary HHV-6B infection occurs during infancy. This virus was recognized as the causative agent of exanthem subitum (ES) in 1988 (4).

Another novel human herpesvirus, human herpesvirus 7 (HHV-7), was isolated in 1990 by Frenkel et al. from CD4+ lymphocytes of a healthy adult (5). Seroepidemiologic studies have indicated that the primary HHV-7 infection also occurs during childhood.

## VIROLOGY

### Classification

HHV-6A, 6B, and HHV-7 are members of the *Herpesviridae* family. Genomic analysis supports their classification as *Roseolovirus* genus of betaherpesviruses. On the basis of similarity between the amino acid sequences, gene organization, and putative protein functions, human cytomegalovirus (HCMV) is the closest phylogenetic relative of HHV-6A, 6B, and HHV-7 (6, 7).

HHV-6 strains, which were isolated in different regions of the world, are closely related to one another. Two distinct variants of HHV-6, named HHV-6 variant A (HHV-6A) and variant B (HHV-6B), exist, as demonstrated by restriction enzyme analysis, DNA sequence, and reactivity with monoclonal antibodies (MAb). Recently, these two variants have been classified as distinct species (8). Virus strains belonging to HHV-6A, including the original isolate (GS strain), are isolated mainly from patients with lymphoproliferative disorders or AIDS. HHV-6B strains are isolated mostly from patients with ES.

HHV-7 cross-hybridizes with some HHV-6A/B DNA probes. There are no recognized HHV-7 variants to date, but there is significant genetic variation among isolates. Pre-

dictably, there is also antigenic cross-reactivity between HHV-6A, 6B, and HHV-7 (6, 9).

### Virus Composition

#### Virion Structure

Electron microscopic examination of infected cells showed that HHV-6 is an enveloped virion with an icosahedral capsid with 162 capsomeres (Figure 1) (10). Most of the capsids are in the nucleus and have cores of low density with a diameter of 90 to 110 nm. Enveloped viral particles are observed in cytoplasmic vacuoles as well as extracellularly, and have a diameter of 170 to 200 nm. In the nucleus, tubular structures were occasionally observed (11). Naked particles gradually acquire a full tegument in a nuclear vacuole. Fusion events with the nuclear membranes result in the release of the tegumented capsids into the cytoplasm. The tegumented capsids then undergo envelopment in cytoplasmic vacuoles, yielding mature virions. Fusion of the vacuole membrane with the cell membrane releases the intact virion into the extracellular space.

The virion glycoproteins are absent from nuclear and plasma membranes (12) but are concentrated in cytoplasmic structures known as *annulate lamellae* (13, 14). Final envelopment of viral particles occurs at intracellular membranes that are characteristics of endosomes and the trans Golgi network (15). HHV-6 virions collect in multivesicular bodies (MVB) that contain numerous mature virions and small exosomal vesicles (15). MVB membranes can fuse with the plasma membrane, resulting in release of mature virions. In addition to exocytosis, mature virions can be released by cell lysis (14).

#### Genomic and Genetic Properties

The HHV-6 genome is a linear, double-stranded DNA molecule with a size of 160 to 170 kbp composed of a central segment of a largely unique sequence (U) of approximately 141 kbp with a sequence of approximately 10 to 13 kbp duplicated in the same orientation at both left and right genomic termini (DR) (16). The DNA length variation map to the left end of both DR elements is termed the heterogeneous or het region (17, 18). The left and right termini of the DR contain homologs of the herpesvirus cleavage and packaging signals, *pac-1* and *pac-2*, respectively. The mean G+C content of genomic DNA is 43% (17). The entire

coproteins associate with major histocompatibility complex (MHC) class I molecules (35, 36), and the association functions in lysosome sorting, which may reduce cytotoxic T lymphocyte (CTL) recognition of infected cells. HHV-6 and HHV-7 U24 proteins induced internalization of the T-cell receptor/CD3 complex at the cell surface, resulting in aberrant T-cell activation (37). HHV-6B IE1 interacts with STAT2 and sequesters it in the nucleus, preventing ISG3 from binding to IFN-responsive promoters, resulting in silencing of ISG (38).

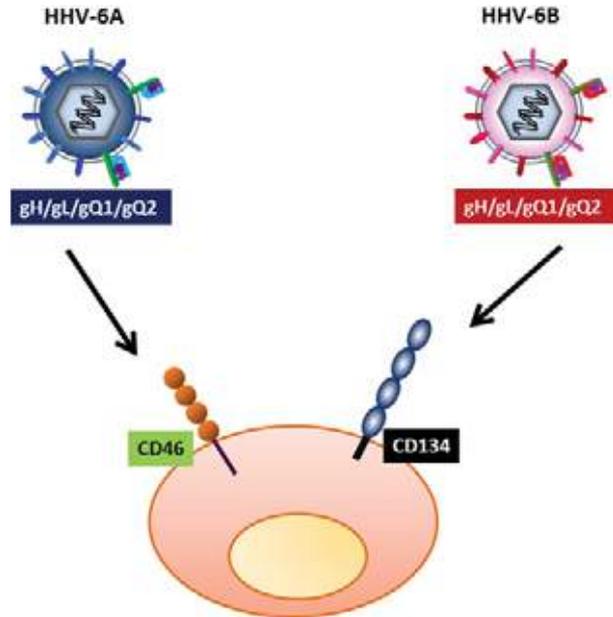

The predominant protein species immunoreactive with human serum are p100 (HHV-6A) and p101 (HHV-6B) (39). These proteins function as a tegument protein like HCMV pp150. A polypeptide with an approximate molecular weight of 41 kDa is produced early in the replicative cycle (40). The immediate early proteins may transactivate the HIV long terminal repeat (LTR). HHV-6 also codes virus-specific DNA polymerase, uracil-DNA glycosidase and alkaline DNase, and induce thymidine kinase and deoxyuridine triphosphate nucleotidohydrolase. The HHV-6B rep gene, which is a homologue of adeno-associated virus type 2 rep and is unique in the herpesvirus family, has been identified (41). HHV-6 and HHV-7 encode viral chemokine and chemokine receptor homologs (42, 43). U83A encoded by HHV-6A binds a human chemokine, CCR5, and inhibits HIV replication *in vitro*, suggesting that HHV-6 U83A acts as a novel inhibitor of HHV-6 infection (44).

At least 20 proteins, including 7 glycoproteins, are specific to HHV-7 and range in apparent molecular weight from 136 to 30 kDa (45). Human antibodies raised to HHV-7 are directed predominantly to one or more HHV-7-infected cell proteins with apparent molecular weight of about 85 (phosphoprotein 85 or pp85) to 89 kDa. The pp85 is considered a major determinant of the human immune response to HHV-7, discriminating HHV-6 from HHV-7 infection. Further, human sera recognize additional epitopes of pp85 that are required for their full reactivity (46, 47). Some MAbs reacted in immunofluorescence assays with HHV-6 antigens to the same degree as to HHV-7 protein (45, 48).

### Biology

HHV-6 is isolated only from human mononuclear cells (mainly CD4<sup>+</sup> lymphocytes) and propagates in CD4<sup>+</sup> lymphocytes (49, 50). HHV-6 infects a variety of human cells such as T and B lymphocytes of peripheral blood, cell lines of lymphocyte, and macrophage *in vitro*, and infects also lymphocytes of chimpanzees. The cytopathic effect (CPE) induced by HHV-6 begins 1 to 2 days post-infection as evidenced by enlargement of infected lymphocytes. These refractive giant cells usually contain 1 or 2 nuclei, and following the development CPE, lytic degeneration of the cells occurs. CD46 is a cellular receptor for HHV-6 (51). HHV-6A can induce fusion-from-without (fusion that does not require viral protein synthesis) in a variety of human cells, dependent on CD46 expression (52). Human CD134, which is expressed in activated T-cells, was found to be a cellular receptor specific for HHV-6B, but not HHV-6A (53). HHV-6B gH/gL/gQ1/gQ2 complex binds to CD134 and that of HHV-6A binds to human CD46 (53) (Figure 3).

HHV-6 has been shown to integrate into host cell chromosomes and be vertically transmitted in the germ line. HHV-6 specifically integrates into telomeres of chromosomes during latency rather than forming episomes, and the integrated viral genome is capable of producing virions (54). A single HHV-6 genome integrates such that telomere repeats join the left end of the integrated viral genome (55).

**FIGURE 3** HHV-6A/B and cellular receptors. gH/gL/gQ1/gQ2 complex expresses in HHV-6A/B envelope. HHV-6A gH/gL/gQ1/gQ2 complex binds to human CD46, and that of HHV-6B binds to human CD134.

In contrast, HHV-7 uses CD4 as a receptor for infection in T-cells (56). Although all HHV-6 isolates can infect and replicate in human umbilical cord blood mononuclear cells, HHV-6A strains replicate in immature lymphocytes and more rapidly in a variety of established cell lines including EBV-positive B-cells, continuous T-cell lines, fibroblasts, megakaryocytes, and glioblastoma cells (2). HHV-6B strains fail to replicate in most continuous cell lines (57), with the exception of Molt 3 and MT-4 cells. The different cellular affinity between the two variants may be due to the lack of viral receptors for entry into the cells, or a deficiency in gene expression and viral replication. HHV-6B strains replicate in mature lymphocytes. Prior mitogen activation and full progression of the cell cycle are required for efficient replication, particularly for HHV-6B strains. High levels of IL-2 can delay or inhibit the viral replication (58).

Animal models of HHV-6 or 7 infections are lacking. Inoculation with the serum of a patient during the febrile period of ES transmitted a fever-producing agent to monkeys (59). Western blotting and immunofluorescent antibody assay (IFA) demonstrated the presence of HHV-6 antibody in monkeys (60). Chimpanzees are susceptible to productive infection by HHV-6 (61).

## EPIDEMIOLOGY

### Seroprevalence

The prevalence of antibody to HHV-6B is high in most, but not all, populations of the world. An HHV-6B serological study in Japan found that the incidence of antibody in different age groups was similar, even in those younger than 10 years. From 6 months of age, the number of children having antibodies gradually increased, and almost all children older than 13 months were seropositive, indicating past infection (62). This indicates that almost all children are exposed to HHV-6B in the latter half of the first year of life. Since most

pregnant women have antibody to HHV-6B, immunoglobulin G (IgG) antibody is transferred from mother to child across the placenta, and is detectable in infants during the early months after birth. Very young infants (younger than 6 months) are probably protected against HHV-6B infection by antibodies from their mother.

HHV-6A seems to predominantly infect infants in sub-Saharan Africa (63), and both HHV-6A and B infect persistently in the same individuals (64).

Infection by HHV-7 occurs slightly later in life than HHV-6 (9, 65), although a study in the United Kingdom indicated no difference in the prevalence of antibody to both viruses with respect to age-matched controls (66). No antibody was detectable in children younger than 2 years in the United States (9), but the seropositivity to HHV-7 was 75% in children aged 12 to 23 months in Japan (67).

### Mode of Transmission

The mode of transmission of HHV-6 and -7 to children is not fully understood. No difference has been found in the prevalence rates of HHV-6B infection between breast- and bottle-fed infants (68) or between babies born by cesarean section and those born vaginally. HHV-6B DNA has been detected in saliva and throat swabs of ES patients by polymerase chain reaction (PCR), as well as in healthy adults including mothers (69–71). HHV-6B is also present in vaginal secretions of pregnant women (72, 73). HHV-6 reactivation seems common during pregnancy, and HHV-6B infection of the fetus may occur.

Local spread and seasonal outbreaks of ES are rare, although outbreaks of HHV-6B infection are occasionally observed among institutionalized children (74). Persistent excretion or recurrent episodes of shedding HHV-6B from saliva and cervical secretions of adults suggest that close contact is a mode of transmission early in life, mainly from mother to child. Specific DNA could be detected in 1 to 1.6% of cord blood specimens from babies born to ostensibly healthy mothers (75, 76). Since an intact HHV-6A or B genome is universally integrated in several distinct chromosomes (77, 78), congenital transmission of HHV-6 can be caused by either genetic transmission of chromosomal integration of HHV-6 (ciHHV-6) from mother or father or both parents, or by transplacental transmission with ciHHV-6 (79, 80).

HHV-7 can be frequently isolated from saliva of the healthy adults (81–83), and horizontal transmission of HHV-7 may occur even from grandparents or parents to children through close household contact. Thus, the transmissions of HHV-6 and HHV-7 are very similar; however, it is not clear why HHV-7 infection occurs generally later than HHV-6 infection. There is no report of ciHHV-7 to date.

### PATHOGENESIS

The mechanisms by which HHV-6 induces pathology in humans have not been precisely defined. Suppression of bone marrow function is one of the most serious effects of HHV-6 infection in bone marrow transplant recipients. Immunological and molecular analyses indicate that CD4+ T lymphocytes are the predominant target cells for HHV-6. Direct viral cytolysis may be responsible from acute diseases such as ES and heterophile-negative infectious mononucleosis. Besides the direct infection of immune cells, indirect pathogenic mechanisms following HHV-6 infection may result from modulation of the immune system. Infection of PBMC by HHV-6A suppressed IL-2 synthesis *in vitro*, and

levels of IL-2 transcripts were diminished (84). Recently virus specific regulatory T-cells were induced by HHV-6, suggesting immunosuppression in infected hosts (85).

HHV-6 up-regulates CD4 (86) and NK cells (87) and down-regulates CD3 molecules in T-cells (88). It also induces the release of IFN- $\alpha$  (89–91), IL-1b, and tumor necrosis factor alpha by infected cells (92). Such altered polyclonal cell stimulation and cytokine bursts might contribute to the development of lymphoproliferative disorders, including lymphoma and leukemia.

These proinflammatory cytokines can upregulate HIV replication *in vitro* and contribute to the pathogenesis of AIDS. Both viruses infect CD4+ T lymphocytes. HHV-6 expression transactivates HIV-1 LTR. HHV-6 infection also induces CD4 molecules on the surface of CD4-CD8+ cells at the transcriptional level, resulting in enhanced susceptibility to HIV-1 infection (86, 93, 94). This concept remains controversial since other reports suggest inhibition of HIV replication in the case of co-infection (3, 95–97).

HHV-6A dramatically accelerates progression from HIV to full blown AIDS in monkeys (98). Since HHV-6 is neuroinvasive, as described below, it may contribute to the neuropathogenesis of HIV/AIDS. HHV-6 is extensively disseminated in neural cells in brains of HIV-infected patients, suggesting a contribution to the pathogenesis of AIDS encephalopathy (99). In contrast, HHV-7 down-regulates CD4, the cellular receptor shared by HIV and HHV-7. HHV-7 suppresses the replication of CCR5 tropic HIV isolates through CD4 modulation, suggesting that HHV-7 and HIV-1 may interfere in lymphoid tissue *in vivo* (100).

As described above, HHV-6 and HHV-7 establish latency after primary infection, but the mechanism is not understood completely. An immediate-early 1 protein of HHV-6 inhibits transcription of the IFN- $\beta$  gene and may contribute to latency (101).

## CLINICAL MANIFESTATIONS

### Acute Infection

Primary HHV-6 infection in early infancy causes ES (roseola infantum), a common illness characterized by high fever for a few days and the appearance of a rash coinciding with defervescence. The rash appears on the trunk and face and

FIGURE 4 Clinical feature (typical rash) of a patient with exanthem subitum.

spreads to lower extremities during subsiding fever (Figure 4). Human-to-human transmission has been documented by experimental inoculation of blood from ES patients into other infants (59, 102). Novel cell culture techniques allowed isolation of the virus (4). HHV-6 infection can occur without clinical symptoms of rash or fever (68, 103–106). When people escape childhood HHV-6 infection and are infected as adults, they develop a self-limited febrile disease that resembles infectious mononucleosis (47, 107).

The clinical features of primary HHV-7 infection have not been established. In 1994, HHV-7 was isolated from peripheral blood mononuclear cells of two infants with typical ES and the DNA patterns of the isolated viruses which were digested with various restriction enzymes very similar to that of the prototype HHV-7 (RK strain) (108). During the convalescent period of one patient, the antibody titer to HHV-7 increased significantly whereas the antibody titer to HHV-6 remained negative. In the second patient, who had two independent episodes of ES over 2 months, both HHV-6 and HHV-7 were sequentially isolated; HHV-6 seroconversion occurred during the first episode and HHV-7 seroconversion occurred during the second episode. These results suggest that HHV-7 is also a causative agent of ES. Temporally, isolation of HHV-7 before HHV-6 is uncommon; thus, it is still not completely clear whether HHV-7 causes ES-like symptoms.

ES is a common disease of infancy, and the symptoms are usually mild. Normally, children can recover from this disease after a few days without any complications. However, a few infants show hepatic dysfunction associated with ES (109, 110). Another common complication associated with ES is seizures (111), reported to occur in 0.6 to 50% of patients, but the exact incidence of seizures occurring with ES is difficult to estimate. Thus, ES has been suggested to be a risk factor for recurrent febrile seizures. Encephalitis and other complications of the central nervous system (CNS) have been also reported (112–114). HHV-6 DNA can be detectable in the cerebrospinal fluid of some of patients (115). These data suggest that HHV-6 may invade the brain during the acute phase of ES. HHV-6 has also been detected by PCR in brains of normal cadavers and brains of AIDS patients (116). HHV-6 may also cause lymphadenitis (117, 118). Idiopathic thrombocytopenic purpura has been associated with primary infection of HHV-6 (118).

Primary HHV-7 infection results in a febrile illness in childhood, complicated by seizures (119), and children with ES developed CNS disease including acute hemiplegia (120), suggesting that HHV-7 may also infect the brain. One study in hospitalized children during the first two years of life (121) found that 17% of the encephalitis cases were associated with primary infections of HHV-6 and 7, and that the two viruses contributed equally.

### Diseases During HHV-6 and HHV-7 Reactivation

After primary infection, all three viruses establish latency and can be reactivated to cause disease, particularly immunosuppressed states. The site of latent infection with HHV-6 is unknown, but HHV-6 antigen has been detected in salivary glands. HHV-6 DNA can be detected in peripheral blood of normal adults at low frequency, as well as in both the monocyte/macrophages and lymphocytes during the acute phase of ES and mainly in monocyte/macrophages of patients in the convalescent phase and of healthy adults (121).

Reactivation of HHV-6 occurs after bone marrow transplantation (BMT), solid-organ transplantation, and AIDS. Asymptomatic HHV-6 reactivation is common in allogeneic

BMT patients (122); symptomatic HHV-6 reactivation may result in bone marrow suppression (90), encephalitis (123), pneumonitis (124), and acute graft-versus-host disease (125). In fact, HHV-6 DNA is detectable in cerebrospinal fluid of patients after BMT and stem-cell transplant (126).

An association between rejection of transplanted kidneys and HHV-6 reactivation has been reported (127). HHV-6 reactivation in liver transplant recipients is associated with severe cytopenia (128, 129). Liver transplant recipients with ciHHV-6 experience more bacterial infections and allograft rejection than those without ciHHV-6 (130). Other associations include interstitial pneumonitis due to HHV-6, life-threatening thrombocytopenia, progressive encephalopathy, and rash in adults. HHV-6, HHV-7, and HCMV may contribute to the disease burden by reactivating at the same time during the course of transplantation (131).

HHV-6 has been demonstrated in some neoplasms, including non-Hodgkin's lymphoma and Hodgkin's disease. A high prevalence of HHV-6 has been found in oral, particularly salivary gland, carcinomas (132). A possible association of HHV-6 with the unusual disorder S100-positive, T-cell chronic lymphoproliferative disease has been reported (133). The frequency of HHV-6 variants in certain tumors suggests that they might serve as cofactors in multistep carcinogenesis, but there has been no conclusive demonstration that HHV-6 plays a causative role in any malignancy.

A reported association between chronic fatigue syndrome (CFS) and HHV-6 infection (134, 135) requires confirmation. More CFS patients than controls had elevated levels of HHV-6 early-antigen specific IgM, perhaps indicating active replication of HHV-6 in CFS (136). Further work is required to determine whether HHV-6 contributes to the clinical manifestations.

Several studies have suggested an association between HHV-6 and multiple sclerosis (MS). A DNA fragment containing the major DNA binding protein gene of HHV-6 was detected in the brains of patients with MS by representational difference analysis, as reviewed (137). Examination of 86 brain specimens by PCR demonstrated that HHV-6B was present in the brains of >70% of both MS patients and controls. Nuclear staining of oligodendrocytes using MAb against HHV-6 virion protein 101K and DNA binding protein p41 has been observed in samples from MS patients but not in controls. Samples from MS patients showed prominent cytoplasmic staining of neurons in gray matter adjacent to plaques, although neurons expressing HHV-6 were also found in certain controls (138, 139). One study reported increased IgM serum antibody responses to HHV-6 early antigen (p41/38) in patients with relapsing-remitting MS, compared with those with chronic progressive MS or other patients with neurologic disease, autoimmune disease, and normal controls. Other groups, however, have not confirmed these findings (140) and further studies are required (141).

HHV-6 DNA has been detected in brain tissues from patients with mesial temporal lobe epilepsy (142, 143); this association was restricted to patients with history of encephalitis (144). Numerous studies have found that HHV-6B persistently infects the human brain.

Detection of HHV-6 DNA has been reported in affected heart tissues from children and adults with acute myocarditis (145, 146).

Drug-induced hypersensitivity syndrome is characterized by a severe, potentially fatal, multi-organ reaction that usually appears after prolonged exposure to certain drugs (147). Clinical features overlap those for Stevens-Johnson

syndrome and toxic epidermal necrolysis. Clinical signs include a maculopapular rash progressing to exfoliative erythroderma, fever, and lymphadenopathy. It is uncertain whether the virus reactivation causes the disease, is triggered by the disease, or contributes to the disease.

Association of pityriasis with HHV-7 infection is a clinical presentation of HHV-7 reactivation (148). No significant differences in DNA and antibody tests are noted between patients and control groups. Further experiments are necessary.

## LABORATORY DIAGNOSIS

### Virus Isolation and Assay

HHV-6B is easily recovered from the peripheral blood lymphocytes of ES patients on the first or second day of the disease, which is during the febrile phase of ES, but the isolation rate gradually decreases thereafter. Virus has been isolated on some occasions from saliva, but the isolation rate is extremely low.

An effective method for virus isolation (4) involves use of uninfected cord blood lymphocytes. Cord blood cells are recommended because HHV-6 and HHV-7 may latently infect and reactivate during cultivation in peripheral blood mononuclear cells. CPE, with characteristic, balloon-like syncytia, usually appears 2 to 4 days post-infection. Mitogen-stimulated human cord blood mononuclear cells and adult peripheral mononuclear cells are readily infected by HHV-6. HHV-6A also infects HSB-2, an immature T-cell line, and HHV-6B infects several T-cell lines, including MT-4 and Molt 3 cells. Since high concentrations of IL-2 inhibit viral replication (58), culture medium after infection should contain only very low concentrations of IL-2.

HHV-7 is occasionally isolated from peripheral blood of patients with ES, and frequently from saliva of individuals who have antibody to HHV-7. Inoculation of salivary samples onto mitogen stimulated human cord blood lymphocytes results in CPE by 2 to 4 weeks.

### DNA Detection

HHV-6 DNA can be detected by DNA hybridization and by PCR. Southern blot hybridization is useful for rapid screening of large numbers of specimens, but it is generally a less sensitive technique than PCR. Numerous PCR primer sets, which are sensitive and specific, have been described for HHV-6 DNA, and some of these allow easy discrimination of the variants (25, 149–151). Variant-specific oligonucleotide hybridization is based on the amplification of two distinct regions of the HHV-6 genome, followed by hybridization of amplicons with variant-specific oligonucleotide probes. The putative coding region of immediate-early genes of HHV-6A is 2,517 nucleotides long, and two large additional regions of 108 and 228 bp were found in HHV-6B. PCR amplification, using primers covering one of these regions results in PCR-products with different molecular mass, permitting discrimination between HHV-6A and 6B. HHV-6 DNA is easily detectable by PCR in peripheral blood of ES patients during the acute phase, but detection of cell-free virus in serum or plasma by PCR offers the possibility of diagnosing active HHV-6 infections.

A RT-PCR assay can determine the presence of HHV-6 RNA in clinical specimens. The primers for amplification of mRNA of a major structural gene (gQ), which has a spliced structure and is expressed as a late gene and its mRNA, are employed. Therefore, the amplification of this gene has the advantage of detecting replicating virus and readily distin-

guishes mRNA from residual DNA contamination. This method showed a low false-positive rate (1.2%) and a high specificity of 98.8%.

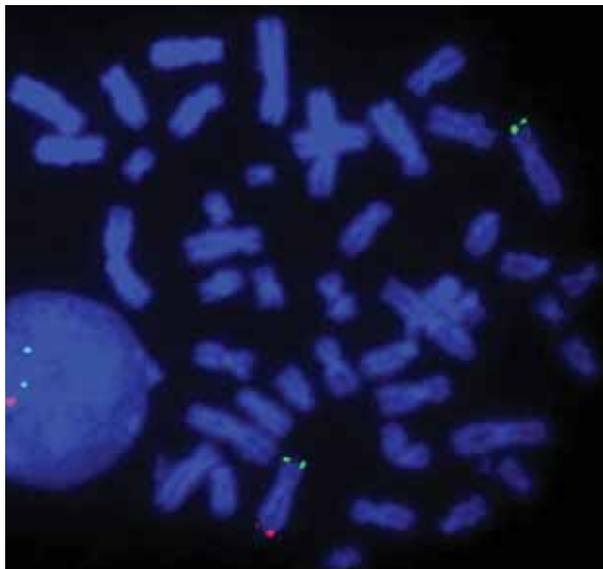

A quantitative competitive PCR assay for HHV-6 has demonstrated the persistence of a high HHV-6 load in the absence of apparent disease (152). The primer sequences based on consensus sequences in the DNA polymerase gene of herpesviruses can be used for testing for six different herpesviruses simultaneously (153).

PCR can also be used for detection of HHV-7 DNA in a throat swab or peripheral blood. The method is essentially the same as for the detection of HHV-6 DNA. Qualitative and competitive-quantitative nested PCR assays have also been developed for the detection of HHV-7 DNA. These assays amplify a DNA sequence encoding part of the HHV-7 U42 gene (154).

Loop-mediated isothermal amplification (LAMP) is a novel technique of rapid detection of HHV-6 DNA using simple and relatively inexpensive equipment, making it suitable for rapid diagnosis of roseola (80, 155).

A multiplex PCR method was also developed for the simultaneous detection of HHV-6 and HHV-7 in clinical samples, using primers to amplify a segment of the HHV-6, U67 gene, and the HHV-7, U42 gene. Comparison of the multiplex assay with the respective single PCR assays, using cloned HHV-6 and HHV-7 sequences as targets for amplification, demonstrated equivalent sensitivity and specificity of the assays. This multiplex assay is an efficient and cost-effective approach to the analysis of large numbers of samples to determine the epidemiological importance of HHV-6 and HHV-7(156).

Since both HHV-6A and B have been found integrated into the chromosomes of immunocompetent patients at persistently high levels of viral DNA in blood, sera, and hair follicles (157, 158,159) (Figure 5), the PCR test should be carefully interpreted for diagnosis, even in cerebrospinal fluid.

**FIGURE 5** Fluorescent *in situ* hybridization (FISH) on metaphase chromosomes from a patient shows integration of HHV-6. The red and green signals indicate HHV-6 DNA and chromosome 6, respectively (the method is written in reference 159.)

### Antigen Detection

A quantitative antigenemia assay using monoclonal antibody enables enumeration of HHV-6B-infected cells and has been used to monitor HHV-6 activity in liver transplant recipients (160).

Latent and replicating virus can be discriminated by assays that combine reverse transcription and PCR (RT-PCR) (144, 161, 162). Such assays target spliced mRNAs, enabling easy discrimination between mRNA and residual DNA contamination.

### Serological Assays

Several serological assays are available for HHV-6 studies, including IFA, enzyme-linked immunosorbent assay (ELISA), neutralization (NT), radio-immunoprecipitation, and immunoblotting. Indirect IFA is presently the most commonly applied method for HHV-6 viral antigen and antibody detection. Separation of serum IgM from IgG and IgA significantly increases the specificity of HHV-6-specific IgM detection. Density gradient columns and protein A absorption and anti-IgG treatment techniques can be applied for removal of interfering substances such as heterotopic cross-reactions, rheumatoid factors, and antinuclear antibodies.

NT antibody tests using a CPE reading, chemically attached MT-4 cells (T-cell line), or dot blot assays have been reported (163). Neutralizing antibody titers appear to correlate with the antibody titers determined by the indirect IFA test (164).

An enzyme immunoassay, an immunoblot assay, and an indirect IFA have been developed for the detection of HHV-7 antibodies in human serum. Cross-absorption studies with ELISA or IFA using HHV-7 and HHV-6 antigens indicated that most human sera contain cross-reactive HHV-6 and HHV-7 antibodies. The degree of cross-reactivity varies between individual serum specimens. An 85/89 kDa protein was identified as an HHV-7-specific serologic marker by immunoblot analysis (165). To detect antibody to HHV-7 specifically and sensitively, the p89/85 proteins were expressed as recombinant proteins in bacteria, and developed for immunoblot kit. Of the three assays, the ELISA is the most sensitive, while the immunoblot assay is the most specific (166). A recently described assay appears to enable HHV-6A and B-specific serologic testing (167).

From a natural history perspective, IgM antibodies are detected by day 7 and persist for 3 weeks, but are not detectable in most sera 1 month after the onset of disease. IgG antibody is first detected 7 days after the onset of illness, increases in titer until 3 weeks after onset, and persists at least 2 months. Interesting, antibody titers to HHV-6 are boosted during other virus infections such as HHV-7 (62, 145) or measles (168).

### TREATMENT AND PREVENTION

No effective measures have been determined for the prevention of infection. Similarly, no vaccines are in development.

Many anti-HHV-6 and HHV-7 drugs have been described, but three drugs which have been developed for HCMV treatment can be used for HHV-6 and HHV-7 infections, as reviewed in (169). Ganciclovir, cidofovir, and foscarnet are inhibitors of DNA polymerase of these viruses. Other nucleoside or nucleotide analogues are efficient *in vitro* and are under preclinical stage or early clinical phase (169, 170). The sensitivity of HHV-7 to the guanine analogs

differed from HHV-6, suggesting a different selectivity of specific viral enzymes (171). Prophylaxis with ACV did not prevent the occurrence of HHV-6-associated CNS disease after allogeneic bone marrow transplantation. IFN- $\alpha$  and IFN- $\beta$  inhibit HHV-6 replication *in vitro* (91).

# Epstein-Barr Virus

JOYCE FINGEROTH

## 25

In the century preceding the discovery of Epstein-Barr virus (EBV), physicians speculated that a common clinical syndrome characterized by fever, tonsillar adenopathy, splenomegaly, and mononuclear leukocytosis termed glandular fever was caused by a pathogen (1). In 1920, the name infectious mononucleosis (IM) was introduced by Thomas P. Sprunt and Frank A. Evans to characterize this syndrome (2). Three years later, Hal Downey and C.A. McKinlay described the now-classic atypical lymphocyte as a common feature of this disease (3), and in 1932 John Rodman Paul and Walls Willard Bunnell demonstrated high titers of spontaneously occurring heterophile antibodies in the sera of patients with IM (4), ensuring more accurate diagnosis. In 1961, the British surgeon Denis P. Burkitt gave the first account outside of Africa of “The Commonest Children’s Cancer in Tropical Africa” at Middlesex Hospital London, detailing the geographic relationship between Burkitt’s lymphoma (BL) and conditions of temperature, altitude, and rainfall associated with development of *Plasmodium falciparum* malaria (5, 6). M. Anthony Epstein, who was in the audience, became intrigued by the idea that a biological agent might be involved in the etiology of BL, and in 1964, the Epstein laboratory analyzed BL biopsy samples by thin-section electron microscopy and discovered a new, large, icosahedral herpesvirus that could be directly reactivated from *in vitro*-grown BL cells (7). These initial findings were reported in *The Lancet*, and the virus was named after Epstein and his graduate student Yvonne Barr (8). Shortly thereafter, two independent groups (9, 10) demonstrated the ability of EBV to transform primary human B lymphocytes into permanently growing lymphoblastoid cell lines (LCLs), providing the first concrete evidence of the ability of EBV to promote human cancer. In 1968, Gertrude Henle and Werner Henle made two further critical observations: (1) that EBV seroconversion occurred during the course of acute IM (AIM) in a laboratory technician (9) and (2) that EBV-carrying LCLs spontaneously formed from a peripheral blood leukocyte culture obtained during the acute phase of the technician’s illness. The Henles confirmed their observations through study of sera provided by James Corson Niederman and Robert W. McCollum, who collected blood from incoming Yale freshmen and later from individuals who developed AIM. This study and others demonstrated EBV-specific antibodies in the sera of the students who

developed AIM, confirming the etiologic association between EBV and AIM (11).

## VIROLOGY

### Classification

EBV is a member of the Gammaherpesvirinae subfamily of the family Herpesviridae and is the prototype of the *Lymphocryptovirus* genus (gamma-1 herpesvirus). *In vitro*, all gamma herpesviruses infect and replicate in lymphoid cells and variably in other hematopoietic lineage cells, epithelial cells, smooth muscle cells, and fibroblasts. The host range of the *Lymphocryptovirus* genus is restricted to primates. *Lymphocryptovirus* infection of primate B lymphocytes results in persistence of the viral genome, which is maintained through variable expression of a restricted set of latent gene products that typically sustain quiescence, but can also help drive cell proliferation and contribute to the transformation process (12).

### Type and Strain Variations

The quest to define what constitutes “wild-type” EBV for vaccine development and to determine whether genetic strain differences correlate with specific EBV-associated disease began shortly after sequencing of the entire EBV genome in 1984 (13, 14). Two main types of EBV, namely EBV-1 and EBV-2 (or A and B, respectively), were identified in distinct global populations on the basis of analysis of the strains then available (15). With the advent of advanced DNA sequencing technologies, there is now sequence information from at least 83 independent EBV strains originating from different parts of the world, and much work is ongoing. Identification of additional polymorphisms has added to the complexity of interpreting whether strain variants predict disease. Although most EBV genes differ in sequence by <1% to 5%, the EBV-1 and EBV-2 latent infection cycle nuclear antigen gene 2 (EBV nuclear antigen 2 [EBNA-2])-encoded proteins share only 54% identity. African EBV genomes are almost as frequently type 2 as type 1, in contrast to American, European, and Asian EBV genomes, which are 10 times more likely to be type 1 than type 2.

Individuals, particularly those who are immunocompromised, can be infected with multiple strains, and new polymorphisms can arise within an infected host. Type 1 EBV

cell contains 1 to 200 nuclear copies of the circular EBV genome (known as an episome) that is attached to, but not integrated into, host chromosomes by the viral protein EBNA-1 (25). Episome amplification occurs early after infection. The terminal DNA repeat elements serve as landmarks on the EBV episome that distinguish between EBV isolates as individual viruses and tend to maintain a constant number of terminal repeats upon serial passage of latently infected cells. This finding has proved extremely useful in determining whether latently infected tumor cells, such as BL, arise from a single progenitor (26).

Antigenic cross-reactivity between EBV and other herpesviruses is rare, even among proteins encoded by conserved genes. In fact, the EBV genes expressed in latent infection as well as several lytic-cycle genes, such as the tegument genes, have no detectable homology to other herpesvirus genes and are believed to derive in part from cellular DNA (12) or possibly DNA of coinfecting pathogens. As an example, an irregular repeat motif, GGGGCAGGA, present in the latent-cycle gene EBNA-1, is also interspersed in human DNA. Some other examples of EBV lytic-cycle genes with significant homology to the human genome, but little homology to other herpesviruses, include BZLF1, BHRF1, and BARF1. BZLF1 is an immediate early gene closely related to the *fos* and *jun* transcriptional activators (27). BHRF1 is an EBV early gene with significant homology to the human *bcl-2* gene (28) involved in prevention of apoptosis. BARF1 is an early gene with amino acid sequences similar to that of *c-fms* (colony-stimulating factor) or the colony-stimulating factor-1 receptor (CSF-1R) (29). Many noncoding RNAs (ncRNAs) with diverse functions are produced by EBV, including EBV-encoded RNAs (EBERs), BamHI-A rightward transcripts (BARTs), a small nucleolar RNA (snoRNA), and multiple microRNAs (miRNAs) generated in particular from the BamA and BamH DNA fragments (30–32).

### Host Range and Virus Receptor

EBV is restricted to humans, although related lymphocryptoviruses have been detected in both Old and New World nonhuman primate (NHP) species (33, 34). Lytic cycle proteins are the most conserved and latent cycle proteins are the most diverged between humans and NHPs. The B cells of certain NHPs, including squirrel/owl monkeys and cotton-top tamarins are susceptible to EBV immortalization *in vitro*. These animals may undergo EBV infection upon percutaneous inoculation (35, 36), but do not provide physiologic disease models; cross-species infection is essentially absent (37). Upon oral infection with rhesus lymphocryptovirus (rhLCV), but not with EBV, rhesus macaques develop a spectrum of EBV-like illnesses (34). More recently, immunodeficient mice transplanted with human immune systems, “humanized mice,” were shown to be susceptible to infection and to recapitulate many forms of EBV-associated disease, providing many new avenues for the study of EBV pathogenesis (38–40).

B lymphocytes are the primary cellular reservoir of EBV infection. The initial stage of infection involves a high-affinity interaction between the major EBV outer envelope glycoprotein gp350 with CD21 on the surface of B cells (41–43). Multiple lines of evidence confirm CD21, the receptor for the C3d component of complement, as the primary human cellular receptor on B cells: (1) purified CD21 binds to EBV, (2) virus infection of B-cell lines is blocked by antibody directed against the CD21 glycoprotein, and (3) the expression of CD21 on heterologous cells confers binding to

EBV. Comparison of the primary amino acid sequences of gp350 and C3d reveal a shared nonapeptide (EDPGFFNVE) that may account for some conserved receptor contacts (44). In addition to infecting B cells, EBV can variably infect other hematopoietic lineage cells, including T cells, natural killer (NK) cells, monocytes, smooth muscle cells, and others (45). CD21 can be detected on some thymocytes and peripheral blood T cells (46). CD35, a human complement regulatory protein closely related to CD21, can also bind gp350 and initiate entry (47). The cellular distribution of CD35 is broader; thus, CD35 may facilitate EBV infection of some non-B-cell targets that sometimes become infected. As discussed below, the receptor(s) used for attachment of EBV to primary epithelial cells is distinct and interactions are more complex, although CD21 transcripts are present in primary tonsil and adenoid epithelial cells, and epithelial cell lines that express CD21 protein can utilize the CD21 receptor to support latent infection efficiently (48, 49).

### EBV Adsorption, Penetration, and Uncoating

gp350-CD21 attachment on B cells initiates intracellular signaling (50–52) and transfers virus toward the cell surface for envelope fusion with the plasma membrane or endocytic vesicle membranes, depending on cell origin (53). EBV envelope fusion with B-lymphocyte cell membranes is initiated by interactions between human leukocyte antigen class II (HLAII) on the B-cell surface and the virion membrane glycoprotein gp42 in complex with glycoproteins gH and gL (gH/gL heterodimer) (54). EBV glycoprotein B, gB (gp110), a highly conserved herpesvirus family glycoprotein, then functions as the viral fusogen (55).

EBV also infects epithelial cells *in vivo*, and oral epithelial cells produce high-titer transmissible virus. Studies of epithelial infection *in vitro* have proved more challenging than those of B cells due in part to the complexity of polarized epithelial structures. However, recent models using organotypic (raft) cultures, similar to those used for human papillomavirus (HPV) studies, are beginning to yield new information (56, 57). Interaction between B cells and epithelial cells may be required to promote epithelial cell infection constitutively (58), as agammaglobulinemic patients, who harbor immature B cells, lack all evidence of EBV infection (59). Moreover, EBV latency is sometimes (although rarely) eradicated following aggressive bone marrow transplantation (60). CD21-independent epithelial attachment is more effective in the relative absence of gp350 (61), which is less abundant on virions produced by B cells than by epithelial cells (62).

Whether a single predominant ligand is used to initiate attachment to all primary epithelial cells is unclear. Several attachment proteins have been proposed, including the BMRF2 protein (contains an RGD sequence that can bind  $\beta$ 1 integrins), gH (has a KGD sequence that binds  $\alpha$ v $\beta$ 5,  $\alpha$ v $\beta$ 6, or  $\alpha$ v $\beta$ 8 integrins), and possibly gp150 (63, 64). Fusion of the EBV envelope with epithelial cell membranes occurs at the plasma membrane, does not require BMRF2, and is initiated by cell membrane interaction with gH/gL and gB in the absence of gp42. Despite the observation that fusion with both B cells and epithelial cells requires gH/gL and gB, differences in the respective fusion pathways have been described (63).

The mechanisms involved in transport of the nucleocapsid to the nuclear membrane and delivery of viral DNA are not well understood. Differences between B cells and epithelial cells have been observed *in vitro* (65). Upon dissolution of the capsid, tegument proteins and RNAs are

released into the cytosol; some of these prevent lytic cycle activation, for example, by blocking access of critical lytic cycle transactivators to the nucleus, thereby favoring viral persistence (66). Once inside the nucleus, the linear EBV genome circularizes, which precedes or at least coincides with *de novo* gene expression directed from the first latent infection promoter *Wp*. The EBV genome is replicated by cellular DNA polymerases during S phase of the cell cycle and persists as multiple, extrachromosomal double-stranded EBV episomes, which are organized into nucleosomes similar to chromosomal DNA (12). Epigenetic modifications occur rapidly and are critical for the establishment of infection. They are complex, varying by cell type and pattern of infection, as reviewed recently (67–69).

### Latent Infection

The hallmark of B-lymphocyte EBV infection is the establishment of latency, which is characterized by three distinct processes: (1) viral persistence; (2) restricted virus expression, which alters cell growth and proliferation; and (3) retained potential for reactivation to lytic replication. Genome persistence is achieved through maintenance of multiple copies of covalently closed episomal DNA in the nucleus. The episomes are replicated semiconservatively during S phase by cellular DNA polymerases, and equal partitioning to daughter cells is mediated by interactions between the latent origin of plasmid replication (*OriP*) and EBNA-1 (70). The ~172-kbp EBV genome encodes between 80 and 100 genes and 30–40 ncRNAs (12, 31). Limited gene products expressed differentially during distinct latency programs are involved in establishing and maintaining the “immortalized” state. These include six EBV nuclear proteins (EBNA-1, -2, -3A, -3B, -3C, and -LP); two latent membrane proteins (LMP-1 and LMP-2A/B); two small, nonpolyadenylated RNAs (EBER-1 and -2); and multiple other forms of ncRNAs (12). *In vitro* latency can be disrupted, although inefficiently, through a variety of cellular activators that stimulate expression of BZLF1 with associated destruction of the host cell (69, 71–73). Specific mutations in BZLF1 inhibit its ability to induce lytic replication, but addition of a second protein, BRLF1, partially restores this activity.

Although only a minority of EBV genes are expressed in latently infected B cells, the transcribed regions encompass a major portion of the viral genome. Following circularization of linear EBV DNA in the nucleus, the EBNA mRNAs are assembled by alternative splicing and 3' processing of a common precursor encoded by more than 100 kb of the genome. Transcription of the EBNA and LMP genes is mediated by cell-derived RNA polymerase II, whereas EBERs are transcribed by RNA polymerase III (74). EBERs are the most abundantly transcribed EBV products in all latently infected cells ( $10^4$  to  $10^5$  copies/cell), distantly followed by the LMP-1 gene, which, in turn, is significantly more abundant than the EBNA and LMP-2 genes in LCLs (12). Figure 1b depicts the extensive transcription and long-range splicing of the EBV genome, which occurs in latently infected B-LCLs. Selection of alternate promoters, complex splicing, and enhancer looping ultimately determine the type and levels of latent gene expression in distinct cell types (75). Transcriptional regulation during latent infection has been reviewed comprehensively (76).

EBNA-2 and its coactivator EBNA-LP are the first EBV proteins expressed during latent infection of primary B cells and reach their steady-state levels within 24–32 hours. EBNA-2 is required for initial expression of other EBV latent

genes and for transactivation of cellular genes in primary cells. Thus, EBNA-2 is essential for immortalization, and viruses with EBNA-2 deletions are incompetent to transform primary human B lymphocytes. By 32–96 hours postinfection, all of the EBNA proteins and LMP-1 can be detected. Concurrent with LMP-1 expression are an increase in surface CD23 and onset of cell DNA synthesis. Cellular DNA repair processes are activated upon primary B-cell infection, and typically a cell fate decision is made that determines whether immortalization will be maintained (77).

### Transformation and Latent Products

Herpesvirus persistence is characterized by the ability of each family member to switch between a lytic and latent life cycle driven by individual transcription programs. Several well-defined transcription programs, known as latency 0, I, II, and III (and abortive replication), characterize the different forms of EBV latency. The latency I, II, and III programs reflect transitions that occur during the course of normal B-cell differentiation (Fig. 2) and are characteristic of different EBV-bearing tumors (Fig. 3). Many of the proteins and RNAs that participate in latency are multifunctional. Classic roles are summarized briefly below, but for each latent product further review is recommended (78).

#### EBNA-1

EBNA-1 is required for replication of episomes and maintenance of the viral genome. It is consistently expressed in EBV-bearing tumors as well as LCLs, where it is able to associate with all chromosomes in the nuclei of latently infected cells. The combined interaction of EBNA-1 with both *OriP* and chromosomal proteins ensures equal partitioning of EBV episomes to progeny cells. EBNA-1 activates other EBV latency genes and also interacts with certain cellular proteins to enhance cell survival (70, 79, 80).

#### EBNA-2

EBNA-2 is essential for primary immortalization of B lymphocytes and for initial expression of EBNA-1, EBNA-3, and the LMPs. EBNA-2 specifically transactivates expression of the B-lymphocyte activation marker CD23, which is abundantly expressed on LCLs and antigen-primed B lymphocytes (12). Together with its coactivator EBNA-LP, EBNA-2 is now known to transactivate cooperatively many viral and cellular genes that participate in *in vitro* immortalization of primary B cells, supporting the latency III program. EBNA-2 does not directly bind DNA, but associates with other proteins that regulate transcription (81), such as cellular CBF1, to bind to both promoter and enhancer regions of predominantly B-cell regulatory factors.

#### EBNA-LP

EBNA-LP (EBNA-5), or leader protein, and EBNA-2 are the first latent proteins expressed upon primary B-cell infection. Transcription of EBNA-LP is complex and multiple isoforms are typically produced. EBNA-LP primarily functions as an EBNA-2 coactivator. However, like EBNA-2, EBNA-LP cannot bind DNA directly. When expressed independently, EBNA-LP activation is limited to promoter regions. Although the functions of EBNA-LP remain unclear, roles in modulating cellular repressors and in prevention of apoptosis early after infection are under investigation (81).

#### EBNA-3

EBNA-3 consists of a family of three high-molecular-weight gene products—EBNA-3A, -3B, and -3C (also known as

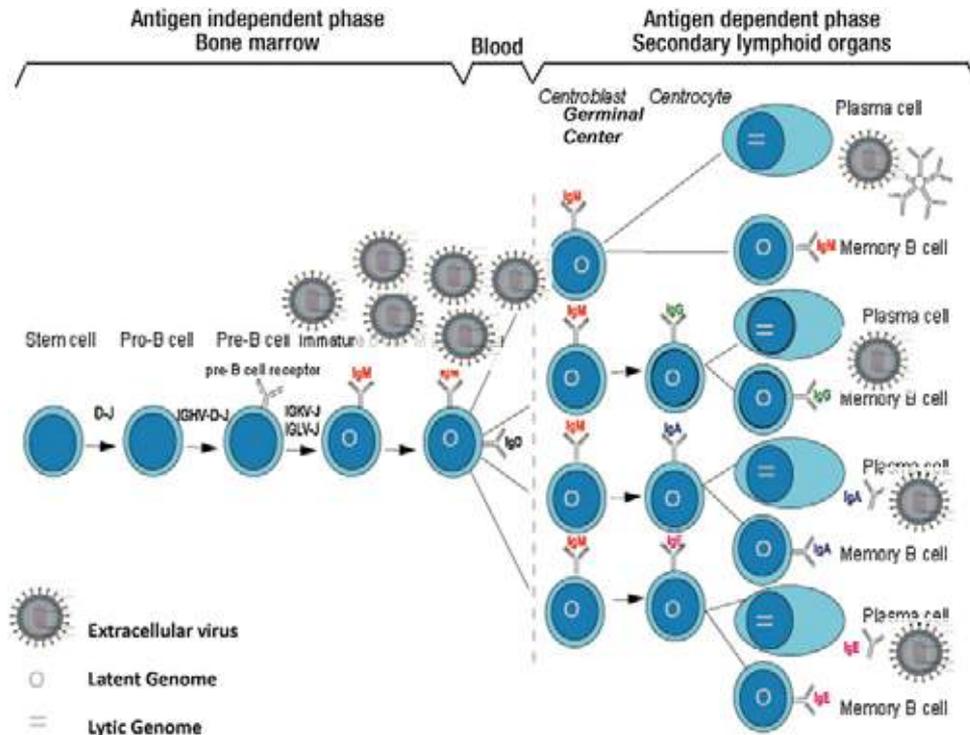

FIGURE 2 Following primary infection, Epstein-Barr virus (EBV) in a latent state accompanies its B cell host through the B lymphocyte maturation process, only switching to the lytic cycle and virus production upon plasma cell (terminal) differentiation. (Diagram of B cell differentiation from Quizlet.com and modified by the author to reflect virus biology.)

EBNA-3, -4, and -6)—that are located in tandem on the EBV genome (see Fig. 1). Like the EBNA-2 gene, the EBNA-3 genes are polymorphic transcription factors that vary in EBV-1 and EBV-2, although type specificity in contrast to EBNA-2 does not appear to affect the ability of the virus to initiate growth transformation *in vitro* (17). Analysis of the immortalization capacity of EBV recombinants with specific

mutations in each of the EBNA-3 genes has demonstrated that while EBNA-3B is dispensable for B-lymphocyte transformation *in vitro*, deletion of either EBNA-3A or -3C renders EBV transformation incompetent (82). Whereas EBNA-3A and 3C operate as oncoproteins, EBNA-3B, in contrast, may function as a tumor suppressor, a role best demonstrated upon analysis of tumor models *in vivo* (83).

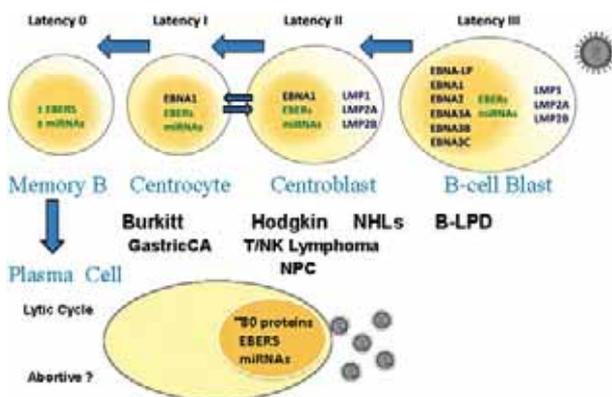

FIGURE 3 Distinct Epstein-Barr virus (EBV) expression programs (latency III, II, I, 0, lytic replication, abortive replication) are linked with defined stages of B lymphocyte maturation. These same latency patterns are detected in the B cell tumors that arise from transformed cells blocked from further differentiation. Major classes of B cell cancers are indicated in bold. Other EBV-associated tumors that share the indicated latency program but are not of B cell origin are shown in plain font.

LMP-1

LMP-1, the second most abundant EBV mRNA in latently infected B lymphocytes (~60 copies/cell), encodes a 63-kDa, multiple-pass, integral membrane protein. A truncated form of LMP-1 is expressed during lytic replication. Full-length LMP-1 functions as a constitutively active receptor and is the major transforming gene product of EBV. In early studies, transfer of LMP-1 into continuous rodent fibroblast lines was found to elicit multiple transformation-associated changes and to promote development of xenograft tumors in nude mice (12, 84).

Although EBNA-2 upregulates LMP-1 in B cells, LMP-1 is expressed in the absence of EBNA-2 during B-cell differentiation and in epithelial as well as several lymphoid tumor types. LMP-1 is essential for B-cell immortalization (LCL formation) *in vitro* (12). Transfer of LMP-1 into EBV-negative cells induces surface expression of a number of molecules involved in activation of B cells (e.g., CD23, CD39, CD40, CD44) and epithelial cells (e.g., EGFR). LMP-1 also protects EBV-infected cells from programmed cell death (apoptosis) through signaling that results in induction of the cellular oncogene *bcl-2* and blocks terminal differentiation. Mice expressing an LMP-1 transgene driven by an immunoglobulin promoter develop B-cell lymphomas, and keratin 14-driven LMP-1 is a modest tumor promoter in

transgenic mice. LMP-1-bearing B cells grow in tight clumps due to increased expression of homotypic cellular adhesion molecules, and LMP-1 induction of the adhesion molecules lymphocyte function-associated antigen 1 (LFA-1), LFA-3, and intercellular adhesion molecule 1 (ICAM-1) promotes interaction between B and T lymphocytes via the LFA-3/CD-2 and LFA-1/ICAM-1 adhesion pathways, as well as others. These heterotypic adhesions are important because *in vivo* elimination of EBV-transformed B lymphocytes is dependent on conjugate formation with cytotoxic T cells. The signaling response induced by LMP-1 partially mimics that induced by CD40 ligation (85) and occurs through engagement of tumor necrosis factor receptor (TNFR) family ligands with the LMP-1 carboxyl terminus. The diverse functions of LMP-1 involve multiple signaling pathways [nuclear factor- $\kappa$ B (NF- $\kappa$ B), mitogen-activated protein kinase (MAPK), phosphatidylinositol 3-kinase (PI3-K)/AKT, interferon regulatory factor 7 (IRF7), and Janus kinase/signal transducers and activators of transcription (JAK/STAT pathways)] (86). Mutations, particularly in the intracellular carboxyl terminus of LMP-1, can eliminate signaling and prevent transformation (87).

#### LMP-2

LMP-2 is an integral membrane protein containing 12 hydrophobic transmembrane domains that localize to cell membranes and can colocalize with LMP-1 in the plasma membrane. Two major isoforms LMP-2A and an amino-terminal truncated isoform LMP-2B predominate. Among the transformation-associated EBV proteins, LMP-2 is not required for establishment of LCLs *in vitro*, but appears to be critical for EBV persistence *in vivo* because it is retained in several EBV-bearing tumors (Fig. 3). The cytoplasmic amino terminus of LMP-2A contains multiple motifs, including several phosphorylated tyrosines, an immunoreceptor tyrosine-based activation motif (ITAM), and proline-rich motifs that interact with and modulate multiple host cell proteins involved in signaling. LMP-2A, but not LMP-2B, subverts normal signal transmission through the B-cell receptor, blocking terminal differentiation by substitution with tonic activation signals that promote B-cell survival and prevent apoptosis. Transgenic mice expressing the LMP-2 transgene under immunoglobulin regulation exhibit increased survival of normal B cells (88). LMP2A expression in epithelial cell lines increases spreading, migration, and clonability in soft agar. In raft cultures, blockade of epithelial cell differentiation and hyperproliferation is observed. LMP-2A and -2B together with EBNA-1, LMP-1, and miRNAs (latency II) are most consistently detected in nasopharyngeal carcinoma (NPC) and EBV-bearing (HLs)'s lymphomas, but can be expressed in other EBV-associated malignancies as well (89, 90).

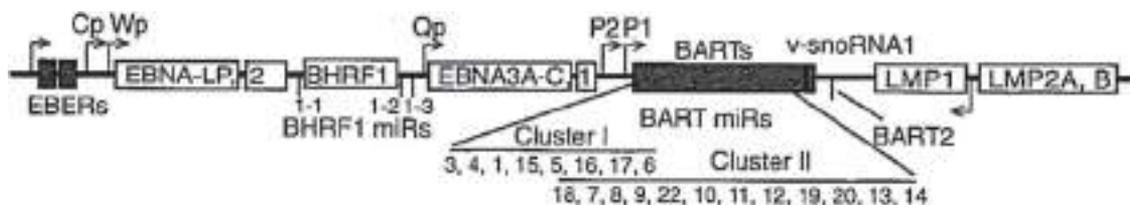

#### EBV-Encoded RNAs—EBER-1 and EBER-2

The most abundant EBV transcripts in latently infected B cells are the small (167- and 172-nucleotide), noncoding, nonpolyadenylated RNAs termed EBER-1 and EBER-2. Unlike other EBV genes expressed during latent infection, the EBERs are also transcribed during lytic infection. EBV-infected cells typically express  $1\text{--}5 \times 10^6$  EBER copies/cell, and detection of EBERs by *in situ* hybridization is a widely used technique to detect EBV-infected cells in clinical samples. The majority of EBERs are localized within the cell nucleus, where they are complexed with the cellular protein La. Additional interactions with cellular proteins including Pax5 (EBER-2) and L22, heterogeneous nuclear ribonucleoproteins (hnRNPs) (EBER-1) have been reported. Despite their prevalence, the role of EBERs in infection remains largely unknown, although different lines of evidence suggest functions related to type I interferon (IFN) regulation. The EBERs are not required for immortalization of primary B cells *in vitro* (91); however, the observation that EBER sequences are highly conserved across EBV strains suggests they are vital to virus persistence *in vivo* (92, 93).

#### ncRNAs and miRNAs

The precise role of the recognized 30–40 EBV ncRNAs, in addition to the EBERs, remains largely unknown. EBV encodes a single snoRNA of  $\sim 65$  nucleotides localized to the BART region. The V-snoRNA1 binds RNPs and is proposed to guide RNA modification. A stable abundantly expressed (comparable to EBER-2) 81-nucleotide EBV–small interfering RNA (siRNA)-1 derived from an intron within the W repeats has been identified recently in latently infected cells, as has a second novel RNA able to form a massive 586-nucleotide hairpin. No functional information is currently available. A family of alternatively spliced, polyadenylated and processed RNAs that arise from the BamHI-A region (BARTs) predominantly localize to the nucleus. They are abundant in EBV-bearing epithelial tumors and less so in EBV-bearing lymphoid neoplasms. They may function similarly to cellular long ncRNAs (lncRNAs) in regulation of viral or cellular gene expression.

The very existence of viral miRNAs was first demonstrated in EBV in 2004. miRNAs are small ( $\sim 22$  nucleotides) ncRNAs that regulate gene expression posttranscriptionally, each altering as many as 200 transcripts. Approximately 30–40 miRNAs have been identified primarily in latently infected cells, but some in lytically infected cells, and appear to variably alter both viral and cellular transcripts. Most are encoded by introns in the BART region and a smaller number adjacent to BHRF1 sequences (Fig. 4). Diverse studies from this rapidly evolving area indicate that several EBV miRNAs contribute to EBV-driven B-cell immortalization *in vitro* as well as to the development of specific cancers (31, 94, 95).

**FIGURE 4** Genomic origin of noncoding RNAs including EBV-encoded RNAs (EBERs), microRNAs (miRNAs), BamHI-A rightward (BART), and an Epstein-Barr virus (EBV) small nucleolar RNA (snoRNA). There is clustering of precursor miRNAs in the BART and to a lesser degree in the BHRF1 region of the genome. (Reproduced from ref. 31 with permission from the journal.)

### EBV DNA Persistence in Latency

During primary infection, EBV sequentially employs distinct transcription programs (see Fig. 3), initially triggering the formation of B-cell blasts that then transit to germinal centers where the EBV-infected B cells undergo switch recombination and somatic hypermutation and emerge as resting latently infected memory B cells (see Fig. 2), the primary reservoir for lifelong EBV infection (96). In all, 25% to 50% of peripheral blood memory B cells are infected latently during primary infection and manifested as AIM. The frequency of latently infected primary B cells falls to 1 in  $10^5$  to 1 in  $10^6$  during persistent infection (97). Latently infected memory B cells typically contain 1 to 20 EBV episomes per cell. These memory B cells are transcriptionally quiescent and express only small amounts of EBNA-1, required for episomal maintenance upon cell division; thus, they remain undetectable during immune surveillance. Periodic activation and differentiation of memory B cells into plasma cells initiates the EBV lytic replication cycle (98). EBV-specific CD8<sup>+</sup> and CD4<sup>+</sup> T cells are important in eradicating these cells and controlling new cycles of infection (99).

### Lytic Infection and Virus Replication

Lytic transcripts are required not only for transmission through production of virions released into saliva, but also directly contribute to primary infection of B cells. *In vitro*, latently infected B cells can be induced to undergo lytic-cycle replication by activation with biological and chemical inducers, including phorbol esters, stress inducers, calcium ionophores, and various genome-modifying agents, or by cross-linking cell surface immunoglobulin (Ig). Cross-linking of membrane Ig by cognate antigen on the surface of memory B cells *in vivo* is believed to constitute the major physiologic signal that, upon stimulation of plasma cell differentiation, initiates epigenetic modifications of the EBV genome required for lytic cycle induction (100). Following induction, host cell protein synthesis is shut off. Induced cells undergo cytopathic changes characteristic of lytic herpesvirus infection, including chromatin margination, viral DNA synthesis, nucleocapsid assembly at the nucleus periphery, and virus budding through the nuclear membrane (12).

During lytic EBV infection, immediate early genes are defined as genes that are transcribed in newly infected cells in the absence of *de novo* viral protein synthesis. The key immediate early transactivators of EBV lytic-cycle genes are the 1-kb BZLF1 (Zta) messenger RNA (mRNA) and the 2.8-kb BRLF1 (Rta) RNA. Early (E) genes (~30 proteins), such as the thymidine kinase and polymerase complex, function in viral DNA replication. The induction of EBV DNA synthesis is preceded by an increased episome copy number that is consistent with a rolling circle replication model. Long concatemers of linear EBV genomes are synthesized, cleaved, and then packaged into viral capsids. The EBV genes expressed during the late (L) stages of lytic infection (~30) primarily encode tegument and structural proteins that mediate virion formation and egress (101). Genes that encode several immunoevasins are synthesized in the course of lytic replication (102, 103).

## EPIDEMIOLOGY

### Distribution and Geography

Seroepidemiological studies show that antibodies to EBV are present in all population groups and about 90% to 95% of adults worldwide are EBV seropositive. In lower-resource

settings, most children acquire EBV infection during the first 2 years of life; for example, 82% of children in Ghana were EBV seropositive by 18 months of age (104, 105). In higher-resource settings, EBV infection typically occurs in late childhood, adolescence, or early adulthood (106, 107). With global development, EBV acquisition has become increasingly delayed worldwide (106, 108).

### Incidence and Prevalence of Infection

The incidence of clinically symptomatic infection AIM is greatest when primary EBV infection is delayed until the second decade of life. In the United States and Great Britain, EBV seroconversion occurs before age 5 in about 50% (20% to 80%) of the population, depending on age, location, race/ethnicity, and socioeconomic factors. The overall incidence of AIM in the United States is about 50 cases/100,000 per year, with the highest incidence in the 15- to 24-year age group. In college-aged populations, 30% to 75% of entering students are EBV seronegative (109). Most susceptible individuals become infected during their freshman year, and >75% of primary infections may be associated with AIM (110, 111). By contrast, AIM is observed in fewer than 10% of primary infections among infants and children, and this discrepancy is currently a major focus of investigation. No obvious yearly cycles, seasonal changes, or sex differences have been noted in relation to AIM incidence (106). AIM is a risk factor for subsequent development of EBV-positive HL, which, because it is associated with AIM, is also increasing among young adults coordinately with global development (112).

EBV is most consistently associated with two endemic malignancies, childhood BL (equatorial Africa) and NPC (southeast Asia) in addition to sporadic B-lymphoid cancers typically linked to cellular immunocompromise (12). The epidemiologic factors that contribute to individual malignancies are discussed below.

### Transmission

EBV is transmitted primarily through contact with infectious oropharyngeal secretions. Virus in saliva is the major route of transmission from mother to child, although breast milk also contains infectious virus (113). Siblings and playmates are additional sources of infectious oropharyngeal secretions (114, 115). Transmission among adolescents and young adults is attributed to deep kissing (107, 110). Whereas detection of EBV in the uterine cervix suggests that sexual transmission can sometimes occur (116), peripartum transmission is extremely rare and description is limited, likely because of the high prevalence of protective antibody among reproductive-age women (117). Acquisition through blood transfusion and following solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) has also been documented.

High viral titers are present in throat washings of 100% of patients during primary infection (99, 118), whereas intermittent, asymptomatic oropharyngeal shedding persists at lower levels for the lifetime of infected individuals (12% to 25%). Immunocompromised patients typically shed the virus between 50% and 90% of the time (119). As a consequence, only a small percentage of patients with AIM recall prior contact with other individuals with AIM, and most infections are acquired from asymptomatic shedders.

## PATHOGENESIS

### Initiation of Infection

B lymphocytes that underlie the tonsillar epithelial crypts are thought to be the initial cells infected *in vivo* (120, 121),

because persons who lack B cells or whose B cells are immature are not susceptible to infection, even of the epithelial cell compartment (122). Productive infection of oropharyngeal B cells followed by epithelial cell transmission leads to amplification of lytic virus replication, release of EBV into salivary secretions, and infection of additional B cells in the lymphoid-rich areas of Waldeyer's ring. As noted, memory B cells are likely responsible for dissemination of the infection throughout the lymphoreticular system and are necessary for EBV persistence (Fig. 5).

### Incubation Period and Early Infection

The incubation period from initial exposure to symptoms is approximately 6 weeks and coincides with the onset of high viral loads detected by PCR in both saliva and blood (111, 123). Large quantities of infected B cells (up to 25% to 50% of memory B cells) can be detected in the circulation upon onset of symptoms (106). The cellular immune response to infection is massive, with extraordinary expansion of CD8 T cells, inversion of the CD4/CD8 ratio, and cytokine storm (124). It is likely that this response not only limits further rounds of viral replication and EBV-positive B-cell expansion, but also directly contributes to many symptoms of AIM associated with the abundant release of inflammatory cytokines (Fig. 5). Perturbations of early cellular immune responses, especially in persons with congenital or acquired immunodeficiency, can result in atypical or uncontrolled EBV infection, including rapid development of EBV-induced malignancy, as described in later sections.

### Humoral Immune Responses

Primary EBV infection induces circulating antibodies directed against viral antigens as well as unrelated antigens found on sheep (heterophile) and horse (monospot) red blood cells. These heterophilic antibodies represent a heterogeneous group of mostly IgM antibodies that do not cross-react with EBV antigens. The detection of heterophile antibodies was used for many years to screen patients with symptoms of AIM for new infection, but has been largely discontinued due to lack of sensitivity (low in young children) and specificity (can be positive in liver disease, lymphoma, autoimmune disease, others) (125). Current diagnosis of acute EBV infection is most often based on indirect antibody immunofluorescence testing (IFT) or modifications thereof. Serum IgM against the viral capsid antigen (VCA) complex is typically detected 2 days after the onset of clinical illness and is followed by stable conversion to IgG anti-VCA. Although the IgM response to VCA reaches high titers early, it disappears within several weeks. IgM VCA antibodies are not detected in the general population, and thus their presence is virtually diagnostic of primary EBV infection. IgG antibody titers to VCA reach peak levels 2–4 weeks later and persist thereafter at lower levels for life. IgG directed against early lytic-cycle replication-related complexes (early antigen, EA) tends to appear with the peak IgM VCA response but reaches maximal levels after the IgM response. IgM antibody to EA may actually appear before antibody to VCA, but is not routinely used in clinical diagnosis. IgG anti-EBNA-1 titers do not usually

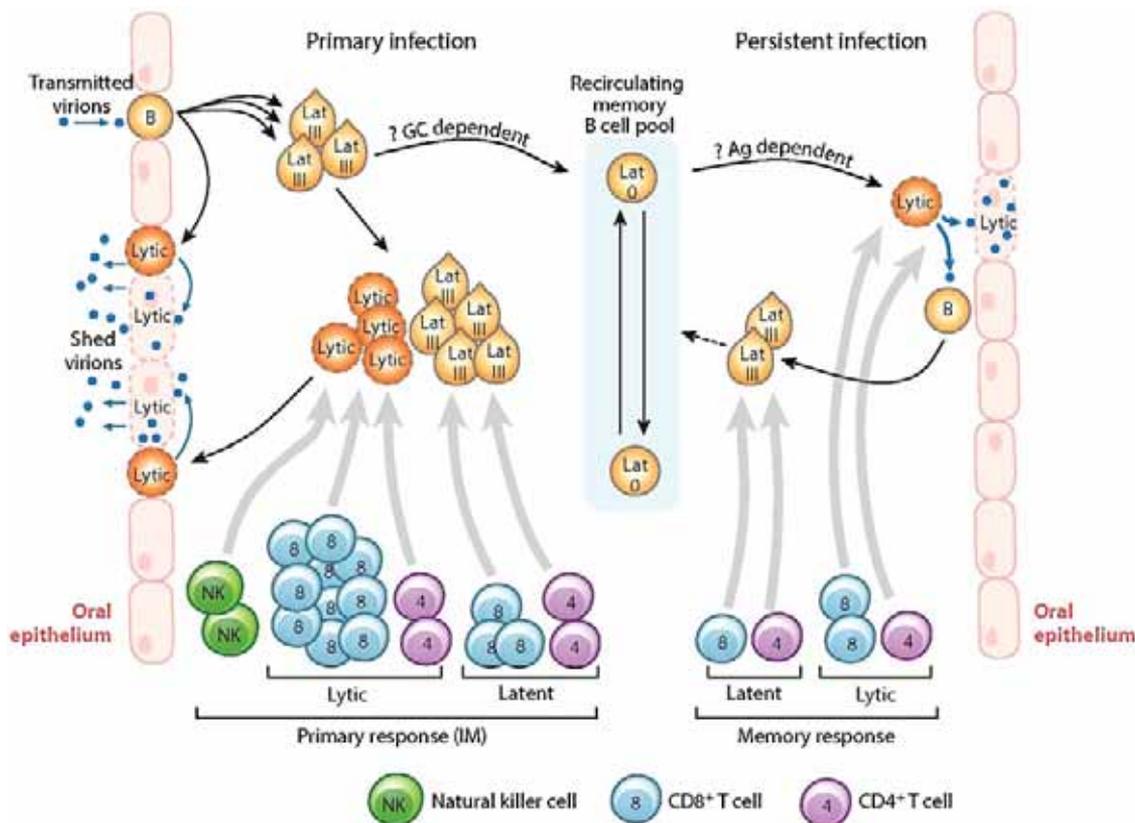

FIGURE 5 Immunobiology of Epstein-Barr virus (EBV) infection in the normal host. Diagram illustrating the transmission, primary infection, persistent infection, and how the cellular immune response becomes activated to prevent disease. (Reproduced from ref. 151 with permission from the journal.)

develop until convalescence, and not all persons develop these antibodies (126).

Immunoblot profiling of EBV antibodies is now used for a number of applications and has recently reached commercial platforms (127). Normal EBV carriers develop and maintain a highly similar anti-EBV IgG antibody titer including antibody diversity patterns, and deviations from these patterns can predict reactivation of infection (e.g., increases in EA) as well as development of disease (rising and more diverse IgG VCA and EA antibodies in chronic active EBV) and NPC (rising and increasingly diverse IgG and IgA VCA and EA) (128). Dramatic increases in antibody titers often occur in the setting of T-cell compromise, suggesting that this is a compensatory mechanism, although how it is triggered is unknown.

In addition to virus-specific antibodies assessed for diagnostic purposes, IgG responses are frequently detected to EBV early lytic antigens (BRRF1 and BORF2) and to tegument proteins (BBRF, BGLF2, BNRF1) (129). Although gp350 is the most abundant viral protein in lytically infected cell plasma membranes, and most of the human EBV-neutralizing IgG antibody response is directed against gp350 (130–132), neutralizing antibody development is typically delayed, reaching detectable levels only 6–7 weeks after the onset of illness and peak levels many weeks later (133, 134). Stable anti-gp350 titers then persist for life. Gp350-specific antibodies can mediate complement fixation and antibody-dependent cellular cytotoxicity (135). Because the gp350 molecule is conserved between EBV-1 and -2 strains, gp350 is considered to be an essential component of a prophylactic EBV vaccine. Figure 6 depicts the onset and time course of peak EBV-specific antibody responses observed in young adults with AIM in clinical practice.

Individual humoral response to EBV proteins, particularly to EBNA-1, may result in cross-reaction with cellular components. In persons who are genetically predisposed, these cross-reactive antibodies have been implicated by some in the pathogenesis of autoimmune diseases including multiple sclerosis (MS), systemic lupus erythematosus (SLE), rheumatoid arthritis, and Sjögren's syndrome, but without rigorous confirmation (136, 137).

## Cellular Immune Responses

### NK cells

Because primary pediatric infection is often asymptomatic or undiagnosed, understanding the cellular immune response that follows EBV transmission is largely based on evaluation of patients with AIM. Innate NK cells play a primary role in immune surveillance against virus-infected or transformed cells, because they do not require priming or prior antigen exposure. NK cells alone are not sufficient to prevent the establishment of EBV-transformed B-cell lines *in vitro*, but they do contribute to improved LCL regression in the presence of EBV-specific CD8<sup>+</sup> T cells (138). This effect may be due to direct cytotoxicity or IFN production, since EBV and EBV-infected cells induce IFN- $\gamma$  production by NK cells (139), and IFN- $\alpha$ , an NK product, is known to inhibit EBV-induced B-cell proliferation *in vitro* (140). One patient with complete absence of CD16<sup>+</sup> NK cells, however, experienced an unremarkable EBV infection following life-threatening infections with varicella-zoster virus, cytomegalovirus (CMV), and herpes simplex virus (HSV) (141), suggesting that not all NK cell subsets are equally required for resolution of primary EBV infection (142). More recently, evaluation in tonsillar tissues, modeling in humanized mice, and studies of young children have again emphasized the importance of NK cells, specifically NK subsets, in controlling EBV infection. As one example, a CD56<sup>+</sup>, CD16<sup>-</sup> NK cell subset, which progressively declines as children age, is highly effective in eliminating lytically infected cells *in vitro* and therefore has been proposed to mitigate the exuberant CD8 T-cell response observed among adolescents with AIM (143, 144).

### Other Innate Immune Cells

Precisely how dendritic cells, monocyte/macrophages, and granulocytes contribute to prevention of primary infection and to EBV-associated disease is an area of active investigation. EBV encodes multiple products (proteins, ncRNAs) believed to function in evasion of innate immunity, including secreted products that are incorporated as exosomes (145). Interactions with Toll-like receptors have been reported both to inhibit or promote EBV infection. In a primate model, infection with an EBV ortholog deleted in BARF1, a decoy receptor for macrophage colony-stimulating factor (M-CSF, a cytokine required for monocyte/macrophage differentiation) limited virion production, although precisely how this cell type functions in relation to EBV infection is not well understood (146). Recently, profound depletion of circulating plasmacytoid dendritic cells, and to a somewhat lesser extent conventional dendritic cells, was shown to accompany AIM, and consistent with this observation, IFN- $\alpha$  was minimally detected in blood (147). The mechanisms underlying this profound though transient dysregulation of the innate immune response are not presently known.

### T cells

A hallmark of AIM is the appearance of “atypical lymphocytes” (primarily CD8 T cells) in peripheral blood, which account for 60% to 70% of the total white cell count that averages 12,000–18,000/mm<sup>3</sup>. Accumulating evidence suggests that the exaggerated T-cell response seen with delayed infection may in part represent activation of cross-reactive T cells, a consequence of exposure to previously encountered pathogens (heterologous immunity) (148). Several lines of evidence indicate that EBV-specific CD8<sup>+</sup> and also CD4<sup>+</sup> T-cell responses are critical for limiting primary infection and

controlling persistent infection (see Fig. 5). EBV-specific CD8<sup>+</sup> and CD4<sup>+</sup> T cells can prevent the transformation of B lymphocytes *in vitro*. The increased incidence of EBV-associated lymphoproliferative disorders or lymphomas in individuals with compromised cell-mediated immunity [human immunodeficiency virus (HIV)-infected patients, immunosuppressed transplant recipients] also indicate that T cells are important for the long-term control of EBV replication. In fact, virtually every congenital immunodeficiency that predisposes to development of EBV-associated disease is characterized by dysregulation within the T/NK-cell limb of the immune response (149–153).

Over the past decades, powerful and precise methods for the enumeration and characterization of virus-specific CD8<sup>+</sup> and CD4<sup>+</sup> T cells in the peripheral blood have been developed (154, 155) (see Chapter 16). These include the use of labeled major histocompatibility complex–peptide complexes (tetramers) to directly detect, measure, and isolate antigen-specific lymphocytes and assays to detect antigen-specific cytokine-secreting cells following *in vitro* stimulation (IFN- $\gamma$  enzyme-linked immunospot assays and flow cytometry-based assays to measure intracellular cytokine secretion). These novel methods have markedly improved knowledge of the strength and breadth of EBV-specific CD8<sup>+</sup> and CD4<sup>+</sup> T-cell responses over the course of primary and persistent infection (156).

During primary EBV infection, high frequencies of EBV-specific CD8<sup>+</sup> and CD4<sup>+</sup> T-cell responses have been detected directly *ex vivo* (157–159). EBV-specific CD8<sup>+</sup> T-cell responses in primary infection are directed primarily against lytic-cycle antigens with greater responses to immediate early and early antigens than late antigens as viral immune evasion mechanisms become sequentially activated; latent antigen-specific responses are detected later and at lower frequencies (Fig. 7) (158). Up to 25% to 44% of peripheral blood CD8<sup>+</sup> T cells are EBV specific and express CD45RO, human leukocyte antigen–antigen D related (HLA-DR), and CD38, suggesting high-level activation and turnover of these cells *in vivo* (157). In contrast, early EBV-specific CD4<sup>+</sup> T-cell responses broadly target lytic antigens as well as latent antigens (159). In persistently infected individuals, EBV-specific CD8<sup>+</sup> T cells decrease, representing up to 5% of

peripheral blood CD8<sup>+</sup> T cells, whereas EBV-specific CD4<sup>+</sup> T cells are detected at much lower frequencies (up to 0.1% to 1.5%). The numbers and/or function appear to decline with old age.

## CLINICAL MANIFESTATIONS

### Congenital and Perinatal EBV Infections

Intrauterine infection with EBV appears to be a very rare event. Primary infection during pregnancy is unusual because in most populations fewer than 5% of pregnant women are susceptible. Nevertheless, isolated cases of infants born with congenital anomalies (biliary atresia, congenital heart disease, hypotonia, micrognathia, cataracts, and thrombocytopenia) have been attributed to primary maternal infection (160). However, a number of lines of evidence argue against EBV as a significant cause of congenital infection. Studies of large numbers of children with congenital anomalies have failed to confirm EBV infection. Furthermore, cord blood samples from thousands of infants have yielded virtually no evidence of EBV-infected or EBV-transformed cells. Finally, prospective studies on seronegative susceptible pregnant women have generally failed to verify either maternal infection or congenital abnormalities in infants of women who did develop primary EBV infection during pregnancy (161).

### Primary EBV Infection in Infants and Children

Primary EBV infections in young infants, children, and some adolescents are usually asymptomatic. When symptoms do occur, they are usually mild and nonspecific (otitis media, diarrhea, abdominal complaints, and upper respiratory infection); classical manifestations of AIM, such as lymphocytosis and fever, are rare (162). In one series, blood smears from only 32 of 200 children under 4 years of age who presented with clinical findings compatible with AIM (pharyngitis and significant cervical adenopathy) had more than 50% mononuclear cells and more than 10% atypical lymphocytes (163). Respiratory symptoms were frequently prominent, especially in young infants. IgM antibodies to VCA were detected 60% of the time in infants compared to

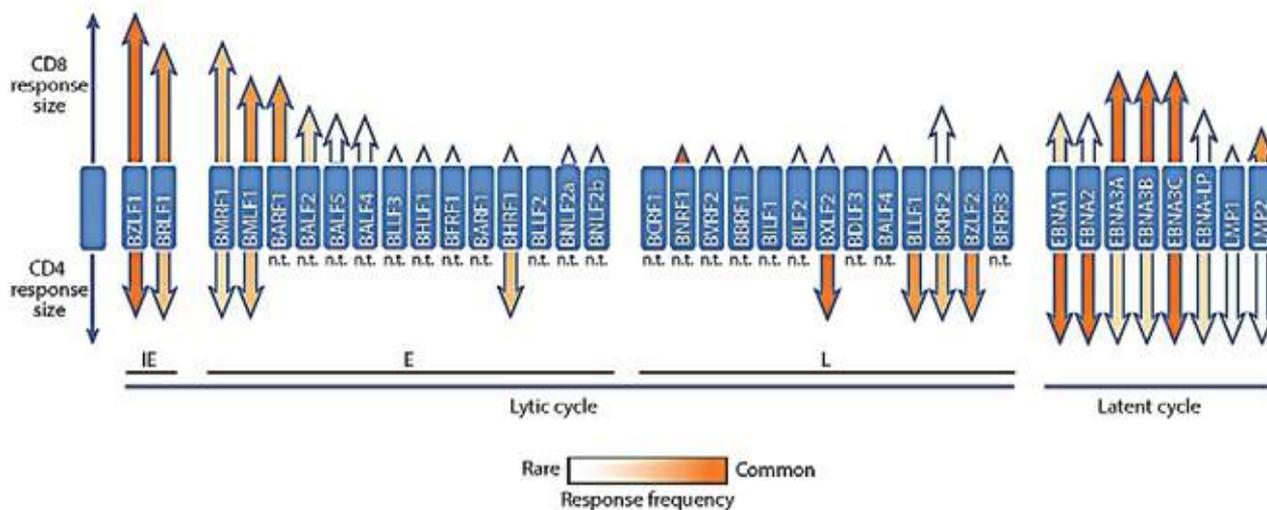

FIGURE 7 Frequency and distribution of CD4 and CD8 T cells in response to lytic and latent cycle Epstein-Barr virus (EBV) proteins. (Reproduced from ref. 151 with permission from the journal.)

100% in older children and young adults; in addition, peak titers of IgG VCA antibodies were lower, and the development of antibodies to EA was less common in infants. Prospective studies of young children demonstrate that at the time of primary infection viral loads in blood are similar to those of older individuals. Despite the reduction in antibody production, young infants mount robust EBV-specific CD8<sup>+</sup> T-cell responses during acute EBV infection, and lytic and latent proteins recognized are identical to those recognized by young adults (164). However, evidence of global T-cell activation and cytokine release, as observed in AIM, is limited.

### Acute Infectious Mononucleosis

EBV-associated AIM is marked by malaise, fever, fatigue, pharyngitis, and cervical lymph node enlargement (165). Although other pathogens may produce a similar constellation of symptoms [e.g., streptococcal pharyngitis, adenoviral pharyngitis, primary CMV or human herpesvirus 6 (HHV-6) infection, acute HIV infection, toxoplasmosis, lymphoma] specific clinical as well as laboratory findings (see below) support a diagnosis of EBV-positive AIM. The lymphadenopathy associated with AIM characteristically is symmetrical and involves the posterior cervical chain more than the anterior chain; inguinal and axillary adenopathy increase the likelihood of AIM. Tonsillar exudates are a frequent component of the pharyngitis; the exudates can have a white, gray-green, or necrotic appearance (Fig. 8); palatine petechiae are often visible (166). Severe fatigue is typically prominent, and other, less common findings include rhinitis, periorbital or palpebral edema, and maculopapular and morbilliform rash. Nausea, vomiting, and anorexia often occur in patients with AIM, probably reflecting the mild hepatitis found in about 90% of infected individuals; however, hepatomegaly and jaundice are uncommon. Splenomegaly is almost universally detected by sonography, but is detected in fewer (20% to 50%) AIM patients by palpation (166).

Many patients with AIM caused by EBV have prominent pharyngeal symptoms; however, there are several other forms of the illness. Some individuals present with the so-called

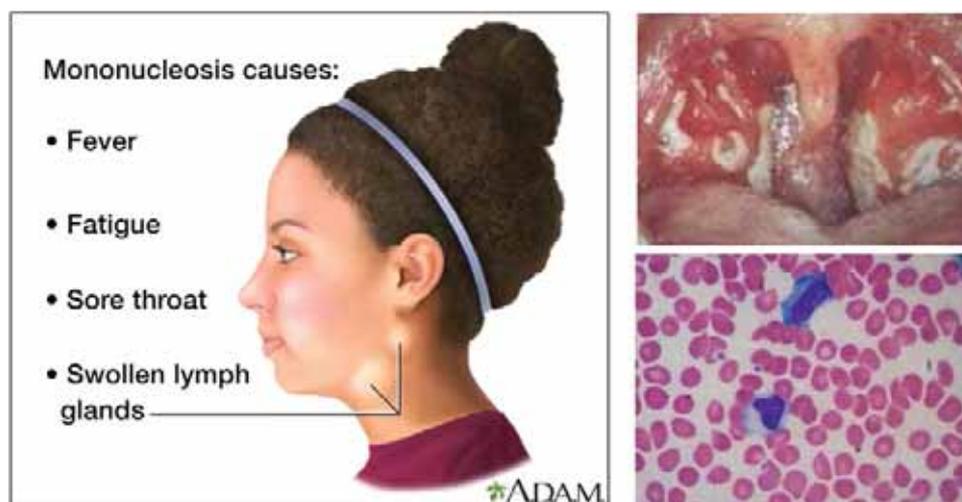

glandular form of the disease, in which lymph node enlargement is out of proportion to the pharyngeal symptoms. Others develop a systemic form of the infection in which fever and fatigue predominate, while lymphadenopathy and pharyngitis are mild or absent. Some patients have hepatitis in the absence of other typical features of AIM. The vast majority of individuals with AIM recover uneventfully and develop durable immunity. Acute symptoms typically resolve in 1–2 weeks, but fatigue may persist for months (106, 111).

### Acute Complications

Numerous other manifestations have been associated with primary EBV infection. Neurologic syndromes can include Guillain-Barré syndrome, facial nerve palsy, meningoencephalitis, aseptic meningitis, transverse myelitis, peripheral neuritis, cerebellitis, and optic neuritis. Hematologic abnormalities, including hemolytic anemia, thrombocytopenia, neutropenia, aplastic anemia, thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome, and disseminated intravascular coagulation, can occur. EBV can affect virtually any organ system and has been associated with such diverse disease manifestations as pneumonia, myocarditis, pancreatitis, mesenteric adenitis, myositis, glomerulonephritis, genital ulceration, and others comprehensively reviewed in a classic book by R.S. Chang (167).

One of the more common complications of AIM is a morbilliform rash following the administration of ampicillin or amoxicillin, and, to a lesser extent, penicillin and other antibiotics. The incidence initially was reported to be as high as 70% to 90% but is probably far lower (168). The mechanism responsible for this rash is not well understood. Development of this rash during AIM does not presage a true ampicillin allergy because patients have subsequently tolerated ampicillin without adverse reactions.

Splenic rupture is a rare but potentially life-threatening complication of AIM, estimated to occur in one or two cases per thousand (169). Almost all cases have been in males. Splenic rupture is often the first symptom of AIM that brings the patient to seek medical attention; it is spontaneous in more than half of the reported cases, with no history of specific injury. Rupture has occurred between the 4th and

**FIGURE 8** Acute infectious mononucleosis (AIM). Swollen lymph nodes, pharyngitis, fatigue, and headache comprise the four classic symptoms of AIM (left). Pharyngitis is often exudative (top right), and atypical lymphocytes are present in blood (bottom right). (Image of symptoms of AIM <https://www.nlm.nih.gov/medlineplus/ency/imagepages/17267>. Image of atypical lymphocytes from Wikipedia; image of pharyngitis from ref. 265 reproduced with permission from the publisher.)

56th days of symptomatic illness and has not correlated with the clinical severity of AIM or with laboratory findings. Despite its life-threatening potential, fatality from this complication is rare. The management of splenic rupture is similar to that of other forms of splenic injury. Nonoperative treatment with intense supportive care and splenic preservation has been successfully carried out in some cases, whereas others require splenectomy (170).

Obstruction of the upper airway due to massive lymphoid hyperplasia and mucosal edema has long been recognized as an uncommon, although potentially fatal, complication of AIM. Severe obstruction can be successfully treated by tracheotomy or endotracheal intubation. Alternatively, the brief use of corticosteroids to reduce pharyngeal edema and lymphoid hypertrophy is advocated for individuals with incipient obstruction despite concerns about corticosteroid therapy in the course of severe virus infection (171).

### EBV-Associated Lymphoproliferative Disorders

Atypical manifestations of EBV infection are often observed in persons with primary (congenital) immunodeficiency disease, particularly those involving the T and NK cell limbs of the immune response. The list of genetic lesions has increased greatly with advanced sequence analysis. Symptoms may be limited to EBV infections or reveal susceptibility to multiple infectious diseases (151, 153, 172). Knowledge of the disease mechanisms involved has expanded the knowledge of how lifelong asymptomatic carriage of EBV is maintained. Atypical manifestations of EBV infection may also represent a serendipitous confluence of environmental factors, for example, transient coinfection facilitating EBV entry into otherwise nonpermissive cells. Several of the described disorders may terminate in malignancy following a prolonged period of dysregulated proliferation (Table 1).

#### Hemophagocytic Lymphohistiocytosis

EBV is one of the recognized causes of sporadic hemophagocytic lymphohistiocytosis (HLH), a disorder characterized pathologically by generalized histiocyte proliferation and hemophagocytosis (173). Patients with this unusual syndrome present with fever, generalized lymphadenopathy, hepatosplenomegaly, hepatitis, pancytopenia, and coagulopathy. T-cell proliferation is a primary feature of HLH. The proposed pathogenesis of this disorder suggests that infection of T cells by EBV selectively upregulates the expression of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), which, in combination with IFN- $\gamma$  and other cytokines, can activate macrophages. While sporadic HLH is not associated with known immunodeficiency (174), unlike familial HLH in which mutations in perforin and other genes compromise cytotoxic granule delivery, it is likely that a significant subset of patients will eventually fall into this category (175). Therapy typically includes corticosteroids, etoposide, and cyclosporin, but some patients may require HSCT. HLH may be a harbinger of chronic active EBV (see below) or an EBV-bearing T-cell malignancy (176).

**TABLE 1** Epstein-Barr Virus–Associated Atypical Lymphoid Hyperplasia

Hemophagocytic lymphohistiocytosis (HLH)
Lymphomatoid granulomatosis (LG)
Lymphocyte interstitial pneumonitis (LIP)
Chronic active EBV (CAEBV)
Some primary immunodeficiency disorders

#### Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis is an angi-destructive disorder of the lymphoid system; over 90% of cases have been associated with EBV infection (177–179). In the majority of cases, EBV-infected B cells are present, and the B-cell proliferation is clonal. Patients often have evidence of immunodeficiency, including congenital and acquired conditions such as HIV infection. The pathogenesis of this disorder is thus likely directly related to the transformation of EBV-infected B cells in an environment with impaired T-cell function. Patients with lymphomatoid granulomatosis may respond to IFN- $\alpha$  (177). Clinical features include fever, cough, malaise, and weight loss, with involvement of lung, kidney, liver, skin, and subcutaneous tissue and the central nervous system, with the typical histologic changes.

#### Lymphocytic Interstitial Pneumonitis

Lymphocytic interstitial pneumonitis (LIP) is a lymphoproliferative disorder characterized by lymphocyte-predominant interstitial lung infiltrates, most often involving the bilateral lower lobes. Diffuse infiltration of the interstitium and alveolar spaces by lymphocytes and plasma cells is typical. The main clinical symptoms are gradual onset of dyspnea and cough of approximately 6 months' duration. Less frequently, systemic symptoms may include fever, night sweats, arthralgia, and weight loss. Hypertrophy of the salivary glands is observed in 20% of patients. LIP is causally associated with autoimmune diseases, as well as other virus infections including HIV (primarily pediatric) and human T-lymphotropic virus 1 (HTLV-1). A subset of cases is associated with EBV, and all forms reflect immune dysfunction. The natural history is variable with immunosuppressive agents, particularly corticosteroids sometimes used to treat disease, although success is variable (180–182).

#### Chronic Active EBV Infection

Chronic active EBV (CAEBV) infection is a rare disorder that is characterized by recurrent fever, lymphadenopathy, and hepatosplenomegaly persisting 6 months or longer (183). CAEBV is accompanied by grossly abnormal EBV antibody titers, with IgG antibody to EBV VCA often in excess of 1:5,000. High EBV viral loads and EBV monoclonality are present in the majority of CAEBV patients. EBV-infected T cells or NK cells circulate in the peripheral blood, particularly of Asian patients with CAEBV, and development of HLH as well as T or NK cell malignancies is frequent. Individuals with EBV-infected T cells had a 5-year survival rate of less than 50%, whereas those with the NK phenotype had a 5-year survival rate of 80%. B-cell disease can also occur, and mutations in perforin and syntaxin binding protein 2 (STXBP2; required for release of cytotoxic granules) have been described in this setting (184). Etoposide-containing therapy may be effective, although HSCT is often required for cure (185).

#### X-Linked Lymphoproliferative and Other Primary Immunodeficiency Disorders

X-linked lymphoproliferative (XLP1) syndrome-1 (Duncan's syndrome) was the first primary immunodeficiency identified by a selective inability to eliminate EBV-infected B lymphocytes (186), although in fact elimination of all activated B cells is compromised in XLP1 (187). XLP1 is manifested by severe or fatal AIM, acquired immunodeficiency, and lymphoma development (186). The gene (SH2D1A) responsible for XLP1 syndrome encodes a 128-amino-acid protein

that binds the cytoplasmic domain of the signaling lymphocyte activation molecule (SLAM) family of surface receptors on hematopoietic cells called SLAM-associated protein (SAP). The SLAM family proteins transduce activating signals that facilitate cell-cell cross talk and require SAP functions to do so (188). During acute EBV infection, males with XLP1 develop vigorous EBV-directed T-cell activation. However, in the absence of SAP, B-T/NK cell conjugates are unstable, T cells show poor effector function, and local responses fail to resolve (150). While acute therapy for XLP1 syndrome is often transiently directed to eliminate EBV-transformed B lymphocytes (Rituximab), definitive treatment of XLP1 syndrome currently requires HSCT, which confers an 80% 1-year survival. Following discovery of the mutation causing XLP1, a subset of other congenital mutations that alter clearance of EBV-bearing cells by T and NK cells has been uncovered. However, in many more cases, EBV represents but one among a broader spectrum of altered pathogen susceptibilities (151).

The second X-linked syndrome (XLP2), with manifestations overlapping those of XLP1, involves mutation of the gene encoding the X-linked inhibitor of apoptosis protein (XIAP). XLP2 T cells are highly susceptible to apoptosis from various stimuli, including T-cell restimulation; thus, effector functions are poor. EBV infection results in hepatosplenomegaly, HLH, and hypogammaglobulinemia. Notably, XLP2 males do not develop lymphoma, but do develop colitis, although the mechanism remains unknown (189).

A third X-linked immunodeficiency disease, XMEN (X-linked immunodeficiency with magnesium defect, EBV infection, and neoplasia) results from mutation of MAGT1, which encodes a magnesium transporter on T cells that transduces signals required for T-cell receptor stimulation. Poor responses to other herpesvirus infections and even bacterial infections have been detected in XMEN patients.

In contrast, CD27 deficiency (a TNF receptor family member and marker of B- and T-cell memory) is caused by an autosomal recessive mutation. CD27 deficiency is highly associated with a spectrum of diseases focused on EBV. Mutations in ITK, CORO1A, and LRBA are primarily, but not exclusively, linked to EBV-related pathology. Mutations in CD16, MCM4, GATA2, and LYST that diminish NK cell responses as well in PIK3CD, PIK3R1, CTPS1, STK4, FCGR3A, CARD11, ATM, WAS, and SCIDs, although often first identified in the setting of progressive EBV disease, in fact cause defective clearance of multiple pathogens (reviewed in 153).

### EBV-Associated Malignancies

Distinction between the lymphoproliferative disorders (LPDs) associated with EBV infection and the EBV-bearing lymphoid malignancies that frequently result can be blurred. In virtually every instance, some form of T- or NK-cell compromise is contributory. In the absence of congenital immunodeficiency, a major environmental insult (e.g., chronic infection, therapy for cancer or autoimmune disease) to the immune system is often, although not always, identified (Table 2 and Table 3). With developments in advanced sequencing, personalized medicine, biologics, and immune-based therapies, the approach to treatment of individual cancers is in flux; therefore, further review for each tumor type is recommended.

### Posttransplant Lymphoproliferative Disorders

EBV is associated with LPDs in transplant patients—both HSCT and SOT recipients on immunosuppressive therapy

(190). Posttransplant LPDs range from polyclonal B-cell proliferations (type III latency) to malignant monoclonal B-cell lymphomas (type II). EBV-positive T-cell LPD occurs, but is rare. Polyclonal LPD is most common during the first year after HSCT when immunosuppression is maximal. EBV-positive recipients who receive HSCT from donors who are EBV-negative are at highest risk due to rapid infection of the new immune system in the absence of functional T cells. Systemic symptoms of fever and sore throat may be evident on presentation. These symptoms and lymphadenopathy will sometimes respond to reduction in immunosuppressive therapy alone. Anti-CD20 monoclonal antibody therapy (e.g., Rituximab) that depletes B cells is often employed,

although it increases the vulnerability of posttransplant recipients to infection (191). Many centers now monitor EBV load in the circulation early after transplant by PCR. Optimized detection methods are in development (192, 193). High or rising loads predict (but do not prove) incipient disease. If immunosuppression cannot be reduced or is ineffective, prophylactic Rituximab is often administered (194). Anecdotal use of other agents such as interleukin 2, IFN- $\alpha$ , and intravenous Igs has been reported. No clear-cut benefits of such modalities have been demonstrated. Prophylactic ganciclovir, administered to prevent CMV disease early after transplant, can effectively reduce lytic replication of EBV and thus may limit new B-cell infection, potentially decreasing early disease, but systematic validation is needed (195, 196). EBV-specific T cells have been employed successfully both prophylactically and therapeutically for treatment of PTLTD with most success in HSCT recipients (see below).

The frequency of LPD following receipt of a solid organ allograft is related to the degree, type, and duration of immunosuppression and history of infection. Reported rates of LPD for children and adults following receipt of different allografts are given in Table 4. In contrast to HSCT, an EBV-seronegative recipient who receives an EBV-positive allograft is at greatest risk of disease, similar to CMV infection (197). Pediatric recipients of SOT who develop primary infection after transplantation have an extremely high mortality rate compared with previously infected children (198), underscoring the need for vaccine development. Onset of a monoclonal B-cell lymphoma may be preceded by benign polyclonal B-cell proliferation or present with sudden growth of a solid tumor mass in the organ allograft or any other tissue.

These lymphomas may be polymorphic in appearance, although the tumor mass is usually monoclonal and gene expression patterns often resemble those of diffuse large B-cell lymphomas (DLBCL). Because SOT recipients maintained on long-term immunosuppressive therapy are more likely to develop monoclonal disease, steps to minimize immunosuppressive therapy over time should be a priority (199). Late-onset disease is often resistant to treatment and the clinical course is usually the same as for an aggressive lymphoma. If chemotherapy [e.g., cyclophosphamide, doxorubicin (hydroxydaunomycin), vincristine (Oncovin<sup>®</sup>), and prednisolone (CHOP) or other] plus Rituximab is ineffective, cell-based therapies, including EBV-specific T-cell lines (EBVSTs), are being used increasingly (190). They are labor

intensive, costly, and can sometimes exacerbate graft-versus-host disease, but can be effective (200). T-cell checkpoint inhibitors in the form of monoclonal antibodies that block the interactions between surface antigens such as PD-L1 on tumors and PD-1 on T cells (as well as other checkpoint inhibitors) show promise for future treatment of EBV-associated LPD in combination with cell-based approaches (201).

#### EBV-Associated Malignancies in HIV Infection

In the setting of profound immunodeficiency associated with HIV infections, non-Hodgkin's lymphomas (NHLs) have been observed to occur approximately 60- to 100-fold more frequently than expected (202). A study conducted from 1984 to 1992 [before combination antiretroviral therapy (cART)] showed that EBV was associated with 39 of 59 (66%) of HIV-related systemic lymphomas (203). Analysis of EBV terminal repeats in these lymphomas again confirmed their monoclonal origin, and *c-myc* rearrangements were noted in up to 40%, indicating a Burkitt-like pathogenesis. B-LPD-like disease was most prevalent among patients with frank acquired immunodeficiency syndrome (AIDS), whereas HL was less common (discussed below). For unknown reasons, many EBV-associated NHLs in persons with HIV present with primary central nervous system lymphomas (204). Whereas B-LPD-like disease has virtually disappeared in the post-cART area, certain NHLs and HL, although decreased in HIV-infected individuals successfully treated with cART, nevertheless remain elevated relative to the general population (205).

A less serious EBV-induced disease in persons with AIDS is oral hairy leukoplakia, an unusual geographic, gray wart-like lesion of the lingual squamous epithelium. Virus replication is evident only in the upper layers of the epithelium and is effectively inhibited by nucleoside analogs, such as acyclovir or ganciclovir. Oral hairy leukoplakia lesions, initially thought to be specific for HIV-related immunodeficiency, have now been observed in other immunosuppressed patients and rarely in healthy individuals (206).

#### EBV and Smooth-Muscle Tumors

Children and young adults with AIDS experience an unusually high incidence of smooth-muscle tumors (leiomyomas and leiomyosarcomas) (207). These tumors are often multifocal and can also localize to the central nervous system (208). Convincing evidence for an etiologic role of EBV in the development of these neoplastic lesions was provided by demonstration that these smooth-muscle tumors contain clonal EBV and also develop with increased frequency in transplant recipients (209).

#### Primary Effusion Lymphoma

Primary effusion lymphoma (PEL) is an uncommon B-cell malignancy that occurs almost exclusively in the T-cell compromised host (e.g., AIDS and transplant patients). It is characterized by lymphomatous effusions in pleural, peritoneal, and other body cavities and is comprised of malignant postgerminal center type B cells. PEL is an aggressive disease with inflammatory-type symptoms and very poor prognosis. While Kaposi's sarcoma herpesvirus (KSHV, HHV-8) is always present in PEL, 70% to 80% of these tumors are coinfecting with EBV (latency I). Studies suggest EBV coinfection provides a survival advantage *in vivo* because coinfecting cell lines are more tumorigenic in small-animal disease models (210). There is no standard therapy for PEL at this time (211).

**TABLE 4** Rates of Posttransplant Lymphoproliferative Disease among Solid Organ Transplant Patients

Organ	Pediatric		Adult	
	1 year	5 years	1 year	5 years
Lung/heart-lung	4.0%	16%	1.0%	1.5%
Liver	2.1%	4.7%	0.25%	1.1%
Pancreas (isolated)	N/A	N/A	2.3%	2.3%
Heart	1.6%	5.7%	0.3%	0.7%
Kidney	1.3%	2.4%	<0.2%	0.6%

Cumulative 1- and 5-year incidence of PTLTD in pediatric and adult SOT recipients by transplanted organ as reported in the 2010 Organ Procurement and Transplant Network (OPTN)/Scientific Registry of Transplant Recipients (SRTR) Annual Report. Data for intestinal transplant recipients not broken down by pediatric versus adult and therefore not included.

PTLTD, Posttransplant lymphoproliferative disease; SOT, solid organ transplant; N/A, not available.

### Hodgkin Lymphoma

EBV genomic DNA was first reported in HL in 1987. Evidence supports a role for EBV in the pathogenesis of classical HL because malignant Reed-Sternberg cells contain the EBV genome in up to 50% of “Western” cases (212). Furthermore, AIM is a risk factor for subsequent development of classical HD (nodular sclerosing, mixed cellularity) that is variably reported as 3- to 10-fold increased during the 10-year period after AIM. The basis for this association remains unknown, but is supported by studies in countries such as Singapore, where rapid development has led to an increase of both diseases in young adults (108). As with BL (see below), detection of EBV in Reed-Sternberg cells appears to vary geographically and by age; for example, 94% of classical HD (mixed cellularity) cases occurring in Peru contain EBV transcripts (213) and globally almost all childhood cases of HD are EBV positive (214). Recently, a risk locus for EBV-bearing HL in European populations was described on chromosome 6p21.3 (215). The pattern of EBV latency in HD resembles type II latency as observed in NPC. Both are characterized by rich cellular infiltrates. EBNA-1 is expressed from the Q<sub>p</sub> promoter, whereas expression of other EBNAs is prevented by the silent Cp and W<sub>p</sub> promoters. LMP-2, LMP-1, EBER transcripts, and BART miRNAs are detected irrespective of histologic subtype (216). The EBV genome is also usually present in cases of HL (mixed cellularity) that appear in individuals with primary immunodeficiency or AIDS (217). Among persons successfully treated with cART, the incidence of LPD-like tumors has greatly diminished and other NHLs are somewhat diminished, whereas the incidence of HL has remained high for reasons that are not well understood (216, 218).

### Burkitt's Lymphoma

BL is among the most common childhood malignancies in equatorial Africa (219, 220). This unmistakable tumor is typically localized to the jaw of young patients and occurs more frequently in males, as do all EBV-associated malignancies. The majority of endemic cases occur in discrete geographic climates located along the *P. falciparum* malaria belt across Africa. Analysis of the EBV genome terminal-repeat copy number in endemic BLs showed that tumors originate from a single EBV-infected B cell. Products derived from recurrent bouts of *P. falciparum* malaria during early childhood (e.g., Pfemp1, hemazoin, others) are believed to provide a chronic stimulus for proliferation and differentiation of B lymphocytes (221, 222) that already carry high loads of latent EBV because of T-cell exhaustion resulting from chronic malaria infection (223). As these B cells differentiate, expression of activation-induced cytidine deaminase (AID) in the course of the germinal center reaction facilitates *c-myc* translocation and multistep tumorigenesis (224).

Tumor cells from areas where BL is endemic virtually always contain copies of the EBV genome in contrast to tumor cells from patients with sporadic cases of BL from areas of low incidence (>95% versus 20%). BL-like tumors are increased in HIV-infected persons, even on highly active antiretroviral therapy (HAART) (40% to 50% EBV positive) (225). The malignant cells obtained from fresh tumor biopsy samples consistently display a homogeneous surface phenotype, including the pan-B-cell marker (CD20), the common acute lymphoblastic leukemia antigen (CALLA, CD10), and the BL-associated antigen (CD77), consistent with a germinal center origin. These cells do not express the

common B-cell activation antigens CD23, CD30, CD39, and CD70 or the cell adhesion molecules LFA-1 (CD11a/18), ICAM-1 (CD54), and LFA-3 (CD58) in contrast to the malignant B cells that characterize LPDs and variably certain NHLs. Fresh BL tumor cells retain a resting B-cell phenotype and typically express only EBNA-1, EBERs, and ncRNAs. It is speculated that eradication of *P. falciparum* malaria will result in eradication of endemic BL, but studies to date are inconclusive (220). In cases of sporadic BL and classical HL that lack EBV genomes, the specter of a transient EBV infection has been raised, but has not been proven to date.

### T-Cell and NK-Cell Lymphomas

Although much less common than B-cell infection, normal activated T-cell populations can variably express the EBV attachment receptors CD21 and CD35 as well as HLA class II, providing a local environment permissive for EBV entry (226, 227). Supporting this observation, studies by Anagnostopoulos et al. demonstrated EBV-infected tonsillar T lymphocytes in individuals with AIM (120). The events that determine whether T-cell latency or immortalization results are unknown. EBV-positive T- and NK-cell lymphomas, though rare, occur in several settings. EBV T-cell LPD is sometimes diagnosed following iatrogenic immunosuppression as required for transplant, similar to B-LPD (228). Individuals with CAEBV infection often succumb to EBV-bearing T-cell lymphomas (229). Two major forms of primary EBV-associated T-cell lymphoma display distinct geographical distributions. Both are aggressive tumors, poorly responsive to chemotherapy, and both occur most frequently in middle-aged men. Peripheral T-cell lymphomas not otherwise specified (PTCL-NOS) are ~40% EBV positive and are primarily encountered in North America and Europe. In contrast, extranodal NK/T-cell lymphomas, nasal type (ENKT), the most common form of extranodal lymphoma worldwide, are prevalent in Asia and South and Central America. Similar to several EBV-associated malignancies, a rich lymphoid infiltrate is present in these tumors. The molecular biology of T-cell tumors is currently poorly understood. Reports of viral gene expression include EBERs, EBNA-1, and LMP-1 (more variably), most consistent with type I/II latency (230).

### Nasopharyngeal Carcinoma

Worldwide, nonkeratinizing NPC is relatively rare; however, it is one of the most common cancers in southern China, with age-adjusted incidence rates of up to 25 to 100 per 100,000 (231). Middle-aged men are most frequently affected. The incidence of undifferentiated NPC is also increased throughout Southeast Asia, among Alaskan natives, and around the Mediterranean, with North African men typically diagnosed at younger ages than Asian patients. Genetic predisposition and environment are recognized as contributory factors. In contrast to BL, EBV is present in every anaplastic NPC cell regardless of geography. The presence of a single clonal form of EBV in premalignant lesions, such as nasopharyngeal dysplasia or carcinoma *in situ*, indicates that EBV-induced cellular proliferation precedes the acquisition of full invasiveness. EBERs and EBNA-1 are universally detected, whereas LMP-1 and LMP-2 are detected in most tumors as are ncRNAs (latency II). Although EBNA-2 is essential for the initial transformation of lymphocytes, its absence in preinvasive neoplasia in NPC indicates that EBNA-2 is not required for the altered epithelial cell growth associated with NPC (232, 233). Radiation has long been a major component of treatment together

with chemotherapy; new potential therapeutic targets are emerging (234).

### Gastric Carcinoma

EBV-associated gastric carcinoma was first reported by Burke et al. in 1990. The EBV-bearing tumors that contain a rich lymphoid infiltrate similar to NPC form part of the spectrum of EBV-associated lymphoepithelial carcinomas (NPC, thymoepitheliomas, salivary gland tumors), whereas the gastric adenocarcinomas are distinct (235). The distribution of the latter appears to be worldwide, with young rather than middle-aged men primarily affected. Although only ~10% of all gastric cancers contain EBV, because gastric cancer is the second leading cause of cancer deaths worldwide, EBV-bearing gastric carcinoma is potentially the most common of all EBV-related malignancies. Current treatment is the same as for other forms of gastric cancer. Complete surgical resection is especially effective because the EBV-associated adenocarcinomas do not readily metastasize to lymph nodes and carry an improved prognosis compared with EBV-negative forms of gastric cancer. Viral gene expression is most consistent with a latency I/II program, although expression of limited lytic cycle proteins, such as the immunoevasin BNLF2a has also been detected (236, 237).

### Other EBV-Infected Tumors

There are limited reports of atypical tumor types sometimes bearing EBV genomes, primarily tumors of other hematopoietic and epithelial lineages. In some cases, detection of contamination by EBV-positive B cells in the tumor microenvironment has been a concern, especially when PCR alone was applied for detection. In others, more extensive analyses complemented by immunohistochemistry, *in situ* hybridization, and other technologies (238) have provided more compelling evidence that EBV is present in these cancer cells and may have contributed to multistep tumorigenesis, perhaps following aberrant expression of virus entry proteins by a premalignant host cell in a microenvironment where EBV load is serendipitously high.

### EBV and Autoimmune Disease

Genetic predisposition combined with an environmental trigger(s) can result in a spectrum of diseases manifested by immune dysregulation and pathologic targeting of self. Similar to patients with AIM, who often manifest transient autoimmunity, patients with systemic autoimmune disease often demonstrate elevated antibody levels to VCA and EA as well as elevated titers of EBV DNA in blood, consistent with altered T-cell function. Although controversy persists (239), more definitive epidemiologic and clinical data support EBV as a major environmental trigger for MS (240) and possibly SLE. In the case of MS: (1) virtually all patients, including very young children, are EBV seropositive; (2) development of AIM almost always precedes MS; and (3) elevated IgG responses to a distinct subdomain in EBNA-1 similar to myelin, but not to most other EBV antigens, occurs years before MS becomes clinically apparent, supporting molecular mimicry as a disease mechanism (241). In contrast, AIM does not predict lupus development, and the spectrum of autoantibodies is distinct and broader (242, 243). However, among young children that develop SLE the seroprevalence of EBV is much higher (99%) than that of closely matched peers (70%). Whether EBV contributes to the pathogenesis of rheumatoid arthritis (244), Sjögren's syndrome (245), or other autoimmune diseases is under investigation in several laboratories.

## LABORATORY DIAGNOSIS

### Primary Infection

To establish a diagnosis of AIM among persons with clinically suspected disease, evaluation of the white blood cell count can be especially useful, as lymphocytosis with >10% atypical lymphocytes is often present before either heterophile or IgM antibodies to VCA, conventional criteria for confirming new infection, can be detected. Total lymphocytosis of >50%, the presence of monocytosis, together with >10% increasing to >40% atypical lymphocytes in combination virtually assures a diagnosis of AIM, although relatively few patients will meet all of these conditions (166). (See also the section on Humoral Immune Response for additional discussion.)

The classic serologic response that is used to diagnose primary EBV infection in clinical practice is depicted in Fig. 6 (above), although variation often occurs. IgM to VCA, predicted to arise at the time of clinical illness, may be delayed by several days and may first appear together with IgG to VCA. If IgM VCA is negative and suspicion of primary infection is high, retesting is warranted. IgM antibodies to VCA (also heterophile) disappear within 2–6 months and failure to do so suggests a process other than primary EBV infection should be suspected. Antibody to the EA complex rises at the time of clinical presentation and then, like IgM antibody, disappears after several months. Both may reappear in the setting of poorly controlled lytic reactivation associated with T-cell compromise and malignancy. Production of antibodies to the nuclear antigen complex EBNA is delayed by several months following primary infection. Thus, detection upon initial evaluation indicates that the clinical syndrome is not primary. One caveat is that some individuals never develop anti-EBNA antibodies.

Although primary infection is usually accompanied by viremia, EBV PCR is not useful in healthy individuals because intercurrent viremia may occur among persistently infected individuals. On the other hand, EBV PCR can be an important tool for diagnosing primary infection in the immunocompromised host who is known to be EBV negative and may fail to mount a detectable or conventional antibody response upon primary infection. In many centers, EBV-negative transplant recipients (testing is performed pretransplant) are surveyed by EBV PCR at defined intervals to identify a new infection and implement strategies to control disease.

### Reactivation

Although rising antibody titers to EBV lytic-cycle antigens appear to reflect loss of cellular immune control relevant to several EBV-associated diseases, they have been primarily used to (1) establish a diagnosis of CAEBV (high titers of IgG to VCA) and (2) diagnose and treat NPC (high or rising titers of IgA to VCA). Determination of viral load by PCR has now been validated as a biomarker of incipient or established malignant disease in multiple settings, although optimal methods remain under investigation (192). Changes in viral load have been used to implement preemptive strategies to diminish the risk of PTLD as well as to follow the response to treatment of the various EBV-associated tumors.

## PREVENTION

### Immunization

Evidence implicating EBV in the etiology of a variety of human diseases has made the prospect of developing a

virus-based vaccine very appealing. Vaccine administration in resource-rich countries and increasingly on a global basis would prevent AIM in young adults. With the annual incidence of AIM estimated in the United States at 100,000 cases, EBV causes significantly more illness than mumps, for which a successful vaccination strategy exists.

As discussed, gp350 mediates B-cell attachment. It is one of the most abundant late viral proteins present in lytically infected cell plasma membranes and is the most abundant protein on the outer surface of the virus coat. Passively transferred antibodies are likely important in protecting infants from EBV infection. As most of the human EBV-neutralizing antibody response is directed against gp350 (130), gp350 has been the major EBV lytic-cycle protein targeted for subunit vaccine development. The largest study, a phase II, randomized, double-blind, placebo-controlled trial of an adjuvanted recombinant gp350 vaccine was undertaken in healthy, EBV-seronegative young adults (246). More than 90% of vaccinated individuals developed anti-gp350 antibodies. Importantly, the vaccine demonstrated efficacy (78%) in preventing symptomatic primary EBV infection (AIM), but was not effective in preventing asymptomatic infection. These data justify development and testing of anti-gp350 vaccines (247) such as virus-like particle vaccines (248) and others that incorporate gp350 (as well as other novel candidates) and also recruit T cells. Although development of potent neutralizing antibody responses is important, given that CD8<sup>+</sup> T-cell responses are essential for controlling EBV replication and LPD, future vaccine research defining additional protective T-cell epitopes for inclusion in EBV vaccines will also be key (249).

### Prophylactic Therapy

Antivirals have been administered transiently to prevent primary EBV infection, particularly in seronegative children who are at high risk of PTLD following an EBV-positive SOT; however, antivirals will not prevent tumors that arise from latently infected donor B cells. IVIG or CMVIG, which contains high-titer anti-EBV antibodies, has been used with unproven benefit to prevent primary EBV infection (250, 251). Administration of monoclonal antibodies, such as anti-CD20 (e.g., Rituximab) can abort expansion of EBV-positive B cells en route to PTLD but compromise humoral responses to new infections. Prophylactic treatment of HSCT recipients at high risk of PTLD with EBV-specific T cells (EBVST) has been successful in some settings. These varied approaches to prophylaxis and treatment are discussed in more detail below.

## TREATMENT

### Symptomatic and Anti-Inflammatory

The mainstay of treatment for individuals with AIM is supportive care. Acetaminophen or nonsteroidal anti-inflammatory agents are recommended for the treatment of fever, throat discomfort, and malaise. Provision of adequate fluids and nutrition is also appropriate. Although ensuring adequate rest is prudent, bed rest *per se* is unnecessary. Contact sports should be avoided due to the risk of splenic rupture.

The use of corticosteroids in the treatment of EBV-induced AIM remains controversial. Studies looking at the use of corticosteroids have been imperfect, but they do suggest that these agents induce a modest improvement with reduction of lymphoid and mucosal swelling. Thus, a trial of corticosteroids in individuals with impending airway ob-

struction (manifested clinically by difficulty breathing in the recumbent position) is warranted. In addition, individuals suffering from severe, overwhelming, life-threatening infection (e.g., liver failure), along with individuals who sustain other severe complications such as aplastic anemia, should also be considered for corticosteroid therapy, although data supporting benefits in these situations, because of their rarity, are lacking.

Despite the recommendations of some experienced clinicians that corticosteroids be administered in routine cases of AIM, the literature does not support this approach. The clinical illness of AIM represents the immune response to EBV, an agent that establishes lifelong latency and that has oncogenic potential. For this reason, the administration of immunomodulating agents such as corticosteroids during primary infection is theoretically contraindicated because of the possibility of altering the immune response and predisposing the patient to a long-term lymphoproliferative complication. Indeed, studies of individuals with AIM who received corticosteroids many weeks earlier have demonstrated globally diminished numbers of B cells and T cells, including diminished numbers of CD4 T-helper and CD8 T cytotoxic cells (252). Since no long-term data obtained for individuals who received corticosteroids during primary EBV infection are available, it would seem prudent, despite the potential of short-term improvement, to withhold such treatment from most individuals given the self-limited nature of this infection in the vast majority of cases (171).

### Antiviral Treatment

Acyclovir and ganciclovir are nucleoside analogs that can inhibit lytic EBV replication following phosphorylation by the EBV phosphotransferase (BGLF4) (253). This enables incorporation of their triphosphate form into viral DNA by the EBV DNA polymerase and is followed by DNA chain termination (replication arrest). These agents have no effect on latent infection. Specific therapy of acute EBV infections with intravenous and oral formulations of acyclovir has been studied (254, 255). Short-term suppression of viral shedding can be demonstrated, but significant clinical benefit has not been demonstrated. These results are not surprising in view of data documenting that viral load has likely peaked at the time of presentation with AIM and that the manifestations of AIM are more likely due to aberrant immune responses (99). Long-term administration of valacyclovir over 1 year diminished the frequency of EBV-infected B cells in normal volunteers. On the basis of this study, it was estimated that if possible, it would take 11.3 years of continuous treatment to eradicate EBV (256).

In the majority of the EBV-associated malignancies, where the stage of the virus infection cycle has been characterized, there is little evidence for permissive (lytic) infection. Standard chemotherapy that varies based on tumor type and not specifically directed at the virus is still employed for most EBV-associated tumors discussed in the above section. Because nucleoside analogs that inhibit polymerase function (acyclovir, ganciclovir, cidofovir, foscarnet, and their congeners) are only effective in inhibiting replication of linear EBV DNA, there is little to be gained by their use as single agents in diseases associated with latent infection. There is anecdotal support for their use in EBV-induced histiocytic hemophagocytosis (acyclovir), where evidence of replicating EBV has been demonstrated (257). Definitive studies regarding prophylactic use in the immunocompromised host, such as children who are EBV seronegative at the time of SOT and are at risk of severe primary infection and

subsequent PTLD, are lacking (196). However, routine prophylactic use of the aforementioned nucleoside analogs to prevent CMV and HSV in the peritransplant period may also diminish the risk of primary EBV infection and PTLD. Measurements of EBV viral load in the circulation reflect both lytic replication and outgrowth of latently infected cells; thus, if the titer of circulating virus is decreased, the likelihood of additional B-cell infection and posttransplant lymphoproliferative disease (PTLD) may also be decreased. Robust lytic cycle induction of latently infected tumor cells—“lytic induction therapy”—remains an area of active research, and, if successful, would potentially expand a role for both antivirals and novel cell-based therapies (258). Small-molecule inhibitors that target key viral as well as cellular proteins are also under investigation (259).

### Cell-Based Therapies

The presence of viral proteins in EBV-associated tumors has provided an impetus for development of T-cell-based immunotherapies crafted with increasing sophistication over the years (260, 261). Although labor intensive, expensive, and only available in limited cancer centers, the tide is beginning to turn due to increasing support of cell-based therapies by the biotechnology sector. To date, the greatest success of EBVSTs has been achieved upon treatment of PTLD in HSCT recipients, as viral protein expression is robust (type III latency) creating multiple potential T-cell targets and decreased cellularity has facilitated outgrowth and function of infused T cells. Although use of unselected donor lymphocyte infusions (DLIs) was often accompanied by side effects, including graft-versus-host disease and cytokine release syndromes, EBVSTs have proved far more efficacious and devoid of most toxicity. Therapy of SOT patients has proved more challenging because of potential HLA mismatch, diminished viral protein expression in most tumors, and the requirement for ongoing immunosuppression reducing the efficacy of infused T cells. However, banks of EBVSTs have now been developed that are able to provide a rapid source of cells with partial HLA matches that have been used with some success. Tumors in which viral gene expression is comparatively reduced (type II latency, e.g., NPC, HL, some NHLs) have responded less well to EBVSTs, but there is optimism that the introduction of checkpoint inhibitors together with EBVSTs will improve outcomes. Type I latency-expressing tumors have not been assessed systematically at this time. The introduction of T-cells activated with chimeric antigen receptor (CAR; often a monoclonal antibody directed to a specific cell type) into clinical practice suggests that a combination strategy could result in enhanced tumor cell localization of EBVSTs increasing future efficacy (262, 263).

### Therapeutic Immunization

Although the safety bar is set very high for a prophylactic vaccine, therapeutic vaccine candidates that incorporate EBV products expressed by EBV-associated malignancies are also under development using vectors optimized to stimulate a vigorous cellular immune response capable of eradicating established tumors (249). Current targets include, in particular, NPC and gastric carcinoma with some promising early-phase results.

### Acknowledgments

Drs. Katherine Luzuriaga and John Sullivan were coauthors of the comprehensive original version upon which this revised chapter was built.

# Kaposi's Sarcoma-Associated Herpesvirus (KSHV/HHV8)

YUAN CHANG, SHOU-JIANG GAO, AND PATRICK S. MOORE

## 26

Discovered in 1994, Kaposi's sarcoma-associated herpesvirus (KSHV or HHV8) causes several human cancers, including Kaposi's sarcoma (KS), primary effusion lymphomas (PEL), and some forms of multicentric Castleman's disease (MCD). KSHV is commonly associated with cancers among AIDS patients but it is also a significant public health problem in developing countries for both HIV-infected and uninfected populations. KSHV is a gammaherpesvirus with unique features in its gene products, gene distribution and evolution, and mechanisms of cellular transformation. The epidemiology of KS in different risk groups and geographic regions parallels the prevalence of KSHV infection. While modes of transmission of KSHV are still to be fully determined, specific measures can be implemented to prevent its spread. Specific assays, including serologic and antigen immunohistochemistry tests, have been developed that allow detection of infected patients and patient tissues. Understanding of the molecular mechanisms for KSHV-related pathogenesis should facilitate the detection, prevention, and therapy of KSHV and its associated cancers.

### INTRODUCTION

Kaposi's sarcoma-associated herpesvirus (KSHV; also called human herpesvirus-8 [HHV-8]) is a large double-stranded DNA herpesvirus that is the cause of Kaposi's sarcoma (KS) and primary effusion lymphomas (PEL). KSHV is also the etiologic agent in the majority of multicentric Castleman's disease (MCD). KSHV belongs to the Rhadinovirus genus of the gammaherpesvirus subfamily. Similar to other herpesviruses, KSHV has both latent and lytic replication cycles, and infection is presumed to be lifelong. KSHV has evolved sophisticated mechanisms at multiple levels to facilitate its infection and replication, resulting in maintenance of persistent infection in immunocompetent hosts and induction of disease, predominantly in immunocompromised hosts.

KS, the most common malignancy associated with KSHV, has a dynamic and evolving epidemiologic profile. A rare cancer in the Western world prior to the emergence of HIV, the onset of the AIDS epidemic resulted in an explosive increase in the incidence of KS. With the success of antiretroviral therapy (ART), KS rates have declined but it remains a significant problem with distinct clinical manifestations (1). In Africa, where it has long been a highly

prevalent cancer, KS is now the most common cancer in several regions (2), in large part because of the AIDS pandemic in populations lacking effective preventive and therapeutic intervention.

KS, a spindle cell tumor arising from lymphatic endothelium, was first described in 1872 by the Austrian dermatologist and dermatopathologist Moriz Kaposi (3). An infectious agent had been suspected as the cause of the tumor since the 1950s (4). This was reinforced by the emergence of KS as an AIDS-related tumor and its differential occurrence among different HIV risk groups (5). KSHV was discovered in 1994 through a PCR-based DNA subtractive hybridization method in AIDS-KS tissues (6). Shortly after the initial description of KSHV, all forms of KS, in both HIV-positive and HIV-negative patients, were found to harbor the virus. The virus was also found to be B-lymphocyte tropic by its identification in PEL and MCD (7), and cell lines from PELs have become a source for growing the virus in culture (8–10). KSHV was sequenced in 1996 (11) and shown to possess a remarkable array of viral genes homologous to cellular regulatory genes.

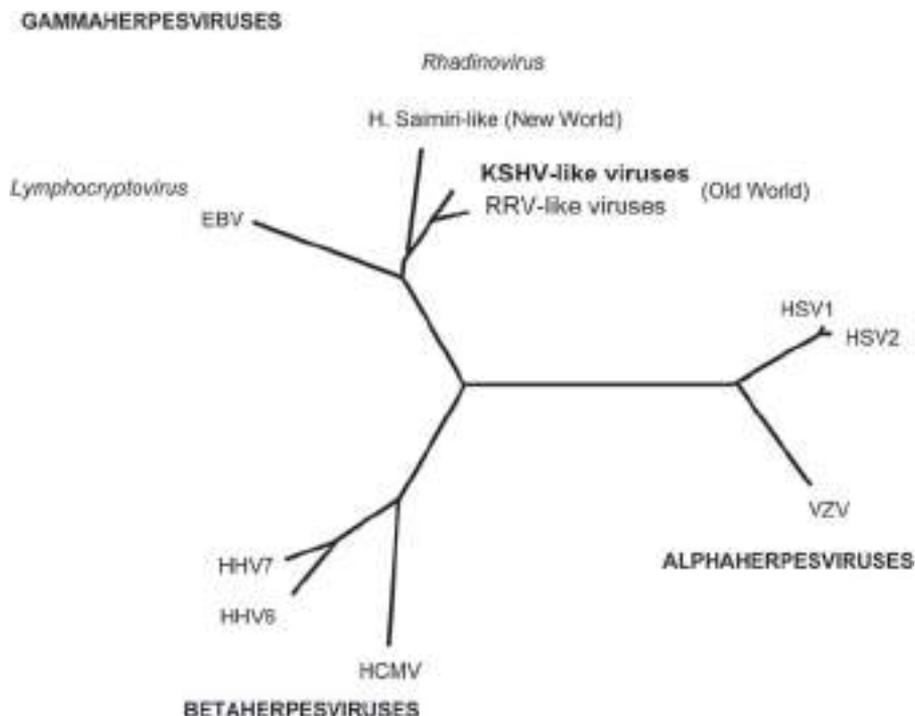

### VIROLOGY

#### Classification

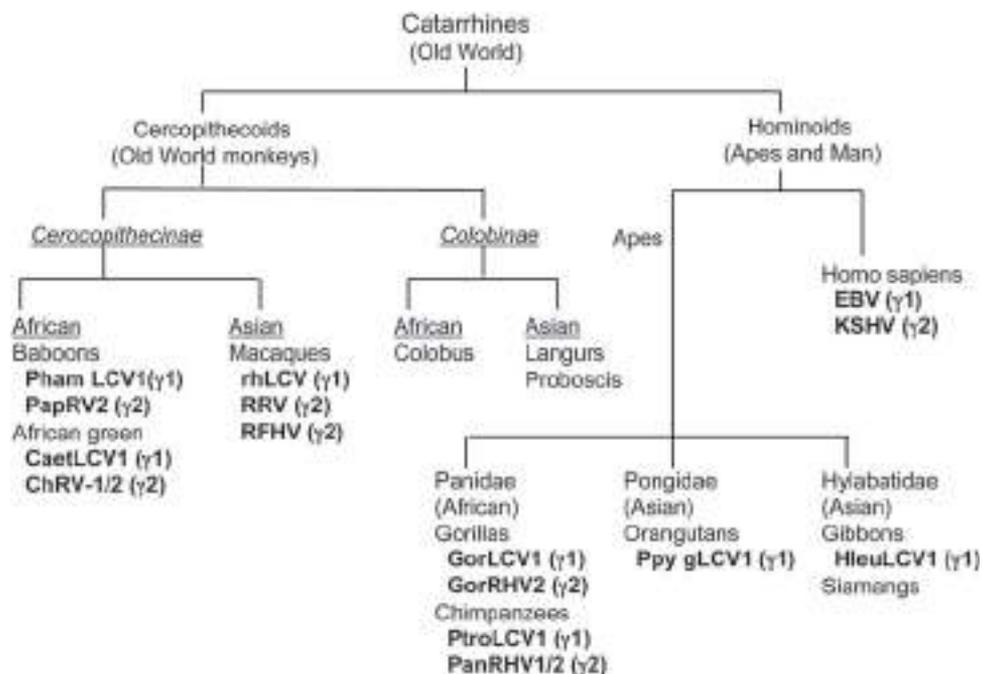

KSHV belongs to the genus *Rhadinoviridae* (gamma-2 herpesvirus) of the subfamily *Gammaherpesvirinae* of the family of *Herpesviridae* (12). Among the human herpesviruses, KSHV is most closely related to Epstein-Barr virus (EBV or HHV4), a member of the genus *Lymphocryptovirus* (gamma-1 herpesvirus) (Figure 1). Although *Gammaherpesvirinae* has members broadly represented in mammals, KSHV and EBV are notable as the sole human members of this subfamily, and both are uniquely recognized among human herpesviruses for their tropism for B lymphocytes and their ability to cause human cancer.

#### Evolution and Genotypes

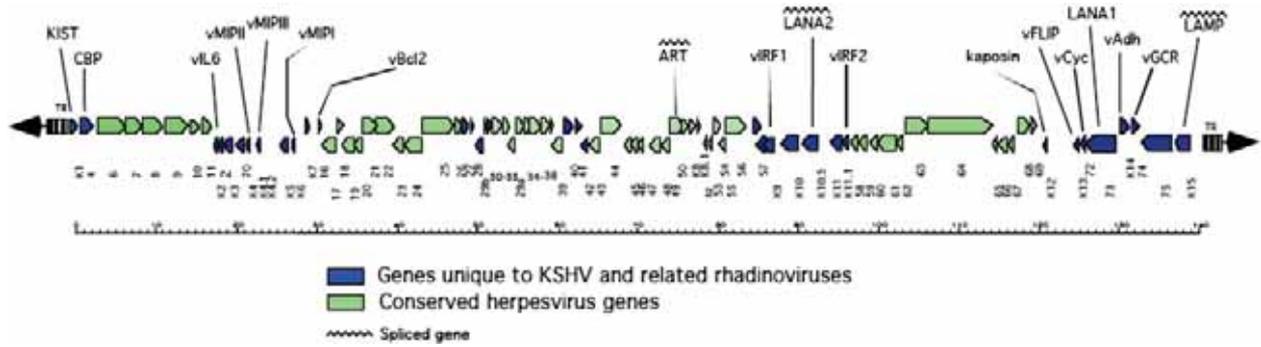

Early searches for KSHV-like viruses among primates revealed several surprises: KSHV-like rhadinoviruses were discovered to infect rhesus macaques (13) and similar viruses were later discovered among higher primates (Figure 2). All Old World and New World primates appear to be infected with KSHV-like rhadinoviruses (RV-1) that have coevolved

**FIGURE 1** A phylogenetic tree showing the alpha-, beta- and gammaherpesvirus subfamilies. KSHV belongs to the genus *Rhadinovirus*, also known as  $\gamma$ -2 herpesviruses, in the lymphotropic gammaherpesvirus subfamily. Other related gammaherpesviruses are also associated with lymphoproliferative disorders, including EBV in humans and herpesvirus saimiri (HVS) in New World monkeys. Herpesviruses from the alphaherpesvirus (e.g., herpes simplex and varicella-zoster virus) and betaherpesvirus subfamilies (e.g., cytomegalovirus and human herpesviruses 6 and 7) have not been found to cause tumors in humans. (From Moore et al. (12) with permission.)

**FIGURE 2** Old World primate hosts and their gammaherpesviruses. It is evident from this phylogenetic tree that these are ancient viruses that have coevolved with their hosts. A second rhadinovirus, rhesus rhadinovirus, has been found widely distributed among primates including chimpanzees. It is likely that a human version of this virus exists but has not yet been found. (Courtesy of B. Damania, University of North Carolina, Chapel Hill.)

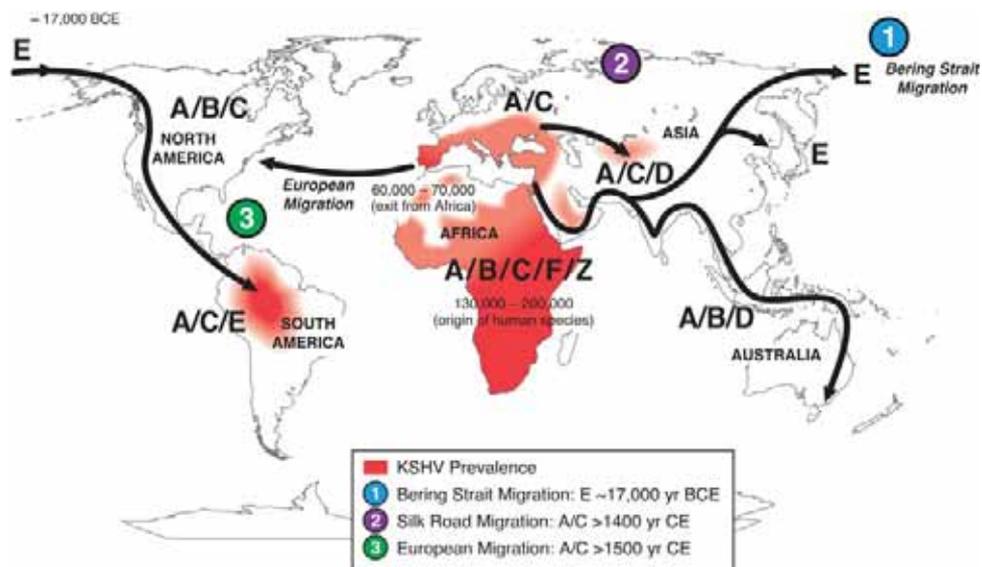

**FIGURE 3** Genomic map of KSHV sequenced from the BC-1 KSHV-infected PEL cell line. The viral genome contains a ~145 kb long unique coding region (LUR) flanked on both sides by reiterated terminal repeat (TR) units of high GC content (>85%). Conserved herpesvirus gene blocks (dark blue) are interspersed with blocks containing genes unique to KSHV and other Rhadinoviruses (light blue). These nonconserved regions contain numerous homologs to host cell genes involved in cell-cycle regulation, apoptosis, and immune regulation.

with their hosts. During this search, however, a second distinct but closely related rhadinovirus lineage (RV-2) was found. Members of this lineage include rhesus rhadinovirus (RRV) (14), and pig-tailed macaque RV2 rhadinovirus (MneRV2). These viruses have similar genomic structures and coding genes (15–17). Viruses of this lineage were also found among higher primates (18), leading to the intriguing possibility that there may be an undiscovered RRV (“HHV-9”) infecting and possibly causing disease among humans.

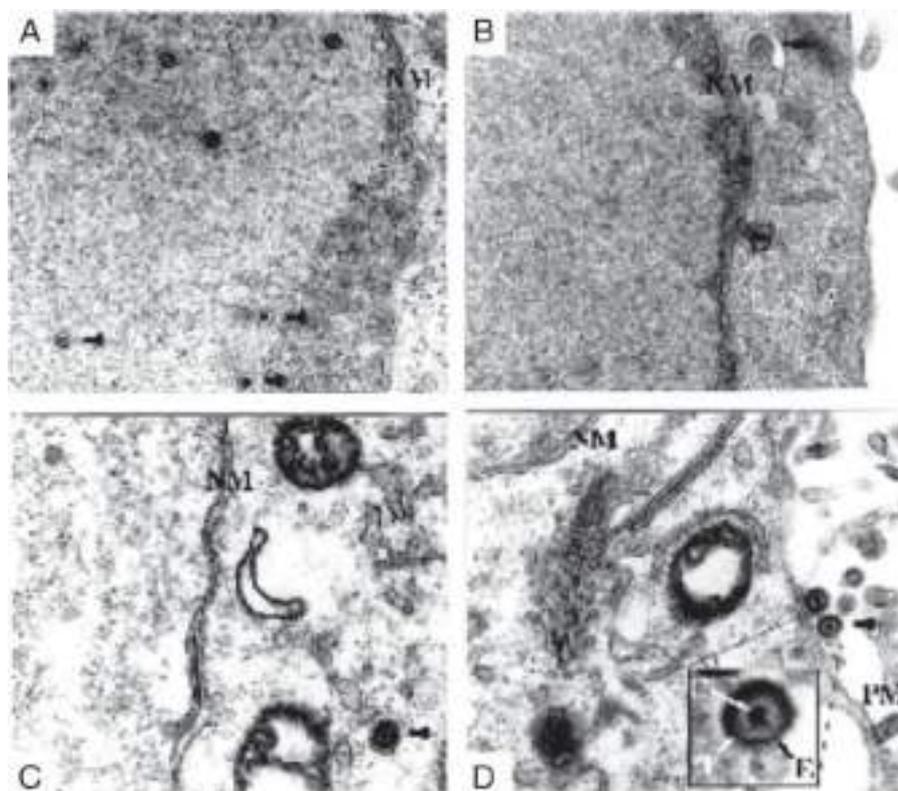

KSHV genotyping has been useful in characterizing KSHV transmission (19), and a strong correlation exists between virus evolution and human migration patterns (20, 21). Genotypic diversity among KSHV isolates is highest at the left and right ends of the long unique region (LUR) in open reading frames (ORF)-K1 and -K15, respectively (Figure 3). The K1 ORF displays up to 30% amino acid variability, allowing designation of major viral clades A, B, C, D, E, F, and Z. Subtypes B, F, and Z are found almost

exclusively in KSHV-infected patients from Africa or of African heritage. Subtype D is found in Pacific Island populations, and subtype C is common in patients from the Middle East and Asia. Both subtypes A and C are seen in North America, and subtype E is present predominantly in ancient populations such as Brazilian Amerindians (Figure 4).

At the opposite end of the viral genome, the K15 ORF can occur in multiple forms that encode for distinct groups of alternatively spliced K15 proteins. These forms, designated as predominant (P) and minor (M) forms (20), apparently arose from rare intertypic recombination events (see reference 22 for a thorough overview of KSHV molecular typing). Internal repeat regions in the latency associated nuclear antigen (LANA)1 gene (ORF73) show strain-to-strain variation in repeat numbers that has also been used for typing (23, 24) and measuring viral monoclonality in KSHV-infected tumors (25).

**FIGURE 4** The global KSHV seroprevalence, subtype distribution, and migration. KSHV migration might be correlated with the major migrations of modern humans out of Africa over the past 100,000 years.

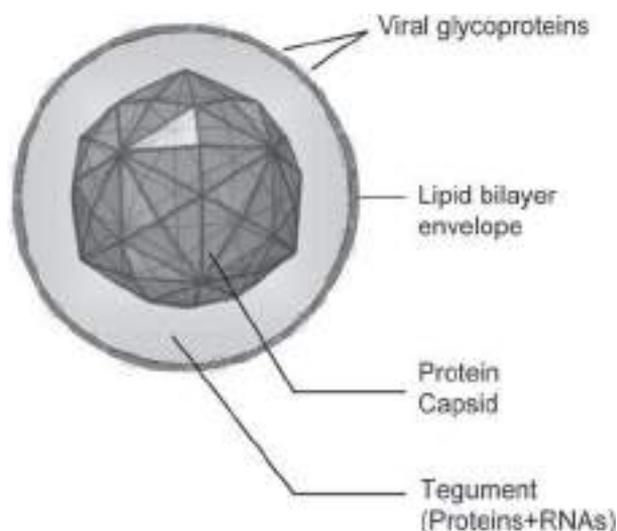

**FIGURE 5** Electron photomicrographs of KSHV virion formation and egress in a PEL cell line induced into lytic replication with TPA. A. Naked virus capsids are formed in the nucleus of the cell (NM, nuclear membrane). B. Virions budding through the nuclear membrane and becoming enveloped viruses. C. ### KSHV Structure

Typical herpesvirus virion structures of approximately 100-nm diameter have been detected in the nuclei of KSHV infected B cell lines 24–48 hours after chemical induction (10, 26) (Figure 5). Electron cryomicroscopic reconstruction shows that KSHV has a three-dimensional structure similar to those of other herpesviruses (Figure 6). The capsid shell is composed of 12 pentons, 150 hexons, and 320 triplexes arranged on an icosahedral lattice (27, 28). The primary capsid component is the major capsid protein (ORF25) that forms both the pentons and the hexons (29). Triplex proteins (ORF62 and ORF26 proteins), a small capsomere interacting protein (SCIP, ORF65), and the scaffolding protein (ORF17.5) are other components of the capsid. Similarities in capsid structure and replication mechanisms between herpesviruses and bacteriophage suggest that herpesviruses may have distantly evolved from these prokaryote phage viruses (30).

The space between the virus capsid and the viral envelope is filled with an amorphous protein structure called the tegument, which is organized into three prominent regions: a penton-binding globular region, a helix-bundle stalk region, and a  $\beta$ -sheet-rich triplex-binding region (31). The tegument is composed of specific proteins, such as ORF45 and ORF75 proteins (32, 33), that are microinjected into cells after viral membrane fusion with the host cell and prepare it for infection. Remarkably, the tegument also incorporates a number of viral mRNAs and small noncoding microRNAs

**FIGURE 6** Schematic diagram of KSHV enveloped virus structure. The capsid is composed of hexons, pentons, and triplexes arranged in an icosahedral lattice that contains the virus genome. This is surrounded by an amorphous tegument layer composed of viral and cellular proteins and viral RNAs that are microinjected into the cell on infection. The bilayer envelope surrounding the tegument contains viral glycoproteins such as gB that act as receptor and entry proteins.

**TABLE 1** KSHV genes with mitogenic or cell cycle regulatory functions

KSHV protein	KSHV gene	Features and functions	References
LANA1	ORF73	Activates multiple mitogenic and oncogenic pathways including $\beta$ -catenin, c-myc, ERK, hypoxia, surviving, Notch, and BMP-SMAD1-IDs pathways	(191–198)
vCyclin	ORF72	Associates with cdk6 to phosphorylate RB and histone H1; Phosphorylates and downregulates p27; Promotes high density cell proliferation and cellular transformation	(199, 200, 204)
vFLIP	ORF71	Induces lymphoma; Transform rodent fibroblasts; Activate NF- $\kappa$ B; Induce inflammatory cytokines	(215, 222, 223, 289, 290)
vGPCR	ORF74	Induces cellular transformation, angiogenesis, and VEGF in rodent fibroblast; Signals through heterotrimeric G proteins, JNK/Sapk, p38/HOG, and Akt	(291–294)
vIL-6	ORF K2	B-cell proliferation factor; Induces angiogenesis and VEGF in rodent fibroblasts	(101, 211)
vIRF-1	ORF K9	Cellular transformation	(228)
KIST	ORF K1	ITAM-mediated signaling, cellular transformation	(110, 218, 219)
Kaposin	ORF K12	Induces cellular transformation; Activates the p38/MK2 pathway	(295, 296)
K-bZIP/RAP	ORF K8	Inhibits G2/M transition	(48)

(miRNAs) (34–36) that similarly can directly act on their targets once injected into a new cell during the initial stages of infection.

### Replication of KSHV

KSHV has both lytic and latent life cycles. During lytic replication, the virus expresses its own DNA polymerase, replicates its own DNA, and generates hundreds to thousands of viral particles per cell over a 24- to 96-hour period, a process thought to invariably lead to cell death. During latent replication, viral DNA exists as a circular nuclear episome that relies on host enzymes for genome replication.

#### Lytic Replication

Lytic replicating viruses can be seen as massed nuclear inclusions containing electron-dense cores in KSHV-infected cells (10, 26). The virus replicates in the cell nucleus and packages its genome into the viral capsid as a linear molecule that acquires an initial membrane envelope by budding through the inner nuclear membrane. Components of this membrane mature as the virus passes through the outer nuclear membrane and transits through the Golgi apparatus, where the virus incorporates specific viral glycoproteins prior to reaching the plasma membrane. A number of viral proteins including gB, K8.1, ORF33, ORF67, and ORF69 have been identified as participating in this process (37–39). The virus can be released from the cell by direct plasma membrane budding, although release through exocytic vesicles is thought to be more common (40).

The lytic viral genome replicates through a rolling circle mechanism from the circular genome, like the unrolling of a tape, producing a linear strand of concatenated genomes. The KSHV genome concatemer is packaged into the nascent capsid through a portal protein complex (41) and cleaved within the terminal repeat region, resulting in a linear viral genome having variable numbers of terminal repeat sequences at both ends. Lytic viral genome replication is most efficient when cells enter the S phase (40, 42), and KSHV genes expressed during lytic replication act to overcome the G1/S cell cycle checkpoint (35, 43, 44) as well as to disarm host cell innate immune signaling pathways

(Tables 1 and 2) (45–47). During late stages of infection, structural component proteins of the capsid are synthesized; the capsid forms on a putative scaffolding that is turned over or incorporated into the capsid as the virion matures.

Rapid viral synthesis after initiation of lytic replication results in many capsids being only partially filled (29), and only a portion of virus produced during lytic replication is fully mature and transmissible. When KSHV lytic replication is initiated, early genes alter cell cycle transit (48) and inhibit cellular mRNA processing and stability to maximize production of viral DNA (49). Simultaneously, nonstructural KSHV gene expression alters the cell to prevent adaptive and innate immune activation. Although anti-apoptotic proteins are expressed during lytic virus replication to prolong survival of the infected cell (Table 3) (50–52), damage caused by host protein synthesis shutoff (49), fragmentation of viral DNA (53), and activation of innate immune signaling (54) pathways ultimately lead to host cell death during lytic replication.

#### Latent Replication

During latent viral replication, the viral genome is present in cells as an extrachromosomal circular episome (plasmid). This may limit activation of DNA damage responses from free viral DNA ends. The viral DNA is replicated in tandem with host DNA by using the host cell machinery so that stable copy numbers of KSHV are maintained in latently infected cells. Latent viral gene expression is highly restricted to viral proteins and miRNAs essential for maintaining the viral episome and preventing premature cell death and senescence (Table 3) (55, 56). The bulk of KS tumor cells infected with KSHV are in a latent state, and less than 5% of tumor cells are actively undergoing lytic replication at any one time.

#### KSHV Tropism and Primary Infection of Cells

KSHV primarily infects B-cells and endothelial cells but also can infect dendritic cells, macrophages, epithelial cells, fibroblasts, and mesenchymal stem cells in laboratory cell culture. Initially, the virus attaches through electrostatic interactions with heparin sulfate (57) and then initiates

**TABLE 2** KSHV genes with immune evasion functions

KSHV protein	KSHV gene	Features and functions	References
vIRF1	ORF K9	Inhibits interferon-related transcription	(228, 229)
vIRF2	ORF K11.1	Inhibits PKR signaling	(235)
LANA1	ORF73	Inhibits IRF3 activation; Prevents MHC I peptide processing; Inhibits CIITA by blocking the IRF-4 binding to pIII and pIV promoters and by binding to RFX complex	(234, 252, 253, 255)
LANA2 (vIRF3)	ORF K10.5	Inhibits IRF7 activation; Antagonizes PKR signaling; Inhibits the PML-mediated transcriptional repression; Inhibits expression of interferon- $\gamma$ and CIITA	(236, 243, 254)
RTA	ORF50	Targets IRF7 for degradation	(231)
ORF45	ORF45	Blocks IRF7 activation to inhibit type I interferon induction	(233)
vIL-6	ORF K2	Abrogates signaling from the interferon- $\beta$ receptor; Polarizes anti-KSHV immune signaling towards Th2 response	(101, 260, 261)

vMIP-II	ORF K4	Chemotaxis; Polarizes anti-KSHV immune signaling towards Th2 response	(260, 261)
vMIP-III	ORF K4.1	Chemotaxis; Polarizes anti-KSHV immune signaling towards Th2 response; Acts as a CCR4 agonist and stimulates angiogenesis	(260, 261)
RIF	ORF10	Blocks Jak1/Tyk2-STAT2 interferon signaling	(238)
ORF63	ORF63	Inhibits NLRP1-dependent innate immune responses	(241)
ORF64	ORF64	Reduces RIG-I ubiquitination to inhibit its activation and suppresses RIG-I-mediated interferon signaling	(239)
MIR1	ORF K3	Functions as an E3 ligase; Downregulates surface expression of MHC I; Inhibits cell surface presentation of T cell costimulatory molecule B7.2, NKT cell CD1 signaling, and interferon- $\gamma$ receptor	(237,248–250 257, 258)
MIR2	ORF K5	Functions as an E3 ligase; Downregulates surface expression of MHC I, NKG2D ligands MICA and MICB, and NKp80 ligand AIICL; Inhibits cell surface presentation of T-cell costimulatory molecule B7.2, NKT cell CD1 signaling and interferon- $\gamma$ receptor	(237,248–250257–259)
ORF75	ORF75	Antagonizes ND10-mediated intrinsic immunity	(242)
KIST	ORF K1	ITAM-mediated signaling; Mimics activated B-cell receptor (BCR)	(218, 219, 247)
vCBP	ORF4	Complements inhibitory protein; Mimics BCR signaling; Promotes survival of infected B cells	(220)
miR-K1	miR-K1	Downregulates I $\kappa$ B $\alpha$ ; Activates NF- $\kappa$ B pathway	(298)
miR-K11	miR-K11	Decreases IKK $\epsilon$ -mediated IRF3/IRF7 phosphorylation; Inhibits the activation of IKK $\epsilon$ -dependent ISGs	(232)

membrane binding (through interactions with integrins  $\alpha 1\beta 3$ ,  $\alpha v\beta 3$  and EphrinA2) (58–60) and membrane fusion (through xCT interactions) (61). The presence of these receptors on the cell surface largely determines whether a host cell is susceptible to KSHV infection.

KSHV-receptor interactions activate a number of cellular pathways, including MEK/ERK, JNK, p38, and FAK pathways, that are needed for KSHV entry and transport to the nucleus (62–65). KSHV enters cells by endocytosis (66–68) and then undergoes activated intracellular transport by the cytoskeletal machinery to perinuclear regions, where it delivers the viral genome into nuclei (67, 69, 70).

The extent of cell-specific activation of signaling pathways during infection determines the expression of viral genes and the scale of viral lytic versus latent replication. Robust induction of the MEK/ERK, JNK, p38, and MSK pathways promotes lytic replication by activating the AP-1 and CREB1 transcriptional complexes, while the NF- $\kappa$ B pathway suppresses KSHV lytic replication and promotes viral latency (63, 65, 71, 72). In human foreskin fibroblasts and dermal microvascular endothelial cells, KSHV has a short and limited scale of lytic gene expression and quickly enters latency upon infection (73). In human umbilical vein

endothelial cells, KSHV has a robust lytic replication program producing high titers of infectious virions before entering into latency (35, 74).

### Latent and Lytic Gene Expression

Initiation of lytic replication begins with a highly choreographed cascade of gene expression that determines the sequence of events leading to linear genome replication, virion synthesis, genome packaging, and egress of the virus from the infected cell (75, 76). Lytic replication begins with immediate-early expression of the replication and transcription activator protein, RTA, encoded by ORF50 (75, 77). RTA in combination with the transcription factor RBP-J $\kappa$  activates its own promoter (78), resulting in a positive feedback loop to generate sufficient RTA to maintain the remaining steps in lytic or productive virus replication. PKC, ERK, JNK, p38, MSKs, H-Ras, hypoxia, and ER stress promote KSHV lytic replication by inducing RTA expression through activation of transcriptional factors including c-Fos, c-Jun, CREB1, Ets-1, HIFs, and XBP-1 (Figure 7) (63, 65, 72, 79–84).

Viral lytic gene expression is associated with increased histone activation marks such as histone H3 trimethyl Lys4

**TABLE 3** KSHV genes with anti-apoptotic and anti-autophagic functions

KSHV protein	KSHV gene	Features and functions	References
vFLIP	ORF K13	Activates canonical and noncanonical NF- $\kappa$ B pathways; Promotes cell survival; Induces spindle morphology; Inhibits autophagy by preventing Atg3 from binding and processing LC3	(205–207, 221–223 289, 290)
vBCL-2	ORF16	Inhibits Bax-mediated apoptosis; Suppresses cellular autophagy pathway by interacting with Beclin1 complex	(50, 215)
vIL-6	ORF K2	Act as a B-cell proliferation factor; Prevents apoptosis in IL-6-dependent plasmacytoma cells; Induces angiogenesis and VEGF in rodent fibroblasts	(101, 211)
LANA1	ORF73	Promotes cell survival by inhibiting p53 and p73 pathways and TGF- $\beta$ signaling	(109 Santag, 2013 #611, 299)
LANA2	ORF K10.5	Inhibits p53 mediated transcription	(99)
vIAP	ORF K7	Inhibits apoptosis by binding to Bcl2 via BH2 domain and blocking caspase-3 activity via BIR motif; Interacts with rubicon to inhibit autophagosome maturation by blocking Vps34 enzymatic activity	(51, 216)
vIRF-1	ORF K9	Inhibits p53; Induces Bim nuclear translocation to inhibit apoptosis	(214, 300)
vIRF-4	ORF K9	Inhibits p53	(301)
K-bZIP	ORF K8	Inhibits p53	(213)
RTA	ORF50	Inhibits p53; Induces autophagy during viral lytic replication	(302, 303)
miR-K1	miR-K1	Activates NF- $\kappa$ B pathway by downregulating I $\kappa$ B $\alpha$	(298)
miR-K10	miR-K10	Inhibits TGF- $\beta$ signaling and TGF- $\beta$ -induced apoptosis	(115)
miR-K11	miR-K11	Inhibits TGF- $\beta$ signaling and TGF- $\beta$ -induced apoptosis	(304)

(H3K4me3) and decreased repressive histone marks such as H3 trimethyl Lys27 (H3K27me3), resulting in chromatin unwinding (85, 86). Similarly, phorbol esters and histone deacetylase inhibitors that cause chromatin modifications can induce KSHV reactivation (87–90). The most abundant KSHV transcript during lytic replication, the long non-coding PAN RNA (polyadenylated nuclear RNA, ORFK7), is involved in epigenetic regulation of viral and cellular gene expression by interacting with demethylases UTX and JMJD3 and PRC2 complexes (91, 92). PAN RNA is required for viral reactivation in part by binding to LANA1 and sequestering LANA1 away from the KSHV genome to counter its repressive effects on lytic gene expression (92, 93). Cellular molecules identified as negative regulators of lytic replication promote viral latency and include KAP1, HEY1, SIRT1, and several miRNAs (88, 94–97).

Latent KSHV gene expression, in contrast, is constitutive, and not dependent on the replication status of the virus, although it may be regulated by cell cycle stage or tissue type (98–100). Individual genes are often referred to as “latent” or “lytic” genes, although in reality their expression patterns are controlled by a number of factors beyond the KSHV replication cycle. Some viral genes encoding proteins, such as vIL-6, that are induced during lytic replication are also induced entirely independently of lytic replication (101). Notch signaling has been demonstrated to induce a wide variety of KSHV nonstructural genes without lytic viral replication (so-called class II genes) (102, 103). KSHV has many different gene expression profiles that depend on virus replication status, cell and tissue type, immune signaling and other factors—a complexity that is obscured by dichotomizing KSHV gene expression into only latent and lytic forms.

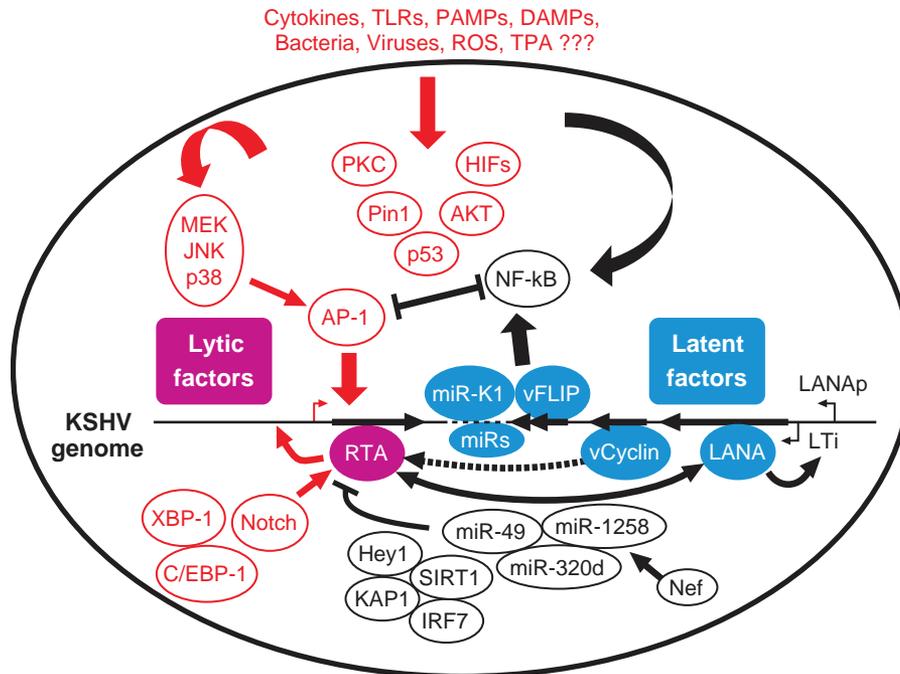

### Organization and Features of the KSHV Genome

The KSHV genome was first sequenced from the virus-infected lymphoma cell line BC-1 (11). Because of the ex-

tensive collinear homology between KSHV and the first sequenced rhadinovirus, herpesvirus saimiri, KSHV genes (or ORFs) are named according to their herpesvirus saimiri positional homologs (e.g., ORFs 4–75) if obvious gene similarity is present (Figure 3). Those genes unique to KSHV are given a K prefix starting from the left end of the genome (e.g., ORFs K1–K15) (11). KSHV is unique among the human herpesviruses in the extent of its extensive molecular piracy of genes from the host genome. These stolen genes include not only DNA replication genes found in other herpesviruses but also regulatory, cytokine, receptor, and immune signaling genes that contribute to KSHV-related pathogenesis.

The long unique region (LUR) is approximately 145 kilobases in size and possesses close to 90 viral genes thus far identified (Figure 3). Structural (e.g., capsid) and lytic replication genes common to other herpesviruses are present in the KSHV genome and tend to be grouped together. These KSHV genes generally share the highest degree of homology with other herpesvirus genes. Conservation of structural proteins leads to cross-reactivity with virion structural antigens of other herpesviruses in serologic assays, although this problem can in part be overcome by identifying unique antigens through peptide mapping (104–107).

DNA polymerase (ORF9), thymidine kinase (ORF21), and phosphotransferase (ORF36) (108) are conserved with other herpesviruses and are targets for antiherpesvirus drugs. KSHV has other DNA synthesis enzymes that are not found in most other herpesviruses, including a dihydrofolate reductase (ORF2), a ribonucleotide reductase (ORF66), and a thymidylate synthase (ORF70). The cellular counterparts to these genes are regulated by the retinoblastoma cell cycle checkpoint protein. KSHV probably uses these viral enzymes to overcome the G1/S checkpoint during lytic replication or by inducing an artificial S phase, which can allow viral DNA replication. These genes are also potential drug targets against lytic virus production.

**FIGURE 7** Schematic illustration of mechanisms of KSHV latency and reactivation. Expression of KSHV latent products including LANA, vCyclin, vFLIP, and miRNAs enhance/maintain latency by inhibiting KSHV lytic replication, promoting cell survival, and facilitating the viral episome replication and segregation. Several cellular factors such as NF- $\kappa$ B, Hey1, SIRT1, KAP1, and IRF7 as well as cellular miRNAs inducing miR-1258 and miR-320d repress KSHV lytic replication. In contrast, several physiological factors including hypoxia, HIV infection, inflammatory cytokines, oxidative stress, and ROS can induce RTA expression by activating specific cellular pathways and transcriptional factors including MEK/ERK, JNK, p38, AP-1, MSKs, Ets-1, Pin1, HIF1/2, PKC, and Notch. RTA interacts with several host proteins such as XBP-1, Notch, and C/EBP $\alpha$ , as well as viral proteins such as MTA and kb-ZIP to induce the expression of viral lytic genes and activation of the entire viral lytic transcriptional program.

While genes required for lytic replication are largely conserved with other herpesviruses, those genes expressed during latency are unique to KSHV. KSHV, for example, does not possess direct sequence homologs to any of the EBV latency genes, such as the Epstein-Barr nuclear antigens (EBNAs) or latent membrane proteins (LMPs). Despite these genetic differences, KSHV and EBV tend to target the same regulatory cellular circuits. In general, KSHV has pirated, modified, and targeted cellular genes for use during its replication and survival, while EBV tends to regulate these same pathways using complex viral transcriptional activating proteins. As an example, KSHV encodes an IL-6 homolog whereas EBV LMP1 induces expression of cellular IL-6; many other parallel examples exist. Conserved and non-conserved genes are segregated into blocks of genes, which tend to be regulated together.

The KSHV pirated genes express proteins that function similarly to host proteins but have modified regulatory functions. Known homologs to cellular genes include a complement binding protein (KCP), vIL-6, viral macrophage inflammatory proteins (vMIPs or viral CC-chemokine ligands, vCCLs), vBcl-2, viral interferon regulatory factors (vIRF1, vIRF2, LANA2, and vIRF4), a viral FLICE-inhibitory protein (vFLIP), a viral cyclin (vCyclin), a viral adhesion molecule (vOX2 or vAdh), and a viral G-protein-coupled receptor (vGCR, ORF74). Additional KSHV proteins, such as LANA1 and KIST (KSHV immunosignaling transducer or ORF K1 protein), do not have known cellular homologs but have roles similar to those of oncoproteins found in other viruses (109, 110).

KSHV encodes a large number miRNAs that are expressed during latency (111). A number of KSHV miRNAs share seed sequences with cellular miRNAs. KSHV miR-K11 mimics miR-155 (112, 113), miR-K10a/b and variants mimic miR-142-3p variants (114, 115), and miR-K3 (variant miR-K3+1) mimics miR-23a/b/c (116). KSHV miRNAs mediate viral latency by suppressing lytic replication, and promote cell growth and survival (56).

Recent mapping of KSHV transcripts and 3' UTRs by high throughput sequencing (117–120) have revealed a far more complex KSHV transcriptome than previously described (103): over one third of the genes may be bicistronic and polycistronic. The extended 3' UTRs of these transcripts are presumably regulated by a variety of mechanisms including targeting by miRNAs, providing additional layers of unexpected complexity in controlling viral gene expression (121).

## EPIDEMIOLOGY

KSHV-related diseases are a major unmet public health problem. Although the incidence of AIDS-associated KS declined 70% to 90% after the introduction of effective antiretroviral therapy, these drugs do not inhibit KSHV infection and a second emergence of KS among persons with low HIV loads and high CD4<sup>+</sup> cell counts has been reported (122, 123). Clinical manifestations such as immune reconstitution inflammation syndrome (IRIS)-KS in the era of cART pose additional new challenges (1, 124). Finally, although KSHV is poorly transmissible through transfusion,

**TABLE 4** Patterns of KSHV infection and KS prior to the AIDS epidemic

KS incidence	Regions	Population KSHV prevalence	Transmission	Risk groups
Low	North America, North Europe, East Asia	0–5%	Sexual, iatrogenic	Homosexual men, STD attendees, transplant recipients
Intermediate	Mediterranean, Middle Eastern countries, Caribbean	5–20%	Sexual, iatrogenic, nonsexual	Homosexual men, STD clinic attendees, transplant recipients, older adults
High	Africa	>50%	Nonsexual, sexual	Children, older adults, lower socioeconomic status

this route of transmission can occur and may cause silent infection and disease (125, 126).

### Distribution and Geography

Unlike other human herpesviruses, KSHV is an uncommon infection (~2% to 3%) in North American and northern European populations (Table 4) (127). Rates of infection are higher among Mediterranean, Eastern European, and North-Western Chinese populations, and highest in African populations, particularly Central-Eastern African populations (9, 128–131). This correlates generally with the worldwide distribution of KS disease prior to the emergence of the AIDS epidemic (Figure 4) (129). There are population-wide correlations between KSHV infection and KS disease rates, as seen by comparing provincial Italian KSHV infection rates in blood donors with historic pre-AIDS rates of KS disease with increasing rates of infection and disease occurring in a north-to-south gradient along the Italian peninsula (128, 132). Not all studies, however, find a close geographic correlation between infection rate and disease. Despite overall low infection rates in the Americas, very high KSHV infection rates are present among isolated South American indigenous populations (133–135). Viral genotypes isolated from these Amerindian populations most closely match KSHV strains isolated in Asia, suggesting that the virus first migrated with humans to the Americas across the Bering Strait thousands of years ago (Figure 4) (136).

### Transmission

#### Sexual Transmission

In American and European populations, the groups at highest risk for KSHV infection are men who have sex with men (MSM), in whom infection rates range from 30% to 60% (Table 4) (9, 130, 131). While compelling evidence indicates that KSHV is sexually transmitted (Figure 8), the specific behaviors resulting in KSHV transmission are disputed. Heterosexual transmission appears to be uncommon in these areas.

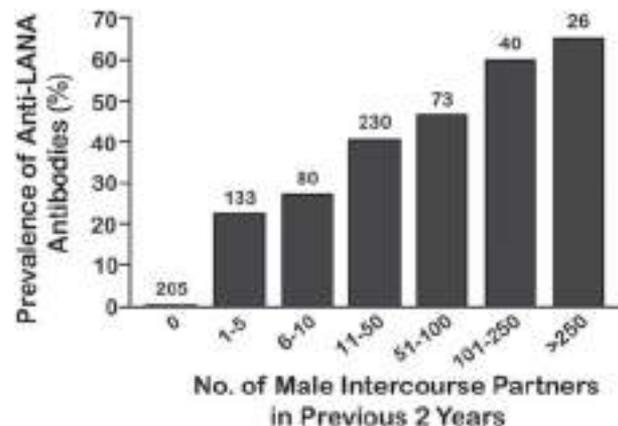

KSHV is not appreciably shed into semen and direct transmission through unprotected anal intercourse is unlikely. KSHV, like most other herpesviruses, is asymptotically shed from the oropharynx (137). A significant risk factor for virus transmission among homosexual men has been found to be deep kissing, although oral-penile contact and oral-anal contact are also significant risk factors for infection or seroconversion (138, 139). Since heterosexual couples also engage in kissing and oral-penile contact, the reasons MSM couples are much more susceptible to infection remain unclear. Use of saliva as a sexual lubricant for anal intercourse may also contribute to high infection rates.

#### Nonsexual Transmission

Explanations for the extremely high endemic rates of KSHV and KS in sub-Saharan Africa are also lacking. KSHV infection is common among presexually active African children. Areas of relatively high endemicity in Europe, including Italy, also show evidence for horizontal nonsexual transmission among children and possibly among adults (140). Congenital and perinatal mother-to-child transmission is rare, but transmission from mothers to older infants and children may be more common (141, 142), presumably related to oropharyngeal shedding and saliva contact (143, 144).

Initial investigations of KSHV among AIDS patients found that persons infected with HIV through blood products had low rates of KS (5). This led to the assumption that the agent causing KS is not transmitted by transfusion. However, case-control studies demonstrate that the virus is detectable in approximately one-half of peripheral blood mononuclear cell (PBMC) samples from AIDS-KS patients using standard PCR techniques (145), and the rate of virus detection may be dependent on the level of host immunosuppression (146).

Direct demonstration of bloodborne transmission has been found in both U.S. and African studies (2, 125, 126). Transfusion transmission is less efficient than for other viruses (~4% per infected transfusion) (126) and may be markedly reduced by blood processing. Despite the low

**FIGURE 8** KSHV seroprevalence increases linearly with numbers of recent sex partners in this population-based sampling of gay and bisexual men (sera collected in 1984) from San Francisco. This and related risk-factor data suggests that KSHV is sexually transmitted although the precise mechanism for transmission remains unclear. (From Martin et al., (319) with permission.)

efficiency of bloodborne transmission, large numbers of transmission events might take place in the United States alone each year.

### Transplantation

KSHV transmission during transplantation presents the most immediate public health concern that is amenable to simple interventions. Initial high rates of transplantation-related KS have been reported (147, 148) but these rates have precipitously declined with lowered immune suppression regimes (149). European studies demonstrate KS resulting from transplantation is principally due to reactivation of KSHV infection. Approximately one third of transplant KS patients are infected from the donated organ (150). The rate of disease among KSHV-positive transplant patients can be strikingly high, between 25% and 68% (151, 152). Intriguingly, some KS tumors are derived from the donor rather than the recipient, suggesting that transmission of tumor cells rather than infectious virus contributes to transplantation KS (151, 152). Transmission can occur after transplantation of any organ including heart, bone, as well as liver and kidney, and all KSHV-related diseases including KS, PEL, MCD, and bone marrow failure, have been reported in the transplant setting. Mortality and graft loss is high among transplant KS patients (153), strongly arguing for primary screening.

### African KS Epidemic

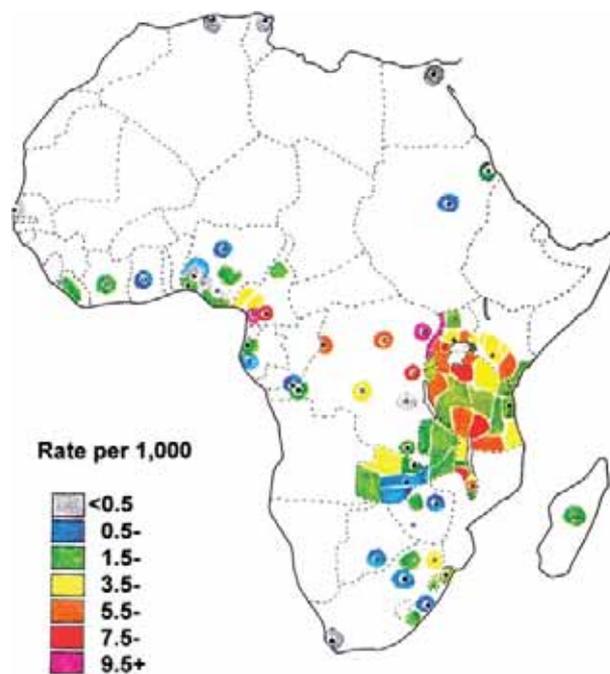

Prior to the AIDS epidemic, KS was the third most commonly reported tumor in some areas of Africa (Figure 9). With the onset of the AIDS epidemic, rates of KS have dramatically risen and it is now the most commonly reported cancer in many sub-Saharan African countries. In Zimbabwe, for example, KS accounts for 31% of cancers (154) and in Uganda it is the most common tumor in males and the second most common in females (behind cervical cancer) (155). Unlike the North America and Europe, men and women have similar KSHV infection rates in African countries (156). KS tumors, however, are more common in men, leading to speculation for a role of sex hormones in disease expression.

KS is virtually nonexistent among children from developed countries, but it is one of the most common cancers among African children (157). Pediatric KS is a fulminant disease that spreads via the lymphatic system, generally resulting in death within a year (157). As previously indicated, horizontal transmission appears to be the predominant means of infection (142).

## CLINICAL MANIFESTATIONS AND PATHOGENESIS

### Primary Infection in Humans

Primary KSHV infection is generally asymptomatic; rare cases of seroconversion-associated atypical lymphocytosis with mononucleosis-like symptoms (158) and rashes with or without fever have been reported in immunocompetent children from regions of high KSHV seroprevalence (159, 160). In immune-suppressed individuals, KS can develop within weeks or months of primary infection. For transplant patients infected by organ donation, KSHV-related diseases can erupt within 2 to 6 months of transplantation, indicating that the incubation period for KS is primarily dependent on the state of immune surveillance rather than length of time of infection. Among Dutch and American homosexual cohorts with both HIV and KSHV infection, those persons infected with KSHV first and HIV second tend to have a

**FIGURE 9** Map of KS prevalence throughout Africa prior to the AIDS epidemic. This map was constructed from surveys performed by Denis Burkitt who first described Burkitt's lymphoma. It is evident that KS was hyperendemic throughout this continent. With the onset of the AIDS epidemic, a second epidemic of KSHV-related cancer has occurred and KS is the most commonly reported cancer in most sub-Saharan African countries.

lower rate of developing KS (161, 162), suggesting that HIV-induced immune dysfunction impairs immunologic surveillance and control for KSHV.

### Kaposi's Sarcoma

KS is a complex tumor characterized by proliferation of spindle-shaped, KSHV-positive endothelial cells forming abnormal slit-like vascular channels. KS lesions frequently contain inflammatory infiltrates comprised of lymphocytes and macrophages suggesting an immune response against tumor-specific antigens. Neoangiogenic vessels can also be seen in KS tumors but these are negative for KSHV and are distinct from the disorganized tumor endothelial cells (163).

KS often first appears on the skin (Figure 10), particularly of the extremities, face, and genitalia but can disseminate to mucosal surfaces, lymphoid tissues, and viscera, especially in immunocompromised patients. KS skin lesions initially appear as bruised or discolored macules that progress to nodules and plaques, often with ulceration in late stages of disease. Advanced disease may be associated with edema and spread to surrounding lymph nodes. Gastrointestinal dissemination is frequently asymptomatic and can be difficult to diagnose because of submucosal infiltration by the tumor. Pulmonary involvement has a markedly worse prognosis than isolated skin or mucocutaneous disease and also may be difficult to distinguish radiologically from other opportunistic infections.

At initial presentation, KS lesions can be confused with other conditions or even simple bruises "that don't go away." The Koebner phenomenon, where KS tumors appear at the site of an old scar, is not uncommon. The differential diagnosis, particular among HIV/AIDS patients, should include

bacillary angiomatosis (due to *Bartonella*) and even skin manifestations of *Mycobacterium haemophilum*. KS tumors can occur in combination with MCD in lymph nodes or with PEL in visceral cavities, resulting in a mixed tumor cell population and complex clinical presentation.

All forms of KS (classical, endemic, epidemic, and iatrogenic) are KSHV positive, histologically indistinguishable, and differ only in clinical or epidemiologic characteristics. Classical KS is generally an indolent tumor occurring in elderly patients, particularly men of Mediterranean, Eastern European, or Middle Eastern ethnicity. No specific risk factors for classical KS have been identified although country or region of birth (139, 164) and receipt of blood transfusions (165) may be associated with elevated disease risk. HIV-seronegative homosexual men also appear to be at increased risk for classical KS (166).

Endemic or African KS is similar to classical KS in having a male predominance but can be a progressive and rapidly fatal disease, especially in children. While the geographic pattern of occurrence in Africa overlaps with EBV-associated Burkitt's lymphoma, areas with high rates of KS and Burkitt's lymphoma are not identical (167). Endemic KS is not associated with specific immunodeficiency al-

though some patients may have diminished responses to skin test antigens (168).

AIDS-KS or epidemic KS is clinically aggressive, and visceral involvement is common. Male homosexual and bisexual AIDS patients are approximately 20 times more likely to present with KS at AIDS diagnosis than hemophilic AIDS patients (5), and cohort studies demonstrate that up to one half of homosexual/bisexual men with AIDS develop KS over the course of their lifetimes. The reported proportion of U.S. AIDS patients with KS as an initial AIDS-defining condition has declined since the beginning of the AIDS epidemic, perhaps due to changes in sexual practices (5) and the use of potent antiretroviral therapy. However, there is an increased incidence of KS-IRIS, which often has high mortality rates, particularly in sub-Saharan Africa (1).

#### Primary Effusion Lymphomas (PEL)

Primary effusion lymphomas (PEL) are a rare type of non-Hodgkin B cell lymphomas first described in AIDS patients as body cavity-based lymphomas (BCBL) (169). PEL are infected by KSHV at high copy number (50 to 150 viral genome copies/cell). The KSHV populations infecting a particular PEL are monoclonal by viral terminal repeat

**FIGURE 10** A. Typical appearance of KS lesions on arm and chest for an AIDS patient. B. KS frequently involves mucosal surfaces, in this case sublingual palette. C. Disseminated skin KS occurring in a dermatomal distribution on the back of an AIDS patient. D. An AIDS patient's leg showing post-radiation hyperpigmentation, ulceration, and nodular KS lesions that have recurred within the radiated area. (Photos courtesy of Bruce Dezube, Beth Israel Deaconess, Boston, MA, and Susan E. Krown, Memorial Sloan-Kettering Cancer Center, NY, NY.)

analysis, indicating that each lymphoma arises from a single KSHV infected cell. Although PELs are most frequently observed in the setting of AIDS and coinfecting with EBV, PELs solely infected with KSHV have been described for both HIV-positive and HIV-negative patients (170). PELs characteristically present as intracavitary pulmonary, abdominal, or cardiac effusions with tumor cells growing in suspension. Usually there is no direct local tumor destruction or invasion into serous membranes although spread to lymph nodes and lymphatics occurs, and circulating lymphoma cells can be isolated from the peripheral blood (9, 171). Extracavitary PEL have been reported (172).

PEL are composed of postgerminal center, preterminally differentiated malignant B-cells. Consistent with their plasmablastic stage of differentiation, the PEL tumor cell phenotype is inclusive of CD45 and CD138/syndecan-1 but exclusive of CD19, CD20, and CD79a/b antigens (173). Although PEL do not usually express surface B-cell markers, they have clonal immunoglobulin chain rearrangements and display lymphocyte activation markers including CD30, CD38, CD71, and epithelial membrane antigen (7, 169, 174). PEL tumor cells have morphologic features that span those of large cell immunoblastic lymphomas and anaplastic large cell lymphomas with abundant atypical mitosis, marked nuclear/cytoplasmic pleomorphism, and prominent nucleoli. These lymphomas consistently lack genetic alterations that have been associated with other lymphomas, including activation of the proto-oncogenes *c-Myc*, *Bcl-2*, and *Ras* as well as mutations of *p53* (169, 175). However, recurrent chromosomal gains have been detected in six chromosomes (176). A search for driver mutations that complement KSHV in PEL tumorigenesis has revealed strong evidence that mutations to X-chromosome-linked interleukin 1 receptor-associated kinase (*IRAK1*) are likely to be critical to PEL etiology (320).

The majority of PEL are described in patients with compromised immune status, especially those with AIDS. In these individuals, PEL respond poorly to therapy and are highly aggressive, often rapidly fatal with a median survival of 2 to 3 months after initial diagnosis (177). Symptoms are frequently due to the mass effect of the rapidly expanding malignant effusion on adjacent vital organs, and drainage procedures can provide short-term symptomatic and functional relief. In contrast, PEL often have a much less aggressive course in HIV-seronegative patients, and they tend to occur in elderly persons.

### Multicentric Castleman's Disease

Castleman's disease is a rare non-neoplastic, lymphoproliferative disorder related to excess IL-6-like activity. It encompasses a spectrum of clinicopathologic entities that range from circumscribed involvement of localized lymph nodes, referred to as unicentric Castleman's disease (UCD), to generalized lymphadenopathy, also called multicentric Castleman's disease (MCD) (178). Castleman's disease patients can be infected by KSHV with or without HIV coinfection or may be found in patients with no evidence of infection with either virus. Histologically, Castleman's disease is divided into two subtypes: hyaline-vascular and plasma-cell variants, but mixed forms of the two can be juxtaposed in a single lymph node. The majority of the hyaline-vascular variant occurs in a clinical setting of UCD and presents as solitary lymph node hyperplasia typically in the mediastinum or retroperitoneum. Other than isolated nodal enlargement, patients have few other symptoms and surgical excision of involved lymph nodes is curative. In

contrast, the plasma cell histologic variant is most frequently correlated with multicentric or generalized involvement, and is challenging to treat. Clinically, MCD patients present with a variety of proinflammatory systemic symptoms including fever, night sweats, and fatigue. Physical examination is often notable for cachexia and hepatosplenomegaly in addition to generalized lymphadenopathy. Laboratory findings include anemia, hypergammaglobulinemia, hypoalbuminemia, elevated inflammatory markers, and high circulating levels of IL-6 and IL-10. Intercurrent diseases frequently diagnosed with MCD or during follow up include Kaposi's sarcoma, lymphomas, and hemophagocytic lymphohistiocytosis (HLH) (179, 180).

KSHV infection is present in essentially all cases (99.7%) of MCD occurring in HIV-infected individuals; and in approximately a quarter to half of MCD in HIV-seronegative patients (181). In MCD, KSHV infected cells have a distinctive distribution. Immunohistochemical localization studies show that KSHV-infected cells comprise a minority population of B-cells in the mantle zones, which surround germinal centers (182–184). These infected cells have a plasmacytoid immunoblastic or plasmablastic morphology and express abundant KSHV vIL-6 (182) supporting the notion that Castleman's disease is a syndrome of multiple etiologies involving aberrant IL-6 activity.

### Other Disorders Associated with KSHV

KSHV is identifiable in several rare lymphoproliferative disorders in addition to PEL, which can be broadly grouped as PEL-like solid lymphomas, plasmablastic proliferations arising in MCD, and germinotropic lymphoproliferative disorder. Descriptive names given these entities include KSHV-associated large B-cell lymphoma (KSHV-LBL), intravascular large B-cell lymphoma, and HHV8+ plasmablastic microlymphoma/lymphoma (172, 185, 186). The literature suggests a significant degree of overlap in these entities with PELs and MCD in terms of phenotypic markers, EBV status, and HIV status. Non-neoplastic diseases including bone marrow failure and some forms of autoimmune hemolytic anemia in the setting of Castleman's disease have been attributed to KSHV infection (19, 182).

### Pathogenesis

The specific mechanisms by which KSHV induces tumor formation remain incompletely defined and vary in each of its associated diseases. KSHV is a monoclonal infection in PELs, which are clearly composed of fully transformed B cells (11, 171, 187). KS lesions, in contrast, can be oligoclonal or polyclonal but probably evolve into monoclonal lesions with disease progression (11, 188). The bulk of cells in KSHV Castleman's disease MCD lesions, in further contrast, consist of hyperplastic, uninfected, untransformed cells. Only a fraction of cells, localized to the marginal zone of germinal centers, are infected with KSHV. Interestingly, while these infected cells are not monoclonal, they tend to show monotypic lambda light chain expression (189). Among the three main KSHV-associated human diseases, the mechanistic underpinning of KSHV MCD is most accessible, can be attributable to KSHV vIL-6 expression, and even has a naturally occurring human disease counterpart, KSHV negative MCD. KSHV MCD is the first recognized disorder that is likely to be caused by a virus-encoded cytokine.

### Cell Transformation and Proliferation

KSHV is primarily in a latent, unencapsidated, and non-transmissible form in KS lesions and PELs. While a small

percentage of tumor cells undergo productive virus replication at any one time, the bulk of tumor cells are noninfectious. Therefore, genes expressed during latency are likely to play important roles in KSHV-induced malignancies. Several of these genes have oncogenic functions (Tables 1 and 3). For example, LANA1 is functionally similar to SV40 T antigen in that it targets and inhibits both p53, which controls apoptotic signaling (109), and retinoblastoma protein (pRB1), which is responsible for cell cycle regulation (190). LANA1 has been reported to activate a myriad of mitogenic and oncogenic pathways including  $\beta$ -catenin (191), c-myc (192, 193), ERK (194), hypoxia (195), survivin (196), Notch (197), and BMP-SMAD1-IDs (198) pathways. vCyclin affects the cell cycle in inducing pRB1 phosphorylation by partnering with cyclin-dependent kinases (199, 200). The functions of vCyclin appear to be very similar to those of the cellular class of D cyclins, although vCyclin can also induce phosphorylation of H1 (201, 202). This suggests that vCyclin may be active at stages of the cell cycle other than the G1 checkpoint controlled by pRB1. KSHV vCyclin has been shown to counter the senescence/G1 arrest response triggered by NF- $\kappa$ B hyperactivation (203) and to promote KSHV-induced cellular transformation by overriding contact inhibition (204). Activation of the NF- $\kappa$ B

pathway and inhibition of the autophagy pathway by vFLIP are essential for the survival of latent cells (205–207). Several KSHV miRNAs provide oncogenic and pro-survival signals (Table 5). Deletion of a cluster of 10 pre-miRNAs triggers cell cycle arrest and apoptosis in KSHV-transformed cells (208). Thus, these viral miRNAs are required for maintaining the homeostasis of KSHV-transformed cells.

Several viral proteins traditionally associated with lytic replication also activate oncogenic pathways and promote cell survival. vGCR and vIL-6 have mitogenic activity that promote cell cycle entry and may lay the cell cycle groundwork for genome replication (Table 1). Surprisingly, some KSHV proteins, such as K-bZip appear to arrest the cell in late G1 by interacting with the cyclin-dependent kinase CDK2 (48) and by activation of the cyclin-dependent kinase inhibitor p21 (209). This is counterintuitive to the goal of generating an S-phase state for the infected cell and raises the interesting possibility that aberrant arrest may benefit viral DNA over cellular DNA replication.

Many of the functions of the proteins encoded by the viral homologs of cellular genes affect apoptotic signaling. KSHV viral inhibitors of apoptosis including K-bZip, vIRF-1, RTA, vBcl-2, vIL-6, and vIAP are expressed at high levels after KSHV enters lytic replication, and which effectively

counter innate stress response and prevent premature cell death to ensure the completion of lytic replication (50, 53, 101, 210–214). Some of these proteins are expressed at low levels during virus latency, suggesting the possibility that they may also contribute to tumor cell survival. KSHV also manipulates autophagy to counter stress by targeting autophagy protein Beclin1 (215), preventing Atg3 from binding/processing LC3 (207) and blocking Rubicon-mediated autophagosome maturation (216) (Table 3). vFLIP inhibition of autophagy is essential for preventing cells from vCyclin-induced senescence (217).

KSHV also employs several other mechanisms to promote cell survival. For example, KSHV promotes B-cell survival by mimicking an activated B cell receptor (BCR) (218–220). While vFLIP was first described as a dominant-negative inhibitor of Fas-signaling pathways activated during cell-mediated immune killing (221), it is now recognized that it has a more active role in inducing NF- $\kappa$ B signaling, contributing to infected cell survival and proliferation (222, 223). Multiple KSHV miRNAs also activate the NF- $\kappa$ B pathway (208).

Direct KSHV transformation of primary human cells remains elusive. However, a single clone of transformed cells has been isolated from long-term culture of KSHV-infected telomerase-immortalized human umbilical vein endothelial cells (TIVE-LTC) (224). Cell cultures from mouse bone marrow endothelial-lineage cells transfected with a KSHV genome cloned in artificial chromosome (BAC36) (225) can also induce KS-like tumors when subcutaneously inoculated into SCID/NOD mice (226). More recently, it has been shown that KSHV can efficiently infect and transform rat mesenchymal stem cells (227). Subcutaneous inoculation of the KSHV-transformed cells into nude mice induced KS-like tumors expressing markers of lymphatic endothelial, vascular endothelial and mesenchymal precursor cells. The highly efficient nature of this model makes it useful for investigating the functions of KSHV genes in cellular transformation (204, 208).

### Immune Evasion

KSHV possesses a number of proteins that target both adaptive and innate immunity (Table 2). Multiple nodes for both type I and type II antiviral interferon signaling are manipulated by KSHV, including interferon-related transcription (101, 228, 229) and the related IRF3, IRF7, and IKK $\epsilon$ -proteins (230–234); RNA dependent protein kinase (PKR) signaling (235, 236); interferon- $\alpha$  and - $\gamma$  receptors (237, 238); and RIG-I activation (239). The inflammasome is induced during KSHV infection (240); however, KSHV blocks NLRP1-dependent innate immune responses (241).

Other components of the innate immune system manipulated by KSHV include ND10-mediated intrinsic immunity (242), PML-mediated transcriptional repression (243), C/EBP $\beta$  transcriptional activation of IL-6 and IL-10 (244), NKG2D mediated elimination by natural killer (NK) cells through activation-induced cytidine deaminase (AID) (245), expression of the stress-induced NK cell ligand, MICB (246) and BCR (247), and complement attack during lytic replication (220) (Table 2).

KSHV uses several strategies to prevent efficient viral immune clearance (Table 2). KSHV targets MHC I by inhibiting the processing of viral peptides and down-regulating their plasma membrane presentation to evade CTL surveillance (42, 248–252) and MHC II by inhibiting IRF-4 transactivation of the promoters of CIITA and interferon- $\gamma$  (253–255). Inhibition of MHC I and II prevents

the opportunities for the host immune system to sample viral peptides and blocks initiation of specific CTL responses against latently infected cells (256). During latency, KSHV protein expression is kept to minimal levels to avoid immune recognition, and those proteins that must be expressed to maintain the virus have evolved structural features to inhibit antigen presentation or to mimic host epitopes. KSHV proteins also play a role in inhibiting the cell-surface presentation of costimulatory molecules required for T-cell receptor activation such as B7.2 (257), CD1 involved in NKT cell signaling (258), and the interferon- $\gamma$  receptor (237). Reduction of cell surface expression of the NKG2D ligands MICA and MICB and the ligand for NKp80, activation-induced C-type lectin (AICL), via its ubiquitin E3 ligase activity, provides a novel way for KSHV to evade NK cell antiviral functions (259). Furthermore, KSHV-secreted proteins, including vIL-6 and three virus-encoded chemokines, may help polarize anti-KSHV immune signaling towards an antibody-predominant Th2 response rather than a cell-mediated Th1 response (260, 261).

### LABORATORY DIAGNOSIS

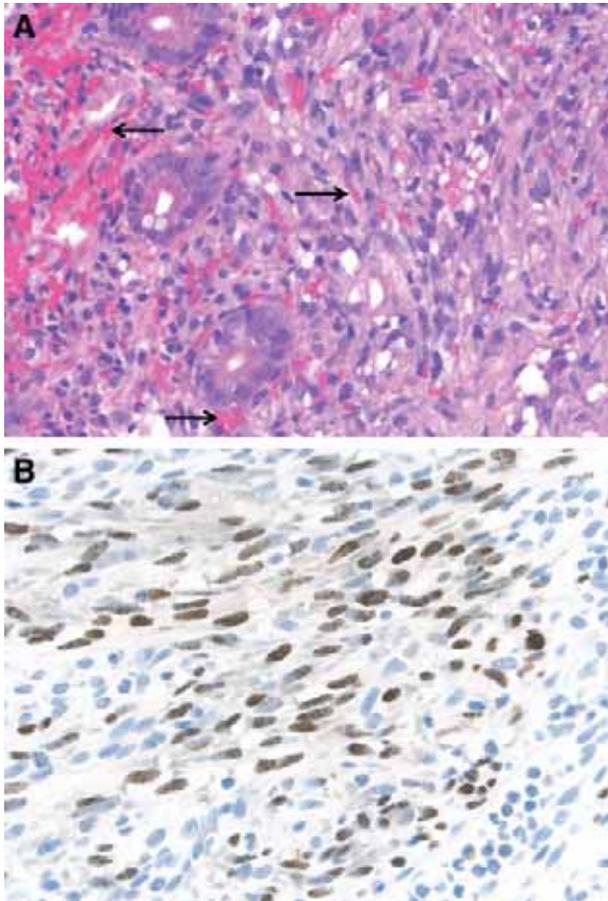

#### Diagnosis and detection

Direct virus culture from patient specimens is not performed because of the technical limitations in primary isolation of KSHV in cell culture. PCR, however, has been used extensively as a research tool to detect viral DNA in tissues. While PCR detects KSHV DNA sequences in nearly all of the KS tumors examined to date, this technique is of limited use when examining peripheral blood mononuclear cells (PBMC), since only 1 in 50,000 to 1,000,000 cells are normally infected (145). Given the small amounts of circulating virus in infected individuals (including those with advanced KS), PBMC preparations are PCR positive only in about one half of patients with KS. Nested PCR, which is plagued by problems of contamination, is frequently required to detect the virus genome under these conditions. Pathologic diagnosis of KSHV-associated diseases from tissue biopsies or cytology is usually straightforward and can be confirmed by immunostaining for LANA1 (Figure 11) (184), a viral protein expressed in every KSHV-infected cell regardless of histogenesis.

#### Serologic Assays

Serologic assays have reasonable sensitivity and specificity in detecting KSHV infection (Table 6). No assay is currently approved for routine use in patient screening. The most common assays use whole-cell antigen preparations from KSHV-infected PEL cell lines in an indirect immunofluorescence assay (IFA) format (12). These assays are divided into latent or lytic antigen assays depending on whether or not the virus is induced into lytic replication through the use of TPA or another chemical agent. IFA assays, which tend to be labor intensive and require specialized training, are generally being supplanted by ELISA-based assays using recombinant antigens.

Latent-antigen IFAs detect antibodies directed against the ORF73-encoded LANA1 protein (262, 263). This highly charged nuclear phosphoprotein clusters in discrete nuclear speckles and migrates on immunoblots as a ca. 220 to 230 kiloDalton doublet despite its predicted molecular weight of 150 kilodaltons (130). Assays based on LANA1 IFA use unstimulated whole PEL cells, preferably adhered to glass slides using a cytospin technique, in which the characteristic LANA1 nuclear speckling pattern of staining is

**FIGURE 11** A. A photomicrograph of KS tumor infiltrating the duodenum on an AIDS patient. All forms of KS (both HIV+ and HIV-) have similar histologic appearances. Vascular clefts (arrows) within the tumor are filled with red cells, giving the tumor its characteristic reddish-brown appearance. A mononuclear infiltrate in the tumor can be present but cellular atypia or pleomorphism is generally uncommon in KS lesions ( $\times 40$  magnification). B. Typical speckled nuclear staining pattern (brown) for LANA1 antigen can be seen in many cells of a skin KS tumor ( $\times 60$  magnification). (Photos courtesy of Liron Pantanowitz, University of Pittsburgh, Pittsburgh, PA.)

present (9, 131). LANA1 positivity is usually determined at a 1:100 or 1:160 serum dilution and extremely high antibody titers ( $>1:100,000$ ) are not uncommon. This assay gives a 70% to 85% sensitivity rate in experienced hands and is generally highly specific. Generation of recombinant or peptide-mapped LANA1 epitopes tends to reduce assay sensitivity (264). In part this can be overcome by use of baculovirus-prepared antigen, suggesting posttranslational modifications of immunodominant LANA1 epitopes. Immunoblotting for LANA1 gives similar results as does whole-cell IFA but extra effort is needed to efficiently transfer the antigen on gel electrophoresis because of its high molecular weight (130).

Lytic-antigen IFA assays generally have higher sensitivity than LANA1 assays but lower specificity. PEL cells non-specifically bind low-affinity human antibodies (9) and thus serum dilutions less than 1:40 are likely to lead to a false-positive reaction. When appropriately counterstained, diffuse cytoplasmic staining at 1:40 or greater dilution on lytic antigen IFAs can have sensitivity greater than 95%.

**TABLE 6** Serologic antigen assays for detecting KSHV infection

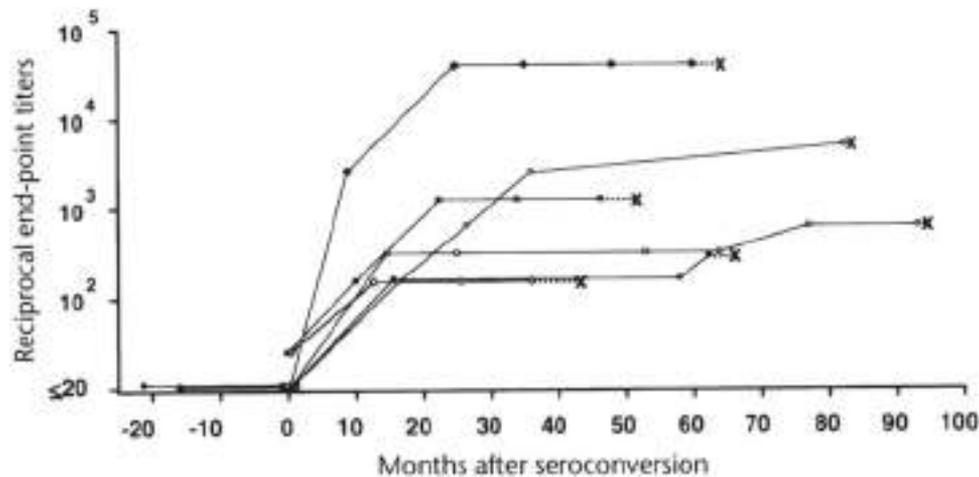

Antigen	Gene	Sensitivity	Specificity	Format
LANA1	ORF73	~80%	High	WB, ELISA
K8.1A, B	K8.1	>90%	Intermediate	WB, ELISA, peptide ELISA
SCIP	ORF65	~80%	Intermediate	WB, ELISA
Whole cell (latent)	—	80%	High	IFA, WB
Whole cell (lytic)	—	>95%	Low	IFA, WB

Given concerns about antigenic cross-reactivity in the lytic IFA, considerable effort has been put into development of recombinant lytic protein antigens. Most recombinant assays rely on two proteins, a viral glycoprotein similar to EBV gp220/350 that is encoded by K8.1 and a small capsomere protein, SCIP, encoded by ORF65 (104, 106, 265). Epitope mapping of both proteins has been performed and peptide ELISAs have been developed which work well, particularly for the K8.1 peptide (105, 266). Some cross-reactivity of the amino terminus for KSHV ORF65 protein occurs with EBV hyperimmune sera but this can largely be avoided by using either a truncated C-terminus fragment or a synthetic peptide epitope.

Use of recombinant antigen ELISA has distinct advantages in terms of cost, reproducibility and ease of use. Individual sensitivities for these assays tend to be less than those of whole cell IFAs, but combinations of recombinant antigen assays (including a recombinant LANA1 fragment assay) can be used to achieve greater than 90% sensitivity (267). A combined three-antigen ELISA algorithm using K8.1 and ORF65 peptides together with recombinant LANA1 has been optimized to have ~93% sensitivity and 95% specificity (107). As in the diagnosis of other virus infections, recombinant antigen ELISAs are often used for screening followed by immunoblot assay confirmation. Antibody responses to KSHV tend to be rapid and persistent (Figure 12).

LANA1 antibodies often arise prior to ORF65 protein antibodies (particularly among HIV-infected persons) although exceptions to this are frequent (267, 268). Both LANA1 and ORF65 protein antibodies persist for years after infection and have stable titers throughout the asymptomatic period of infection (9, 267). Antibody titers may increase immediately prior to the onset of KS tumor formation, perhaps reflecting increased viremia concurrent with loss of immunologic control of the virus. However, the variability in absolute virus antibody titer in different individuals limits the usefulness of following antibody titers as a means of predicting onset of disease unless other risk factors are also taken into consideration (123).

For about 20% of HIV-positive persons, antibodies against LANA1 fail to develop at any time during the course of infection. In addition, seroreversion can occur during late-stage AIDS even in persons with florid KS (130). In contrast, persons with HIV-negative KS tend to develop robust humoral immune responses. When responses of HIV-negative KS patients are used as a "gold standard," the sensitivity of some assays may approach 100%, suggesting that assay performance may be affected by the types of populations for which it is used. This has been confirmed by studies showing

**FIGURE 12** Antibody responses to KSHV infection are persistent for years after initial infection. This graph shows the reciprocal end-point titers for six men with AIDS who seroconverted to LANA1 IFA positivity at time 0. Antibody positivity remained stable for up to 8 years until the patients developed KS (marked with an X). Note that anti-LANA1 titers are plotted on a log scale and in some patients can be positive at 1:50,000 dilution or greater. (From Gao et al., (9) with permission.)

loss of LANA1 reactivity, but not other KSHV antigens, among HIV patients with low CD4 counts (269).

## PREVENTION

Since the exact modes of transmission are unknown, practical prevention measures have not been developed. Avoiding deep-kissing or use of saliva as a sexual lubricant seem to be evidence-based, simple, and reasonable recommendations to avoid oropharyngeal spread during sexual activity. Condom use is of unclear benefit for preventing KSHV transmission because of limited shedding in semen but should be encouraged to prevent other sexually transmitted infections. While it is unknown whether safe-sex practices have any practical effect on KSHV transmission, clinicians should counsel both HIV-seropositive and HIV-seronegative patients to engage in safe-sex practices to reduce the risk of acquiring opportunistic pathogens such as KSHV as well as limit the spread of HIV.

Screening guidelines for KSHV in the transplant setting have not yet been formally established. Assays to detect KSHV are not readily available to most clinicians although they can be developed in-house by clinical laboratories with sufficient resources and expertise. Since rejection of otherwise healthy allografts from transplantation has critical clinical repercussions, only assays with high specificity (low false-positive rates) should be considered for screening. At this time, elimination of KSHV-infected allografts from transplantation is not routinely practiced. Knowledge of the infection status of the donor and the recipient may allow the clinician to either consider antiviral prophylaxis or to at least monitor the transplant patient for early signs of KSHV-related disease.

Antibody screening for transplant patients, if available, should be strongly considered, particularly for patients in whom reduction in immunosuppressive therapy would have a fatal outcome (e.g., heart, liver transplants). For these patients, if they are KSHV positive or received a KSHV-positive organ, careful follow-up, antiherpesvirus chemoprevention, and use of sirolimus can be considered.

There is no current development of a vaccine despite the established need in African and transplant populations.

Unlike other herpesviruses, KSHV has been naturally lost from many populations and is poorly transmissible in others. This suggests that immunogenic vaccines may be capable of preventing infection and, if effective latent antigens are included, used as therapeutic vaccines once infection is established.

## Chemoprevention

Chemoprevention is an important and underappreciated prevention possibility for persons at high risk for KS. *In vitro* assays suggest that cidofovir, foscarnet, and ganciclovir have higher specific activity against KSHV than acyclovir (108, 270, 271). A retrospective epidemiologic study shows that AIDS patients receiving foscarnet for prevention and control of CMV retinitis have a lower incidence of KS occurrence (272). In a prospective, randomized clinical trial AIDS patients receiving either oral or intravenous ganciclovir (plus intraocular ganciclovir implants) had 75% and 93% reductions, respectively, in onset of new KS tumors compared to placebo (273). Similarly, foscarnet treatment used to prevent CMV retinitis can delay or prevent KS recurrence and spread among persons with established KS (274). Thus far, these drugs appear to have little activity once KS is established but may prevent emergence of new tumors.

## TREATMENT OF KSHV-ASSOCIATED DISEASES

### Kaposi's Sarcoma

No specific antiviral therapy against KSHV has been developed to treat KS. KS is currently treated by surgical excision, intralesional or systemic chemotherapy, and localized irradiation. Localized tumors, particularly tumors in non-immunosuppressed individuals, can be excised or irradiated (up to 40 Gy over 20 fractions) with good outcome. KS is, however, a systemic viral disease and local therapy does not prevent dissemination to other sites. Similarly, intralesional injection with vinblastine (0.2 mg/ml for 0.1 ml/cm<sup>2</sup> of tumor tissue) has a high partial response rate after single injection, but tumor regrowth is common. A wide range of chemotherapeutic agents either as single agents or in combination have moderate to good responses as palliative

agents in AIDS-KS. KS is also responsive to systemic interferon- $\alpha$  (1–50 MU/m<sup>2</sup>) but whether this is due to antitumor, immunomodulatory, or antiviral activity remains to be explored.

Several novel therapies are being investigated (275). In contrast to KS, KSHV MCD has been reported to respond to ganciclovir treatment (276) as well as to rituximab (277, 278). Combined use of zidovudine (AZT) and valganciclovir to target the viral phosphotransferase and thymidine kinase appear to be particularly effective in treating MCD (321). In tissue culture cells, nutlin-3a, a reactivator of p53, prevents LANA1 interaction with p53 and MDM2, thereby leading to apoptosis in PEL cells and KSHV-infected endothelial cells (279–281). Sirolimus and similar mTOR inhibitors are effective in controlling classical and transplant KS in contrast to other traditional immunosuppressive agents that induce KS (282). While AIDS-KS patients had partial responses to rapamycin, pharmacokinetic interactions with antiretroviral drugs were observed resulting in a greater than 200-fold escalation of higher doses (283). Molecular studies have identified a number of pathways such as ERK, XBP-1, and ROS hydrogen peroxide that mediate KSHV reactivation. Targeting these pathways might have preventive and therapeutic benefits. In a PEL mouse model, the use of hydrogen peroxide scavenger N-acetyl-L-cysteine (NAC) was sufficient to inhibit KSHV lytic replication, progression of PEL, and significantly prolongs the lifespan of the mice (284).

Among AIDS patients, the most reliable control measure for KS is effective antiretroviral therapy. The rate of new KS diagnoses is markedly lower among persons on highly effective antiretroviral therapy (272, 285). Despite the efficacy of effective antiretroviral therapy, treatment has no apparent effect on long-term KSHV carriage, and as the AIDS population ages there are worrisome reports of reemergence of KS among patients with low HIV loads and high CD4+ counts (1, 122).

### Multicentric Castleman's Disease

Treatment for HIV and KSHV coinfecting MCD is not standardized at present; however anti-CD-20 (rituximab) alone or in combination with chemotherapeutics (etoposide, vinblastine, cyclophosphamide, chlorambucil, doxorubicin, and vincristine) appears to confer symptomatic and survival benefits (181, 286). Although anti-CD-20 treatment of MCD may lower the risks for subsequent development of lymphoma, it can perversely exacerbate flares of KS disease and HLH in some patients (287). In a treatment strategy based on the targeting of the IL-6-driven pathogenesis of MCD, human anti-IL-6 antibody (siltuximab) has been demonstrated to attain a significant level of durable tumor regression and symptomatic response for MCD in HIV and KSHV negative individuals (288).

# Adenoviruses

OLLI RUUSKANEN, JORDAN P. METCALF, MATTI WARIS, AND GÖRAN AKUSJÄRVI

## 27

Adenoviruses were first isolated in 1953 from adenoids and tonsils surgically removed from children (1). Soon after the recovery of adenoviruses from patients with respiratory illness, their role as a major cause of febrile infections in young children and in army recruits was recognized. The illness was originally called acute respiratory disease (or ARD), but the signs and symptoms are similar to those of other viral respiratory syndromes, which should replace the old nonspecific expression.

Adenoviruses are most closely linked with infections of the respiratory tract and conjunctivae and account for 5 to 8% of all pediatric respiratory illnesses. They are also an important cause of childhood diarrhea and have also been implicated in causing myocarditis, encephalitis, aseptic meningitis, hepatitis, and hemorrhagic cystitis. Adenoviruses are increasingly recognized as an important cause of morbidity and mortality in stem cell and solid-organ transplant recipients (2–6).

An effective oral vaccine for adenovirus types 4 and 7 was used in US basic military training populations from 1971 to 1997. During the break in production, adenovirus infections reemerged as the major cause of morbidity. After reintroduction of the vaccine in 2012, marked reductions in adenovirus-related illnesses occurred (7–9).

## VIROLOGY

### Classification

Adenoviruses are widespread in nature and have been isolated from a large number of species, including fish (*Ichtaedenovirus*), amphibians (*Siadenovirus*), reptiles (*Atadenovirus*), and the two most-studied genera, those isolated from primates (*Mastadenovirus*) and birds (*Aviadenovirus*) (10). There is no common antigenic determinant that characterizes the whole family. However, all members of the Adenoviridae family have virus particles of similar sizes, structures and polypeptide compositions.

The human adenoviruses are a rapidly expanding class of viruses comprising more than 54 distinct serotypes that are grouped into seven species (A to G) originally based on serology, hemagglutination properties, oncogenic potential in rodents, and other biological characteristics. The species B adenoviruses are further divided based on tropism and other criteria (Table 1). Members within each species are

traditionally subdivided into serotypes based on immunologic differences. Antibodies directed against the two major capsid proteins, hexon and fiber, are the most important determinants in this classification. The genetic relatedness of serotypes within each species is high, and members of each species generally share greater than 85% DNA sequence homology, whereas serotypes belonging to different species show less than 20% homology (11). With the development of new rapid whole genome sequencing methods, the number of adenovirus types is rapidly increasing, the current number being 67. Adenovirus isolates, characterized and numbered based on genomic sequencing data, are often referred to as genotypes, whereas serotypes are reserved for strains classified by serological methods (12). Since the method of typing does not change the numbering, this chapter applies the widely accepted term “type.”

### Virus Composition

Adenoviruses are nonenveloped icosahedral (20 triangular surfaces and 12 vertices) double-stranded DNA viruses with a diameter of approximately 95 nanometers. The three-dimensional structure of the approximately 150-megadalton (MDa) adenovirus particle has been determined using atomic resolution by X-ray crystallography and cryoelectron microscopy (13, 14).

Figure 1 summarizes the current view of the arrangement of viral polypeptides in the virion. The capsid consists of 252 major capsomers; 240 hexons form the facets of the icosahedron, and 12 pentons, which are located at the corners of the virus particle. The hexon capsomer is a trimer of the hexon polypeptide held tightly together by noncovalent interactions. The pentons consist of two distinct structural entities: the penton base, which anchors the pentons to the capsid, and the fiber, which forms an elongated structure protruding from the vertices. The fiber is a trimer of polypeptide IV, and the penton base is a pentamer of polypeptide III. Adenoviruses belonging to different subgroups have fibers of different lengths and flexibility. The fiber shaft is built up from an approximately 15-amino-acid repeating motif. Hence, the length difference of the fibers results from a difference in the number of repeat units in the fiber shaft. The viral capsid consists of four additional minor capsid protein components, polypeptides IIIa, VI, VIII, and IX, whose location is graphically illustrated in Figure 1. Polypeptide VI binds to an inner cavity of the hexon capsomer

**TABLE 1** Classification of 54 types of human adenoviruses<sup>a</sup>

Species	Type	Site of infection	Receptor	Tumor in animals
A	12, 18, 31	Intestine, respiratory	CAR	High
B1	16, 21, 34, 35, 50	Respiratory, ocular, urinary tract	CD46	Weak
B2	3, 7, 14		Desmoglein-2	Weak
B3	11		CD46/DSG-2	Weak
C	1, 2, 5, 6	Upper respiratory	CAR	Low
D	8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, 51, 53, 54	Ocular, intestine	CAR Sialic acid (types 8, 19, 37)	Low
E	4	Respiratory	CAR	Low
F	40, 41	Intestine	CAR	Low
G	52	Intestine	Unknown	Low

and provides a link between the inside surface of the capsid and the viral DNA. Polypeptide VI is located underneath the peripentonal hexons and polypeptide VIII under the facets. Polypeptide VIII and polypeptide IX stabilizes capsid facets by forming interactions with neighboring hexon capsomers on the inside (pVIII) and the outside (pIX) of the capsid, respectively. Polypeptide IIIa is located at the inner capsid surface as a ring underneath each vertex region. The viral core consists of four proteins, polypeptides V, VII, X ( $\mu$ ), and TP (terminal protein). In contrast to most DNA viruses, adenovirus codes for its own basic histone-like proteins, V, VII, and  $\mu$ , that complex to the viral DNA within the virion. In addition, the termini of the viral DNA are covalently linked to the terminal protein (TP), which functions as a protein primer during viral DNA replication. For a more extensive review on virus structure (15).

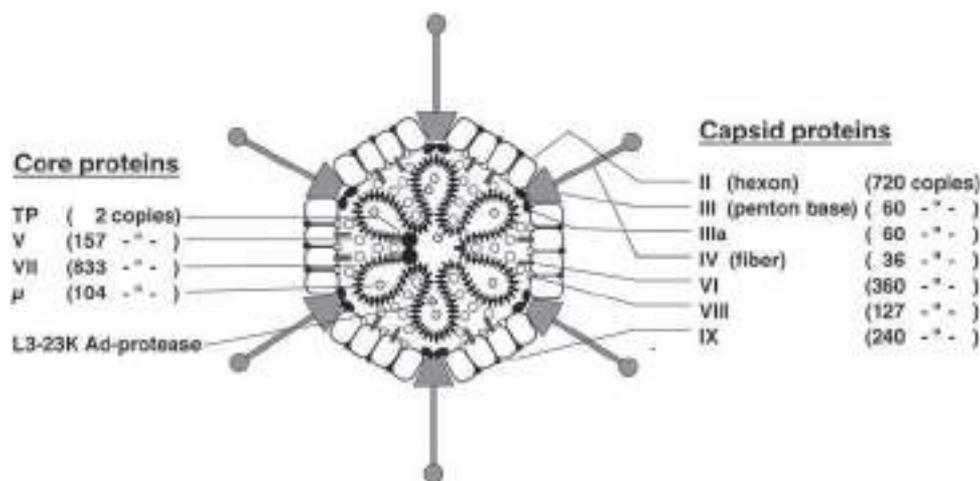

### Viral Genome

The viral genome consists of a linear dsDNA molecule with a length of approximately 30,000 to 38,000 base pairs. With the development of new rapid sequencing technologies, the entire sequences for a large number of human and animal adenovirus types have been established (see GeneBank). The lytic replication cycle is divided into two distinct phases: an early phase preceding viral DNA replication during

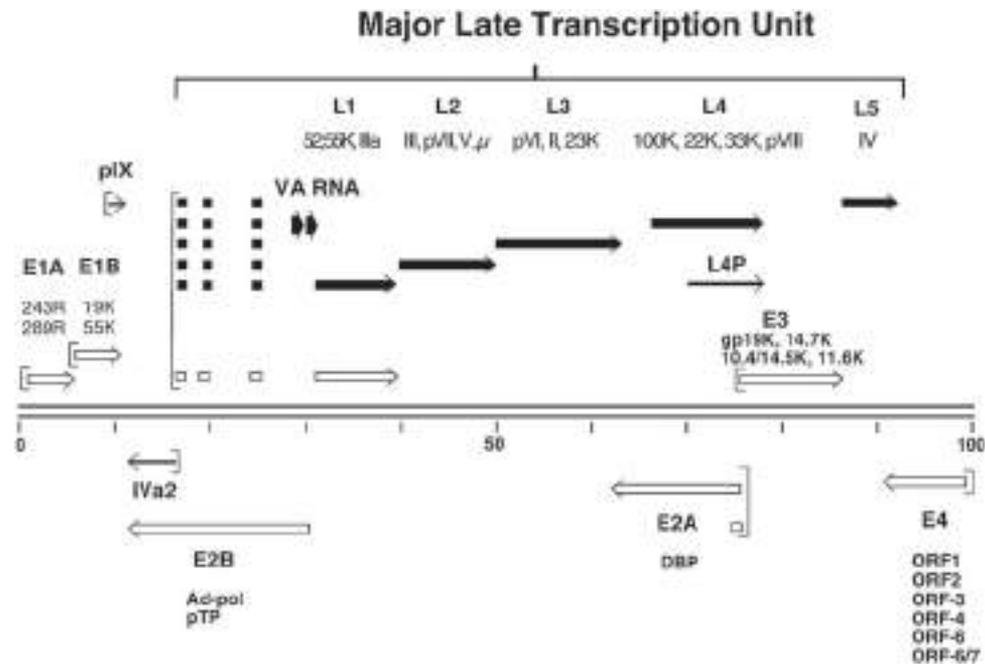

which mainly regulatory proteins are expressed, and a late phase that follows DNA replication and is characterized by the expression of the structural proteins of the viral capsid. The viral DNA encodes for 10 different RNA transcription units, 6 that are active early after infection (E1A, E1B E2A, E3, E4, and L1) and 4 that become activated at intermediate (pIX, IVa2, and L4P) and late (major late transcription unit) times of infection (Fig. 2). All transcription units, except pIX and IVa2, mature as a complex set of alternatively spliced mRNAs that codes for multiple proteins, many that have distinct biological activities (see below). In addition, adenoviruses encode for at least one (usually two) highly structured small RNAs, the so-called virus-associated (VA) RNAI and VA RNAII (16) that perform important functions during the lytic infection cycle by interfering with the interferon response pathway and the RNAi/miRNA machinery in cells (17).

### Biology

The replication cycle of adenovirus is summarized in Figure 3. This cycle takes approximately 30 hours in cultured cells and results in the production of approximately 50,000 to 100,000 new virus particles per cell. Here we will divide the replication cycle into four stages: entry, early events, late events, and virus assembly.

**FIGURE 1** Schematic model illustrating the architecture of the adenovirus virion. The current view of the location and the copy number of polypeptides are indicated for the core and capsid proteins. Adapted and updated from (263).

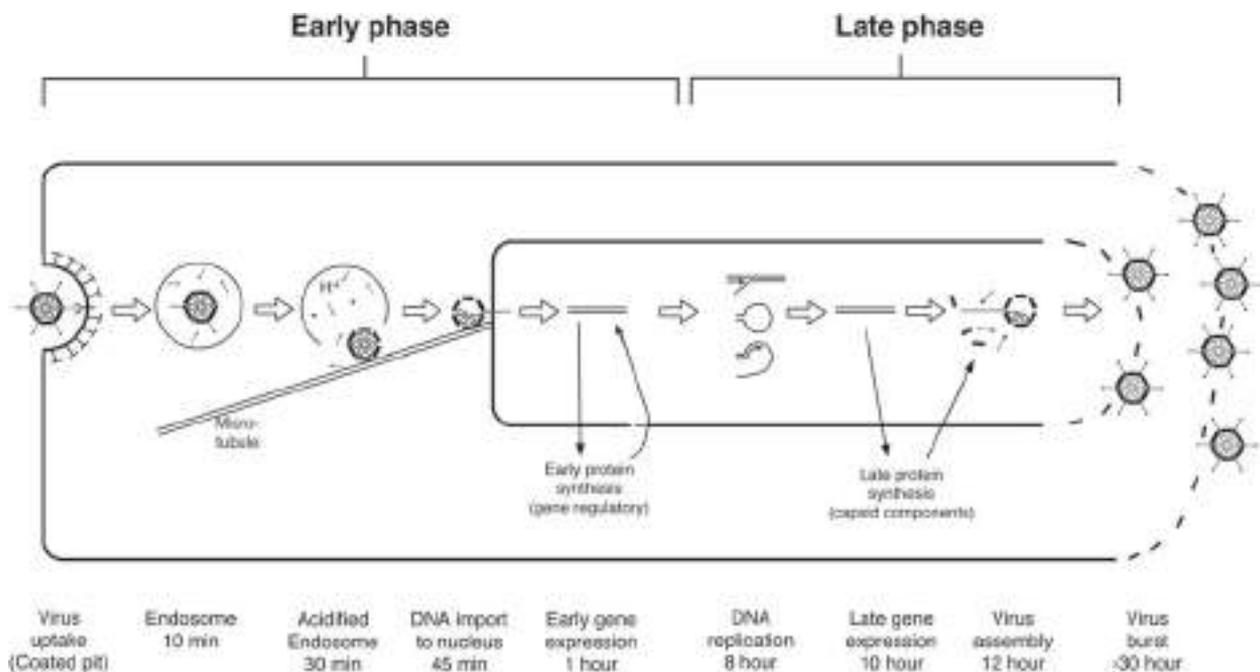

**FIGURE 2** Adenovirus transcription map here exemplified with human adenovirus type 2. Note that the alternatively spliced structure of individual mRNAs expressed from the different early and late units are not shown (42). White arrows indicate early transcription units, thin arrows intermediate transcription units and black arrows late transcription units.

### Entry

Adenovirus binds with high efficiency to two receptor types on the surface of the host cell; the primary receptor interacts with the carboxy-terminal knob region of the fiber, whereas the secondary receptor interacts with an RGD motif on the penton-base protein. The cellular receptors mediating the

initial binding of adenovirus to the cell surface has been identified for several types (Table 1). The best-studied adenovirus receptor is CAR, an immunoglobulin superfamily member-protein, containing two immunoglobulin-like extracellular domains, that is also used by Coxsackie B virus for infection (18). CAR appears to be a preferred primary

**FIGURE 3** Diagram of adenovirus replication cycle. The approximate time scale for the different steps in the adenovirus life cycle is indicated at the bottom of the figure.

receptor used by most types across species, except the species B viruses. In general, species B1 adenoviruses use the complement regulatory protein, CD46, for virus attachment, whereas species B2 viruses use desmoglein-2 as the high-affinity receptor (19). Also, some members of species D, which are associated with epidemic keratoconjunctivitis, use sialic acid as the primary receptor (20). Interestingly, adenovirus infects many cell types efficiently *in vitro*, while adenovirus infection *in vivo* of ciliated lung epithelia is relatively inefficient. This inefficiency appears to result from the fact that CAR plays a role in maintaining the integrity of tight junctions and therefore is sequestered on the basolateral side of polarized epithelial cells (21). Of interest, a single CAR isoform, which is translated from an alternatively spliced mRNA, traffics to the apical surface and is likely to mediate the initial binding of the virus to the airway epithelial cells (22).

Cellular integrins function as the secondary receptor promoting internalization of the virus, most often via clathrin-mediated endocytosis (23). With the exception of the species F viruses, Ad40 and Ad41, all characterized adenovirus types encode for a penton-base protein with an arginine, glycine, aspartic acid (RGD) peptide motif, which mediates the contact with the cellular  $\alpha\beta$  integrin adhesion receptors. In addition to the first-discovered  $\alpha\beta 3$  and  $\alpha\beta 5$  integrins, additional RGD binding integrins have been characterized (24). Penton-base interaction with the integrins facilitates adenovirus internalization by activating the mitogen-activated protein kinase (MAPK) and phosphoinositide-3-kinase (PI3) signaling pathways, which cause actin cytoskeleton rearrangement (25, 26). The vertex capsomer, the penton, is lost in the acidic endosome (Fig. 3). Following this opening of the capsid, polypeptide VI manages to escape from the interior of the virus particle. Polypeptide VI has a highly conserved amino-terminal amphipathic helix that tethers polypeptide VI to the endosomal membrane and case-membrane rupture (27, 28). After escape from the endosome, the partially dismantled virus is transported by the microtubule-associated kinesin-1 motor protein (29) to the nuclear membrane, where it docks to a nuclear pore complex (30). Here the final disassembly occurs to promote importation of the viral DNA into the nucleus. Virus entry is a highly efficient process with 40% of the particles bound to the cell surface delivering their DNA to the nucleus. Less than 5% of the incoming viruses fails to escape from the endosome and ends up in lysosomes for degradation (31).

### Early Events

Expression of the early viral mRNAs and proteins are temporally regulated during the infectious cycle. Thus, the first transcription unit to be activated is the E1A region, and transcripts from this region can be detected within 45 minutes after infection. The maximum rate of E1A transcription is then maintained for at least 16 hours. The E1A proteins are essential for the initiation of the lytic infectious cycle, since they are key regulators of both viral and cellular transcription and necessary for efficient S-phase entry of the infected cell (32, 33). E1A encodes for two major protein isoforms, E1A-289R and E1A-243R. The E1A-289R protein is the major transcriptional activator protein and is responsible for the activation of the early viral transcription units. E1A-289R activates transcription by recruiting the MED23 mediator subunit to the early viral promoters. E1A is not absolutely essential for early viral gene transcription. Thus, each early unit binds cellular transcription factors that promote a low level of viral transcription. However, at low

multiplicities of infection early gene expression needs to be boosted by the E1A-289R protein to initiate effective viral replication. Both the E1A-243R and E1A-289R proteins have the capacity to activate the cell cycle by binding the retinoblastoma (RB) family of proteins thereby derepressing E2F transcription factors, which are required for expression of genes required for cell cycle progression. The E1A proteins also sequester the cellular p300/CBP proteins, thereby contributing to the cell proliferative effect of E1A (33). The p300 and CBP proteins are considered as global transcriptional activator proteins that stimulate transcription by inducing histone H3 acetylation. Therefore, the sequestration of p300/CBP by E1A results, on many promoters, in a repression of cellular transcription.

Transcription from regions E1B, E3, and E4 begins around 1.5 hours postinfection. The E1B region encodes for two major proteins, the E1B-55K and the E1B-19K proteins (34). Both proteins serve key functions as suppressors of apoptosis in the virus-infected cell at multiple levels. E1B-55K binds to the activation domain of the p53 transcriptional activator protein, thereby converting p53 from an activator to a repressor of pro-apoptotic genes (32). The viral E1B-55K and E4-ORF6 proteins form a complex with several cellular proteins to form a Cullin5-based ubiquitin-ligase complex. This complex targets the p53 protein for ubiquitination and proteasomal degradation (35). The E1B-55K protein is the substrate-binding protein, whereas the E4-ORF6 protein mediates the contact with the ubiquitin complex. The E1B-55K/E4-ORF6 ubiquitin-ligase complex has several substrates, of which p53 and the cellular MRN complex are the best studied (32). The MRN complex is involved in DNA double-strand break repair by initiating the process of nonhomologous end-joining (NHEJ). The MRN complex needs to be inactivated in adenovirus-infected cells, since the NHEJ proteins disturb viral DNA replication by ligating the linear adenoviral DNA into long concatemers (36). The E1B-19K protein is a homolog of the cellular BCL-2 protein and inhibits apoptosis by sequestering the pro-apoptotic BAK and BAX in inactive complexes (34). In the absence of the E1B-19K protein, an adenovirus infection would cause the BAK and BAX proteins to oligomerize and form pores in the outer mitochondrial membrane, which would result in a release of apoptogenic proteins to the cytoplasm (34).

The E3 region encodes for proteins that counteract the antiviral defense mechanisms of host cells (37). The E3-gp19K glycoprotein protects the virus-infected cell from cytotoxic T-cell lysis by downregulating cell-surface expression of class I major histocompatibility complex (MHC) proteins. E3-gp19K binds and retains MHC in the endoplasmic reticulum, thereby reducing peptide presentation at the cell surface. The E3-14.7K protein inhibits TNF- $\alpha$ -induced apoptosis and the E3-10.4K/14.5K protein complex (the RID complex) inhibits apoptosis by internalizing and degrading the Fas-L and TNF-related apoptosis-inducing ligand (TRAIL) receptors. In contrast, the E3-11.6K adenovirus death protein (or ADP) has a pro-apoptotic activity and participates in the release of the virus after completion of the replicative state of the virus (38).

The E4 region encodes for six proteins, which have been named as open reading frames (ORFs), E4-ORF1, E4-ORF2, E4-ORF3, E4-ORF4, E4-ORF6, and E4-ORF6/7. The E4 proteins participate in a diverse set of activities during virus infection. The best characterized is the E4-ORF6 protein, which forms a complex with the E1B-55K protein and regulates protein stability, as described above. The E4-ORF6

and the E4-ORF3 proteins appear to serve redundant activities, and both proteins can individually replace the entire E4 region to support virus growth in tissue culture cells (39). The E4-ORF4 protein targets the cellular protein phosphatase IIA (PP2A) and redirects the phosphatase to new substrates in the infected cell. E4-ORF4 contributes to the virus replication cycle by downregulating early viral gene expression and inducing hypophosphorylation of various viral and cellular proteins, for example, transcription and alternative RNA splicing factors.

Region E2 is the last early transcription unit to be activated, and RNA synthesis begins around 3 hours post-infection. The E2 region encodes for the three viral proteins needed for viral DNA replication, the viral DNA polymerase (E2B-Ad-pol), the terminal protein (E2B-pTP), and the single-stranded DNA binding protein (E2A-DBP) (40).

### Late Events

The late phase of the replication cycle follows DNA replication, which begins around 8 hours postinfection in cell culture experiments. Adenoviruses use an unusual single-stranded DNA displacement strategy to replicate its DNA (40). Initiation of viral DNA replication requires origin sequences that are physically located within the approximately 100-base-pair long inverted terminal repeats located at both ends of the viral chromosome. Replication initiates at either the left or right origin sequence and results in the displacement of the complementary strand as a single-stranded molecule (Fig. 3). Because of the inverted terminal repeat sequences, the displaced single-stranded DNA molecule can form partial duplex DNA structures that can be used for initiation of DNA synthesis of the second strand. Initiation of adenovirus DNA replication occurs by a protein-priming mechanism, where the E2B-pTP, covalently attached to dCMP, the first nucleotide of the nascent strand, functions as primer for the virus-encoded DNA polymerase (E2B-Ad-pol). Elongation is rapid and processive and requires the viral single-stranded DNA binding protein (DBP), which binds to the displaced single-stranded DNA. Only about 10% of viral DNA is incorporated into new virions. Late after infection transcription initiates predominantly at the so-called adenovirus major late-promoter. Transcription from this promoter accounts for more than 30% of total RNA synthesis at late times of infection. This does not necessarily mean that the major late-promoter is a strong promoter, since efficient transcription requires viral DNA replication, which amplifies the number of DNA templates available for transcription initiation (41). The major late transcription unit generates five families of late mRNAs with coterminal 3'-ends (L1-L5; Fig. 2). Following selection of the poly(A) site, a complex set of mature mRNAs are generated by alternative RNA splicing (42). Most of the major late mRNAs encode for structural proteins of the virion (42). A few mRNAs encode proteins that are non-structural. For example, the L3-23K protease is required for proteolytic trimming of some capsid components late during virus maturation (43). The L4-100K protein is required for late viral protein synthesis and hexon trimer assembly and nuclear transport (44). The L4-22K and L4-33K proteins appear to be the key viral proteins regulating the accumulation of alternatively spliced late mRNAs (45). In addition, the L4-22K and the L1-52,55K proteins are required for viral DNA encapsidation (46, 47). Late during infection, large amounts of the adenovirus VA RNAs (VA RNAI and VA RNAII) are synthesized. VA RNAI protects virus-infected cells against the antiviral effect of interferon by binding to,

and preventing activation of, the interferon-induced eIF2 $\alpha$ -protein kinase (PKR) (17). In its active form, PKR would otherwise phosphorylate translation initiation factor eIF2, which would result in a general block of translation in virus-infected cells. The noncoding VA RNAs target the cellular RNAi/miRNA pathway and saturate the nuclear exportin 5 receptor and the cytoplasmic Dicer enzyme, thereby interfering with cellular miRNA biogenesis (17). Further, the VA RNAs are cleaved by Dicer into viral miRNAs (so-called mivaRNAs) that are incorporated into functional RNA-induced silencing complexes (RISC).

Late during infection cellular protein synthesis diminishes, resulting in almost exclusive translation of late viral proteins. Mechanistically this occurs by selective transport of late viral mRNAs to the cytoplasm, combined with an almost exclusive translation of mRNAs derived from the major late transcription unit late after infection. The rate of transcription of cellular genes is not inhibited, but nuclear to cytoplasmic transport of cellular mRNAs is strongly reduced in late virus-infected cells (48). Despite this inhibition of transport, viral mRNAs account for only 20% of the total cytoplasmic pool of mRNA. Nevertheless, more than 90% of total protein synthesis in late-infected cells is virus-specific. The mRNAs expressed from the major late transcription unit possess the unique ability to be translated independent of the normal cap-recognition process. During the late stage of infection, the early viral mRNAs and cellular mRNAs are not translated efficiently. The reason for the selective translation of the late mRNAs stems from the fact that all mRNAs produced from the major late transcription unit carry an identical long untranslated 5' sequence of approximately 200 nucleotides, the so-called tripartite leader. This sequence functions as translational enhancer and allows an mRNA to be translated in the absence of a functional cap-recognition complex. Inhibition of host protein synthesis has been shown to result from a virus-mediated block in cap-binding complex phosphorylation. The viral L4-100K protein blocks the association of the Mnk1 protein kinase that is responsible for phosphorylation of the eIF4E component of the cap-binding complex (49). Under these conditions the L4-100K protein binds to the tripartite leader and recruits the cap-binding complex selectively to the viral late mRNAs. Hence, a selective recruitment of the ribosome-to-tripartite leader-containing mRNAs has been shown to be crucial for the cap-independent translation of viral mRNAs in the late phase of infection.

### Virus Assembly

Most viral polypeptides are rapidly transported to the cell nucleus after synthesis. The early first step in virus assembly involves the formation of capsomers from monomeric polypeptide subunits: hexon, penton base, and fiber capsomers. The penton base and the fiber are then combined to form the penton, the vertex capsomer. Formation of the hexon capsomer requires the viral L4-100K protein, whereas fiber trimerization appears to be a spontaneous process. Structural components are made in huge excess in late virus-infected cells. Only 20% of hexon capsomers are incorporated into virions, and only 10% of viral DNA is encapsidated. Despite this wasteful process, as many as 100,000 virus particles are produced per infected cell (50).

The first step in the assembly process is the formation of so-called empty capsids. These appear to contain specific scaffolding proteins and the structural proteins of the virion, except for the core proteins and viral DNA. Empty capsids, which have a light density, mature into heavy intermediates

by encapsidation of increasing amounts of the viral DNA. A cis-acting packaging element has been localized at the left end of the viral DNA, immediately downstream of the left inverted terminal repeat (51). This sequence element causes a preferential encapsidation of viral DNA into an empty capsid beginning with the left end of the viral chromosome. The nonstructural virus encoded IVa2 protein has been implicated as a key ATP driven motor protein that drives the encapsidation of the viral DNA. IVa2 appears to reside at only one unique vertex and, together with the L4-22K protein, binds to the packaging sequence to facilitate the incorporation of the viral DNA into the empty capsid (47, 52, 53). The encapsidation process is complex, and many additional viral proteins have been implicated in the process. After DNA packaging is completed, the young virions mature into fully infectious virions by proteolytic cleavage of six capsid proteins that are made as precursor polypeptides (pIIIa, pVI, pVII, pVIII, pμ, and pTP). This final maturation step is carried out by the adenovirus protease (L3-23K) (43), which is an integral part of the virus particle (Fig. 1). The viral protease requires the viral DNA as a cofactor. The protease has been speculated to use the viral DNA as a guide to slide on, and to reach, all target substrates in the crowded capsid environment (54).

The replication cycle is completed by the release of new virus particles from the infected cell. The adenovirus death protein (ADP or E3-11.6K), which is synthesized at very late stages of infection (more than 20 hours postinfection), promotes cell lysis and appears to be the key factor that ensures efficient release of the virus from infected cells (38).

### Experimental Models

Adenovirus prototypes can be propagated in many different continuous cell lines, much of the data on adenovirus replication being produced using HeLa, KB, HEP-2, and A549 cells. Determination of infectious virus titers can be performed in cell cultures by plaque titration assays or immunostaining or a combination of both. Small animal models of adenovirus infection include mouse, Syrian hamster, cotton rat, and woodchuck. Other larger animals like cats and dogs have also been used, while most of the primate experiments have been performed in rhesus monkeys. Because of the large body of research on the use of adenoviruses as therapy vectors, fast molecular methods have been developed to assess the titer and quality of recombinant adenovirus stocks (55).

### Inactivation of Environmental Contamination

Nonenveloped adenoviruses with the dsDNA genome are physically and chemically among the most resistant viruses, and water-borne transmission is an important route for epidemic spread of adenovirus infections. Effective water disinfection is achieved with ozone or chlorine treatment (56). For thermal inactivation in liquid, heat-treatment at 70°C or more for 20 minutes or more is recommended (57). Ultraviolet light doses normally used in water treatment are relatively ineffective against adenoviruses, but polychromatic, as compared to standard monochromatic, ultraviolet light shows increased efficiency (58). For surface decontamination, oxidative disinfectants are to be preferred (59).

## EPIDEMIOLOGY

Adenovirus infections occur worldwide as causes of endemic and epidemic illnesses. The most common adenovirus types

in clinical specimens are the low-numbered respiratory types of species C (types 1, 2, and 5) and B (types 3 and 7), as well as the gastroenteritis types 40 and 41. In the comprehensive WHO epidemiological study from 1967 to 1976, types 2, 1, 7, 3, and 5 (in decreasing order) made up 90% of the 24,184 typed isolates (60). This study did not, however, include types 40 and 41, which could not be isolated during that time. A U.S. study from 2004 to 2006 with 2,237 adenovirus-positive specimens collected from 22 medical facilities found that adenovirus types 3 (35%), 2 (24%), 1 (18%), and 5 (5%) were the most prevalent. In children younger than 7 years, types 1 and 2 were more prevalent than in older children (61). In a recent 4-year study from Finland, types 3 (32%), 4 (22%), 2 (17%), and 1 (9%) were most prevalent among 499 cases; an outbreak of type 3 was evident during autumn of 2010 (Fig. 4) (62). In another recent 8-year prospective study from Spain, types 3, 6, and 5 were most frequent (63).

Since 2003, adenovirus type 14 has emerged and spread throughout the United States causing outbreaks in military training centers and among civilians (64). The causative strain was shown to be a variant type 14 (“14p1”), and the observed virulence was evidently a result of increased transmission in the absence of immunity, rather than increased pathogenicity of the strain (65). The spread of 14p1 has also been reported from Europe and China (66–68). An outbreak of severe pneumonia was associated with 14p1 infections among prisoners in Scotland in 2011 (69).

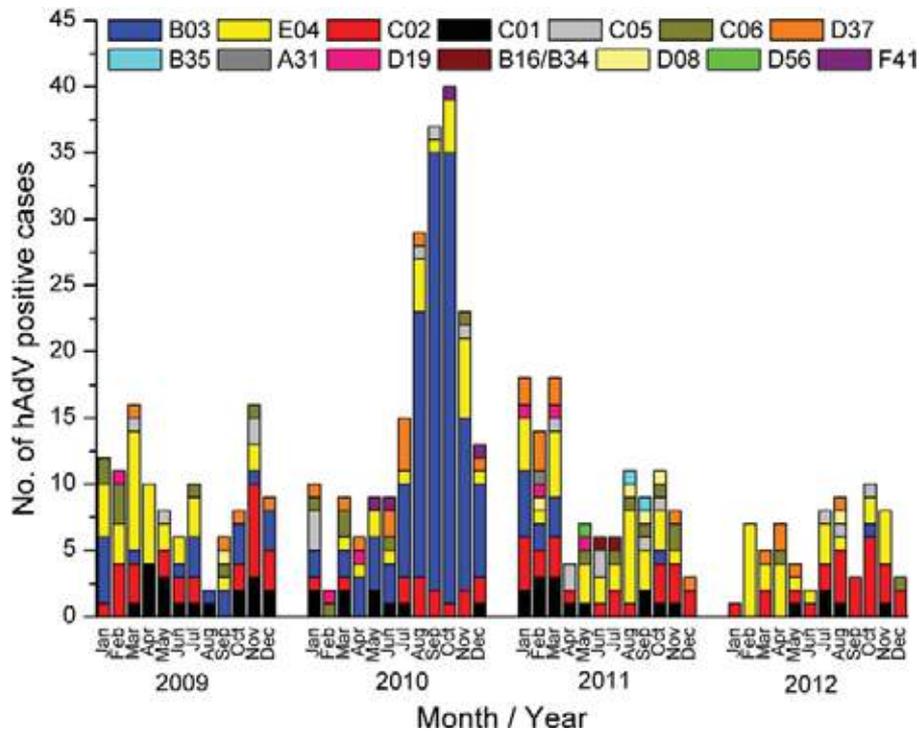

New types evolve through intertypic recombination within species, especially species D (70). In hospital outbreaks, sequence analysis has been used to confirm the transmission pathways and similarities of strains. For stem cell transplant recipients, molecular typing can be used to discern whether a patient is having a reactivation of a latent adenovirus infection, a nosocomial infection, a community-acquired infection or a donor-associated infection (61).

### Incidence and Prevalence of Infection

Many adenovirus infections are subclinical. In large population-based studies, about 50% of persons from whom virus is isolated are asymptomatic (71, 72). However, some of these isolations are made during prolonged excretion of virus in stools after symptomatic infection. Thus, it is possible that the proportion of asymptomatic infections is smaller. One meta-analysis encompassing 1,958 asymptomatic subjects found 5.3% of respiratory specimens positive for adenovirus by PCR (73). Infection caused by gastroenteritis types 40 and 41 is often asymptomatic. In a study of gastroenteritis in Texas day care centers, 46% of such infections were asymptomatic.

Of adenovirus types causing respiratory infections, types 1, 2, 5, and 6 are mostly endemic, whereas 4, 7, 14, and 21 cause epidemics. Type 3 occurs both endemically and epidemically. Outbreaks have been described to occur in closed communities, such as boarding schools and day care centers, and among new military recruits (74). Community-wide epidemics also occur. The types causing epidemic keratoconjunctivitis (types 8, 19, and 37) are often endemic under the poor hygienic conditions of developing countries, but in Western countries, they occur mostly in epidemics which are sometimes nosocomial. The gastroenteritis types 40 and 41 occur endemically throughout the world.

Adenovirus infections elicit neutralizing antibody responses that are type-specific and offer protection against reinfections caused by the same type. Protection is not complete, however, and reinfections may occur. In a Seattle,

**FIGURE 4** The seasonal distribution of adenovirus types circulating in Finland over a period of 4 years. The genotypings performed at the Department of Virology, University of Turku, represent 10 to 23% of adenovirus infections diagnosed in Finland each year. Courtesy of Dr. Minna Ylihäsälä.

WA, virus-watch study, reinfections were observed in 6% of seropositive family members (72); many of these were asymptomatic. In an adenovirus type 3 outbreak in a boys' boarding school, previous infection provided 88% protection against type-specific reinfection (75). Similarly, previous neutralizing antibodies provided 87% protection in staff exposed to the index patient during a hospital epidemic caused by adenovirus type 3a (76).

#### Age-Specific Attack Rates

Adenovirus infections are most common between 6 months and 5 years of age but continue to occur throughout life. In the metropolitan New York virus-watch study, the incidence of infection per 100 person-years was 40.8 in the age group 0 to 1 years, 33.6 between 2 and 4 years, 15.6 between 5 and 9 years, and 14.4 in the age group 10 years and older (71, 72). These figures concur with seroepidemiological figures showing that about 33% of children have contracted at least one adenovirus infection by the age of 6 to 12 months, and some have already contracted three or four adenovirus infections.

The incidence of enteric adenovirus infections is 4 to 7 per 100 person-years in young children (77). About half of preschool-age children have neutralizing antibodies against these types.

The WHO epidemiological study indicates that types 1, 2, and 5 are commonly contracted during the first years of life; types 3 and 7 are contracted during school years; and some other types, such as 4, 8, and 19, are not contracted until adulthood (60). However, geographical variations exist (78, 79).

#### High-Risk Groups

Persons with impaired T-cell-mediated immunity have an increased risk of developing severe adenoviral infections. Severe and occasionally fatal disseminated infections have

been observed in neonates, in patients with congenital immunodeficiency and in recipients of hematopoietic stem cell transplants. Adenovirus infections are common in human immunodeficiency virus (HIV)-infected patients, but most of these infections are mild or asymptomatic.

#### Seasonality

In general, adenovirus infections are endemic and detected all year round. Seasonal patterns depend on viral types, population groups, and types of exposure (Fig. 4). Outbreaks of adenoviral respiratory disease are most common in winter and spring (80). Outbreaks of pharyngoconjunctival fever have been associated with swimming pools and occur most often in summer. In the military facilities, adenovirus infections spread when introduced to newly enlisted recruits (81). Adenovirus gastroenteritis shows no distinct seasonal pattern (60, 71).

#### Transmission

##### Routes

Adenovirus infections are transmitted by direct contact, by small-droplet aerosols, the fecal-oral route, and sometimes water. The endemic adenoviruses of subgenus C (types 1, 2, and 5), causing childhood respiratory infections, spread by direct contact via respiratory secretions or feces. Self-inoculation with fingers contaminated with infectious secretions is the most important route of transmission (60). For the epidemic types (especially types 4 and 7), respiratory spread by large droplets in close contact and by aerosols is important (81, 82). Aerosol exposure, as measured by adenovirus DNA in ventilation filters, correlated with the number of hospitalizations during an outbreak caused by adenovirus 4 (82). In a military recruit setting, adenovirus DNA was identified in the air and on the surfaces of pillows,

lockers and rifles; virus was also cultured in some samples (81). In hospitals, adenovirus DNA have been frequently found on surfaces like door handles, floors, nurse chair arms, reception desks, and toys, showing that the environment can act as a potential reservoir (83). Types causing pharyngoconjunctival fever and keratoconjunctivitis spread by contact through contaminated fingers or ophthalmologic instruments and also by swimming pool water. The enteric types 40 and 41 spread via the fecal-oral route.

### Risk Factors

Close contact in crowded institutions and under low socioeconomic conditions increases the risk for adenovirus infections. Outbreaks have been described to occur in day care centers, schools, hospitals, shipyards, and military quarters. In households, about 50% of susceptible members will become infected after exposure (72). The risk increases with prolonged shedding of the virus. In one family study, 94% of the siblings and 56% of the parents had acute illness during follow-up after exposure; adenovirus disease was confirmed in 63% and 20% of these cases, respectively (84).

Variable attack rates have been observed in closed communities. In an epidemic caused by adenovirus type 3 in a boys' boarding school, the infection rate was 80% among susceptible persons without type-specific neutralizing antibodies, but about half of the infections were subclinical. On the other hand, in an outbreak caused by adenovirus 21 in an isolated Antarctic station, the infection rate was only 15%, although 89% of the personnel were susceptible (85).

### Nosocomial Infections

Adenoviruses cause outbreaks of nosocomial respiratory infections. In one outbreak due to adenovirus type 3 in a pediatric long-term care facility, 56% of 63 residents developed adenoviral illness. Seventeen patients (49%) were admitted to intensive care units and two died (86). An epidemic of adenovirus 7a infection in a neonatal nursery causing the death of two patients most likely spread from patient to staff and subsequently to other patients by infected staff (87).

Adenoviruses frequently cause epidemics of keratoconjunctivitis that spread via contaminated fingers, dropper bottles, and improperly disinfected tonometers (88). One outbreak (89) comprised 110 nosocomial cases, and an attack rate of 17% was observed in another (90). An audit study found nosocomial infection rates dropped from 48% to 23% after implementation of infection-control measures, but the rate fell to 3.4% only after patient segregation (91).

### Duration of Infectiousness

The median duration of detection of adenovirus DNA in respiratory specimens after acute infection is 11 days (interquartile range 5 to 26 days) in children and 5 days (2 to 20 days) in adults (92). Respiratory adenoviruses, especially types 1 and 2, are excreted in stool for weeks or months after initial infection. Patients are usually considered infectious a few days before the onset of symptoms to approximately 14 days after the onset of symptoms (88). Adenoviruses can remain viable for weeks under proper conditions on common surfaces. With gastroenteritis caused by adenoviruses 40 and 41, fecal excretion lasts 1 to 14 days.

## PATHOGENESIS

### Incubation Period

The incubation period for adenovirus infection, calculated from index cases or point source exposures, has been cal-

culated to average 7 to 13 days with a range of 2 to 21 days (84, 87, 93–96).

### Site of Infection

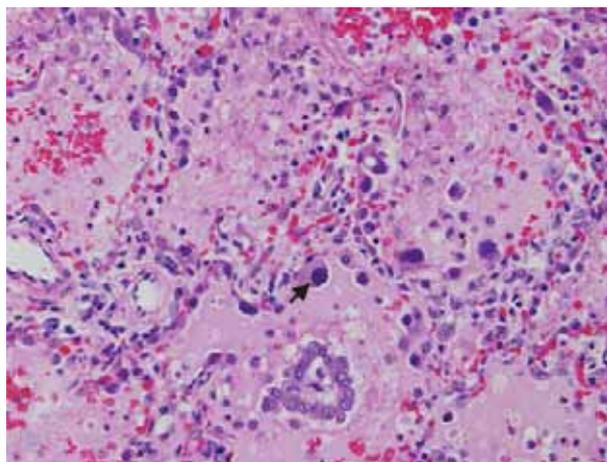

The primary site of replication of adenovirus is the epithelium of the organs involved. This includes the corneal epithelium, the epithelial lining of the upper and the distal lower respiratory tracts, and the urinary tract (97–100). In contrast, lymphocytes may be the site of chronic persistence of the virus in the nasopharynx (101). The virus may also persist in other tissues, as it can be detected by PCR in 10% of biopsies from patients with various forms of interstitial lung disease not thought to be related to adenovirus infection (102), and in 30% of normal duodenal biopsies (103).

In disseminated infection, adenovirus has also been recovered from blood and from solid organs, including the liver, spleen, kidney, heart, and brain (104, 105).

### Histology

Adenovirus pneumonia is characterized by a necrotizing bronchiolitis and alveolitis. The alveolar and bronchiolar cells are enlarged. Alveolar hyaline membranes may be prominent, and there may be extensive alveolar cellular debris. Characteristic cells with basophilic intranuclear inclusions with indistinct nuclear membranes known as “smudge” cells are usually seen (Fig. 5). Other epithelial cells with small eosinophilic nuclear inclusions, amphophilic nuclear inclusions or basophilic inclusions with a clear halo may be seen. An interstitial or alveolar infiltrate is also present. The type of infiltrate may be either neutrophilic, monocytic or lymphocytic or mixed monocytic/lymphocytic (98, 105–107). Based on data from experimental infection, the type of intranuclear inclusions and type of infiltrate likely depend on the duration of infection prior to examination.

Histologic examination of adenovirus ocular infections in humans is limited to visualization of the cornea and conjunctiva *in situ* by live confocal microscopy, as biopsies are not performed.

**FIGURE 5** Pulmonary histopathology from a fatal case of adenoviral pneumonia. Characteristic epithelial smudge cells (arrow) show markedly enlarged nuclei containing inclusion bodies surrounded by thin rims of cytoplasm. Inclusion bodies are basophilic or amphophilic when stained with hematoxylin and eosin. Unlike with herpesvirus infections, no syncytia or multinucleated giant cells are present.

When there is hepatic involvement, fatty necrosis with neutrophilic infiltration or monocytic infiltration has been described, and amphophilic, basophilic intranuclear inclusions and smudge cells are seen (97, 107–109).

Adenovirus colitis occurs in the immunocompromised, particularly in patients with HIV or those post-bone-marrow transplantation. Pathologic findings include characteristic adenovirus epithelial intranuclear inclusions and disorientation of the epithelia with a chronic inflammatory infiltrate. Focal mucosal necrosis has also been described (97, 110–112).

In rare cases of encephalitis, autopsy findings reveal perivascular mononuclear infiltrates, which have also been seen in patients with fatal, disseminated, adenoviral pneumonia with encephalitis (104). In a child with end-stage HIV infection, characteristic intranuclear inclusions were also observed (113).

### Virus-Mediated Tissue Damage

There are three mechanisms that are likely responsible for the extensive tissue damage that occurs: 1) direct cytotoxicity due to viral replication or viral components; 2) cytotoxicity due to the inflammatory cell infiltrate; and 3) cytotoxicity due to effects related to pro-inflammatory cytokines stimulated by the virus.

### Modulation of Cellular Functions by Adenovirus

During adenovirus replication cycle, the virus profoundly alters normal cellular function, presumably to create conditions that enhance replication. E1A proteins activate cell cycling through subdomain interactions with retinoblastoma protein and p300 (114, 115). Pro-apoptotic effects of E1A are counteracted by several adenovirus proteins including E1B-55K, E4orf6, and E1B 19K, partially by inhibiting nuclear translocation of apoptosis-inducing-factor (116–118). These functions prolong survival of host cells to promote viral replication. However, at late stages in the viral infectious pathway, viral proteins inhibit ongoing cellular processes and viability. E1B-55K and a peptide expressed from the E4 region inhibit nuclear export of cellular mRNAs (119–121). Host mRNA translation is also inhibited (122). Cellular integrity is disturbed through the action of a viral L3 viral protease on the cellular cytokeratin K18 (123). Furthermore, production of the E3 11.6K ADP induces cell death through caspase-dependent and non-caspase-dependent pathways (38, 124). These processes may involve modulation of ubiquitination of cellular mediators of apoptosis by E1A, E1B-55K, and E4orf4 (125).

Adenovirus cellular structural proteins also interfere with cellular processes. Several of the adenovirus subtypes bind the Coxsackie and adenovirus receptor (CAR). This binding disrupts cellular tight junctions and facilitates virus release (126). The penton base of adenovirus binds to cellular integrins and inhibits cell adhesion (127).

It should be noted that adenovirus replication is not required for inflammation to occur. Wild-type adenoviruses cause inflammation in nonpermissive mouse models (128). Nonreplicating Ad vectors clearly cause significant tissue damage in mice, rats, primates and, unfortunately, in humans (129). This damage likely comes from induction of pro-inflammatory cytokines and recruitment of inflammatory cells (130).

### Innate Immune Responses to Adenovirus

Much of the data regarding induction of cytokines by adenovirus is derived from animal models or from studies

using nonreplicating adenovirus vectors. In a nonpermissive mouse model exposed to adenovirus intratracheally, TNF- $\alpha$  and IL-6 mRNA were induced in alveolar macrophages but not in epithelial or endothelial cells (131). Intravenous infusion of a nonreplicating adenovirus vector in mice induced TNF- $\alpha$ , IL-6, and IL-12, with tissue macrophages and splenic dendritic cells and macrophages contributing to this response (132). Instillation of WT Ad3p and Ad7h, which cause pneumonia in humans, into a mouse model induces the proinflammatory cytokines IL-1  $\beta$ , TNF- $\alpha$ , IFN- $\gamma$ , and IL-12 and the mouse IL-8 homologues, MIP-2 and KC (128). In human monocytes and monocyte-derived macrophages exposed to WT adenovirus type 2, TNF- $\alpha$  was induced in both cell types, but IL-1 $\beta$  was only induced in monocytes (133).

Exposure of human peripheral-blood mononuclear cells to WT adenovirus type 7-induced interferon (not further specified) in culture (134). Blood interferon alfa levels were also elevated in two patients with adenovirus-induced hemolytic uremic syndrome (135).

The source of adenovirus-induced cytokines and chemokines is likely not limited to dendritic cells and macrophages. IL-8 is also induced in pure epithelial cultures by WT adenovirus and adenovirus vectors and in a human lung slice model, where epithelial cells are the predominant cell type (130, 136).

Induction of cytokines during active adenovirus infection in humans appears to be a marker of disease severity. Among 38 children with lower respiratory tract infections with adenovirus, serum TNF- $\alpha$  and IL-6 were detected with higher frequency in patients with severe disease or fatal outcome; IL-8 was detectable in serum in all groups of patients, and levels correlated with disease severity (137). Similarly, in military trainees with febrile respiratory illness due to adenovirus type 55 (14p1), the degree of elevation of serum IL-4, IL-10, IL-15, interferon gamma and interferon alfa-2 levels correlated with either the severity of infection or the presence of symptoms during infection (138). Additional cytokines shown to be induced during adenovirus infection include IL-5, IL-12, IL-17, IL-18, MIP-1, IP-10, and OSM but not MCP-1 or RANTES (139, 140). The cytokine response is likely important in inflammation and cell injury, but it may also be important in limiting dissemination or severity of adenovirus illnesses. Although anti-TNF- $\alpha$  strategies may decrease inflammation during administration of adenovirus vectors to mice, (141) this therapy may predispose humans to severe adenovirus infections (142, 143).

### Adaptive Immune Responses

The adaptive immune response is important in preventing reinfection, or, in the case of immunization, illness with adenovirus. Neutralizing and nonneutralizing antibodies to adenovirus are produced during infection. Serologic studies show a high rate of seroconversion. In children with acute adenovirus infection determined by antigen detection or seroconversion, virus-specific IgG antibody increased in 77%, IgM in 48% and IgA in 37%. The IgM titer peaked 10 to 20 days after the onset of illness and remained elevated for two months. IgA titers were variable, decreasing to undetectable levels in some patients and persisting at least 90 days in others (144). In military recruits, IgG levels increased in 89% of the subjects; IgA and IgM titers increased in 77% and 39%, respectively. IgA levels also increase in relevant secretions during adenovirus infections of the nasopharynx, conjunctiva, and intestine (145–147).

The importance of T-cell responses is not well understood, but it is generally regarded that T-cells play a role in

limiting the severity of disease. For example, there is high morbidity and mortality associated with adenovirus infection of patients with transplants, hematologic malignancies or AIDS. Many of these patients are infected with a type of adenovirus, which usually only causes mild disease in immunocompetent patients (148–150). Furthermore, recovery of T-cell counts, decrease in T-cell suppression or infusion of donor lymphocytes decreases viral shedding and the severity of the illness (151).

Both adenovirus-specific CD4+ and CD8+ T-cells are present in normal adults (152, 153). A role for both in containment of adenovirus infection has been proposed. Adenovirus-specific CD4+ T cell clones contain viral replication in infected cell lines and primary bronchial epithelial cells (152). Resolution of viremia is accompanied by the appearance of adenovirus-specific CD4+ and CD8+ T cells (154). Adenovirus-specific CD8+ T cell clones kill transformed lymphoblastoid cells and fibroblasts expressing adenovirus hexon (153, 154).

### Adenovirus Persistence and Latency

The classic example of adenovirus persistence dates back to the discovery of the virus. Rowe and colleagues, while trying to develop cell lines from resected human adenoids, noted the development of a cytopathic effect in culture (155). This was due to infection of the cells with adenovirus, which was present in the original subjects in an asymptomatic persistent or latent state. In a similar fashion, viral shedding occurs for months to years after infection, and the half-life of viral DNA persistence in tonsillar and adenoidal tissue has been estimated at 2.6 years (148, 156). Interestingly, more than one strain may persist in the same subject (157).

There are several adenovirus proteins that appear to play a role in evasion of the immune system. This was discovered when infection of cells with adenoviruses with mutations of these proteins increased the sensitivity of lysis of these cells by TNF. These proteins in the E3 region, 10.4K, 14.5K, and 14.7K, act by downstream inhibition of TNF, either through phospholipase A2 or NF- $\kappa$ B (158). Another mechanism that may assist in immune evasion is displayed by E3 19K, which decreases expression of MHC class I molecules in adenovirus-infected cells. Also, adenovirus E1B19K and E3 proteins counteract destruction of infected cells through inhibition of TNF-related apoptosis-inducing ligand (TRAIL), and E3 proteins also inhibit Fas-ligand-induced apoptosis (158, 159). Viral microRNA species are also produced in latently infected cells in culture, and these could facilitate adenovirus persistence by downregulating targeted cellular antiviral mRNAs (160). Additionally, E4orf6/E1B55k protein complexes have ubiquitin ligase activity and degrade specific cellular targets depending on the types of origin. Degradation of these targets, including p53, DNA ligase IV and integrin  $\alpha$  3, has been proposed as a mechanism whereby the virus facilitates the development of latency (161).

These factors are likely responsible for persistence of the adenovirus in human tissues by preventing elimination of virus-infected cells. There has also been speculation that persistence, or true latency with integration of adenovirus genes, plays a role in the development of human illnesses. One study, comparing lung tissue from patients with COPD to patients with similar smoking histories without the disease, found that afflicted patients had increased amounts of adenovirus E1A by PCR and increased detection of the E1A RNA by *in situ* hybridization (162). Follow-up studies by the same group showed that areas of increased E1A expression in alveolar epithelia correlated with cellular inflammation and

severe emphysema (163). This issue has not been settled, however, as a subsequent study has shown a low incidence of E1A RNA expression and E1A DNA in patients with COPD (164).

In a study of adenovirus-persistence in children, adenovirus capsid in BAL fluid from children with treatment-resistant asthma was detected at high rates compared with children of similar age without asthma (165). This finding should be tempered by the fact that others have shown that steroid treatment of patients with interstitial lung disease increases the detection of adenovirus by PCR (102).

There are several cross-sectional studies suggesting that adenovirus type 36, and possibly type 5, infections, as determined by the presence of antibodies to these strains, are associated with obesity (166). A meta-analysis of 11 of these studies showed a 1.6 odds ratio (95% CI=1.14–2.25;  $P < 0.01$ ) for obesity for subjects seropositive for adenovirus type 36 and that the odds ratio was increased to 1.95 in children (95% CI=1.34–2.85;  $P < 0.01$ ) (167). The role of adenovirus 36 as a causative agent of obesity remains controversial because there have been negative studies and because few longitudinal studies have been performed (168). In any case, these studies raise provocative questions about the possible role of persistent or latent adenovirus in the development of chronic respiratory diseases and other illnesses.

## CLINICAL MANIFESTATIONS

### Acute Respiratory Infection

Adenovirus infections most commonly occur in children between 6 months and 5 years of age and manifest as febrile upper respiratory tract infections. Asymptomatic infections are common and most symptomatic infections are mild and self-limited. Adenoviral infections cannot be distinguished clinically from infections induced by other respiratory viruses (72, 80, 169). In one 12-month study, adenovirus was identified by PCR in 3% of 543 acute respiratory illnesses; the mean duration of adenovirus illness was 18.6 days. Importantly, another respiratory virus is present in up to 60% of adenovirus-positive cases (63,170–172).

Clinical syndromes during adenovirus infections include tonsillitis, pneumonia, acute otitis media, conjunctivitis, febrile convulsions, fever without focus of infections, and laryngitis (173–175). High and persistent fever is common in children. In hospitalized children with adenovirus infection, the mean maximal temperature was 39.4°C, and the mean duration of fever was 5.4 days (range, 2 to 13 days) (174, 176).

About half of children with adenovirus infection have a marked leukocytosis ( $> 15,000/\text{mm}^3$ ), elevated erythrocyte sedimentation rate ( $> 30 \text{ mm/h}$ ), and elevated serum C-reactive protein levels ( $> 40 \text{ mg/liter}$ ), in contrast to most cases of influenza virus, parainfluenza virus and respiratory syncytial virus-induced illnesses (63,177–179). Except for respiratory syncytial virus infections (in which as much as 60% of cases also manifest acute otitis media), the number of possible bacterial coinfections does not differ with different virus infections. The cause of the elevated laboratory values in adenovirus infections is unknown (177, 178).

Adenoviral infection may mimic a bacterial infection and is a common cause of ineffective and unnecessary antibiotic treatment. High-grade and prolonged fever and common abnormal laboratory findings are the major reasons for antibiotic treatment in clinical practice.

### Tonsillitis

Tonsillitis is a frequent clinical manifestation of adenovirus infection. Two studies of acute febrile tonsillitis found that adenoviruses were the most common single causative agents and accounted for 19% of cases (180, 181). Adenoviruses and group A streptococci usually do not cause mixed infections in children. In adenoviral tonsillitis, the exudates are most often thin and follicular or netlike but sometimes may have thick membranes (176, 180) (Color Plate). White blood cell (WBC) count, serum C-reactive protein and erythrocyte sedimentation rate do not distinguish bacterial from viral tonsillitis. Although age groups overlap, adenoviral tonsillitis occurs most often in children less than 3 years of age, whereas beta-hemolytic streptococci induce tonsillopharyngitis in 5- to 17-year-old children. Adenovirus infection is a frequent cause of tonsillitis unresponsive to antibiotic therapy and requiring referral to a hospital (144, 181, 182).

### Pneumonia

Approximately 10 to 20% of childhood pneumonias and 1 to 4% of pneumonias in adults are attributed to adenoviruses (171, 183, 184). Conversely, pneumonia is a main diagnosis of 4 to 18% of hospitalized children identified with an adenovirus infection (174, 185–188). In basic military trainees, adenoviruses have been implicated in 90% of pneumonia-related admissions. Adenoviral pneumonia results primarily from infections with types 4, 7, 21, and 3. These types may also cause disseminated disease.

Adenoviral pneumonia cannot be clinically distinguished from other viral or bacterial pneumonias. Chest roentgenogram findings vary from diffuse to patchy interstitial infiltrates. Consolidation and pleural effusions have been described. Parahilar peribronchial infiltrates and atelectasis occur in most children with abnormal roentgenographic findings associated with adenovirus infection. Adenoviral pneumonia may be associated with disseminated infection involving the heart, liver, pancreas, kidneys, and central nervous system. The fatality rate can be as high as 30% (189). Permanent lung damage after adenoviral pneumonia has been reported to occur in 27 to 65% of those who had adenovirus type 7 pneumonia. These changes include bronchiectasis, bronchiolitis obliterans, and unilateral hyperlucent lung (McLeod) syndrome. Many patients with normal chest roentgenograms have abnormal pulmonary function tests, often consistent with pulmonary obstruction (190). The young age of the child and measles are risk factors predisposing patients to chronic lung damage.

### Pharyngoconjunctival Fever and Keratoconjunctivitis

Pharyngoconjunctival fever and keratoconjunctivitis are two well-described adenovirus syndromes affecting the eye. Pharyngoconjunctival fever occurs principally in children and was recently associated with types 8 and 4 (191).

Pharyngoconjunctival fever is often associated with preauricular adenopathy. Conjunctivitis is usually unilateral or asymmetric. In the early stage, adenoviral conjunctivitis cannot be distinguished clinically from bacterial, allergic, or other viral acute conjunctivitis. Manifestations include watering, redness, discomfort, and photophobia, typically lasting 1 to 2 weeks. The palpebral conjunctiva is hyperemic and contains diffuse infiltration and papillary or follicular hypertrophy. In severe cases, subconjunctival hemorrhages, chemosis, or pseudomembranes occur.

Epidemic keratoconjunctivitis occurs mainly in adults and is usually caused by adenovirus types 8, 19, and 37 (60,

192, 193). In 99 children with acute conjunctivitis seen in a pediatric practice, *Haemophilus influenzae* (42%), adenoviruses (20%), and *Streptococcus pneumoniae* (12%) were the most common etiologic agents. Simultaneous infection with two pathogens was uncommon. The clinical features of conjunctivitis by the three different pathogens are summarized in Table 2. Eleven (65%) of the 17 children with both pharyngitis and conjunctivitis had adenovirus cultured from the conjunctiva (194).

A large number of epidemics of adenoviral keratoconjunctivitis have been described. During 2008 to 2010 in the United States, 6 unrelated outbreaks with 411 cases were reported to CDC (88). Outbreaks of keratoconjunctivitis typically occur in industrial plants, ophthalmology clinics, hospitals, nursing homes, camps, military bases, and child care centers. The virus is transmitted by the hands of medical personnel and by contaminated ophthalmic solutions and instruments. In industrial and military base outbreaks, spread may occur by the common use of bathrooms and by inadequate hygiene. Adenoviruses can remain viable for several weeks on wash basins and hand towels. The illness is first characterized by conjunctivitis, chemosis, pain, photophobia, and lacrimation. A diffuse punctate epithelial keratitis occurs within 3 to 4 days. It may resolve within 2 weeks but can develop into focal subepithelial keratitis with pathognomonic corneal opacities. In rare cases, stromal infiltration may persist for months or even years. Fortunately, the illness is usually self-limited, and the patient's vision remains unaffected (192, 193).

### Enteric Infection

Adenoviruses are detected in 3 to 14% of stools from children with gastroenteritis in hospitals, outpatient clinics, and day care centers but also in 9 to 42% of asymptomatic children when PCR is used (195–197). Of the adenoviruses detected in the feces, types 40 and 41 comprise 30 to 80%, respectively, in different studies. The other common adenovirus types found in the stools are 1, 2, 3, 5, 7, and 31. Adenoviral diarrhea is most common in children less than 2 years of age. By the age of 3 years, 30 to 100% of children have neutralizing antibodies to adenovirus types 40 and 41.

No special feature clinically differentiates adenoviral diarrhea from diarrheas induced by other viruses (196, 198). The stools are usually watery and nonbloody, in contrast to bacterial diarrheas. Mucus is noted in 19 to 57% of cases. The maximum daily frequency of stools varies from 3 to 15. The mean duration of diarrhea is 3 to 11 days, often being

**TABLE 2** Clinical features of conjunctivitis caused by three different pathogens<sup>a</sup>

Clinical feature	<i>H. influenzae</i> (n = 42)	<i>S. pneumoniae</i> (n = 12)	Adenoviruses (n = 20)
Mean age of patients (yr)	3.6	3.1	8.5
Bilateral disease (%)	74	50	35
Purulent exudate (%)	93	83	45
Concurrent otitis (%)	33	8	10
Concurrent pharyngitis (%)	5	8	55

<sup>a</sup>Modified from reference (194) with permission.

significantly longer than rotavirus-induced diarrhea. In patients seeking care for diarrhea, the severity of adenoviral diarrhea has been similar to that of rotavirus infection, whereas in studies of outpatients, rotaviral disease seemed to be more severe (199). Type 41 adenovirus-induced diarrhea lasts longer than type 40-induced diarrhea (means, 12.2 days versus 8.6 days, respectively). Enteric adenoviruses seem to induce longer enteritis than nonenteric adenoviruses (200). Fever and vomiting in enteric adenovirus infections are common. Although adenoviral gastroenteritis is usually a mild disease, fatal cases in immunocompromised patients have been described.

Viral and bacterial copathogens in adenoviral diarrhea have been found in 13 to 18% of the cases, and other viruses were detected in respiratory specimens from 26% of 47 patients when adenovirus was visualized in the fecal sample (196).

### Fever Syndromes

In 105 hospitalized patients with adenovirus infection, 17% had fever with no identifiable site of infection (174). In another study, adenovirus was cultured from 6% of 116 patients with fever without a localized cause (201). Samples for PCR tests from the nasopharynx and feces should be included in the workup of febrile patients without focus of infection.

Adenoviruses are the most common single etiologic agents of febrile convulsions in young children and caused 13% of 144 cases in one study. In three patients, adenovirus was also detected from cerebrospinal fluid, suggesting that febrile convulsions may have been the sole manifestation of adenoviral central nervous system infection (202).

### Hemorrhagic Cystitis

Hemorrhagic cystitis is a self-limited illness in otherwise healthy children, occurring more often in boys than girls. Adenovirus type 11 has been recovered from the urine of 19 to 91% of the patients. In addition to gross hematuria, the clinical manifestations included urgency, frequency, and fever. The duration of gross hematuria varies from 2 days to 2 weeks, and there are no changes in serum creatinine levels (203).

Hemorrhagic cystitis associated with adenovirus has been described to occur following bone marrow and renal transplantations. Coinfection with BK polyomavirus and cytomegalovirus may occur. Female sex, seropositivity for adenovirus prior to bone marrow transplant (BMT), and acute graft-versus-host disease are significant risk factors. Studies from the United States reported adenovirus-associated hemorrhagic cystitis after BMT in only 0.3 to 1.0% of recipients (204). In renal transplant recipients, the disease is associated with gross hematuria, urinary frequency, burning urination, fever, and negative bacterial cultures. The symptoms last for 2 to 4 weeks and serum creatinine increases (205).

### Infection in Military Recruits

Prior to vaccination, up to 80% of recruits experienced adenovirus infection. Among 58,103 febrile respiratory illnesses in the U.S. military basic trainees, 64% were laboratory-confirmed adenovirus infections (8). Physical and mental stress and crowding are considered major reasons for the susceptibility. The most common clinical manifestations in military recruits mimic those found in children, sore throat, nausea/vomiting, cough, and fever. Adenovirus-associated illness occurred most commonly in training weeks 3 to 6 while influenza occurred in weeks 0 to 2 (206). A large ep-

idemic of keratoconjunctivitis with nearly 3,000 cases occurred at a U.S. military base in the Philippines, and this event led to recommendations for management of the epidemic (Table 3) (207). In one study of 108 young men with febrile tonsillitis in the military service, adenoviruses caused 31% of the cases, whereas group A streptococcal infections were detected in 38% (207). In 17% of cases of streptococcal tonsillitis, evidence of concurrent adenovirus infection was also found, in contrast to adenoviral tonsillitis in children (180).

Adenoviral pneumonia in military conscripts is most often caused by adenovirus types 4 and 7, which are the types included in the oral live vaccine used successfully between 1971 and 1999 and from 2012 onwards in the U.S. military. During vaccine unavailability, severe epidemics of adenovirus 4 infections affecting thousands of trainees were reported, and adenovirus 4 was responsible for nearly all diagnosed cases of adenovirus infections in the U.S. military recruits. Eight deaths were reported during the break of adenovirus vaccination, mostly due to pneumonia (9). From 2002 to 2006, epidemiological studies using molecular diagnostic procedures revealed the emergence of adenovirus type 14 (64). Interestingly, annual cases of adenovirus 14 decreased markedly after the resumption of adenovirus 4 and 7 vaccination (8).

### Infection in Newborn Infants

Severe adenovirus infection in newborn infants is rare, but infants are susceptible to a disseminated form of adenovirus infection, which has been fatal in 68% of cases (208). Transmission may occur either vertically, in utero from the infected mother, or horizontally, after birth. Adenovirus outbreaks in neonatal intensive care units have been reported. In vertical infections, mothers often have viral symptoms preceding, or shortly after, delivery, and there may be prolonged rupture of membranes. The illness starts within 10 days of age with lethargy, fever or hypothermia,

**TABLE 3** Epidemic keratoconjunctivitis preventive measures<sup>a</sup>

General recommendations	
	Wash hands thoroughly.
	Clean and sterilize instruments.
	Use unit doses of ophthalmic solutions.
	Examine "red eye" patients in a separate area.
	Educate staff about epidemic keratoconjunctivitis and other transmissible eye diseases.
	Avoid use of cloth towels in bathrooms.
Termination of an outbreak	
	Observe above recommendations.
	Communicate the existence of an outbreak to all staff.
	Segregate patients by presence or absence of epidemic keratoconjunctivitis.
	Discard all open ophthalmic solutions.
	Remove infected personnel and patients from clinic for 2 wks.
	Determine the cause of the outbreak and mode of transmission.
	Educate patients about epidemic keratoconjunctivitis.
	Postpone elective procedures.
	Act with speed and decisiveness.

<sup>a</sup>Adapted from reference (192) with permission of Oxford University Press.

anorexia, apnea, hepatomegaly, bleeding, and progressive pneumonia. Adenovirus types 3, 7, 21, and 30 have been cultured most often from the lungs and liver (209). In horizontally transmitted infections, neonates often have ill contacts. The mean age of the patients in one study was 16 days. Four neonates required extracorporeal membrane oxygenation (ECMO).

### Infection in Immunocompromised Patients

Adenovirus infections in immunosuppressed patients are more often disseminated, persistent, and associated with different types of adenoviruses than in healthy hosts. Severe adenovirus infections are increasingly being recognized, especially in recipients of hematopoietic stem cell transplants (HSCT) (2, 150). The incidences of adenovirus DNAemia in pediatric allo-HSCT recipients vary from 6% to 42% and in adult allo-HSCT patients from 3% to 15%, depending on the transplant type and intensity of surveillance (5). Among 2,879 adult allo-HSCT patients between 1999 and 2008, adenovirus infection was diagnosed by viral culture in 73 patients (2.5%), in whom mortality was 22% (210). Among 624 adult and pediatric allo-HSCT patients, adenovirus DNAemia occurred significantly more often in T-cell depleted, compared to conventional, allografts (4% versus 7.9%), and, importantly, the risk for invasive adenovirus disease was 10-fold higher in the T-cell depleted allograft group. Half of the patients with very high adenovirus DNAemia ( $>2 \times 10^5$  copies/mL) died (211). One early study, conducting weekly viral surveillance cultures from the throat and stools and also in the urine of adults during the first 100 days after transplant in 201 BMT recipients, found that the incidence of adenovirus isolation was 31% for children and 14% for adults. Thirty-one percent of all adenovirus-positive patients had definite or probable adenoviral disease, representing 6.5% of all patients (212). Most adenovirus infections in children develop within 30 days after transplantation, whereas in adults infection usually develops more than 90 days after transplantation (5). The infection is thought to be secondary to reactivation of persistent or latent viruses or the transmission of latent virus via donor graft. In young children, infection may be acquired from a family contact or nosocomially (213).

The adenovirus types detected from HSCT recipients differ from those detected from otherwise healthy subjects. The most commonly reported adenovirus types include adenovirus C1, C2, B3, B7, B21, A31, E4, and F41. However, typing is not necessary for optimal treatment (5, 214).

According to the 2013 Guidelines from the American Society of Transplantation, adenovirus disease necessitates the presence of attributable organ signs and symptoms combined with virus detection in biopsy specimens on immunohistochemical staining or in bronchoalveolar lavage and cerebrospinal fluid (culture, antigen detection, or PCR), in the absence of another diagnosis. Disseminated adenovirus disease requires involvement of two or more organs, not including viremia (6).

The clinical manifestations of adenovirus infection in HSCT recipients may include high fever, pneumonia, hemorrhagic cystitis, encephalitis, hepatitis, nephritis, and colitis. Adenovirus has been the major contributor to mortality in about one-half of those with definite disease. Most of the fatal outcomes result from fulminant pneumonia, hepatic failure, nephritis, or colitis. Male sex, young age, alemtuzumab treatment, cord transplant, T-cell-depleted grafts, acute graft-versus-host disease, lymphocytopenia ( $<300/\text{mm}^3$ ),

and detection of adenovirus from multiple sites are clear risk factors for disease (5, 210, 211, 213). Routine PCR tests for detection of adenovirus DNA in nasopharyngeal mucus, feces, conjunctivae, and possibly from lung biopsy samples should be included in the etiologic workup of immunocompromised patients with suspected infection.

Weekly monitoring of blood samples for adenovirus DNA by real-time quantitative PCR has been shown to be useful in recognizing patients at risk for a potentially severe infection (215). In one study of 238 consecutive pediatric allo-HSCT recipients, weekly DNAemia monitoring revealed adenovirus loads greater than 1,000 copies per milliliter in 15.5% of all patients. Adenovirus DNA in blood before day-50 posttransplantation predisposed to development of high adenovirus loads ( $>10,000$  copies/mL) (214). Increased or increasing viral loads in blood or stool are associated with an increased risk of death, and preemptive antiviral treatment should be considered (2, 213, 215).

Adenovirus DNAemia is also relatively common (5 to 20%) in adult lung, kidney, and heart transplant recipients, but most infections were asymptomatic, and routine screening for adenovirus DNA is not recommended in solid-organ transplant recipients (2, 5). In one study adenovirus was cultured from 10% of over 400 liver transplant patients at a median of 26 days from transplantation, most commonly in urine. Hepatitis was the most common invasive disease (29% of infections), and type 5 caused most cases of hepatitis. All patients had high fever lasting 6 to 44 days. In addition to elevated transaminase levels, the patients had characteristic histopathology in the liver consisting of adenoviral inclusions or microabscesses.

Adenovirus infections occur frequently in HIV-positive patients. The actuarial risk of adenovirus infection at 1 year in late-stage HIV disease was 31 to 38%. Infection occurred most often in the gastrointestinal tract inducing diarrhea only, but half of the patients remained asymptomatic or minimally symptomatic (216). In AIDS patients adenoviruses may be associated with pneumonia, hepatitis, encephalitis, nephritis, and gastroenteritis (150).

### Uncommon Clinical Manifestations

Adenoviruses have been infrequently isolated from the cerebrospinal fluid and brains of patients with meningoencephalitis. Often the patients have been neonates or immunocompromised persons with disseminated disease. In one adenovirus type 7 epidemic affecting 32 previously healthy children, 25% had meningoencephalitis, and 10% died. All children also had respiratory symptoms, including pneumonia in six cases (217). In 2,398 children with adenovirus infection, 3.3% had manifestations of central nervous system dysfunction (188, 218). In the California Encephalitis Project, adenovirus was found as a possible cause of encephalitis in about 1% of 1,570 patients studied (219).

Sensitive molecular techniques have suggested that adenoviruses may be causative agents of myocarditis. In three studies, cardiac samples were obtained for PCR analysis from patients with myocarditis and from patients with dilated cardiomyopathy. Adenoviruses were identified in 8 to 23% and 1.6 to 12% of the samples, respectively (220).

Adenovirus infections have been thought to induce mesenteric lymphadenopathy, which then could act as a mechanical lead point for the intussusception. In one study, 47% of 53 children with intussusception had adenovirus in their stools. Of 25 cases, adenovirus group C was most common. Of note, simultaneous infection with HHV-6 and adenovirus carried the highest risk for intussusception (221).

Forty cases of adenovirus urethritis and concurrent conjunctivitis have been reported. Patients typically present with dysuria, clear or mucoid urethral discharge, and evidence of meatitis. Conjunctivitis may be bilateral. The mean duration of this self-limited illness is 14 days. Oral sex is the likely transmission route (222).

### Bacterial Complications

Acute otitis media (AOM) occurs in 30 to 37% of children with adenovirus infection, and 3 to 10% of AOM patients have evidence of adenovirus infection. Adenovirus was found in 2% of 581 middle-ear fluid samples from AOM patients (223).

Excluding military conscripts, adenovirus-induced febrile tonsillitis is seldom associated with group A beta-hemolytic streptococci. Similarly bacterial coinfections have been very rare in adenoviral keratoconjunctivitis. Serologic evidence of bacterial infection was found in 47% of 19 children with adenoviral pneumonia (185). Recently, a U.S. study of childhood community-acquired pneumonia reported 248 cases of adenovirus pneumonia, out of which 10% had evidence of bacterial coinfections (171). Approximately one-half of military conscripts with adenoviral pneumonia have evidence of concomitant bacterial infection. One study in a developing country showed that adenovirus lower-respiratory-tract infection is associated with high nasopharyngeal pneumococcal colonization and, further, with invasive pneumococcal pneumonia (224).

## LABORATORY DIAGNOSIS

The clinical picture of a respiratory adenovirus infection is variable and commonly resembles that due to other microbes (175). Up to 80% of acute conjunctivitis is caused by viruses, of which 65 to 90% are adenoviruses, but the accuracy of clinical diagnosis is only 50% (225). Therefore, adenovirus infections can seldom be diagnosed on clinical grounds alone, and laboratory testing is needed for specific diagnosis.

### Virus Isolation

#### Specimen Types

Adenoviruses have been isolated from stool, throat swabs, nasopharyngeal aspirates, conjunctival swabs and scrapings, urine, cerebrospinal fluid, blood, and a variety of biopsy specimens. The optimal specimen type depends on the clinical picture and, to some extent, on the adenovirus type in question.

Most adenovirus infections involve viral excretion in stool, which makes it a practical specimen for detection. However, excretion of the respiratory types in stool can continue for several months. Therefore, isolation from stool does not have the same diagnostic significance as isolation from the involved site, for example, the respiratory tract or eye specimens. On the other hand, detection of high adenovirus DNA load in stool of transplant patients may precede viremia by several weeks (226).

Specimens should preferably be collected within a week after onset of illness. After that, in most cases, the excretion of virus and the sensitivity of isolation will decrease. Swab and biopsy specimens should be collected in transport medium. Stool and cerebrospinal fluid specimens can be transported, as such, in clean containers. Adenoviruses are relatively stable. Shipment on ice (4°C) or frozen is preferable for maximum sensitivity, but most adenoviruses can be grown in specimens transported at room temperature.

### Cell Culture

Cultures of the appropriate site during active infection have high yields. This includes cultures of nasopharyngeal swabs or aspirates, throat swabs or washes, conjunctival swabs or scrapings, bronchoalveolar lavage fluid, stool or rectal swabs, urine or urethral swabs, cervical swabs, CSF, and tissue samples. Adenoviruses are species-specific, and isolation is best achieved in human cells, although cynomolgus monkey kidney cells can also be used. All adenovirus types, except 40 and 41, grow well and produce cytopathic effect in a variety of human epithelial cells. The best sensitivity is achieved with human embryonic kidney cells, but because these are expensive and difficult to obtain, continuous cell lines are commonly used. Suitable continuous cell lines include A549, HeLa, HEp-2, KB, and MRC-5 strains.

Some strains of the enteric types 40 and 41 will grow in these cell lines, but the best growth is achieved in HEK 293 cells (human embryonic kidney cells transformed by adenovirus type 5 DNA). Because of strain variation in the growth pattern, sensitivity is increased by simultaneous inoculation of the specimens into two or three different cell lines.

Adenoviruses produce typical cytopathic effects (CPE), which often start at the periphery of the monolayer. The cells become rounded, with characteristic refractile intranuclear inclusions. The appearance of CPE is relatively slow, especially in the continuous cell lines. For the best sensitivity, a 4-week incubation with blind passage is recommended. Among healthy children, adenovirus is rarely cultivable ( $\leq 1\%$ ) from throat swab specimens, and adenovirus isolation can be considered diagnostically significant and indicative of an acute infection (201, 227). Shell vial assay, in which monolayers are tested with monoclonal antibodies to the hexon protein, can shorten detection time to 1 to 2 days, although the sensitivities of different shell vial cultures are variable.

Isolated viruses can be identified as adenoviruses by various immunologic techniques; e.g., immunofluorescence, enzyme immunoassay (EIA), PCR, or latex agglutination. Serotyping of the isolates can be done by neutralization, or with some isolates, by hemagglutination inhibition. Reference antisera are available from American Type Culture Collection. Today, serotyping has been largely replaced by genotyping using PCR combined with sequencing, probe hybridization or restriction endonuclease analysis (62,228–230). Whole genome sequencing is needed for in-depth analysis of co-evolution versus intertypic recombination events for the designation of novel types (65, 70, 231, 232). Next generation sequencing will facilitate these efforts (233).

### Antigen Detection

Monoclonal or polyclonal antibodies directed against the group-specific hexon antigen can be used for the direct detection of adenoviruses in clinical specimens. Commercial monoclonal antibodies and immunoassays, showing similar performances as laboratory-designed tests, are available.

In respiratory and eye specimens, infected cells can be detected by immunofluorescence, whereas immunoassay methods (EIA and time-resolved fluoroimmunoassay) can be used to detect both cell-bound and free antigenic proteins. Nasopharyngeal aspirates are preferable respiratory specimens for immunoassays, but for adenovirus, throat swabs also have good performance (234). The best sensitivity is obtained if the specimen is collected during the first 4 to 5 days after onset of illness, but some patients remain positive for 2 to 3 weeks. The sensitivity of the immunoassay methods has been 75 to 90% for children, compared to

culture or serology, but is considerably lower for adults (144,235–238). Compared to culture, immunofluorescence has a lower sensitivity than immunoassays (239). There are several commercial point-of-care tests for adenovirus. A meta-analysis of Japanese studies on immunochromatography tests reported 88%, 91%, and 67% sensitivities and 97%, 98%, and 100% specificities for throat, stool, and conjunctival specimens, respectively (240). A rapid test of adenovirus conjunctivitis (AdenoPlus), designed for direct sampling of tear fluid with a sterile collector and automatic transfer of the sample to the test strip, showed 85% sensitivity and 98% specificity as compared to PCR (241). EIAs have also been used to detect adenovirus antigens in conjunctival specimens. Compared to culture, EIA has shown a sensitivity of 70 to 80%, when specimens were collected early in the course of illness.

In fecal specimens, adenovirus antigens can be detected by immunoassays and by latex agglutination. Antigen detection is especially suitable because the enteric types 40 and 41 grow poorly in cell culture and stool samples are often cytotoxic. In addition to group-specific immunoassays, immunoassays specific for the enteric types have also been developed. The sensitivity of EIAs for enteric adenoviruses in stool has been 85 to 100%, compared to culture (144, 242). Direct visualization by EM is also used to detect adenoviruses in stool, although it is impractical under most diagnostic circumstances. The characteristic morphology of adenoviruses makes them easy to identify by EM and allows a rapid diagnosis whenever the amount of viral particles in the specimen is large enough. Enteric adenoviruses occur in stools in considerably larger quantities than respiratory adenoviruses, and the sensitivity of EM is comparable to that of immunoassays. The enteric adenoviruses can be identified by the use of immuno-EM.

#### PCR Tests

Adenovirus DNA can be detected directly from respiratory specimens, plasma, conjunctivae, stools, urine, and genital specimens using PCR. As with many other respiratory viruses, PCR is more sensitive than conventional virus culture or virus antigen detection. Specificity of PCR can be confirmed through sequencing. In one study of 1,038 samples from children with respiratory illness, 130 specimens were positive for adenovirus by PCR compared to 29 by FA testing (243). In another study of 181 respiratory samples from children, virus culture and direct immunofluorescence identified 7 positive samples, compared to 17 by real-time PCR (244). Similar test sensitivity has been obtained for nasopharyngeal aspirates and throat swabs (234). The high number of types and continuous evolution of new variants are challenges for PCR test development. The first priority in clinical setting is adenovirus identification; the type may become relevant later. Therefore, the conserved motifs of the hexon gene have been the target for quantitative pan-adenovirus PCRs, and protocols have been developed that use 1 to 6 different primer and probe sets (245). Multiplex PCR methods, including adenovirus as one of the targets, have been developed for the detection of respiratory, enteric, and ocular spectrum of infections (246–248). Multiplex PCR has lower sensitivity compared to individual PCRs, and adenovirus might be a particularly difficult target for these assays (249). If a severe adenovirus infection is suspected on clinical grounds, a negative multiplex PCR result should be confirmed with a more sensitive singleplex test.

Quantitative detection of adenovirus is helpful for clinical decisions (250). Since PCR may detect latent adeno-

virus in the respiratory, gastrointestinal, or urinary tract, a high adenovirus DNA load may be more often associated with active disease or more severe disease (226,251–253). *In situ* hybridization is a valuable method in pathogenesis studies, but it is rarely applicable in everyday diagnosis (254).

#### Serology

Serological studies of acute and convalescent sera may be needed to establish evidence of infection. Significant increases in titer of antibody can be measured to the common hexon antigen by complement fixation or by EIA. The sensitivity of complement fixation is about 50 to 70% and that of EIA is about 70 to 80%, compared to virus antigen detection (144). In small children, seroresponses are more attenuated than in older children and adults, and immunocompromised hosts may fail to mount responses. IgM antibodies are detectable in 20 to 50% of infections, but the immune responses are often poor and difficult to interpret. Neutralization and hemagglutination inhibition tests are sensitive but measure type-specific antibodies, so these assays are not suitable for routine diagnosis.

#### PREVENTION

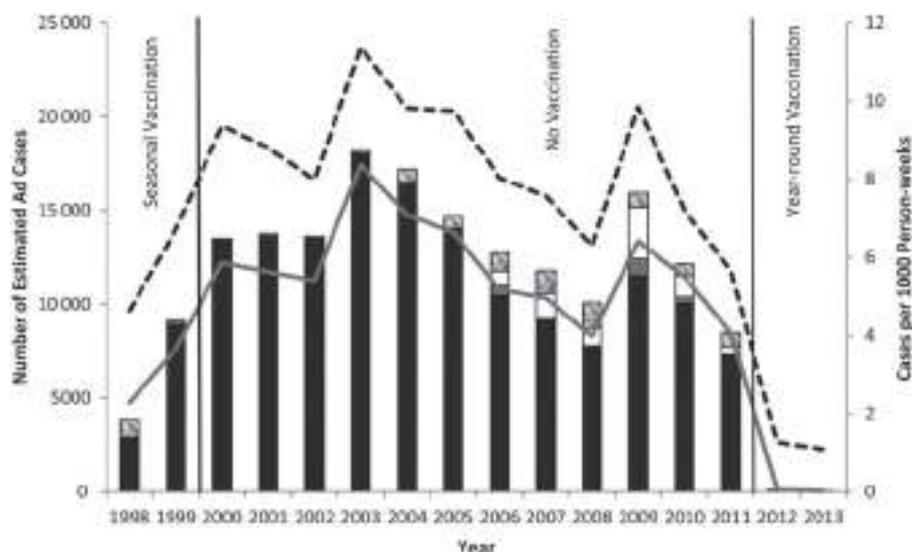

Isolation of patients with adenoviral illness has not been recommended routinely. Detection of adenoviruses by PCR in the air and on surfaces (81, 82) suggest that proper cleaning, isolation of patients with suspected or confirmed cases of adenovirus infection, and restriction of new admissions may be essential in limiting the risk of nosocomial spread. As droplet precautions may not be effective, airborne precautions with a properly ventilated isolation room should be considered when the patient is treated in the intensive care unit and for patients with severe adenovirus type 3, 7, or 14 infections.

Rigorous hand-washing both before and after contact with the patient is recommended, but routine soap and water may not reliably remove adenovirus. An 85% ethanol hand gel reduced significantly the infectivity titer of adenovirus in 2 minutes (255). However, adenoviruses are resistant to many disinfectants, and the use of 70% isopropyl alcohol in disinfection of instruments, for example, is not reliable (88). The antiadenoviral activity of chlorhexidine is low. Surfaces should be treated with 85 to 95% alcohol for at least 2 minutes or with sodium hypochlorite for 10 minutes (5). Use of disposable gloves should be considered when examining a patient with suspected adenovirus infection. During epidemics, medical staff should be instructed not to rub their eyes or to do so only with a clean tissue or paper towel (192).

Hospital outbreaks have been controlled by grouping of patients into cohorts; the use of gloves, gowns, and goggles; and the exclusion of symptomatic staff from the unit. Environmental surfaces have been disinfected daily with sodium hypochlorite. Dirty towels may be the source of infection in outbreaks, and disposable paper towels or hot-air blowers have been recommended. Table 3 lists preventive measures for epidemic keratoconjunctivitis.

#### Immunoprophylaxis

Based on the observations that adenovirus infects the gastrointestinal tract but uncommonly causes gastrointestinal illness in adults, a safe and effective live oral adenovirus vaccine containing wild types 4 and 7 in enteric tablets was developed (256). These adenovirus strains replicate in the intestine and induce type-specific neutralizing serum antibodies. Since 1971, the vaccine program dramatically

**FIGURE 6** Use of adenovirus vaccines and febrile respiratory illness and adenovirus infection rates among United States Army trainees from 1998 to 2013. Reprinted from reference (8) with permission.

reduced adenoviral disease rates by 95 to 99% and total respiratory disease rates by 50 to 60% in the U.S. military, findings demonstrating the dominant role of adenovirus infections in military populations (Fig. 6). Due to the cessation of production by the sole manufacturer, no adenovirus vaccine was available from 1999 to 2012. During that time a dramatic increase in the occurrence of adenovirus infections was recorded. Two years after reintroduction of the vaccine, a 100-fold decline in adenovirus disease burden was reported. It is estimated that adenovirus vaccines now prevent approximately 13,000 febrile illnesses per year saving approximately 50 million dollars per year (8).

## TREATMENT

At present there is no specific antiviral treatment of proven value for adenovirus infections. Ribavirin, ganciclovir, valganciclovir, cidofovir, and brincidofovir (formerly CMX-001) are variably active against adenoviruses *in vitro* and thus potentially effective for treatment. Ribavirin shows *in vitro* inhibitory activity only for group C adenoviruses, and intravenous ribavirin has poor or no efficacy in the treatment of severe adenoviral disease (5). A great number of case-series studies have provided anecdotal support for the clinical efficacy of cidofovir (a monophosphate nucleotide analog of cytosine) treatment, especially when given early and combined with withdrawal of immunosuppression (215, 257). Cidofovir is commonly used in the clinic as preemptive or as therapeutic treatment, but its use is associated with high rates of nephrotoxicity, and, in case of severe adenovirus disease, the efficacy of cidofovir is limited. However, prospective randomized clinical trials have not been carried out. In many centers, adenovirus DNA loads in plasma are monitored weekly in HSCT patients, and preemptive cidofovir treatment is started when adenovirus DNA is detected or increases progressively. Cidofovir treatment led to stable or reduced viral load in 70% of 18 HSCT children with blood adenovirus load greater than  $1 \times 10^3$  copies per milliliter (214). Among 135 patients, mostly HSCT recipients, who had been treated with cidofovir (5 mg/kg of body weight), once per week for 1 week to 11 months, renal

toxicity (mostly mild proteinuria or mild elevation of the serum creatinine) was recorded in 13%. Of 20 patients with pneumonia, 9 (45%) survived. Among patients treated with 1 milligram per kilogram, three times per week, for 2 weeks to 8 months, renal toxicity developed in 7 (29%) of 24 patients, but all 6 patients with pneumonia survived (258). A decrease in the plasma virus load has been shown to predict a clinical response. On the other hand, retrospective studies have shown that antiviral therapy may not be necessary for all children who develop adenovirus viremia after BMT (215). In neonates with disseminated infection, cidofovir or ribavirin treatment did not improve outcomes (208).

Brincidofovir is a promising orally bioavailable lipid conjugate of cidofovir. It is not associated with nephrotoxicity or myelosuppression but causes diarrhea as a dose-limiting side effect. It is *in vitro* 65-fold more potent against adenoviruses than cidofovir. A controlled clinical trial to evaluate the safety and efficacy of brincidofovir for adenovirus disease in 200 HCT recipients have been recently completed (5, 259, 260).

Proper T cell function is crucial for clearance of adenoviral infection. Adoptive transfer of adenovirus-specific T cells is a promising treatment for allo-HSCT recipients not responding to antiviral chemotherapy (5). Peripheral blood mononuclear cells of the HSCT donor are stimulated *in vitro* with adenovirus hexon protein and enriched and transferred to the patient. With this treatment protocol adenovirus-related mortality was 9.5% in 21 patients who had immunological response to the therapy, compared with 100% mortality in 8 patients did not respond (261). Hemorrhagic cystitis after bone marrow and renal transplantation is treated with steroid pulse therapy, but the value of this therapy is unproven. Intravesical instillation of cidofovir in the treatment of adenovirus-induced hemorrhagic cystitis has been reported (205).

# Polyomaviruses

JOHN E. GREENLEE AND HANS H. HIRSCH

## 28

Polyomavirus infections are widespread among humans and animals. The prototype of this viral family, polyoma virus of mice, was discovered in 1953 as an agent capable of producing tumors in its natural host (1). A second polyomavirus, murine K virus (KV; now known as mouse pneumotropic virus or MPtV), was discovered in 1952 (2). The simian polyomavirus, SV40, was discovered in 1960 as a contaminant of lots of rhesus monkey kidney cells used to prepare polio vaccine stocks (3). Infectious SV40, subsequently detected in both the Salk and Sabin polio vaccines, as well as in adenovirus vaccines, was inadvertently administered to millions of individuals worldwide (3).

The first evidence that polyomaviruses might also be infectious for humans came in 1965, when Zu Rhein et al. and Silverman and Rubinstein independently reported the electron microscopic detection of structures resembling polyomaviruses in brain sections from patients with the fatal demyelinating disease, progressive multifocal leukoencephalopathy (PML) (4). Isolation of the agent was achieved in 1971, when Padgett et al. recovered a previously unknown human polyomavirus, JC virus (JCPyV), by inoculation of PML brain material from patient J.C. into primary cultures of human fetal glial cells (5). In that same year, a second polyomavirus, BK virus (BKPpyV) was recovered from the urine of a human renal transplant patient (6). BKPpyV has since been repeatedly recovered from urine and also been associated with hemorrhagic cystitis in allogeneic hematopoietic stem cell transplant patients (7) and nephropathy/interstitial nephritis in renal transplant patients.

For over 40 years, JCPyV and BKPpyV were the only polyomaviruses unequivocally associated with human infections. Recently, however, 11 additional human polyomaviruses have been identified (Table 1), and nearly 100 additional polyomaviruses have been recovered from non-human primates, other mammals, birds, and fish (8, 9). An unambiguous link to tissue pathology and disease is missing for most polyomaviruses. This chapter will emphasize the major polyomaviruses that have been associated with human clinical illness and cancer: JCPyV, BKPpyV, MCPyV, and TSPyV. The simian *betapolyomavirus* SV40, however, remains controversial as a cause of human illness and neoplasia (10).

## VIROLOGY

### Classification

Polyomaviruses were initially considered a genus within the family *Papovaviridae*, which included papillomaviruses and polyomaviruses. In 2000, these agents were reclassified as two separate families, *Papillomaviridae* and *Polyomaviridae*. Subsequently, the rapidly increasing number of polyomaviruses isolated from human and nonhuman animal species led the *Polyomaviridae* Study Group of the International Committee on Taxonomy of Viruses (ICTV) to propose dividing the polyomaviruses into three separate genera: *Orthopolyomavirus*, which included JCPyV, BKPpyV, and SV40; *Wikipolyomavirus*; and *Avipolyomavirus*, which was restricted to polyomaviruses infecting birds. As of December 2015, a new classification system has been proposed, based on the observed distance between large T coding sequences: this designates four genera: *Alpha-*, *Beta-*, *Gamma-*, and *Delta-polyomavirus* according to host species and order of detection (9). The recently recognized human polyomaviruses are distributed across *Alphapolyomaviridae* HPyV8, HPyV9, HPyV12, and NJPyV; the *Betapolyomaviridae* KIPyV and WUPyV; and the *Deltapolyomaviridae* HPyV6, HPyV7, and HPyV11 genera (9). This classification has been accepted by the ICTV but is still subject to modification.

### Virus Structure and Composition

Polyomaviruses are unenveloped 40 to 45 nm, icosahedral agents encapsidating a supercoiled, circular, double-stranded DNA genome wrapped around two histones (Figure 1). The genome consists of 4,900 to 5,900 base pairs (bp), which comprise three functional regions (Figure 2). The noncoding control region (NCCR) of approximately 400 bp harbors the origin of replication (*ori*), and promoter/enhancer units directing the bidirectional expression of the early and late viral genes in concert with host cell factors reflecting differentiation and activation. The early viral gene region (EVGR) of approximately 2,500 bp encodes the key regulatory proteins including large T-antigen (LTag) and the small T-antigen (sTag). The primary EVGR transcript is also spliced to give rise to several smaller T-Ag derivatives with partly overlapping domains, which are replication cycle, host cell, or species dependent. Examples include LTag and truncT' of JCPyV and MCPyV, respectively, or the middle T-antigen (mTag) of

TABLE 1 Human polyomaviruses<sup>1</sup>

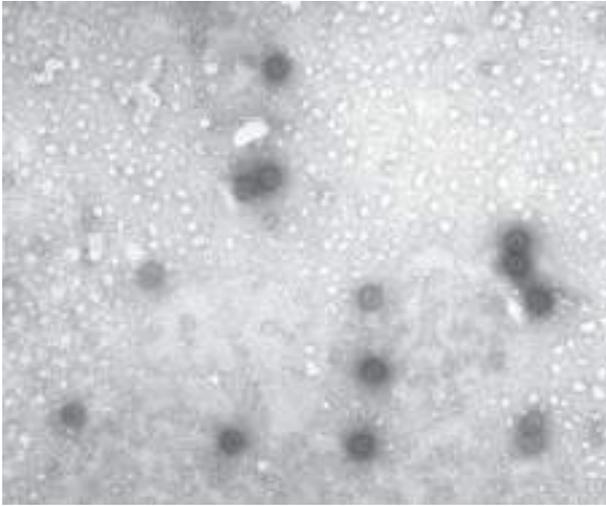

Common agent name (abbreviation)	Taxonomic name	Major site(s) of persistence	Infection in immunologically normal individuals	Symptomatic infection, immunocompromised individuals
<b>Genus <i>Alphapolyomavirus</i></b>				
Merkel cell polyomavirus (MCPyV1)	Human polyomavirus 5	Skin	Unknown	Isolated from 80% of cutaneous Merkel cell carcinomas
Trichodysplasia spinulosa (TSPyV)	Human polyomavirus 8	Skin	Unknown	Trichodysplasia Spinulosa
Human polyomavirus 9 (HPyV9)	Human polyomavirus 9	Unknown: recovered from plasma and urine	Unknown	Unknown
Human polyomavirus 12 (HPyV12)	Human polyomavirus 12	Liver (colon, rectum)	Unknown	Unknown
New Jersey polyomavirus (NJPyV)	Human polyomavirus 13	Unknown	Unknown	Microvasculitis of muscle, necrotizing dermopathy, and retinal blindness in a pancreatic transplant patient (1 case)
<b>Genus <i>Betapolyomavirus</i></b>				
BK virus (BK polyomavirus) (BKPyV, BKPpV)	Human polyomavirus 1	Kidney	Inapparent or mild Periodic viruria	Nephropathy Hemorrhagic cystitis Ureteral obstruction
JC virus (JC polyomavirus) (JCPyV, JCPpV)	Human polyomavirus 2	Kidney (brain, PBMCs, possibly other organs)	Inapparent or mild Periodic viruria	PML (cerebellar granule cell infection) (cortical encephalitis)
KI virus (KI polyomavirus) (KI PyV)	Human polyomavirus 3	Respiratory tract, possibly gastrointestinal tract	Possible but unconfirmed association with respiratory tract infection	Possible but unconfirmed association with respiratory tract infection
WU virus (WU polyomavirus) (WUPyV)	Human polyomavirus 4	Respiratory tract, possibly gastrointestinal tract	Possible but unconfirmed association with respiratory tract infections	Possible but unconfirmed association with respiratory tract infections
<b>Genus <i>Deltapolyomavirus</i></b>				
Human polyomavirus 6 (HPyV6)	Human polyomavirus 6	Skin	Unknown	Unknown
Human polyomavirus 7 (HPyV7)	Human polyomavirus 7	Skin	Unknown	Unknown
MW polyomavirus (MWPyV)	Human polyomavirus 10	Gastrointestinal tract	Unknown	Unknown
STL polyomavirus (STLPyV)	Human polyomavirus 11	Tonsillar tissue (gastrointestinal tract?)	Chronic tonsillitis	Unknown

<sup>1</sup>Agents associated with disease are shown in bold type.

mouse polyomavirus (MPyV) and the human MCPyV (11). The late viral gene region (LVGR) of approximately 2,900 bp encodes the capsid proteins Vp1, Vp2, and Vp3, which are posttranscriptionally derived from different splice and translation start signals. In the 5' end of the LVGR, some polyomavirus species including JCPyV, BKPpV, and SV40 encode a small regulatory leader protein called agnoprotein. In addition, microRNAs have been detected in the distal LVGR; these are complementary to EVGR transcripts and may play a role in down-regulation of T-antigen expression (11).

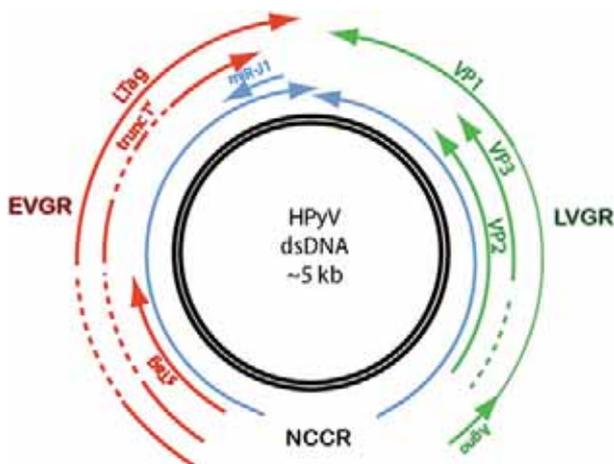

JCPyV, BKPpV, and SV40 DNAs exhibit extensive (69% to 75%) DNA homology, with greatest sequence divergence being found in the regulatory region (RR), on the late side of the ori (11). In contrast, although the more newly discovered polyomaviruses are phylogenetically related to other human and primate polyomaviruses in the early region of their genomes, each of these newer agents is divergent from JCPyV, BKPpV, and SV40 in the amino acid homology in the LVGR encoded Vp1 (12).

Although the genomes of JCPyV, BKPpV, and SV40 encode only single serotypes of virus; extensive variation

**FIGURE 1** Electron micrograph of BKPyV extracted from human fetal kidney cells, concentrated by ultracentrifugation, and stained with 2% phosphotungstic acid, showing characteristic 42 nm particles.

may occur in the NCCRs of each (11), resulting in multiple genotypes (often referred to as “strains”) of each agent. Genotypes that are shed in urine and involved in transmission of infection are termed “archetypal.” Genotypes differing from the archetype in their rNCCR are termed “variant” or “rearranged” (13). As discussed below, variance from archetypal genomic sequences has been postulated to account for differences in the biological behavior of these agents, including host range, regulation of viral growth, and ability to cause disease. In the case of SV40, archetypal genotypes isolated directly from simians usually contain only a single 72 bp enhancer element, whereas partial duplication of this region is characteristic of genotypes of virus cultivated *in vitro* (14).

**FIGURE 2** Schematic representation of a human polyomavirus genome, made up of circular double-stranded DNA. Regions comprising the NCCR are shown in blue; those comprising the EVGR are shown in red: these encode LTag, truncT as found in MCPyV, and sTag. LVGR sequences encoding VP1, VP2, VP3, and the agno protein are shown in red. The agno protein-encoding gene is not found in every HPyV genome.

BKPyV was initially considered to be comprised of prototypic Dunlop (DUN) and five other genotypes, MM, GS, MG, AS, and RF (11, 15). Subsequently, BKPyV was divided into four major genotypes (I, II, III, and IV), based on heterogeneity of VP1 gene and immunoreactivity (15), with genotype I being most common worldwide, and subtype IV being common in Europe and East Asia but rare in Africa (16, 17). Group I comprises the DUN genotype, as well as two other genotypes, MM and GS. Group II encodes the SB genotype; group III the AS genotype; and group IV the MG and RF genotypes (11). GS and MM viruses have sequence differences around the replication origin. MG and RF, although antigenically similar to BKPyV, have a bipartite genome consisting of two complementing defective molecules, one having a deletion corresponding to the BKPyV early region, and the other, to the BKPyV late region (18, 19). More recently, BKPyV has been further classified into subgroups, which also appear to correlate with geographic distribution (16, 17). Individuals may harbor more than one genotype of virus.

### Regulatory and Structural Proteins

Polyomaviruses encode two groups of viral proteins: “early proteins,” which are regulatory and control viral synthesis but are not components of the virion; and “late” proteins, which include the structural virion proteins (Table 2) (11). EVGR and LVGR are separated at their 5′ termini by the NCCR of approximately 400 bp, which contain a single origin of replication (Figure 2). The NCCR plays an important role in controlling EVGR and LVGR expression and also in initiating viral DNA replication.

The early proteins have been most thoroughly studied in the case of SV40. The roles of these proteins in SV40 synthesis are thought to apply to other polyomaviruses as well. The most important early protein is large T-antigen (LTag), a 708 amino acid protein, which is expressed predominantly in the cell nucleus but is also present at the cell membrane (Figure 3) (11, 20). LTag binds to the viral origin of replication as well as the NCCR and has multiple functions, many of which are accomplished by the ability of LTag to bind to and modulate the activity of different host cell proteins (11). Functions of LTag include initiation and execution of viral genome replication, and regulation of synthesis of both viral and cell proteins (Table 2) (20). LTag is the only viral protein essential for viral DNA synthesis and interacts with multiple cellular proteins including tumor suppressor proteins pRb, p107, p130, and p53 (Figure 4). LTag also plays an essential role in “virus-induced” cell transformation (11, 20), such that the presence of LTag in cells has been used as a marker for polyomavirus-mediated cell transformation (Figure 4) (20). LTag also serves as a recognition site for cytotoxic T-lymphocyte-mediated immune control (21, 22). sTag is a histone-rich protein that shares its N-terminus with LTag but has a unique C-terminus. The functions of sTag and of the late, nonstructural agno protein are outlined in Table 3 (11, 23, 24, 25).

Three structural proteins comprise the viral capsid in most human polyomaviruses: the 45 kDa protein Vp1, and two smaller proteins, Vp2 and Vp3. These are arranged into 72 capsomeres, each comprised of 5 molecules of VP1 and one molecule of VP2 or VP3. VP1 is the only protein exposed on the capsomere surface and is the major protein involved in viral attachment to cells (11). In contrast, MCPyV contains only VP1 and VP2; VP3 is not detected (26). A smaller derivative called Vp4 has been reported to

**TABLE 2** Functions of early and late polyomavirus-encoded proteins

<b>Large T-antigen</b>	
1) Viral DNA replication	T-Ag forms a double hexamer and in the presence of ATP causes untwisting of the early viral DNA palindrome within the origin. Using its helicase activity, the complex unwinds the viral DNA bidirectionally. Cellular proteins, topoisomerase I and DNA polymerase/primase are recruited to the replication origin to form a replication complex that is involved in the initiation of the replication of viral DNA molecules.
2) Activation of late viral gene expression	T-Ag effects an alteration of the cellular repressors that normally bind near the late promoter. This derepression, perhaps in combination with recruitment of transcription factors, activates late transcription. Alternatively, replicated viral DNAs appear in sufficient amounts to titrate the repressors.
3) Down regulation of T-Ag expression	Two possible mechanisms for this down-regulation have been reported: 1) T-Ag activates expression of the late genes at the late promoter by helping to recruit transcription factors. Activation of the late promoter sequesters the transcription factors also required for the activation of the T-Ag promoter causing its own down-regulation. 2) Autoregulation: T-Ag binds to viral DNA at sites that block expression of the T-Ag gene.
4) Initiation and maintenance of cell transformation	By binding to and/or inactivating tumor suppressors p53, Rb, and perhaps several others, the suppression or control of cell growth is then reversed and the cells become morphologically transformed and display several parameters of transformation. Also, the cells may form tumors in appropriate animals and can assume an immortal phenotype in culture. T-Ag may be required for immortalization of polyomavirus-transformed cells.
<b>Small T-antigen</b>	
1) Intracellular accumulations of viral DNA and viral replication. Regulates PP2A.	
2) Reverses the apoptotic effect of large T-Ag.	
3) Causes cell cycle progression. Increases tumorigenicity of LTag transformed cells.	
4) Binds several cellular proteins, e.g., p300, PP2A.	
5) Induces telomerase and AKT activities.	
<b>Late (Capsid and Agno) proteins</b>	
VP1	Major capsid protein: involved in virus attachment to cell surface receptors.
VP2, VP3	Minor capsid proteins.
Agno protein	<ol style="list-style-type: none"> <li>1) May serve a role in viral morphogenesis perhaps by retarding polymerization.</li> <li>2) May help with intracellular migration of VP1 to the perinuclear region and entry of VP1 into the nucleus with consequent viral assembly.</li> <li>3) Involved with late transcriptional regulation.</li> <li>4) May play a role in cell to cell spread of virus.</li> </ol>

function as a viroporin for SV40 (27). Extensive antigenic similarity exists between the large and small T-Ags of JCPyV, BKPyV, and SV40. A lesser degree of antigenic cross-reactivity exists among intact JCPyV, BKPyV, and SV40 virions or among the newer polyomaviruses (28, 29, 30).

## Biology

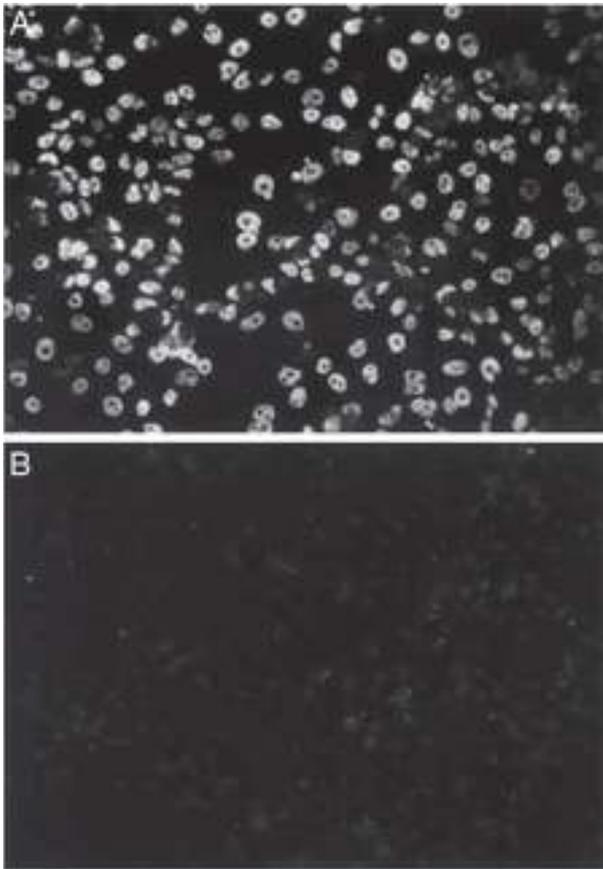

### Virus Attachment and Entry into Cells

Most PyV capsids bind host cell membrane structures, which consist of glucose: galactose, N-acetyl-galactosamine, and N-acetyl-neuraminic acid, connected by glucosidic linkages to lipids in the host cell membrane and to each other. JCPyV binds to two receptors in brain: an  $\alpha$ 2,6-linked sialic acid on the lactoseries tetrasaccharide c (LSTc) glycan and also the 5-HT2AR serotonin receptor (31, 32, 33). The distribution of LSTc, serotonin receptors, and virus binding sites overlap in the kidney, a major site of JCPyV persistence and in the choroid plexus (34). Within the brain, however, the two receptors are not coexpressed: LSTc is found on microglia, vascular endothelial cells, and cells in the choroid plexus, whereas 5-HT2AR serotonin receptors are found on oligodendrocytes and astrocytes. These data suggest that LSTc might allow JCPyV binding at the blood-brain barrier, but

that 5-HT2AR serotonin receptors, rather than LSTc, are necessary for JCPyV attachment to its target glial cell populations (34).

BKPyV attachment to cells involves binding of viral pentamers to gangliosides GD1b carrying one branch of  $\beta$ 1,4-N-acetyl-galactosamine- $\beta$ 1,4-galactose and one branch of  $\alpha$ 2,3 N-acetyl-neuraminic acid- $\alpha$ 2,8 N-acetyl-neuraminic acid (35). BKPyV also binds to GT1b, which corresponds to a GD1b carrying one additional  $\alpha$ 2,3-N-acetyl-neuraminic acid coupled to the  $\beta$ 1,4-N-acetyl-galactosamine (35). Addition of the gangliosides GD1b and GT1b to LNCaP cells, which are normally resistant to BKPyV infection, makes the cells susceptible to infection by the virus (35). The events involved in attachment and uptake of the more recently discovered polyomavirus are less well understood, because of the difficulty in generating replication competent PyV virions from *in vitro* cell culture systems. MCPyV has been reported to bind to GT1B (36) but may also undergo a two-step attachment and entry process, with initial binding of VP1 to heparin sulfate and other sulfated glycosoamines, followed by transfer of the virus to a sialylated glycan, which appears to play a role in viral uptake (37).

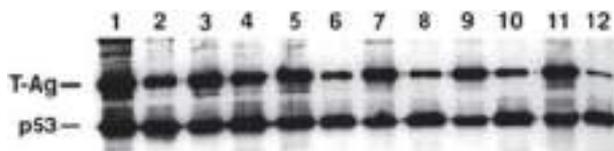

The ability of polyomaviruses to bind to cell membrane glycosylation structures enables many of these agents, such as

**FIGURE 3** (A) Identification of SV40 T-Ag by immunofluorescence in transformed simian TC-7 kidney cells. Cells were grown in a monolayer and reacted with monoclonal antibodies PAb 416, PAb 108, and PAb 101 directed against T-Ag as described by O'Neill et al. (272). (B) Naïve TC-7 cells (not containing T-Ag-encoding DNA sequences) reacted with monoclonal antibodies as in panel A (negative control).

JCPyV and BKPyV, to agglutinate red blood cells of various species. In contrast, SV40 does not hemagglutinate as it binds to the branched glycan GM1 ( $\beta$ 1,4-glucose- $\beta$ 1,4-galactose- $\beta$ 1,4-*N*-acetyl-galactosamine and one  $\alpha$ 2,3-*N*-acetyl-neuraminic acid), which is not found on erythrocytes.

BKPyV and SV40 enter cells by endocytosis into caveosomes and from there into the endoplasmic reticulum

**FIGURE 4** Western blot of SV40 T-Ag and p53 from transformed human cells. SV40 T-Ag was immunoprecipitated in even-numbered lanes and p53 was immunoprecipitated in odd-numbered lanes, and the immunoprecipitates were subjected to electrophoresis in agarose gels and analyzed by Western blotting using a cocktail of antibodies to T-Ag or p53 (95). The illustration shows that immunoprecipitation of either protein results in coprecipitation of the second protein.

(38, 39). Virus-containing vesicles are then transported intracellularly to fuse with the outer membrane of the cell nucleus, releasing viral particles into perinuclear cisternae. Uncoating of SV40 and MCPyV DNAs begins in the endoplasmic reticulum (11). In contrast, internalization of JCPyV involves endocytosis of the virus within clathrin-coated pits, and transport of JCPyV to the cell nucleus involves microtubules and microfilaments (11). Uncoating of JCPyV DNA is thought to occur exclusively within the cell nucleus.

### Viral Replication

The steps of viral replication have been most clearly defined for SV40 and BKPyV. Other polyomaviruses are thought to replicate in a similar fashion. Replication of the SV40 genome occurs in two stages, with early viral genes being transcribed off of one DNA strand in one direction and late viral genes being transcribed after the early genes and off the other strand in the opposite direction (11). Polyomavirus gene transcription is governed by *cis*-acting sequences in the regulatory region (11). The early promoter of SV40 is located near the origin of replication and contains a TATA box, three G-C rich regions, and an enhancer region of 72 bp tandem repeats all contained within the NCCR (11). The early G-C rich regions are bound by the Sp1 cellular transcription factor and the enhancer region, which are thought to interact with other transcription factors. EVGR and LVGR expression is critically controlled by a hierarchy of transcription factors, in which Sp1 and Ets1 sites play a major role (40). These sites are altered in natural BKPyV NCCR variants from immunocompromised patients with nephropathy (41), hemorrhagic cystitis (42), and disseminated infection (43, 40). Transcription is mediated by cellular RNA polymerase II, resulting first in the production of EVGR mRNAs encoding LTag and sTag (11). During late transcription there is differential splicing to form the mRNAs encoding the agnoprotein, as well as VP1, VP2, and VP3. Assembly of virions occurs in the cell nucleus, followed by release of viral particles during cell lysis (11).

### Host Range

Polyomaviruses are extremely species-specific and are for the most part unable to cause productive infection in unrelated species. SV40 represents an exception to this rule: the virus naturally infects rhesus and cynomolgus monkeys but was shown to produce limited infection in humans following exposure to contaminated vaccines (44). Similarly, BKPyV has been shown in one study to cause systemic infection and interstitial nephritis in immunosuppressed cynomolgus monkeys (45). Species specificity and ability to infect specific cell populations are controlled by regulatory elements unique to each virus and their interaction with host cell proteins (11). Inoculation of laboratory rodents (or in the case of JCPyV or BKPyV, nonhuman primates) with JCPyV, BKPyV, or SV40 causes a variety of neoplasms, usually at or near the site of inoculation. Other animal models are discussed in the Pathogenesis section.

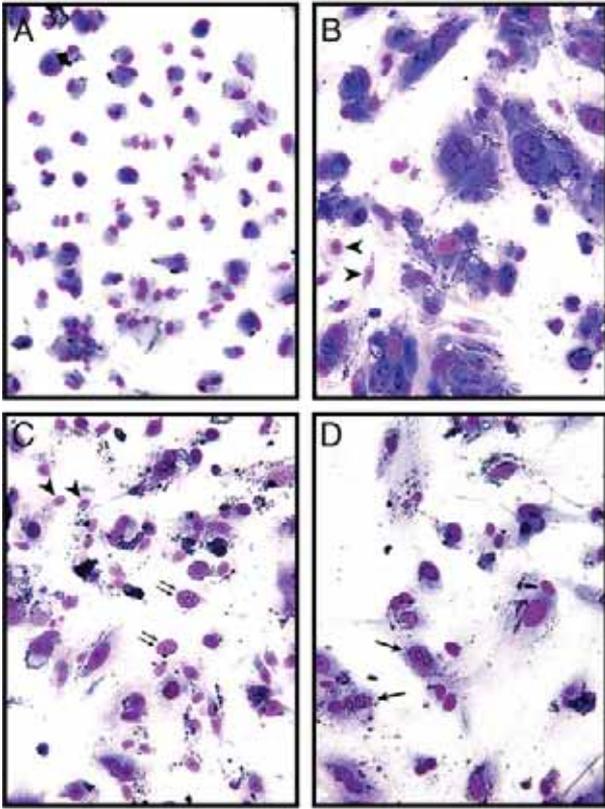

### Growth in Cell Culture

SV40, BKPyV, and PML-associated genotypes of JCPyV can be grown in primary human fetal glial (PHFG) cells. In this culture system, SV40 results in a progressive lytic infection of certain cell populations, resulting in high titers of infectious virus, and a transforming infection in others (Figure 5) (14, 46). Inoculation of PHFG cultures with BKPyV produces an infection that is nearly identical to that seen with

TABLE 3 Major immunotherapeutic and cytotoxic agents associated with PML

Agent	Mechanism of action	Therapeutic use	Frequency of PML	Duration of treatment before diagnosis	Treatment	Mortality
Natalizumab	Binds to $\alpha 4$ subunit of $\alpha 4\beta 1$ and $\alpha 4\beta 7$ integrins expressed on leukocytes. Inhibits lymphocyte trafficking into brain	Multiple sclerosis Crohn's disease	8.5/1,000 in JCPyV-positive patients treated for 49–72 months; 13/1,000 in patients with prior immunosuppression	Months to years	Discontinue drug. Plasma exchange plus immunoadsorption	23% <sup>1</sup>
Rituximab	Anti-CD20 monoclonal. Produces destruction of B lymphocytes and pre-B lymphocytes	Lymphoproliferative disorders; collagen-vascular diseases and other autoimmune disorders; AIDS-related lymphomas	1:30,000 (most cases in patients receiving multiple immunosuppressive drugs)	Months to years	Discontinue drug. Plasma exchange. Use of immunoadsorption not reported	Death in most reported cases <sup>2</sup>
Alemtuzumab	Binds to CD52 receptors on lymphocytes	B-cell chronic lymphocytic lymphoma Multiple sclerosis	Rare cases in B-CLL, none as yet in multiple sclerosis	Months	Discontinue drug. Use of plasma exchange or immunoadsorption not reported	Unknown <sup>3</sup>
Brentuximab vedotin	Binds to CD30 receptors on Reed-Sternberg and other Hodgkins or leukemia cells, activated T cells, resting B cells	Anaplastic large cell and Hodgkin lymphomas	Unknown	Weeks to months	Discontinue drug. Use of plasma exchange or immunoadsorption not reported	80%
Mycophenolate mofetil	Inhibits inosine monophosphate dehydrogenase, involved in B- and T-cell proliferation	Solid organ transplants; systemic lupus erythematosus; other autoimmune diseases Hodgkin's disease	Rare	Weeks to months	Discontinue drug.	Death in most reported cases <sup>2</sup>
Fludarabine	Inhibits DNA polymerase alpha, DNA primase, ribonucleotide reductase	Chronic lymphocytic leukemia	0.52% of treated patients	Months	Unknown	Death in most reported cases
Dimethyl Fumarate	Mechanism unknown	Multiple sclerosis Psoriasis	<10 cases reported	Months	Discontinue drug	Unknown <sup>3</sup>
Fingolimod	Prevents transit of lymphocytes out of lymphoid organs	Multiple sclerosis	<10 cases reported	Months <sup>4</sup>	Discontinue drug	Unknown <sup>3</sup>

<sup>1</sup>As of March 2015.<sup>2</sup>Most reported cases are in individuals treated with two or more immunosuppressive agents.<sup>3</sup>Numbers of reported cases too small to allow estimation of overall mortality.<sup>4</sup>Some cases have occurred in patients following transition from natalizumab to fingolimod.

**FIGURE 5** Comparative cytopathic effects produced by JCPyV, BKPyV, and SV40 in primary cultures of human fetal brain cells. Cultures were infected with a 1/10 dilution of the PML-associated Mad-1 genotype of JCPyV or with 1/1,000 dilutions of SV40 or BKPyV. (A) Uninfected human fetal brain cells containing relatively small, moderately stained nuclei. (B) Cultures infected with a 1/10 dilution of the PML-associated Mad-1 strain of JCPyV, showing cells with enlarged nuclei and multinucleated cells. Occasional giant multinucleated cells were present in some cultures (not shown). (C) Cultures infected with a 1/1,000 dilution of SV40. Cultures show large, darkly staining nuclei. Some nuclei were reticulated or mottled (double arrows), but multinucleated cells were rare. Arrowheads in panels B and C designate cells with small nuclei, similar to those seen in uninfected cultures. (D) Cultures infected with a 1/1,000 dilution of BKPyV, showing enlarged, intensely stained nuclei. Some nuclei contained what appeared to be doughnut-shaped nucleoli (arrows). This was unique to BKPyV infection. As in SV40-infected cultures, multinucleated cells were rarely present. In cultures infected with BKPyV or SV40, cytopathic effect became extensive within 8 to 10 days. In cells infected with Mad-1 JCPyV, cytopathic effect did not appear until 3 to 4 weeks. (Wright's stain; magnification,  $\times 152$ ).

SV40, and serial passage of BKPyV-infected brain cultures results in the development of both persistently infected and transformed cell lines (Figure 5) (46). In contrast, PML-associated genotypes of JCPyV cause a productive infection in PHFG that evolves over weeks. JCPyV infection in this culture system has a more limited cytopathic effect than does that produced by BKPyV or SV40 and in some studies has been described to involve spongioblasts or oligodendroblasts almost exclusively (Figure 5) (46).

Other than their ability to replicate in PHFG cells, the culture requirements of these three agents differ considerably

(47). SV40 can be isolated in cell lines derived from African green monkey kidney cells (BSC-1, CV-1, and Vero cells), and has also been propagated in several human tumor cell lines (47, 48). SV40 grows poorly in human fibroblasts, such as WI-38, and even less efficiently in HEK cells (47, 48, 49, 50). BKPyV readily replicates in primary human proximal tubular epithelial cells, which represent the natural target in nephropathy, and has become the preferred experimental model in tissue culture (51, 52, 40). BKPyV also grows in human fibroblasts, early passage primary cultures of human embryonic kidney (HEK) and PHFG cells, simian BSC-1 cells, and, to a limited extent, in simian Vero cells (53). JCPyV was initially isolated from PML brains using PHFG cells, and this culture system has been used most extensively in studies of the virus (5). Although several other cell culture systems have been developed, these have been less extensively employed (4). The human glial cell-derived line SVGp12 expressing SV40 LTag supports JCPyV replication, but because of its contamination with BKPyV, researchers have resorted to the BKPyV-free clone SVG-A (54). Limited growth of the JCPyV archetype has been shown to occur in PHFG cells, and very slow growth of the virus also occurs in HEK and human endothelial cultures (55). Efficient propagation of the archetype forms of both BKPyV and JCPyV has been reported in 293TT (human embryonic kidney) cells overexpressing SV40 T-Ag (56). Efficient propagation of the archetype forms of both BKPyV and JCPyV has been reported in cells expressing the SV40 LTag such as HEK293TT, COS-7, SVG-A cells, and SVGp12, which carries infectious BKPyV (56, 54). Although transduction of cells in culture has been reported with MCPyV DNA (57), infection of cells in culture using the newer polyomaviruses has not yet been reported.

#### Cell Transformation by Polyomaviruses

In primary cell cultures or cell lines that are “permissive,” polyomaviruses replicate to generate progeny virus. Infection of cells that are “nonpermissive” for these viruses, however, is characterized by integration of the viral genome into that of its host; these cells usually express early but not late viral proteins, develop distinctive biological and biochemical properties such as the ability to grow from single cells or to grow in agar or serum-free media, and are considered transformed (11, 58). Some, but not all, transformants become capable of indefinite serial passage and are considered immortal in culture (59). In general, cell transformation has required the use of cell culture systems derived from species other than those infected in nature by the virus. Most cell transformation studies involving SV40, BKPyV, and JCPyV have employed cultured rodent cells. In addition, BKPyV and SV40 have been shown to transform primary cultures of human diploid cells, including PHFG cells, HEK cells, and fibroblasts (47). Studies of chimeric SV40/BKPyV and SV40/JCPyV LTags demonstrated that three regions of SV40 LTag are required for immortalization of human cells: the N-terminus, a central region containing the Rb-binding domain, and the C-terminus (60). The mechanisms by which immortalization occurs are incompletely understood. In the case of SV40 these appear to involve inactivation of the cellular growth suppressors pRB, p53, and SEN6 (59). Neither JCPyV nor BKPyV matches SV40 in its ability to immortalize human cells. Cell transformation by inoculation with intact MCPyV virions has not been described, but MCPyV sTag is sufficient to transform rodent fibroblast cell lines (61).

### Inactivation by Chemical and Physical Agents

Polyomaviruses withstand prolonged drying at room temperature and are relatively resistant to heat. Because they lack a lipid envelope, they are unaffected by ether and other lipid solvents. The viruses can be inactivated by  $\beta$ -propiolactone, proteolytic digestion, formaldehyde, prolonged heating to above 50°C, and exposure to ultraviolet light. The ability of these agents to persist at room temperature can present significant risks of inadvertent contamination in laboratories in which these agents have been studied.

## EPIDEMIOLOGY

Polyomavirus infections are worldwide in distribution among human populations. The prevalence of antibody to JCPyV is 10% in children 5 years of age and rises to over 50% by late adult life (62, 63, 64). Serological evidence of infection by BKPyV is present in 37% of individuals by 5 years of age and 83% by adolescence, falling to 53% in individuals over 50 years of age (65, 63, 64). Prevalence of antibodies to MCPyV is over 45% by age 10 and over 80% by age 69 (66, 67), whereas seropositivity rates for KIPyV, WUPyV, and HPyV7 in adults over 21 years of age have been reported to be 55%, 69%, and 56%, respectively (68, 67). Seroprevalence of antibodies to TSPyV are 41% in children under 10 years of age rising to 70% in adults overall, but falling in older individuals (69). Antibodies to BKPyV and JCPyV have been detected in populations so isolated as to be without evidence of contact with measles and influenza viruses (70). The high prevalence of serum antibody response to JCPyV or BKPyV is not further increased in immunosuppressed patients, including those with HIV infection.

### SV40 as a Human Agent

Over 150 million individuals worldwide received SV40-contaminated polio or adenovirus vaccines (3). The frequency of antibody response to SV40 in groups receiving contaminated polio vaccines was as great as 24% (71). Children receiving contaminated vaccines developed subclinical SV40 infection with prolonged fecal excretion of the virus (4), and experimentally infected volunteers showed both transient viremia and prolonged viremia (71). Up to 27% of personnel working for monkey export companies have anti-SV40 antibodies, and serological evidence of SV40 infection has been reported in 51% to 55% of laboratory workers in contact with monkeys or involved in preparation of monkey cells for tissue culture purposes (71). These data all indicate that SV40 is capable of replication in human hosts.

Serological, virological, and polymerase chain reaction (PCR) studies from a number of laboratories have also suggested human infection with SV40 or an SV40-like agent in individuals not exposed to contaminated vaccines (4, 72, 73, 74). The evidence for a human SV40-like agent has been controversial, however, in part because antibodies to SV40 in human sera have for the most part been at low titer, and because many of the reports failed to exclude cross-reacting antibodies to JCPyV or BKPyV (75, 76, 77). One serological study of sera from 699 patients, with and without cancer, detected antibodies to JCPyV or BKPyV in all patients and control subjects (75). Although antibodies reactive with SV40 were found in 6.6% of serum samples, preabsorption experiments confirmed that these were actually antibodies to JCPyV or BKPyV, which were cross-reactive with SV40. Attempts to amplify SV40 from urine of AIDS patients or from human sewage collected from widely dispersed areas in

Europe and Africa were unsuccessful despite the fact that JCPyV and BKPyV were readily detected in urine and stool (78, 79). In one study, SV40 and BKPyV coinfection was reported in some patients (80), but this was not the case in molecular studies of renal tissue from 19 patients with interstitial nephritis, although these studies did identify JCPyV and BKPyV (81). Furthermore, although infectious JCPyV and BKPyV virions have been repeatedly recovered from human urine, these studies have not detected SV40, nor was SV40 detected in molecular studies of renal tissue from 19 patients with interstitial nephritis, although these studies did identify JCPyV and BKPyV (81). The existence of an SV40-like agent of humans thus remains disputed (10).

## Transmission

Because no human polyomavirus has as yet been consistently associated with symptomatic illness during primary infection, the routes by which human polyomavirus infections are acquired naturally have not been defined, nor do we know the cells and tissues that support viral replication during primary infection. The most thorough data concerning polyomavirus transmission come from studies of nonhuman agents. Mouse polyomavirus is transmitted by respiratory spread (82). Mouse pneumotropic virus (MPtV) is acquired orally, with initial replication of the virus in intestinal endothelial cells (83). SV40 produced asymptomatic infection in volunteers after either oral or respiratory inoculation (71). JCPyV and BKPyV DNAs have been detected in human feces, suggesting that both viruses, like MPtV, may be transmitted by the oral route (84, 85, 86). Both JCPyV and BKPyV DNAs have been detected in human tonsils. However, PCR analysis of nasopharyngeal aspirates from children requiring hospitalization for acute respiratory illnesses detected BKPyV DNA—but not infectious virus—in only 2 of 201 patients and did not detect JCPyV DNA (87). Neither JCPyV DNA nor BKPyV DNA were identified in saliva from 60 HIV-infected adults or 10 healthy adult controls (87). However, BKPyV DNA can be detected in saliva by PCR, and the virus can productively infect submandibular and parotid gland cells lines (88). These data, in aggregate, suggest that JCPyV and BKPyV may persist in tonsillar or salivary tissues and that, in the case of BKPyV, salivary tissues might play a role in viral transmission. For the newer polyomaviruses associated with cutaneous shedding of virus, like MCPyV, infection is thought to be acquired by direct skin-to-skin contact among individuals or from environmental surfaces contaminated with virus (89). Suspected, but unproven, sites for primary infection by the newer human polyomaviruses include nasopharynx and lung for WUPyV and KIPyV; the skin for MCPyV, HPyV6, HPyV7, TSPyV, and HPyV9; and the gastrointestinal tract for MWPyV and STLPyV (90). Sexual transmission of human polyomavirus infection has not been documented, nor has detection of polyomavirus DNAs in human semen been reported.

Individuals with impaired host immunity do not appear at greater risk of acquiring polyomavirus infection. However, as will be discussed below, urinary excretion of both JCPyV and BKPyV are increased under conditions of immunosuppression, and clinical disease caused by JCPyV, BKPyV, MCPyV, and TSPyV occurs essentially only in immunosuppressed patients (91, 92).

### Progressive Multifocal Leukoencephalopathy

PML is an opportunistic demyelinating infection caused by JCPyV. The disease was initially identified as an extremely

rare, almost invariably fatal condition seen in patients immunosuppressed because of hematological malignancies, cancer chemotherapy, immunosuppression for organ transplantation, or collagen vascular disease (4). The disease was also reported, but rarely, in patients with protracted granulomatous disorders (including tuberculosis or sarcoidosis), with congenital immune deficiencies, or with celiac disease (4). With the advent of the AIDS epidemic, PML became much more common, causing death in 4% of patients (93). Following development of combination antiretroviral therapy (cART), however, this number has fallen significantly, and many treated patients with AIDS-PML now survive (94, 95).

In recent years, increasing numbers of cases of PML have been reported in non-AIDS patients receiving potent monoclonal immunomodulatory agents (Table 3), as well as in individuals receiving aggressive immunosuppression for organ transplantation (96, 97, 98). The agent most commonly associated with PML has been the humanized monoclonal antibody, natalizumab (99). Natalizumab reacts with the  $\alpha 4$  subunit of  $\alpha 4\beta 1$  and  $\alpha 4\beta 7$  integrins, which are expressed on the surface of all leukocytes except neutrophils (99). The agent is thought to inhibit migration of T lymphocytes and other peripheral blood mononuclear cells (PBMCs) across vascular endothelial cells and could thus interfere with lymphocyte-mediated immune surveillance within the central nervous system (CNS). Natalizumab has also been shown to reduce numbers of B lymphocytes in CSF, which could affect antibody-mediated control of JCPyV replication within brain parenchyma but could conceivably also reduce numbers of JCPyV-infected B cells entering CSF and brain. Other agents associated with PML have included rituximab (100), alemtuzumab, brentixumab vedotin, mycophenolate mofetil, and, more recently, dimethyl fumarate (Table 3) (101, 96). The effects of each of these agents on JCPyV persistence and reactivation have not been defined. Serum and JCPyV antibody levels in patients treated with natalizumab may have value in predicting patients who will develop PML (102), as may CSF anti-JCPyV antibody index (103, 104).

### Association of BKPyV with Renal and Other Urological Diseases

BKPyV replication with high-level viremia and viremia is more prevalent in children or adults undergoing kidney or hematopoietic stem cell transplantation and may progress to tubulointerstitial nephropathy (105, 106, 107, 108), and/or hemorrhagic cystitis (7, 109, 110, 111, 112, 113). BKPyV-associated nephropathy affects 1% to 15% of kidney transplant recipients. Although the intensity of immunosuppression unquestionably plays a role in development of nephropathy, it is clearly not sufficient since BKPyV-associated nephropathy is rare in nonkidney solid organ transplantation receiving similar or even higher immunosuppression. Other risk factors include HLA-mismatches, older age and male sex of the recipient, transplantation of a graft from a seropositive donor with high antibody titers into a recipient with low or no antibody titers, cumulative steroid exposure, and tacrolimus-mycophenolate versus cyclosporine or mTOR inhibitor combinations. In rare cases, BKPyV nephropathy may be associated with congenital immunodeficiency (114, 115) or with HIV infection (116). BKPyV-associated hemorrhagic cystitis affects 5% to 20% of human stem cell transplant (HSCT) patients (7, 110, 111, 113). Risk factors include unrelated donor, myeloablative conditioning with urotoxic drugs including cyclophosphamide and

busulphan, total body irradiation, and graft versus host disease. At present, BKPyV-associated urothelial carcinoma is a rare condition in immunosuppressed transplant patients and has occasionally been linked to chromosomal integration of the viral genome (117, 118).

### Merkel Cell Carcinoma

MCPyV, like all other human polyomaviruses, is a ubiquitous and normally benign agent, without associated symptomatic infection (119). However, the virus is associated with Merkel cell carcinoma (MCC), a highly aggressive skin neoplasm first discovered in 1980, with an incidence of 0.24 per 100,000 patient years (120). MCC is predominantly a condition of the elderly and is most common under conditions of immunosuppression (120). Merkel cell carcinoma represents the only human condition in which clonal integration of a polyomavirus has been definitively associated with human cancer (121). The disorder is infrequent, with roughly 1,500 cases being reported per year but has a median survival of 9 months (119).

### Trichodysplasia Spinulosa

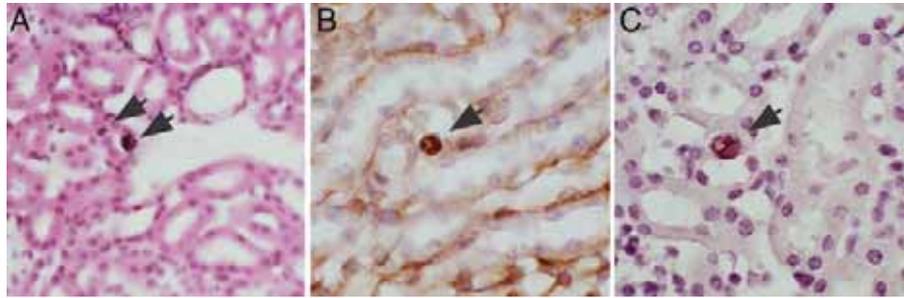

Trichodysplasi spinulosa (TS) represents a rare, potentially disfiguring cutaneous condition caused by TSPyV infection (69). The majority of cases have been reported in immunosuppressed individuals undergoing organ transplantation; a minority of cases have involved patients undergoing treatment for chronic lymphocytic leukemia (69). TSPyV is detected more frequently on the skin of HIV-positive than HIV-negative males but, somewhat surprisingly, the actual disorder has not as yet been reported to be increased in patients with HIV infection (122).

## PATHOGENESIS

### Animal Models of Human Polyomavirus Infection

None of the human polyomaviruses appear capable of causing productive infection in nonhuman species. For this reason, much of the current knowledge about the biological behavior of polyomaviruses in their natural hosts comes from studies of nonhuman agents. SV40 produces renal involvement in its simian host, as do JCPyV and BKPyV in humans. In immunocompromised animals, SV40 has been associated with fatal interstitial pneumonia, renal tubular necrosis, meningoencephalitis, and a PML-like illness (4, 123, 124). Under experimental conditions, mouse polyomavirus (MPyV) produces a protracted, widely disseminated infection followed by a latent renal infection that can be reactivated by pregnancy (4, 125).

The polyomavirus most extensively studied as a possible model for human infection is mouse pneumotropic polyomavirus (MPtV), formerly known as K virus. Infection is acquired by ingestion of virus, with initial replication of virus in intestinal endothelial cells (126, 83). In mice less than 6 days of age, MPtV produces an overwhelming infection of systemic and pulmonary vascular endothelial cells; death results from interstitial pneumonia (126). Older animals also develop widespread infection of vascular endothelial cells but survive acute infection. By 2 to 3 months following initial infection, viral nucleic acids, T-Ag, and V antigens can be detected in renal tubular epithelial cells, suggesting that viral persistence involves not actual latency but rather a chronic, low-level productive infection, similar to that now believed to occur in humans (127, 128) (Figure 6). Initial protection against lethal infection depends on a

**FIGURE 6** Polyomavirus persistence as a chronic productive infection, as shown in a kidney of a nonimmunosuppressed mouse 6 months after inoculation with murine pneumotropic (K) virus. Arrows indicate the presence of viral nucleic acids (A), T-Ag (B), and VP1 antigen (C) indicative of viral replication in renal tubular epithelial cells.

prompt antibody response. Cell-mediated immunity appears to be required for containment of persistent infection, and failure of T-lymphocyte function allows progression of infection by cell-to-cell spread (128).

With the exception of PML in simian AIDS, PML has not been observed in animals, nor have most attempts to produce PML in genetically modified animals been successful (129). Recently, CNS infection, with demyelination, has been produced following JCPyV inoculation into the brains of human glial chimeric *Rag2*<sup>-/-</sup> *Mbp*<sup>sh1/sh1</sup> mice (130). Although this model reproduces several features of PML, it differs from the disease seen in humans in that the model involves productive infection of astrocytes, an infrequent finding in human PML; also, oligodendrocyte death in this model involves apoptosis rather than the productive, lytic infection seen in humans. Attempts to reproduce human JCPyV infection in nonhuman species, using either JCPyV T-Ag or purified virus have resulted in dysmyelination in JCPyV T-Ag transgenic mice or in induction of a variety of tumor types in a number of species. However, none of these efforts has produced lesions resembling human PML (129).

### Viral Replication and Persistence

Although none of the human polyomaviruses has been associated with symptomatic acute infection, primary infection by JCPyV or BKPyV is thought to result in viremia and dissemination of infection to organs distant from the site of initial exposure in particular the renourinarytract (131). TSPyV and MCPyV genomic sequences have been detected in urine, kidneys, lung, and blood, suggesting that these agents are also capable of causing disseminated infection (89, 132). Both JCPyV and BKPyV have been shown to persist in renal tubular epithelial cells (11). In addition, however, JCPyV DNA sequences have also been identified in multiple other organs from individuals without PML (133–136). Both archetypal and variant forms of JCPyV DNA have been detected in the brains of up to 33% of individuals without HIV infection or PML (137–139). These findings suggest that JCPyV may persist in the brain and that PML might be a consequence of reactivated infection within the CNS. It is not known whether persistence of these agents represents truly latent infection as opposed to productive infection at very low levels, controlled by host immune response.

Following initial detection of JCPyV DNA by *in situ* hybridization in B lymphocytes within the spleen and bone marrow of an AIDS patient with PML (140), a number of studies using PCR methods have detected JCPyV in PBMCs or other leukocytes (141, 142), suggesting that infection of

circulating blood leukocytes could provide a mechanism for viral entry into the brain. Detection of JCPyV DNA sequences has been reported in PBMCs from 28.9% of 157 HIV-positive patients and from 16.5% of HIV-negative patients (143). In contrast, JCPyV DNA sequences both for the noncoding region of the genome and for VP1 were detected in only 0.9% of blood donors (144). In another study, DNA encoding JCPyV T-Ag was detected in blood from 31.8% of 60 AIDS patients but only in 2.3% of 88 immunologically normal blood donors (145). mRNA sequences encoding JCPyV VP1 were found in 38% of JCPyV DNA-positive urine samples from AIDS patients but in blood from only one individual (145). Other investigators have detected JCPyV DNA in T lymphocytes, monocytes, and polymorphonuclear leukocytes (146). In summary, these studies confirm that JCPyV may infect B lymphocytes and that the frequency of infection may be increased by immunosuppression. However, the studies also suggest that blood leukocyte infection by JCPyV may be latent and that other leukocyte populations may also support viral persistence, making it uncertain to what extent these cells are involved in dissemination of viral infection (139).

BKPyV is known to persist in kidneys. Infection of other organs and tissues is exceptional and essentially always associated with inherited immunodeficiency, immunosuppression for transplantation, or HIV-AIDS. In these settings, BKPyV has been detected in lungs, eyes, and brain (147–150).

MCPyV DNAs are readily recovered from normal skin, as are TSPyV, HPyV6, HPyV7, and HPyV9 (89), and studies employing next-generation sequencing may identify a wide diversity of polyomavirus species (151). MCPyV DNA has also been amplified from mucosal surfaces, and MCPyV DNA recovery has also been reported from internal organs, buffy coat preparations, and peripheral blood monocytes (132, 152). TSPyV is readily amplified from plucked eyebrows but has also been detected in nasopharynx, urine, and stool (69).

### Reactivation of Infection

Earlier studies of persistent infection by JCPyV or BKPyV strongly associated reactivation or urinary excretion of JCPyV or BKPyV with immunosuppression. In these studies, serologic evidence for reactivation of BKPyV was detected in 22% to 44% of individuals undergoing renal transplantation or chemotherapy for malignant disease (65). Further, longitudinal studies of HIV-infected patients documented urinary excretion of BKPyV in 37% of patients and JCPyV in 22% (153). Urinary excretion of either virus was more likely in patients with low CD4 counts or low  $\beta_2$ -microglobulin

levels and did not correlate with serologic markers for either virus. Excretion of JCPyV did not appear to increase the likelihood of developing PML (153).

More recent studies employing PCR methods demonstrate that asymptomatic urinary excretion of JCPyV and BKPyV is common in healthy individuals and is unaccompanied by a rise in antibody titers. Urinary excretion of JCPyV DNA has been shown to occur in up to 62% of normal individuals (154, 63). In most studies, excretion of BKPyV has been less common, occurring in roughly 5% of patients (154, 63). However, one study has identified urinary excretion of BKPyV in 55% of premenopausal women, without detectable variation in viral excretion throughout the menstrual cycle (155), and another study detected urinary excretion of BKPyV DNA in 24% of children under 9 years of age, possibly reflecting excretion during primary infection (156). BKPyV DNA excretion fell to under 20% until age 30 and then gradually increased, reaching 44% by age 80 to 89 (156). Urinary excretion of JCPyV DNA was less than 10% in children 0 to 9 years of age and then steadily increased thereafter, reaching 75% by age 80 to 89 (156). Other studies have confirmed high rates of JCPyV DNA tend to be continuous, whereas excretion of BKPyV DNA appears to be more sporadic (154). These data plus older studies would suggest that urinary excretion of JCPyV or BKPyV, lasting days to weeks, is a recurrent event in many immunologically normal individuals, but that excretion of actual infectious virus is increased under conditions of immunosuppression. JCPyV and BKPyV DNAs recovered from nonimmunocompromised patients have been almost invariably archetypal (63), whereas JCPyV genotypes recovered from immunocompromised patients may consist of both archetypal forms and rearranged variants (11).

Reactivation of BKPyV or JCPyV infection, with urinary excretion of virus, usually as the archetype, is a common event during pregnancy in most women (157, 158). Rise in antibody titers indicative of reactivated JCPyV or BKPyV infection occurs in approximately one-third of pregnant women, most frequently at the end of the second trimester and irrespective of initially high antibody titers (157). Urinary excretion of BKPyV DNA may also be increased in pregnant women compared to healthy controls, with most individuals excreting the archetype (158, 159). Some, but not all, studies have detected increased excretion of the JCPyV archetype. Although reactivation of most of the newer polyomaviruses during pregnancy has not been studied, limited data suggest that urinary excretion of WUPyV, KIPyV, or HPyV9 is not increased during pregnancy (158).

Whether reactivation of human polyomavirus infection during pregnancy might result in infection of the fetus is debated. Although one group has reported detection of JCPyV IgM and BKPyV IgM in newborn infants (160), this has not been a consistent observation (161), and attempts to detect polyomavirus nucleic acid sequences in aborted fetuses or placentas have been inconsistent (162, 163, 164).

### Immune Responses to Polyomavirus Infection

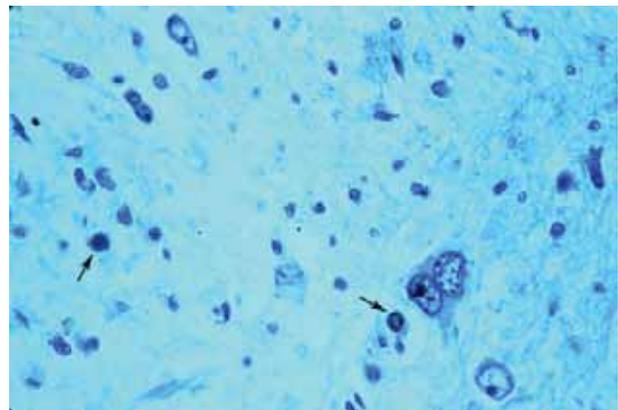

Polyomavirus infections elicit both antibody- and T-cell-mediated immune responses (11, 165, 166). The respective roles of the B- and T-cell responses in control of primary infection are not well understood. Impairment of the T-cell-mediated immune response results in increased urinary excretion of JCPyV or BKPyV despite continued high levels of circulating antibody, similar to the effect of immunosuppression on persistent MPrtV infection in mice (167). Impaired T-cell function is almost invariably present in

individuals succumbing to PML or BKPyV-associated nephropathy (168–174), and are presumed to play a role in the development of Merkel cell carcinoma, or *trichodysplasia spinulosa* (11, 89).

### Pathogenesis of PML

#### Pathology

PML may involve cerebrum, cerebellum, or brainstem; the spinal cord is only rarely involved (4, 175, 176). Cerebral cortex and deep gray matter appear normal, but areas of retraction within subcortical or deep white matter indicate myelin loss. Histopathological examination of PML lesions demonstrates loss of oligodendrocytes in demyelinated areas, and remaining oligodendrocytes may have enlarged nuclei or contain actual intranuclear inclusions (4, 175). Astrocytes in and around PML lesions frequently develop hyperchromatic or multiple nuclei and mitotic figures (Figure 7) (4, 175). JCPyV nucleic acids and early and late viral proteins are present within nuclei of infected oligodendrocytes (4) (Figures 7 and 8). Atypical astrocytes in PML contain viral nucleic acids, but only occasionally express early or late viral proteins (Figures 7 and 8) (4, 177, 178). Electron microscopic examination of PML brains demonstrate crystalline arrays of viral particles within infected oligodendrocytes. Small numbers of viral particles can be found in occasional morphologically normal astrocytes but not within atypical astrocytes (4). Myelin breakdown and lipid-laden macrophages become evident as the disease progresses. In non-AIDS PML, extensive inflammation is unusual, although small numbers of lymphocytes may be seen around vessels and in demyelinated areas. Demyelination in AIDS-PML is often more extensive than in non-AIDS cases (179), and brains may contain areas of actual necrosis (180, 179). Lymphocytic perivascular infiltrates are more evident (180, 179), and may at times be accompanied by parenchymal infiltrates, which may include macrophages and multinucleated giant cells (179). Although atypical astrocytes have been considered a pathological hallmark for PML, these cells are often infrequent or absent in AIDS-PML brains and may also be rare or absent in non-AIDS cases. Lesions in PML accompanied by immune reconstitution inflammatory syndrome (PML) may lead to actual cavitation and show

**FIGURE 7** Section from edge of a PML lesion, stained for polyomavirus common structural antigen, and labeled using immunoperoxidase techniques. There is extensive loss of myelin. Oligodendrocytes have enlarged nuclei that exhibit intense immunostaining indicating productive infection (arrows). Giant astrocytes within the lesion remain unlabeled. Magnification,  $\times 216$ .

**FIGURE 8** Section of PML-affected brain probed for JCPyV nucleic acids using *in situ* hybridization methods. Large numbers of exposed emulsion grains, indicative of specific hybridization, overlie nuclei of infected oligodendrocytes. Smaller numbers of exposed emulsion grains overlie atypical astrocytes, again indicating presence of viral nucleic acids. Magnification,  $\times 400$ .

extreme lymphocytic infiltration consisting of CD8+ and/or CD4+ lymphocytes and macrophages (181). Cases of PML in remission, an event that was essentially unknown before the late 1990s, may show persistence of viral antigen in areas of prior involvement (182). Although JCPyV infection of brain has been tightly associated with infection of oligodendrocytes and astrocytes, the virus can also produce productive infection of cerebellar granule cells or cortical neurons (183, 184).

### Immune Responses

PML almost always occurs in the setting of immunosuppression, involving both T-cell-mediated and, to a lesser extent, antibody-mediated immune responses (4, 139). Abnormalities of T-cell response are essentially universal in patients with PML. Patients with non-AIDS PML have demonstrated a general impairment of T-cell-mediated immunity, with selective impairment of JCPyV T-cell responses (4, 139). The presence of JCPyV-specific cytotoxic CD8(+) T cells has been associated with better prognosis in PML, including those patients who develop immune reconstitution inflammatory syndrome (185, 186). In one series, 9 of the 10 patients whose PML entered remission following cART had positive CDA T cell responses, and restoration of JCPyV-specific CD4 T-cell responses was associated with clearance of JCPyV DNA from the CSF (187). In another study comparing prospectively identified PML survivors with nonsurvivors and CD4 matched controls for either group in the setting of HIV-AIDS, survival was linked to higher antibody titers and JCPyV-specific T-cell responses (174). This and other studies suggest that individual gaps in JCPyV-specific humoral and cellular immune response might explain why some patients succumb to PML, whereas others do not despite similar overall immunologic risk factors (174, 188).

Although patients with both AIDS-PML and non-AIDS PML may mount both systemic and intrathecal antibody responses to JCPyV, this response may not prevent the onset of disease. A rise in anti-JCPyV antibody response may occur before the onset of PML (189, 102, 174), and an intrathecal antibody response occurs in up to 76% of patients with PML (190). On the other hand, a rise in antibody titers may also

accompany recovery, and a rise in titers of antibody to JCPyV has been observed during immune reconstitution in patients receiving cART (191, 174, 104).

Despite the fact that large numbers of individuals are persistently infected with JCPyV, PML is an unusual event, even in AIDS or during immunosuppressive treatment. This discrepancy suggests that compromised immune status alone does not account for the development of disease. The detection of JCPyV DNA in brains of immunologically normal patients suggests that PML might arise from reactivation of infection latent in the CNS (137, 138, 139, 136). It is possible that individual gaps in the JCPyV-specific immune response account for progression to PML and closing these gaps may be critical for disease prevention or survival outcome (174). Alternatively the frequent detection of JCPyV DNA in PBMCs from AIDS or other immunocompromised patients, with the caveats discussed above, could also provide a mechanism for viral entry into the brain.

### Virological Features

An important question concerning the pathogenesis of PML has to do with the nature of the infectious virus. Archetypal JCPyV is at best rarely associated with PML, and most PML isolates have had NCRR duplications, deletions, or rearrangements. Although these genomic changes have been shown to alter the behavior of JCPyV in cell culture, their role in causing PML has not been determined (192, 139). JCPyV tropism for cerebellar granule cells, however, appears to correlate with a unique deletion in the region of the VP1 gene corresponding to the C terminus (193), suggesting that the deletions or rearrangements seen in the genomes of PML-associated JCPyV genotypes may have pathogenic importance.

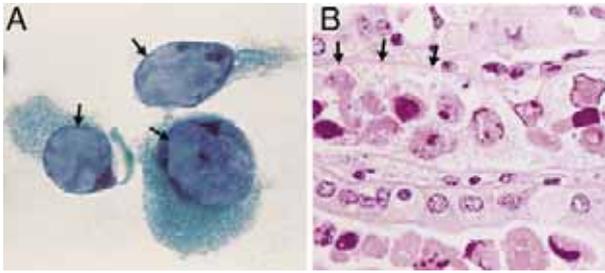

In AIDS, pathological studies have documented a close association between AIDS PML lesions and HIV-infected T-cell/macrophage infiltrates, and large amounts of HIV antigens have been identified in some AIDS PML lesions (180). A direct facilitating role for HIV Tat or other proteins has been suggested by pathological and virological studies implicating *Tar*-sequences in the JCPyV archetype NCCR, which may no longer be necessary following NCCR rearrangements (194, 195, 192). Although PML has been reported in patients with a number of congenital immunodeficiency syndromes, no clear genetic association leading to PML *per se* has been reported (196). The association of PML with newer monoclonal immunomodulatory and other immunosuppressive agents has been discussed above.

### Pathogenesis of BKPyV-Associated Urinary Tract Disease

#### Pathology

The finding associated with BKPyV excretion (and occasionally JCPyV excretion) under conditions of immunosuppression is the excretion of decoy cells (Figure 9), and of Haufen bodies, which represent clusters of cells expressing LTag (197). Decoy cell inclusions typically contain BKPyV virions, although cells infected by JCPyV may contain similar inclusions. In cases of ureteral stenosis, BKPyV-infected cells may be numerous enough to cause luminal narrowing or actual occlusion (198).

The characteristic pathological changes in the kidneys of individuals developing BKPyV-associated nephropathy are thought to progress through three stages, beginning with viral cytopathic effects (Stage A), cytopathic-inflammatory changes (Stage B), and tubular atrophy with interstitial

**FIGURE 9** Urine and allograft-biopsy specimens from a patient with BKPyV-associated nephropathy. fibrosis (Stage C) (Figures 9 and 10) (198). In the few biopsied cases of hemorrhagic cystitis, BKPyV replication has been demonstrated by LTag staining together with inflammatory cell infiltrates. Clinical studies suggest the role of urotoxic drugs administered as part of the myeloablative conditioning as contributing factors to the urothelial damage (113).

Hemorrhagic cystitis may occur together with urethritis with or without ureteral obstruction, or less frequently, with interstitial nephritis (110, 113). Although most patients with hemorrhagic cystitis after allogeneic HSCT are seropositive, children with low or negative serostatus have been shown to develop hemorrhagic cystitis implicating nosocomial or even primary infection (112).

#### Immune Responses

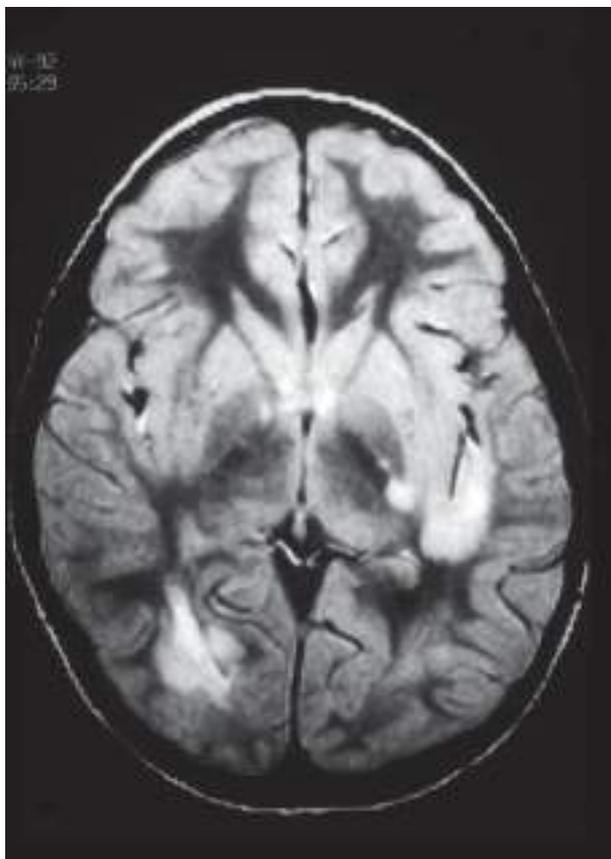

The conditions that predispose to BKPyV nephropathy following renal transplantation are complex and involve not only host and viral factors but also presence of BKPyV in the donor kidney, HLA-mismatches, and types of treatment used post transplantation (199–201). Recent clinical and virological studies suggest that immunosuppressive drugs may have different direct effects on BKPyV replication leading to higher numbers of viremic patients (202, 203). JCPyV-associated nephropathy differs in that JCPyV viremia is usually low or undetectable, despite high urine viral loads and the presence of “decoy cells” (199).

#### Virological Features

The major known site of BKPyV persistence is the renal tubular epithelium. However, latent infection and low-level replication of BKPyV cannot be reliably distinguished, and it is not known to what extent the virus exists in a truly latent state or is maintained as productive infection at low levels involving cell-to-cell spread. Clinical disease can be caused by BKPyV replication in the tubular epithelial cells of the

**FIGURE 10** Histological patterns of polyomavirus-associated nephropathy (PVAN) in kidney transplant biopsies. (A) BKPyV nephropathy pattern A consisting of focal viral cytopathic changes with little inflammation or tubular atrophy of a patient with a BKPyV archetype NCCR in plasma. kidneys, the urothelial lining of the ureters, and the bladder. In BKPyV-associated nephropathy, however, the entire viral replication cycle has been documented, with initial detection of LTag in renal tubular epithelial cells followed by the expression of late VP1 and agnoprotein, consistent with cell-to-cell of infection within individual nephrons (172, 204). BKPyV replication in urothelial cells may play a role for disease progression via retrograde spread within nephrons in addition to hematogenous seeding through viremia (205, 198, 201, 206).

### Pathogenesis of Merkel Cell Carcinoma and Trichodystrophy Spinulosa

MCPyV DNA has been detected in approximately 80% of tumors and found to be clonally integrated in cellular DNA of both primary tumors and metastases (132). Although development of Merkel cell carcinoma occurs in patients with impaired immune response, the malignancy is rare, even among severely immunocompromised patients. Merkel cell carcinomas express LTag. Seroreactivity to MCPyV LTag, as opposed to antibodies to MCPyV VI antigen, is rarely seen in normal individuals but is seen at high titer in patients with Merkel cell carcinoma. MCPyV genomes isolated from MCC tissues harbor point and other mutations that result in expression of prematurely terminated LT (LTtrunc) lacking C-terminus sequences that are growth-inhibitory. It is thus of

note that MPyV intact LTag and sTag sequences transform cells *in vitro* far less readily than do LTtrunc and sTag, which is consistent with observations that Merkel cell carcinomas express high levels of both LTtrunc and sTag (132). The interplay between impaired host antibody-mediated and T-cell-mediated immune responses, alterations in viral genomic function, and induction of neoplasia remains poorly understood (132).

As with MCC, trichodystrophy spinulosa is uncommon, associated predominantly with immunosuppression for organ transplantation or in patients with acute or chronic lymphocytic leukemias. At present the molecular and host events leading to the onset of trichodystrophy spinulosa are not understood. In contrast to the nonproductive MCPyV infection detected in Merkel cell carcinomas, the TSPyV infection leading to trichodystrophy spinulosa is productive, with expression of late viral proteins and production of actual virions (69).

### Carcinogenesis

Murine polyomavirus was discovered through its ability to produce tumors following inoculation into its natural host, and SV40, BKPyV, and JCPyV had been shown before 1980 to cause central nervous system tumors in experimental animals (4, 207). For this reason there has been long-standing interest in whether or not polyomaviruses might also cause tumors in humans. To date, however, no human polyomavirus other than MCPyV has been definitively linked to a human tumor. Tumor production by any of these viruses in animals usually requires conditions such as the use of large quantities of virus, inoculation into species other than its natural host, and inoculation under conditions of compromised immune status or into sites such as the CNS, which are relatively sequestered from host immune response. In the case of JCPyV, the most suggestive evidence that the virus might cause tumors in humans lies in 3 reported cases characterized by multifocal gliomas abutting PML lesions (208–210). However, none of these cases has been studied using modern molecular techniques. An important area of ongoing research has been the possible causative role of BKPyV in bladder or other urinary tract carcinomas in solid organ transplant (SOT) patients, a group of patients at high risk for productive BKPyV infection (118). In 20 patients reported to date, clonal expression of polyomavirus large T-antigen or BKPyV DNA, but not cytopathic effects indicating viral replication, has been detected in these tumors and their metastases (118). Similar clonal expression of large T-antigen has also been detected in tumors arising in native and transplant kidneys and ureters (118). Chromosomal integration of BKPyV has been demonstrated in one case (117).

JCPyV, BKPyV, and, in particular SV40 antigens or DNA have been detected by immunohistological or PCR methods in a number of human tumors; including choroid plexus papillomas and other brain tumors, mesotheliomas, colonic and esophageal tumors, non-Hodgkin's lymphomas, and prostate tumors. However, detection of viral DNA or antigens within a tumor does not necessarily indicate causation and could be explained by one of two other scenarios (207). First, the virus could be a "passenger," meaning that it finds favorable conditions for replication in an already transformed cell. Second, the virus could be present not within the tumor itself but in nonneoplastic adjacent cells or tissue compartments (207). In addition, absence of viral DNA from a tumor could also be the result of a "hit-and-run" process in which malignant transformation was initially

caused by the virus, but the virus is no longer detectable after transition of the cell to a fully malignant state (207). An additional complicating factor is that polyomaviruses are extremely hardy, and viral DNA can be assumed to be a potential contaminant in any laboratory in which the virus has been handled. In general, confirmation of polyomavirus association with individual tumors—other than MCPyV—has not been confirmed in independent laboratories; and studies employing improved PCR methods and more stringent controls have also failed to confirm most earlier reports identifying polyomavirus DNA in human tumors. The association of BKPyV and neoplasia is particularly perplexing in prostate neoplasms: studies employing high-throughput RNA sequence (RNA-Seq) methods have failed to detect BKPyV nucleic acids in a total of 213 prostate cancers or in 39 nonmalignant prostate samples (211–213). These observations could be consistent with a “hit-and-run” hypothesis of viral causation but could also indicate that BKPyV had no role in these neoplasms. A more recent study showed that higher antibody titers to the common N-terminus shared by LTag and sTag were associated with a better prognosis of prostate cancer and improved the predictive value of tumor stage, Gleason score, and surgical margin status (214).

SV40 has been postulated to cause human neoplasia since its discovery as a contaminant in batches of poliovirus and adenovirus vaccines, and detection of SV40 sequences in human tumors is still being reported and discussed (213, 215). Studies of army veterans exposed to SV40 in contaminated adenovirus or poliovirus vaccines have not shown an increased incidence of cancer over time (216). Some SV40 isolates have been found, upon careful examination, to contain plasmid DNA sequences indicating laboratory contamination (217). Other isolates have been shown to be 776-SV40, a widely used laboratory strain that has never been directly isolated from monkeys and that may also represent contamination rather than natural infection (14). Only one group of investigators has attempted to duplicate PCR amplification of polyomaviruses from the same tumor material in two geographically separated laboratories (218). Although JCPyV, BKPyV, or SV40 DNAs were detected in a small number of cases, neither laboratory could confirm the other laboratory's positive cases (218). At present, other than the possible association of BKPyV with renourinary tumors in solid organ transplant patients, there is insufficient evidence to associate JCPyV, BKPyV, or SV40 with human neoplasia.

## CLINICAL MANIFESTATIONS

Acute JCPyV or BKPyV infections are usually asymptomatic. One 13-year-old, immunocompetent girl was reported to have undergone seroconversion to JCPyV in association with chronic meningoencephalitis (219), and JCPyV DNA has been detected in the CSF from an individual with meningitis in the setting of systemic lupus erythematosus (220). BKPyV has been isolated from the urine of pediatric patients with both hemorrhagic and nonhemorrhagic cystitis. JCPyV and BKPyV DNAs were detected by PCR in 3.8% and 1.5% of 181 CSF samples from individuals with meningitis or encephalitis but not in 20 CSF samples from control subjects (221). In none of these reports, however, was a causative role for either virus proven, and two of the positive samples (one positive for JCPyV and one for BKPyV) were also positive for *Mycobacterium tuberculosis*, suggesting a much more likely cause of the neurological illnesses (221).

## Progressive Multifocal Leukoencephalopathy

PML usually begins insidiously, with initial symptoms and signs suggesting focal cerebral involvement: these may include alterations in personality, changes in intellect, focal weakness, difficulty with motor skills, or sensory loss (4, 175). Involvement of the dominant cerebral hemisphere may result in expressive or receptive dysphasia. Visual field abnormalities, including actual cortical blindness, occur in 50% of patients (4). Occasionally, PML begins with signs of brainstem or cerebellar involvement, with difficulty in phonation, swallowing, abnormalities of extraocular movements, or ataxia (4). Spinal cord involvement is rare and is virtually never symptomatic (176).

Without intervention, the course of PML is remorselessly progressive. Initial symptoms are followed by the appearance multifocal neurological signs, increasing dementia, and progression to a vegetative state. Most patients with non-AIDS PML die within one year, but death may occur within as little as 2 months, and cases have been reported with survivals of 8 to 10 years or longer (4). Survival in untreated AIDS patients with PML averages 4 months. cART has significantly altered the frequency and course of AIDS-PML, so that the 1-year and 3-year survival rates for AIDS-PML are 55% and 50%, respectively, and 79% at 1 year for patients with CD4+ count above 100 cells/mm<sup>3</sup> at diagnosis (95). The Swiss HIV Cohort Study of 186 cases of PML, 159 of whom were diagnosed before death, demonstrated a significant reduction in mortality in patients starting cART compared to mono- or dual drug therapies (94). Survival in AIDS-PML is highly dependent upon adherence to cART (222).

Patients developing PML while receiving immunomodulatory or immunosuppressive agents may also stabilize or improve after withdrawal of the therapeutic agent. In patients developing PML following treatment with natalizumab and treated with withdrawal of medication plus plasma exchange and/or immunoadsorption, mortality is now 23% (223), although survivors may be left with significant neurologic deficits (223). Development of IRIS is an almost universal concern in these patients (224); and onset of PML-IRIS *de novo* has been reported after discontinuation of natalizumab (225).

## Clinical Diagnosis

PML should be considered in any immunocompromised patient who develops progressive neurological deficits involving multiple areas of brain (4). Patients with untreated HIV and patients receiving natalizumab should be considered at high risk. Hematological studies and blood chemistries are unhelpful in the diagnosis of PML. Cerebrospinal fluid is usually normal but may occasionally contain increased protein or, rarely, a lymphocytic pleocytosis (4).

The most useful screening study for PML is magnetic resonance imaging (MRI) (4), which will show altered signal in subcortical and deep white matter on T2 and FLAIR images (Figure 11). Some, but not all, PML lesions enhance with intravenous gadolinium. MRI should be followed by analysis of CSF for JCPyV DNA (226). A particular challenge in dealing with patients with multiple sclerosis is the differentiation of demyelination due to PML from that due to the underlying disease. MRI changes considered suggestive of PML include lesion size over 3 cm; subcortical localization; presence of lesions in the basal ganglia; hyperintensity on T2, FLAIR, and DWI images with hypointensity on T1 images; lesions that are sharp toward gray matter and ill-defined toward white matter, and a tendency

for lesions to increase in size and for new lesions to appear (227). Hyperintensity of lesions on T1-weighted images suggests PML-IRIS (227).

Several other infectious agents may mimic PML clinically in immunosuppressed patients. In patients with AIDS, these include central nervous system invasion by *Toxoplasma gondii*, *Cryptococcus neoformans*, or *Mycobacterium tuberculosis*. These infections may occur together with or in the absence of PML. Central nervous system lymphoma may also mimic PML, in particular in AIDS patients. Brain biopsy to rule out treatable conditions may thus be crucial in these patients where the diagnosis of PML is at all in question or where there is concern about other, coexisting conditions.

### Other CNS Infections Associated with JCPyV

Although JCPyV has traditionally been thought to produce an infection limited to cells of glial origin—oligodendrocytes and astrocytes—it has also been associated with infection of cerebellar granule cell neurons and of pyramidal neurons, causing a cortical encephalitis. Granule cell neuronopathy has been described in AIDS patients and patients treated with monoclonal antibodies and may occur in the presence or absence of PML (228, 229, 183). In such cases, cerebellar atrophy and white matter changes may be detectable on MRI (229). Analysis of JCPyV DNA from the granule cells of one patient with coexisting PML revealed a unique deletion in the C terminus of the VP1 gene not found in JCPyV DNA present in the patient's white matter lesions, suggesting that the deletion, with its accompanying frame shift, may have enabled the virus to infect granule cell neurons (193). Unlike PML *per se*, granule cell neuronopathy may run a non-fatal course (183). Cortical encephalitis has been associated with a JCPyV genotype with a unique 143 bp deletion in the gene encoding the agno protein (230, 231).

### BKPyV Renourinary Tract Infection

Urinary tract involvement by BKPyV may cause cystitis, ureteral obstruction, or nephropathy with stage B nephropathy previously being called interstitial nephritis. Nephropathy is most frequently seen following organ or stem cell transplantation and is seen in 4% to 8% of renal transplant patients (232, 65, 233). Rare cases of nephropathy have also occurred in children with severe immunodeficiency syndromes and in occasional patients with AIDS (234). In some cases, nephropathy may be accompanied by symptomatic cystitis or ureteral obstruction. More commonly, however, BKPyV-associated nephropathy is clinically silent and is manifested in 40% to 60% of cases by progressive renal failure (232, 65). In renal transplant patients, the condition may be confused with graft rejection (232, 65). The risk for BKPyV nephropathy following renal transplantation is known to be associated with a number of factors including high BKPyV antibody titers in the donor, low or absent BKPyV antibodies in the recipient, HLA-mismatches, and potent immunosuppressive therapy often involving tacrolimus-mycophenolate combinations (235, 236, 202). A minority of cases of posttransplantation nephropathy are associated with JCPyV (237–239). Ureteric stenosis due to BKPyV has become much less common today in kidney transplantation despite extensive urothelial replication, presumably due to improved surgical techniques and ureteric stent implantation.

Cystitis due to BKPyV may be hemorrhagic or non-hemorrhagic, occur during primary or reactivated infection, and be occult or symptomatic (240). In transplant patients, hemorrhagic cystitis associated with BKPyV usually occurs

well after organ transplantation and should be differentiated from that seen soon after transplantation, which is more commonly due to cyclophosphamide or other immunosuppressive agents (65, 240). Hemorrhagic cystitis is, by definition, clinically symptomatic with urgency, dysuria, and macrohematuria (110, 113). The condition may occur together with urethritis with or without ureteral obstruction, or less frequently, with interstitial nephritis. Although most patients with hemorrhagic cystitis after allogeneic HSCT are seropositive, children with low or negative serostatus have been shown to develop hemorrhagic cystitis implicating nosocomial or even primary infection (112). The disease has to be differentiated from other etiologies including direct toxic effects, herpes simplex, cytomegalo-, and adenovirus infection (113).

### Other Conditions Associated with BKPyV Infection

In a handful of cases, all of them in profoundly immunocompromised patients, BKPyV has been reported to cause interstitial pneumonia (241). In one renal transplant patient, BKPyV was associated with a widespread infection of vascular endothelial cells resulting in muscle weakness, anasarca, and myocardial infarction (242). BKPyV has been occasionally detected in the CSF of children with encephalitis (221) and was identified in CSF from one patient with frontal and temporal encephalomalacia in the setting of renal transplantation (243). BKPyV has also been associated with cases of retinitis and of meningitis or encephalitis but in most of these cases there has not been clear proof that BKPyV was the causative agent (241).

### Merkel Cell Carcinoma and Trichodystrophy Spinulosa

Merkel cell carcinoma and TS are both conditions involving the skin, but with radically different clinical course, morbidity, and mortality. The tumor most commonly occurs on sun-exposed areas of skin as a small, cystic lesion that enlarges over weeks to months. MCC metastasizes to draining lymph nodes and also to brain, bone, and systemic organs. Mean survival in patients is under 6 months (120).

Trichodystrophy spinulosa is a rare skin condition, characterized by development of spiny follicular papules located predominantly on the face and, in a smaller number of cases, on extremities, trunk, or scalp. The disease has been observed under conditions of immunosuppression and occasionally in patients with chronic lymphocytic leukemia. The condition can be disfiguring but, in contrast to MCC, is not yet known to have appreciable mortality (69).

### Manifestations of Other Polyomaviruses

Nine other human polyomaviruses have been identified (Table 1). Most if not all of these agents are widespread agents of human infection. To date, however, the majority of these agents have not been associated with clinical illness. HPyV6 and HPyV7 are shed from the skin of healthy subjects as well as patients with a variety of skin tumors. KI and WU viruses have been recovered from nasopharyngeal aspirates of children with respiratory tract infections and STLPyV has been recovered from tonsils of children with chronic tonsillitis. However, the actual role of these agents in disease causation has not been established. To date, of the newer polyomaviruses, the only one linked to clinical illness is NJPyV, which has been associated with microvasculitis of muscle and retina and with a necrotizing dermatopathy in one pancreatic transplant patient (244). Pathological evaluation

of muscle in this patient revealed a vasculitis affecting small vessels. NJPyV DNA was recovered from both skin and muscle, and polyomavirus inclusions were found in vascular endothelial cells, similar to the vascular involvement seen with the mouse agent, MPtV (244, 127).

## LABORATORY DIAGNOSIS

### JCPyV Infection and PML

PML was initially a pathological diagnosis, with diagnostic accuracy enhanced by immunohistochemistry for JCPyV antigens or *in situ* DNA hybridization methods. At present, the diagnostic study of choice for PML is PCR analysis of CSF for JCPyV DNA (226). In earlier studies, use of PCR analysis of CSF enabled specific diagnosis in 80% to 90% of cases (4), and this level of sensitivity is still thought to apply in cases of non-AIDS PML, including cases associated with natalizumab and other agents affecting host immune response. In patients with AIDS-PML, however, cART has been shown to reduce viral load of JCPyV in CSF, so that diagnostic yield in patients treated with cART has been reduced to 57.5% (245). Cell culture isolation is extremely cumbersome and not used for diagnostic purposes.

### BKPyV Infection

Renourinary infection by BKPyV may be suspected by the detection of decoy cells (urothelial cells containing nuclear inclusions) in urine (Figure 9). Urinary decoy cells, although highly specific, are seen in 40% to 60% of transplant patients but associated with nephropathy in only 20% of cases (232). Viremia with over 7,000 copies of BKPyV DNA per ml has a predictive value of approximately 60%, and urinary excretion of over 100 times the number of copies per ml in plasma has a predictive value of 40% (232). Although transplant biopsy remains the gold standard to diagnose BKPyV, quantitative analysis of urinary decoy cells and identification of urinary Haufen bodies provide good surrogate markers for surveillance (246, 247).

### Serologic Assays for JCPyV and BKPyV

Antibodies to JCPyV and BKPyV can be measured by hemagglutination inhibition (248) or ELISA methods. Detection of antibodies to JCPyV or BKPyV is not itself diagnostic of disease, since most individuals have antibody. The presence of antibody does, however, indicate prior infection, and elevation of JCPyV antibody index in patients on natalizumab or other agents may suggest increased risk of PML. Severe immunosuppression may prevent a rise in antibody titer.

## PREVENTION

Vaccines or other specific measures to prevent JCPyV or BKPyV infection have not been developed. In recent years, however, major attention has focused on the identification of individuals at increased risk of developing PML while under treatment with natalizumab or other immunomodulatory agents, or of developing BKPyV nephropathy and then adding risk stratification to alter their immunosuppressive regimens. The presence of antibodies to JCPyV has been intensively studied as a tool for risk stratification in individuals receiving natalizumab, based on findings that individuals who are seropositive for JCPyV appear to be at a higher risk for developing PML (102). Use of a commercially available JCPyV antibody index has demonstrated that natalizumab-treated patients developing PML maintain

higher anti-JCPyV antibody index values over time than did patients not developing PML, suggesting that antibody index may provide a means of assessing PML risk in antibody-positive natalizumab-treated patients (102).

BKPyV-associated nephropathy is asymptomatic in almost all cases, and the disease is not recognized until renal function is significantly impaired. Therefore, current guidelines emphasize the role of screening for BKPyV in urine and blood (246, 247, 201). The paradigm of BKPyV reactivation after kidney transplantation proceeds from low-level viremia detected by quantitative PCR to high-level viremia with BKPyV loads above 7 log<sub>10</sub> copies/ml and the appearance of “decoy cells” in 20% to 40% of patients (108, 249, 206). BKPyV-associated nephropathy is more likely if plasma viral loads are above 7,000 copies/ml (108, 198). Although transplant biopsy remains the gold standard for a proven disease, plasma viral loads above 10,000 copies/ml are widely accepted for the diagnosis of presumptive nephropathy and preemptive treatment, e.g., by reducing immunosuppression (201). Patients with high urine viral loads above 10 million copies/ml are considered to be at risk for viremia and nephropathy, but a preemptive treatment approach by immunosuppression may not be justified (249) as it unnecessarily increases the risk of precipitating rejection (250).

### Treatment of PML

Attempts to treat PML with antiviral agents have employed cytosine arabinoside, camptothecin, topotecan, cidofovir, mefloquine, and serotonin receptor blockers such as mirtazapine, but no agent of proven value has been identified to date. Brincidofovir, a lipid conjugate of cidofovir (formerly called CMX001), has been found to inhibit JCPyV replication in human brain progenitor-derived astrocytes and human fetal brain SVG cultures but has not as yet been reported in clinical trial (251, 252). The use of cytosine arabinoside, cidofovir, camptothecin, and topotecan may be accompanied by significant toxicity. An uncontrolled study reported neurological stabilization or improvement in 7 of 19 non-AIDS PML treated with intravenous cytosine arabinoside at 2 mg/kg for 5 days (253), but controlled studies have shown no benefit in HIV-infected individuals (254). Clinical improvement has been described in individual AIDS and non-AIDS patients treated with cidofovir, including cases in which cidofovir was added to cART or other antiviral agents (255–258). However, efficacy has not been demonstrated in case series of AIDS-PML, and controlled trials have not been reported (259). Camptothecin and topotecan have been used in individual cases of PML, but therapeutic efficacy has not been confirmed (260). Mefloquine, which has been shown to have antiviral activity against JCPyV *in vitro*, has been used in individual patients, as has the serotonin reuptake inhibitor, mirtazapine, with or without concomitant treatment with cidofovir or mefloquine. Although individual case reports have suggested clinical improvement with these agents, mefloquine was not demonstrated to be effective in a controlled trial (261), and controlled studies of mirtazapine have not been reported. The use of monoclonal agents directed against JCPyV capsid proteins has been suggested but not yet used in clinical practice (262).

In contrast to the poor results seen with antiviral agents in treatment of PML, virological and clinical improvement have been definitively shown to occur in cases in which it is possible to restore host immunocompetence by treatment of AIDS patients with cART, removal of monoclonal agents,

such as natalizumab, by plasma exchange with or without immunoadsorption, or discontinuation of other immunosuppressive agents (95, 263). In such cases, restoration of immunocompetence may result in life-threatening IRIS, whose treatment may require corticosteroids or other measures (262); IRIS will occur in over 70% of cases of PML associated with natalizumab following discontinuation of medication (262).

### Treatment of BKPyV Nephropathy

There is currently no specific antiviral therapy to treat BKPyV nephropathy. A placebo-controlled prospective randomized trial of levofloxacin prophylaxis for the first 3 months after kidney transplantation did not demonstrate lower rates of BKPyV viremia or viremia, but an increased risk of bacterial resistance (264). Monitoring of viral load and preemptive withdrawal of immunosuppression were associated with resolution of BKPyV viremia and decreased rates of nephropathy (249, 171, 265, 250, 236, 266). Multiple case series have suggested therapeutic benefit from cidofovir, but controlled trials demonstrating efficacy have not been published. Commercially available immunoglobulin G, which contains neutralizing antibodies to all BKPyV genotypes, has shown potent antiviral activity against BKPyV *in vitro*. In one study of 30 patients with BKPyV nephropathy unresponsive to cidofovir and use of leflunomide, treatment with IgG intravenously at 1g/kg produced clearing of viremia in 90% of patients and 12-month graft survival rates of 96.7% (267). Brincidofovir has shown a good inhibitory effect of BKPyV replication in tubular epithelial and urothelial cells *in vitro*, and it is currently in clinical trials (268–270).

### Treatment of MCC and TS

Treatment of MCC may involve surgery, radiation treatment, and chemotherapy. Antiviral treatment has as yet no place in treatment of the neoplasm. Improvement in TS has been reported with withdrawal of immunosuppressive agents, and individual cases have been reported to improve with topical cidofovir or oral valganciclovir (271).

# Papillomavirus

WILLIAM BONNEZ

## 29

Human papillomaviruses (HPV) are a large group of viruses (more than 200 types identified) that infect the epithelium of the skin and mucous membranes. The infections can be latent, subclinical, or clinically manifest, causing lesions that range from the benign (warts, papillomas, condylomas) to the malignant. Some of these viruses are responsible for cutaneous warts; a different group of HPVs (types 6 and 11) is responsible for most genital warts. The major importance of HPVs is because 20 types (especially HPV-16 and -18) are regarded as the necessary, if not sufficient, cause of cervical cancer as well as other cancers of the vagina, vulva, penis, anus, and oropharynx. Although most sexually active individuals get infected with genital HPVs, most of these infections are transient and innocuous. It is the persistence of the high-risk oncogenic HPVs that leads to malignant transformation. Cancer caused by these viruses is preceded by a precancerous stage whose detection is the basis of cytologic screening (Pap smear) for cervical cancer. Ten years ago HPV vaccines were introduced for the prevention of diseases associated with HPV-16 and -18 and for the prevention of anogenital warts caused by HPV-6 and -11. The introduction of HPV vaccination has been a major advance because it is the first time a vaccine has been able to directly prevent virally induced cancers. When used broadly before the onset of sexual activity, HPV vaccination has caused a dramatic reduction in the incidence of genital warts and HPV-related cervical lesions. This should be the harbinger of a decline in the rates of cervical and other cancers.

### HISTORICAL BACKGROUND

Hand and plantar warts and external anogenital warts, also called condylomata acuminata, have been known since antiquity. However, it was in 1871 that Mackenzie recognized the existence of laryngeal papillomas and in 1922 that Lewandowsky and Lutz described epidermodysplasia verruciformis (1, 2). Variot in France was the first to demonstrate the transmissibility of warts in 1891, while Ciuffo in Italy established their viral nature in 1907 (3, 4). Human papillomaviruses (HPVs), first identified by electron microscopy in 1949 by Strauss et al. (5), primarily infect stratified squamous epithelia of humans. The Crawfords showed that the virus had a double-stranded DNA genome (6). HPV was originally thought to cause only warts, but during the past 40

years the great biological importance of these ubiquitous viruses has become recognized. HPVs are, in fact, responsible for a wide array of diseases, both benign and malignant. Rarer diseases such as recurrent respiratory papillomatosis (laryngeal warts) and epidermodysplasia verruciformis were found in the late 1960s and early 1970s to be related to HPV infection. In 1974 the role of HPV in cancer of the uterine cervix was first suspected. This oncogenic potential had already been established for the cottontail rabbit (Shope) papillomavirus in 1932 and for bovine papillomaviruses (BPV) in 1951. In the 1970s, analysis of HPV isolates led to the recognition of multiple HPV genotypes by the groups of Gérard Orth at the Pasteur Institute in Paris and Harald zur Hausen in Freiburg and then Heidelberg (7–12). zur Hausen and his colleagues established an association between HPVs and squamous benign and preinvasive malignant lesions of the uterine cervix. These preinvasive malignant lesions, also called dysplasias, intraepithelial neoplasias, or squamous intraepithelial neoplasias (SIL), are the precursors to invasive cervical carcinoma. As studies on the biology of HPVs progressed, it became clear that some of these viruses possessed genes capable of transforming and immortalizing cells *in vitro*. Subsequent epidemiological observations showed that some genital HPV types, the “low-risk” HPVs (e.g., types 6 and 11), were never or rarely associated with malignancies, whereas others, the “high-risk” HPVs (e.g., types 16 and 18), were linked to cancers. Harald zur Hausen was awarded the Nobel Prize in Medicine or Physiology in 2008 for his original contributions to the association between HPV and cervical cancer. The use of polymerase chain reaction (PCR) assays to diagnose HPV infection in prospective epidemiological studies demonstrated that HPVs play a central role in the vast majority of cervical cancers. HPVs are also associated with many other cancers, with a causal link becoming increasingly established for squamous cell carcinomas (SCC) of the anus, vulva, vagina, penis, and oropharynx. In 2006 the first highly effective HPV vaccine directed at HPV type 6 (HPV-6), -11, -16, and -18 became available, followed in 2009 by a second, bivalent (HPV-16 and -18) vaccine. Already, substantial reductions in the burden of anogenital HPV infections and associated diseases have been observed in many countries. Anogenital warts are almost eradicated wherever the quadrivalent vaccine is being used. In 2015, a third, nonavalent vaccine (HPV-6, -11, -16,

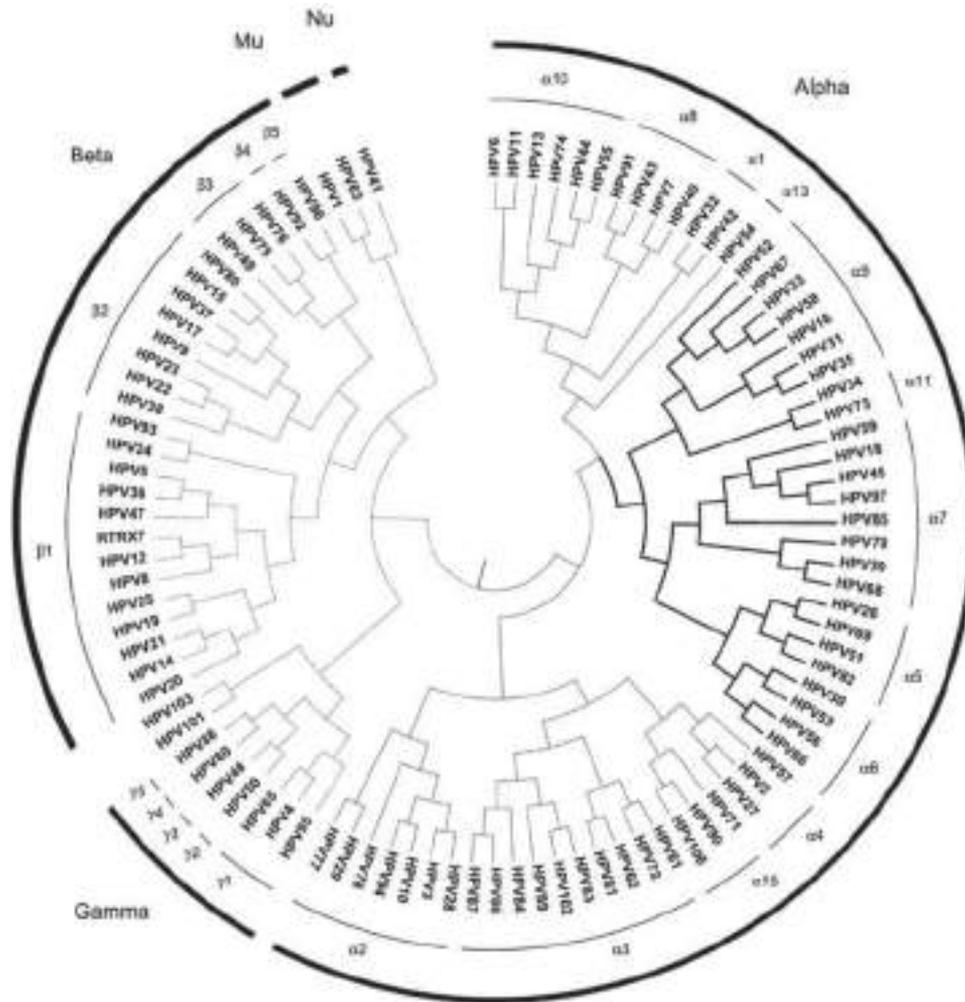

FIGURE 1 Phylogenetic tree of 99 human papillomaviruses, their genera and species. The tree was established on the concatenated amino acids and nucleotide sequences of six open reading frames (E6, E7, E1, E2, L2, and L1) (reprinted from reference 2 with permission).

-18, -31, -33, -45, -52, and -58) was introduced to the market, which promises greater vaccination rate and an accelerated disappearance of the Papanicolaou (Pap) smear for the primary screening of cervical cancer.

## VIROLOGY

### Classification

All the members of the *Papillomaviridae* family, including HPVs, have a supercoiled, single double-stranded circular DNA genome enclosed in an unenveloped, icosahedral capsid (<http://www.hpvcenter.se/html/refclones.html>, <http://pave.niaid.nih.gov/>). Papillomaviruses are widespread among higher vertebrates but are species specific (13). Because HPVs could not be grown for many years, and because sufficient quantities of most of them cannot be purified for direct biochemical and antigenic characterization, HPVs are classified by genotypes and not serotypes.

### Genotypes

Papillomaviruses are classified as distinct genotypes if they have less than 90% DNA sequence homology of the L1 open

reading frame (ORF), which encodes the major capsid protein. Subtypes have between 90% and 95% DNA homology, and variants have between 95% and 98% DNA homology. The *Papillomaviridae* family has 49 genera at present (<http://www.ictvonline.org>). HPVs belong to the Alpha-, Beta-, Gamma-, Mu-, and Nupapillomavirus genera. Although papillomaviruses share the same general genomic organization, some particularities characterize each genus. For example, the Beta- and Gammapapillomaviruses lack an E5 ORF. A genus may be further divided into species defined by a particular representative. For example, HPV-16, an alphapapillomavirus, is the representative type of species 9, which also includes types 31, 33, 35, 52, 58, and 67 (Fig. 1) (14–17). At the end of 2015, 205 HPV genotypes had been formally identified, a number that is continuously expanding. Most recent types do not appear to be associated with any disease (Table 1). There is an imperfect concordance between the phylogeny of the HPV types and their biology. All the Betapapillomaviruses are associated with cutaneous lesions, with species 1 and 2 encompassing the epidermodysplasia verruciformis HPV types. The Gamma-, Mu-, and Nupapillomaviruses are all associated with cutaneous lesions. Among the Alphapapillomaviruses the situ-

**TABLE 1** HPV types and their disease associations<sup>a</sup>

<sup>a</sup>DNA sequence information is available at [http://pave.niaid.nih.gov/#explore/reference\\_genomes/human\\_genomes](http://pave.niaid.nih.gov/#explore/reference_genomes/human_genomes)

<sup>b</sup>The distinction between frequent and less frequent is arbitrary in many instances. Large descriptive statistics of HPV type distribution by disease are not available for all HPV types. Moreover, many HPV types have been looked for or identified only once or a few times.

<sup>c</sup>First recovered from immunosuppressed or HIV-infected patients.

<sup>d</sup>The malignant potential of this type is definite, probable (e.g., types 26, 53, 66, 68, 73, 82), or uncertain but possible because it has been isolated in one or a few lesions that were malignant (e.g., types 14, 17, 20, 38, and 47).

<sup>e</sup>HPV-46 was found to be a subtype of HPV-20, HPV-64 was found to be a subtype of HPV-34, and HPV-55 was found to be a subtype of HPV-44.

<sup>f</sup>Includes types isolated from a cystic plantar wart, oral cavity, kerathoacanthoma, hand SCC, or malignant melanoma.

<sup>g</sup>Identified in normal skin.

<sup>h</sup>Identified in normal cervicovaginal cells.

ation is more complex. Species 1, 6, 7, 9, 10, 11, 13, 14, and 15 include only genital (mucosal) HPV types, while species 2 includes only cutaneous types, and species 3, 4, 5, and 8 include both types.

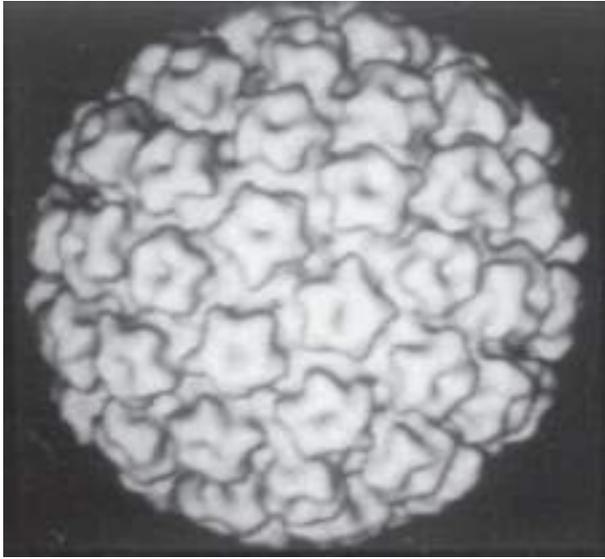

### Serotypes

HPV virions induce humoral and cellular immune responses in animals and humans (18, 19). Antibodies react with major (L1) and minor (L2) proteins that constitute the viral capsid. Denatured papillomavirus virions exhibit a common antigen, not displayed during natural infection, which has been used to generate a diagnostic antibody for immunocytochemistry (20). The DNA sequence encoding this common papillomavirus antigen has been mapped to a small region of the gene coding for the major capsid protein. Undenatured virions from different HPV types do not appear to share a common dominant antigen, even though the amino terminus of L2 contains epitopes shared broadly

among papillomaviruses (21). Virus-like particles (VLPs) that have the same conformation and size as the native capsid can be made by expressing the capsid genes, either L1 alone or L1 and L2 together. VLPs are the constituents of the current vaccines. The study of papillomavirus L1 VLPs has shown that serotypes generally correspond to genotypes (22).

### Composition

Papillomaviruses share the same structure, a naked, T = 7 icosahedral capsid containing a double-stranded, super-helical, circular DNA molecule associated with cellular histone proteins H2a, H2b, H3, and H4. The capsid consists of 72 pentamers that are either pentavalent or hexavalent (Fig. 2) (23). Each pentamer is composed of five major capsid proteins. The minor capsid protein is located in the center of the pentamer, possibly only in the pentavalent pentamers. Purified papillomavirus virions measure 55 to 60 nm in diameter (Fig. 2).

**FIGURE 2** Structure of the papillomavirus virion. A cryoelectron micrograph of the HPV-1 capsid is shown (diameter, 60 nm). (Reprinted from reference 11 with permission.)

### Genome

The viral genome is approximately 8,000 bp long (40% to 50% G+C content). The apparent molecular weight of 3 to  $5 \times 10^6$  represents 10% to 13% of the virion's weight. Papillomavirus genomes share the same general organization (Fig. 3), which usually consists of eight ORFs, all located on the same strand (24). These have been designated as either early or late. The early ORFs (E1, E2, E4, E5, E6, and E7), originally numbered by diminishing size, code for nonstructural, regulatory proteins. The E3 ORF does not code for a protein, and different E8 ORFs have been identified only in Kappa- and Xipapillomaviruses—in the latter, E8 has the properties of E5. E5 is absent from the Beta- and Gammapapillomaviruses, along with E4 from the Etopapillomaviruses. E6 is absent from the Xi- and Thetapapillomaviruses, and E7 is absent from the Omicronpapillomaviruses. The late ORFs (L1 and L2) code for the capsid proteins.

An important, typically 1-kb-long, noncoding region, referred to as the upstream regulatory region (URR) or long control region (LCR), lies between the early and late ORFs. The URR includes the origin of replication (*ori*), the E6/E7 gene promoter (promoter P97 of HPV-16), and the enhancer and silencers. The URR is thought to determine HPV tissue specificity. The function of the URR is governed by at least several of the internal transcriptional regulatory motifs (Fig. 4) (25–28). These *cis*-acting elements bind to the various cellular and viral proteins that trans-regulate genomic function. At least four components are shared by the URRs of the papillomavirus types examined so far: (i) a polyadenylation signal for late mRNAs at the 5' end, (ii) E2 protein binding sites, (iii) an E1 binding site associated with the origin of replication, and (iv) a TATA box in the E6 gene promoter. The molecular mechanisms of URR function and regulation are complex (27). Viral gene transcription results in an abundance of mRNA species due to complicated and multiple splicing patterns that reflect a post-transcriptional regulation that is tightly linked to the state of differentiation of the infected cell (29). These splicing pat-

terns also differ among HPV types (Fig. 4). In addition, full or truncated ORFs may appear on different messages (e.g., E2 and E6). Some mRNAs are translated as fusion proteins (E1 and E4), whereas others are polycistronic (E6 and E7).

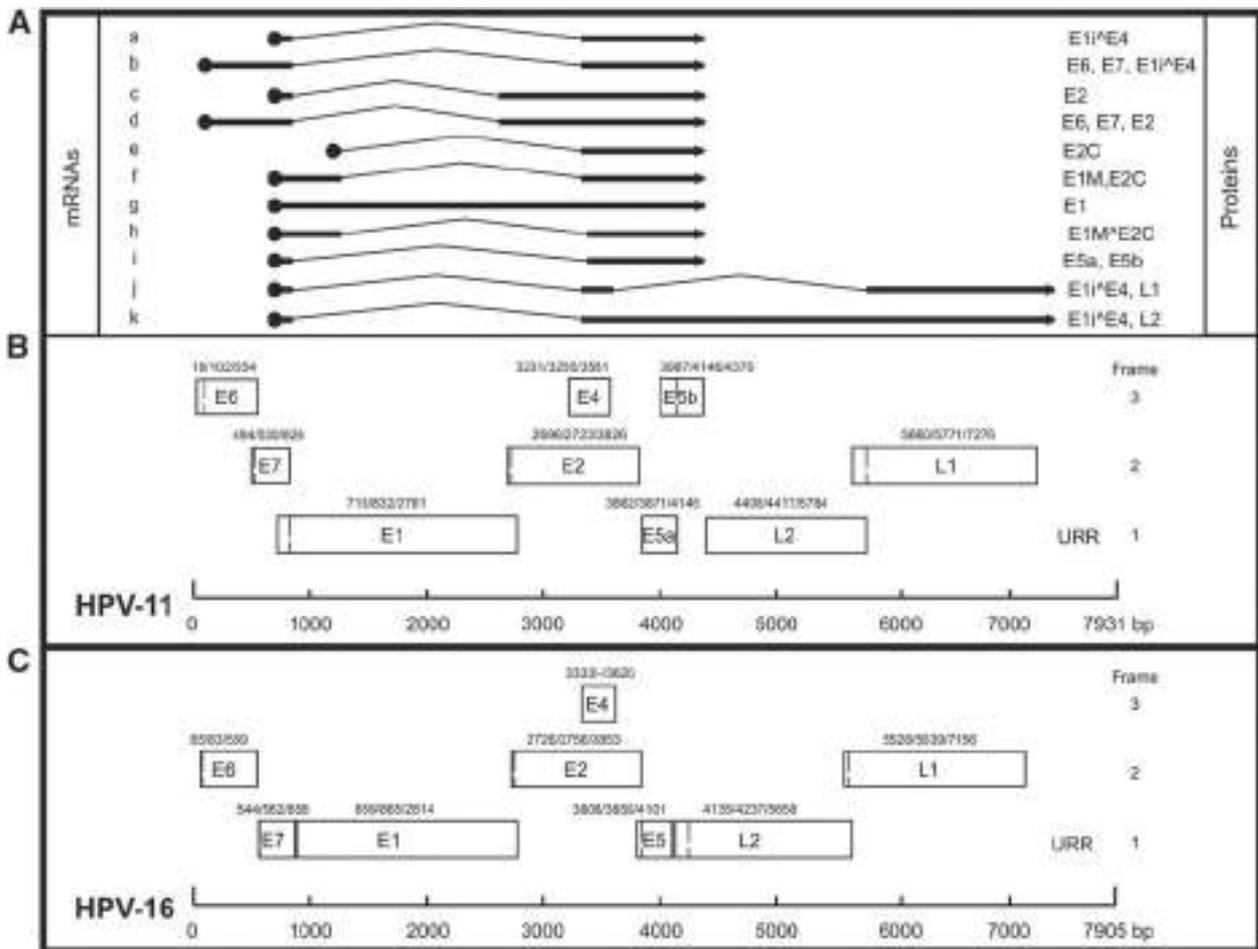

### Proteins

Because of the multiple splicing patterns of viral gene expression, there are more protein products than ORFs. Table 2 summarizes the information on characterized proteins. L1 is called the major capsid protein because it represents 83% of the viral coat and has hemagglutinating activity (30). Experimentally, HPV L1 induces a strong and type-specific neutralizing antibody response (22, 31). L2 is larger and dispensable in the formation of the capsid, but it appears to be important for both entry and egress of the viral genome and for encapsidation of the viral DNA (21). Experimentally, it also generates a weak but cross-specific neutralizing antibody response.

E1 and E2 proteins are involved in viral DNA replication (see “Biology” below) (28, 32–35). E1, the only viral protein with enzymatic activity, has an ATPase that is part of the helicase function of E1 (32). E1 also contributes to the maintenance of the viral episome and is often absent when the viral DNA is integrated. The E2 of HPV-16 possesses transcription regulatory properties and represses the activity of the E6/E7 promoter by binding to the E2 binding sites proximal to the E6 promoter (Fig. 4) (20). In contrast, viral integration disrupts the E2 ORF and allows the free trans-activation of the E6/E7 promoter by several cellular transcription factors (29). The differential methylation of the E2 binding sites appears to be important in carcinogenesis (36).

Differential RNA splicing and proteolytic cleavage produce various forms of the most abundant cytoplasmic HPV protein, E4 (actually E1-E4 proteins, because they retain the first five amino acids of E1) (28, 37). With the exception of a conserved leucine-rich motif that appears to be important in the interaction with the cytokeratin networks, the E4 family of proteins shows substantial heterogeneity at the amino acid level among HPV types. Although the role of E4 remains to be fully defined, these proteins form a filamentous cytoplasmic network that co-localizes with the cytokeratin network of intermediate filaments in the lower epithelial layers. E4 proteins form solitary perinuclear structures in the more differentiated layers of the epidermis. E4 may function in coordination of genome amplification, suppression of cell proliferation through a G2-M arrest, and post-transcriptional gene regulation. It is also speculated to play a role in virus release and transmission.

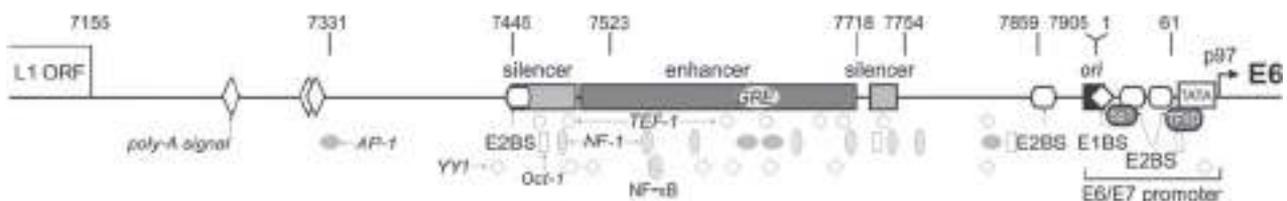

E5 is a small, membrane-bound protein that has weak transforming abilities in high-risk HPVs (28, 35, 38). However, it is unclear how this is accomplished because the protein is undetectable in tissues and the gene is often found to be deleted in cervical carcinomas. E5 interacts with cellular growth factor receptors, including the epidermal growth factor (EGF) receptor and, in the case of HPV-6, also with the erbB2 and platelet growth factor receptors (Fig. 5). Because it associates with an adaptin-like protein, E5 may interfere with the endocytosis and inactivation of these cell receptors. E5 also binds to the endosomal pore-forming protein, a 16-kDa protein with ATPase activity that participates in the endosomal proton pump. The resulting inhibition of endosome acidification increases the half-life of the EGF receptor. EGF activates the phosphokinase C (PKC) pathway of signal transduction, which leads through the mitogen-activated protein (MAP) kinase activation pathway to the activation of the *c-jun* and *c-fos* oncogenes.

**FIGURE 3** HPV genetic maps. (C) linearized HPV-16 DNA map; (B) linearized HPV-11 DNA map; (A) HPV-11 transcription map. By convention, the map origin of papillomaviruses is defined as the position homologous to the *Hpa*I single restriction site of HPV-1. The open boxes correspond to the ORFs in the respective translation frames. The numbers above each ORF indicate the nucleotide position of the preceding stop codon (left solid vertical line)/start codon (dashed vertical line)/stop codon (right vertical line). Each HPV-11 mRNA is depicted with its cap site (solid circle), exons (thick line), introns (thin angled line), and poly(A) site (arrow). The putative corresponding proteins are indicated on the right of the mRNAs.

*c-Jun* and *c-Fos* assemble in a heterodimer to form activation protein 1 (AP-1), which has potent transcriptional activity. *c-fos* is required for the malignant progression of skin tumors. Rather than acidifying the endosome, E5 may act by disturbing the protein trafficking from early to late endosomal structures. E5 may also activate the MAP kinases, ERK1/2,

and phospholipase *Cy*-1 directly and can enhance endothelin-1-induced keratinocyte growth. E5 may also cause a decreased expression of HLA-A and HLA-B molecules, thus contributing to immune evasion. In addition, E5 suppresses cellular apoptosis and gap-junction communication between keratinocytes.

**FIGURE 4** Organization of the HPV-16 URR. The URR begins after the stop codon of the L1 ORF and finishes at the cap site of the E6 mRNAs. The positions of some of the potential binding sites of various viral and cellular factors are indicated by the symbols placed on and below the line. E1BS, E1 binding site; E2BS, E2 binding site; ori, origin of replication; TATA, TATA box; GRE, glucocorticoid responsive element. AP-1, Oct-1, NF-1, NF- $\kappa$ B, Sp1, TEF-1, TFIID, and YY1 are cellular transcription factors.

TABLE 2 HPV proteins and their possible functions

Viral protein	Size (kDa)	Functions and properties <sup>a</sup>
E1	68–76	<p>Participation in viral DNA replication</p> <p>Has a binding site in the URR and forms a hexameric ring around the DNA (with Hsp 40/70)</p> <p>Forms a heterodimer with E2</p> <p>Interacts with several of the cellular replicative proteins (DNA polymerase, primase complex, RP-A, p80/Uaf1, etc.)</p> <p>Associates with histone H1</p> <p>Binds to Ini1/hsSNF5, a chromatin remodeling complex that facilitates the access of transcription factors to DNA regulatory sequences</p> <p>Interacts with several cyclin/cyclin-dependent kinase complexes, especially cyclin A/E-Cdk2, leading to E1 phosphorylation, which is necessary for E1 nuclear localization</p> <p>DNA-dependent ATPase and helicase activities (with Topo1, E1-BP/TRIP13, p56, Ubc9)</p> <p>Nuclear import (with ERK1 and JNK2, importins <math>\alpha</math>3/ <math>\alpha</math>4/ <math>\alpha</math>5, Crm-1 exportin)</p> <p>Maintenance of viral episomes (p80/Uaf1)</p> <p>Amplification of viral genomes in differentiated cells (with caspases-3/-7)</p> <p>Transcriptional repression (alone)/activation (with E2)</p>
E2	40–58	<p>Participation in DNA viral replication</p> <p>Has several binding sites in the URR. High-risk HPVs have four binding sites.</p> <p>Forms a heterodimer with E1 and dramatically increases the DNA-binding specificity of E1</p> <p>Partitioning of viral episomes during cell replication by interacting with Brd4, a double bromodomain-containing chromatin adaptor protein</p> <p>Recruits histone acetyltransferases and may alter chromatin remodeling</p> <p>Viral transcription repression of E6/E7 at high level</p> <p>Viral transcription activation (E2 N-terminus) at low level</p> <p>Cellular differentiation transcription regulation, including through interaction with the C/EBP transcription factors (control of MMP-9, IL-10, hTERT, <math>\beta</math>4-integrin, SF2/ASF)</p> <p>Interacts with L2 and may contribute to encapsidation of viral DNA</p> <p>Induces apoptosis (estrogen- and progesterone-dependent effect)</p>
E4 (several) and E1-E4	10–17	<p>Most abundant cytoplasmic viral protein, but function poorly defined</p> <p>Bind to the cyokeratin filament network</p> <p>Are associated with the cornified cell envelope and may contribute to virion assembly, release, and transmission</p> <p>? Coordination of genome amplification</p> <p>? Mitosis blockade (by binding of Cyclin B/Cdk1 and Cyclin A/Cdk2)</p> <p>? Post-transcriptional gene regulation by binding to E4-DBP helicase</p>
E5	10	<p>? Malignant transformation</p> <p>Binds and enhances epithelial growth factor receptor signal transduction (HPV-6 but not HPV-16) (which controls Erk1/2, AKT, cyclooxygenase, VEGF, c-Cbl)</p> <p>Binds to Golgi's vacuolar ATPase 16-kDa protein (proton pump) and inhibits the acidification of endosomes and Golgi complex, which stabilize the epithelial growth factor receptor and platelet-derived growth factor, respectively</p> <p>Activates cellular oncogenes <i>c-jun</i> and <i>c-fos</i>, whose protein products form the AP-1 transcription factor (may be able to activate AP-1 directly)</p> <p>Can enhance endothelin-1-induced keratinocyte growth and target p38 MAP kinase, calpain 3, phospholipase C-<math>\gamma</math>1, ErbB4, EVER1 and EVER2, ZnT-1, Bap31, calnexin, calpactin 1, karyopherin <math>\beta</math>3, cyclin A</p> <p>Might stimulate arachidonic acid metabolism independent of binding to platelet-derived growth factor</p> <p>Inhibits cell-to-cell communication through gap junctions (connexins 26 and 43)</p> <p>Inhibits cell motility</p> <p>Immune evasion by inhibition of HLA-A and HLA-B cell surface antigens</p> <p>Apoptosis inhibition (Fas, Bcl-2, Bax)</p>

<sup>a</sup>TRIP-13, thyroid hormone receptor interactor 13; VEGF, vascular endothelial growth factor; DLG, disk large; MUPP1, multiple PDZ protein1; IRF-3, interferon regulatory factor 3; TLR-9, Toll-like receptor 9; HDAC, histone deacetylase; mTORC-1, mammalian target of rapamycin complex 1. Note that most of these data are derived from the study of HPV-16.

E6 and E7 are nuclear proteins that play a central role in malignant transformation (28, 35, 39–41). Both proteins bind to a variety of cellular factors (Table 2), with the highest affinity belonging to the E6 and E7 proteins of high-risk oncogenic HPVs, like HPV-16 and -18. Thus, what follows mostly applies to E6 and E7 of the high-risk HPVs.

E6 is a zinc-binding protein that binds tightly to specific motifs on double-stranded DNA (40). It also binds to the E6-associated protein (E6-AP), also known as the E3 ubiquitin ligase. In combination, these two proteins associate with the p53 protein, prompting the accelerated degradation

of p53 through the ubiquitin pathway. p53 is an important cell cycle regulator, a tumor suppressor protein, that is activated by DNA damage. Among its different functions, p53 contributes to cell cycle arrest in the G1 phase (Fig. 6). It transactivates the gene families WAF1/CIP1 and INK, whose respective p21 and p16INK4A proteins directly interact with a cyclin/cyclin-dependent kinase/proliferating cell nuclear antigen (PCNA) complex that is responsible for phosphorylating and inactivating the retinoblastoma (pRB) protein. The Notch1 gene is induced; its protein is a determinant of keratinocyte differentiation and acts as a tumor

**FIGURE 5** Epithelial growth factor (EGF) receptor, phorbol ester, and HPV E5 protein interactions. (A) Upon exposure to a phorbol ester, phosphokinase C (PKC) is activated and phosphorylates the EGF receptor. This allows the binding of a complex of proteins, Grb2 and Sos, that are brought in contact with the cytoplasmic membrane. The Ras protein becomes activated by Sos after exchange of GDP for GTP. This is the trigger for the actuation of a cascade of protein kinases, Raf-1, MEK, MAPK, that ultimately induces the expression of the transcription factor AP-1, which is made up of two proto-oncoproteins, Fos and Jun. The net result is a stimulation of cell proliferation and differentiation. (B) Under physiological conditions, the EGF receptor is activated by the binding of its ligand, EGF. Autophosphorylation ensues, which precipitates the sequence of events detailed in panel A. Eventually, the process stops when the EGF receptor becomes internalized by endocytosis. As the endosome becomes acidic, the EGF receptor is degraded. The acidification of the endosome is dependent on a proton pump that includes a p16 protein subunit. Papillomavirus E5 inactivates the proton pump by binding to the p16 subunit. It is believed that the undegraded EGF receptor is then recycled to the cytoplasmic membrane. The overall effect is an increase of cellular differentiation and proliferation.

suppressor protein. The net result is the arrest of the cell cycle in the G1 phase. Another function of p53 is the induction of apoptosis through the downregulation of the bcl2 gene and the activation of the bax gene. E6 interacts with various other cellular proteins, including tumor suppressors (e.g., disk large [DLG], hScrib, and MAGI), transcription factors (e.g., c-Myc, p300/CBP, interferon regulatory factor 3 [IRF3], TBP, hADA3, p-CAF, and AMF-1), and proteins implicated in cell signaling, cell-to-cell communication, cell polarity, cell proliferation (toll-like receptor 9 [TLR9] and PDZ domain-containing proteins such as DLG, MAGI family, MUPP1, TIP-1/2) (Table 1). The virus escapes immune recognition by downregulating the expression IRF3 and TLR9 (42). E6 can cause cell immortalization by interacting with the promoter complex of the human telomerase (hTERT), a ribonucleoprotein enzyme that maintains the length of chromosomal telomeres, thus preventing cellular senescence. E6\* proteins are truncated polypeptides resulting from splicing patterns present only in high-risk HPVs. They inhibit the E6-mediated degradation of p53 and have a negative regulatory effect on cellular and viral replication.

E7 is a zinc-binding protein whose amino terminus has homologies to adenovirus E1A and the large T antigen of polyomaviruses (39). E7 binds to and inactivates the hypophosphorylated pRB, a product of the tumor suppressor gene Rb-1. pRB associates with the transcription factor E2F and its associated protein, DP1 (differentiation-regulated transcription factor 1 protein). This results in the arrest of the

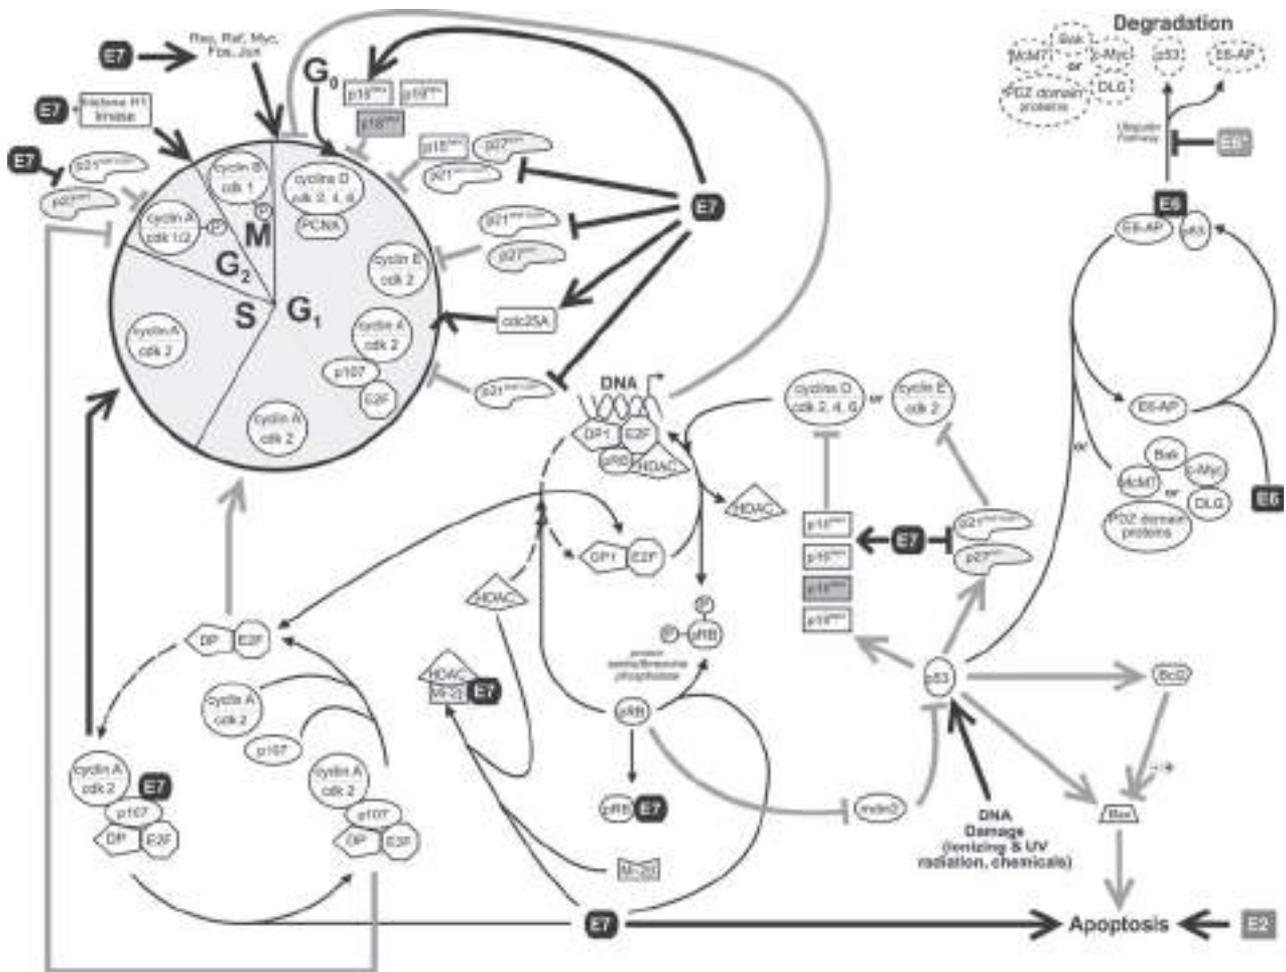

cell cycle in the G1 phase. E7 protein can also bind to pRB-related proteins p107 and p130 (these three proteins are called the pRB pocket proteins) and through slightly different mechanisms (Fig. 6) cause the same overall effect, namely the triggering of cell cycle progression. E7 sequesters the histone deacetylases (HDAC), thus triggering the activation of pro-angiogenic genes. In addition, E7 inhibits inhibitors of the cyclin-dependent kinases (p21WAF1/CIP1 and p27KIP1), thus stimulating cell proliferation, interfering with IRF1 and IRF9 thus facilitating the virus immune escape, and the downregulating an apoptosis. E7 also possesses some transcription regulatory activity (it stimulates the AP-1 transcription factor), and it is able to cooperate with v-ras in transforming primary rodent cells.

The transforming and immortalizing properties of the E6 and E7 genes have been demonstrated in various cell lines but also in transgenic animals, in which they induce carcinomas at the site of expression. Considerably less is known about the role of E6 and E7 in the low-risk HPVs (39, 40).

## BIOLOGY

### Replication Strategy

Papillomavirus DNA replication is governed by the state of differentiation of the keratinocytes in the squamous epithelium (Table 3). First, the HPV virion has to enter the basal keratinocyte (43–47). This process begins with the binding of the viral capsid to the heparin sulfate

**FIGURE 6** Model of the biological interactions of high-risk proteins with the cell cycle and apoptosis (see text for details). Symbols:  $\rho$ , activation;  $\sigma$ , inhibition. Thick lines with open arrowheads ( $=I$ ) indicate upregulation; the same lines with a broken end denote downregulation. Thick gray lines represent the regulations in normal cells, whereas the thick black lines show the regulations in HPV-infected cells; thin arrows ( $=R$ ) show direct interactions. Note that the symbols are not drawn proportional to the protein molecular weights and that the protein complex aggregations are not necessarily concomitant or involve the direct protein-to-protein contacts shown. DP, differentiation-regulated transcription factor polypeptide; HDAC, histone deacetylase; mdm2, murine double minute 2 protein; DLG, disk large.

proteoglycans (various protein backbones covalently “decorated” by heparin sulfate molecules) present in the basal membrane. Syndecan 1 is the most abundant of these proteoglycans. Once bound, the capsid undergoes a conformational change in the vicinity of the basal keratinocyte cell membrane that is mediated by cyclophilin B, a cellular chaperone protein that binds to the L2 viral protein and exposes a furin cleavage site. Once L2 is cleaved by furin, the capsid likely binds a second receptor on the cell membrane. The second receptor has not been firmly identified but could include one or more transmembrane proteins such as integrins and growth factor receptors, which with the assistance of tetraspanin CD151 then allow cellular entry of the viral capsid by endocytosis. Several signaling molecules, including the EGF receptor, PKC, and p21-activated kinase 1 (PAK-1), control this intracytoplasmic process. The viral capsid is fully disassembled in the endosome after acidification. The L2 protein and viral DNA complexes are then transported through the trans-Golgi network with the assistance of retromers, large, multi-subunit protein complexes (45). Eventually, at the time of cell division, when the nu-

clear envelope is broken, the L2-viral DNA complex can enter the nucleus (47). The viral DNA can then initiate its replication as an episome, generating a low number (less than 20 to 50 copies per cell). Viral replication is dependent on the replicative machinery of the cell and is in part controlled by the transport of E1 into the nucleus, which is dependent on phosphorylation by cellular cyclin-dependent kinases. Viral DNA replication begins with displacement of the histones associated with the viral DNA and the unwinding of the supercoiled viral DNA (34, 48). E1 binds to a receptor in the URR that incorporates the origin of replication. E2 contributes to the specificity of this binding and is then released. E1 has helicase and ATPase activities. In cooperation with E2, topoisomerase I, and replication protein A, E1 displaces the histones associated with the viral DNA and unwinds the DNA supercoiled conformation (Fig. 7). E1 subsequently forms a bidirectional replication fork complex with cellular proteins (polymerase  $\alpha$ /primase, DNA polymerase  $\delta$ /PCNA, replication factor C, topoisomerase II, and DNA ligase). HPV DNA replication progresses bidirectionally from the origin of replication. Viral DNA is then

**TABLE 3** Tissue differentiation and HPV markers of productive infection<sup>a</sup>

Tissue layer	DNA	RNA <sup>b</sup>					Virions
		E1, E2	E6, E7	E4, E5	L1, L2

<sup>a</sup>Relative abundance, from low (+) to high (+++).

<sup>b</sup>In high-grade intraepithelial neoplasias, E6 and E7 mRNAs are usually more abundant than E4, E5, L1, and L2 mRNAs; the converse is true in low-grade lesions. The table applies mostly to anogenital HPVs.

encapsidated in a process that involves its association with cellular histone proteins (H2a, H2b, H3, and H4), but the whole *in vivo* process is poorly understood (49, 50). A transient binding of L2 with E2 protein presumably guides the DNA into the aggregation of viral L1 and L2 proteins that eventually form the capsid. The release of viral particles is probably passive, resulting from the disintegration of the upper squamous epithelium, possibly facilitated by the E1-E4 protein. Desquamating cells are infectious (51).

### Host Range

Papillomaviruses are widespread among higher vertebrates, but each type usually has narrow species specificity, and HPVs infect only humans. BPV cause papillomas or fibropapillomas in cattle, but those BPV types producing fibropapillomas (BPV type 1 [BPV-1] and BPV-2) can induce, naturally or experimentally, fibromas and fibrosarcomas in a variety of mammals, such as horses (sarcoïd tumor), rabbits, and hamsters (13). The cottontail rabbit (Shope) papillomavirus causes skin papillomas in its natural hosts, the cottontail rabbit (*Sylvilagus floridanus*) and the jackrabbit (*Lepus californicus*), but papillomas and carcinomas in its experimental host, the domestic rabbit (*Oryctolagus cuniculus*) (52). The rabbit oral papillomavirus is a distinct virus that infects the oral cavity of the domestic rabbit and has been used as a model of mucosal infection (53). More recently, a genital murine papillomavirus model of transient infection was identified in *Mus musculus* (54, 55). No animal papillomaviruses have been shown to infect humans.

### Growth in Cell Culture and Animal Models

Infection with HPV virions or transfection with HPV DNA of keratinocyte monolayers results in transient replication of the viral DNA without visible cytopathic effect or production of virus. Tissue cultures derived from cutaneous warts or laryngeal papillomas have a normal morphological appearance and no viral gene expression. In contrast, cell lines from cervical carcinomas can exhibit a transformed phenotype and retain HPV DNA, such as HPV-16 (CaSki and SiHa) or HPV-18 (HeLa and C4-1). These cell lines carry HPV DNA in integrated form with a disruption of the early region of the viral genome and therefore do not yield viral particles (permissive infection). Permissive infections have been established using immortalized, nonmalignant cell lines

derived from a cervical intraepithelial neoplasia (CIN) containing episomal HPV-16 (W12 cells) or HPV-31b (CIN 612 cells). This has been accomplished by induction of full epithelial differentiation by planting the cells either on the musculofascial layer of the flank of a nude (athymic) mouse (W12 cells) or on an organotypic “raft” culture system (CIN 612 cells) followed by stimulation with phorbol ester, an inducer of phosphokinase C and cell differentiation (Fig. 5). The raft system has undergone further refinements that now enable the propagation of infectious virions *in vitro* (56, 57).

Immunodeficient mice (e.g., athymic or with severe combined immunodeficiency [SCID]) grafted orthotopically or heterotopically with HPV-infected human xenografts are otherwise the only means to reproduce the natural infectious cycle. They provide sustained propagation of HPV virions and duplicate the macroscopic, microscopic, and molecular features of natural lesions (58). These models demonstrated that HPV-6 and -11 induce condylomata acuminata and that HPV-16 induces intraepithelial neoplasias (59).

### Inactivation by Physical and Chemical Agents

Little is known about their resistance to physical and chemical agents, but papillomaviruses are hardy. Viral capsids resist treatment with ether, acid, and heat for 1 h at 50°C. Exposure to 100°C for 1 h is necessary to abolish HPV-11 gene expression in the SCID mouse xenograft model (60). However, HPV is inactivated by autoclaving and 70% ethanol (61). Consequently, standard autoclaving procedures should be used to sterilize surgical instruments that are potentially contaminated with HPV, and the smoke released from vaporized HPV lesions should be evacuated.

## EPIDEMIOLOGY

### Distribution and Geography

HPV infections and diseases are distributed worldwide, although some geographic variations occur. For example, focal epithelial hyperplasia (Heck’s disease), an oral disease related to HPV-13 and -32, mostly affects American Indians, Inuits, and South Africans (62). Geographic disparities in the prevalence of common warts can be seen within countries. The most comprehensive surveys of the worldwide distribution are those of cervical HPV infections and diseases (63–66). HPV DNA is identified in the cervical cells of 11.7% of women with normal cervical cytology worldwide (66). However, this percentage varies from 1.7% of women in Western Asia to 35.4% in the Caribbean. HPV-16 is the dominant genotype worldwide, but there are exceptions such as sub-Saharan Africa where HPV-42 is more common than HPV-16. HPV-18, which is usually second in worldwide prevalence, is replaced at that rank by HPV-58 in South America and by HPV-31, -35, -45, -56, and -58 in sub-Saharan Africa (63).

Overall, in invasive cervical carcinomas (both squamous cell carcinomas and adenocarcinomas), HPV-16 is the most common HPV type (56.6%), followed by HPV-18 (16.0%), HPV-58 (4.7%), HPV-33 (4.6%), HPV-45 (4.5%), HPV-31 (3.8%), HPV-52 (3.4%), HPV-35 (1.7%), HPV-59 (1.3%), and others (65). Although the ranking rarely changes for HPV-16 and -18 according to location, in North America HPV-45, -31, and -33 are, respectively, the third, fourth, and fifth most common HPVs, but in Eastern Asia, HPV-58, -52, and -33 occupy these ranks. The geographic variation is more striking when looking at the variants of HPV-16 with their North American, European, African, Asian, and Asian

American lineages (67). Squamous cell carcinomas represent about 90% of all cervical cancers associated with HPV, and genotypes 16 and 18 are present in 59% and 13%, respectively, of these tumors worldwide. In contrast, cervical adenocarcinomas, which represent the other 10%, contain HPV-16 and -18 in about equal proportions, 36% (65).

### **Incidence and Prevalence of Infection**

HPV infections are endemic. No epidemic patterns of HPV infection have been recognized. The moderate transmissibility, variable incubation period, latency, and spontaneous resolution of HPV infections impede the recognition of HPV disease outbreaks.

### **Cutaneous Warts**

Cutaneous HPV infections are extremely prevalent, with rates of 80% in immunocompetent hosts and 95% in immunocompromised patients (68). In a study of 744 cutaneous warts from 246 patients, the HPV genotypes were HPV-27 (23.7%), HPV-57 (21.8%), HPV-2 (21.7%), HPV-1 (18%), HPV-4 (5%), and others (69). HPV-1 was the predominant genotype in plantar warts of children younger than 12 years old. HPV DNA can be found on healthy skin, especially from types usually associated with epidermodysplasia verruciformis and can still be present in half of the subjects when new samples are obtained from them 6 years later (70, 71).

Cutaneous warts (common, plantar, and flat warts) are very common among the general population. Mostly a disease of school-age children, common (hand) warts represent about 70% of all cutaneous warts (72). The prevalence of common warts ranges from 0.8 to 22% (72). Plantar warts make up to a third of cutaneous warts and are found in a wider age group, primarily adolescents and young adults. Flat or juvenile warts constitute 4% to 8% of the cutaneous warts, with peak prevalence among 10- to 12-year-olds (72). An increased incidence of plantar warts has been noted in the winter months.

### **Genital HPV Infections and Diseases**

No seasonality is recognized in the acquisition of HPV infection or the expression of HPV diseases. In the U.S. female population, one study of urine samples collected from 3,262 sexually active women aged 18 to 25 found that 26.9% of subjects were positive for a genital HPV, with 20% of the total sample being positive for a high-risk HPV (73). Remarkably, 62% of the infections were by multiple types; 14.3% of women reporting only one lifetime sexual partner were positive. A second survey with a sample of 4,150 females aged 14 to 59 years found that between 2003–2006, before the introduction of HPV vaccination, the overall prevalence of HPV DNA in vaginal swabs was 42.5%, with the majority represented by high-risk HPV infections (74). The peak rate was in the 20- to 24-year-old group (53.8%), followed by the 14- to 19-year-old group (32.9%). Here again, having only one lifetime sexual partner offered limited protection, as 18.2% of these women were positive. When repeated over the 2007–2010 period after the introduction of HPV vaccination, overall HPV prevalence declined modestly to 39.8% (75). A significant reduction was noted in the 14- to 19-year-old group (26.1%) but not in the 20- to 24-year-old group (59.8%); the former group was more likely to have been immunized. A meta-analysis of 78 studies of women with normal cytology indicated an overall worldwide HPV prevalence of 10.4%, with prevalence as low as 8% for Asia to as high as 22% for Africa (76). Rates of HPV DNA

prevalence on the male genitalia vary from 1.3% to 79%, with a majority of studies reporting rates of 20% and higher (77). In the United States, about 20 million people are estimated to be infected with genital HPVs, half of them aged between 15 and 24 years (78). It is estimated that of the U.S. sexually active population 85% of women and 91% of men will get a genital HPV infection during their lifetime (79).

Most infections are rapidly cleared, or at least become undetectable (80). In a prospective study of 331 18- to 35-year-old women who had HPV DNA-positive cervical samples, half had cleared the virus by 9 months (81). The median time to clearance was longer for high-risk types (9.8 months) than for low-risk types (4.3 months). By 14 months, only a tenth of the subjects were still positive. Typically, with repeated testing over time, only a minority of patients will be positive every time, while another subgroup will be consistently negative (82).

Until recently, the incidence of anogenital warts was increasing in the United States. The number of initial visits for genital warts to physicians' offices in the United States increased from 222,000 in 2000 to its zenith of 453,000 in 2011 but declined to 404,000 in 2013 (83). Wherever the quadrivalent HPV vaccine has been introduced in the world, a major impact commensurate to the rate of vaccine coverage has been noted on the prevalence or incidence of genital warts (84, 85) (see "Active Immunization"). The NHANES survey indicates that in the United States, 5.6% of persons aged 18 to 59 years reported ever having genital warts, and there were more in women (7.2%) than in men (3.4%) (86). A random survey of 69,147 women 18 to 45 years of age from the general populations in Denmark, Iceland, Norway, and Sweden showed that 10.6% reported ever having had clinically diagnosed genital warts (73). The peak incidence is around ages 25–29 years in males and 20–24 years in females (74).

The prevalence of HPV infections in neonates and infants appears to be low (87). No more than 1% of babies have oral or genital HPV infections. Genital warts are highly unusual in children (88). Fifty percent to 75% of children with genital warts acquire them from sexual abuse, and 1 to 2% of sexually abused children have genital warts (87). Nevertheless, the presence of genital warts alone is not sufficient to establish a case of sexual abuse. Nonsexual transmission of anogenital warts appears to be possible (87, 89, 90). Family members of children with anogenital warts have been shown to have cutaneous warts that harbor HPV-6. Conversely, the presence of HPV-1 or HPV-2, nongenital genotypes, in about 20% of genital warts recovered from prepubertal children suggests the existence of nongenital sources, such as auto-inoculation or nonsexual contact but does not necessarily exclude fondling (87). In young children, anogenital warts are more likely the result of vertical transmission, whereas horizontal nongenital or genital transmission is more likely in older children, but there is no firm age cut-off (90, 91). Recommendations for the evaluation of children with genital warts suspected of sexual abuse are available (92).

The prevalence of cervical HPV disease is best measured by cervical cytology. Rates vary between 0.9 and 4.8% depending on the criteria and age and decrease after age 24 (93). In one study, 2.5% of cervical cytology samples had evidence of HPV-related cervical disease with low-grade SIL (LSIL) (1.97%), high-grade SIL (HSIL) (0.51%), SCC (0.026%), and adenocarcinomas (0.0046%) (94). In addition to these well-recognized entities, ambiguous cytological abnormalities are as common. They are called atypical squamous cells (ASC), either of unknown significance

(ASC-US) or which cannot exclude HSIL (ASC-H) (both subcategories used to be grouped as ASCUS) (95).

An HPV infection is present in virtually all cervical cancers (SCC and adenocarcinomas) (96, 97). It is a necessary, if not sufficient, condition for the development of cervical cancer (86). In 2008, cervical cancer was the third most common cancer in women worldwide, with 529,800 new cases and 275,100 deaths (98). The burden is mostly in developing countries, where 86% of the cases occur. In the United States, according to 2014 estimates, cervical cancer is in decline; it ranks 14th in incidence (12,360 new cases) and 16th in mortality (4,020 deaths) among all female cancers (99).

Cervical cancer is not the only cancer attributable to HPV. In 2008 global estimates indicated that 100% cases of 530,000 cervical cancers could be attributed to HPV worldwide, but so could 43% of 27,000 vulvar cancers, 88% of 27,000 anal cancers, 50% of 22,000 penile cancers, 70% of 13,000 vaginal cancers, and 27% of 85,000 oropharyngeal cancers (100). Globally, 16.1% of new cancers are attributed to an infection, with about 30% of that fraction caused by HPV worldwide (101). These figures do not account for the premalignant conditions attributable to HPV.

### Recurrent Respiratory Papillomatosis

The age of onset of recurrent respiratory papillomatosis has a bimodal distribution that includes young children and young adults but not the elderly (102, 103). In the United States, the estimated annual incidence rates are 1.7-4.3/100,000 in children less than 14 years of age and 1.8/100,000 in young adolescents (older than 15 years) and adults. The estimated prevalence rates for these two populations are 10.9/100,000 and 4.5/100,000, respectively.

### Other HPV Infections and Diseases

HPV can be present in the oral cavity (104). Among the U.S. population, 7.3% of individuals were estimated to have one or more oral HPV found in an oral rinse (105). However, only 1.9% of young female enrolled in an HPV vaccination study were found to have the presence of oral HPV DNA (106). Focal epithelial hyperplasia (Heck's disease) is also a relatively uncommon disease that is mostly found in children and adolescents (62). Epidemiological data are lacking for other HPV diseases, such as the very rare epidermodysplasia verruciformis.

## RISK FACTORS

### Cutaneous Warts

Use of heated swimming pools or communal baths is an activity that appears to promote the acquisition of plantar warts, and in one controlled experiment, students who wore protective footwear during swimming were much less prone to developing plantar warts than those who did not (107-109). However, a large study has failed to show an increased transmission rate in public areas (110). Transmission within the family home may be the most common mode of acquisition (111). Nail biting is associated with the presence of periungual warts.

Some primary (see "Immune Responses" below) and secondary immunodeficiencies are risk factors for acquiring cutaneous warts. An approximate 10-fold increase in prevalence of cutaneous warts has been noted in lymphoma patients, whereas a 4- to 12-fold increase has been reported for human immunodeficiency virus (HIV)-infected indi-

viduals (112). Organ transplant recipients are particularly susceptible to developing cutaneous warts or HPV-containing SCC in the sunlight-exposed areas of their body (112). Three years post-transplantation, between 25 and 42% of patients have cutaneous warts; this number rises to 92% after 5 years or more (112). In transplant patients the lifetime risk of developing SCC or basal cell carcinoma increases 100- and 10-fold, respectively (112, 113).

People working with meat, poultry, or fish are uniquely susceptible to hand warts and up to one-half of them are affected (103). Particularly intriguing is the predominance of HPV-7 in these lesions, since HPV-7 has rarely been found elsewhere, with the exception of oral lesions in immunosuppressed or immunodeficient patients. Associations between UV tanning beds and body warts and between cocaine snorting and nasal warts have also been reported.

### Genital HPV Infections and Diseases

Sexual intercourse with a partner who has genital warts is a risk factor for the development of genital warts. About two-thirds of the sexual partners of persons with anogenital warts will develop the disease within 2 years (93, 114). The risk of developing genital warts is most strongly and directly linked to lifetime number of sexual partners (93, 115). Other markers of sexual behavior, such as sexually active years and number of regular partners, are additional risk factors. Markers of sexual behavior yet to be identified could be the confounding variables explaining inconsistent risk factors such as cigarette smoking, contraceptive use, prior sexually transmitted diseases, pregnancy, and alcohol consumption (93, 115).

Consistent with sexual transmission, age is a major risk factor for the acquisition of cervical infection, with a peak in the 14- to 19-year-old group (116). Genital HPV infection is very uncommon in virgins, but when present it is likely the reflection of nonintromissive sexual play (117). Such activity, practiced by about a third of self-declared virgin adolescents, is not regarded by the subject as sexual intercourse, yet it is conducive to the transmission of infectious agents, including HPV. The risk of infection rapidly decreases after age 30, but an unexplained second peak at older ages may occur (80). Sexual behaviors begun at an early age, higher number of lifetime sexual partners, and higher number of recent sexual partners are risk factors (80). Lesbians are not free from these risk factors (118). Sexual partners share, at least in part, the same HPV infections or diseases (76,119-124). Similarly, the association between anal warts and anal intercourse also indicates a direct route of transmission through sexual contact (76, 114). The past and present sexual activity of the male partner is also important (125). Less consistent risk factors include the use of oral contraceptives, smoking, not using condoms, and some HLA polymorphisms (80, 126, 127). For example, HLA class I allele A\*0301 increases the risk of cervical cancer, while B\*1501 decreases it (128) (see the "Pathogenesis in Humans" section).

There may also be a protective effect from the consumption of fruits and vegetables or from absorbing or having circulating levels of vitamins C and E, carotenoids, and xanthophylls (80). Other potential risk factors include multiparity, other sexually transmitted infections (herpes simplex virus and Chlamydia trachomatis), and cervical chronic inflammation. The risk factors may have different effects on low-risk and high-risk HPV infections and how they contribute to the progression from infection to premalignancy and to cancer (80, 129). In that regard, the most

decisive factor is the HPV genotype, and HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, and 59 are recognized carcinogens (130–132). Different HPV types have different oncogenic risks, and HPV-16 is very clearly the most oncogenic of all (133). Different variants of HPV-16 carry their own oncogenic profiles, with the African and Asian variants being more oncogenic than the European ones (67). Other HPV types are probable, HPV-68, or possible carcinogens, HPV-26, -53, -66, -67, -68, -70, -73, and -82 (132). Multiple HPV infections are common, especially in CIN lesions, and there is a clustering of some HPV types with one another, although the significance remains unknown (134). Very similar risk factors for anogenital HPV infections have been implicated in males, including number of sexual partners, lack of condom use, smoking, and lack of circumcision (135).

Although less well studied, the risk factors related to sexual behavior, sexual partner history, and presence of high-risk oncogenic HPV DNA have been identified in the development of anal, penile, and vulvar or vaginal SCC (100, 115). Anal receptive intercourse, in both men and women, is a risk factor for the acquisition of anal warts and preinvasive and invasive SCC (136). Because all genital HPVs share the same mode of transmission, it is not surprising that a history of anogenital warts carries an increased risk for the presence of all of these anogenital cancers (115).

Renal allograft recipients have a 10- to 100-fold increased risk of developing anogenital warts, intraepithelial neoplasias, and cancer, a risk that is proportional to the duration of immunosuppression (113). The risk probably extends to other allograft transplant recipients and has been observed in women treated with immunosuppressive agents for glomerulonephritis. Cervical and oral malignancies associated with HPV have also been observed in these populations (137–139). Patients with diabetes mellitus may be at risk for the development of condyloma acuminatum. However, diabetic women do not appear to have an increased risk of cervicovaginal infection during pregnancy. Furthermore, general immune responsiveness appears to be blunted in older women with HPV infection compared to age-matched controls (140).

The association between infections with HIV and anogenital HPV has been well documented. Conversely, the presence of genital HPV infection appears to about double the risk of HIV infection acquisition (141). In HIV-seropositive women, depending on populations and methods of diagnosis, there is a 2- to 40-fold increase in the incidence and prevalence of condylomata acuminata and CIN compared to that in HIV-seronegative controls (142–146). This added risk is present even in HIV patients with a normal CD4 cell count, although it rises with lower CD4 counts or higher HIV viral load. HIV infection probably promotes the reactivation of HPV infection rather than new acquisition, since HIV-seropositive women shed HPV more persistently and in larger quantities than controls do (125). The quantity and persistence of HPV DNA, as well as the presence of high-risk HPV types within lesions, are risk factors for the development of CIN (147, 148). HIV infection also increases the incidence of vulvar (VIN) and vaginal (VAIN) intraepithelial neoplasias, a risk also augmented with a low CD4 cell count (<200 cells/ml) (145, 149). Anal intraepithelial neoplasias (AIN) are more common in HIV-positive men and women (150–152). This risk and that of high-risk anal infection is greater in men who have sex with men (MSM) than in heterosexual men, 32% versus 7%, respectively (151, 153). Curiously, MSM do not have a higher risk of penile HPV infection than heterosexual men,

both having an approximate 8.5% prevalence and similar incidences (153). In addition to HIV infection and receptive anal intercourse, the factors that increase the risk of AIN include a low current or nadir CD4+ cell count, high-risk HPV type infection, persistent anal HPV infection, multiple HPV type infections and high anal viral load (154). Concomitant anal and cervical infections or lesions are more common in HIV-seropositive than in seronegative women (155). Furthermore, the HPV genotypes are more likely to be concordant in the two anatomic sites if the subject is HIV-seropositive than seronegative, 18% versus 3%, respectively (155). Surprisingly, HPV has been found to be more prevalent in the anus (79%) than in the cervix (53%) in HIV-seropositive women (156). The same imbalance is found in the anus (43%) and cervix (24%) in HIV-seronegative women (156). The risk for oral warts and HPV-associated cancers is likely elevated in HIV-infected persons (157).

Cervical cancer was incorporated in the case definition of AIDS in 1993 (158), but it was later noted that the risk of invasive cervical cancer did not increase with increasing time after AIDS or correlate with the CD4+ cell count at the time of cancer diagnosis (159). In other words, although HIV infection was associated with an increased risk of cervical cancer (as well as of cancers of the anus, vagina, vulva, penis, and oropharynx), this risk and that of anal cancer did not appear to be related to HIV-induced immunosuppression (160, 161). Nevertheless, more recent studies indicate HIV-related immunosuppression contributes to the risk of cervical cancer (162–164). This has not been established with anal cancer, although the increased risk for this cancer in solid organ transplant recipients argues in favor of an immunosuppressive effect (165, 166). Undoubtedly, different confounding factors are at play, because the HIV infection is a risk factor for anal cancer in males but not in females (151). One of these factors is the recent availability in some areas of anal cancer screening, which likely contributes significantly by early detection to the very rapid rise in the incidence of anal cancer *in situ*, something that has not otherwise altered the steady but much slower rise in invasive anal squamous cell carcinoma incidence (167).

### Recurrent Respiratory Papillomatosis

The juvenile- and adult-onset variants of recurrent respiratory papillomatosis are usually linked to different risk factors (102, 103). With the juvenile-onset form, the children are often firstborn and delivered vaginally by teenage mothers who have condyloma acuminatum. For the adult-onset form of the disease, patients report a higher number of lifetime sexual partners and a higher frequency of oral sex than controls. The disease is very rare among siblings. Unexpectedly, recurrent respiratory papillomatosis has not been reported to occur in transplant recipients or HIV-infected individuals.

### Association between HPV and Cancer

HPV infection is a necessary condition for the development of preinvasive and invasive cervical cancer (66, 168, 169). The epidemiological evidence can be summarized as follows: (i) HPV DNA is consistently present in virtually all CIN, SCC, or adenocarcinoma specimens, and specific genotypes (mostly 16 and 18), so-called high risk, are responsible for this association; (ii) the presence of HPV-16 antibodies is associated with cervical cancer (18, 170); (iii) the prevalence of the high-risk HPV types increases relative to the low-risk types as the grade of the preinvasive cancer worsens (64); (iv) the strength of the association between HPV and

preinvasive or invasive cervical cancers, as measured by the relative risk, ranges in most studies from 20 to 70, which is larger than the magnitude of the association between lung cancer and smoking (64); (v) no other risk factors for preinvasive and invasive cancers approach the strength and consistency of HPV infection (64); (vi) persistent but not transient exposure to high-risk HPV leads to cervical disease progression, which suggests that the cancer risk disappears with exposure cessation (80); and finally, (vii) HPV infection precedes the development of preinvasive cancer.

High-risk HPVs are also implicated in the development of SCC at sites other than the cervix (66, 168, 169). It is estimated that 88% of anal cancers, 70% of vaginal cancers, 50% of penile cancers, 43% of vulvar cancers, and 27% of oropharyngeal cancers are attributable to HPV (100). In the case of the penile, vulvar, and vaginal cancers, the percentage attributed to HPV is not higher because among those cancers, only the basaloid and Bowenoid histologic variants are related to HPV.

In the nasal and sinus cavities, four of five exophytic papillomas and only a third of the inverted (Schneiderian) papillomas contain HPV, usually HPV-6 or HPV-11 (171). HPV likely plays a role in some of the SCC of the mouth, sinonasal tract, and larynx (168, 172-175). However, strong evidence has now emerged to attribute up to 70% of oropharyngeal cancers to oncogenic HPVs, mostly HPV-16 (175). The incidence of these HPV-related oropharyngeal cancers is rising (176). They tend to occur in younger subjects and are associated with sexual behavior markers of young age at intercourse, number of lifetime sexual partners, history of genital warts, performance of oral sex, and number of oral sex partners (174, 175). Limited or conflicting evidence exists for an association between HPV infection and SCC of the esophagus, lung, breast, colon, urothelium, prostate, ovary, and endometrium (168, 173, 177-181). Squamous cell carcinomas associated with HPV-16 of the conjunctiva (possibly also prompted by ultraviolet light exposure or HIV infection) and around the nail bed have been described (182-184).

Nonmelanoma skin cancers (NMSCs) include mostly SCC and basal cell carcinomas. Actinic keratoses represent the precursor lesion for SCC. HPV infection is present in 33 to 99% of NMSCs and precursors in immunosuppressed patients and in 21 to 100% of immunocompetent patients (185-187). A wide assortment of cutaneous and anogenital HPV types are detected in these NMSCs (188). However, the great majority of the genotypes are related to epidermodysplasia verruciformis-associated HPVs, for which better understanding of their oncogenicity is needed (189, 190). The clear oncogenic potential of a subset of these HPVs may, along with UV light, contribute to the development of NMSCs and precursor lesions. However, a causal link with HPV is difficult to prove for several reasons: (i) the high number of HPV types, including most of the novel ones, that are isolated from these lesions is perplexing; (ii) the HPV types found vary from patient to patient but also from lesion to lesion, and multiple infections are common; (iii) these HPVs are found in the normal skin (and in a small number of melanomas) of 33% to 73% of tested subjects; (iv) they are typically present at low copy numbers; and (v) they are often at the surface of the epithelium rather than within (185).

### Reinfections

HPV-associated diseases can recur, and relapses are well documented. How often these events represent reinfection versus relapse of a previous subclinical or clinical infection is

often impossible to determine. Laryngeal and genital HPV infections can remain latent and subsequently relapse either at the site of the former lesion or in the normal-appearing skin surrounding the ablated lesion (191, 192). Five types of observations suggest that relapses are more common than reinfections. First, attempts to treat the male sexual partners of women with genital HPV lesions have had no effect on the treatment failure rate in the females (193). Second, studies of HPV types present in the lesions of both sexual partners show only partial concordance either at the genotype or subtype level (76, 119-124). In males but not in females, a history of genital warts in the previous 5 years in the sexual partner does not predict anogenital wart recurrence. Third, the frequent presence of HPV-6 or HPV-11 DNA in the plucked pubic or perianal hairs of patients with condyloma acuminatum indicates a potential viral reservoir for relapse (194). Fourth, with the use of ever more sensitive and specific HPV PCR assays, it is possible to demonstrate that infections that appear to be transient are in fact persistent (195, 196). Fifth, therapeutically induced immunosuppression in solid-organ transplantation leads to an increase of HPV infections and diseases (see "Risk Factors" above). Although this could be the result of increased susceptibility to HPV, relapse of infection is a more likely explanation.

Several studies on the male condom detailed in the Prevention section indicate that reinfection may also contribute to recurrences. Moreover, recurrence of genital warts affects subjects who do not use condoms or involves anatomical areas not protected by the male condom (197).

### Transmission

#### Routes

The epidemiology of plantar warts suggests an indirect mode of transmission, for example, through fomites present in communal baths or swimming pools (109, 110). The virus probably enters the epidermis directly, because special footwear is protective. Direct natural or experimental transmission is possible (198), as is autoinoculation from genital lesions. Because epidermodysplasia verruciformis is so rare, until recently it was unclear where the natural viral reservoir was. It is now evident that these HPV types are widely distributed at low levels in the population, in normal skin, or in actinic keratoses and NMSCs (185, 188).

As discussed above, young children can acquire anogenital HPV infections by nonsexual routes, like *in utero* and perinatal exposure, nonsexual direct contact, and autoinoculation. However, the importance of alternate routes of transmission is probably negligible. Even the very low rate of HPV infection in virgin women does not exclude all forms of sexual activity (117). Although HPV DNA can be recovered from the underwear of women with anogenital warts or on surgical instruments used for gynecologic examination, a role for fomites in the transmission of anogenital HPV has not been demonstrated, but it is reasonable to assume that sex toys could be such a vehicle.

There is evidence that oral HPV infections are transmitted sexually and that there is a concordance between the types found in the genital area and the oral cavity (105, 106).

The mode of transmission of respiratory papillomatosis has not been directly established. In its juvenile-onset form, the disease could be acquired by vaginal delivery through an HPV-infected birth canal, whereas the adult form of the disease might result from oral sex (103). Nevertheless, respiratory papillomatosis can be present at birth or after ce-

sarean delivery, indicating possible *in utero* transmission (103). Transmission among family members is very rare.

### Risk Factors

The risk of transmission after direct or indirect contact with cutaneous warts is probably low and may be mitigated by the presence of cofactors such as the immunity of the recipient and the nature and duration of the contact (196). Plantar warts tend to appear on weight-bearing areas. This suggests that microscopic injury to the skin fosters viral entry. Shaving (even using depilatory creams), finger sucking, or nail biting may favor the transmission or extension of lesions and cause a Koebner phenomenon (lesions appearing on a line of trauma) (198–202). *In vitro* observations suggest that the wound repair epithelium is more susceptible to an active infection. However, manual workers other than meat packers, abattoir workers, or fish handlers do not appear to be prone to the development of warts, and trauma was not found to be a risk factor in meat handlers. Perhaps moisture and warmth are additional risk factors (109).

The risk of developing condyloma acuminatum or acquiring an anogenital HPV infection after one sexual contact with an affected individual is unknown but is presumably low, but as expected, repetitive contact increases the risk. In a study of 603 female college students negative for HPV DNA at baseline, resampling every 4 months with a cervicovaginal lavage found a cumulative prevalence of 29% at 1 year, 32% at 2 years, 48% at 3 years, and 54% at 4 years (117). In a study of 18- to 20-year-old male students sampled at 4-month intervals, the cumulative incidence of any genital HPV infection was 62% after 2 years (203). About two-thirds of sexual partners of individuals with anogenital warts will develop warts within 2 years (114). Genital warts appear in areas, such as the vulvar fourchette, that are more likely to be traumatized during intercourse; microabrasions or lacerations are also thought to play a role in HPV transmission.

Macroscopic lesions are possibly more contagious than microscopic ones. In one study of women with HPV infection, 67% of 42 male consorts of women with visible condylomata acuminata developed clinical or subclinical lesions, compared to 46% of 39 partners of women with subclinical lesions (204). Transmission of condyloma acuminatum by household contact is probably very rare in the absence of sexual contact or abuse.

The risk of acquiring recurrent respiratory papillomatosis following vaginal delivery from a woman with anogenital warts has been estimated to range between 1:80 and 1:500 (102, 103). Firstborn babies carry more risk than babies of subsequent births, presumably because of longer delivery (103). Furthermore, viral load has been shown to condition the risk of HPV-16 transmission from mother to child. Oral sex appears to be a risk factor for the adult-onset form of the disease.

Nosocomial transmission is addressed in the “Prevention” section.

### Duration of Infectivity

The duration of infectivity is unknown. Patients with anogenital warts of long duration may be less infectious than those with a shorter disease history (114).

## PATHOGENESIS IN HUMANS

The incubation period for HPV diseases is poorly understood. For cutaneous warts, experimental inoculation leads

to lesion development within 3 to 4 months on average, but as early as 6 weeks or as late as 2 years (198). Similar incubation periods have been observed in sexual partners of patients with condyloma acuminatum for whom the date of exposure could be estimated (114, 205). In a study of 51 female university students with an incident cervical HPV-6 or -11 infection, 51% developed genital warts within a median of 2.9 months (112). Among 603 subjects monitored over a 36-month period after an incident HPV infection, 47% and 29% of the students developed LSIL of the cervix and vagina, respectively (117). The median times for lesion clearance were 5.5 and 4.7 months, respectively. When limited to HPV-16 and -18 infections, the cumulative incidences for CIN 2 and CIN 3 were 20% and 7%, respectively. Half of cutaneous warts disappear within 1 year (206, 207).

### Virus Replication

HPVs infect squamous keratinized (skin) and nonkeratinized (mucosal) stratified epithelia. The mucosae of the mouth, upper airways, vagina, cervix, and anal canal are major targets, but HPV has been found in other locations such as the conjunctiva, lacrimal sac, nasal passages, bronchi, esophagus, cervical glandular tissue, and bladder (171, 208–211). Epithelia next to a squamocolumnar junction (sinuses, larynx, anus, and cervix) are particularly vulnerable. In the uterine cervix, a process called squamous metaplasia triggered by hormonal and pH changes causes this squamocolumnar junction to recede toward the os, with the glandular epithelium being replaced by squamous epithelium. The area traveled by this slowly moving junction is called the transformation zone and is the site where cervical cancer occurs. The squamous metaplasia is guided by unique cells expressing p63 and keratin 6 that lie between the squamous cells and glandular cells. These cells trigger the emergence beneath themselves of squamous reserve cells, which then proliferate and differentiate (212). HPV DNA has been found in prostatic tissue and semen, although conflicting reports exist on the prevalence and biological significance of this association. Metastases of HPV-induced lesions also contain HPV DNA. However, whereas some BPsVs can infect lymphocytes and establish metastatic tumors, similar evidence for HPV remains inconclusive (213).

The duration of HPV infections and diseases is highly variable, ranging from weeks to years. Lesion regression is not random. The regression of treated lesions may be accompanied by the regression of the untreated lesions, a phenomenon consistent with a host response (214, 215).

HPV can be recovered not only from skin and mucosal lesions but also from the normal surrounding tissues, where lesions usually relapse (191, 192). Remarkably, HPV-6 or -11 DNA is found in a third to a half of the hair follicles plucked from the pubic and perianal area of patients with condylomata acuminata (194). The vast majority of HPV infections are latent (185, 194, 216, 217). Many of the cervical HPV infections are transient, especially in younger women, and usually contain a low copy number of HPV DNA (82, 129, 218). Transient expression is more common during the luteal phase than during the follicular phase of the menstrual cycle. In the cervix, HPV persistence was estimated to be 9.8 months, with high-risk HPV persisting longer than low-risk HPVs, HPV-16 persisting the longest (12.4 months) (218).

### Latency and Cancer

Infection with a high-risk HPV is associated with a risk of developing CIN that appears to be specific for each

genotype, but the effect of viral load on persistence and disease progression is more complex than previously appreciated, and the relevance of multiple concomitant HPV infections is largely unknown (195, 219). The issue of persistence itself is fraught with methodological difficulties, including the frequency of sampling and the detection sensitivity of the HPV DNA assay used (195). Therefore, it is unclear if immune responses are capable of fully clearing an HPV infection, or if the virus persists in a latent state, undetected and producing no viral particles (66, 195). The viral and cellular factors that induce, maintain, or abrogate latency are unclear, other than immunosuppression, which facilitates the reactivation of latent infection (129, 195, 217). Anecdotally, the initiation of an oral contraceptive treatment has been associated with a flare-up of genital warts.

The oncogenic properties of several animal papillomaviruses, such as BPV and cottontail rabbit papillomavirus, were experimentally demonstrated long ago (52). A cancer precursor can be produced by infecting human foreskin with HPV-16 prior to grafting in SCID mice (59). The anogenital HPV types most capable of immortalizing and transforming cells *in vitro* are those associated with cervical cancer. Different viral genes, notably E6 and E7 from high-risk types, have transforming, immortalization, and oncogenic potential, especially in combination, when introduced into cell lines or transgenic animals. These genes interfere with cell cycle regulation and apoptosis (see “Virology” above) (Table 2).

HPV-induced malignant transformation seems to result from a complex series of events that are independent of viral particle production. Integration of HPV DNA into the host genome appears to be associated with the progression from high-grade CIN to cancer. Integration occurs in the majority of invasive cervical carcinomas but is rare in benign and premalignant lesions; however, this may be an underestimation (28, 195, 220). Integrated and episomal forms may coexist in the same cells. The sites of viral integration in the host genome are not random and exist on a variety of chromosomes. They contribute to oncogenicity by being in proximity to cellular oncogenes or by creating areas of host genomic instability in the manner they integrate (220). The site of integration in the viral genome is typically restricted between the 3' end of E1 and the 5' end of E2, resulting in disruption, deletion, or inactivation of the E2 ORF. These changes appear to disrupt the viral and cellular regulatory controls of viral gene expression mediated by the E2 proteins. This allows the free transactivation of the E6/E7 promoter by several cellular transcription factors (28, 29, 35, 195, 219, 221). Integration may also disrupt the E1, E4, E5, L1, and L2 ORFs, but the E6 and E7 ORFs are typically spared. Viral integration does not appear to be necessary for progression to malignancy, given that up to a quarter of invasive cervical cancers contain only viral episomes (195). In addition, on the rare occasions when low-risk oncogenic HPVs such as HPV-6 and -11 have been associated with squamous cell cancers, the viral genome undergoes deletions, mutations, and amplifications in the URR but remains episomal. DNA sequence heterogeneity exists within each genotype, and molecular variants have different oncogenic potentials (67).

Although the E6 and E7 genes are necessary for immortalization and malignant transformation, they are not sufficient. Hybrid clones from the fusion of cell lines containing HPV-16 do not necessarily retain their malignant phenotype, as would be expected if this phenotype was solely de-

pendent on the presence of the viral genes (222). Therefore, intracellular molecular mechanisms, so far mostly unidentified, are often capable of keeping the oncogenic process in check. However, one internal signal that has been identified is the CDKN2A gene, which codes for the p16INK4A protein. Its role is to inhibit the cell cycle by inactivating cyclin D1-CDK4 or cyclin D1-CDK6 complexes, thus down-regulating cyclin E. Methylation, mutation, or deletion of CDKN2A is necessary for E6 to exert its immortalizing effects. E7 by itself increases p16INK4A levels, which makes this protein a potentially useful biomarker of malignancy, but it also circumvents the inhibiting effect p16INK4A would have by stimulating the downstream cyclins A and E (Fig. 6). Additional genes participating to S-phase progression are upregulated by high-risk HPV infection; they include MCM, PCNA, Ki67, and they have been used as potential biomarkers of malignancy progression. Another of these activated genes is paradoxically p14ARF, which by inactivating MDM increases the levels of p53, but E6 is available to accelerate through ubiquitination the degradation of p53, the net effect being a decrease in p53 (28). External signals also contribute to the downregulation of the transcription and oncogenesis of the high-risk HPVs. These cytokines include tumor necrosis factor alpha (TNF- $\alpha$ ), alpha interferon (IFN- $\alpha$ ), IFN- $\beta$ , IFN- $\gamma$ , retinoic acid, and tumor growth factor  $\beta$  (TGF- $\beta$ ) (28, 29, 219, 221, 222). Some potential mechanisms have been identified. The transcription complex AP-1 is a heterodimer made of c-Jun and c-Fos (Fig. 5) or c-Jun and Fra I. Only c-Jun and c-Fos can bind and participate in the activation of the HPV E6/E7 promoter. Tumor necrosis factor alpha and retinoic acid induce the Fra I gene, thus favoring the formation of the c-Jun-Fra I complex, the net effect being downregulation of the HPV promoter.

Other endogenous factors associated with malignant transformation have been identified. Cellular oncogenes (e.g., c-myc and c-ras) may be activated by the nearby integration of viral DNA into the host chromosome. This is significant because the E7 gene can cooperate with activated ras to induce transformation in primary rodent cells.

Methylation has emerged as an important epigenetic mechanism of carcinogenesis control by causing the inactivation of viral and cellular genes and their regulatory sequences (36, 195, 223). The promoter region of several tumor suppressor genes can be inactivated by aberrant methylation of the GpC islands. E7 is thought to be able to stimulate the transcription of some DNA methylases, causing methylation of the pRB pocket proteins and inhibition of E2F-regulated transcription.

Various cytogenetic abnormalities have been observed in cervical carcinomas, such as alterations of chromosome 1 and allelic losses on the short arm of chromosome 3 or 17 or the long arm of chromosome 11 (219, 222). This loss of heterozygosity may eventually lead to the disappearance of suppressor genes; for example, p53 is located on 17p. E6 and E7 genes can induce chromosomal abnormalities *in vitro*. Chromosome markers have been used to study the cellular clonality of cervical lesions. Low-grade lesions are typically polyclonal, while high-grade lesions seem to be oligoclonal, or monoclonal if concomitant with an invasive cancer. Invasive cancers are monoclonal.

Genetic host factors appear important in the development of cervical cancer. For example, the family-attributable risk of cervical cancer is higher in full sisters than in adopted or half-sisters of women with cervical cancer (224). One case control study found that HLA allele combinations af-

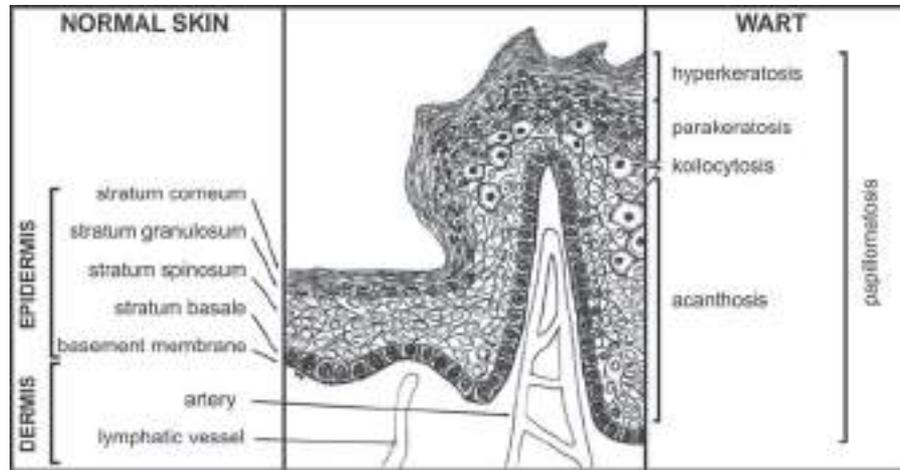

FIGURE 8 Drawing of the histologic features of normal skin and of a wart.

fect cervical SCC risk, with effects all less than 2-fold in magnitude (128). The HLA class I alleles A\*0301, B\*4402, and Cw\*0501 conferred an increased risk, and B\*1501 conferred a decreased risk. The combination of HLA class II alleles DRB1\*1101 and DQB1\*0301 decreased the risk, while the combination of DRB1\*1302 and DQB1\*02 increased the risk. In high-order interaction effects, most of the combinations containing B\*4402 or DQB1\*0301 were associated with an increased risk. Of interest, the combination B\*4402-DRB1\*1101-DQB1\*0301 increased the risk of cancer 10-fold. All these associations were also observed in cervical adenocarcinoma and vulvar squamous cell cancer.

Numerous exogenous factors play a putative role in HPV-related malignant transformation, including UV and X-ray irradiations, smoking tobacco, steroid hormones, chlamydia, and viruses like HIV, herpes simplex virus, and Epstein-Barr virus. However, much remains to be learned about their contributions and mechanisms of action.

### Histopathology

Epidermal basal cells are arranged around a central, putative basal stem cell in groups of approximately 10. These groups define the base of the epidermal proliferative unit. One may speculate that HPV needs to infect the basal stem cell to become established. As the putative basal cell divides, the

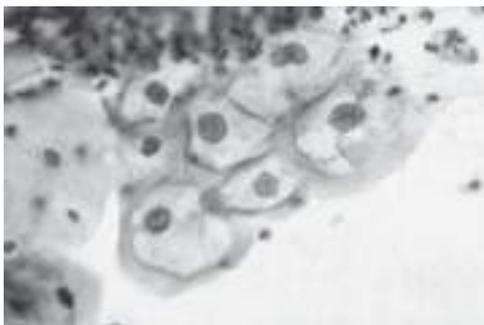

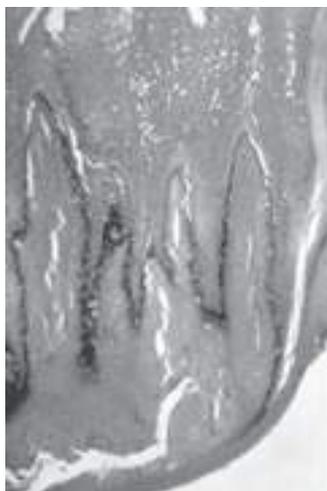

FIGURE 9 Pap smear demonstrating koilocytic atypia. In contrast to the histologic specimen, by cytology koilocytes have one or two relatively large, smooth, oval nuclei, surrounded by a very large halo of amorphous substance. (Courtesy of Clara E. Mesonero, Cape Cod Hospital, Cape Cod, MA.)

viral genome replicates. Some viral copies are transmitted to the daughter cell that is eventually thrust upward to form a parabasal cell. As they ascend toward the surface of the epithelium, the keratinocytes stop dividing but continue to differentiate (Fig. 8). Differentiation is a process associated with the expression of different keratins. Viral replication is independent of cellular replication and may continue as the keratinocytes reach the upper layers of the stratum spinosum. However, to replicate, the virus has to activate and appropriate the cell molecular replicative machinery. The viral particles are shed with the desquamating cells of the stratum corneum.

The typical histologic features of benign cutaneous HPV disease include thickening of the stratum spinosum (acanthosis), stratum granulosum (parakeratosis), and stratum corneum (hyperkeratosis) (Fig. 8). The persistence of nuclei in the stratum corneum is also a feature of parakeratosis. The presence of koilocytes (koilocytosis) (from the Greek *koilos*, cave) is strongly indicative of HPV infection. The koilocyte is an enlarged keratinocyte that develops in the upper layers of the stratum spinosum and in the stratum granulosum. It is recognized by a clear halo that surrounds a central nucleus, shrunken and shrunken on tissue sections and enlarged on cytologic smears (Fig. 9). The cell may be binucleated or the nucleus may be bilobar. The cytoarchitecture of the lesion is papillomatous, with fronds of epidermis extending toward both the dermis and the surface. A combination of the same histologic characteristics can be found in the mucosal epithelia infected by HPV. Because such epithelia are not keratinized, hyperkeratosis is not a frequent or prominent feature. In an inverted papilloma, the papillomatosis is frank but strictly limited to the dermis, thus giving a flat lesion. HPV type also contributes to variations in the histology of lesions. Figures 10 and 11 illustrate the histology of different types of warts.

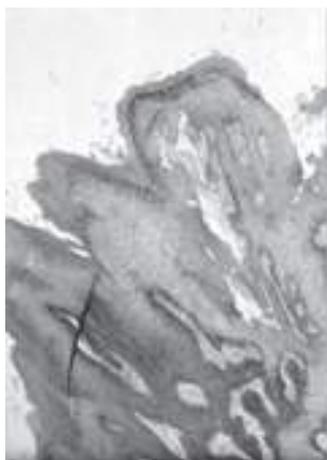

HPV infection of the cervical squamous epithelium can result in a range of histopathological entities for which different classification schemes have been designed (Fig. 12). This evolution reflects the many fine points of the surgical pathology diagnosis and the debates that surround them. What follows is only a crude description of the squamous epithelial changes.

Cervical flat condylomas are benign lesions characterized by the presence of koilocytes. The abnormal proliferation of the basal layer is one of the features that define

**FIGURE 10** Histology of a cutaneous wart (hemalum-eosin stain; low-power view). The darkly stained layer is the stratum granulosum. Koilocytes are profuse and disrupt the stratum granulosum. The persistence of nuclei in the stratum corneum is a feature of parakeratosis. Note the thick stratum corneum. (Courtesy of Clara E. Mesonero, Cape Cod Hospital, Cape Cod, MA.)

intraepithelial neoplasia. These lesions, which are pre-invasive cancers, are graded according to the extent of basal-type cell proliferation. Proliferation up to the lower third of the epithelium is mild dysplasia or CIN 1, up to the upper two-thirds is moderate dysplasia or CIN 2, and up to the full epithelium is severe dysplasia/carcinoma *in situ* (CIS), or CIN 3. In CIS, the full epithelium is abnormal. The local breach of the basal membrane by the epithelial cells characterizes an invasive SCC. The other features of this abnormal cellular proliferation are more prominent as the severity of the lesion increases. They include an enlarged cell nucleus/cytoplasm ratio, coarse granularity of the nucleus, numerous and abnormal mitotic figures, and some abnormal

**FIGURE 11** Histology of condyloma acuminatum (hemalum-eosin stain; high-power view). The figure demonstrates many koilocytes in the stratum spinosum. Koilocytes are relatively large cells with a shrunken, irregular nucleus surrounded by a halo. (Courtesy of Clara E. Mesonero, Cape Cod Hospital, Cape Cod, MA.)

and necrosed cells (atypia defines these abnormal or atypical cellular changes). Koilocytosis may be absent, particularly in the higher grades, which otherwise display anisocytosis. The cytological equivalents of cervical condyloma and CIN are LSIL for cervical condyloma and CIN 1 and HSIL for CIN 2 or 3 (Fig. 12). As a parallel, some pathologists now use the terminology of low-grade CIN (L-CIN) and high-grade CIN (H-CIN) for histology. In 2012, the LAST project of the College of American Pathologists and the American Society for Colposcopy and Cervical Pathology proposed to apply the terminology LSIL and HSIL to both cytology and histology of the cervix, as well as to use p16INK4A immunostaining to better classify formerly CIN2 lesions (225).

From a normal-appearing cervix to CIS there is a graded risk of progression toward invasive cancer (226). This gradient can be superimposed on a gradient of increased prevalence of high-risk HPV types (Fig. 12) (64, 227, 228). Although it would seem that lesions slowly progress through each stage of CIN before becoming invasive, a rapid progression can occur without recognition of the intermediate stage, and progression from a normal cervix to H-CIN can occur in as little as 2 years (129).

Several histologic events accompany the spontaneous regression of warts (214, 215, 229). Spongiosis of the basal cells occurs and a lymphomonocytic infiltrate develops in the dermis and lower epidermis. Necrosis and apoptosis are present in the epidermis; the dermis exhibits focal thrombosis and hemorrhages. The lymphocytic infiltrate is primarily T cells, with CD4 cells predominating. The lymphocytes display the isomorphs CD45RA+ and CD45RO+, indicating the presence of naive and memory cells, respectively. Lymphocytes, Langerhans cells, and keratinocytes are immunologically activated, displaying HLA-DR and ICAM-1 molecules. In addition, the lymphocytes exhibit high-affinity interleukin 2 (IL-2) receptors (CD25). These histologic changes are consistent with a delayed-type hypersensitivity reaction. An increase in natural killer (NK) cell activity has also been associated with resolution of CIN 1. Thus, the cellular immune system appears to be important in HPV disease regression.

### Immune Responses

The immunology of HPV infections is imperfectly understood in its details (215, 230-234). The frequency, severity, and persistence of HPV infections and diseases in immunocompromised patients have long indicated that immunity, cell-mediated immunity in particular, contributes to the development and resolution of HPV infections (113, 139, 229, 230, 235). For example, primary immunodeficiencies such as ataxia-telangiectasia, Wiskott-Aldrich syndrome (due to the WAS protein deficiency), and common variable immunodeficiency are risk factors for the development of extensive verrucosis (113). The original model for an association between a genetic alteration and verrucosis has been epidermodysplasia verruciformis, a genodermatosis associated with inactivating mutations in two genes, EVER1/TMC6 and EVER2/TMC8, that code for endosomal zinc transporter proteins that are part of the NF- $\kappa$ B cell signaling cascade essential to the immune response (189, 190, 236, 237). However, in the past decade a great number of other conditions have been added to the list. They include the WHIM syndrome (warts, hypogammaglobulinemia, infections, myelokathexis) related to a CXCR4 deficiency, the WILD syndrome (warts, immunodeficiency, lymphedema, anogenital dysplasias), XHIGM1 (X-linked hyper-IgM syndrome type 1), hyper-IgE syndrome, atopic dermatitis,

Classification Schemes								
Cytology Equivalence	Bethesda Classification	Normal	Low-grade squamous intraepithelial lesion		High-grade squamous intraepithelial lesion		Invasive cancer	
	Papanicolaou Grades	I	II*	III	IV	V		
	Cervical Intraepithelial Neoplasia (Richart)	Normal	Flat condyloma	CIN 1	CIN 2	CIN 3		Invasive cancer
	Dysplasia (Reagan)	Normal	Flat condyloma	Mild dysplasia	Moderate dysplasia	Severe dysplasia	CIS	Invasive cancer
Histology of the Squamous Cervical Epithelium								
Associated HPV Types (Relative Frequency)	negative or other HPV types	100%	0%	0%	0%	0%	0%	0%
	HPV-6, 11, 42, 43, 44	0%	0%	0%	0%	0%	0%	0%
	HPV-31, 33, 35, 52, 58	0%	0%	0%	0%	0%	0%	0%
	HPV-16	0%	0%	0%	0%	0%	0%	0%

FIGURE 12 Diagrammatic representation of the nomenclature, histologic features, and distribution of associated HPV types in HPV-related cervical lesions. The dysplasia and the CIN classifications are primarily histologic classifications that are also used for cytology, whereas the Bethesda classification is designed mainly for cytology (see text for details).

\*This category in the Pap classification also included atypical squamous cells of the Bethesda classification.

Netherton syndrome, severe combined immunodeficiency (SCID) due to defective  $\gamma$ c chain of the IL-2 receptor, adenosine deaminase (ADA), or the Janus kinase 3 (JAK-3), deficiencies in the dedicator of cytokinesis 8 (DOCK8) protein (the cause of autosomal recessive hyper-IgE syndrome) or of GATA2 (a transcription factor), and others (113, 230).

The keratinocyte is the first barrier to an HPV infection because it expresses various Toll-like receptors (TLR) able to recognize pathogen-associated molecular patterns (PAMPs) (232). One of them, TLR-9, recognizes double-stranded CpG-rich DNA and in turn stimulates the production of several cytokines, TNF- $\alpha$ , IL-8, CCL2, CCL20, CXCL9, monocyte chemoattractant protein 1 (MCP-1), vascular endothelial cell growth factor, IL-5 and -8, retinoic acid, TGF- $\beta$ , and type 1 interferons (IFN) (IFN- $\alpha$ , - $\beta$ ), as well as IFN- $\gamma$ -inducible protein 10 (IP-10 [CXCL10]) and IFN- $\gamma$ . Some of these responses are consistent with the notable mononuclear cell infiltrate present in the dermis and epidermis during regression of a wart or condyloma. These cells allow the development of a local and systemic specific immune response, a predominantly Th1 cytotoxic response. However, HPV has ways to blunt this part of the immune response. HPV-16 E6 and E7 may abrogate the production of TLR-9. HPV also dysregulates the interferon response in different ways (215, 232, 233). E6 likely interferes with the TYK2 kinase, preventing its binding to the interferon receptor and blocking the phosphorylation of TYK2, STAT1, and STAT2 an essential step for the activation of the JAK-STAT cascade. HPV E7 can bind to the p48/IRF9 complex, preventing its translocation to the nucleus where it would bind

the IFN-stimulated gene factor 3 (ISGF3) to form the transcription complex for the IFN-specific response element (ISRE). HPV E7 also interacts with IRF1 and not only blocks the expression of IFN- $\beta$  but also downregulates the transporter associated with antigen processing 1 (TAP1), IFN- $\beta$ , and monocyte chemoattractant protein 1 (MCP1).

The respective roles in antigen presentation of the Langerhans cells, which are the epidermal professional antigen-presenting dendritic cells, and the keratinocytes, which upon immunologic activation can also behave as antigen-presenting cells, are unclear. However, the density of Langerhans cells is generally decreased in nonregressing warts, which may be related to the downregulation of E-cadherin by HPV E6 and E7. HPV capsids do not activate Langerhans cells, and dermal dendritic cells and macrophages may have a greater role in presenting the HPV antigens to the lymphocytes. Nevertheless, HPV can reduce antigen presentation by downregulating this process, inhibiting the expression of proteasome subunits of the major histocompatibility complex (MHC) class I, TAP, and also by reducing the cytoplasmic trafficking of MHC-1 molecules and stopping them in the Golgi apparatus (215, 232, 233).

Cervical cancer progression can be associated with a shift induced by E7 in the cytokine profile from a Th1 to a Th2 response. This is mediated through the production of IL-10, which represses the production of HLA-1, stimulates the production of HLA-G, and inhibits natural killer cells (233). The presence of infiltrating FOXP3+ Treg, likely with specificity to E6 and E7, is associated with a poor survival because they blunt the antitumor response (234).

Apoptosis, or programmed cell death, allows a cell to abort a viral infection and end tumor cell proliferation, but HPV can evade this antiviral and antitumor response. HPV E5 affects both apoptosis-activated caspase pathways by inhibiting TNF-related apoptosis inducing ligand (TRAIL) and CD95L (233). It also downregulates the CD95 receptor and the formation of the death-inducing signaling complex (DISC). HPV E6 participates in this inhibition by stimulating the degradation by ubiquitination of pro-apoptotic proteins FADD, procaspase-8, or c-Myc.

The humoral response to the early viral proteins is typically modest or absent in most patients. Patients with invasive cervical cancer are the most significant exception; approximately half of whom develop antibodies to HPV-16 E6 and E7 peptides or fusion proteins. Otherwise, the most consistent and strongest immune response in HPV-infected patients is to the native conformation of the L1 protein present in virions or recombinant VLPs (18, 238). These L1 antibodies can be neutralizing, but this requires them to be of high titer, which is rarely the case, as the HPV VLP vaccine studies have shown (239–242). The immune response to native L1 is typically type specific (10).

Lymphoproliferative responses to different HPV proteins can be detected in some patients with HPV infections, especially those with cervical preinvasive cancers. The most consistent and strongest of these responses are against E6 and E7 (18, 19). The same proteins are also the targets of a cytotoxic T-cell response (18, 19). NK cell cytotoxicity against HPV-infected keratinocytes is present in epidermodysplasia verruciformis and CIN (105, 106). The precise nature and role of these responses in disease persistence and resolution largely remain to be established and explained in the context of the immunogenetic factors that govern HPV disease (189, 237).

## CLINICAL MANIFESTATIONS

### Cutaneous Warts

Three major types of cutaneous warts are recognized: deep plantar warts, common warts, and flat or plane warts (196). Deep plantar warts (*verrucae plantaris*), also termed myrmecias (from Greek, ant hill), are usually solitary lesions preferentially located on the weight-bearing surfaces of the foot. These deeply set painful lesions can be 2 mm to 1 cm in diameter. They interrupt the ordered pattern of surrounding rete ridges and look like a circular, disorganized bundle of keratotic fibers, sometimes containing dark speckles, surrounded by a slightly raised keratotic ring. The black dots represent thrombosed capillaries (Color Plate 34). Occasionally, the lesion is completely covered by the keratotic ring and can take on the appearance of a corn or callus. Tenderness and the appearance of punctate, thrombosed capillaries after paring the horny layer with a scalpel are features distinguishing a deep plantar wart from a callus or a fibrokeratoma. Occasionally, myrmecias can develop on the palms of the hands.

Common warts (*verrucae vulgaris*) are usually multiple, well-circumscribed, exophytic, hyperkeratotic, round papules with a coarse surface ranging in size from 1 mm to 1 cm (Color Plate 35). They are normally found on the dorsum of the hand, between the fingers, and around the nail bed. They can also grow under the nail bed, causing nail loss (onycholysis). Mosaic warts, a variant of common warts, may be found on several areas of the foot, including the sole, the knuckles, and around the toenails (Color Plate 36). They

appear as multiple, confluent, shallow, slightly raised, keratotic lesions. These painless lesions coalesce and may cover several square centimeters. Filiform warts are common warts usually located on the face, particularly the lips, nares, or eyelids. They are thin, fleshy projections, usually 1 to 3 mm in diameter and a few millimeters long. Cutaneous horns are an uncommon presentation of common warts and may be confused with keratoacanthoma, basal carcinomas, SCC, actinic keratoses, or seborrheic keratoses. The warts of meat handlers usually resemble typical common warts (243). Common warts may be confused with nevi, seborrheic keratoses, acrochordons (skin tags), molluscum contagiosum, keratoacanthomas, lichen planus, lichen nitidus, syringomas, dermatofibromas, or SCC. In the healthy host, malignant transformation of common warts into Bowen's disease, verrucous carcinoma, or SCC is a rare event and may be related to the presence of high-risk oncogenic HPV types in the lesions (244).

Most cutaneous warts are asymptomatic. Bleeding and pain, particularly with deep plantar warts, may occur in pressure areas. The natural history of cutaneous warts is poorly defined. In children, the rates of spontaneous resolution after 1 and 5 years of follow-up are 50% and 90%, respectively (206, 207). Individual deep plantar and common warts take about 1 month to disappear spontaneously. They blacken, become inflamed, or involute. In any given patient, two-thirds of the warts that resolve spontaneously will do so within the first 2 months.

Plane or flat warts (*verrucae planae*) present as multiple, flat, small, asymmetric, smooth papules with a pink to tan color. They are found mostly on the face (especially the chin and eyelids), neck, and hands of children. Taller lesions are sometimes called intermediate warts. Lichen planus and freckles may be confused with flat warts. Reddening, swelling, and itching of lesions announce simultaneous flat wart regression, a process that lasts 2 to 7 weeks.

In immunocompromised patients, HPV-associated lesions may take on appearances other than that of common warts, such as warty keratoses (Color Plate 37), or epidermodysplasia verruciformis-like plaques distributed in the sun-exposed areas (dorsum of the hands, face, scalp, and neck). In these patients, malignant or benign lesions such as SCC, basal cell carcinomas, Bowen's disease, keratoacanthoma, or actinic keratoses can contain HPV (185).

### Epidermodysplasia Verruciformis

Epidermodysplasia verruciformis is an autosomal recessive genodermatosis causing an abnormal susceptibility to Beta-papillomaviruses (189, 236, 237). It results from the mutation of two adjacent genes, EVER1/TMC6 and EVER2/TMC8 on chromosome 17 that code for two endosomal zinc transport proteins, which participate in NF- $\kappa$ B cell signaling (190). Of note, lesions that resemble epidermodysplasia verruciformis are have been observed in HIV-infected patients, solid organ allograft recipients, and patients with tuberculoid leprosy (189, 245). The disease is characterized by the appearance of flat wart-like lesions, red to brown plaques (Color Plate 38), or pityriasis versicolor-like lesions over the face, the torso, and the extensor surfaces of the extremities, usually during the first decade (189, 236, 237, 246). Over 20 different HPV types have been isolated from epidermodysplasia verruciformis lesions (Table 1), often coexisting in the same patient. HPV-3 is uniquely associated with lesions resembling large flat warts. The prevalence of plantar and common warts appears to be increased in these patients. In about half the patients, beginning before the age

of 30 years and extending over the following decades, lesions in sun-exposed areas, primarily those associated with HPV-5, -8, or -47, undergo premalignant and malignant changes. They form papillomas, seborrheic keratoses, and SCC. The malignancies remain locally invasive and slow growing, unless they have been exposed to local irradiation. Biopsy is useful in the diagnosis and management of epidermodysplasia verruciformis.

### Anogenital HPV Diseases

The full evaluation of a patient with potential anogenital HPV disease should include a history that reviews symptoms, particularly those pertaining to emotional well-being, sexual intercourse, urination, and defecation. Duration of symptoms and treatment received should be asked along with age at first intercourse, number of past and current sexual partners, sexual practices, and use of barrier methods of contraception. The patient's history of other sexually transmitted diseases (STD) (including HIV infection) and treatments should be recorded, as should the histories of anogenital warts, intraepithelial neoplasias, and cancers in the sexual partners. The physical examination should be done aided, if necessary, by the application for 3 to 5 minutes of 3% to 5% acetic acid (white vinegar) and the use of a colposcope (a biomicroscope offering several magnifications, ranging typically from  $\times 6$  to  $\times 40$ , and a long focal length) or a powerful magnifying glass. The female internal genitalia should be examined with a speculum. A Pap smear may be obtained at that time prior to further interventions (247). A diagram displaying the anatomic location of the lesions will facilitate evaluation and monitoring. A digital rectal examination completes the examination in immunocompromised patients (HIV patients and transplant recipients) as men who have sex with men, or if anal symptoms are present. Immunocompromised women should have a pelvic examination.

### External Genitalia and Anus

Condylomata acuminata (singular, condyloma acuminatum; from the Greek *kondyloma*, knuckle, knob, and Latin *acumen*, sharp point), also known as anogenital warts or venereal warts, are slightly hyperkeratotic, firm, exophytic papules that are flesh colored to dark gray and are either sessile or attached by a broad, short peduncle (Color Plate 39). On the skin, small lesions tend to be smooth, round papules with an accentuation of the skin ridges. Larger skin lesions or mucosal lesions are more cornified and may have an irregular, jagged, mulberry-like, or pointed surface contour. Sizes usually vary from a millimeter to 2 cm but can reach several square centimeters, particularly when several lesions coalesce like cobblestones to form a plaque. Individual lesions are devoid of hair.

In men, the predominant location of lesions is the penile shaft in circumcised individuals and the preputial cavity otherwise (114, 248). One percent to 25% of patients will have urethral warts that are usually located between the meatus and the fossa navicularis (114). Warts rarely extend beyond the distal first 3 cm, and involvement of the proximal urethra and bladder is exceptional. Meatal eversion or the use of an otoscope or pediatric nasal speculum facilitates the inspection of meatal warts. Although perianal warts can occur in heterosexual men, they are much more common in homosexual men (249–251). The scrotum, perineum, groin, and pubic area are rarely affected.

In women, the great majority of lesions are found over the posterior introitus, including the fourchette, spreading toward the labia minora and majora and clitoris. In decreasing

order of frequency, the perineum, vagina, anus, cervix, and urethra represent less than 25% of the usually affected sites (114, 248). Young girls with anogenital warts should have a careful examination of the anus and genitals, and according to the findings or age of the patient, proper referrals need to be made (87, 90, 92).

For both sexes, anoscopic examination is recommended if there is a history of receptive anal intercourse, if perianal warts are present, or if the patient has anal symptoms. Because lesions rarely extend beyond the pectinate line, sigmoidoscopy is not ordinarily performed. An oral examination is indicated for the presence of associated oral warts.

Itching, burning, and even pain and tenderness are the most common symptoms of condylomata acuminata (248). Yet approximately three-quarters of patients are asymptomatic (248). Nonetheless, the disease has a significant psychosexual impact on about half of the patients before or after treatment. During pregnancy or immunosuppression, warts may increase in number or size and may obstruct the birth canal. The natural history of condyloma acuminatum is poorly defined, but 10% to 20% of patients will experience a spontaneous remission within 3 to 4 months of presentation. Genital warts disappear spontaneously by involution.

### Diagnosis and Differential Diagnosis

The poxvirus infection, molluscum contagiosum is the disease most frequently mistaken for condyloma acuminatum. Lesions of molluscum contagiosum are usually small, circular, well-defined, dome-shaped, sessile papules (see Chapter 19). They are flesh to wax colored, not pigmented, with a smooth or dotted surface containing a central depression from which a cheesy material can be extruded. Their anatomic distribution helps the differential diagnosis because they predominate over the pubis and can extend to the trunk. Condyloma lata of syphilis are relatively large, smooth, sessile, moist, flat-topped lesions that are few in number. The medical history and serology help with the diagnosis. Nodular scabies appears as red, scaly or crusted, deeply set nodules accompanied by an intense pruritus, particularly at night. The differential diagnosis includes other dermatologic conditions. Hidradenoma papilliferum, encountered on the keratinized vulva, resembles a large wart. Acrochordons (skin tags) are soft, skin-colored tumors. Epidermoid cysts and angiokeratomas can be found on the scrotum. Lichen planus, lichen sclerosus et atrophicus, lichen nitidus, or syringomas manifest as small, planar lesions that may be difficult to recognize. Small penile warts in the corona glandis may be very difficult to distinguish from a normal anatomic variant called hirsutoid papillomatosis (pearly coronal papules, papillae corona glandis). Whether the sometimes painful papillae that may be present on the vulvar introitus represent the female equivalent of hirsutoid papillomatosis or are lesions caused by HPV (i.e., vulvar papillomatosis) has been controversial. In both sexes, one may encounter sessile papules or macules that have a brown to slate blue pigmentation (Color Plate 40). These lesions are particularly important to recognize because they may represent benign condylomas infected with HPV-6 or -11 (252), nevi, seborrheic keratoses, or intraepithelial neoplasias infected with HPV-16 or -18 (252). The poor correlation between appearance and histology or HPV type argues for the biopsy of these lesions. Biopsy should also be considered if lesions are large, bleed, appear in plaques, or are in unusual locations. There should be a lower threshold to biopsy immunosuppressed or immunodeficient patients.

Subclinical HPV lesions, either revealed by the colposcope or the application of acetic acid, are more often than

macroscopic lesions associated with high-risk HPV infections (253). Subclinical lesions appear mostly as small acetowhite papules. In male partners of patients with condyloma acuminatum, one-third to more than two-thirds have detectable lesions that are seen only with the aid of the colposcope, and a smaller percentage is seen by acetowhitening alone (253). On the vulva, HPV infection may produce white patches that are enhanced or exposed after application of acetic acid. In some surveys, over 80% of women with or exposed to condyloma acuminatum were found to have subclinical infections. The clinical significance of acetowhite lesions is unknown, in part because acetowhitening lacks specificity and possibly sensitivity for diagnosis of HPV infection on the external genitalia (254). Acetowhite lesions may also be caused by menstruation or recent coitus. Subclinical lesions are usually transient, and diagnosis and treatment of asymptomatic subclinical diseases are not recommended (247, 253). Furthermore, dermatitis, folliculitis, candidiasis, psoriasis, lichen sclerosus et atrophicus, lichen simplex chronicus, and trauma can produce the same symptoms of pain, discomfort, and itching in the absence of visible lesions. The distinct entity of vulvar vestibulitis, also called focal vulvitis, does not appear to be related to HPV infection.

### Vagina and Cervix

Vaginal warts manifest as either spiked condylomas, white, keratinized nodosities centered on a capillary loop, or flat condylomas (114). The latter may be confused with the occasional normal anatomic variant of micropapillary projections that are located over the distal third of the vagina and extend over the introitus (vulvar papillomatosis).

Cervical warts are found in less than 10% of women with genital warts (114). Three variants are recognized: the flat condyloma (Color Plate 41) and the rarer exophytic and inverted (endophytic) condylomas. These lesions are also acetowhite, and colposcopic examination facilitates their identification (Color Plate 42). Because colposcopy is not entirely reliable, several biopsies of suspicious-looking areas are usually required for evaluation. Nevertheless, in the developing world, simple naked-eye visual inspection aided by acetic acid is able to contribute effectively to the prevention of cervical cancer. This screening can be further improved when followed by HPV DNA testing.

### Preinvasive and Invasive Malignant Lesions

The clinical appearance of HPV-related preinvasive and invasive malignant cervical lesions is defined by colposcopic criteria that attempt to match histopathology (Color Plates 41 and 42) (255). Most of the lesions of CIN and SCC develop in the transitional zone. Usually not accessible to visual inspection, the glandular epithelium is vulnerable to HPV infections, especially by HPV-18, which may cause adenocarcinoma (65).

Depending on histologic grade, CIN lesions may regress, persist, or progress at various rates. According to a meta-analysis, the risks of progression over 2 years to HSIL from ASCUS and LSIL are 7% and 21%, respectively (226). Over 2 years, the risks of progression to invasive cancer are low, 0.25% for ASCUS, 0.15% for LSIL, and 1.4% for HSIL. In contrast, the rates of regression to normal cytology or histology are high, 68% for ASCUS, 47% for LSIL, and 35% for HSIL, and independent of duration of follow-up.

Intraepithelial neoplasias at the anogenital sites are often referred to by the acronyms of PIN (penile intraepithelial neoplasia), VIN (vulvar intraepithelial neoplasia), VAIN

(vaginal intraepithelial neoplasia), and AIN (anal intraepithelial neoplasia). Intraepithelial neoplasias can coexist in different anatomic locations, thus reflecting the multicentric nature of the disease. Clinically, these lesions may present on the skin as pigmented papules, leukoplakia, or red macules (252). Bowenoid papulosis is a distinct clinicopathological entity made of the multicentric aggregation of pigmented papules, ranging from dark red to dark blue, with the histologic features of an intraepithelial neoplasia and the cytoarchitecture of a condyloma (Color Plate 40). It may evolve into Bowen's disease, which is a carcinoma *in situ* that presents as a red to brown, flat, scaly plaque with an irregular surface but well-demarcated borders. On the glans penis, Bowen's disease is known as erythroplasia of Queyrat. High-risk HPVs are typically associated with these premalignant conditions. Natural history data on intraepithelial neoplasias of the external genitalia are inadequate. Like CIN, VAIN and early vaginal cancer are best recognized with the colposcope, after the application of acetic acid; biopsy is necessary to establish a diagnosis.

On the external genitalia, warts may exceptionally evolve into verrucous carcinoma, a slow-growing, large, locally invasive SCC (244). Some authors distinguish Buschke-Loewenstein tumor (also called condylomatous carcinoma or giant condyloma) from what others consider to be a less aggressive form of verrucous carcinoma (Color Plate 43) (244). Buschke-Loewenstein tumors look like large condylomas with a locally invasive behavior.

### Recurrent Respiratory Papillomatosis

An altered cry in infants or hoarseness of voice in older individuals is the presenting clinical manifestation of recurrent respiratory papillomatosis (102, 103). Stridor or respiratory distress may also be present. On laryngoscopic examination the lesions are fungating and smooth (Color Plate 44), and are encountered specifically where the ciliated and squamous epithelia are juxtaposed. The lesions are also found along the tract of tracheostomies. The severity of the disease is inversely related to the age of onset; tracheostomy is required more often in children (14%) than adults (6%) and extralaryngeal spread is also more common in children (31%) than adults (16%). Lesion growth and extension toward the lung compromise the respiratory tract, and frequent surgical treatment may be needed to prevent asphyxiation. About one in five patients requires more than 40 lifetime operations. Most lesions contain HPV-6 or -11. Lesions containing HPV-11 might be more aggressive. Malignant transformation resulting in verrucous carcinomas or SCC occurs in less than 10% of individuals, but the risk is the greatest if the lesions were previously treated with irradiation. Disease extension to the lung or the aerodigestive tract carries a risk of malignant transformation as high as 85%. Recurrent respiratory papillomatosis appears to be surprisingly rare in the HIV-infected population.

### Miscellaneous

The different HPV-related lesions of the oral cavity are clinically similar but can be differentiated by histology (62, 256-258). The most common are oral squamous cell papillomas (or squamous papillomas) and the closely related entity oral condylomata acuminata, both caused by the same HPV types, mostly HPV-6, -11, and -16. Verrucae vulgaris lesions are less common and are caused by cutaneous HPVs, such as HPV-2, -4, and -57. HPV DNA, particularly HPV-16 DNA, can be found in various oral intraepithelial neoplasias, verrucous carcinomas, and SCC, as well as in prolifer-

<sup>c</sup>In HIV patients and in men who have sex with men.

<sup>d</sup>Possible for HPV-16 and -18 with some of the FDA-approved tests. Non-FDA approved kits do exist for the genotyping of genital HPVs.

ative verrucous leukoplakia (62, 258). Focal epithelial hyperplasia (Heck's disease) manifests as multiple, asymptomatic, 1- to 5-mm, soft, sessile papules distributed preferentially on the lower lip but also on the buccal mucosa, lower lip, tongue, and gums (62, 257, 258). The lesions usually disappear over time. In HIV-infected patients oral hairy leukoplakia is caused by Epstein-Barr virus infection, although coinfection with HPV does occur (62). HPV infection may cause papillomas and malignant tumors of the conjunctiva, a risk increased by a concomitant HIV infection (183, 184).

## LABORATORY DIAGNOSIS

The role of the laboratory includes both confirming the clinical diagnosis by histology or screening precursor and malignant lesions in the cervix by cytology and detecting HPV DNA in cervical samples to aid in the screening and prevention of cervical cancer (Table 4). A practical method for HPV isolation by *in vitro* culture is not yet available.

### Cytology and Colposcopy

Cytology has been applied to the diagnosis of HPV infections of the penis, vulva, and anus, but cervical cytology, in the form of the Papanicolaou (Pap) smear, remains the most extensively used. Cells can be collected by washings, but swabbing or scraping is standard. The optimal method of

collection combines the use of the Ayre spatula to scrape the exocervix and the Cytobrush® to sample the endocervix (259). The Cervex-Brush® ("broom"), which is designed to sample both areas simultaneously, does not perform as well in traditional cytology (259). The sample can be placed directly on a glass slide and fixed (traditional cytology). An alternative and now widely used approach is to place the sample (ThinPrep with the PreservCyt™ Solution; Hologic) or the head of the broom (SurePath™; Becton, Dickinson and Company) in a liquid fixative (260, 261). The cells are dispersed and are either gathered on a filter and transferred to the glass slide (ThinPrep) or centrifuged on a gradient, with the suspended cells allowed to sediment on the glass slide (SurePath). Both liquid-based preparation technologies appear to offer approximately equivalent performance characteristics that are at least equal to those of traditional cytology (260-265). Their higher cost and longer processing time are offset by the ability to test the cervical sample for HPV DNA, as well as the possibility to combine the tests with a computer-automated imaging system that analyzes the slide and selects the areas of interest for the cytologist to review.

Koilocytes and dyskeratocytes (small, very keratinized squamous cells with orange cytoplasm and nucleus atypia) are hallmarks of cervical HPV infection (Fig. 9). However, atypical squamous metaplasia and, to a lesser degree, dyskeratosis correlate independently with the presence of HPV

infection by PCR better than koilocytosis (266). Cytology is at least 10 times less sensitive than PCR for the diagnosis of HPV infection and should not be used for such a purpose (see “Epidemiology” above).

Over the years different classification schemes have been applied to the Pap smear (Fig. 12) and multiple ones remain in use globally. Their shortcomings led to a consensus effort in the United States that resulted in the Bethesda system in 1988, which was revised in 2006 ([www.asccp.org/ConsensusGuidelines/tabid/7436/Default.aspx](http://www.asccp.org/ConsensusGuidelines/tabid/7436/Default.aspx)) (267). The Bethesda system has three main components: a judgment on the adequacy of the specimen, a categorization of the smear with a codified descriptive diagnosis, and a set of guidelines for management and follow-up. Squamous cell abnormalities fall into four categories: (i) atypical squamous cells (a) of undetermined significance (ASC-US) or (b) for which HSIL cannot be excluded (ASC-H), (ii) LSIL, (iii) HSIL, and (iv) SCC. The performance characteristics of the Pap smear are difficult to determine accurately. The estimated sensitivity ranges from 30% to 87% and the specificity ranges from 86% to 100% (268). It is clearly an imperfect tool for the diagnosis of preinvasive and invasive cervical cancer, but it is still a preferred screening test because it is easy to obtain, has low cost, and with periodic repetitions diminishes the chance of missing invasive cancer. The liquid-based system has allowed the use of computer-aided diagnosis systems to attempt to increase speed, accuracy, and reproducibility while keeping the cost down (269, 270). Automated screening can be implemented for initial screening (triage), thus diminishing technologist workload considerably (269, 270). The BD FocalPoint™ Slide Profiler (Becton, Dickinson and Company) imaging system is FDA-approved for primary screening of conventional slides (approved in 1998) and liquid-based SurePath prepared slides (2003), while the ThinPrep Imager (Hologic) is FDA-approved (2003) for the primary screening of liquid-based ThinPrep prepared slides (274–276). The BD FocalPoint Guided Screening Imaging system the FDA approved in 2008 is a further development of the BD FocalPoint Slide Profiler that eliminates the need for a cytopathologist to review a sampling the slides identified as negative by the machine (270–272).

Abnormal cervical cytology is usually supplemented by colposcopy to visually inspect the lesion and select a biopsy site for histologic analysis (255). After applying 5% acetic acid, the cervix is examined with a colposcope. The application of an iodine solution (Lugol solution) may be included in the examination (Schiller test). Various scoring schemes have been developed to try to differentiate between typical condylomas, low-grade and high-grade intraepithelial neoplasia, and cancer. They rely to various degrees on color, shape of lesion margins or surface contours, appearance of the vessels (punctation and mosaicism), and iodine staining (Color Plates 41 and 42) (255). Like all visually based diagnostic methods, colposcopy suffers from limited accuracy compared to histology, as well as poor intra- and interobserver agreement, particularly when contiguous diagnostic categories are concerned (273, 274). However, it is an indispensable tool for identifying the biopsy sites. Taking additional biopsies when multiple lesions are present clearly improves the confirmation rate by histology of a cytologic diagnosis of HSIL (275).

The colposcopic technique has been applied to the screening of patients at risk of anal cancer. The scoring system developed for the cervix is as effective for the anus in allowing discrimination between L-CIN and H-CIN (150, 276–279).

Cervicography generates a picture of the cervix for review by an expert (255), but like colposcopy, it suffers from poor intra- and interobserver agreement and has not performed well (274, 280, 281). It may retain a place in cancer screening in areas with low resources, to augment the performance of visual inspection with acetic acid (VIA) (282). Given its feasibility and affordability, VIA has been widely implemented in low- and middle-income countries in Asia and Africa, in which WHO currently recommends a screening strategy of HPV testing, followed if necessary by VIA and immediate treatment with cryotherapy or loop electrosurgical excision procedure (LEEP) if cryotherapy is inappropriate (283, 284).

## Histology

Histology is the “gold standard” for confirming diagnosis of HPV disease and is the most important among the laboratory resources available to the clinician. However, sampling error, sample size, and fixation artifacts can all contribute to inconclusive results. Histology is not an appropriate tool for the diagnosis of HPV infection because it selects only small areas for biopsy, and most HPV infections are asymptomatic associated with a normal histology (73–76, 192).

Histologic criteria enabling the diagnosis of the different HPV diseases (Figs. 10 and 11) are neither absolute nor easy to define. Interobserver variability is a substantial limitation that affects histology and cytology equally. Even among well-trained pathologists, interobserver agreement on cervical biopsies is only moderate, and it is worst for CIN 2 (129, 285). These difficulties have motivated the use of the LSIL and HSIL nomenclature for the histologic diagnosis and the addition of the p16INK4A immunostaining to better classify CIN2 lesions (225). The clinical identity of a lesion cannot always be established from the histology. For example, whereas anogenital warts, flat warts, and myrmecias are easily differentiated, other cutaneous warts are more difficult to identify (286–288). Histologic criteria have been elaborated for HPV-diseases of the head and neck, vulva, and anus (289, 290).

Transmission electron microscopy is of little use in the diagnosis of HPV lesions, but it may reveal the presence of intranuclear viral particles that are typically organized in crystalline arrays or pseudoarrays (5, 291–295). HPV intranuclear particles have been noted in histologically or colposcopically normal cervical samples (295).

## Immunocytochemistry

Denaturation of papillomavirus virions by boiling and mercaptoethanol treatment exposes an antigen that is shared among papillomaviruses. Antibodies to the common papillomavirus or genus-specific antigen are commercially available and have been used for the immunocytochemical diagnosis of HPV infection (Fig. 13). The sensitivity of this test is limited and varies with lesion type (20, 296).

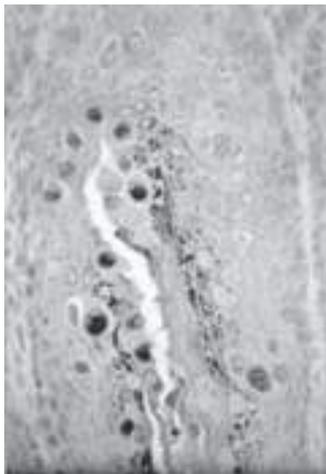

Immunocytochemistry plays an important role in cervical cancer screening to complement histopathology by identifying the presence of cellular and viral proteins that indicate a greater oncogenic risk. The detection of the E6, E7, E4, and L1 viral proteins, for example, has been used to indicate the onset of cancer progression (297, 298). Among the cellular proteins, p16INK4A, the minichromosome maintenance protein 2 (MCM2), topoisomerase II alpha (TOP2A), Ki-67 (a marker of cell proliferation), MYBL2 (a member of the MYB proto-oncogene family that encodes DNA-binding proteins) have been targeted to improve the identification of the risk of progression (298–300). The

biomarkers Ki-67, the pair MCM2 and TOPO2A (Pro-ExC™ assay; Becton-Dickinson), and p16INK4A have slightly different performance profiles for the diagnosis of ASC-US, LSIL, and HSIL (298, 301). The identification by immunocytochemistry of biomarkers that improve the histologic diagnosis has led to the LAST project recommendations, which include not only the use of the LSIL/HSIL nomenclature for histology but also the use of the p16INK4A stain in instances when a CIN2 diagnosis is considered (225). A p16INK4A positive lesion would be classified as HSIL, while a p16INK4A negative lesion would be degraded as LSIL. The immunocytochemistry of biomarkers also applies to HPV-associated lesions at other anatomic sites (302–304).

### Nucleic Acid Detection Assays

*In situ* hybridization (ISH) enables the visualization of HPV nucleic acids in cells or tissues under the microscope, typically a paraffin-embedded tissue section. Probes can be sense or antisense. Antisense probes offer the advantage of binding to both viral DNA and mRNAs, and either of these targets can be selected by denaturing and pretreating with RNase or not (305, 306). The advantages of *in situ* hybridization include the ability to type the infecting HPV, to detect double infections, to distinguish integrated (speckled nuclear signal) from episomal (diffuse nuclear signal) infections, and to relate infection to associated histopathological features. Different commercial tests have been developed, but none are approved by the FDA (306).

PCR diagnosis offers the highest analytical sensitivity and specificity for the detection of HPV DNA (307, 308) and also permits typing. A variety of methods have been described for mucosal and cutaneous HPV types that are based on the use of either general (also called consensus or generic) primers or a mixture of primers (degenerate primer system) (298, 307–313). Typing can be done by retesting the sample with type-specific primers or by applying type-specific probes to the amplicon. Other technologies developed for viral nucleic acid detection and genotyping (298) include real-time PCR, reverse line blot hybridization assays, restriction

fragment length polymorphisms (RFLP), microarrays, loop-mediated isothermal amplification method (LAMP), nucleic acid sequence based amplification (NASBA), and transcription mediated amplification (TMA).

MicroRNAs are noncoding cellular RNAs that contribute to cell regulation, and at least two of them, miR-34a and miR-125b, can be altered in an HPV infection and used as biomarkers (314). The expression of miR-34a is directly controlled by p53 and behaves as a tumor suppressor while miR-125b intervenes in the immune response and apoptosis. Similarly, the upregulation the TERC gene that codes for a component of the telomerase, an enzyme activated in rapidly dividing cells, could be useful as a cellular biomarker of lesion progression (304).

The FDA-approved assays are all designed to detect high-risk mucosal HPV (Alphapapillomavirus genus) nucleic acids (DNA or RNA) from cervical cells to achieve at least one of three goals: a) primary screening of cervical cancer; b) reflex testing of specimens diagnosed as ASC-US to identify the women who need to be referred to colposcopy; and c) cotesting with cytology for women 30 years and older to guide their management. Five tests are currently available and are part of automated platforms (see Table 5) (298, 315).

Direct comparative studies of the performance of these assays for the detection of CIN2+ show equivalent sensitivities in the 91% to 96% range but specificities lower than 29% and in decreasing order for the APTIMA, COBAS, HC2, and Cervista assays (316, 317).

All these assays are approved for two basic indications: the reflex-testing of ASC-US samples and adjunct HPV DNA testing in cervical cytology samples of women 30 years and older. In addition, the COBAS HPV assay has been FDA-approved (2014) for the primary screening of women 25 years and older.

### Serologic Assays

There are no serologic assays satisfactory for the clinical diagnosis of HPV infection. The most consistently sensitive assays are VLP-based enzyme-linked immunosorbent assays used chiefly for the diagnosis of HPV-6, -11, -16, and -18 infections (18, 318, 319). They cannot identify much more than half to two-thirds of infected subjects if they are to retain a high specificity and detect an immunoglobulin G (immunoglobulin A to a lesser extent) immune response that decreases only a little over time (242, 320–322). Hence, they measure HPV exposure. This makes them useful, if imperfect, seroepidemiological tools to measure past and present infection (18, 319). These assays and their derivatives, such as the Luminex® bead technology, are investigational, but they have been also useful for the assessment of the immune response following immunization (319, 322–324). Assays vary in their ability to detect various neutralizing antibodies or binding antibodies (319, 324, 325).

## PREVENTION

### General

No specific environmental precautions have been developed for the control of HPV infections, and there is limited knowledge about the resistance of HPV virions to physical and chemical agents (60, 61). However, surgical instruments in contact with areas potentially infected by HPV should be properly sterilized according to standard procedures developed for viruses. Disposable materials should not be reused. Contaminated surfaces can be disinfected with household

**Table 5** Diagnostic tests for the detection anogenital HPV nucleic acids

Test name (Manufacturer)	Sample	Target, Assay principle	Nature of probes, HPV types detected	Signal detection, Result interpretation	Comments
Hybrid Capture II High Risk DNA assay (Qiagen)	Cells <sup>a,b</sup> or extracted DNA	HPV DNA DNA:RNA hybridization	RNA 16, 18, 31, 33, 35, 39, 45, 51, 52, 58, 59, 68	Antibody to DNA:RNA complexes, conjugated to alkaline phosphatase Positive/negative/indeterminate	<ul style="list-style-type: none"> <li>• Does not differentiate HPV types</li> <li>• Retesting is necessary for the indeterminate results</li> <li>• Cross-react with some of the non-oncogenic HPV types (false-positives)</li> <li>• Does not assess for the presence of human cells in the sample</li> <li>• Scalable to automation with Rapid Capture System (Qiagen)</li> </ul>
Cervista® HPV HR (Hologic)	Extracted DNA using GenFind® (Hologic) <sup>b</sup>	HPV DNA E6/E7 Invader chemistry and hybridization	Three oligonucleotides: 2 invader HPV E6/E7 specific for each genotype and 1 universal hairpin FRET <sup>c</sup> signal 16, 18, 31, 33, 35, 39, 45, 51, 52, 58, 59, 66, 68	Upon binding, a flapping 5' end of the type specific probe is released by a Cleavase enzyme. This flapping end will act as an invader probe to the universal hairpin FRET signal oligonucleotide. This again triggers the Cleavase enzyme to separate on the probe the fluorophore from its quencher. The process repeats itself, generating a large signal. Positive/negative	<ul style="list-style-type: none"> <li>• Does not differentiate HPV types</li> <li>• May cross-react with HPV types 67 and 70 (false-positives)</li> <li>• Contains control probes against histones to ascertain the presence of cells</li> <li>• Scalable to automation with the Cervista® High Throughput Automation (HTA) system</li> </ul>

bleach (5.25% sodium hypochlorite) diluted 1:10 in water. Cryoprobes have been responsible for transmission of warts from patient to patient, thus making sprays preferable for cryotherapy.

Electrosurgery and laser surgery are accompanied by the release of smoke that contains HPV DNA that may lead to the contamination of the surgeon's mucosal membranes or of the operating room surfaces (326, 327). Whether this leads to higher prevalence of hand and nasopharyngeal warts is unclear (328, 329). Smoke evacuation systems and the wearing of gloves, gown, mask, and goggles are recommended when performing these procedures (326, 327, 329–331).

Covering the warts with dressings while at the swimming pool has been useful for the prevention of plantar warts (108). However, there is conflicting data regarding the use of protective footwear in communal areas of swimming pools, public showers, or gyms (107, 109, 110).

Strong evidence indicates that male condoms are effective in reducing the transmission of genital HPV (127) (see "Epidemiology" section). For example, in a prospective study of 82 college-age, initially virgin women, 100% consistent male condom use in partners was associated with a 3-fold decreased risk of cervical, vulvar, and vaginal HPV infection, compared to 5% or less use (332). Among condom users, genital warts are more likely to occur in the anatomical area not covered by the condom (197). Furthermore, in a randomized study of 125 couples of women with CIN, there was a greater rate of CIN (1.5-fold) and HPV DNA clearance (5.7-fold) in the women from the couples assigned to condom use (333) as well as higher (1.9-fold) rate of clearance of HPV-associated flat lesions in the males, and the clearance effect of condoms in males was seen only in the couples with concordant HPV types (334, 335). In a prospective study of 82 college-age, initially virgin women, 100% consistent condom use, as opposed to 5% or less use, was associated with a statistically significant (3-fold) decreased risk of cervical, vulvar, and vaginal HPV infection (332). Condom use can be recommended after treatment of one sexual partner for HPV disease.

Patients with epidermodysplasia verruciformis and immunodeficient or immunosuppressed patients with cutaneous lesions should avoid UV light exposure to minimize the risk of malignant conversion.

There are no validated isolation procedures of HPV-infected individuals. There is no evidence that school activities should be restricted for children with recurrent respiratory papillomatosis.

### Passive Immunoprophylaxis

Although the potential efficacy of passive immunoprophylaxis using hyperimmune globulins raised against VLPs has been demonstrated with experimental animal papillomavirus infections, no data are available for HPV infections (336).

### Chemoprophylaxis

It is possible to prevent the relapse of anogenital warts with either podofilox or 5-fluorouracil (5-FU) (see "Treatment" below), but effective chemoprophylaxis against new HPV infection is not available. Carrageenan, a readily available polysaccharide already included in some vaginal lubricants, has shown excellent microbicidal activity *in vitro* and in an animal model (337, 338). Clinical studies are ongoing to assess its prophylactic effectiveness. In contrast, the spermicide nonoxynol 9 has been shown to potentiate HPV transmission (337).

### Active Immunization

HPV vaccination, introduced in 2006, is the most important advance in HPV care and is expected to sharply reduce the occurrence of anogenital infections and cancers. The current vaccines are based on expressing the gene coding for the major capsid protein (L1), which spontaneously assembles to form a virus-like particle (VLP) that has the same appearance and antigenic properties as the native virions, but is not infectious. Papillomavirus VLPs induce a strong humoral response that neutralizes the papillomavirus of the homologous type (238, 318). This response is much higher than the one triggered by a natural infection, which possibly confers only a weak protection (242, 339). Studies done in an animal natural host validated the concept, which was then applied to human vaccination (336, 340–342). In a pivotal randomized controlled trial, a monovalent HPV-16 VLP vaccine was shown to completely prevent persistent cervical HPV-16 infection compared to adjuvant at 1.5 years of follow-up (343).

There are currently three vaccines on the market (344–347). The first to appear in 2006 was a quadrivalent vaccine (Gardasil/Silgard; Merck & Co., Inc.) directed at HPV types 6, 11, 16, and 18 (345). In all likelihood, it will be replaced completely by a nonavalent extension (Gardasil®9; Merck & Co., Inc.), FDA-approved in 2014, that adds types 31, 33, 45, 52, and 58 (these types are related to HPV-16, except 45, which is related to HPV-18) (347). A bivalent vaccine, covering only types 16 and 18 (Cervarix; GlaxoSmithKline) was FDA-approved in 2009 (344). HPV-6 and -11 cause about 85% to 95% of genital warts (348), while HPV-16 and -18 account for about 70% of cervical cancers and over 90% of the other cancers associated with HPV (including vulva, vagina, penis, anus, oropharynx) (97, 100, 349–351). The five types added to Gardasil-9 represent 30% of the genotypes associated with CIN2/3 and 25% of those causing CIN1, while HPV-16 and -18 are present in 50% and 30% of these lesions, respectively (352). Gardasil and Gardasil-9 are made in yeast (*Saccharomyces cerevisiae*) while Cervarix is made in a baculovirus expression system. The other major difference is the adjuvant, amorphous aluminum hydroxyphosphate sulfate for Gardasil and Gardasil-9 (225 and 500 µg, respectively), and aluminum hydroxide (500 µg) plus 3-O-desacetyl-4'-monophosphoryl lipid A (MPLA) (50 µg) for Cervarix. All vaccines are delivered in a 0.5 ml per dose intramuscular injection (deltoid muscle), in a three-injection series given at time 0, 1 month (Cervarix) or 2 months (both Gardasil), and 6 months.

### Efficacy in Clinical Trials

The efficacy of the current vaccines was established in registrational trials conducted in adolescent and young women aged 16 to 26 years. Gardasil when compared to the placebo (adjuvant alone) was found to have a 99% efficacy (95% CI, 96–100) against genital warts, a 98% efficacy (95% CI, 93–100) in preventing CIN2/3 or adenocarcinoma *in situ* (AIS), and an efficacy of 100% (95% CI, 83–100) against VIN2/3 and VAIN2/3 caused by HPV-6, -11, -16, or -18 (353). The efficacy of Cervarix compared to placebo (a hepatitis A vaccine containing the same adjuvant) was 93% (95% CI, 80–98) for the prevention of CIN2/3 or AIS caused by HPV-16 or -18 (354). The evaluation of Gardasil-9 generated the same levels of neutralizing antibodies against HPV-6, -11, -16, and -18 as Gardasil and had an efficacy of 97% (95% CI, 81–100) in preventing CIN2+, AIS, VIN2+, or VAIN2+ caused by HPV types 31, 33, 45, 52, or 58 (347).

Full vaccine efficacy is provided only against the infections or diseases caused by the HPV genotypes contained in the vaccine with which the subjects have not been infected before (355). Consequently, HPV vaccination should be initiated before the onset of sexual activity to have its greatest impact. Because conducting efficacy studies in children would have required an impractical long period of follow-up for a clinical efficacy endpoint, HPV neutralizing antibody levels were used as correlates of efficacy in “bridging” studies of Gardasil and Cervarix-9. In studies conducted in girls and boys aged 9 years through 15 years, antibody titers were demonstrated to be higher than in the female adolescents and young adults enrolled in other studies (356–363). The same successful bridging studies were conducted with Gardasil-9 (362).

Gardasil was also effective in 16- to 26-year-old males in preventing genital warts, 90% (95% CI, 69–98), and any grades of AIN in MSM, 78% (95% CI, 40–93), caused by the HPV vaccine-types (364). There are no data yet on vaccine efficacy in the HIV-infected population, but these subjects are capable of seroconverting in response to Gardasil or Cervarix, although specific antibody levels that may be 2- to 5-fold lower than in HIV-seronegative individuals (365–368). The significance of this finding is unclear because antibody thresholds below which protection is lost have not been established. When directly compared in HIV-seropositive subjects, Cervarix was more immunogenic than Gardasil in women, but equivalent in men (369, 370).

Gardasil has been evaluated in older women (24–45 years) and the serologic response was lower with age, an observation also made with Cervarix in 15- to 55-year-old women (371, 372). Vaccine efficacy was demonstrated with Gardasil but only by combining external genital warts with CIN as the endpoint (371). This has led to approval of the vaccine in women up to 45 years old in Canada but not in the United States.

At the end of 2015, none of the available vaccines had shown failure of clinical efficacy in the follow-up of the phase 2/3 studies, including 8.5 years of follow-up with the original HPV-16 VLP vaccine (373, 374). Gardasil has retained full protection against genital warts and CIN1-3 at 5 years (373, 374). Specific neutralizing antibody levels have been sustained for up to 7 years, with a slight decline after 8 years, but no occurrence of disease, in boys and girls immunized between ages of 9 and 15 years (375). Cervarix was also still effective at 6.4 years, and at 9.4 years the limited data were still encouraging (376, 377). When compared directly, Cervarix induced higher levels of antibodies to HPV-16 or -18 than Gardasil, likely on the account of the stronger adjuvant (378, 379). The clinical significance of these differences is unknown at present. The same can be said of the stronger cross-reactive antibody response induced by Cervarix against nonvaccine types 31, 33, and 45 (380). These differences, if present, did not appear to be as pronounced when the two vaccines were compared in the same study (381). Furthermore, in Australia where HPV immunization was mostly conducted with Gardasil, some cross-protection was noted against nonvaccine types 31, 33, and 45 HPV prevalent cervical infection, with a vaccine efficacy of 58% (95% CI, 26–76) (382).

### Efficacy in the General Population

There is now sufficient experience with HPV vaccination throughout the world to measure its substantial clinical impact through various observational studies. In Australia, where Gardasil was used extensively to immunize girls, the

cervical prevalence of HPV strains dropped from 28.7 to 6.5% between the prevaccination (2005–2007) and postvaccination (2010–2012) periods (382). This was also likely accompanied by a herd-immunity effect. In the United States, a large survey of over 4,000 females aged 14 to 59 years showed a drop by 44% in the prevalence of vaginal swab HPV DNA for the vaccine types (6, 11, 16, and 18) from the period 2001 to 2006 to the period 2007 to 2010 in the cohort of 14- to 19-year-old girls, the ones most likely to have received the vaccine but not in older women (75). More recently, the same survey was revisited, focusing on 14- to 34-year-old females and comparing the 2001–2006 prevaccine period to the 2009–2012 postvaccine eras (383). Vaccine HPV DNA prevalence declined significantly by 64% in the 14- to 19-year-olds and by 34% in the 20- to 14-year-olds. A 68% reduction in prevalent HPV-16 and -18 cervical infections was found in countries where the vaccine coverage rate was more than 50% (85). These benefits have also been observed in the HPV infection rates of other anatomic areas, such as the anus and oral cavity (384).

Epidemiologic surveys have almost all demonstrated drastic reductions in the prevalence of anogenital warts. A recent meta-analysis reported a 61% reduction between the pre- and postimmunization periods in 13- to 19-year-old girls for those countries where the vaccination coverage was superior to 50% (85). The magnitude of the effect increased over time and was accompanied by evidence of herd-immunity only for those countries with more than 50% vaccine coverage. Similarly, HPV vaccination has led in reductions in the prevalence of CIN or SIL in the United States (385), Australia (386, 387), Denmark (388), and Scotland (389). Although the HPV vaccines appear to be devoid of any therapeutic activity, an unexpected benefit of HPV vaccination has been an apparent reduction in the recurrence rates of HPV cervical diseases and possibly AIN (390, 391).

### Safety

The HPV vaccines are safe and generally well tolerated, with the adjuvants contributing to most of the early adverse reactions (344, 345, 392, 393). The most common side effects are local injection-site reactions of mild to moderate intensity, lasting about 3 days on average, although some vaccinees experience systemic symptoms within 1 week after immunization. In a direct comparison trial of Gardasil and Cervarix, the respective rates were 72% and 92% for any local pain, 26% and 44% for any local erythema, and 22% and 36% for swelling at the local injection site, 40% and 50% for fatigue, 42% and 46% for headaches, 27% and 33% for gastrointestinal symptoms, 16% and 22% for arthralgia, and 11% and 14% for temperature of 37.5°C or more (394). Discontinuation from participation in the clinical trials for adverse reactions was noted in only 0.2% of the almost 12,000 patients receiving either Gardasil or placebo (adjuvant alone) (393). In a similar analysis including almost 30,000 patients receiving either Cervarix or various controls, the withdrawal rates were 0.17% and 0.09%, respectively (392). Adverse reactions are more frequent after the first injection than with the subsequent ones (344, 345). Owing to its double amount of adjuvant compared to Gardasil, Gardasil-9 has slightly more frequent local (but not systemic) adverse reactions, 90% versus 84% for pain, 34% versus 26% for erythema, and 40% versus 29% for swelling (347).

An extensive and worldwide series of postlicensure monitoring programs have been put in place (392, 395–399).

The Vaccine Adverse Event Reporting System (VAERS), a passive surveillance system that allows the reporting by laymen and health professionals of any presumptive problems with vaccines, promptly identified an excess of fainting episodes at the time of the immunization (400). This led to the recommendation of keeping the vaccine recipient under observation for 15 minutes after the vaccine injection. Twenty-six cases of anaphylaxis, none lethal, were also reported, 17 occurring after the first dose. Known allergic reactions to components of the vaccine, in particular baker's yeast for Gardasil and latex for Cervarix (contained in the cap of prefilled syringes) are contraindications for the vaccine administration.

The HPV vaccination is contraindicated in pregnant patients; any vaccination series interrupted by pregnancy should be completed after delivery. Nevertheless, pregnancies occurred during the clinical trials, and among about 1,700 women exposed to either Gardasil or Cervarix during their pregnancy, no excess of abnormal pregnancies, spontaneous abortions, or major birth defects were found (401, 402). These reassuring observations were replicated elsewhere (403, 404). Lactation is not a contraindication for vaccination.

In the postmarketing surveillance programs, particular attention has been directed at detecting any possible risk of thromboembolic or autoimmune diseases, in particular Guillain-Barré syndrome and demyelinating diseases (397, 405–410). None has been found except, in the largest survey done to date, among French females aged 13 through 16 years, including 842,000 who had received the HPV vaccine (Gardasil for 93 %) and 1,414,596 who had not; the only strong risk identified among 14 different conditions was for Guillain-Barré syndrome, with a hazard ratio of 4.0 (95% CI, 1.8–8.7) (411). This represented a low incidence of 1 to 2 cases per 100,000 vaccinees, with mostly no severe sequelae.

### Recommendations

The FDA has approved Cervarix for the prevention of CIN1-3, cervical cancer, and AIS caused by HPV-16 and -18 in females aged 9 through 25 years. The indications for Gardasil are broader. For subjects 9 to 26 years of age, they include the prevention in the appropriate sex of (a) cancers of the cervix, vulva, vagina, and anus caused by HPV-16 and -18; (b) cervical AIS, CIN1-3, VIN1-3, VAIN1-3, and AIN1-3, caused by HPV-6, -11, -16, and -18; and (c) external genital warts caused by HPV-6 and -11. For Gardasil-9, the indications are similar to those of Gardasil, but to HPV-16 and -18, they add types 31, 33, 45, 52, and 58.

The Advisory Committee on Immunization Practices (ACIP) issued recommendations for HPV vaccination (247, 346, 412). Any of the three existing vaccines can be used in females, who should receive the vaccine between ages 11 and 12 years, although it can be given as early as 9 years. A catch-up immunization is recommended for 13- to 26-year-olds not vaccinated previously or who did not complete the three-dose series. For males only Gardasil and Gardasil-9 are recommended. Vaccination should be started at ages 11 to 12 years but can be given as young as 9 years. A catch-up immunization is recommended for 13- to 21-year-olds not vaccinated previously or who did not complete the three-dose series. Vaccination of the 22- through 26-year-old males should be considered.

The three vaccines are to be administered according to a three-dose schedule, at time 0, at least 1 to 2 months after the first dose, and at least 6 months after the first dose. Inadequate doses, or doses administered too soon, should be

readministered. If the series is interrupted, it simply needs to be completed, not restarted. The HPV vaccines can be co-administered with the other age-appropriate vaccines (tetanus, diphtheria, acellular pertussis, and quadrivalent meningococcal conjugate vaccines) but using separate syringes and separate injection sites. It is expected that one subject immunized with one of the HPV vaccines should be able to mount a protective immune response and not incur additional adverse reactions if subsequently immunized with a different HPV vaccine. This was confirmed in females aged 12 to 26 years old who received Gardasil-9 after receiving Gardasil (363).

In addition to the general population, special populations are particularly targeted for HPV vaccination. They include MSM for whom vaccination is recommended up to age 26 years old if they have not been previously vaccinated or have not completed the three-dose series. Both females and males immunocompromised due to transplantation, medication, or HIV infection should be immunized up to the age of 26 years old. Those with a history of sexual abuse or assault should follow the general recommendation, but the immunization should be started as early as 9 years of age.

Immunization is also recommended for those patients with an abnormal Pap test, a known HPV infection, anogenital warts, or HPV-associated lesions. The HPV vaccines have no therapeutic effect, but they still will protect against the HPV types that have not yet infected the patient. No prior HPV DNA or antibody testing is either available or recommended. Most importantly, HPV vaccination does not modify the recommendations for continued cervical cancer screening (see below).

### Prevention of Perinatal and Congenital Infection

Delivery by cesarean section in pregnant women with condyloma acuminatum is not indicated for the prevention of transmission to the baby (102, 103). There is no consensus on the use of cesarean section for the delivery of babies whose mothers have had a child with recurrent respiratory papillomatosis.

### Prevention of Anogenital Malignancies

Several guidelines issued in 2012 are available for the screening of cervical cancer (Table 6) (413). The two notable innovations are the initiation of screening at age 21 years and the role of high-risk HPV DNA testing, either as an adjunct to cytology or alone as the primary screening method. Guidance is also available on how to approach abnormal screening tests both online (<http://www.asccp.org/Guidelines-2/Management-Guidelines-2>) and in print (267, 414). In addition, with the recent introduction (2004) of high-risk HPV DNA as the primary screen, interim guidelines have been issued on how to approach the results (415, 416). The cervical cancer screening and management of women infected with HIV should be differentiated (<http://aidsinfo.nih.gov/guidelines/html/4/adult-and-adolescent-oi-prevention-and-treatment-guidelines/0>) (417). It is important to emphasize that at present HPV vaccination status does not change any of these guidelines.

Screening strategies for anal cancer based on anal cytology have been proposed (418, 419). The procedure, which can be self-administered, consists of the introduction into the anal canal, more than 2 cm from the anus, of a Dacron swab moistened with saline or water or of a cervical Cyto-brush. The collected material is processed like a conventional or liquid-based Pap smear. Nevertheless, anal cytology

TABLE 6 Summary of cervical cancer screening guidelines<sup>a</sup>

Parameter	Organization	Guideline
When to begin Pap test screening?	ACS, ACOG, USPSTF	At age 21 years
How often?	By cytology ACS, ACOG, USPSTF	Every 3 years for women ages 21–65 years
	By HPV co-testing (cytology + HPV test) ACS, ACOG, USPSTF	Not to be used below the age of 30 years Every 5 years for women aged 30–65 years
	By Primary hrHPV testing USPSTF, ACS ACOG	Not recommended Every 3 years, starting at age 25 years
When to stop?	ACS, ACOG, USPSTF ACS, ACOG USPSTF	After age 65 years with adequate negative prior screening AND no history of CIN2+ within the last 20 years AND not otherwise at high risk for cervical cancer
When to screen after age 65 years?	ACS, ACOG USPSTF	If history of CIN2/3 or AIS, continue screening for 20 more years If never screened, does not meet criteria for adequate prior screening, or history of adequate prior screening cannot be accurately documented, screening should continue for at least 20 years after spontaneous regression or appropriate management of high-grade precancerous lesion
Screening post-hysterectomy	ACS ACOG, USPSTF	Women who have had a hysterectomy (including removal of the cervix) should stop screening. Women who had a supra-cervical hysterectomy (cervix intact) should continue screening according to guidelines. Women who have had a hysterectomy (including removal of the cervix) should not be screened anymore.
Screening among women who have received the HPV vaccine	ACS, ACOG, USPSTF	Screen according to guidelines
Screening of HIV-seropositive women	CDC	Women less than 30 years <ul style="list-style-type: none"> <li>● Screening should start within 1 year of onset of sexual activity or at the time of HIV diagnosis, but not later than 21 years old.</li> <li>● Screening is done by cytology alone. Co-testing is not recommended.</li> <li>● If the initial testing is negative, it should be repeated 12 months (possibly 6 months) later.</li> <li>● If the results of three consecutive tests are normal then testing is done every 3 years.</li> </ul> Women aged 30–65 years <ul style="list-style-type: none"> <li>● Screening starts at the age of HIV diagnosis if not started earlier.</li> <li>● Screening is done by cytology or co-testing.</li> <li>● If screening is done by cytology, the testing frequency guidelines are the same as for younger women. If cytology shows &gt; ASC-US, refer for colposcopy. If cytology shows ASC-US, repeat it in 6–12 months. If the result is ASC-US or worse, refer to colposcopy.</li> <li>● If screening is done by co-testing: <ul style="list-style-type: none"> <li>- Both tests (cytology + HPV) are entirely negative; screening is repeated in 3 years.</li> <li>- Cytology is negative but HPV is positive (but not for HPV-16/18), screening is repeated in 1 year. If at that time either test is abnormal, refer the patient to colposcopy.</li> <li>- Cytology is negative and HPV is positive for types 16 or 18, refer the patient to colposcopy.</li> <li>- Cytology is abnormal for ASC-US and HPV positive or cytology is abnormal for &gt;ASC-US, refer the patient to colposcopy. If the cytology is positive for ASC-US and HPV is negative, repeat cytology in 6–12 months. If the result is ASC-US or worse, refer the patient to colposcopy.</li> </ul> </li> </ul> Screening stops after age 65 years

<sup>a</sup>ACS, American Cancer Society (272); ACOG, American College of Obstetrics and Gynecology (407–409); USPSTF, U.S. Preventive Services Task Force ([www.uspreventiveservicestaskforce.org/uspstf11/cervcancer/cervcancers.htm](http://www.uspreventiveservicestaskforce.org/uspstf11/cervcancer/cervcancers.htm)); CDC, Centers for Disease Control and Prevention (<http://aidsinfo.nih.gov/guidelines/html/4/adult-and-adolescent-oi-prevention-and-treatment-guidelines/0>) (410)

is not yet recommended by public health authorities in the United States, except in New York State, as a standard practice in the HIV-infected populations (247, 417). The United Kingdom and Australia have also ruled against this approach at present (150, 420) Any symptomatic patient should be appropriately evaluated. Annual digital rectal exams may also be helpful in detecting intra-anal masses that may be cancerous in HIV-infected individuals or in HIV-negative MSM (247).

Although male circumcision may reduce penile HPV viral load and the risk of transmission to the female partner, the evidence is inconsistent and there are no data on the effect on disease (421–428). Consequently, routine male circumcision is not presently recommended for the control of HPV diseases.

## TREATMENT

A consistently effective and safe treatment for HPV infections is not available. Present therapeutic options are directed at eradicating the disease by destroying the lesions with physical or chemical means or by stimulating an inflammatory or immune response (Tables 7 to 9). A majority of these treatments have been developed empirically, but few have been thoroughly tested, and none is completely satisfactory. This section reviews the most commonly used and best-evaluated forms of treatment for HPV diseases. Additional information on these and other approaches is available (247, 429–441).

## Chemical Methods

### Acids

Salicylic acid alone or in combination with lactic acid (SAL) has well-established efficacy for the topical treatment of cutaneous warts (432, 436, 442). This is a keratolytic agent, but the exact mode of action is unknown. Many salicylic acid-based compounds are available as over-the-counter medications for self-treatment of cutaneous warts. They are well tolerated, although there can be hypersensitivity reactions to colophony, a component of the collodion base often used in salicylic acid preparations.

Bichloroacetic acid (BCA) and trichloroacetic acid (TCA) are keratolytic, cauterizing agents favored by gynecologists for the treatment of genital warts on moist areas (436, 441–443). They should not be applied on large areas, and their application is painful. Adverse reactions, including ulceration and scabbing, are more common than with cryotherapy. Monochloroacetic acid in combination with 60% salicylic acid has been more effective than placebo (83% versus 54%) for the treatment of plantar warts (444).

### Fixatives

A 3% formaldehyde solution or 10% glutaraldehyde solution or gel is effective for the treatment of plantar warts, but sensitization to these compounds can occur. In addition, formaldehyde may cause painful skin fissures. The true efficacy of these approaches is difficult to assess in the absence of controlled trials (432, 442).

**TABLE 7** Some common treatment modalities for cutaneous warts

Agent (U.S. commercial preparation)	Usual formulation and regimen <sup>a</sup>	Wart type <sup>b</sup>	Complete response rate <sup>c</sup> (%)
Salicylic acid (17%)-lactic acid-collodion, 1:1:4 or salicylic acid (40% or 17%) (e.g., Duofilm, Occlusal-HP, Wart-Off, CompoundW, Clearaway Wart Renover)	Daily for up to 12 wk	HW	67
		Single PW	84
		MW	50
<b>Fixatives</b>			
Formaldehyde, 3%	Daily (bedtime)	PW	94
Glutaraldehyde	Daily	MW	47

<sup>c</sup>Results given for the solution formulation.

<sup>d</sup>Based on randomized comparative studies.

### Antimitotics, Antimetabolites, and Cytotoxic, Blistering, and Cauterizing Agents

Antimitotics and antimetabolites take advantage of the increased cellular replication in wart tissues. Podophyllin, an extract from the rhizome of *Podophyllum peltatum* or the more potent *Podophyllum emodi* (436, 441, 442), is usually prepared as a benzoin tincture, 25% podophyllum (USP). Podophyllotoxin, a lignan, is the molecule most responsible for the anti-wart and toxic activities of podophyllin. It is available as a purified compound, podofilox. Podophyllin and podofilox act by preventing microtubule polymerization, thus disrupting the mitotic spindle. Podophyllin may also damage HPV DNA. These preparations have been most extensively used for the treatment of condyloma acuminatum. Local adverse reactions (pain, erythema, tenderness, erosions, and ulcerations) result from the intense acute inflammation and necrosis following topical application. Care should be exercised not to paint the healthy skin or to leave the medication on for more than 24 h. Podofilox (solution or gel) can be applied by the patient, but podophyllin should be applied by a health practitioner and typically no more than once a week (441). The efficacy of these agents is probably equivalent and superior to placebo, and the side-effects are similar (439, 441, 445). Systemic adverse reactions include sensitization to benzoin or guaiacum wood. Ingestion or extensive application of these compounds has been responsible for gastroenteric, neurologic, hematologic, and renal toxicities that may be fatal (439, 441). Podophyllin or podofilox should not be used during pregnancy. Treatment is contraindicated if the wart area is greater than 10 cm<sup>2</sup>. Podofilox should be preferred over podophyllin because of ease of use and purity; podofilox does not contain the mutagenic flavonoids quercetin and kaempferol.

5-FU, a pyrimidine analog, prevents DNA synthesis by blocking the methylation of thymidylic acid (436, 441, 442) and is used as a 5% cream for the treatment of anogenital

warts. Sensitization dermatitis and ulcerations occur infrequently but can be severe. Topical 5-FU has been associated with hematologic abnormalities, including bone marrow suppression and vaginal adenomatosis or carcinoma. The use of 5-FU is contraindicated during pregnancy. Another pyrimidine antagonist, 5-iodo-2'-deoxyuridine (idoxuridine) has been used topically for condylomata acuminata, with up to an 80% complete response rate (446, 447).

Bleomycin is a glycopeptidic mixture that causes breaks in single- and double-stranded DNA. This cytotoxic agent is effective for the intralesional treatment of cutaneous warts, particularly periungual warts (432, 436, 441, 442). At the recommended doses (<5 mg), no systemic toxicities have been reported. Most patients experience pain that can be severe. Administration of a local anesthetic or the addition of lidocaine to bleomycin helps control pain. Intralesional administration imposes a limit on the number of lesions to be treated. Alternate modes of delivery, such as bifurcated needle puncture, dermatography (tattooing machine), and medicated topical dressing, have been used. Bleomycin should not be used in children, pregnant women, or patients with peripheral vascular disease.

Estradiol and 16- $\alpha$ -hydroxyestrone are estrogenic compounds that stimulate the growth of experimental human papillomas. Indole-3-carbinole (I3C), a molecule abundant in cruciferous vegetables (e.g., cabbage and broccoli), has an inhibitory effect by increasing the 2-hydroxylation of estradiol, thus favoring the formation of 2-hydroxyestrone instead of 16- $\alpha$ -hydroxyestrone (448). I3C (Indoplex) is a popular dietary supplement in the management of recurrent respiratory papillomatosis. While one study of oral I3C for the treatment of CIN 2 or 3 has shown promising results, its effectiveness for the treatment of recurrent respiratory papillomatosis has not been rigorously established (102, 103, 449).

Retinoids impede epidermal growth and differentiation. A 0.05% tretinoin cream more than doubles the complete

TABLE 9 Suggested approaches to the treatment of warts

Type of wart or lesion	Treatment options <sup>a</sup>
Plantar and hand warts	First line

<sup>a</sup>H, home treatment; O, office-based treatment. The reader may also consult several published guidelines or reviews mentioned in the text (references 3, 9, 16, 26, 42, 86, 88, 89, 134, 160).

<sup>b</sup>Recommended for intrameatal warts.

response rate compared to placebo in patients with plantar warts (442). Their efficacy in the treatment of CIN or genital warts has been limited or absent (442). Uncontrolled trials have also indicated a beneficial effect of oral or systemic retinoids for the treatment of plantar, flat, and common warts (442, 450–452). Retinoids are teratogenic.

Cantharidin is a compound extracted from the blister beetle, *Cantharis vesicatoria* (Spanish fly) (442). Its topical application causes acantholysis. Excellent responses have been documented for the treatment of cutaneous warts. The blistering is painful, but it is usually tolerable and does not cause scars. Cantharidin should not be applied on healthy skin or near mucosal membranes, especially the conjunctiva.

It is not recommended for use during pregnancy. Systemic absorption of cantharidin causes severe toxicities.

Silver nitrate sticks are chemical cauterizers that have been applied to cutaneous warts (442). Three applications at 3-day intervals on common warts resulted in a 4-fold increase in complete response compared with placebo (453). Occasional hyperpigmentation is reported. Different oral or topical preparations of zinc sulfate have been reported superior to placebo for the treatment of cutaneous warts (432, 454, 455).

### Allergic Sensitization

Sensitization with 1-nitro-2,4-dinitrochlorobenzene followed by application of the compound on the lesions has been used for the treatment of recalcitrant cutaneous and genital warts (456). Complete response rates of about 80% to 100% have been reported in uncontrolled studies. The occurrence of severe allergic reactions has led to a decline in use. More recently, other sensitizing agents, 2,3-diphenylcyclopropanone (diphencyprone), squaric acid dibutyl ester, and 10% masoprocol cream (Actinex), have been advocated because of their greater safety (456).

### Interferons, Immunomodulators, Antivirals, and Others

Interferons have been extensively evaluated in the treatment of condyloma acuminatum and also used to treat other HPV diseases (436, 441). Intralesional administration is more effective than placebo or parenteral IFN administration, and most studies have failed to show benefit with parenteral interferon. Recent studies suggest superiority to either placebo or podofilox for the treatment of external genital or intravaginal warts (441). When used in combination, interferon treatment adds little to the efficacy of cryotherapy or laser therapy, but it enhances the effectiveness of podophyllin (457). Topical interferon formulations are not available in the United States. Systemic interferon has little effect on HPV DNA copy number *in vivo* (457). Experience with the pegylated formulations of interferon is lacking. The common side effects of interferon are well known, and their intensity is in part related to dose. Interferons are very costly and contraindicated during pregnancy.

Imiquimod, an imidazoquinoline, is an inducer of IFN- $\alpha$  and other cytokines that is available as a 5% cream (Aldara) administered thrice a week or a 3.75% cream (Zyclara<sup>®</sup>) applied daily for the treatment of condyloma acuminatum (441, 442, 458, 459). An attractive feature of this immunotherapy is that it is patient applied. In patients randomized to topical treatment with imiquimod at 5% or 1% or vehicle cream every other night for up to 16 weeks (459), the complete response rates were 50%, 21%, and 11%, respectively. During a 12-week follow-up for those free of lesions, the corresponding recurrence rates were 13%, 0, and 10%, respectively. Side effects of imiquimod are local and include itching and burning sensations, as well as erythema, erosion, and swelling. Women respond approximately twice as well as men, but higher rates of disease eradication, as well as of local side effects, can be obtained with daily application (459, 460). The 3.75% imiquimod cream formulation administered daily has given a complete clearance rate of 28% compared to 9% in the vehicle arm 16 weeks after treatment initiation (461). Imiquimod has been used for the treatment of cutaneous warts, Bowen disease, and Bowenoid papulosis (459, 462, 463). It is superior to placebo or lesion ablation for the treatment of VIN (464, 465).

Cimetidine has immunomodulatory properties in addition to its H<sub>2</sub>-blocking effect. Although advocated for the treatment of cutaneous warts, it was ineffective in controlled studies (466, 467). Cidofovir [(S)-1-(3-hydroxy-2-phosphonyl-methoxypropyl) cytosine (HPMPC); Vistide], a nucleotide analog inhibitory for several DNA viruses (see Chapters 12–14), is effective in a variety of HPV diseases when delivered either intralesionally or topically (468, 469). These include condyloma acuminatum, recurrent respiratory papillomatosis, aerodigestive tumors, VIN, CIN, and cutaneous and oral warts (468–470). These results, except for condyloma acuminatum, are all based on observational studies. Cidofovir is a potential carcinogen in humans. Ribavirin, a nucleoside analog with known activity against RNA viruses, was found to have some efficacy in a cottontail rabbit papillomavirus animal model, as well as an encouraging effect in a few pilot studies on recurrent respiratory papillomatosis (102, 103, 469).

Veregen (sinecatechins or polyphenon E) is a botanical made from a partially purified fraction of a water extract of green tea (*Camellia sinensis*) leaves. It contains more than 65% epigallocatechin gallate and other catechins. The mechanism of action is unknown, but it includes cytotoxic and apoptotic properties (471, 472). It is available as a 15% ointment that is self-applied three times a day until complete lesion disappearance, but for not more than 16 weeks. In clinical trials, it showed a complete response rate of 55%, compared to 35% for the placebo (473), with better results in females than males. Erythema, itching, burning, pain or discomfort, and erosion or ulceration occur in at least about half of treated patients. The drug is contraindicated during pregnancy. The potential drawbacks of this new medication are the frequency of application—no compliance data are available—and its red color, which may stain undergarments.

### Physical Methods

#### Curettage and Cold-Blade Excision

Curettage is used for the removal of cutaneous warts but has not been rigorously evaluated (474). Its main drawback is the formation of scars that are sometimes painful. Excision of anogenital warts with scissors has been used with good success (475, 476). Scarring is also a complication but is minimal (476). Local anesthesia is required with either technique.

Cold-blade conization of the cervix has long been the standard mode of biopsy and treatment for CIN (477, 478) but is now being replaced by electro-surgical techniques. The development of microresectors, small instruments that resemble biopsy forceps, has facilitated the resection of laryngeal papillomas.

#### Electrosurgery

Electrosurgery encompasses various techniques in which tissue ablation is the result of electric current. Depending on the wave form of the current, its voltage and amperage, and the number (one or two) and contact of the electrodes with the tissue, the methods are called electrocautery, electrodesiccation, electrofulguration, electrocoagulation, and electrosection (479). It is unknown which method is best, but scarring is a notable side effect with all. Electrosurgery should be discouraged for plantar warts, because the scars tend to be painful (480). Electrofulguration is useful for the treatment of facial warts, and electrocoagulation and electrodesiccation are appropriate for the treatment of condy-

loma acuminatum (441, 481). A topical anesthetic containing prilocaine and lidocaine (EMLA cream) provides good pain control for the removal of condylomata acuminata (482).

Large loop excision of the transformation zone (LLETZ), also known under the more general descriptor of loop electrosurgical excision procedure (LEEP), is an electrosurgical procedure that has largely replaced cold-blade conization of the cervix in the management of CIN (483, 484). It requires local anesthesia. It has been associated with higher rates of preterm deliveries (485).

### Cryotherapy and Heat Therapy

Cryotherapy relies on four types of cryogenics: mixture of dimethyl ether and propane (DMEP) (boiling temperature  $-40^{\circ}\text{C}$ ), carbonic ice ( $-78.5^{\circ}\text{C}$ ), nitrous oxide ( $-89.5^{\circ}\text{C}$ ), and liquid nitrogen ( $-196^{\circ}\text{C}$ ) (486, 487). The treatment is delivered by a cryogenic pencil, a cotton swab, a melamine sponge, a cryoprobe, or a spray. Cryogenic pencils have been responsible for wart transmission, making liquid nitrogen spray the preferred method of delivery. The aim is to produce an ice ball around the lesion in the form of a frozen halo extending 1 to 2 mm beyond the margins. Some advocate a second freezing immediately after the lesion thaws, which may be advantageous for the treatment of plantar warts if not hand warts. Freezing is accompanied by a brief stinging sensation. Mild discomfort or pain may reappear after tissue thawing. Scarring is infrequent and usually minimal (457). The procedure is well tolerated by the vast majority of patients (457). Cryotherapy is widely used for the treatment of most HPV diseases, including CIN (484, 488). It is also the procedure of choice for pregnant patients.

Heat has been used to a lesser extent than cold to treat HPV diseases. In one study, the infrared coagulator was effective in completely eradicating condyloma acuminatum in 82% of patients (489). This technique is also becoming attractive for the treatment of AIN, including high grade, because of good clearance and control rates of the disease (490). Cold coagulation requires a  $100^{\circ}\text{C}$  probe to be in contact with the lesion for 20 s. This technique has been applied to the treatment of CIN, with success rates exceeding 93% in some uncontrolled reports (491). Anecdotal but dramatic improvements have been reported after either immersion of cutaneous warts in a 45 to  $50^{\circ}\text{C}$  water bath for up to 75 min or application of a radiofrequency heat generator for 30 to 60 s (492). In a controlled experiment, 86% of 29 treated warts disappeared, compared to 41% of 17 control warts (492). Further support comes from a randomized, patient-blinded, placebo-controlled trial in which 54% of 28 patients with plantar warts responded, compared to 12% of the 26 controls (493).

### Laser Therapy

The CO<sub>2</sub> laser has been the laser of choice for the treatment of HPV diseases, but others, including the pulsed-dye, argon, and KTP lasers, have also been used (441, 494, 495). The energy of its infrared light ( $\lambda = 10,600\text{ nm}$ ) is well absorbed by the intracellular water, which is then vaporized. Varying the width of the beam controls the energy density of the light delivered, which can be used for cutting (narrow beam) or superficial vaporization (broad beam) (496). One can reduce the energy of a broad beam so that the tissue is coagulated rather than vaporized, a technique called brushing. An additional variable is how the light is emitted: continuously, pulsed, or superpulsed, the last being favored. The determination of proper laser techniques has been largely

empirical. The great variation in the techniques used may account for differences in outcomes (441, 496–498). Because of the pain generated and the need for the patient's cooperation, laser ablation usually requires local or general anesthesia. A lidocaine/prilocaine cream (EMLA cream) is an effective solution for local anesthesia of the external genitalia (499). Postoperative pain, bleeding, swelling, and scarring occur in up to a quarter of the patients treated. The high cost of the procedure is an additional drawback. Laser therapy is a suitable option for the treatment of vulvar warts during pregnancy.

Photodynamic laser therapy is an evolving and successful approach for the treatment of cutaneous warts, genital HPV diseases, and recurrent respiratory papillomatosis (102, 103, 247, 432, 434, 436, 441, 500, 501). The concept is to deliver a photosensitizing agent to the lesion, either topically (5-aminolevulinic acid) or systemically (e.g., meso-tetra ( $\mu$ -hydroxyphenyl)porphyrin ( $\mu$ -THPP) or 5-aminolevulinic acid). Exposure of the tumor to intense light of the proper wavelength activates the compound and selectively destroys the tissue.

### Occlusive Therapy

The therapeutic application of a poultice on a wart is a very old idea, and it has received a lot of popular attention, especially after the positive results of a randomized clinical trial in which the occlusive dressing was made of duct tape (502). This trial had limitations with blinding and follow-up, and two subsequent trials failed to replicate these results (503, 504).

### Therapeutic Vaccines

Many efforts are ongoing to develop a therapeutic vaccine, but none is presently commercially available (505–507).

### Suggestion, Hypnosis, and Homeopathy

The idea that cutaneous warts respond to suggestion is widely disseminated, but randomized, controlled studies have failed to provide convincing evidence of a suggestion effect (442). Hypnosis was found by some investigators to be superior to suggestion, but it appears that the results are inconsistent and the methodologies are defective (442, 508, 509). Homeopathy has so far failed to show superiority to placebo for the treatment of either plantar or cutaneous warts (432).

### Management and Treatment Approaches

Our incomplete knowledge of the natural history of HPV diseases and of the comparative effectiveness and tolerance of the available therapies has unfortunately resulted in a wide variety of management options whose merits are difficult to ascertain (247, 429–436, 438–441). Furthermore, some of the treatment options are often guided by the resources available. Table 9 offers some guidelines, and the following section addresses more specific points of management.

### Cutaneous Warts

In most patients cutaneous warts cause little inconvenience and resolve spontaneously in half of the patients within 1 year (206, 207), making treatment unjustified. If treatment is initiated, SAL paints have demonstrated their efficacy when compared to a placebo (432). SAL paints and fixatives can be applied by the patient and should be the first line of treatment. Cryotherapy is as efficacious as SAL (510). Contact immunotherapy and photodynamic therapy are likely to be effective treatment, but they require a skilled

practitioner and are probably better reserved for recalcitrant disease. The more traditional treatments that include bleomycin, glutaraldehyde, cantharidin, and fixatives largely remain of uncertain effectiveness (432, 442). Paring of plantar warts prior to topical treatment increases the effectiveness of the treatment. This can be done by the patient's using a pumice stone or by the practitioner with a scalpel blade. The surgical methods (cold-blade, electrosurgery, and laser surgery) should be used wisely, as they can create painful or disfiguring scars. No treatment is highly successful, the complete response rate being about 60% to 70% at 3 months (432). Therefore, it is important to avoid the production of scars and to know when to withhold treatment. It is well established that plantar warts, especially mosaic warts, are more difficult to eradicate than common warts. Flat warts are the easiest to eliminate.

Epidermodysplasia verruciformis lesions should be monitored for premalignant and malignant transformation as well as protected from sun exposure (246, 511). Excisional surgery, cryotherapy, or laser surgery can be used for the management of the lesions (246, 511). Medical treatments have also been applied, including with interferon and retinoids (246, 512). Grafting may be necessary to cover extensive skin defects, and artificial skin has been used successfully to that effect.

## Anogenital Lesions

### Condyloma Acuminatum

Treatment for condyloma acuminatum is aimed at improving cosmesis, relieving symptoms, or freeing an obstructed birth canal. It is also directed at the often seriously compromised psychological well-being of the patient (513–518). The possible impact of treatment on HPV transmission, development of an HPV-related malignancy, or on the acquisition of recurrent respiratory papillomatosis in the newborn are uncertain (114, 205). Presently, treatment should not seek to eradicate subclinical HPV infection; such attempts have failed and caused high morbidity (193). The benefits of treating lesions should be weighed against adverse effects and costs associated with therapy and against the possibility of spontaneous resolution, which occurs within 3 to 4 months in approximately 10% to 20% of patients. Other than immunosuppression or immunodeficiency, with the possible exception of long disease duration, there are no strong or reliable indicators of disease refractoriness to treatment (457). Warts appearing at new sites (recurrence) or during treatment can be treated with the same therapy. Warts appearing at previously treated sites (relapse) may benefit from a different therapy.

There is no evidence that evaluating and treating the male partner has an impact on HPV infection, CIN risk, or disease relapse in the treated woman (193, 247, 438). However, no comparable data exist regarding the female partner of the male patient. Nevertheless, it is appropriate to evaluate the sexual partner for three reasons: (a) a chance to address specific STD transmission risks; (b) the possibility to lighten the patient's psychosexual burden and reassure about the partner's health status; and (c) the offer of education and counseling (247). Condom use can be beneficial in couples in which at least one of the partners has HPV disease and should be advocated during the treatment period (see "Prevention" section).

Podophyllin is inferior to podofilox, excisional surgery, electrosurgery, and cryotherapy (247, 441, 519). Although podofilox is more effective than podophyllin, both drugs are

associated with high recurrence rates. Podofilox is superior to a vehicle only in preventing recurrences when used prophylactically after podofilox treatment. Cryotherapy and TCA application appear to be therapeutically equivalent, and cryotherapy is not significantly different from electrosurgery (519).

Self-treatment options offer convenience and privacy. Imiquimod and podofilox are attractive, the former being likely more effective if one takes into account the relapse rate. Veregen is more costly, requires three applications a day, and stains the skin and clothing. The downside of self-treatment is the long duration and frequency of treatment. A practitioner can offer possibly more effective and definitely faster solutions with cryotherapy and TCA application. Electrosurgery (and that would include the infrared coagulator) and laser surgery require both equipment and skills. Surgical excision with scissors is well suited to the treatment of lesions that are small in size and number. Urethral warts can be treated with cryotherapy or surgical excision (247). Laser surgery should not be first-line choice because of high cost. For recalcitrant lesions laser surgery is useful, especially if the lesions are numerous. Other options to consider are higher frequency of administration of imiquimod, intraleisional interferon, photodynamic therapy, allergic sensitization, 5-FU application, or cidofovir. Lesions in moist areas appear to resolve better than ones on dry areas but not necessarily because of the treatment received (520–522). Furthermore, warts located within the occluded foreskin have a favorable outcome (523).

Cryotherapy, BCA/TCA application, electrosurgery, cold-blade excision, and laser surgery are all appropriate for the treatment of condyloma acuminatum in the pregnant patient. Anogenital warts in immunocompromised patients respond relatively poorly to treatment and have a high rate of relapse (524, 525). Nevertheless, some patients do respond and there are few reasons to withhold treatment in these patients, if otherwise indicated. The efficacy of imiquimod is reduced by half in HIV-seropositive patients when comparing then to HIV-seronegative patients, but it remains a useful agent to control disease (often the main goal in these patients) and recurrences (526, 527). It is uncertain whether HAART affects the natural history of genital warts, oral warts, CIN, or AIN (144, 528–538). From a practical standpoint, it is unlikely to have a significant effect on the treatment decisions related to HIV and HPV.

No intervention, either as a primary approach or because of previous treatment failures, may be necessary in the absence of changing lesions, intraepithelial neoplasia, or carcinoma, provided proper follow-up and evaluation (e.g., yearly) are done.

### Internal Warts and Intraepithelial Neoplasias

The evaluation and management of intraepithelial neoplasias and internal warts should be left to experienced practitioners (247, 484, 494, 539–543). Guidelines have been established for the cervix (<http://www.asccp.org/Guidelines-2/Management-Guidelines-2>) (267).

### Patient Education

The public is largely uninformed about genital HPV disease, and the information is complex; thus, education is a necessary part of the practitioner-patient interaction. The diagnosis of genital HPV disease is emotionally charged, and education is also an opportunity to engage the trust of the patient so that optimal care can be offered. For patients and health professionals, abundant high-quality and current

information materials (including in Spanish) about HPV are easily available from the Centers for Diseases Control and Prevention (CDC) (<http://www.cdc.gov/hpv/> and <http://npin.cdc.gov/>). The CDC offers a hotline 1-800-CDC-INFO (232-4636), TTY: 1-888-232-6348 (Monday through Friday from 8:00 a.m. to 8:00 p.m., EST), e-mail: [cdcinfo@cdc.gov](mailto:cdcinfo@cdc.gov). The American Social Health Association (<http://www.ashastd.org>) also offers excellent resources for patients, including links to support groups. It also offers person-to-person counselling that can be arranged on the web site (<http://www.ashsexualhealth.org/person2person-2/>).

### Recurrent Respiratory Papillomatosis

Although numerous therapeutic options have been considered for the treatment of recurrent respiratory papillomatosis, the microdebrider device is now favored by most American surgeons instead of the CO<sub>2</sub> laser or cold-steel surgery (103, 544). Photodynamic laser therapy will probably gain acceptance due to early encouraging results. Because many patients require scores of procedures during a lifetime, selection of a skilled operator is essential to minimize long-term side effects. Tracheostomy should be avoided since the surgical site often becomes involved with the disease, which may also spread further down the respiratory tree. Radiotherapy of recurrent respiratory papillomatosis has been associated with malignant transformation and is contraindicated. Parenteral interferon is used as an adjuvant therapy. Another adjuvant treatment, intralesional cidofovir, has now replaced oral ribavirin (544, 545). Most patients will have tried IBC (Indoplex). Patients and families may find support and information at the Recurrent Respiratory Papillomatosis Foundation (<http://www.rpf.org>), or the International RRP ISA Center (<http://www.rpfwebsite.org>).

### Oral Warts

Surgical excision and cryotherapy application are among the therapeutic choices for the management of oral warts (62, 258). Focal epithelial hyperplasia usually does not require treatment because of its self-limited evolution.
