Perhaps the most important lesson from the West African epidemic is that doctors and nurses can be counted on to stay at their posts, caring for Ebola patients at the risk of their own lives. In Guinea, Liberia, and Sierra Leone more than 800 health care workers became infected, and at least 500 died. The support of the industrialized countries to create and maintain an effective public health system in West Africa, capable of responding both to a filovirus outbreak and to the range of more common endemic diseases, will be their best memorial.

# Influenza Virus

FREDERICK G. HAYDEN AND PETER PALESE

## 43

“If influenza is a riddle wrapped in mystery inside an enigma, then the viral genes are the riddle, the variable surface antigens for which they code are the mystery, and the course and cause of epidemics the ultimate enigma.”

E. Kilbourne, 1980.

Influenza viruses are unique among the respiratory viruses with regard to their frequent antigenic changes, seasonality, and impact on the general population. They can cause explosive outbreaks of febrile respiratory illness across all age groups and often substantial mortality, particularly in aged and chronically ill persons. Epidemics resembling influenza have been recorded since antiquity. The plague of Athens in 430 to 427 BC, described by Thucydides, has been postulated to have been due to epidemic influenza complicated by toxigenic staphylococcal disease (1). The greatest effects of influenza are seen when novel strains, to which most persons are susceptible, cause worldwide outbreaks, or pandemics. The most profound of these in modern times was the 1918 pandemic that may have claimed as many as 100 million lives worldwide (2). Sequencing of RNA fragments from tissue samples taken from 1918 pandemic victims enabled reconstruction of the extinct 1918 virus and study of its virulence in animal models (3, 4).

Influenza virus was first isolated from chickens with fowl plague in 1901. Swine influenza virus, possibly transmitted to swine from humans during the 1918 pandemic, was isolated initially in 1931, and the first human influenza A virus was recovered in 1933 (Fig. 1, Fig. 2). Recognition of antigenic variation, growth in embryonated eggs, and the ability of virus to agglutinate erythrocytes followed shortly. These discoveries provided reliable means of virus isolation and serologic testing. Influenza B and C viruses were first isolated in 1940 and 1947, respectively. Recent studies identified a new genus, provisionally designated influenza D, with reservoirs in pigs and cattle (5, 6).

During the 1940s, crude inactivated vaccines were introduced, and these were followed by more purified, less reactogenic ones. In 1948, WHO established an influenza surveillance program that continues to monitor global activity and to facilitate strain selection for vaccines. Among the first antiviral agents, amantadine and rimantadine were shown to have prophylactic and therapeutic activity for influenza A in the mid-1960s; the neuraminidase (NA) inhibitors followed in the late 1990s. Despite the availability of

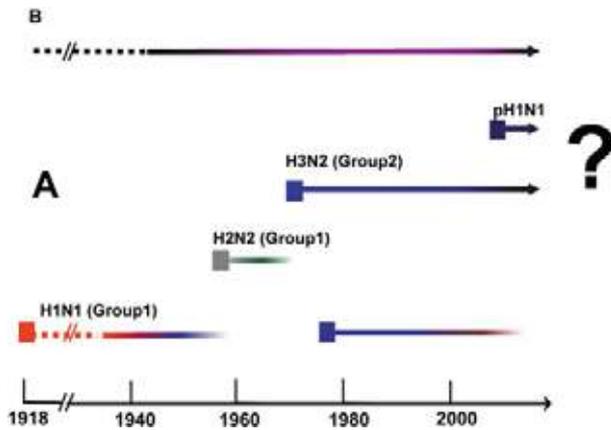

improved vaccines and antivirals, seasonal influenza remains an important public health problem. The annual burden of inter-pandemic influenza in the United States has averaged approximately 20 million respiratory illnesses, over 200,000 hospitalizations, and between about 3,000 to 49,000 deaths in recent years (7). The first pandemic of the 21st century, due to a swine-origin virus emerging initially in North America, rapidly spread globally but was fortunately less severe than predicted. However, emerging zoonotic influenza viruses, like avian A(H5N1) in 1997 and again 2003, swine variant A(H3N2) in 2012, and avian A(H7N9) in 2013, continue to cause outbreaks and pose potential pandemic threats (Table 1).

## VIROLOGY

### Classification

Influenza A, B, and C viruses belong to the family *Orthomyxoviridae*, which is characterized by a segmented, negative-strand RNA genome (8). The influenza A and B virus types each carry eight different RNA segments, whereas the influenza C virus genome has seven. Infections by strains of all three influenza types (genera) can be associated with classical influenza symptoms in humans. The fourth genus of the *Orthomyxoviridae* consists of the Thogoto viruses. Two of its six members, Dhori and Thogoto viruses, are tick-borne agents that have caused human infections, including one in the United States by a novel Thogoto virus tentatively called Bourbon virus (9). The fifth orthomyxovirus genus is made up of the isaviruses (infectious salmon anemia virus), and recently a sixth genus was added, Quarantivirus. A novel influenza C-like virus has been proposed as a new D genus because it shares approximately 50% identity with influenza C, and, unlike members of the same genus, it fails to yield infectious progeny during reassortment studies with influenza C (5).

The influenza A, B, and C virus types were defined originally by the observation that antisera made against the core proteins of a specific strain cross-reacted only with those

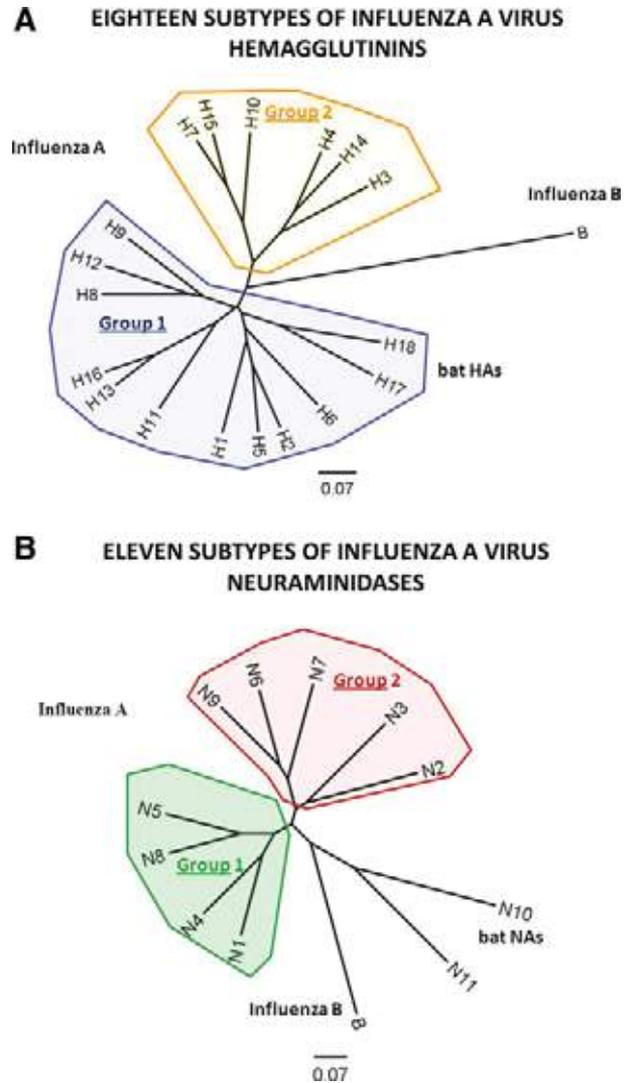

**FIGURE 1** Circulation of human influenza A and B viruses. Solid lines indicate that strains have been isolated and characterized. Three different influenza A virus HA subtypes (H1, H2, and H3) and two NA subtypes (N1 and N2) were identified in humans over the last 100 years. The RNA genome of the extinct pandemic 1918 virus has been sequenced from RNA fragments in formalin-fixed and frozen tissue samples from 1918 victims following RT-PCR (3). The virus was then reconstructed in the laboratory by reverse genetics (solid square) (4).

belonging to the same type and not with those of another type. Sequencing studies have confirmed this classification scheme, showing that genes coding for the matrix protein (M1) or the nucleoprotein (NP) of strains belonging to one type are more closely related to each other than to the corresponding genes of strains from different influenza virus types; however, nucleotide-sequence comparisons indicate that all influenza virus types share a common ancestor (8). Low intertypic (20 to 30%) and high intratypic (>85%) identity exists for the M1 and NP proteins.

Subtypes occur only among the influenza A viruses. The extent of serologic cross-reactivity for the surface glycoproteins, the hemagglutinin (HA) and the NA, was previously used to differentiate them; more recently, sequencing of the corresponding genes has been used to differentiate them. Based on sequence analysis, 18 distinct HA and 11 distinct NA subtypes are now recognized, but only 3 HA subtypes (H1, H2, and H3) and 2 NA subtypes (N1 and N2) are known to have caused extensive outbreaks in humans (Fig. 1, Fig. 2). Virus strains recovered from humans are named on the basis of type, location of isolation, serial number from that location, year of isolation, and, in the case of influenza A viruses, the subtypes of the HA and NA antigens (e.g., A/Switzerland/9715293/2013 [H3N2]).

### Composition

Influenza viruses are spherical lipid-containing viruses with a diameter of approximately 100 nm (Fig. 3A). Filamentous forms of the virus can also be observed with electron microscopy, appear to be infectious, and are postulated to be predominant particles during productive infection in the lungs. The activities and functions of the viral structural and nonstructural (NS) proteins are summarized in Table 2. The virus surface is covered by HA and NA glycoprotein spikes, the structures of which have been resolved by X-ray diffraction (10, 11). A small number of molecules of the M2 protein are also found in the membrane of the virus particle. Below the lipid membrane is a layer of the M1 protein surrounding the ribonucleoprotein (RNP) core. This core consists of the

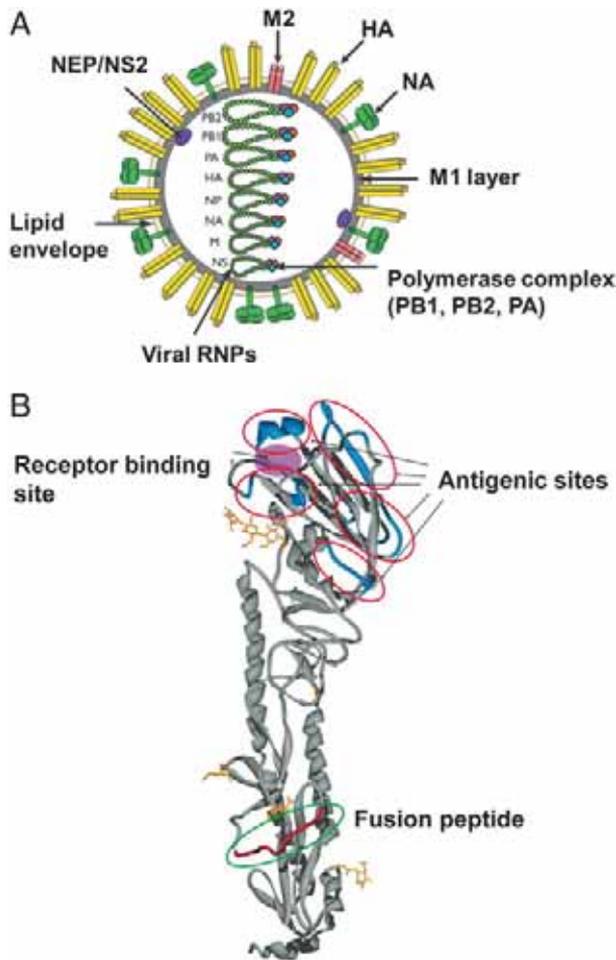

**FIGURE 2** Phylogenetic tree of influenza virus hemagglutinins (HA) (A) and influenza neuraminidase (NA) (B). Twelve HA subtypes, including two bat HAs, make up group 1 (blue) and 6 HA subtypes make up group 2 HAs (orange). There is only one influenza B virus HA type (no subtypes). Four NA subtypes make up group 1 (green) Influenza A virus NAs, and 5 are in group 2 (red). Influenza A virus NA. The bat NAs (N10 and N11) and the influenza B virus NA (no subtypes) are evolutionarily divergent. Scale represents a 7% change in amino acid differences. Courtesy of Krammer (486), reprinted with permission.

eight RNA segments, which are associated with one to several copies of the viral polymerase complex (PB1, PB2, and PA) proteins and are covered by viral NP molecules.

### Surface Proteins

The HA is a trimeric rod-shaped spike with a hydrophobic carboxy terminus anchored in the viral envelope and the hydrophilic end projecting outward from the virus. The exposed portion contains the antigenic domains and binding sites for sialic acid (N-acetylneuraminic acid) residues in receptors of host cells or erythrocytes (Fig. 3B). The HA facilitates both attachment of the virus to host cell receptors and penetration of the virus. Posttranslational proteolytic cleavage into HA1 and HA2 by a serine protease is essential

**FIGURE 3** (A) Schematic diagram of an influenza A virus. HA, NA, and M2 are transmembrane proteins anchored in the lipid membrane of the virus. Inside the lipid membrane is a layer of the M1 protein. The RNP core consists of the different RNA segments, which are covered by NP molecules. In addition, they carry an RNA-dependent RNA polymerase complex (P proteins). The 3' and 5' ends of the RNA segments are stabilized by the polymerase complex into panhandle structures. NEP is also part of the viral core structure. (B) Schematic depiction of influenza virus HA. Antigenic changes cluster into five highly variable regions surrounding the receptor-binding pocket (purple oval). Courtesy of James Stevens and Ian Wilson (487), reprinted with permission.

for infectivity. Certain avian HAs (H5 and H7) contain extra basic amino acids in the HA cleavage site, which allow for activation by cellular proteases widely distributed in tissues and result in systemic replication in birds and sometimes mammalian hosts (12). These so-called highly pathogenic avian influenza (HPAI) viruses have caused multiple outbreaks in poultry, and, recently, sporadic disease in humans (Table 3). The HA2 portion is principally responsible for fusion of the virus envelope and cell membrane, whereas the HA1 portion contains the binding sites for host-cell receptors, as well as at least four major antigenic domains. The overall configuration of the HA and its functions are conserved during virus evolution, but frequent amino acid substitutions occur in the antigenic sites. Antibodies to the head domain of HA can prevent attachment of the virus to cells, and antibodies to the stalk domain of HA can also inhibit virus replication by blocking fusion.

NA is a mushroom-shaped tetramer that is anchored in the lipid envelope at its amino terminus (13). It cleaves terminal sialic acid residues from various glycoconjugates and plays an essential role in release of virus from infected cells and the spread within the respiratory tract. By removing sialic acid residues from the virion envelope and cell surface and from mucins present in respiratory tract secretions, the NA activity (receptor-destroying enzyme [RDE]) prevents aggregation of viral particles and may enable penetration of virus through respiratory secretions (8). Anti-NA antibodies and NA enzyme inhibitors prevent release of virus from infected cells. A balance of HA and NA activities is essential for efficient virus replication.

The M2 protein, a homotetramer present only in influenza A viruses, appears on the surface of infected cells and is also incorporated into virions as a third integral membrane protein. The ion channel activity of M2 plays a role in uncoating of virus in endosomes and possibly in regulation of virus assembly. Amantadine and rimantadine inhibit the ion channel activity of M2. Antibody to M2 is associated with reduced viral replication and heterosubtypic protection in animals. The ectodomain of M2 (M2e) is highly conserved and has been targeted by both investigational monoclonal antibodies (14) and vaccines.

The single glycoprotein of influenza C virus encompasses receptor-binding, membrane-fusing, and receptor-destroying activities. It is directed against 9-O-acetyl-N-acetylneuraminic acid, a receptor different from N-acetylneuraminic acid, which is recognized by influenza A and B viruses (8).

## Genome

Influenza A and B viruses each possess eight different RNA segments that can code for at least 11 different proteins (Fig. 4A). Influenza C and D (proposed) viruses lack an NA gene and thus have only seven RNA segments that code for at least nine different polypeptides. Dhori and Thogoto viruses possess six and seven RNA segments, respectively. In nature, a reassortment of gene segments after co-infection of

**TABLE 2** Influenza A virus RNA segments and proteins

RNA segment	Protein	Protein size (amino acids)	Functional activity(ies)
1	PB2	759	Cap recognition
2	PB1	757	RNA polymerase, elongation

8	NS1	~230	Interferon antagonist, multifunctional protein
	NEP (NS2)	121	RNP nuclear export, regulation of RNA synthesis

cells by human and animal influenza A viruses may be responsible for the emergence of new pandemic strains (see following paragraphs and Fig. 5). However, reassortment of genes among viruses belonging to different influenza virus types has not been observed. Apparently, the proteins of

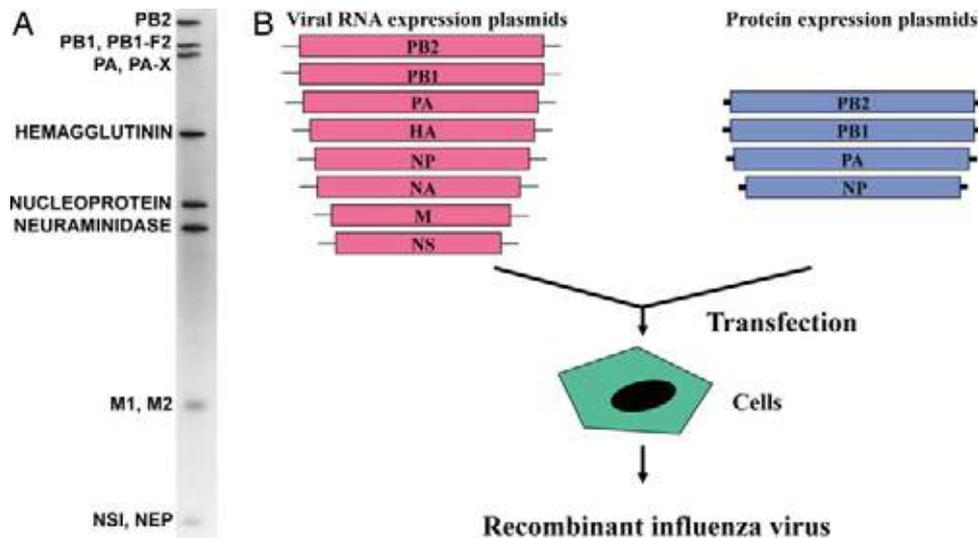

different virus types have evolved sufficiently to preclude replication of intertypic reassortants. Homologous recombination between corresponding RNA segments of different influenza viruses has not been observed, in contrast to the high frequency of recombination observed among the genomes of retroviruses or of positive-sense RNA viruses, like polioviruses. Influenza A virus isolates obtained during a single outbreak are variable in genetic sequence. This genetic heterogeneity provides a basis for evolutionary adaptation and the ability of the virus to cope with selective immunologic and drug pressures.

Influenza A viruses code for approximately 13,600 nucleotides (nt), influenza B viruses for 14,600 nt, and influenza C viruses for approximately 12,900 nt (15). A genomic map of an influenza A virus is shown in Fig. 4. Each RNA codes for a different protein, with the two smallest RNA segments each transcribing an additional spliced mRNA.

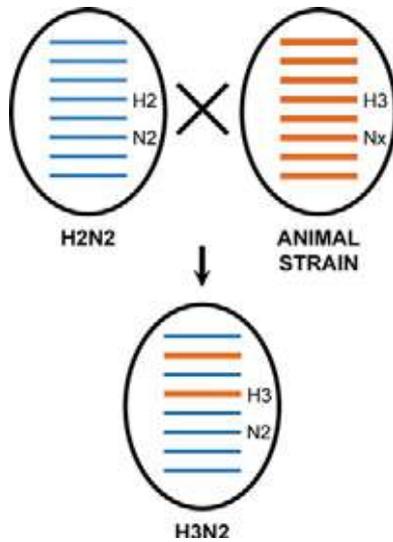

## Biology

### Replication Strategy

Influenza A and B viruses adsorb to receptors on the cell surface, which contain sialic acid (8) (Fig. 6). It is not known which specific carbohydrate-containing membrane proteins (or, less likely, glycolipids) are the major targets for the initial binding. Human influenza viruses preferentially attach to sialic acid with an  $\alpha(2,6)$  linkage to galactose-containing oligosaccharides, whereas avian and equine viruses prefer  $\alpha(2,3)$  linkages. Influenza C virus binds to 9-O-acetyl-N-acetylneuraminic acid-bearing receptors. After internalization into endosomes, the cleaved HA undergoes an acid pH-triggered conformational change into a fusogenic form. This event facilitates the fusion of the viral and endosomal membranes. The ion channel in the viral membrane, comprised of M2 polypeptides, is also activated by the acid pH in the endosomes. This process results in an influx of protons into the virion, which probably loosens the

**FIGURE 4** Reverse genetics of influenza viruses. (A) Genetic map of influenza A/PR/8/34 (H1N1) virus. Purified RNAs were separated on a polyacrylamide gel; assignment of genes coding for one or two viral proteins is indicated. (B) Plasmid-only rescue of infectious influenza virus. Twelve plasmids are introduced into mammalian cells: four plasmids lead to expression of the viral proteins required for viral RNA replication (PA, PB1, PB2, and NP), and eight plasmids express precise copies of the eight viral RNA segments (PA, PB1, PB2, HA, NP, NA, M, and NS). The resulting viral RNAs are replicated and transcribed by the reconstituted influenza virus RNA-dependent RNA polymerase. Recombinant infectious influenza virus is generated 48 to 72 hours after transfection of cells (26, 27). Recently, several improvements of the plasmid-only rescue for influenza A viruses have been introduced (28, 29). Also, reverse-genetics systems for influenza B and C viruses have been successfully developed (28, 30–32, 488).

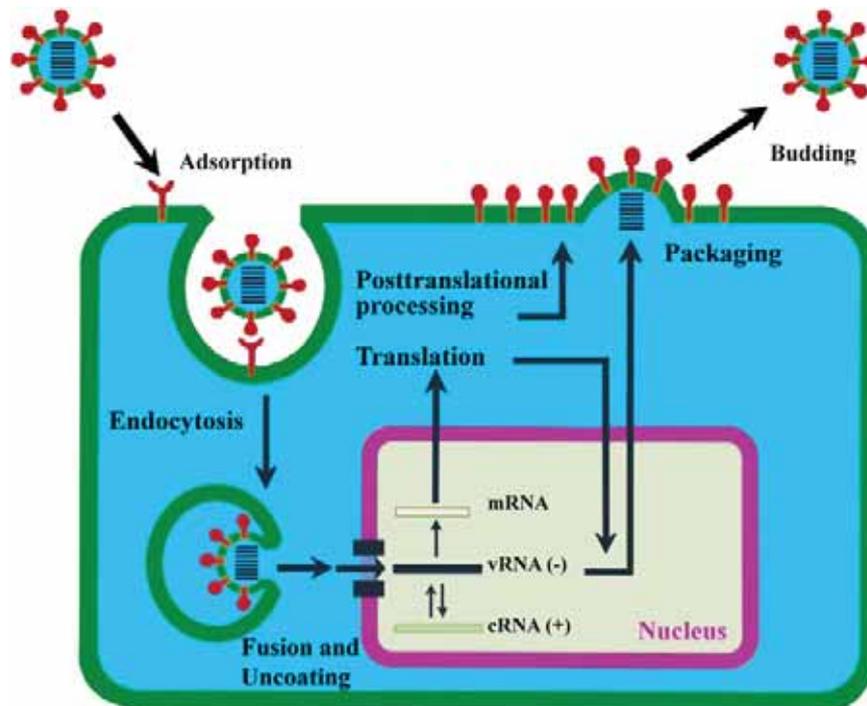

**FIGURE 5** Reassortment of influenza A viruses leading to a new pandemic strain. Co-infection of the same cell with a human A(H2N2) (thin blue lines) virus and an animal (avian) strain with an H3 HA (thick orange lines) results in reassortment. The A(H3N2) virus responsible for the pandemic in 1968 is postulated to derive its PB1 and H3 genes (thick lines) from the animal strain and its remaining six RNAs, including the N2 gene, from the A(H2N2) parent (thin lines) (12, 489).

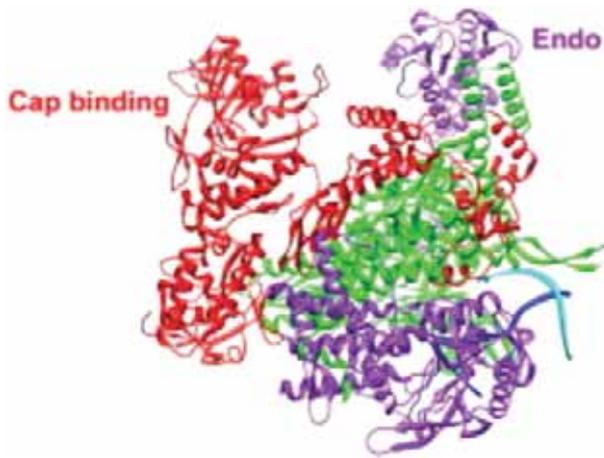

M1 protein from the RNP core and ultimately facilitates RNP release into the cytoplasm (uncoating). The RNA segments of the incoming virus particle (vRNA) remains associated with viral protein throughout the uncoating process and enters the nucleus as RNP through the nuclear pore complex (16).

Following uncoating of the virus and transportation of the RNP into the nucleus, transcription and replication of the viral genome take place in the nucleus. The recently reported X-ray diffraction analysis of the full polymerase complex, consisting of PB1, PB2, and PA proteins, shows the precise location of the cap-binding and nuclease activity in the polymerase complex, as well as those of the domains allowing for RNA elongation and poly(A) addition (17, 18). The incoming viral RNP is the template for the viral RNA-dependent RNA polymerase, which produces two different species of viral RNA: (i) an mRNA that derives its first 9 to 15 nt from host mRNA, is capped at the 5' end, and carries a poly(A) tail lacking the 3' 15 to 16 nt of the template RNA, and (ii) a full-length complementary copy (cRNA) of the template RNA. This cRNA itself becomes a template for the amplification of viral RNAs, leading to additional copies of vRNA (Fig. 7). The minimal promoter sequences of the vRNA and the cRNA molecules appear to be the highly conserved 3' sequences. In addition, the 5' sequences of the templates are part of the transcription-replication complex.

mRNA synthesis is regulated, but control of the switch from transcription (mRNA synthesis) to replication (amplification of vRNA) is still not well understood. Although the different vRNA molecules appear to be equimolar in the virus and in infected cells, the mRNAs of the HA, M, NP, and NS genes are much more abundant than those of the three polymerase (P) genes or of the NA gene. Also, mRNA synthesis is down-regulated late in the replication cycle, while vRNA synthesis continues. Finally, protein expression is affected by several additional mechanisms: (i) for the M and NS genes, partial splicing of their mRNAs leads to the expression of two viral proteins from each of these RNA segments; (ii) coupled stop-start translation of tandem cistrons gives rise to two proteins, the M and the BM2 proteins, from the M segment of influenza B viruses; (iii) ribosomal initiation from AUG codons located in different reading

**FIGURE 6** General replication scheme of influenza virus. For a description of different replication steps, see the text.

**FIGURE 7** RNA transcription/replication by influenza virus polymerase. Structure of the influenza A virus (bat) polymerase from Ortin and Martin-Benito (490) according to Pflug et al. (17). The PB1 (green), PB2 (red), and PA (magenta), and the cap binding (part of PB2) and endonuclease (part of PA) domains are indicated. The synthesis of viral mRNA is initiated by cap-snatching, which involves the binding of the cap of a host RNA followed by an endonuclease (PA) cleavage. The host mRNA-derived capped RNA primer is then used to allow the RNA synthesis by the PB1 domain of the viral polymerase complex (491).

frames on the PB1 gene of influenza A viruses and on the NA gene of influenza B viruses leads to the expression of two additional proteins, PB1-F2 and NB, respectively (in addition to the PB1 and NA proteins of the corresponding RNAs) (8, 19); and (iv) ribosomal frame shifting in the case of PA-X. The latter is a fusion protein with the C-terminal portion derived from a second open reading frame of the PA segment (20).

Assembly and packaging of RNAs into infectious viruses involve several cellular compartments. The viral P proteins and the NP have specific nuclear localization signals, so they can travel into the nucleus, where they associate with viral RNAs to form RNPs. The nuclear export of these RNPs likewise requires a unique mechanism and depends critically on the presence of the M1 protein and nuclear export protein (NEP) (21, 22). M1 binds to viral RNPs in the nucleus and promotes their export by interacting with NEP, which possesses a nuclear export signal and the ability to interact with M1 (22, 23). The virus-induced Raf/MEK/ERK signal cascade is essential for efficient replication, and blockade of this pathway slows viral RNP export and reduces viral titers (24).

Following the export of the RNPs into the cytoplasm, they assemble at the cytoplasmic membrane under patches of the viral glycoproteins HA and NA. M1 plays a critical role in the assembly and budding of infectious virus. Virus particles bud from the cytoplasmic membrane, while the NA clears the virus and the cell membrane of sialic acids to prevent virus-virus aggregation and virus-cell surface retention, respectively. Once the virus particle is outside the cell, the NA may further help to remove sialic acids from mucous substances in the respiratory tract, thus allowing the virus to reach other epithelial cells (8).

The packaging of vRNAs into influenza virus particles most likely involves a specific packaging mechanism: the 3' and 5' noncoding regions of the vRNA segments contain cis-acting signals, which are required for packaging the

vRNAs into virus particles. In addition, sequences in the coding regions of the influenza A virus RNAs contribute to the efficient packaging of just the eight different segments in virus particles (8). Thus, packaging is not random, although the precise mechanism by which the packaging of a full complement of just eight RNAs occurs remains to be fully elucidated.

### Genetic Engineering of Influenza Viruses

The genome of negative-sense RNA viruses is not infectious, and thus direct transfection of cDNA-derived influenza virus RNAs does not result in the formation of infectious virus particles. However, systems have been developed which allow the *in vitro* reconstitution of biologically active RNP from synthetic RNAs and purified viral proteins. Transfection of synthetic RNPs into helper virus-infected cells allowed the rescue of transfectant viruses which contain one or more genetically engineered segments (25). Helper virus-free systems for producing recombinant influenza A viruses have been developed (26, 27) (Fig. 4B). Plasmids are transfected into cells, and infectious virus can be generated within 48 to 72 hours. In these plasmid-only systems, the vRNAs, as well as the viral RNA polymerase, are generated from the transfected plasmids. Improvements in this technology now make it easy to do structure-function analysis of individual viral proteins and have opened the way for the construction of improved influenza virus vaccines and influenza virus vectors (28, 29). Reverse-genetics systems have also been successfully developed for influenza B and C viruses (30–32).

### Host Range

Type A influenza viruses have a broad host range (33, 34). Wild avian species, particularly ducks and other aquatic waterfowl, are the primary reservoir and harbor viruses expressing the 16 (non-bat) HA and 9 (non-bat) NA subtypes. In avian species, influenza viruses replicate in both the respiratory and gastrointestinal tracts, and there can be shedding of high quantities of virus in the feces. Infectious virus is readily recovered from cold lakes and other water sources frequented by birds. In contrast to the progressive changes of human viruses, avian viruses generally show little antigenic variation within the same subtype, although the rapid evolution and antigenic variation of HPAI A(H5N1) viruses is an exception (35). Thus, aquatic birds represent an enormous migratory reservoir of influenza A virus genes that can be potentially incorporated into influenza viruses transmitted to other species (12).

Recently, the RNAs of two new HA (H17 and H18) and of two new NA (N10 and N11) subtypes have been identified in bats, but no infectious viruses with these new subtypes have been isolated so far (36). Vesicular stomatitis virus, pseudotyped with the surface glycoproteins from bat influenza viruses, efficiently infect bat cell lines but not those derived from primates or swine and do not attach to sialic acid receptors, findings that suggest low potential for zoonotic infection (37).

The principal natural hosts of mammalian influenza A viruses are humans, swine, and horses (H7N7 and H3N8 subtypes). Outbreaks have also been documented in other species, including marine mammals (whales and seals), mink, dogs, and ruminants (e.g., reindeer). The HPAI A (H5N1) virus has caused severe disease in felids although not swine. Influenza A(H3N8) subtype virus infections in dogs represents a species jump from horses (38), and receptors recognized by equine influenza viruses are present on

canine respiratory epithelial cells (39). Both equine and dog influenza viruses are endemic in the United States, but, to date, in contrast to swine influenza viruses, they have not been recognized to infect humans.

The fact that influenza A viruses populate nonhuman species has important epidemiologic consequences. First, human and nonhuman influenza A reassortant viruses may lead to new pandemic viruses (see Fig. 5 and below). Second, the presence of an animal reservoir enables the virus to continue to circulate outside the human population, so eradication of human influenza A by immunization of humans is unlikely. Influenza B and C viruses are primarily pathogens of humans, but influenza B virus may infect seals, dogs, cats, and possibly swine. However, widespread animal-to-animal or human-to-animal transmission of influenza B viruses has not been identified to date. Influenza C viruses have been isolated from swine. Recently identified influenza D (proposed) viruses can cause respiratory illness in pigs and cattle (5, 6, 40). Full explanations do not exist currently for the host-range characteristics of the different influenza viruses. The virulence and host range of influenza viruses relate to the surface glycoproteins, as well as to other viral proteins (8).

Experimental infection has been accomplished in a variety of species, including hamsters, cotton rats, horses, and nonhuman primates, but mice, ferrets, guinea pigs, chickens, and swine are most commonly used. Pigs can be experimentally infected with avian influenza viruses representing nearly all HA subtypes. Ferrets can be infected with non-adapted human influenza viruses and serve as a useful model for studying viral virulence and transmission (4). A useful transmission model has also been developed using guinea pigs (41).

#### Growth in Cell Culture

Traditionally, influenza viruses have been grown in embryonated chicken eggs, both for laboratory purposes and for vaccine production. Primary cell cultures, including African green and rhesus monkey, hamster, bovine, or chicken kidney cells, and established cell lines like Madin-Darby canine kidney (MDCK) and mink lung epithelial cells, can be used to replicate influenza viruses (42). Propagation in non-primary cell lines lacking the protease needed for HA cleavage requires the addition of trypsin in serum-free medium. Hemagglutination by chicken, turkey, horse, or human erythrocytes remains a frequently used tool to identify and measure the replication of influenza viruses in eggs and cell culture. Future influenza vaccine manufacturing will rely increasingly on the growth of virus in cell culture to avoid the cumbersome use of embryonated eggs, and various cell systems are being developed or already used for vaccine virus production (e.g., MDCK, Per.C6, EB66, and Vero).

#### Inactivation by Physical and Chemical Agents

Influenza virus proteins and RNAs can be readily inactivated by ionizing radiation, high (>9) or low (<5) pH, and temperatures above 50°C. The stability of the virus depends on the surrounding medium, its protein concentration, and its ionic strength. Influenza viruses are enveloped viruses and thus are susceptible to agents that which affect membranes, including ionic and nonionic detergents, chlorination, and organic solvents (43). At 4 °C in phosphate-buffered saline solution containing physiological protein (albumin) concentrations, influenza viruses can be stable for months. On the other hand, drying of viral suspensions inactivates the

virus in less than 12 hours on porous environmental surfaces and in 24 to 48 hours on nonporous environmental surfaces (44, 45). The virus can remain infectious for 24 hours or more after aerosolization under conditions of low (25%) or high (80%) relative humidity but is less stable under conditions of intermediate (50%) relative humidity (46). Environmental persistence studies indicate that influenza virus retains infectiousness longer at low temperatures, in water compared to in air, and in fresh, compared to salt, water (47).

## EPIDEMIOLOGY

Influenza viruses have a worldwide distribution and cause outbreaks with variable intensities annually. Rapid onset and dissemination of infection are characteristic features of epidemic influenza. These relate to a short incubation period, which averages 2 days and ranges from 1 to 5 days, and to high concentrations of virus in respiratory secretions during the initial phase of illness (48). Influenza surveillance information is available through the CDC and WHO websites (Table 1).

### Transmission

Influenza viruses spread from person to person by airborne droplets expelled during coughing, sneezing, or speaking. The relative efficiencies of different exposure routes (droplet, short-distance small-particle aerosols, hand contamination with self-inoculation following direct or fomite contact) are uncertain and likely vary with epidemiologic and environmental conditions (49, 50). Zoonotic influenza virus infections (discussed below; Table 3) are also spread by these routes through direct and indirect exposures and perhaps rarely by oral ingestion.

In volunteers experimentally infected with a human virus, approximately 10- to 100-fold-smaller viral inocula are needed to initiate infection after small-particle aerosol exposure of the lower respiratory tract than after intranasal inoculation of the upper respiratory tract. The human infectious dose is estimated to be 1 to 5 50% tissue culture infectious doses following experimental small-particle (1 to 5  $\mu\text{m}$ ) aerosol exposure (49). Intervention studies with topically delivered antivirals, like zanamivir and interferons (51), indicate that natural infection by human influenza viruses is initiated most commonly in the pharynx or tracheobronchial tree. Aerosol transmission has been implicated in both household (52) and closed outbreaks, where clinical attack rates may exceed 70% after common-source exposure in confined spaces (53). Influenza virus RNA is readily detected on fomites (44), and virus retains infectiousness longer on hard, nonporous surfaces, in low humidity, and at cooler temperatures (41, 45, 54), but the importance of transmission via fomites is uncertain. In acute care settings, small-particle aerosols containing influenza virus RNA are detected at decreasing concentrations within 6 feet from the patient's head during routine patient care (55), and aerosol-generating procedures have been implicated in nosocomial transmission (56). In households, upper respiratory tract viral loads and symptom severity in the index case, contact susceptibility, and social behaviors affect the risk of transmission (57). Deep sequencing studies indicate that most infections in contacts are acquired within the household, many index cases harbor mixed lineage infections that are transmissible, and an estimated 90 to 250 virus particles appear to be required for productive multilineage infection in contacts (58).

**TABLE 3** Examples of human illness due to infection by avian influenza viruses<sup>a</sup>

Years of reported detection	Locations	Influenza A subtype	Cumulative no. of laboratory-confirmed human illnesses (to April, 2016)	Primary syndromes/comment
1959, 1977, 1980, 1996	USA, Australia, UK	H7N7 (LP)	~5	Conjunctivitis
1997	Hong Kong SAR	H5N1 (HP)	18	Pneumonia; six deaths
1999-ongoing <sup>b</sup>	Hong Kong SAR, China, Egypt, Bangladesh	H9N2 (LP)	28	ARI, ILI; circulating in poultry in parts of Africa, Asia and Middle East
2002, 2007	USA, UK	H7N2 (LP)	2	ILI
2003-ongoing <sup>b</sup>	Multiple countries in Asia, Middle East, eastern Europe, and Africa (exported case to Canada)	H5N1 (HP)	850	Pneumonia, ARDS, multiorgan failure; mortality >50%. Limited, nonsustained human-human transmission to date <sup>b</sup>
2003	The Netherlands	H7N7 (HP)	89	Conjunctivitis, ILI; 1 fatal pneumonia. Limited human-human transmission likely.
2003	USA, UK	H7N2 (LP)	5	ARI in immunocompromised host; ILI, conjunctivitis
2004, 2010	Egypt, Australia	H10N7 (LP)	2	ILI
2003, 2004, 2006, 2012	Canada, Mexico, UK, Italy	H7N3 (LP)	3	Conjunctivitis; seropositivity
		H7N3 (HP)	4	
2013-ongoing <sup>b</sup>	China (exported cases to Malaysia, Canada)	H7N9 (HP)	770	Pneumonia, ARDS; mortality >35% in hospitalized; ARI, ILI; Limited, nonsustained human-human transmission to date <sup>b</sup>
2013	China	H10N8 (LP)	3	Pneumonia/ARDS, 2 fatal cases
2013	Taiwan	H6N1 (LP)	1	ILI
2014- ongoing <sup>b</sup>	China	H5N6 (HP)	14	Pneumonia/ARDS, mortality >35%. Circulating in poultry in China, Laos, Vietnam

<sup>a</sup>Abbreviations: LP, low chicken pathogenicity; HP, high chicken pathogenicity; ILI, influenza-like illness; ARI, acute respiratory illness (not specified).

<sup>b</sup>Consult the WHO and USCDC websites (Table 1) for updated information.

Airline travel plays a role in long-range dissemination of influenza (59), and high rates of virus movement occur internationally between urban centers (60). One hypothesis, that epidemic spread involves long-range atmospheric transmission of aerosolized influenza virus (61), remains unproven, although viral RNA detection has been reported in airborne dust samples (62), and wind dispersal may contribute to spread of avian influenza viruses between farms (63).

### Antigenic Change

The changing antigenicity of influenza viruses enables continued circulation in human populations and makes their behavior unpredictable (64). Relatively minor changes, called antigenic drift, result from stepwise point mutations in the gene segment coding for the HA or NA. Antibody-driven sequential amino acid changes occur in antigenically important regions over time; this process sometimes requires concurrent changes in both glycoproteins for maintenance of viral fitness (65). In the case of influenza A virus, these result from the selective pressure of increasing levels of population immunity and lead to the emergence of epidemiologically important drift variants every 2 to 3 years. Amino acid substitutions in HA and NA have been observed at rates of approximately 0.5 to 1% per year over a two-decade period. Changes occur predominantly in the HA1 peptide and are distributed over the

surface of the molecule, as well as clustering into five hypervariable regions (Fig. 3B). Viral lineages undergoing the greatest number of mutations in a restricted number of rapidly evolving HA1 codons appear to be the progenitors of future epidemic strains (66). Drift strains of epidemiological importance usually have substitutions in two or more of the antigenic sites of the HA and arise when such mutations lead to substantial antigenic change (67). Such variants are able to spread because of larger numbers of susceptible individuals and have a higher likelihood of causing symptomatic infections. Antigenic variation has occurred more rapidly in H3 than H1 subtype influenza A viruses and is less pronounced in influenza B and C viruses. Multiple evolutionary lines of influenza B or C viruses may co-circulate. Viruses representing two influenza B virus lineages, designated B/Victoria/2/87 and B/Yamagata/16/88, have circulated in various proportions in recent years. Seasonal influenza viruses undergo frequent gene reassortments that contribute to their evolution and genetic diversity (68). New antigenic variants of public health concern are usually identified by monospecific antisera raised in animals, typically ferrets, and by convalescent-phase sera from persons immunized with vaccines containing previous strains.

For influenza A viruses, marked changes in HA, with or without change in NA, called antigenic shift, are due to the acquisition of new gene segments. This may occur during

**TABLE 4** Influenza A virus pandemics and related influenza events since late 19th century

Year of appearance	Duration of circulation (yr)	Virus subtype	Common designation	Estimated mortality in the United States	Comment
1889	28	H3N2 <sup>a</sup>		High. Estimated mortality of 270,000–360,000 in Europe	Perhaps H3N8 virus
1918	39	H1N1	Spanish, swine	548,000	Possible reassortant between a preexisting human H1 virus lineage and an avian virus <sup>b</sup>
1957	11	H2N2	Asian	86,000	Avian-human reassortant virus
1968	Ongoing	H3N2	Hong Kong	34,000	Avian-human reassortant virus
1976	<1	H1N1	Swine	1 death	Outbreak limited to one U.S. military base
1977	31	H1N1	Russian	Negligible	Reappearance of earlier circulating virus
2009	Ongoing	H1N1	Swine, A(H1N1)pdm09	12,500 <sup>c</sup>	Swine-origin reassortant virus

<sup>a</sup>The subtype designation of this virus is uncertain but is proposed on the basis of retrospective serologic studies of elderly adults who were living at the times of the pandemic (77).

<sup>b</sup>Earlier work postulated that the origin of the 1918 H1N1 virus represented an introduction of all eight genes from an avian ancestor or a reassortant involving progenitor viruses circulating in humans and swine (2, 4, 74).

<sup>c</sup>First year of circulation.

genetic reassortment in cells dually infected by a human and an animal virus (Fig. 5) or possibly by direct interspecies transmission (33). When such viruses are introduced into a susceptible population, they cause zoonotic infections, and if efficiently transmitted from person to person, can lead to pandemics.

### Pandemic Influenza

Over the past 300 years, at least seven pandemics of influenza have probably occurred, including three well-characterized ones in the 20th century and one starting in 2009 (69). These have appeared at irregular intervals and been notable for efficient transmission, high illness rates in all susceptible age groups, particularly in young persons, and usually for significant increases in mortality rates (Table 4). Earlier pandemics have spread globally over 6- to 9-month periods at the pace of human traffic and often irrespective of season. However, the 2009 pandemic H1N1 virus [A(H1N1)pdm09] disseminated much more rapidly, in part because of air travel patterns (70, 493). The estimated median reproduction (R) values for the 1918 (1.80), 1957 (1.65), and 1968 (1.80) pandemics are somewhat higher than those for the 2009 pandemic (1.46) or seasonal epidemics (1.28) (71). Second and sometimes third waves of infection separated by several months may occur. As observed with the 2009 pandemic, the impact of subsequent waves can sometimes exceed that observed during the initial one (69).

Cumulative illness rates have often exceeded 50% in the general population during successive waves of a pandemic. During its first year of circulation, the A(H1N1)pdm09 virus was estimated to have caused approximately 60.8 million cases, 274,304 hospitalizations, and 12,469 deaths in the United States (72), as well as an estimated 151,700 to 574,900 respiratory and cardiovascular deaths worldwide, over half of which occurred in southeast Asia and Africa (73). Marked age-related differences in impact often occur with pandemics. Older adults usually experience lower illness frequency, likely related to prior experience with other influenza viruses and perhaps less frequent exposure, but the case fatality ratios are usually highest in the very young and elderly. During the 2009 pandemic mortality rates in the United States increased 8.5-fold in those 0 to 17 years old

and 12.5-fold in those 18 to 64 years old compared to seasonal influenza, but decreased 5.3-fold in those 65 years and older (72). The 1918 pandemic also caused an increase in mortality in young adults, perhaps because an H1 virus circulated in the human population before 1889 and resulted in partial protection against the 1918 virus in the older segment of the population. In adults aged approximately 20 to 40 years a possible adverse effect of childhood priming with a heterosubtypic influenza A virus has been postulated (74). During the 1918 pandemic, >30-fold differences in population mortality occurred across countries and about 4-fold differences occurred within countries, including the United States (75). In the era encompassing virus isolation, pandemics in 1957 and to a lesser extent in 1968 also caused increases in mortality compared to interpandemic periods (Table 4). In each of the recent pandemics, large portions of the excess influenza-related deaths (estimated >99% in 1918, 36% in 1957, 48% in 1968, 87% in 2009) occurred in those aged <65 years in the United States, followed by smaller proportions over the subsequent decade (72, 76). In contrast, disease due to the reappearance of an A(H1N1) subtype virus in 1977, after a 20-year hiatus since circulation of essentially the same strain, principally affected those younger than 25 years and caused negligible excess mortality.

Serologic studies with elderly individuals suggest that viruses with HA of the H3 subtype caused pandemic disease in the late 19th century (Table 4) (77). The origin of these pandemic strains and the mechanisms for apparent recycling of strains in the human population remain unresolved issues. Explanations include dormancy in a frozen state, which may have been the case for the 1977 A(H1N1) strain, interspecies transmission and adaptation of an animal influenza virus to become infectious and pathogenic for humans, and, more commonly, genetic reassortment between animal and human influenza viruses. Analysis of the 1957 pandemic strain found that this A(H2N2) subtype virus resulted from acquisition of three new gene segments (HA, NA, and PB1) of avian origin by the previously circulating human A(H1N1) strain. Similarly, the 1968 pandemic A(H3N2) virus acquired two new genes (HA and PB1) from an avian virus closely related to viruses isolated from ducks in Asia in 1963 (69) (Fig. 5).

Changes in the receptor specificity of the avian influenza virus HA appear to be one key factor in generation of viruses

that are capable of sustained human transmission, and the HAs of all pandemic viruses characterized to date bind to human-like  $\alpha 2,6$ -sialylated glycans. One or two amino acid changes can alter receptor binding patterns of the 1918 virus HA and reduce transmissibility among ferrets without altering replication or lethality, and one 1918 virus HA from a fatal case shows dual  $\alpha 2,3$  and  $\alpha 2,6$  binding (78). Avian A(H5N1) viruses transmit inefficiently or not at all among ferrets, despite several H5 HAs showing mutations associated with dual  $\alpha 2,3$  and  $\alpha 2,6$  binding (79). Although the predictive value of the ferret model for human transmission is uncertain, several A(H5N1) viruses engineered to bind preferentially to  $\alpha 2,6$  receptors and selected by serial ferret passage show airborne transmission in ferrets (80). Changes in multiple genes are likely necessary to generate a pandemic virus.

Although avian viruses usually cannot directly infect humans, swine can be infected by both human and avian viruses and may serve as an intermediate host needed for reassortment of these viruses, the so-called “mixing vessel,” or as the species in which avian viruses can adapt to a mammalian host. Avian-human reassortment and avian-like influenza A viruses with limited zoonotic spread to humans have been identified in swine (81). Of note, Eurasian (contributing NA, M genes) and North American (HA, NP, NS) lineages of swine A(H1N1) viruses, the latter having undergone earlier reassortment events to acquire both avian (PA, PB2) and human (PB1) gene segments, reassorted to form the A(H1N1)pdm09 virus (82). This virus was reintroduced from humans into swine in which new reassortants have emerged (75), including the swine A(H3N2) variant virus that caused a large zoonotic outbreak in 2012 (see below) after having acquired the Eurasian M gene from A(H1N1)pdm09 (83). The origin of the genes of the 1918 pandemic strain remains unknown, but it is likely that some of the genes were derived from avian influenza viruses (3, 4, 74).

The ecology and interspecies transmissions of influenza viruses are complex. At least two of the 20th-century pan-

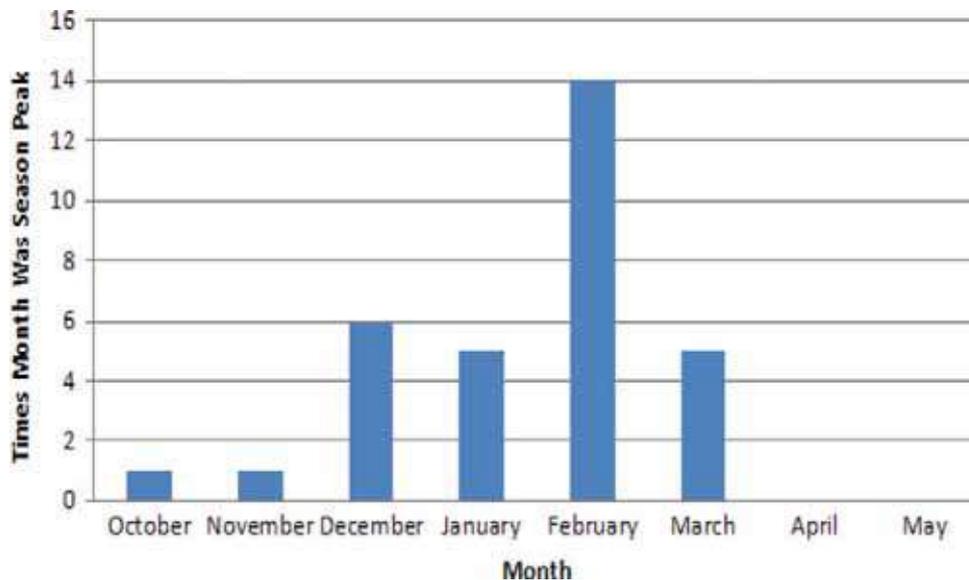

demical strains likely emerged from China, whereas the A(H1N1)pdm09 virus first appeared in North America. The concept of China and Southeast Asia as the site of origin or epicenter of new pandemic viruses has been supported by the presence of high concentrations and cohabitation of domestic poultry (especially ducks), swine, and humans. The avian reservoir provides a mechanism for maintaining and reassorting virus genes, as well as a source for the introduction of novel subtypes into humans (Table 3). For example, avian viruses, which contain an antigenically conserved H2 HA similar to that of the 1957 pandemic strain, continue to circulate in birds and have been identified in swine (84).

## Epidemic Influenza

### Seasonality

Influenza activity of varying intensity occurs annually in temperate areas, most often during the winter or early spring months (Fig. 8). The distinct seasonality of epidemic influenza appears to be related to reintroduction of virus each season, behavioral factors influencing exposure (e.g., school attendance and indoor crowding), factors affecting viral survival in the environment (e.g., low temperature and humidity), and possibly host determinants influenced by seasonal changes (41, 85). Low temperature and low relative humidity enhance transmission in the guinea pig model, thus confirming one explanation for the wintertime seasonality of influenza A and B viruses (86–89). A(H3N2) epidemics in temperate regions are seeded from temporally overlapping epidemics in East-Southeast Asia or other sites and not from persistent circulation of virus in temperate areas during the summer months (60, 64, 90, 498).

The onset of influenza activity ranges from October to April in the northern hemisphere but usually peaks between December and March (between May and August in the southern hemisphere) (Fig. 8). More than one epidemic annually occurs in some tropical countries, and year-round activity may be present in the tropics (91). Summertime

**FIGURE 8** Peak month of influenza activity, USA, 1982–2014. During 2008–2009, influenza activity peaked twice because of the 2009 H1N1 pandemic. Activity in the United States peaked once in February due to seasonal influenza activity and then again in June, with the first wave of A(H1N1)pdm09 virus, followed by a second, larger peak of A(H1N1)pdm09 virus activity occurring in October, the peak of the 2009–2010 season. (Figure reproduced with permission from Influenza Division, US CDC.)

outbreaks may occur on cruise ships and among large groups of land-based travelers, especially when new antigenic variants are introduced from elsewhere. Consequently, an influenza diagnosis should be considered outside the influenza season in those with febrile respiratory illness who have recently traveled in the tropics, in the southern hemisphere, or with international groups (92).

In a given community or region, outbreaks due to a particular virus usually peak in about 3 weeks and are of short duration (6 to 10 weeks). Successive or overlapping waves of infection by different influenza A subtypes and influenza B virus may cause prolonged influenza activity, such that the overall epidemic influenza lasts 3 to 5 months within countries (91). Influenza B viruses cause widespread epidemics every 3 to 4 years, but co-circulation of two or three influenza viruses (H3, H1, and B lineages) may occur within a single season. The isolation of an antigenically drifted virus late in the spring months during a limited outbreak (herald wave) may foreshadow an epidemic in the next season.

### Community Impact

Seasonal influenza occurs globally with variable annual attack rates higher in children (estimated 20 to 30%) than adults (estimated 5 to 10%) (494, 500, 501). The overall incidence of seasonal influenza is highest in school-age children and adolescents and declines with increasing age, such that attack rates are about four-fold lower in people over age 60. School-age children play a central role in the dissemination of influenza in the community and spread virus to their younger siblings and parents in the household. Most secondary cases in households occur within 1 week of symptom onset in the index case (57). Increased school absenteeism is an early epidemiological marker of epidemic influenza, and early school closings may blunt outbreaks and even pandemic waves (93, 94). Epidemic attack rates of 60 to 75% have been described to occur in schoolchildren. Worldwide in children < 5 years old, there were an estimated 90 million (95% CI: 49–162 million) new cases of seasonal influenza and 20 million (95% CI: 13–32 million) cases of influenza-associated acute lower respiratory infections during 2008 (95).

Epidemics are also marked by increases in visits to primary care physicians and emergency rooms for febrile respiratory illness, workplace absenteeism, and subsequently hospitalizations for pneumonia and underlying conditions. Influenza is the single most common cause of medically attended acute respiratory illness. Up to one-half of influenza A(H3N2) subtype or B illnesses lead to physician contact. Approximately 5 to 15% of teens or adults and 25% of children < 5 years old seek medical care for acute respiratory disease during epidemics (512). Influenza virus has been associated with 15 to 25% of all respiratory illnesses seen by physicians and up to 40% of those seen in patients over the age of 15 years.

The impact of influenza varies considerably with age, underlying medical comorbidities, and the epidemic strain (96). In the United States, increases in pneumonia and influenza hospitalizations range from 16,000 to more than 220,000 per epidemic, less than one-half of which involve adults 65 years of age or older. Admissions for exacerbations of chronic respiratory diseases and cardiovascular disease, particularly congestive heart failure, also increase. The peak of hospitalizations lags about 1 week after the peak of influenza activity. Hospitalization rates for all influenza-related complications are about 1 to 3 per 1,000 persons. During 15 years to the 2007–08 season, the estimated seasonal

influenza-related hospitalizations for respiratory and circulatory disease averaged  $63.5/10^5$  person-years but varied about 3-fold across seasons and were highest among persons aged  $\geq 65$  years ( $309/10^5$ ) and those aged < 1 year ( $151/10^5$ ) in the United States (97). Among children, hospitalization rates are highest in those < 6 months of age and decline through 6 years of age. A(H3N2) subtype epidemics are associated with two- to threefold increases in pneumonia rates and two- to fivefold increases in hospitalization rates for adults with high-risk medical conditions. Diabetic persons experience increased hospitalizations and mortality due to ketoacidosis and pneumonia during influenza epidemics. However, most adults, but less than one-half of children, requiring hospitalization for respiratory disease have a previously recognized underlying medical condition (98). Contemporary strains of A(H3N2) subtype viruses typically cause the highest hospitalization and mortality rates (Fig. 9).

### Mortality

The overall case fatality of seasonal influenza is low, generally 0.01% or less, but epidemics are often associated with mortality rates well in excess of those observed during comparable time periods in the absence of influenza outbreaks. In the United States annual influenza-associated mortality is estimated to have ranged from 3,349 to 48,614 deaths (1.4 to  $16.7/10^5$  persons) between 1976–2007 (99) and from 4,915 to 27,174 during the 3 seasons from 2010–2013 (100). Mortality rates are highest in infants, the elderly, and those with underlying cardiopulmonary disease. Globally, during 2008, an estimated 28,000 to 111,500 deaths occurred in children < 5 years of age, almost all of which occurred in developing countries (95). For seasonal influenza, about 90% of deaths in developed countries occur in those  $\geq 65$  years of age, and the mortality rates in those over 65 years old are more than 50-fold higher than in younger persons (72) and are especially high in those aged 85 years and older.

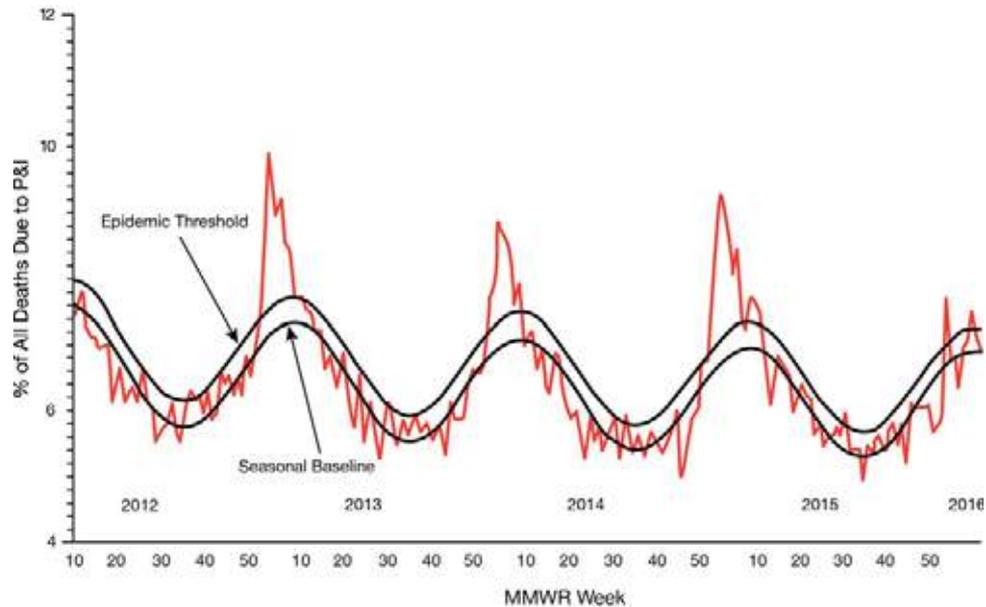

Most seasonal influenza mortality is attributable to lower respiratory complications or cardiovascular disease (503). Pneumonia and influenza deaths account for only about one-quarter of all excess deaths, but they serve as important markers of influenza activity (Fig. 9). Up to two-thirds of the excess deaths are related to cardiovascular disease. Excess mortality due to pneumonia and influenza-related deaths in the United States occurs particularly in association with A(H3N2) subtype epidemics. Increases in mortality rates generally lag several weeks behind the peak of influenza activity and persist for approximately 6 weeks afterwards.

### Influenza C

Influenza C virus infection is worldwide in distribution and generally nonseasonal but may cause prolonged community outbreaks (101, 102). Symptomatic infections usually occur between 1 and 4 years of age, but influenza C virus usually represents < 1% of viruses from children with respiratory illness (101, 102). Most children  $\geq 6$  years and adults are seropositive. Influenza C virus has been associated with outbreaks in closed populations, including those in children's homes and the military.

### Nosocomial Infections

Influenza A and, less often, B viruses are important causes of nosocomial outbreaks involving hospital wards, intensive care units, nursing homes, and other semi-closed populations (53, 103). Because of the short incubation period of influenza and its efficient transmission, rapid dissemination of virus can lead to explosive outbreaks in such populations.

**FIGURE 9** Pneumonia and influenza (P&I) deaths presented as a percentage of total deaths in the United States, 2011 to 2016. Total deaths and those attributed to pneumonia and influenza deaths are reported weekly from 122 cities in the United States to the CDC. Excess mortality above the epidemic threshold has been seen particularly in association with influenza A (H3N2) subtype activity. A(H3N2) viruses predominated nationally during the 2012–13 and 2014–15 seasons, and there was a mismatch with the vaccine strain during the latter season. However, during the 2013–14 season, A(H1N1)pdm09 viruses predominated and increased overall mortality, and higher rates of hospitalization among adults aged 50 to 64 years occurred. Figure reproduced with permission from the Influenza Division, US CDC.

Outbreaks are typically brief, lasting from 1 to 3 weeks. Clinical attack rates among groups of institutionalized adults range from 10 to 60%, with substantial ward-to-ward variation. Lower respiratory tract complications develop in one-third or more of affected adults, and mortality rates range widely (0 to 30%). Healthcare workers (HCWs) are often involved during the course of both community and hospital outbreaks of influenza. The incidence of influenza infection among unvaccinated HCWs has been estimated at 16 to 22% per season (104). During outbreaks secondary HCW infections are common (20 to 50% attack rates) and can lead to absenteeism and disruption of services. Infected workers can initiate or perpetuate outbreaks by transmitting infection to susceptible patients, and healthcare-provider immunization has been associated with reduced influenza-associated illness and mortality in chronic-care facilities (105).

Nursing home residents are disproportionately impacted by influenza because of higher frequencies of underlying disease, decreased vaccine responsiveness, and greater likelihood of influenza exposure, due to residence in semi-closed facilities, compared to elderly persons in the community. Nursing home outbreaks are more likely in larger homes and in those with lower immunization rates (106), although outbreaks have occurred despite immunization rates exceeding 90% and sometimes out of season during the summer months. Nosocomial influenza should be considered in hospitalized or nursing home patients with unexplained febrile illness or respiratory deterioration, especially during periods of influenza activity in the community or if multiple cases occur.

### Zoonotic Infections

Animal influenza viruses cause occasional zoonotic infections, but such events are usually associated with inefficient human-to-human spread, although they create the conditions for the potential emergence of an animal-human re-

assortant virus. Ongoing surveillance in animal populations and their human contacts is essential to look for new variants that may pose threats and warrant the development of candidate vaccines (107).

### Swine Influenza Viruses

Swine-origin influenza A viruses that cause zoonotic infections are now termed variant (v) influenza viruses and include H1N1v, H1N2v, and H3N2v subtypes that have caused illness in humans uncommonly cause zoonotic infection. Human influenza viruses also transmit to swine and may contribute to generating new variants (108). Transmission of A(H1N1) subtype virus from swine has been frequently implicated, including the Fort Dix outbreak in 1976 and sporadic fatal pneumonic disease, particularly in pregnant or immunocompromised persons (81). Influenza virus is readily detectable in the air and environment of live animal markets and production facilities containing infected swine, and swine workers and their close contacts have increased risk of infection by such viruses (109, 110). During the summer of 2012 H3N2v outbreaks across 10 U.S. states caused 306 proven cases including 16 hospitalizations and 1 death; more than 90% of those infected were children and reported agricultural fair attendance and/or contact with swine, although some limited human-to-human transmission likely occurred (111). Of note, transmission of influenza viruses to humans can occur from healthy-appearing swine.

A low prevalence of antibodies to influenza D virus has been found in humans (112), but it is unclear whether such viruses may cause disease in humans. Detection of a novel A(H2N3) subtype virus in swine has not been associated with recognized human infection (84).

### Avian Influenza Viruses

Serologic evidence of infection by multiple subtypes of avian viruses is present in Chinese agricultural workers, and

experimental human infection has developed after intranasal exposure to H4, H6, and H10 subtype viruses (113). Purulent conjunctivitis due to A(H7N7) subtype influenza virus has followed exposure to infected seals or laboratory materials (Table 3). In 2003, a large outbreak of highly pathogenic avian influenza (HPAI) A(H7N7) virus in poultry in Holland and Belgium was associated with many human illnesses, principally conjunctivitis but also influenza-like illness and one fatal pneumonia in a veterinarian, as well as evidence of human-to-human transmission (114). Sporadic human infections by other H7 subtype viruses, sometimes without apparent symptoms and detected serologically, have been reported in multiple countries. Avian A(H9N2) subtype viruses continue to circulate widely in poultry populations in parts of Asia, Africa, and the Middle East. While these viruses have caused few recognized human infections (Table 3), they have been the source of key internal genes implicated in the emergence of other avian viruses causing zoonotic infections including both A(H5N1) and A(H7N9) viruses (115, 116). Of great concern have been sporadic cases of avian influenza infections, particularly major outbreaks of avian A(H5N1) and A(H7N9) viruses (Table 3). Increased poultry infection-associated risk to humans occurs during the winter months when seasonal influenza viruses are circulating, thus creating the potential for dual infections (117).

#### H5N1 Virus

In 1997, direct interspecies transmission of a highly pathogenic avian influenza (HPAI) A(H5N1)-subtype virus led to 18 illnesses and six deaths in Hong Kong (Table 3) (118). This experience established that avian influenza viruses could cause human infections without adaptation in an intermediate host and despite differences in receptor specificity. The virus possessed a polybasic amino acid HA cleavage site characteristic of HPAI viruses and was uniquely lethal in animals without adaptation (119). The virulent A(H5N1) subtype appeared to arise as a reassortant of avian influenza viruses, likely including a goose A(H5N1) subtype virus and possibly a quail A(H9N2) subtype virus, which provided multiple internal genes. Subsequent reassortment events and genetic changes led to further variants causing fatalities in one family visiting Fujian Province in 2003, and then major poultry outbreaks and associated human cases in Thailand, Vietnam, and Cambodia starting in 2003 to 2004, followed by spread across Asia to Europe, the Middle East, and Africa (35). Poultry raising and trade practices, live-poultry markets, duck abundance, and rice-cropping intensity are contributory to the persistence of the virus, which is currently entrenched in poultry populations of multiple countries in Asia and Africa (notably China, Egypt, Indonesia, parts of India and Bangladesh, the Greater Mekong subregion, and, likely, parts of West Africa). Sporadic cases continue to occur, and a major outbreak affecting 165 persons, almost all with history of poultry contact, caused a 35% case-fatality rate in Egypt during the winter months of 2014–2015 (120). The HA gene has continued to evolve, with 10 first-order clades recognized in poultry, four of which (clades 0, 1, 2, and 7) have caused fatal human illness (121), and multiple higher order ones (122).

The epizootic in birds has resulted in loss through illness or culling of hundreds of millions of birds, predominantly chickens and ducks, but has resulted in relatively few human cases to date, despite numerous exposures (Table 3). Episodes of nonsustained person-to-person transmission to household and healthcare contacts have been recognized

uncommonly; subclinical human infections have also been uncommon to date (121). One explanation for the rare event of a chicken-to-human transmission is that only large amounts of virus lead to infection (and disease) in humans, but the host factors that might contribute to susceptibility are poorly understood. Of note, the combination of relatively few substitutions in the HA, including change in HA binding preference from  $\alpha 2,3$ -linked to  $\alpha 2,6$ -linked sialic acid receptors, and in the polymerase complex, confer airborne transmissibility of A(H5N1) in ferrets, a model thought by some investigators to be predictive of human transmissibility (80, 123, 124). Some of the required changes already exist commonly in field isolates (125). However, the fact remains that the virus-host interactions leading to effective transmission of avian viruses in humans remain undetermined.

Since early 2014, rapid spread of HPAI H5Nx reassortant viruses, possessing the genetic clade 2.3.4.4 HA, has occurred among wild and domestic birds leading to poultry outbreaks in Asia, Europe, and, for the first time, in North America (107). A HPAI A(H5N8) virus, first detected in January 2014 in South Korea, spread within the year to North America leading to emergence of reassortant A(H5N2) and A(H5N1) viruses that caused loss of approximately 40 million chickens and turkeys in the United States in 2015, although there were no recognized human cases (126). These viruses are less virulent in mouse and ferret models than an Asian lineage A(H5N1) virus and are not transmitted by direct contact in ferrets (127). Outbreaks of A(H5N1) and A(H5N2) viruses in poultry have also occurred in European countries. Their spread may have occurred through infections in wild birds and migratory bird dispersal, activities associated with poultry production, and possibly, in some countries, by illegal poultry transports.

#### H7N9 Virus

Avian A(H7N9) virus infection was first detected in fatal human cases in March 2013 (115) and has subsequently caused at least 770 cases in China, with a case fatality exceeding 30% in hospitalized (128). This novel virus arose from sequential reassortments in domestic poultry involving genes from A(H9N2) donor viruses, as well as from H7 and N9 precursors from wild birds. Although composed of avian influenza genes, the virus contains some markers of mammalian adaptation, including the ability of some isolates to be transmitted by airborne route in ferrets (129, 130). Lacking a polybasic amino acid cleavage site in HA, the virus does not cause overt disease in infected birds, which makes recognition and control difficult. The virus is now widely endemic in poultry markets in China. Most human cases have resulted from exposure to live birds or live bird markets prior to onset of disease, and large waves of human infections occurring during the winter months have ceased in temporal association with closures of live bird markets (131, 132). Family clusters and several instances of nosocomial transmission to unrelated healthcare workers have occurred (133–135). In contrast to A(H5N1) and A(H1N1)pdm09 infections, older males with comorbidities have been disproportionately affected by severe A(H7N9) disease (136, 137). Many milder infections have likely taken place (134), and subclinical infections, specifically in poultry workers, have been detected (138), although serologic studies indicate that most persons in the community lack specific antibody and hence are susceptible.

## PATHOGENESIS

### Viral Replication

The initial site of infection is the respiratory tract mucosa (12) and is mediated by HA binding to sialylated glycans on epithelial cells. The  $\alpha 2,6$ -linked sialic acid receptors preferred by human viruses are present in both the upper and lower respiratory tract, particularly tracheobronchial epithelium and type 1 pneumocytes, whereas the  $\alpha 2,3$ -linked receptors preferred by avian viruses are present in the distal bronchioles, type 2 pneumocytes, and alveolar macrophages, as well as conjunctival mucosa (139). These distribution patterns may explain in part the high frequency of tracheobronchitis in seasonal influenza, conjunctivitis in avian A(H7) infections, and viral pneumonia but the relative paucity of upper respiratory manifestations in avian A(H5N1) and A(H7N9) infections.

In experimentally infected volunteers, virus shedding begins about 1 day before onset of illness, and titers in nasal washings peak within several days at  $10^4$  to  $10^7$  50% tissue culture-infectious doses (TCID<sub>50</sub>) per ml (140). In uncomplicated influenza A virus infections, viral RNA titers in upper respiratory secretions are often detectable 1 to 2 days before symptom onset, peak on the first 1 to 2 days of clinical illness, and decrease gradually to undetectable levels by day 6 to 7, generally matching the dynamics of clinical illness; influenza B virus RNA titers may be more sustained (48). The duration of infectious virus detection in upper respiratory secretions is generally 3 to 6 days during uncomplicated influenza in adults and older children. Viral loads determined by molecular assays for viral RNA are higher and more prolonged, generally by 2 to 3 days (141). Fever and the severity of illness correlate temporally with the quantity of virus detectable in respiratory secretions. Hospitalized adults may have detectable infectious virus or viral RNA in upper respiratory samples for a week or longer after illness onset; comorbidities and systemic corticosteroid use are associated with slower viral clearance (142, 143). Nasopharyngeal infectious virus levels correlate with viral RNA loads in hospitalized adults but decline more rapidly, and are often negative, when RNA detectability persists (144). Longer periods of shedding (1 to 3 weeks) are commonly seen in infants and children, in critically ill patients, and in those experiencing severe zoonotic infections (121, 141, 145–148). In avian A(H5N1) and A(H7N9) disease, viral levels are higher in lower respiratory than in upper respiratory tract specimens and higher in the throat than in the nose. Prolonged virus shedding (weeks to months) has been described to occur in patients with immunodeficiency, including advanced human immunodeficiency virus (HIV) disease (149, 150).

Recovery of infectious influenza virus from blood (viremia) or extrapulmonary tissues has been documented rarely in seasonal influenza. Virus has been recovered from the heart, liver, spleen, kidneys, adrenals, muscles, and meninges, and, in children with encephalopathy, viral RNA has been detected sometimes in cerebrospinal fluid (CSF). Detection of viral RNA in blood (RNAemia), found in as many as 10% of those hospitalized with A(H1N1)pdm09 illness, has been associated with more severe clinical presentation and higher mortality (136, 151). In HSCT-transplant patients with influenza, the detection of viral RNA in the blood is associated with disease progression and mortality (152). Viral RNA positivity in stool may be associated with gastrointestinal symptoms (153, 154). Viremia, gastrointestinal infection, and extrapulmonary dissemina-

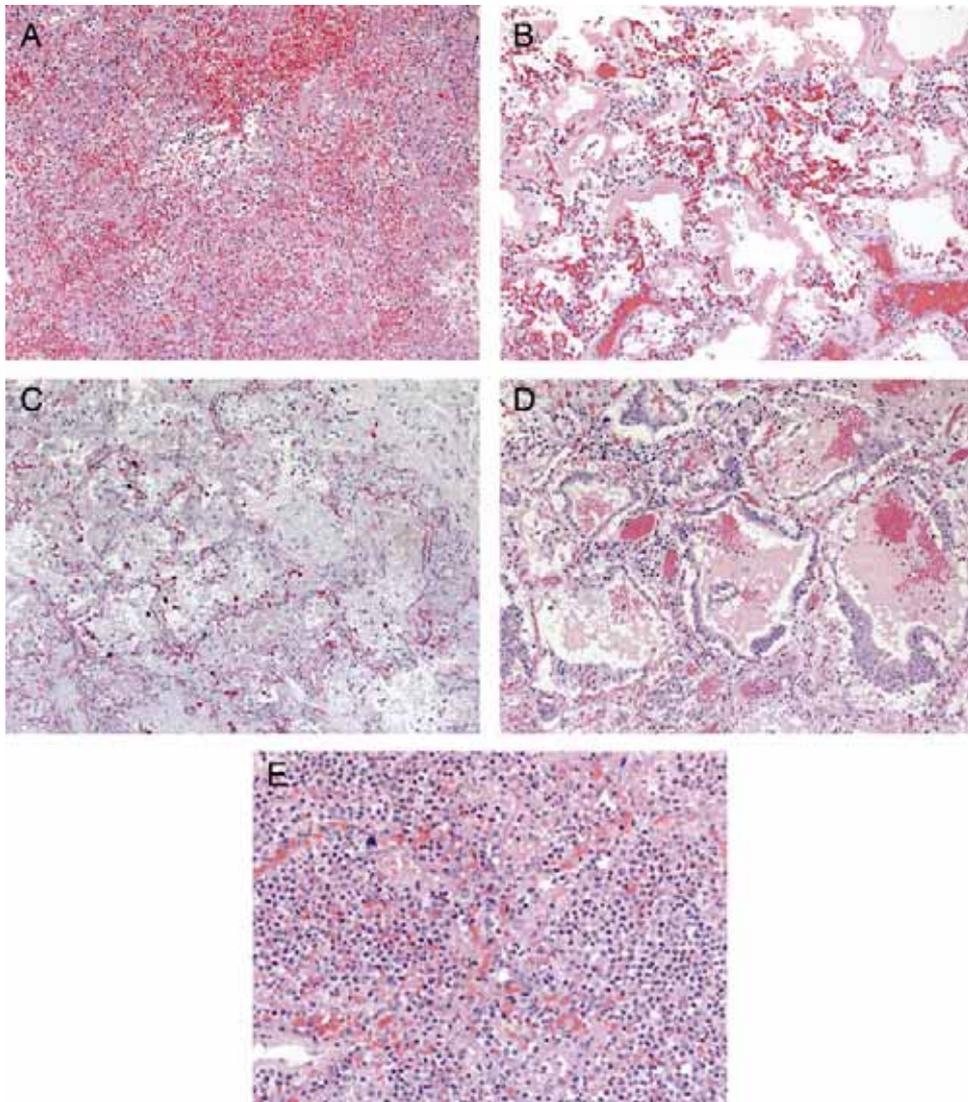

tion, sometimes including the central nervous system (CNS), occur in some avian A(H5N1)-infected patients, and detection of viral RNA in blood or feces is associated with a worse prognosis (121, 147, 155).

### Pathological Changes

In apparently uncomplicated influenza, bronchial histopathology shows degeneration of respiratory epithelial cells with loss of ciliated tufts and desquamation, pseudometaplastic changes of the epithelium, and edema, hyperemia, and mononuclear cell infiltrates in the lamina propria (156, 504). In fatal influenza viral pneumonia, the gross pathological findings include hemorrhagic, airless lungs and severe tracheobronchitis (157). The pathological features include necrotizing tracheobronchitis and bronchiolitis with loss of ciliated epithelium, fibrin exudation, and inflammatory cell infiltration; diffuse alveolar damage with hyaline membrane formation and intra-alveolar and intrabronchiolar hemorrhage; and interstitial edema, hemorrhage, and mononuclear cell infiltration (Fig. 10A-C) (156). Later changes include lymphohistiocytic alveolitis, metaplastic epithelial regeneration, and sometimes extensive fibrosis (Fig. 10D). Influenza virus antigens (Fig. 10C) or RNA have been demonstrated in virtually all cell types of the respiratory tract, including type 1 and 2 pneumocytes, and virus has been recovered from pulmonary tissues as late as 3 weeks after illness onset in fatal cases and sometimes later in those treated with corticosteroids (155). Similar pulmonary changes occur in severe viral pneumonias caused by diverse influenza viruses, including the 1918 pandemic virus, A(H1N1)pdm09, A(H5N1), and A(H7N9) viruses (157–159). When bacterial superinfection develops, lung pathology is dominated by an influx of polymorphonuclear leukocytes (Fig. 10E).

Both direct cytopathic effects (CPE) and virally induced apoptosis contribute to the pathological changes. Exuberant local and systemic cytokine and chemokine responses (145, 148, 160) have been postulated to cause inflammation and cellular infiltration in the lungs and other organs. In the mouse lung, a subpopulation of lung epithelial cells, club cells (formerly Clara cells), survive for weeks after infection producing proinflammatory mediators, which initially contribute to an antiviral response but, after prolonged activation, enhance immunopathology (161, 162). The severity of pneumonitis relates to cell-mediated immune responses and can be enhanced by transfer of certain types of T lymphocytes in murine models, but the extent to which such immunopathological host responses contribute to human disease remains uncertain. Lymphocytopenia in lethal human influenza appears to be associated with a lung T lymphocytosis, although not necessarily increased cytokine elaboration (163). Of note, nonneutralizing, cross-reacting antibodies, that lead to immune complex formation and complement deposition in the lung, are postulated to be a major pathogenetic mechanism leading to severe pulmonary disease, and, in contrast to seasonal influenza, extensive C4d deposition in bronchioles has been demonstrated in fatal A(H1N1)pdm09 and 1957 pandemic influenza cases (163).

Patients with fatal cases of influenza often show pathological changes in other organs. Diffuse congestion and generalized swelling of the brain and myocardial inflammation with edema, interstitial hemorrhage, myocyte necrosis, and lymphocytic infiltration have been found in one-third or more of autopsies. Pathologic evidence of acute myocardial injury has been found in a majority of fatal influenza B cases in children (164). The few autopsies of patients with fatal A(H5N1) and A(H7N9) have also shown lymphocyte

**FIGURE 10** Photomicrographs of lung tissue from patients dying with primary viral (A-D) or secondary bacterial (E) pneumonia following influenza A(H1N1)pdm09 infection. Unless otherwise indicated, histologic sections were stained with hematoxylin and eosin. (A) Diffuse alveolar damage and alveolar hemorrhage with erythrocytes and exudate filling alveoli; (B) extensive hyaline membrane formation; (C) widespread influenza A nucleoprotein antigen staining by immunohistochemistry; (D) early regenerative phase with type II pneumocyte hyperplasia and alveolar exudates; (E) polymorphonuclear leukocytes (PMNs) filling alveolar spaces in *Streptococcus pyogenes* suprainfection. Photomicrographs kindly provided by Dr. Sherif Zaki, US Centers for Disease Control and Prevention, Atlanta, Georgia; republished with permission from reference 158.

depletion, hemophagocytosis, hypoxic changes in liver and kidney, and hepatitis, consistent with observed changes in clinical laboratory values (157, 159).

### Pathogenesis of Symptoms

Direct viral involvement of the upper and lower respiratory tract accounts for much of the illness associated with influenza, particularly the high frequencies of cough and tracheal irritation, coryza, and sore throat. Even in apparently uncomplicated influenza, bronchoscopy shows tracheobronchial inflammation, and pulmonary function abnormalities persist for weeks to months after infection (223, 224, 504). Pulmonary function studies have detected restrictive and obstructive ventilatory defects, abnormal gas exchange with

increased alveolar-arterial oxygen gradients, decreased carbon monoxide diffusing capacity, and airway hyperreactivity.

The cause of the marked constitutional symptoms during influenza relates, in large measure, to elaboration of proinflammatory cytokines and chemokines. During experimental human influenza, nasal lavage levels of IFN- $\alpha$ , IFN- $\gamma$ , interleukin-6 (IL-6), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), IL-8, IL-1b, IL-10, MCP-10, and MIP-1 $\alpha$  and -1 $\beta$  and blood levels of IL-6 and TNF- $\alpha$  levels occur; early increases in nasal IFN- $\alpha$ , IFN- $\gamma$ , and IL-6 correlate with viral titers and illness measures (140). Interferon levels increase in respiratory secretions and blood during uncomplicated human influenza. Interferon concentrations peak about 1 day after the peak of virus shedding and fall in temporal association with

decreases in viral replication. In uncomplicated influenza, levels of IL-6, IFN- $\alpha$ , IFN- $\gamma$ , TNF- $\alpha$ , and IL-10 in the nose and blood are increased early; IL-6 levels correlate with illness measures, and nasal IFN- $\gamma$  levels correlate with decreases in viral titers (165).

Hypercytokinemia occurs in patients hospitalized with serious human influenza, in whom elevated plasma IL-6 levels correlate with prolonged hospitalization (166), and is especially marked in A(H5N1) patients, in whom the highest cytokine levels are found in those with fatal illness (147). High plasma levels of IL-6, IL-8, CCL-2 (monocyte chemoattractant protein-1), and soluble TNF receptor-1 occur in severe A(H1N1)pdm09 pneumonia and complicated seasonal influenza and correlate with the extent and progression of pneumonia (148, 160). In A(H7N9) influenza virus infections, high plasma concentrations of IL-6, IL-8, IL-10, and MIP-1 $\beta$  are also predictive of poor or fatal outcome (137). Matched bronchoalveolar lavage (BAL) samples show up to 1,000-fold greater cytokine/chemokine levels relative to plasma, indicative of local elaboration in the lung.

The mechanisms of cytokine induction are incompletely defined, but the extent of viral replication is an important variable. Upper respiratory tract viral loads in patients hospitalized with either seasonal influenza or A(H5N1) infection correlate with plasma cytokine and chemokine levels (147, 166). Viral virulence factors also play a role (see below). For example, human isolates of A(H7N9) virus replicate more efficiently in *ex vivo* cultures of human bronchus and lung than A(H5N1), but A(H5N1) virus are more potent inducers of pro-inflammatory cytokines than A(H7N9) or A(H1N1)pdm09 viruses (167). Influenza HA activates cellular transcription factor-NF- $\kappa$ B binding and transactivation of target genes encoding certain cytokines, cellular adhesion molecules, and other acute-phase proteins. Viral NA can also stimulate TNF and IL-1 production by monocytes and activate latent-transforming growth factor  $\beta$ . Virus-associated double-stranded RNA, interacting with Toll-like receptors 3 and 7 and with the helicase retinoic acid-inducible gene (RIG-I), appear to play an important role in initiating acute-phase responses and inducing cytokine elaboration during acute influenza (168).

### Viral Pathogenicity

Virulence is a multigenic characteristic that does not relate to a specific subtype and varies within subtype. Viral genetic features that increase replication, especially in the distal airways and lungs, inflammatory responses, or pathogenicity contribute to disease severity. The H1N1 pandemic of 1918 was especially severe, likely related to the greater pneumotropism of the virus, absence of effective herd immunity, and the consequences of secondary bacterial infections (169). Unlike seasonal viruses, the 1918 virus causes a lethal pneumonia with sustained viral replication in experimentally infected macaques and a dysregulated immune response characterized by deficient interferon responses early and prolonged proinflammatory responses (170). The polymerase genes from the 1918 influenza virus are required for full pathogenicity in animals (3, 4). Some influenza A viruses like 1918 pandemic virus and A(H5N1) express full-length PB1-F2 that contributes to cytotoxicity and inflammatory responses in the lungs and airways, and one mutation in PB1-F2 (Asp66Ser) is associated with increased viral replication (171, 172).

Requirements for airborne transmissibility in ferrets appear to include HA acid stability, with lower pH needed for

HA cleavage activation, binding capacity to  $\alpha$ -2,6 sialic acid receptors, and efficient polymerase activity at 33°C, the temperature of mammalian upper airways (173). The extent of HA glycosylation status affects lung tropism, and viruses possessing a poorly glycosylated HA, as well as the ability to bind both  $\alpha$ 2,3- and  $\alpha$ 2,6-linked sialic acid-bearing receptors, are able to penetrate deep into the lungs and increase the risk of bacterial co-infections (174). Pathogenicity and cell tropism of influenza viruses also relate in part to the HA cleavability by particular host cell enzymes (33). Serine proteases, presumably derived from host epithelial cells, cleave the HA precursor molecule into HA1 and HA2 to render human influenza viruses infectious. Protease activity present in human nasal secretions, common house dust mites, and proteases produced by some bacteria, including *Staphylococcus aureus*, can enhance viral replication. Certain bacterial enzymes like streptokinase can proteolytically activate plasmin to cleave HA. Host range restriction, replication kinetics, and virulence are also influenced by multiple other genes. Apoptosis appears to be an important mechanism for inducing cell death by influenza viruses and is mediated by several viral proteins, including PB1-F2, NA and NS1 (8).

Influenza viruses have evolved multiple immune evasion mechanisms. For example, the multifunctional NS1 protein counteracts the double-stranded-RNA-activated protein kinase and other antiviral responses induced by interferon, limits the induction of IFN- $\beta$ , interacts with the cellular protein nucleolin, and also interacts via its C terminus with PDZ-binding proteins to modulate viral pathogenicity (175). Viral NA may destroy sialic acid-dependent NK cell-activating receptors on HA expressed on the surface of infected cells, and block their clearance (176). The ability of NA inhibitors to block this effect may provide an indirect antiviral effect through NK elimination of infected cells. HA glycosylation is one mechanism of humoral immune evasion, but lectins in respiratory secretions bind to highly glycosylated HA and thus may limit infection to the upper respiratory tract (174). The unique virulence of A(H5N1) viruses appears to be multifactorial, including high HA cleavability, high replication competence related to its polymerase complex (especially the PB2 protein for certain strains), and ability to subvert host innate immune responses (177, 178).

### Bacterial Coinfections

Multiple viral, bacterial, and host factors contribute to the increased risk and severity of bacterial respiratory tract infections following influenza (174, 179, 180). Infection damages the bronchial epithelium and disrupts mucociliary clearance, promotes pharyngeal colonization by bacterial pathogens by increasing adherence to epithelial cells, and depresses the chemotaxis and bactericidal activity of alveolar macrophages and polymorphonuclear leukocytes (PMNs) (Table 5). Viral NA activity can expose cellular receptors that enhance binding by pneumococci and meningococci (174). Decreased bacterial clearance results from decreased PMN chemotaxis, intracellular killing, and other functional changes that have been linked to altered signal transduction steps. Purified viral NP inhibits PMN chemotaxis and superoxide production. The production of nitric oxide, which exerts antiviral effects, is depressed in influenza virus-infected macrophages.

Enhancement of adaptive immune responses designed to establish antiviral immune memory suppress innate antibacterial defenses (179). Type 1 IFN impairs macrophage

and neutrophil responses, in part by inhibiting the IL-17 responses of  $\gamma\delta$  T cells (181). IFN- $\gamma$  causes inhibition of alveolar macrophage-mediated bacterial phagocytosis. Increased IL-10 production during recovery suppresses bacterial clearance mechanisms.

The mechanisms involved may vary by bacterial pathogen; e.g., influenza suppression of NADPH oxidase reduces *S. aureus* but not *S. pneumoniae* killing in neutrophils and macrophages (182). Certain strains of *S. aureus* and other bacteria secrete proteases that enhance the infectivity of influenza viruses through HA cleavage and induce severe viral-bacterial pneumonia in animals (183, 184).

### Host Genetics

A hereditary predisposition to influenza-related death has been postulated, particularly in association with the 1918 pandemic and with avian A(H5N1) infections, but mechanisms have not been elucidated (185). Genetic polymorphisms in IFITM3 (interferon-inducible transmembrane 3) have been found to be associated with both severe A(H1N1)pdm09 (186) and A(H7N9) infections (137). Other genetic changes, including heterozygosity for the chemokine receptor 5 (CCR5)  $\Delta$ 32 allele (187), polymorphisms in CD55, which encodes an important complement regulatory protein (188), the C/C genotype in the surfactant protein B gene (189), and certain HLA alleles affecting T cell functions (190), may also be associated with severe A(H1N1)pdm09 disease. Autosomal recessive interferon regulatory factor 7 (IRF7) deficiency from two mutant alleles, leading to reduced type I and III interferon (IFN) responses, has been reported in an otherwise healthy child with life-threatening A(H1N1)pdm09 disease following primary infection (191). Low mannose-binding lectin production may increase the risk for invasive MRSA coinfection (192). Mutations in the gene encoding carnitine palmitoyltransferase II (CPT2) have been associated with influenza-related encephalopathy in Asian children (193).

### Immune Responses

Recovery from infection and protection against reinfection are associated with specific host immune responses (194). The observation that the 1977 A(H1N1) reemergence rarely affected persons who had been infected with essentially the same virus more than 20 years earlier indicates that immunity to reinfection and illness caused by homotypic virus is durable. Serologic evidence of reinfection by the same, or closely related, strains is common, especially in closed populations, but reinfections are usually subclinical in adults. The first lifetime influenza A virus infection results in immune memory for the subtype to which the strain belongs, such that subsequent infections or immunizations reinforce the antibody response to the first virus. This phenomenon has been termed "original antigenic sin" (195). Upon subsequent infections, persons may produce cross-reacting antibodies to the subtype causing initial infection, as well as strain-specific antibodies to previously encountered related viruses.

### General

Nonspecific host factors may contribute to protection or early response to influenza infection. Various lectins, including mucins in nasal secretions, surfactant proteins, and serum mannose-binding lectin, directly inhibit influenza viruses through binding to their surface glycoproteins, as well as by promoting uptake by phagocytic cells (196).

Neutrophil-derived  $\alpha$ -defensins inhibit influenza virus replication *in vitro*, possibly by interfering with protein kinase C activation (197). Neutrophils have antiviral effects in animal models, and neutropenic hosts are at increased risk of severe influenza. The pattern of HA glycosylation influences viral opsonization and complement-mediated lysis of infected cells. Human BAL fluids also inhibit HA activity.

Nasal IFN levels peak early and correlate directly with viral titers in uncomplicated influenza. Of note, deficient IFN responses in macaques infected by the 1918 virus (170), lack of detectable lung IFN in fatal pneumonia cases (198), and low plasma IFN- $\alpha$  levels in severe A(H1N1)pdm09 infections (199) indicate the importance of endogenous IFN responses. Type I IFNs cause Mx protein expression that leads to species-specific cellular resistance to influenza virus infection (168) and upregulation of multiple other antiviral pathways (see Chapter 16). Whole-blood gene expression microarrays indicate that influenza patients have attenuation of NK and T cell responses and that both interferon and ubiquitination signaling are strongly decreased in patients with severe outcomes, suggesting the protective roles of these pathways in disease pathogenesis (200). Influenza virus can infect and cause apoptosis and reduced responsiveness of natural killer (NK) cells (511); marked reductions in natural killer (NK) cells have been seen in severe A(H1N1)pdm09 cases (201). In murine models depletion of polymorphonuclear leukocytes is associated with increased influenza replication and worsened disease (202). Apoptosis-dependent phagocytosis by macrophages of virus-infected cells may contribute to elimination of virus.

### Humoral Immunity

Following primary infection in children, serum hemagglutination inhibition (HAI) and anti-NA antibodies develop within 10 days and persist for years. The principal neutralizing antibody responses are strain-specific serum immunoglobulin M (IgM) and IgG antibodies and nasal IgA antibodies directed against HA. Virus-specific serum IgM, IgG, and IgA antibodies are present in adults within the first week after the onset of illness (203). Serum HAI titers gradually decrease over the first 6 months but may be boosted by infection with related viruses; IgA responses remain detectable for several months. Otherwise healthy persons infected with avian A (H5N1) virus produce serum-neutralizing antibody responses with kinetics similar to those following primary infection in children with human influenza A viruses.

Protection against infection and illness by the homologous virus correlates directly with levels of neutralizing IgA in nasal secretions and of serum IgG-neutralizing or HAI antibodies (194). Serum HAI antibody titers of 1:32 to 1:40 generally correlate with approximately 50% protection against illness due to the homotypic strain in immunocompetent persons (204), but protective titers vary widely with virus strain, age, and general immune status, and likely intensity of virus exposure. In one household-based study an HAI titer of 1:40 was associated with only 31% protection and a microneutralization (MN) titer of 1:40 with 49% protection against seasonal influenza A virus infection (57).

Antibodies in either serum or nasal secretions confer resistance regardless of subclass if present in sufficient titer. Heterosubtypic humoral immunity, as assessed by HAI titers, provides no significant protection against infection. Non-neutralizing antibodies, which increase phagocytosis of opsonized viruses by Fc receptor-bearing cells, occur following primary infection and may contribute to viral

**TABLE 5** Factors Contributing to Bacterial Coinfections with Influenza<sup>a,b</sup>

<b>Disruption of mechanical clearance mechanisms</b>
Epithelial damage leading to loss of mucociliary clearance
Eustachian tube dysfunction
Loss of surfactant
<b>Increased bacterial adherence and replication</b>
Exposure of bacterial receptors (e.g., platelet activating factor receptor, laminin, type I and IV collagen, others)
Viral NA exposure of receptors
Prolonged bacterial colonization and increased replication in the nasopharynx
Favorable milieu for bacterial replication (e.g., serum, fibrinous exudates, erythrocytes, dead cells in airways and alveoli)
<b>Inefficient host clearance of bacteria</b>
Viral depletion of alveolar macrophages
Impaired neutrophil and macrophage bacterial killing (see below)
Impaired NK cell recruitment and function
Downregulation of chemokines and inhibition of immune cell recruitment
Anergy of bacterial sensing pattern recognition receptors (e.g., the Toll-like receptors [TLRs])
<b>Immune dysregulation with increased inflammatory and anti-inflammatory responses</b>
Type I IFN impairment of macrophage and neutrophil responses, in part by inhibiting IL-17 responses of $\gamma\delta$ T cells
Type II IFN impairment of alveolar macrophage phagocytosis
Bacterial cytotoxins (e.g., pneumococcal pneumolysin. Pantone-Valentine leucocidin) increase tissue damage and inflammation
Synergy between influenza and bacteria in activating many of the same cytokines, inflammatory cells, and pattern recognition receptors
Increased interleukin-10 (IL-10) production.
<b>Increased viral replication and reduced viral clearance mechanisms</b>
Bacterial enzymes that cause cleavage activation of viral HA (e.g., <i>S. aureus</i> )
Bacterial neuraminidases expose receptors, cleave sialic acids from protective mucins, and possibly overcome inhibitory effects of viral NA inhibitors (e.g., oseltamivir)
Bacterial interference with antiviral immunity

<sup>a</sup>*In vitro* and animal model studies have shown that many factors contribute to enhanced influenza viral-bacterial disease in acute otitis media and pneumonia (174, 179, 180).

<sup>b</sup>Adapted from Hayden FG and de Jong MD. Table 24.2, page 378 in Chapter 24 in *Textbook of Influenza*, Second Edition, Wiley Blackwell; John Wiley & Sons, Ltd., 2013 with permission.

clearance by macrophages. In addition, subtype-specific antibodies, which mediate cell lysis by complement binding or by antibody-dependent cellular cytotoxicity (ADCC), develop after infection or immunization. Antibody to M2 protein is nonneutralizing but inhibits virus replication by ADCC, complement-dependent cytotoxicity, interfering with virus budding, and perhaps other mechanisms (14). Antibody to neuraminidase is not known to neutralize virus infectivity but prevents release of virus from infected cells (205). If present in sufficient titers, anti-NA antibodies can reduce influenza virus replication and prevent illness in experimentally infected animals and humans (206).

### Cell-Mediated Immunity

T-cell immunity plays an essential role in influenza immunity, and infection elicits cell-mediated immune responses that are detectable before the appearance of humoral ones (207). Virus-specific lymphocyte blastogenic responses, T-lymphocyte cellular cytotoxicity, and cutaneous delayed-type hypersensitivity are detectable within 6 days after infection. These responses, particularly cytotoxic T lymphocytes (CTLs), play a role in termination of virus replication and recovery from infection, as well as in modifying the risk of illness or complications. Depressed mitogen-stimulated blastogenic responses may occur early in illness and are accompanied by cutaneous anergy. Lymphopenia with decreases in both T- and B-cell counts with normal CD4/CD8 ratios occurs early during acute infection. Decreased mitogenic responses may persist for 4 weeks after infection. T cell anergy has been associated with severe A(H1N1)pdm09 illness during the acute phase of infection (199).

Human CTLs are generally type specific but cross-reactive for cells infected by different influenza A virus subtypes (208). Influenza specific CD8<sup>+</sup> T cell responses are directed primarily to the internal proteins (NP, M1, and PB1), although the immunodominant epitopes differ among individuals. CD8<sup>+</sup> T-lymphocytes contribute to hetero-subtypic immunity in influenza A and, for influenza B, show cross-lineage reactivity (209, 506). CD4<sup>+</sup> T cells can also kill virally infected cells directly and recruit other immune cells by producing cytokines; M1 and NP also appear to be immunodominant targets of CD4<sup>+</sup> T cells (210). In one experimental study of seronegative volunteers, the presence of influenza A virus-specific memory CD4<sup>+</sup>, but not CD8<sup>+</sup>, T cells correlated with lower virus shedding and less illness upon seasonal virus reinfection (211). However, during the 2009 pandemic, higher frequencies of preexisting IFN- $\gamma$ + IL-2-T cells to conserved CD8 epitopes were found in individuals who developed less severe illness; CD45RA+ CCR7- late-effector T cells appeared to be the cellular immune correlate of protection (212). Human CD8<sup>+</sup> and CD4<sup>+</sup> CTLs recognize epitopes of animal influenza viruses (213), and nonexposed healthy adults possess CTLs reactive to A(H5N1) and A(H7N9) viruses that may provide some degree of protection (214, 215). T-cell epitopes are under selective pressure, and substitutions may allow escape from immune recognition (505). Granzyme B elaboration in virus-stimulated peripheral-blood mononuclear cell cultures of CTL activity appears to be lower in immunized elderly adults who develop influenza than those who do not (321). The half-life of influenza CTL memory has been estimated to be 4 years.

### CLINICAL MANIFESTATIONS

Influenza causes illness in the majority of those with virus-positive infection (216), but one-half or more of serologically proven infections in adults may be subclinical (217). Infection results in a range of clinical syndromes, including common cold, influenza-like illness (ILI), pharyngitis, tracheobronchitis, pneumonia, and, in children, bronchiolitis or croup. Other respiratory viruses cause ILI (218) and similar syndromes (see Chapter 2). Influenza A and B viruses cause similar illness manifestations and outcomes in ambulatory (219) and hospitalized patients (220). A wide range of acute and sometimes later-onset complications are recognized with such influenza (Table 6) (222), and particular host groups are at higher risk of complications (Table 7) (221).

TABLE 6 Influenza-associated complications<sup>a</sup>

<b>Upper Respiratory Tract</b>	
Acute otitis media, sinusitis	
<b>Lower Respiratory Tract</b>	
Acute bronchitis	
Exacerbations of asthma, chronic bronchitis, cystic fibrosis, or other chronic obstructive airways disease	
Acute bronchiolitis, obliterative bronchiolitis in children	
Laryngotracheobronchitis (croup) in children	
Viral pneumonia, acute respiratory distress syndrome (ARDS)	
Bacterial pneumonia, empyema, lung abscess, aspergillosis	
Bacterial tracheitis	
Pneumothorax, pneumomediastinum	
Pulmonary fibrosis, bronchiolitis obliterans organizing pneumonia (BOOP)	
<b>Central Nervous System</b>	
Febrile seizures (children)	
Encephalopathy, <sup>b</sup> delirium, acute psychosis, mutism	
Acute hemorrhagic leukoencephalopathy	
Meningoencephalitis; transverse myelitis; cerebellitis	
Hemiballismus; Alice in Wonderland syndrome	
Immune-mediated postinfectious encephalitis	
Guillain-Barré syndrome; polyneuropathy	
Bacterial meningitis, brain abscess	
Transient ischemic attack, stroke, vasculitis	
Reye's syndrome	
Narcolepsy (uncertain)	
Parkinson's disease (uncertain)	
<b>Cardiovascular</b>	
Electrocardiographic abnormalities	
Exacerbation of congestive heart failure	
Myocardial infarction, acute ischemia	
Atrio-ventricular block; arrhythmias; sudden death	
Myocarditis, pericarditis	
Fulminant heart failure	
Cardiac tamponade	
<b>Musculoskeletal</b>	
Myositis, compartment syndrome	
Rhabdomyolysis, myoglobinuria	
Rectus abdominis muscle tear	
<b>Hematologic</b>	
Disseminated intravascular coagulopathy (DIC)	
Hemophagocytic syndrome, thrombotic thrombocytopenic purpura	
Hypogammaglobulinemia, aplastic anemia (uncertain)	
<b>Renal</b>	
Renal failure from myoglobinuria, DIC, hemolytic uremic syndrome	
Exacerbation of nephrotic syndrome	
Glomerulonephritis (uncertain)	
<b>Gastrointestinal</b>	
Reye's syndrome	
Parotitis	

(Continued)

TABLE 6 Influenza-associated complications<sup>a</sup> (Continued)

Gastritis, duodenitis, hematemesis, bowel ulceration	
Transaminase elevations	
<b>Maternal/fetal</b>	
Low birth weight	
Fetal distress, spontaneous abortion, stillbirth	
Preterm labor, premature delivery	
<b>Systemic/Other</b>	
Hypotension, sepsis syndrome	
Toxic shock syndrome from secondary staphylococcal or streptococcal infection	
Poor diabetes control, adrenal hemorrhage	
Alopecia areata	
Transplant organ rejection	
Conjunctivitis, retinitis, choroiditis (uncertain) optic neuritis

<sup>b</sup>Described syndromes include acute necrotizing encephalopathy (ANE), acute encephalopathy with biphasic seizures and late reduced diffusion (AESD), clinically mild encephalitis/encephalopathy with a reversible splenial lesion (MERS), posterior reversible encephalopathy syndrome (PRES) (276).

The incubation period of seasonal and pandemic influenza averages about 2 days with a range of 1 to 5 days. However, the average incubation period of avian influenza infection is often several days longer and may extend up to 10 days, or, rarely, longer (115, 121).

### Influenza Syndrome

Classic influenza presents abruptly with prominent systemic symptoms, including fever, malaise, headache, and myalgia, and with respiratory symptoms of cough and often sore throat (222). In household-based studies the most common symptoms at influenza onset are cough, runny nose, and sore throat with fever present in about 30% of cases (48). Fever may be quite high and may be continuous or intermittent, especially if antipyretics are used. Pharyngeal and conjunctival injection, minor cervical adenopathy, and clear nasal discharge are common, but physical findings are generally nonspecific. Fever and systemic complaints usually abate by 3 to 5 days in adults, but respiratory complaints increase, with dry cough, substernal burning, and nasal congestion. Slight neutrophilia and lymphopenia occur early, followed by neutropenia. Influenza is associated with elevations of acute-phase proteins, serum amyloid A, and C-reactive protein, especially in hospitalized elderly persons. Acute influenza impairs psychomotor performance and lengthens reaction times.

Recovery is often slow; cough and malaise commonly persist for 2 to 4 weeks. Apparently uncomplicated influenza is often associated with prolonged abnormalities in gas exchange and pulmonary mechanics indicative of small-airway dysfunction (223, 224). These may contribute to the asthma and decreased exercise tolerance reported by patients during convalescence. The frequency and severity of clinically apparent influenza are greater in smokers (225–227). Allergic patients also experience increased severity of acute symptoms, bronchospastic exacerbations, and prolonged convalescence. Premorbid psychological status correlates with prolonged convalescence. Obesity (body mass indices [BMI]  $\geq 30$  kg/m<sup>2</sup>) and especially morbid obesity (BMI  $\geq 40$ ), recognized initially as risk factors for severe influenza during the 2009 pandemic (226, 228, 229), are also associated with increased respiratory hospitalizations

**TABLE 7** Groups at increased risk of serious influenza complications<sup>a</sup>

- Persons aged 65 years and older
- Children younger than 2 years of age<sup>b</sup>
- Persons with chronic pulmonary (including asthma and likely chronic cigarette smokers), cardiovascular (except hypertension alone), renal, hepatic, hematological (including sickle cell disease), metabolic disorders (including diabetes mellitus)
- Persons with neurologic and neurodevelopment conditions (including disorders of the brain, spinal cord, peripheral nerve, and muscle such as cerebral palsy, epilepsy [seizure disorders], stroke, intellectual disability [mental retardation], moderate to severe developmental delay, muscular dystrophy, or spinal cord injury)
- Persons with immunosuppression, including that caused by medications or by HIV infection
- Women who are pregnant or postpartum (within 2 weeks after delivery)
- Persons aged <19 years who are receiving long-term aspirin therapy (due to risk of Reye's syndrome)
- American Indians/Alaska Natives, other indigenous groups
- Persons who are morbidly obese (i.e., body-mass index [BMI]  $\geq 40$ )<sup>c</sup>
- Residents of nursing homes and other chronic care facilities
- Those infected by zoonotic influenza viruses (e.g., avian H5N1 or H7N9)
- Those with genetic predisposition (e.g., IFITM3 polymorphisms)

<sup>a</sup>Adapted from *Antiviral Agents for the Treatment and Chemoprophylaxis of Influenza: Recommendations of the Advisory Committee on Immunization Practices (ACIP)*, 2011 (221) with permission.

<sup>b</sup>All children aged <5 years are considered at higher risk for complications from influenza, but the highest risk is for those aged <2 years; the highest hospitalization and death rates occur among infants aged <6 months.

<sup>c</sup>Increased risk of complications has been reported at lower BMI ( $\geq 30$ ) in some studies (227–230).

during seasonal influenza (230). Increased influenza-associated pneumonia risk is reported in markedly underweight (BMI <18.5) persons (231). Severity also relates to virus type; A(H3N2) subtype infections have been associated with higher frequencies of lower respiratory symptoms, pulmonary function changes, physician visits, and hospitalizations than seasonal A(H1N1) subtype infections.

Influenza C virus has been associated with 3.5% of common colds in adults (232) and may cause febrile bronchitis and influenza-like illnesses, as well as a range of syndromes, including febrile coryza, bronchiolitis, and pneumonia, in children (102). Rhinorrhea and cough are the most commonly recognized symptoms and may last several weeks.

The diagnosis of influenza is often based on clinical and epidemiological grounds in the context of a known outbreak. In adults presenting with recent-onset fever and cough during community outbreaks, a suspected influenza diagnosis has been confirmed virologically in up to 80% (233, 234). The absence of fever, cough, or nasal congestion decreases the likelihood of influenza. However, clinical diagnosis often lacks accuracy, especially in children below the age of 5 years or when influenza prevalence is low, since the acute respiratory symptoms of influenza mimic those of other viral infections, including those due to respiratory syncytial virus, parainfluenza virus, and adenoviruses. Many influenza virus-positive patients, including those with high-risk conditions or requiring hospitalization, lack typical influenza-like illness and do not receive a clinical diagnosis of influenza (235).

Fever may be the only initial manifestation in nosocomial influenza.

## Specific Populations

### Infants and Children

Influenza virus infection occurs in about one-third of infants during the first year of life and is associated with increased severity because of their lack of immunity and their small-caliber airways. Maternally derived antibodies provide some protection in infants, although influenza hospitalization rates are highest in children younger than 6 months and progressively decrease thereafter (236). Approximately 40% of initial infections in young children are subclinical or cause afebrile upper respiratory tract illness (512). About 90% of symptomatic patients have fever, cough, and rhinitis, up to 40% have emesis or diarrhea, and 25% or more have otitis media or lower respiratory tract disease (98). Pneumonia develops in 5 to 15% of young children. Underlying conditions, like bronchopulmonary dysplasia and congenital heart or neurologic disease, are present in a minority. In adolescents, otitis media, usually resolving without antibiotics, and pneumonia complicate about 5% of cases. More than 1% of infections in the pediatric population result in hospitalization (236). Influenza A and B virus infections have been associated with 68% and 36%, respectively, of croup admissions and 36% and 11%, respectively, of all pediatric hospitalizations for respiratory illness during epidemic periods.

Influenza is underrecognized in infants and young children (98). Unexplained fever or suspected sepsis, bronchiolitis, croup, vomiting, diarrhea, and neurologic manifestations, including apnea, seizures in up to 36%, and meningitis-like presentations, lead to hospitalization. Abdominal pain can mimic acute appendicitis. Myositis, usually manifested as calf tenderness and pain impeding ambulation for hours to several days, occurs in about 20% of influenza B virus-infected children. Myositis and gastrointestinal symptoms are associated more frequently with influenza B than with influenza A virus infections. A range of acute CNS syndromes have been described in influenza-infected children (Table 6) (see below). Abnormal transaminases without the hyperammonemia or hypoglycemia typical of Reye's syndrome may occur. The incidence of Reye's syndrome in children with influenza, estimated to be less than 1 case per 10<sup>5</sup>, has markedly decreased in temporal association with the reduced use of salicylates (237).

### Pregnancy

Approximately 5 to 10% of pregnant women have serologic evidence of influenza virus infection. Excess mortality during pregnancy, primarily due to overwhelming pulmonary disease, has been well-documented during pandemics and sporadically during epidemics (238). In the 2009 and past pandemics as many as 10% of influenza deaths have been among pregnant women, as well as increases in hospitalization and ICU admissions (239, 240). Increased risks of complications and hospitalization (two- to fourfold) occur with increasing stage of pregnancy in women with seasonal influenza, especially in those with comorbidity (241). The second and especially third trimester of pregnancy or early puerperium appear to be periods of increased risk for severe disease and viral pneumonia. Maternal infection has also been associated with preterm delivery and perinatal mortality, primarily because of an increased rate of stillbirths, fetal distress, and emergency cesarean delivery, which were reported frequently during the 2009 pandemic (240, 242). Progressive cardiopulmonary changes during pregnancy including elevation of the

diaphragm, increased respiratory rate, increased intra-abdominal pressure, and decreased chest compliance may increase the risk of respiratory compromise and possibly pulmonary edema (243). Immunologic changes including increased expression of some proinflammatory cytokines, suppression of IFN- $\gamma$ , and relative immunosuppression related to fetal tolerance likely contribute to the increased risk of severe disease, particularly during the third trimester (243).

First trimester influenza may be associated with congenital anomalies including neural tube defects that have been related to maternal hyperthermia (244). Influenza during pregnancy has been linked to an increased risk of bipolar disorder in offspring (245). Reported associations with an increased risk of childhood leukemia, schizophrenia (1957 pandemic), or Parkinson's disease remain to be proven (238). Transplacental spread of virus has been documented rarely. A (H5N1) disease is associated with high mortality rates, fetal loss, and transplacental dissemination of virus (121, 155).

### Elderly

Viral replication and duration of illness may be more prolonged in older adults, especially the frail elderly, and the risks of acute complications and long-term reduction in functional status are increased (246). Elderly patients with influenza may not complain of typical systemic symptoms. Lassitude, lethargy, confusion, anorexia, decreased activity level, cough, and low-grade fever may be the primary findings (222). Presentation with complications, such as bacterial pneumonia or exacerbations of underlying conditions, also occurs. The elderly may experience myalgia or muscle weakness profound enough to impair ambulation in association with high creatine phosphokinase (CPK) levels (247). In murine models influenza leads to mobility impairments with greater and more prolonged induction of inflammation, atrophy, and proteolysis genes in aged compared to young animals, although without direct evidence of muscle infection (248).

### Immunocompromised Hosts

Although not at increased risk of infection, HIV-infected persons and other immunocompromised hosts may have more severe and prolonged illness; viral shedding for months has been observed in those with advanced immunodeficiency (150). An increased frequency of cardiopulmonary complications and hospitalizations occurs in HIV-infected persons, and persons with AIDS experience excess pneumonia and influenza-related mortality during epidemics (249, 250). Influenza in HIV-infected children has been associated with an eightfold-increased risk of hospitalization for lower respiratory illness. In South Africa HIV-positive adults, 5 to 64 years of age, have been estimated to account for 28% of seasonal influenza mortality (251), and increased mortality has occurred in HIV-infected pregnant women during both seasonal influenza and the 2009 pandemic (252).

Influenza virus infections in cancer patients have been associated with variable prolongation of clinical course, increased hospitalizations, and interruption of chemotherapy. Acute-leukemia patients with chemotherapy-induced neutropenia are at high risk of pneumonia and death following influenza. Chronically immunosuppressed solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) patients are at increased risk for influenza complications, prolonged virus replication, and emergence of antiviral drug-resistant variants. (253, 254). They may present with few symptoms initially but subsequently progress. Most solid organ transplant patients have self-limited infections, but fever may be prolonged and hospitalization frequent. Infection in

transplant patients has been linked with rejection, graft loss, and possibly hemolytic-uremic syndrome. Up to 50% of HSCT recipients develop lower respiratory tract disease, and up to 20% die without antiviral therapy, with the highest risk occurring during the period of aplasia.

### Complications

Influenza complications are common and may be manifested in the upper (otitis media and sinusitis) or lower (bronchitis, croup, and pneumonia) respiratory tract, as exacerbations of preexisting chronic diseases (e.g., asthma, chronic obstructive pulmonary disease, cystic fibrosis, diabetes mellitus, and congestive heart failure) or, less often, in extra-pulmonary sites or systemically (222, 255) (Table 6). The most common complications are bronchitis in adults, which occurs in as many as 20% of patients seeking care, and otitis media in children. Influenza is linked to approximately 10% of community-acquired pneumonias in adults, and about 30% of adults hospitalized with seasonal influenza have radiographic evidence of pneumonia (256, 257). A wide range of bacterial co-infections has been reported in hospitalized influenza patients (2–65%) depending on age, co-morbidities, prior antibiotic receipt, and illness severity (513). In patients with reactive-airway or chronic obstructive pulmonary disease, influenza is an important cause of exacerbations, and most illnesses are associated with spirometric deteriorations, usually lasting less than 3 months. Exacerbations of asthma, with FEV<sub>1</sub> (forced expiratory volume in 1 second) decreases lasting 2 to 9 days, occur in most cases of clinically apparent influenza. In patients with cystic fibrosis, influenza virus infections are associated with increased hospitalizations and disease progression, including decreases in spirometry.

### Viral Pneumonia

Influenza A, and less often influenza B, virus can cause severe primary viral pneumonia in those with underlying conditions and in previously healthy persons (256). Approximately 15 to 20% of young adults with influenza developed pneumonia in 1918, with associated fatality rates of 30% or higher; bacterial pathogens were detected from the lungs or blood in most fatal cases (169). During the 1957 pandemic, approximately 30% of fatal cases had influenza viral pneumonitis and/or tracheobronchitis without coexistent bacterial infection (258). Rapidly progressive viral pneumonia leading to acute lung injury and often refractory hypoxemia has been well-documented following A(H1N1)pdm09 infection (239). Mild forms of viral pneumonia with patchy radiographic infiltrates are more common, particularly in children, than severe primary influenza viral pneumonia. The latter occurs in 2 to 18% of adults hospitalized with pneumonia during epidemic periods. More than 90% of cases have been linked to influenza A virus infection, and most recognized cases occur in those over the age of 40 years. Various risk factors, including underlying cardiopulmonary disease, rheumatic heart disease (particularly mitral stenosis), malignancy, organ transplantation, corticosteroid or cytotoxic therapy, pregnancy, and possibly HIV infection, have been identified.

Patients present with a preceding influenza syndrome, followed by increasing cough, tachypnea, and dyspnea. The interval from onset of illness to disabling pulmonary symptoms is variable (<1 to 20 days), but most patients deteriorate within 1 to 4 days. Sputum production occurs in about one-half, and hemoptysis occurs in about one-third. Sputum Gram smear may show abundant PMNs without significant numbers of bacteria. The illness progresses over 1 to 4 days to cause severe respiratory failure, associated acute respiratory

distress syndrome (ARDS), and often multiorgan failure. Chest radiographs are nonspecific but typically show bilateral, diffuse mid-lung and lower-lung infiltrates (Fig. 11). Computed tomography is more sensitive than chest radiography at detecting parenchymal changes, which are often peripheral in location, and may show a wide spectrum of abnormalities including airway thickening and dilatation, peribronchial ground glass opacities, bilateral consolidation, centrilobular nodules, and tree-in-bud opacities (Fig. 12) (259, 260). The course may be protracted, but clinical and radiographic improvement usually occurs within 2 to 3 weeks in survivors. Presentation as Goodpasture's syndrome or a syndrome mimicking pulmonary embolism has been described. Bronchiolitis obliterans with organizing pneumonia, pulmonary fibrosis, and chronic functional impairment may develop in survivors.

Progressive pneumonia with development of ARDS and often multiorgan failure occur in the majority of hospitalized patients with avian A(H5N1) and A(H7N9) disease (Table 3) (115, 121). Similar patterns of leukopenia, lymphopenia, thrombocytopenia, and elevated aminotransferases, creatine phosphokinase (CPK), and LDH are seen in such patients (135). The median times from illness onset to presentation for care and to death are about 4 and 9 days in A(H5N1), illness, respectively.

### Secondary Pneumonia

Secondary bacterial pneumonias account for about 25% of influenza-associated deaths in interpandemic periods and were found in about 70% of patients with life-threatening pneumonia during the 1957 and 1968 pandemics (258, 261, 262). Reappearance of fever, increased respiratory symptoms, or cough productive of purulent sputum suggests the possibility of superimposed bacterial infection (262), but presentation with bacterial or mixed viral-bacterial pneumonia without a biphasic illness also occurs. The most common bacterial pathogen complicating influenza is *Streptococcus pneumoniae*, but *S. aureus* accounts for 12 to 25% or more of secondary bacterial infections, and *Haemophilus influenzae* is common (262). Group A beta-hemolytic streptococci, gram-negative bacilli, and *Neisseria meningitidis* infections are also seen. Severe pneumococcal pneumonia including empyema and lung abscess has been associated with influenza in previously healthy children. During the 1957 pandemic, *S. aureus* superinfection was the most common cause of fatal respiratory tract disease related to influenza and was associated with mortality rates of 28 to 48% irrespective of age or prior disease. Severe and often fatal cases of community-acquired, methicillin-resistant *S. aureus* pneumonia associated with influenza are being increasingly seen in both children and adults. Fungal infections, particularly *Aspergillus* infections, have been rarely reported in association with cutaneous anergy, lymphocytopenia, and sometimes systemic corticosteroid use. No clear association between preceding influenza and the occurrence of *Mycoplasma pneumoniae* or *Legionella* infections has been found (509). Specific transcriptomic signatures may prove useful in distinguishing influenza from bacterial pneumonia (263, 264). Blood procalcitonin measurement appears helpful in detecting mixed influenza-bacterial infections, in that low levels suggest that bacterial coinfection is unlikely (265).

### Extrapulmonary Complications

Other recognized but rare (<1% of cases) complications include a range of CNS syndromes (encephalitis or encephalopathy, meningitis, transverse myelitis, and polyneuritis),

acute parotitis, myocarditis and pericarditis, acute myositis, rhabdomyolysis with myoglobinuria, and acute renal failure, disseminated intravascular coagulopathy, arthritis, and Stevens-Johnson syndrome (Table 6) (222). CPK elevations may be as high as 10,000 IU/ml in influenza-associated rhabdomyolysis, which very rarely causes compartment syndromes. Transient subclinical electrocardiogram changes without associated cardiac enzyme elevations or echocardiographic abnormalities, lasting usually 2 weeks or less, occur in as many as one-quarter of adults with apparently uncomplicated influenza (266). While direct myocardial injury is rare in ambulatory adults (267), influenza is associated with increased risk of acute coronary and cerebrovascular events (268–270, 503). Severe cardiac involvement, rarely associated with recovery of virus from the myocardium or blood, has manifested as acute heart failure, pericardial tamponade or effusion, and fatal arrhythmia (271). Hepatic decompensation may occur in those with preexisting liver disease.

Acute CNS manifestations include seizures, coma without focal signs, delirium, behavioral disturbance, cerebellar signs, and increased intracranial pressure (272, 273). These events are more common in children but also occur in adults (274); both influenza A and B viruses have been implicated (275). Acute influenza encephalopathy in children is typically manifested by fever, seizures, altered mental status, and often rapidly progressive coma, usually within 5 days of illness onset. Multiple syndromes have been described (Table 6) (276), and less common findings include thalamic necrosis, increased CSF protein or pleocytosis, and presence of viral RNA in the CSF. Full recovery is usual in milder cases but necrotizing encephalopathy is associated with mortality >25% (276). Virus has rarely been isolated antemortem from the CSF or brain, although CNS dissemination has been documented in A(H5N1) disease (145).

Postinfluenza encephalitis begins 1 to 3 weeks after the illness and is ascribed to an autoimmune process with demyelination and vasculopathy. Patients develop fever and decreased consciousness or coma in association with lymphocytic pleocytosis and diffuse slowing on electroencephalograms. Encephalopathic symptoms usually resolve in 2 to 25 days. Influenza may uncommonly trigger Guillain-Barré syndrome (GBS) (277) and possibly narcolepsy (278). Possible linkage of influenza to delayed-onset encephalitis lethargica and postencephalitic parkinsonism remains to be proven (279–281).

Toxic shock syndrome may follow within 1 week of onset of influenza and has been linked to either respiratory tract colonization or infections, including sinusitis, pneumonia, or enterocolitis, with toxigenic *S. aureus* strains or group A streptococci (507). Influenza outbreaks are associated with an increased risk of invasive meningococcal disease (282), possibly related to virus-induced mucosal damage or immunosuppression. Cases usually occur within 2 weeks following influenza. Both influenza A and B virus infections have been associated with theophylline toxicity related to decreased clearance.

### Thogoto and Dhori Viruses

The small number of recognized human infections have been associated with meningitis, encephalitis, or systemic febrile illness, including rash, thrombocytopenia, leukopenia, and multiorgan failure (9).

## LABORATORY DIAGNOSIS

Influenza diagnostic testing is possible with a wide variety of laboratory assays (42, 283) (see Chapter 15). Testing is

generally indicated if the findings would result in a change in clinical management or have public health implications. Consequently, testing is clearly warranted in seriously ill or hospitalized patients, investigation of unexplained illness clusters and nosocomial outbreaks, and in patients with possible zoonotic infection by novel strains (e.g., history of exposure to swine, poultry, or markets or travel to areas with enzootic influenza). Under such circumstances molecular detection methods are preferred because of their greater sensitivity. However, single negative RT-PCR results do not exclude influenza, and, for critically ill patients with suspected influenza, testing additional respiratory specimens from multiple sites, especially lower respiratory tract ones, is important.

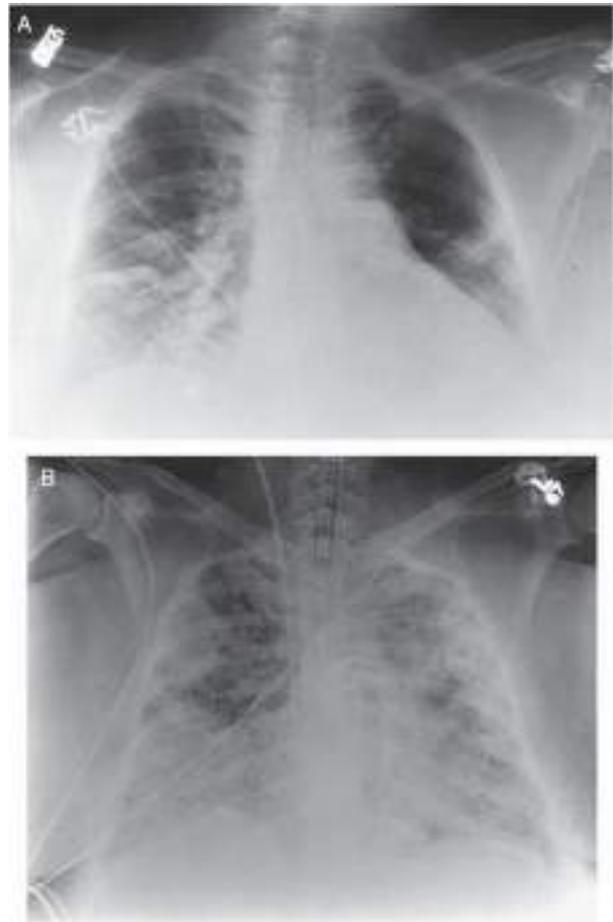

### Specimen Collection and Transport

Detection of influenza in clinical specimens depends on sample type and quality, duration of illness, patient age, and influenza virus strain. Influenza viruses can be readily isolated early in illness from various respiratory specimens, including nasopharyngeal swabs, nasal aspirates or washes, sputum, and tracheal aspirates. Throat swabs or washings contain lower virus concentrations and are usually less sensitive than nasal samples, except in sporadic A(H5N1) disease, in which the converse holds (147). Nasopharyngeal swabs or combined nose and throat swabs are reasonable specimens for upper respiratory tract sampling in uncomplicated illness, but lower respiratory ones (i.e., tracheal aspirates, bronchial washings) are advisable for seriously ill patients with lower respiratory disease. One recent study reported that upper respiratory tract samples were negative in 43% of critically ill influenza patients positive for virus in the lower respiratory tract (284). Upper respiratory specimens should be collected as soon as possible, preferably less than 3 to 4 days after illness onset. A swab with a wood shaft should not be used for respiratory specimen collection because it may interfere with molecular assays.

Samples for molecular testing can tolerate a broader range of transport conditions. Because freezing, especially in standard  $-20^{\circ}\text{C}$  freezers, of specimens may cause greater loss of infectivity than short-term storage at  $4^{\circ}\text{C}$ , refrigerated samples should be transported for processing within 1 to 4 days for virus isolation. Freezing at or below  $-70^{\circ}\text{C}$  more effectively preserves infectivity.

### Virus Isolation

Embryonated hen's eggs are a practical isolation system but may be less sensitive than cell culture for many contemporary human influenza viruses (42, 285). Primary rhesus or cynomolgus monkey kidney cell cultures are sensitive for most strains. Several continuous epithelial cell lines, particularly MDCK and the rhesus monkey kidney-derived LLC-MK2, are useful for primary isolation in conjunction with incorporation of trypsin into serum-free medium to effect proteolytic activation of HA. Because of its relative temperature stability, 1-tosylamide-3-phenylethylchloromethyl ketone-treated trypsin (TPCK trypsin) is recommended. MDCK cells are comparable in sensitivity to primary rhesus monkey kidney cells for most influenza virus strains. MDCK cells that are stably transfected to overexpress  $\alpha 2,6$ -linked sialic acid receptors appear to be useful for both *in vitro* susceptibility testing and isolation of virus from clinical specimens (286). Other cell types (e.g., Vero, mink lung, and MRC-5 human embryonic lung cells) will support primary isolation if trypsin is used. Isolation may be facilitated by incubation at  $33^{\circ}\text{C}$ , rolling cell culture tubes, and centrifugation of the sample

**FIGURE 11** Sequential chest radiographs from a 30-year-old nonimmunocompromised female with acute influenza A virus pneumonia. (A) Her symptoms began 1 day before first radiograph, which shows right middle and bilateral lower lobe infiltrates. Her respiratory status deteriorated rapidly, and she required mechanical ventilation but survived. (B) The second radiograph, taken approximately 24 hours after admission, shows diffuse infiltrates.

onto cell monolayers. Laboratory cross-contamination sometimes causes false-positive isolation results.

The CPE, particularly of influenza A viruses, is nonspecific and may be absent or difficult to detect. More than 50% of cultures show CPE within 3 days of inoculation, and more than 90% show CPE within 5 days. Virus replication is usually detected in cell culture by hemadsorption with guinea pig, turkey, or chicken erythrocytes, with detection performed at fixed times after inoculation or when CPE is noted. Because of changes in receptor specificity since 1993, use of chicken erythrocytes is not advised for detection of human strains. Blind hemadsorption of monolayers is positive in more than 85% of samples at 2 days, and nearly 100% of samples at 3 days, after inoculation. For detection of avian influenza viruses or HAI antibody testing, avian or horse erythrocytes are used, since these predominantly express  $\alpha 2,3$ -linked sialic acid receptors.

Identification of isolates can be done by HAI testing using antisera to current strains and appropriate types of erythrocytes or by immunofluorescence (IF) or enzyme immunoassays (EIAs) using type- or subtype-specific antisera. Nucleic acid amplification tests with selected primers and probes or sequence analysis of HA and NA genes provide

**FIGURE 12** Computed tomography of chest without contrast in a HSCT patient who developed severe A(H1N1)pdm09 pneumonia approximately 5 months posttransplantation, while taking prednisone 20 mg/day for chronic GVHD. The study was made approximately 5 days after illness onset and shows diffuse bilateral interstitial opacities, bronchial wall thickening, and a denser left posterior chest consolidation with air bronchograms. Figure courtesy of Dr. Michael Ison, Northwestern University, reprinted with permission.

rapid typing. Rapid detection of influenza virus antigen can also be accomplished by EIA or IF testing of monolayers.

Centrifugation of samples onto MDCK monolayers in shell vials or plates combined with antigen detection has a sensitivity of about 80% (range, 56 to 100%) at 1 or 2 days. Shell vial monolayers of mink lung or rhesus monkey kidney cells may provide greater sensitivity. A commercial mixture of mink lung and A549 cells (R-Mix) in shell vials is useful for detection of influenza and other respiratory viruses.

Primary isolation of influenza C virus has been accomplished in embryonated hen's eggs and a human malignant melanoma cell line (HMV-II) or sometimes MDCK cells, in which hemadsorption is positive with chicken, but not guinea pig, erythrocytes (102).

### Antigen Detection

Direct detection of influenza viral antigens in respiratory specimens has been accomplished with IF, EIA, radioimmunoassay, and time-resolved fluoroimmunoassay within 1 to 4 hours. Monoclonal antibodies directed against type-specific NP or M proteins overcome the variable antigenicity of the surface glycoproteins. Direct and indirect IF microscopy of respiratory epithelial cells with commercially available monoclonal antibodies is rapid and has a sensitivity greater than point-of-care (POC) antigen tests (below) (42). Nasopharyngeal aspirates usually have higher cellular content and are superior to swabs; cytocentrifugation may enhance sensitivity.

Multiple commercial EIAs for rapid ( $\leq 30$  minutes) laboratory-based or CLIA-waived POC diagnosis are available (287). The results are qualitative, and sensitivity depends on sample type and quality, duration of illness, patient age, and influenza virus type. Assay sensitivities are approximately 50 to 70% (range, 10 to 80%) and are higher in

children than in adults and higher in influenza A than in B virus infections (285, 288). Nasopharyngeal aspirates and swabs have somewhat higher yields than washing and throat swabs or gargles (285). Approved respiratory specimens vary among the FDA-cleared influenza assays. Clinical sensitivity is highest on days 2 and 3 of illness but decreases rapidly thereafter (288). Analytic sensitivity varies across assays and viruses, in part, related to the ability of the various proprietary monoclonal antibodies used to detect NP differences, and may be lower for A(H1N1)pdm09, swine variant, and some avian influenza viruses (289–291). Mucoïd samples, like sputum or tracheal aspirates, cause false-positive or -negative reactions in some assays. Consequently, false negative results are common, especially in adults when influenza activity is high, and negative results should not be used to guide management decisions. Although assay specificities (range, 85–100%) are generally high, false positive results occur, especially during periods of low influenza activity, so that confirmation by RT-PCR or viral culture may be required. The use of objective readout devices (Sofia Influenza A+B and BD Veritor System) help reduce false positive results. Positive results may occur up to one week after intranasal live-attenuated influenza vaccine (292).

### Nucleic Acid Detection

Many commercial (293) and in-house RT-PCRs (singleplex and multiplex; real-time and other RNA-based) and other molecular assays are available for influenza virus RNA detection. Depending on the specific assay, a broad range of specimen types can be tested with performance times ranging from 1 to 8 hours. Such assays are more sensitive than virus isolation in detecting influenza virus in clinical samples, in part, because they can detect noninfectious virus RNA, although their higher sensitivity may also overestimate the infectious period (57). Multiplex commercial assays (e.g., FilmArray Respiratory Panel, BioFire Diagnostics, LLC; Verigene Respiratory Pathogen Nucleic Acid Test, Nanosphere, Inc.; x-TAG Respiratory Viral Panel, Luminex Molecular Diagnostics Inc.) can also detect other respiratory pathogens. Multiplex primer combinations can distinguish between A and B types and, in some assays, circulating influenza A H1 and H3 subtypes; positive but nontypable results should prompt consideration of infection by novel strains.

Recently FDA-approved, influenza-specific rapid molecular assays can provide results in less than 30 minutes for POC testing. One (Alere i Influenza A&B) is CLIA-waived for use with nasal swab specimens (294), and another (Roche Cobas Influenza A/B) is CLIA-waived for use with nasopharyngeal swabs. Their reported sensitivities range from 70 to 100% (293).

Lower respiratory tract samples (tracheal aspirates, BAL) have higher yields than upper respiratory tract samples in those with viral pneumonia, especially when due to zoonotic influenza viruses. Only the USCDC RT-PCR assay, available at qualified public health laboratories, is currently FDA-approved for lower respiratory tract specimens. Off-label use of commercial assays is an alternative, but some may lack sensitivity for detecting swine or avian viruses (290). Sensitive multiplex real-time RT-PCR assays provide rapid quantitative detection of influenza A and B virus RNA and can be used in combination with shell vials, which can also provide isolates for analysis (295). Nucleic acid amplification assays with selected primers, or combined with restriction enzyme analysis, can detect influenza A viruses harboring M2 gene mutations associated with resistance to adamantanes or

selected NA mutations associated with resistance to neuraminidase inhibitors. In addition, this approach can differentiate between the genes of vaccine-like strains and circulating ones and provide data about HA genetic drift.

### Serology

Serologic studies are not useful for the rapid diagnosis of influenza because most cases are reinfections, and paired acute- and convalescent-phase sera are usually needed. Commonly used assays include complement fixation (CF), HAI, and enzyme-linked immunosorbent assay (ELISA). Less commonly employed tests include neutralization (Nt) or microneutralization, single radial hemolysis, radial immunodiffusion, passive hemagglutination, and NA inhibition. The CF test utilizes type-specific internal antigens (NP), and, unlike the HAI test, it is not influenced by the antigenic variability of the circulating strain or by the presence of serum inhibitors. However, CF is less sensitive than HAI or ELISA and detects a rise in antibody titer in no more than 70% of infections. HAI titers reflect subtype- and strain-specific antibodies directed to HA. HAI testing requires inactivation of nonspecific inhibitors in the sample, and its sensitivity depends on the antigenic variant employed. Sensitivity is enhanced by antigen preparation in cell culture and, particularly for influenza B virus, ether treatment of antigen. Because anamnestic responses frequently occur, inclusion of antigens that resemble circulating strains and those of past prevalent strains increases diagnostic yield. Fourfold-or-greater rises in antibody titer occur in 80% or more of infections. The Nt test is the most specific of the conventional assays, correlates best with protective immunity, and is the current serologic method of choice in A(H5N1) infections but is labor-intensive. Detection of HAI antibodies to H5 with horse erythrocytes or by Nt testing with pseudotyped virus expressing H5 HA may overcome this problem (296). Antibody detection by ELISA is more sensitive than other assays and can be used to measure HA-specific responses or particular antibody types.

## PREVENTION

### Nonpharmaceutical Interventions

The effectiveness of various nonpharmaceutical interventions like social distancing, hand hygiene, cough etiquette, and masking in influenza prevention has received considerable attention in the context of both seasonal influenza and pandemic response. Timely implementation of multiple public health measures, including combinations of school closures, cancellation of mass gatherings, case isolation, and voluntary quarantine of contacts that were taken in some cities during the 1918 pandemic, appears to have reduced its community impact, although the value of any individual intervention is uncertain (297). Holiday periods are associated with reduced seasonal influenza rates, and prolonged school closures are predicted to reduce peak attack rates and cumulative numbers of cases in children and adults (298). Such interventions are being contemplated as part of a community mitigation strategy in the face of a pandemic or outbreak associated with high mortality.

In community and household settings, reduced risk of virus exposure can be accomplished with adherence to frequent hand hygiene and cough etiquette for those with illness. Soap and water or alcohol-based hand rubs are highly effective in reducing influenza virus on hands (299). Other common sense interventions include minimizing visitors

other than necessary caregivers, maintaining adequate ventilation in shared areas, and avoiding exposure of at-risk persons to ill ones (e.g., pregnant women should not provide care for ill persons). The value of hand hygiene alone in preventing influenza transmission remains uncertain and may vary by context. Regular hand hygiene appeared partially effective in Egyptian schoolchildren (300). Early implementations and compliance with both masks and hand hygiene appear to lower the risk of transmission to household contacts (301, 302).

### Zoonotic Infections

Avoidance of exposure can reduce the risk for zoonotic infections. Live bird markets are central to human infections by avian influenza viruses, and their closures have been temporally associated with cessation of avian A(H7N9) infections in humans (131, 132). Travelers to countries with known outbreaks of avian influenza should avoid poultry farms, contact with animals in live bird markets, entering areas where poultry may be slaughtered, and contact with any surfaces that may be contaminated with excreta from poultry or other animals. Similarly during swine influenza outbreaks, persons at increased risk for complications from influenza should avoid swine and swine barns at agricultural fairs or other affected sites. Frequent hand hygiene and adherence to good food safety and hygiene practices are always sensible and may contribute to risk reduction.

### Nosocomial Infections

Patients hospitalized with human influenza should be managed with standard and droplet precautions, preferably in an individual room. Cohorting of influenza patients may be necessary during high demand periods. When feasible, masking of suspected or proven influenza patients in healthcare settings (e.g., emergency department, during transport, in radiologic facilities) probably reduces environmental contamination and the risk of nosocomial transmission. Surgical masks are effective in preventing the dispersion of influenza RNA-containing droplets from coughing patients (303). For protection of healthcare workers caring for influenza patients, the incremental value of using fit-tested respirators compared with surgical or procedure masks remains uncertain (304). Cloth masks are much less effective than medical masks (305). Under experimental conditions fit-tested N-95 respirator and eye protection are required for protection against exposure to influenza virus in small particle aerosols (306). Respirators should be used in circumstances of aerosol-generating procedures, and eye protection (goggles or face shields) is also warranted. Visitors should be minimized in general during community outbreaks and prohibited if ill. Healthcare worker immunization and, under some circumstances, antiviral chemoprophylaxis are important tools to mitigate the risk of nosocomial transmission (see below).

### Inactivated Vaccines

Inactivated influenza vaccines were initially introduced in the 1940s but were impure, reactogenic, and variably potent. During the 1970s, split and subvirion preparations, using embryonated hen's eggs as the substrate, were introduced. In most countries, whole virus vaccines have been replaced by these less reactogenic split virus ones, in which virus has been disrupted by detergent, and subunit ones, in which the HA and NA antigens have been purified by removal of other viral components. More recently, vaccine production in cell

culture, recombinant HA vaccines, and adjuvants including proprietary oil-in-water ones (e.g., MF-59, AS03) have been introduced into clinical use. A wide variety of seasonal vaccines are now approved for use in the United States (Table 8) and many other countries. Additional vaccines, including virosomes and higher-dose intradermal ones, are approved in different countries (307). Antigens for the majority of inactivated vaccines are still mass produced in embryonated chicken eggs by use of high-yield reassortant viruses that express the HA and NA of circulating strains, although cell culture-based production methods are increasing. Residual egg proteins can rarely cause immediate hypersensitivity reactions in those with severe egg allergy and possibly contribute to other adverse effects (see below), but a recombinant HA vaccine devoid of egg proteins is now available (Table 8).

The HA content of inactivated vaccines is standardized at a minimum of 15 µg per antigen for those aged ≥ 3 years (9 µg for intradermal vaccine), although higher HA dose vaccines are approved in certain age groups (Table 8). Hemagglutination-inhibition (HAI) antibody titers correlate closely with those measured by microneutralization and are the traditional ones used to assess vaccine-induced serologic responses and cross-reactivity to new variants. The composition of influenza vaccines is determined semiannually on the basis of the antigenicity of circulating influenza viruses through the WHO's Global Influenza Surveillance and Response Network (308). Recent seasonal vaccines contain antigens of two influenza A virus subtypes (H3N2 and H1N1) and of one or two influenza B virus lineages. Quadrivalent vaccines provide greater influenza B coverage and are increasingly replacing trivalent ones. The waning of vaccine-induced immunity over time necessitates annual reimmunization even if the vaccine antigens are unchanged. Annual guidelines for immunization are published by the U.S. CDC (Table 1).

### Immunogenicity

Inactivated vaccine is highly immunogenic in young adults but less so in the elderly, infants, and persons with chronic illness or immunosuppression, including those with HIV disease, solid-organ and bone marrow transplant recipients, and in those receiving cancer chemotherapy. Immunogenicity is also lower in those with high preexisting antibody levels. Vaccine seroresponses, and perhaps vaccine effectiveness, may be diminished with repeated annual immunization, especially when there are small or no changes in vaccine strains (309–312). Protection against illness correlates with serum HAI antibody levels (generally titers ≥ 1:40 provide 50% protection against illness in healthy adults), but illness may occur despite high postimmunization HAI titers (313). Parenteral immunization may stimulate limited mucosal antibody production and CTL responses. In primed healthy adults, immunization results in presumably protective levels of serum HAI antibody in >85% for the homologous strain. Because 60% or fewer of unprimed children respond, two doses of vaccine at least 1 month apart are required. Protective HAI antibody responses usually occur within 10 days in responding adults, including those with cardiopulmonary disease. The duration of protection following immunization against homotypic virus is uncertain but may last up to 2 to 3 years. Vaccine-induced antibodies to NA also appear to confer protection against illness (314), but anti-NA responses are seen in less than one-half of vaccine recipients, and the NA content of FDA-approved vaccines is not routinely measured.

Age-related declines in serologic and CTL memory responses to vaccine occur with advancing age, and failure of vaccine boosting occurs more commonly in the elderly. The degree of infirmity, rather than increasing age by itself, is a critical determinant of decreased vaccine responsiveness. Chronic statin use may be associated with reduced antibody responses in the elderly (315). However, vaccine administration in the morning appears to increase immunogenicity (508). A second dose of vaccine at 1 or 3 months does not boost serum HAI titer responses in healthy, elderly persons (316). High dose vaccine containing fourfold-higher antigen content (60 µg of HA) improves immunogenicity in the elderly, HIV-infected persons, and adult oncology patients receiving chemotherapy compared to standard-dose inactivated vaccine (317–319). An MF-59 adjuvanted vaccine, available in multiple countries, appears to induce somewhat higher and broader antibody responses in the elderly than nonadjuvanted vaccine (320) and was approved for this age group in 2015 in the United States (Table 8). T-cell responses may be better correlates of vaccine protection in the elderly than antibody levels (321). While later booster doses do not appear to increase protection in the frail elderly, a second dose may improve immunogenicity in certain high-risk groups (e.g., organ transplant or chemotherapy recipients).

### Effectiveness

Influenza virus vaccines vary in their effectiveness depending on the formulation used in a particular year, on the age and health status of the vaccinee, and on the overall virulence of the circulating strains. Seasonal vaccine efficacy in preventing clinical influenza is generally moderate but may be low or absent in some seasons, in part, related to the degree of antigenic match between the epidemic virus and vaccine strains. The efficacy of inactivated vaccines in preventing illness is generally 50 to 70% in adults aged 18 to 64 years, but high-quality data are lacking in the elderly (≥ 65 years) (322). MDCK-produced vaccine provides similar protection to vaccine from eggs (323). Immunization of ambulatory adults reduces absenteeism and physician visits due to respiratory illness by about 30 to 60% during epidemic periods, as well as the risk of influenza-associated pneumonias (324). Vaccine coverage level among adults aged 18 to 64 years is also associated with reduced influenza risk in the elderly (325).

Inactivated vaccine efficacy in children aged 6 to 72 months is generally low (43% in one major trial) but can be increased by using MF-59 adjuvant (326). Influenza vaccine in children is more efficacious in preventing moderate-severe than mild illness (327). Immunization of children (inactivated or LAIV) reduces the risk of influenza-related otitis media and influenza-associated pneumonia (324), as well as the likelihood of illness in nonimmunized household and community contacts (328, 329). Wide-scale immunization of school-age children may lessen the community impact of epidemic influenza and, in Japan, was temporally associated with reduced respiratory and overall mortality in older adults (330).

Among ambulatory older adults in the community, immunization provides about 50 to 60% protection against influenza, is cost saving, and reduces hospitalizations and mortality during outbreaks (331, 332). During the seasons 2005/06 through 2013/14, immunization was estimated to have prevented a total of 25,694 to 59,210 deaths in the United States (333). Immunization is associated with a lower risk of major adverse cardiovascular events, particularly in those with more active coronary disease (334). Compared to standard vaccine, high-dose vaccine (Table 8)

**TABLE 8** Seasonal influenza vaccines approved for use in the United States, 2015–2016 season<sup>a</sup>

Vaccine type designation	Production substrate	No. companies (trade names)	Approved age range (years)	Route of delivery	HA dose (ug) per antigen	Comment
Inactivated influenza vaccine, quadrivalent (IIV4)	Eggs	3 (Fluarix Quadrivalent, FluLaval Quadrivalent, Fluzone, Quadrivalent,	≥0.5 <sup>b</sup>	IM (0.25 for 6–35 months, 0.5 ml for >36 months)	15 (for 0.5 ml dose)	
Inactivated influenza vaccine, trivalent (IIV3)	Eggs	3 (Afluria <sup>c</sup> , Fluvirin, Fluzone)	≥0.5 <sup>b</sup>	IM (per above)	15 (for 0.5 ml dose)	Needle-free jet injector approved 2014 for delivery of Afluria in those aged 18 to 64 years. Potential risk of febrile reactions in children <9 years old with Afluria <sup>c</sup>
IIV3, High-dose	Eggs	1 (Fluzone High Dose)	≥65	IM	60	
IIV3- Intradermal	Eggs	1 (Fluzone Intradermal Quadrivalent)	18–64	ID (0.1 ml by microinjector)	9	
IIV3- Cell culture	MDCK cells	1 (Flucelvax)	≥18	IM	15	Minute quantities (<5x10 <sup>-8</sup> µg) of total egg protein including ovalbumin per dose
IIV3- MF59-Adjuvanted	Eggs	1 (Fluad)	≥65	IM	15	Approved 2015 in the USA
Recombinant influenza vaccine, trivalent (RIV3)	Insect cells	1 (FluBlok)	≥18	IM	45	No ovalbumin or egg protein Expanded age range approved 2014.
Live-attenuated influenza vaccine, quadrivalent (LAIV4) <sup>f</sup>	Eggs	1 (FluMist)	2–49 <sup>d</sup>	IN spray (0.2 ml divided between nostrils)	~10 <sup>7</sup> infectious doses per virus	Not approved for pregnant women or those with comorbidities. See contraindications and precautions <sup>d</sup>

<sup>a</sup>Adapted from US Centers for Disease Control and Prevention (341). Contraindications to influenza vaccines include severe allergic reaction to any vaccine component, including egg protein, or after previous dose of any influenza vaccine. Precautions include moderate to severe acute illness with or without fever; history of Guillain-Barré syndrome within 6 weeks of receipt of influenza vaccine.

<sup>b</sup>Approved age range varies with particular product.

<sup>c</sup>ACIP recommends Afluria not be used in children aged 6 months through 8 years because of increased risk of febrile reactions noted in this age group with bioCSL's 2010 Southern Hemisphere IIV3.

<sup>d</sup>ACIP recommends LAIV4 not be used for pregnant women, immunosuppressed persons, persons with egg allergy, and children aged 2 through 4 years who have asthma or who have had a wheezing episode noted in the medical record within the past 12 months, or for whom parents report that a healthcare provider stated that they had wheezing or asthma within the last 12 months.

Persons who care for severely immunosuppressed persons who require a protective environment should not receive LAIV4 or should avoid contact with such persons after vaccination.

<sup>f</sup>Because of LAIV's poor and/or lower than expected vaccine effectiveness in three recent seasons, the ACIP has recommended against use of LAIV in children for the 2016-17 season (CDC Media Statement, 22 June 2016).

is associated with further reductions in influenza illness and associated hospitalizations or emergency department visits in those aged  $\geq 65$  years (317, 335). MF-59 adjuvant also appears to increase the protection of inactivated standard vaccine in the elderly (320, 336). Although not approved for use, an AS03-adjuvanted seasonal vaccine also has higher efficacy for prevention of influenza A(H3N2) illness than does a nonadjuvanted one (337).

In nursing home residents, protective efficacy against influenza illness ranges widely and averages only 20 to 45%. However, immunization reduces influenza-related hospitalizations and mortality in such persons. High nursing home immunization rates ( $\geq 80\%$  of residents) may indirectly confer protection against outbreaks by increasing levels of herd immunity (106).

### Reactogenicity

Injection may cause local redness, tenderness, and induration for 1 or 2 days in as many as one-third of vaccinees. Fever and constitutional symptoms beginning 6 to 12 hours after vaccination and lasting for several days occur in 1 to 5% of adult recipients and more often in young children. Elderly subjects tend to have lower rates of local and systemic reactions, although high-dose and MF-59 adjuvanted inactivated vaccines are associated with higher frequencies of injection site reactions than standard dose vaccine. Because of the potential for causing febrile reactions, only split-virus or subvirion vaccine should be used for seasonal immunization in children. An oculo-respiratory syndrome (red eyes, facial edema, sore throat, and respiratory complaints) starting within 2 to 24 hours of immunization and resolving spontaneously within 2 days has been described uncommonly with some vaccine lots but is not a contraindication to immunization (338).

Immediate hypersensitivity reactions (e.g., hives, wheezing, anaphylaxis) are usually secondary to egg protein hypersensitivity, so the vaccine should be used with caution in patients who have documented allergies to eggs or egg products. However, allergic reactions are rare even in those with history of egg allergy (339) and have occurred after receipt of egg-free recombinant vaccine, indicating that some reactions are not due to egg proteins (340). Those who had serious reactions to eggs (e.g., angioedema, respiratory distress, lightheadedness, recurrent emesis, resuscitation) may receive RIV3 if they are aged  $\geq 18$  years (Table 8) and there are no other contraindications (341). Severe allergic reaction to influenza vaccine is a contraindication to future receipt of the vaccine.

A temporal association between immunization and GBS development within 6 weeks was found during the 1977 swine influenza immunization program, during which approximately 430 GBS cases occurred among 41 million vaccinees, a rate estimated to be sevenfold higher than expected (342). Whether influenza vaccines in certain seasons may be associated with a low risk of GBS ( $\sim 1$  per  $10^6$ ) in older vaccinees is unresolved. The causes of an association between receipt of AS03-adjuvanted A(H1N1)pdm09 vaccine and narcolepsy in genetically predisposed children and adolescents remain under investigation (343, 344). Reported associations of influenza immunization with exacerbations of asthma, systemic vasculitis, recurrent GBS, adverse ocular effects, or pericarditis remain unproven; asthma exacerbations are not associated with inactivated vaccine. No important changes in drug metabolism have occurred with current vaccines. Pneumococcal and influenza vaccines can be given at the same time at different

sites. When administered together with either pneumococcal or a diphtheria-tetanus-acellular-pertussis-containing vaccine, inactivated influenza vaccine is associated with a small increased risk of febrile seizures in children aged 6–23 months (510).

### Target Populations

The United States adopted a policy of universal influenza immunization for all persons aged 6 months or older and without contraindications in 2010. In other countries, populations targeted for immunization vary but generally include both those at increased risk for influenza-related complications (Table 7) and persons who are in close contact with high-risk individuals, particularly healthcare workers. Healthcare worker immunization probably reduces both absenteeism and the risk of nosocomial transmission with its associated mortality (345, 346). Strategies that increase vaccine uptake in healthcare providers include ready access to no-cost vaccine in the workplace and especially mandatory employer requirement (514).

WHO recommends that pregnant women should have the highest priority for seasonal influenza immunization and that additional risk groups for consideration (in no particular order of priority) are children aged 6 to 59 months, the elderly, individuals with specific chronic medical conditions, and healthcare workers (347). Pregnant women are an important risk group, in whom immunization reduces influenza risk in both mother and newborn (348, 349). Immunization also appears to reduce the risk of stillbirths by about one-half (350). Inactivated vaccines are safe, and pregnant women can be vaccinated at any stage of pregnancy (347). Administration of inactivated vaccine is considered safe during any stage of pregnancy. Foreign travelers, particularly elderly or high-risk persons, should be immunized before travel to the tropics during any time of the year or during April to September if travel is to the southern hemisphere. Immunization is appropriate for anyone who wishes to reduce his or her risk of acquiring influenza.

In HIV-infected persons, advanced disease is associated with low antibody responses, which are not augmented by a booster dose or doubled HA antigen content. Those with CD4 counts of  $< 100/\text{mm}^3$  rarely show antibody rises, but immunization appears to be protective in those with CD4 counts of  $> 200/\text{mm}^3$  despite diminished HAI responses (351). Influenza immunization may be followed 1 to 4 weeks later by transient increases in plasma virus titers in some recipients, but the clinical significance of such changes is doubtful, and no long-term effects on CD4 counts or clinical progression have been recognized (351, 352).

Those with hematologic malignancies, including myeloma, often have reduced responsiveness to vaccine (351). Oncology patients manifest HAI antibody responses less often when they are immunized concurrently with, or shortly after, chemotherapy compared to immunization between courses of chemotherapy. If immunization is required during chemotherapy, a two-dose schedule of vaccination separated by 3 to 5 weeks has been suggested, since this significantly increases the antibody responses in lymphoma patients. For children with malignancy, immunization after at least 1 month off chemotherapy and when the peripheral leukocyte count exceeds 1,000 improves immunogenicity. Immunization within the first 6 to 12 months following bone marrow transplantation is ineffective, but responsiveness gradually returns by 2 years in most patients.

Immunization is generally safe in solid-organ transplantation, but many recipients of such transplants, including

heart, lung, and liver transplants, have deficient HAI responses (351, 353). A booster dose 1 month after the initial one does not generally improve response rates but may in some transplant patients. Antiviral chemoprophylaxis (discussed below) offers an alternative or supplemental means of protection.

### Pandemic Candidate Vaccines

A wide range of candidate A(H5N1) vaccines have been tested in humans (354). The H5 HA is a weak human immunogen, and two doses of nonadjuvanted, inactivated split-vaccine with a high HA-antigen content (45 to 90 µg) are needed for immunogenicity in the majority of healthy adults and children (355). In 2007 this vaccine was approved by the FDA for use in first responders and individuals at risk for A(H5N1) infection, becoming the first avian influenza vaccine licensed in the United States. Alum adjuvants do not improve immunogenicity much, but proprietary oil-in-water adjuvants (e.g., MF-59 and AS03) provide substantial HA antigen sparing and cross-clade immunogenicity (356, 357). Whole-virus A (H5N1) vaccines also appear to reduce antigen requirements and give broader immunogenicity. AS03-adjuvanted vaccine with HA doses as low as 3.8 µg elicit strain-specific neutralizing antibodies and cross-reactive antibodies to heterologous A(H5N1) viruses. AS03-adjuvanted A(H1N1)pdm09 vaccine was also more effective than a nonadjuvanted one in children <10 years of age (358). This vaccine (Prepandrix, GSK) has been approved in multiple countries, including in the United States since 2013, for use in persons 18 years of age and older, at increased risk of exposure to the influenza A(H5N1) virus, and is included in the USA national stockpile. In general antibody titers decline rapidly but can be boosted with additional vaccine doses; prime-boost strategies elicit more robust immune responses (354). One dose of a nonadjuvanted A(H3N2)v vaccine is immunogenic in healthy adults (359).

Inactivated A(H7N7) and A(H7N9) vaccines are also poorly immunogenic in humans, but two doses of AS03- or, to lesser extent, MF-59- adjuvanted inactivated A(H7N9) vaccine induces robust antibody responses in adults (360, 361).

### Live Attenuated Vaccines

Intranasally administered live attenuated influenza virus vaccines (LAIV) have been used extensively in Russia and were licensed for commercial use in the United States in 2003. Cold-adapted, temperature-sensitive, attenuated donor viruses (A/Ann/6/60/H2N2 and B/Ann Arbor/1/66), which are able to grow at 25°C but are restricted at 39°C, have been used to make reassortants containing six internal genes from donor virus and two genes encoding the HA and NA from wild-type strains. Several gene segments contribute to the attenuation/temperature sensitivity phenotype of the live attenuated influenza A (with mutations in PB1, PB2, and NP) and influenza B (with mutations in PA, NP, and M1) virus vaccines (362, 363). These reassortant viruses are well tolerated, genetically stable, rarely transmissible to contacts, and immunogenic, following intranasal administration in seronegative children and adults. Serum antibody responses are lower in adults than those detected after administration of inactivated vaccines.

### Immunogenicity

Immune responses to multivalent LAIV are influenced by preexisting immunity, the infectivity of each vaccine virus, and interference among vaccine viruses. The 50% infectious

doses are about 10- to 100-fold lower for seronegative infants than for adults, but interference among vaccine strains reduces responses in seronegative children. Although single doses are often immunogenic (364), two doses appear to be necessary to confer multistrain protection in young children. Potential advantages of cold-adapted (ca) vaccines include ease of administration (nose drops or coarse spray), induction of local secretory antibody, protection against drift variants, and possibly induction of heterosubtypic CTL responses.

### Effectiveness

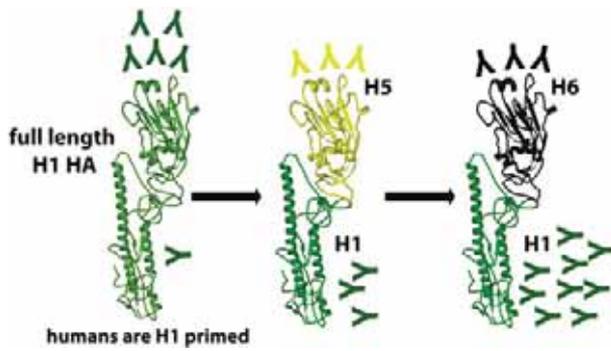

The efficacy of LAIV in children aged 6 to 59 months is approximately 70 to 90% but has been negligible in some seasons (322, 364, 365). Its efficacy has been superior to that of inactivated vaccine in healthy children, including protection against antigenically drifted strains (366, 367), although not during recent seasons (365). As a consequence, the ACIP has recommended against use of LAIV in children for the 2016–17 season. LAIV efficacy is often lower than that of inactivated vaccine in healthy adults ≤65 years old (368–370), perhaps because of preexisting immunity inhibiting LAIV replication. In children, LAIV is protective against influenza-associated complications, including otitis media (364). School-based immunization programs can increase coverage, decrease influenza rates, in part through herd immunity, and improve school attendance (371). Wide-scale immunization of school-aged children appears to lessen the community impact of epidemics (372). Compared to inactivated vaccine alone, combined administration of inactivated and intranasal LAIV may have given greater protection against influenza in elderly nursing home residents in one trial (373), although not significantly so in ambulatory patients with chronic obstructive pulmonary disease (374).

### Reactogenicity

LAIV is licensed for use in the United States only in healthy persons aged 2 to 49 years, but it appears to be safe in those with underlying pulmonary disease or HIV infection (CD4 count, >200 cells/mm<sup>3</sup>) (Table 8). Intranasal LAIV may be associated with coryza (5 to 30% of recipients), sore throat (10%), and in children, transient febrile reactions (5%) or decreased activity level, typically on the second or third day after inoculation. An increased frequency of medically significant wheezing episodes has been found in children younger than 2 years of age (367). Detection of LAIV virus lasts up to 1 week in adults and up to 3 weeks in very young children. Transmission of vaccine virus may sometimes occur among young children. Healthcare workers and others who receive LAIV should avoid contact with highly immunocompromised persons (e.g., stem cell transplant recipients in protected environments) for 1 week after immunization. Whether LAIV might be associated rarely with GBS requires further study (375). LAIV appears to be safe in children aged 2–18 years with a history of egg allergy (499).

### Pandemic Candidate Vaccines

Candidate A(H5) LAIV vaccines, 6:2 reassortants containing the HA and NA genes of an influenza virus of pandemic potential, have shown variable immunogenicity. One with an Ann Arbor backbone had very limited replication and antibody responses in volunteers, despite high intranasal doses (376). However, this vaccine induces long-lasting immunity that leads to cross-clade immunogenicity after boosting with inactivated vaccine (377). Another LAIV using the A/Leningrad/134/17/57 ca/ts virus backbone and an HA derived from low pathogenicity A/duck/

**FIGURE 13** Chimeric hemagglutinin-based universal influenza virus vaccine approach. Most humans have preexisting immunity against the H1 hemagglutinin (HA) (green). The majority of the antibodies is directed against the immunodominant head of the HA (green) because of repeated exposure to H1N1 viruses. Few antibodies (green) are made against the immunosubdominant stalk of the HA. Upon vaccination with a chimeric HA vaccine containing, for example, a cH5/1 HA, the HA stalk antibodies (green) will be boosted, but only a primary (low) response against the novel H5 head (yellow) will be measured. A second boost with another chimeric vaccine cH6/1, which expresses the same H1-stalk (green), will further enhance the stalk antibodies. The response to the H6 head domain is again a (low) primary response (black). For a complete universal influenza virus vaccine, two chimeric influenza A virus components are needed (one, expressing a group 1 HA stalk and the other, expressing a group 2 HA stalk) and a third one, which expresses an influenza B virus stalk (all in the context of exotic HA head domains). Such a vaccine with chimeric HAs should also result in enhanced protective anti-NA responses mediated by the (immunosubdominant) neuraminidases present in the preparation. Courtesy of Krammer reprinted with permission.

Potsdam/1402-6/86 (H5N2) virus (378) and has been licensed for use in Russia; it also is effective at priming responses to inactivated vaccine (379). LAIV vaccines have also been developed for H7 virus infection (380) and also prime for responses to inactivated vaccine (381). The potential for reassortment during co-infection with a LAIV pandemic vaccine and seasonal influenza viruses to yield transmissible, virulent strains constrains use of the former until a pandemic virus has emerged.

### Novel and Universal Vaccines

Public health needs exist for more effective, long-lasting, and more broadly protective influenza vaccines. The first approach to make improved vaccines and to produce them faster would be to undertake efforts to eliminate the more than half-century-old manufacturing process using embryonated eggs for growth and utilize cell culture-based production. Most current vaccine production does not take advantage of reverse genetics techniques (382) (see Figure 4B) that would allow the rapid use of master seed viruses with defined high yielding characteristics and permit sequence-based quality controls of the vaccine products (383, 384) (Table 9). Further strategies involve the expression of recombinant proteins in a variety of cell systems including plant and insect cells (385–387) and the production of recombinant virus-like particles (VLP) in insect cells. An experimental A(H7N9) vaccine of this type combines the HA and the NA with an M1 protein (388).

In order to broaden the protective efficacy of influenza virus vaccines, different combinations of prime-boost vac-

ination strategies are being investigated with promising results (389). Whereas these approaches are not aimed at heterosubtypic immunity (against different subtypes), they are likely to provide better heterogeneous protection (against different variants of the same subtype) than currently available vaccines. Whether virus-vectored influenza virus vaccines will be successful remains uncertain because repeated vaccination with the vector is probably made more difficult due to initial immune responses against the vector itself. Such an approach may, however, be advantageous in inducing strong T cell-mediated responses (390, 391). Other approaches include live-attenuated vaccines based on either the truncation of the NS1 protein (392) or the complete deletion of the NS1 (393), PB2 (394), or HA (395, 396) proteins. The latter constructs induce potent T cell responses. Another approach is the use of novel constructs (31) that present B- and T-cell epitopes, which are combined into a cocktail (Multimeric-001) for the purpose of inducing broad immunity against A and B strains.

The development of a universal influenza virus vaccine providing long-lasting immunity against viruses expressing different HA and NA subtypes remains elusive. Early on, subviral particles, prepared by acid (pH5) and mercaptoethanol treatment of purified virus, induced a strong immune response in animals against the conserved HA2 domain of the HA. However, this vaccine construct did not protect against subsequent virus challenge (397), presumably because the epitopes inducing a protective response had been destroyed by the chemical treatment of the virus. More recently, the highly conserved 22-23 amino-acid ectodomain of the M2 transmembrane protein (M2e) has been used (in the form of fusion proteins) to induce cross-protective immune responses (398, 399), although these have yet to undergo field testing. Another concept of a universal influenza virus vaccine is based on “centralized sequences” or computationally optimized broadly reactive antigens (COBRAS) of HAs (400). Although the earlier attempt to construct a vaccine based on the conserved HA2 (in essence the conserved stalk domain) was not successful (397), an H1-based headless HA displayed on a virus-like particle showed cross-reactive antibodies against subtype 2 and subtype 5 HAs (401). Additional headless and peptide constructs comprising epitopes of the stalk region are being studied, but they show limited efficacy in mouse models as yet (402–405).

A more promising approach to expanding anti-HA stem responses appears to be the use of vaccines containing a chimeric HA. In the simplest application, individuals who have been exposed to H1N1 viruses would be immunized once with vaccine expressing a chimeric HA (e.g. cH5/1), which has an exotic H5 head domain and the stalk of the H1 HA. This vaccination strategy would amplify the B memory cells directed against the stalk of the H1 HA (and very few antibodies would be directed against the H5 head). A second immunization with a virus containing the chimeric cH6/1 HA (expressing an H6 head domain and the same H1 stalk) would result in further stimulation of stalk antibodies but a low response to the H6 head domain (Fig. 13). In effect, this immunization strategy represents a redirection of the immune response from the immunodominant head domain towards the HA stalk component of the vaccine (406, 407). It is hoped that this redirection towards the immunosubdominant HA stalk would enhance the induction of NA antibodies. The NA exhibits low antigenic drift and antibodies against the NA can be cross-protective in animal challenge models and are correlated with protection in

**TABLE 9** Novel influenza virus vaccine technologies

Technology	Comments
Cell culture, reverse genetics and sequencing, synthetic vaccines	Rapid production, embryonated eggs not needed, improved quality control (382–384)
Recombinant protein expression in insect cells, plant cells, lactobacillus, algae, yeast	Rapid vaccine production, low production costs (385–387)
Virus-like particles expressed in mammalian, insect, or plant cells	Good safety and efficacy (385, 388, 482)
DNA LAIV, recombinant proteins, IIV combination booster vaccinations	Broader and stronger immune responses than vaccination with individual vaccine preparations (389, 482)
Virus vector vaccines	Potent humoral and cell-mediated responses (390, 483)
M2e (universal) fusion proteins and multimeric constructs	Promising approach to develop universal vaccine (398, 399)
Attenuated constructs, peptide vaccines	Induction of humoral as well as cellular immunity (392–396, 484)
Centralized (COBRA) HAs	Elicit broadly-reactive set of antibodies in animals (400)
Headless and chimeric HAs	Induce broadly protective antibodies to the conserved HA stalk domain and also allows the redirection of the immune response to the conserved NA protein (397, 401–407, 485)

humans (314). Thus, enhanced antibody responses to the conserved regions of influenza viruses (HA stalks and NAs) may be the key for a universal influenza virus vaccine. The influenza A virus HAs fall into two groups (Fig. 2); thus, a vaccine inducing protective responses to group 1 HA stalk and to the stalks of group 2 may be protective against viruses from all known HA subtypes. Although it is not known what the overall contributions of the NA antibody responses to protection are relative to those of the HAs, it is possible that there is sufficient cross-protection within the NA groups that an N1 and N2 NA (belonging to group 1 and group 2, respectively) will cover all the NAs of circulating influenza viruses. A trivalent universal influenza virus vaccine would be designed to enhance immune responses against the group 1 HA stalk, the group 2 HA stalk, as well as the B virus HA stalk. At the same time, the trivalent vaccine would contain a group 1 NA (N1), a group 2 NA (N2), and a B virus NA (385). Such a vaccine (on different available platforms, plus or minus adjuvants), might provide universal protection against all influenza A and B viruses is to be tested in human trials.

### Antiviral Chemoprophylaxis

The neuraminidase inhibitors (NAIs), inhaled zanamivir, oral oseltamivir, and inhaled laninamivir, are effective for prophylaxis for both influenza A and B virus infections (408, 409). Amantadine and rimantadine are effective for prophylaxis and treatment of influenza A virus infections due to susceptible strains (410), but neither is effective for influenza B, and recently circulating influenza A viruses are resistant (411). Oseltamivir and inhaled zanamivir are approved in the United States and many other countries for prophylaxis. Neuraminidase inhibitors have been stockpiled by WHO for both treatment and possible use in mass-targeted chemoprophylaxis for containing emergence of a pandemic virus (412).

### Effectiveness

The efficacy of oseltamivir at 75 mg once daily for 6 weeks for seasonal (preexposure) prophylaxis is approximately 84% in unimmunized working adults and 89% in immunized

nursing home residents. Preexposure prophylaxis also protects high-risk immunocompromised hosts (413). When used for postexposure prophylaxis in family contacts, 7 to 10 days of once-daily oseltamivir provides 68 to 89% protection (408). Inhaled zanamivir at 10 mg once daily is also highly protective against influenza when used for seasonal (82 to 83% efficacy) or postexposure (82% efficacy) prophylaxis (408).

Prophylactic oral amantadine and rimantadine are 70 to 90% effective in preventing illness caused by susceptible strains of influenza A virus (410). With sensitive strains, postexposure prophylaxis with rimantadine or amantadine for 10 days was effective in protecting family contacts when index cases were not treated, but concurrent treatment of ill children may lead to rapid selection and spread of drug-resistant virus to contacts and cause prophylaxis failures (410). In contrast, use of inhaled zanamivir or oral oseltamivir, both for treatment of ill index cases and for prophylaxis of contacts, is protective and usually not associated with resistance transmission. In one nursing home-based trial, zanamivir prophylaxis was more effective than oral rimantadine in protecting against influenza, in part, because of the frequent failure of rimantadine prophylaxis due to drug-resistant strains (414).

Seasonal prophylaxis is an alternative or adjunct to immunization when the epidemic strain differs antigenically to a significant extent from the vaccine strain or when high-risk patients have a contraindication or are not expected to mount an adequate response to immunization. Combined use of inactivated vaccine and chemoprophylaxis offers the highest level of protection for high-risk patients. Protection requires drug administration for the duration of the epidemic, generally 6 to 10 weeks; inhaled zanamivir and oral oseltamivir have been well-tolerated in healthcare workers up to 16 weeks (415). Drug recipients may experience subclinical infection, which usually confers protection against reinfection by the same strain.

Because antiviral chemoprophylaxis does not interfere with the immune response to inactivated vaccine, they can be administered concurrently. However, concurrent use of any anti-influenza antiviral drug might interfere with the

immunogenicity of LAIV. If influenza has already occurred in the community, prophylaxis can be given to unimmunized high-risk persons for 2 weeks beginning at the time of immunization. For likely exposure, NAI chemoprophylaxis is a consideration for unvaccinated persons, including pregnant women, at increased risk of complications. Inhaled zanamivir may be the preferred prophylaxis agent for pregnant women.

### Management of Nosocomial Outbreaks

Prevention of outbreaks in institutional populations requires an established plan that includes preapproved vaccine and medication orders; preseason immunization of residents and staff members, surveillance for influenza during the season, restriction from work of employees with possible influenza illness, and, in the event of an outbreak, use of appropriate isolation techniques, immunization of residents and staff who have not received vaccine, and often antiviral chemoprophylaxis (416, 417). Chemoprophylaxis both for patients, irrespective of immunization status, and often for staff, is indicated for outbreak control. A policy of oseltamivir-treatment of ill persons and prophylaxis for residents and staff appears effective during influenza outbreaks in aged care facilities (418, 419). Administration for 2 weeks, or until new cases have ceased to occur for at least 1 week, appears to be adequate in most nursing home outbreaks. Currently NA inhibitors should be used for chemoprophylaxis since circulating influenza A strains are resistant to M2 inhibitors, and, even when outbreak strains are susceptible, resistance emergence and transmission is problematic with M2 inhibitors (414). However, nosocomial transmission of oseltamivir-resistant A(H1N1)pdm09 virus has sometimes caused lethal illnesses within hematology-oncology units (420, 421). Failures of oseltamivir prophylaxis, particularly in immunocompromised hosts, should prompt investigation for resistance emergence and other pathogens, as well as consideration of zanamivir use.

Whenever possible, infected patients should be isolated using standard and droplet precautions. In the context of nursing home outbreaks, efforts to reduce transmission include confinement of ill residents to their rooms for at least 72 hours; restriction of movement of nonsick residents to other parts of the facility and consideration of confinement to their rooms, if an outbreak with high attack rates or severe illness is occurring; decentralization or postponement of activities, which could expose large numbers of nonsick residents to influenza; minimizing work assignments of staff to multiple units of the facility; restricting visits by persons with respiratory illness; and discouraging visits to sick residents.

## TREATMENT

### Supportive Care

Symptomatic treatment of influenza commonly involves antipyretic-analgesic drugs, particularly acetaminophen or nonsteroidal anti-inflammatory agents, for relief of fever, aches, and other systemic symptoms. Aspirin should be avoided in children because of its association with Reye's syndrome. Increased mortality with aspirin or paracetamol has been observed in some animal models of influenza (422), and high-dose salicylates were reported to be associated with increased mortality during the 1918 pandemic (423). Maternal hyperthermia during the first trimester increases the risk of neural tube defects and possibly other birth defects,

and maternal fever during labor has been shown to be a risk factor for adverse neonatal and developmental outcomes. Acetaminophen appears to be the best option for treatment of fever during pregnancy.

Antitussives are often needed for relief of cough. Antibiotics have not been shown to benefit the course or reduce the likelihood of complications and should be used for proven or presumed bacterial complications. In those with lower-airway disease, correction of hypoxemia and treatment of bronchospasm are important. Advanced mechanical ventilation techniques (low tidal volumes, judicious use of positive end-expiratory pressure [PEEP]) and increasing use of extracorporeal membrane oxygenation (ECMO) have improved the outlook in severe cases, but case fatality remains high in influenza-associated ARDS.

### Immunomodulators

Because host responses contribute to influenza disease pathogenesis, anti-inflammatory and immunomodulatory agents are important considerations for therapeutic intervention (424). Systemic corticosteroids have been given commonly to patients with influenza-associated pneumonia and ARDS without evidence of benefit. Retrospective studies of patients with A(H1N1)pdm09 or avian influenza infections indicate an association between corticosteroid use and increased risks of complications, including nosocomial pneumonia and invasive fungal infections, possibly increased mortality, and prolonged viral replication and emergence of antiviral resistance (121, 146, 425–427). Consequently, corticosteroid treatment of influenza patients should be avoided unless clinically indicated for other reasons (e.g., exacerbation of reactive airways disease, adrenal insufficiency, low-dose hydrocortisone for refractory septic shock). The value of corticosteroids to treat bronchiolitis obliterans with organizing pneumonia or the fibroproliferative phase of ARDS associated with viral pneumonia is uncertain (428). Pulse methylprednisolone is part of the commonly used treatment regimen (combined with antivirals and intravenous immunoglobulin) for treating influenza-associated encephalopathy in Japan.

A wide variety of immunomodulatory agents, most directed against excessive proinflammatory host responses, show benefits in animal models of influenza (e.g., gemfibrozil, pioglitazone, cyclo-oxygenase 2 inhibitors, pamidronate, N-acetylcysteine, erythromycin, resveratrol) (426, 429), but clinical data are limited or absent. During severe influenza A virus infection in mice, platelet activation worsens acute lung injury, and anti-platelet therapies diminish its severity (430). The use of widely available, low-cost interventions like HMG-CoA reductase inhibitors (statins) has generated considerable interest (431). While retrospective studies have reported mortality reductions in patients receiving statins, who were subsequently hospitalized for influenza (432) or pneumonia, findings are negative in some animal models (433, 434) and clinical studies (435). Large randomized controlled trials (RCTs) testing statins as therapy for ARDS due to sepsis or other causes have not shown clinical benefit (436, 437). Further clinical studies are needed to determine the possible benefits and optimal timing of use for particular host-directed therapies.

### Antivirals

The antiviral spectra, pharmacology, effectiveness, tolerability and safety, and dosing regimens of approved influenza antivirals are discussed in Chapter 14. In general, antiviral treatment is warranted as soon as possible for patients with

suspected or confirmed influenza who have severe, complicated, or progressive illness, and in those requiring hospitalization (221). Treatment is also recommended as soon as possible for outpatients who are at higher risk for influenza complications on the basis of their age or underlying medical conditions (Table 7), depending on their clinical circumstances. Early antiviral treatment (within 2 days of symptom onset) can also benefit previously healthy persons those with apparently uncomplicated illness.

#### Amantadine and Rimantadine

Currently, the use of M2 inhibitors is not recommended because of widespread resistance among circulating influenza A strains (221). Resistance due to the Ser31Asn substitution in M2, sometimes in association with other M2 changes, is present globally among strains of A(H3N2) and A(H1N1)pdm09 viruses and is present in all A(H7N9) and clade 1 and some clade 2 A(H5N1) viruses (221, 496). During therapeutic use in infections, due to susceptible strains, viruses cross-resistant to amantadine and rimantadine have been recovered from patients as early as 2 to 3 days after starting treatment and from about 30% of outpatient children and adults treated for influenza. Resistant variants are fully transmissible and cause typical influenza illness and associated complications (410).

In uncomplicated influenza A due to susceptible strains, early treatment (within  $\leq 48$  h of illness onset) with amantadine or rimantadine reduces viral replication and the duration of fever, symptoms, and functional disability by about 1 to 2 days in previously healthy adults. Treatment is associated with more rapid improvement in peripheral airway dysfunction but not airway hyperreactivity. Whether treatment reduces the risk of influenza-related complications or provides therapeutic benefit in established complications or severe influenza in hospitalized patients is unknown. In children, rimantadine treatment has been associated with lower symptom burden and viral titers during the first 2 days of treatment than with acetaminophen but also with more prolonged shedding of virus and emergence of resistance. Rimantadine is not approved for therapy of influenza in children in the United States.

#### Zanamivir

Inhaled zanamivir treatment provides 1- to 2.5-day reductions in time to alleviation of illness and return to usual activities compared to placebo in adults and children  $\geq 5$  years old, including those with mild to moderate underlying reactive airway disease, with uncomplicated influenza (497). Zanamivir appears to be more effective than oseltamivir in treating influenza B virus infections in children (438). Zanamivir treatment reduces the frequency of antibiotic prescriptions for clinically diagnosed lower respiratory complications by about 40% (495). Among older adults, including those developing influenza despite immunization, inhaled zanamivir treatment appears to have therapeutic effects and tolerance similar to those in younger adults. Whether treatment of ill persons reduces the risk of virus transmission to contacts remains uncertain (439, 440). The effectiveness and safety of inhaled zanamivir in treating influenza-associated pneumonia is unproven, and effective lung delivery is likely problematic in those with serious disease (441). Attempted delivery of the lactose-containing commercial formulation in intubated patients has been complicated by blockage of ventilator filters and fatal outcome (442); this formulation is not appropriate for use in

nebulizers or for mechanical ventilation. Inhaled zanamivir is generally well tolerated during therapeutic use, although rare cases of bronchospasm and exacerbations of underlying airway disease, sometimes fatal, have been reported, and the drug is contraindicated in those with significant airways disease. The breath-activated proprietary Diskhaler device for delivery of inhaled zanamivir requires a cooperative patient who can effectively inspire, and certain groups (children  $< 5$  years old, persons with cognitive impairment, and very frail or hospitalized elderly persons) may not be able to use it reliably.

Zanamivir is inhibitory for most, although not all, oseltamivir-resistant variants, and intravenous delivery has been used extensively for treating influenza in seriously ill or immunocompromised patients with suspected or proven oseltamivir-resistant influenza infections (492). Its use in critically ill patients has been associated with acceptable tolerability and apparent antiviral effects (443). However, a phase 3 RCT did not find superiority to oral oseltamivir in treating adults hospitalized with influenza (444). Although uncommon, substitutions at residue Glu119 to Gly or Asp can confer resistance to zanamivir and other NA inhibitors in influenza A(H1N1)pdm09 viruses, particularly in combination with His275Tyr, and can cause therapeutic failure in immunocompromised patients (445, 446).

#### Oseltamivir

Early oseltamivir treatment of previously healthy adults with apparently uncomplicated influenza reduces the time to illness alleviation by approximately 1 to 1.5 days, time to resumption of usual activities by 2 to 3 days, frequency of lower respiratory secondary complications leading to antibiotic prescriptions, and all-cause hospitalizations by approximately 50% (447). The magnitude of clinical benefit relates to timing of initiation and is greater with therapy started within 12 hours of onset of symptoms (448). Oseltamivir treatment of children, aged 1 to 12 years with acute influenza, reduces illness duration by 1.5 days and the frequency of complications, particularly otitis media, leading to antibiotic prescriptions. Oseltamivir therapy appears to reduce the risk of progression to pneumonia in highly immunocompromised hosts with influenza and to reduce the risk of death in patients hospitalized with influenza, including pregnant women (240, 449, 450). Timely oseltamivir treatment is also associated with lower mortality in severe avian influenza virus disease, although progressive illness, sometimes related to resistance emergence, occurs (121, 145, 146, 502).

The safety of neuraminidase inhibitors in pregnancy have not been established, but no teratogenicity has been documented to date. Both zanamivir and oseltamivir carboxylate distribute across the placenta and into breast milk in animals. Given antiviral resistance patterns and the potential teratogenicity of the M2 inhibitors, the NA inhibitors are preferred for influenza treatment; the lower systemic exposure of inhaled zanamivir is a consideration in this decision.

Oseltamivir-resistant variants have been recovered from immunocompetent outpatient adults ( $\sim 1\%$ ), outpatient children ( $\sim 4\%$ ), inpatient children ( $\sim 18\%$ ), and subtype A (H5N1)-infected persons ( $\sim 25\%$ ) during or immediately after treatment (496). These variants typically possess amino acid substitutions (primarily Arg292Lys or Glu119Lys in N2 and His275Tyr in N1) in the NA. Oseltamivir-resistant seasonal A(H1N1) virus, harboring His275Tyr and other enabling NA substitutions (451), replaced susceptible virus and circulated globally before being replaced by the

A(H1N1)pdm09 virus. Since 2011 influenza A(H1N1)pdm09 viruses have also acquired NA substitutions that balance the adverse effects of H275Y on NA activity and surface expression. Temporally this has coincided with increasing evidence for community transmission of oseltamivir-resistant influenza A(H1N1)pdm09 H275Y viruses (452). Prolonged replication with resistant variants, usually with dual resistance to M2 inhibitors and sometimes with resistance to zanamivir, has been recognized in immunocompromised hosts (453, 496). Transmission of oseltamivir-resistant variants has been observed in healthcare settings and in the community (420, 421, 454). Intravenous zanamivir, available on compassionate use basis, is currently the most reliably active single agent for treating oseltamivir-resistant infections (455).

#### Peramivir

Single-dose intravenous peramivir is comparable in antiviral and clinical effects to a standard 5-day course of oral oseltamivir in uncomplicated influenza, although it is no better than oseltamivir for infections due to oseltamivir-resistant A(H1N1) virus (456). Treatment within 24 hours of symptom onset is associated with a shorter clinical course compared to placebo (457). Multiple dose regimens have been used in hospitalized patients, including those with severe viral pneumonia, but one RCT in hospitalized children and adults did not confirm more rapid clinical improvement (458). Peramivir has reduced inhibitory effects for many oseltamivir-resistant variants, including viruses containing His275Tyr in N1 or Arg292Lys in N2 and N9, and cannot be used reliably in such infections (146, 456). While no parenteral antiviral is currently FDA-approved for influenza management in seriously ill patients, intravenous peramivir is available in some countries (Japan, South Korea, United States, China).

#### Laninamivir

Single doses of the long-acting, orally inhaled NA inhibitor laninamivir are reported comparable in effectiveness to oral oseltamivir for treating uncomplicated influenza in adults (459) and to inhaled zanamivir in children aged 3 to 15 years (460). Laninamivir, currently approved only in Japan, has an antiviral spectrum similar to zanamivir and appears effective in treating oseltamivir-resistant A(H1N1) infection in children aged 3 to 9 years (461), although not in adults (459). However, an international RCT testing a higher dosage failed to show more rapid clinical recovery compared to placebo (462).

#### Favipiravir

Favipiravir (also designated T-705) is an influenza polymerase inhibitor active against all three influenza types, including variants resistant to M2 and NAIs, and some other RNA viruses in animal models (463). It has been approved in Japan but is under government control for potential use only when there is an outbreak of novel or reemerging influenza virus infections in which other anti-influenza virus agents are not effective or insufficiently effective, in part because of its teratogenicity in preclinical studies and contraindication for use in pregnant women. A twice-daily regimen showed significantly better antiviral and clinical effects than placebo in uncomplicated influenza (464), and the results of recently completed RCTs in outpatient adults are awaited. Favipiravir shows enhanced antiviral effects in combination with NAIs in preclinical models (465), but combination studies have not been undertaken as yet in severe influenza.

#### Investigational Agents

A number of anti-influenza compounds and combinations of antivirals or antivirals and immunomodulators have been described in preclinical studies, but few have undergone clinical testing (426, 465–467). One retrospective analysis suggested that therapeutic use of convalescent-phase blood products in pneumonia patients in 1918 reduced mortality (468), and early serotherapy with convalescent plasma or hyperimmune globulin-containing higher-neutralizing antibody titers, in combination with NA inhibitors in recent reports, likely reduces mortality in seriously ill patients (469, 470). A number of heterosubtypic, neutralizing antistem monoclonal antibodies, targeting HA group 1 and/or group 2, show therapeutic activity in animal models of lethal influenza including A(H5N1) and A(H7N9) viruses (471–473), and several of these and other antibody preparations (474) are in clinical trials.

Older investigational agents include ribavirin, a nucleoside analog active in preclinical models against influenza A and B viruses. If initiated early after symptom onset, aerosolized ribavirin variably reduces illness in adults with uncomplicated influenza, but it was associated with no important clinical benefits in young children hospitalized with influenza (475). Aerosolized, oral, and intravenous forms have been used to treat individual patients with influenza pneumonia or other severe complications, but ribavirin remains an investigational agent of unproven efficacy in influenza. Intranasal recombinant IFN- $\alpha$ 2 partially protects against illness in experimental human influenza but is ineffective in preventing natural influenza (51).

Other novel inhibitors under clinical study include the oral PB2 inhibitor V-787 (476), the inhaled sialidase DAS181 (477), nitazoxanide (478), and the HA inhibitor arbidol (479). Various combinations of antivirals immunotherapeutics show enhanced antiviral activity in preclinical studies, including lethal avian influenza virus models, and warrant testing in severe infections in humans (465, 471). Ribavirin shows enhanced antiviral activity when combined with M2 or NAIs for dually susceptible strains under experimental conditions (465). A triple-drug regimen of amantadine, oseltamivir, and ribavirin, which is inhibitory for variants resistant to single drugs, has been used in critically ill and immunocompromised patients (480, 481) and is undergoing further clinical testing in at-risk outpatients.

# ***Bunyaviridae*: Orthobunyaviruses, Phleboviruses, Nairoviruses, and Hantaviruses**

GREGORY J. MERTZ, CLAS AHLM, AND COLLEEN B. JONSSON

## **44**

The family *Bunyaviridae* is the largest family of viruses and includes many known human, animal, and plant pathogens. The clinical diseases produced in humans range from acute febrile illnesses, such as sandfly fever, to more distinct clinical syndromes such as California encephalitis (CE), Rift Valley fever (RVF), Crimean-Congo hemorrhagic fever (CCHF), hemorrhagic fever with renal syndrome (HFRS), and hantavirus cardiopulmonary syndrome (HCPS), which is also referred to in the literature as hantavirus pulmonary syndrome (HPS). Sandfly fever, RVF, and HFRS are common. Although most of the remaining diseases probably cause no more than a few hundred cases each year, some are associated with a high mortality rate (particularly CCHF and HCPS), and two (CE and HCPS) are endemic in North America.

New and emerging viruses are still recognized and included in the large and growing family of *Bunyaviridae*. A new tick-borne phlebovirus that emerged in China during 2007 to 2009 has caused more than 2,500 cases of “severe fever with thrombocytopenia syndrome” (SFTS) (1), and, a new genetically related phlebovirus, the Heartland virus, was detected in two farmers with severe febrile illness and thrombocytopenia in Missouri in 2009 (2). Heartland virus is now recognized in 15 states. Heartland virus is spread by *Amblyomma americanum* (lone star tick) and may also infect wildlife and domestic animals, which could serve as reservoirs (3–5). Thus, clinicians should be aware that in undiagnosed febrile and severely ill patients with thrombocytopenia it is important to collect blood and other specimens for analyses.

### **VIROLOGY**

#### **Classification**

The family *Bunyaviridae* includes more than 300 viruses and is divided into five genera: Orthobunyavirus, Phlebovirus, Nairovirus, Hantavirus, and Tospovirus (6). All genera except the Tospoviruses, which are plant viruses, infect vertebrate hosts and include human pathogens.

Representative groups and complexes for the orthobunyaviruses, phleboviruses, and nairoviruses, including major human pathogens, are shown in Table 1. In general, the genotypes are determined by molecular features, including

conserved nucleotide sequences, genomic size, and genomic organization, whereas groups within each genus are determined primarily by serologic methods (6, 7). Within the larger genera, viruses may be classified into groups and complexes.

Antibodies are directed against a nucleocapsid protein (NP) and two major envelope glycoproteins. The nucleocapsid protein is more conserved within a genus than the glycoproteins. Serologic tests that are solely or primarily directed against nucleocapsid protein antigens tend to be sensitive but exhibit significant cross reactivity, whereas assays that are directed solely or primarily against glycoprotein antigens tend to be useful in distinguishing between closely related viruses (6, 7).

#### **Virion Structure, Genome Composition, and Major Proteins**

Bunyaviruses are enveloped viruses about 100 nm in diameter (80 to 120 nm) with 5 to 10 nm glycoprotein spikes projecting from the envelope (Figure 1) (8–10). The virion structures are known for several members of the *Bunyaviridae*, and the structures of the spike proteins on the surface vary considerably across genera (11–14). The viruses are generally spherical but may be oval and elongated. Virion size may vary, and by cryoelectron microscopy (Cryo-EM) and Cryo-EM tomography Hantaan virus (HTNV) particles range in size from 120 to 154 nm (12). The envelope surrounds a tripartite ribonucleoprotein complex containing the small (S), medium (M), and large (L) genome segments of single-stranded RNA with negative polarity (Figure 1).

The lengths of the genomic segments vary among the genera, ranging from 6.3 to 12 kb for the L segment, 3.5 to 6 kb for the M segment, and 1 to 2.2 kb for the S segment. The range within each genus is much more restricted. For hantaviruses, segment lengths range from 6.5 to 7.0 kb for the L segment, 3.6 to 3.7 kb for the M segment, and 1.6 to 2.1 kb for the S segment.

Four major structural proteins are encoded by the three segments, and nonstructural proteins are coded by some but not all viruses within the family. RNA-dependent RNA polymerase (RdRp or L protein) is coded by the L segment, nucleocapsid (N) protein by the S segment, and glycoproteins by the M segment (Figure 1). Many of the structural

**TABLE 1** *Bunyaviridae*: Genera, subgroups, and selected viruses that are human pathogens, excluding hantaviruses

Genus	Serogroup or complex	Geographic location of human pathogens	Selected human pathogens
Orthobunyavirus	California	North America, Europe	California encephalitis, La Crosse, Jamestown Canyon, Tahyna
	Simbu	South America	Oropouche
	Anopheles A	South America	Tacaiuma
	Bunyawera	Africa, South America	Bunyamwera, Fort Sherman, Shokwe, Xingu
	Group C	North and South America	Apue, Itaqui, Madrid, Oriboca
Nairovirus	Crimean Congo Hemorrhagic Fever (CCHF)	Africa, Asia, Europe	CCHF and Dugbe
	Nairobi sheep disease	Africa, Asia	Nairobi sheep disease
Phlebovirus	Severe fever with thrombocytopenia syndrome	Asia, North and South America, Africa, Europe, Asia	Severe fever with thrombocytopenia syndrome
	Sandfly fever group	Europe, Asia	Alenquer, Punta Toro, Rift Valley fever, Sandfly fever Naples, Toscana, Chagres, Sandfly fever Sicilian

proteins for the major viruses in the family have been sequenced (15–19), and successful reverse genetics systems have been described (20–23).

### Replication Strategies

Large gaps exist in understanding the mechanisms for Bunyavirus entry and assembly. As an example, Hantavirus virions are generally asymmetric, pleomorphic particles; the virion has a surface structure composed of an unusual square, grid-like pattern distinct from other genera in the *Bunyaviridae* and a lack of icosahedral symmetry typical of most viruses. The square spike on the outer surface reflects the glycoprotein (GP) projections, which extend ~12 nm from the lipid bilayer and comprise 4 molecules of Gn and Gc (12). Hantaviruses bind epithelial and endothelial cells via interaction of Gn with the host's cell surface receptor(s);  $\beta$ 1 integrin for apathogenic and  $\beta$ 3 integrin for pathogenic hantaviruses (24, 25); although these may not be the sole receptors (26). HTNV enter through clathrin-coated pits, followed by movement to early endosomes, and subsequent delivery to late endosomes or lysosomes (27, 28).

Internally, the virion contains three rod-like ribonucleoprotein (RNP) structures, which presumably contain the viral RNA genome wrapped in N proteins. The viral RNA dependent RNA polymerase (RdRp) or L protein would be expected to be part of the RNP. For hantaviruses, the N protein is the most abundant viral protein synthesized early in infection and likely plays key roles in several important steps in the virus replication cycle (27) including assembly into the RNP and packaging. It is highly likely that different oligomeric states or conformations of N occur during the life cycle. The HTNV N protein traffics via microtubules in the cell to the ER-Golgi intermediate compartment (ERGIC) prior to viral assembly (28). It is unclear where or how the assembly of the RNP takes place; however, the RNPs must traffic to the Golgi since this is the compartment where virions have been visualized. The RNP presumably buds into the Golgi to produce the virion, and then the virion exits the Golgi through the formation of a vesicle, which would surround the hantavirus particles.

There is also considerable diversity in the replication strategies within the family, although all members of the family replicate in the cytoplasm and mature in the Golgi (Figure 1) (8–10, 29, 30). Attachment and entry are medi-

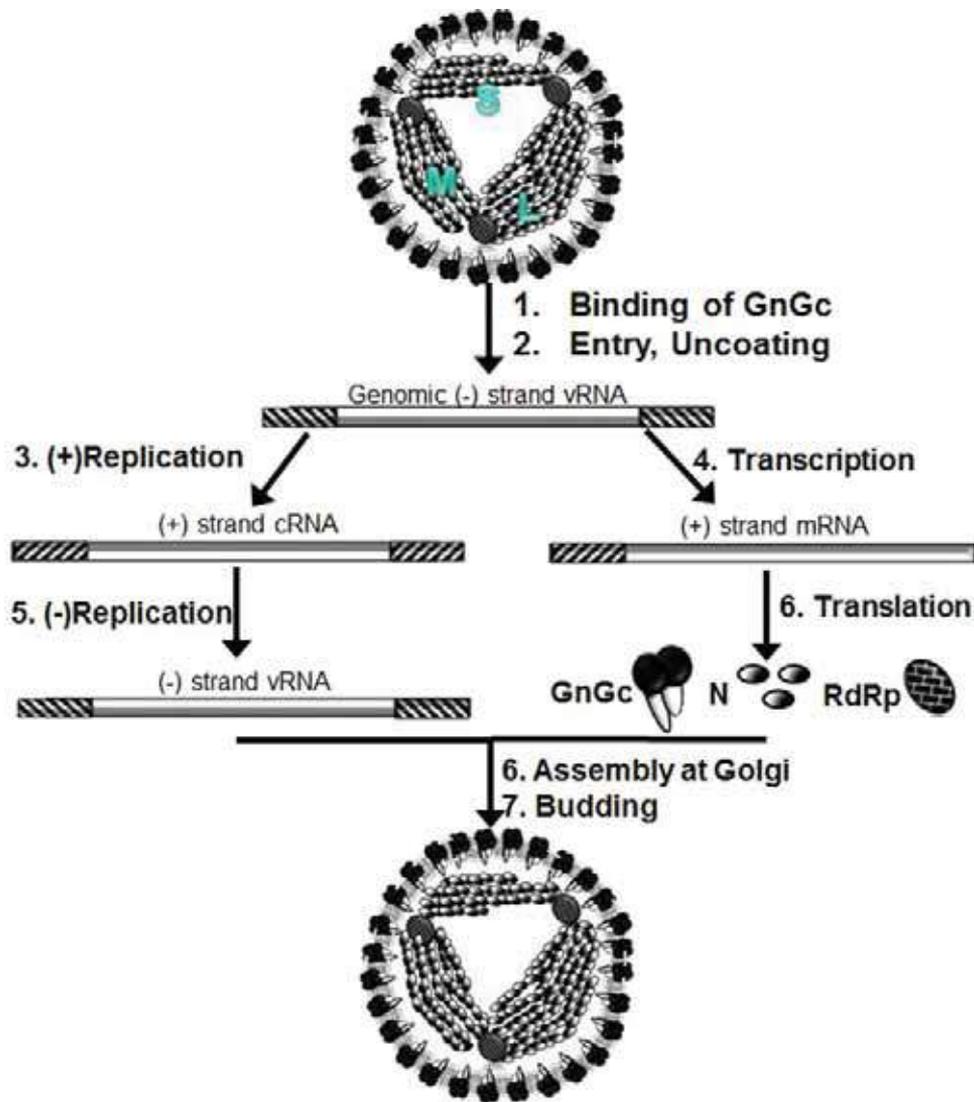

ated by one or both of the glycoproteins (Figure 1). Phleboviruses enter cells by endocytosis, a mechanism that may be shared by other members of the family. *Bunyaviridae* can fuse cells at acid pH, and conformational changes in G1 have been described in the *Orthobunyavirus* genus. Thus, for members of the family, entry and uncoating may occur through a common mechanism of entry by endocytosis followed by uncoating and release of the three nucleocapsids into the cytoplasm following fusion of the viral envelope and endosomal membrane at acid pH.

After uncoating, primary transcription of the negative-sense vRNA to mRNA minimally requires vRNA, host primers derived from mRNA, and the viral polymerase (RDRP). The N protein is always associated with genomic RNA, so this protein may also be required. Transcription is followed by translation and trafficking of the RDRP and N proteins to the perinuclear area. This is followed by genome replication, usually through synthesis of a full-length positive-strand cRNA that serves as a replicative intermediate, followed by synthesis of negative-strand vRNA. These events are followed by continued translation and RNA replication.

Replication of the S segment in the *Phlebovirus* and *Tospovirus* genomes is accomplished via an ambisense coding strategy. The NS protein is encoded in the 5' half of the S segment, the N protein is encoded in the 3' half of the segment, and the proteins are translated from separate mRNAs. Genetic reassortment has been demonstrated both in cell culture and *in vivo* in arthropod vectors between members of the same serogroup in the genus *Orthobunyavirus*, but not between members of different serogroups in the same genus.

A key point in genome replication is the switch from transcription of genomic RNA to production of the positive-strand cRNA that serves as the replicative intermediate. This is also a key component in the transcription and replication strategies of other negative strand viruses such as vesicular stomatitis virus (VSV), influenza virus, and rhabdovirus. For VSV, the switch appears to be regulated by the N protein, and a similar mechanism may exist for members of the family *Bunyaviridae*.

These events are followed by terminal glycosylation of the glycoproteins, assembly of viral particles by budding into Golgi vesicles, transport of the cytoplasmic vesicles to the cell surface, fusion of the cytoplasmic vesicles with the plasma membrane, and release of virions through exocytosis.

**FIGURE 1** Model for *Bunyaviridae* replication. The principal steps in replication are (1) attachment of Gn to integrin receptor; (2) entry and uncoating; (3) replication, cRNA synthesis from vRNA genome; (4) transcription, mRNA synthesis from vRNA genome; (5) replication, vRNA synthesis from cRNA template; (6) translation, L and M mRNA translated on free ribosomes and M translation on RER; N and RdRp and L, M, and S genomes move to Golgi; (7) packaging, assembly of genomic RNAs and proteins at Golgi (some evidence for New World viruses assembling on plasma membrane); and (8) budding. Virion release, Golgi vesicles release virion by budding with plasma membrane.

Unlike other negative-strand RNA viruses, *Bunyaviridae* lack a matrix protein that bridges the gap between envelope proteins and the nucleocapsids during assembly. Thus, there may be direct transmembrane recognition between viral glycoproteins that accumulate on the luminal side and the ribonucleoprotein structures (ribonucleocapsids) that accumulate on the cytoplasmic side of vesicular membranes. In addition to morphogenesis in the Golgi that occurs in all members of the family, additional mechanisms have been described. For example, one member of the genus *Phlebovirus*, RVF virus, can bud at the surface of rat hepatocytes as well as into the Golgi cisternae.

#### Host Range, Growth in Cell Culture, and Inactivation

Members of the *Orthobunyavirus*, *Phlebovirus*, and *Nairovirus* genera infect both vertebrates and arthropods. Given the

large number of viruses in the family, it is not surprising that the overall range of natural vertebrate hosts is broad, including rodents, lagomorphs, deer, birds, and sheep and other domestic animals (6, 7). Humans are not a natural reservoir for any members of the family *Bunyaviridae*, but human infections, some of substantial medical importance, occur by members of each genus except the *Tospovirus* genus. However, for a particular virus, the range varies from broad to very limited, the latter being particularly true of hantaviruses. Although “spillover” may occur between small rodent species in nature and rats, mice, and rabbits can be infected in the laboratory, each hantavirus tends to have a very restricted host range in nature (Table 2). The limited host range and similar phylogenetic relationships among hantaviruses and among the rodent hosts have led to the suggestion that hantaviruses may have co-evolved with their rodent hosts. Recent evidence also suggests remote

**TABLE 2** Hantavirus species recognized to date. Only those that are well characterized and clearly differentiated from previously characterized species are listed. Courtesy of Dr. B. Hjelle.

<sup>a</sup>Possibly synonymous with variant forms Bermejo, Oran, Lechiguana.

divergence of a clade of insectivore-borne hantaviruses (31, 32). Although many members of the latter clade have recently been identified in soricids (shrews), none have been clearly associated with human disease.

The range of arthropod hosts tends to be more limited within each genus and to be even more limited for groups or individual viruses within each genus (Table 3). With only a few exceptions, members of the genus *Orthobunyavirus* infect only mosquitoes. Most phleboviruses infect sandflies, but RVF virus can infect a wide range of arthropods and appears to be transmitted primarily by mosquitoes. The arthropod host range for nairoviruses appears to be largely limited to ticks, particularly those in the genus *Hyalomma* (33, 34).

Most bunyaviruses replicate in BHK-21 (hamster) or Vero E6 (monkey) cells, are cytolitic, and plaque efficiently. In contrast to most other Bunyaviruses, hantaviruses are fastidious in cell culture and are generally not cytopathic. They can only be grown in a few types of cells, particularly Vero E6 cells, and in experimental infections in rodents such as suckling or adult mice. Hantaan, Seoul, Puumala, Prospect Hill, and Sin Nombre Virus (SNV and Convict Creek isolates) were originally recovered from their usual rodent hosts, albeit with some difficulty (7, 35–40). Viral antigen can be detected by fluorescent antibody or other techniques, and plaque reduction assays are also possible in Vero E6 cells. Bunyaviruses in the *Orthobunyavirus* genus have been shown to cause persistent, noncytopathic infections in mosquito cell cultures. Suckling mice may also be used for isolation of many members of the family. Like other enveloped viruses, bunyaviruses are sensitive to acid pH, detergents, formalin, heat, and lipid solvents.

## EPIDEMIOLOGY

### General Principles

For members of the *Orthobunyavirus*, *Phlebovirus*, and *Nairovirus* genera, the infection is arthropod borne, although RVF may also be acquired by direct contact with infected animal carcasses or blood. Person-to-person transmission may also occur with CCHF, SFTSV, and with Andes virus (ANDV) infections, including nosocomial transmission of CCHF through contact with infected blood and person-to-person transmission of ANDV within households and other close contacts, as well as rare nosocomial transmission in Chile and Argentina (41).

For most bunyaviruses, the period of viremia in the vertebrate host is brief, suggesting that infection in vertebrates is generally more important for amplification than for viral perpetuation. In contrast, infection in the insect is persistent. For several viruses in these genera, virus perpetuation can be maintained solely in the insect host for prolonged periods through both transovarial and horizontal transmission. For example, La Crosse virus survives over the winter in mosquito eggs, and RVFV can survive in mosquito eggs for years during drought.

In contrast to the genera described above, hantaviruses have no arthropod vector, although infection and transovarial transmission in gamsid mites have been described (42). Virus perpetuation and amplification occur largely within a single rodent species that is chronically infected (Table 2). Infected rodents appear asymptomatic, but PUUV impairs overwinter survival in bank voles and SNV-infected juvenile deer mice have shorter survival than uninfected

**TABLE 3** Natural vertebrate hosts, vectors, and mechanism of transmission for representative bunyaviruses that are human pathogens

Genus/virus	Vertebrate hosts	Vectors	Transmission
<b>Orthobunyavirus</b>			
La Crosse	Woodland rodents	<i>Aedes triseriatus</i>	Insect bite
Bunyamwera	Rodents, lagomorphs	<i>Aedes</i> species	Insect bite
<b>Nairovirus</b>			
CCHF	Herbivores, lagomorphs	<i>Hyalomma</i> ticks	Insect bites, infected animal tissues, person-to-person
<b>Phlebovirus</b>			
Rift Valley fever	Sheep/domestic animals	Mosquitoes	Insect bite, contact with blood/tissue of animals
Sandfly fever	Unknown	Phlebotomus species	Insect bite
Severe fever with thrombocytopenia syndrome	Domestic & wild animals	Ticks	Insect bite, contact with blood/tissue of animals
Hantavirus	Rodents (persistent)	None	Aerosolized rodent excreta, person-to-person (Andes)

ones (43). SNV-infected adult male deer mice and SEOV-infected male rats are more aggressive when compared to uninfected adult males. This enhanced aggressive behavior likely facilitates transmission, since wounding is the primary mode of horizontal transmission (44). There is no evidence for vertical transmission, and most evidence points to horizontal transmission following weaning and clearance of protective maternal antibodies (45). Virus is chronically shed in rodent excreta, and humans appear to acquire infection from aerosols from infected rodent excreta. The viability virus in rodent excreta is not known, but hantavirus remains viable for at least 12 days at room and much longer at lower temperature (46, 47). Finally, laboratory infections have been documented with many members of the family. In most cases, aerosol transmission has been the probable mode of transmission, but direct transmission of hantaviruses from contact with infected animals may also occur. Particular care, including BL-4 containment for some applications, should be taken with agents that carry a high risk of mortality, like CCHF virus and the hantaviruses that cause HCPS.

## CALIFORNIA ENCEPHALITIS SEROGROUP VIRUSES (*BUNYAVIRUS* GENUS)

### Epidemiology

The virus type or subtype, geographic location, and primary mosquito vector and vertebrate host or hosts for California serogroup viruses that cause human infection are shown in Table 4. The CE group is named for the first virus in this group isolated from humans with encephalitis in Kern County, California in 1943. Since then, however, this virus has not been associated with human disease, and La Crosse virus, first identified in 1960 from a fatal case of encephalitis, has accounted for most reported cases of CE (48).

California encephalitis is endemic in the Midwest. Most cases occur between July and September in children, particularly boys, between the ages of 6 months and 16 years with a peak incidence in children between the ages of 4 and 10. Most infections appear to be subclinical or result in a febrile syndrome without encephalitis (48). One survey in Minnesota estimated that one encephalitis case occurred for every 26 childhood La Crosse virus infections, while a large serosurvey in Indiana suggested that there might be more than 1,000 infections for every reported case of encephalitis in children less than 16 years old. Acquisition of La Crosse infection continues throughout life with about 20% of the population seropositive in endemic areas by the age of 60; presumably, adults who acquire infection are at little risk of developing encephalitis.

The primary vector is the mosquito *Aedes triseriatus*. The female *Ae triseriatus* is a daytime feeder that breeds in rainwater in tree holes or other small containers, including discarded tires, thereby allowing breeding and disease transmission in areas distant from the mosquito's usual forest habitat. The virus can overwinter by transovarial transmission where eggs deposited in the fall can survive the winter and hatch in the spring (49). Evidence suggests that infected female mosquitoes may hibernate during the winter and lay eggs in the spring. At that point, virus can be amplified through infecting small mammals, particularly chipmunks and squirrels, and through horizontal transmission through mating with male mosquitoes. Humans are infected through bites from chronically infected female mosquitoes. As with other infections in this genus, infections in the mosquito are chronic, whereas viremia in the primary vertebrate hosts and humans is limited.

Another California serogroup virus, Jamestown Canyon virus, is widely distributed in North America and may be amplified in the white-tailed deer. It is transmitted by

**TABLE 4** California serogroup viruses

Virus	Geographic location	Vector	Host	Human infection
California encephalitis	Western US, Canada	<i>A. melanimon</i> , <i>A. dorsalis</i>	Rodents, rabbits	Very rare
La Crosse	Midwestern, Eastern US	<i>A. triseriatus</i>	Chipmunks, squirrels	Endemic
Tahyna	Europe	<i>A. vexans</i> , <i>C. annulata</i>	Domestic animals, rabbits	Endemic
Jamestown Canyon	North America	<i>A. sp.</i> , <i>C. inornata</i>	White-tailed deer?	Uncommon

*Culexeta inornata* and *Aedes* species. In contrast to La Crosse virus, Jamestown Canyon virus more commonly causes encephalitis in adults compared to children.

### Pathogenesis in Humans

The incubation period is approximately 3 to 7 days based on exposure histories and the incubation period in experimental animals. Virus has only rarely been isolated from brain tissue of persons dying from encephalitis; virus has not been recovered from blood, CSF, or throat or rectal swabs (50). The few reported autopsies and a brain biopsy showed cerebral edema, mild leptomeningitis, glial nodules, perivascular cuffing and rare, focal necrosis distributed in cortical gray matter of the temporal, parietal, and frontal lobes; basal nuclei; midbrain; and pons (50–52).

Antibodies against G1 neutralize virus, block fusion, and inhibit hemagglutination and presumably are important for virus clearance, recovery from infection, and prevention of reinfection. Passive administration of neutralizing antibody protects experimental animals, and development of specific immune responses is correlated with recovery from illness in humans and in clearance of viremia in animals (50).

### Clinical Manifestations

At the onset of the illness, patients typically have fever (100%), headache (~75%), malaise, and nausea and vomiting (50 to 65%) (6, 51, 53, 54). Within 1 to 3 days this is accompanied by meningeal signs (~60%) and lethargy, with total resolution within 7 to 8 days. In the most severe form, fever and headache may begin abruptly with progression to seizures in 12 to 24 hours. Overall, approximately half of cases develop seizures, including some with status epilepticus. Approximately 10% develop coma. Most of the remainder develop disorientation or altered consciousness, but aseptic meningitis without altered consciousness is also described. Less commonly, hemiparesis, tremor, aphasia, ataxia, dysarthria, abnormal reflexes, and chorea have been reported. The case fatality rate is 1% or less, and the total duration of the illness rarely exceeds 10 to 14 days. Most persons recover without any obvious residua. However, persistent focal neurologic findings or learning difficulties have each been reported in about 2% of patients, and emotional lability is reported to persist in about 10%. Epilepsy persists in about 20% of those who experience seizures during the acute episode, and most persons tested within the first five years after an acute episode have an abnormal electroencephalogram (55).

Most children with CE have a peripheral white blood cell (WBC) count between 10,000 and 20,000 (median ~16,000), but normal counts and counts as high as 30,000 have been reported (47, 51–54). The cerebrospinal fluid (CSF) is almost always abnormal at some point during the acute illness. The CSF white blood cell count is elevated (median ~100, range 0 to 600 cells/mm<sup>3</sup>) in at least 90% of cases, with a predominance of mononuclear cells in 60 to 85% of patients. The CSF glucose is normal and the protein concentration is usually normal, but in about 30% of patients the latter is minimally elevated (range 40 to 100 mg/dl).

In the age group at greatest risk for CE, the most common illnesses in the differential diagnosis include herpes simplex virus encephalitis (HSE), mumps, meningitis or encephalitis, West Nile virus, or enteroviral meningoencephalitis (51, 54). Mumps and enteroviral infections tend to occur during community-wide epidemics. Parotitis would be diagnostic of mumps and rash would suggest enteroviral infection, although rash is rarely reported in CE. Focal CNS findings,

seizures, stupor, or coma would suggest CE or HSE. Absence of exposure to a rural, wooded area in the past two weeks, occurrence outside the months of June through September, or illness in a child less than one year or greater than 15 years of age would suggest a diagnosis other than CE. Bacterial meningitis might be suggested in the 30% of patients with a predominance of leukocytes in the CSF, but the clinical course, normal glucose, and negative Gram stain and cultures would rule out bacterial meningitis (51).

### Laboratory Diagnosis

Although California serogroup viruses cause productive, cytotoxic infections and replicate in many cell lines, including Vero or BHK-21, repeated attempts to grow virus from throat swabs, blood, CSF, and stool have been unsuccessful. The diagnosis is usually established by serologic methods, including neutralization, hemagglutination inhibition (HI), complement fixation (CF), and ELISA (50, 51, 53, 54, 56). Most patients are seropositive by IgM ELISA at the onset of illness. The neutralization assay is positive in most patients by the end of the first week of illness, and neutralizing antibody appears to persist for life. HI antibodies appear with neutralizing antibodies but are not as persistent, and CF antibodies appear only after two to three weeks of illness and are absent within a year (51).

### Prevention

Infection with California encephalitis serogroup viruses may be prevented by use of insect repellants and by mosquito control through insecticide spraying and through control of breeding sites. Some communities have attempted removal of discarded tires and other artificial breeding sites, but control of natural breeding sites such as tree holes in woodlands is probably impractical.

Isolation of infected persons is not necessary. There is no known role for passive immunoprophylaxis or antiviral chemoprophylaxis. No vaccine is available, although immunization of mice with a vaccinia recombinant that expresses La Crosse virus glycoproteins protects mice from lethal challenge (57).

### Treatment

Treatment of California encephalitis is supportive.

## HANTAVIRUSES

### Epidemiology

Hantavirus Cardiopulmonary Syndrome (HCPS)  
Hantavirus cardiopulmonary syndrome (HCPS) was first recognized in 1993 following a cluster of unexplained deaths in young adults in the rural, Four Corners area of northwestern New Mexico and northeastern Arizona (58–60). Sin Nombre virus, a previously unrecognized hantavirus associated with the deer mouse, *Peromyscus maniculatus*, was found to be responsible for most HCPS cases. Specific serologic tests and tests for viral RNA by reverse transcriptase-polymerase chain reaction (RT-PCR) were quickly developed (35, 59, 61–64). Notably, serologic surveys retrospectively documented cases from as early as 1959 (15, 65, 66). To date, cases have been reported in 31 states in the continental United States, of which over 95% have occurred in states west of the Mississippi (67). Through 6 January 2016, 690 cases of HCPS have been reported in the United States; 109 cases have been reported in Canada through December 2014. There is a male predominance, and the mean age is 38

(range 5 to 84) in the United States and 40 in Canada. Among US cases, 78% have been white, 18% Native American, 19% Hispanic, and 1% African American. The overall case fatality rate among reported cases is 36% in the United States. Cases occur year-round, but most occur in the spring and summer.

Although Sin Nombre virus (SNV) remains by far the most important Bunyavirus pathogen in the United States and Canada, a limited number of HCPS cases in the United States have occurred outside the range of the deer mouse (Figure 2) and are caused by distinct species. These include Black Creek Canal virus (BCCV) from the cotton rat, *Sigmodon hispidus*, in Florida (68, 69), New York virus (NYV), from *P. leucopus* (white-footed mouse) in the Northeastern United States (70–72), and Bayou virus (BAYV) from rice rats (*Oryzomys palustris*) in Louisiana and Texas (73, 74). NYV is closely associated with SNV, whereas BCCV and BAYV are more closely associated with ANDV.

HCPS has also now been reported in Argentina, Canada, Bolivia, Brazil, Chile, Panama, Paraguay, and Uruguay. ANDV, which is carried by the long-tailed pygmy rice rat, *Oligoryzomys longicaudatus*, causes severe HCPS along the southern Andes Mountains in central and southern Argentina and Chile. Andes virus is of particular concern because of strong evidence for person-to-person transmission (41, 75–77). Laguna Negra virus (host *Calomys laucha*) is a recognized pathogen in Paraguay and Bolivia, and Juquitiba virus is a pathogen in Brazil. In Panama, Choclo virus was identified in patients and in the host, *Oligoryzomys fulvescens*, in an outbreak in 2000 (78).

In Chile, where 759 ANDV cases were reported through February 2013, a mean of 55 cases are reported annually, and the case fatality rate is 32%. The mean age (32 years) is lower than in the United States, in part because ANDV causes disease in young children whereas SNV does not. Through the end of 2006, 841 cases were in Argentina (79) and similar numbers of cases have also been reported in Brazil. As such, both the number of cases and deaths from

HCPS in South America exceed the number of cases and deaths in the United States and Canada by a factor of at least three.

In addition to the viruses implicated in HCPS, hantaviruses that have been identified in New World rodents include Rio Mamore virus amplified by RT-PCR from *Oligoryzomys microtus* collected in Bolivia in 1985, Calabazo virus (host *Zygodontomys brevicauda*) in Panama (78); Prospect Hill virus in the meadow vole, *Microtus pennsylvanicus*; Isla Vista virus in the California meadow mouse, *M. californicus*; Bloodland Lake virus in the prairie vole, *M. ochragaster*; El Moro Canyon virus in the western harvest mouse, *Reithrodontomys megalotis*; and Rio Segundo virus from *R. mexicanus* (80–84).

#### Sero-epidemiology

Current evidence suggests that subclinical infections with SNV and ANDV are uncommon. Although a small number of individuals without a history of HCPS, including mammalogists and persons living in rural areas of the Four Corners region of New Mexico and Arizona, have been found to have hantavirus antibodies, it is not clear whether these individuals have been infected with SNV. Surveys of hundreds of individuals presenting to healthcare facilities in the Four Corners region and equal numbers of national park workers and others presumed to have high-risk occupations have failed to identify seropositive persons (85, 86). Seroprevalence rates of 3 to 30% have been reported in some areas in Central and South America. Rates as high as 12% have been reported in some high-risk areas in Chile when testing was done by the CDC EIA using standard cutoff values, whereas seroprevalence rates were much lower (3%) and there was intertest agreement when samples were tested by the strip immunoblot assay and by neutralizing antibody testing and a higher cutoff was used for the EIA (P. Vial, personal communication). Seroprevalence rates exceeding 30% have been reported in Panama, where Choclo virus causes a mild form of HCPS with a low case fatality rate and

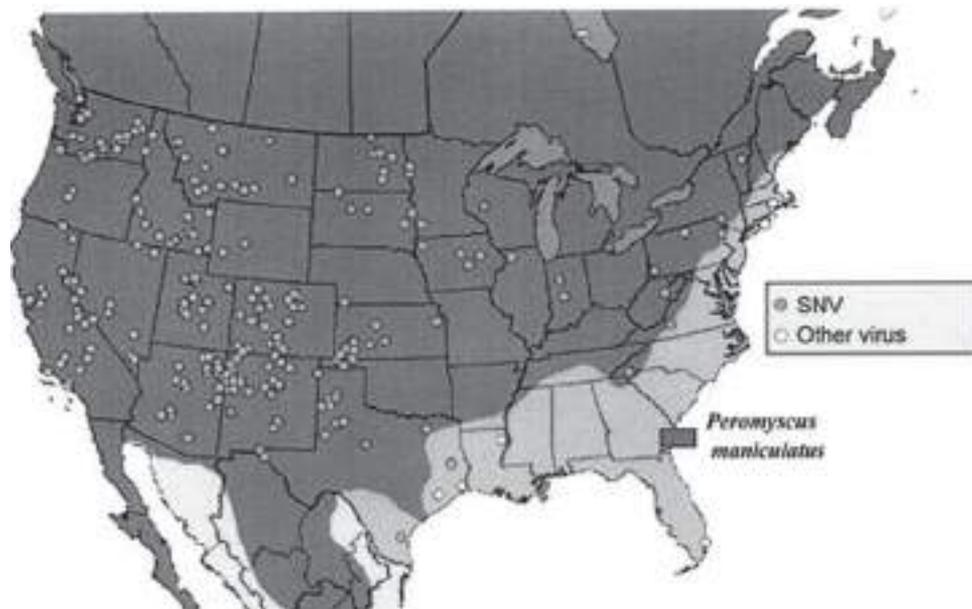

FIGURE 2 Distribution of *Peromyscus maniculatus* and location of HPS cases as of 9 May 2006. Total cases (N = 438 in 30 states) (from Centers for Disease Control and Prevention).

where a high proportion of seropositive individuals have no history of HCPS (87). Although subclinical infections with SNV and ANDV may be rare, mild, symptomatic infections are probably underreported for all hantaviruses that cause HCPS. A number of persons have been identified in New Mexico, Chile, and elsewhere that have not been hospitalized or only hospitalized for a few days.

### Risk Factors

Most persons with HCPS lived in rural areas or had occupations or recent activities that involved exposure to rural areas (85, 86, 88). In case-controlled studies, the risk factors for HCPS included seeing increased numbers of small rodents in the home, cleaning home food storage areas, cleaning feed storage areas (barns), and cleaning animal sheds (86, 88, 89). Of note, risk factors almost always include indoor exposure (89). A 2012 outbreak in Yosemite National Park (10 cases with 3 deaths) was linked to deer mice nesting in the insulation of tent cabins (90).

Risk factors for person-to-person transmission of ANDV infection include close contact with the index case before or shortly after the onset of symptoms rather than following development of the cardiopulmonary phase when patients typically present for hospital admission (75, 91, 92). In a prospective study of 476 household contacts of index cases with HCPS in Chile, the risk of HCPS was 17.6% in sex partners versus 1.2% in other household contacts ( $P < 0.001$ ), and 32.6% of 96 HCPS cases occurred in household clusters with two or more cases in the household (75). Despite conclusive evidence for person-to-person transmission with ANDV among close household contacts, nosocomial transmission is exceedingly rare. While nosocomial transmission was suspected in the 1996 outbreak in Argentina (77, 93) clear evidence of nosocomial transmission of ANDV has been documented in a single case cluster in Chile (41).

### Hemorrhagic Fever with Renal Syndrome (HFRS)

The first recognized hantavirus associated with HFRS was Hantaan virus (HTN) transmitted by *Apodemus agrarius* (striped field mouse) and distributed throughout the Far East, particularly in China and Korea, eastern Russia, and the Balkans (Table 2) (6, 36, 48, 94–100). Another severe form of HFRS associated with Dobrava (DOB) virus from *Apodemus flavicollis* (yellow necked field mouse) occurs in the Balkans (101, 102). Saaremaa virus, carried by *A. agrarius* (striped field mouse), causes mild HFRS and occurs in eastern and central Europe. Another mild form of HFRS associated with Seoul virus (SEO) and *Rattus norvegicus* (brown rat) occurs worldwide (6, 37, 38, 95, 100–105). The mildest form of HFRS, also denoted nephropathia epidemica, is caused by Puumala virus (PUUV), which is carried by *Myodes glareolus* (bank vole); PUUV occurs throughout Scandinavia, western Russia, and central Europe (39, 95, 100, 106–108).

Although infection with the hantaviruses causing HFRS occurs in all age groups, infection and disease peak in adults 15 to 40 years of age; like HCPS, HFRS is uncommon in children (109–111). There may be 150,000 cases of HFRS per year with the majority in Asia. In an agricultural district in China, the ratio of subclinical to clinical hantavirus infections was 5.4:1 based on cross-sectional data versus 14:1 based on prospective data, and clinical infections were more likely to be caused by Hantaan than by Seoul virus. Among rodents trapped in the area, most Hantaan infections were

found in *A. agrarius*, whereas most Seoul infections were found in *Rattus norvegicus* trapped in homes (110).

### Risk Factors

Human infections with Hantaan virus occur primarily in adults in rural areas. Some studies report a male preponderance of Hantaan virus infection in men (2:1), but rates among men and women may be equal in areas where agricultural work is performed near the home or where crops are stored near homes during winter months (109–111). In the latter case, the field mice may be likely to invade homes and food storage areas. Specific occupational groups, including farmers, forest workers, and field soldiers, have been shown to be at higher risk, as have activities such as harvesting and sleeping in straw huts (111).

Seoul infection appeared to account for approximately 20% of infections and <5% of cases of HFRS in rural China, but Seoul virus appears to cause most urban outbreaks due to the distribution of the reservoir host, the brown rat. Large outbreaks have been described in Osaka, Seoul, and seaports in China, but limited outbreaks have been described in seaports throughout the world.

Puumala virus-associated HFRS (also called nephropathia epidemica) primarily occurs among farmers and others living in rural areas (107, 112–114). In Scandinavian countries, where more than a thousand cases occur annually, most cases occur in the fall and early winter when bank voles infest homes and peridomestic buildings (115). In Europe, cases are more frequent in relation to rodent population peaks every 3 to 4 years (115, 116). Seroprevalence in endemic areas of Sweden is approximately 10% (114). The male to female ratio ranges from almost 2:1 to almost 5:1. The peak ages for Puumala infection and disease are similar to those for Seoul and Hantaan infections. Fewer than 5% of persons with PUUV infection are <15 years of age (117). There are approximately 100 hospitalizations a year in Sweden with serosurveys suggesting 10 to 20 infections for every hospitalized case (114, 118).

### Transmission

As indicated above, humans acquire hantavirus infections by aerosol transmission from inhalation of infected rodent excreta, including urine, droppings, or saliva (100, 117). There is no evidence of human-to-human transmission of the viruses that cause HFRS, including nosocomial transmission in hospitals. Seroconversion and clinical infection have occurred among animal handlers and persons visiting the laboratories housing small rodents, and, rarely, following bites and dissection of infected animals and in persons working with hantaviruses in cell culture (117, 119). Transmission through blood products has been reported (120).

### Pathogenesis in Humans

The incubation period between rodent contact and onset of symptoms is difficult to determine, since the period of potential exposure may be prolonged. A small study of persons with PUUV infection suggested that the median was about four weeks, with a range of one to eight weeks (121). For the more severe forms of HFRS, the average incubation period has been estimated to be 21 days, with a range of four days to six weeks (111, 122, 123). For HCPS the median incubation period was reported as 18 days (range of 10 to 34 days) in a small series of 11 patients with ANDV-associated HCPS in Chile (124). In another report, the potential period of exposure was limited to 48 hours or less, and the median incubation period was 30.5 days (range 20 to 49 days) among

10 persons who acquired SNV infection at the Yosemite National Park in California in 2012 (90).

### Viral Replication Patterns

The role of viremia in the pathogenesis of HFRS and HCPS is not known. However, in household contacts ANDV RNA could be routinely detected in peripheral blood for up to 15 days before the onset of symptoms or development of antihantavirus antibodies (75), and PUUV RNA has been detected in a serum sample obtained at the time of an incidental urinary tract infection three weeks prior to symptom onset in a case of severe HFRS (125). High levels of viral RNA can be detected by quantitative RT-PCR in patients with SNV-associated HCPS at the time of hospital admission, and there is a significant association between high viral load at admission and severe disease (126).

Virus isolation from humans with HFRS is difficult (73, 127, 128); there has been only one successful isolation of ANDV from the serum of a 10-year-old, seronegative Chilean boy two days before he developed fever and six days before he died from HCPS (129). Furthermore, in a recent prospective study of household contacts of index patients with HCPS in Chile, ANDV RNA was detected by RT-PCR in peripheral blood cells 5 to 15 days before the onset of symptoms or detection of antihantavirus antibodies in four household contacts who subsequently developed HCPS (75).

In persons who die from HFRS and HCPS, hantaviral antigens are widely distributed in organs as demonstrated by immunohistochemical stains (130, 131). In HCPS these include lung, kidney, heart, spleen, pancreas, lymph nodes, adipose tissue, skeletal muscle, intestine, adrenal gland, and brain; in contrast, only rare sinusoidal lining cells are stained in the liver (131). Viral antigens are detected primarily within capillary endothelial cells but are rarely detected in large veins or arteries. In HCPS, the most intense staining is found in pulmonary capillary endothelial cells. In the kidney, immunostaining is found in interstitial capillaries in the medulla and cortex and in glomerular endothelial cells. In contrast, in persons dying of HFRS, immunohistochemical staining is most intense in the kidney. Immunohistochemical staining in tubular epithelial cells is prominent in HFRS but rare in HCPS.

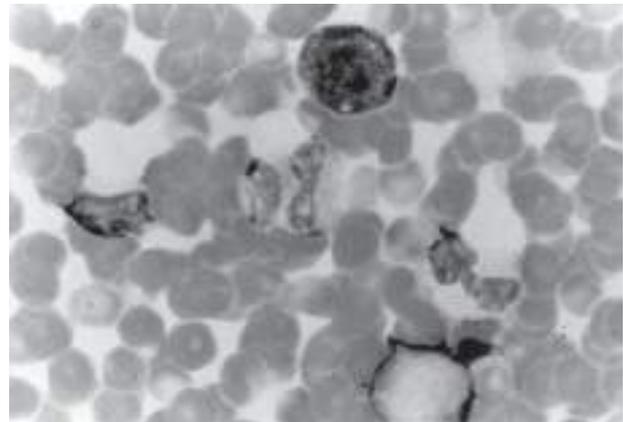

Electron microscopic (EM) studies of HCPS autopsy tissue demonstrate infrequent hantavirus inclusions in pulmonary capillary endothelial cells, and, more rarely, virions in both pulmonary capillary endothelial cells and interstitial macrophages (131, 132). Hantaviruses have been infrequently recovered from humans, so the duration of viremia and viral excretion has not been clearly determined. However, SNV RNA has been uniformly detected in peripheral blood mononuclear cells (PBMC) by RT-PCR from persons hospitalized with HCPS, but only intermittently in specimens collected 16 to 23 days after onset of symptoms and not in later specimens (133). In contrast, SNV RNA was detected by RT-PCR in only one of three bronchoalveolar lavage samples in patients in whom SNV RNA was easily detected in PBMC.

### Histopathology

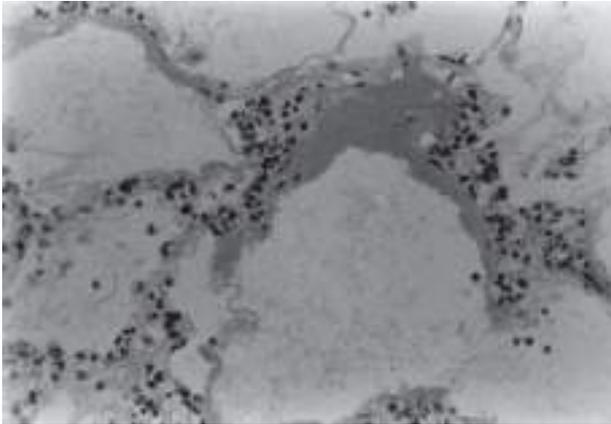

Autopsies of HFRS cases show capillary engorgement and focal hemorrhages widely distributed in the kidneys and hemorrhagic necrosis of the renal medulla (134). Retroperitoneal edema is present in persons who die of shock early in the course of illness. Widespread hemorrhages with or without hemorrhagic necrosis occur in the subepicardium

and epicardium of the right atrium, anterior pituitary, meninges and subarachnoid space, pancreas, and skin. Hemorrhage and necrosis are most marked in the right atrium in patients who have died early in the shock phase, whereas hemorrhagic necrosis of the anterior pituitary has been most prominent in patients who survived the shock phase and died during the oliguric or diuretic phases (see below). Although pulmonary edema has been described in HFRS, most cases of fatal pulmonary edema from the Korean War occurred during the oliguric and diuretic phases rather than the shock phase (134–137). Pulmonary interstitial infiltrates also appeared much less prominent in HFRS than in HCPS (131, 132, 134–136). When using modern radiologic techniques, high-resolution computed tomography showed thoracic effusions or pulmonary edema in almost half of HFRS patients infected with PUUV (138). In both HFRS and HCPS, there were infiltrates of large, atypical mononuclear cells in the spleen, lymph nodes, and in the hepatic portal triads. Renal biopsies of patients with NE have shown interstitial edema and hemorrhage, tubular degenerative changes, and glomerular inflammatory infiltrates, and changes consistent with acute tubular necrosis may persist for several months (136).

In a series of 13 autopsies of patients with HCPS performed at the University of New Mexico, all had large, bilateral pleural effusions, and large, rubbery, edematous lungs with significantly increased weight (132). Splenomegaly was found in 5 of 12, and gastric mucosal hemorrhage was found in 3 of 13. Histologically, the lungs showed intra-alveolar and septal edema, interstitial infiltrates with mononuclear cells (primarily T lymphocytes with a CD4/CD8 ratio about 2:1 and macrophage/monocytic cells), and sparse to moderate hyaline membranes (132). Large immunoblasts, primarily activated CD8+ cells, were found in pleural fluid and peripheral blood (Figure 3) (132, 139). In contrast to findings in patients with adult respiratory distress syndrome, the type I alveolar lining cells were intact and type II lining cells were not activated; hyaline membranes were composed primarily of fibrin, and neutrophils and cellular debris were uncommon (Figure 4). In contrast to the findings in HFRS, gross and histologic findings in patients with HCPS were normal in the brain, pituitary, heart, kidneys, adrenals,

**FIGURE 3** Peripheral blood smear from a patient with the cardiopulmonary stage of hantavirus cardiopulmonary syndrome. Note the immunoblast with basophilic cytoplasm, prominent nucleolus, and high nuclear to cytoplasmic ratio. Also note immature neutrophils. Courtesy of R. Feddersen.

**FIGURE 4** Pulmonary histology in a patient who died from hantavirus cardiopulmonary syndrome. Note the intra-alveolar and septal edema, interstitial infiltrates with mononuclear cells, and sparse hyaline membrane. In contrast to patients with ARDS, the hyaline membranes are largely devoid of inflammatory cells and cellular debris. Courtesy of Dr. K Nolte.

pancreas, and skin, and no patient had retroperitoneal edema (132). Of note, pathologic evidence of myocarditis has been reported in patients who died from HCPS (140).

### Immune Responses

Both HCPS and HFRS cause capillary leak syndromes. The differences between the two syndromes include the primary target organs (the lung in HCPS and the kidney in HFRS) and lack of widespread hemorrhage and hemorrhagic necrosis in HCPS despite the presence of thrombocytopenia in both syndromes. Although capillary endothelial cells are infected with hantaviruses in both syndromes and the degree of hantavirus infection is greatest in the capillary endothelial cells in primary target organ, EM studies in both syndromes have failed to show any evidence of capillary endothelial cell necrosis or cytotoxicity. Thus, it has been postulated that virus-infected endothelial cells may be injured by T cells, cytokines, or other immune-mediated factors creating gaps between endothelial cells (139). Recently, it was shown that hantavirus infected endothelial cells actually were protected from injury by cytotoxic cells and apoptosis was inhibited (133, 141). In both syndromes, antihantavirus antibodies are invariably present at the onset of clinical involvement of the primary target organ. In HCPS, elevated plasma levels of IL-2 and its receptors, gamma-interferon, IL-6, and soluble receptors for TNF suggest marked cytokine activation, and the same is suggested by increased levels of soluble IL-2 receptor, TNF, kallikrein-kinins, and by gamma-interferon expression in HFRS. Circulating immune complexes, activation of the complement pathway, and deposition of immunoglobulins and complement in both the glomerular basement membrane and tubules are present in HFRS but not HCPS.

Early development of high neutralizing antibody titers to Sin Nombre virus is associated with mild HCPS. Patients with severe or fatal acute SNV and PUUV infection have significantly lower neutralizing antibody titers on the day of hospital admission compared with patients with mild disease (142, 143).

$\beta_3$  integrins mediate cellular entry of pathogenic hantaviruses (Hantaan, Seoul, Puumala, Sin Nombre, and New York viruses) but do not mediate the entry of Prospect Hill

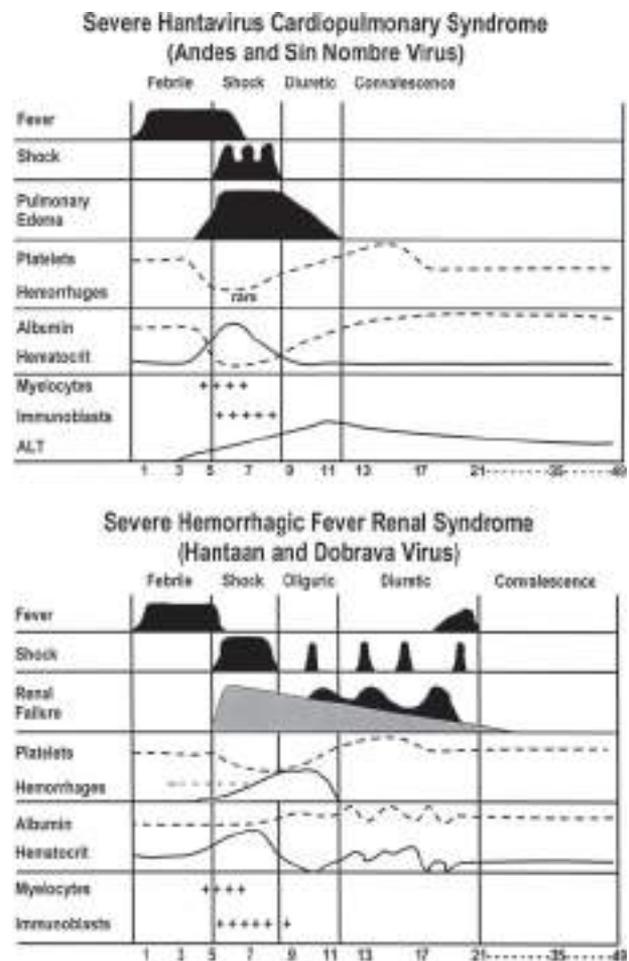

virus, a virus not associated with human disease, in human umbilical vein endothelial cells and in Vero E6 cells (24, 144).  $\beta_3$  integrins are present on platelets, endothelial cells, and macrophages and are also known to regulate vascular permeability and platelet function.

Humoral and cell-mediated immune responses appear to persist for decades, and recurrent episodes of HFRS or HCPS have not been reported. Thus, it is presumed that infection leads to lifelong protection from repeat infection.

### Clinical Manifestations

#### Hantavirus Cardiopulmonary Syndrome (HCPS)

The illness typically begins with a febrile prodromal phase characterized by fever and myalgia; the latter is often prominent (Figure 5) (145). Headache, backache, abdominal pain, diarrhea, nausea, and vomiting may also be present, particularly after the first 24 to 48 hours. As with HFRS, fever and abdominal pain may dominate the clinical presentation suggesting acute appendicitis or another cause of an acute surgical abdomen (Table 5). The febrile phase, which usually lasts 3 to 4 days but may last 10 to 12 days, is followed by the sudden onset of noncardiogenic pulmonary edema and, in some cases, by shock (58–60, 146).

**FIGURE 5** Clinical course and typical laboratory findings in severe hantavirus cardiopulmonary syndrome and severe hemorrhagic fever with renal syndrome. Reprinted from reference (145) with permission of the publisher.

**TABLE 5** Clinical and laboratory features of Hantaan-associated hemorrhagic fever with renal syndrome (HFRS) and hantavirus cardiopulmonary syndrome (HCPS)

Abnormality	HFRS	HCPS
Prodrome with fever and myalgias	Present	Present
Facial flushing	Common early	Absent
Petechiae	Common late in prodrome	Absent in Sin Nombre virus, often present with Andes virus
Conjunctival injection	Common early	Absent
Pulmonary edema	Uncommon except in oliguria	Present during cardiopulmonary stage
Proteinuria	Present with onset late in prodrome	Uncommon
Hemorrhage	GI, CNS and right atrial hemorrhage seen in severe cases/deaths	Rare with Sin Nombre virus; clinical bleeding (from venipuncture sites, pulmonary hemorrhage) more common with Andes virus
Renal failure/azotemia	Common	Uncommon/mild
Hemoconcentration	Uncommon except with 9BP/shock	Present in 50% of patients
Thrombocytopenia	Present early	Present early
Nonproductive cough/shortness of breath	Uncommon	Present at onset of cardiopulmonary stage
Shock	Uncommon	Common during cardiopulmonary stage
Hypotension	Common	Very common

The cardiopulmonary or shock phase of HCPS is heralded by the abrupt onset of cough and shortness of breath, which may be accompanied by dizziness. Pulmonary edema develops rapidly, usually over 12 hours or less. All hospitalized cases have become hypoxic during this stage, and nearly all have required supplemental oxygen. Approximately 75% of cases require mechanical ventilation, and mortality is approximately 50% in those who require intubation. Monitoring with a flow-directed pulmonary artery catheter typically shows normal pulmonary wedge pressure (PWP), decreased cardiac index (CI), and elevated systemic vascular resistance (SVR) (Table 6). These parameters are helpful in clinically differentiating HCPS from septic shock. In the latter, the CI is typically elevated and the SVR is depressed.

Among hospitalized patients, death is usually preceded by the abrupt onset of a profound lactic acidosis, cardiogenic shock, and by pulseless electrical activity despite the ability to maintain adequate oxygenation. Death may occur within the hours of the first pulmonary symptoms, with death being uncommon after approximately 48 hours of intubation. A

lactate  $\geq 4$  mmol/l, marked hemoconcentration, cardiac index  $\leq 2.2$ , and persistent hypotension are indicators of a poor prognosis. Among hospitalized patients, death almost always results from shock with very low cardiac output and from cardiac arrhythmias. Death rarely occurs from respiratory failure provided that mechanical ventilation is available. As such, this chapter and many recent publications use the term hantavirus cardiopulmonary syndrome (HCPS) rather than hantavirus pulmonary syndrome (HPS) to call attention to the important role of shock and arrhythmia in serious and fatal HCPS.

After two to four days, recovery is heralded by the onset of the diuretic phase. Clinical improvement is often rapid, allowing many patients to be extubated within 12 to 24 hours after the onset of diuresis. Supplemental oxygen may be required for several days following extubation. The diuretic phase is typically followed by a convalescent phase that may last up to several months and is characterized by weakness and fatigue, but limited long-term follow-up studies suggest that patients recover fully without residual abnormalities.

Chest radiographs are usually normal during the prodromal, febrile phase and may be normal at the onset of pulmonary symptoms, but radiographic abnormalities invariably appear shortly after the onset of pulmonary symptoms (147). Early findings include radiological signs of bilateral interstitial edema, including Kerley B lines, hilar indistinctness, or peribronchial cuffing. Within 48 hours (often within 2 or 3 hours), radiographic signs of bilateral air space disease develop in a majority of patients, including all who require mechanical ventilation or die (Figure 6).

The platelet count begins to drop shortly after the onset of fever (Figure 5) (145). Isolated thrombocytopenia has been present in samples obtained 24 to 48 hours before the onset of the shock phase. In the shock phase, characteristic hematological abnormalities include thrombocytopenia, increased white blood cell counts with immature granulocytes,  $\geq 10\%$  immunoblasts, and elevation of LDH. Patients with severe disease also exhibit hemoconcentration, hypoalbuminemia, and lactic acidosis. The immunoblasts are characterized by basophilic cytoplasm (occasionally with

**TABLE 6** Hemodynamic summary at clinical nadir of 8 HCPS patients with shock

	HCPS (mean $\pm$ SEM)	Normal (range)
Cardiac index (l/min/m <sup>2</sup> )	2.1 $\pm$ 0.33	2.5–4.2
Pulmonary artery wedge pressure (mm Hg)	15.6 $\pm$ 2.6	8–10
Systemic vascular resistance index (dyne.sec.cm <sup>-5</sup> /m <sup>2</sup> )	2,114 $\pm$ 258	1,700–2,500
Pulmonary artery mean (mm Hg)	29.7 $\pm$ 3.5	8–20
Stroke volume index (ml/beat/m <sup>2</sup> )	17.9 $\pm$ 3.5	33–47

Clinical nadir defined by lowest value of stroke volume index. All patients were receiving vasoactive or inotropic drugs at the time of measurement and had received volume resuscitation. Reprinted from reference (146) with permission of the publisher.

coarse granules), prominent nucleoli, and a high nuclear-to-cytoplasmic ratio (Figure 3). Elevations in aspartate aminotransferase typically occur after the onset of the cardiopulmonary/shock phase and peak early in the convalescent phase (Figure 5).

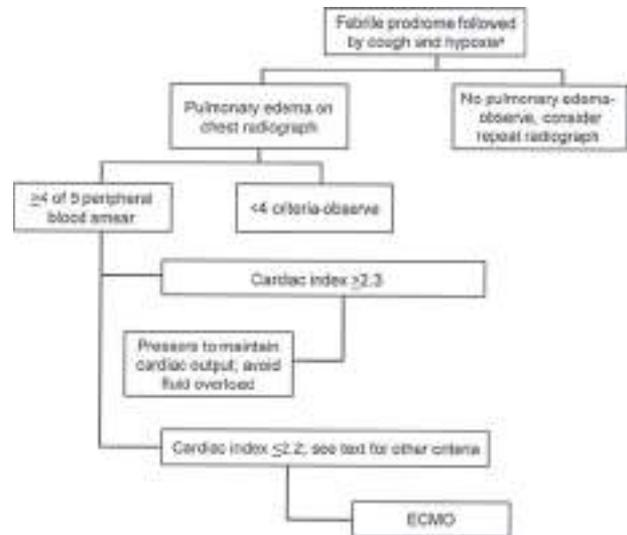

### Diagnosis

The diagnosis should be considered in persons who present with fever and moderate to severe myalgia, particularly if the person has had recent rural exposure or a recent high-risk exposure such as cleaning food or feed storage areas, catching rodents, agricultural work, or increased numbers of rodents in the home. Whenever practical, a complete blood count, including a platelet count, should be obtained. In the setting described above, the presence of thrombocytopenia should trigger both serologic testing for hantavirus and consideration of referral to a center with critical care capabilities.

Clinical decisions regarding patient care including institution of ECMO must often be made before the results of serologic testing are available (Figure 7) (148). Fortunately, an initial clinical diagnosis of HCPS can be made with a high degree of confidence in patients who are in the cardiopulmonary phase based on the clinical presentation and a review of the peripheral blood smear. In a recent blinded analysis of patients with a febrile prodrome followed by pulmonary edema, the presence of four or more of the following findings had a sensitivity of 96% and specificity of 99% for diagnosis of HCPS (149): thrombocytopenia, myelocytosis, lack of significant toxic granulation in neutrophils, hemoconcentration, and more than 10% lymphocytes with immunoblastic morphologic features. Thus, pending results of serologic testing, a probable diagnosis can be established for patients in the shock or cardiopulmonary phase of HCPS through examination of the peripheral smear and by measurement of the CI, PWP, and SVR with a flow-directed pulmonary artery catheter or approximated by noninvasive monitoring (146, 148–150).

### Differential Diagnosis

The differential diagnosis is broad, but should include pneumonia, sepsis, endocarditis, and septic shock; antibiotic

**FIGURE 7** Flow diagram for the management of patients suspected of having hantavirus cardiopulmonary syndrome in the cardiopulmonary stage pending IgG and IgM antihantavirus antibody results. Reprinted from reference (148) with permission of the publisher.

coverage should be provided to cover the most likely clinical syndromes. At the University of New Mexico, antibiotic coverage includes pathogens such as *N. meningitidis*, *S. pneumoniae*, *Y. pestis*, and *F. tularensis* unless a specific pathogen or syndrome is suspected. Although SNV has not been transmitted nosocomially, isolation should be considered until the diagnosis is established or until infection with agents such as *N. meningitidis* or *Y. pestis* has been ruled out. Rare nosocomial transmission of ANDV has been reported, so contact and droplet isolation should be utilized for routine care, and N95 respirator masks should be used during procedures such as suctioning and intubation (41).

Unfortunately, it is very difficult to differentiate patients who are in the febrile, prodromal phase of HCPS from patients with other febrile illnesses. The differential diagnosis of fever and thrombocytopenia is broad. For patients with rural exposure in North America, the differential diagnosis varies by region and the type of exposure but could include plague, tularemia, leptospirosis, ehrlichiosis, Colorado tick fever, relapsing fever, or spotless Rocky Mountain spotted fever.

### Hemorrhagic Fever with Renal Syndrome (HFRS)

The clinical severity of HFRS varies according to the virus type. Hantaan-associated HFRS, also called Korean and epidemic hemorrhagic fever, has been divided into five stages: febrile, hypotensive, oliguric, diuretic, and convalescent (Figure 5). Not all patients with Hantaan-associated HFRS have all five stages, and the stages appear somewhat less useful in understanding the clinical course of HFRS caused by the other viruses (136, 151–153).

### Hantaan-associated HFRS

The illness of Hantaan-associated HFRS begins with the onset of fever, which is universal and lasts from three to seven days (136, 151–153). Symptoms like malaise, myalgias, and headache are common, as are flushing of the face and neck in conjunction with periorbital edema and conjunctival injection or hemorrhage (Table 5). After several days, the symptoms may worsen and be accompanied by

nausea, vomiting, abdominal pain, and lower back pain. Petechiae may be found, particularly on the head, neck, and trunk and palate. Laboratory findings include a normal or slightly elevated WBC and decreasing platelet count. Proteinuria is present, gradually increases during this phase, and persists through the oliguric phase.

Coincident with or shortly before resolution of the fever, some patients develop hypotension and shock. Mild degrees of hypotension may develop in up to 50% of patients, whereas shock develops in 10 to 15%. In patients with shock, the WBC is markedly elevated with a left shift and immature forms; there is marked thrombocytopenia and hemoconcentration. Patients at this stage may exhibit more widespread petechiae and bleeding, and disseminated intravascular coagulation is usually present (136, 151, 152). In the remainder, the hypotensive phase resolves after a period of several hours to two or three days.

During the second half of the first week of the illness, oliguric renal failure develops in up to 60 to 70% of patients. If present initially, hypotension and elevations in the hematocrit resolve during the oliguric phase, but hypervolemia with pulmonary edema, neurologic complications, and increased bleeding may occur. Dialysis may be required, particularly in patients with renal failure and pulmonary edema. In a recent series, oliguric renal failure was present for a mean of 8 days (range 3 to 17 days) (136). Deaths may occur secondary to pulmonary edema, electrolyte disturbances, shock, and CNS and other hemorrhages.

The diuretic phase begins about the middle of the second week of illness. Patients who have had mild disease generally recover quickly during this phase, but more severely ill patients are at risk of death from intravascular volume depletion, electrolyte disturbances, and secondary infection. This stage may be brief in patients with mild disease or may gradually resolve over several weeks in those with more severe disease; the mean duration is about 6 days (range 2 to 12) (136). The diuretic phase may be followed by a prolonged convalescent phase.

The risk of death from Hantaan-associated HFRS during the Korean War was about 15% but more recently has been 5 to 7%. A recent publication from China reported an overall case-fatality rate of 1.2% (154). Among survivors during the Korean war, four of five who developed pulmonary edema during the oliguric phase required hemodialysis, suggesting that the risk of death during the oliguric and diuretic phases may have been reduced by critical care treatment and hemodialysis (136). Enhanced clinical care has improved the outcome of HFRS, although in many HFRS endemic countries it is difficult to determine the causative hantavirus and estimated case-fatality rates may be confounded by including both Seoul and Hantaan virus infections.

#### HFRS from Seoul, Saarema, and Dobrava Viruses

Seoul-associated HFRS is less severe and has fewer distinct phases with overall mortality estimated at less than 1%. Hemorrhagic manifestations appear less common, whereas abdominal pain, hepatomegaly, and hepatic dysfunction may be more common. Serologic evidence of hantavirus infection was found in 6.5% of patients with end-stage renal disease due to hypertension in Baltimore (155, 156). These data suggest that a hantavirus may cause hypertension and end-stage renal disease but need to be confirmed by other groups and with prospective studies. Although the serologic data suggest that the antibodies react most strongly to Seoul virus, hantaviral RNA should be examined to determine whether the syndrome is caused by Seoul or a closely related virus.

Saarema virus is also reported to cause a mild form of HFRS. Dobrava virus, in contrast, causes a severe form of HFRS with mortality of 9 to 12%, hypotension in almost 50%, and oliguric renal failure requiring dialysis in 30 to 47% (115). Hemorrhage or hemorrhagic complications are reported in 9 to 26%, and shock is reported in 21 to 18% (115).

#### HFRS from Puumala Virus, Nephropathia Epidemica

Mild HFRS caused by PUUV infection, also denoted nephropathia epidemica, has a mortality estimated to be less than 0.5% (115, 118), but may be considerably higher for elderly patients (157). The syndrome begins with a fever that typically lasts between two and nine days. Within one to two days of the onset of fever, most patients also develop headache, malaise, and backache. Abdominal pain has been reported in most patients, and, as with other hantavirus infections, this presentation may mistakenly suggest an acute surgical abdomen. Hypotension occurs but overt shock is rare. Disseminated intravascular coagulation and minor hemorrhagic manifestations such as macroscopic hematuria and epistaxis were reported in around one-third of patients (121, 158). Proteinuria (almost 100%), elevated creatinine (in almost 100%) with peaks of 2 to 10 mg/dl, and oliguria (~50% of cases) typically begin at about the third or fourth day of illness and last only a few days (115). This phase is followed by a diuretic phase that lasts for a week to ten days. Rarely patients with NE have also been reported to have encephalitis, Guillain-Barré syndrome, and disseminated encephalomyelitis as well as acute perimyocarditis (115, 159). CSF examination is usually normal but may show slight elevations in protein and white blood cells. Blurred vision has been reported in about 30% of cases (160). This phenomenon is due to myopia that may be caused by ciliary body and lens edema (161). The mean duration of hospitalization has ranged from 8 to 22 days, and the median time of missed work ranges from 36 to 48 days (121).

#### Laboratory Diagnosis

Direct virus isolation from humans with HFRS and HCPS is difficult (129). In addition, virus isolation requires BSL-3 facilities, and animal models for HCPS require BSL-4 animal facilities (40).

#### Hantavirus Cardiopulmonary Syndrome

As in the case of HFRS, specific IgG and IgM antibodies have been almost uniformly present in the first serum samples tested (60, 63, 162), including testing of limited numbers of serum samples obtained early in the febrile prodrome. Available serologic tests include ELISA, neutralization, hemagglutination inhibition (HI), Western immunoblot, and strip immunoblot assays.

In the United States, serologic testing to date has used ELISA and Western and strip immunoblot assays. The Centers for Disease Control and Prevention (CDC) has developed an IgG ELISA and an IgM-capture ELISA based on recombinant N proteins of SNV. Commercial ELISA antibody testing is for hantavirus; testing for SNV antibodies is also available through Focus Technology, but the antigens employed in these assays are proprietary. N protein is highly immunogenic and tends to be cross-reactive among hantaviruses. Inclusion of the N protein enhances the sensitivity of an assay, and cross-reactivity may be useful as in the case when one is performing serologic screening for a previously unrecognized hantavirus. However, it is difficult to differentiate between hantavirus species using the N protein.

In the Western immunoblot format, the first 59 amino acid (aa) residues of SNV N protein contain almost all the epitopes of the 428 protein, and the dominant linear epitope of SNV G1 protein is confined to a variable region at residues 58 to 68 (63, 163). The latter elicits little or no cross-reactivity among hantaviruses but is conserved among SNV from different regions.

Quantitative measurement of neutralizing antibody is limited to research laboratories. A plaque reduction assay is available, but this assay takes several weeks to perform and must be performed in a BSL-3 laboratory. More recently, rapid, BSL-2 based neutralization assays have been developed utilizing VSV pseudovirions expressing hantavirus glycoproteins (164).

Viral RNA can be readily detected by RT-PCR in peripheral blood mononuclear cells in persons with acute SNV or ANDV infection. Post mortem, hantavirus infection can be documented with serologic studies or by examination of tissue (particularly lung tissue) by RT-PCR or by immunohistochemical studies using monoclonal antibodies. Sequence analysis is helpful in determining the hantavirus species and has proven useful in molecular epidemiological studies (35, 41, 61, 62, 64, 70, 71, 76, 81, 105, 129).

### Hemorrhagic Fever with Renal Syndrome

In eastern Asia, infection with Hantaan and Seoul hantaviruses is usually diagnosed serologically with IFA, ELISA, or bead-agglutination formats, and IgM antibody is determined by IgM-capture ELISA. Similarly, Puumala hantavirus is commonly diagnosed by detection of specific IgG and IgM antibodies by IFA, ELISA, or RIA (112, 113, 115). As in the case of HCPS, IgM antibodies are almost invariably present at or within days of the onset of symptoms. Viral RNA is detectable from blood or serum by RT-PCR in 90% the first three days after onset of disease and in 81% of patients when collected at day 4 to 7 (143) and in less than two-thirds of patients with acute Dobrava virus infection (115, 165).

### Prevention

General guidelines for prevention of infection with hantaviruses include efforts to seal sites of potential rodent entry into homes and peridomestic buildings (particularly storage sheds), careful attention to prevent rodent access to food, and by discouraging rodent nesting by eliminating potential nesting sites around the home and workplace. Detailed guidelines for cleaning up rodent-infested areas and for working with potentially infected rodents have been published (166, 167). There is no known role for passive immunoprophylaxis or antiviral chemoprophylaxis, but animal models using HTNV suggest that antiviral chemoprophylaxis with intravenous ribavirin would probably offer some protection from clinical infection. In addition, passive administration of anti-ANDV neutralizing antibody four or five days after ANDV infection was protective in the Syrian hamster model (168).

Candidate recombinant Hantaan vaccines, including a vaccinia recombinant vaccine and a baculovirus-expressed subunit vaccine, have been developed at USAMRIID (169, 170, 174, 175). Vaccines with both G1 and G2 of Hantaan virus can elicit neutralizing antibody responses and provide partial protection from challenge in hamsters, and administration of baculovirus-expressed N protein also prevented virus expression in hamsters. However, these vaccines have been dropped from development, since the vaccinia recombinant vaccines were poorly immunogenic in humans, and the baculovirus products did not produce sufficient

quantities of purified antigen (171, 176). Investigational strategies include DNA vaccination for pathogenic hantaviruses, including HTNV, SNV, and ANDV (164, 168).

Formalin-inactivated tissue culture–derived Hantaan and Seoul vaccines have been developed in Asia. A formalin-inactivated, mouse-brain-derived Hantaan vaccine has been licensed and widely used in Korea since 1990 (172, 177). The vaccine is immunogenic and well tolerated, but rigorously performed, controlled efficacy trials have not been reported. In China, formalin-inactivated Hantaan virus vaccines have been prepared in Mongolian gerbil kidney cells (MGKC) or golden hamster kidney cells (GHKC) (173). These vaccines appear immunogenic, and field trials suggest efficacy. However, neither of the vaccines has been tested in randomized, placebo-controlled trials. A bivalent vaccine with inactivated Hantaan and Seoul virus has also been developed in China (173). The bivalent vaccine appears immunogenic, but efficacy trials have not been reported. Three doses are required to obtain protection according Chinese reports. Incompletely vaccinated patients display a milder course of HFRS infection than unvaccinated ones (174).

### Treatment

#### Hantavirus Cardiopulmonary Syndrome

Principles of critical care management for patients with the cardiopulmonary syndrome include oxygen delivery with intubation and ventilatory support as necessary (146). Because of the high potential for rapid clinical deterioration, whenever feasible patients should be transferred to a facility with sophisticated critical care facilities, ideally including the availability of extracorporeal membrane oxygenation (ECMO). Monitoring of cardiac index, pulmonary wedge pressure, and systemic vascular resistance with a flow-directed pulmonary artery catheter should be performed or approximated using noninvasive monitoring if feasible. Inotropic support and vasopressors should be employed rather than fluids whenever possible to reduce the likelihood of worsening pulmonary edema.

ECMO has been used in patients with severe HCPS in the cardiopulmonary phase who are judged to be at high risk of death (175). In a series of patients treated with ECMO between 1994 and 2010 who had predicted mortality of almost 100% without ECMO, overall survival was 66%. Furthermore, survival was 80% among 25 patients treated between 2003 to 2010 when the group practiced elective insertion of vascular sheaths with almost concurrent intubation and initiation of ECMO when the patients became unstable. Criteria for ECMO include a cardiac index of less than 2.31 per min per square meter, or an arterial oxygen tension to fractional inspired oxygen ( $\text{PaO}_2/\text{FIO}_2$ ) ratio of less than 50, and lack of response to conventional (non-ECMO) support (148).

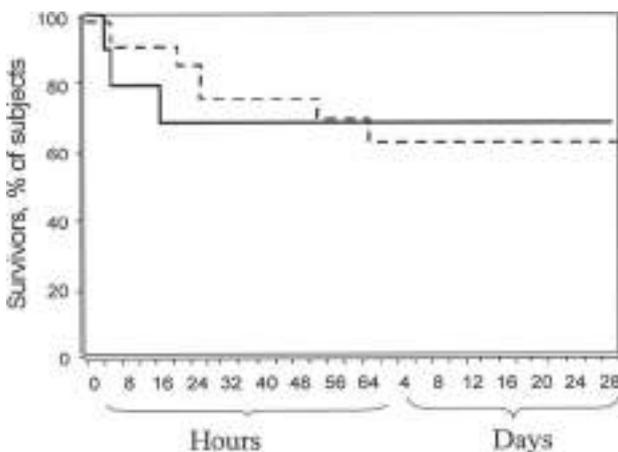

Shortly after recognition of HCPS in the United States in 1993, open-label intravenous ribavirin was available for persons with suspected HCPS through a CDC-sponsored protocol. Therapy was considered justified because it had reduced mortality in hantavirus-associated HFRS in a controlled trial and because all previously tested hantaviruses had been sensitive to ribavirin *in vitro* (176, 177). Among 140 persons suspected of having HCPS who received ribavirin, HCPS was confirmed in 30 and ruled out in the remaining 110 (178). Among the 64 patients diagnosed in the United States during the study period, death occurred in 14 (47%) of 30 patients treated with ribavirin as compared to

17 (50%) of 34 who were not enrolled in the treatment study. Ribavirin-associated toxicity included reversible anemia in 71% of recipients; 19% required transfusions (178). Adverse events that were less clearly related to ribavirin therapy included pancreatitis or hyperamylasemia that were documented in 8% of patients.

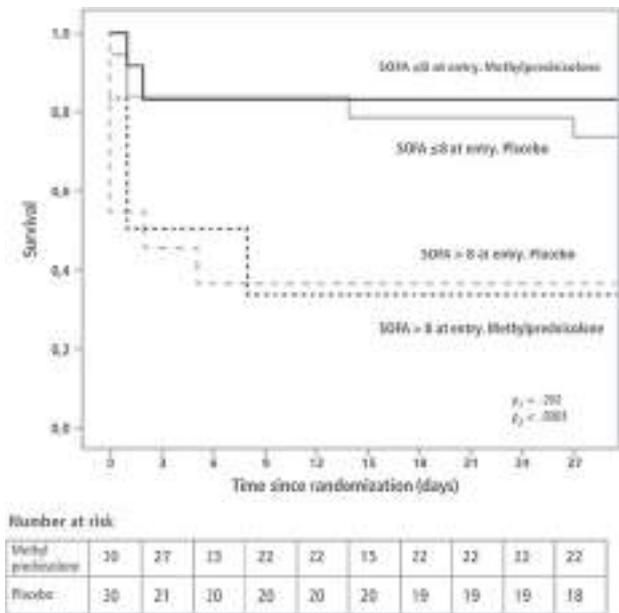

A subsequent, prospective, placebo-controlled trial of intravenous ribavirin for suspected HCPS in the United States and Canada, sponsored by the National Institute of Allergy and Infectious Diseases Collaborative Antiviral Study Group, failed to reach its target accrual and was closed based on a futility analysis (179). However, there were no trends suggesting a reduction in mortality in patients enrolled during the cardiopulmonary phase (Figure 8), and the investigators were unable to enroll subjects in the febrile prodrome. The median time to progression to death or initiation of ECMO was 24 hours or less in both treatment groups, suggesting that there is a very limited window of opportunity for intervention once patients present in the cardiopulmonary phase (Figure 8) (179).

Studies suggested benefit from intramuscular cortisone treatment of HFRS during the Korean conflict, and observational studies suggesting benefit from high-dose intravenous methylprednisolone for HCPS in Chile (180, 181). A randomized double-blind, placebo-controlled trial in Chile assessed high-dose intravenous methylprednisolone treatment of HCPS in the cardiopulmonary phase (182). Among the 60 with confirmed ANDV infection, there was no significant difference in progression to primary endpoints, including shock, respiratory failure, or death. Furthermore, the risk of death was determined by the severity of illness at study entry, whereas methylprednisolone treatment had no impact on survival after adjustment for disease severity at entry (Figure 9).

More recently, investigators in Chile conducted an open trial of human immune plasma with an ANDV neutralizing antibody (NAb) dose of 5,000 U/kg for treatment of HCPS (183). Donors were plasmapheresed at least 6 months after recovery from HCPS, and ANDV NAb titers were measured by a focus reduction assay. Low case fatality rates, 14/29 (14%) were low, but efficacy could not be evaluated in this

**FIGURE 8** Survival without extracorporeal membrane oxygenation among ribavirin recipients versus placebo recipients in a trial of intravenous ribavirin therapy for hantavirus cardiopulmonary syndrome. **FIGURE 9** Kaplan-Meier survival analysis by treatment arm and severity at entry. P1: significance between methylprednisolone and placebo arm. P2: significance between sequential organ failure assessment (SOFA) >8 and ≤8 at entry. Reprinted from reference (182) with permission of the publisher.

nonrandomized, open trial. Future studies should ideally be performed with a product without the need for blood type compatibility, NAb directed against both SNV and ANDV, and feasibility of development of a commercial product (183).

### Hemorrhagic Fever with Renal Syndrome

Management of HFRS should include monitoring for shock, hypotension, renal failure, and hemorrhage. Whenever possible, both critical care facilities and hemodialysis should be readily available. Comparison of case fatality rates before and after the availability of hemodialysis and critical care suggest that mortality rates have been significantly reduced by the availability of the latter (136, 151–153).

A prospective, placebo-controlled trial of high-dose intravenous ribavirin in patients with serologically confirmed hantavirus-associated HFRS in the People's Republic of China has established the value of this intervention (176). Nonpregnant patients 14 years of age or older with fever and proteinuria with a significant exposure history or the presence of hantavirus-specific IgM antibodies were eligible for enrollment unless they had had symptoms for more than six days, advanced renal failure, coma, or shock refractory to fluid replacement. Patients who received ribavirin received a loading dose of 33 mg/kg followed by 16 mg/kg every 6 hours for 4 days and 8 mg/kg every 8 hours for 3 days.

Of 242 patients with serologically confirmed hantavirus-associated HFRS who were included in the efficacy analysis, there was a 7-fold decrease in the risk of mortality among ribavirin-treated patients ( $P = 0.01$ ) after adjustment for baseline predictors of mortality (176). Ribavirin therapy also significantly reduced the risk of developing oliguria and hemorrhage. The primary adverse effect of therapy was hemolytic anemia that resolved after discontinuation of therapy. The proportion of patients with severe anemia (hematocrit below 20) was similar in the two treatment

groups. Development of severe anemia was gradual in the ribavirin-treated patients, whereas placebo-treated patients with severe anemia tended to develop acute drops in hematocrit secondary to gastrointestinal or urinary tract hemorrhage.

A similar, placebo-controlled trial, also conducted in the People's Republic of China, evaluated the efficacy of treatment with alpha-interferon at doses of  $1 \times 10^7$  units per day. Although the risk of hemorrhage was reduced with treatment, treatment with interferon did not reduce mortality (184). Recently, another approach was suggested to interact with the pathogenesis, i.e., to inhibit the bradykinin receptor with an antagonist, icatibant, and thereby decrease the capillary leakage syndrome. One severe case treated using this method survived but further studies are needed (185).

## PHLEBOVIRUSES

### Rift Valley Fever

#### Epidemiology

Rift Valley fever is endemic in Africa and the Arabian Peninsula, with major outbreaks in Egypt in 1977 and 1993, in Yemen in 2000, in Saudi Arabia in 2000 to 2001, and in Kenya in 2007 (186–189). Epizootics, particularly in sheep and cattle, and epidemics may occur after periods of high rainfall and flooding, as well as following the introduction of irrigation projects. During outbreaks, the economic consequences, including the ban of animal trade and loss of livestock, may be devastating for the rural communities in endemic countries.

Transmission of RVF virus is by insect vectors for epizootics and for most human infections by direct contact with infectious tissues or blood from abortion or slaughter of infected animals (189, 190). The virus has been isolated from several genera of mosquitoes and from sandflies, suggesting that multiple insect vectors may be important in maintaining epizootic disease. In the absence of epizootic disease, the virus can be maintained for years during drought through transovarial transmission of virus (particularly in *Aedes mcintoshi*), persistence of infected viable mosquito eggs in soil, and reemergence of infection after rainfall and hatching of the infected eggs (7, 191). Also, an enzootic cycle of the virus may be present in wild animals (192). Amplification in sheep, cattle, and goats would appear to be more important than transmission between mosquitoes. The infection has a mortality rate of 10 to 30% in sheep, cattle, and goats and is associated with abortion and almost 100% mortality in pregnant animals.

Humans at risk include persons residing in rural, agricultural areas where an epidemic or epizootic is recognized, persons with exposure to areas where deaths and abortions are occurring in livestock, particularly if they perform necropsy, and those with exposures in laboratories or abattoirs. In an analysis of an outbreak of RVF in Kenya in 1997 to 1998, contact with sheep body fluids and sheltering livestock in one's home were significantly associated with infection (193). Although humans can be infected from bites of mosquitoes and other arthropod vectors, contact with viremic animals, particularly livestock, appears to be the most common mode of acquisition. This is supported by multivariate analyses of risk factors for infection, which include contact with sheep body fluids and sheltering livestock in the home, as well as by relatively low rates of infection in young children (193, 194). The disease occurs in all age

groups and in both sexes. Men seem to have an increased risk, presumably through agricultural activities and animal contact. In the large outbreaks in East Africa in 2007, more male than female cases were recognized (195–197). Since the RVFV has a broad vector competence, there is a rising concern that it may spread to Europe and the Americas similar to West Nile and Chikungunya viruses (198, 199).

#### Pathogenesis

The incubation period ranges from two to six days (7, 189, 190). Viremia occurs in domestic animals and in humans during the acute illness. In animals, target organs include the liver and brain, and in sheep, death usually results from hepatic necrosis. Deaths in humans most commonly occur among those who develop a hemorrhagic fever, shock, and liver necrosis during the acute episode, and virus can be detected or isolated from postmortem blood or liver samples (7, 64, 189, 190, 200, 201). In contrast, virus cannot be isolated from persons with the late clinical complications (encephalitis, retinitis, and uveitis). The time course, lack of viremia, and presence of virus-specific antibodies all suggest that these late complications may be immune-mediated. Animal models for both the acute hepatic necrosis and the late encephalitis are available.

#### Clinical Manifestations

Infection may be asymptomatic, mild, or cause severe disease with substantial morbidity and mortality (193, 202). Most patients with Rift Valley fever (RVF) develop a benign febrile illness with fever, myalgia, and malaise (189, 190, 200, 202–204). Symptoms typically resolve in two to five days but may be followed by a prolonged convalescent period.

The overall mortality of RVF has been estimated to be 1% or less (194). In approximately 1 to 3% of patients the infection presents as a more severe and life-threatening viral hemorrhagic fever; among hospitalized patients with confirmed RVF, both mortality and complications have been reported at much higher frequency. Among 165 patients hospitalized at one hospital in Saudi Arabia in 2000, hepatic failure occurred in 75%, acute renal failure in 41%, and hemorrhagic complications in 19%. Hepatorenal failure, shock, and severe anemia were major factors associated with death among the patients who died (186).

Mortality is also much higher than 1% in case series, probably because of underreporting of mild cases in the case series. In an analysis of 834 reported cases of RVF in Saudi Arabia in 2000 to 2001, of which 81% were laboratory confirmed, the overall mortality rate was 13.9%. Bleeding, neurologic manifestations, and jaundice were independently associated with increased mortality, and patients with leucopenia had lower mortality than patients with normal or increased leukocyte counts (188). Similarly, a case-fatality rate of 29% was reported among 404 probable or confirmed cases of RVF in Kenya between November 2006 and January 2007 (194).

Patients with encephalitis often have a biphasic illness, with onset of headache, nuchal rigidity, confusion, hallucinations, coma, or focal neurologic findings one to four weeks after onset of RVF.

Ocular complications of RVF have long been recognized as a serious but relatively uncommon complication (203). In a cross-sectional study in Saudi Arabia, 165 eyes in 113 outpatients and 47 eyes in 30 inpatients were affected with an interval of 4 to 15 days (mean 8.8 days) between onset of symptoms of RVF and onset of visual symptoms (205). Macular or perimacular retinitis was identified in all affected

eyes, ranging from retinal hemorrhage to optic disc edema and retinal vasculitis. Transient anterior uveitis was present in 31% of cases. Visual acuity was less than 20/200 in 80%, and vision remained the same in 72% and deteriorated in 15% of affected eyes over time. Permanent visual loss was associated with macular and perimacular scarring, vascular occlusion, and optic atrophy.

#### Laboratory Diagnosis

Detection of viral antigen and virus-specific IgM antibodies are the preferred diagnostic tests during acute illness, although detection of IgM antibody in the absence of IgG antibody should be interpreted with caution. The presence of only IgG could be due to a previous infection, so convalescent serum with 4-fold increase of IgG titer is required to verify the diagnosis. Serologic diagnosis may be accomplished with a single convalescent serum using IgM-capture ELISA (or less reliably by IgM-IFA) or with comparison of acute and convalescent sera by neutralization, HI, IFA, or ELISA.

Virus isolation is straightforward, provided blood is obtained during the acute illness, and BSL-3 facilities are available (189–191, 200, 202, 204). Sensitive isolation systems include Vero or AP61 mosquito cells, intracranially inoculated suckling mice, or intraperitoneally inoculated adult mice or hamsters. The virus grows efficiently in many cell lines, is cytopathic, and plaques easily.

As for other viral hemorrhagic fever viruses, the diagnostic use of qualitative or quantitative RT-PCR is safer and more efficient than viral culture. Neither virus isolation nor antigen or nucleic acid detection is helpful in patients with late complications like encephalitis or ocular disease, but a presumptive diagnosis can be established based on rising serum IgG titers and through detection of specific IgM in serum and, occasionally, in CSF.

#### Prevention

As one mode of transmission of Rift Valley fever virus is via mosquito bites, the risk of infection could presumably be reduced by careful use of mosquito repellents, particularly during periods of high rainfall and high mosquito density when the risk of epizootics is most marked. The risk of direct transmission from animals during handling, slaughter, autopsy, or disposal is greatest during epizootics, and particular care should be taken at this time. The presence of an epizootic should be suspected in the setting of unexplained deaths of lambs and sheep and abortions in ewes in an area that is known to be at risk for RVF (202).

Early case recognition by physicians and veterinarians together with surveillance of animals and vector control are important to mitigate outbreaks. This approach has been suggested as the “One Health” concept, which combines the efforts of human and animal health together in the prevention of zoonotic infectious diseases (206).

No special precautions are indicated when caring for infected persons or when handling blood or other tissues beyond those routinely used to prevent nosocomial transmission of blood-borne infections. However, when the differential diagnosis could potentially involve diseases such as CCHF, Lassa fever, or Ebola infection that have substantial risk of nosocomial transmission, strict isolation is indicated until RVF is diagnosed or the patient recovers.

Currently, there is no approved human vaccine (207, 208). Live attenuated vaccines have been used to prevent Rift Valley fever in animals, especially during outbreaks. They are not safe enough to be used in humans, and the live attenuated vaccine can induce abortion in animals. Less

reactogenic clones of RVFV vaccine have been evaluated in animal trials, but the issue of reversion to more virulent strains remains. The technique of reverse genetics has enabled researchers to delete genes associated with virulence and potentially create safer vaccines (208–210).

Both inactivated and attenuated vaccines have been tested for their ability to prevent infection in sheep, cattle, goats, and other animals both to prevent epizootics and economic loss and to prevent human infections. Control measures in a recent outbreak in Kenya included a ban on slaughter of livestock, closure of livestock markets, and use of a live attenuated vaccine for animals (194).

#### Treatment

There is no specific therapy for Rift Valley fever, for the hemorrhagic complications or for the late complications of encephalitis and retinitis. Parenteral ribavirin therapy is effective in preventing or significantly reducing the level of viremia in a rhesus monkey model, and alpha or purified human leukocyte interferon therapy is effective in the same model (211–213). Passive antibody and interferon inducers are also effective in animal models. No human trials have been reported for prevention or treatment of RVF, and there are no current guidelines for passive immunoprophylaxis or antiviral chemoprophylaxis of RVF. Thus, early treatment with ribavirin, alpha or human leukocyte interferon, or passive neutralizing antibody might reduce the risk of complications, but no trials have been performed in humans. Systemic corticosteroids have been used in patients with retinal vasculitis and encephalitis without apparent benefit. The RNA polymerase inhibitor, favipiravir (T-705) has antiviral activity against RVFV *in vitro* and in animal models (214, 215).

### Sandfly Fever Viruses

#### Epidemiology

Phlebotomus fever viruses are found in both hemispheres (6, 7). Sicilian and Naples viruses, transmitted by phlebotomine sandflies, continue to cause human disease in countries bordering the Mediterranean Sea. Residual spraying of walls in homes has been particularly successful, since the vectors feed primarily at night within buildings and tend to rest on building walls, but sandflies may penetrate mosquito netting. Most human infections occur in late spring, summer, and early fall. Epidemics have been described, particularly during wartime, including epidemics in Italy during the Second World War (216). The flight range of the sandfly is limited, so attack rates may vary considerably during epidemics. Toscana virus, which is transmitted by *P. perniciosus* and other sandflies, is a common cause of aseptic meningitis and meningoencephalitis in the Mediterranean basin (217, 218).

The viruses are presumably amplified in wildlife vertebrate hosts, but these have not been identified. Transtadial and transovarial transmissions in sandflies have been demonstrated and are probably the primary mechanisms of perpetuation, particularly in the desert (219, 220).

New World phleboviruses, including Chagres, Punta Toro, and Alenquer, have been isolated during sporadic febrile illnesses from humans in Panama and Brazil who work or live in jungle areas. No epidemics have been identified, and the sandfly vectors appear to be limited to forests.

#### Pathogenesis

In volunteers, the incubation period ranges from two to six days (216). Infected humans are viremic during the acute

febrile illness, and Toscana virus has been isolated from CSF of patients with aseptic meningitis and meningoencephalitis (217, 218, 221–223). No deaths have been reported. Neutralizing antibodies persist after infection, and immunity is probably lifelong.

### Clinical Manifestations

Most infections with sandfly fever viruses appear to result in clinical disease, but mild or subclinical infections may be more common in children. After an incubation period of two to six days, the patient develops a febrile illness that lasts two to four days (216). Toscana virus causes aseptic meningitis and meningoencephalitis (217, 218, 221–223), but high seroprevalence rates in central Italy suggest that most persons infected with this virus either have subclinical infection or a clinical syndrome other than aseptic meningitis (224). No deaths have been reported with these viruses, but neurologic sequelae including deafness and personality changes may develop (225, 226).

### Laboratory Diagnosis

Virus isolation is easily achieved from blood obtained during the three-day fever; the viruses replicate well, are cytotoxic, and form plaques in Vero cells (191, 216, 219, 220, 227). Toscana virus has been isolated from CSF and may also be detected by RT-PCR (218, 228). Serologic diagnosis can be performed with IGM-IFA, or preferably, by IgM-capture ELISA shortly after resolution of the fever or by serology on paired sera using techniques such as ELISA, HI, or plaque reduction neutralization (228).

### Prevention

Infection with sandfly fever virus can best be avoided by use of insect repellants containing DEET. No special isolation requirements are necessary for persons with sandfly fever. Although oral treatment with 1,200 mg/day of ribavirin prevented viremia and clinical manifestations in volunteers inoculated with Sicilian sandfly fever virus, this approach has not been evaluated during a natural epidemic (213). No specific therapy is available for patients with symptomatic infection. Investigational pyrazine derivatives, including T-705 (favipiravir), have shown activity against Naples virus *in vitro* and in animal models (214).

## Severe Fever with Thrombocytopenia Syndrome

### Epidemiology

Severe fever with thrombocytopenia syndrome (SFTS) is caused by a novel tick-borne phlebovirus, SFTS virus, which was first recognized in China during 2007 to 2009 (1, 229). The disease had been reported from at least 11 provinces in China, and cases have also been detected in Korea and Japan (1). A similar disease caused by Heartland virus, which is spread by *Amblyomma americanum* (lone star tick), has also been detected in the United States (2).

Among 171 patients fulfilling the case definition of SFTS (acute fever of unknown cause, temperatures of 38°C or more, and thrombocytopenia), 154 were laboratory confirmed as SFTS (232). Most of the patients with SFTS have been farmers, living in wooded and hilly areas that had been exposed when working in the fields. The virus has been found in *Haemaphysalis longicornis* ticks collected from domestic animals in the same area as the cases reside (229). More cases occur in spring and summer when persons are out in the field and more exposed to ticks. Slightly more women (55 to 57% of cases) have been affected (218, 230). Among 504 confirmed cases in the most affected region, Xinyang,

the vast majority have been older farmers (median age 61 years) living in rural areas (231). Environments with risk include shrub, rain-fed cropland, and forest areas. Seroprevalence studies from affected counties in China show that 1 to 3.8% of the populations in endemic areas have specific IgG antibodies toward SFTS virus (1).

### Pathogenesis

Both the level of viral replication and the host immune responses likely play roles in the pathogenesis of SFTS. Higher blood viral load when the patient is admitted to the hospital and when sustained during the second week of illness is associated with fatal outcome (232). Viremia may last several weeks after onset of illness (232). The infection leads to elevated levels of cytokines, chemokines, acute phase proteins, and coagulation disturbances, which are correlated to viral RNA levels. SFTS viral RNA can be detected not only in blood, but also in the upper respiratory tract, urine, and feces (232). The infection leads to an innate immune response with elevated natural killer cells and increased plasma cytokine levels, e.g., G-CSF, IP-10, MCP-1, IL-1RA, IL-6, and IL-10 (233, 234). The cytokine levels seem to correlate to the severity and outcome of the infection (234). In contrast, the nonstructural protein, NSs, and the nucleocapsid protein both encoded by the S segment may suppress the activation of beta-interferon and NF-κB (235).

A mouse model for the pathogenesis of SFTS has been established and showed similar pathological changes as in humans, i.e., thrombocytopenia and leukopenia in the infected mice (236). Histopathological changes and viral RNA were identified in several organs, the liver, kidney, and spleen. Similarly, infection with SFTS virus in rhesus macaques was characterized by fever, thrombocytopenia, leukopenia, and increased levels of liver and myocardial enzymes but less severe symptoms (237).

### Clinical Manifestations

The most prevalent symptoms in SFTS are fever, myalgia, anorexia, fatigue, nausea, and gastrointestinal symptoms (229, 238). Common laboratory findings are thrombocytopenia, leukopenia, elevated levels of lactate dehydrogenase (LDH), serum aspartate aminotransferase (AST), alanine transaminase (ALT), and creatine kinase (238). Severe cases may have disturbance of consciousness, acute respiratory distress syndrome, hemorrhagic signs, coagulopathy, renal function impairment, and arrhythmia. Disseminated intravascular coagulation may lead to organ dysfunction, multi-organ failure, and death (229, 239, 240). Patients with older age, decreased level of consciousness, elevated levels of lactate dehydrogenase, and creatine kinase have significantly higher risk for fatal outcome (238). The case-fatality rate is 12 to 30% in China (230, 231, 238, 240).

Many of the symptoms presented in SFTS are nonspecific and there are several differential diagnoses, for instance hantavirus, dengue, and infections caused by leptospira and rickettsia. Therefore, an adequate case definition together with fast and reliable diagnostic methods are important. In South Korea, using a case definition including fever (body temperature >38.0°C), leukocytopenia, thrombocytopenia, and symptoms from the gastrointestinal tract, 35 patients were identified in a hospital-based surveillance during 2013 (241).

### Laboratory Diagnosis

The diagnosis of SFTS is based on detection of specific antibodies, viral antigen, or viral RNA by RT-PCR (241).

The virus can be cultivated on Vero E6 and other cells, but culture takes time and could be hazardous. The virus should be handled at Biosafety level 3 laboratories. For detection of contagious and potentially lethal Bunyaviruses, RT-PCR is recommended instead of culture since the virus is killed off during RNA extraction, providing a rapid, safe, and specific method for diagnosis of SFTS in viremic patients with disease (242–244).

Serological testing is done by detection of specific IgM and IgG antibodies by ELISA, using recombinant nucleocapsid protein of SFTS virus (229, 245, 246). Antibodies develop after 7 days after disease onset. If only IgG is analyzed, seroconversion, or a 4-fold raise of titer, is required for diagnosis of SFTS, especially in endemic areas. In addition to diagnosis of acute SFTS patients, an ELISA method can also be useful to study the prevalence of the infection among humans and animals (245, 246).

### Prevention

There is no available vaccine for SFTS virus infection. Prevention is based on avoiding ticks and tick bites in endemic regions. Insect repellents that are effective against ticks may be used for prevention of several tick-borne infections. When bitten, ticks should be removed as quickly as possible. It has been recommended that patients should be isolated during the acute and viremic phase (1). When handling blood and other specimens, gloves and other protective clothing should be used.

### Treatment

The case fatality rate may be as high as 30%, and there is no effective antiviral treatment. Symptomatic treatment, supportive care, and fluid replacement therapy can decrease the risk for shock and fatal outcome. The antiviral ribavirin appeared ineffective when used for SFTS patients (238, 241). In one nonrandomized, observational study of 311 SFTS patients, there was no difference in case fatality rates (CFR) between 138 patients that received ribavirin (CFR 17.4%) compared with 164 who did not receive ribavirin (CFR 17.1%). Furthermore, ribavirin had no significant effect on viral loads or platelet counts (238). A promising approach and alternative treatment may be human neutralizing monoclonal antibodies toward SFTS virus, which is inhibitory *in vitro* (247).

## NAIROVIRUSES

There are at least 34 viruses in the genus *Nairovirus*, all of which are tick-borne, which have been classified in seven serogroups (248–250). The latter included the CCHF group, which include the human pathogens CCHFV and Hazara virus, and the Nairobi sheep disease (NSD) group includes the human pathogens NSD virus (NSDV) and Ganjam virus. Ganjam virus, which has been isolated from ticks collected from goats in India and has been associated with febrile illness in humans in India, appears to be an Asian variant of NSD virus (250). Dugbe virus infection was described in a patient who suffered from a febrile illness with prolonged thrombocytopenia in South Africa (251).

### Crimean-Congo Hemorrhagic Fever

#### Epidemiology

Crimean-Congo hemorrhagic fever (CCHF) virus is distributed over the geographic range of *Hyalomma* ticks and includes Africa, Eastern Europe, the Middle East, and Asia through the western provinces of China (Figure 10) (7, 33,

248, 252). There is little evidence for subclinical infection, and most humans are seronegative in endemic areas.

Infection occurs through tick bites or by direct contact with infected animals or humans or their tissues. Cows, sheep, goats, hares, and other herbivores have all been implicated in transmission and amplification of CCHF virus. While birds are not susceptible to CCHF virus infection, many *Hyalomma* species feed on birds, thereby allowing the migrating birds to play an important role in disseminating CCHF virus-infected ticks. Antibody to CCHF virus has been found in 28% of cattle sera and 78% of cattle herds tested in South Africa and in 45% of cattle sera and 94% of herds tested in Zimbabwe (252). CCHF appears to be maintained both by transovarial and transtadial cycles in ticks and by a tick-vertebrate cycle. In temperate climates, peak transmission generally occurs in the spring and summer when populations of ticks and their vertebrate hosts peak.

The risk of infection in humans after a bite from a CCHF-infected tick is not known but is presumed to be high. Secondary cases have occurred both in laboratory workers and in hospital workers with direct contact with patients or their blood and respiratory secretions (253–255). There are multiple reports of nosocomial transmission, including one in which infection occurred in 8.7% of healthcare workers exposed to blood and in 33% of those with a needlestick injury (248, 256). Viremia is highest during the first three days of illness and may persist through the second week (257). Tertiary cases have also been described in family contacts of healthcare workers with CCHF.

#### Pathogenesis

The pathogenesis of CCHF is less well understood than for many of the other hemorrhagic fevers, in part due to the lack of an appropriate animal model. Viremia is present during the illness, and titers are highest during the first three days of illness (257). Disseminated intravascular coagulation (DIC) is present, particularly in the more severe cases (258). Fatal infections are also heralded by markedly elevated serum aspartate amino transaminase, alanine amino transaminase, and creatine kinase and, terminally, by elevated bilirubin, creatinine, and BUN. Clinically, multiple organ failure precedes death, with involvement of the brain, liver, kidneys, lungs, and heart. Haemophagocytosis, which may be associated with high levels of Th1 cytokines, has been reported in severe CCHF, and levels of pro-inflammatory cytokines IL-6 and TNF alpha and DIC scores are higher in patients with fatal versus nonfatal CCHF (259, 260). Of note, a CCHF virus glycoprotein precursor is cleaved to generate a novel glycoprotein that is similar to an Ebola virus domain associated with increased vascular permeability and development of hemorrhages (261).

At autopsy, edema and focal hemorrhage and necrosis are present in multiple organs, including the liver and brain. Although focal hepatic necrosis is most common, massive hepatic necrosis has also been described (258). Focal hemorrhage and necrosis may be found in the brain, and herniation may occur. Renal lesions are characterized by focal, tubular necrosis.

Clinical recovery is temporally associated with resolution of viremia and with appearance of specific IgG and IgM antibodies, generally between days 7 and 9 of illness. In contrast, endogenous antibody production was demonstrated in only 2 of 15 patients who died of CCHF (262). There is little information regarding the role of cell-mediated immune responses or the role of nonspecific defenses such as natural killer cells or cytokines.

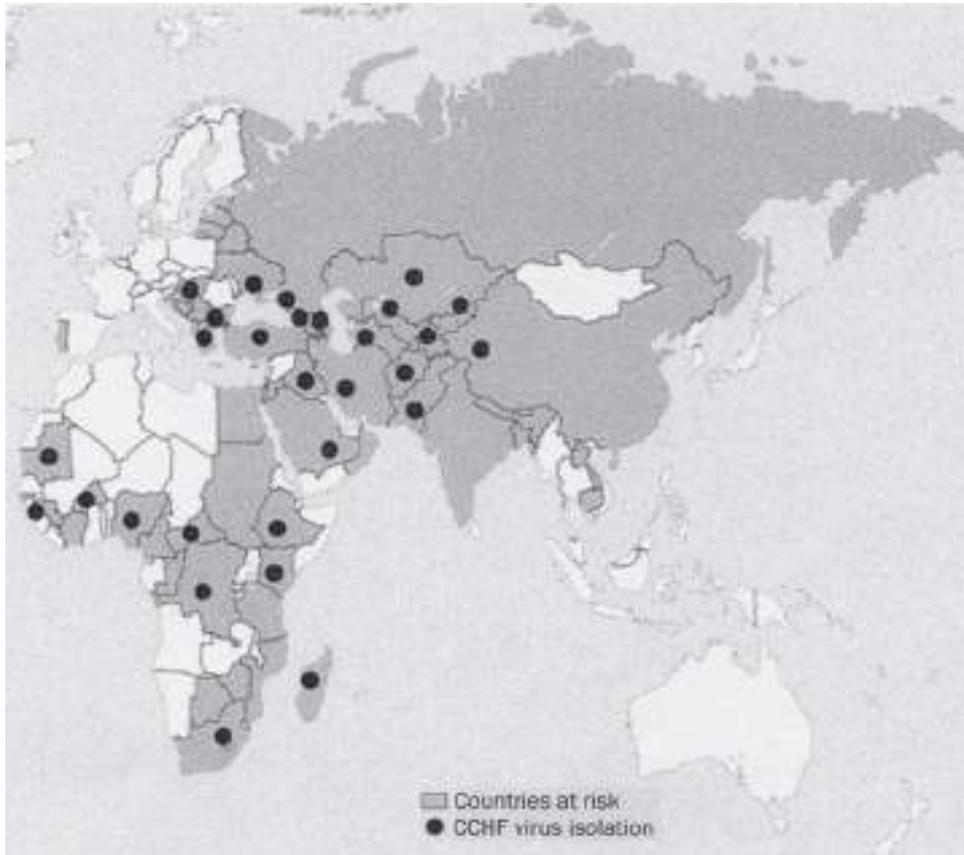

FIGURE 10 Worldwide distribution of CCHF virus. Reprinted from reference (248) with permission of the publisher.

### Clinical Manifestations

The incubation period ranges from three to six days in nosocomial transmission, whereas after exposures to animals or ticks it ranges from two to twelve days (56, 190, 252, 253). The illness typically begins as an acute febrile illness with fever, chills, myalgia, headache, and nausea, with or without abdominal pain and emesis (252, 253, 258, 262). During this stage, patients are often flushed and have injected conjunctivae or chemosis. After three to six days of illness, often after a brief period of clinical improvement, most patients develop hemorrhagic manifestations (Figure 11) (248). These may be limited to petechiae over the trunk and limbs or may involve large ecchymoses. Epistaxis, hematemesis, melena, and hematuria are common during this phase. Both hepatomegaly (20 to 40% of cases) and splenomegaly (14 to 23%) may be present (248). Patients may be somnolent, and dizziness and mild meningeal signs are common. Beginning at about the fifth day of illness, the most severely ill patients develop disseminated intravascular coagulation. Some series have emphasized hepatorenal failure, bradycardia, and hypotension in fatal cases, but this was not reported in recent series in Turkey (248).

Patients who survive have rapid resolution of fever and hemorrhagic manifestations that may be followed by a convalescent stage characterized by persistent fatigue. Poor prognostic indicators include overt DIC; hematemesis, melena, and somnolence; AST and ALT levels >700 and >900 IU/l, respectively; platelet counts below 20,000 and low platelet counts (below 50,000 cells/ml) that fail to increase over the first few days of hospitalization (248). The

case-fatality rate has averaged about 30%, but has ranged from 10% to more than 64% (248); the case-fatality rate may be greater in nosocomial cases. In a series from South Africa from 1981 to 1987, 15 of 50 patients died between days 5 to 14 of illness (258, 262). The proportion of subclinical infections is not known, but one model suggested that CCHF developed in 20% of infected persons (263).

Clinical laboratory abnormalities are helpful in suggesting the diagnosis, and marked elevations in hepatic transaminases, thrombocytopenia, and findings consistent with severe DIC during the first few days of illness are of prognostic value. Leukopenia is usually present from the onset of illness in nonfatal cases, whereas granulocytosis is often present during the first week in fatal infections. Thrombocytopenia is uniformly present early in the course of the illness in fatal cases and appears to be universally present by the end of the first week of illness. DIC occurs in both fatal and nonfatal infections, but abnormal activated partial thromboplastin times (APTT), thrombin times (TT), and fibrin degradation products (FDP) occur earlier and are more abnormal in fatal as compared to nonfatal cases (258).

Before the development of hemorrhagic manifestations, the differential diagnosis would include any cause of febrile illness. Many patients will have an occupational or rural exposure history. Depending on the patient's location and recent travel history, the differential diagnosis could include leptospirosis, brucellosis, septicemic plague, malaria, tularemia, tick typhus, Rift Valley fever, or sandfly fever. Once hemorrhagic manifestations develop, the differential diagnosis should include other hemorrhagic fevers that are

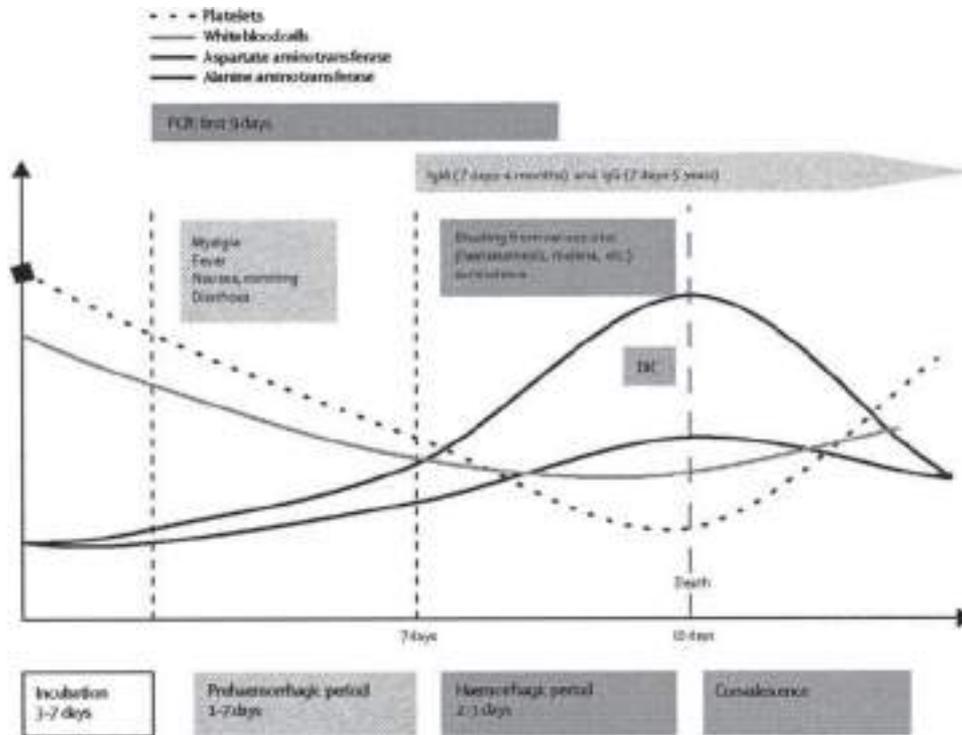

FIGURE 11 Clinical and laboratory course of CCHF. Reprinted from reference (248) with permission of the publisher.

known to be present in the region. These may include Kyasanur Forest disease, Omsk hemorrhagic fever, HFRS, Lassa fever, yellow fever, Ebola, or Marburg virus infection, and dengue hemorrhagic fever or dengue shock syndrome. If nosocomial transmission occurs following an index case with an undiagnosed hemorrhagic fever, the differential diagnosis would be limited to known, regional causes of hemorrhage and to agents that are known to be transmitted nosocomially. The latter include CCHF virus, SFTS virus, Lassa fever virus, Marburg virus, and the Ebola viruses.

#### Laboratory Diagnosis

CCHF virus can be easily isolated from blood during the acute illness, particularly during the first three days when virus titers are greatest (252, 253, 257, 258, 262), but should only be attempted in BSL-4 facilities. After intracranial inoculation of suckling mice, the mice die in four to eight days, and the diagnosis can be established by CF or FA testing of brains. Primary isolation can also be performed in cell culture and confirmed by detection of viral antigen by FA once cytopathic effect is seen. Comparison of primary isolation in suckling mice and in chicken embryo related (CER) cells or Vero E6 cells suggests that the former is somewhat more sensitive (257).

The method of choice for rapid viral diagnosis is real-time reverse transcriptase PCR (RT-PCR), which is highly sensitive and specific (264). An antigen-capture ELISA, which is less sensitive, in one series detected antigen in most fatal cases and approximately half of nonfatal cases (265).

Serodiagnosis can be made using acute and convalescent titers or by detection of IgM antibody in early convalescence. Serologic assays are usually negative during the first week of illness and in persons who die from CCHF. The relative sensitivities of serologic assays in a series of 35 survivors of CCHF (262) were ELISA, reversed passive

hemagglutination-inhibition (RPHI), IFA, fluorescent-focus reduction, CF, and immunodiffusion in decreasing order. IgG antibodies became detectable by IFA on days 7 to 9 in the 35 survivors; IgM antibody was present in one patient on day 5, and was usually present one day before or after the first detection of IgG antibody. A neutralization test is also available in some research centers.

#### Prevention

The risk of tick bites can be reduced by use of permethrin-impregnated clothing, by frequent inspection for the presence of ticks, and by gentle removal of ticks (without crushing the tick) if tick bites occur (266). Repellants such as DEET are relatively ineffective against ticks, but application of acaricides to domestic animals may be helpful. In light of the numerous examples of secondary transmission to healthcare workers, and sometimes to their own family contacts, strict isolation should be followed when caring for a patient with known or suspected CCHF. Recommendations for veterinarians, abattoir workers, and others who may acquire CCHF from direct contact are less clear, but presumably would include avoidance of contact with blood and body tissues, particularly with animals that appear sick.

A formalin inactivated-suckling mouse-brain-derived vaccine has been evaluated for immunogenicity in humans but appears to elicit only very low neutralizing antibody titers. There are no controlled data regarding antiviral chemoprophylaxis, but limited *in vitro* and animal data suggest that oral or intravenous chemoprophylaxis with ribavirin might be effective. In a nosocomial outbreak of CCHF at the Tygerberg hospital in South Africa, six of nine persons with needle-stick exposure were given prophylactic ribavirin. One of the six treated persons developed a mild clinical disease and the remainder remained clinically well and seronegative (256, 267). While this limited experience does not prove

efficacy, this approach might be considered following a high-risk exposure in the laboratory or in a healthcare setting. Close follow-up for 14 days with administration of ribavirin if fever develops is another strategy (248).

### Treatment

Aggressive, supportive therapy, preferably in a setting with critical care capabilities, is essential for patients with this serious hemorrhagic fever. Hemorrhage can lead to large requirements for blood replacement with attendant complications. Replacement of platelets and coagulation factors with fresh frozen plasma may be indicated, and shock and less severe intravascular volume disturbances may necessitate invasive monitoring.

There is no proven, specific antiviral therapy for CCHF in humans. Ribavirin is active *in vitro* and in an infant mouse model of CCHF (268, 269). No controlled trials of ribavirin have been reported in humans. However, several open series have documented low mortality rates in persons with CCHF treated with ribavirin when compared with historical controls (254, 270), and nonrandomized case series also suggest that oral ribavirin treatment reduces mortality (271, 272). If intravenous ribavirin is available, the recommended regimen is a 30 mg/kg loading dose followed by 15 mg/kg every 6 hours for 4 days followed by 7.5 mg/kg every 8 hours for 6 days; we recommend maximum intravenous doses of 2 g, 1 g, and 500 mg, respectively (179, 248). IV administration of specific immunoglobulin for CCHF virus has also been reported in uncontrolled trials (273, 274). Notably, the new compound favipiravir (T-705) showed better efficacy than ribavirin in a lethal mouse model for CCHF (275).

# Arenaviruses

DANIEL G. BAUSCH

## 45

Viruses of the *Arenaviridae* family (genus *Arenavirus*) are zoonotic; they are maintained in nature, with a few possible exceptions, by chronic infection in rodents of the superfamily Muroidea (1). Over 40 arenaviruses have been identified, although less than half of these are clearly recognized as human pathogens (Table 1 and Figures 1 and 2). Arenaviruses continue to be discovered at a quickening pace in recent decades (2–10).

Arenaviruses are perhaps best known as agents of viral hemorrhagic fever (VHF), an acute systemic illness classically involving fever, a constellation of initially nonspecific systemic signs and symptoms, and a propensity for causing bleeding and shock (11, 12). Similar VHF syndromes are caused by members of the virus families *Bunyaviridae*, *Filoviridae*, and *Flaviviridae* (see chapters 9, 42, 44, and 53). A few arenaviruses have been associated with aseptic meningitis and other central nervous system (CNS) diseases, including congenital malformations when transmitted *in utero*. Many arenavirus infections are asymptomatic or result in a nonspecific febrile illness difficult to distinguish from many more common diseases.

Seven arenaviruses have been clearly established as causative agents of VHF via natural infection (i.e., excluding laboratory infections): Lassa and Lujo in Africa, and Junín, Machupo, Guanarito, Sabiá, and Chapare in South America (Table 1). Two Old World arenaviruses, lymphocytic choriomeningitis virus (LCMV) and an LCMV variant named Dandenong virus, are typically associated not with VHF but rather with febrile illness and CNS disease (13). Whitewater Arroyo virus has been detected in three sick persons in California but its role as a pathogen remains to be confirmed. Tacaribe, Pirital, and Flexal viruses have caused nonspecific febrile illnesses after laboratory accidents but no natural infections have been recorded. Pichinde and Pirital viruses are frequently used in animal models (guinea pig and hamster, respectively) of arenaviral hemorrhagic fever.

Because of their potentially high lethality, risk of secondary spread (although this is often overestimated), and tendency to cause public panic and social disruption, some VHF-causing arenaviruses are considered “Select Agents” that could possibly be used as bioweapons. Attempts to weaponize various arenaviruses were reportedly made by the Soviet Union during the Cold War era (14). Many arenaviruses have been classified as biosafety level four (BSL-4) or “maximum containment” (15).

## VIROLOGY

### Classification

Arenaviruses are grouped serologically, phylogenetically, and geographically into Old World/Lymphocytic Choriomeningitis (i.e., Africa, Europe, Asia, and Oceania) and New World/Tacaribe (i.e., the Americas) complexes (Figure 3). As with other causes of VHF, arenaviruses are generally named after the geographic location of the first recognized case or place of first virus isolation. For the New World arenaviruses, the diseases are often named after the country where they were first detected, with the virus named after a local geographic feature. For example, Junín virus was first isolated from a human in the town of Junín, in northern Argentina, and subsequently designated as the causative virus of Argentine hemorrhagic fever.

Both Old and New World complexes are further divided into major lineages or clades. Genetic diversity within virus species may vary with the host and geographic region. Sequence diversity is generally higher among strains obtained from rodents than from humans, reflective of chronic infection and frequent transmission among the rodents (16, 17).

The Old World complex is grouped into two monophyletic lineages that correlate with monophyletic genera within the rodent family Muridae, subfamily Murinae (see below). The most attention has been paid to characterizing Lassa viruses, which show considerable sequence heterogeneity across West Africa, with 4 recognized lineages—3 in Nigeria and 1 in the area comprising Sierra Leone, Liberia, Guinea, and Ivory Coast (18, 19). There is also considerable genetic heterogeneity within lineages (20). The largest variation is in the L and Z genes, with mean differences of 26% and 20% at the nucleotide and amino acid levels, respectively. The structural genes nucleoprotein (NP) and glycoprotein (GPC) are more conserved, with mean differences of about 20% and 8% at the nucleotide and amino acid levels, respectively (21). Phylogenetic analyses suggest that Nigerian strains are ancestral to those found further west in Africa (19). Migration across the region was accompanied by changes in genome abundance, fatality rates, codon adaptation, and translational efficiency, with the virus evolving to evade immune-determined selection pressures (22).

Field and laboratory data suggest variation in virulence among the 4 lineages and strains of Lassa virus. In laboratory

TABLE 1 Arenaviruses known or suspected to cause human disease

Virus	Associated human disease	Annual incidence of human disease	Human disease-to-infection ratio	Human-to-human transmissibility	Case fatality
<i>Old World</i>					
Dandenong	Fever with encephalopathy and multiorgan-system failure	Only 3 cases recognized	Unknown	All known cases infected through organ transplantation	100% of 3 known cases
Lassa	Lassa fever	Poor surveillance. Estimated 30,000–50,000	1:5–10	Moderate	20% of hospitalized cases, but mild or asymptomatic infection frequent
Lujo	Lujo fever	Only 5 cases recognized	Unknown	Moderate-to-high	80% of 5 known cases
Lymphocytic choriomeningitis	Nonspecific febrile illness/aseptic meningitis	Estimated 100s to 1,000s but poor surveillance. Incidence declining with improved housing and sanitation.	Unknown but appears to be low	Congenital transmission as well as transmission through organ transplantation	< 1%
<i>New World</i>					
Chapare	Chapare HF	Small cluster reported in 2003. None since.	Unknown	Unknown	1 fatality reported among small cluster
Flexal	Nonspecific febrile illness	2 laboratory infections	Unknown	Unknown	None of 2 known cases
Guanarito	Venezuelan HF	< 50	1:1.5	Low	30–40%
Junín	Argentine HF	50–100. Incidence declining due to vaccination.	1:1.5	Low	15–30%
Machupo	Bolivian HF	< 50	1:1.5	Low	15–30%
Pirital	Nonspecific febrile illness	1 laboratory infection	Unknown	Unknown	One known case was nonfatal
Sabiá	Brazilian HF	1 natural and 2 laboratory infections	1:1.5	Low?	33% of 3 known cases
Tacaribe	Febrile illness with mild CNS symptoms	1 laboratory infection	Unknown	Unknown	Single nonfatal case
Whitewater Arroyo	Pathogenic potential unclear. 3 putative cases with fever and some signs of hemorrhagic fever	Unknown	Unknown	Unknown	Unknown

HF, hemorrhagic fever.

experiments, virulence of Lassa virus strains in guinea pigs roughly correlates with the severity of disease in the humans from whom the viruses were isolated (23). However, strains isolated from pregnant women and infants, in whom disease was often severe, were often completely benign in guinea pigs, suggesting that host factors such as immunosuppression play a role in human disease. Strains of Lassa virus from Nigeria may be more virulent than those from farther West in Africa, but data to support or refute this theory are lacking. The virulence factors of the Lassa virus genome are not known, although for LCMV they are suspected to map to the L segment (24).

The New World complex is classified into 4 distinct lineages, A, B, C, and D, that generally correlate with monophyletic genera of the rodent family Cricetidae (see below). All of the pathogenic New World viruses are in lineage B. Viruses of lineage D appear to be the product of recombination between viruses of lineages A and other ar-

naviruses, and are thus also known as lineage A/Rec. Lineage A, B, and C viruses are restricted to South America, while lineage D is exclusively North American.

There is also considerable genetic diversity among strains of LCMV, Guanarito, and Mopeia viruses, but no clear relationships between strain and pathogenicity in humans has been sought or recognized. Sequence diversity may also exist for other arenaviruses but the matter has not been extensively studied. Although pathogenic viruses generally cluster phylogenetically, Lujo virus, first identified in 2008, illustrates the limitations in predicting clinical syndromes based on genetic sequence alone (2); Lujo and Lassa viruses cause almost identical VHF syndromes, despite being genetically distinct (up to 38.1% on the nucleotide level)(25). Lujo virus is an outlier between New World and Old World arenaviruses but appears to be closest to the Old World viruses, corresponding to its site of isolation in Zambia.

**FIGURE 1** Geographic distribution of Old World arenaviruses. The virus name and known or suspected rodent reservoir are listed. Although the virus has been isolated from the animal listed, the status of that animal as the natural reservoir is not established in all cases. Countries where Lassa fever, the major arenaviral disease in Africa, has been definitively shown are depicted in dark gray and the distribution of rodents of the genus *Mastomys* is shown in light gray. Only Lassa, Lujo, lymphocytic choriomeningitis, and Dandenong viruses have been definitively associated with human disease. The distribution of the virus and incidence of associated disease may vary significantly within each country. With the exception of Lassa and lymphocytic choriomeningitis viruses, most Old World arenaviruses have been isolated on single or very few occasions and the precise distribution of the virus beyond the place of first identification is unknown. Not shown on the map: Lymphocytic choriomeningitis viruses (reservoir *Mus musculus*), which has a worldwide distribution, Dandenong virus (unknown reservoir), which is thought to be found in Eastern Europe, and Wenzhou virus (reservoir various rodent species and *Suncus murinus*) found in China.

### Virus Composition

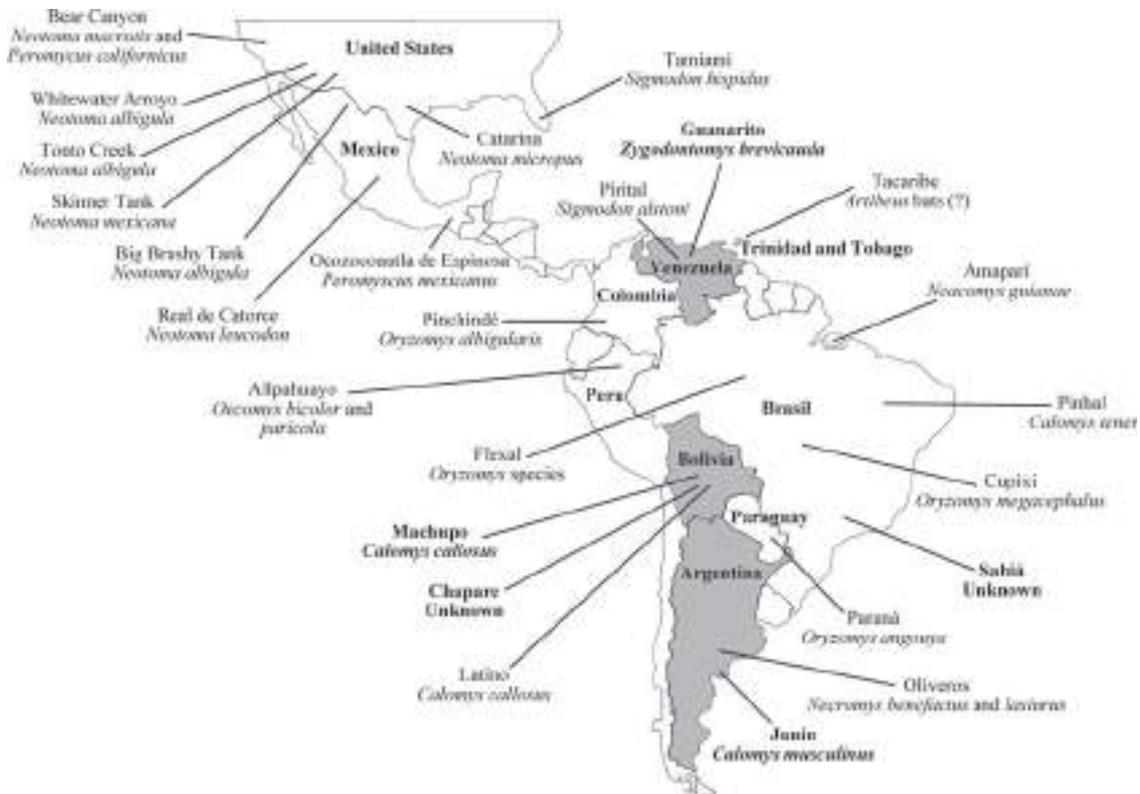

Arenaviruses derive their name from the Latin “arena” for “sand,” referring to the grainy appearance of infected host cell ribosomes seen in virions on electron microscopy (Figure 4)(26). Surface glycoproteins appear as club-shaped projections or spikes protruding from lipid envelope membrane (26). The virions are pleomorphic, ranging from 60 to 300 nm. Arenaviruses are bisegmented with an ~11 kb genome comprised of two single-stranded RNA segments denoted small (S) and large (L) of 3.4 kb and 7.2 kb, respectively (27, 28) (Figure 5). The S RNA encodes the viral NP and a precursor GPC that is posttranslationally cleaved into GP1 and GP2 by the cellular subtilase SK1-1/S1P. Proteolytic processing of GPC is necessary for arenavirus infectivity. GP1 is an outer membrane protein while GP2 is transmembrane. Both are involved in receptor binding and cell entry. The L RNA encodes the viral polymerase (L protein) and a small zinc-binding protein (Z), which appears to play a regulatory role in virus replication, particle formation, and budding, as well as having a structural function as a matrix protein. The genes on the two RNA segments are separated by an intergenic region that folds into a stable secondary structure.

### Replication

Arenavirus genes are oriented in both negative and positive senses on the two RNA segments, a coding strategy

called ambisense (Figure 6). Through this mechanism, GPC and NP gene expression are independently regulated. Viral RNA must be transcribed before GPC can be expressed, which may be fundamental to the maintenance of persistent infection in the animal reservoir. Replication and transcription of the genome occur in the cytoplasm and require the association of viral proteins with the viral RNA in the form of ribonucleoprotein (RNP) complexes. The NP and L proteins, together with virus RNA, are the minimal components of the RNP complex and are sufficient for genome replication and transcription. Purified RNPs are competent for RNA synthesis *in vitro* and can initiate virus replication after transfection into cells. Naked RNA is not infectious.

During genome replication, a full-length copy of the genome is synthesized yielding the corresponding antigenomic S and L RNAs. Due to the ambisense coding strategy, both genomic and antigenomic RNA serve as templates for transcription of viral mRNA. The transcripts contain a cap but are not polyadenylated. The viral RNA species that are packaged into virions are defined as the genomic RNAs; however, smaller amounts of antigenomic RNA and Z gene mRNA are also packaged. In addition to viral RNA, ribosomal RNA is present within virions. Virions mature by budding from the plasma membrane.

**FIGURE 2** Geographic distribution of New World arenaviruses. Above: The virus name and known or suspected rodent reservoir are listed, with viruses associated with natural infection and disease in humans in bold. Although the virus has been isolated from the animal listed, the status of that animal as the natural reservoir is not established in all cases. Countries with arenaviruses definitively associated with human disease are shaded gray. The distribution of the virus and incidence of associated disease may vary significantly within each country. Many of the New World arenaviruses have been isolated on single or very few occasions and the precise distribution of the virus beyond the place of first identification is unknown. On next page: Closeup of administrative regions in which Venezuelan, Bolivian, Chapare, and Argentine hemorrhagic fever have been recognized. The distribution of the viruses and incidence of disease may vary significantly within the region.

## Receptors

Arenaviruses enter cells by attachment of the GP1 to one or more cellular receptors (29);  $\alpha$ -dystroglycan, a protein found ubiquitously on primate and rodent cells, is a principal receptor for Old World viruses and pathogenic viruses of the New World clade C, while human transferrin receptor 1 protein is a receptor for the New World clade B arenaviruses (30). The transmembrane proteins Axl, Tyro3, dendritic cell-specific intercellular adhesion molecule 3-grabbing nonintegrin (DC-SIGN), and liver and lymph node sinusoidal endothelial calcium-dependent lectin (LSECtin) may also serve as Lassa virus receptors independent of  $\alpha$ -dystroglycan (31). GP2 is thought to mediate fusion of the viral envelope with the cellular membrane, and thus entry of the virus into the host cell. Lassa virus and other non-pathogenic arenaviruses bind  $\alpha$ -dystroglycan with equal affinity. Orthologs of transferrin receptor 1 protein appear to be the major receptors in the respective rodent host of each New World arenavirus and likely dictate species specificity (32).

## Animal Reservoirs and Host Range

Arenaviruses are generally maintained in nature by chronic infection in rodents of the superfamily Muroidea (Figure 4)

(1). Transmission may be vertical (dam-to-progeny) or horizontal, depending on the specific arenavirus. Infected animals may chronically shed virus in urine, feces, and saliva. Old World arenaviruses are maintained in rodents of the family Muridae, subfamily Murinae, and New World arenaviruses in the family Cricetidae, subfamilies Sigmodontinae and Neotominae. There is a tight host-virus species pairing, thought to be the result of long-term rodent-virus coevolution (1)(Table 2). Occasional findings of a given arenavirus in species other than its recognized rodent host are usually considered to result from spillover infection (i.e., incidental transient infection of a nonreservoir host). These incidental animal hosts do not play a role in long-term virus maintenance, but may nevertheless still pass virus on to humans who are exposed during the period of transient infection in the rodent.

The endemic area of each arenaviral disease is restricted to the geographic distribution of its rodent reservoir. Rodent populations are usually not uniformly infected; rather, the distribution of the virus and disease is usually restricted to a small portion of the overall host range. The reasons for this are unclear, but may relate to evolutionary bottlenecks in dispersal of the virus, rodent reservoir, or both. Landscape features are the most likely barriers to host migration. Both rodent abundance and prevalence of infection are highly

FIGURE 2 (Continued)

variable over space and time, with the prevalence of virus infection in reservoir populations likely linked to population density. Humans are dead-end hosts who play no role in the natural maintenance of arenaviruses. There are generally few human cases relative to the frequency of infected rodents. Incidence of human infection may vary with changes in rodent abundance that relate to both climatic and seasonal weather changes and human-induced habitat alterations. Detailed discussions of the epizootology of arenaviruses and their animal reservoirs have been reviewed elsewhere (1, 33).

### Growth in Cell Culture

Arenaviruses grow well in most mammalian cell lines, including endothelial cells, and infect most mammals. Vero cells are most commonly used, in which most cells are productively infected in 4 to 9 days with peak infectivity titers approaching  $10^8$ /ml. Carrier cultures are readily established with cyclic production of infectious virus. Although rounding and detachment of affected cells and subsequent cell death are occasionally seen, arenaviruses generally produce little or no cytopathic effect, so all cultures should be harvested and examined by immunofluorescent antibody

(IFA) assay using virus-specific antiserum (34). Infected cells from these cultures may contain large quantities of N protein but minimal GPC. There is evidence for the presence of defective interfering particles that can suppress replication both in cell culture and animals but the significance of this observation relative to natural infection is unknown (35).

### Animal Models

Models for arenavirus propagation and disease have been developed for suckling mice, hamsters, guinea pigs, and monkeys. In addition to being a human pathogen in its own right, LCMV has played a major role in elucidating our concepts of viral immunopathology and of T-cell function through experiments with laboratory strains of virus and inbred mice (36).

### Inactivation by Physical and Chemical Agents

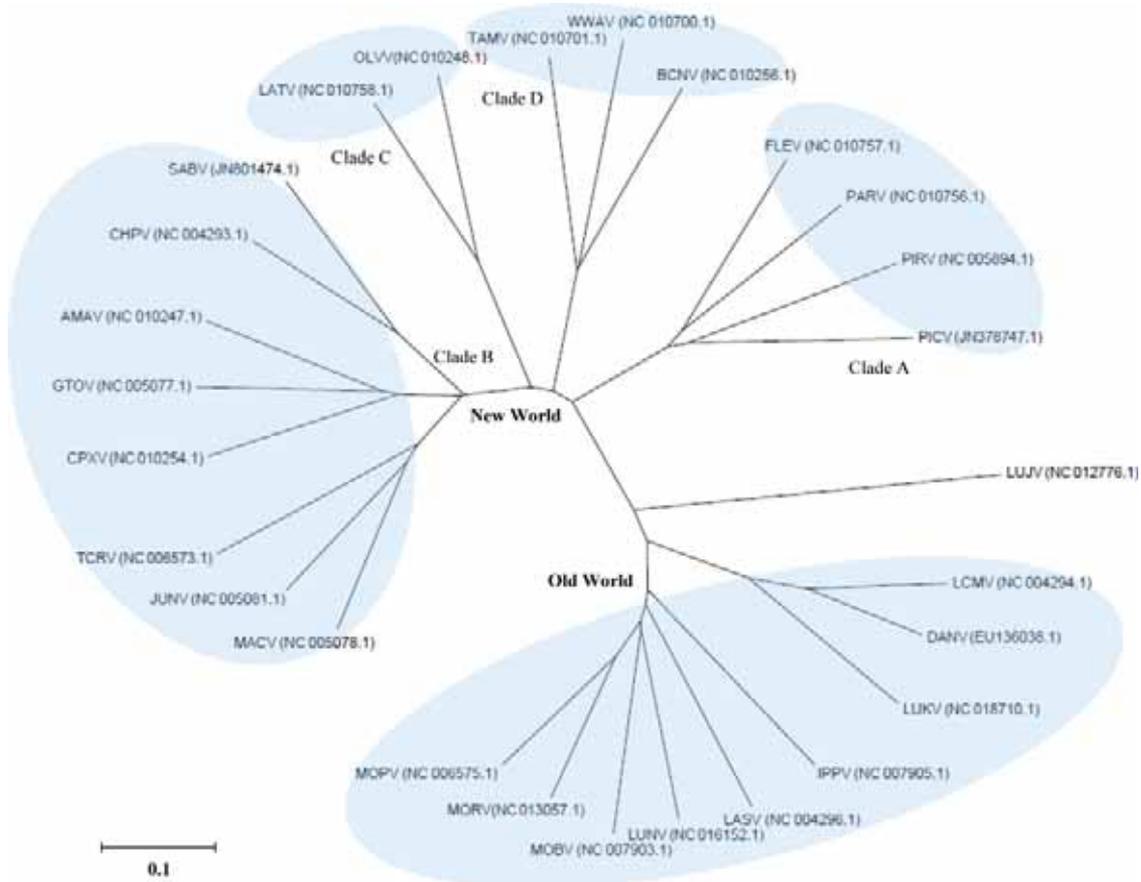

The arenavirus lipid envelope is easily disrupted, limiting their viability outside a living host.

Arenaviruses can be inactivated by heating to 60°C for 1 hour, use of disinfectants containing phenolic compounds, hypochlorite, quaternary amines, acidic or basic pH, ultraviolet light (surface disinfection only), gamma irradiation and surfactant nanoemulsions, and various proprietary detergent-containing lysis buffers (37–51). Some of these inactivation techniques, such as heat and gamma irradiation, preserve the arenavirus proteins for serologic testing. Toxicity and corrosion may be concerns with some of these compounds depending upon the frequency of use and concentrations.

The transmission dynamics and viability of arenaviruses after shedding into the environment are not well characterized. However, there is generally little concern required regarding arenaviruses seeping into groundwater or posing any long-term risk through casual exposures in the general environment, where harsh thermal and pH conditions would likely readily inactivate them. When shed naturally in animal excreta or human body fluids, which would then usually dry, infectivity appears to last from a few hours to days, varying with the specific virus and environmental conditions such as temperature and light (52–54). However, other nonarenavirus causing VHF have been isolated from samples kept for weeks at ambient temperatures if stored hydrated in a biological buffer, such as blood or serum. This may hold true for arenaviruses as well. The viruses are also stable when frozen or freeze-dried (55).

### EPIDEMIOLOGY

Arenavirus infections are noted in both sexes and all age groups. The geographic distribution and impact of arenaviral infections vary widely by particular agent (Table 1). The combination of the remote, geographically restricted endemic areas (often in resource-poor countries), nonspecific clinical presentation (56, 57), lack of availability of reagents and laboratories for diagnostic confirmation (58), and, in some areas, logistical impediments presented by civil unrest (59) and unstable governments (60) make surveillance for arenavirus infection, and thus precise estimates of incidence, difficult (61). One exception is Argentine hemorrhagic fever, for which intensive surveillance with supporting laboratory diagnosis is applied in its circumscribed endemic area, resulting in precise incidence estimates—usually less than 100 cases per year. Lassa virus is the most common arenavirus infection, with upwards of 50,000 cases and an estimated 10,000 deaths annually. LCMV may cause up to several thousand infections yearly, whereas much smaller

**FIGURE 3** Phylogenetic relationships of arenaviruses inferred based on full S segment nucleotide sequences. Phylogenies were reconstructed by neighbor-joining analysis applying the JUKES-Cantor model (1,000 replicates). The A, B, C, and D clades of the New World and Old World arenaviruses are delineated. Lujo virus (LUJV) falls between the two groups but appears to be closest to the Old World viruses, thus corresponding to its site of isolation in Zambia. The scale bar indicates substitutions per site. Genbank accession numbers are shown after each virus. Similar relationships are demonstrated based on L segment analysis (not shown). Abbreviations: AMAV, Ampari virus; BCNV, Bear Canyon virus; CHPV, Chapare virus; CPXV, Cupixi virus; DANV, Dandenong virus; FLEV, Flexal virus; GTOV, Guanarito virus; IPPV, Ippy virus; JUNV, Junín virus; LASV, Lassa virus; LATV, Latino virus; LCMV, Lymphocytic choriomeningitis virus; LUJV, Lujo virus; LUKV, Lunk virus; LUNV, Luna virus; MACV, Machupo virus; MOBV, Mobala virus; MOPV, Mopeia virus; MORV, Morogoro virus; OLTV, Oliveros virus; PARV, Paraná virus; PICV, Pichinde virus; PIRV, Pirital virus; SABV, Sabiá virus; TCRV, Tacaribe; TAMV, Tamiami virus; WWAV, Whitewater Arroyo virus. Viruses not shown due to incomplete or unavailable sequence data: Allpahuayo, Big Brushy Tank, California Academy of Sciences, Catarina, Collierville, Gairo, Gbagroube, Golden Gate, Kodoko, Lemniscomys, Mariental, Menekre, Merino Walk, Ocozocoautla de Espinosa, Okahandja, Pinhal, Real de Catorce, Skinner Tank, Tonto Creek, and Wenzhou.

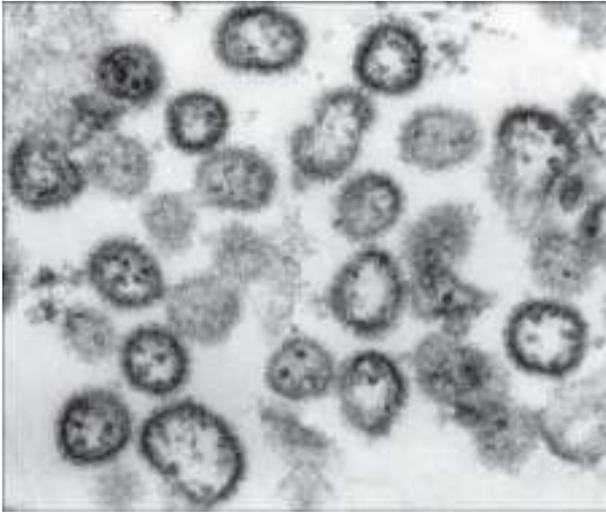

numbers of human cases have been recognized for the other arenaviruses.

While New World arenavirus infection usually results in disease that can ultimately be recognized as VHF, the majority of Old World arenavirus infections, at least for LCMV and Lassa virus, are thought to be asymptomatic or produce milder nonspecific febrile illness (62). However, antibody reversion (i.e., loss of antibody after infection) after Lassa virus infection and the possibility of cross-reacting antibodies from previous infection with other nonpathogenic arenaviruses in West Africa, such as Kodoko, Gbagroube, or Menekre viruses (Figure 1), may confound interpretation of laboratory findings, potentially resulting in misclassification between true first Lassa virus infections and reinfection, which is associated with milder disease. Studies of the rate of asymptomatic transmission as well as reinfection bear repeating with newer more sensitive and specific diagnostic modalities (63, 64).

Because arenaviruses are maintained in wild animals, factors in disease emergence and increased incidence of human disease logically often relate to anthropogenic disturbance of natural habitats, such as conversion of forest to cultivated fields, resulting in loss of biodiversity and selection for opportunistic rodent species that are frequently hosts for zoonotic pathogens (Table 2)(65). Conversion to agriculture also prompts incursion of reservoir rodents from the surrounding bush seeking food in croplands, with resultant increased human exposure to rodents, usually with recognizable seasonal peaks (66, 67). Some reservoir species may also enter towns and homes, further increasing risk to humans.

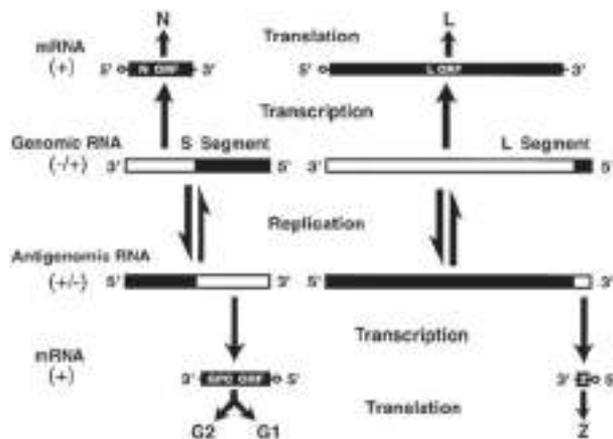

#### Rodent-to-Human Transmission

With the exception of the LCMV reservoir, all arenavirus reservoirs occupy almost exclusively sylvatic rural habitats. Consequently, primary arenavirus infections in humans are seen almost exclusively in rural and often remote settings.

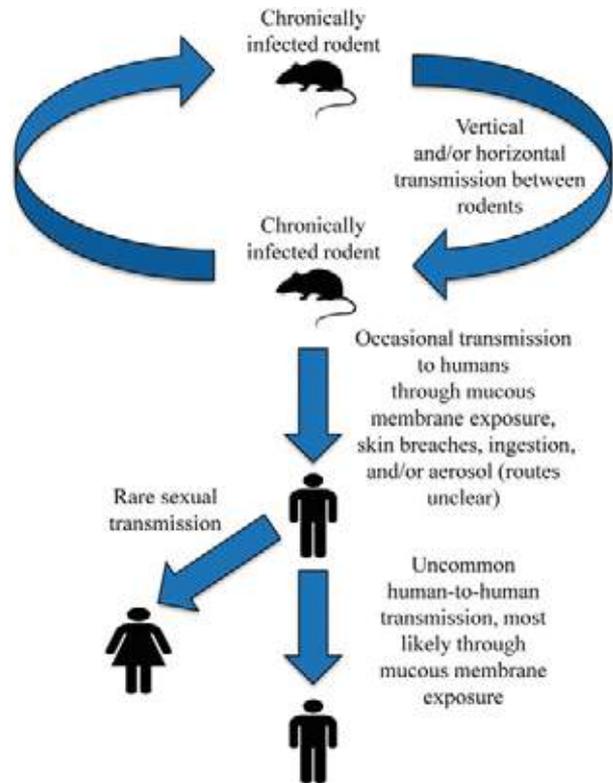

**FIGURE 4** Electron micrograph of Lassa virus. The typical sandy appearance of arenaviruses from the internal ribosomes is evident, as well as the surface glycoprotein spikes. Magnification approximately  $\times 55,000$ . Micrograph courtesy of F. A. Murphy, University of Texas Medical Branch, Galveston, Texas.

Virus transmission to humans is believed to occur via exposure to rodent excreta, either from direct inoculation on to the mucous membranes or broken skin, or from inhalation of aerosols produced when rodents urinate (1, 62, 68, 69). The relative frequency of these modes of transmission is unknown. Although the infectious dose for arenaviruses is thought to be low, rodent-to-human transmission appears to be inefficient, occurring infrequently even where infected rodents are common (70). Transmission by aerosolized rodent urine or virus-contaminated dust particles is often mentioned in the scientific literature, but there are few data to support or refute its occurrence (71). Although household clusters of VHF due to arenaviruses occasionally occur, single cases are much more common, suggesting that aerosol transmission to humans is not common, since it would logically often simultaneously infect multiple people in proximity to the aerosol source (72). Secondary aerosol generation,

**FIGURE 5** Replication strategy of arenaviruses. See text for details. (Prepared by A. Sanchez.)

**FIGURE 6** Transmission cycle of arenaviruses illustrating chronic infection in rodents. Transmission between rodents may be vertical or horizontal depending upon the specific arenavirus. Humans are incidental hosts who play no role in virus maintenance in nature. (Adapted from reference 13 with permission of the publisher.)

such as what might be produced through sweeping an area contaminated by rodent urine, is inefficient and is thus a less likely mechanism of infection. However, infectious and moderately stable aerosols of Lassa, LCMV, and Junin viruses have been artificially produced in the laboratory, and a laboratory infection with Sabiá virus resulted from a centrifuge accident (73) so the possibility of aerosol infection is not zero (74, 75). Regardless of their role in natural infection, the artificial production of infectious aerosols has obvious implications for the potential use of arenaviruses as bioweapons (15, 76).

Experiments in mice and monkeys show that arenavirus infection may also occur by the oral route, perhaps through a gastric portal (77, 78). In a monkey model using LCMV, hemorrhagic fever was produced with intravenous (IV) but not intragastric inoculation (78). Lassa virus has been contracted when rodents are trapped and prepared for consumption, a common practice in some parts of West Africa, although it is usually impossible to determine whether infection resulted from exposure during preparation or consumption (79). LCMV has been identified in wild rodent feces by reverse transcriptase polymerase chain reaction (RT-PCR) (80). Since arenaviruses are easily inactivated by heating, eating cooked rodent meat should pose no danger (1). Various arenaviruses have been found in rodent saliva, although reports of human infection from rodent bites are rare (81, 82). Although the primary reservoir for LCMV is the common house mouse (*Mus musculus*), spillover

TABLE 2 Natural reservoirs of the arenaviruses

Virus	Primary reservoir-species (common name)	Mode of virus maintenance in animals	Typical habitat	Known geographic distribution of infected rodents	Seasonal trends and risk factors for human exposure
Dandenong	Unknown	Unknown	Unknown	Balkan Peninsula?	Unknown. All known cases infected through organ transplantation in Australia
Lassa	<i>Mastomys natalensis</i> (natal mastomys or multimammate rat)	Vertical	Peridomestic and surrounding cultivated fields and grasslands. Rural areas only	West Africa, especially Nigeria, Sierra Leone, Liberia, and Guinea	Peak transmission in dry season (November–April). Rodent consumption, poor quality housing, open food storage and closed shutters during the day, favoring prolonged foraging
Lujo	Unknown	Unknown	Unknown	Zambia?	Unknown
Lymphocytic choriomeningitis	<i>Mus musculus</i> (house mouse)	Vertical	Peridomestic. Rural and urban areas. Most infections inside homes	Worldwide	Peak transmission in fall and winter in northern temperate zones due to seasonal invasion of homes by house mice. Also risk among rural dwellers and low-income groups Infections documented from infected laboratory mice and pet mice and hamsters
Chapare	Unknown	Unknown	Unknown	Chapare region of Cochabamba, Bolivia	Unknown
Flexal	Unknown	Unknown	Unknown	Unknown	Only known cases through laboratory infection
Guanarito	<i>Zygodontomys brevicauda</i> (short-tailed zygodont mouse or cane mouse)	Split horizontal/vertical response	Crop fields, borders, and roadside habitats in rural areas. Rarely peridomestic	Plains of western Venezuela, especially Portuguesa and Barinas States	Peak incidence during peak agricultural activity (November–January). Agricultural workers highest risk. Often 4–5 year cyclical pattern

Junín	<i>Calomys musculus</i> (drylands vesper mouse or corn mouse)	Split horizontal/vertical response	Stable linear border habitats (roadsides, fence lines, and railroad rights of way) in rural areas. Movement into mature and postharvest crop fields in summer and early fall	Central and northwestern Argentina	Peak incidence during peak agriculture activity (March–June). Agricultural workers highest risk
Machupo	<i>Calomys callosus</i> -Beni Department clade (big laucha or large vesper mouse)	Split horizontal/vertical response	Peridomestic and disturbed habitats where forest and grasslands meet. Seeks higher ground with seasonal inundations. Rural areas	El Beni Department of Bolivia	Peak incidence during peak agricultural activity (June–August). Agricultural workers at highest risk but family and community clusters occasionally noted
Piritál	<i>Sigmodon alstoni</i> (Alston's cotton rat)	Unknown	Crop fields, borders, and roadside habitats in rural areas. Rarely peridomestic	Plains of northwestern Venezuela	Only known cases through laboratory infection
Sabiá	Unknown	Unknown	Unknown	Rural area near Sao Paulo, Brazil?	Only known case outside of laboratory infections occurred during dry season (January)
Tacaribe	<i>Artibeus</i> bat*	Unknown	Unknown	Trinidad	Only known cases through laboratory infection
Whitewater Arroyo	Related viruses found in various species of <i>Neotoma</i> genus, including <i>N. micropus</i> (southern plains woodrat), <i>N. Mexicana</i> (Mexican woodrat), ( <i>N. stephensi</i> (Stephen's woodrat), and <i>N. cinerea</i> (bushy-tailed woodrat)	Unknown	Rural areas	Southwestern United States	Unknown

\* Tacaribe virus has been isolated from mammals only once, from bats from the genus *Artibeus*, but the definitive role of this animal as the natural reservoir is uncertain. The virus has also been isolated from ticks in the state of Florida in the United States (202).

infection can occur in a variety of pet animals, such as Syrian hamsters (*Mesocricetus auratus*) and guinea pigs (*Cavia porcellus*), and laboratory mice, and have resulted in human infection (83).

### Human-to-Human Transmission

With the exception of LCMV, and perhaps Dandenong virus, arenaviruses can be transmitted between sick humans through direct contact with infected blood or bodily fluids. However, contrary to popular concept, secondary attack rates are generally low, probably of the order of 5% or less as long as strict barrier nursing practices are observed (Table 1). Tertiary transmission is unusual. Large outbreaks are almost always fueled by nosocomial transmission, usually in resource-poor regions where sound infection control and barrier nursing practices may not be maintained (84–87). Nosocomial outbreaks of Lassa fever have been associated with reuse of nonsterilized needles and use of contaminated multiuse antibiotic vials (84).

Viremia and infectivity of persons infected with arenaviruses generally parallel the clinical state, with highest infectivity late in the course of severe disease, especially when bleeding is present. Data on the precise modes of human-to-human transmission are lacking, but infection presumably results from oral or mucous membrane exposure, most often in the context of providing care to a sick family member (community) or patient (nosocomial transmission). Although aerosol spread of Lassa virus was speculated in the first recognized outbreaks in Nigeria, extensive field experience since then has not suggested aerosol transmission of arenaviruses between humans in natural settings (86). Funeral rituals that entail the touching of the corpse prior to burial may also result in transmission of hemorrhagic fever viruses, although this has not been specifically recognized with arenaviruses (88). Although a few anecdotal reports exist of transmission during convalescence disease (62, 89), presumably from virus persistence in the semen as noted in some other VHF, there are no reports of virus isolation from the semen. However, intermittent shedding of Lassa virus in the urine has been documented up to 67 days after the onset of illness (90, 91). Transmission during the incubation period has not been noted.

New World arenaviruses appear to be less transmissible between humans than their Old World counterparts, although human-to-human transmission of Machupo virus has been reported in both community and nosocomial settings (92, 93). Only one family cluster of Argentine hemorrhagic fever is described, with the index case presenting with atypical skin lesions that may have facilitated transmission. Person-to-person transmission or nosocomial infection has not been observed with Guanarito virus despite the fact that patients with Venezuelan hemorrhagic fever are usually admitted to open wards with minimal isolation precautions. It is unknown whether the perceived differences in transmissibility between the arenaviruses reflect true biological properties or varied cultural and infection control practices in the endemic areas of each virus.

Contrary to popular misconceptions, the risk of imported arenavirus infections initiating outbreaks in industrialized countries, where barrier nursing techniques are usually maintained, is generally low. Because of the considerable travel between the United Kingdom and their former West African colonies, which also often happen to be the hyperendemic areas, Lassa fever is the most frequently exported arenavirus infection. Foreign military personnel, peacekeepers, aid workers, and tourists in rural settings are occa-

sionally infected, sometimes importing Lassa virus back to their countries of origin, most commonly the United Kingdom and Europe, but occasionally as far away as Japan (94). In over 25 imported cases of Lassa fever reported since 1969 with at least 1,500 cumulative identified contacts, only a single putative and asymptomatic instance of secondary transmission has been noted (95, 96). Although 3 secondary cases and 1 tertiary case occurred in South Africa after the arrival of a traveler from Zambia infected with Lujo virus, transmission occurred in settings in which proper infection control practices may not have been maintained (2, 97).

Small clusters of severe neurologic disease and organ failure have been reported in the United States among persons who were transplanted solid organs from persons unknowingly recently infected with LCMV (98, 99). A similar transplant-related cluster of 3 fatal cases occurred in Australia in 2009, leading to the discovery of the LCMV variant Dandenong virus (100). The donor died of cerebral hemorrhage 10 days after returning to Australia from a 3-month visit to the Balkan Peninsula, where he had traveled in rural areas. None of the donors in these outbreaks had a recent history of acute febrile disease and no virus could be identified in them, although the presence of IgG and IgM antibodies in the Australian donor confirmed recent infection. One donor in the United States had been exposed to a pet hamster from which LCMV was isolated and corresponded to the virus detected in the transplant recipients. With the exception of congenital transmission and through transplanted organs, there is no human-to-human transmission of LCMV.

## PATHOGENESIS

### Incubation Period

The incubation period for arenavirus infection is typically between 8 and 13 days, with a range of 3 to 21 days. Direct percutaneous inoculations, such as needlesticks, are thought to be associated with shorter incubation periods.

### Pathology

A recurring question with the arenavirus infections is how the virus causes disease. The histologic lesions observed do not usually provide an obvious cause of death; overt cell damage by arenaviruses is minimal or modest. Rather, arenaviruses are thought to alter cell function and through direct infection or indirectly through immunopathologic mechanisms. Extensive macrophage and lymphoreticular infection are thought to be the basis for local and systemic release of physiologically active soluble mediators leading to many of the abnormalities observed (101). Findings at necropsy are often composed of petechial and mucosal hemorrhages, vascular dilatation and congestion, and small foci of necrosis in organs such as the liver, adrenals, and kidneys, with a mild or absent inflammatory response (155). The pathogenesis of LCMV and Dandenong viruses causing CNS disease appears to be distinct from that of the arenaviruses that cause VHF.

### Patterns of Virus Replication and Immune Responses

#### Central Nervous System Disease

Laboratory studies show arenavirus tropism for Schwann cells (though not neurons), which abundantly express  $\alpha$ -dystroglycan (102). Immune cell activation, particularly CD8+ lymphocytes, is thought to be the fundamental process in the pathogenesis of LCMV, although without the same

effects on endothelial cell function and hemostasis as in VHF (see below) (13). CNS involvement typically occurs a week or two after disease onset, after the virus has cleared from the blood, and is thus thought to be immune mediated, although virus can still be recovered from the CSF at this time.

### Arenaviral Hemorrhagic Fever

As with all VHFs, microvascular instability and impaired hemostasis are the hallmarks of arenaviral hemorrhagic fever. Unchecked viremia appears to be central to the pathogenesis (103, 104). While both Old and New World viruses cause disruption of the vascular endothelium, the immune responses of these two groups appear to be distinct.

Abnormal platelet aggregation has been noted in Lassa fever and is thought to be the primary functional defect resulting in bleeding when it occurs (105). Old World viruses generally result in suppression of the innate immune response (106–108), while New World viruses elicit a strong inflammatory response consistent with cytokine storm (109, 110). Tumor necrosis factor alpha and alpha/beta interferon are among the candidates for such mediators; both have been found at high concentrations in the blood that correlate with mortality in patients with Argentine hemorrhagic fever (111). In animal models, leukotrienes, platelet-activating factor, and endorphins appear to contribute (74). Apoptosis has also been reported from experiments with New World viruses in cell and animal models (112). Immune complexes, disseminated intravascular coagulation, and complement activation by other means appear to have no important role in arenaviral hemorrhagic fever.

Viremia is usually present at patient presentation (presumably starting with disease onset, although patients are rarely available for testing at this time), peaking between days 4 and 9 and clearing within 2 to 3 weeks in survivors. Cell mediated immunity is thought to be primarily responsible for clearance of Old World arenavirus infection, while the humoral arm is important in disease caused by New World viruses (113–115). Antibody titers are significantly lower in fatal cases relative to survivors (63, 103, 116). Neutralizing antibodies may be produced in Old World arenavirus infection, but usually months after recovery and often at a low titer. The continued increase in antibody titer to Lassa virus months after infection suggests a sustained B-cell response that might be attributable to low-level virus persistence in immunologically protected sites; in vaccine experiments in monkeys, replication-competent virus was cleared within 14 days after Lassa virus challenge, but detection of RNA up to 112 days suggested low-level viral persistence or the presence of defective interfering particles (117).

A long-standing mystery of arenavirus infection, especially Lassa fever, is the apparent extreme range of clinical severity (28). The reasons for this variation are unknown, but may relate to heterogeneity in the virulence of infecting Lassa virus strains, route and dose of inoculation, genetic predisposition, underlying coinfections or premorbid conditions (e.g., malaria, malnutrition, or diabetes), or misclassification of reinfection as new infection due to waning of antibody. Unfortunately, since most studies in nonhuman primates use viral challenge doses designed to produce uniformly fatal disease in order to evaluate the efficacy of therapeutics and vaccines, they shed little light on any clinical spectrum related to inoculum size. Route of exposure appears to be one important variable; in a monkey model of Lassa fever using the WE strain of LCMV, IV inoculation resulted in fatal VHF while monkeys inoculated via the gastric route mostly had an attenuated infection with no disease (78, 113). Human genes

encoding “like glycosyltransferase” (*LARGE*), dystrophin (*DMD*), and IL-21 have apparently undergone positive selection in populations in endemic areas for Lassa fever in Nigeria, suggesting a protective effect (118, 119).

## CLINICAL MANIFESTATIONS

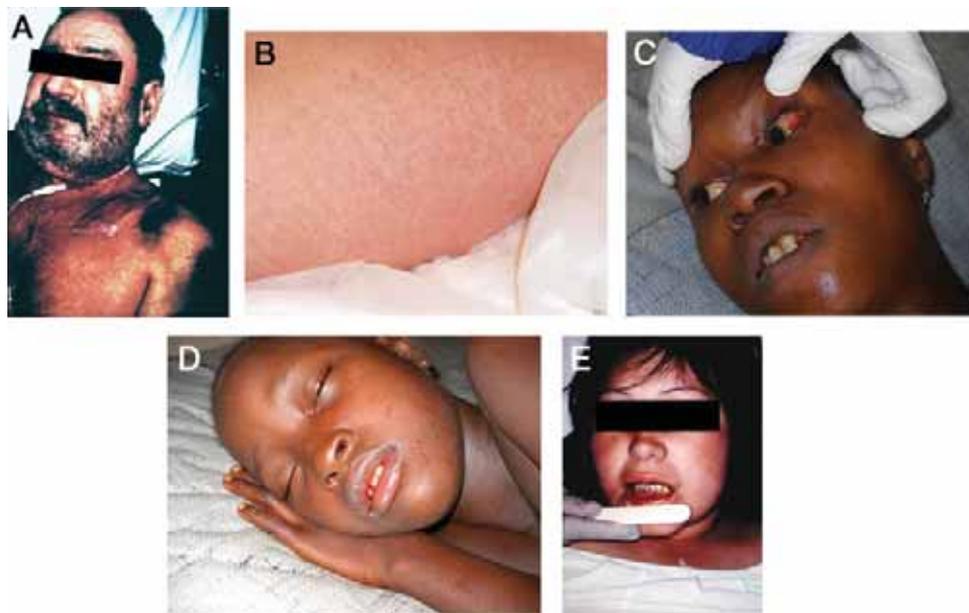

### Central Nervous System Disease

Despite the name, a minority of patients infected with LCMV develop meningitis or CNS disease. Rather, most LCMV infections are asymptomatic or result in a nonspecific febrile illness (120). After 7 to 14 days of nonspecific illness (fever, headache, malaise), and often with a brief period of defervescence, CNS manifestations may ensue in a minority of patients. These encompass a spectrum ranging from aseptic meningitis (the most common) with headache, stiff neck, and photophobia to fulminant encephalitis with cranial nerve palsies, abnormal reflexes, focal seizures, polyneuritis, flaccid paralysis, and papilledema. CNS symptoms can also occur without recognized febrile illness. Rarer manifestations and complications of LCMV infection include hydrocephalus, transverse myelitis, Guillain-Barré syndrome, hearing loss, arthritis, parotitis, orchitis, myocarditis, mucosal bleeding, and pneumonia. Congenital infection has been associated with spontaneous abortion in early pregnancy and, when occurring later in pregnancy, a variety of neurological deficits, including psychomotor retardation, microcephaly and macrocephaly, hydrocephalus, chorioretinitis with visual loss, and seizures. LCMV and Dandenong virus infection in immunosuppressed organ transplant recipients has resulted in a fatal syndrome with graft dysfunction, CNS symptoms, and multiorgan system involvement, in some cases resembling VHF, within three weeks after transplantation, with case-fatality approaching 90% (98).

### Arenaviral Hemorrhagic Fever

Disease severity generally correlates directly with the level of viremia, and thus infectivity. Although there are differences in the pathogenesis and clinical manifestations produced by the various arenaviruses, they are usually too subtle to allow for distinction on clinical grounds, at least in the early stages of disease. Nevertheless, some notable distinctions can be made between the syndromes caused by Old World and New World viruses. The disease caused by the various New World arenaviruses is usually referred to simply as “South American hemorrhagic fever.”

The spectrum of disease due to arenavirus infection ranges from mild to shock, multiorgan system failure, and death. Most patients present with nonspecific signs and symptoms difficult to distinguish from many other more common febrile illnesses. The incubation period is usually about 1 week (range 3 to 21 days). Illness typically begins with the gradual onset of fever and constitutional symptoms, including general malaise, anorexia, headache, chest or retrosternal pain, sore throat, myalgia, arthralgia, lumbosacral pain, and dizziness (56, 57). The pharynx may be erythematous or even exudative in Lassa fever, a finding that has at times led to misdiagnosis of streptococcal pharyngitis (56). Gastrointestinal signs and symptoms occur early in the course of disease and may include nausea, vomiting, epigastric and abdominal pain and tenderness, and diarrhea. Lassa fever has sometimes been mistaken for acute appendicitis or other abdominal emergencies. A morbilliform, maculopapular, or petechial skin rash is very frequent in South American hemorrhagic fevers (Figure 7A). Although

**FIGURE 7** Clinical manifestations of arenaviral hemorrhagic fever. (A) Petechial rash in Argentine hemorrhagic fever. (B) Maculopapular rash in Lujo hemorrhagic fever (photo by T. H. Dinh). (C) Conjunctival injection in Lassa fever (photo by Donald Grant). (D) Facial swelling and mild gum bleeding in Lassa fever (photo by Donald Grant). (E) Gum bleeding in Argentine hemorrhagic fever. Photos used with permission from Blumberg L, Enria D, and Bausch DG. *Viral Haemorrhagic Fevers*. In J Farrar et al. (ed): *Manson's Tropical Diseases*, 23rd Edition, Elsevier Publishing, 2013.

rash almost always occurs in fair-skinned persons with Lassa and Lujo fever, it is rarely recognized in native black Africans (Figure 7B). The reasons for this observation are unknown, but prior infection with partial immunity and genetic differences have been postulated. Conjunctival injection or hemorrhage (Figure 7C) is frequent but is not accompanied by itching, discharge, or rhinitis. A dry cough, sometimes accompanied by a few scattered rales on auscultation may be noted, but prominent pulmonary symptoms are uncommon early in the course of the disease. Jaundice is not typical and should suggest another diagnosis.

In severe cases, patients progress to vascular instability, which may be manifested by subconjunctival hemorrhage, facial flushing, edema, bleeding, hypotension, shock, and proteinuria. Swelling in the face and neck and bleeding are particularly specific but not sensitive signs in Lassa and Lujo fevers—seen in less than 20% of cases (56) (Figure 7D). Despite the term “VHF,” clinically discernible hemorrhage is not always seen, being less frequent in disease produced by Old World than New World arenaviruses, and never in the first few days of illness (56, 57). Hematemesis, melena, hematochezia, metrorrhagia, petechiae, epistaxis, and bleeding from the gums (Figures 7D and 7E) and venipuncture sites may develop, but hemoptysis and hematuria are infrequent. Significant internal bleeding from the gastrointestinal tract may occur even in the absence of external hemorrhage.

Neurological complications are more common in the South American hemorrhagic fevers and include disorientation, tremor, ataxia, seizures, and coma, particularly in the late stages, and usually portend a fatal outcome (121). The cellular and chemistry profile in CSF is often normal. Lassa virus can be isolated from the CSF of some, but not all, patients with neurological manifestations, without apparent correlation between disease severity and detection of virus (103, 122). In one unusual case, Lassa virus was isolated from the CSF, but not the blood, of a patient with encephalop-

athy after the febrile stage of disease—a finding consistent with virus persistence in the immunologically protected CNS (123).

Pregnant women with arenaviral hemorrhagic fever often present with spontaneous abortion and vaginal bleeding, with maternal and fetal mortality rates approaching 100% in the third trimester (124). Anasarca has been described in a single report of four children with Lassa fever (termed the “swollen baby syndrome”) but may have been related to aggressive rehydration (125). One instance of polyserositis with pleural and pericardial effusions and ascites 6 months after infection was reported (126). Lassa virus could not be recovered from the effusion fluid, but lymphocytes and high levels of antibody were noted, suggesting an immune-mediated mechanism. Various clinical manifestations of arenaviral hemorrhagic fever are shown in Figure 6.

Typical clinical laboratory findings in arenaviral hemorrhagic fever include early leukopenia and lymphocytopenia, sometimes with atypical lymphocytes, followed later by leukocytosis with a left shift; mild-to-moderate thrombocytopenia, hemoconcentration; elevated aspartate aminotransferase (AST), alanine aminotransferase (ALT), and amylase; electrolyte perturbations; and proteinuria (103, 127). Unlike classic viral hepatitis, but similar to filoviral disease, the AST is typically much higher than the ALT in arenaviral hemorrhagic fever, suggesting that its source is not exclusively the liver. Since a broad range of tissues can release AST, it should be considered a marker of systemic organ damage (103). Radiographic and electrocardiographic findings are generally nonspecific and correlate with the physical examination (128, 129).

### Prognosis

Death in fatal cases of arenaviral hemorrhagic fever usually occurs within 2 to 3 weeks after the onset of disease. Case fatality proportions vary according to the specific infecting

virus (Table 1). Hospital mortality data generally represent an overestimate considering the mild and asymptomatic infections that are thought to frequently occur in the community with some arenaviral hemorrhagic fevers, especially Lassa fever (62). Common indicators of a poor prognosis include shock, bleeding, neurological manifestations, viremia  $>10^8$  TCID<sub>50</sub>/ml (or viral RNA copy number or enzyme-linked immunosorbent assay (ELISA) antigen as surrogates), AST  $>150$  IU/l, and pregnancy, especially during the third trimester when maternal and fetal mortality approach 100% (56, 130).

### Convalescence and Sequelae

Convalescence from arenaviral hemorrhagic fever may be prolonged, with persistent myalgia, arthralgia, anorexia, weight loss, and alopecia up to a year after infection. Cerebellar ataxia has also been occasionally reported (131). The psychological effects of the disease may also be significant and are often overlooked, with some patients experiencing depression or posttraumatic stress, as well as social stigmatization.

Sensorineural deafness is a well-recognized sequela specific to Lassa fever. It is reported to occur in as many as 25% of cases, although this seems like a significant overestimate from experience in Sierra Leone and Guinea over the last 20 years (132). Deafness typically presents during convalescence and is not associated with the severity of the acute illness or level of viremia, suggesting an immune-mediated pathogenesis (132). It may be uni- or bilateral, and is permanent in approximately two-thirds of cases. Auditory patterns resemble idiopathic nerve deafness (133).

### Differential Diagnosis

Difficulties in diagnosing arenavirus infection, both clinically and in the laboratory, pose a major impediment to surveillance and control. Even if more clearly recognized VHF or neurologic syndromes eventually develop, most patients present with a nonspecific febrile syndrome difficult to distinguish from many other diseases that are usually more common in the area. The differential diagnosis of arenaviral hemorrhagic fever includes a broad array of febrile illnesses, including malaria, typhoid fever, leptospirosis, bacterial septicemia, rickettsial infections, dengue fever, and other VHF syndromes, depending upon the specific geographic region and patient history of exposures (127).

The classic presentation of LCMV infection is aseptic meningitis, particularly if an initial prodromal period of fever, perhaps with a remission, occurs before the CNS phase. The differential diagnosis includes the arboviral meningitides, herpes encephalitis and, for congenital manifestations, the classic TORCH organisms (*toxoplasma*, rubella, cytomegalovirus, and herpes virus). The presence of thrombocytopenia and leukopenia should enhance suspicion of arenavirus infection.

A diagnosis of arenavirus infection should be considered in patients with a clinically compatible syndrome who, within 3 weeks prior to disease onset, (i) lived in or travelled to an endemic area (Figures 1 and 2), (ii) had potential direct contact with blood or bodily fluids of a person with arenaviral hemorrhagic fever during their acute illness (this group most often is comprised of health care workers or persons caring for family members at home), (iii) worked in a laboratory or animal facility where arenaviruses are handled, or (iv) had sex with someone recovering from arenaviral hemorrhagic fever in the last 3 months. Even persons who meet the above criteria most commonly have a disease other than arenaviral hemorrhagic fever, so alternative diagnoses

should always be aggressively sought, especially malaria. Recognized direct contact with rodents in endemic areas, including laboratory mice and pet hamsters and guinea pigs if LCMV infection is suspected (83), should heighten suspicion but is rarely noted even among confirmed cases.

### LABORATORY DIAGNOSIS

The difficulty in clinical diagnosis makes prompt laboratory testing imperative, especially when arenaviral hemorrhagic fever is suspected. Unfortunately, no commercial assays are available, a situation further complicated by the BSL-4 designation and Select Agent status of many arenaviruses that limit access and research potential even to many legitimate scientists. Various “in-house” assays are performed in a few specialized laboratories. Common diagnostic modalities include cell culture (restricted to BSL-4 laboratories for most pathogenic arenaviruses), the reverse transcriptase polymerase chain reaction, serologic testing by enzyme-linked immunosorbent assay or immunofluorescent antibody assay, and postmortem immunohistochemistry, each with its unique advantages and disadvantages (134). Although extensive standardization and validation of these assays have not been conducted, they generally appear to have high sensitivities and specificities when performed in experienced laboratories (63, 135).

### Virus Isolation

The most definitive and perhaps sensitive diagnostic technique is cell culture. Serum is the most reliable sample to test, but virus can be variably isolated from throat washings, urine, CSF, breast milk, and various other tissues (103, 136–140). A particular advantage of cell culture is that, with appropriate antiserum, it enables detection of virtually any strain of virus. However, the time required for virus propagation and the need for a BSL-4 laboratory render cell culture more of a confirmatory test and research tool. Cell culture at higher dilutions may yield a positive result from a specimen found negative at lower dilutions.

### Nucleic Acid Detection

RT-PCR has become an increasingly valuable tool for the VHFs, capable of detecting Lassa virus in over 80% of cases in the first 10 days of illness (18, 141, 142). The technique can be performed in hours, appears to be at least as sensitive as cell culture, and has the significant advantage of not requiring any reagent that must be produced in a BSL-4 laboratory. Since high viremia (or viral RNA copy number or ELISA antigen as surrogates) correlate with death, quantitative RT-PCR also provides prognostic value (56, 63). Sequence heterogeneity of Lassa viruses across West Africa has traditionally posed a challenge to PCR-based diagnostics due to primer-target mismatch but recent development of assays targeting conserved portions of the Lassa virus GPC or arenavirus L genes may have resolved this problem (142, 143). Real time and multiplex PCR assays have been developed that may vastly improve the rapidity and ease of diagnosis of Lassa fever and the many diseases in its differential diagnosis (144–147).

Due to the extreme sensitivity of RT-PCR, contamination and false-positive results are a real concern, especially when the assay is performed in more rudimentary facilities in resource-poor areas where separate spaces for pre- and post-PCR procedures and the routine use of positive and negative controls are not always possible. In the worst case, outbreaks or even bioterrorism could be falsely suspected. The use of one-step assays, sequencing of PCR products to distinguish

them from reference strains, targeting different portions of the genome, and use of multiple supporting diagnostic methods can minimize the risk of false positives (146). False-negative RT-PCR results in VHF are also a concern, which may be due to inhibition by substances circulating in blood, perhaps released by tissue damage or during the RNA extraction process (143, 148). Appropriate inhibition controls must be included in all assays. False-negative results may also occur when patients are tested very early in the course of disease before viremia reaches the threshold of detection for the assay. In this case, if arenavirus infection is still suspected on clinical grounds, the patient should be managed empirically as for VHF and retested in 48 hours when viremia should logically have risen above the detection threshold. Serologic detection of IgM antibody (see below) is also of use in these cases.

### Serologic Assays

In-house ELISA and IFA assays for arenaviral antigen and IgM and IgG antibody have been developed over the years and have been a mainstay of diagnosis, although now the antigen assay is increasingly replaced by RT-PCR (63). Since antigen and IgM antibody detected by ELISA are not typically seen at the same time in the course of the disease, both components are necessary. ELISA assays are high throughput and can be performed with inactivated specimens using standard equipment present in many diagnostic laboratories. ELISA testing for Lassa fever appears to have a sensitivity and specificity over 90% when antigen and IgM antibody assays are conducted in tandem (63, 135). Detection of antibody through IFA can also be a valuable tool, but it is not as routinely sensitive or specific and is more subjective in its interpretation, varying with the experience of the technician (63, 64).

In survivors, IgM antibodies begin to appear about a week after disease onset and progressively increase as virus clears, lasting at least some months (63). There are conflicting reports regarding the timing of IgM antibody appearance; this discrepancy may reflect differences in the production of reagents and their target epitopes, variations in assay sensitivity and specificity, and experience of the persons conducting the assay (63, 103, 149). IgG antibody begins to appear 2 to 3 weeks after onset and recovery and lasts for years. Antibody has been found in persons who left the Lassa fever endemic area over 40 years earlier and had no opportunity for reexposure (150).

Although ELISA assays have the advantage of being high throughput and less prone to false positives due to contamination than RT-PCR, the lack of commercially available reagents is a major drawback to their development; both ELISA and IFA traditionally rely on antigen produced through virus propagation in cell culture in BSL-4 laboratories, which poses a major barrier to production given the scarcity of such laboratories. Cross reactions between antigenically similar arenaviruses may also pose a problem with the serologic assays, although sometimes can be resolved by neutralization testing (74). Various recombinant-protein and virus-like particle-based assays are being developed that may eventually relieve the diagnostic bottleneck, as well as improve sensitivity and specificity, although interpretation and validation of these assays is proving challenging (151, 152).

### Immunohistochemistry

Postmortem diagnosis of some VHFs may be established by pathology examination with immunohistochemical staining of formalin-fixed tissue, but the assay does not appear to be

as reliable for arenavirus infection as for some of the other VHFs (153).

## PREVENTION

### Patient Isolation and Infection Prevention and Control

All patients with a clinically compatible syndrome should be presumed infectious and kept under "VHF isolation precautions" (including use of mask, double gloves, gown, protective apron, face shield or goggles, and boots or shoe covers) until a specific diagnosis is made (154, 155). Powered air-purifying respirators and other small particle aerosol precautions should be used when performing procedures that may generate aerosols, such as endotracheal intubation and sample centrifugation. If available, placement in a negative airflow room is prudent, but hermetically sealed isolation chambers are not required and may have severe adverse psychological effects on both patient and staff. Access to the patient should be limited to a small number of designated staff and family members with specific instructions and training on the implementation of VHF isolation precautions. Protective measures for agricultural workers, field biologists, pest control and pet store workers, and pet owners who may face occupational exposure to rodents and their excreta are reviewed elsewhere (1, 33, 156).

### Disinfection

When contamination is suspected, such as in homes or hospitals treating persons with VHF, disinfection is effective. Sodium hypochlorite (i.e., household bleach) is the most readily available effective inactivation method (154). Bleach solutions should be prepared daily; starting with the usual 5% chlorine concentration, a 1:100 (1%) solution should be used for reusable items, such as medical equipment, patient bedding, and reusable protective clothing before laundering. A 1:10 (10%) bleach solution should be used to disinfect excreta, corpses, and items to be discarded. Workers cleaning areas potentially contaminated by the excreta of small mammals should let the area aerate before entering, then spray the area with the 10% bleach solution and let it sit on the surface for at least 15 minutes before mopping or wet sweeping (157). A site with appropriate security should be dedicated for waste disposal if routine autoclaving is not available.

Specific guidelines exist regarding handling and burial of corpses of victims of VHF (154). The question of the safety of exhuming remains of persons who died of arenaviral hemorrhagic fever overseas for transport to their native home occasionally arises. No data regarding the viability of arenaviruses under these circumstances are available, but it is unlikely that the viruses would survive long under the harsh pH conditions of a decomposing corpse unless the ambient temperature is below freezing, which is unlikely in the endemic areas of most arenaviral diseases. If corpses are to be exhumed, the same protective measures used for burial of victims of VHF, including placing the cadaver in a sealed body bag, should be used.

### Vaccines

In Argentina, use of a live attenuated vaccine called "Candid #1" began in 1991, decreasing the incidence of Argentine hemorrhagic fever from 837 cases that year to an average of 122 cases yearly from 1992 to 2009 (158). The vaccine may also protect against Bolivian hemorrhagic fever,

although it does not appear to cross-protect against other arenaviruses (159). However, “Candid #1” is generally not available or approved outside of Argentina, and even within Argentina supplies are insufficient to cover the population at risk. Furthermore, despite the efficacy and generally excellent safety profile of “Candid #1” for Argentine hemorrhagic fever, fear of reversion to virulence with live-virus vaccines is a major disincentive to exploring its application to other arenavirus infections.

Other arenavirus vaccines are in developmental stages. A number of vaccine platforms have been explored in animal models of arenaviral hemorrhagic fever, primarily aimed at preventing Lassa fever. Approaches include inactivated or attenuated viruses (160, 161), recombinant vaccinia viruses (117), RNA replicon vectors derived from an attenuated strain of Venezuelan equine encephalitis virus (162), recombinant salmonella typhimurium (163), arenavirus protein subunits (164), naked DNA (165), chimeric viruses using the yellow fever 17D vaccine strain (166, 167), reassortant Lassa/Mopeia viruses (168–170), virus-like particles (171), and recombinant vesicular stomatitis virus (VSV) (172, 173). The arenavirus GP1 appears to be the most important immunogenic protein.

The recombinant VSV platform is perhaps the most promising candidate, providing 100% protection after a single dose in a monkey model of Lassa fever (174). This vaccine may be effective when given by the nasal or oral route, potentially facilitating its use in epidemics or as postexposure prophylaxis (175). A vaccine for Ebola virus using this same platform has recently been shown to be safe and effective (176). However, the social, economic, and political barriers to development of arenavirus vaccines are perhaps at least as formidable as the scientific ones, considering that most arenavirus diseases exist in geographically restricted areas with resource-poor populations.

### Postexposure prophylaxis

Although data from clinical trials are sparse, most arenaviruses show *in vitro* and *in vivo* sensitivity to the nucleoside analogue antiviral drug ribavirin. However, given the low secondary attack rate of arenaviruses, postexposure prophylaxis is rarely indicated (177–179). Furthermore, there are no data on the efficacy, dose, or duration of administration of ribavirin for this purpose. Postexposure prophylaxis with oral ribavirin should be considered only in cases of direct unprotected contact with blood or bodily fluids from a person with confirmed or highly suspected arenaviral hemorrhagic fever (Table 3). Persons who develop manifestations of VHF should be immediately converted to the IV form. Prophylaxis should not be given if the only exposure was during the incubation period. Specific guidelines have been published (180).

### Outbreak Management

Control of most VHFs relies on classic public health principles of identification and isolation of cases and monitoring of their contacts. However, the early nonspecific presentation of arenavirus infection poses a serious challenge to case identification. Fortunately, the low secondary attack rate affords a measure of reassurance even when cases go unrecognized as long as proper barrier nursing is maintained. Furthermore, since mild cases are not very infectious, missed or delayed diagnosis of these patients is unlikely to pose a problem from an infection control standpoint.

Persons with unprotected direct contact with a patient during the symptomatic phase of arenaviral hemorrhagic fever should be monitored daily for evidence of disease for three weeks (the longest known incubation period) after their last contact. Contacts should check their temperature daily and record the results in a log. Despite the lack of evidence for transmission during the incubation period, exposed persons should avoid close contact or activities with household members that might result in exposure to bodily fluids, such as sexual contact, kissing, and sharing of utensils. Hospitalization or other confinement of asymptomatic persons is not warranted, but persons who develop fever or other signs and symptoms consistent with VHF should immediately be isolated until the diagnosis can be excluded.

### Rodent Control

In the absence of effective vaccines for most arenavirus infections, effective and sustainable control relies on avoidance of known reservoir host habitats or, when this is not feasible, implementation of measures to prevent direct contact with rodents and their excreta. Most successful control programs entail principles of integrated pest management, combining biological and chemical control measures with education or regulation to change human behaviors that put them at risk (181, 182). Structural improvements to homes may be important for arenaviruses whose rodent hosts invade houses (183).

For LCMV, Lassa, and Machupo viruses, whose hosts often colonize human dwellings, measures to improve “village hygiene” are advocated to discourage rodent invasion, including assuring proper waste disposal, eliminating unprotected storage of garbage and foodstuffs, reducing clutter and vegetation around houses that give rodents shelter, and plugging holes that allow entry into homes (184). These measures may not always be possible with the rudimentary construction of houses in some regions, especially with regard to Lassa fever in areas of West Africa that have been ravaged by war or civil unrest.

Although complete elimination of rodents from the environment through trapping or poisoning is not feasible or

**TABLE 3** Ribavirin therapy for Lassa fever

Indication	Route	Dose	Interval
Treatment	IV*	30 mg/Kg (maximum 2 g)**	Loading dose, followed by:
	IV*	15 mg/Kg (maximum 1 g)**	Every 6 hrs for 4 days, followed by:
	IV*	7.5 mg/Kg (maximum 500 mg)**	Every 8 hrs for 6 days
Prophylaxis	PO	35 mg/Kg (maximum 2.5 g)**	Loading dose, followed by:
	PO	15 mg/Kg (maximum 1 g)**	Every 8 hrs for 10 days

IV, intravenous; PO, oral administration.

\* The drug should be diluted in 150 ml of 0.9% saline and infused slowly.

\*\* Reduce the dose in persons known to have significant renal insufficiency (creatinine clearance of less than 50 ml/min).

desirable, considering their importance to overall healthy ecosystems, short-term intensive rodent elimination in defined areas may occasionally be useful to control outbreaks. One outbreak of Bolivian hemorrhagic fever in 1963 to 1964 in the village of San Joaquin ended abruptly after 2 weeks of continuous trapping in homes during which 3,000 big laucha were captured (185, 186). However, a single trapping session in houses in Sierra Leone did not diminish the incidence of human Lassa virus infection (184). A sustained elimination program would be necessary for effective long-term control because rodents from surrounding fields and forests may quickly recolonize villages and homes. Rodent elimination programs are unlikely to control transmission of Junín and Guanarito viruses to humans because their reservoir hosts are widespread in agricultural fields, although targeting the linear habitats preferred by drylands vesper mice might be plausible (1). Crop replacement or periodic burning of tall grassy areas that are in close proximity to agricultural fields and human habitation have been recommended to control these viruses, although the measures are untested (187).

## TREATMENT

### General supportive measures

When possible, patients with VHF should generally be treated in intensive care units since severe microvascular instability, often complicated by vomiting, diarrhea, and decreased fluid intake require continuous hemodynamic and electrolyte monitoring and aggressive fluid replacement (188). Overaggressive and unmonitored rehydration may lead to significant third-spacing and pulmonary edema. Fluid and blood pressure management guidelines for septic shock are recommended for VHF, although there are no efficacy data on their use for this condition (127). IV fluids, blood products, and vasopressors may be indicated. Although disseminated intravascular coagulopathy is not frequently noted in arenavirus infection, the possibility merits monitoring the relevant laboratory parameters if bleeding and thrombocytopenia persist, requiring transfusion of platelets or fresh frozen plasma. Vitamin K (10 mg on 2 consecutive days) may be given, especially if underlying malnutrition or liver disease is suspected. Until the diagnosis of arenavirus infection is confirmed, patients should be immediately treated with appropriate broad spectrum antibacterial or antiparasitic therapy, with specific consideration of anti-malarial agents for malaria and doxycycline for tick-borne rickettsial diseases. Secondary bacterial infection should be suspected if patients have persistent or new fever after about two weeks of illness.

Acetaminophen (500 to 1,000 mg q4 to 6 hr), tramadol (50 to 100 mg q4 to 6 hr), opiates, or other analgesics should be used for pain control, but salicylates and nonsteroidal anti-inflammatory drugs should be avoided due to the risk of bleeding. Prophylactic therapy for stress ulcers with H<sub>2</sub> receptor antagonists (e.g., ranitidine 50 mg IV every 8 hr) is appropriate. Seizures can usually be managed with benzodiazepines or phenytoin, with careful attention to possible respiratory depression. The use of sedatives and neuromuscular blocking agents should be minimized, but haloperidol (0.5 to 5 mg two or three times daily) or a benzodiazepine (e.g., lorazepam 1 to 10 mg orally daily in 2 to 3 divided doses) may be used. Impaired gas exchange is not typically a prominent feature of arenavirus infection, especially in the absence of iatrogenic pulmonary edema. Intubation and mechanical ventilation should be avoided if possible because

of the risk of barotrauma and pleural and pulmonary hemorrhage. Uterine evacuation appears to lower maternal mortality and should be considered in pregnant patients, although performed with extreme caution as this can be considered a high-risk procedure with regard to potential nosocomial transmission (130).

### Antiviral therapy

#### Ribavirin

Ribavirin should be considered in all cases of arenaviral hemorrhagic fever. In Lassa fever, IV ribavirin has been shown to decrease mortality of severe disease from 55% to 5% when begun within the first 6 days of illness (Table 3) (178). The mechanism of action is unknown, although lethal mutagenesis has been proposed (180). Although few data are available, oral ribavirin may also be effective in some cases, but less so than the IV form, most likely because the serum concentration achieved through oral administration is on the borderline of the mean inhibitory concentration of ribavirin for most arenaviruses (178, 179, 189). Absorption of oral ribavirin from the gut may also pose a barrier given the vomiting and diarrhea often present in VHF. Until more data are available on the efficacy of oral ribavirin, the entire treatment course of ribavirin should be administered IV (Table 3).

Major adverse effects due to short-term ribavirin are rare. The primary adverse effect is a dose-dependent, mild-to-moderate hemolytic anemia that infrequently necessitates transfusion and disappears with cessation of treatment (95, 178, 190, 191). Rigors may occur when ribavirin is infused too rapidly. Relative contraindications include severe anemia or hemoglobinopathy, coronary artery disease, renal insufficiency, decompensated liver disease, breast feeding, and known hypersensitivity. Although findings of teratogenicity and fetal loss in laboratory animals have rendered ribavirin technically contraindicated in pregnancy (pregnancy category X), its use must still be considered as a life-saving measure given the extremely high maternal and fetal mortality associated with arenaviral hemorrhagic fever in pregnancy.

Hemoglobin, hematocrit, and bilirubin levels should be checked at initiation of ribavirin therapy and then every few days, with consideration of transfusion of packed red blood cells if significant anemia develops. Because of the long terminal half-life (~24 hours) and large volume of distribution, ribavirin may still have effect for a time even after cessation, particularly in red blood cells where it accumulates.

#### Convalescent Plasma

Convalescent plasma is efficacious in Argentine hemorrhagic fever and may be indicated, when available, in other New World arenavirus infections. However, in Argentine hemorrhagic fever it has been associated with a convalescent-phase neurologic syndrome characterized by fever, cerebellar signs, and cranial nerve palsies in 10% of treated patients. The complication has not been seen in other arenavirus infections. Limited observations in humans and animal studies suggest that convalescent plasma is also efficacious for Lassa fever, but only if the plasma contains a high titer of neutralizing antibody, which is not always the case even in survivors, and there is a close antigenic match between the infecting viruses of the donor and recipient. The late neurologic syndrome has not been reported in patients with Lassa fever, although opportunities for observation and possible detection of this syndrome have been limited. Given the logistical

challenges inherent in the use of immune plasma, including risk of concomitant transmission of other blood-borne pathogens and lack of an existing bank of immune plasma for this purpose, this therapy should be reserved for severe and refractory cases unresponsive to ribavirin or when ribavirin is not available.

## Experimental Therapies

### Antivirals

A number of experimental antiviral therapies for arenavirus have shown activity *in vitro* and *in vivo*, including small molecules (192–194), nucleoside analogs (195, 196), inhibitors of S-adenosyl-L-homocysteine hydrolase, and tyrosine kinase inhibitors, but are not yet ready for clinical application (197). Transcriptome profiles from monkey models of arenavirus infection may aid in identifying key genes, some of which are the targets of drugs already in clinical use, and thus could potentially be used “off-label” for arenavirus infection, perhaps, depending on the mechanism of action, in combination with ribavirin (198, 199). Ribavirin combined with IFN alfacon-1, a consensus IFN, diminished mortality and disease severity in a hamster arenavirus model (200). Although approved for clinical use in humans, IFN alfacon-1 has not been tested in human arenavirus infection, perhaps in part due to its high cost, systemic toxicity, and need for repeated doses.

### Host-Directed Therapies

Interest is increasing in approaches that would mediate the underlying pathogenesis of VHF and thus have efficacy regardless of the specific etiologic virus. These include immune and coagulation modulators. However, although yet to be systematically tested in humans with arenaviral hemorrhagic fever, trials of various immune modulators in septic shock, including ibuprofen, corticosteroids, anti-TNF- $\alpha$ , nitric oxide inhibitors, statins (HMG-CoA reductase inhibitors), and interleukins, have not shown conclusive benefit. Other immunomodulating approaches being explored include enhancing immune recognition of infected cells and dampening immune responses through the blockage of toll-like receptors (197).

An experimental recombinant inhibitor of the tissue factor/factor VIIa coagulation pathway, rNAPc2, decreased mortality in Ebola virus-infected monkeys and has completed a Phase I trial in humans, but has not yet been tried in arenavirus infection. Data on the use of other anticoagulants, such as heparin sulfate, antithrombin III, recombinant factor VIIa, and tissue-factor pathway inhibitor to treat VHF are either non-existent or inconclusive. Until more efficacy and safety data are available, neither immune nor coagulation modulating drugs can be recommended for arenavirus infection.

### Criteria for Hospital Discharge

In the past few years the relative widespread availability and ease of RT-PCR testing has prompted the use of laboratory, as opposed to clinical, discharge criteria for many VHF (201). Common criteria are to require two RT-PCR negative blood tests at least 72 hours apart. However, the matter remains up for debate; for almost half a century before the availability of RT-PCR testing in West Africa, patients with Lassa fever were routinely discharged when considered to be clinically recovered, with no reports of further virus transmission with the exception of rare cases of presumed male-to-female sexual transmission. This empiric observation is not surprising, considering the well-established direct relationship between level of viremia (and thus infectivity), and the

clinical status of the patient. Furthermore, due to logistical and biosafety concerns, most RT-PCR results are usually not confirmed with cell culture, making it difficult to determine whether a positive RT-PCR indicates the presence of infectious virus, especially when cycle thresholds (which are inversely related to level of viremia) are high. Furthermore, swabs of other body fluids and surfaces of VHF survivors may continue to test RT-PCR positive even after the virus has been cleared from the blood. More thought and research is clearly needed to develop evidence-based discharge criteria that incorporate both laboratory results as well as knowledge gained from decades of empiric observation.

### Management of Convalescence

Clinical management during convalescence includes the use of warm packs, acetaminophen, nonsteroidal anti-inflammatory drugs, cosmetics, hair-growth stimulants, anxiolytics, antidepressants, nutritional supplements, and nutritional and psychological counseling as indicated.

Because of the potential delayed clearance of virus from the urine and semen, abstinence or condom use is recommended for 3 months after acute illness. Transmission through exposure to urine or feces during convalescence has not been noted, but simple precautions to avoid contact with potential excretions in this setting are prudent, including separate toilet facilities and regular hand washing. Breastfeeding should be avoided during convalescence unless the breast milk can be tested and determined to be negative or there is no other way to support the baby.

## ACKNOWLEDGMENTS

The author thanks Lara Schwarz for assistance preparing the manuscript.

### VIROLOGY

#### Taxonomy

The genus *Enterovirus* (EV) was so designated because its members replicate primarily in the human gastrointestinal (GI) tract. The original taxonomic classification of the EVs recognized 64 prototype serotypes within the family *Picornaviridae* (“pico” meaning small, “rna” for ribonucleic acid genome) (Table 1) (1, 2). Additional serotypes continue to be discovered, and the original genus currently has more than 100 confirmed serotypes (3, 4). The “traditional” species designation within the genus includes the polioviruses (PV), coxsackieviruses A and B (CV-A and CV-B, respectively), echoviruses (E), and the “numbered” EVs (Table 1). The original speciation of the EVs was based on the ability of individual serotypes to grow in various cell cultures and produce disease in animal systems (1).

More than a century ago the PVs were the first of the EVs identified as a result of their pathogenicity in humans (5). In animal models they could produce flaccid paralysis in monkeys but failed to induce disease in murine systems. With the advent of tissue culture, they were found to replicate prolifically in cells of human and simian origin. The coxsackieviruses followed as the next species within the genus to be identified. The CV-A serotypes characteristically were capable of replication in suckling mice, resulting in a diffuse myositis and flaccid paralysis (6). They did not readily replicate in cultured simian- or human-derived cells. In contrast, CV-Bs grew readily in tissue cultures of both simian and human origin as well as in suckling mice (7). Their pathology in suckling mice differed from type A serotypes in that the myositis was more focal, and direct infection of brain, myocardium, pancreas, and liver also occurred. Neither the CV-As nor CV-Bs were pathogenic for monkeys. The echoviruses (enteric cytopathic human orphan viruses), so designated because of their initial apparent lack of association with human disease, were defined by their ability to grow well in simian-derived tissue culture cells but not at all in suckling mice and monkeys (8). The original distinctions based on cell culture and animal systems became significantly blurred as new strains were identified and as use of new cell lines resulted in crossover patterns of EV growth. For that reason, serotypes reported from 1973 to date have been designated as “numbered” EVs (enteroviruses 68, 69, etc.) (9).

Assigning a new serotype within each of the EV species was based on generating antisera against the new serotype and reciprocal cross-neutralization testing using a complete panel of prototype strains and antisera (10). Even using such an approach misclassification occurred, requiring reclassification of several of the original EV serotypes. Coxsackievirus A23 and E-8 were found to be identical to E-9 and E-1, respectively. Echovirus 10 and E-28 have been reclassified as reovirus 1 and human rhinovirus 1A, respectively.

The advent of molecular virology opened the way for further refinement of definition of the genus *Enterovirus*, its species and constituent serotypes (3, 4). Hepatitis A virus (previously EV 72) was moved into a new genus, *Hepatovirus*. Sequence analysis of echoviruses 22 and 23 has demonstrated them to be genotypically distinct from other members of the genus (11) and has led to their reclassification into a genus unto themselves, designated *Parechovirus* (12). Phylogenetic analysis using the complete or partial coding sequence of VP1, the major EV capsid protein, has been found to be extremely useful in defining EV taxonomy at the species and serotype levels (3, 13, 14). Using this approach, it was recognized that several EVs originally accepted as individual serotypes were, in fact, strains of one another (CV-A11 [prototype strain Belgium-1] and CV-A15 [prototype strain G-9], CV-A13 [prototype strain Flores], and CV-A18 [prototype strain G-13]) (13).

Criteria for species demarcation within the genus *Enterovirus*, based on molecular and biologic characteristics, have been issued by the International Committee on Taxonomy of Viruses (3). Criteria currently in use for species demarcation of the EV require that members of an EV species share a amino acid identity of >70% in the polyprotein, 60% in the capsid P1 coding region, and 70% nonstructural proteins 2C plus 3CD; share a limited range of natural hosts and host receptors; possess a genome base composition of guanine and cytosine that varies by no more than 2.5%; and share a significant degree of compatibility in proteolytic processing, replication, encapsidation, and genetic recombination. Based on these criteria, EVs that infect humans are now classified into four species, *Enterovirus A* through *D*. This has resulted in a redistribution of the original EV into these new groupings (Table 1). Another result of the use of molecular phylogeny for the classification of the EVs has been the reassignment of the rhinoviruses as species within the genus *Enterovirus* (*Rhinovirus A–D*) rather than an independent

<sup>a</sup>Coxsackieviruses A15, A18, A23, echoviruses 8, 10, 22, 23, 28, 34, and enterovirus 72 have been reclassified.

<sup>b</sup>The Enterovirus E-H and J species infect bovine, porcine, ovine, and simian hosts. No Enterovirus I species exists due to concern that “I” could be confused with “1.”

genus (3, 4). The genus *Enterovirus* currently is comprised of seven species that infect humans (*Enterovirus* A-D, *Rhinovirus* A-C) and five that infect bovine, porcine, ovine, and simian hosts (*Enterovirus* E-H, J). The *Rhinoviruses* will be discussed in a separate chapter.

The use of oral polio vaccine (OPV) strains of PV (Sabin strains types 1–3) has resulted in the emergence of genetically divergent vaccine-derived PVs (VDPV) (15, 16). OPV types 1 and 3 isolates with > 1% divergence or type 2 isolates with > 0.6% divergence in the nucleotide sequence of VP1 from their respective parental strains are considered VDPVs. Depending on type, VDPVs may diverge 0.6%–16.7% from their parental Sabin strains in the VP1 coding region. Further characterization of the VDPV is based on epidemiologic or clinical characteristics. If community evidence of person-to-person transmission exists they are designated circulating VDPVs (cVDPVs). The cVDPVs arise from recombination between OPV strains and the nonpolio EVs, generally C-species EVs, in nature. Circulating VDPVs (cVDPVs) emerge in areas with inadequate OPV coverage. Strains isolated from individuals with primary immunodeficiencies as a result of exposure to one of the Sabin strains of PV, usually from vaccination, are designated immunodeficiency associated-VDPVs (iVDPVs). VDPV strains isolated from individuals without an immunodeficiency and without evidence of transmission or isolates from the environment in whom the ultimate source was not identified are designated ambiguous VDPVs (aVDPVs).

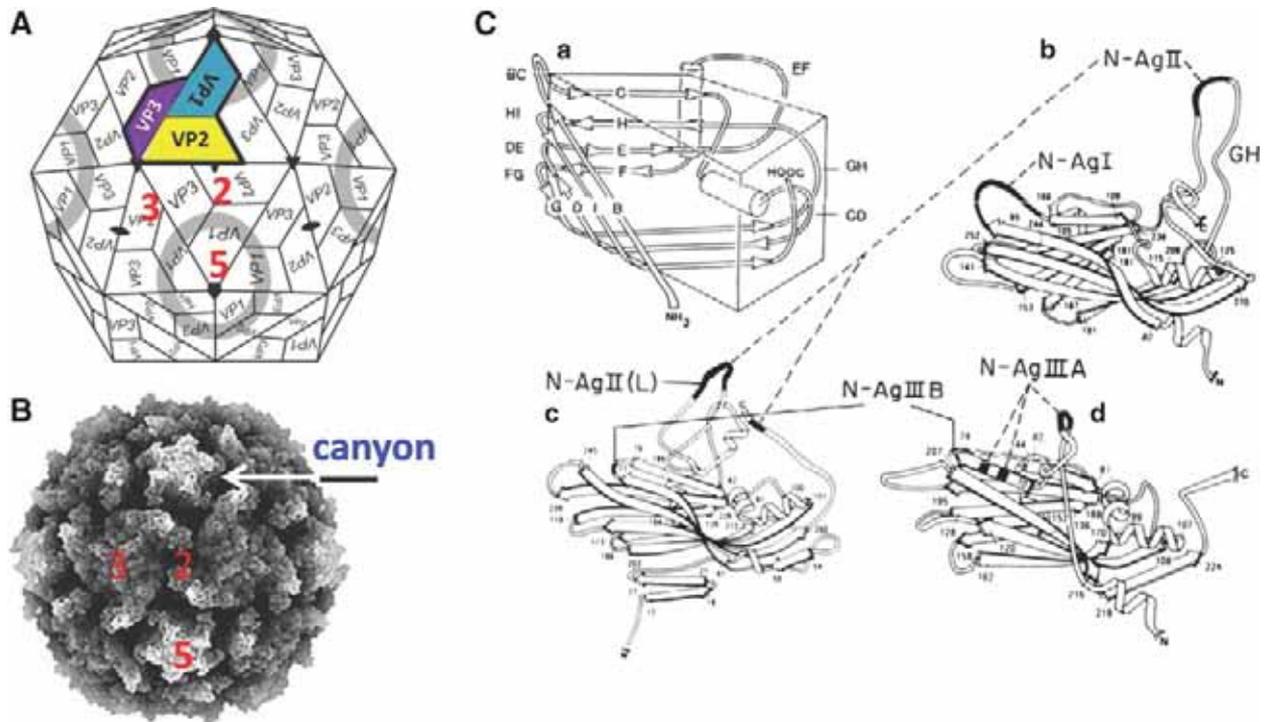

### Viral Structure

As with other members of the family *Picornaviridae*, the EVs are small (30 nm in diameter), consisting of a nonenveloped protein capsid and a single strand of positive (message) sense RNA (17). The encapsulated RNA of the human EVs constitutes approximately 30% of the virion mass (17). The buoyant density of the EVs in CsCl is 1.34 g/cm<sup>3</sup> (3, 17). Because of their lack of a lipid envelope the EV are insensitive to organic solvents. They are insensitive to nonionic

detergents. The EVs are stable at an acid pH of 3.0 or lower, a characteristic that allows them to traverse the stomach and gain access to the intestine where they replicate. The EVs are inactivated by heat (> 56°C), UV light, chlorination, and formaldehyde. These physical and chemical characteristics confer environmental stability to the EVs, permitting them to survive for days to weeks in water and sewage.

The capsid is comprised of four proteins, VP1, VP2, VP3, and VP4. The amino acid chains that comprise proteins VP1, VP2, and VP3 arrange themselves to form eight-stranded antiparallel  $\beta$ -sheet structures in what has been playfully designated a “ $\beta$ -barrel jelly-roll” (18) (Fig. 1). The amino acids that connect the  $\beta$ -strands and that make up the N- and C-terminal sequences extending from the  $\beta$ -barrel domain provide each EV serotype with its surface topography and unique antigenicity. The amino acid loops that connect the  $\beta$ -strands and C-terminal sequences determine the EV serotype (2). The four capsid proteins assemble to yield a protomer with proteins VP1, VP2, and VP3 exposed on the surface of the virion and VP4 beneath them lacking a surface exposure (Fig. 1). Five protomeric units assemble to form a pentamer. In turn, 12 pentamers assemble to form the mature virion. Thus, each virion is comprised of 60 repeating protomeric units consisting of equimolar amounts of each of the capsid proteins. For all PV serotypes neutralization sites are most densely clustered on VP1, the largest of the capsid proteins and which has the most surface exposed (19).

The atomic structures of several EVs have been resolved and reveal multiple common structural motifs (18, 20, 21). The apex of each pentameric unit (i.e., five-fold axis of symmetry) forms a “star-shaped” promontory or “plateau” surrounded by a deep cleft or “canyon” (Fig. 1). The canyon serves as the viral receptor-binding site for some but not all EVs. At the floor of the canyon is a hydrophobic “pocket” that tunnels toward the five-fold axis. The pocket is occupied by lipids of cellular origin designated “pocket

**FIGURE 1** A. Schematic representation of the icosahedral viral capsid structure of the enteroviruses, as represented by poliovirus. The five-fold (5x), three-fold (3x), and two-fold (2x) axes of symmetry are indicated. The position of one of the 60 repeating protomeric units, each comprised of the surface exposed proteins VP1, VP2, and VP3. B. Computer model of poliovirus. The five-fold (5x), three-fold (3x), and two-fold (2x) axes of symmetry are indicated. The canyon is indicated by an arrow. C. Schematic representation of the poliovirus proteins. a) Diagram of the structurally conserved core of the 3 major capsid proteins (VP1-3) comprised by an eight-stranded, wedge shaped, antiparallel beta-barrel core. The ribbon diagrams of b) VP1, c) VP2, and d) VP3 are shown with the locations of the major neutralizing antigenic sites (N-Ags) of poliovirus type 1. factors.” At the three-fold axis of symmetry the surface topography of the EV resembles that of a “propeller.”

### Viral Genome

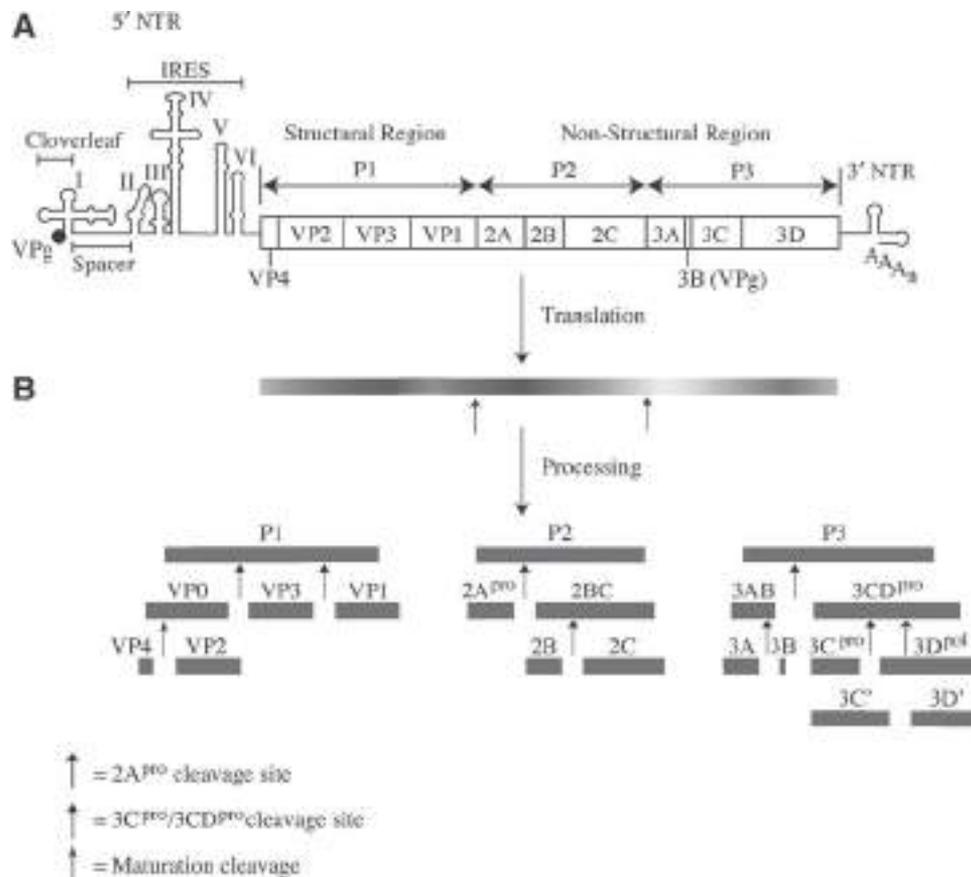

The RNA genome of the EVs is approximately 7.4 kilobases in length (Fig. 2). At the 5′ end of the genome is a virally coded, covalently linked polypeptide, VPg (3B) (2). A long 5′ non-translated region (NTR), approximately one-tenth the length of the total genome, precedes a single open reading frame (ORF) that spans from approximately nucleotides 740 to 7370. The ORF is followed by a short 3′NTR and a terminal polyadenylated (polyA) tail.

The 5′NTR possesses regions of high nucleotide identity in which nucleotide sequences with absolute (or nearly absolute) conservation exist among the EVs (22). These regions have been exploited for the design of primers and probes used for the detection of the EV through nucleic acid amplification (NAA) techniques (i.e., reverse transcription polymerase chain reaction [RT-PCR] and nucleic acid sequence-based amplification [NASBA]) (23). Additionally, internal RNA-RNA interactions within this region result in higher order structures that have essential functions in replication and translation (24–27) of the EV genome. A cloverleaf-like RNA secondary structure formed by the initial 108 nucleotides of the viral genome, designated stem-loop I, is involved in RNA replication (24). A discontinuous region upstream of stem-loop I approximately 450 nucleotides long, designated the internal ribosome entry site

(IRES), is essential for translation of the EV RNA genome (25, 26). Lastly, the 5′NTR contains virulence determinants for PV and possibly other EVs (28, 29).

The EV ORF can be subdivided into three regions that code for the viral proteins designated P1-3 (2). The P1 region codes for the four structural proteins (VP1-4) that form the viral capsid. The capsid protein coding sequences are contiguous to one another and are organized 5′ to 3′ as VP4 (1A), VP2 (1B), VP3 (1C), and VP1 (1D) without intervening stop codons (Fig. 2). VP4 and VP2 exist as the precursor VP0 until encapsidation of the viral RNA genome yields the two mature capsid proteins after cleaving of VP0. The largest capsid protein and the one with the most surface exposed is VP1. It contains type-specific epitopes correlating with PV serotypes (3, 13, 30, 31). For all PV serotypes, neutralization sites are most densely clustered on VP1. Additional major neutralizing epitopes have been identified on VP2 and VP3. It is probable that immunodominant epitopes also exist on the VP1 proteins of other EVs. VP1 coding sequences serve as the target for “molecular serotyping” of the EVs (14). Destabilization of VP4, as a result of viral binding to its receptor, results in virus uncoating (32).

The P2 and P3 regions code for seven unstructural proteins (5′- 2A<sup>pro</sup>, 2B, 2C, 3A, 3B<sup>VPg</sup>, 3C<sup>pro</sup>, and 3D -3′) as well as three uncleaved precursor proteins (2BC, 3AB, and 3CD<sup>pro</sup>) required for viral protein processing and genome replication (Fig. 2) (2). The proteases 2A<sup>pro</sup>, 3C<sup>pro</sup>, and 3CD<sup>pro</sup> are required for cleavage of the EV polyprotein.

Epidemics to eradication: the modern history of poliovirus. *Virology* 4:70. Open access article.)

The 2A<sup>pro</sup> also plays a role in RNA replication by stimulating initiation of negative strand synthesis (33). The 2B protein plays a role at an early, as of yet not clearly elucidated, step in viral RNA synthesis. Its synthesis results in inhibition of protein synthesis from the Golgi apparatus and permeabilization of cell membranes. It causes proliferation of membrane vesicles, the site of RNA replication. Protein 2C may have two functions, one as an NTPase and the other directing replication complexes to the cell membranes. It also causes disassembly of the Golgi apparatus as well as the endoplasmic reticulum and formation of vesicles. The protein 3A or VPg is essential for viral replication by acting as the primer for synthesis of the viral RNA genome. Protein 3AB is believed to anchor VPg (3B) to membranes for priming of RNA synthesis. It also interacts with 3D<sup>pol</sup> and 3CD<sup>pro</sup> and may stimulate the polymerase and proteolytic activity of each, respectively. Enteroviruses encode a viral RNA-dependent RNA polymerase designated 3D<sup>pol</sup>.

### Viral Replication

The viral life cycle begins with attachment of EV to its cellular receptor. Multiple cell-surface molecules have been identified that serve as receptors or coreceptors for the EV

(2). For the PV a single protein, CD155, or PVr (PV receptor) is sufficient for cell entry (34). The PV receptor maps to chromosome 19. CD155 is an adhesion molecule and a member of the immunoglobulin superfamily that helps to form adherens junctions and is a recognition molecule for natural killer (NK) cells. PVs interact with CD155 via the canyon that surrounds the five-fold axis of symmetry of the virion, where domain 1 of PVr inserts itself.

In the case of other EVs (i.e., CV-B3, CV-A21), interaction with two cell-surface proteins (receptor and coreceptor) may be required for access to the cell cytoplasm. For CV-B3 interaction with CD55, decay-accelerating factor (DAF) (a protein of the complement cascade), is required in order to transport the virus from the apical surface of the cell to the tight junction of the cell (35) where it can interact, via the canyon, with its primary receptor, the coxsackievirus and adenovirus receptor (CAR) (36). Coxsackievirus A21 binds to CD55 but requires ICAM-1 for infection (37). For both CV-B3 and CV-A21, interaction with the primary cellular receptor also occurs at the level of the canyon (38). Coreceptors are believed to be required for several CV-Bs and Es (2).

For CV-A9, interaction with its cellular receptor occurs at a 3-amino-acid stretch (Arg-Gly-Asp) located in a 17-amino-acid extension of the C-terminus of the capsid

protein VP1 (39). However, altering the Arg-Gly-Asp motif does not completely nullify viral infection of cells, indicating that a secondary receptor may be used (40).

Lastly, some EVs may have two or more receptors. EV-A71 has been shown to interact with several cellular proteins: scavenger receptor B2 (SCARB2), P-selectin glycoprotein ligand-1 (PSGL-1), sialylated glycan, heparan sulfate, and annexin II (41, 42). However, binding only to SCARB2 will lead to viral internalization and viral uncoating (42).

The effect of binding of the cellular receptor to the EV canyon has been extensively studied in PV and has led to several models for creation of transmembrane pores that could be used for translocation of the viral RNA across the cell membrane into the cellular cytoplasm (32, 43). Receptor binding to the canyon results in shifts of the capsid proteins VP1, VP2, and VP3 that would allow for extrusion of VP4 and the hydrophobic N-terminus of VP1. Depending on the model, 1) the hydrophobic N-termini of VP1 form a pore traversing the cell membrane, 2) the hydrophobic N-termini of VP1 serve as a membrane anchor while VP4 plays a major role in forming a transmembrane pore, or 3) the hydrophobic N-termini of VP1 act together with VP4 to form a transmembrane pore.

Upon entry into the cell the VPg protein (3B<sup>VPg</sup>) covalently linked to the 5' end of the viral genome is removed by a cellular protein. The EV 5'- and 3'-NTRs play critical roles in viral regulatory activities such as translation and replication (2). The EVs subvert host cell protein synthesis by inhibiting the formation of the cap (m<sup>7</sup>G(5')ppp(5')N) binding complex eIF4F (eIF4E + eIF4G + eIF4A) essential for translation of the majority of cellular messenger RNAs (27). The eIF4G is the scaffolding protein with which other proteins or protein complexes (e.g., eIF4A, PABP, eIF3) interact to form the initiation complex for protein synthesis. The EV protease 2A<sup>pro</sup> cleaves eIF4G so that it cannot interact with the cap-binding protein, eIF4E, and recruit the eIF3-40S ribosomal complex to the mRNA. Within as little as 2 hours after infection nearly all host-cell protein synthesis has been shut down by the EV. In addition to cleavage of eIF4G, 2A<sup>pro</sup> as well as 3C<sup>pro</sup> and 3CD<sup>pro</sup> cleave multiple other cellular proteins in order to subvert normal cellular functions for EV translation and replication (44).

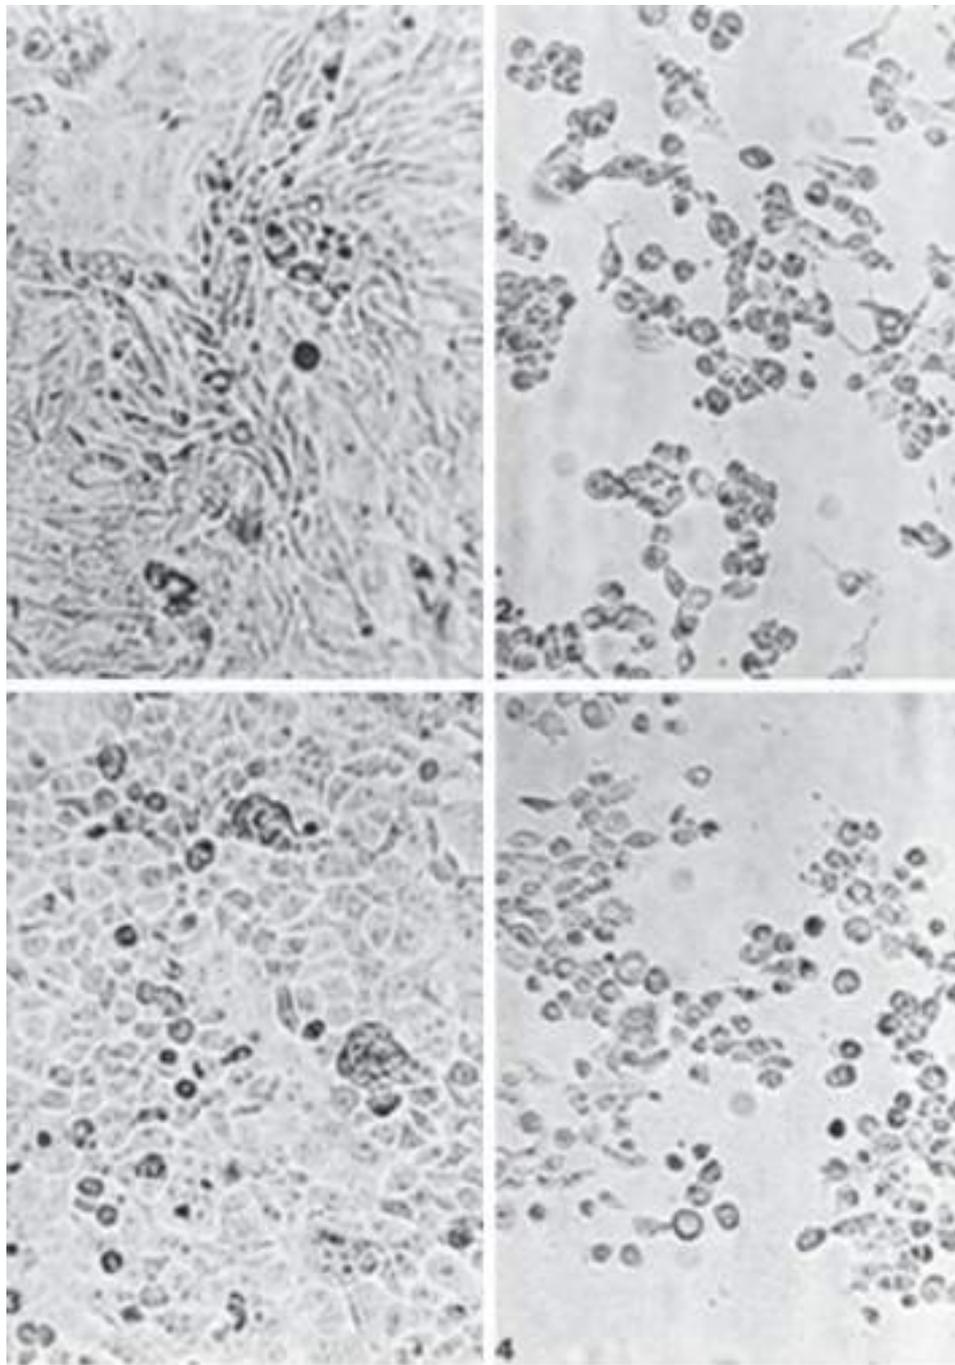

Translation of the viral genome is carried out in a non-canonical cap-independent manner and is mediated by the IRES (25, 27). This highly structured region promotes binding of the 40S ribosomal subunit, which then scans to the initiation codon located at approximately nucleotide 740. The model for 40S ribosomal subunit binding to the IRES proposes that EV protease-cleaved eIF4G binds to the IRES. The C-terminal domain of the cleaved eIF4G interacts with the eIF3-40S ribosomal complex, recruiting it to the IRES (27). Additional cellular proteins (La, polypyrimidine tract-binding protein, unr, poly r(C)-binding protein 2 [PCBP2], SRp20) have been shown to be important for IRES function and either bind directly to the IRES or are part of protein complexes bound to the IRES (2, 27, 44).

Translation of the EV genome results in the generation of a single, large polyprotein (Fig. 2) that is immediately posttranslationally processed by the three virally encoded proteases: 2A<sup>pro</sup>, 3C<sup>pro</sup>, and 3CD<sup>pro</sup>. The 2A<sup>pro</sup> and 3C<sup>pro</sup> are active in the polyprotein and release themselves from it autocatalytically. The 3CD<sup>pro</sup> also self-releases from the polyprotein. The primary cleavage between the P1 and P2 regions is carried out by 2A<sup>pro</sup>. In addition, it cleaves cellular proteins eIF4GI, eIF4GII, poly A binding protein, dystro-

phin, and nucleoporins. The 3C<sup>pro</sup> is responsible for the cleavage between 2C and 3A as well as secondary cleavages of the P1 and P2 precursors. The 3CD<sup>pro</sup> is more efficient than 3C<sup>pro</sup> in the cleavage of the capsid proteins contained in the P1 precursor.

Genomic RNA replicates itself tens of thousands of times within each infected cell via the virally encoded RNA-dependent RNA polymerase 3D<sup>pol</sup> (Fig. 2). Synthesis of viral RNA is asymmetric, resulting in a 30- to 70-fold excess of positive sense RNA. Viral proteins 2A<sup>pro</sup>, 2BC, 2B, 2C, 3AB, and 3B (VPg) (Fig. 2) are also involved in RNA replication (45). Viral RNA exists in three forms in an EV infection: 1) Single-strand, positive-sense (plus strand) RNA is the most abundant form; 2) Replicative intermediate (RI) RNA consists of full-length plus-strand RNA from which six to eight nascent minus-RNA strands are attached. 3) The replicative form (RF) is double-stranded and composed of one strand each of full-length plus- and negative-RNA strands. EV infection of a host cell results in cytoplasmic accumulation of smooth membrane vesicles as a result of viral proteins, the surfaces of which serve as a platform for viral RNA replication. A ribonucleoprotein complex formed by the binding of PCBP2 and 3CD<sup>pro</sup> to the cloverleaf domain located at the extreme upstream portion of the 5'NTR interacts with polyA binding protein (PABP) bound to the terminal polyA tail of the viral genome (45). This results in circularization of the viral genome template. Binding of 3D<sup>pol</sup>, 3C<sup>pro</sup>/3CD<sup>pro</sup>, and VPg to a specific viral genomic element (*cis*-binding RNA element or *cre* element) within the 2C protein coding results in uridylylation of VPg (i.e., VPgpUpU). The uridylylated VPg is transferred to the viral genome's polyA tail where it serves as the primer for 3D<sup>pol</sup> to synthesize the minus strand from the plus-strand template. The resultant RNA, known as the RF, is a double-stranded molecule composed of the plus-RNA template and the newly synthesized minus strand. In order to initiate the synthesis of the plus-RNA strand, the RF must be unwound so that the 5' end of the plus strand can refold into the cloverleaf domain and interact with a protein complex composed of 3CD<sup>pro</sup>, PABP, and PCBP2. How this occurs is not yet understood but may involve binding of either 2C/2BC<sup>ATPase</sup>, the cellular protein hnRNP C, or 3AB to one or both of the RNA strands of the RI (45). Uridylylated VPg again serves as the primer for 3D<sup>pol</sup> to initiate RNA synthesis of the plus strand of the viral genome. From each minus strand arise several (six to eight) RNA plus strands that create the RI. The nascent plus strands eventually give rise to the full-length plus-strand RNA viral genomes.

Morphogenesis of the virion begins with cleavage of capsid precursor protein P1 from P2 by 2A<sup>pro</sup> (46). The protein 3CD<sup>pro</sup> further cleaves P1 to yield capsid proteins VP0 (the precursor of VP4 and VP2), VP3, and VP1. These proteins self-assemble into a protomer that sediments at 5S in sucrose gradients. Five protomers, in turn, self-assemble to yield a 14S pentamer. Twelve pentamers can assemble to form the 75S empty capsid. One model for encapsidation proposes that positive-sense viral RNA threads itself into the 80S capsid to yield a 150S provirion. In another, more accepted model, the 4S pentamers assemble around the RNA to yield the 150S provirion. In this scenario, the empty 80S capsid may serve as a depot for pentamers. For both models, maturation of the virion occurs with cleavage of VP0 to VP2 and VP4, resulting in an infectious 160S virion, and believed to be mediated by the viral RNA. Cleavage of VP0 stabilizes the virion structure.

Infectious virions are released by cell lysis. The cytopathic effect of the EVs in tissue culture cells has been well described (47) and remains an important diagnostic tool. Light microscopy reveals a characteristic rounding of cells and ultimately detachment from the tissue culture dish (Fig. 3). As seen under electron microscopy, a series of changes occurs, beginning with alteration of nucleus morphology and margination of the chromatin (48). Ribosomes aggregate in

the cytoplasm and many clusters of membranous vesicles form; ultimately, the rounded and detached cells lyse.

### EPIDEMIOLOGY

Humans are the only natural reservoir for the EVs. The nonpolio EVs are worldwide in their distribution (49–51). With the introduction of polio vaccines, indigenous

transmission of PVs has ceased in all but three countries of the world (Pakistan, Afghanistan, Nigeria) (52, 53). In temperate climates, EV infections appear to have a marked summer/fall seasonality (50). This being said, winter outbreaks of EV disease are well documented (54–56). A high year-round incidence occurs in tropical and subtropical areas with higher incidence during the rainy season (17). The nonpolio EVs are estimated to cause between 10 to 15 million symptomatic infections in the United States each year (57).

The fecal-oral spread of these agents appears to be facilitated, particularly among children, during periods of warm weather. In addition to transmission by direct person-to-person contact, EVs may be recovered from bivalves, houseflies, wastewater, and sewage (58–62). While the role of houseflies in outbreaks has not been established, sewage- and water-associated EV outbreaks have been documented (63–65). The EVs have also been shown to be vertically transmitted from mother to infant congenitally and/or perinatally (2). Rarer routes of transmission include through breast milk and organ transplantation (66–68).

Wild-type PVs, once major contributors to the epidemiologic profile of the EVs in the United States, are no longer causes of acute flaccid paralysis (AFP). However, occasional imported cases of VDPV infection and vaccine-associated paralytic poliomyelitis (VAPP) do occur (69, 70), stressing the need for maintaining immunization against the PVs. Although efforts toward the global eradication of PV infections resulted in the elimination of wild-type infections from the Western Hemisphere in 1991, efforts continue elsewhere in the world (52, 53).

In developing countries the prevalence of paralytic disease remained high (2 to 11 cases/1000 population) throughout the 1970s. In 1988, the World Health Assembly resolved to eradicate poliomyelitis worldwide (52). In 1988, PV was endemic to 125 countries, and in the early 1990s as many as 15,000 cases of paralytic disease were estimated to occur worldwide annually. Despite setbacks (52), continued progress towards total elimination of PV transmission worldwide continues. Transmission of wild-type PV 2 has not been detected anywhere in the world since October 1999 (71). Similarly, there has been an apparent disruption of wild-type PV 3 transmission in Nigeria with no detected cases of AFP since November 2012 (52, 53, 72).

All but two of the six World Health Organization regions (African and Eastern Mediterranean Regions) have been certified polio free. By 2014 indigenous PV transmission had been interrupted in all but three countries, Pakistan, Afghanistan, and Nigeria (52, 53). Encouragingly, no new cases have been identified in Nigeria since July of 2014, suggesting that possible interruption of transmission has occurred (53). The number of cases of AFP due to wild-type PV dropped to 359 worldwide in 2014, with 85% of cases occurring in Pakistan (52). Cases of AFP due to importation of polio to countries previously polio free continue to occur but have decreased as a result of control of disease in endemic countries (53).

An issue encountered as a result of vaccination efforts directed toward global eradication of PV has been the appearance of cVDPVs (15). Factors favoring their development include low OVP coverage and dense populations (73). The public health threat posed by these strains is analogous to that of the wild-type PVs and results in disease indistinguishable from them. The first reported outbreak of poliomyelitis secondary to cVDPV occurred in 2000 on the island of Hispaniola (73). Since then, outbreaks have been reported in 19 countries (15, 16). Approximately 90% of

cVDPV outbreaks have been due to strains derived from the type-2 Sabin strain, while type-1 cVDPVs account for approximately 10%. Outbreaks due to type 3-derived cVDPVs are rare (15). In 2014 only four countries reported cVDPV-related AFP cases (74).

Approximately 80 persons with primary immunodeficiencies excreting iVDPVs have been identified worldwide since 1961 when OPV was introduced (15, 16). Type-2 iVDPVs account for 64% of cases, and types 1 and 3 are responsible for the remaining 21% and 15%, respectively. Excretion of iVDPV strains may persist for greater than a decade. From January 2014 through March 2015 aVDPVs were isolated from 16 countries (16).

For the nonpolio EVs, each EV season in each part of the world is dominated by only a few serotypes and, in any given year, multiple EV serotypes may circulate within a community or geographic region (50, 75–81). During the years 1970 to 2008, the predominant nonpolio EV isolates identified in the United States, listed in descending order, were E-9, -11, -30, CV-B5, E-6, CV-B2, CV-A9, E-4, CV-B3, E-7, CV-B4, E-18, CV-B1, E-3, and E-5 (50, 82). These 15 serotypes account for approximately 80% of all EVs reported during that period. The annual determination of predominant serotypes may be influenced by reporting bias, the inability to readily grow certain serotypes in cell culture, particularly the CV-As and the newer EVs, as well as by a skew toward those serotypes causing more serious disease (and hence prompting more laboratory investigation). The predominant serotypes cycle with varying periodicity (75–82), a reflection of the availability of new susceptible host populations, especially children, within a community. Children are the primary victims of EV infections. Data derived from a number of sources spanning the latter half of the 20<sup>th</sup> and early part of the 21<sup>st</sup> centuries document that the overall incidence of infections with CVs and Es were highest among children (50, 51, 76, 83).

Because central nervous system (CNS) infections generate the most medical attention among the many manifestations of the EVs, much of the age-related incidence data come from surveys of meningitis and encephalitis. In a Finnish cohort (84), an annual incidence of viral meningitis of 219/100,000 children < 1 year of age was noted, versus 19/100,000 in children between the ages of 1 and 4 years. The vast majority of identified viral pathogens were EVs. In England and Wales the nationwide incidence of EV meningoencephalitis was 313/100,000 in infants < 3 months of age (85). In both reports the incidence dropped with increased age. In Athens, Greece, the annual incidence of EV meningitis was estimated to be 17/100,000 in children < 14 years of age (86). The highest incidence, 26/100,000, was in children 1 to 5 years of age, followed by 24/100,000 in infants < 1 year of age. Past and recent surveys of meningitis and encephalitis have revealed a similar skew toward young infants (51, 87, 88); an incidence peak among young school age children, ages 5 to 10 years of age, has also been reported in several studies (89–91). Occasional outbreaks of EV CNS infections involving predominantly adults occur (54, 92, 93). A surveillance report on causes of viral meningitis among active and reserve U.S. military personnel over a 10-year period documented that the EVs accounted for 86.4% of all confirmed cases. The incidence among active duty members demonstrated lower rates among younger and older personnel (< 20 years of age: 13.1/100,000 person-years; > 40 years of age: 11.7/100,000 person-years) and highest among 25- to 29-year-olds (20.9/100,000 person-years) (94).

A possible explanation for the incidence findings in older children and adults may lie in the recent history of particular serotypes in the geographic area studied. Serotypes with “endemic” patterns, i.e., occurring with significant incidence every year, are most likely to affect only the youngest children (50). They are the most susceptible to these serotypes due to the absence of previous exposure and immunity. Older children and adults are more likely to predominate in an outbreak of a serotype that has not been present in a community for several years, creating a reservoir of susceptible people among children born since the last appearance of that serotype. Although EVs are the most common cause of aseptic meningitis among adults as well, the lower incidence and the greater ease of physical assessment in adults, compared with young infants, reduces the vigor with which a specific viral etiology is sought. When a serotype is introduced into a community that has many susceptible adults, perhaps after a period of absence or because an antigenic variant of a common serotype has emerged, the large number of affected adults will spark renewed interest and increased efforts toward specific diagnosis (51, 92, 93). EV infections other than meningitis and encephalitis are also more commonly identified in children than adults (51, 95, 96), but because of the benign nature of many of these infections, investigations of these other diseases are less commonly performed.

While infection incidence is higher in children, severity of infection as a function of age varies from disease to disease and sometimes from serotype to serotype. Traditional teaching has been that adults suffer the most severe infections with the PVs, manifesting paralytic disease much more commonly than children, in whom asymptomatic infection, aseptic meningitis, or abortive infection are the more common presentations (97, 98). A re-examination of the epidemiology of poliomyelitis, however, finds that the apparent increase in paralytic case:infection ratios with age may actually be the result of increasing immunity within a population following initial introduction of the viruses (99). In PV-naïve populations where poliomyelitis had never appeared, the highest rate of paralysis occurred in the youngest infants (99). Only subsequent to the introduction of PVs, as immunity and hygiene increase in parallel, does the incidence of paralysis appear to increase with increasing age, probably because the actual incidence of susceptible individuals increases with increasing age (99). Similarly, neonates are more likely to suffer severe complications of infections with the Es and CVs than are older children or adults (66, 100, 101). Comparison of case series of adults versus children with aseptic meningitis due the EVs suggests a more severe disease in adults (102, 103); the same is true for pleurodynia (51), an illness usually due to CV-Bs. Myocarditis is most common and most severe in infants <6 months of age and in young adults; patients from 10 to 19 years of age account for 10% of cases while patients between the ages of 20 to 39 years constitute 52% of cases; the incidence then decreases so that patients over 60 years of age comprise only 5% of all cases of EV myocarditis (104).

Host factors that predispose to or increase the severity of EV infections, other than age and immunodeficiency, have been difficult to identify. Similarly, tonsillectomy and adenoidectomy around the time of PV infection predispose to bulbar poliomyelitis. Perhaps by the same mechanism, physical exercise is an established risk factor for paralytic poliomyelitis (105–107) and a hypothesized one for EV myocarditis (108). A male-to-female incidence ratio for EV infections of 1.4:1 is seen in individuals <20 years of age

(109). The male predominance in cases is not observed in older individuals and may be a reflection of more female caregivers being exposed to the EV. Infection rates with the nonpolio EVs are higher among persons of lower socioeconomic status and in areas of crowding (110). In contrast, poliomyelitis incidence transiently increases with improved societal hygiene as the age of first PV infection is shifted to an older age group. Pregnancy may increase the severity of PV infection and myocarditis (104).

## PATHOLOGY

The pathogenesis of EV infections has been studied at molecular, cellular, and organ-system levels (2, 111, 112) and, while much has been learned, much more remains unexplained. The majority of what is known about the pathogenesis of the EV infections in humans has been based on the study of the PVs, the prototypic members of the genus, in experimental infections using chimpanzees more than seven decades ago, and, most recently, from transgenic mice expressing the PV receptor CD155 (112–114). Observations in humans have supplemented these findings.

### Pathophysiology

The EVs are transmitted by the fecal-oral route and less commonly by respiratory droplets and transplacentally. The virus may be shed for up to 4 weeks from the nasopharynx and for several weeks to months in the feces. While some replication occurs in the nasopharynx, with spread to upper respiratory tract lymphatics (PV can be isolated from the tonsillar tissue in infected humans), most of the virus inoculum is swallowed (115). The characteristic stability of the EVs at acid pH allows them to traverse the stomach en route to the site of primary infection in the lower GI tract. The site of PV replication in the GI tract is yet to be identified. In human infection, PV has been identified within the ileal wall within Peyer's patches and mesenteric lymph nodes (115). It is believed that the EVs may infect enterocytes of the follicle-associated epithelium (FAE) or M cells within it in the lower GI tract. Supporting this is the finding that CD155 protein has been identified on the surface of FAE, M cells, and in the germinal centers of Peyer's patches (116). Alternatively, M cells have been shown to bind and endocytose PVs, suggesting a similar role in in-vivo infection (117). The M cells could thus transport PV from the gut lumen to cells in Peyer's patch where they then replicate.

A minor (primary) viremia follows replication in the lower GI tract and possibly the nasopharynx, seeding numerous organ systems including the CNS, liver, lungs, and heart. More significant replication at these sites results in a major (secondary) viremia associated with the signs and symptoms of viral infection. If the CNS has not been seeded with the initial viremic episode, spread there may occur with the major viremia. The exact route by which PVs and other EVs gain entry to the CNS is still unclear, but two routes have been proposed and supported by observational and experimental data.

Viremia has been shown to be essential for development of paralytic disease in chimpanzees and supports this route as a mode of entry to the CNS (113). Further support for this mode of access to the CNS comes from studies comparing PV accumulation in the CNS of CD155 transgenic mice and nontransgenic mice (118). Pharmacokinetic analysis of PV injected into these two mice strains indicates that PV is delivered to the brain in significantly greater amounts than would be expected from the vascular concentration. The

mechanism by which the virus gains entrance to the CNS is not known. The mechanism by which EVs leave the blood and enter the CNS is also unknown.

Evidence for access to the CNS via a neural route is available from simian, murine, and human studies. Sciatic nerve inoculation of PV in monkeys results in spread of virus along the nerve and the spinal cord (119). In monkeys and CD155 transgenic mice the initial limb to develop paralysis following inoculation of PV is the one injected (120, 121). Freezing or transection of the sciatic nerve prevents the development of paralysis of the limb of monkeys or CD155 transgenic mice inoculated intramuscularly with PV (119, 121). Historically, a significant number of children inadvertently inoculated with an incompletely inactivated polio vaccine developed initial paralysis in the limb receiving the vaccine (122). Trauma to a limb is associated with paralysis of that limb following PV infection. This so-called “provocation poliomyelitis” is well described following intramuscular injections into the leg or arm of a patient incubating wild-type PV or those that receive live attenuated PV vaccines (123, 124). Using the CD155 transgenic mice model, it was discovered that the mechanism of provocation poliomyelitis appears to be the induction of retrograde axonal transport (121, 125, 126). Poliovirus may gain access to neurons at the level of the neuromuscular junction, which had been shown to contain CD155 protein (127). Recent evidence also suggests that a CD155-independent uptake mechanism may exist (126). Experimental evidence indicates that intact poliovirions (160S) are transported in endocytic vesicles along the axon by fast retrograde transport (121). Upon arrival at the neuronal body, viral RNA is released and replication ensues (112).

The ability of the EV to replicate in different tissues is not determined solely by the presence of a viral receptor on the cell surface. In humans and CD155 transgenic mice, CD155 expression has been documented in tissues that are not sites of PV replication (34, 128, 129). Although it was initially suggested that the IRES was a determinant of cell tropism for PVs, subsequent experiments failed to support this hypothesis (112). However, the same may not hold true for all the EVs. A chimera containing the 5′NTR of E-12 (Travis strain) in the background of a full-length infectious clone of CV-B3 failed to replicate in murine cells that normally supported the replication of CV-B3 (130). Because the chimera contained the capsid of CV-B3 and its nonstructural proteins, viral entry was eliminated as a replication-limiting factor. This was supported by the finding that the chimera replicated with equal efficiency to that of CV-B3 in HeLa cells. Using reverse genetics, the block to replication in murine cells was localized to a specific stem-loop structure within the 5′NTR, indicating that for the nonpolio EV the 5′NTR may be a determinant of tissue tropism.

Experimental evidence indicates that for the PVs alpha/beta interferon (INF  $\alpha/\beta$ ) response may determine cell tropism (131). PV infection of CD155 transgenic mice lacking the INF  $\alpha/\beta$  receptor resulted in viral replication in the liver, spleen, pancreas, and CNS, all of which expressed CD155. Infection of CD155 transgenic mice expressing the INF  $\alpha/\beta$  receptor yielded viral replication in the brain and spinal cord only. In the latter mice, PV infection of extraneural tissues led to rapid and robust production of INF-stimulated genes that limited viral replication in those tissues. In both groups of mice INF-stimulated gene expression in neural tissue was low in the noninfected state and a robust response after infection was not observed. Thus, INF  $\alpha/\beta$  may function as a determinant of cell tropism in CD155 transgenic mice.

Further support for this hypothesis was found by documenting that PV-susceptible monkey and mouse kidney cells in culture, as well as primate cell lines, failed to provide a rapid INF response upon infection (132).

The finding that INF  $\alpha/\beta$  is a determinant of PV tissue tropism may provide a long-sought explanation for the relatively rare occurrence of paralytic disease as a result of PV infection (112). In the majority of individuals infected with PV, the INF  $\alpha/\beta$  response limits the replication of PV in extraneural tissues, thereby preventing extension of infection into the CNS. In the <1% of individuals infected with PV who develop paralytic disease, the INF  $\alpha/\beta$  response may be defective, allowing for significant replication of PV in extraneural tissues that permits CNS infection.

Molecular determinants of pathogenesis are being investigated to understand the clinical phenotypes of specific EV serotypes and subgroups. While all three serotypes of wild-type PVs are known to be neurotropic and neurovirulent, specific tissue tropisms and virulence patterns vary widely among the nonpolio EVs, with certain serotypes consistently reported as causes of specific organ-system disease and others only rarely so. Worldwide, members of the B species of EV are almost uniformly the principal causes of viral meningitis (50, 86, 133). In the United States the serotypes most frequently encountered are, in descending order of frequency, E-9, E-11, E-30, CV-B5, E-6, CV-B2, CV-A9, E-4, CV-B4, E-7, E-18, and E-5 (50). CV-Bs are the most frequent EVs implicated in heart infection (104). Echovirus 11, followed by several other E and CV-B serotypes, are the most important pathogens of neonatal EV sepsis (66, 109); E-11 is also the most common serotype causing chronic meningoencephalitis in antibody-deficient patients (134). Confounding the analysis of genotype-phenotype correlation is the observation that while certain serotypes are more commonly associated with certain diseases, virtually every EV serotype has been associated with virtually every EV disease manifestation.

The determinants of neurotropism and neurovirulence have been investigated extensively for the PVs. Following vaccination with attenuated vaccine strains, reversion to virulence has been observed in the fecally shed virions recovered from normal children (135). The viral RNA of both wild-type and attenuated vaccine strains has been sequenced, and only a few differences exist between them. Comparison of wild-type, vaccine, and revertant PV strains has been extremely useful in identifying neuroattenuating regions of the PV genomes. For the PVs the 5′NTR has been documented to be a major determinant of virulence phenotype (i.e., the ability to cause paralysis) (28). For all three PV Sabin strains the major neurovirulence attenuating sites are clustered within a 10-nucleotide region of the 5′NTR (nucleotides 472–484 relative to type-3 Sabin strain of PV). Additional determinants of virulence are also found in the amino acids encoded in the P1 and P3 coding regions. Neurovirulence-determining genomic regions have yet to be identified for the nonpolio EV.

The search for determinants of virulence in other EVs has been less conclusive. CV-B4 strains with murine pancreatic tropism and virulence are distinguished from avirulent CV-B4 strains by a single amino acid residue in the VPI capsid protein. The extension of this finding to humans has yet to be established. Genotypic determinants of myocarditis remain to be conclusively identified. One mechanism of CV-induced cardiomyopathy may involve the ability of that virus 2A protease molecule to cleave dystrophin, a cytoskeletal protein found in the heart (136). Using a series of

intratypic capsid and 5′NTR chimeras derived from laboratory and clinical strains of CV-B3 with cardiovirulent and noncardiovirulent phenotypes in mice, a genomic determinant was mapped to the 5′NTR (137). Subsequent evaluation revealed that a higher order RNA structure (stem loop II) within the 5′ portion of the 5′NTR was a major determinant of cardiovirulence in mice (29).

### Immune Responses

As with other viral infections, the host immune response to EV infection has both humoral and cell-mediated components (reviewed in 1); the humoral response appears to be the most important. The importance of antibody formation in the clearance and recovery from EV infections is illustrated by the severity and chronicity of EV infections in agammaglobulinemic individuals (134). Similarly, the severity and timing of neonatal EV infections likely reflects antibody deficiency. Poliovirus vaccination has demonstrated the protective benefits of humoral immunity. Anti-EV IgM antibodies are rapidly produced and persist for up to 6 months; IgA and IgG antibodies to the EVs may be detectable for decades following infection. There are four primary antigenic sites on the PVs to which neutralizing antibodies attach (2). Chimeric viruses derived from PVs and CV-B serotypes have been used to show that the BC loop of VP1 (Fig. 1) is an important neutralizing epitope of PV 1 and CV-B4 (31). Epitopes for the nonpolio EVs remain to be determined.

Evidence continues to mount for the important role of innate immunity in EV infections. As discussed previously, INF  $\alpha/\beta$  plays a role in PV infection of mice (131). Toll-like receptor (TLR) 3, which senses double-stranded RNA (dsRNA), was demonstrated to be nearly essential for murine innate response to CV-B3. TLR3-deficient mice had more severe myocarditis and increased mortality when infected with CV-B3 (138). The TLR-3-mediated response may be important in protection of EV myocarditis in humans. Two TLR-3 sequence variants, shown to have reduced responsiveness to dsRNA, have been found in patients diagnosed with EV myocarditis or dilated cardiomyopathy (39). Evidence suggests that increased expression of TLR-8 may be associated with adverse outcomes (heart failure and death) in patients with dilated cardiomyopathy (140).

The study of cell-mediated immune responses to the EVs has been much more limited and the importance of the cellular response in preventing or clearing infection is unclear. T-cell epitopes have been identified on the capsid, near previously discussed B-cell antigens, as well as on nonstructural proteins of CVs and PVs. These studies have been conducted in murine models, and the relevance of T-cell epitopes and lymphocyte responses to human EV infections is still debated. Similarly, EVs and the T-cell responses to them have been implicated in the actual pathogenesis of chronic diseases. Myocarditis, for example, appears to represent an intricate interplay between virus and host genetics/immunity in which direct viral injury (e.g., by dystrophin injury as noted above) and innocent-bystander damage due to the immune response both probably affect the ultimate outcome of disease (1, 136).

### Histopathology

The benign nature of the majority of EV infections has resulted in somewhat sparse human pathological data. In patients dying of acute poliomyelitis, mixed inflammatory infiltrates (neutrophils, microglia, and lymphocytes), initially perivascular in location and later in the gray matter, as

well as neuronal necrosis and neuronophagia are found from the spinal cord's anterior horn to as far anterior as the hypothalamus, thalamus, and the motor area of the precentral gyrus (141). Outside of the spinal cord the three areas most often severely affected are the reticular formation, vestibular nuclei, and the roof nuclei of the cerebellum. Small hemorrhages and edema are associated with the inflammation. Involvement of the cerebellum, cerebrum, and midbrain may also be found.

Occasional pathological descriptions of nonpolio EV meningitis, meningoencephalitis, or encephalitis have been reported (142–147). The pachy- and leptomeninges may be edematous with lymphohistiocytic infiltration. In severe cases, there may be edema of the parenchyma and inflammation of the choroid plexus. Perivascular lymphocytic or neutrophilic infiltrates may be present in the meninges or parenchyma. With encephalitis, especially that due to EV-A71, neuronal necrosis, neuronophagia, and microglial nodules may be present. Microscopic hemorrhage, microabscesses, or tissue softening have been reported. In the case of encephalitis due to EV-A71 inflammation of the entire medulla is present to greater or lesser degree. Inflammation in the nuclei of the brainstem and spinal cord is often more severe than that seen in the cerebral cortex or cerebellum.

Histopathological evaluation of the myocardium in cases of acute myocarditis reveals predominantly lymphocytic interstitial infiltrates; however, polymorphonuclear infiltrates of varying degree may also be present (147, 148). The infiltrates may be focal, patchy, or diffuse. Interstitial edema and varying degrees of cardiomyocyte necrosis are common. With resolution, fibrosis may replace most inflammatory changes.

In addition to the findings listed above, infants with severe neonatal EV disease may have involvement of multiple other organs (147, 149). Hepatocellular necrosis, which may range from multifocal to extensive, and hemorrhage are commonly present. Hemorrhagic necrosis of the adrenal glands, renal medullary hemorrhages, pancreatitis, and hemorrhagic pneumonitis may be seen.

Biopsy of the vesicular lesions seen in hand-foot-and-mouth disease (HFMD) demonstrates loose strands of fibrin, lymphocytes, monocytes, and neutrophils within the vesicular fluid (150). The overlying epidermis has extensive acantholysis with reticular degeneration. Edema, perivascular foci of lymphocytes, monocytes, and neutrophils are seen in the upper dermis.

## CLINICAL SYNDROMES

### Neurologic Illnesses

#### Poliomyelitis

A total of 90% to 95% percent of wild-type PV infections are asymptomatic. Only 1% to 2% of PV infections during epidemics and <0.1% of infections under nonepidemic conditions result in paralysis. The remaining 4% to 8% of infections result in a flu-like illness termed “abortive poliomyelitis” or the “minor illness.” In these patients, fever, fatigue, headache, anorexia, myalgias, and sore throat may last 2 to 3 days followed by complete recovery. Symptoms suggestive of an upper respiratory tract infection (fever, sore throat) are more commonly reported in children (98). Older adolescents and adults may report a “grippe”-like prodrome characterized by fever and generalized aching (98).

The onset of the major illness (i.e., CNS involvement) may be more abrupt in children than in adults (151) and

may follow rather than accompany the flu-like “minor illness.” The illness may take on a biphasic appearance, particularly in young infants and children, with “minor illness” preceding “major illness” (98, 151). A biphasic or “dromedary” pattern of fever may occur and is commonly seen in approximately one-third of children. The onset of the major illness in adults may be more gradual and may occur up to 2 weeks from the onset of nonspecific signs and symptoms. Approximately one-third of patients with CNS involvement develop aseptic meningitis (“non-paralytic poliomyelitis”) that is indistinguishable from that due to the nonpolio EVs.

Paralysis is often preceded by severe myalgias, more so in adults (98). The pain is most commonly localized to the lower back and the involved limb(s). Meningismus may be prominent. Hyperesthesias and paresthesias may be observed in the same affected muscle groups. Exercise relieves the muscle aches, resulting in anxious movement by affected patients. Loss of superficial and deep tendon reflexes precedes the development of weakness or paralysis. Paresis or paralysis typically appears within 1 to 2 days of onset of myalgias. The risk of onset of paralysis or of its progression continues until the fever subsides.

The paralytic manifestations of PV infection reflect the regions of the CNS most severely affected (98, 151–153). The distribution of the paralysis is characteristically asymmetric with proximal muscles more affected than distal ones and legs more than arms. Single-limb involvement is most common, but quadriplegia may occur. Paralysis of the muscles of the diaphragm may also occur and result in respiratory failure. Paralysis of the bladder and intestinal atony are common.

Cranial nerve involvement may result in so-called “bulbar paralysis” with resultant difficulties in any or all speech, swallowing, breathing, eye movement, and facial muscle movements. Medullary centers controlling respiration and vasomotor function can become involved, with potentially fatal outcome (152). Similarly, involvement of the cranial nerves IX, X, and XII can result in paralysis of the tongue, pharynx, and larynx leading to airway obstruction from secretions.

The natural history of the illness is highly variable, ranging from transient paresis with complete resolution, to rapid progression with complete and permanent paralysis. The short-term outcome, i.e., resolution or paralysis, is evident within several days. The long-term outcome of paralytic poliomyelitis appears to be determined during the first 6 months after onset; absence of improvement during that time period usually suggests permanent paralysis, ultimately, with concomitant limb atrophy and deformity. If improvement occurs, the greatest strength gains occur during the first 6 months (154) and may continue for up to 9 months. The overall mortality of spinal poliomyelitis is approximately 5%. Bulbar and medullary poliomyelitis had high mortality (50% or greater) during the epidemic years in the United States when modern respiratory support techniques were not available (152).

As many as 25% of individuals who recover from paralytic disease may develop the syndrome of post-poliomyelitis muscular atrophy (155). Characterized by recurrent weakness, pain, and atrophy 25 to 30 years after the initial infection, the clinical course is usually a gradual one that seldom results in total disability of the affected areas but does negatively affect quality of life. While viral persistence or reactivation has been postulated, the predominant theory is that the syndrome is a result of aging and neuronal drop-

out in already compromised neuromuscular connections (156, 157).

### Aseptic Meningitis

The clinical disease observed during EV meningitis varies with the host’s age and immune status. Neonates are at risk for severe systemic illness, of which meningitis or meningoencephalitis is commonly a part (100, 101, 158, 203). Group B coxsackieviruses were associated with aseptic meningitis in 62% of infants < 3 months of age in one study (100). Echoviruses identified in infants < 2 weeks of age were associated with meningitis or meningoencephalitis in 27% of cases (101). In a prospective study of neonates (< 2 weeks of age) with proven EV infection, 75% had clinical or laboratory evidence of meningitis (158).

The natural history of typical EV meningitis is shown in Fig. 4 (159). Onset is usually sudden, and fever of 38 to 40° C is the most consistent clinical finding, occurring in 76% to 100% of patients (86, 100, 160–164). The fever pattern may be biphasic (100, 159), appearing first with nonspecific constitutional symptoms, followed by resolution and reappearance with the onset of meningeal signs. Nuchal rigidity is found in more than half of the patients, particularly in children older than 1 to 2 years of age (103, 160, 161, 162), but may be less common in infants (160). Headache is nearly always present in adults and children old enough to report it, and photophobia is also common. Non-specific and constitutional signs and symptoms of viral infection, in decreasing order of occurrence, include vomiting, anorexia, rash, diarrhea, cough and upper respiratory findings (particularly pharyngitis), and myalgias (86, 100, 159, 161, 162, 163). Symptoms other than fever may also be biphasic, a presentation observed more often in adults than children.

Aseptic meningitis with certain EV serotypes is associated with particular clinical stigmata, e.g., HFMD frequently occurs with EV-A71 meningitis (164) and rashes are especially common with E-9 meningitis (165), although both incidental findings can occur with numerous other serotypes as well. A history of concomitant family illness, rashes, upper respiratory or GI symptoms, and, occasionally, meningitis, is often obtained (166).

Neurologic abnormalities are unusual; the literature on EV meningitis rarely includes more than 10% of patients with abnormal neurologic examinations. Febrile seizures are among those neurologic “abnormalities” that may complicate aseptic meningitis without implicating parenchymal brain involvement. The syndrome of inappropriate anti-diuretic hormone has been reported (167). Additional complications include seizures, coma, increased intracranial pressure (167, 160).

Cytochemical examination of the cerebrospinal fluid (CSF) of patients with EV meningitis usually reveals a modest monocytic pleocytosis (100–1000 cells/mm<sup>3</sup>) with normal or slightly depressed glucose levels and normal to slightly increased protein. However, wide variations in these findings have been reported (168), with cell counts ranging from 0 to several thousand, marked hypoglycorrhachia, and markedly elevated CSF protein concentration. Absence of CSF pleocytosis is common in infants (169, 170). Neutrophils may be the predominant cell type in early EV meningitis with a shift to monocyte predominance within 24 to 48 hours (168). Interestingly, CSF eosinophilia has been reported with meningitis due to CV-B4 (171).

The duration of illness due to EV meningitis is usually about 1 week (172), with many patients feeling better immediately after the lumbar puncture (173), presumably due

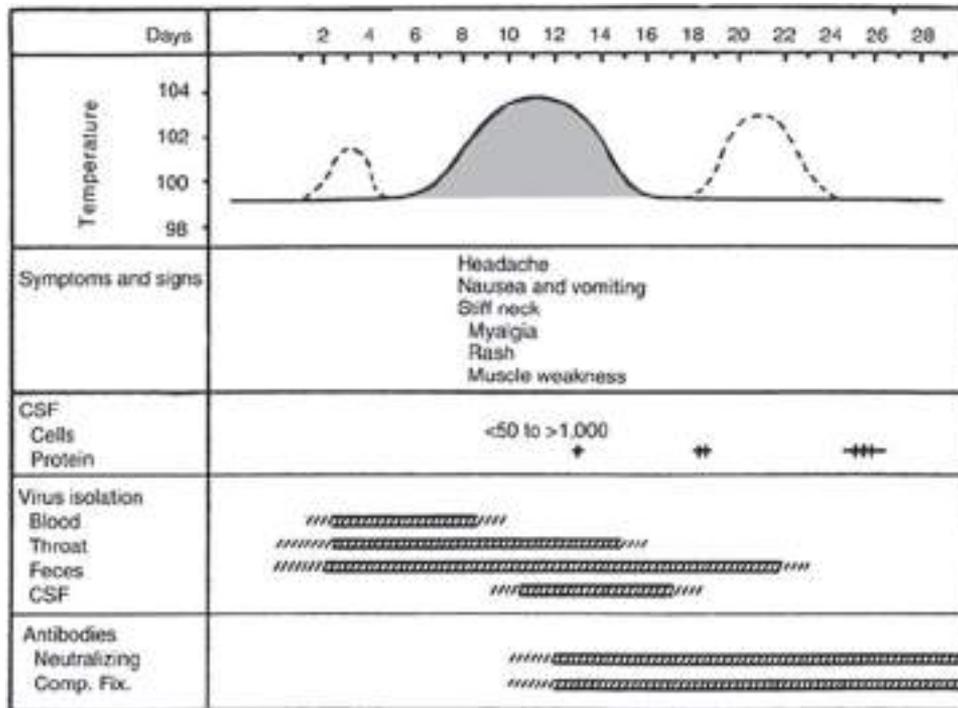

FIGURE 4 The natural history of enteroviral aseptic meningitis. Comp. Fix., complement fixation. (Reprinted from reference 159 with permission.)

to the transient reduction of intracranial pressure with CSF removal. Adult patients often have symptoms that persist for several weeks (162). Comparison of case series of adult EV meningitis (54, 93, 162) with similar series in children (87, 89, 91) suggests that the disease is more severe in adults. Difficulties in eliciting symptoms from young infants may contribute to this impression, in contrast to adults who readily attest to prolonged headaches, dizziness, photophobia, etc.

EV meningitis outside of the immediate (<2 weeks of age) neonatal period is rarely associated with severe disease or poor outcome. The short-term prognosis of young children with EV meningitis early in life appears to be good; however, there has been some controversy as to possible later sequelae. Uncontrolled studies found numerous subtle long-term behavioral and neurologic abnormalities (174). Neurologic, cognitive, and developmental/language abnormalities have been reported in controlled studies of long-term outcome in children with EV meningitis during infancy (175–180). In the largest and most meticulously controlled study, however, no differences between patients and controls could be demonstrated in any of the neurodevelopmental parameters studied (181). However, the outcomes following EV-A71 CNS infection appear to be different. A study examining the neurodevelopmental outcomes of children with EV-A71 CNS disease found that 5% of children with severe CNS involvement without cardiovascular failure had delayed neurodevelopment (182). In a second study, children with EV-A71 CNS disease exhibited an elevated attention-deficit/hyperactivity disorder-related symptoms, 20% vs. 3% for matched controls (183). Less well studied are the ultimate outcomes of aseptic meningitis in older children and adolescents; preliminary data suggest possible school and learning difficulties, but control patients were not studied (184).

### Encephalitis

Encephalitis due to the EVs is well known (185). An 8-year study of 1571 cases of encephalitis identified EVs as the confirmed or possible cause in 4.6% of all cases. EVs comprised 36.5% of viral causes and 29.4% of all etiologies identified (186). Eighty-five percent of isolates serotyped belonged to the Enterovirus B species, 10% to A species, and 5% to C species. In a Spanish study, the EV accounted for nearly 10% of all identified viral causes of encephalitis (133). Children and adolescents accounted for 73%, with a median age of 12 years among confirmed cases. However, in other studies adults accounted for approximately 40% (186).

In contrast to the typical focal disease seen with herpes simplex virus (HSV) encephalitis, EVs have been more commonly associated with global encephalitis and generalized neurologic depression (89, 162, 187, 188). The illness usually begins like aseptic meningitis with a prodrome of fever, myalgias, and upper respiratory symptoms. Onset of CNS signs and symptoms is often abrupt, with confusion, weakness, lethargy, drowsiness, or irritability. Progression to coma or generalized seizures may occur. When meningeal signs and CSF pleocytosis accompany these findings, *meningoencephalitis* is the appropriate term. Unusual but occasional findings include blurred optic discs and other signs of increased intracranial pressure, multifocal encephalomyelopathy, apnea, truncal ataxia, abnormalities of cranial nerves, and paralysis; the latter sign is usually a manifestation of spinal cord involvement and, when accompanying central signs and symptoms, is appropriately termed *encephalomyelitis*.

Focal EV encephalitis is less commonly reported than global disease but may be underappreciated. EVs are demonstrable by brain biopsy in 13% of patients suspected of having HSV encephalitis (189, 190). In a case series and literature review of focal EV encephalitis (191), a variety of focal neurologic findings were seen as well as abnormalities

by imaging studies. Only 28.5% of patients grew EV from cultures of the CSF, reinforcing the insensitivity of cell culture for detection of the EV.

Enterovirus A71-associated rhombencephalitis merits special mention (192) due to its unique epidemiology, clinical presentation, and sequelae. The prevalence of EV-A71 is particularly high in countries of the Asia-Pacific rim where large epidemics, involving hundreds of thousands to millions of individuals, have been reported (165, 193). The syndrome affects principally infants and toddlers. The use of glucocorticoids and/or pyrazolones may be factors for the development of rhombencephalitis (194).

The onset of the rhombencephalitis may follow a biphasic course, during which the onset of the principal neurologic manifestation, myoclonus, is preceded by either hand-foot-and-mouth disease (HFMD) or herpangina (192). Myoclonus associated with tremor and/or ataxia (Grade I rhombencephalitis) comprises the majority of cases. Grade II rhombencephalitis, myoclonus plus cranial nerve involvement, which may include ocular disturbances, or rapidly progressive cardiopulmonary failure following a brief period of myoclonus (Grade III rhombencephalitis) may occur in the remainder of cases. In addition to EV-A71, rhombencephalitis has also been associated with infections due to E-7, CV-A16, CV-B1, and EV-D68 (146, 194a, 195, 196).

Encephalitis due to the EV, and in particular EV-A71, may have more profound acute disease and long-term sequelae. With EV-A71 infections, CNS involvement and brainstem involvement are associated with neurologic sequelae, delayed neurodevelopment, and reduced cognitive functioning (182, 192, 197). However, those with CNS involvement without cardiopulmonary failure did well on neurodevelopment tests.

Individuals with a congenital or acquired absence or deficiency of humoral immunity are at risk for development of chronic CNS or severe disease if infected by EV. Unlike other viruses that are largely controlled by cellular immune mechanisms, the EVs are cleared from the host by antibody-mediated mechanisms. Agammaglobulinemic individuals infected with the EVs may develop chronic meningitis or meningoencephalitis lasting many years, often with fatal outcome (134). This syndrome can also occur in patients with mixed humoral and cellular immune deficiencies such as common variable immunodeficiency and hyperIgM syndrome (198, 199). Although CSF culture-negative periods occur, more consistent evidence of persistent virus has been obtained using PCR (185). Approximately 50% of these infected patients also develop a rheumatologic syndrome, most often dermatomyositis, which is also felt to be a direct result of EV infection of the affected tissues (134). Treatment with antibody preparations intravenously and intrathecally or intraventricularly has resulted in stabilization of some of these patients; however, virus persistence has been documented during therapy (134, 185). With the availability of intravenous and subcutaneous preparations of immune globulin and the early recognition of this illness, fewer patients appear to be progressing to the classic description of this disease, and atypical neurologic presentations have appeared, including emotional lability, dementia, ataxia, paresthesias, deafness, memory loss, and dysarthria (162, 200). The expanded clinical spectrum of chronic EV meningoencephalitis has been revealed by PCR studies of CSF from patients with these atypical manifestations (200).

Anit-CD20 monoclonal antibody therapy with rituximab or obinutuzumab has been shown to predispose individuals to severe or fatal EV infection (201–204). Cases of myocarditis,

meningoencephalitis, and hepatitis have been reported. Similarly, patients receiving chemotherapy for malignancies may also be at risk for severe EV disease (205, 206).

### Acute flaccid paralysis

Although AFP has been traditionally linked to the PVs, many nonpolio EVs can also cause this syndrome. In regions of the world where the PVs have been eradicated, the nonpolio EVs and cVDPVs are now the principal causes of AFP. Several nonpolio EVs have been associated with outbreaks of AFP, including CV-A7 (207), EV-D70 (208), and EV-A71 (192). Sporadic cases of paralysis have been reported in association with isolation of an EV from the CNS or stool. In the latter situation, causality is difficult to establish due to the known prolonged fecal shedding period of the EVs. Reported nonpolio EV serotypes associated with AFP include CV-A4, -A7, -A21, -A24; CV-B2, -B3, -B5; E-3, -7, -9, -18, -19, -33; EV-D68, -A71, -B93, -D94, and -B107 and are mostly from the B species EV (50, 51, 207, 209–214). Acute flaccid paralysis due to the nonpolio EVs tends to differ from that observed with PV infection. Fever is not uniformly present at the time of onset of paralysis. It affects the upper extremities and face more frequently, is associated with a more rapid recovery, and is less likely to result in residual paralysis and atrophy. Interestingly, AFP due to the nonpolio EVs tends to be more severe in infants (209, 215).

A recent nationwide outbreak of EV-D68 respiratory disease coincided with the appearance of over 100 cases of AFP (216–219). Although EV-D68 was not isolated from the CSF in any cases, it was identified in upper respiratory tract or throat specimens of 45% of patients in one series (218), leading to presumption of its role in causality. The median age of patients was 11.5 years old (218). All had a preceding febrile illness that was accompanied by cough, nasal congestion, or a sore throat in >90%. Fever at the onset of neurologic symptoms was observed in nearly all, as were meningeal signs. Limb weakness was predominantly flaccid and asymmetric, without alterations of sensation. Unlike the AFP associated with PVs, the upper extremities were frequently involved as were the cranial nerves (VI, VII, IX, X). Pleocytosis was noted in all who had CSF drawn within 7 days of onset of neurologic symptoms. The CSF protein concentration was elevated in more than half but CSF glucose was normal in all. Magnetic resonance imaging demonstrated spinal cord abnormalities involving the anterior horns at multiple vertebral levels. Three-quarters of the cases had brainstem lesions. Neurologic sequelae were noted in all patients for whom the information was available.

### Other neurologic syndromes associated with EV infections

Febrile seizures in association with RT-PCR detection of EV genome in CSF have been reported (220). Cerebellar ataxia has occasionally been associated with EV infections, as have Guillain-Barré syndrome and transverse myelitis (221, 222). All such associations suffer from the same difficulty in distinguishing pathogenicity of a throat or stool isolate from coincidental shedding.

### Infections of the Neonate and Young Infant

#### Neonatal enteroviral infection and sepsis

The infected neonate appears to be at greatest risk for severe morbidity and mortality when signs and symptoms develop in the first days of life, consistent with either intrapartum or perinatal acquisition (66, 100, 101, 158). The timing of

maternal infection versus delivery of the infant appears to be critical; when enough time for antibody formation in the mother has elapsed, passive protection of the baby occurs. If, however, delivery occurs during maximal viremia and prior to adequate maternal antibody formation, the prognosis for the neonate is worse (66, 101, 158). An additional risk factor for disease severity may be EV serotype. A 20-year evaluation of the epidemiology of neonatal EV infections identified case fatality that ranged from approximately 17% to 20% for infants <1 month of age infected with E-6, -11, -20, -30, and CV-B4 (109). However, only CV-B4 was associated with a higher risk of death than other EV.

The onset of clinical illness within the first 2 weeks of life is associated with a greater risk of development of severe disease (101, 158). A history of maternal illness in the form of fever, abdominal pain, or a respiratory syndrome has been reported in 59 to 68% of infected neonates (66, 100, 101, 158). Even in the youngest patients, fever is generally present. In some, hypothermia or temperature instability may occur. Nonspecific signs such as irritability, lethargy, anorexia, emesis, abdominal distention, and jaundice are common (100, 158, 223). An exanthem may be present and has been variously described as macular, maculopapular, and on occasion, papulovesicular, nodular, or bullous (Figure 5) (66). Upper respiratory findings may be present and consist of apnea, tachypnea, grunting, retractions, cough, or wheezing (100, 158, 223, 224). Diarrhea, sometimes associated with blood, may occur (223).

In the majority of neonates the infection is benign and self-limited with fever resolving in an average of 3 days and other signs and symptoms in about a week (100, 158, 223). In some, a biphasic course may occur with a mild nonspecific febrile illness preceding the onset of more severe disease (100). As the neonatal disease progresses, major systemic manifestations such as hepatic necrosis, myocarditis, and meningoencephalitis may develop (66). Severe neonatal EV disease is a multisystem organ syndrome comprised by multiple combinations of hepatitis, meningoencephalitis, myocarditis, coagulopathy, sepsis, and pneumonia. Two major clinical presentations are generally encountered: encephalomyocarditis syndrome (severe myocarditis in association with heart failure and meningoencephalitis) and hepatitis-hemorrhage syndrome (severe hepatitis with hepatic failure and disseminated intravascular coagulopathy) (109). The former syndrome is predominantly associated with infections due to CV-B serotypes, while the latter is often associated with E-11 infection (100, 101). Neurologic involvement may be variably associated with signs of meningeal inflammation, including nuchal rigidity and bulging anterior fontanelle. The CNS disease may progress to a more encephalitic picture with lethargy, seizures, and focal neurologic findings suggestive of HSV. Cardiomegaly, hepatomegaly, poor perfusion, cyanosis, congestive heart failure, and arrhythmias are indicative of myocarditis. The severe nature of the hepatitis is evidenced by hepatomegaly, jaundice, increased serum transaminases, and hyperbilirubinemia. Disseminated intravascular coagulation and other findings of "sepsis" can occur in a patient with illness that may be indistinguishable from that due to overwhelming bacterial infection. The pneumonia may require mechanical ventilation. Renal failure, intracranial hemorrhage, adrenal hemorrhage, necrotizing enterocolitis, and inappropriate secretion of antidiuretic hormone have been reported (66).

The reported incidences of morbidity and mortality due to perinatal EV infections are not precisely known but may be as high as 80% and 10%, respectively (100, 101, 158, 223, 225).

Although a more recent report indicated that fatal outcome among EV infected neonates was found to be 3.3%, neonates had higher risk of death than persons  $\geq 1$  month of age (11.5 vs. 2.5%) infected with EV (109). When death occurs in neonates with EV infection it is typically due to hepatic failure with Es or myocarditis with CVs.

#### Nonspecific febrile illnesses of infancy

It is estimated that between 10 and 15 million people in the United States annually develop minor EV infections characterized by fever and nonspecific symptoms, with or without rashes (57, 226). These illnesses are of significance mainly for other diseases that they mimic including bacterial sepsis, other viral exanthematous diseases, and HSV infections; also, their age distribution makes them of great practical concern to the clinician. EVs are a major cause of hospitalization of young infants for suspected sepsis during the summer and fall months (227). Most affected patients are younger infants (<1 year of age) in whom differentiation of viral illness from the more alarming causes of nonspecific fevers and rashes is extremely difficult. In a recent study, EVs were detected in the blood of 16% of infants <36 months of age evaluated for fever of unknown origin who underwent NAA testing (228). In a prospective study of newborn infants, as many as 13% of infants born in the summer months were infected with EVs during the first month of life; 21% of those infected were hospitalized with suspected bacterial sepsis and received antibiotics or antiviral therapy (225). During the months of seasonal prevalence, about 7/1000 live births required hospitalization for neonatal EV infection. Clinical manifestations include abrupt onset of fever, usually  $>39^{\circ}$  C, with accompanying irritability; the fever may be biphasic (229). Additional symptoms, in order of decreasing frequency, include lethargy, anorexia, diarrhea, vomiting, rash (23% of patients), and respiratory symptoms. Signs and symptoms do not differ in this age group between the Es and CVs (229). Aseptic meningitis may accompany the nonspecific symptoms of EV infection in infants and there are no clinical features that distinguish between those EV-infected infants with and without meningitis (229). The systemic, global nature of this illness results in hospitalization of many of these infants to exclude bacterial sepsis. The duration of symptomatic illness in young infants beyond the neonatal period is usually 4 to 5 days.

#### Respiratory Illnesses

Many EV infections are accompanied by nonspecific respiratory signs and symptoms that are usually mild in nature. The summer cold, pharyngitis, tonsillitis, and laryngotracheobronchitis (croup) have been frequently reported (229). Bronchiolitis, pneumonia, and influenza-like illness are less common (229, 230, 231). Most EV respiratory illness is benign, but symptoms may persist for many days and the resultant disruption in school and workdays may be substantial. The EVs are responsible for approximately 15% of upper respiratory infections (URIs) for which an etiology is identified (232). In a 10-year review of EV-associated respiratory illnesses, 46% of patients presented with URIs, 13% with respiratory distress/apnea, 13% with pneumonia, 12% with otitis media, and fewer with bronchiolitis, croup, and pharyngotonsillitis (232). Using NAA detection, EVs have been identified in up to 18% of children with lower respiratory tract infections and in 25% with acute wheezing (233, 234). Many EV serotypes are identified in respiratory infections, approximately equally divided among the major subgroups (51, 226). The clinical manifestations of

EV-associated upper respiratory infections (URIs), otitis media, wheezing, and pharyngotonsillitis are indistinguishable from those due to other respiratory viruses. Pneumonia due to the EVs has been associated with numerous serotypes in infants and children (235, 236), including several of the newer *Enterovirus C* types (EV-C104, -C109, -C117) (237, 238). The clinical manifestations include fever, hyperpnea, and cyanosis. The laboratory findings usually include a normal leukocyte count, although extreme leukocytosis is occasionally encountered. Chest X-ray may reveal perihilar infiltrates. Fatalities have occurred in infants and young children. Histopathologic study of the lungs reveals thickening and infiltration of the alveolar septa but no necrosis or giant cells.

EV-D68 has recently emerged as a significant cause of respiratory disease. Originally identified in 1962 from four children with pneumonia and bronchiolitis (239), in the last 5 years it has been associated with clusters of respiratory infections or epidemics (236, 238, 240–243). Phylogenetic analysis of isolates obtained worldwide over the past 20 years indicates that multiple clades have emerged and spread rapidly (243), possibly accounting for the increase in reported clusters and epidemics worldwide. Because EV-D68 is acid labile and replicates poorly at 37° C, characteristics commonly found among the rhinoviruses, it is phenotypically anomalous among the EV species A–D (50, 245–247).

Clinically significant lower respiratory tract disease occurs primarily in young children and infants (236, 240–243, 248, 249). Some studies have reported asthma or wheezing as pre-existing conditions in approximately 70% to 80% of cases (240, 243). Pneumonia, bronchiolitis, asthmatic bronchitis, asthma exacerbation, and wheezing have been reported with EV-D68 infection (236, 240, 242, 243, 248, 249). Fever is seen only in approximately one-quarter to one-half of children. Hypoxia is very common. Chest radiographs may show infiltrates and atelectasis. The severity of the illness may require admission to an intensive care unit and assisted ventilation or extracorporeal membrane oxygenation. Deaths have been reported.

### Syndromes Involving the Mucous Membranes and Integumentary System

#### Herpangina

CV-As are the most common causes of herpangina, but the syndrome has been reported with the CV-Bs, Es, and numbered EVs as well (250, 165). The highest incidence is among children 1 to 7 years old (172), but has also been described in neonates and adults. Onset is usually abrupt with high fever associated with sore throat, dysphagia, sialorrhea, and malaise. One-fourth of patients may have vomiting and abdominal pain. Early in the illness an oral exanthem appears as grayish-white vesicles measuring 1 to 4 mm in diameter. The lesions are located primarily on anterior pillars of the tonsillar fauces but may involve the posterior portion of the palate, uvula, and occasionally the oropharynx (Figure 6). The vesicles are discrete, surrounded by erythema, and usually number fewer than 20. Over 2 to 3 days the vesicles usually rupture, leaving punched-out ulcers that may enlarge slightly, while new vesicles may appear. There may also be mild cervical adenopathy, headache, myalgia, arthralgia, and, rarely, parotitis or aseptic meningitis. Clinical laboratory studies are usually normal. The fever lasts 1 to 4 days; local and systemic symptoms begin to improve in 4 to 5 days, and recovery is usually complete within 7 to 10 days of onset (172, 250, 251).

**FIGURE 5** Newborn with overwhelming sepsis due to echovirus 11. Note typical enteroviral exanthem. This child's illness began within the first week of life and ended with her death due to hepatic failure at approximately 1 month of age.

#### Hand-foot-and-mouth disease

Although HFMD is one of the more common and unique syndromes typically associated with CV-A16, multiple other CV and EV serotypes (in particular EV-A71 and CV-A6) may be isolated (165). In outbreaks, the highest attack rates are among children <4 years of age but adults are also frequently affected (252, 253). The disease is usually mild and the onset is associated with a sore throat with or without a low-grade fever. Scattered vesicular lesions occur randomly on the oral structures, the pharynx, and the lips; these ulcerate readily, leaving shallow lesions with red areolae. Approximately 85% of patients also develop sparse grayish vesicles (3 to 5 mm in diameter, surrounded by erythematous areolae) on the dorsum of the fingers, particularly in periungual areas, and on the margins of heels (Figure 7). Occasionally, palmar, plantar, and groin lesions may appear, particularly in young children. Resolution is usually complete within 1 week (172). Neurologic complications have been associated with HFMD due to EV-A71 (165).

An atypical, more severe presentation of HFMD associated with a novel CV-A6 genotype has been observed since

**FIGURE 6** Herpangina due to Coxsackie A viruses. Small, discrete vesicles surrounded by erythema are seen on the palate, uvula, and elsewhere in the posterior oropharynx.

**FIGURE 7** Characteristic lesions of enteroviral hand-foot-mouth disease involving the dorsum of the hand and fingers

2008. The syndrome is associated with higher fever and a wider distribution of lesions involving the extremities, face, lips and perioral area, buttocks, groin, and perineum. The lesions tend to be vesiculobullous in character and can form large bullae. Skin erosions, ulcerations, and eschar formation are commonly seen. Individuals with active or dormant eczema may develop lesions concentrated in these areas known as “eczema coxsackium.” The duration of illness is longer (mean 12 days) than with “typical” HFMD. Palmar and plantar desquamation or nail dystrophies (transverse ridges of the nail plate [Beau lines], shedding of the nail [onychomadesis]) may be observed 1 to 3 weeks and 1 to 2 months, respectively, after the illness (254–258).

### Hemorrhagic Conjunctivitis

Acute hemorrhagic conjunctivitis (AHC) is associated with EV-D70 and CV-A24 variant (CV-A24v) and have both been associated with pandemics of AHC (110). Epidemics and pandemics of EV-D70 AHC first arose in 1969. Molecular fingerprinting has indicated that the common origin for all EV-D70 strains was West Africa approximately 2 to 3 years prior to the first known pandemic. Recently, enterovirus D70 was responsible for an outbreak in Florida (259).

Outbreaks of CV-A24v have also been widespread (110). Although originally confined to Southeast Asia and the Indian subcontinent, in 1985 it spread to Japan, Taiwan, Oceania, South America, and Africa. Phylogenetic analysis of CV-A24v isolates from outbreaks in Japan, Taiwan, and China indicate that the AHC outbreaks in these countries were the result of three successive waves of genetically distinct CV-A24v strains. Outbreaks continue into the present. A 2012 outbreak affected several islands in the Indian Ocean including the Union of Comoros, Mayotte, Madagascar, and Mauritius, with spread to France (260, 261).

The illnesses caused by the two serotypes are indistinguishable from each other, although CV-A24v-associated AHC cases may be more commonly accompanied by upper respiratory and systemic symptoms and may have less severe conjunctival hemorrhage (262). After an incubation period of about 1 to 2 days, rapid onset of swelling of the eyelids with congestion, lacrimation, and severe ocular pain occurs. Photophobia and blurring of vision are common. Subconjunctival hemorrhages vary from petechiae to large blotches. Epithelial keratitis is common, transient, and seldom followed by subepithelial opacities. Fever is an un-

common accompaniment. Preauricular adenopathy is frequent. Occasionally, a mucopurulent discharge from the eyes is found. The illness is generally nonsystemic, although transient lumbar radiculomyelopathy and a poliomyelitis-like illness was described in some cases (208, 263). Recovery is usually complete within 1 to 2 weeks of onset. High secondary attack rates within households are common.

Other EV serotypes have been known to cause outbreaks of keratoconjunctivitis, usually without hemorrhagic manifestations (264).

## Muscular Syndromes

### Pleurodynia

Pleurodynia is a misnomer for a clinical condition that is, in actuality, primarily a disease of muscle with clinical manifestations that suggest a pleuritic origin. The disease was fully characterized in 1934 by Sylvest, who also provided its geographically linked eponym, Bornholm disease (265). It is known by other descriptive designations: epidemic myalgia, devil’s grip, etc. Various CV-B serotypes are the usual causes of sporadic and epidemic pleurodynia. However, it may also be caused by other EV serotypes (266).

An incubation period of approximately 4 days precedes the onset of illness, which is abrupt in about three-fourths of patients; the remainder first develop prodromal symptoms of headache, malaise, anorexia, and vague myalgia lasting 1 to 10 days. The major symptom is severe paroxysmal pain referred to the lower ribs or the sternum (51, 266, 267). Deep breathing, coughing, sneezing, or other movement accentuates the pain, which is described as knife-like stabbing, smothering, or catching; it may radiate to the shoulders, neck, or scapula and is characteristically absent between paroxysms. Abdominal pain occurs concomitantly in about half of patients but may occur alone. Abdominal pain may be more commonly seen in children (268). Other symptoms include fever, headache, cough, anorexia, nausea, vomiting, and diarrhea. Fever is usually about 38° C but ranges to 40° C and may be biphasic. The mean duration of the illness is 3.5 days, varying from 1 to 14 days. Muscle tenderness is ordinarily not prominent, nor is frank myositis or muscle swelling, but some patients experience marked cutaneous hyperesthesia over the affected areas. A pleural friction rub may be heard in 25% of patients. There may be splinting and tenderness on abdominal examination especially in the upper quadrants and periumbilical area. The chest X-ray is typically normal.

### Inflammatory Myositis

It is known that EVs can cause inflammatory muscle disease because about 50% of agammaglobulinemia patients with chronic EV CNS infections also develop myositis (134). In these patients, cultivable virus is recovered from muscle tissue. An occasional patient with myositis and normal immunoglobulin concentrations has responded to gammaglobulin therapy, with improvement or resolution of the disease.

An autoimmune response to a triggering EV infection is thought to be a possible mechanism in polymyositis and dermatomyositis. Evidence for associating these rheumatologic diseases with EVs include serologic studies (269), visualization of EV-like particles by electron microscopy (270), as well as *in situ* and dot blot hybridization and NAA studies suggesting the presence of EV RNA in muscle tissue of these patients (271, 272). However, other investigators failed to find evidence of EV genome in affected muscles from myositis patients.

## Cardiovascular Illnesses

### Acute Myocarditis

The EVs are the second most commonly identified etiologies of myocarditis, although most cases of that disease may be undiagnosed or, if diagnosed, have no identifiable cause. EVs may cause between 25% to 35% of cases of myocarditis for which a cause is found based on serologic, nucleic acid hybridization, and PCR-based studies of endomyocardial biopsies and autopsy specimens (104, 273). Conversely, it is estimated that only 1% to 2% of all symptomatic EV infections have associated signs or symptoms of myocardial involvement (51), with the latter more common during CV-B infections than with other serotypes. Bias in the estimation of frequency of myocarditis during EV infection is possible in both directions; the subclinical nature of some cardiac involvement may result in an underestimate of the true cardiopathogenicity of the EVs, but the study of patients presenting with EV infections probably selects for the sickest patients and may overestimate the cardiac impact of the EVs.

Neonates and young infants (< 6 months of age) are particularly susceptible to CV-B-associated myocarditis accompanying systemic infection with those serotypes (100). Most cases occur in young adults between the ages of 20 to 39 years. Males are more affected than females (male:female ratio approximately 1.5:1). Rigorous exercise is anecdotally reported as a precedent to many cases of myocarditis; in animal models, exercise increases the incidence and severity of myocarditis during EV infections (108).

Clinical manifestations reflect the regions and extent of the cardiac involvement. Symptoms include palpitations and chest pain, often with accompanying fever or a history of recent viral respiratory illness. Arrhythmias and sudden death reflect a prominent involvement of the conduction system, which may be of very recent onset; congestive heart failure or myocardial infarction-like presentation suggest more significant necrosis of myocytes and likely longer-standing disease. Pericardial friction rub indicates myopericarditis. Electrocardiographic findings include an evolution from early stage S-T segment elevation and T-wave inversion to intermediate stage normalization to late stage recurrence of T-wave inversion (104). Myocardial enzyme elevations are detected in the blood. Magnetic resonance imaging and nuclear imaging may be of ancillary help in establishing a diagnosis of myocarditis, but endomyocardial biopsy remains the "criterion standard" technique for confirming the histopathologic diagnosis of myocarditis (104).

While most patients recover uneventfully from clinically apparent myocarditis, many have residual electrocardiographic or echocardiographic abnormalities for months to years. Smaller percentages of patients develop congestive heart failure, chronic myocarditis, or dilated cardiomyopathy.

### Chronic Dilated Cardiomyopathy

Evidence suggests that some cases of acute myocarditis progress to chronic dilated cardiomyopathy. The latter syndrome is characterized by dilation and dysfunction of the cardiac ventricles. The incidence of this chronic illness is estimated at between 1 to 10/100,000 population, and the contribution of preceding EV myocarditis to those figures is highly disputed. Some serologic, nucleic acid hybridization, and NAA studies suggest ongoing EV involvement in 15% to 30% of cases, less than that in acute myocarditis but still substantial (104, 273). Other studies fail to find evidence of persistent EVs in patients with chronic cardiomyopathy (274–277).

Like acute myocarditis, heart failure, chest pain, or arrhythmias may herald the onset of recognizable disease in patients with dilated cardiomyopathy. Ventricular dilation and its concomitant physical findings of mitral insufficiency, cardiomegaly, and congestive failure dominate the physical examination, electrocardiographic and echocardiographic findings.

## Gastrointestinal Illnesses

EVs derive their name from their site of replication and shedding in the GI tract; however, enteric illness (vomiting and diarrhea) is usually a minor manifestation of EV infections. Neither CVs nor Es have been epidemiologically implicated as important primary causes of acute gastroenteritis. Isolation of an EV from the feces of a patient with gastroenteritis must be interpreted with caution because it may represent asymptomatic shedding in a patient made ill by a noncultivable agent. The CV-Bs have been rarely associated with acute abdominal pain and mesenteric adenitis syndromes, which may mimic acute appendicitis. EVs have been associated with hepatitis in neonates (discussed above) and older children and on rare occasions in adults (206, 278, 279).

## Possible Enterovirus-Associated Diseases

### Type 1 Diabetes Mellitus (T1DM)

For nearly 50 years investigators have sought to establish a causal link between EV infection and the development of T1DM (280, 281). Fifteen EV serotypes have been reported to be associated with T1DM, all but one from the B species, and most heavily favoring the CV-Bs (282). Diabetes has been shown to occur with an increased incidence in the months following EV season, consistent with a postinfectious autoimmune disease mechanism (79). An increased incidence of T1DM has been demonstrated following community outbreaks of CV-B5 (283).

Although multiple serologic studies found higher antibody titers to CV-Bs in children with T1DM than in controls (284), others failed to do so (285, 286). A review of 26 case-controlled studies failed to provide evidence in support of or contrary to an association between CV-B infection and T1DM (287).

Occasional patients have developed anti-islet cell antibodies in proximity to acute EV infection (288). However, a nested matched case-control study of incident cases of beta-cell autoimmunity within two prospective cohorts of genetically high-risk children found no evidence that EV infections were a risk factor for the development of beta-cell autoimmunity (289).

An occasional diabetic patient has had CV isolated from the pancreas and elsewhere at autopsy (290). With the development of modern molecular techniques, investigators have searched for the presence of the EV genome or capsid protein (VP1) in serum, plasma, peripheral blood mononuclear cells, pancreatic tissue, and GI tissue of prediabetic and diabetic patients. A meta-analysis of 26 reports published from 1994 to 2010 demonstrated a clinically significant association between EV infection and T1DM (281). However, the authors noted that larger prospective studies were needed to clearly establish a temporal relation between EV infection and the development of T1DM.

A 2015 report supports the possibility of EV persistence in T1DM (291). Six recently diagnosed adults with T1DM who underwent pancreatic biopsy 3 to 9 weeks after diagnosis were studied. EV genome was detected in the medium

of cultured islet cells by RT-PCR in four patients. The EV VP1 was detected immunohistochemically in the pancreatic islets of all patients. However, only 1.7% of islets contained intensely staining VP1 cells. While promising, the report contained several weaknesses. The antibody used to detect VP1 was known to cross-react with tissue proteins. EV genome was detected in only one patient using biopsy tissue. The authors were not able to identify the EV serotype(s) responsible due to low viral titer.

## Laboratory Diagnosis

### Nucleic Acid Amplification

The most significant development in rapid, direct detection of the EVs has been the development of NAA tests (e.g., PCR and NASBA) (22, 23). NAA tests have become the standard for the clinical detection of the EVs. RT-PCR-based EV detection has provided a sensitive, specific, rapid, versatile, and clinically useful (22, 292, 293) method for the detection of the EVs. They have been employed for universal detection of all EV serotypes; species-, serotype-, and strain-specific EV detection; and strain-specific detection within a single serotype (22, 23, 294–299). For general diagnostic purposes universal detection of the EV is the most useful. Species- and strain-specific approaches to RT-PCR diagnosis may be useful for the screening of uncharacterized EV isolates, discrimination of wild-type PVs from nonpolio EV isolates or from vaccine strains, and for the detection of specific serotypes such as EV 71 (294, 295, 297, 298).

The first reports of sets of primers and probes for universal amplification of the EVs appeared in 1989 and 1990; all were broadly reactive among many EV serotypes and had high specificity for the EVs (300–302). All are directed at highly conserved regions of the EV 5′NTR (22). The sensitivity and specificity of RT-PCR for the detection of the EVs in CSF compared to the traditional criterion standard of cell culture has been shown to range from 86% to 100% and from 92% to 100%, respectively (23, 303). The sensitivity and specificity of EV detection using RT-PCR in serum is similarly high ranging from 81% to 92% and 98% to 100%, respectively (22). Commercial, FDA-approved assays are available for the clinical detection of the EV from CSF and have similar sensitivity and specificity to in-house developed tests (304–306).

No cross-amplification has been found with myriad nonrelated viruses, bacteria, fungi, and yeast (22). This being said, some primer pairings may amplify a limited number of rhinoviruses (307), a finding that is not surprising given that the rhinoviruses are members of the same genus (4, 3) and share 5′NTR sequence motifs. This should be of minor importance when samples such as CSF, serum, or nonrespiratory tract tissues are being tested. However, for commercially available multiplex NAA assays for the detection of respiratory pathogens that lack the ability to differentiate between EV and rhinoviruses, this may be problematic.

In the clinical setting RT-PCR is extremely sensitive for the detection of EV in CSF specimens. Paired analysis (i.e., cell culture and RT-PCR testing) of RT-PCR detection of EV from CSF specimens demonstrated it to be consistently and substantially more sensitive than cell culture (22). Using RT-PCR, it is possible to detect EV CNS infection in agammaglobulinemic patients with associated meningoencephalitis or encephalopathy in the absence of cell culture recovery of viruses (23, 200). RT-PCR results can be available in hours, a substantial time saving when compared with

detection by cell culture. This reduction in time to positive detection has been documented to shorten hospital stays, reduce antibiotic use, and affect patient management (292, 293, 308). Testing of CSF for EVs should not be determined by the presence or absence of pleocytosis. Multiple studies have documented a high proportion of young infants with EV CNS infection but without pleocytosis (169, 170).

### Virus Isolation

Dr. John Enders and colleagues received the Nobel Prize in 1954 for successfully propagating PV in a cell culture system (309). Isolation of EVs in cell culture and recognition of cytopathic effect require a high level of expertise and are labor intensive. Some serotypes, particularly within the CV-A, do not grow in cell culture (310, 311). Of greater significance, 25% to 35% of specimens from patients with characteristic EV infections will be negative by cell culture (312) because of antibody neutralization; inadequate collection, handling, and processing of the samples; or intrinsic insensitivity to the cell lines used. EVs that do grow in cell culture may do so slowly. Mean isolation times for EVs from CSF range from 3.7 to 8.2 days (313); EVs from other sites, where viral titers are higher, often grow more rapidly (312, 314, 315). Shell vial culture may shorten detection time to 2 to 3 days.

For reasons listed previously, isolation of EVs by cell culture has been replaced by NAA testing as the method by which the majority of clinical laboratories attempt detection of the EVs. Monkey kidney cell lines have good sensitivity for PV, CV-B, and E. RD cells and HuT 292 cells, derived from a human rhabdomyosarcoma and pooled human saliva, respectively, are the most sensitive for detection of CV-As (310). Even with the addition of newer cell lines as well as those genetically engineered to express the PV receptor or decay-accelerating factor, L20B and BGMK-bDAF, respectively, no single cell line is optimal for all EV serotypes (23). Most laboratories use a combination of a primary monkey kidney cell line with a human diploid fibroblast line. Commercially available mixtures of cell lines may be useful in attempting to achieve maximum sensitivity (23). Cell culture continues to be important in the detection and surveillance efforts by the World Health Organization for control and surveillance of wild-type PV strains and VDPVs (290).

Although isolation using suckling mice inoculation is the most sensitive method for laboratory diagnosis of CV-A infections (310), it is rarely performed any longer because of the difficulty of the technique and need for animal maintenance.

### Serologic Assays

Serologic testing has a limited role, if any, in EV diagnosis because of the great diversity of EV serotypes and the failure to identify a single common EV antigen, lack of sensitivity, and cross-reaction with non-EV members of the *Picomaviridae* family. The sensitivities of hetero- and homotypic immunoassays for the diagnosis of EV infections pale in comparison to that of RT-PCR, ranging from 34% to 75% in patients with RT-PCR-confirmed EV meningitis and 46% in patients in whom EV was detected in stool by RT-PCR (271, 316).

If the specific serotype of an infecting EV is known or suspected, confirmatory homotypic serology can be performed on individual patients to document a rise in antibody titer from the acute to the convalescent phase of infection, thus providing useful epidemiologic information. In a situation where an EV is recovered from feces or throat of a

patient with unusual clinical manifestations, the etiologic role of the EV may be more firmly established by documenting a four-fold rise in antibody titer to that serotype in paired acute and convalescent sera. In the usual scenario when a patient presents with meningitis or other acute manifestations of illness and an EV is suspected, serology is not a practical option. A recent report further supports this, concluding that virus serology had no relevance for the diagnosis of myocarditis (317).

### Specific Identification of the EVs

The traditional method for determination of EV serotype is the use of intersecting pools of equine antisera, as established by Lim and Benyesh-Melnick (LBM pools) (318–320). Two sets of antibody pools are available, eight pools (A to H) of antisera that identify 42 EV and seven pools (J to P) of antisera that identify 19 strains of CV-As. A checkerboard analysis localizes the isolate to a single serotype designation on the basis of the pattern of neutralization with the intersecting serum pools. The LBM pools are available in limited supplies from the World Health Organization.

Limitations exist with this methodology (321, 322). Principally, the LBM pools fail to identify the newly identified EV. Because the LBM pools were developed over 50 years ago, genetic drift has given rise to antigenic variants of the prototypic strains that may be difficult to conclusively serotype. Additionally, viral aggregation may negatively affect the performance of the pools, the procedure is labor intensive and time consuming, and the supply of LBM pools is limited.

Broadly reactive and serotype-specific EV monoclonal antibodies in conjunction with cell culture have been used. However, this approach should best be used as a preliminary screen for species or serotype identification due to lack of sensitivity and cross-reactivity with the rhinoviruses (323).

Nucleic acid amplification technology has provided the means to “molecularly type” the EV (13, 14, 324, 325). This approach relies on amplification of the sequence of the EV VP1 coding region. The amplicons generated are rapidly sequenced using PCR and computationally compared to a database of known EV VP1 sequences to establish identity. This method greatly reduces the time required for identification of the EV from weeks to days. “Molecular typing” has been extremely useful in the identification of isolates considered “non-typeable” EVs due to a failure to be neutralized by the LBM pools (321). This approach has been used to successfully identify new EV types (321, 326–328). It is possible to perform species identification directly from clinical specimens (324).

The determination of the specific serotype of infecting EVs is generally unnecessary because the diseases caused by the EVs are not serotype specific. Further identification to the level of specific serotype may be useful under certain circumstances such as epidemiologic studies of patterns of EV infections, descriptions of unusual or novel clinical manifestations, and incursions of rarely encountered serotypes. In most circumstances it is adequate for the diagnostic laboratory to report the presence of “an EV” without further detail.

A notable exception to this principle is where distinguishing between wild-type PVs, vaccine strain PVs, VDPV, and nonpolio EVs is critical to interpretation of viral culture results. These include regions of the world where live attenuated PV vaccines continue to be used and where surveillance for wild-type PVs and VDPV is undertaken as part of the global effort for eradication of polio (299). The standard method for distinguishing between PVs and non-

polio EVs employs neutralization of the isolate with a pool of antisera directed against the three PV serotypes (299). Molecular typing of wild-type, vaccine, and vaccine-derived PVs is extremely useful (297–299).

### Interpretation of Results

The body site at which EVs are isolated is critical to the interpretation of EV detection assays and to the differentiation between EV “shedding” and actual EV-associated disease. The nasopharynx and GI tract are permissive sites of infection, i.e., EVs have ready access to these sites and may infect and subsequently be “shed” from them for weeks to months. Detection of EVs by virus isolation or NAA at these sites must be interpreted cautiously because their presence alone does not establish causality of the illness in question (329). Indeed, virtually 100% of patients with EV aseptic meningitis will have detectable EV in feces (315), but most persons shedding EV in the feces at any particular time are asymptomatic; feces are thus the most sensitive and least specific site for detecting true EV-associated illness. Since the shedding period in the nasopharynx after EV infection is shorter than in the feces, the specificity of an EV isolate from the nasopharynx for true causation of current symptoms is better than with feces but far short of a definitive association. In contrast, the CNS, bloodstream, and genitourinary tract are not usually infected with EVs, i.e., detection of virus in specimens from these sites implies true invasive infection and a high likelihood of association with current illness.

A notable exception to the above relates to the diagnosis of neonatal EV infections occurring within the first 2 weeks of life. Because the incubation period for the EV is 3 to 6 days, the identification of EV in the stool or oropharynx of newborns with EV-compatible syndromes is highly supportive of their role in disease.

Rare reports of co-infections of the CSF by bacteria (*S. pneumoniae*, *H. influenzae*, *S. agalactiae*, *N. meningitidis*), mycobacteria (*M. tuberculosis*), or viruses (St. Louis encephalitis virus, HSV) and EVs have appeared (187, 330–335). In cases of bacterial or mycobacterial co-infection, the bacteria/mycobacteria-associated clinical signs and symptoms usually dominate. In the much more common situation, where the clinical presentation is typical of viral meningitis, coinfection with a clinically “silent” bacteria would be extraordinarily unlikely. Hence, identification of an EV from a site not ordinarily infected in a patient with a clinically compatible illness is usually sufficient evidence for establishing EV causality.

### PREVENTION

The provision of potable water and adequate sanitation are cornerstones in public health efforts toward the prevention of EV infections. Handwashing has been shown to be effective in the prevention of EV infections (336). Vaccines are available only for the PVs, and those provide no protection against the nonpolio EV serotypes. In an attempt to eliminate the few remaining vaccine-associated cases of poliomyelitis that occurred annually in the United States, the use of live attenuated oral PV vaccines was abandoned nearly two decades ago. Today, only inactivated PV vaccines are used for immunization of children in this country. Elsewhere in the world, however, the majority of countries continue to use OPVs as a part of their vaccination regimens.

Because of the burden and severity of EV-A71 disease in China, promising efforts are under way to develop vaccines against the most common subgenotype, C4, circulating in

that part of the world. Three candidate inactivated EV-A71 subgenotype C4 vaccines have undergone successful Phase III studies (337–339). All were safe and well tolerated. Seroconversion, as defined by a 4-fold increase in baseline neutralizing titer, occurred in 88.1%–100%. Efficacy against HFMD and other EV-A71 related disease ranged from 90% to 97.4% and 80.4% to 88%, respectively. However, antibody titers waned after the first 6 months, indicating that boosting immunity may be necessary. At least two of the vaccines cross-neutralized several other EV-A71 genotypes and subgenotypes, suggesting that they could induce cross-protection against other strains (340).

## TREATMENT

As with other viral pathogens, there are several steps in the replication cycle of the picornaviruses that are potential targets in antiviral therapy. Cell susceptibility, viral attachment, viral uncoating, viral RNA replication, and viral protein synthesis have all been studied as targets of anti-picornaviral compounds.

### Immunoglobulin

The primary mechanism of clearance of EVs by the host is humoral immunity. As noted above, patients who lack antibodies because of congenital or acquired immunodeficiencies are uniquely susceptible to infections with the EVs (134). Similarly, normal neonates are at high risk for severe EV disease because of a relative deficiency of EV antibodies (158). Antibodies act by binding to EVs and preventing attachment and binding to host cells.

Immune serum globulin has been used prophylactically and therapeutically against the EVs in two situations, the neonate and the immunocompromised host. Neonates may develop an overwhelming sepsis syndrome from transplacental/peripartum acquisition of EV infection. The high mortality of this disease, coupled with the known association of severe EV disease with absolute or relative antibody-deficiency states, has prompted numerous investigators to administer antibody preparations to neonates with EV sepsis. Anecdotal reports of clinical success with maternal serum or plasma (341) or commercial immunoglobulin preparations against a variety of EV serotypes causing neonatal sepsis have been reported; other reports describe progressive disease and death despite such therapy (342, 343). A blinded, randomized controlled study was too small to demonstrate clinical benefit but did show a reduction in viral titer in infants receiving intravenous immunoglobulin (IVIG) preparations that were subsequently shown to contain high antibody titers to the infecting serotype. Individuals with congenital or acquired antibody deficiencies are also at risk for severe EV infections. Since antibody-deficient patients have begun receiving maintenance supplementation with IVIG, the incidence of chronic, progressive EV meningoencephalitis has fallen, demonstrating the prophylactic benefit of these preparations, and the clinical profile of patients developing such infections has been modified (134, 162). Therapeutic efficacy in established EV meningoencephalitis in antibody-deficient patients has only been anecdotally studied.

### Capsid-Inhibiting Compounds

Capsid-inhibiting compounds have been the most extensively studied antiviral agents for the therapy of the EV. Capsid-inhibiting compounds block viral uncoating and/or viral attachment to host cell receptors. As noted above, the resolved 3-dimensional structure of the EVs reveals a “can-

yon” formed by the junctions of VP1 and VP3. Beneath the canyon lies a “pore,” which leads to a hydrophobic pocket into which a variety of diverse hydrophobic compounds can integrate. Although the compounds integrate into a virus capsid via a number of noncovalent, hydrophobic-type interactions, the affinity is high. Several hypotheses have been proposed for the mechanism of picornavirus inhibition by compounds that affect the function of the virus capsid. Filling the hydrophobic pocket results in increased stability of the virus, making the virus more resistant to uncoating. The increased stability of the virus-compound complex is evidenced by the resistance to thermal inactivation (344). It is also possible that a degree of capsid flexibility may be required for uncoating, and activity of these compounds within the hydrophobic pocket may reduce this necessary flexibility, inducing a more rigid structure. Alternatively, changes in the conformation of the canyon floor as a result of drug activity within the underlying pocket may affect the attachment of the virus to the host cell receptor (345). It has been shown, however, that such perturbations in the canyon floor do not absolutely correlate with antiviral potency (346).

Two drugs, pleconaril and pocapavir, have undergone clinical trials in humans. Pleconaril demonstrates broad spectrum and potent anti-EV activity and is highly orally bioavailable, approaching 70% in humans (347–349). Published reports of the therapeutic efficacy of pleconaril provide a mixed picture. A challenge study of the efficacy of pleconaril in the reduction of viral shedding, relief of symptoms, and decrease in severity of clinical illness following CV-A21 infection in nonimmune individuals demonstrated a statistically significant decrease in nasal secretion viral titers in subjects compared with controls (350). The mean volume of nasal secretions in pleconaril treated subjects was consistently less than in controls. Mean respiratory symptom scores in placebo-treated individuals were significantly higher than in the treated group.

A clinical trial of pleconaril for the treatment of EV meningitis in infants (102) demonstrated no significant difference between the treatment and placebo groups with regard to EV detection by culture or PCR, duration of hospitalization, or symptoms. It was concluded that the small numbers of subjects, low yields of serial viral cultures, and the short, benign clinical course precluded the ability to demonstrate efficacy.

A post hoc subgroup analysis of two efficacy trials that failed to define clinical benefit for FDA registration of pleconaril indicated that it was beneficial in the acceleration of headache resolution (103). Pleconaril has been used in a compassionate release protocol for the treatment of more than 90 patients with potentially life-threatening EV infections, 38 of whom were followed long enough to assess therapeutic responses (351). Seventy-eight percent of patients had a favorable clinical response, while 92%, 88%, and 60%, respectively, with virologic, laboratory, or radiologic abnormalities responded favorably.

A prophylactic study for the prevention of picornaviral respiratory tract infection demonstrated an increase in menstrual irregularities in women receiving pleconaril (349). Investigation revealed induction of cytochrome P-450 3A activity by pleconaril and raised the possibility of the potential for drug interactions, in particular, interference with oral contraceptives and antiretroviral drugs. The FDA concluded that the risks of pleconaril use outweighed its modest benefits and did not license pleconaril for the treatment of the common cold (352).

A recently published study of pleconaril therapy of neonates with suspected EV sepsis found that in the treatment group, EV-infected subjects became culture negative from all sites combined faster than subjects in the placebo group. Fewer subjects in the treatment group remained PCR-positive from the oropharynx when last sampled. Intent-to-treat analysis demonstrated a reduction in mortality in the treatment group. The authors concluded that the results supported potential efficacy and that they warranted further evaluation of pleconaril for the therapy of neonatal EV sepsis (353).

The Committee on Development of a Polio Antiviral and Its Potential Role in Global Poliomyelitis Eradication of the National Research Council has recommended that at least one polio antiviral drug be developed to supplement efforts currently being employed for control of poliomyelitis outbreaks in the posteradication era (354). Pocopavir has been shown to be a potent inhibitor of wild-type, vaccine, vaccine-derived, and laboratory strains of PV. It has been shown to have potent and rapid antipolio activity in a randomized, double-blinded, placebo-controlled human monovalent oral PV type-1 vaccine challenge study. Primary and secondary endpoints were the time to clearance of PV from stool and total stool virus titer, respectively. Nearly half of the pocopavir recipients had clearance of PV from the stool before placebo recipients. Drug resistance was not observed in this group. The remainder of the pocopavir recipients responded similarly to placebo recipients. Pocopavir resistance was higher than anticipated in this group but was found to be due to PV transmission and reinfection within the study unit, not due to the development of resistant PV (355). A single report of the successful treatment of a non-polio EV exists (356).

Supportive care for the patient with EV meningitis is usually adequate to assure complete recovery. Attention to fluid balance is necessary to avoid or ameliorate the syndrome of inappropriate antidiuretic hormone or brain edema. Electrolytes, urine, and serum osmolality may require monitoring. Brain edema is a rare complication of EV meningitis but is readily managed with mannitol. Seizures may result from fever alone or may reflect direct viral or indirect inflammatory damage of brain parenchyma. Phenytoin or phenobarbital are the preferred agents for managing this complication. Patients with EV-A71 encephalitis or EV-D68 lower respiratory tract infection may require assisted mechanical ventilation.

Treatment for the neonate with sepsis or the child or adult with myocarditis is likewise symptomatic. Maintaining adequate blood pressure is paramount in each of those syndromes. Steroids have been widely debated in the therapy of myocarditis but are felt to be contraindicated in most cases (104). No significant benefit has been reported for other immunosuppressive classes of drugs either.

Adequate hydration is the only indicated therapy in children with herpangina and HFMD due to the EVs. Other respiratory manifestations of EV infections are managed symptomatically.

# Rhinovirus

WAI-MING LEE AND JAMES E. GERN

## 47

Rhinoviruses (RVs), members of the *Picornaviridae* family (1), constitute the largest group of respiratory viruses. RVs are recognized as causing more than 50% of all acute respiratory infections and represent the single most important causative agent of common colds. The name “rhinovirus” stems from the virus’s special adaptation to infect the nasopharynx. It was already known in 1930 that “colds” were easily transmitted from human to human and to apes, and that the responsible agent was probably a virus (2, 3), but it was not until 1956 that the first RV was discovered by isolation in cell culture (4, 5). The discovery of the low temperature optimum (32–35°C) for viral replication (6), the development of sensitive primary human embryonic lung cell cultures (WI-38 and MRC-5), and the continuous H1-Hela cell line (7, 8) facilitated the isolation, classification, and epidemiological and biological studies of RVs. A total of 100 serotypes were identified over the next 30 years (9). The first complete genome sequence was determined for RV14 in 1984 (10), a reverse genetics system was developed in 1985 (11), and the X-ray crystallographic structures of the viral capsids of five serotypes (1A, 2, 3, 14, and 16) were solved soon afterward (12–17). The recent use of more sensitive RT-PCR-based molecular assays for RV identification has generated clear evidence that RV infections are also common causes of more severe lower respiratory illnesses, such as bronchiolitis, pneumonia, exacerbations of asthma, and other chronic lung diseases (18–22). RT-PCR has also led to the discovery of more than 50 genotypes of previously unrecognized RVs that belong to a new species (RV-C). These viruses escaped traditional culture-based detection (23–26). This discovery has promoted a new wave of interest in RV research.

## VIROLOGY

### Classification

RVs belong to the family *Picornaviridae* and were traditionally classified into their own genus, *Rhinovirus*, according to their clinical and biological characteristics (9, 27). As molecular methods became available for virus identification, RVs were re-classified and merged into the genus *Enterovirus* because of similar molecular genetic properties (1). RVs are comprised of three species: rhinovirus A, B and C (RV-A, RV-B, and RV-C). Species A and B, consist of the 100 serotypes

that were identified by traditional methods and species C consists of over 50 genotypes that have been identified by molecular genetics methods.

### Acid Lability and Buoyant Density in Cesium Chloride

One of the defining characteristics of the human RVs is their acid lability; their infectivity is reduced at least 10-fold when incubated at pH 4 for one hour at 37°C in 0.1 M sodium citrate. In contrast, most human enteroviruses are stable under these conditions. All human RVs so far examined exhibit higher buoyant density (1.38 to 1.42 g/ml) in cesium chloride gradient than do enteroviruses, which characteristically band at 1.34. This property is due mainly, if not entirely, to replacement of potassium ions bound to the RNA genomes of RVs by heavier cesium ions. Cesium-potassium exchange does not occur in enteroviruses because the protein shell is impermeable to the cesium ion.

### Serotypes

One of the characteristic features of human RVs is the large number of serotypes. The 100 serotypes (1A, 1B to 86, and 88 to 100) were identified with culture-based, biochemical, and serological methods between 1956 and 1987 (9). The traditional method for identification of a RV serotype is neutralization of a virus inoculum containing 30 to 300 TCID<sub>50</sub> (tissue culture infectious dose) by an antiserum dilution containing 20 units of antibody (28). One antibody unit is the minimum amount of antiserum that neutralizes 30 to 300 TCID<sub>50</sub> of that virus. Each serotype was defined by 20-fold or greater differences in antisera neutralization titers during reciprocal cross-neutralization tests against the other 99 serotypes. Antigenic subgroups have been identified among 50 serotypes-(1A,1B), (2,49), (3,6,14,79), (9,32,67), (11,15,40,74,76), (12,78), (13,41), (22,61), (5,17,19,21,29,30,42,43,44,70), (18,36,50,58,89), (38,60), (39,54), (48,55), (56,57), (59,63,85), and (66,77)-in a comprehensive serological study of 90 serotypes (29). Moreover, certain serotypes, such as type 17, appear prone to serohypervariation (30).

Serovariability of RV may be related to the size of the receptor binding site (footprint) on the virion surface (31). Unlike rhinovirus, closely related poliovirus, has only three serotypes that use CD155 as their receptor. Like ICAM-1

(the receptor for 88 rhinovirus serotypes), CD155 binds to the canyon area on the virion surface. Structural studies of virus-receptor complexes show that ICAM-1 has a smaller footprint than CD155. This could permit the emergence of more viable antibody-escape mutants because the rhinovirion surface has more amino acid residues that could be mutated without disabling virus binding to the receptor.

### Phylogenetic Groups

In the past 10 years, RT-PCR-amplification of viral genomic RNA, DNA sequencing, and phylogenetics have gradually become routine procedure for the identification of RVs in clinical samples, because this approach is significantly more sensitive, faster, and easier to perform than traditional culture and serology-based identification. With phylogenetic analyses, the genome sequences of the 100 RV serotypes segregate into 2 groups: RV-A, consisting of 75 serotypes and RV-B, consisting of 25 serotypes (32–35). When molecular methods were used for RV identification, a large group of previously unculturable RVs were discovered (23–26). These viruses were detected by RT-PCR assays using RV-A and -B specific primers and their sequences were most closely related to RV-A and -B sequences in BLAST searches of the GenBank database. However, they segregated into a third group, with 30% to 40% pairwise sequence divergence from RV-A and -B, in phylogenetic trees. This new group is named RV-C (species C). RV-Cs are not newly evolved viruses because they could be found frequently in frozen clinical samples from the early 1980s, the oldest analyzed samples to date (36).

### RV-C Viruses

RV-C viruses were first detected by sequencing of PCR fragments of 5' nontranslated regions (NTR) and capsid protein coding VP4-VP2 regions of viral genomic RNA in human nasal samples (23–26). To date, over 50 types of RV-C have been tentatively identified by partial genome sequences, and 19 of them have been definitively identified with their complete genome sequences (37). RV-C does not grow in traditional cell culture systems, so their biological and immunological properties are still poorly understood. Recently, several groups have developed methods to grow them in sinus organ culture, differentiated airway epithelial cells in air-liquid interface culture, or HeLa cells transfected with the putative RV-C receptor (38–42).

### Receptor Types

The 100 human RV serotypes are divided into two groups on the basis of receptor specificity (Fig. 1). The “major” receptor group, containing 88 serotypes, utilizes the intercellular adhesion molecule-1 (ICAM-1; Fig. 2A) as receptor for infecting host cells (43). This receptor is a member of the Ig superfamily and maps to human chromosome 19 (43). Adhesion molecules like the ICAMs play a natural role in allowing cells to adhere to each other or to extracellular matrix molecules. The major group RVs are highly specific for ICAM-1 from humans and apes, such as chimpanzees and gibbons. Twelve serotypes, constituting the “minor” receptor group, utilize three members (LDLR, VLDLR, and LRP) of low-density lipoprotein receptor family as receptors (44, 45). The minor group RVs can bind to LDLR of the mouse. All 12 members of minor receptor group are RV-A viruses, while major receptor group consists of 63 RV-A and all 25 RV-B viruses. The study of the receptor(s) for RV-C is still at its early stages due to the complexity of growing RV-C in culture. Recently, a putative receptor for RV-C viruses has been

identified as cadherin-related family member 3 (CDHR3). HeLa cells transfected with CDHR3 expression vector support the replication of three RV-C types (C2, C15, and C42) tested (40).

### Composition

The virion has no lipid envelope and is composed of a single-stranded RNA genome tightly packed into the center of a protein shell known as the capsid (Fig. 2B). The concentration of purified virions can be measured spectrophotometrically with a conversion factor of  $9.4 \times 10^{12}$  virions per OD<sub>260</sub> unit (46). Water is an important part of the virion structure. In its fully hydrated state (observed during conventional X-ray crystallography or by cryoelectron microscopy), the particle is about 30 nm in diameter. When dried (e.g., during preparation for conventional electron microscopy), the virion shrinks about 30% and loses infectivity. The protein shell, about 5 nm thick, is composed of 60 copies of each of four viral proteins, termed VP1-VP4. Protein subunits called protomers, consisting of one copy of each of the viral proteins, are organized into 12 pentamers. Each of the 12 pentamers contains a prominent depression or “canyon” in VP1 running moat-like around a central plateau (i.e., around the 5-fold axis of symmetry) (47). Amino acid residues at the canyon base are more conserved than residues at exposed viral surfaces.

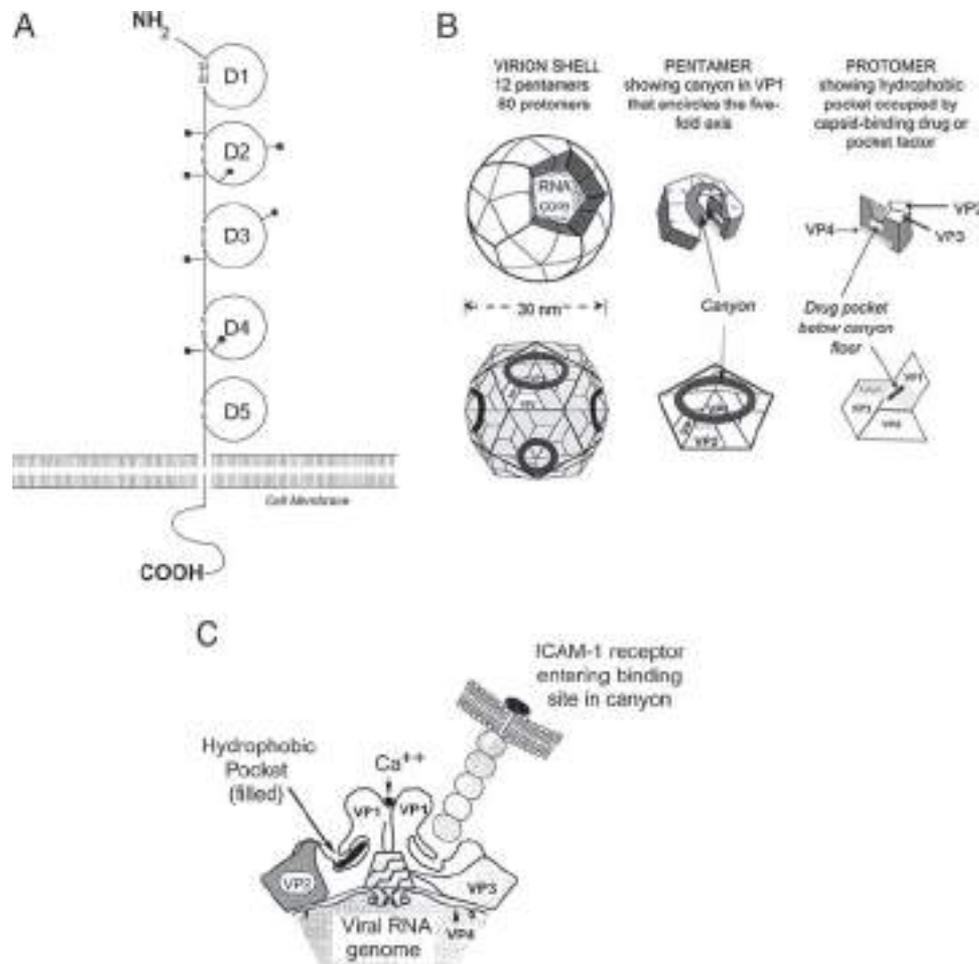

The canyons of major group RVs are the binding sites for the ICAM-1 receptors (48, 49). Cryoelectron microscopy (using purified fragments consisting of the distal two domains of ICAM-1) has shown that the canyon (Fig. 2C) is the site at which the receptor binds to RV16 and that purified virions can bind up to 60 such receptor fragments (49). Initially, it was hypothesized that the 20 Å deep canyon was used to hide the viral receptor attachment site on a viral surface from immune surveillance (50). However, the X-ray structure of the RV14-Fab complex showed that the antibody molecule penetrated deep into the canyon

### RV-A and RV-B serotypes:

		ICAM-1 (Major) <span style="float:right">LDLR (Minor)</span>

### RV-C types (C5, C15 and C42):CDHR3

**FIGURE 1** Receptor groups of rhinoviruses. Majority of RV serotypes (63 RV-A and all 25 RV-B) use ICAM-1 as the receptor. The remaining 12 RV-A serotypes bind to low-density lipoprotein receptor (LDLR) family proteins. RV87 was originally misidentified as a RV and has been reclassified as an enterovirus (EV-D68). The receptor for RV-C has been recently identified as cadherin-related family member 3 (CDHR3) protein.

**FIGURE 2** (A) Schematic drawing of ICAM-1, the receptor used by the major group RVs. S-S represents disulfide bridges, and small circles represent sites of glycosylation. (B) Key features of the structure of a human RV. The virion shell consists of 12 pentamers, one of which has been removed to show the approximate location of the RNA packed tightly into a central cavity. Each pentamer, in turn, consists of five wedge-shaped protomer subunits. The canyon (shaded) is shown encircling the five-fold axis of the pentamer; the hydrophobic (drug-binding) pocket is indicated below the floor of the canyon in VP1. (C) A side view of the pentamer showing the spatial relationship between the receptor-binding site and the hydrophobic pocket. An ion, located at each pentamer center in serotypes 1A, 14, and 16 is tentatively identified as calcium.

space (51), and so the canyon may not conceal the receptor-binding site at all. Interestingly, minor group RVs do not use the canyon for receptor binding; rather, the minor group receptor binds to the plateau area near the tip of the icosahedral five-fold vertex (52). Molecular modeling indicates that the RV-C capsid has less pronounced canyons that likely do not contain receptor binding sites (40). Nevertheless, the canyons of both major and minor group viruses play a critical role in the uncoating (release of genomic RNA) step following attachment by providing a flexible region for the conformational change in the viral capsid. It is thought that the binding of multiple receptors per virus particle (receptor “recruiting”) triggers a major conformational change of the capsid proteins, accompanied by 20% expansion of the shell, to allowing the eventual release of RNA (47).

At the base of the canyon lies a hydrophobic “pocket” which may be empty (e.g., RV14) but which in many other RVs (e.g., RV16) is filled with a still uncharacterized molecule called “pocket factor.” A pocket factor may play a role

in the replication cycle of RVs by regulating the stability and receptor-induced conformational changes of the viral capsid (47, 53, 54). This pocket is the binding site for several classes of antipicornavirus capsid-binding antivirals (e.g., pleconaril and varendavir). In general, capsid-binding antivirals block the binding of major receptor RVs to ICAM-1 and inhibit uncoating of receptor-bound minor group RVs (55, 56). For RV-C, the pore to the pocket is more constricted, and these viruses are resistant to several capsid binding antivirals including pleconaril (57).

Immunoglobulins bind to the virion surface to neutralize infectivity of RV. Several mechanisms for antibody-mediated neutralization of RVs have been proposed, including aggregation, virion stabilization, induction of conformational changes, and abrogation of cellular attachment (58, 59). Taken together, numerous biochemical and structural studies suggest that neutralization of RV *in vitro* results from steric blockage of the interaction between the virus and its receptors due to the binding of the antibody molecules on the virion surface (59).

## Genome

The rhinoviral genome is a single strand of positive-sense RNA about 7200 bases long. Sequence analysis indicates a genome organization similar to that of poliovirus, the prototype of enteroviruses (Fig. 3A). Both viruses contain poly (A) tracts which are required for infectivity of the viral genomic RNA, and both are covalently linked through the 5'-terminal uridylic acid to a small viral protein (VPg) which can be removed from the genomic RNA without reducing its infectivity. The viral genomic RNA contains a single open reading frame (ORF) for a large polyprotein of about 2,200 amino acids. Both polioviruses and RVs have unusually long nontranslated regions (NTR; 600 to 750 bases) at the 5'-ends with distinctive secondary and tertiary structures called internal ribosomal entry sites (IRES). IRES enable the translation of viral genomes by promoting the internal binding of the ribosomes to viral RNAs since rhinoviral RNAs lack 5'-terminal caps that are used by most cellular mRNAs for ribosome binding (47). IRES are used by many positive-stranded RNA viruses and some eukaryotic genes. The RV genome also includes a relatively short 3'-NTR that is required for efficient viral replication (60).

## Proteins

The organization of the polyprotein of human RVs is also very similar to that of poliovirus (Fig. 3B), though much less is known of the details of rhinoviral processing and assembly because of the less vigorous translation of rhinoviral RNA in cultured cells and incomplete shutoff of host protein synthesis by viral proteases (54). The RV genome, like that of polio, is organized into three major regions based on proteolytic processing: P1, P2, and P3, representing genes for precursor proteins. These precursors are subsequently cleaved

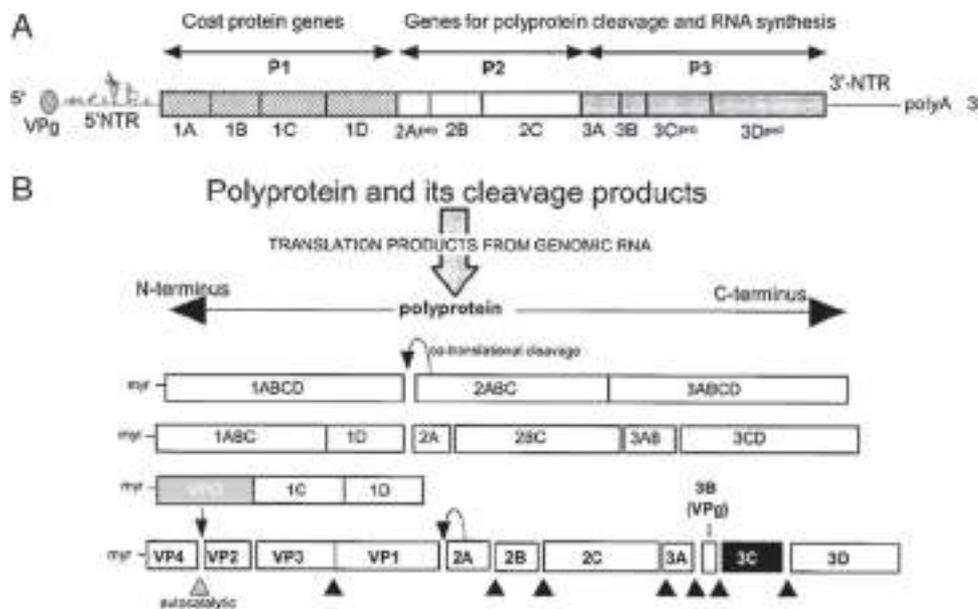

into 4, 3, and 4 end products, respectively. Protein P1 is a precursor for the four coat proteins. P2 and P3 are precursors for proteases 2A and 3C and for proteins required for replication of the viral RNA.

Before assembly, the coat precursor protein, P1, is cleaved twice to form mature protomers (VP0, VP1, VP3), which then package RNA to form noninfectious provirions containing 60 protomer subunits (Fig. 4) (54, 61). The maturation cleavage of VP0, producing VP4 and VP2, occurs only after the RNA has been packaged in the protein shell (54). The VP0 cleavage site lies buried inside the shell near the viral genomic RNA: thus, the protease event responsible for this cleavage is thought to be an element of the coat protein and may actually use bases in the viral RNA as part of its active site (15). The P1 region is released by a cis-cleavage at the N-terminus of the 2A protease. All remaining cleavages are carried out by the 3C protease or its precursor form, 3CD. A molecule of myristic acid, which appears to play a role during virus assembly and disassembly, is covalently linked to the amino termini of VP4 and its precursor forms.

## BIOLOGY

### Multiplication Strategy

Multiplication of RVs is believed to take place entirely in the cytoplasm. The initial event in infection is attachment of the virion to specific receptor units embedded in the plasma membrane (Fig. 5, step 1). Receptors then bring the virion close to the membrane. Recruitment of additional receptors (step 2) eventually triggers the uncoating of the virion that involves extrusion of the protein VP4 and delivery of the viral RNA genome across the membrane and into the cytosol (step 3) where translation can begin. The study of the

**FIGURE 3** (A) RNA genome of a human RV. P1, P2, and P3 refer to precursor proteins that are subsequently processed to produce 11 end products. (B) Cleavage of the polyprotein is accomplished by two viral proteases, 2A and 3C. The 2A protease co-translationally releases the coat precursor, P1, from nascent polyprotein, whereas the 3C (or precursor 3CD) protease cleaves all the remaining precursors and intermediates except for VP0 (1A-1B). Cleavage of VP0 to VP4 (1A) and VP2 (1B), maturation cleavage, occurs only after the RNA has been packaged in the protein shell. The VP0 cleavage site lies buried inside the shell near the RNA; the active site for this cleavage is not yet precisely known and might include bases in the RNA genome. The amino termini of coat proteins P1 and VP4 are blocked by a myristoyl group. Cis-cleavage of the N-terminus of 2A is shown by an arrow; black triangles indicate 3C cleavage sites.

uncoating pathway of RVs has been difficult because the interpretation of biochemical data is clouded by the fact that only 1% or fewer input virions initiate a successful infection. One major reason for the low infection efficiency is elution of noninfectious 135S and 80S subparticles. More than 50% of attached particles are typically lost to this abortive event. The site of uncoating, whether at the cell surface plasma membrane or acidic endocytic vesicle, may be determined by the stability of the virus-receptor complexes. For some serotypes whose receptor complexes are labile at neutral pH (62), binding of the virus to the receptors on the cell surface is sufficient to trigger uncoating. For the serotypes whose receptor complexes are stable at neutral pH (62), some additional stimulus such as low pH is required, so uncoating is delayed until the complexes are transported into the endosomes by normal cellular internalization and trafficking process of receptors and their ligands (47). Clathrin-mediated endocytosis is the major pathway of all cells to internalize receptor-ligand complexes. Both major and minor group RVs use this pathway to enter the endosomes via the interaction of the cytoplasmic domains of their receptors with clathrin (63, 64).

Translation (step 4) is the crucial first step of viral multiplication because synthesis of new viral RNA cannot begin

until the necessary viral proteins are made. By using the IRES to appropriate ribosomes and other components of the protein synthesizing machinery from the host cell, the incoming viral RNA strand directs synthesis of a polyprotein that is progressively cleaved into the final products already described. RV translation requires multiple cellular translation proteins, including most of the canonical translation initiation factors, with the exception of the cap-binding protein eIF4E (eukaryotic translation initiation factor 4E) and three additional cellular RNA-binding proteins, PTB (polypyrimidine-tract binding protein), PCBP2 (poly(rC)-binding protein 2), and unr (upstream of N-ras). PTB, PCBP2, and unr interact with IRES to help it to bind directly to the cellular translation machinery.

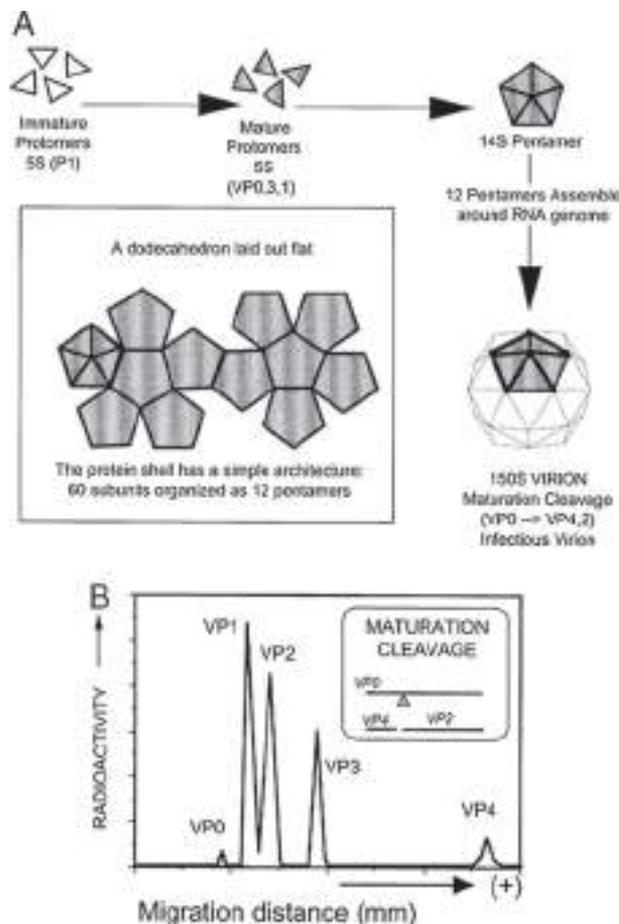

The initial step in synthesis of new viral RNA is copying of the incoming genomic RNA to form complementary minus-strand RNA (step 5), which then serves as the template for synthesis of new positive-strands (step 6). Synthesis of positive-stranded RNA, which occurs in viral-induced membranous vesicles derived from endoplasmic reticulum, is initiated rapidly to generate multistranded replicative intermediates consisting of one minus-stranded template and many nascent positive-stranded copies. The initiation of minus-strand synthesis is apparently down-regulated by the presence of translating ribosomes on the positive-strands (65). Generally, an infected cell has 30 to 70 times more positive-strands than minus-strands (66).

A molecule of VPg is covalently linked to all RNAs involved in transcription. The role of VPg in the initiation of minus-strand RNA transcription has been elucidated for poliovirus. Following uridylylation by the 3D polymerase, VPg-pUpU primes the transcription of poly(A) RNA to produce VPg-linked poly(U) RNA. The template for the uridylylation reaction is a small RNA hairpin, called the cis-acting replication element (cre), located in the coding region of protein 2C gene of poliovirus (67). Cre hairpin structure is also present in the RNA genomes of RVs. Unlike polioviruses, cre hairpin structure is located in the coding region of 2A, VP1 and the VP2 genes of RV-A, RV-B, and RV-C viruses, respectively (33, 68, 69).

In the early stages of RNA synthesis, newly synthesized positive-stranded RNA molecules are recycled to form additional replication centers (step 7) until, with an ever-expanding pool of positive-stranded RNA, an increasing fraction of the positive-stranded RNA in the replication complex is packaged into provirion. The RNA replication machinery interacts directly with the capsid proteins so that only newly synthesized positive-stranded viral RNAs are packaged (70).

Virion assembly (steps 8 to 10) is controlled by a number of events. Before assembly can begin, coat precursor protein P1 must be cleaved to form mature protomers composed of three tightly aggregated proteins (VP0, 3, and 1). Early in the infection cycle this cleavage is likely very slow because of the low concentrations of P1 and its protease. Later, with increasing protease activity, the rising concentration of mature (5S) protomers triggers assembly into pentamers that then package the newly synthesized VPg-(+)RNA to form provirions. Formation of infectious 150S to 160S particles results from the final maturation cleavage (61). Completed virus particles are ultimately released by infection-mediated disintegration of the host cell (step 11).

To better exploit cellular factors for its own reproduction, RV uses its proteases 2A and 3C to inhibit host transcription and translation. The 2A protease reduces the efficiency of host-cell translation of capped mRNA via the cleavage of

**FIGURE 4** (A) Diagram representing virion architecture and assembly. (B) The mature virion contains four major proteins (VP1 [1D], 2 [1B], 3 [1C], and 4 [1A,]) plus traces of VP0, representing residual precursor following the maturation cleavage required for acquisition of infectivity.

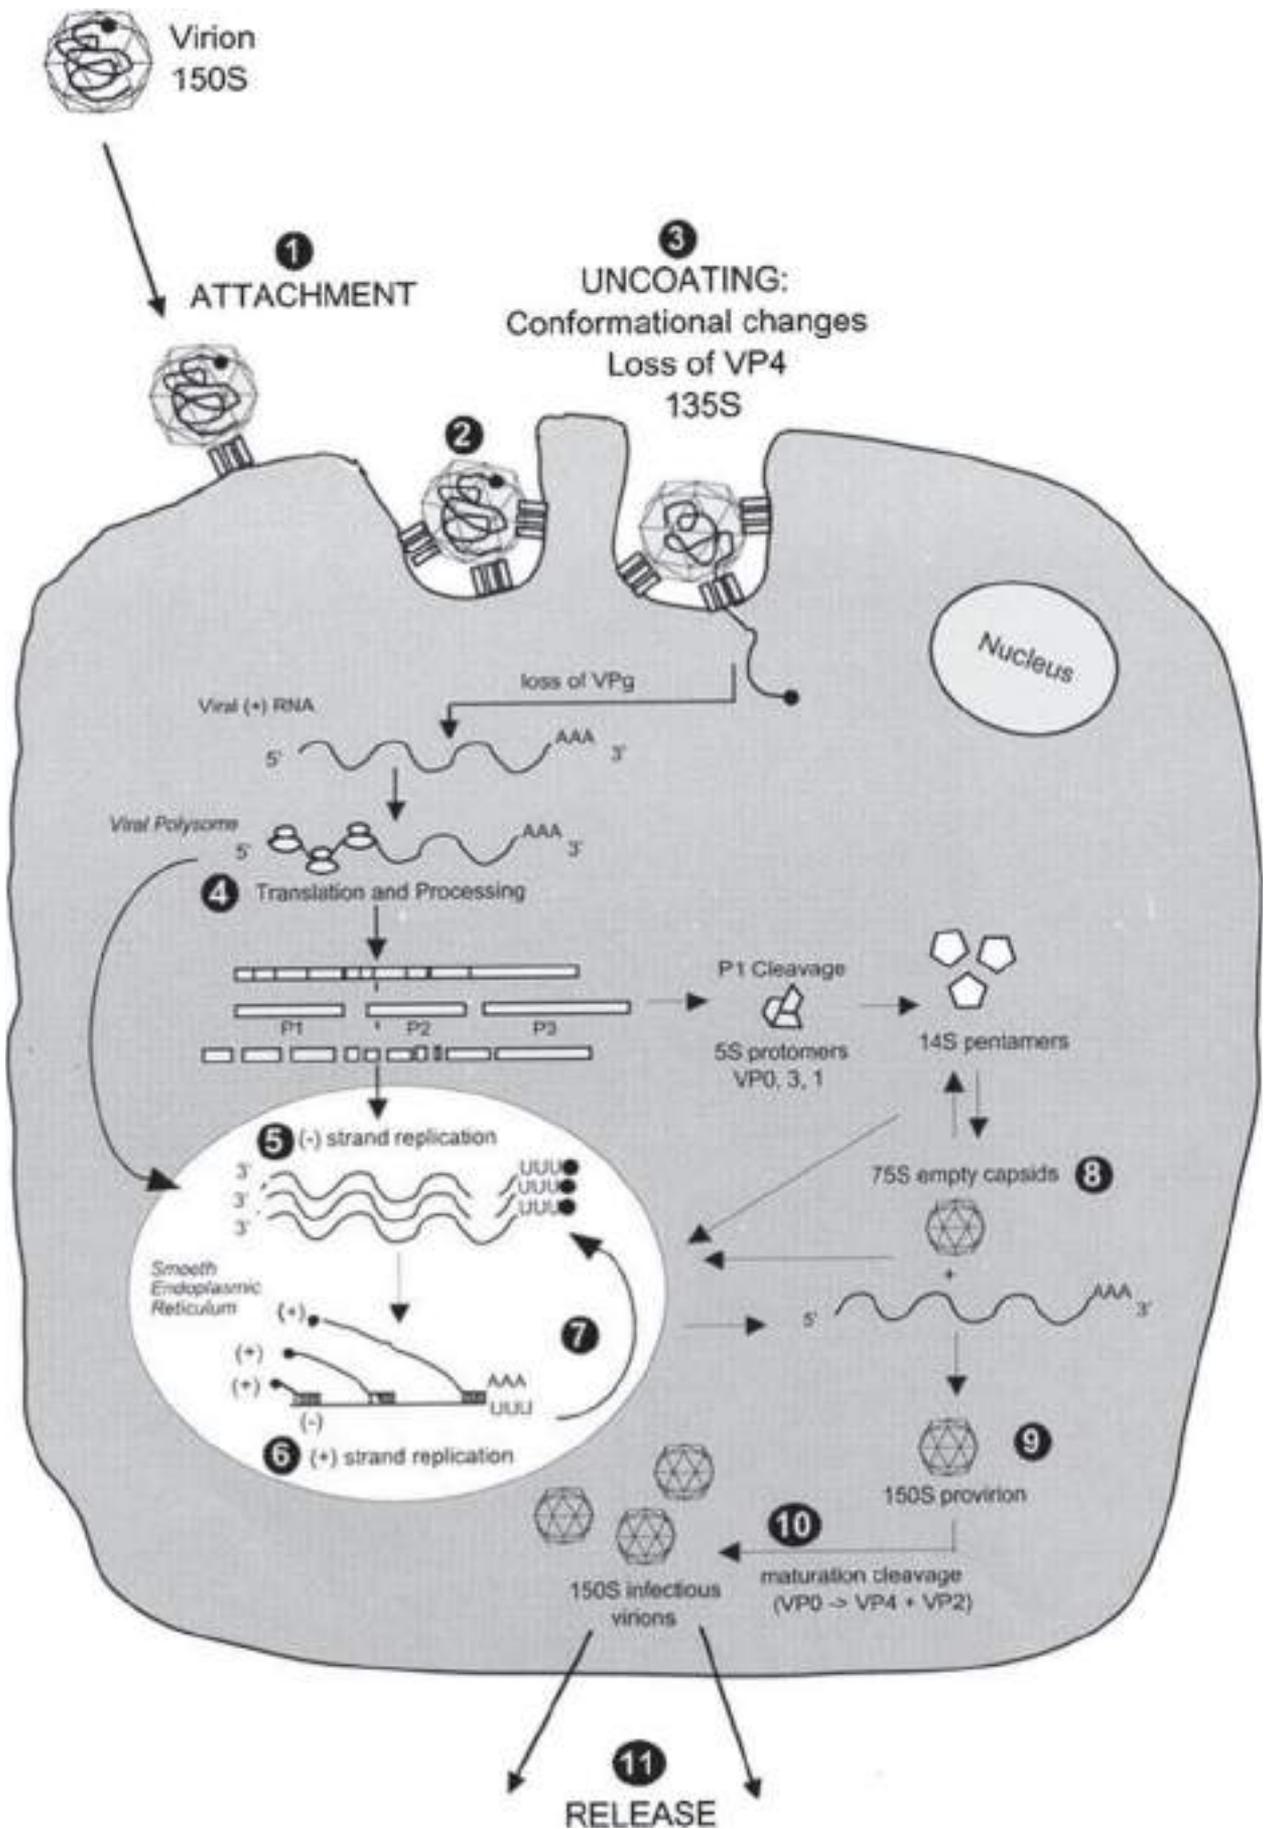

FIGURE 5 Overview of the RV infection cycle.

the eIF4G subunit of the cap-binding protein complex. The cleavage separates the N-terminal eIF4E (cap-binding protein) binding domain from the C-terminal fragment (p100) that has the binding sites for IRES and the translation machinery and thus reduces the ability of capped mRNA to compete with viral mRNA for translation (71). The 3C protease and its precursor 3CD inhibit transcription of host RNA polymerases I, II, and III via the degradation of transcriptional accessory proteins in the nucleus. Because 3C lacks a nuclear localization signal (NLS), it enters the nucleus in the form of its precursor, 3CD, that has an NLS in 3D.

#### Host Range

Human RVs have a high degree of species specificity. The natural host range of RV-A and RV-B viruses is restricted to humans and closely related apes. Early efforts to seek an animal model found that the chimpanzee and gibbon are the only two nonhuman hosts that can be productively infected with RV-A and RV-B viruses (72, 73). Chimpanzees and gibbons that were exposed intranasally to RV-A or RV-B shed large amounts of virus for several days, produced specific neutralizing antibody, and were protected when re-challenged with the same virus, although they did not have clinically detectable symptoms (72, 73). The nonhuman host range of RV-C has not been reported.

#### Mouse Model

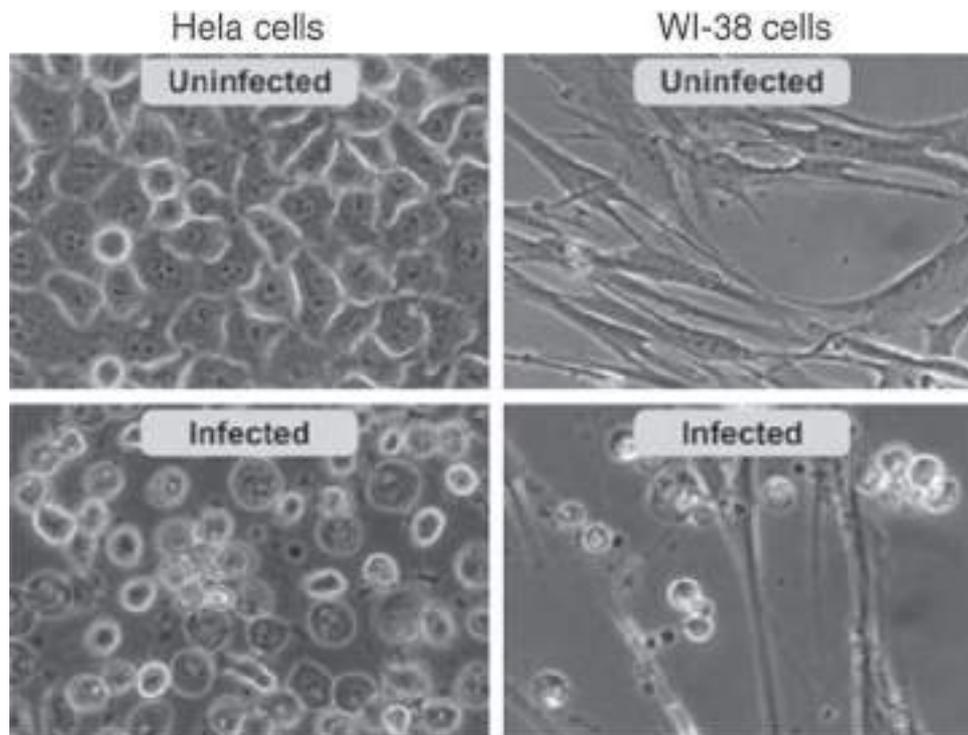

Genomic RNA of a number of RV serotypes, such as 1A, 1B, and 16, can replicate in mouse cells to yield some infectious progeny virus (72–77). Encouraged by these findings, investigators have developed mouse models for studying RV infection: intranasal inoculation of transgenic mice

expressing human ICAM-1 with major group RV16 and of nontransgenic mice with minor group RV1A or RV1B. Some studies have reported the observation of inflammatory changes, similar to those induced by RV infection of human airways, including neutrophilic and lymphocytic inflammation, mucin secretion, and cytokine production when a large virus inoculum (typically  $5 \times 10^6$  TCID<sub>50</sub> units per mouse) was used. However, none of these studies has demonstrated convincing evidence of viral replication in mice (78–82).

#### Growth in Cell Culture

Primary WI-38 (ATCC CCL-75), MRC-5 (ATCC CCL-171), and continuous H1 HeLa cells (ATCC CRL-1958) are the most commonly used cells for studying live RV-A and RV-B viruses (Fig. 6). WI-38 and MRC-5 are strains of human embryonic lung fibroblast diploid cells and are sensitive to the prototype strains of all 100 RV-A and -B serotypes, as well as several other human viruses. They are useful for isolating RV-A and -B viruses from clinical samples, titrating their infectivity and producing virus inocula for human studies (83). They have a finite passage life of about 50 cell divisions, however, and require a solid substrate for growth. Recently, a master cell bank from passage one of a well-characterized strain of human diploid embryonic lung cells (WisL cells) was created under good manufacturing practice (GMP) conditions (Waisman Clinical Biomanufacturing Facility, University of Wisconsin-Madison) for producing RV inocula for human studies. These WisL cells have passed the tests required by FDA for cell lines used to produce biologicals for human use.

H1-HeLa is an RV-sensitive HeLa strain originally developed as a monolayer culture in the lab of Vincent Hamparian in the early 1960s. It has been adapted for

**FIGURE 6** Cytopathic effect (CPE) in H1-HeLa and WI-38 cells caused by RV infection. Cells were exposed to 100 PFU of human RV type 16 (RV16) per cell and incubated at 35°C. Infected HeLa cells became rounded and detached from growth surface by 12 hours but WI-38 cells required 48 hours to develop CPE.

growth in suspension culture (46). H1-HeLa cells support vigorous multiplication of HeLa-adapted serotypes and are also the standard cell for plaque assays of RV-A and -B viruses (83). However, this cell line is derived from a human cervical carcinoma and is therefore unsuitable for preparing virus inocula for studies in human volunteers. In cultured H1 HeLa cells, the time required for a replication cycle of RV16, from infection to completion of virus assembly, is about 6 to 8 hours at 35°C with a yield of about 300 plaque-forming units per cell (46, 54).

*In vitro* differentiated human tracheobronchial epithelial cultures have also been exploited as a model for studying RV infection of the native airway (84). These cultures were developed by differentiating primary airway epithelial cells, isolated from human tracheobronchial tissues, in air-liquid interface cultures to form a polarized mucociliary epithelium with structural characteristics similar to native airway tissues (85).

RV-C grows only in human sinus organ culture, differentiated airway epithelial cells in air-liquid interface culture and HeLa cells transfected with its putative RV-C receptors (38, 39, 41).

### Inactivation by Physical and Chemical Agents

When subjected to any of a variety of treatments including gentle heating, ultraviolet light, high pH, mercurials, phenol, or desiccation, rhinovirions lose their native (N) antigenicity and acquire a new set of surface determinants called the C (coreless) or H (heated) antigen. RVs are characteristically sensitive to acidic pH less than about 5 or to alkaline pH exceeding 9. Increasing ionic strength generally increases thermostability. Capsid-binding inhibitors markedly stabilize RVs against heat inactivation (86). Their thermostabilizing effect has been attributed to either increasing rigidity of the coat proteins or to increasing compressibility of the capsid. Susceptibility of RV-C to thermal, osmotic, and pH stress resembles that of RV-A (87).

Sodium dodecyl sulfate, particularly in the presence of organic acids such as malate and citrate, inactivates RVs rapidly even at room temperature. Infectivity of aqueous suspensions of RV survives extraction with diethyl ether, a treatment commonly used for the selective killing of bacterial and fungal contaminants and as a preliminary test to distinguish lipid-enveloped viruses from nonenveloped ones. Infectivity is less refractory to extraction with more polar organic solvents such as chloroform, possibly because of the removal of the hydrophobic “pocket factor,” partial solvent denaturation of the protein shell, or oxidation due to contamination of the solvent by phosgene. Chemicals that alter the nucleic acid include nitrous acid, which deaminates purine and pyrimidine bases, and alkaline reagents including ammonia, which cleaves RNA within the virus particle. Halogens (chlorine, bromine, iodine), hydrogen peroxide, and ozone are also commonly used disinfectants, and one exploratory study used an iodine hand treatment in efforts to inhibit transmission (88).

## EPIDEMIOLOGY

### Geographic Distribution

RVs are distributed worldwide, and antibody to RV is detected in serum specimens collected from many different parts of the world. Of particular interest has been the detection of RV antibody in serum specimens collected from members of an isolated Amazon Indian tribe shortly after

their initial contact with civilization (89). Infection in this group was presumably acquired through intermittent contact with semicivilized tribes in the same region.

### Incidence and Prevalence of Infection

Recent studies using reverse transcriptase PCR (RT-PCR) for detection indicate that RV infections are ubiquitous, especially in young children. In 15 healthy children followed for three seasons with weekly nasal swabs, the overall rate of infection was 0.5 infections per month (90). Highest rates were in the fall (0.63 infections per month), and lower rates were present during summer and winter (0.43 and 0.44 infections per month respectively). In a family surveillance study involving 108 persons from 26 households, analysis of weekly samples collected over a year demonstrated that 93% of participants had at least one RV infection detected (91). Asymptomatic RV infections were common but varied by age. Infections in children younger than 5 years were less likely to be asymptomatic compare to all other age groups (33% vs. 49%) (91). Detection of RV in asymptomatic individuals can be due to a recent infection after symptoms have resolved, individuals who are prodromal, and true asymptomatic infection (92). With the exception of immunosuppressed individuals, persistent infection with a single RV type does not occur (92–95). The relationship between infection and illness severity appears to vary by season; infections of infants in the winter are about 10-fold more likely to cause moderate-to-severe colds compared to infections during the summer months (96).

In the absence of protective antibody, the risk of infection with a new RV type is primarily a function of exposure to the virus. The prevalence of RV-specific antibody in serum indicates that infection with the various serotypes begins in early childhood and continues throughout life. The peak prevalence of RV antibody is found in young adults, probably reflecting exposure to young children in the home, and the subsequent decline in prevalence is probably related to less frequent exposures in older adults. Type-specific neutralizing antibody provides serotype-specific protection, but this is associated with little reduction in overall infection risk due to the large number of RV types.

### Seasonality

Frost and Gover (97) suggested that the respiratory disease season is composed of “successions of epidemics” caused by different infectious agents, based on epidemiological observations made between 1923 and 1925. This ingenious observation was confirmed with the subsequent detection of the several families of respiratory viruses. In temperate areas of the northern hemisphere, a distinct peak of colds is observed in September (97, 98). This early-fall peak of colds is strongly associated with RV infections, a finding confirmed by studies using culture or RT-PCR. In young adults the RV infection rate reaches its highest annual point (3.5 illnesses/1,000 persons/day in Charlottesville, VA during this period (99). Thereafter, RV prevalence declines, usually remaining low throughout the late fall, winter, and early spring (90). A second period of increased RV activity occurs in late spring, April and May. Although the overall incidence of colds is low during the summer months, RV infections account for up to 50% of the illnesses during this season (90, 99). In the temperate areas of the southern hemisphere, the seasonal incidence of infection mirrors that in the northern hemisphere. In tropical climates, RV activity is detected throughout the year, with a peak incidence in the autumn months (100).

The cause of the seasonality of colds has been the subject of much speculation but remains largely unexplained. However, at least two factors influence this phenomenon: the effect of relative humidity on virus survival and the herding of children during the school term (101, 102). RV and other nonenveloped viruses retain infectivity best in conditions of high relative humidity, in contrast to enveloped viruses like influenza virus. In 1960 Hemmes et al. (103) suggested that the relative humidity indoors is an important factor controlling the seasonal fluctuations of the different virus families.

Observations suggest that weather has both biological and behavioral consequences that influence the incidence of RV infection. In a 15-year longitudinal study in Charlottesville, VA, the occurrence of colds with culture-detected RV was greatest from April to October, which is the period when indoor relative humidity tends to remain above 45% (101). School openings also correlated with the fluctuating incidence of colds. In 8 of 14 years, the interval between the date of school opening and the date on which cold rates reached the defined peak was 11 to 14 days. School openings also precede fall exacerbations of asthma, which are usually associated with RV infections (104).

### Transmission

RV infection is readily initiated by inoculation of virus onto the nasal mucosa or conjunctiva where transport by the lacrimal duct leads to deposition in the posterior nasopharynx (105). In those lacking serotype-specific neutralizing antibody, the 50% human infectious dose (HID<sub>50</sub>) has ranged from 0.1 to 6 TCID<sub>50</sub> after intranasal inoculation. In contrast, experimental inoculation of RV into the mouth or exposure to infected volunteers by prolonged kissing is an inefficient method of initiating infection (106). A similar difference in susceptibility is observed between the upper and lower respiratory tracts. The HID<sub>50</sub> for antibody-free volunteers given RV type 15 by nasal drops corresponded to 0.032 TCID<sub>50</sub>, compared to 0.68 TCID<sub>50</sub> when the virus was given by small-particle aerosol (107). This 20-fold disparity in infectious dose between nose drops and inhaled particles suggests that the lower respiratory tract is less susceptible to RV infection than is the nasopharynx. In addition, interferon applied intranasally by drops or coarse spray prevents natural RV infection and illness (108). Since application of interferon by this method would not be expected to prevent infection in the lower airway, this also points to the upper airway as the usual portal of entry for RV.

Delivery of RV to the nasal mucosa can occur either by droplets or by direct contact. Sneezes and coughs generate both large- and small-particle aerosols, but the amount of RV in respiratory secretions produced by coughs and sneezes is usually small. Although the RV genome may be present in small-particle aerosols, such aerosols do not appear to be an important mechanism of spread. Large-particle aerosols produced by coughs and sneezes and deposited onto the nasal or conjunctival mucosa contribute to transmission (109). RV is recovered from the fingers of approximately 65% of experimentally infected volunteers after finger-to-nose contact, and the virus survives for several hours on skin (110, 111). Contact with the contaminated fingers reliably transfers virus to the skin of a recipient individual. Once the fingertips of the recipient are contaminated, infection is readily induced by self-inoculation of the nasal mucosa by rubbing the nose or the eyes.

The role of fomites in the transmission of virus is less clear. The virus contaminating the hands is readily trans-

ferred to objects in the environment. When fingertips have been experimentally contaminated with nasal mucus containing known amounts of RV, 13% of the starting virus titer was transferred to inanimate objects after brief contact, although transfer was less efficient if the virus inoculum was allowed to dry (110, 111). Virus on nonporous environmental surfaces may survive for up to 3 to 4 days and can be transmitted to the skin by contact. Although these various steps in fomite transmission have been demonstrated, there is a substantial loss of infectious virus at each step. An attempt to document transmission of infection from fomites under experimental conditions that would favor transmission was unsuccessful, suggesting that this mechanism may not be efficient for the spread of RV infections (112).

Studies in the natural setting have confirmed many of these steps in virus transmission. Virus is recovered from the skin of the hands of approximately 40% of individuals with natural RV colds and from 6% to 15% of objects in their environment (110, 111). Individuals in the natural setting routinely make finger-to-eye or finger-to-nose contact in a manner that would transfer virus to the nasal mucosa. However, the mechanism of transmission of virus under natural conditions can be determined only by blocking transmission using an intervention that is specific for a particular route. In one trial using a 2% aqueous iodine as a virucidal treatment for the hands (110), regular applications to the fingers by mothers who had been exposed to a child with a fresh cold in the home reduced colds by 67% compared to placebo. None of the 11 mothers using iodine became infected with the same RV recovered from the index case, compared to 31% of mothers using placebo. Another study of the hand contact route of cold transmission in asthmatic children (113) found that a group of children trained to avoid finger-to-nose contact had significantly less self-inoculation behavior, fewer viral respiratory infections, and fewer attacks of asthma. Thus, direct evidence is available that supports the hypothesis that RV colds are transmitted by accidental self-inoculation of the nose or conjunctiva following inadvertent contamination of the fingers with virus.

The duration of infectiousness for RV colds parallels the period of maximum virus shedding in nasal secretions. RV concentrations in nasal secretions are highest during the second and third days after experimental infection. Deliberate infection of one member of a dually susceptible (i.e., antibody-free) married couple (114) determined that the features of the donors that were associated with transmission included a concentration of >1,000 TCID<sub>50</sub> per ml nasal washings, virus on the hands and anterior nares, and symptoms of at least a moderately severe cold. In most instances, these conditions occurred only on the second and third days after virus inoculation. In households, secondary cases are seen 1 to 3 days after exposure to an index case. In longitudinal studies within families, transmission from children to other children and adults is much more common than transmission from adults to children or to other adults (115, 116).

## PATHOGENESIS IN HUMANS

### Incubation Period

In experimentally infected volunteers, RV is first recovered in nasal washes a median of 10 hours (range 8 to 18 hours) after inoculation. Respiratory symptoms occur surprisingly early, with the throat becoming sore or scratchy between 10 and 12 hours after virus inoculation as newly produced virus

appears (117). Nasal symptoms follow soon afterward, and experimental inoculation studies demonstrate that lower respiratory symptoms, when present, may begin 1 to 3 days following the onset of cold symptoms (118). The incubation period ranges from 1 to 4 days following inoculation and is similar following natural transmission (114).

### Patterns of Virus Replication

In studies of natural or experimentally induced colds, RV protein or genome is detected in the epithelial layer (39, 119, 120) and in some subepithelial macrophages (121). Replication does not occur in macrophages (122), although these cells likely mediate immune surveillance by binding virus and transporting it to regional lymph nodes. RV can also bind to monocytes, eosinophils, and fibroblasts (123). RV can replicate in airway fibroblasts in tissue culture (122–124) but whether these cells are infected *in vivo* is speculative. Infection occurs in a patchy distribution, with small foci of infected cells (119), and greatest viral shedding in the nasopharyngeal and adenoidal regions (125). In the adenoids, RV may replicate in nonciliated cells that express high levels of ICAM-1 and resemble intestinal M cells (126). In cultured epithelial cells, ciliated cells are preferentially infected by major group RV (127). The duration of RV shedding is generally limited to 7 to 10 days, but prolonged shedding of the same RV type occurs in a subset (<10%) of infections in young children (93, 128) and in neonates (129).

Because early studies indicated that RV replicates best at 33–35°C, it was assumed that RV infection was limited to the upper airways. Contrary to these initial assumptions, direct measurements in the lower airways have shown that large and medium size airways maintain the ideal temperature for RV replication (130), and many RV types replicate efficiently at 37°C (87, 131). Accordingly, RV replicates readily in cultured lower airway epithelial cells (132, 133). Furthermore, RV can be detected in the lower airway following experimental inoculation of the upper airway (120, 134) and in lower airway secretions of children with natural colds in whom samples are obtained through tracheostomies, which eliminates the potential confounding effect of sample contamination with upper airway secretions (135).

In addition to infecting the nasopharynx and adenoids, conjunctiva, and lower airways, RV can also be detected in specimens obtained from the middle ear and sinuses (136, 137), presumably because the virus has spread from the nasal epithelium to contiguous areas.

### Factors in Disease Expression

An impressive feature of RV pathogenesis is that the non-specific host defense mechanisms of the nose are unable to prevent infection in the nonimmune individual and may, in fact, contribute to the pathogenesis of RV-associated illness. Following intranasal RV challenge, infection rates of more than 90% are routinely achieved in nonimmune volunteers, irrespective of the season of the year or of the allergic status, smoking history, physical condition, or stress level of the subject (138–140). Following infection, symptomatic individuals shed higher titers of virus in nasal secretions than do asymptomatic individuals.

Infection with RV produces no detectable histopathological change in the respiratory epithelium. Nucleic acid hybridization studies demonstrate small foci of infection interspersed among large areas of uninfected cells (141), and examination of nasal secretions with labeled RV antibody demonstrates occasional antigen-positive epithelial cells that

have been shed from the nasal mucosa (142). These studies suggest that RV infection involves sparse and scattered areas of the nasal epithelium and that infected cells are shed from the epithelium, with rapid repair of the involved areas.

Despite the absence of overt histopathological damage to the nasal mucosa, inflammatory responses occur in the nasal epithelium and increased numbers of nasal epithelial cells are shed in secretions. Polymorphonuclear leukocytes (PMN) infiltrate the nasal epithelium early after infection, and PMN concentrations increase in the nasal secretions and peripheral blood but only in symptomatic individuals. The correlation between the lymphocytic response to RV infection and symptomatic illness is less clearly characterized. Modest increases in T-lymphocyte concentrations have been reported both for the nasal mucosa and for nasal secretions during RV infection; few B lymphocytes are noted in the nasal mucosa.

The evidence summarized above suggests that nonspecific host inflammatory responses may play a role in symptom expression (Fig. 7). A number of inflammatory mediators are increased in nasal secretions and/or the serum during RV colds, including bradykinin, interleukin (IL)-1b, IL-6, IL-8, interferon-inducible protein 10, and tumor necrosis factor alpha. The concentrations of IL-6 and IL-8 in nasal secretions have some correlation with symptom severity, and intranasal instillation of IL-8 in healthy volunteers produces symptoms that are similar to the common cold. Inhalation of bradykinin by healthy volunteers produces nasal obstruction, rhinorrhea, and sore throat. The detection of these mediators in association with illness, however, does not provide definitive evidence of a role in RV-associated illness. The role of kinins, in particular, is unclear in light of a study demonstrating that inhibition of the kinins with corticosteroids had no effect on cold symptoms (143).

Neurogenic mechanisms, particularly the parasympathetic nervous system, also appear to play a role in the expression of illness during RV infections (Fig. 7). The parasympathetic nervous system controls the secretory activity of nasal seromucous glands. These glands, in association with plasma transudation, provide most of the nasal fluid produced during an RV cold. Drugs with anticholinergic activity, such as atropine methonitrate and ipratropium bromide, given intranasally and first-generation antihistamines given orally reduce mean nasal fluid volumes by approximately 30% in volunteers with experimental RV colds. The mechanisms by which these mediators and neurogenic reflexes are stimulated by RV infection remain unknown. In addition to the obvious interaction between RV and the known cellular receptors, other nonspecific interactions may play a role in pathogenesis. Toll-like receptor 3, which recognizes double-stranded RNA, appears to mediate some cellular responses to RV (144). RV replication complexes occur in ceramide-enriched cell membrane platforms that may play a role in stimulating relevant signaling pathways (145). A number of secondary signaling pathways have been implicated in the elaboration of inflammatory mediators *in vitro*, but the relevance of these studies to the *in vivo* elaboration of mediators remains to be determined.

Other host factors include possible roles of the host psychological state, sleep patterns, and genetics in promoting infection or illness. Shorter duration of sleep has been associated with an increased risk for developing cold symptoms after experimental RV inoculation (146). Stress is not a factor in the acquisition of infection, but chronic stress in particular is associated with the development of more severe symptoms (147). Genetic factors related to RV illness

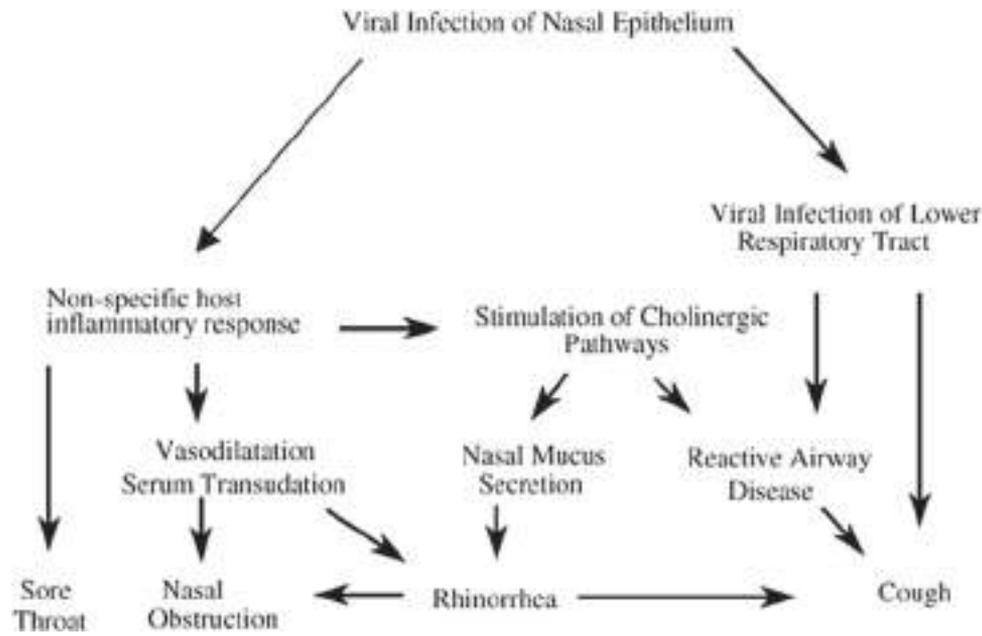

FIGURE 7 Proposed pathogenesis of symptoms associated with RV infection.

severity include polymorphisms in regions related to antiviral responses (e.g., *IFNB1*, *JAK2*, *IL28A*), immunoregulation (e.g., *IL6*), and the vitamin D receptor (148, 149).

### Immune Responses

Individuals who develop symptomatic RV illness have a prompt inflammatory response, with elaboration of inflammatory mediators and PMN infiltration. Whether these inflammatory responses help to control the infection is uncertain. Peak virus shedding occurs at approximately the same time as the peak of symptoms, and virus concentrations in secretions fall coincidentally with the resolution of symptoms. Low levels of virus shedding can continue for 2 to 3 weeks, however, and the termination of viral shedding and protection from subsequent infection are most closely correlated with the appearance of neutralizing antibody. Serum neutralizing antibody titers rise in 40% to 80% of persons following natural or experimental RV infection, depending on the serotype involved. The reason for the differences in antigenicity of the various RV serotypes is unknown. Studies using serial specimens collected from the same individuals have shown that serum neutralizing antibody can persist for years. Serum neutralizing antibody levels of  $\geq 8$  are associated with good protection following natural exposure in the home, and levels of  $\geq 16$  are generally associated with solid immunity.

Although it appears that neutralizing antibody is important in elimination of RV shedding from nasal secretions, recovery from illness and the initial reduction in the viral load in nasal secretions occur before specific antibody appears. Type I interferons likely contribute but are detected in the nasal secretions during only one third of infections. Preinfection gamma-interferon concentrations are inversely correlated with both severity of illness and duration of virus shedding during experimental colds (150). Type III interferons are more readily detected in nasal secretions and have anti-RV effects *in vitro* (151), but their role in clinical illness is not well understood.

Several mechanisms for antibody-mediated neutralization of RVEs have been proposed, including aggregation, virion stabilization, induction of conformational changes, and abrogation of cellular attachment (58, 59). Taken together, numerous biochemical and structural studies suggest that neutralization of RV *in vitro* results from steric blockage of the interaction between the virus and its receptors due to the binding of the antibody molecules on the virion surface (59).

The relative importance of serum versus nasal neutralizing antibody for protection has been difficult to determine, because serum antibody is found in close association with nasal antibody. The ratio of nasal to serum antibody following recent infection is in the range of 1:2. Over time the ratio falls to the range of 1:16, apparently because nasal antibody concentrations decline more rapidly than in the serum.

The dynamics and the role of neutralizing antibody during acute illness vary depending on the antibody status of the host. During the acute phase of RV colds, there is considerable transudation of serum proteins into nasal secretions (152). In seronegative persons, RV neutralizing antibody appears in serum and nasal secretions approximately 2 weeks after onset of infection. The neutralizing activity is present in the immunoglobulin A (IgA) and IgG antibody classes, as well as in IgM in early infection. Neutralizing titers rapidly increase during the third and fourth weeks, at which time viral shedding in nasal secretions is no longer detectable (125).

Investigations into cellular mechanisms of innate immunity against RVs indicate that epithelial responses can be initiated by engagement of cell surface receptors to the virus (153, 154), detection of intracellular viral RNA (e.g., PKR, TLR3, and RIG-I) (144, 155, 156), and activation of proinflammatory signaling cascades (e.g., NF $\kappa$ B, p38 MAP kinase) (153, 157). The net result of these processes is increased transcription and production of intracellular antiviral effectors, as well as a host of secreted cytokines, chemokines, interferons, and mediators (158, 159).

### Mechanisms of RV-Induced Exacerbations of Asthma

Several factors contribute to the pathogenesis of virus-induced exacerbations of asthma. More severe colds generally provoke exacerbations of asthma (118). Accordingly, RV-A and RV-C cause greater severity of illness compared to RV-B (96, 160), and are more likely to be associated with exacerbations of asthma (20, 161). As in COPD, RV infections in individuals with asthma are often followed by overgrowth of bacterial pathogens, and the combination of RV infection and detection of bacterial pathogens is associated with an increased risk for exacerbation of asthma (162). Whether secondary effects on airway bacteria contribute to the pathogenesis of airway obstruction and clinical symptoms remains to be determined.

Host factors are also important, including allergic sensitization (163), eosinophilic inflammation (138, 164), type 2 inflammatory responses (e.g., IL-5, IL-13, IL-33) (118, 165, 166), and epithelial interferon production (167). The combination of allergic sensitization and allergic exposure increases the risk for exacerbations (168). Interestingly, allergies that are associated with fall exacerbations, most often caused by RVs, are perennial allergens such as dust mite and cockroach instead of fall seasonal allergies (169).

The strong relationship between respiratory allergies and exacerbations of asthma has led to a number of studies into potential mechanisms of synergy between these two factors. There is evidence that respiratory allergies may inhibit interferon responses of blood dendritic cells and monocytes (170, 171). In addition, allergy can interfere with antiviral responses by affecting transcription factors (e.g., suppressor of cytokine secretion-1, FoxA3) that influence cell differentiation and the antiviral response (172, 173). Recently, in children susceptible to exacerbation, treatment with omalizumab, which blocks attachment of IgE to high-affinity IgE receptors, demonstrated that focused inhibition of IgE led to improved blood cell virus-induced interferon responses and reductions in total and virus-induced exacerbations of asthma (174, 175).

### CLINICAL MANIFESTATIONS

The major clinical syndrome associated with RV infection is rhinosinusitis, which is traditionally characterized as “the common cold.” RV colds frequently begin as a sore or scratchy throat that is followed closely by development of nasal obstruction and rhinorrhea. Over the course of the illness, the signs and symptoms of RV colds typically include various combinations of sneezing, rhinorrhea, nasal obstruction, facial pressure, sore or scratchy throat, hoarseness, cough, headache, malaise, and feeling chilly or feverish. Cough occurs in approximately 30% of colds; it frequently appears after the onset of nasal symptoms and often persists longer. The clinical features of RV colds are similar in adults and older children. Infants and young children may at times display only mucus discharge from the nose. In addition, infants more likely to have fever, which is uncommon in infected children and adults, and less likely to have asymptomatic infection (116, 176).

The median length of natural RV colds is 7 days, with approximately one fourth lasting 2 weeks. However, their duration is quite variable and has ranged from 1 to 33 days in prospective epidemiological studies (177). Resolution of the most severe symptoms occurs quite rapidly in most cases, and lingering minor symptoms generally account for the prolonged duration of illness reported by some individuals.

### Acute Sinusitis and Otologic Changes

RV has been recovered from sinus aspirates of patients with acute community-acquired sinusitis, and RV RNA has also been detected in brushings from the sinus cavities of similar patients. Sinus imaging studies show that sinus involvement is an inherent feature of colds; thus, a RV cold is a viral rhinosinusitis. In young adults with early self-diagnosed common colds, sinus cavity abnormalities have been observed on computed tomography in up to 87% of patients (178). These individuals recover from their illness without intervention.

RV infection also results in abnormalities of the eustachian tube and middle ear (179, 180). Abnormalities in middle ear pressures are seen in 40% to 75% of volunteers with experimental RV colds and 72% to 76% of patients with natural RV colds, sometimes in association with middle ear effusions. RV has been recovered alone and in combination with bacteria in middle-ear fluids from 24% of patients with otitis media (181). It is unclear whether viral invasion of the middle ear is required for the development of the eustachian tube and middle ear abnormalities.

### Laboratory Abnormalities

Routine laboratory tests are not useful in the clinical evaluation of patients with suspected RV colds. During experimental RV infection, there is a modest increase in blood neutrophils, and a moderate elevation of the erythrocyte sedimentation rate in some volunteers. A predominance of PMN in the nasal secretions is characteristic of uncomplicated colds and does not aid in the diagnosis of bacterial superinfection. Nasal resistance is increased and nasal mucus transport times are mildly decreased in patients with natural and experimental RV colds. Because sinus and nasal cavity computed tomography scans show abnormalities (178), the latter tests are not appropriate or useful in the clinical management of patients with RV colds.

### Complications

#### Acute Bacterial Sinusitis

The incidence of secondary acute bacterial sinusitis is difficult to ascertain given the changes that occur in the sinuses in uncomplicated RV colds. Various reports have estimated that 0.5% to 8% of viral colds are complicated by bacterial sinusitis. The factors leading to secondary bacterial invasion of the sinus cavity during colds are incompletely understood. Nose blowing propels nasal secretions into the sinuses, and occlusion of the ethmoid infundibulum in many patients with colds may trap nasopharyngeal bacteria in the sinus cavity, thus leading to secondary bacterial infection.

#### Acute Bacterial Otitis Media

Acute bacterial otitis media complicates an estimated 2% of colds in adults and up to 30% of colds in children. A high incidence of eustachian tube dysfunction during the common cold has been reported, and bacteria presumably reach the middle ear by a mechanism similar to that described above for sinusitis.

#### Exacerbations of Chronic Obstructive Lung Disease (COPD)

Up to 40% of exacerbations of COPD have been associated with respiratory viral infections, most commonly caused by RV (182, 183). The episodes are characterized by fever,

increased purulence of the sputum, and worsening of ventilation. Transient decreases in pulmonary function have occurred in patients with chronic obstructive pulmonary disease experiencing natural RV colds and following experimental inoculation with RV (184, 185). The pathogenesis of these abnormalities likely involves direct viral invasion of the large airways, which may facilitate overgrowth of proteobacteria including bacterial pathogens such as *H. influenzae* (186).

#### Exacerbations of Asthma

RV is the principal virus implicated in precipitating asthma attacks in older children and adults and is associated with 60% to 90% of the asthma exacerbations in children (187, 188). Both a fall peak of asthma exacerbation and the fall increase in the incidence of RV infection have been reported in association with the start of the school year (102, 104). RV is particularly important in precipitating episodes of asthma in children over 2 years of age, in whom the infection is often associated with allergen-specific IgE (163), and the timing of the asthma peak may be due to a convergence of RV infection spread among schoolchildren and seasonal allergen exposure (168).

#### Other Lower Respiratory Syndromes

RV is often detected in upper airway secretions in children with pneumonia (20, 189, 190). RV-associated lower respiratory syndromes are most common in very young children, and RV is the second most common pathogen associated with infant bronchiolitis (191, 192). RV-C and RV-A are more likely associated with lower respiratory symptoms than RV-B (20). Given the difficulty in obtaining lower respiratory specimens, it is uncertain how often RV is a sole pathogen vs. serving as an initiating factor for secondary bacterial infections. In wheezing infants, RV has been detected in lower airway biopsies, and RV detection was associated with reduced lung function in these infants (193). One study reported that 24% of children with pneumonia had RV detected in the upper respiratory tract by RT-PCR (189), although over one half of these patients had evidence of a concurrent bacterial infection. Seasonal trends for invasive pneumococcal disease in young children correlate with RV prevalence, suggesting an interaction (194). In adults, RV is the virus most often detected, either alone or more commonly associated with a bacterial pathogen, in patients requiring ventilation for severe pneumonia (195, 196).

RV infections have also been implicated in exacerbations of chronic lung symptoms in cystic fibrosis (CF) (197, 198). Lower airway antiviral responses may be impaired in CF, as viral load in lower airway secretions in CF exceeds that of samples from patients with asthma, or samples from normal individuals (199).

#### Infections in Immunocompromised Patients

RV infections can be problematic in adults and children with immune deficiencies or in those who are immunosuppressed following bone marrow or organ transplantation (200, 201). For example, weekly surveillance of 215 patients following bone marrow transplantation demonstrated a cumulative incidence of RV infections of 22% in the first 100 days following transplantation (202). Prolonged viral shedding was detected in 6 of 45 patients, but only 2 developed lower respiratory illness. Furthermore, persistent infection of the lower respiratory tract with the same RV type can occur

(203), and viral load correlates with severity of symptoms in immune compromised individuals (204). Adults with X-linked agammaglobulinemia (XLA) have more frequent and prolonged infections and illnesses with RV, even when taking appropriate immunoglobulin replacement (205). BTK, which is the defective gene in XLA, contributes to signaling through TLR8, which detects intracellular single-stranded RNA. This may explain the increased susceptibility of patients with XLA to infections with both RVs and enteroviruses (205).

When RVs are detected in lower airway secretions, interpretation of the virology should be tempered by knowledge of the high prevalence of RV in the general population, the potential for contamination of the lower airway specimens by upper respiratory secretions, and the possibility of concurrent infection with a respiratory pathogen, lending support to the concept that the virus can cause prolonged viral shedding and clinically meaningful infections in the context of immune suppression.

### CLINICAL DIAGNOSIS

Colds are familiar to everyone, and the illness is usually self-diagnosed before the patient seeks medical attention. The physical findings in the common cold are limited to the upper respiratory tract. Increased nasal secretion is frequently obvious, and a change in the color or consistency of the secretions is common during the course of the illness and is not an indication of sinusitis or bacterial superinfection. Examination of the nasal cavity may reveal swollen, erythematous nasal turbinates; however, this finding is non-specific and of limited diagnostic usefulness.

Colds are different from episodes of allergic rhinitis; persistent sneezing, thin nasal discharge, watery eyes, and sensation of mucosal itch are more common in the latter. Also, other symptoms of colds such as sore throat, cough, malaise, and headache are less common with allergic or vasomotor rhinitis. When viral culture and nasal smear eosinophilia were used as criteria for diagnosis, colds could be reliably distinguished from allergic rhinitis in adults.

The clinical features of RV infection do not allow reliable differentiation from respiratory infections caused by other viral pathogens. Knowing the seasonal prevalence of the different respiratory viruses helps in suspecting the specific viral etiology of a cold, but a firm diagnosis depends on viral culture or serology, which is usually not practical or necessary for routine patient care.

Distinguishing the rhinosinusitis of an RV cold from a secondary acute bacterial sinusitis is often difficult. Two clinical presentations of acute bacterial sinusitis can be recognized. First, the classical features of acute bacterial sinusitis include fever and facial pain, swelling, or tenderness. There may also be maxillary toothache if the infection is of dental origin. The features of this presentation, while specific, are often not present and thus lack sensitivity. The second and more common presentation of acute bacterial sinusitis is that of an acute respiratory illness which begins as a cold or "flu" but lasts longer than expected. Most natural RV colds have ended by 12 to 14 days, and almost all colds have improved by the second week of illness (177, 206). Therefore, the diagnosis of secondary bacterial sinusitis should be suspected in acute respiratory illnesses that have not improved or are worse after 10 days. Radiographic imaging for diagnosis of bacterial sinusitis is of limited utility (178), and the imaging abnormalities seen with viral and bacterial sinusitis are often indistinguishable.

## LABORATORY DIAGNOSIS

### Virus Isolation

Human RVs are found in airway secretions, with the highest concentration in nasal fluids. Specimens used for viral culture have been primarily deep nasal swabs or nasal washes. Specimens of respiratory secretions intended for RV culture should be placed in a viral collecting broth that contains proteins, for example BSA, to prevent virus loss due to nonspecific adsorption to plastic or glass surface of the vials.

Historically, cell culture has been the standard method for RV isolation and propagation. Most work has been done in diploid strains of human embryonic lung cells (WI-38 and MRC-5) (83). Diploid fetal tonsil cells and heteroploid cell lines such as HeLa have also been used. Different lots of these cells may vary 100-fold or more in their sensitivity to RV for unknown reasons. RV-C will grow only in sinus organ culture, fully differentiated cultures of primary airway epithelial cells, or in cells engineered to express CDHR3. Therefore, cell cultures should be selected and monitored for sensitivity when used for growing RV.

Most RV types grow best at temperatures of 33–34°C under conditions of motion (e.g., roller drum). Cytopathic effect is readily apparent in sensitive cells (Fig. 6). The 50% human infectious dose (HID<sub>50</sub>) and the 50% tissue culture infectious dose (TCID<sub>50</sub>) are essentially the same for RV in limited testing (207). One TCID<sub>50</sub> per 0.5 ml of inoculum was sufficient to cause a productive infection in human without preexisting antibodies (208).

### Antigen Detection

Fluorescent antibody and immunoperoxidase methods for detecting RV antigen have been used in experimental studies. However, these techniques are generally serotype specific. Because of the relative difficulty of growing RV in cell culture and the low concentration of RV in respiratory secretions, these methods have not been adapted for clinical use. Immunodetection assay for RV is not commercially available.

### Nucleic Acid Detection

RT-PCR-based molecular assays have become the standard tools for the detection, identification, and quantification of RVs in clinical specimens because they are more sensitive and faster and easier to perform than traditional culture-based and serological methods. The 5' NTR of the rhinoviral genomic RNA has several short stretches of sequence that are highly conserved among all RVs. The PCR primers based on these conserved sequences can be used for sensitive and specific detection of RV-A–B, and -C as a group (209, 96). However, these PCR primers also detect closely related enteroviruses (e.g., EV-D68) which can also cause some respiratory illnesses (209). High throughput multiplex RT-PCR assay kits, such as xTAG RVP (Luminex Corporation) and FilmArray RP (BioFire Diagnostics), are commercially available for the detection of RV/enterovirus and other common respiratory viruses in clinical specimens (91, 210, 211). Molecular typing assays have also been developed for rapid identification of individual RV-A, -B serotypes, or RV-C types in clinical samples (25, 96, 212, 213). These assays use very sensitive and specific two-step PCR method to amplify a 390-bp variable region in the 5' NTR or a 640-bp region of the capsid protein genes VP4-VP2 of the rhinoviral genome for direct sequence determination. The type is then determined by phylogenetic comparisons of the resulting sequences to corresponding reference sequences of the 150 known RV

types (213). The 5'NTR assay is very sensitive. It detects as low as 10 copies of RV cDNA per reaction. The VP4-2 assay is about 80% as sensitive as the 5'NTR assay, and is useful for confirming the typing results of the 5'NTR assay (96). In addition, real-time quantitative (q) PCR methods also been established to measure viral loads of all known RV-A and—B serotypes and some RV-C types (213).

*In situ* hybridization using RV-specific probes has been used to locate the anatomic sites and cell types which support viral replication in the airways of infected subjects (119, 124), making it a useful technique to study pathogenesis.

### Serologic Assays

Viral neutralization assay is the standard serologic method for RV-A and -B viruses (207), and these techniques are under development for RV-C. Complement fixation and hemagglutination tests have been developed but have not proven useful. The neutralization assay is used to identify specific viral serotypes and to measure antibody in human serum and nasal secretions. Viral shedding is a more sensitive indicator of infection than serological response with experimental RV infections (207). However, in some studies of natural infection, either procedure alone identified two thirds of the total diagnosed infections, and in family studies, 20%–40% of infections were detected only by serological assays.

Hyperimmune RV antisera have been produced in several animal species (207). Antiserum preparations from goats and calves have contained cytotoxic substances not found in rabbit and guinea pig preparations. Identification of RV serotypes in epidemiologic studies has been accomplished using antiserum pooled by a combinatorial method that has been adapted to a microtitration system. To measure RV neutralizing antibody in human serum and nasal washes, a small inoculum (3.2–16 TCID<sub>50</sub>) of virus should be used in a neutralization assay to provide sufficient sensitivity to detect the relatively low concentration of antibody in these specimens (215). ATCC has a collection of antisera against 89 RV-A and -B serotypes.

A major problem with using the neutralization assay for diagnosis is the existence of 100 RV-A and RV-B serotypes, as well as difficulties with culturing RV-C types. Thus, serological diagnosis is practical only when the serotype of the infecting virus is known or suspected, such as in experimental virus challenge studies or in family studies where a RV has been recovered from a family member.

## PREVENTION

The only source of RV is the human airway and possibly sites in the environment contaminated with virus-containing nasal secretions. Thus, it may be possible to lower the risk of infection by avoiding exposure through modifying personal behavior (handwashing, avoiding contacts when infected) and by selected environmental measures. Eradication of virus contaminating the hands by use of virucidal agents is an attractive approach to prevention of RV infection; however, trials with virucidal agents have not led to commercial products (216, 217). Commonly used hand sanitizers containing 62% ethanol are effective for removing RV from the hands (218).

Hope for the development of a common-cold vaccine was considerably reduced when the large number of common-cold viruses was discovered in the 1950s and 1960s. The application of new technology to identify shared B-cell

epitopes among RV types has led to renewed interest in an RV vaccine (219–222). To date, immunization of mice with cross-reactive epitopes has led to a limited breadth of cross-protection (220). There are also some shared T-cell epitopes among RV types (223), and some evidence that T-cell proliferative responses confer some protection against illness (224).

Chemoprophylaxis of RV infections is an important goal, especially for young children, the elderly, and patients with chronic respiratory disease. Progress in the development of antiviral medications that could be suitable for prophylactic use is described in the next section.

## TREATMENT

### Symptomatic Therapies

The current treatment of RV-associated illness relies on remedies directed at specific symptoms. For common colds the efficacy of treatments for nasal obstruction, rhinorrhea, and the pain symptoms (i.e., sore throat and headache) has been demonstrated in studies done with adults (225). Attempts to demonstrate beneficial effects of these agents in children have failed, although it is not clear whether this failure is due to a lack of effect in children or simply due to the difficulty in assessing subjective symptoms in this population.

Adrenergic agents given either by topical intranasal administration or orally have demonstrable effects on nasal obstruction. Topical administration of phenylephrine, oxymetazoline, or xylometazoline produces a prompt and marked reduction in nasal obstruction, with a gradual return to the baseline over a period of several hours. The use of these agents may be associated with nasal irritation, and prolonged use may be associated with rebound nasal obstruction. Although there has been no systematic comparison of the effect of topical and oral adrenergic agents on the nasal obstruction associated with the common cold, the oral agents produce about a 20% reduction in obstruction severity, compared to about 80% with the topical agents. The oral agents may also be associated with systemic side effects, including irritability and insomnia, and are contraindicated in children.

Rhinorrhea can also be treated topically or systemically. The first-generation antihistamines are the most commonly used treatment for runny nose and reduce rhinorrhea severity by approximately 25%. The effect on rhinorrhea appears to be related to the anticholinergic effects of the first-generation antihistamines, since the second-generation (nonsedating) antihistamines that have reduced anticholinergic side effects have no effect on colds. Sedation is a major side effect of the first-generation antihistamines and can be incapacitating for some individuals. Ipratropium bromide is a topical anticholinergic agent that is marketed for treatment of rhinorrhea and has effects comparable to those of the first-generation antihistamines. Nasal irritation and occasional bloody nasal mucus are side effects.

Cough associated with the common cold is frequently bothersome, but there are no satisfactory treatments for this symptom. Treatment with the antitussives codeine and dextromethorphan has not been shown to have a clinically significant effect on cough in colds (226).

Although some of these symptomatic treatments appear to have beneficial effects on common-cold symptoms, there is no evidence that the use of these treatments will have an impact on complications. The use of symptomatic therapies

in children is not recommended given the inability to demonstrate beneficial effects in this population as well as the potential side effects associated with their use. Notably, the FDA has prohibited marketing of combination cough and cold medications for children due to reports of toxicity with overdoses and even in a small number of children receiving standard doses of these medications.

### Other Remedies

The lack of specific therapies, concern about the relative risk of symptomatic treatments, and the relatively benign nature of the common cold have produced popular and commercial interests in the use of alternative medicines for treatment of this illness. Many different nonconventional remedies have been promoted, but few have been subjected to rigorous scientific evaluation. Vitamin C and zinc have been studied extensively; however, meta-analyses found no significant effects on either prevention or treatment (227, 228). Furthermore, intranasal zinc was taken off the market for treatment of colds due to association with anosmia (229). Likewise, clinical trials of oral echinacea or topical iota-carrageenan nasal spray have provided no evidence of efficacy against colds (230–232). Probiotics reduced the rate of RV illnesses in a double-blind, placebo-controlled trial involving preterm infants (233), but had no significant benefit when administered to adults who were experimentally inoculated with RV (234). Treatment with topical corticosteroid can lead to prolonged RV shedding but has no clinically significant effects on cold symptoms (235).

### Antiviral Treatment

A variety of antiviral approaches to prevent or treat RV infections have been studied, but no antivirals are currently approved for the treatment of RV infections in the United States. The failure of this effort to produce useful antiviral therapies is due, in part, to the fact that RV colds are self-limited and of short duration. As a result, treatments for the common cold must be rapidly effective, inexpensive, and virtually without toxicity or side effects.

Interferons, given as either prophylaxis or treatment for RV infections, have been studied extensively. Recombinant alpha-interferon given intranasally either as seasonal prophylaxis or as contact prophylaxis was effective for prevention of RV colds but caused local side effects and was not effective when given as treatment after onset of symptoms (108, 236, 237). Inhaled IFN- $\beta$  has been tested as an approach to prevention of virus-induced exacerbations of asthma. Subjects with persistent asthma and a history of exacerbations provoked by colds were randomized to treatment with either nebulized IFN- $\beta$  or placebo within 24 hours of the onset of cold symptoms (238). Although IFN- $\beta$  treatment did not reduce asthma symptoms scores in the study population as a whole, exacerbation risk was reduced in participants with more severe asthma. Larger trials are underway to determine whether inhaled IFN- $\beta$  could be useful for preventing asthma exacerbations induced by colds in patients with more severe asthma.

Capsid-binding agents bind in a pocket below the “canyon” region of the virion act by altering the conformation of the canyon to prevent receptor binding and/or by stabilizing the capsid and preventing uncoating. Compounds exhibiting this mechanism of action include a variety of isoxazole derivatives, flavonoids, pyridazines, and others. Pleconaril was the most extensively studied of these compounds. In large phase 3 clinical trials, an oral formulation of this drug reduced the total duration of colds by about 1 day and

reduced symptom severity by about 19% (239). This drug was not approved for use as a common-cold treatment by the U.S. Food and Drug Administration because of safety concerns related to induction of cytochrome P450 3A isoenzymes. Vapendavir is a newer capsid binding agent that is now being tested for effects on virus-induced exacerbations of asthma (240). Decoy soluble ICAM-1, antibody to ICAM-1, 3C protease inhibitors, interferon inducers, and the benzimidazole derivative enivoxime have all been studied as common-cold treatments, but none of these has yet been developed into an effective product for prevention or treatment of the RV infection.

# Hepatitis A Virus

SARA E. WILLIFORD AND STANLEY M. LEMON

## 48

Hepatitis A is an acute, self-limiting infection of the liver by hepatitis A virus (HAV), an enterically transmitted, hepatotropic member of the picornavirus family. Although HAV infection may occasionally result in fulminant hepatitis and death, it is not recognized to cause persistent infection or chronic hepatitis, even in severely immunocompromised individuals.

Reports of icteric disease in early Chinese literature and in the writings of Hippocrates may represent hepatitis A, but the disease discussed cannot be distinguished reliably from jaundice due to other causes (1). The earliest documented outbreaks of probable hepatitis A occurred in soldiers in Europe in the 17th and 18th centuries. Hepatitis A has plagued military campaigns throughout history, and many of the earliest terms used to describe the disease, like *kriegsikerterus* and *jaunisse des camps*, reflect this close association (2).

Studies of hepatitis before and during World War II clearly established the existence of two distinct infectious forms of the disease, which later came to be known as hepatitis A and hepatitis B (3, 4). Experimental transmission studies defined the major features of hepatitis A: a relatively short incubation period (15 to 49 days), a fecal-oral mode of transmission, and long-lasting immunity that could be passively transferred. An animal model of HAV infection in marmosets was established by 1967 (5). The responsible virus was visualized in fecal extracts from adult volunteers in 1973 using immune electron microscopy (6), a finding that also resulted in a crude, but sensitive, test for antibody to HAV (anti-HAV). Viruslike particles approximately 27 nm in diameter were specifically aggregated by convalescent, but not preinfection, human sera (Fig. 1). The identification of HAV and the demonstration that infection could be transmitted to marmosets and tamarins, and, later, to seronegative chimpanzees ushered in a new era of research on hepatitis A that culminated in the propagation of the virus in cell culture (7), molecular cloning and sequencing of the viral genome (8), and the subsequent development and licensure of safe, effective vaccines (9, 10). Although the intensity of research on hepatitis A declined significantly following the licensure of effective vaccines, renewed interest in the virus has arisen because of its unusual alternative extracellular forms, circulating within the infected host in a quasi-enveloped form (eHAV) completely cloaked in host membranes, but shed in feces as a highly stable, naked, nonenveloped virion (11).

## VIROLOGY

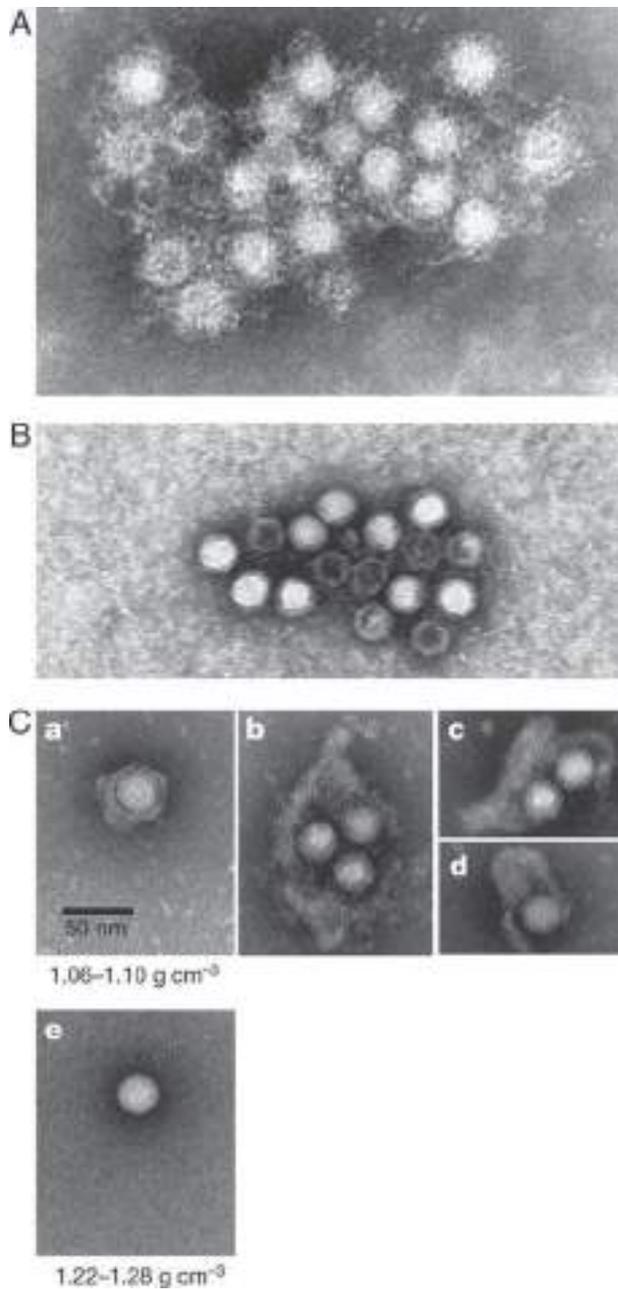

### Classification

Based on the structure of its capsid and the organization and sequence of its positive-strand RNA genome, HAV is classified as the type species of the genus *Hepatovirus* within the *Picornaviridae*, a large and diverse family of viruses that includes many other agents of medical and veterinary importance. Although HAV shares many features in common with other members of this family, very limited nucleotide sequence relatedness (12) and several attributes specific to HAV (13) distinguish it from other picornaviruses and warrant its classification in a separate genus. Other viruses classified within the hepatoviruses include HAV strains recovered from nonhuman primates and viruses identified recently in bats, hedgehogs, shrews, and rodents, some of which appear to share antigenic determinants with human HAV (14).

### Physical Characteristics of HAV

#### Genome Organization

The single-stranded, messenger-sense RNA genome of HAV contains a single, long, open reading frame (ORF) flanked by both 5' and 3' untranslated RNA segments (UTRs) (Fig. 2). It lacks the 5' m<sup>7</sup>G cap structure typical of host mRNAs, and is instead covalently bound at its 5' end to a virus-encoded protein termed VPg (3B) (15). As with other picornaviruses, VPg likely serves as a protein primer for RNA synthesis. The 5'UTR contains a high degree of secondary and tertiary RNA structure that has been defined by a combination of phylogenetic analyses, functional genetic studies, and direct biophysical and nuclease mapping techniques (16). This part of the genome contains both essential RNA replication elements and a highly structured segment that functions as an "internal ribosome entry site" (IRES) directing interactions of the RNA with 40S ribosomal subunits. The IRES drives internal initiation of viral translation in a 5' cap-independent fashion, bypassing multiple upstream AUG codons (16). Translation may initiate at either of two AUG codons at positions 735–737 and 741–743, although the second of these codons is preferred (17). Although cap independent, HAV translation requires most, if not all, eukaryotic translation initiation factors, and results in a polyprotein of approximately 2,227 amino acids residues

**FIGURE 1** Electron micrographs of HAV. (A) Immune electron micrograph of HAV particles from human stool reacted with convalescent serum. The particles are heavily coated with and aggregated by antibody. Both “full” and “empty” particles can be seen. (B) An immune electron micrograph showing particles from human stool reacted with a preinfection serum. The 27- to 28-nm particles are nearly devoid of antibody and some fine structure can be seen. (C) Quasi-enveloped eHAV particles (panels a–d) and a non-enveloped HAV virion purified by density gradient centrifugation from supernatant fluids of infected Huh-7 cell cultures. The density of the fractions containing the particles is shown below the images. (A) and (B) Reprinted from Richman DD, Whitley RJ, Hayden FG (ed) *Clinical Virology*, 3rd ed, with permission. (C) (Reprinted from reference 39 with permission of the publisher.)

that is proteolytically processed into both structural (P1) and nonstructural (2BC and P3) polypeptides (Fig. 2). Following a translation terminator sequence, the genome ends with a 3′ nontranslated region of 63 nucleotides followed by a poly(A) tail of variable length as is typical of picornavirus genomes.

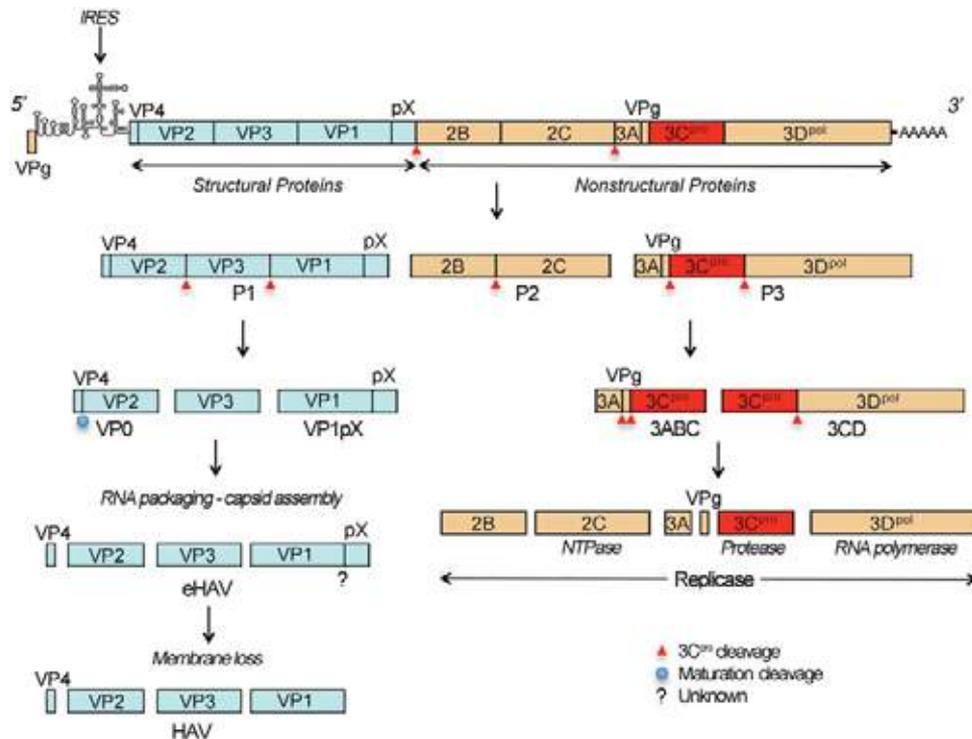

In addition to critical RNA structures within the 5′ and 3′ UTRs that have regulatory functions in the replication cycle, a large, conserved, complex stem-loop structure within the polyprotein-coding segment of the genome (3D region) functions as a *cis*-acting replication element (*cre*) (18). Similar *cre* elements are found in other picornaviruses, although in different regions of the genome, and function as RNA structures (see below) while also encoding proteins to be translated.

### Structural and Nonstructural (Replicase) Proteins

The primary cleavage of the polyprotein occurs cotranslationally between the VP1pX and 2B protein segments of the polyprotein, producing P1 (structural proteins) and P2-3 (nonstructural proteins) precursor polypeptides (Fig. 2). This cleavage is mediated by the only protease encoded by the virus, the 3C protein (3C<sup>pro</sup>) (19, 20). 3C<sup>pro</sup>, a cysteine protease (21), is responsible for all processing events in the polyprotein with the exception of scission at the VP4-VP2 junction—a late event following RNA packaging into the capsid and that may, in part, be catalyzed by RNA—trimming at the VP1-pX junction, mediated by one or more unknown host proteases (22, 23).

The P1 segment comprises four structural polypeptides in order from the amino terminus, VP4 (also known as 1A), VP2 (1B), VP3 (1C), and VP1pX (1D), named according to picornaviral convention, with VP1 being the largest (Fig. 2). The carboxy-terminal pX extension is found only in quasi-enveloped eHAV particles, and is absent in the mature, nonenveloped virion shed in feces (see below). Thus, the proteins in the mature naked capsid are approximately 23, 222, 246, and 273 amino acids in length, respectively. While pX is often referred to as “2A,” this segment of the polyprotein lacks homology with any other picornaviral 2A proteins (indeed, with any other protein in the database), and does not possess the *cis*-active protease activity found in the 2A proteins of other picornaviruses. pX functions in capsid assembly and is present in early assembly intermediates (24–26), and is thus best considered a part of the structural protein complement of the virus (i.e., P1 segment). VP4 (1A) is substantially smaller than its homologs in other picornaviruses, but recently has been confirmed to be present in the HAV capsid (27).

Each of the nonstructural proteins derived from the P2-P3 segment of the polyprotein is likely to contribute to assembly of a membrane-bound viral replicase complex that is responsible for synthesis of new RNA genomes. Unlike other *Picornaviridae*, HAV has no nonstructural 2A protein. 2B and 2C, and probably the unprocessed precursor 2BC, are involved in directing rearrangements of cellular membranes required for replicase assembly (28, 29). The 2B protein is very hydrophobic, and may anchor the replicase complexes to altered intracellular membranes (28). On the other hand, 2C has NTPase activity and contains a helicase motif. The P3 nonstructural proteins include an RNA-dependent RNA polymerase (3D<sup>pol</sup>), the cysteine protease (3C<sup>pro</sup>), and 3B (VPg), the protein primer for RNA synthesis. VPg is likely to be doubly uridylated in a slide-back reaction templated by the RNA *cre* and catalyzed by 3D<sup>pol</sup> and 3CD (30). It remains covalently linked to the 5′ end of both positive- and negative-strand RNAs, but is probably stripped from the

**FIGURE 2** HAV genome organization and polyprotein processing cascade. The positive-strand RNA genome of HAV is approximately 7.5 kilobases (kb) in length and contains a single long open reading frame (ORF, box) flanked by relatively short 5' and 3' untranslated regions (UTRs, solid lines) as shown. The 5' UTR is covalently linked at the 5' end to the genome-linked protein VPg (otherwise known as 3B), and contains a highly structured internal ribosome entry site (IRES) that drives 5' cap-independent translation of the polyprotein encoded by the ORF. The 3' UTR terminates in a lengthy poly(A) sequence. The HAV polyprotein is co- and posttranslationally processed by the viral protease 3C<sup>pro</sup> (red box) that cleaves the polyprotein and its derivatives at sites indicated by the red triangles, producing both the structural (P1, turquoise) and nonstructural proteins (P2+P3, tan and red) that go to form the capsid and replicase complex, respectively. Yet-to-be-identified protease activities cause a final maturation cleavage in the VP0 (VP4+VP2) capsid protein, and trim the C-terminal pX domain off of VP1, during late stages in viral maturation.

positive-strand RNA by an unknown VPg unlinkase following viral entry and release of the genome into the cytoplasm. 3A contains a hydrophobic 21 amino acid stretch that is believed to anchor the 3ABC precursor of VPg to cellular membranes. Interestingly, the 3A transmembrane domain targets 3ABC to mitochondrial membranes, where it proteolytically cleaves mitochondrial antiviral signaling protein (MAVS), an important adaptor protein involved in the induction of interferon responses to virus infection (31).

### Virion Structure

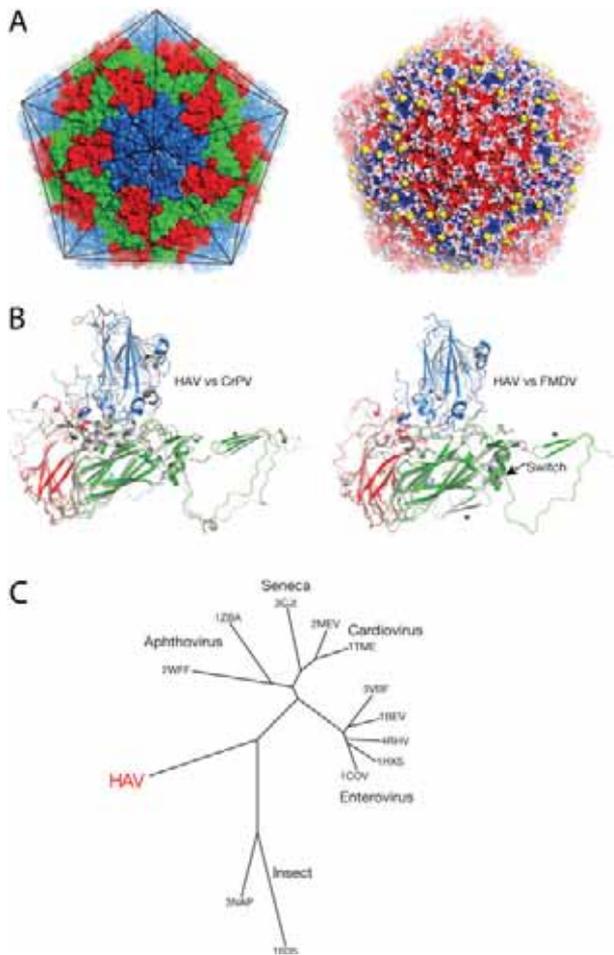

The viral genome is encapsidated within a stable icosahedral protein shell (the capsid) comprised of 60 copies of each of the four P1 polypeptides: VP1, VP2, VP3, and VP4. Mature virions purified from the feces of infected humans or chimpanzees band at 1.32 to 1.34 g/cm<sup>3</sup> in cesium chloride (CsCl) and sediment at approximately 160 S (32). Particles with lower density that band at about 1.27 g/cm<sup>3</sup> in CsCl and sediment at 70 to 80 S can often be detected in HAV preparations, and may represent empty capsids devoid of genomic RNA (32, 33) (Fig. 1). Unlike poliovirus and other well-studied picornaviruses, the smallest of the structural proteins, VP4, is not myristoylated at its amino terminus (34). Mutational studies suggest a noncanonical capsid assembly pathway that differs from that of other well-studied picornaviruses, with the 8-kDa carboxy-terminal pX extension on the largest capsid protein, VP1, playing a critical role

in assembly of pentamer subunits rather than VP4 as is the case with other picornaviruses (24, 25).

Recent X-ray crystallographic studies of formalin-inactivated virus (27) (Fig. 3) indicate that the surface of the capsid is relatively smooth, devoid of depressions present in other picornaviruses that serve to shield receptor-binding sites from antibodies. The protein chains within the capsid are organized like other viruses in the picornavirus family with the exception of VP2, the amino terminus of which is dramatically repositioned such that it interacts with adjacent pentamer subunits, potentially contributing to the high physical stability of the particle (see below). This “domain swap” recapitulates the capsid structure of insect cripaviruses that are distantly related to the picornaviruses, distinguishing HAV from other mammalian picornaviruses and suggesting an ancient evolutionary relationship (Fig. 3) (27).

### Antigenic Composition

HAV strains recovered from humans and from nonhuman primates appear to comprise only a single serotype worldwide (35), a fact that has important implications for the success of vaccines. However, neutralizing murine monoclonal antibodies (MAbs) do not recognize denatured capsid proteins, but only their completely folded native conformations within the capsid. Antisera raised to synthetic peptides or proteins expressed from recombinant DNA show only weak reactivity with native capsids and have very limited virus

**FIGURE 3** X-ray crystallographic structure of the HAV capsid. Overall structure of the HAV capsid as deduced from X-ray crystallographic studies of formalin-inactivated vaccine virus (27). (A) Left: Accessible surface of the capsid, showing residues contributed by VP1 as red, VP2 green, and VP3 blue (60 copies of each are present within one capsid). VP4 is internal and is not seen. Right: Electrostatic surface of the capsid; red=negative charge, blue=positive charge, white=neutral. Yellow dots are sulfate ions. (B) Overlay of folded VP2 structure of HAV with that of VP2 protein from (left) cricket paralysis virus (CrPV) and (right) the mammalian picornavirus, foot-and-mouth virus (FMDV), showing prominent domain-swap paralleling structure in the insect virus. (C) Structural phylogeny of the HAV capsid showing its intermediate position between that of other mammalian picornaviruses and distantly related viruses such as CrPV. (Reprinted from reference 27 with permission of the publisher.)

neutralization activity (36), ruling out the development of vaccines based on recombinant DNA technology.

Antigenic variants of HAV resistant to neutralizing MAbs have been selected by repeated passage of cell culture-adapted virus in the presence of these antibodies (37). These neutralization escape variants contain a limited set of substitutions in closely spaced neutralization epitopes in polypeptide loops within VP3 and VP1 (38). The critical neutralization epitopes of HAV are thus conformationally defined structures rather than linear epitopes, and involve residues of VP1 and VP3. The exact structure of these epitopes is now known from X-ray crystallographic studies (27).

Competition studies with various neutralizing MAbs suggest the existence of a single immunodominant site. Remarkably, a combination of only two murine MAbs is capable of efficiently blocking the binding of antibodies present in polyclonal human convalescent sera (38).

#### Quasi-enveloped eHAV Virions

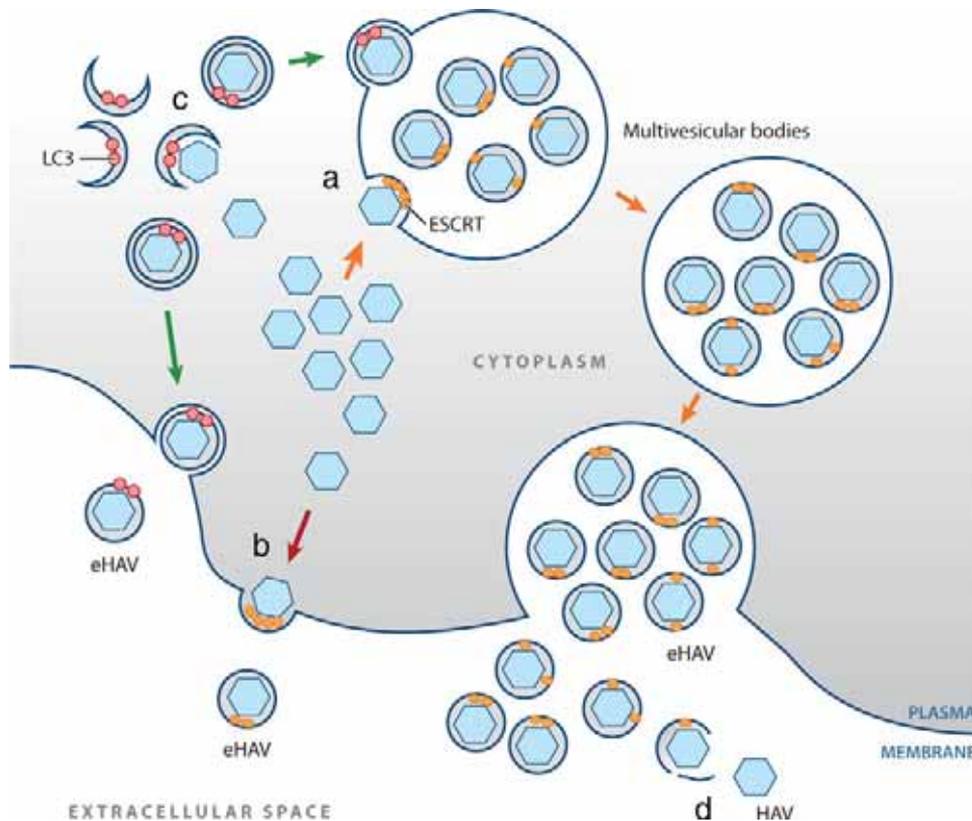

In addition to the nonenveloped, naked virions described above, HAV has been recognized recently to be released from cells noncytolytically, completely wrapped in host-cell membranes (39) (Fig. 1). The membranes enveloping the capsid in these particles appear to lack any virally encoded protein, distinguishing these “quasi-enveloped” virions (termed “eHAV”) from classic enveloped viruses that possess glycosylated viral peplomers on their surface (11). Nevertheless, these eHAV virions are fully infectious in cell culture, yet completely resistant to neutralizing antibodies targeting the capsid in standard infection focus-reduction assays due to the surrounding membranes. The biogenesis of eHAV appears to involve the recruitment of fully assembled, intracellular capsids by components of the cellular endosomal complex required for sorting (ESCRT) complex, and likely involves the budding of the capsid into multivesicular bodies (MVBs) that subsequently release their contents into the extracellular space at the plasma membrane (39) (Fig. 4). This process provides a mechanism for viral egress from the cell, allowing the virus to cross the plasma membrane without cell lysis, and may have many features in common with the biogenesis of exosomes.

Quasi-enveloped eHAV virions are readily separated from naked virions by isopycnic ultracentrifugation in density gradients. The capsid proteins present in eHAV differ from those in the naked virion in that VP1pX is incompletely processed, retaining its 8 kDa carboxy-terminal pX extension (39). pX is clipped off the particle following removal of the membrane with detergents.

Surprisingly, quasi-enveloped eHAV particles appear to be the only form of virus circulating in blood during acute infection, both in humans and in experimentally infected chimpanzees, whereas virus shed in stool is composed exclusively of naked, nonenveloped virions (39). It is likely that both types of virus are produced within hepatocytes, and that the eHAV membrane is lost during passage through the biliary system due to high concentrations of bile salts in the proximal biliary canaliculus. Interestingly, hepatitis E virus, an unrelated positive-strand RNA virus that also causes acute hepatitis, has evolved very similar alternative extracellular forms (11).

#### Genetic and Antigenic Diversity

Partial sequencing of the genomes of HAV strains recovered from human or nonhuman primate sources in widely separated geographical areas has revealed only limited genomic diversity (40, 41). Thus, primate-derived viruses are closely related genetically, especially when compared with the genetic diversity evident among other picornaviruses. Two major genotypes (I and III) have been described among these strains, as well as two minor genotypes (II and VII), whose nucleotide sequences differ from each other at 15% to 25% of base positions in the genomic region studied (VP1-2A junction). Three other genotypes (IV, V, and VI) each include a single simian HAV strain (41). Much greater diversity is evident among related viruses in bats, shrews, hedgehogs, and rodents, which show a 32.4% to 47.4% distance from human HAV in their amino acid sequences (14). These novel viruses have yet to be assigned to specific

**FIGURE 4** Biogenesis of quasi-enveloped eHAV virions (11). Several hypothetical mechanisms may account for the release of quasi-enveloped virions from hepatocytes. The most likely mechanism for eHAV biogenesis involves (a) the recruitment of assembled intracellular HAV capsids to cytoplasmic multivesicular bodies (MVBs) by protein components of the cellular ESCRT (Endosomal Sorting Complex Required for Transport) system such as ALIX, followed by the budding of capsids into MVBs such that they become enclosed in membranes within the MVB. Movement of the MVB to the plasma membrane and fusion of the outer MVB membrane and plasma membrane then delivers eHAV to the extracellular environment. Alternatively, (b) ESCRT-associated proteins might mediate release of eHAV directly at the plasma membrane. A third possibility (c) is that HAV capsids are engulfed in autophagosomes for transport to either MVBs or the plasma membrane. Loss of the eHAV membrane after egress from the cell (d) leads to the production of naked, nonenveloped virions. (Reprinted from reference 11 with permission of the publisher.)

genotypes, but they are close enough in sequence to human HAV to warrant their assignment to the *Hepatovirus* genus. A considerable number of distinct HAV strains have been entirely or nearly entirely sequenced (8, 14, 42–44). Multiple, cell culture–adapted variants derived from one human HAV strain (HM175) have also been fully sequenced, revealing genomic regions that undergo change during propagation in cell culture and may result in attenuation of the virus (42, 45–47).

HAV strains recovered from humans demonstrate high-level (90% to 95%) conservation in the amino acid sequences of the viral capsid proteins. Consistent with this finding, viruses belonging to distinct genotypes elicit antibodies with substantial cross-neutralizing activity, indicating that these viruses comprise only a single HAV serotype (35). Although some MAbs are capable of distinguishing unique epitopes that are variably present in strains of HAV isolated from humans or from naturally infected cynomolgus and African green monkeys (44, 48), simian and human strains of HAV demonstrate substantial antigenic cross-reactivity. This close antigenic relatedness may extend even to non-primate hepatoviruses, as some bat sera appear to recognize human HAV antigens (14). Given the distance between sequences encoding structural proteins, however, it seems

likely that at least some of these recently identified viruses comprise one or more additional HAV serotypes.

#### Stability and Resistance to Chemical Agents

In common with type C enteroviruses, the naked, non-enveloped HAV particle is stable at low pH (pH < 3.0) (49, 50). However, the thermal stability of HAV is considerably greater than that of enteroviruses (50, 51). Incubation of the virus for 4 weeks at room temperature results in only a 100-fold decrease in infectivity. Significant loss of infectivity starts to occur with exposure at 60°C for short periods and infectivity is destroyed almost instantaneously by heating above 90°C (52). However, outbreaks of hepatitis A have been reported following ingestion of partially cooked shellfish, suggesting that brief steaming may be insufficient to destroy the virus. In addition, HAV infectivity is highly resistant to drying, and infectious virus has been recovered from acetone-fixed cell sheets. It is also highly resistant to detergents, surviving a 1% concentration of sodium dodecyl sulfate, as well as to such organic solvents as diethyl ether, chloroform, and trichlorotrifluoroethane (50, 53). Solvent-detergent inactivation procedures thus do not reduce the infectivity of HAV, explaining why hepatitis A transmission has occasionally been associated with the administration of

high-purity clotting-factor concentrates that are devoid of antibody (54). These properties of the virus may contribute significantly to its ability to persist in the environment and cause common-source outbreaks.

HAV can be reliably inactivated by autoclaving (121°C for 30 minutes) and by exposure to hypochlorite (chlorine bleach) in concentrations of 1.5 to 2.5 mg/l for 15 minutes (53). Although chlorine is most commonly used to avoid HAV contamination in water, environmental surfaces can also be decontaminated by quaternary ammonium formulation containing 23% hydrochloric acid (toilet-bowl cleaner). Glutaraldehyde (0.50% for 3 minutes), iodine (3 mg/l for 5 minutes) and potassium permanganate (30 mg/l for 5 minutes) probably are also effective. HAV is also inactivated by short incubation (5 minutes at 25°C) in 3% formalin or in diluted formalin for 3 days at 37°C, and by ultraviolet irradiation (55, 56).

## Biology of HAV

### Host Range

Serologic studies and direct experimental challenge support the capacity of human HAV strains to infect chimpanzees and other old world primates, including vervet, rhesus, and cynomolgus monkeys, as well as several species of new world primates, including tamarins (*Saguinus* sp.), marmosets (*Callithrix* sp.), and squirrel (*Saimiri* sp.) and owl (*Aotus* sp.) monkeys. Chimpanzees have extensively been used as a model of human HAV infection (57, 58), as have marmosets (59) and owl monkeys (60). HAV has also been isolated from monkeys in the wild. Some simian strains have significant sequence variation and minor antigenic differences with human HAV (44, 61). Guinea pigs are susceptible to experimental infection, but replication is very limited and there is no pathology (62). Nonetheless, a much broader host range for hepatoviruses is indicated by the recent discovery of multiple HAV-like viruses among bats, shrews, hedgehogs, and rodents (14). Whether any are capable of infecting humans or nonhuman primates is not known.

### Growth in Cell Culture

HAV was first isolated *ex vivo* in marmoset liver explant cultures and was subsequently propagated in continuous fetal rhesus monkey kidney cells (7, 63). HAV can be propagated in a variety of different types of mammalian cells, including those of primate origin such as BS-C-1, FRhK-4, and MRC-5 cells (64, 65). However, wild-type viral strains from infected patients usually replicate very slowly and to relatively low titers in cultured cells, requiring weeks to months to reach maximal titers. With continued *in vitro* passage, the virus becomes progressively adapted to growth in cell culture, replicating more rapidly and achieving higher titers (65). Cell cultures of murine, guinea pig, porcine, or dolphin origin can also support HAV growth (66).

In contrast to the invariably transient nature of HAV infections in humans, infection of cultured cells is typically noncytopathic and commonly leads to long-term persistence of the virus in cells. This is consistent with the fact that HAV replication does not induce shutoff of cellular protein or nucleic acid synthesis as observed with poliovirus. However, highly cell culture–adapted variants of HAV that replicate very rapidly can cause cytopathic effects in culture, and can even be adapted to conventional plaque assays (47, 67). Cellular injury appears to arise from the induction of apoptotic pathways leading to programmed cell death (67). Continuous passage of the virus in cell culture may result in a reduction in the ability of the virus to replicate and cause

disease in primates (68). Adaptive mutations that permit HAV to replicate efficiently in cell culture include mutations within the IRES that enhance cap-independent viral translation in a cell-type–specific fashion and mutations within 2B that promote viral RNA replication in multiple cell types (69–72).

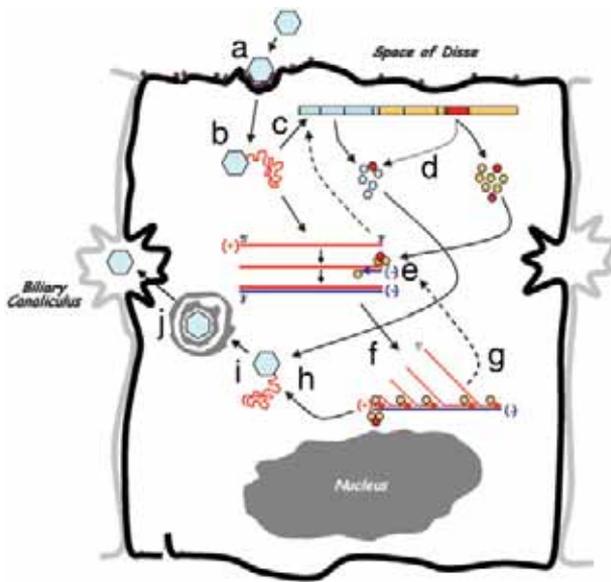

As with other positive-strand viruses, purified genomic RNA, whether extracted from virions or produced synthetically from cloned cDNA, is replication competent when transfected into permissive cultured cells (73). This characteristic has allowed for reverse molecular genetics studies that have elucidated many aspects of HAV biology. However, recovery of virus from synthetic wild-type RNA (in contrast to HAV RNA with cell-culture–adaptation mutations) is difficult in transfected cell cultures, and usually requires inoculation into the liver of susceptible primates (74).

### Viral Attachment and Cellular Entry

HAV enters cultured cells via two distinct mechanisms. Quasi-enveloped eHAV particles enter via an acidification-dependent endosomal pathway that entails very slow uncoating of the viral RNA, probably subsequent to dissolution of the enveloping membranes in a late endosomal/lysosomal compartment (39). Initial attachment is likely mediated through phosphatidylserine receptors, as the uptake of eHAV by plasmacytoid dendritic cells is reduced in the presence of annexin V (75). In contrast, entry of mature, nonenveloped virions occurs rapidly and is not inhibited by agents blocking endosomal acidification. A specific cellular protein, HAVCR1 (also known as TIM-1), a mucin-like glycoprotein, has been suggested to serve as a receptor for the virus (76, 77). HAV binds to the cysteine-rich, globular C-terminal extracellular domain of the protein (78). TIM-family proteins facilitate the entry of many enveloped viruses by mediating interactions with phosphatidylserine on the virion surface, suggesting a possible role in quasi-enveloped eHAV entry (79). However, HAVCR1 is widely distributed in different tissues, and the hepatotropic nature of HAV infection cannot be explained by this interaction. Although the hepatocellular asialoglycoprotein receptor has also been suggested to play a role in viral entry by mediating the uptake of IgA-virus complexes (80), it cannot explain initial infection of the liver before the development of antibodies. X-ray crystallography has revealed that the HAV capsid lacks a receptor interaction site similar to those found in other picornaviruses, and this finding has led to speculation that HAV may have a completely different mechanism of cellular entry (27). More studies are needed to define this aspect of the viral replication cycle.

### Translation and Replication of the HAV Genome

Following viral entry and release of the genome into the cytoplasm, the RNA undergoes translation under direction of the IRES, leading to expression of both structural and nonstructural proteins (Fig. 5). The nonstructural proteins (2BC) direct the reorganization of intracellular membranes into a tubular-vesicular membranous network within which they direct the synthesis of new viral RNAs (28, 29). The HAV IRES requires intact cellular initiation factor eIF-4G to function, which distinguishes it from other picornavirus IRES (81). Several cellular proteins, including poly-pyrimidine track-binding protein (PTB), significantly stimulate its ability to direct internal initiation of translation (82). Studies of other picornaviruses suggest that the virion RNA serves as a template for negative-strand RNA synthesis by the RNA-dependent RNA polymerase 3D<sup>pol</sup>, thereby

**FIGURE 5** HAV replication cycle. (a) HAV interacts with a cellular receptor (possibly HAVCR1/TIM-1) at the basolateral membrane of the hepatocyte, is internalized, and (b) the viral genome is released into the cytoplasm; (b) the positive-strand RNA genome is translated in a cap-independent IRES-driven manner, resulting in a polyprotein that is (d) proteolytically processed to generate nonstructural proteins involved in genome replication (2B, 2C, 3AB, 3D<sup>pol</sup>) and the protease (3C<sup>pro</sup>), as well as capsid proteins (see Fig. 2). Changes in intracellular membranes are induced by 2BC, resulting in assembly of the nonstructural proteins into a membrane-bound replicase complex that (e) directs the synthesis of a complementary minus-strand RNA intermediate (blue) that is then used as template to (f) generate multiple new copies of positive-strand RNA (red). These newly synthesized positive-strand RNAs can (g) be directed to engage in additional translation or RNA synthesis or (h) packaged into capsids to generate intracellular viral progeny. These newly assembled viral particles (i) are recruited to multivesicular bodies for ultimate release from the infected cells across either (j) the apical plasma membrane into the biliary canaliculus (as shown) or across the basolateral membrane into the hepatic sinusoids (not shown). (Adapted from Martin A, Lemon SM, *Hepatology* 2006 with permission of the publisher.)

generating a fully double-stranded duplex, which acts in turn to template the synthesis of multiple positive-strand RNA progeny (Fig. 5). As with poliovirus, 3B (VPg), the small genome-linked protein, is thought to function as a protein primer for viral RNA synthesis following its uridylation by 3C<sup>pro</sup> and 3CD in a reaction templated by the *cre* (18).

#### Virion Assembly and Release

Assembly of the HAV capsid differs significantly from the process followed by other picornaviruses. The C-terminal pX extension of VP1 is essential for the P1 capsid protein precursor to fold as required for efficient 3C<sup>pro</sup> processing and for assembly of pentamer subunits that contain five copies each of VP4-VP2, VP3, and VP1pX (24, 25). Twelve of these pentamers subsequently assemble into a complete capsid, thereby packaging newly synthesized RNA genomes and triggering the cleavage of VP4-2 to VP4 and VP2. This “maturation cleavage” is likely associated with a conformational rearrangement of the capsid proteins that stabilizes the final structure.

Current data suggest that these nascent VP1pX-containing virions are then recruited to MVBs through interactions with ALIX and probably other ESCRT-related proteins, acquiring a membrane as they bud into this compartment (39) (Fig. 4). Fusion of the outer MVB membrane with the plasma membrane then releases membrane-wrapped eHAV virions to the extracellular environment.

Several lines of evidence, including unpublished data from our laboratory, suggest that release occurs across both the apical (canalicular) and basolateral (liver sinusoidal) membranes of polarized hepatocytes (83, 84), with loss of the eHAV membrane mediated by high bile-salt concentrations in the proximal biliary canaliculus. The pX domain of VP1pX is subsequently trimmed off the particle, resulting in fecal shedding of naked HAV virions produced in the liver and secreted via the biliary tract, coupled with a viremia composed of quasi-enveloped eHAV virions. Large numbers of naked virions have been visualized in the bile of infected chimpanzees (85), supporting this scenario. However, an enteric site of replication for fecally shed virions cannot be ruled out.

## PATHOGENESIS

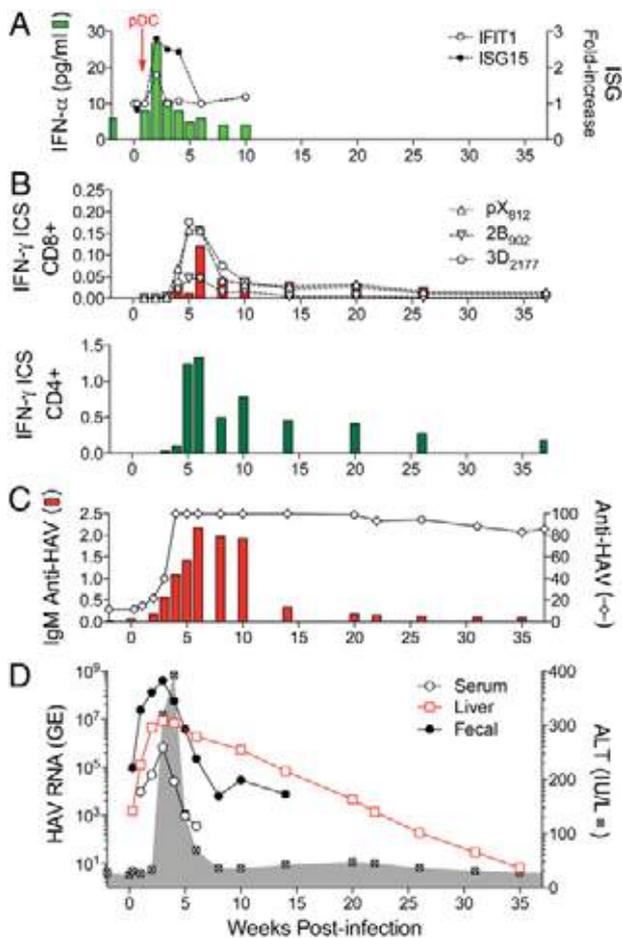

### Animal Models

Current understanding of the pathogenesis of hepatitis A comes largely from studies of experimentally challenged nonhuman primates. Many of these studies were carried out several decades ago and used currently outdated methods for detecting virus and assessing immune responses. However, recent detailed analyses describe HAV infection in two intravenously inoculated chimpanzees, and a third, cohoused animal that became infected by the natural fecal-oral route (57, 58, 75) (Fig. 6). Infection is self-limited in chimpanzees and other nonhuman primates and is generally similar to nonicteric infections in children rather than more severe presentations of hepatitis A in adults. Following inoculation intravenously or orally, a lengthy incubation period (2 to 5 weeks) is followed by the relatively abrupt onset of liver injury marked by elevations of ALT and inflammatory infiltrates within the liver. In tamarins, the duration of the incubation period (measured to the onset of elevated serum liver enzyme activity) correlates inversely with inoculum size, increasing by approximately 5 days for each log<sub>10</sub> reduction in dose (86). Progressively higher amounts of virus are found in serum and shed in feces throughout this phase of the infection (87). Both fecal shedding and the magnitude of the viremia begin to decline abruptly following the elevation of serum alanine aminotransferase (ALT), a measure of liver injury. Virus-specific antibodies first appear at this point in the infection (Fig. 6), which typically occurs several weeks after challenge. Laboratory parameters return slowly to normal over a period of 4–12 weeks, although, for reasons that are not understood, viral genomes persist within the liver in slowly decreasing quantities for months after infection in chimpanzees (57). It is not known whether the presence of this RNA indicates the persistence of infectious virus.

### Tissue Tropism

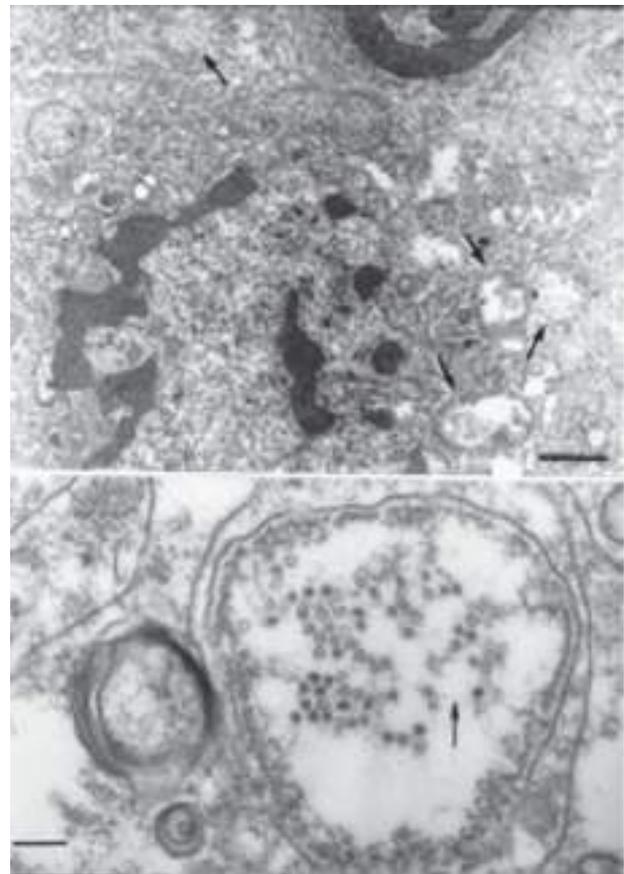

#### Liver

While there may be extrahepatic sites of replication of HAV (discussed below), pathology for the most part is restricted to the liver. HAV, like many other picornaviruses, is very organ specific, perhaps because of specific hepatocyte receptors or intracellular replication factors. Large amounts of virus are

**FIGURE 6** Composite graph depicting HAV infection in an intravenously inoculated, experimentally infected chimpanzee (105). (A) Innate immune response: minimal increases in serum IFN- $\alpha$  occur during the first weeks of the infection in association with the transient presence of plasmacytoid dendritic cells (pDCs) in liver sinusoids and minimal intrahepatic expression of interferon-stimulated genes (ISGs) such as IFIT1 and ISG15. These early responses diminish prior to the peak in viral replication. (B) Intracellular cytokine staining shows that the virus-specific CD4+ T cell response (bottom) is more robust than the virus-specific CD8+ T cell cytokine or tetramer-specific response (top), and that the CD4+ T cell response correlates better with viral control. (C) IgM and total anti-HAV antibody responses detected in enzyme-linked immunosorbent assays. The total anti-HAV is measured in a blocking assay, where 100% indicates high-titer antibody. (D) Relative viral RNA abundance (GE=genome equivalents) in serum, liver tissue, and feces determined by reverse transcription polymerase chain reaction assays. Results are layered onto serum alanine transferase values that show a sharp spike indicative of acute liver injury at 4 weeks post inoculation. present within the liver throughout the asymptomatic, prodromal, and acute phases of the infection (Fig. 6). Viral antigen has been identified by immunofluorescent microscopy and immunohistochemistry within hepatocytes and in tissue-resident macrophages (Kupffer cells) of experimentally infected nonhuman primates (88), whereas electron microscopy has revealed viruslike particles enclosed within membrane-limited vesicles in hepatocytes (89) (Fig. 7).

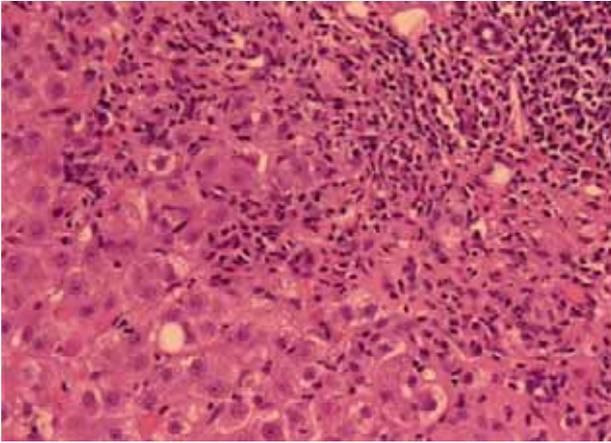

**FIGURE 7** Electron micrographs of a marmoset hepatocyte during acute hepatitis A. The arrows in the upper panel point to cytoplasmic vesicles containing probable HAV capsids. The lower panel is a higher powered view of one of the vesicles more clearly showing viruslike particles. Bar=500 nm in the upper panel and 100 nm in the lower. Courtesy of Yohko Shimizu.

While it is clear that antigen present in hepatocytes is indicative of active replication, antigen found in macrophages may reflect only the scavenger function of these cells.

In chimpanzees, low-grade, focal hepatocellular necrosis is observed in the early stages of the infection in chimpanzees (90), followed by more severe changes as serum ALT activity rises; these changes include increasing focal areas of necrosis in the lobular periphery and then throughout the hepatic parenchyma, coupled with widely scattered Councilman bodies, remnants of apoptotic hepatocytes. Periportal inflammatory cell infiltrates composed of lymphocytes and occasional polymorphonuclear leukocytes are present in the liver of infected chimpanzees and owl monkeys (60) as well as from humans (91) (Fig. 8). Virus particles are abundant in the bile of chimpanzees (85), reflecting secretion of HAV from hepatocytes into the proximal biliary canaliculi—commonly considered to be the source of virus shed in feces. Thus, both the naked virus particles shed in feces as well as quasi-enveloped virus circulating in blood (39) originate from hepatocytes.

Wild-type or low-passage HAV is not cytopathic in cell culture, and liver histopathology does not suggest widespread necrosis or apoptosis of hepatocytes *in vivo*. The presence of large quantities of virus in hepatocytes before the onset of hepatic inflammation and ALT elevation also argues against a

**FIGURE 8** Photomicrograph of a liver section from a patient with acute hepatitis A, showing inflammation of the portal and periportal areas by lymphocytes coupled with lobular disarray and hepatocellular ballooning degeneration (cytoplasmic vacuolization). (Hematoxylin and eosin stain; original magnification 40x). (Adapted from Martin A, Lemon SM, *Hepatology* 2006 with permission of the publisher.)

major direct cytopathic effect of HAV. Clinical hepatitis coincides with the appearance of cellular and humoral immune responses, and the pathology of hepatitis A is thus likely to result from the immune response to the infection.

#### Gastrointestinal Tract

It is not known how HAV reaches the liver in the initial stages of the infection. Because the virus is acid resistant, it can survive passage through the stomach and thus could initially replicate somewhere lower in the gastrointestinal tract, although this hypothesis remains to be proven. While HAV antigen was identified by immunofluorescence microscopy in isolated cells lining the crypts of both the jejunum and ileum in owl monkeys in which the virus was inoculated via feeding tube (60), a similar search for viral antigen in gut tissue failed to identify any infected cells in a cohort of intravenously infected marmosets (88). Virus has also been identified in saliva from infected chimpanzees, but the significance is uncertain (92). The lack of compelling evidence for a primary site of replication in the gut rules out this possibility, however, given similar difficulties in identifying a gastrointestinal site of replication for noroviruses. An alternative possibility is that HAV might be taken up by specialized M cells in the small intestine, undergo transcytosis, and pass into the lymphatics, as proposed for poliovirus (93).

#### Other Extrahepatic Sites of Replication

Viral antigen has been detected in splenic macrophages and in Kupffer cells, but this finding may not represent active replication in those cells (88). Nonetheless, fluorescent *in situ* hybridization has revealed appreciable amounts of viral RNA in the spleen of bats infected with a nonprimate hepatovirus, suggesting that the HAV may replicate in this organ (14). Replication in other organs appears less likely. Meningoencephalitis and transverse myelitis have been described in association with acute hepatitis A (94, 95), as has acute renal failure in nonfulminant hepatitis A (96, 97). However, no direct evidence suggests replication of the virus

in renal or central nervous system tissue. A more interesting possibility is the pancreas: acute pancreatitis sometimes accompanies hepatitis A (98).

### Immunity

#### Innate Immune Response

HAV is a surprisingly stealthy virus in chimpanzees, evoking very little type I interferon (IFN- $\alpha/\beta$ ) production and intrahepatic interferon-stimulated gene (ISG) expression despite replicating to high levels within the liver (57) (Fig. 6). This characteristic distinguishes it sharply from hepatitis C virus (HCV), which induces robust transcriptional upregulation of numerous ISGs in the liver. The basis for this difference is not clear. Stable HAV polyprotein-processing intermediates with cysteine protease activity disrupt signaling pathways by cleaving adaptor proteins required for induction of IFN- $\alpha/\beta$  responses. Thus, 3ABC (Fig. 2) is directed to mitochondrial membranes by a transmembrane domain in 3A, cleaving MAVS (IPS-1), and thereby disrupting signaling from RIG-I-like receptors (31, 99), whereas 3CD (Fig. 2) cleaves TRIF (TICAM-1), which is essential for Toll-like receptor 3 (TLR3) signaling (100). In both cases, the HAV processing intermediates are more active than mature 3C<sup>PRO</sup> in effecting these cleavages, indicating an exquisite adaptation of HAV to the human innate immune response. The unrelated HCV NS3/4A serine protease similarly degrades both of these adaptor proteins. However, the HAV 3C<sup>PRO</sup> protease also degrades NEMO (IKK $\gamma$ ) (101), which contributes to NF- $\kappa$ B activation and the induction of type I interferons, whereas NS3/4A does not. HAV also achieves much higher levels of viral protein expression than HCV (57), and this is likely to contribute to its greater capacity to suppress interferon responses in the liver.

Despite the low levels of IFN- $\alpha$  and ISG expressed in HAV-infected chimpanzees, freshly isolated human plasmacytoid dendritic cells (pDCs) are capable of sensing quasi-enveloped eHAV virions released from infected cell cultures, thereby producing IFN- $\alpha$  through a TLR7-dependent mechanism (75). pDCs appear to be recruited to the liver and are found within the sinusoids during the first week of infection in the chimpanzee but, for reasons that are not clear, such cells are no longer detectable within the liver at the onset of hepatic inflammation.

*In vitro* studies suggest that natural killer cells are capable of recognizing and lysing HAV-infected cells, and thus may contribute to control of the infection (102). Consistent with phenomenon, microarray analyses of liver tissue from acutely infected chimpanzees are indicative of a strong type II IFN- $\gamma$  response correlating with the onset of liver injury and elevation of serum ALT (57).

#### T Cell Immunity

The mononuclear inflammatory infiltrates that typify the histopathology of acute hepatitis A (90, 91) have long suggested that adaptive T cell responses may mediate HAV-associated liver injury. Early studies demonstrated that HAV-specific CD8<sup>+</sup> cytotoxic T cell clones could be isolated with appropriate cytokine stimulation from the livers of acutely infected humans, whereas CD4<sup>+</sup> T cell clones were more likely to be recovered during convalescence (103). The CD8<sup>+</sup> T cells produce IFN- $\gamma$  and are capable of killing HAV-infected fibroblasts in cell culture (103, 104). Granzyme B and perforin mRNA transcripts are also upregulated in acutely infected chimpanzee liver (57). These findings indicate that CD8<sup>+</sup> T lymphocytes mediate liver damage and

possibly contribute to viral control. However, recent studies in infected chimpanzees suggest a more important role for noncytolytic virus control mediated by virus-specific CD4+ helper T cells (58, 105). Direct *ex vivo* analyses demonstrated that virus-specific CD4+ T cells are multifunctional, and produce multiple cytokines (IFN- $\gamma$ , TNF- $\alpha$ , IL-2 and IL-21) in response to a variety of HAV-specific peptides (58). This CD4+ T cell response correlates temporally with reductions in viremia, and the decline in HAV genome copy number in the liver during convalescence (Fig. 6). In contrast, direct *ex vivo* analysis revealed the CD8+ T cell response to be relatively abbreviated, and that virus-specific CD8+ T cells acquire effector functions only after viremia had begun to decline. These findings thus suggest an alternative model of noncytolytic, cytokine-mediated control of the infection (105). T cell responses to HAV infection are thus important for recovery and pathogenesis, but their role in subsequent protection against reinfection is not known.

As discussed above, a member of the T cell immunoglobulin mucin family, HAVCR1 (TIM-1), has been suggested to function as a cellular receptor for HAV (77). This cell surface receptor family is important in T cell regulation. TIM-1 stimulates T cell expansion and cytokine production and is associated with atopic disease (106). An inverse relationship between asthma and childhood exposure to HAV has been suggested but not conclusively demonstrated (107). One hypothesis is that activation of T cells through TIM-1 by HAV or by its natural ligand may affect T cell differentiation and the regulation of Th2-driven allergic inflammatory responses, such that recent reductions in childhood HAV infections may be associated with increases observed in the incidence of atopic diseases (108).

### Humoral Immunity

Although the onset of liver damage correlates closely with the appearance of circulating anti-HAV antibodies (Fig. 6), neither antibody-dependent nor complement-mediated cytotoxicity has been demonstrated in hepatitis A (109). While circulating immune complexes containing HAV and HAV-specific antibodies (primarily IgM) have been found during acute infection, immunoglobulin and complement deposits are not found at the sites of liver cell damage (110). Virus-specific antibody responses thus play an uncertain role in the pathogenesis of hepatitis A, but they are likely responsible for solid protection against symptomatic reinfection and for the protection afforded by immunization with formalin-inactivated vaccines (111). Passive immunization with pooled human immune globulins (IGs) results in low levels of circulating antibody that nonetheless provide complete protection against symptomatic infection.

The antibody response to HAV infection is vigorous and long lasting. Both IgM and IgG anti-HAV antibodies are capable of neutralizing HAV infectivity (112, 113); they first appear coincident with the onset of hepatic inflammation and ALT elevation (Fig. 6). Microarray assays show that genes involved in B cell development and the recruitment of B cells to the liver (for example, CXCL13) are transcriptionally upregulated to impressive levels in liver biopsies from infected chimpanzees (57). This transcriptional activation persists for months, and IgG antibodies targeting the viral capsid may comprise as much as 12% to 15% of all IgG present in convalescent serum collected several months after infection. Immunity to HAV persists for life, and second infections associated with hepatic disease are unknown.

Although nonenveloped HAV virions are readily neutralized by antibody *in vitro*, quasi-enveloped eHAV virions

show no reduction in titer when incubated with neutralizing antibodies (39). This is surprising, given the protective nature of anti-HAV and the fact that only eHAV virions are detectable in the blood during acute infection (39). However, while not well understood, eHAV appears to be susceptible to neutralization within an endocytic compartment following uptake into cells. This is evidenced experimentally by the ability of neutralizing antibodies to inhibit viral replication when added to cultures as late as 4 to 6 hours after adsorption and removal of an eHAV inoculum (39). The antibodies appear to traffic to a late endosomal/lysosomal compartment in which the eHAV membrane is slowly degraded, allowing antibodies to interact with the capsid and neutralize infectivity prior to interactions of the capsid with its receptor. Such postentry neutralization is not observed with naked, nonenveloped virions (39). Whether an IgG receptor is involved in trafficking of the antibody is not known.

While serum antibodies are clearly protective against infection, it has been difficult to judge the role of mucosal immunity because antibodies in saliva or feces either are not detected or are present only at very low levels (114). Individuals with agammaglobulinemia are at risk for particularly severe or persistent infections with other picornaviruses, but this risk has not been described with HAV.

## EPIDEMIOLOGY

### Global Incidence and Prevalence of HAV

The World Health Organization (WHO) estimates that approximately 1.5 million cases of hepatitis A occur worldwide annually, but the rate of infection is probably ten times higher (115). Although HAV is the most common cause of hepatitis globally, major geographic differences in endemicity exist that are linked to the level of economic development and sanitary conditions.

Three principal patterns of endemicity (high, intermediate, and low) are considered to exist worldwide based on the results of age-specific prevalence of anti-HAV antibodies (Fig. 9). In areas of high endemicity, including underdeveloped regions of Africa, Asia, and South America, HAV is readily transmitted due to poor socioeconomic conditions; the prevalence of anti-HAV reaches 90% in younger adults. Most infections in these areas occur in childhood (before the age of 10 years), many of which are asymptomatic or not recognized as hepatitis. The burden of overt disease is quite low in these areas because the majority of the population has achieved immunity to the disease by adolescence. In areas of intermediate endemicity, only 50% to 60% of adults and 20% to 30% of children have been infected because HAV is not transmitted as readily secondary to improved sanitation. Since there are more adults susceptible to infection, larger outbreaks occur and more persons have symptomatic illness. In areas of low endemicity, such as the United States, Canada, and Western Europe, less than 30% of adults have anti-HAV. When HAV is introduced into such populations, cyclical waves of transmission can occur (116).

Important changes have happened in these three classic patterns of global endemicity over the last few decades (Fig. 10). Improvements in sanitation and socioeconomic development in many previously undeveloped regions has resulted in a transition from a high- to intermediate-endemicity pattern. This "epidemiologic transition" has been associated with a paradoxical increase in disease incidence, as it is associated with a decline in the age-specific prevalence of

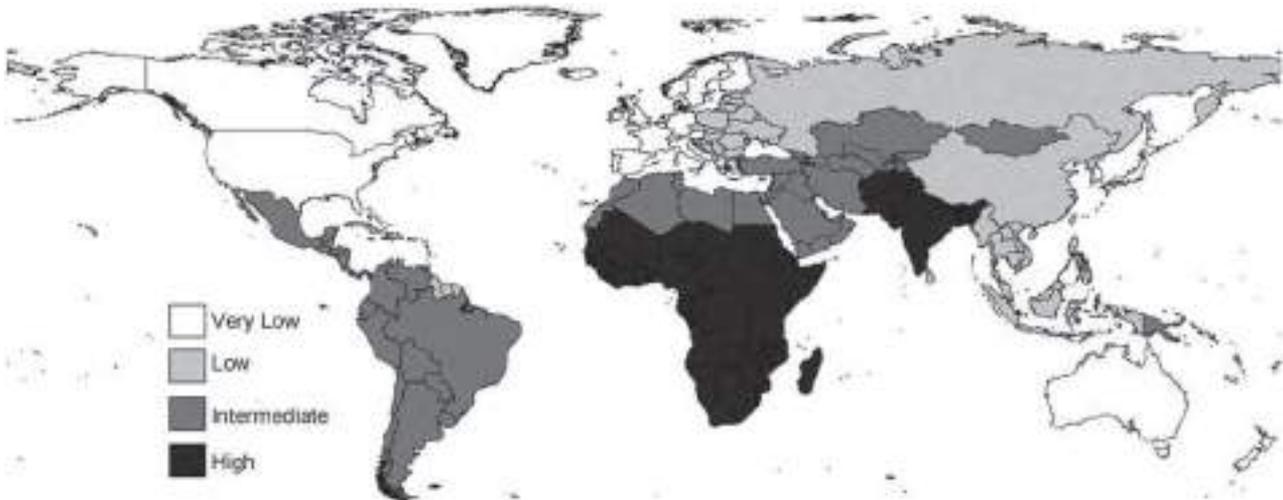

FIGURE 9 Estimated global prevalence of hepatitis A virus, 2005. (Reprinted from reference 117 with permission of the publisher.)

immunity to HAV, leading to increased susceptibility to infection among older individuals, who are more likely to become symptomatic if infected. Regions of transitional endemicity include China and countries in South America, Central and Southeast Asia, and the Middle East (116).

The median age at seroconversion increased between the years 1990 and 2005 (117). This phenomenon can be expected to result in disease patterns characterized by increased morbidity as cohorts of susceptible older children and adults become infected. There is also greater potential for outbreaks as the susceptible population grows, but relatively high levels of circulating virus persist. Significant outbreaks have occurred in China, including one in 1988 caused by the ingestion of raw clams contaminated with HAV, resulting in nearly 300,000 cases (2). Smaller-scale outbreaks have occurred in China more recently, including one in 2006 involving a large school (118). Korea has also recently experienced a large national outbreak of hepatitis A, probably due to the importation of contaminated shellfish from less-developed regions (119). As a result of such outbreaks and increasing morbidity in older populations,

more countries are introducing universal childhood immunization programs, the most notable including South Korea and Argentina (120).

### Hepatitis A in the United States

#### The Prevaccine Era

Before licensure of an effective vaccine in 1995, HAV incidence in the United States was primarily cyclic, with peaks occurring every 10 to 15 years. During the 1980s and 1990s, an average of 26,000 hepatitis A cases were reported annually to public health agencies. The outcome of one incidence model, however, predicted an average of 271,000 infections per year between 1980 and 1999, thereby suggesting that only one in ten cases of acute hepatitis A had been reported. More than one-half of those infections, according to the model, were in children aged less than 10 years and likely would have been clinically unrecognizable as hepatitis (121).

Before widespread immunization, approximately one-third of reported cases occurred among children aged less than 15 years, with the highest overall incidence in children

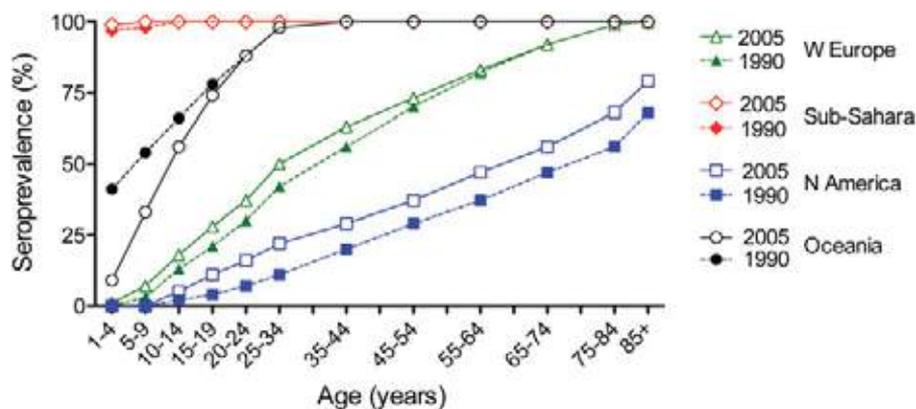

FIGURE 10 Estimates of anti-HAV seroprevalence by age group and selected populations in different world regions, 1990 and 2005. Groups shown include those in Western Europe, South sub-Saharan Africa, North America (high income), and Oceania. The impact of changing standards of sanitation and immunization programs is evident in shifts in age-specific prevalence of anti-HAV antibody. No changes were estimated to have occurred in the African region. (Adapted from reference 117 with permission of the publisher.)

aged 5 to 14 years (122). Large serosurveys conducted between 1988 and 1994 found that the overall prevalence of anti-HAV was 31.3%, with antibody prevalence increasing markedly with age, ranging from 9.4% among persons aged 6 to 11 years to 74.6% among persons older than 70 years. The age-adjusted prevalence was significantly higher among foreign-compared to U.S.-born persons, and was highest among Mexican Americans and lowest among non-Hispanic whites. In a multivariate analysis, only Mexican-American ethnicity and income below the poverty level were associated with HAV infection among U.S.-born children (123).

Nearly half of all hepatitis A cases in the United States were associated with no identifiable source of infection in the prevaccine era (124). Of those cases with an identifiable source, the majority resulted from person-to-person spread of HAV during community-wide outbreaks. Cyclic outbreaks, however, occurred among users of illicit drugs and among men who have sex with men (MSM) (125). Overall, this suggested that nationwide reductions in incidence were more likely to result from routine childhood vaccination than from targeted vaccination of high-risk groups, because children often have unrecognized or asymptomatic infection and play a major role in perpetuating HAV transmission during outbreaks.

### Postvaccine Era

The epidemiology of HAV has changed radically since licensure of the hepatitis A vaccine and implementation of a national childhood immunization strategy in the United States. Hepatitis A rates have fallen dramatically and the country has not experienced a nationwide cyclic spike in hepatitis A incidence since 1995 (123). Nevertheless, hepatitis A remains one of the most frequently reported vaccine-preventable diseases in the United States.

Soon after the hepatitis A vaccine was licensed in the United States, the Advisory Committee on Immunization Practices (ACIP) recommended routine vaccination of children aged 2 to 18 years living in communities with the highest rates of infection and disease. An estimated 50% of hepatitis A cases were averted by immunizing children in this age group despite low overall vaccine coverage (10%) (126). Targeting children for immunization resulted in impressive reductions in the incidence of hepatitis A among adults, vividly demonstrating the role young children play in the transmission and propagation of HAV within populations. Although effective regionally, this immunization strategy had only a limited impact on the national incidence of hepatitis A, leading to the expansion of routine immunization to other locations where disease rates were high. By 2003, the incidence of acute hepatitis A had declined overall by 76%, from a rate of 10.7 per 100,000 population during 1990 through 1997 to 2.6 per 100,000 population (127). Due to this precipitous decline, universal vaccination was recommended for all children in the United States aged 12 to 23 months in 2006 (128).

Concurrent with the overall decline in hepatitis A incidence in the United States since the introduction of immunization has been the narrowing of historic differences in rates among racial/ethnic populations and geographical locations. Among Native Americans and Alaska Natives, current rates indicate a 99% decline compared with the prevaccine era and are now approximately the same or less than those of other racial/ethnic populations (129). Rates among Hispanic Americans have fallen almost 90%, although the rates remain higher than those for non-Hispanics (130).

The incidence of HAV-related disease reached the lowest recorded rate (0.4 cases per 100,000 population) in 2011.

However, the incidence rate started to increase again in 2012 through 2013, reflecting increased numbers of cases among adults aged more than 20 years. A steady increase in hospitalizations due to HAV infection has been noted since 1999 (131). In 2013, a total of 1,781 cases of hepatitis A were reported from 50 states to the Centers for Disease Control and Prevention (CDC), a 14% increase from 2012 (132). Most cases in the United States are associated with exposure during travel, although nationwide outbreaks still occur due to contaminated food. For example, a nationwide foodborne outbreak in 2013 was found to be associated with a frozen fruit product containing contaminated, imported pomegranate arils (133). Approximately 93% of those infected were adults.

The most recent National Health and Nutrition Examination Survey (NHANES), conducted by the CDC, revealed the prevalence of anti-HAV among adults aged more than 20 years to be 24.2% during 2007 through 2012, a significant decline from 29.5% during 1999 through 2006 (132). The lowest age-specific prevalence was among adults aged 30 to 49 years (16.1% to 17.6%). Thus, a continuing shift in the age-specific prevalence of anti-HAV is occurring subsequent to the institution of universal childhood immunization. This is resulting in a higher anti-HAV prevalence among children but a lower prevalence among adults due to herd protection. The NHANES survey also revealed that vaccination coverage among adults aged 18 to 49 years was only 12.2% in 2012. Although adults are less likely to acquire infection from children during the vaccine era, they are at greater risk of becoming infected through travel and food imported from endemic areas.

### Mortality

The overall fatality rate among cases reported through the CDC surveillance system in the United States typically ranges from 0.3% to 0.6%. Between 2009 and 2013, the hepatitis A–related mortality rate was 0.02 deaths/100,000 population per year, which was consistent with rates over the past few decades. Age-specific mortality rates rise with increasing age, ranging from 0.00 deaths/100,000 population among persons aged 0 to 34 years to 0.08 deaths/100,000 population among persons aged 55 to 74 years in 2013, and 0.07 deaths/100,000 population among persons aged more than 75 years (134).

### Transmission

The most important mode of HAV transmission is undoubtedly from person to person via the fecal-oral route. Fecal excretion of the virus is highest during the 2 weeks before and a few days immediately after the onset of symptoms but is likely to continue for many weeks (135). The highest infection rates are seen among family and school contacts, indicating that the infective dose is low and interpersonal spread is efficient. The other major mode of transmission is through contaminated food and water. Many types of food products, including seafood, produce, and meat, have been implicated during outbreaks. Transmission following parenteral exposure, including transfusion of blood products and use of contaminated needles, is also possible but is relatively infrequent due to the brief duration of viremia associated with acute infection.

Of the 1,063 cases in the United States in which risk exposure/behavior was reported in 2013, only 24.5% indicated a possible exposure for hepatitis A during the 2 to 6 weeks before the onset of illness. The most frequently identified risk factor for hepatitis A was linkage to a food- or

waterborne outbreak (12.8%). The second most common risk factor was international travel (6.2%), with most cases involving travel to Mexico and Central and South America. Whereas sexual and household contact with another person with hepatitis A have been traditionally among the most frequently identified risk factors, these risk factors were reported for only 5.6% of cases in 2013. MSM and injection drug users accounted for 5.5% and 4.0% of reported cases, respectively (134).

### Groups at Increased Risk for Hepatitis A

#### Travelers

Hepatitis A remains one of the most common vaccine-preventable diseases acquired during international travel. Persons from developed (low-endemicity) countries who travel to developing (intermediate- or high-endemicity) countries are at significant risk for acquiring hepatitis A (136). The risk is higher among travelers visiting areas with poor sanitation and limited access to clean water, although the disease occurs in travelers who report observing strict protective measures and staying in more developed cities or luxury hotels. The incidence rate for nonimmunized travelers is estimated to be 3 cases per 1,000 travelers per month of stay in developing countries. Hepatitis A among Hispanic children who live along the United States–Mexico border has been associated with cross-border travel to Mexico and food-borne exposures during travel (137). Many recommendations and guidelines have been issued in different countries regarding prophylaxis for travelers.

#### Men Who Have Sex with Men

Numerous outbreaks of hepatitis A have been reported among MSM in the United States, Canada, Europe, and Australia, sometimes in the setting of a larger community-wide outbreak. However, surveys of anti-HAV prevalence among MSM have neither consistently demonstrated a greater propensity for infection compared with a similarly aged population, nor have specific sex practices been consistently identified (138).

#### Users of Illicit Drugs

Outbreaks among drug users, both injecting and noninjecting, have been reported frequently in the United States and other developed countries since the 1980s (124). In the United States, many outbreaks have involved the use of methamphetamine and transmission by both percutaneous and fecal-oral routes (139). Injection drug users appear to have a higher prevalence of anti-HAV than the general U.S. population (138). Transmission is likely connected to socioeconomic factors, sexual promiscuity, syringe exchange, and contamination of instruments, and to involve both fecal-oral and parenteral routes.

#### Persons with Clotting-Factor Disorders

Before improvements in viral-inactivation procedures, widespread hepatitis A immunization, and improved donor-screening methods, rare outbreaks of hepatitis A among persons with clotting-factor disorders and hemophilia were reported in Europe and the United States (140)—the result of HAV contamination of high-purity clotting factor concentrates devoid of protective IGs and prepared from very large donor-plasma pools. However, in recent years, no cases of hepatitis A attributable to administration of blood products have been identified in the United States, and hemophiliacs are not at a higher risk than the general population of acquiring HAV (141).

### HAV Transmission in Special Settings

#### Food-Service Establishments

Food-borne hepatitis A outbreaks are recognized relatively infrequently in the United States. According to CDC surveillance in 2013, about 12.8% of cases in which an exposure was reported could be linked to a food-borne outbreak. This was an increase from previous years because of a nationwide outbreak related to contaminated pomegranate seeds in 2013. The proportion of sporadic cases that might be from food-borne sources is unknown but could be considerable, as approximately 50% of reported cases of hepatitis A still do not have an identified source of infection. HAV contamination of agricultural products can occur at any point during cultivation, harvesting, processing, or distribution (142).

A single HAV-infected food handler can transmit the virus to dozens or even hundreds of persons. However, food handlers are not at a higher risk of hepatitis A because of their occupation, and most infected food handlers do not transmit HAV to consumers or restaurant patrons (142).

Molecular epidemiologic techniques comparing RNA sequences of HAV strains has made possible the identification of previously unrecognized links between cases, as exemplified in a multistate outbreak of HAV subgenotype IB infection among European travelers returning from Egypt in 2012 to 2013. A persistent common source of infection was suspected, as HAV strains isolated from various cases over a period of several weeks were indistinguishable genetically. The 107 cases of hepatitis A infection were eventually linked to strawberries (143). Similar molecular epidemiologic studies have elucidated the origins of HAV strains involved in a recent nationwide outbreak of hepatitis A in South Korea (119).

#### Child Care Centers

The frequency of outbreaks among children attending day care centers and persons employed at these centers has decreased substantially, as the overall hepatitis A incidence among children has declined since the implementation of vaccination, especially in the United States, since 2006. Because infection among children is typically mild or asymptomatic, outbreaks are often not identified until adult contacts become ill (144).

#### Schools

In the United States, the appearance of cases of hepatitis A in schools is ordinarily a reflection of disease acquisition and transmission in the community. Secondary transmission to other students is uncommon. However, if multiple cases occur among students, a common source of infection is possible and should be investigated (128).

#### Health Care Institutions

Nosocomial transmission of HAV is rare, and the CDC recommends adherence to standard precautions. Health care personnel who become infected should avoid patient contact and food handling for 7 days after the onset of jaundice. Patients with typical cases of hepatitis A are not routinely admitted to hospitals, and even when patients are hospitalized, the probability of transmission is low because most are admitted after the onset of jaundice, when the period of maximum infectivity has passed. Outbreaks in hospital settings have been linked to inadequate hand cleaning. Anti-HAV seroprevalence is similar in health care workers and control populations, indicating that health care workers are not at increased risk of acquiring infection (145).

### Workers Exposed to Sewage

Among wastewater workers, no work-related instances of HAV transmission have been reported in the United States, and serologic surveys have shown no substantial or consistent increase in the prevalence of anti-HAV. Surveys performed in other countries indicate a possible elevated risk for HAV infection among workers exposed to sewage; however, those analyses did not control for other factors, such as socioeconomic status (146).

### Nonhuman Primate Colonies

Persons working with captive nonhuman primates were previously at risk for hepatitis A, but immunization of animal handlers has largely eliminated that risk.

## CLINICAL FEATURES

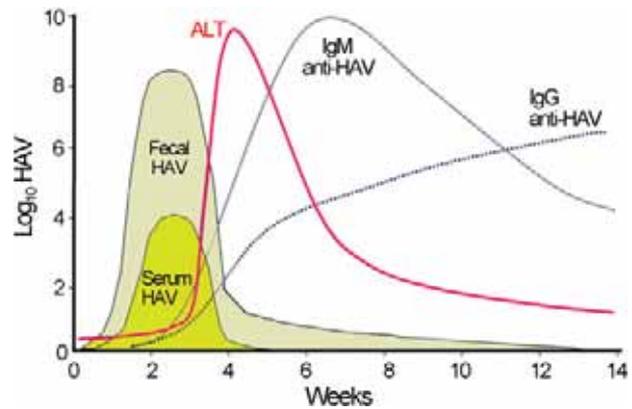

The clinical manifestations of hepatitis A are highly variable, ranging from asymptomatic infection, to mild anicteric hepatitis, acute icteric viral hepatitis, and even fulminant hepatic failure. The risk of clinical disease following HAV infection is determined primarily by the age of the person infected. In children younger than 6 years, 70% of infections are asymptomatic and, if illness does occur, it is typically not associated with jaundice. By contrast, infection during late childhood through adulthood is likely to cause icteric illness in more than 70% of patients. The risk of fulminant hepatitis and death is also much higher in older patients.

### Uncomplicated Acute Hepatitis A

#### Clinical Course

Clinical signs and symptoms of acute hepatitis A are indistinguishable from those caused by other types of hepatitis (see Chapter 5 for differential diagnosis). Thus, while clues from the epidemiologic setting may be present, laboratory tests are required for specific diagnosis. The incubation period is approximately 15 to 50 days, with a mean of about 30 days (Fig. 11). In older children and adults, the illness usually begins with abrupt onset of prodromal symptoms including fatigue, malaise, nausea, vomiting, anorexia, fever, and abdominal pain. Typical symptoms of hepatitis, beginning with darkening of the urine and followed by jaundice and pale or clay-colored stools, will appear after a period of several days to a week. During a large shellfish-associated epidemic in Shanghai in 1988, prodromal symptoms included anorexia (82%), malaise (80%), fever (76%), nausea (69%), and vomiting (47%) among the more severely affected patients who were hospitalized (147). Hyperbilirubinemia was seen in 91%, and 84% were overtly jaundiced (147). Itching, often a sign of cholestasis, occurs in less than 5% of symptomatic patients but may be severe enough to require antipruritics and corticosteroid therapy. The two most common physical findings are jaundice and tender hepatomegaly, which occur in 70% and 80% of symptomatic patients, respectively. Less common clinical findings include splenomegaly (9%), rash, arthritis, and leukocytoclastic vasculitis.

Serum ALT and aspartate aminotransferase (AST) activities are sensitive, but nonspecific, measures of parenchymal liver damage associated with acute HAV infection. ALT elevations, usually higher than AST, may be found even during the prodromal stage. In icteric acute hepatitis A, serum ALT levels are typically less than 2,000 IU/l, but may exceed 20,000 IU/l. While high ALT levels occur in patients with severe hepatitis, the elevation of ALT is not necessarily

**FIGURE 11** Natural history of hepatitis A. The infection is typically acute in nature, with symptoms and signs of the infection usually occurring within 3 to 5 weeks of exposure. The sequence of events includes shedding of infectious HAV in feces and viremia, followed by increases in serum ALT activity (red line), and the appearance of IgM and IgG anti-HAV antibody responses (the latter typically measured as total anti-HAV antibody). (Adapted from Martin A, Lemon SM, *Hepatology* 2006 with permission of the publisher.)

correlated with the severity of the illness. Alkaline phosphatase levels are usually only mildly elevated in hepatitis A, except when the illness is complicated by cholestasis. Biochemical abnormalities may persist for 2 to 3 months, but usually return to normal by 4 weeks (Fig. 11).

The duration of illness varies. In many patients, the appearance of jaundice is associated with rapid resolution of the prodromal symptoms. After 3 to 4 weeks, most patients feel better, no longer have hepatomegaly, and have normal or near-normal serum levels of ALT and bilirubin. Prolonged jaundice or a relapsing pattern may also occur but ultimate resolution in these cases is universal. Infection with HAV does not cause chronic infection. HAV infection, whether asymptomatic or associated with disease, is associated with the development of a robust immune response, which provides lifelong protection against future reinfection with the virus.

#### Children

HAV infection in younger children is typically mild; only 30% of children younger than 6 years are symptomatic. Symptoms, when present, are often nonspecific, and include fever, malaise, anorexia, and nausea. Serum aminotransferase levels can be elevated during the prodromal period and jaundice, when it occurs, usually develops occurs 1 to 2 weeks after symptom onset. Jaundice typically lasts for less than 2 weeks, with aminotransferases returning to normal limits in approximately 2 to 3 months. Acute liver failure is extremely rare in children, occurring in less than 1% of cases.

#### Hepatitis A in Pregnancy

HAV infection in pregnant women is usually self-limiting and not a threat to the fetus. Although HAV infection does not increase the risk of congenital malformations or spontaneous abortions, there have been rare reports of increased preterm labor and premature rupture of membranes (148).

## Complications and Atypical Presentations

### Cholestatic Hepatitis A

Prolonged jaundice is often associated with fever and pruritus and is an indication of cholestatic hepatitis. Peak serum bilirubin levels may reach 12 to 29 mg/dl, and jaundice may continue for up to 18 weeks (149). The cause of prolonged cholestasis is unknown, but is usually reflected histologically by predominantly cholestatic features. The duration of viremia has been found to be longer in patients with cholestatic hepatitis but the virologic and host factors implicated in the pathogenesis are unknown. In a prospective, Korean multicenter study of 595 hepatitis A cases, prolonged cholestasis occurred in 4.2%; preexisting chronic hepatitis B infection, prolonged prothrombin time, and higher total bilirubin levels were associated with increased risk (150). Peak biochemical markers including serum aminotransferases and alkaline phosphatase were not significantly different in patients with prolonged cholestasis (136). Cholestasis ultimately resolves spontaneously with no complications or sequelae. It is important to be aware of this relatively common but atypical feature of hepatitis A and to avoid overly aggressive interventions.

### Relapsing Hepatitis A

A relapsing form of hepatitis A has been observed in 3% to 20% of patients. One study reported 12.5% of 297 adults had a relapsing course, of whom 22% had more than one relapse (151). The relapses are usually milder than the initial illness and typically occur after the serum aminotransferases have normalized from the initial episode, and long after the development of anti-HAV. Nonetheless, it seems likely viral replication is ongoing in such cases: HAV has been found in the stool of some patients during relapse (152). The mechanisms underlying relapse are unknown and predisposing factors have not been identified. Similar minor relapses have been observed in experimentally infected chimpanzees, and were not associated with mutations in the viral capsid that might suggest immune escape. The prognosis for relapsing hepatitis is excellent, and all cases ultimately resolve without chronic sequelae.

### Fulminant Hepatitis A

Fulminant hepatitis, characterized by rapid onset of liver failure and coma, is rarely associated with HAV infection but is potentially fatal. Fulminant disease is more common in older persons, and recovery from severe disease is less common in patients older than 50 years. The Acute Liver Failure Study Group (ALFSG) study of adults with acute liver failure from 1998 to 2005 found that HAV accounted for 3.1% of patients and only 0.12% of those listed for liver transplantation (139).

The initial clinical presentation is not significantly different from other cases of acute hepatitis A (153). Patients typically have a coagulopathy (prothrombin time >15 seconds or international normalized ratio >1.5) and encephalopathy. The ALFSG evaluated 29 patients with fulminant hepatitis A and developed a prognostic index to predict transplantation or death. The index incorporates four presenting features (serum ALT <2,600 IU/L, creatinine >2.0 mg/dL, intubation, pressors) and was shown to be better than other published models including the laboratory Model for End-Stage Liver Disease score. Laboratory and clinical evidence of deteriorating liver function correlates with a histologic picture of virtually complete destruction of the hepatic parenchyma with only a reticulin framework and

portal tracts remaining. Occasionally, small groups of surviving hepatocytes can be seen close to portal tracts, which may be evidence of regeneration (154). As many as 50% of patients with acute, HAV-associated fulminant liver failure may die or require emergency liver transplantation. Spontaneous recovery rates in fulminant hepatitis A range between 30% and 60%, and survivors regain complete liver function. Prognosis is influenced by age, clotting factor levels, stage of coma, and presence of kidney disease. Recovery from fulminant hepatitis is difficult to predict, and the only effective treatment is liver transplantation.

Host factors associated with increased risk of fulminant hepatitis include older age and underlying chronic liver disease, particularly chronic HCV infection. In a study of 163 patients with chronic hepatitis B and 432 patients with chronic hepatitis C, HAV superinfection occurred in 27 patients (155). All 10 of the patients with hepatitis B infection had an uncomplicated course. In contrast, fulminant hepatic failure developed in 7 of the 17 patients with chronic hepatitis C who acquired hepatitis A, and 6 of those patients died (155). There were 47 deaths (0.015%) recorded among the 310,746 cases in the 1988 Shanghai epidemic that primarily involved adolescents and young adults (147). Of the 47 deaths, 25 were due to fulminant hepatic failure and at least half of the affected individuals had underlying liver disease.

### Extrahepatic Manifestations

Rarely, in patients with prolonged illness, extrahepatic disease, including optic neuritis, transverse myelitis, aplastic anemia, and thrombocytopenia, may be noted. Although these conditions are possibly manifestations of immune-complex disease, the relationship of these syndromes to the HAV infection is not established (149). Mild to moderate pancreatitis has also been reported in association with acute hepatitis A (98), but its pathogenesis is equally obscure.

## LABORATORY DIAGNOSIS

The serologic detection of IgM anti-HAV is the simplest, least expensive, most sensitive, and most specific approach to laboratory diagnosis. Detection of an HAV-specific antibody of the IgM class (primarily against capsid antigen) indicates current or recent infection and is the gold standard for diagnosis of acute hepatitis A. Such an antibody is almost always present at the onset of symptoms, peaks during the acute or early convalescent phase of the disease, and remains positive for approximately 4 to 6 months (112) (Fig. 11). Many methods have been used to detect IgM anti-HAV, but enzyme-linked immunosorbent assay (ELISA) is now the most commonly used. IgM anti-HAV ELISA assays are available commercially and generally do not detect the low levels of IgM that may persist in patients more than 6 months after acute HAV infection (156).

However, persons who are unlikely to have acute viral hepatitis should not be tested for IgM anti-HAV, and the use of IgM anti-HAV as a screening tool or as part of a test panel used in the workup of nonacute liver function abnormalities should be discouraged. Testing in the absence of clinical signs or symptoms of acute HAV infection lowers the predictive value of the IgM anti-HAV test and can result in increased numbers of false-positive tests for acute HAV infection (157). A positive IgM anti-HAV does not necessarily indicate acute infection because individuals can have a prolonged presence of IgM. In one study of 140 persons reported to have a positive IgM test result in 2003, a total of

87 (62%) did not have an illness that met the case definition for hepatitis A or any other type of viral hepatitis (143).

IgG anti-HAV appears at the same time as IgM antibodies to HAV but, unlike IgM anti-HAV, remains detectable for decades thereafter (Fig. 11). Commercial assays are not generally available for specific detection of IgG anti-HAV. However, multiple types of assays are available for detection of total anti-HAV antibody, which, in the absence of acute infection, is largely comprised of IgG antibody and indicative of previous or resolved HAV infection. Conversely, the absence of anti-HAV in a sample collected during the acute phase of illness or early convalescence is strong evidence against a diagnosis of HAV infection. However, if the clinical or epidemiologic situation strongly suggests HAV infection, the test should be repeated within a few days to a week to formally exclude the diagnosis.

Liver biopsy is rarely indicated to establish a diagnosis of acute hepatitis. This procedure is associated with discomfort to the patient, and carries a small but finite risk of death. Moreover, tissue morphology is usually not diagnostic.

Detection of virus or viral antigen in the stool is a useful research tool but has no place in routine clinical diagnosis. Since HAV clinical isolates usually replicate very slowly and then to very low titers in cell culture, virus isolation is insensitive, unreliable, and expensive.

Nucleic acid detection techniques are more sensitive than immunoassays for viral antigen to detect HAV in samples of different origin (e.g., clinical specimens, environmental samples, or food). Amplification of viral RNA by reverse transcription-polymerase chain reaction (RT-PCR) is currently the most sensitive and widely used method for detection of HAV RNA (44). Real-time RT-PCR is rapid, sensitive, reproducible, and potentially quantitative. Nucleic acid sequencing of PCR amplicons may confirm their specificity and provide the ultimate means of identifying and characterizing the responsible virus genotype or strain (158). Sequencing of selected genomic regions of HAV is used to determine the genetic relatedness of isolates for epidemiologic investigations (159).

RT-PCR may be used for HAV detection in environmental samples. The same characteristics that facilitate the likelihood of transmission of HAV by contaminated food and water—i.e., the stability of HAV in the environment, especially when associated with organic matter, and its resistance to low pH, drying, and heat—also improve the likelihood of detection in environmental samples. However, HAV detection in food traditionally has not been included as a part of outbreak investigations because of the lengthy incubation period of the disease and the probability that the offending foodstuff usually has been consumed or discarded by the time the outbreak is recognized (160).

## PREVENTION

### General

Hepatitis A is a vaccine-preventable disease. The WHO recommends hepatitis A vaccination be integrated into the childhood schedule if disease incidence and cost effectiveness support its use (115). Before vaccines were licensed beginning in 1995, prevention of hepatitis A was primarily aided by adherence to sanitary practices such as hand washing, appropriate heating of foods, and avoidance of food and water from endemic areas. Hand washing is highly effective in preventing transmission, since the virus can survive for up to 4 hours on the hands (161). General

hygienic measures are most important in limiting person-to-person spread in the home, school, or work settings. While nosocomial transmission is rare and hospitalized patients require only enteric precautions and private rooms, gloves should be worn when handling anything that is potentially contaminated (162). Chlorination and household bleach (1:100 dilution) are sufficient to inactivate the virus (see above).

The provision of clean water, availability of proper waste disposal, and general improvement in overall living conditions rapidly reduce the incidence of hepatitis A within a population. However, the epidemiologic transition that occurs as a result of these preventive measures leads to a declining hepatitis A seroprevalence that may pose a public health problem; greater numbers of older people may be susceptible to infection and symptomatic illness.

### Passive Immunization

Before the licensure of effective hepatitis A vaccines, IG was the sole means of prevention of hepatitis A for people who either were likely to become infected or had recently been exposed. Passive immunization with polyclonal serum IG prior to exposure has been available since the 1940s and has been shown to decrease the incidence of HAV infection by more than 90% (163). IG is a sterile preparation of concentrated antibodies made from pooled human plasma processed by cold ethanol fractionation (164). In the United States, only plasma that has tested negative for hepatitis B surface antigen, antibody to human immunodeficiency virus, and antibody to HCV is used to produce IG. Since 1995, the U.S. Food and Drug Administration (FDA) has required that the process used to make IG include a specific viral inactivation step or that final products test negative for HCV RNA by PCR (128). Despite concern that the decline in the prevalence of anti-HAV in the population might reduce the effectiveness of IG, there is no standard for anti-HAV levels in IG preparations, and at present no evidence of reduced efficacy of IG.

IG provides protection against hepatitis A through passive transfer of antibody. When administered for pre-exposure prophylaxis, 1 dose of 0.02 ml/kg IM confers protection for no more than 3 months, and 1 dose of 0.06 mL/kg IM confers protection for 3–5 months. When administered within 2 weeks after an exposure to HAV (0.02 mL/kg IM), IG is 80%–90% effective in preventing hepatitis A (163). Efficacy is greatest when IG is administered early in the incubation period. When administered later in the incubation period, IG may only attenuate the clinical manifestations of HAV infection (163).

The level of anti-HAV detected in persons one week after the administration of a single intramuscular (IM) 5-cc dose of IG is typically in the range of 50 to 100 mIU/ml (111). By comparison, the titer of anti-HAV detected after recent infection often exceeds 15,000 mIU/ml, and following active immunization with three doses of HAV vaccine, approximately 3,500 mIU/ml. While measurable antibody following IG may disappear rapidly, protection persists for several months (165).

Serious adverse events from IG are rare. Because anaphylaxis has been reported after repeated administration to persons with immunoglobulin A deficiency, those persons should not receive IG. Pregnancy or lactation is not a contraindication to receipt of IG. A thimerosal-free preparation of IG is available and is preferable for use in infants and pregnant women (128). Less-serious reactions can also occur, including pain at the injection site.

## Active Immunization

### Hepatitis A Vaccines

Several types of hepatitis A vaccine have been developed and evaluated in nonhuman primate models of HAV infection and in human clinical trials. These include formalin-inactivated vaccines (9, 166), live attenuated vaccines (167), and combination HAV and hepatitis B vaccines (168). For the most part, only inactivated HAV vaccines have been evaluated for efficacy in rigorous, prospective, controlled clinical trials, and they comprise the only vaccine type approved for use in the United States (169). However, a live-attenuated HAV vaccine has been used extensively in China since 1992, reportedly with effective results (170). A live-attenuated vaccine (BioVac-A; Wockhardt; Mumbai, India) is also available in India and in other countries (Mevac-A) including Guatemala, Philippines, Bangladesh, Nepal, and Chile.

Havrix (GlaxoSmithKline, Rixensart, Belgium) was the first HAV vaccine licensed for use in the United States in 1995. It is a purified, formalin-inactivated vaccine manufactured from the HM175 virus strain propagated in a human cell line. A second formalin-inactivated vaccine, Vaqta (Merck & Co., Inc., Whitehouse Station, New Jersey), became available in the United States in 1996. It is produced with the CR326 viral strain and has equivalent immunogenicity and tolerance compared to Havrix (171). These two vaccines are indistinguishable in terms of their efficacy. Both have been demonstrated to provide high-level (95% or greater) protection against symptomatic HAV infection in prospective clinical trials of strikingly different design (10, 169). The results of the Vaqta trial even suggested that inactivated HAV vaccine can provide a high level of post-exposure protection against disease (10), a fact confirmed in a later clinical trial (172). The dosing and vaccination schedule approved by the Advisory Committee on Immunization Practices is shown in Table 1.

Twinrix (containing both HAV and HBV antigens; GlaxoSmithKline) was approved by the FDA in 2001. Twinrix is licensed for use in persons aged more than 18 years and contains 720 enzyme-linked immunosorbent assay units (EL.U.) of hepatitis A antigen (half the Havrix adult dose) and 20 mcg of recombinant hepatitis B surface antigen protein (the same as the Engerix-B [GlaxoSmithKline] adult dose). Primary immunization consists of three doses according to the same schedule as that commonly used for single-antigen hepatitis B vaccine (0, 1, and 6 months) (Table 2). After three doses of Twinrix, antibody responses to both antigens are equivalent to responses seen after the single-antigen vaccines are administered separately on standard schedules (173). Clinicians may choose to use an

**TABLE 1** Recommended regimens: dose and schedule for hepatitis A vaccines

Vaccine	Age (yr)	Dose	Volume (ml)	Two-dose schedule (mo) <sup>a</sup>
Havrix	1–18	720 (EL.U.)	0.5	0 (6–12)
	> 18	1,440 (EL.U.)	1.0	0 (6–12)
Vaqta	1–18	25 (U)	0.5	0 (6–18)
	> 18	50 (U)	1.0	0 (6–18)

Abbreviations: EL.U.=enzyme-linked immunosorbent assay units; U=units.

accelerated schedule for Twinrix (i.e., doses at days 0, 7, and 21). The FDA approved an accelerated schedule for Twinrix in 2007; persons who receive a vaccination on an accelerated schedule should also receive a booster dose at 1 year after the start of the series to promote long-term immunity (174).

### Vaccine Immunity

Although inactivated hepatitis A vaccine elicits both anti-HAV antibody and virus-specific T-cell responses (175), protection is likely afforded primarily by serum-neutralizing antibodies, based on early studies with passively transferred, pooled human IG (176). Low levels of neutralizing antibody correlate with high-level protection against disease (111).

### Indications for Immunization

Indications for hepatitis A immunization have evolved over time, and the current U.S. recommendation, issued by the Advisory Committee on Immunization Practices (ACIP) of the CDC in 2006, is to routinely immunize all children at 1 year of age. Globally, the WHO recommends immunization for children greater than 1 year of age in places with intermediate to low endemicity (115). These recommendations are intended to further reduce hepatitis A morbidity and mortality and make possible the consideration of eventual elimination of HAV transmission. Immunization is also recommended for persons who are at increased risk for infection and for any person wishing to obtain immunity. Children who are not vaccinated by the age of 2 years can be immunized at later ages. Catch-up vaccination programs are strongly encouraged, especially in the context of increasing incidence and outbreaks since 2011.

Persons at increased risk of infection or more severe disease who should be immunized include individuals traveling to or working in countries with high or intermediate rates of hepatitis A (see specific recommendations below in “Pre- versus Postexposure Prophylaxis”), persons with chronic liver disease (especially chronic hepatitis C) or clotting factor disorders, alcoholics, MSM, illicit drug users, individuals with close personal contact with an international adoptee from a country of high or intermediate endemicity during the first 60 days following arrival to the United States, persons working with HAV-infected primates or with HAV in a research laboratory, and individuals with recent exposure (for postexposure prophylaxis). Immunization against HAV infection is safe and effective in persons with chronic liver disease; susceptible people who are either awaiting or have received liver transplants should also be vaccinated (128).

The safety of hepatitis A vaccine during pregnancy has not been determined. However, because the vaccine is produced from inactivated HAV, the theoretical risk to the fetus is low. Nonetheless, immunization is typically not performed during pregnancy unless the risk of exposure to HAV is very high.

### Vaccine immunogenicity

After a primary vaccination course, most studies have shown a seroconversion rate approaching 100% in both children and adults (177). Inactivated HAV vaccine produces substantially higher titers of circulating anti-HAV antibody than administration of protective doses of IG. Since long-term persistence of antibody has been demonstrated, HAV booster vaccination is not necessary after the primary series.

Two main groups have shown a diminished response to HAV vaccine: patients with advanced liver disease and those who are immunocompromised. In one study, rates of seroconversion were lower in those with decompensated cirrhosis (66%) compared with those with compensated cirrhosis (98%) (178). Patients with low CD4 counts (<300 cells/mm<sup>3</sup>) also experience lower seroconversion rates; persons with advanced human immunodeficiency virus (HIV) infection show seroconversion rates ranging from 52% to 94% (179). Patients who are receiving immunosuppressive medications respond well to a two-dose vaccination series but have suboptimal response to one dose (180).

Diminished vaccine response has been observed in infants with passively acquired antibody as the result of previous maternal HAV infection (128), which is why hepatitis A vaccination is deferred until the infant is 1 year old. In the majority of studies, all infants subsequently had protective levels of antibody, but the final levels were substantially lower than those of infants born to anti-HAV-negative mothers and vaccinated according to the same schedule. Despite lower antibody levels after the primary series, the majority of infants with passively acquired antibody respond to a booster dose 1 to 6 years later (128). Passively acquired antibody declines to undetectable levels in the majority of infants by 1 year of age. After that time, hepatitis A vaccine is highly immunogenic, regardless of maternal anti-HAV status.

In populations with high rates of previous HAV infection, prevaccination testing may be considered to reduce costs by not vaccinating persons who are already immune. However, prior infection does not pose any special risk for vaccination. Postvaccination testing is not indicated because of the high rate of vaccine response. Furthermore, not all testing methods approved for routine diagnostic use in the United States have the sensitivity to detect low (but protective) anti-HAV titers that may be present after vaccination.

### Side Effects and Adverse Events

An estimated 1.3 million persons in Europe and Asia were vaccinated with Havrix before its licensure in 1995 and no serious adverse events were reported (128). Since the institution of routine childhood vaccination in the United States, no serious adverse events have been reported. Among adults, the most frequently reported adverse events occurring less than 3 days after administration were soreness at the injection site (56%), headache (14%), and malaise (7%) (181). Vaccination of a person who is immune because of previous infection does not increase the risk for adverse events.

### Immunization Policies and Vaccine Coverage

Vaccination policies range from being part of a national universal immunization program for children to targeting the vaccine exclusively to high-risk groups. Immunization programs have been very successful in most cases and have reduced the incidence of infection to up to 90%. Countries that have implemented a universal immunization program for children include Argentina, Israel, Italy, Spain, and the United States (118). Targeted policies for travelers have also been effective.

Vaccine coverage in countries that have implemented universal immunization programs has varied. In Argentina, approximately 95% of children were vaccinated in 2006 (182), but in the United States, coverage has ranged from 49.7% to 57.5% between 2010 and 2014 (134). Vaccination coverage in the United States has been slowly increasing each year by approximately 2% since 2010, but there is still room for improvement. In contrast to vaccination coverage rates among children, the rate among adults in the United States is substantially lower (132). In 2013, estimated hepatitis A vaccination coverage was only 12.3% among adults aged 19 to 49 years and 5.4% among adults older than 50 years. Coverage was higher among Asians (16.1%) compared with whites (12.6%) and Hispanics (10.6%). Surprisingly, only 13.3% of adults aged more than 19 years with chronic liver disease were vaccinated.

### Pre- Versus Postexposure Prophylaxis

#### Postexposure Prophylaxis of Hepatitis A

Active immunization with vaccine and passive immunization with IG have equivalent efficacy when used for

**TABLE 3.** Summary of recommendations for prevention of hepatitis A after exposure to hepatitis A virus (HAV) and in departing international travelers

	Hepatitis A vaccine	Immune globulin
<b>Postexposure prophylaxis</b>	1) Healthy persons aged 12 mo to 40 yr at the age-appropriate dose 2) Healthy persons aged > 40 yr if IG cannot be obtained	1) Persons aged > 40 yr 2) Children aged < 12 mo 3) Immunocompromised persons and persons with chronic liver disease, or for whom vaccine is contraindicated
<b>International travel<sup>a</sup></b>	For most healthy persons, one dose of single antigen before travel  Older adults, immunocompromised persons, and persons with chronic liver disease or other chronic medical conditions planning to depart to an area in <2 weeks should receive the initial dose of vaccine and also simultaneously can be administered IG at a separate anatomic site	Persons who elect not to receive vaccine, are aged < 12 mo, or are allergic to a vaccine component

<sup>a</sup>To countries with high or intermediate endemicity for hepatitis A  
IG=immune globulin.

postexposure prophylaxis (172). Among 1,090 healthy individuals (aged 2 to 40 years) randomly assigned to vaccine or IG within 14 days of exposure, symptomatic HAV infection occurred in a similar proportion of patients in both groups (4.4% versus 3.3%, respectively) (172). Following this study, U.S. guidelines were revised to allow for hepatitis A vaccine to be used after exposure to prevent infection in healthy persons aged 1 to 40 years. Such persons should receive a single dose of hepatitis A vaccine or IG (0.02 ml/kg) as soon as possible, but ideally no later than 2 weeks after exposure (172) (Table 3). Vaccine is preferred over IG in this setting due to long-term protection and ease of administration. However, in children younger than 12 months, or individuals aged more than 40 years, and in immunocompromised persons, persons with chronic liver disease, and persons for whom HAV vaccine is otherwise contraindicated, IG should be given if possible. If immunization against HAV is otherwise warranted, a dose of vaccine should be given simultaneously with IG.

Postexposure prophylaxis should be given to close personal contacts of individuals with serologically confirmed HAV who have not been vaccinated previously, both household and sexual contacts, as well as persons who have recently shared illicit drugs with someone with hepatitis A. Postexposure prophylaxis is also warranted for unvaccinated staff and attendees of child care centers or homes if one or more cases of hepatitis A is recognized in children or employees, or if cases are recognized in two or more households of center attendees. When an outbreak occurs in a day care center, prophylaxis should be considered for members of households that have diapered children attending the center. If a food handler is diagnosed with hepatitis A, then prophylaxis should be given to other food handlers at the same location. However, prophylaxis is not indicated when only a single hepatitis A case has been identified in a school, hospital, or office setting.

#### Prevention of Hepatitis A in International Travelers

In June 2007, the ACIP concluded that hepatitis A vaccine alone provides protection for healthy international travelers aged more than 40 years (Table 3). The first dose of vaccine should be given as soon as travel is considered. However, for optimal immediate protection, IG can be considered in addition to vaccine and should be given to older adults, immunocompromised persons, and individuals with chronic liver disease who are traveling to an endemic area within 2 weeks. Travelers who are allergic to a vaccine component or who are aged less than 12 months should receive a single dose of IG, which provides protection for up to 3 months (Table 3) (128).

#### TREATMENT

Treatment of typical hepatitis A is supportive; there are no approved antiviral agents that are effective against HAV. Avoiding hepatotoxic medications and abstaining from alcohol is recommended. Hospitalization is rarely needed but occasionally age-appropriate management of nausea and diarrhea, including intravenous hydration, is required. Bed rest has no specific benefit. In contrast to typical acute hepatitis A, in which corticosteroids should never be used, the duration and degree of symptoms associated with cholestatic hepatitis may be reduced by a short course of corticosteroids (149).

Many agents have been studied for the treatment of fulminant hepatitis (e.g., corticosteroids, prostaglandin E, IFN,

and ribavirin) with inconclusive results. Liver transplantation is the only potentially successful intervention, although criteria for selecting patients for transplantation have been difficult to establish. Survival is moderately high, even for patients with coma (approximately 66%) and no single factor is predictive of a poor outcome. Overall survival is 55% to 75% among patients undergoing transplantation (153). There is no conclusive evidence that HAV is able to reinfect the transplanted liver.

#### ACKNOWLEDGMENTS

The authors wish to acknowledge the authors of the chapter on hepatitis A virus included in the previous edition of this textbook that formed a solid foundation for this chapter: Drs. Philip R. Spradling, Annette Martin, and Stephen M. Feinstone.

# Human Caliciviruses

ROBERT L. ATMAR AND MARY K. ESTES

## 49

Norwalk virus (NV) was first recognized from an outbreak of epidemic gastroenteritis in an elementary school in Norwalk, Ohio in 1968, in which 50% of the students and teachers became ill and secondary cases occurred in 32% of family contacts (1). Subsequently, NV was visualized using immune electron microscopy (IEM) and described as a 27-nm filterable agent (2). This provided definitive proof that viruses cause diarrhea, an idea initially proposed during the 1940s and 1950s when a filterable infectious agent (although not propagated in cell culture) was passaged serially in volunteers. The first clear description of the basic virological, clinical, and immunological responses to nonbacterial infections came from studies in volunteers administered a bacteria-free fecal filtrate of NV (3). The history of these early investigations leading to visualization of the agent by IEM provides an excellent example of how major scientific advances often require and parallel new technological opportunities (4). The subsequent application of IEM to other diarrheal stool samples ultimately led to the discovery of other viral agents of gastroenteritis and hepatitis A virus (see Chapters 4, 25, 34, and 48). The later cloning and expression of the NV genome resulted in the development of new assays and reagents that permit large-scale epidemiologic studies.

### VIROLOGY

#### Classification

Although the first report of the visualization of NV was in 1972, the virus was not classified until 1990. Classification required the successful cloning of the viral genome because NV and related agents were noncultivable in cell culture. Molecular cloning and characterization of the NV genome allowed this virus to be classified as a member of the family *Caliciviridae* (5). Caliciviruses are nonenveloped, icosahedral particles containing a single-stranded RNA of positive polarity, approximately 7.7 kilobases (kb). The name calicivirus, from the Latin *calyx* meaning “cup” or “goblet,” describes the cup-shaped depressions observed by EM (see Fig. 1). Although structural studies confirm that NV contains cup-shaped depressions, these depressions are often clearer in other strains of animal and human caliciviruses (Fig. 1).

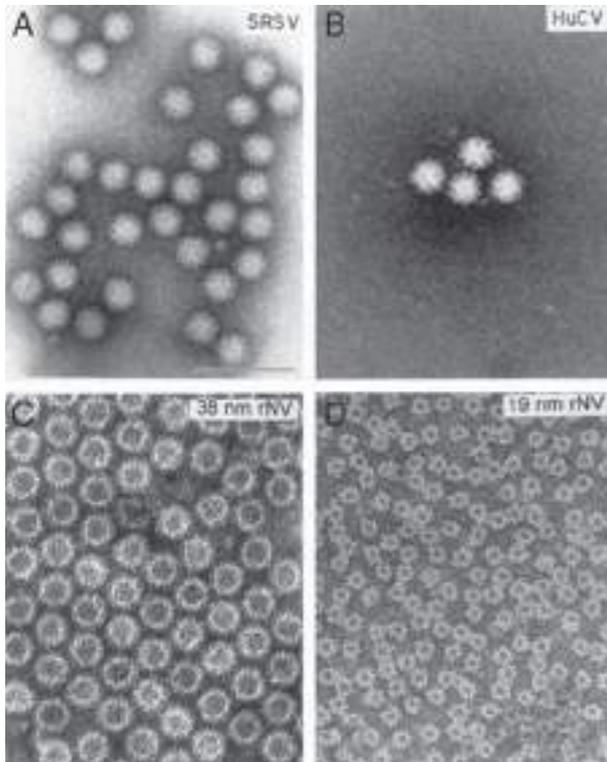

There are five genera currently recognized within the *Caliciviridae* family (6). Two of these genera (*Norovirus*

[NoVs] and *Sapovirus* [SaVs]) contain human and a few animal strains while the other three genera, *Vesivirus* (e.g., vesicular exanthem virus of swine, feline calicivirus, San Miguel sea lion virus), *Lagovirus* (e.g., rabbit hemorrhagic disease virus, European brown hare syndrome virus), and *Nebovirus* (e.g., Newbury-1 virus), contain only animal strains. Classification of NV as a calicivirus based on its genomic characteristics replaced a previous interim classification in which these and other small-sized fecal viruses were classified morphologically according to whether they contained visible structural features. In this morphological system, two groups of human viruses that contain members of the *Caliciviridae* family were recognized: the classical (or morphologically typical) caliciviruses and the small round-structured viruses (SRSVs). NV was the prototype SRSV strain. Although most morphologically typical caliciviruses have been found to be SaVs and most SRSVs have been identified as NoVs, a few morphologically typical caliciviruses have been found to be NoVs. Thus, correct classification requires obtaining sequence data. Although electron microscopists in diagnostic laboratories may continue to use the morphological appearance as a tentative classification system, other rapid diagnostic assays to detect human caliciviruses (HuCVs) are available (see below).

#### Genogroups and Genotypes

The availability of the first NoV nucleotide sequence opened a new era in the characterization of HuCVs, including the agents previously characterized as SRSVs. Primers were designed to amplify viral sequences from clinical samples, and numerous different strains were identified. Eventually, the complete sequences of several HuCV strains were reported, and phylogenetic analyses of these and other virus strains allowed the classification of a virus strain into the genus *Norovirus* or *Sapovirus* (4).

Strains within a genus can be further subdivided based upon phylogenetic analysis of the polymerase region, the capsid region, or the third open reading frame (ORF3). Such analyses have allowed the subdivision of NoVs into seven genogroups (7) and SaVs into five genogroups (8), and virus strains in both genera into different genotypes (Tables 1 and 2). Each genogroup has been proposed to represent a separate species (9, 10), although this designation has not yet been accepted by the International Committee on Taxonomy of Viruses. Criteria for the separation of NoVs

**FIGURE 1** Electron micrographs of caliciviruses. Negative-stain electron micrographs of (A) an NoV (previously called small round-structured virus, or SRSV) from the stool of a volunteer given NoV/NV/8fIIa; (B) an SaV with the classical calicivirus morphologic features including distinct cuplike indentations in the surface of the particles, taken from the stool of a child and containing SaV/Sapporo; (C) 38 nm rNV particles produced and purified from insect cells infected with a baculovirus recombinant that expresses the NV ORF2; and (D) 19-nm particles produced and purified from insect cells infected with a baculovirus recombinant that expresses NV ORF2. Bar, 50 nm. Panel D adapted from White et al. (33) and courtesy of Dr. L. White.

into genogroups and further into genotypes have been developed and build upon previously reported genotypes (9). The primary designation is based upon phylogenetic analysis of the complete amino acid sequence of the major structural protein, VP1 (10). New genotypes are assigned by an international group of experts and require at least two complete capsid sequences from strains in the new genotype and differ from the closest genotype cluster by at least two standard deviations. For GI strains, this represents at least a 20% to 21% uncorrected pairwise difference of the VP1 amino acid sequence for strains in different genotypes, while for GII strains the uncorrected pairwise difference between strains in different genotypes is at least 13% to 15% (9). Sapoviruses are also classified based upon analysis of the complete VP1 sequence, although they have less genetic diversity (11).

Recombination occurs among both NoVs and SaVs, most commonly near the start of the VP1 gene, and is likely a common mechanism by which new strains are generated (12, 13). Thus, although similar phylogenetic relationships are frequently identified when both the polymerase and capsid regions of the genome are analyzed (14), discordant results can occur following a recombination event (12). This has led to the classification of norovirus strains by poly-

merase genotype in addition to the capsid genotype. The polymerase genotype is preceded by a capital 'P' to distinguish it from the capsid genotype. An Arabic number is used when the polymerase genotype has previously been associated with an established reference capsid genotype; a letter is used for orphan polymerase sequences. To date, P types have only been assigned to GI and GII strains (Table 1). At least 1300 nucleotides (nt) of sequence at the 3' end of the first open reading frame are required to assign a new polymerase genotype.

The formal designation of norovirus strains has been proposed to include the genogroup, the host (e.g., human, bovine, porcine), a two-digit country of origin, the genogroup and genotype (and variant name, if appropriate), and the strain name. Thus, the original Norwalk virus is designated as GI/Hu/US/1968/GI.P1-GI.1/Norwalk while a GII.4 variant is GII/Hu/GB/2010/GII.P4-New Orleans2009/London48 (9).

### Serotypes and antigenicity

Norovirus and sapovirus serotypes are not yet defined due to the lack of robust cultivation systems. However, based on cross-challenge studies in volunteers and some comparisons of different prototype particles by immune electron microscopy (IEM) and enzyme-linked immunosorbent assay (ELISA), an initial proposal (before classification into genera) identified at least five serotypes, represented by NV, Hawaii virus (HV), Snow Mountain virus (SMA), the Taunton virus, and Sapporo virus (SV) (15). Subsequently, additional antigenic groups were proposed based on IEM studies. These serotype designations assume that antibody reactivity by IEM reflects reactivity of antibody with neutralization epitopes on the surface of particles. However, some polyclonal and monoclonal antibodies that bind virus do not block virus binding to cells (16). The antigenic relationships between a subset of these viruses have been evaluated in ELISAs using hyperimmune antisera generated against recombinant virus-like particles (VLPs). Although only limited comparisons have been performed to date, viruses belonging to distinct genotypes are antigenically distinct from strains belonging to other genotypes for both NoVs (17) and SaVs (18). Better characterization of distinct serotypes will become possible as cell culture methods are developed.

Recombinant VLPs have been used to characterize serological immune responses of individuals involved in experimental human infection studies (19, 20) and in outbreaks of NoV infection (21). The likelihood of detecting a serological response is greater when the antigen used is derived from a virus in the same genotype, but there are not enough data available at this time to determine the significance (in terms of biologic or type differences) of genotype designations. For example, patients infected with GI.1 viruses can show cross-reactive immune responses to other genogroup I viruses, although usually at a lower frequency and magnitude compared to the response to the homologous strain (19, 20). In some instances, persons infected with genogroup I viruses from genotypes distinct from NV (GI.1) show seroresponses to NV VLPs that are similar to those seen when the infecting strain is from the NV genotype (21). In contrast, patients infected with genogroup II viruses have had such "homologous" responses to Toronto virus (GII.3) and Hawaii virus (GII.1) VLPs only when the infecting strain is in the genotype from which the test antigen strain was derived (21). Cross-genogroup responses have also been observed, and it is likely that a person's past NoV infection history influences the occurrence of such responses.

**TABLE 1** Prototype strains *Norovirus* strains by genogroups and genotypes based upon (9, 10, 7)

Capsid genogroup genotype	Capsid prototype strain	GenBank number	Polymerase genogroup genotype*	Polymerase prototype strain	GenBank number

Viruses with similar antigenic reactivity have been identified at different times and geographic locations such that viruses antigenically similar to some prototype viruses are still circulating, and these strains show relatively good conservation of amino acid sequences over long periods of time (22). On the other hand, viruses belonging to some genotypes appear to undergo antigenic drift through epochal evolution. This phenomenon is best described for GII.4 viruses, with new variants emerging every 2 to 4 years over the past two decades. Analysis of the amino acid sequences of the major capsid protein of GII.4 strains found that changes preferentially accumulate in the outer portion of the capsid protein (the P domain, see below) (23). The emergence of new variants with the concomitant occurrence of epidemic disease suggests that immunity in the human population drives antigenic drift and the evolution of at least some norovirus genotypes (24).

## COMPOSITION

### Virion Morphology, Structure, Size

NV originally was described as a 27-nm particle based on analysis of particles obtained from stools that were aggregated with antibody (2). Structural analysis of particles from stool is limited by the necessity to perform IEM due to the low numbers of particles present in most samples. Based on such micrographs, NV appeared to have a feathery outer edge that lacked a definitive surface substructure (Figure 1a); in certain orientations, NV has minor surface indentations.

A more precise description of the structure of NV is now available based on the analysis of recombinant Norwalk virus (rNV) particles produced in insect cells infected with a baculovirus recombinant expressing the cDNA that encodes the capsid proteins (Fig. 1c and Fig. 2) (25). The NV capsid

**FIGURE 2** Structure of Norwalk virus particles. (a) Surface representation of the three-dimensional surface structure of rNV particles viewed along the icosahedral 3-fold axis. This structure was determined by image processing of the rNV particles shown in Figure 1c. The rNV particles have a distinct architecture and they exhibit T = 3 icosahedral symmetry; the 2-fold, 3-fold, and 5-fold axes of symmetry are shown. Cuplike depressions are evident at the 3-fold and 5-fold axes. The capsid structure is made up of 90 archlike dimers of a single protein that form two types of capsomers; A/B capsomers (n=60) surround the 3- and 5-fold axes of symmetry and C/C capsomers (n=30) are located at the 2-fold axes of symmetry. (b) Summary of the properties of the single protein that makes up the NV capsid structure. A linear schematic of the three domains (c, conserved; v, variable; lc, less conserved) in the single capsid protein and a region predicted to fold into an eight-stranded antiparallel beta-barrel is shown. (c) X-ray crystallographic structure of rNV capsid at 3.4 Å resolution, as viewed along icosahedral 2-fold axis. Only backbone atoms of the 180 subunits are depicted, and the structure is depth-cued, with deeper blue at lower radii and lighter blue at higher radii. (d) Ribbon presentation of the C sub-unit of rNV capsid protein. N-terminal arm, S domain, P1 and P2 subdomains are colored in green, yellow, red, and blue, respectively. N- and C-termini of the capsid protein are indicated. The C-terminus faces a hollow, the N-terminus faces the interior of the capsid, and the P2 subdomain faces the exterior of the capsid. Figures a, c, and d kindly provided by B.V.V. Prasad; modified from Prasad et al. (27, 28), with permission.

is composed of 180 copies of a major polypeptide (VP1) that folds to produce the capsid structure and a few (<5) copies of another polypeptide (VP2) (26). By negative-stain electron microscopy, rNV particles have a similar morphology to the native NV (Fig. 1). The rNV particles have a distinct architecture and exhibit T=3 icosahedral symmetry (Fig. 2) (27). The major capsid protein folds into 90 dimers that form a shell domain from which archlike capsomers protrude (Fig. 2 b-d). The crystallographic structure of rNV particles

shows that the major capsid protein is folded into two domains, a shell domain and a protruding domain. The shell domain has a classical eight-stranded beta sandwich motif found in many viral capsid structures, and the amino acid sequence of this domain is the most conserved region of the capsid protein sequence (28). The arches are made from the protruding domain and are arranged in such a way that there are large hollows at the icosahedral 5- and 3-fold positions (Fig. 2b), which appear as cuplike structures in classical caliciviruses. The three-dimensional structures of other caliciviruses are quite similar to that of NV (29). The S domain serves as an icosahedral scaffold (Fig. 2d). The P2 domain is an insert into the P1 domain, and it has the greatest sequence and structural variability in the protein. The protruding domain of the classical calicivirus is longer than that for NV, and the shape of the top of the arch also differs in such a way that the NV would show a feathery appearance by negative stain EM.

These three-dimensional structures provide independent evidence of the similarities of distinct morphologic types of caliciviruses, as well as structural information on where antigenic epitopes and the cellular attachment site in the virus capsid might be located. Although not yet proven to be cellular receptors for NoVs, histoblood group antigens such as the type A and B trisaccharides bind by extensive hydrogen bonding to the outer portion of the P2 domain of GI and GII NoVs, although at distinct locations on the capsid (30, 31). The greatest sequence variation in the major capsid protein is in the top of the protruding arch region, a region that contains distinct epitopes that change among GII.4 variants (28, 32).

Preparations of recombinant NoV [rNV and rMexico virus [GII.3]) particles also contain smaller-sized particles (~19 nm) (Fig. 1d) (33). These particles probably represent an alternative assembly of the single capsid protein, and they possess similar binding and antigenic properties compared to the larger particles. Such smaller-sized empty particles also have been observed in stools of children infected with these viruses, but it is not known if these smaller particles have any distinct biological properties.

### Genome Organization and Viral-Specific Proteins

The first sequence of the NV genome was obtained from sequencing cloned DNA (cDNA) from virus partially purified from stools obtained from volunteer studies (5, 34). The full-length genomic sequence is known for more than 20 NoV strains and several SaV strains. Partial sequences of hundreds of other NoVs and SaVs have also been determined.

The genome is a positive sense, polyadenylated, single-stranded RNA approximately 7.4 to 8.3 kb in length, excluding the 3' polyadenylated tail (6). After a short noncoding region at the 5' sequence, the genome of the NoVs is predicted to encode three open reading frames (ORFs), as shown in Fig. 3. The first (ORF1) and second (ORF2) ORF sequences overlap by a short, variable (14 to 17) number of nucleotides. ORF3 is in a separate reading frame from ORF2, overlapping ORF2 by one (or a few) nucleotide(s). SaVs have only two ORFs, with the genes encoded by NoV ORF1 and ORF2 in the same ORF (ORF1) of the SaVs (Fig. 3).

The longest NoV ORF, ORF1, encodes a polyprotein precursor of nonstructural proteins based on the identification of sequences similar to the picornavirus nonstructural proteins (Table 3). *In vitro* translation of the ORF1 from Southampton virus (a GI.2 NoV) yields a polyprotein that is cotranslationally cleaved to give three major products: a 48 kDa N-terminal protein (NS1-2), a 41 kDa protein NTPase

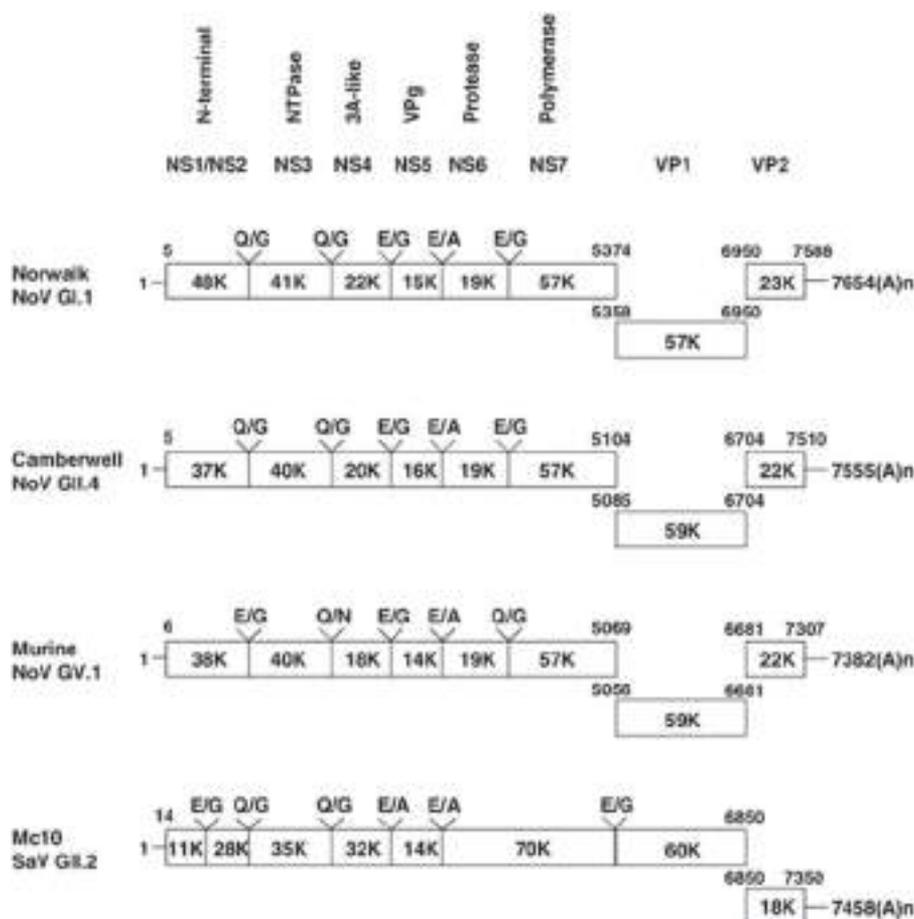

(NS3), and a 113 kDa protein that is homologous to the 3ABCD region of picornaviruses. The 113 kDa protein can be cleaved further into a 22 kDa protein (NS4), a 16 kDa protein (NS5, VPg), a 19 kDa protein (NS6, the 3C protease), and a 57 kDa protein (NS7, the RNA-dependent RNA polymerase). Similar findings have been noted when the ORF1 of a GII. NoV (NoV/Camberwell 101922/1994/AU) virus is expressed in COS cells using a simian virus 40-based expression vector (35). The structures of a GI.1 NoV protease and of a GII.4 polymerase have been solved (36, 37), and these proteins are being evaluated as targets in the future developments of antiviral drugs (38, 39).

Proteins expressed from ORF1 are immunoreactive based on detection by human immune sera of a fusion protein expressed in a  $\lambda$ gt11 library and immunoprecipitation of a 57 kDa protein expressed from ORF1 in insect cells (40, 34) and the development of immune responses to the NV protease by infected persons (41). These results indicate that infected individuals make antibodies to proteins other than the capsid protein, an observation that should be considered when interpreting early data on the antigenic relatedness of these viruses determined by RIA or ELISA using stool extracts as antigen and sera from adult volunteers.

The second ORF of NV encodes a protein of 530 amino acids with a calculated molecular weight of 56,571, similar in size to the viral capsid protein (Fig. 3). The NV ORF2 contains a conserved amino acid motif of PPG that also is found in the picornavirus capsid protein VP3 (34). Expression of ORF2 and ORF3 in insect cells infected with a baculovirus recombinant containing this gene, and the expression of ORF2 alone in cell-free translation systems produces products similar in size to that observed for the capsid protein of native NV particles, confirming that ORF2 encodes the capsid protein that self-assembles into VLPs (Fig. 1c).

A soluble viral antigen with an apparent molecular weight of approximately 30,000 kilodaltons (kDa) is excreted in the stools of volunteers infected with NV (34), and this antigen has been shown to result from the specific cleavage of the capsid protein (42). The amino terminus of the soluble protein detected in the stools of volunteers given NV is the same as that obtained following trypsin treatment of preparations of rNV particles (42). However, this cleavage product is not made from intact capsid protein but from soluble capsid protein; the cleavage site is buried in the hinge region between the protruding domain and shell domain within intact particles. This indicates that this specific cleavage may not be important in activation of infectivity; it remains unknown if it affects the immunogenicity or pathogenicity of these viruses.

ORF3 is at the 3' end of the genome. For NV, it encodes a small protein of 212 amino acids with a molecular weight of 22.5 kDa and a very basic charge (isoelectric point of 10.99). Sequences of the ORF3 of other NoVs indicate that the protein encoded by this gene ranges from 211 to 268 amino acids. The NV ORF3 protein is a minor structural protein, present in both native virions and VLPs expressed from a baculovirus recombinant containing both ORF2 and ORF3 (26). In native virions, the apparent molecular weight of the ORF3 protein was found to be 35 kDa in size. The higher molecular weight apparently results from phosphorylation of the ORF3 protein, based on the observation that the 35 kDa protein is lost following phosphatase treatment of baculovirus expressed ORF3 recombinants (26). The role of the ORF3 protein is still unknown, although it may be involved in nucleic acid binding and encapsidation of the viral RNA (26).

**FIGURE 3** Genomic organization of noroviruses and sapoviruses. Schematic of the genomic organization of two human genogroup I and II NoVs, the murine genogroup V NoV and a human genogroup II SaV. The NoVs have three predicted ORFs that include (1) ORF1, a polyprotein that contains the nonstructural proteins NS1-NS7; (2) ORF2, the major capsid protein (VP1); and (3) ORF3, a minor capsid protein (VP2). For SaVs, ORF1 is longer and contains the major capsid protein, VP1 (see text for details). Nucleotide numbers denoting ORFs are indicated for each of the viruses. Molecular weights of each of the viral proteins are also indicated. Among the NoVs, NS1/NS2 forms a single protein, and for the SaV strain indicated, NS6/NS7 forms a single protein. This information is compiled from GenBank sequences M87661 (NV), AF145896 (Camberwell), AY228235 (Murine), and AY237420 (Mc10) and selected references (35, 43, 44, 160, 161).

**TABLE 3** Human calicivirus structural and nonstructural proteins

Name of protein	Protein size in kDa	ORF	Function	Comments
N-terminal (NS1/NS2)	37-41	ORF1	Unknown	NS1/NS2 is cleaved into two peptides in some NoV and SaV strains
NTPase (NS3)	40-41	ORF1	NTPase	Binds and hydrolyzes NTP
3A-like (NS4)	19-32	ORF1	Unknown	Location in ORF1 analogous to picornavirus 3A protein
VPg (NS5)	14-16	ORF1	VPg	Binds cellular initiation factors involved in protein synthesis
Protease (NS6)	13-19	ORF1	Cysteine protease	Mediates cleavage of ORF1-encoded polyprotein
Polymerase (NS7)	57	ORF1	RNA-dependent, RNA polymerase	May also have protease and polymerase function as uncleaved precursor protein (NS6/NS7)
VP1	58-60	ORF2 (NoV) ORF1 (SaV)	Major structural protein	180 copies per virion, part of ORF1 in SaVs
VP2	12-29	ORF3 (NoV) ORF2 (SaV)	Minor structural protein	A few copies per virion of this basic protein

The overall genomic organization of SaVs differs from that of NoVs, more closely resembling that of the animal calicivirus RHDV. As noted earlier, the VP1 gene lies at the 3' end of ORF1. *In vitro* translation experiments show the ORF1 of SaV/Mc10/2000/Thailand is cleaved into the same proteins as were described for NoVs, with the exception that the N-terminal protein is cleaved into two peptides, NS1 (11 kDa) and NS2 (28 kDa), and no cleavage of the protease and polymerase (NS6-7) occurs (43, 44). ORF2 is in frame -1 relative to ORF1 at the 3' end of the genome and it could encode a basic, hydrophilic protein that contains no cysteine residues and is analogous to ORF3 of the NoVs.

## BIOLOGY

### Norovirus Replication Strategy

Many human NoVs bind to carbohydrate histoblood group antigens (HBGAs) present on the surface of epithelial cells (45). There are strain-specific differences in NoV recognition of HBGAs, and for some NoVs, no HBGA to which the virus binds has been identified (46). The specific HBGA to which a NoV strain binds has been proposed to be a potential viral receptor based upon the lack of susceptibility to infection of persons who have genetic mutations that prevent the expression of the HBGA on the surface of the cell (47, 48, 49). For example, mutations in the fucosyltransferase 2 gene that inactivate or prevent expression of the corresponding enzyme prevent expression of secretor-type HBGAs on gut epithelium and are associated with absolute resistance to GI.1 strains and to most GII.4 strains. A number of HBGA-binding patterns exist for the different NoV strains such that most, if not all, persons have the potential to be susceptible to at least some NoV strains (46). To date, HBGAs have not been found to play a role in the binding of human SaVs to epithelial cells (13).

The mechanism by which the human NoV strains enter the cell is not known. GII.4 VLPs induce invaginations after binding to glycosphingolipids and causing their clustering on the surface of giant unilamellar vesicles; this may be an initial step in virus cell entry (50). Studies of murine NoV and porcine enteric calicivirus (a SaV) indicate that virus entry involves trafficking through endosomes (51). After entry, the NoV genomic RNA serves as a messenger RNA template from which the nonstructural proteins are produced. A subgenomic RNA containing ORF2 and ORF3 is produced during viral replication and serves as a template for production of the structural proteins, VP1 and VP2. Besides the genomic RNA, a major species of subgenomic RNA (over 2 kb) has also been observed in stools of a volunteer infected with NV (40). The availability of cell culture for porcine enteric calicivirus and murine NoV and reverse genetics systems will allow further characterization and improved understanding of the replication strategies of these viruses (52, 53, 54).

### Host Range and Animal Infection

Natural infections with HuCVs suggest that these viruses are largely species-specific. Attempts to experimentally transmit NV and other HuCVs to a wide range of animals (chickens, mice, guinea pigs, rabbits, kittens, puppies, piglets, calves, baboons, and various monkey species) have largely been unsuccessful. Some rhesus monkeys and rabbits have seroconverted when fed HuCV, and a chimpanzee fed NV shed soluble antigen and responded serologically. More recently, replication of human GII.4 NoV strains have been suc-

cessfully demonstrated in gnotobiotic piglets and calves and in immunodeficient Balb/c mice inoculated intraperitoneally (55, 56). Nevertheless, most available data suggest that the host range specificity for HuCVs is narrow. Animal (porcine, bovine, and lion) strains have been noted in both the NoV and SaV genera (7, 8, 9), but it is not known whether these strains can be transmitted to humans. To date, no virus strain identified in a human has had the sequence of an animal NoV. The factors responsible for host restriction are not known at this time. Animal caliciviruses (vesiviruses and lagoviruses) have been noted to cause extraintestinal disease and to have a broad host range, being able to infect more than one species of animal. Additional human illnesses and cross-transmission between species may be discovered as the HuCVs become better characterized.

### Growth in Cell Culture

The HuCVs have been refractory to cultivation in cell culture and in animal models. A report noting the propagation of NoVs in suspensions containing three-dimensional aggregates of human embryonic small intestinal cells (INT-407) has not been confirmed by other investigators (57). More recently, the propagation of a GII.4 strain in a B lymphocyte line (BJAB) has been reported to be dependent on coinoculation with bacteria expressing histoblood group antigen (58). Confirmatory studies of this finding are still needed. A variety of cell lines (including human and animal cells) bind rNV particles, suggesting that host range specificity does not occur at the level of cell binding (16). In addition, NV RNA transfected into several of the mammalian cells that bind virus is infectious, producing viral particles (59). Similar findings have been observed with a NoV reverse genetics system (53).

### Inactivation by Physical and Chemical Agents

Studies of the stability of the HuCVs have been done by experimental infection of humans. Consistent with the fact that these agents are the most important cause of food and waterborne disease, NV is resistant to inactivation following treatment with chlorine concentrations usually present in drinking water, and NV is more resistant to inactivation by chlorine than poliovirus 1, human rotavirus (Wa), simian rotavirus (SA11), or f2 bacteriophage (60). NV retains infectivity for volunteers following (1) exposure to pH 2.7 for 3 hours at room temperature, (2) treatment with 20% ether at 4°C for 24 hours, or (3) after incubation at 60°C for 30 minutes (61). NoVs also have retained infectivity after freezing. However, high hydrostatic pressure treatment of NoV-inoculated oysters inactivated virus infectivity in a human infection model (62), although the palatability of the oyster was adversely affected by the treatment. NoV-contaminated surfaces can be disinfected effectively using a combination of detergent and sodium hypochlorite (63). A variety of cultivable virus surrogates have been used to assess responses to different inactivation procedures and to compare the results measured using molecular assays with those for GI and GII noroviruses (64). No single surrogate satisfactorily represents results seen with human strains, and among the noroviruses there appear to be differences in susceptibility from one strain to another.

## EPIDEMIOLOGY

Epidemiological studies indicate that NoVs are among the most common causes of gastroenteritis worldwide (65, 66).

### Geographic and Temporal Distribution

NoVs are the major causes of epidemic gastroenteritis in both developed and developing countries (65, 66). Infections by NoVs have been detected on all continents, and these viruses appear to have a worldwide distribution. SaVs also are causes of gastroenteritis worldwide but less frequently than NoVs (8). Epidemic viral gastroenteritis usually occurs in family or community-wide outbreaks, affecting adults, school-age children, family contacts, and young children. Epidemic viral gastroenteritis is usually mild and self-limited, distinguishing it from infantile gastroenteritis caused by rotaviruses, which is generally a severe (often life-threatening) diarrheal illness in infants and young children. Infection with both NoVs and SaVs occur year round, although a distinct increase in occurrence of disease has been noted during cold weather months for both viruses (8, 67).

### Incidence and Prevalence of Infection

Specific incidence data for illness associated with NoV and SaV infections are not available in the U.S., although norovirus disease burden has been estimated (68). Investigators at the CDC calculated that 19 to 21 million norovirus illness occur annually in the United States. The illnesses lead to approximately 1.7 to 1.9 million outpatient visits, 400,000 emergency department visits, 56,000 to 71,000 hospitalizations, and 570–800 deaths per year. Children under 5 years of age have the highest rates of outpatient visits and hospitalizations while almost all of the mortality occurs in adults more than 65 years of age. With the introduction of rotavirus vaccination in young children, noroviruses are replacing rotaviruses as the viral pathogen associated with the greatest impact (medically attended illnesses and hospitalizations) (69).

The CDC estimates that the average person in the United States will have approximately five norovirus illnesses over his or her lifetime (68). In the United Kingdom, the Infectious Intestinal Disease II study estimated an annual incidence of 47 norovirus illnesses per 100 person-years (70), which is similar to the estimate for the United States. SaVs were the second most common cause of viral acute gastroenteritis in the IID2 study, which is higher than other epidemiological studies have noted (70, 71). The risk of infection and illness is highest in children under 5 years of age. In low-income countries, the high prevalence of NoV detection in asymptomatic persons (either due to prolonged postsymptomatic infection or to subclinical infection) has made it difficult to assess disease burden. In a multicountry, case-control study of moderate-to-severe diarrhea (Global Enteric Multicenter Study, GEMS) of children under 5 years of age, NoV infection was not associated with a measurable attributable risk of illness in most participating countries because of the high frequency of infection in asymptomatic children (72). On the other hand, in the multicenter Malnutrition and Enteric Disease (MAL-ED) study, GII NoVs had the highest overall attributable risk as a cause of diarrhea in the first year of life (73). NoVs also have been detected in patients with gastroenteritis in the developing world and are a common cause of traveler's diarrhea (74, 75).

NV antibody seroprevalence was examined in relatively large studies performed in the 1970s using reagents from volunteers and a radioimmunoassay (RIA) or immune adherence hemagglutination assay (IAHA) (15). These studies indicated antibody to NV is acquired gradually, beginning slowly in childhood and accelerating in adult years, so that >50% of adults possess antibody to NV by age 50. Similar

observations have been made in the UK, Japan, and Sweden using rNV capsid antigens, although a greater percentage of adults (89% to 98%) possessed antibody to NV. The higher detection rate for antibody likely reflects the greater sensitivity of the rNV antibody test (76). Other recombinant NoV and SaV capsid antigens have been used in seroprevalence studies in both developed and developing countries (15, 77). NoV-specific antibody is transferred transplacentally, with up to 90% or more of newborns having measurable serum antibody (77). Antibody seroprevalence declines during the first 6 months of life, and then it rises progressively thereafter as infants and young children acquire natural infection. Infection with NoVs can occur at a younger age (less than 1 year) than previously recognized.

A number of different NoV strains circulate in a community at any given time. During the epidemic period, strain diversity is greatest at the beginning of the season and declines as the season progresses (78). GI NoVs have been identified more commonly as causes of traveler's diarrhea and are also more commonly linked with shellfish-associated disease, while GII strains are most commonly associated with sporadic infection and outbreaks of gastroenteritis (66, 74, 75, 79). The reasons for the observed differences between genogroups is not known, although NV (a GI NoV) has been shown to specifically bind to oyster tissues (80, 81). GI and GII NoVs may exhibit different stabilities under different environmental conditions.

### Outbreaks of Gastroenteritis

Much of our understanding of the epidemiology of NoVs has come from studying the cause of outbreaks of water- and food-borne gastroenteritis. NoVs are now recognized as the most common cause of outbreaks of nonbacterial gastroenteritis in the United States, Europe, and Japan, with 60% to >90% of these outbreaks being associated with NoV infection (66). Outbreaks have occurred in recreational camps, cruise ships, communities, hospitals, schools (elementary or college), the military, nursing homes, and families. They have been associated with contaminated drinking water, swimming water, consumption of uncooked or poorly cooked shellfish, ice, bakery products (frosting), various types of salads (potato, fruit, tossed), and cold foods (celery, melon, vermicelli, consommé, sandwiches, and cold cooked ham) (82). Outbreaks can occur year-round and affect primarily school-aged children and adults.

Infections with SaVs were first detected among young children with gastroenteritis (83), although infection of adults and the elderly also occur. They have been associated with outbreaks in orphanages, day care centers, schools, and hospital wards (13). SaVs also have been associated with food-borne outbreaks but much less frequently than NoVs (8).

Nosocomial infection with HuCVs may be quite common (84). As noted above, asymptomatic infections can occur (85, 86), and asymptomatic virus shedders may be the source of some outbreaks. NoV infections occur in immunocompromised hosts, and prolonged (>1 year) symptomatic shedding leading to severe malnutrition and dehydration has been described (87). Hospitals and long-term care facilities are among the most common settings where outbreaks occur (84). Outbreaks in hospitals in the United Kingdom have led to the closure of many hospital wards, with a high economic impact, while more than 50% of NoV outbreaks reported in the United States occur in long-term care facilities (88, 89). While NoVs have been found in the stools of HIV-positive patients, its role in the

etiology of gastroenteritis or infection in this patient population is not greater than in non-HIV-infected controls (90, 91). Outbreaks have been associated with military personnel during field or shipboard maneuvers and with the elderly, often in nursing homes or hospital settings (92, 93, 94). These infections can be devastating because of high secondary attack rates leading to sustained chains of transmission, and such outbreaks can last several months. Serial outbreaks on cruise ships have also occurred (95). Reinfections with the same agent can occur, as clearly demonstrated by the susceptibility of volunteers to symptomatic or asymptomatic infection following multiple challenges with the same infectious virus (96, 97).

Since the mid-1990s, the GII.4 genotype has been the predominant cause of NoV outbreaks worldwide (21, 66). Symptomatic infection with these strains has been positively associated with secretor status (expression of the FUT2 gene) (98). Novel GII.4 variants emerged over the past 20 years to cause epidemic disease. As discussed above, it is possible that the development of immunity in the population may drive the evolution of these viruses (99, 100).

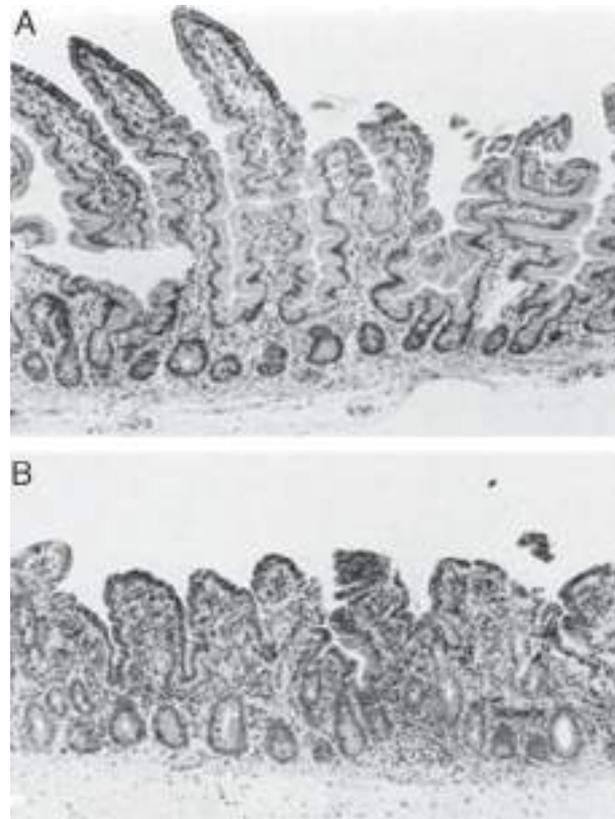

### Transmission

NV is highly infectious, and infections spread rapidly. The human infectious dose 50% has been calculated to be  $\sim 1320$  genomic equivalents (virions) in genetically susceptible persons from human experimental infection studies, with as few as 200 genomic equivalents resulting in symptomatic infection (101). Peak virus shedding in feces is as high as  $10^{12}$  genome equivalents per gram, and in vomitus it has been measured to be as high as  $10^7$  per mL (101, 102). In semi-closed communities or in volunteer studies, illness attack rates are high ( $>50\%$  to as high as  $90\%$ ) and patients present with explosive diarrhea and vomiting. There often is substantial spread to secondary contacts ( $>50\%$  attack rate), and these characteristics may necessitate the closure and disinfection of hospital wards, cruise ships, or hotels (103). Transmission occurs largely by the fecal-oral route, and exposure risks decrease as sanitary conditions improve and population density decreases. However, transmission by the fecal-oral route alone does not fully explain the rapid spread of these infections. Increasing evidence suggests that some outbreaks have been due to airborne or fomite transmission (103, 104). Proximity to projectile vomiters has been identified as a risk factor, and aerosolized viral genomes have been detected in concentrations up to  $2 \times 10^3$  genomic equivalents per  $m^3$  from air samples taken from symptomatic patients' rooms and surrounding hallways and nursing stations in health care facilities (105).

An unresolved question related to transmission is the duration that an affected individual is infectious. The duration of symptomatic illness in healthy adults is 48 to 72 hours. Sensitive antigen detection and RT-PCR assays have shown that excretion occurs in  $>90\%$  of ill volunteers, shedding is detected in asymptomatic individuals, and antigen shedding starts as early as 15 hours after infection, before symptomatic illness in approximately one quarter of subjects, and is detectable in fecal samples for several weeks after infection (85, 106, 102). Correspondingly, epidemiologic studies confirm transmission of NoVs in association with presymptomatic (107) and postsymptomatic (108) infection.

### PATHOGENESIS

In early volunteer studies with NV and SMA, the incubation period ranged from 10 to 51 hours and 19 to 41 hours,

**FIGURE 4** Histologic alterations observed in a volunteer after challenge with Norwalk virus. Jejunal tissue from biopsies of a volunteer prior to challenge (A) and after challenge (B) with Norwalk virus. The villi are broadened and flattened during Norwalk virus gastroenteritis illness. (H&E,  $\times 90$ .) From Agus et al. (111), with permission.

respectively (109, 110). Illness usually lasted 24 to 48 hours. In adult volunteer studies where proximal intestinal biopsies were taken (111, 112), histologic changes were seen in jejunal biopsies from ill subjects (Fig. 4). Symptomatic illness was correlated with a broadening and blunting of the intestinal villi, crypt cell hyperplasia, cytoplasmic vacuolization, and infiltration of polymorphonuclear and mononuclear cells into the lamina propria, but the mucosa itself remained intact. Histologic changes were not seen in the gastric fundus, antrum, or colonic mucosa (112) or in convalescent phase biopsies. The extent of small intestinal involvement remains unknown because studies have only examined the proximal small intestine and the site of virus replication has not been determined. Intestinal biopsies from NoV-infected children who were small intestinal transplant recipients showed increased enterocyte apoptosis and inflammation that was difficult to distinguish from allograft rejection (113). NoV infection also is associated with epithelial barrier dysfunction (114). Studies of GII.4 infection in gnotobiotic pigs demonstrated patchy infection of duodenal and jejunal enterocytes, with a few ileal enterocytes also infected (55).

Clinical studies of experimental human infection also show that small intestinal brush-border enzymatic activities (alkaline phosphatase, sucrase, and trehalase) are decreased, resulting in mild steatorrhea and transient carbohydrate malabsorption (111). Jejunal adenylate cyclase activity is

not elevated (115) and gastric secretion of HCl, pepsin, and intrinsic factor is temporally associated with these histologic changes. In contrast, gastric emptying is delayed (116). It has been suggested that reduced gastric motility may be responsible for the nausea and vomiting associated with this gastroenteritis. Another hypothesis is that symptomatic illness is due to the host's innate immune response to the viral infection.

### Virus Shedding and Extra-intestinal Spread

Fecal viral loads are significantly higher among symptomatically infected persons compared to those with asymptomatic or subclinical infection based upon epidemiological and human experimental infection studies (101, 117, 118), although there is considerable overlap between the two groups. Other factors can also influence the apparent viral load, including the assay used (which can vary in amplification efficiency based upon virus genotype), patient age, and clinical setting (119). Thus, there is not a clear viral load cut-off level that distinguishes between symptomatic and asymptomatic infection. The duration of NoV fecal shedding is similar following asymptomatic and symptomatic infection in otherwise healthy persons (101, 117).

Viral RNA can be detected in the blood of up to one third of young children with NoV gastroenteritis (120, 121). The presence of viral RNA in the blood is associated with higher viral fecal loads and longer hospitalizations for gastroenteritis (120). Viral RNA can be detected in the bloodstream of children with primary immune deficiencies and in NoV-infected adult stem cell transplant recipients (122, 123), but it has not been identified in immunocompetent adults (124). NoV RNA has also been identified in cerebrospinal fluid (123, 125). The clinical importance of the extra-intestinal NoV is unclear at this time.

### Immunity and Immune Responses

Adaptive immune responses play a role in protection from NoV and SaV infection in addition to the innate resistance to infection observed from failure to express HBGAs on the gut epithelium. The contribution of adaptive immunity was difficult to discern in early studies because of the uncharacterized involvement of genetic resistance mechanisms. Nevertheless, these studies found that at least 50% of adult volunteers became ill following administration of NV (GI.1) or Hawaii virus (HV, GII.1) (110). Short-term homologous immunity developed based upon the results of early challenge studies in which volunteers who became ill following an initial NV challenge failed to become ill on rechallenge with the same agent 6 to 14 weeks later (97). In several volunteer studies elevated pre-existing levels of serum or intestinal antibody to NV did not correlate with resistance to illness; instead, higher antibody levels were associated with increased susceptibility to illness (96, 97). In contrast, short-term resistance to infection induced by prior homologous infection correlated with antibody levels in other challenge studies, and a correlation between the level of serum antibody and protection has been observed in epidemiologic studies (96, 110, 126).

The recognition of genetic resistance to infection and illness facilitated the assessment of adaptive immune responses. Although serum antibody levels measured by ELISA do not predict susceptibility to illness in an experimental human infection model, higher levels of pre-existing serum antibody that blocks virus binding to HBGAs are associated with a decreased risk of illness in seropositive individuals administered NV (127, 128). These findings have also

been noted in a GII.4 challenge study (129) and have been proposed as surrogate for neutralizing antibody and as a correlate of immunity. Infection leads to an increase in circulating, virus-specific, IgG- and IgA-producing plasmablasts 1 week later, and as these cells die off, virus-specific memory B cells are generated. Higher levels of IgG memory B cells at the time of virus exposure are also associated with a lower risk of illness (130). Infection also leads to mucosal immune responses that are measurable in saliva and feces. Higher levels of pre-exposure salivary IgA have also been associated with a lower risk of illness, while higher levels of fecal IgA were associated with lower peak levels of fecal virus excretion (130). T cells responses occur after infection, but their relative importance is less well characterized (20). The contribution of past infection with heterologous strains to protection from infection also remains to be determined, as heterotypic HBGA-blocking responses can be observed in both adults and young children (19, 20, 131).

Few studies have examined immunity to SaV infection in young children. One study that measured immunity to SaV/Sapporo/82 using a RIA with hyperimmune antiserum that measured type-specific antibodies found that the presence of serum antibody was clearly correlated with resistance to illness but not to infection (132).

## CLINICAL MANIFESTATIONS

The hallmark of infection with NV and other HuCVs is the acute onset of vomiting or diarrhea or both. No prodrome is seen, and the spectrum of illness may vary widely across individual patients. For example, in adults infected with the same experimental inoculum, one volunteer vomited 20 times and required parenteral fluid therapy, whereas a second volunteer had no vomiting but eight diarrheal stools (3). The relative frequency of these and other symptoms in adults experimentally infected with NV (85) (Table 4) is similar to those seen in natural outbreaks and in infection with related viruses (110). Of 50 volunteers orally administered NV, 41 (82%) became infected; of these infections, 68% were symptomatic and 32% were asymptomatic. The most

**TABLE 4** Response of 50 adult volunteers (19 to 39 years old) administered Norwalk virus

Response	% of Infected volunteers (N=41)*	% of Uninfected volunteers (N=9)
Seroconversion	98	0
Antigen excretion	88	0
Infection	100	0
Asymptomatic	32	0
Symptomatic	68	0
Symptoms with clinical illness (N=28)		
Diarrhea	86	0
Vomiting	57	0
Nausea	96	10
Abdominal cramps	96	0
Headache/bodyache	96	40
Chills	36	0
Fever (> 37.8°C)	32	0

Data from Graham et al. (85).

\*Infection determined by antigen shedding and/or antibody response.

common symptoms with clinical illness are nausea, malaise, and abdominal cramps (Fig. 5). Diarrhea, which is usually watery without mucus, blood, or leukocytes, occurs in most patients, and vomiting is seen in most. Subjective or documented fever and chills occur in a minority of patients. The

illness is generally mild and self-limited, with symptoms lasting 12 to 48 hours, and illnesses caused by the different NoVs are clinically indistinguishable.

More severe disease can be seen in certain populations. Illness lasts longer in children <1 year of age and in

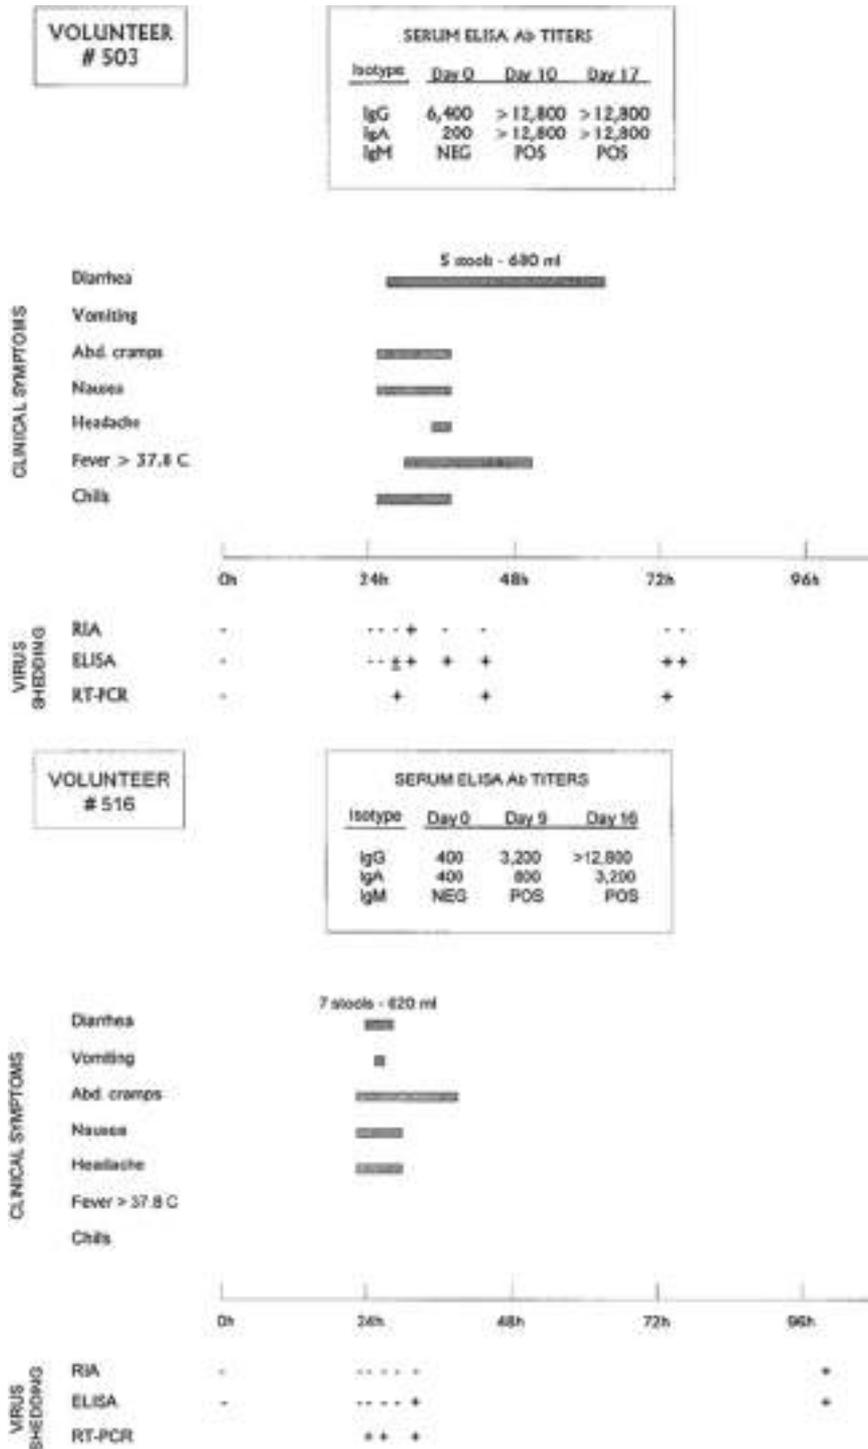

FIGURE 5 Clinical outcome of infection with NV in two volunteers. Clinical course of two volunteers who became ill after challenge with 8fla NV inoculum (at 0 h). Both volunteers were considered to have severe disease. Volunteer 503 was a 29-year-old man and volunteer 516 was a 23-year-old woman (85).

**TABLE 5** Comparison of methods to detect HuCVs.

	Method	Specificity	Sensitivity	Comments
Detection of viral antigen	Electron microscopy	Depends on operator experience	$10^6$ to $10^7$ pp/mL*	Detects viral particles—least sensitive and specific method available; identifies multiple pathogens
	Immune electron microscopy	Depends on antiserum used	$10^5$ to $10^6$ pp/mL	Detects viral particles
	Enzyme immunoassay	Genogroup-specific	Particulate and soluble antigen 0.025 ng protein	Detects viral particles and soluble antigen; low sensitivity and has limited utility for application to individual patients; good for outbreak identification when multiple samples available for analysis
	Immunochromatography	Genogroup-specific	$\sim 10^4$ genomes	Detects viral particles and soluble antigen; similar limitations as enzyme immunoassay, but more rapid result; not currently commercially available in the United States
Detection of genomic RNA	Hybridization	Probes determine specificity	$\sim 10^4$ genomes, if no inhibitors present	Detects genome; more labor intensive than other molecular methods
	RT-PCR	Primers and probes determine specificity	10–40 genomic copies, if no inhibitors present	Need several primer sets and probes to detect all HuCVs; can sequence amplicons from conventional RT-PCR assays to characterize virus; real-time assays allow rapid diagnosis; multiplex assays (also detect other enteric pathogens) commercially available
Detection of seroresponses	IEM	Type-specificity depends on antigen used	Not known, but less sensitive than EIAs using rVLPs	Labor-intensive; rarely used
	EIA	Cross-genotype responses occur	Sensitivity depends on match of antigen with infecting strain	VLPs can be used as antigen; requires paired sera; limited to research laboratories

\*pp/mL = physical particles per mL.

hospitalized patients (133, 134, 135). Volume depletion with renal insufficiency and hypokalemia are more common in the elderly and in persons with underlying disease (e.g., cardiovascular, immunocompromised)(136). Disseminated intravascular coagulation developed as a complication of NoV infection in a group of previously healthy soldiers exposed to severe environmental stress (137). Chronic diarrhea lasting months to years in association with continued viral shedding can be seen in immunocompromised patients (87, 113). Most complications are associated with volume depletion or aspiration of vomitus and can include death, especially in the elderly. Benign infantile seizures have occurred in young children with NoV gastroenteritis, although a causal relationship remains to be established (138).

A provisional diagnosis of infection during outbreaks of gastroenteritis is possible if the following criteria are met: (1) absence of bacterial or parasitic pathogens; (2) vomiting in more than 50% of cases; (3) mean (or median) duration of illness ranges from 12 to 60 hours; and (4) an incubation period of 24 to 48 hours. These criteria were met in 81% to 100% of ill individuals in 38 NoV outbreaks, although more recent analyses of the application of the criteria to food-borne outbreaks investigated by the CDC yielded a sensitivity of 68% (139, 140). A definitive diagnosis, desirable for both clinical and epidemiological studies, requires the use of a detection method for antigen, the viral genome, or antibody responses.

## LABORATORY DIAGNOSIS

Because HuCVs cannot be grown in cell culture initial assays for viral diagnosis were developed using reagents (pre- and post-infection serum and stool) from volunteer studies (reviewed in (15)). The first specific test developed for NV diagnosis was IEM (2), and this method is still used for the examination of fecal samples for the presence of NV and other HuCVs in some diagnostic laboratories. However, laboratory diagnosis of HuCV infections has changed with the sequencing of NV and subsequent expression of the NV capsid protein (Table 5), and molecular diagnostics have become the gold standard for diagnosis (7). Recombinant VLPs for NoVs and SaVs also have been used to develop diagnostic assays described below. The use of some of these assays remains restricted to research laboratories.

### Nucleic Acid Detection

The detection of viral nucleic acids has become the preferred strategy for identifying NoV and SaV infection because of the high sensitivity of this approach. A number of different assay types are currently used for virus detection, although the availability of these assays varies across different countries and clinical settings. RT-PCR-based assays are the most commonly used molecular tests, although isothermal amplification methods such as nucleic acid sequence-based

amplification (NASBA) and loop-mediated isothermal amplification (LAMP) and hybridization-based assays have also been described. Among the RT-PCR-based assays, both traditional RT-PCR and real-time RT-PCR assays are used, with the latter providing more rapid results. An automated sample preparation and real-time RT-PCR assay system (Xpert Norovirus Assay [Cepheid]) has received FDA approval (141). Multi-pathogen assays that identify bacterial, viral, and parasitic pathogens in fecal samples of persons with gastroenteritis are also now commercially available (Luminex xTAG<sup>®</sup> Gastrointestinal Pathogen Panel [Luminex], FilmArray<sup>™</sup> Gastrointestinal Panel [Biofire Diagnostics, LLC]) (142).

Several factors can affect the sensitivity and specificity of RT-PCR assays (15). Clinical samples and environmental samples may contain inhibitory substances that prevent amplification of viral RNA. A variety of methods have been developed to purify viral nucleic acids from these samples, and these methods vary in their ability to remove inhibitors successfully. A strategy for detection of the presence of inhibitors is the use of an internal standard RNA that is amplified only in the absence of significant amounts of inhibitor. Primer and probe selection also impacts assay performance. A number of different primer pairs and different RT-PCR conditions have been described for the detection of NoVs and SaVs (8, 13, 15, 143). No single primer pair will detect all NoVs or SaVs, and no assay has been universally accepted as a standard. Several different conserved regions of the genome have been targets for nucleic acid amplification (viral polymerase VP1, capsid-specific, and NTPase), but recognition that the ORF1-ORF2 junction is highly conserved in NoVs has made this a prime target for amplification (143). Because no single primer pair detects all NoVs or SaVs, two or more primer pairs must be used to have a reasonable likelihood of virus detection.

RT-PCR assays are most commonly used to detect virus in stool samples, but they also have been used to detect virus in vomitus and throat swabs (15). RT-PCR assays are being used increasingly to detect NoVs in foods (primarily shellfish), water samples, sewage, and other environmental samples (e.g., swabs collected from areas potentially contaminated by ill persons) associated with outbreaks of viral gastroenteritis (15, 82). The potential utility of these methods for food and water safety is under evaluation.

### Antigen Detection

The first immunologic assays developed to detect antigen and amenable to large-scale application were radioimmunoassay (RIA) and subsequently enzyme immunoassays (EIAs) (15). Human volunteer pre-infection and convalescent serum were initially used as capture and detector antibodies in these assays, but these antibody reagents have now been replaced with hyperimmune and monoclonal antisera made to rVLPs. Hyperimmune antiserum to rNV VLPs produced in guinea pigs, mice, and rabbits reacts with high titer to the immunogen and to native NV in stool (25, 76, 85). Hyperimmune antisera were used to develop an antigen EIA that has been shown to be highly sensitive and specific for NV antigen (85, 144). The test sensitivity of the standard antigen EIA was determined to be  $\sim 0.025$  ng of capsid protein ( $1.4 \times 10^6$  virions) and antigen was detected in the stools of volunteers at dilutions as high as 1:10,000 (85). The rNV antigen EIA detects both virus particles and soluble protein in clinical samples. Antigen detection assays using hyperimmune antisera generated against a single virus genotype have been found to be sensitive and specific for

viruses belonging to that genotype, but have had limited utility due to their type specificity.

Cross-reactive epitopes that are shared within a NoV genogroup or across genogroups have now been identified, and monoclonal antibodies that detect GI-specific or GII-specific epitope have been used to produce more broadly reactive antigen rEIAs (145). These assays have been commercialized outside of the United States in a variety of assay formats, and one kit has been approved for use in the United States for identification of norovirus outbreaks (7, 146, 147). However, improvements in sensitivity and specificity are needed before these tests are useful as a diagnostic for the individual patient, in contrast to application to outbreak investigations where multiple samples are available (148).

### Serologic Assays

The use of serological assays for diagnosis requires paired serum samples to allow identification of a change in antibody level. Significant rises in virus-specific IgA and IgG titers can be detected as early as 7 days after infection (101). Virus-specific IgM antibody also can be detected within two weeks of infection. The use of serological assays has generally been restricted to research laboratories.

EIAs to detect antibody responses have been developed using rVLPs as the antigen (15, 21, 25, 85). Total, class, or subclass-specific serum antibodies, can be detected depending on the reagents used to detect the bound human antibody. The assay can be modified to detect virus-specific IgA in fecal samples or to detect virus-specific IgM using an antibody capture EIA format.

As noted earlier, antibody that blocks binding of VLPs to HBGAs has been proposed as a surrogate for NoV neutralizing antibody since culture systems have not been available for these viruses (149). Although increases in HBGA-blocking antibody occur after infection, the magnitude of antibody response (i.e., fold-rise) is usually lower than that seen using a standard ELISA.

Heterologous antibody responses can often be detected in subjects following infection (e.g., antibody rise to GII.2 SMA following infection with GI.1 NV) (19, 21, 150, 151). A heterologous response only appears to occur if a homologous antibody response also has occurred, and the heterologous response is of a lower magnitude than that of the homologous response (e.g., 4-fold rise in antibody titer versus a 16-fold rise) (151). Heterologous responses involving IgM or IgA antibody occur infrequently (150, 151).

### PREVENTION

No specific methods are available for the prevention of HuCV infection or illness. Because these agents are highly infectious, handwashing and disposal or disinfection of contaminated material may decrease transmission within a family or institution. Special care must also be given to the hygienic processing of food in view of the frequent occurrence of food-borne outbreaks of NoV infection. Ill food handlers should not prepare food for a minimum of three days after their illness, and plastic gloves should be worn to prepare foods. Consumption of raw shellfish is a risk, since outbreaks have occurred from the consumption of shellfish that meet current microbial (bacterial) sanitary standards. Human breast milk from secretor positive women contains fucosylated mucins that block binding of some NoV strains to HBGAs expressed on epithelial cells and may play a role in protecting infants from NoV infection (152, 153).

## Immunoprophylaxis

Vaccines are being developed to try to prevent norovirus infection and illness (66). A vaccine based upon using a NoV VLP as an immunogen is the only candidate that has been in human clinical trials. This vaccine is immunogenic when delivered as a monovalent vaccine intranasally or as a bivalent vaccine delivered intramuscularly (129, 154). Both routes of administration have led to a modest level of vaccine-induced protection following experimental virus challenge administered shortly after completion of the two-dose vaccine regimen, decreasing illness or illness severity (128, 155). These vaccine studies have been conducted in adults, and many additional studies in other populations (e.g., pediatric, elderly, immunocompromised) along with field efficacy studies are needed to determine the potential utility of a vaccine strategy for prevention of illness or infection. That a vaccine strategy could prove effective is suggested by the short-term immunity to reinfection with NV observed following repeated experimental challenge, the apparent widespread and broad immunity to the SaVs after childhood, and by the correlation of higher serum HBGA-blocking antibody levels with protection from illness and infection (96, 97, 127, 129). The impact of virus diversity, antigenic drift, past infection history, and waning immunity on vaccine responsiveness and effectiveness still need to be determined. The development of HBGA-blocking monoclonal antibodies brings the potential for their use in passive immunoprophylaxis, although the utility of this approach still needs to be assessed (156).

## Management of Outbreaks

Outbreaks can result in significant morbidity and economic loss because of frequent secondary transmission of diseases. Outbreaks are a particular concern in closed environments such as hospitals, nursing homes, or ships because all personnel can rapidly become disabled. Virus can persist in the environment and lead to recurrent outbreaks (95). Ill persons should be isolated and handwashing and disposal or disinfection of contaminated material put into effect immediately. Control measures for outbreaks of viral gastroenteritis should focus on the removal of an ongoing common source of infection (e.g., an ill food handler or the contamination of a water supply), adequate disinfection of contaminated areas (e.g., with a sodium hypochlorite-based or other EPA-approved disinfectant), and on the interruption of person-to-person transmission that can perpetuate an outbreak in a population after the common source has been removed (157, 158).

The facts that asymptomatic infection occurs more frequently than previously realized and that antigen may be shed for 2 to 3 weeks after exposure need to be recognized in managing such outbreaks. This is particularly important in instituting and overseeing the hygienic processing of food for and care of the elderly. The potential for contaminated water sources should be assessed based upon the outbreak setting, and possible sources must be eliminated. Methods for outbreak management will probably improve as new tests are used in epidemiological studies of virus transmission in various settings. For example, if asymptomatic food handlers or hospital staff can be identified, they may be furloughed until they are no longer excreting virus and potentially infectious. Because improvements in environmental hygiene may not be accompanied by reductions of endemic diarrhea caused by viruses, immunization may play an important role in future control.

## TREATMENT

As discussed above, the illnesses caused by these viruses are generally mild and self-limited, and resolution occurs without sequelae (133). Hospitalization for rehydration is occasionally required, but the major impact of this disease has been morbidity and loss of time from work and school. Treatment involves symptomatic therapy, with oral rehydration generally being sufficient. In rare cases, parenteral administration of intravenous fluids is required. Antiemetics and antidiarrheals may provide some relief of symptoms, although no controlled studies have been performed to demonstrate the efficacy of such treatments in HuCV acute gastroenteritis. Deaths from NV gastroenteritis have been reported in the elderly and from HuCV infections in immunocompromised children, although some of these have been attributable to other primary causes. The use of human milk or oral immunoglobulin therapy anecdotally has not had any therapeutic efficacy in an immunocompromised patient (159). Currently no antiviral drugs exist to treat the caliciviruses, but this may change once these viruses are successfully propagated or with the recent availability of high-resolution structures of several of the viral proteins that have enzymatic activities.

# Hepatitis E Virus

HARRY R. DALTON, NASSIM KAMAR, AND JACQUES IZOPET

## 50

Hepatitis E was recognized as a disease in 1980 following a large outbreak of unexplained hepatitis in Kashmir, India, in 1978. The outbreak affected 52,000 individuals, mostly young adults, with a self-limiting hepatitis similar to hepatitis A (1). However, this was not hepatitis A, because there was a very high mortality rate in afflicted pregnant women. Further, most of those infected had previously been exposed to HAV (2). In 1983, the causative virus was discovered by electron microscopy in the stool of a scientist from the former USSR who drank a pooled fecal extract from Soviet troops with unexplained hepatitis serving in Afghanistan (3). The viral genome was sequenced and given the name HEV in 1990 (4). Many of the historical outbreaks of unexplained hepatitis in Asia and other developing areas were subsequently found in retrospect to be caused by HEV (5, 6).

For over 20 years, hepatitis E virus (HEV) was considered a disease that was mainly endemic in developing countries and only of clinical relevance in developed countries in travelers. We now know that this concept is incorrect, because locally acquired zoonotic hepatitis E has been found in every developed country where it has been sought. HEV is endemic in many European countries and hyperendemic in a minority. In addition to acute infection, zoonotic HEV causes chronic infection in the immunosuppressed host and is a surprisingly common contaminant of the human blood supply. Current thinking is that HEV is a pathogen of global significance and is probably the most common cause of acute viral hepatitis worldwide (7).

## VIROLOGY

### Taxonomy

HEV is a member of the *Hepeviridae*, a family that consists of two genera, *Orthohepevirus* and *Piscihepevirus* (8). Only one HEV serotype is recognized. The genus *Orthohepevirus* contains three species that infect mammals (*Orthohepevirus* A, C, and D) and one that infects birds (*Orthohepevirus* B) (Fig. 1). The *Orthohepevirus* A species, which includes strains that infect humans, contains seven genotypes (HEV 1 to HEV 7). HEV1 and HEV2 are found only in humans, whereas the other genotypes infect both human and other animal species, including pigs, wild boar, deer, rabbits, mongoose, and camels. However, the other *Orthohepeviruses* do not infect humans: B infects chickens, C infects rats

and ferrets, while D infects bats. Lastly, the *Piscihepeviruses* infect the cutthroat trout. Despite the lack of robust criteria, subgenotypes have been identified within the four major HEV genotypes (5 for HEV1, 2 for HEV2, 10 for HEV3, and 7 for HEV4) (9). Complete reference genome sequences are available to facilitate genotyping and molecular epidemiology studies (10). Subgenotypes 1a, 1b, and 1c are prevalent in Asia, while subgenotypes 1d and 1e are found in Africa (9). The HEV viruses found in Europe are genotype 3. The distributions of 3f, 3c, and 3e strains in human and pig populations in France are the same, which indicates zoonotic transmission from this animal reservoir (11). The temporal distributions of subgenotypes 3f and 3c in the UK and France seem to be evolving, with increasing frequency of subgenotype 3c (12, 13).

### Virus Structure and Morphology

HEV is a small RNA virus with an icosahedral capsid. Two forms of fully infectious particles have been described. The virions shed in the feces are not enveloped, 27 to 34 nm in diameter, and with a density of 1.27 g/cm<sup>3</sup>. The virions circulating in the blood are cloaked in host cell membranes; their density is 1.15 g/cm<sup>3</sup> (14). The host-derived membranes protect the virus from neutralization by antibodies and may play an important role in cell tropism (14, 15).

### Genome Organization and Proteins

The HEV genome is a single-strand, positive-sense RNA of approximately 7.2 kb. It consists of a short 5' noncoding region that is capped with 7-methyl-guanosine; three open reading frames (ORFs), ORF1, ORF2, and ORF3; and a short 3' noncoding region that ends in a poly-(A) tail (Fig. 2).

ORF1 encodes a non-structural protein about 1700 amino acids long that is involved in HEV RNA replication. This protein contains several functional domains: a methyltransferase/guanylyltransferase, cysteine protease, macrodomain (X domain), RNA helicase that has 5'-nucleoside triphosphatase activity, and an RNA-dependent RNA polymerase (16). A variable region encoding a proline-rich hinge, the polyproline region (PPR), is an intrinsically disordered region in which segments of human genes have been identified (17–22). Immunocompromised patients who develop a chronic infection have a highly heterogeneous mixture of PPR quasispecies at the acute phase of HEV

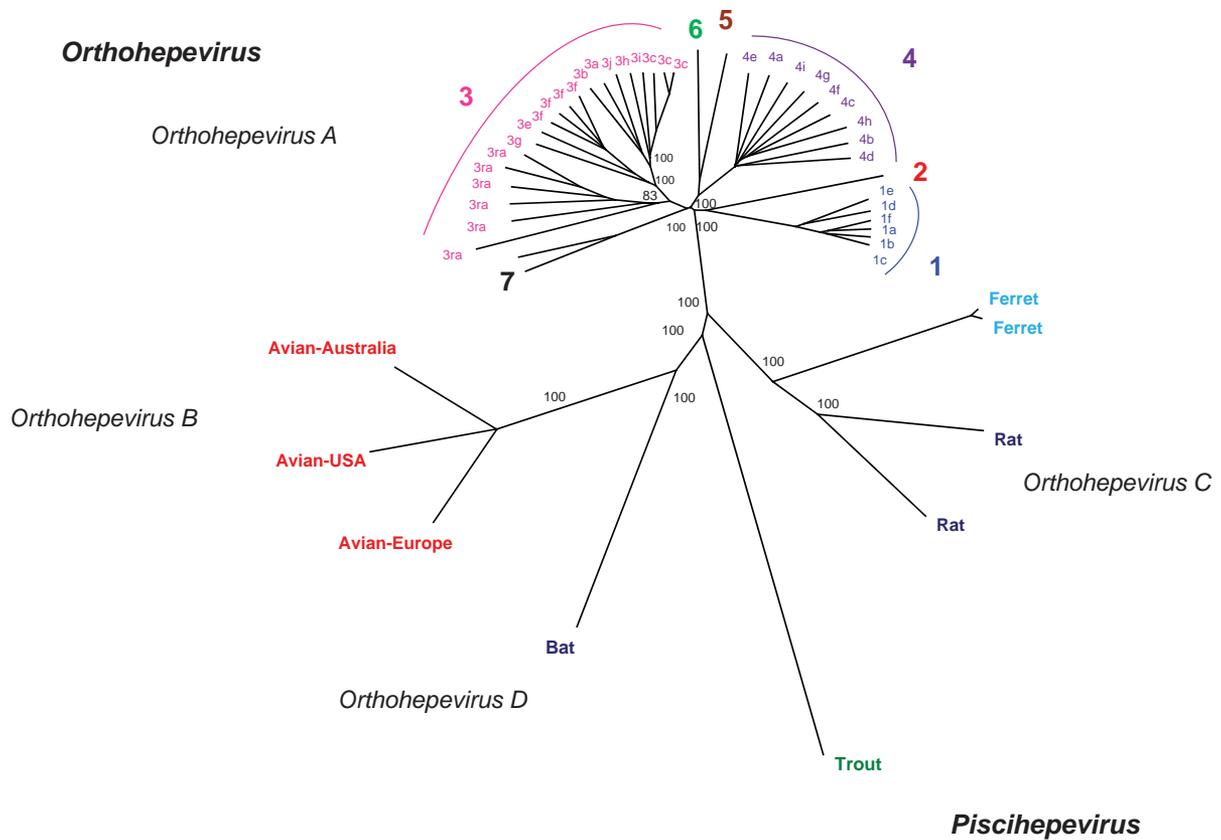

FIGURE 1. Family *Hepheviridae*—Phylogenetic tree based on full-length sequences of HEV strains (neighbor joining method and bootstrap analysis).

infection (23). The ORF1 of HEV1 includes a novel ORF, ORF4 (24). ORF4 is expressed after endoplasmic reticulum stress, and interacts with eukaryotic elongation factor 1 isoform-1 (eEF1 $\alpha$ 1), so stimulating virus polymerase activity.

ORF2 encodes the 660 amino acid virus capsid protein. This protein has three glycosylation sites, Asn 132, Asn 310, and Asn 562 and an N-terminal signal peptide that drives its translocation into the endoplasmic reticulum (25). The capsid protein has been divided into three domains: shell (S), middle (M), and protruding (P) domains. The P domain is the major target for neutralizing antibodies and contains a putative receptor binding domain (26, 27). Capsid monomers self-assemble to form dimers and then the decamers that encapsulate the virus RNA. The capsid consists of 180 copies arranged as an icosahedron with T=3 symmetry (28). Immunological and structural studies of the capsid protein have contributed to the development of a hepatitis E vaccine (29, 30). Immunocompromised patients whose HEV

infection becomes chronic are infected with HEV quasi-species whose genome is highly heterogeneous in regions encoding the M and P domains of the capsid protein (31).

ORF3 encodes a small protein, 113 residues in HEV3 and 114 residues in HEV1, 2, and 4, that is essential for virus egress. ORF3 protein is associated only with enveloped HEV particles, not with naked HEV particles. The ORF3 protein must be phosphorylated on Ser80 before it can interact with the non-glycosylated form of the capsid protein (32). The ORF3 protein contains a conserved PSAP motif that enables it to interact with the endosomal sorting complex required for transport (ESCRT), including the tumor susceptibility gene 101 (Tsg 101) (33–38).

### HEV Replication Cycle

The recent development of several cell culture systems has led to a better understanding of HEV target cells and the virus replication cycle (39, 40).

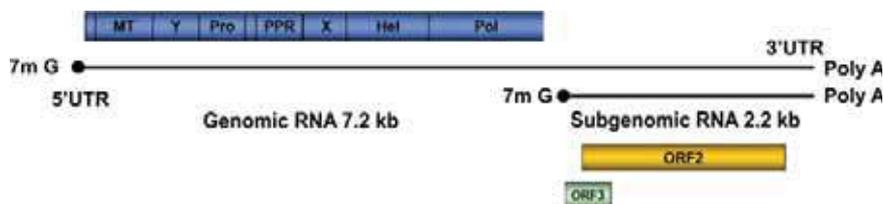

FIGURE 2. Hepatitis E virus genome.

Unenveloped HEV particles attach to the liver cells via heparan sulfate proteoglycans and other potential receptors (Fig. 3) (41). Subsequent events include clathrin-mediated endocytosis involving the dynamin-2 and membrane cholesterol pathways and cytoskeleton remodeling (42, 43). Quasi-enveloped HEV particles are internalized through a clathrin- and dynamin-2 dependent pathway but require (i) Rab5 and Rab7 small GTPases involved in endosomal trafficking, (ii) endosomal acidification, and (iii) lysosomal lipid degradation (44).

The virus RNA is directly translated into ORF1 polypeptide. Whether the polypeptide is cleaved into its separate functional units or functions as a single multidomain protein remains unclear. The viral methyltransferase, protease, helicase and polymerase activities are used to replicate the genomic RNA to give negative-sense RNA intermediates that then serve as templates for the synthesis of genomic and subgenomic positive-sense RNAs. The subgenomic RNA is translated into the ORF2 and ORF3 proteins (45). The positive-sense genomic RNA is packaged into progeny virions.

The tumor susceptibility gene 101 (Tsg101) that interacts with the ORF3 protein and the enzymatic activities of vacuolar protein-sorting protein 4 (Vps4A and Vps4B) are both involved in the release of virions from infected cells (36). HEV particles may acquire a membrane when they are released with internal vesicles from the multivesicular body

(MVB) via the cellular exosomal pathway (35). Bile could degrade the membrane through its detergent action.

### Inactivation by Physical and Chemical Agents

Cell culture and *in vivo* experimental models show that inactivation of HEV in food products derived from infected pork liver is achieved after a cooking time of at least 20 min at an internal temperature of 71°C (46, 47), indicating that infectious HEV can persist after rare and medium-to-rare cooking. Viable HEV has been found in a range of pork products in the human food chain in many countries, and this has led to the proposition that a key route of infection in humans is via consumption of undercooked or uncooked pork. Many pork products are prepared for consumption by air-drying and/or curing. It is unknown if these processes inactivate HEV. Such products are potentially an important source of HEV infection in humans because they are mostly consumed without cooking. Chlorination and UV treatment can reduce HEV in drinking water, but experimental data are still limited (48, 49). Several steps of the manufacturing process of plasma derivatives have been studied by applying HEV inactivation or removal experiments (50). Nanofiltration is effective at removing HEV, ethanol fractionation has limited efficacy, and lowering the pH is ineffective. Liquid heating, like pasteurization, is partially successful at removing HEV but depends on process

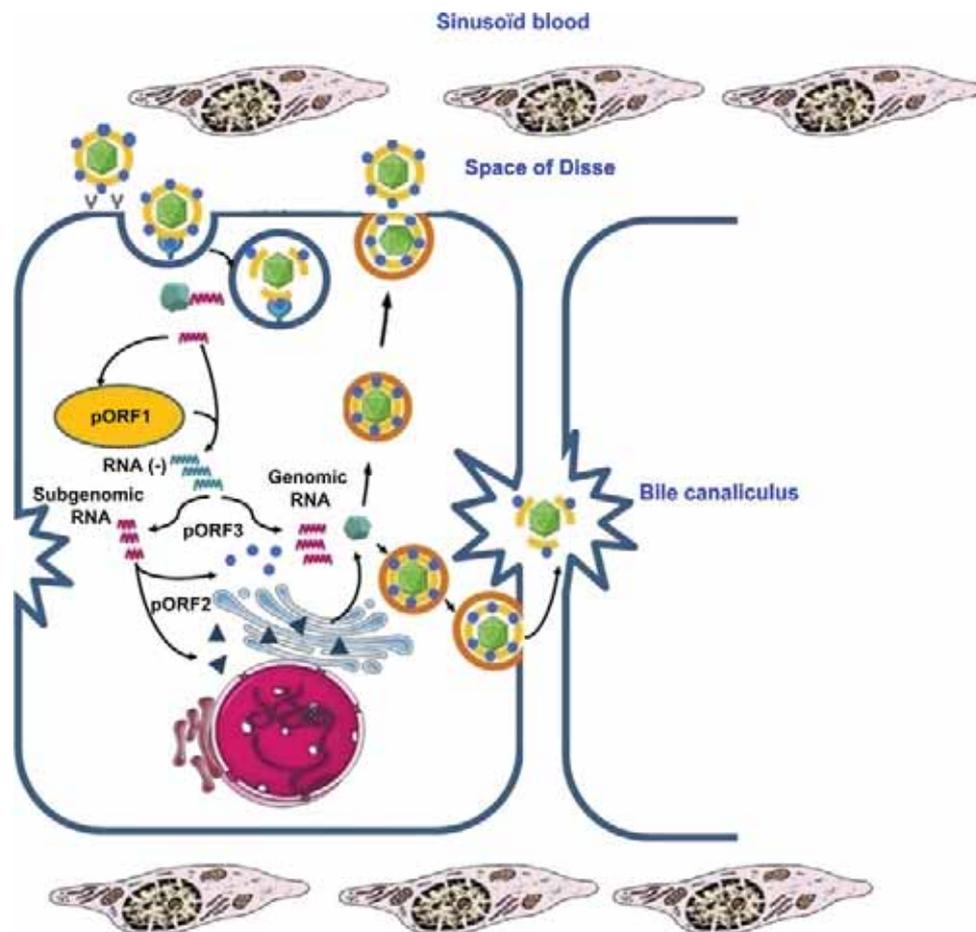

FIGURE 3. Hepatitis E virus replication cycle.

conditions. Treatment by solvent, detergent, or amotosalen does not inactivate HEV.

## EPIDEMIOLOGY

### Classical Hepatitis E

HEV1 and HEV2 are obligate human pathogens spread primarily by ingestion of infected water. HEV1 is endemic in many parts of Asia, particularly in southern countries of the continent, including India, Pakistan, and Nepal. HEV2 is much less common and is found in some African countries. HEV2 caused a large outbreak of hepatitis E in Mexico in the 1980s, but in recent years there have been few documented cases. HEV1 and HEV2 cause sporadic cases of hepatitis E but are also responsible for large outbreaks involving hundreds or thousands of cases. These occur when there is a breakdown in sanitary infrastructure. Examples of this occurred in Delhi, India in 1953 to 1954 (5) when human sewage contaminated the drinking water, resulting in an outbreak involving over 50,000 cases and the Kanpur, India epidemic of 1991 with over 70,000 people affected (51). Outbreaks of hepatitis E have also been particularly common in African refugee camps over the past 20 years.

Direct person-to-person spread of HEV1 and HEV2 is less important than waterborne spread, because secondary cases are rarely seen in household contacts of hepatitis E cases. In Africa, HEV1 and HEV2 are widely distributed and co-circulate in some populations. Both genotypes have been recorded from outbreaks among displaced people. Waterborne transmission is undoubtedly an important route of infection in such cases, often exacerbated by heavy rainfall. However, data from an outbreak of HEV1 infection in Ugandan refugee camps suggest that intra-household transmission can occur (52).

During an outbreak of hepatitis E the clinical “attack rate” (the percentage of infected individuals with clinically evident infection) is variable. This ranges from up to 15% in India (53) to 30% in an outbreak in Uganda (52). Overall, the average clinical attack rate is approximately 20% (54). Previous exposure determines the proportion of the exposed population susceptible to infection, and geographical variations in previous exposure are likely to explain variability in clinical attack rates. However, reinfection can occur when antibody levels fall below a critical level (7, 55). During outbreaks young adult males are most likely to have symptomatic infection. For example, in the outbreak that occurred in Kanpur, India (51), approximately 80% of cases were aged less than 40 years and M:F ratio was 1.7:1. In most cases the illness is self-limiting, but a high mortality is seen in pregnant women and patients with underlying chronic liver disease (7) (see below).

### Zoonotic Hepatitis E

For many years hepatitis E in developed countries was regarded as an uncommon imported infection, largely found in travelers returning home from endemic areas of Africa or Asia. Approximately 10 years ago there were increasing reports of cases of hepatitis E in non-travelers mainly from Europe and Japan. These were found to be caused by HEV3 and HEV4 with very close sequence homology to the HEV found in local pigs, wild boar, and deer populations (56). HEV3 and HEV4 are mainly anthrozoönotic and can be found in a very wide range of mammals, but the true primary host is the pig. The animals infected with HEV appear to have no symptoms. HEV3 is found worldwide, but HEV4 is

geographically limited to East Asia, mainly China and Japan, and more recently documented in both pigs and humans in Europe. In contrast to HEV1 and HEV2, large outbreaks of hepatitis E caused by the zoonotic genotypes have not been observed and cases are generally sporadic. There have been occasional small clusters of hepatitis E in humans in developed countries, which are caused by common consumption of infected foodstuffs (57).

HEV has been detected in range retail meat (mainly pork) products in many different countries (58–61). Consumption of meat or meat products (including pig liver sausage, boar, and deer meat) contaminated with HEV is a proven and probably principal route of infection, but there are other ways HEV can skip from its hosts to human beings. HEV has been found in shellfish in a number of locations (62–64), and an outbreak on a cruise ship in 2008 was epidemiologically linked to consumption of this foodstuff (65). Direct animal contact may be the source of infection in some cases, because anti-HEV IgG antibodies are more commonly found in veterinarians and pig farmers than in control groups (66, 67). Environmental contamination with animal feces may be another source of infection. This might occur either directly via contaminated water (68) from farm water “run-off” or indirectly via contaminated food crops. The latter possibility is given some plausibility by the detection of HEV in strawberries which had been irrigated with infected water (Fig. 4) (7). A recent study from France has shown that drinking bottled water seems to protect against exposure to HEV (69). These findings suggest that, as in developing countries with HEV1 and HEV2, zoonotic HEV might also be spread via contaminated domestic water supplies. Another recent study from China found HEV4 in cows and their milk; HEV4 contaminating the milk can survive pasteurization (70). This route of infection may be important and deserves further study. However, in most cases of documented hepatitis E, it is not possible to be certain of the route of infection. There is no evidence of sexual transmission and little evidence of person-to-person spread, except via the human blood supply (see below). Transfusion-transmitted infection is thought to cause only a very small minority of human infections, approximately 1% in a recent study of English blood donors and recipients (71).

In contrast to HEV in developing countries, HEV3 and HEV4 tend to affect older males and excess mortality in pregnant women is not seen. In one study from England the M:F ratio was 3:1 and the median age 63 years (72). The finding that older males are most likely to develop clinically apparent acute hepatitis on exposure to HEV3 and HEV4 is a consistent observation, but unexplained. It seems likely that this relates to host factors, rather than differential exposure, because individuals of all ages appear to be exposed to HEV. One possible explanation is that clinically apparent hepatitis is more likely to be evident in patients with sub-clinical hepatic steatosis/fibrosis. In a study from England some patients with hepatitis E were heavy alcohol consumers and an excess number were diabetic, both of which are risk factors for hepatic steatosis and fibrosis (73).

### Seroprevalence

The response to infection includes the production of specific IgG antibodies, which persist and protect against further infection. However, until recently, our understanding of anti-HEV IgG seroprevalence has been problematic because many of the early studies employed serologic assays of very poor sensitivity (74). This led to gross underestimations of

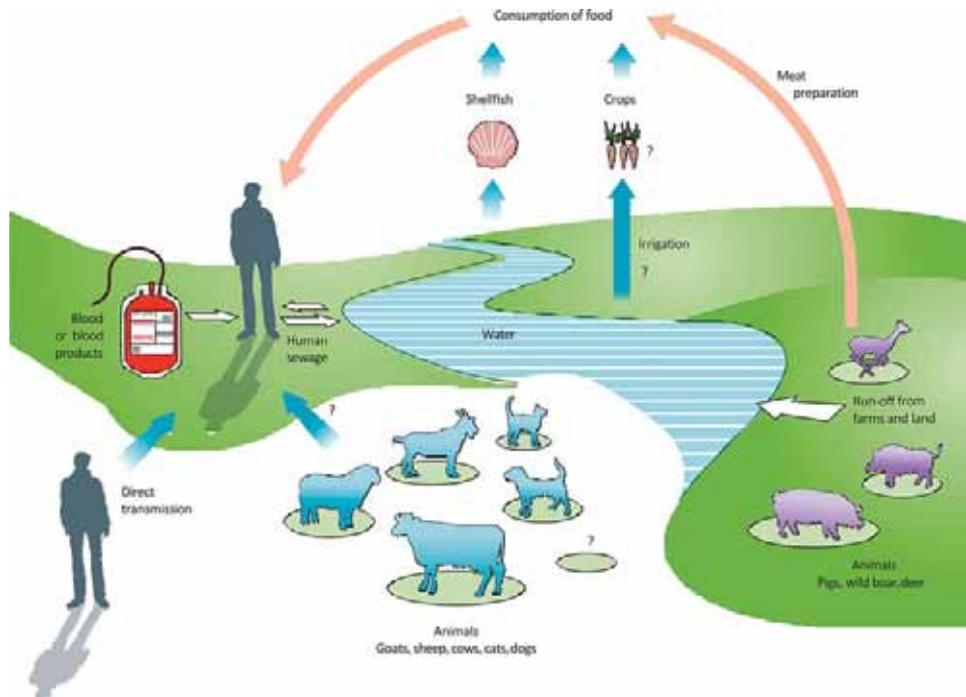

FIGURE 4. Sources and possible routes of infection.

seroprevalence and retarded our understanding of HEV as a pathogen of global significance.

In developing countries, most of the studies are dated and the majority employed assays of poor quality. These studies generally show that seroprevalence is low in children and rises in adolescents and young adults (75). For reasons that are not understood, the situation in Egypt is different, and the seroepidemiology is quite similar to that of HAV: rates of HEV IgG seropositivity rise very rapidly in early childhood

and by early adulthood exposure to HEV appears to be nearly universal (76). A recent study from Bangladesh showed that exposure to HEV was found to be an order of magnitude higher when a more sensitive assay is employed (77). Seroprevalence increases steadily from childhood to the age of 40 years, then plateaus in older people at 75% to 80% (Fig. 5). Only in the last few years have we realized that HEV is endemic in developed countries and has been so for generations. One of the key reasons for this delay in our

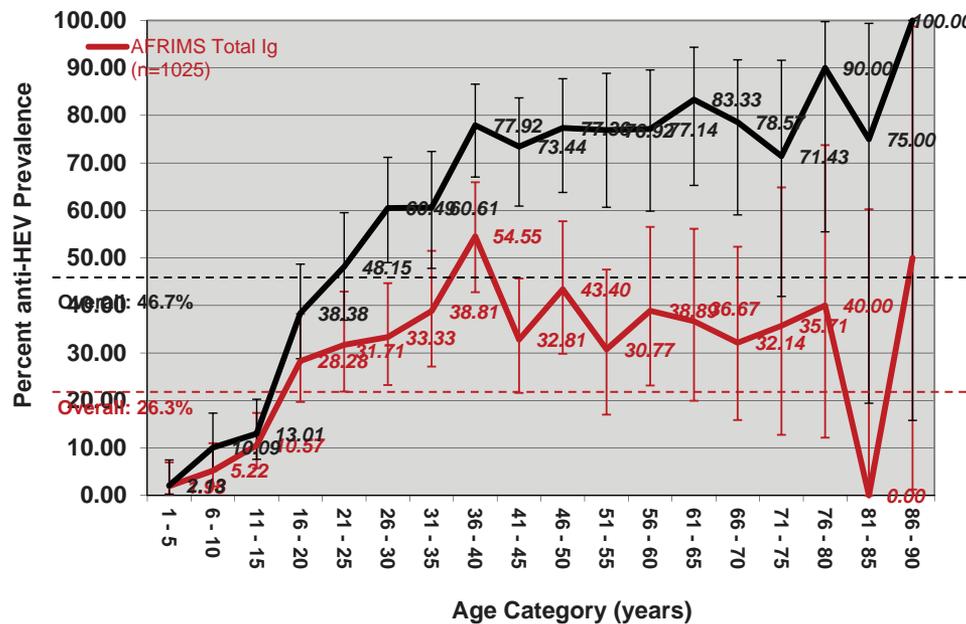

FIGURE 5. Anti-HEV IgG seroprevalence in rural Bangladesh by age. The red line shows the seroprevalence using the AFRIMS assay. The black line shows the seroprevalence (same samples) using a validated Chinese assay, producing seroprevalence estimates an order of magnitude higher.

understanding is that studies from the 1990s showed low (often <5%) seroprevalence rates; anti-HEV IgG positive subjects from developed countries were assumed to be either those who had traveled to endemic areas or had false-positive serology due to cross-reactive antibodies (74). In a Dutch study published in 1993 the anti-HEV IgG seroprevalence was found to be 1% (78). However, using a validated assay of high sensitivity, the seroprevalence from around the same time period was recently found to be 47% (79).

As more recent studies using validated and sensitive anti-HEV IgG assays have been published, the epidemiology of HEV in developed countries has become clearer. In southwest France seroprevalence starts to rise in childhood with a steady increase, which is sustained until old age (80). In western European countries, such as the United Kingdom (81), the Netherlands (79), and Denmark (82), HEV infection was common and seroprevalence rates were high by the mid-20<sup>th</sup> century. It appears that a large cohort of the population was exposed to HEV in the years of turmoil following the 2<sup>nd</sup> World War. Toward the end of the 20<sup>th</sup> century seroprevalence rates in all three countries fell significantly. However, over the last couple of years in the Netherlands seroprevalence has risen quite sharply, particularly in young adults (79). The reason for this recent upswing in seroprevalence is not known.

Seroprevalence also varies between and within countries. Countries with a high seroprevalence include Germany (29%) (83), France (22%) (69), and the Netherlands (21%) (79). In the Netherlands seroprevalence varies little within the regions of the country (84). In contrast, seroprevalence varies significantly in France by region, with values ranging from 8% to 86% (69). Very high seroprevalence rates are found in southern France (Toulouse, Marseille, and Corsica)

and in the northeast of the country. In the United Kingdom, the seroprevalence is 12% to 16% in England (72, 81) and 4.5% in Scotland (85). The reason for these differences is uncertain but may relate to differential rates of exposure to HEV due to differences in national and regional culinary cultures.

### Incidence

Every year, an estimated 20 million HEV infections occur in developing countries, resulting in over 3 million clinical cases and 70,000 deaths (54). This figure of the “Global Burden of disease” is an underestimate of the true impact of HEV in developing countries for two reasons. First, it includes data from only a limited number of developing countries. Second, the calculations were based, at least in part, on seroprevalence data from studies that employed insensitive assays as shown in Figure 5 from Bangladesh (77).

In developed nations, the incidence of locally acquired hepatitis E varies between and within countries and over time. In the United Kingdom the annual incidence has been estimated at 0.2% (81), the Netherlands 1.1% (84), and in Southern France 2% to 3% (69). In the French national study of HEV, incidence mirrored seroprevalence and was found to be significantly higher in southern and northeastern France (69). In most European countries, particularly in western Europe, the number of laboratory-confirmed cases has increased rapidly over the last few years (Fig. 6) (86). While some of the observed increase can be accounted for by improved case ascertainment, it appears that there has been a true increase in incidence in France, England, and the Netherlands (69, 71, 79). The most dramatic increase has been in the Netherlands, where the number of viremic blood donors has increased from 1 in 2,671 in 2011 to 2012 (84) to

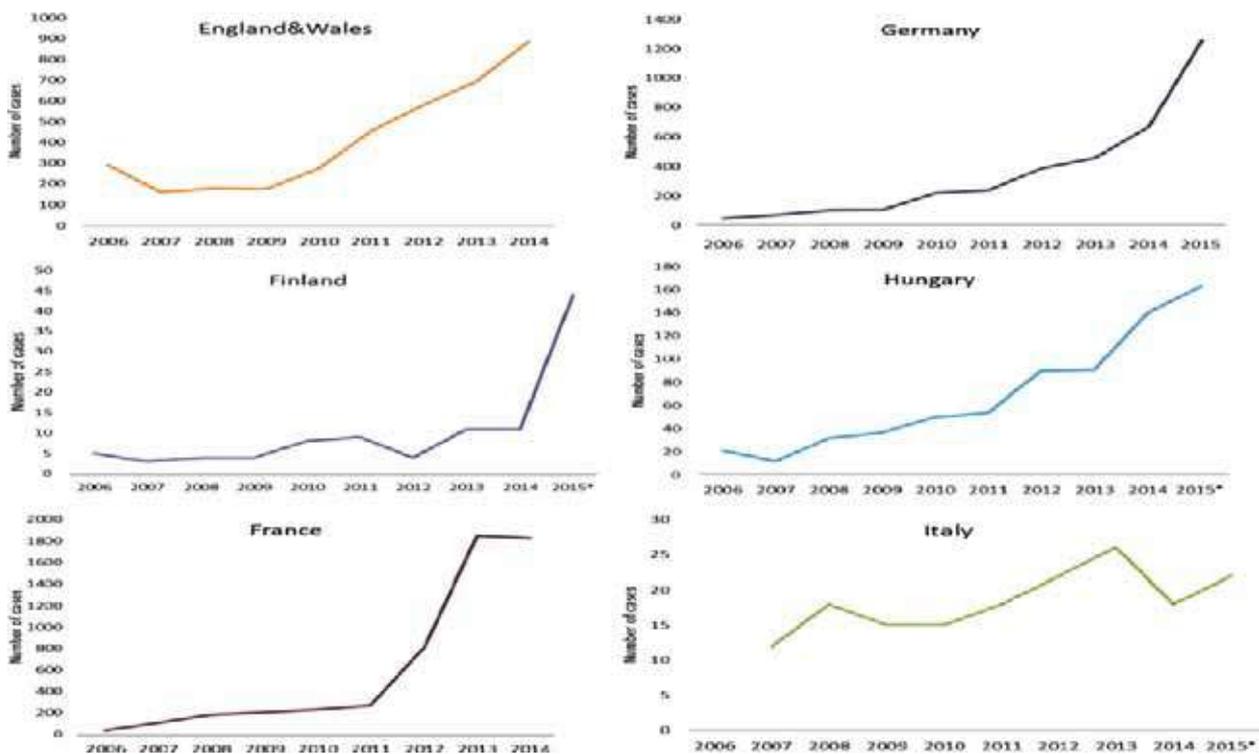

FIGURE 6. Laboratory-confirmed cases of HEV in several European countries. The vast majority of infections were locally acquired and caused by HEV3.

1 in 600 in 2014 (87), accompanied by rapidly increasing seroprevalence rates in young adults (79).

The incidence of hepatitis E has also increased recently in the United Kingdom, and it is currently thought that there are at least 100,000 infections per year, many of which are asymptomatic (71). The increased incidence relates, in part, to improved case ascertainment. However, this has been accompanied by a true increase in incidence (see below). This increase has been accompanied by a change in the strains of HEV recovered from human cases. Historically, HEV RNA causing human disease in the United Kingdom has had very close sequence homology to HEV RNA found in the local pig population. In recent years, coinciding with increased incidence, HEV RNA recovered from human cases in the United Kingdom now bears much more similarity to HEV found in pigs from the Netherlands and Denmark. The explanation for this observation is unclear, but it suggests that there has been a significant and recent increase in HEV contamination of the pork food chain (12). Targeted blood donor screening for HEV was introduced in the United Kingdom in March 2016. Initial, and as yet unpublished, results show a dramatic increase in the number of viremic blood donors, most marked in Scotland. Previously the seroprevalence in Scotland was found to be very low, so currently there appears to be large amounts of circulating virus in a largely HEV-naïve Scottish population. There are a number of other “hot-spots” with high incidence and seroprevalence rates in Europe (Fig. 7).

## PATHOGENESIS

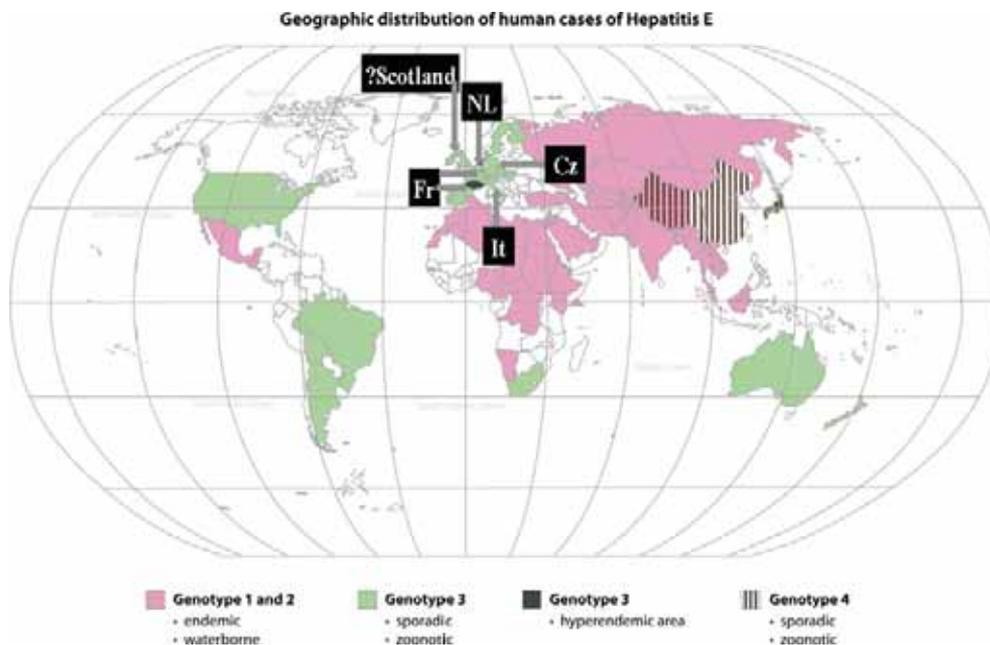

Several animal models of HEV infection have been developed (88). Chimpanzee, rhesus macaques, and cynomolgus macaques have been most frequently used in pathogenesis and vaccine studies. These models are adequate for all

HEV genotypes. Using a low viral inoculum, cynomolgus macaques can be infected without alanine aminotransferase elevation (89). Alanine aminotransferase increase was observed when the inoculum was  $>10^2$ – $10^3$  HEV RNA copies/ml. Other animals such as swine and rabbits can be experimentally infected only by zoonotic genotypes. These models have been used to demonstrate the existence of extrahepatic sites of HEV replication (90–92). Human liver chimeric mice have been developed (93, 94) that can be infected with genotype 1 or zoonotic genotypes. This model may well prove a fruitful method of studying chronic infections and evaluating preclinical antiviral agents.

Studies using animal models of infection and human data have identified three distinct phases of HEV pathogenesis, namely (i) incubation period; (ii) acute hepatitis with various clinical phenotypes (see below); and (iii) convalescent phase. Cell-culture studies suggest that HEV is a non-cytopathic virus and that the outcome of acute HEV infection is determined by the strength of the host’s immune response. Viral replication in the liver appears about 7 days after virus transmission but the percentage of infected hepatocytes is still unclear. Viremia appears a few days before the onset of symptoms, attains its peak with that of serum alanine aminotransferase levels, continues for a few weeks, and is accompanied by prolonged fecal HEV excretion (95). Although HEV is a hepatotropic virus, immunohistochemistry experiments and detection of negative strand of HEV RNA indicate that it can also replicate in other tissues such as the gastrointestinal tract (90, 92), kidney (96), central nervous system (97), and placenta (98).

## IMMUNE RESPONSES

As for many other viruses, a concerted action of innate and adaptive immunity is involved in the outcome of HEV infection and protection. However, our understanding of the

**FIGURE 7.** European “hot-spots” with high incidence/prevalence of HEV, include southern and northeastern France and the Netherlands (see main text). Very recent data show a huge incidence in the Czech Republic (86) and a seroprevalence in blood donors in Abruzzo, Italy of nearly 50% (216).

molecular mechanisms and the crosstalk between the host immune response pathways is still limited.

### Innate Immune Responses

HEV infection elicits the production of type I and III interferon (IFN) after recognition of the viral RNA as a pathogen-associated molecular pattern (PAMP) by pattern recognition receptors (PRR). Secreted IFNs can then induce interferon-stimulated gene (ISG) transcription via the JAK/STAT signaling cascade (39, 99, 100). The ORF3 protein may enhance type I IFN production via a direct interaction with the PRR retinoic acid-inducible gene I (RIG-I). The ORF1 protein inhibits RIG-I signaling and prevents IFN $\beta$  induction by deubiquitination of RIG-I and TANK-binding kinase 1 (TBK1) (101, 102). In addition, the ORF3 protein has been shown to inhibit the IFN- $\alpha$ -induced phosphorylation of Stat 1, thus restricting its activation (103).

Natural killer cells and natural killer T cells show evidence of activation in patients with acute hepatitis E (104). Gamma-delta T cells are mobilized during acute HEV infection in transplant patients (105).

### Cell-Mediated Immune Responses

Potential differences between the different genotypes related to differences in disease severity and outcome are still unknown. This is an important area of research for a better understanding of the pathogenesis of HEV infection during pregnancy. HEV-specific T-cell responses are weaker in patients with fulminant acute hepatitis E than in patients with milder disease (106). Cross-genotype specific T-cell responses are generated during acute infection and are associated with viral control (107). CD4+ and CD8+ T cells from healthy subjects previously exposed to HEV show strong and multispecific responses against HEV peptides, whereas those from immunocompromised patients with chronic infection do not (108).

### Humoral Immune Response

HEV infection is associated with appearance of anti-HEV antibodies. IgM antibodies are the first to appear and persist for 6 to 9 months while IgG antibodies persists for several years. One study detected anti-HEV IgG antibodies in nearly half the patients who had hepatitis E 14 years previously (109). Anti-HEV antibodies have been shown to neutralize the virus *in vitro* (110). Importantly, this neutralization capacity is observed only with naked particles (i.e., stool derived-HEV) (14). The neutralization capacity extends to heterologous strains belonging to all the four major HEV genotypes. Current neutralization tests are based on real-time PCR, immunofluorescence foci assay, and a high-throughput assay using biotin-conjugated HEV recombinant capsid protein (111). Neutralization titers of HEV serum samples are associated with anti-HEV IgG levels. However, the anti-HEV IgG level in humans conferring absolute protection against HEV is unknown. Therefore, the duration of natural protection against HEV reinfection remains unclear.

## CLINICAL MANIFESTATIONS

### Acute HEV

In developing countries, hepatitis E mainly affects young adults with sporadic infections and occasional sizable outbreaks. The incubation period is approximately 40 days. The clinical phenotype ranges from asymptomatic infection, through mild self-limiting hepatitis, to acute liver failure,

with an overall reported mortality of approximately 1%. Symptoms and signs of hepatitis E include anorexia, abdominal pain, nausea, vomiting, fever, general malaise, and jaundice. Biochemical evidence of hepatitis includes elevated serum levels of liver enzymes and hyperbilirubinemia, which usually return to normal within a few weeks (7).

The clinical features of hepatitis E in developed countries are similar to those seen endemically in developing nations, and are virtually indistinguishable from those observed in any form of acute viral hepatitis, except that 5% to 10% of patients present with a primarily neurological illness (see below). However, HEV infection in developed countries is commonly asymptomatic (Fig. 8) (7) and clinical illness is mostly observed in middle-aged and elderly males (72, 112).

### CHRONIC HEV

The first cases of chronic HEV infection were reported in solid-organ-transplant patients (113). Among 14 patients who had been infected by HEV, 8 had persistent HEV replication for at least 6 months with increased ALT and progressive liver fibrosis (113). Thereafter, a large number of cases of chronic HEV infection have been described in transplant and other immunosuppressed patients (see below). All cases of chronic HEV infection have occurred in patients infected by genotype 3 or 4 (7). No case of chronic HEV1 or 2 infection has been reported. A study of 205 renal transplant recipients from India found no evidence of chronic infection with HEV (114).

Most data on the natural history and treatment of chronic HEV infection have been obtained in solid-organ-transplant patients. Initially, chronic HEV infection was defined as persistent replication of HEV for at least 6 months (113). However, in a large cohort of chronically infected transplant recipients, no spontaneous HEV clearance was observed between 3 and 6 months after infection without therapeutic intervention (115). Hence, it has been suggested that HEV replication for more than 3 months should be the definition of chronic infection. This definition is still a matter of debate, because recently a case of spontaneous clearance was observed 4 months after HEV infection (116, 117). In a large multicenter retrospective study that included 85 solid-organ-transplant recipients, 66% of patients developed chronic hepatitis and nearly 10% developed cirrhosis (118). Surprisingly, liver fibrosis progression was rapid and some patients developed cirrhosis only 2 to 3 years after infection (118, 119). No correlation has been observed between HEV viral load and liver fibrosis progression (120).

Chronic HEV infection and cirrhosis have been observed in both adult and pediatric solid-organ-transplant patients (121). The source and route of HEV infection in transplant recipients does not differ from that in the immunocompetent (see above). The one exception is that the grafted organ can occasionally transmit HEV infection (122) to the recipient. As in the immunocompromised patients, the majority of transplant recipients who develop HEV infection are asymptomatic (118). However, compared to immunocompetent patients, chronic HEV in immunocompromised patients usually produces mild elevations in serum transaminases (ALT typically 100-300IU/L) and HEV serology can remain negative (118). Therefore, the use of HEV PCR is mandatory in immunocompromised patients (121), both to establish the diagnosis and to monitor response to therapy.

In the first report of cases of chronic HEV infection, patients having lower CD4 and CD8 lymphocyte counts were more likely to develop chronic HEV infection,

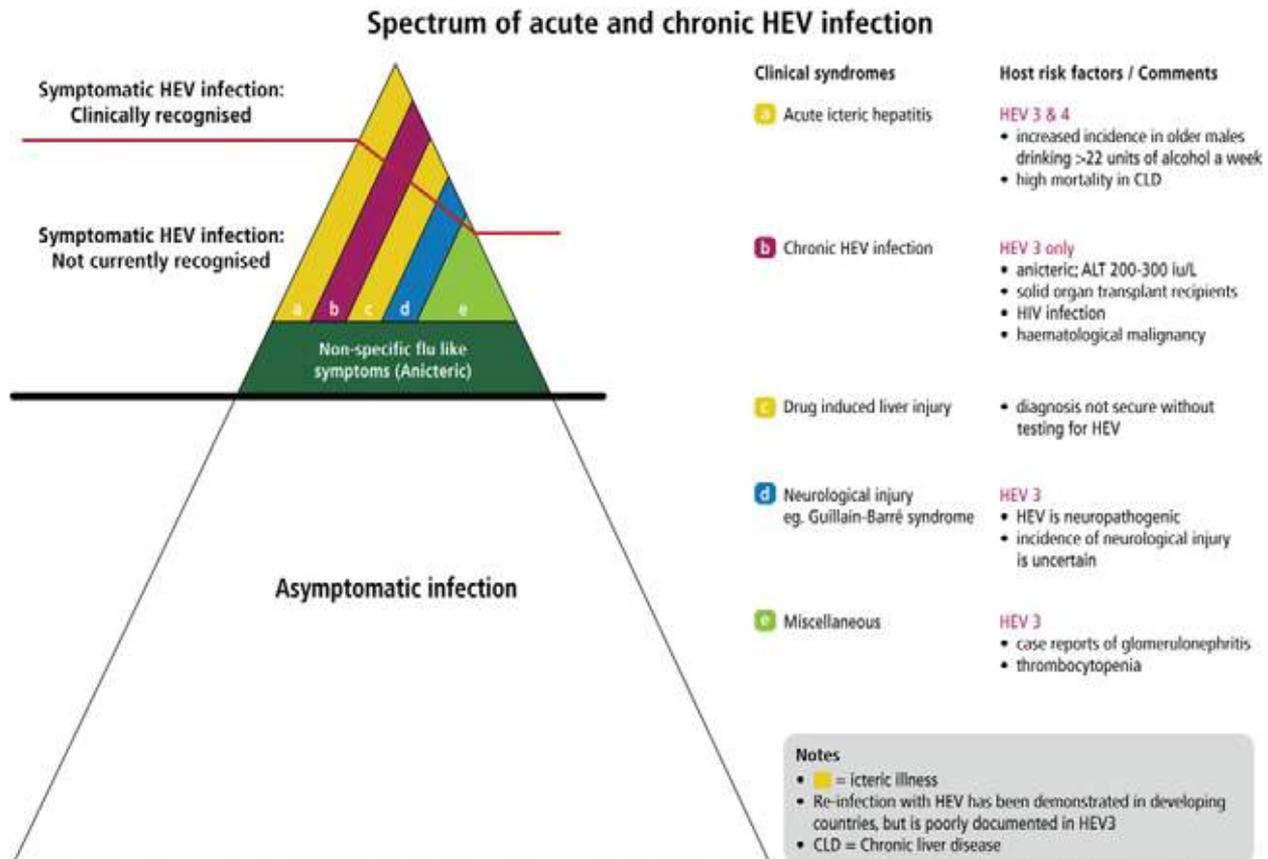

FIGURE 8. Symptomatic and asymptomatic HEV.

suggesting that more immunosuppressed patients were at higher risk of developing chronic HEV infection (113). More recently, a multicenter retrospective study analyzing risk factors for the development of chronic infection following exposure (118) suggested that liver-transplant patients had a higher risk of developing chronic infection compared to non-liver-transplant patients (118). Also, ALT and AST levels were lower at HEV diagnosis in patients who developed chronic hepatitis, suggesting a lower T-cell response in these patients, as has been demonstrated *in vitro* (31, 108, 118). In patients who developed chronic infection, the time following transplantation was shorter than in those who cleared the virus. In addition, the time since treatment of an acute rejection episode was also shorter, and patients were more often treated with tacrolimus than with cyclosporin A (118). Multivariate analysis showed that the use of tacrolimus was an independent predictive factor for the progression to chronic HEV infection (118). Large quasispecies heterogeneity was observed in patients with persistent HEV compared to those with resolving hepatitis (23, 31).

In addition to transplant recipients, chronic HEV infection and cirrhosis have also been observed in a small number of HIV positive patients, mainly in those having a low CD4 count (7, 123). HEV infection can persist in patients who improved their immune status (124). Stem-cell transplant recipients, hematological patients receiving chemotherapy (125, 126), and patients with rheumatologic or autoimmune disease receiving immunosuppressive therapy can also develop chronic HEV infection (127, 128).

## COMPLICATIONS OF HEV

### Hepatic Complications

The mortality of hepatitis E in developing countries is approximately 1%, due largely to subacute hepatic failure in patients with preexisting chronic liver disease (12-month mortality up to 70%) (53). Fulminant hepatic failure occurs in pregnant women in the third trimester (mortality approximately 20%) (129). The latter is a unique characteristic of hepatitis E, and historical studies of outbreaks of hepatitis with deaths in pregnant females show that water-borne hepatitis E was probably quite common in Continental Europe in the 19<sup>th</sup> century (5). Deaths occur toward the end of pregnancy and are mainly caused by a combination of fulminant hepatic failure associated with obstetric complications, including bleeding and eclampsia. In addition, the unborn child frequently does not survive (129, 130). Infected women have higher viral loads than nonpregnant women (131, 132), and several studies have shown differences in immunological and hormonal responses in pregnant women with fulminant hepatic failure caused by hepatitis E (133). However, the cause of high maternal mortality in patients with hepatitis E remains uncertain.

In developed countries, the mortality is unknown. Hospital-based case series report a mortality ranging from 3% to 10% (72, 134). Deaths mostly occur from acute liver failure in older men with preexisting chronic liver disease. Occasionally fulminant hepatic failure occurs in patients without underlying chronic liver disease (135). As noted

above, transplant recipients can develop rapidly progressive cirrhosis and liver failure. This required liver transplantation in some cases, and a number of patients died.

### Extrahepatic Complications

An increasing number of syndromes affecting organ systems other than the liver have been reported that are temporally associated with hepatitis E. These occur during both acute and chronic infection and in developing and developed countries (Table 1). For most of these extrahepatic manifestations, a causal relationship has yet to be established. However, it is likely that in the case of renal and neurological syndromes that the relationship with HEV infection is causal.

#### Renal

Renal impairment in association with HEV has been defined best in immunosuppressed transplant recipients with chronic infection. Renal function deteriorates during the course of infection and improves with viral clearance. Renal biopsy shows a range of renal injury, including membranoproliferative and membranous glomerulonephritis and relapses of IgA nephropathy with or without cryoglobulins (136, 137). Renal injury has also been reported in an immunocompetent patient with acute HEV infection who developed crescentic glomerulonephritis with cryoglobulins that improved after viral clearance (138).

#### Neurologic

Approximately 100 patients with a range of neurologic damage temporally related to hepatitis E infection (139) have been reported to date (Table 1), and there are many more cases not yet published. Neurologic injury was described in 5% to 8% of patients from two large cohorts of patients with mainly acute and chronic hepatitis E from Toulouse, France and Cornwall, England (134, 140). A range of neurologic pathology was documented in this study including Guillain-Barré syndrome, neuralgic amyotrophy, inflammatory polyradiculopathy, ataxia/encephalitis, and peripheral neuropathy. In four patients with chronic HEV

infection, HEV RNA was observed in the cerebrospinal fluid. The incidence of neurological injury is under-recognized because most patients present primarily with a neurologic illness without jaundice. The liver function tests are usually only mildly abnormal and in a minority of patients were completely normal at the time of presentation.

Case-control studies of hepatitis E in Guillain-Barré syndrome (GBS) from the Netherlands (141), Bangladesh (142), and Japan (143) all illustrate that patients with GBS are significantly more likely than controls to have evidence of HEV infection. Between 5% to 10% of GBS patients have evidence of infection at the start of their illness, and interestingly, in a minority viral RNA was found in serum and stool but not CSF.

Neurologic amyotrophy (NA) is a postinfectious immune-mediated neuropathy characterized by damage to the brachial plexus, resulting in severe shoulder pain, muscular atrophy, weakness, and sensory disturbance (144). An Anglo/Dutch cohort study of patients with NA showed that 10% had evidence of HEV infection at presentation (145). Patients with HEV-associated NA have been reported only with HEV3 and are mainly middle-aged males who typically have bilateral neurologic symptoms and signs in the upper limbs. This contrasts to NA without HEV infection where the neurologic damage is unilateral affecting the dominant arm. Central nervous system involvement has also been seen in 12 cases of both acute and chronic infection, and in some cases the outcome was poor, with several deaths (139).

The mechanisms whereby HEV causes neurologic injury are unknown. It could be immune-mediated, or HEV might be directly neurotropic. Some evidence suggests that HEV is neurotropic, and in some cases HEV RNA has been recovered from the CSF (139). The HEV quasispecies in the CSF was different than that recovered from the serum in one chronically infected patient (146). Another patient with a peripheral neuropathy and chronic HEV (HEV RNA in both serum and CSF) showed resolution of his neurological symptoms, which was temporally related to viral clearance with ribavirin and interferon (147). Recent *in vitro* and *in vivo* evidence shows that HEV can grow well

*There is good evidence to support a causal role for HEV in Guillain-Barré syndrome, neuralgic amyotrophy, meningoencephalitis, and renal syndromes. For the other extrahepatic manifestations, causality remains to be established.*

on a range of neurological cell lines and can cross the blood brain barrier in animals (97, 148).

## LABORATORY DIAGNOSIS

HEV infections can be diagnosed either indirectly by detecting anti-HEV antibodies in the serum or directly by detecting HEV RNA or capsid antigen in the blood or other body fluids (121, 149). Current data indicate similar performance for all HEV genotypes and subtypes. An initial incubation period of 2 to 6 weeks (Fig. 9) usually precedes the IgM response, which is detected around the time the alanine aminotransferase activity increases, and persists for 6 to 9 months (150). The IgG response can be delayed; it persists for several years, although the exact duration of this response remains uncertain. HEV RNA becomes detectable in the blood and stools during the incubation period and persists for around 4 weeks (blood) and 6 weeks (feces). Capsid antigen persists in the blood for about the same time (151).

### Serology

The antigens used in enzyme immunoassays (EIA) are usually recombinant ORF2 and/or ORF3 proteins from an HEV1 strain. Sera from patients infected with other genotypes generally cross-react adequately due to shared ORF2/ORF3 epitopes. The diagnostic performance of IgM and IgG assays varies considerably and must be evaluated carefully (152).

The presence of anti-HEV IgM in the serum is a key marker of an acute infection. Both conventional microplate and rapid immunochromatographic commercial assays have been developed. A validated PCR assay was used as a reference in studies that showed that the sensitivity of these assays was >97% for immunocompetent patients and 80–85% for immunocompromised patients; their specificity was >99.5% (153–155).

The presence of anti-HEV IgG alone is a marker of past infection. The limits of detection of commercial anti-HEV IgG assays vary from 0.25 WHO unit/ml to 2.5 WHO unit/ml (WHO reference reagent established in 2002; National Institute for Biological Standards and Control Code 95/584). A specific, sensitive assay (detection limit: 0.25 WHO unit/ml) has been used to obtain a clearer picture of HEV epidemiology (74). This assay generally produces higher estimates of anti-HEV IgG seroprevalence, as highlighted in

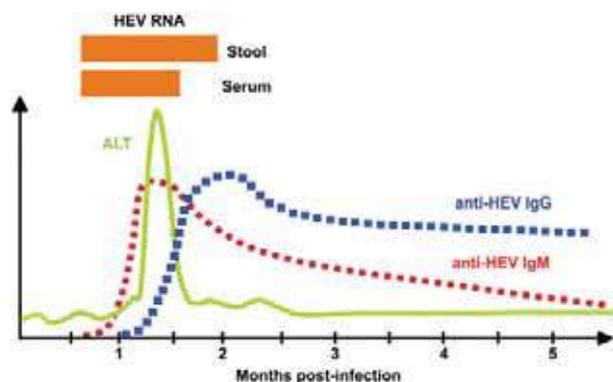

FIGURE 9. Kinetics of hepatitis E virus markers during an acute infection.

a meta-analysis of studies of HEV prevalence in Europe (156). Nevertheless, the high clinical sensitivity does not reflect poor specificity; adult populations in Fiji, New Zealand, and Scotland who have a very low seroprevalence (<5%) were identified using this assay. Similarly, the seroprevalence is only 2% in children aged 2 to 4 years living in southwest France despite the fact that this is a hyperendemic area (157). Knowing the anti-HEV IgG concentration could be useful for estimating the risk of reinfection after a natural infection or vaccination in clinical trials. One study demonstrated that HEV immunocompromised patients with low anti-HEV IgG concentration (<7 WHO unit/ml) could become reinfected and that this could become chronic (55).

### Viral RNA Detection

HEV RNA can be detected and quantified in the blood, stools, and other body compartments using nucleic acid amplification technologies with primers targeting regions that are conserved among HEV genotypes. Most real-time PCR assays, including commercial assays, target ORF3 (158, 159). A transcription-mediated amplification assay (Procleix HEV) performed on a fully automated platform (Panther system) is well adapted for high-throughput testing (160). Lastly, the newly developed loop-mediated isothermal amplification (LAMP) assay provides a one-step, single-tube amplification of HEV RNA without special equipment (161).

The assays based on nucleic acid amplification all require the WHO international reference panel for HEV RNA genotypes for their validation and comparison of their performance. The limit of detection of current assays is 7 to 80 IU/ml. This feature is relevant not only for diagnosis but also for defining an optimal strategy (individual or minipool testing) for blood screening.

HEV RNA can be characterized by sequencing different regions of the HEV genome such as ORF2 or ORF1 polymerase. This can then be used to determine the HEV genotype/subgenotype and hence to identify the source of infection and the mutations in the polymerase of virus infecting patients whose ribavirin therapy fails (162, 163). Current studies are examining the prognostic value of these mutations.

### Antigen Detection

HEV infections can be diagnosed by detecting the HEV capsid antigen using a commercial sandwich EIA. One study found that the specificity was excellent and the lowest HEV RNA concentration detected was 800 to 80,000 IU/ml using serial dilutions with HEV RNA-negative anti-HEV antibody-negative plasma (164). The diagnostic sensitivity for an acute HEV infection was 91%, with no significant difference between immunocompetent (88%) and immunocompromised (94%) patients (164). Although HEV RNA testing is the gold standard for detecting an active infection, testing for HEV capsid antigen is technically simpler, less expensive, and faster. Therefore, this could be a valuable alternative for diagnosing HEV infections for laboratories with no molecular diagnostic facilities.

### Diagnostic Algorithm

The good performance of anti-HEV IgM assays and their wide availability makes them suitable for use as a first-line diagnostic assay (Fig. 10). Immunocompromised patients should be tested for HEV RNA in three clinical settings: (i) if the anti-HEV IgM is negative and ALT activity is elevated, because the immune response of these patients is frequently

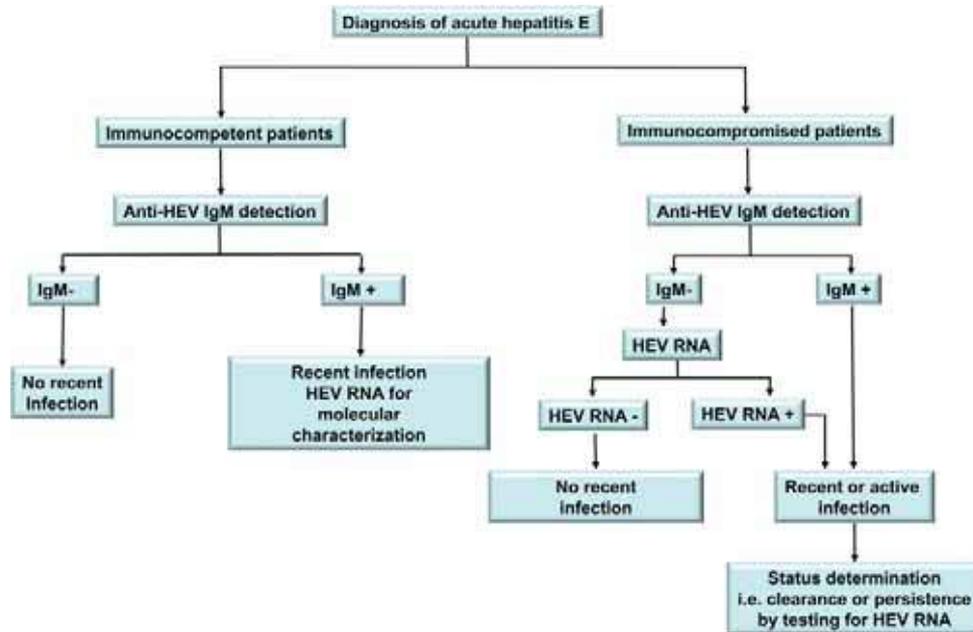

FIGURE 10. Flow diagram for diagnosis of acute hepatitis E virus infection.

impaired, (ii) to identify a chronic infection if the HEV RNA persists for 3 to 6 months, and (iii) to monitor HEV RNA so as to manage a chronic infection after immunosuppression has been reduced or after starting antiviral therapy. Ribavirin therapy is used to reduce the HEV RNA concentration in the blood to undetectable levels. A negative HEV RNA concentration in the feces could also be necessary to indicate successful eradication of the virus after treatment has been interrupted (165).

## TREATMENT

### Acute Infection in the Immunocompetent

Most patients with hepatitis E require no treatment because they have a mild self-limiting illness. Patients with severe infections, including patients with fulminant hepatitis, should receive appropriate supportive care including, where necessary, admission to an intensive care unit experienced in dealing with liver disease (see Hepatitis chapter). A few patients who have presented with severe acute HEV infection, including patients with preexisting chronic liver disease, have been given ribavirin (166, 167). A rapid decrease in HEV RNA concentration occurred with clearance of HEV. However, there are no placebo-controlled data available either in this setting or in patients with chronic infection.

### Chronic Infection in Solid-Organ-Transplant Patients

Clinical studies have shown that tacrolimus is a more potent immunosuppressive drug than cyclosporin A (168). *In vitro*, both calcineurin inhibitors (tacrolimus and cyclosporin A) and mammalian target of rapamycin inhibitors (sirolimus and everolimus) promote HEV replication (169, 170). Conversely, mycophenolic acid, an inosine monophosphate dehydrogenase inhibitor, inhibits HEV replication (169).

The treatments for HEV infection were initially evaluated in solid-organ-transplant patients with chronic HEV

infection. In this setting reduction of immunosuppression that targets T-cells prompts viral clearance in up to 30% of patients (118). Patients who clear the virus by reducing immunosuppressive therapy achieved a lower tacrolimus trough level and needed lower daily doses of steroids compared to those who remained viremic (119). Hence, a reduction in immunosuppressive therapy seems to be the first-line therapeutic option. However, since two-thirds of patients fail to clear the virus despite the reduction of immunosuppressive therapy and since this maneuver cannot be safely performed in high-risk immunological patients, antiviral therapy has been employed.

Interferon has a moderate antiviral activity *in vitro* (170, 171) and has been given to a few liver-transplant patients, mostly for a 3-month period. A sustained virological response was obtained in all patients (172–174). However, the use of interferon is problematic in transplant patients because it increases the risk of acute rejection due to its immunostimulatory effect (175). This prompted several groups to use ribavirin alone in solid organ transplant recipients with chronic hepatitis. Unexpectedly, the results have been impressive (176–178). In a retrospective French study, the effect of ribavirin alone was assessed in 59 solid-organ-transplant recipients with chronic HEV infection (179). The majority of patients received ribavirin at the daily dose of 600 mg (n=17) or 800 mg (n=17) for range of 1 to 18 months; most patients (n=36) were treated for 3 months. Anemia was the main side effect and required ribavirin dose reduction in one-third of the patients, temporary cessation of therapy in two patients, and the use of recombinant erythropoietin in up to 40% of the patients (179). The sustained viral response (SVR) at 6 months after cessation of therapy was 78% (n=46) (179). Two patients were lost to follow-up, another patient was initially a nonresponder, and 10 other patients relapsed after ribavirin therapy was stopped. The nonresponder was retreated and achieved SVR. Six of the 10 relapsers who were initially treated for 3 months were retreated for 6 months. SVR was then observed in 4 of these patients; the 2 remaining patients also had viral clearance but

with limited follow up. Hence, the overall SVR was 85% (179). A lower lymphocyte count at the initiation of ribavirin therapy and persistent HEV shedding in the stools at the end of therapy (165) have been associated with more relapses after ribavirin is stopped (179). A decrease in HEV RNA concentration of more than 0.5 log copies/mL within the first week after initiating ribavirin therapy was found to be a predictive factor for SVR (180). However, ribavirin trough levels early or late after the initiation of therapy did not affect virological response or SVR (180).

Ribavirin monotherapy has become the treatment of choice for chronic HEV infection, but the mechanism of action remains unclear. It has been suggested that ribavirin inhibits HEV replication through depletion of guanosine triphosphate (GTP) (181). *In vitro*, the combination of ribavirin and mycophenolic acid has a synergistic anti-HEV effect (169). *In vivo*, no difference in the slope of HEV RNA concentration and the number of SVRs was observed between transplant recipients who received ribavirin either with or without mycophenolic acid (180). It has been recently shown that ribavirin increases viral heterogeneity and that ribavirin-induced mutagenesis seems to be reversible after therapy is stopped (182).

Cases of ribavirin treatment failure have been reported in patients who have the G1634R mutation in viral polymerase (183). This mutation does not provide ribavirin resistance *in vitro* but increases the replicative capacity of HEV (183). In a series of 63 transplant recipients with chronic infection, 23 (36.5%) had detectable G1634R variants before therapy (163), but the presence of the G1634R mutation before treatment did not have any impact on the early virological response, on the SVR, or on virological response after retreatment (163). Interestingly, G1634R variants were detected during therapy in patients who relapsed after ribavirin cessation (182). Other dominant mutations were described in the polymerase region (i.e., K1383N, Y1587F, D1384G, V1479I, and K1398R) (171). On the one hand, these mutations increase the replicative capacity of HEV, and on the other they improve the antiviral activity of ribavirin (162).

In cases of ribavirin treatment failure there is currently no alternative effective therapy of proven value. Sofosbuvir may inhibit HEV replication *in vitro* and the anti-viral effect is increased when combined with ribavirin (184). However, it failed to decrease HEV replication (185) in one patient chronically infected with both HEV and HCV.

### Chronic Infection in Non-Solid-Organ-Transplant Patients

A few case reports and case series have been published on the treatment of hematological malignancy patients (i.e., patients receiving chemotherapy or stem-cell-transplant recipients). Similar to solid-organ-transplant recipients, hematology patients have been successfully treated with pegylated interferon or ribavirin (186–188). Pegylated interferon, ribavirin, or both were also successfully used in HIV patients (147, 189–191).

### Extrahepatic Manifestations

Antiviral therapy has been used in patients presenting HEV-induced neurological symptoms such as Guillain-Barré syndrome (140). Although viral clearance is achieved, the effects on the outcome of neurological symptoms is uncertain. In contrast, antiviral HEV therapy appears to be very effective in treating patients who developed HEV-associated kidney complications (136, 138).

## PREVENTION

### General Risk Reduction

Providing access to clean drinking water is the most important approach to preventing hepatitis E in developing countries, but this can prove problematic when the sanitary infrastructure fails. For example, recent outbreaks have occurred in African refugee camps. Prevention of locally acquired zoonotic infection with HEV in developed countries is more difficult, because there are a number of animal hosts and several possible routes of infection (Fig. 4). Prevention strategies include thorough cooking of pork-containing foods, appropriate care and precautions when handling uncooked pork, and screening of blood donors to prevent transfusion-transmitted cases.

### Vaccination

HEV 239 vaccine (Hecolin<sup>®</sup>, Xiamen Innovax, China) consists of pORF2 amino acids 368 to 607 expressed in an *E. coli* system that can self-assemble *in vitro* into virus-like particles with a diameter of 20–30 nm. It has been tested in both animals and humans. Two doses of 5 µg, 10 µg, or 20 µg HEV 239 adsorbed in alum adjuvant when administered 4 weeks apart to monkeys induce comparable antibody responses that protect the animals from HEV1 and HEV4 (192). In humans, Phase 1, 2, and 3 clinical trials have been reported from China (193–195). In these studies, the vaccine formulation contained recombinant particulate HEV 239 antigens adsorbed to 0.8 mg of aluminum hydroxide and suspended in 0.5 ml of buffered saline and was given by intramuscular injection.

HEV 239 vaccine appears to be effective at preventing HEV infection. In the Phase 3 clinical trial, over 100,000 participants were randomly assigned to receive three doses of 30 µg HEV 239 vaccine or the hepatitis B vaccine at months 0, 1, and 6 (195). During follow-up for 12 months after the last dose, no HEV 239 vaccine recipients contracted hepatitis E, but 15 cases of hepatitis E occurred in the control group, indicating a vaccine efficacy of 100% (95% CI, 72–100). In participants who received at least one dose the efficacy was 96% (95% CI, 66–99); and those receiving two doses and before the third dose the efficacy was 100% (CI 9–100). In an extended efficacy study (up to 4.5 years after vaccination), the efficacy of HEV 239 was 93% (95% CI, 79–98) (196). Of the 29 identified hepatitis E cases whose viral isolates were sequenced, 26 were infected with HEV4 (3 in the vaccine group and 23 in the control group), and 3 with HEV1 (1 in the vaccine group and 2 in the control group). Data from the Phase 2 clinical trial shows that 2 doses of 20 µg HEV 239 (administered at months 0 and 6 or months 0 and 1) effectively protect from HEV infection with an efficacy of 85% (95% CI, 10–99) for at least 6 months (194).

HEV239 vaccine is well tolerated and no serious adverse events have been reported. In the Phase 3 clinical trial local adverse events (pain and swelling around the injection site) occurred more frequently in the HEV 239 group than in the control group (195). During extended follow-up, similar numbers of participants in both the vaccine and placebo groups experienced serious adverse events, none of which were related to vaccination (196). Thirty-seven pregnant women in the HEV 239 vaccine group and 31 pregnant women in the control group were inadvertently vaccinated. The vaccine was well tolerated in the pregnant women, with only one woman reporting mild inoculation-site pain. The

weights, body lengths, and gestational ages of the newborns were comparable in both groups (197).

HEV 239 vaccine was licensed for use in China in 2012 (193) but is currently not available in other countries. It may be potentially of utility in an outbreak setting in developing countries, because its efficacy after two doses 1 month apart is 100% (194). However, the issue of vaccine availability in developing countries in need is complex. There are a number of issues that have impeded the use of HEV239 in countries other than China, including lack of vaccine pre-qualification and insufficient data regarding efficacy against HEV1, safety and efficacy in pregnant women, and efficacy against genotype 1. In both developing and developed countries, hepatitis E has a poor prognosis in patients with chronic liver disease. Such individuals could be considered for vaccination against HEV. However, the safety and efficacy of HEV239 in patients with chronic liver disease is currently unknown. HEV239 is safe and effective in carriers of HBsAg (198), but how many of the individuals in this study were cirrhotic is unknown. In developed countries, a safe and effective vaccine could potentially be used to prevent chronic infection in the immunosuppressed. The safety and efficacy of the HEV239 in this group of patients is currently unknown. In developed countries with high levels of circulating HEV, there has been interest in vaccination of farmed pigs as a method of reducing exposure of humans. The acceptability of this approach to the farming community is likely to be problematic, as pigs infected with HEV are asymptomatic. In addition, its efficacy in terms of impact on human infection is uncertain, because HEV is ubiquitous in the environment and there are several other animal hosts.

A number of other approaches to vaccine development are ongoing, including a DNA vaccine, chimeric virus particles, fusion proteins, and an oral vaccine (199–209). None of these novel vaccine candidates have yet been used in humans.

### HEV and the Blood Supply

Because HEV infections are widespread and blood donors are often asymptomatic, there is a risk of virus-containing blood donations. Transfusion-related HEV infections have been documented in several countries, including the United Kingdom, France, Germany, and Japan (121). The blood components involved in HEV transmissions were fresh frozen plasma (solvent/detergent-treated, amotosalem-treated, secured by quarantine), pooled or apheresis platelets, and red blood cells. In a retrospective study in England of 43 recipients given HEV-contaminated blood products and followed up, the transmission rate was 42%, but only 1 patient developed symptomatic hepatitis. The patients who were given blood products with high HEV RNA concentrations were more likely to become infected (71). A French kidney transplant patient was infected with HEV when treated by plasma exchange for acute humoral rejection (210).

Published data indicate that the minimum infectious dose in donations is 3.85 log HEV RNA IU (211). This information is crucial for assessing the capacity of HEV inactivation/removal during manufacturing steps of plasma-derived medicinal products and the accompanying risk of infection. The same sensitive validated assay was used in HEV seroprevalence studies of blood donors, identifying three levels of endemic virus frequency in developed countries, low (<10%), intermediate (10%–20%), and high (>20%) (212). The incidence of HEV viremia was 1:600 to 1:2600 in countries where the virus was highly endemic,

including France, Germany, The Netherlands, Japan, and China, and 1:2800 to 1:14500 in the other two categories, including the United Kingdom, United States, Australia, and New Zealand. However, HEV seroprevalence and viremia may vary from one region to another within a country, as illustrated by French studies (69, 213, 214). These epidemiological data are essential for defining optimal policies for screening blood donations for HEV. Universal screening of blood donors for HEV started in Ireland in 2016. Targeted screening of donors in the United Kingdom also started in 2016, with screening of donors whose blood products are destined for high-risk groups, including the immunosuppressed (215).

### CONCLUSIONS

Our understanding of HEV has changed completely in the last 10 years. It was previously considered to be a waterborne pathogen affecting a few resource-poor settings. We now know that it is a virus of global significance and is also endemic in many resource-rich countries where it is largely locally acquired, anthroponozoonotic, and causes both acute and chronic infection. Because it is a very common infection in such settings, and commonly asymptomatic, it has found its way into the human blood supply, and viremic donors are surprisingly frequent in many countries in Europe. Whether and how donors should be screened for HEV remains a “hot topic” in the blood transfusion community. The clinical phenotypes of hepatitis E in humans are still emerging. It is now clear that HEV can cause a number of extrahepatic manifestations and in particular a range of neurological injuries. The range, frequency, and mechanisms of HEV-associated neurological injury are as yet uncertain. The global burden of HEV is unknown. The most recent figure is an underestimate, because it utilized data from 2005 from a limited number of developing countries and took no account of the paradigm shift implicit in the current thinking of HEV as a global pathogen. Maybe in another 10 years we will have a much clearer idea about many of these aspects of HEV, which is proving to be one of the more successful zoonotic viruses currently affecting humans.

# Astrovirus

CARLOS F. ARIAS AND TOMÁS LÓPEZ

## 51

Astroviruses are present in a wide variety of animal species, including mammals and birds. In many species, including humans, these viruses are associated with gastrointestinal diseases and, more recently, with encephalitis and diverse neurological manifestations. Human astroviruses (HAstVs) were first identified in fecal samples of children with diarrhea by electron microscopy as small particles with a star-like morphology, the feature that Madeley and Cosgrove (1) used in 1975 to name this group of viruses (*astron*-star in Greek). This morphology, however, is observed in only a small proportion of the particles present in stool samples, and expertise in electron microscopy is required for their identification. Development of more sensitive and specific diagnostic methods, such as enzyme immunoassays (EIA) and reverse transcription, coupled with polymerase chain reaction (RT-PCR), in diverse formats have revealed that HAstVs represent serious gastrointestinal pathogens that affect distinct groups in the population. Adaptation of HAstVs to tissue culture and the molecular characterization of human, as well as of animal, viruses have contributed to recent advances in the understanding of their molecular biology; however, an animal model to study HAstV pathogenesis is still required.

The *Astroviridae* family consists of icosahedral non-enveloped viruses with characteristic features that distinguish them from other naked viruses with a monopartite RNA genome, like those in the *Caliciviridae* and *Picomaviridae* families. Members of the family *Astroviridae* contain a single-stranded RNA (ssRNA) genome of positive polarity organized in three open reading frames. The virions are formed by proteins that result from the proteolytic processing of a precursor polypeptide (2, 3). During infection with astroviruses, a viral subgenomic RNA (sgRNA) is used as template for the synthesis of the structural proteins (4). Additional features used to distinguish this family are the lack of RNA-helicase and methyltransferase domains in the nonstructural proteins and the use of a ribosomal frameshifting mechanism to translate the viral RNA-dependent RNA polymerase (RdRp) (5).

### VIROLOGY

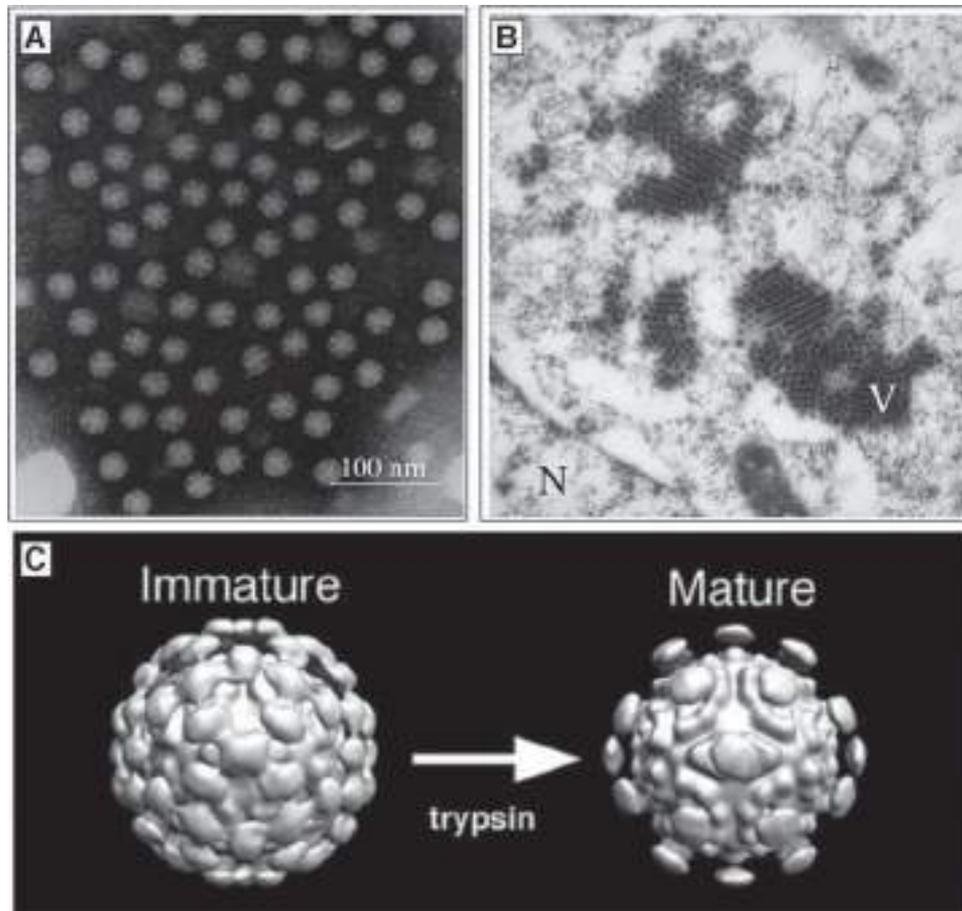

#### Classification

Astroviruses are grouped into the family *Astroviridae*, which is divided into two genera: *Mamastrovirus*, including viruses

infecting mammals (humans, lambs, calves, deer, piglets, kittens, mice, dogs, bats, rabbits, rats, sea lions, dolphins and mink among others), and *Avastrovirus*, including viruses that infect avian species (turkeys, chickens, ducks, pigeons and guinea fowl among others). Based on their reactivity in antibody neutralization assays, HAstVs were initially classified into eight serotypes (HAstV-1 to HAstV-8) (6–8). Since the sequence of the hypervariable carboxy terminus of the structural protein correlates with these serotypes, they are now commonly inferred by sequencing DNA fragments obtained by RT-PCR. Next-generation sequencing and metagenomic studies have recently detected genetically diverse astrovirus strains, and the astrovirus taxonomy is now based on the degree of identity of the amino acid sequence of the complete capsid polyprotein (9). The first novel HAstV was reported in 2008 by deep sequencing of a sample isolated from a child with acute diarrhea (10). Based on the most recent classification, at least four genotypes of astrovirus that infect humans are now recognized. The classical 8 original serotypes are classified now as *Mamastrovirus* genotype 1, and the novel HAstVs that include the MLB, VA and HMO virus lineages are classified into three additional genotypes (9, 11). A fifth genotype of HAstV has been recently proposed to exist (12). Of interest, the novel HAstVs are more closely related to animal astroviruses. In total, 33 mammalian and 11 avian different genotype species have been described to date (11).

#### Composition of the Viruses

Astroviruses are 28 to 30 nanometer particles with small projections from the surface and occasional star-like structure observed by electron microscopy of fecal samples and infected cell cultures (1) (Figs. 1A and 1B). Recently, the three-dimensional structures of immature (see below) and a proteolytically processed, fully mature infectious HAstV were obtained by cryoelectron microscopy at approximately 25Å-resolution (13) (Fig. 1C). The structure of both types of particles showed a solid capsid shell with a diameter of approximately 350Å and a T=3 icosahedral symmetry. The uncleaved, immature HAstV-8 particles display 90 dimeric spikes, compared to 30 globular spikes on the cleaved, mature and fully infectious HAstV-1 particles, located on the icosahedral 2-fold axes. Both immature and mature particles display the same diameters (440 Å). One hundred and eighty copies of either a 70- or a 90-kilodalton protein are

**FIGURE 1** (A) The six- and five-point star-like morphology of astrovirus can be observed in fecal samples by negative staining and EM. (Reprinted from reference 1 with permission.) (B) Paracrystalline arrays of human astrovirus particles observed by transmission EM in infected Caco-2 cells; virus clusters (V) are usually localized at the periphery of nuclei (N). (C) Three-dimensional electron cryomicroscopy density maps of immature and mature HAstV. Mature virions only display 30 of 90 spikes after proteolytic cleavage. (Reprinted from reference 13 with permission.)

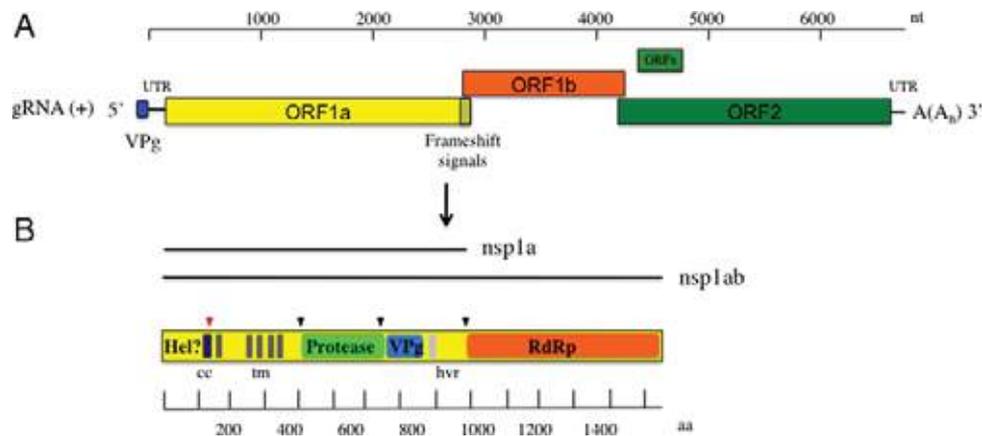

predicted to form the virions (13). The crystal structure of the dimeric surface spike of HAstV-1 and turkey astrovirus 2 (TAsTV-2) have been also determined, and putative receptor binding sites with amino acid compositions characteristic for polysaccharide recognition (14, 15). Surprisingly, the overall TAsTV-2 capsid spike showed only a distant structural similarity to the human astrovirus spike (15).

The astrovirus genome varies in length, depending on the species of origin, ranging from 6.12 kilobases (HAstV MLB-3) to 7.72 kilobases (duck astrovirus 1) (16, 17). The genome of classical HAstVs is around 6.8 kilobases; it is polyadenylated at its 3'-end, and, at its 5'-end, has covalently attached a viral protein genome-linked (VPg) (18, 19). The genome contains three open reading frames (ORFs) (Fig. 2), each encoding a polyprotein that is proteolytically processed into smaller products during the virus replication cycle. The two ORFs located towards the 5'-end of the genome, designated ORF1a and ORF1b, encode nonstructural proteins that are involved in replication and transcription of the genomic RNA, as well as in other functions relevant for virus replication, like the proteolytic processing of the precursor viral polypeptides (5). The ORF2, localized at the 3'-end, encodes the structural proteins (3, 20) (Fig. 3). As a positive-

sense ssRNA virus, the RNA extracted from virions is able to initiate a productive infection (18, 21). Infectious RNA has also been transcribed from a full-length cDNA clone derived from the genome of a HAstV-1 strain (22).

The protein product of ORF1a, called nsp1a, is approximately 920 amino acid residues in length. Nsp1a is predicted to have a serine protease motif and a VPg protein that shows similarity to the VPg protein of calicivirus (18, 19). The VPg protein is covalently linked to its RNA 5'-end and is necessary for virus infectivity. One specific region of nsp1a downstream from the VPg, in which insertion/deletions are found, has been suggested to have a role in RNA replication, since strains with differences in that region synthesize distinct amounts of viral RNA (23) (Fig. 2). In addition, a phosphorylated protein derived from the carboxy-terminal end of nsp1a has also been implicated in RNA replication (24, 25). The ORF1b encodes the viral RdRp of 515 to 528 amino acids (26).

Proteins nsp1a and nsp1ab are processed at their amino terminus by a cellular protease, probably a signalase, to release a 20-kilodalton protein (27, 28) that has motifs in common with the pestivirus RNA helicase (9, 29), although the helicase activity of this protein has not been detected.

**FIGURE 2** Astrovirus genome organization and synthesis of the nonstructural proteins. (A) The genome of astrovirus (shown here for HAstV-8) is organized into three ORFs: 1a, 1b, and 2. A fourth hypothetical ORF<sub>x</sub> is shown. The genomic RNA is a positive-sense RNA of around 6.8 kilobases that has a VPg protein covalently bound to its 5'-end and a polyA tail at the 3'-end. (B) Three nonstructural proteins have been positively identified: the viral protease, a VPg protein, and the RNA-dependent RNA polymerase (RdRp). In addition, other conserved structural motifs in the nsp1a polyprotein have also been identified: a putative helicase (Hel), a coiled-coil (cc) domain, several transmembrane domains (tm), and a hypervariable region (hvr). The RdRp is synthesized as part of a long polyprotein called nsp1ab, that results from translation of ORF1a and ORF1b as a single polypeptide, through a ribosomal frame shift mechanism directed by highly conserved cis-acting sequences (the heptanucleotide AAAAAAC and one pseudoknot) localized in the overlap region between ORFs 1a and 1b (26). The intermediate protease (viral and cellular) cleavage products of polyproteins nsp1a and nsp1b, as well as the final produced polypeptides, are not shown here, but can be consulted for HAstV-8 in other publications (28, 40). The cellular protease (red arrow head) and viral protease (black arrow heads) cleavage sites are indicated.

Most of the downstream cleavage events are thought to be carried out by the viral serine protease. Proposed sites for processing have been mapped in HAstV-1 nsp1a, Val409-Ala410, and Glu654-Ile655 to yield the viral protease (30) and in Gln664-Lys665 and Gln755-Ala756 to generate the VPg protein (18) (Fig. 2).

The structural proteins encoded in ORF2 are translated from a subgenomic RNA (sgRNA) of approximately 2.4 kilobases as a polyprotein precursor of 87 to 90 kilodalton (Fig. 3). Two domains can be clearly distinguished in this protein; the first 415 amino acid residues form the highly conserved amino-terminal domain (more than 80% identical among classical HAstVs) with two small variable regions, while the second domain includes the hypervariable region downstream of amino acid residue 416, whose sequence identity among different HAstVs can be as low as 36% (31, 32). The hypervariable domain forms the spikes of the particles and has been proposed to be involved in the first interactions of the virus with the host cell (14, 33) (Fig. 3).

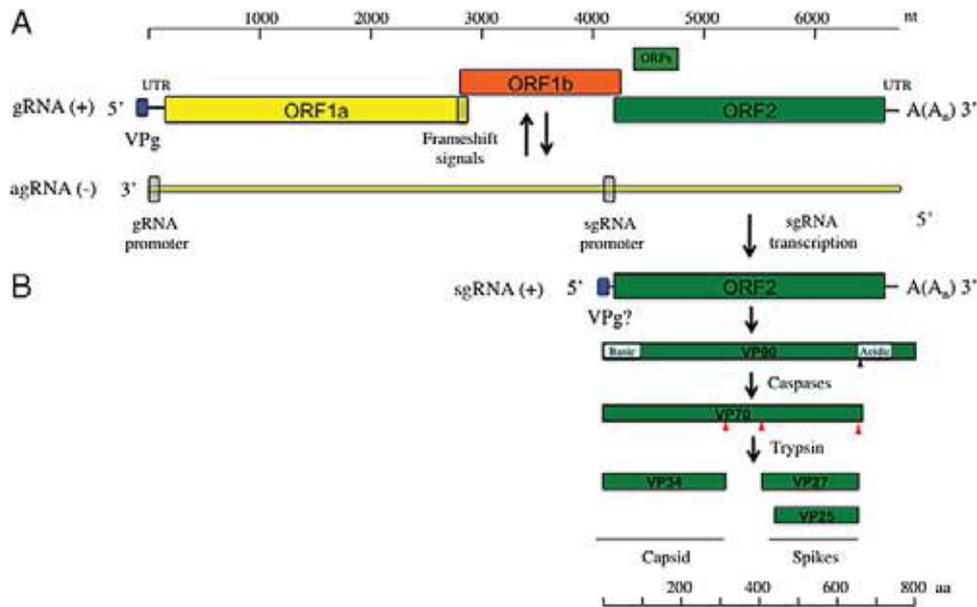

The ORF2 primary translation product is processed to yield three final proteins that are present in fully infectious virions. Thus, the intracellular particles of HAstVs are constituted by polyprotein VP90, while extracellular virions are formed by either VP70 or its final cleavage products, VP34, VP27, and VP25. Proteins in the size ranges 32 to 35, 26 to 29, and 24 to 26 kilodaltons have been found as final cleavage products of the structural polyprotein of different HAstV strains, suggesting that trypsin processing of the precursor capsid polypeptide is similar in other HAstVs (2, 20, 34). Neutralizing antibodies recognize epitopes on the 26 and 29 kilodalton proteins, which are derived from the hypervariable region of the precursor polypeptide (20).

## Biology

HAstVs were originally isolated in primary human embryonic kidney (HEK) cells and subsequently adapted to grow in a continuous monkey kidney epithelial cell line (LLCMK2),

although these cells could not be infected directly with astrovirus extracted from fecal specimens. However, HAstVs can grow in a wide variety of cell lines, mainly of human and monkey origin, although with different efficiencies (35). Human cell lines of intestinal (Caco-2, T84, and HT-29) and hepatic (PLC/PRF/5) origin efficiently support the growth of different HAstV serotypes. Baby hamster kidney (BHK) cells, and probably others, support efficient replication when transfected with authentic astrovirus genomic RNA or with *in vitro* transcribed full-length astrovirus RNA, although they are not easily infected, suggesting that barriers at the entry level could determine the susceptibility of some cells to virus infection (22). The hepatic Huh7.5.1 cell line is an excellent candidate for rescue virus after viral RNA transfection, since they are at least as permissive as CaCo-2 cells for virus infection, but more efficiently transfected (21).

To efficiently infect cells, HAstVs must be activated by treatment of the virus with trypsin. Cellular receptors have not been identified, but the viral spike structure suggests that the receptor-binding site has an amino acid composition characteristic for polysaccharide recognition (14). HAstVs enter cells by endocytosis through a clathrin-dependent mechanism (36, 37). Upon cell infection, the gRNA is translated into the nonstructural proteins. These viral proteins use the gRNA as a template to synthesize a full-length negative-sense, antigenomic RNA (agRNA), which, in turn, is used as a template to produce the two positive-sense viral RNAs, the gRNA and a sgRNA, which are colinear at their 3'-ends (38). Conserved sequences at the 5'-end of the genome, just upstream of the transcription initiation site of the sgRNA, suggest that the sgRNA is synthesized from an internal promoter in the negative sense RNA (39, 40). All three forms of RNA are produced with similar kinetics although their relative proportion is different; the sgRNA is about 5-fold more abundant than the gRNA, while the agRNA abundance ranges from 0.7% to 4% of that of gRNA (38, 41). The production of sgRNA is affected by sequence

**FIGURE 3** Astrovirus genome replication and transcription and synthesis of the structural proteins. (A) The genome of astrovirus (shown here for HAsV-8) is used as template to synthesize the negative-sense antigenomic RNA (agRNA), which, in turn, serves as template to synthesize the full-length positive sense genomic (gRNA) and subgenomic (sgRNA) RNAs. The sgRNA is about 2.4 kilobases and has a polyA tail at the 3'-end and likely also has a VPg protein covalently bound at its 5'-end. (B) The sgRNA is translated into the structural polyprotein precursor VP90, which contains an N-terminal conserved domain and a C-terminal hypervariable domain. The conserved domain has a basic amino acid region that is thought to interact with the viral RNA and a second region that has been predicted to be the shell of the viral capsid. The hypervariable domain conforms the viral spikes, and contains an acidic region towards the carboxy terminus of VP90. The processing pathway of this precursor protein has been described in detail (3). Briefly, VP90 is assembled into particles, and the acidic region at its carboxy terminus is processed to yield a protein of 70 kilodaltons (VP70) (43). This processing is carried out by caspases, cellular proteases activated during virus infection that are involved in cell death by apoptosis. The caspase cleavages correlate with, and are required for, the release of virions from the cells (43, 44). The released virions formed by VP70 are poorly infectious, and full activation of their infectivity requires that VP70 is cleaved by extracellular trypsin. Processing of the VP70-containing particles by this enzyme is sequential, producing final protein products of 34, 27, and 25 kilodaltons through at least eight intermediary polypeptides (3). The black arrow head represents a site for caspase cleavage and the red arrow heads, sites for trypsin cleavage. The intermediate caspases and trypsin cleavage products are not shown but can be found in other publications (28, 40).

changes in the hypervariable domain of the carboxy-terminal region of the nsp1a protein (23).

Astrovirus replication, as with other positive-sense RNA viruses, seems to occur in association with membranes, since the viral structural and nonstructural proteins, including the RNA-dependent RNA polymerase, as well as the gRNA and agRNA and infectious virus, are associated with membranes and colocalize with calnexin [(25, 42), Murillo A et al, submitted for publication]. Recently, the cellular proteins present in membranes, to which astroviral proteins and RNA associate, were determined by LC-MS/MS. Functional analysis of the protein-protein interaction network showed some biological processes that were enriched in these membranes, such as gluconeogenesis, fatty acid beta-oxidation, fatty acid synthesis, long chain fatty acid synthesis and tricarboxylic acid cycle (Murillo A et al, submitted for publication). In astrovirus-infected Caco-2 cells, VP90 assembles intracellularly into viral particles and is then processed by cellular caspases to yield VP70 during virus cell egress through a mechanism that does not involve cell lysis. Extracellular virions grown in cells in the absence of trypsin are composed by VP70 (43, 44).

### Stability/Inactivation

Astrovirus particles are stable at a wide pH range (3 to 10) (45) and tolerate exposure to detergents, such as octylglu-

coside (20) and lipid solvents. HAsV infectivity is affected minimally if the virus is incubated at 4°C for 45 days in drinking water, although the titer drops by about two log<sub>10</sub>s when the virus is maintained at 20°C (46). Temperatures of 60°C for more than 5 minutes drastically reduce infectivity. At -70 to -85°C the virus infectivity is retained for several years, although with repeated freezing and thawing infectivity decays. The stability of the infectivity of HAsV is lower in surface water than in groundwater, and the positive correlation between the detection of the gRNA and infectivity suggests that the detection of genetic material could be used to determine water contamination with infectious HAsV (47). Another indicator of the infectivity of HAsV particles is the amount of oxidative damage they have experienced (48).

## EPIDEMIOLOGY

### Distribution, Incidence, and Prevalence of Infection

HAsVs have been isolated from fecal samples of patients with gastrointestinal disease from all around the world. HAsV infections are recognized mainly in young children, elderly people and immunocompromised patients, although infections in healthy adults can occasionally occur. HAsVs

are an important cause of viral gastroenteritis in young children (mostly under five years of age), second only to rotavirus, although in the last years a clear increase in the detection of noroviruses and adenoviruses has been noted (9). About 75% of children older than 10 years have antibodies to astrovirus. With the use of sensitive molecular methods for diagnosis, the incidence of astrovirus infections has been estimated at 2 to 9% in children with gastroenteritis (9, 49, 50), as compared to less than 2% in healthy children. These rates were previously underestimated mainly due to the less sensitive methods employed. Isolated studies have reported prevalences of HAstV as high as 30% to 61% in children with gastroenteritis (51, 52). Novel HAstV strains have been found in multiple stool samples collected around the world (53), but their correlation with gastroenteritis is not clear and, in one report, HAstV MLB1 was more prevalent in healthy individuals than in patients (54). MLB1 seropositivity was high in children and was estimated as 100% in adulthood, suggesting that MLB1 infection is common (55). Seropositivity for VA-1/HMO-C, depending on the age, was between 20 and 36% in children and 63% in adults (56).

HAstVs have been associated with outbreaks in daycare centers for children (57, 58) and adults (59), in schools and residential institutions (60), and with neonatal gastroenteritis in hospitals (61). Some of the largest outbreaks were observed in Japan, where more than 4,700 primary and junior high school students and staff were affected in a single outbreak (62). HAstV VA-1 was associated with an outbreak of acute gastroenteritis in a childcare center (63). Outbreaks in aged care centers showed attack rates between 12 and 100%, with serotype 1 strains being the most common (59).

In immunodeficient patients, the frequency of astroviruses reported as a cause of gastroenteritis is variable. Some studies report HAstVs as the principal viral cause of diarrhea in HIV-positive patients (12% in patients with diarrhea versus 2% in patients without diarrhea) (64, 65). Yet other studies suggest other viruses as the main cause (66). HAstVs can establish persistent infections in the immunocompromised host (67, 68).

### Serotype Prevalence

As noted above, eight HAstV serotypes have been reported, based on neutralization assays with polyclonal antisera. Studies from different countries have shown that HAstV strains of serotype 1 are the most frequently found (in about 50% of the astrovirus-positive samples) (50), although other serotypes, like serotype 2, have been the most common in some studies (69, 70). Strains of serotype 7 have been rarely found (50). The second most prevalent serotype has varied depending on the particular study (71). Only a few epidemiological studies of novel HAstVs have been performed to date and have found MLB1 or MLB3 as the more prevalent (72, 73). The genotype of novel HAstV is based on the full-length sequence of ORF2.

### Seasonality

In most temperate climates HAstV infections are more frequent in winter, while in tropical regions astroviruses are more frequently detected during the rainy season (74). Also, high water flow in areas of poor water quality or sewage contamination is one of the causes of fecal contamination (75) and, therefore, of transmission of astrovirus and other enteropathogens. In a study describing the seasonality of novel HAstVs, the highest frequency was observed from March to July (73).

### Transmission

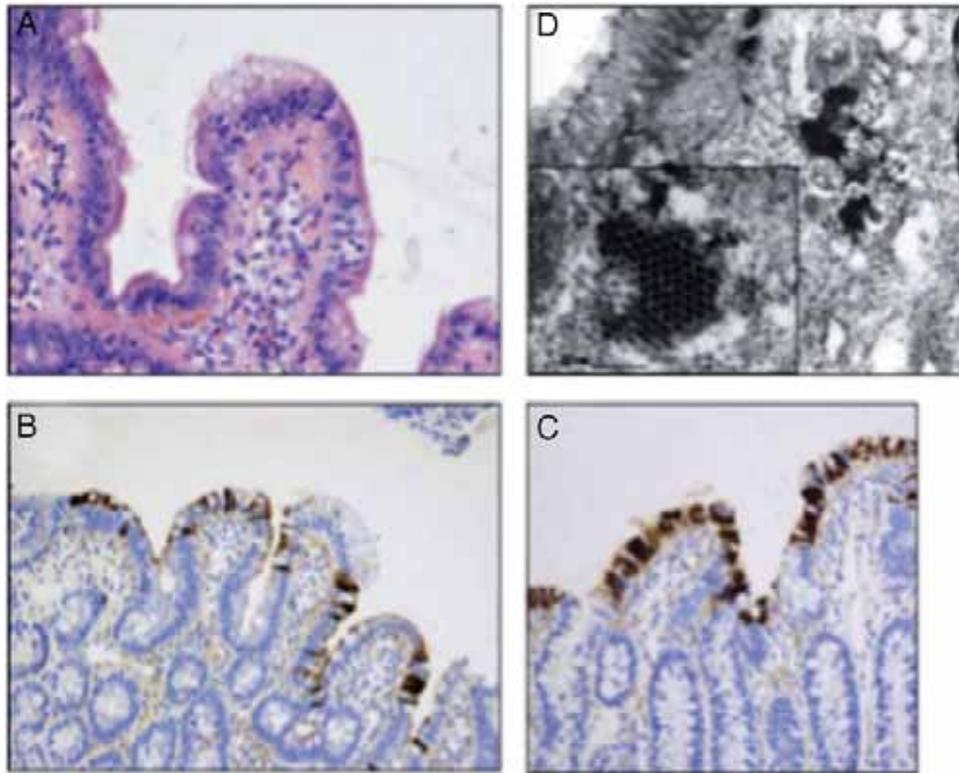

Contaminated food or water is the most frequent source of astrovirus infections. Large outbreaks of gastroenteritis in different countries (76) and sequence analysis of the astrovirus strains present in water supplies and fecal samples from hospitalized patients in South Africa have confirmed that food and water are important sources for virus infection (77). Classical HAstVs have been detected in sewage samples around the world (78–86), and recently HAstV MLB was found by deep sequencing in sewage samples from United States, Spain, Ethiopia (87), and Uruguay (88). HAstV is able to survive on inert materials for long periods, and it has been suggested that it can also be transmitted through fomites in nosocomial infections (46).

In general, astroviruses have a limited host range; however, the identification of novel astroviruses in human populations, which are genetically more closely related to animal than to classical human astroviruses, suggests interspecies transmission; zoonotic events have also been suggested (40, 51, 89). In support of this idea, recombination between human and both porcine (90) or marine mammal strains has been reported (91). People who have contact with turkeys can develop serological responses to turkey astrovirus, but whether this is the result of viral infection was not discerned (92).

## PATHOGENESIS AND IMMUNE RESPONSE

### Pathogenesis

HAstV has a specific tropism for epithelial cells of the small intestine. However, there is limited information on the pathogenesis of HAstV infection. Histopathological studies of biopsies from an immunodeficient patient showed that astrovirus infections are limited mainly to epithelial cells in the small intestine, particularly the jejunum, although the duodenum was also affected (Fig. 4) (68). Studies with this patient, as well as with turkeys infected with a homologous astrovirus (93), indicate that inflammation is not central to illness pathogenesis. The fact that astrovirus induces apoptosis in cultured cells of human origin (43, 94) suggests that this programmed cell death, frequently associated with a very minimal inflammatory response, could play a role in disease pathogenesis. With turkey astrovirus infections, virus can be recovered from different organs, although the small intestine seems to be the only organ where the virus replicates (95). Histological studies with tissues from mammals infected with astrovirus, which are probably more similar to human infections, indicate that the virus is localized in the epithelial cells, as well as in subepithelial macrophages of the small intestine. Intestinal epithelial cells are the primary site of astrovirus replication in humans, reflecting the high quantities of virus particles present in fecal samples. Up to  $10^{10}$  astrovirus particles may be shed per milliliter of stool (23), although many samples contain much lower amounts of virus. Virus can persist in fecal samples of infected children up to two weeks after symptoms disappear, but this period frequently is much longer in immunodeficient patients with chronic infections (74). Gnotobiotic lambs, infected with ovine viruses indicate that the incubation period of the disease is less than 2 days, and they develop diarrhea that ends four days postinoculation (96). In this animal model, infection occurred primarily in the dome of epithelial cells overlying jejunal and ileal Peyer's patches, and virus secretion occurred between days 2 and 9 postinoculation. In humans, the median incubation period in adults was 4.5 days,

**FIGURE 4** (A) Photomicrograph of a jejunal biopsy specimen from a bone marrow transplant recipient with astrovirus infection demonstrating villus blunting, nonspecific alterations in surface epithelial cells and a mixed lamina propria inflammatory infiltrate but without the presence of viral inclusion bodies (original magnification,  $\times 100$ ). Also shown are photomicrographs of duodenal (B) and jejunal (C) biopsy samples from a bone marrow transplant recipient with astrovirus infection immunostained with anti-astrovirus antibody and demonstrating progressively extensive staining of surface epithelial cells, most commonly near the villus tips (original magnifications,  $\times 40$  and  $\times 100$ , respectively). (D) Electron micrographs of a jejunal enterocyte demonstrating cytoplasmic paracrystalline viral arrays of astrovirus (original magnifications,  $\times 32,000$  and  $\times 100,000$  [inset]). (Reprinted from reference 68 with permission.)

with 75% of cases becoming symptomatic by 5.3 days (97). The capsid protein could be involved in the pathogenesis mechanism of astrovirus, since it induces a reduction in the transepithelial resistance in cultured cells (98).

Astroviruses have been shown to be potential neurotrophic pathogens in mink (SMS-AstV) and cattle (BoAstV CH13 and BoAstV NeuroS1). Viruses were detected in brain of cattle with a clinical neurologic disorder and in mink having a neurological disease, termed shaking mink syndrome (SMS) (99–101). In humans, the nonclassical HAstV VA-1/HMO-C has been found in neuronal tissue of patients with encephalopathy (Fig. 5), and this virus groups phylogenetically with SMS-AstV, BAstV CH3, and BoAstV NeuroS1. On postmortem examination, the patient's brain displayed features consistent with viral infection, since viral antigen and viral RNA were detected in glial (102) or neuronal cells (103, 104), while the viral RNA was absent or reduced in stool and intestinal tissue. Only one fatal case of classical HAstV has been reported in a patient with severe combined immunodeficiency. In this case viral RNA was found in stool but only in low levels in the brain. The patient had liver and lung failure, convulsions and evidence of meningoencephalitis (105). In all the cases where HAstV has been detected in brain tissue, the patients were immunocompromised.

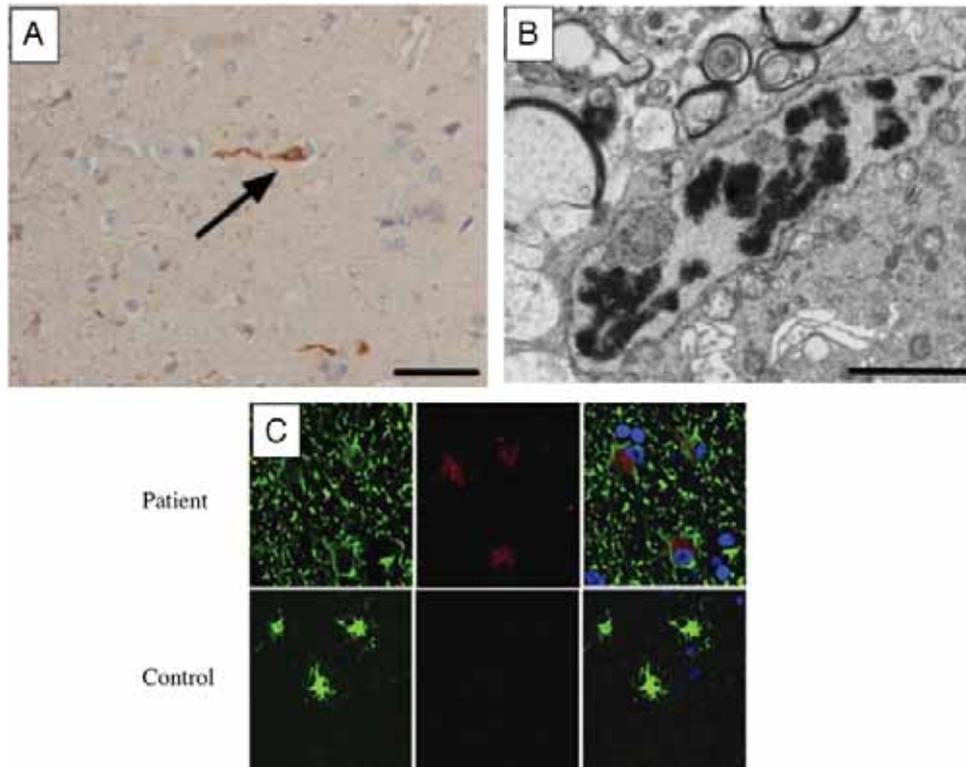

The high prevalence of antibodies to HAstV VA-1/HMO-C suggests that the infection in humans is common

but most frequently asymptomatic. Koch's postulates have not been established for HAstV VA-1/HMO-C and the neuropathology, since these viruses have not been adapted to grow in cultured cells, and currently animal models do not exist to reproduce the disease. However, data with the SMS-AstV can be reproduced by intracerebral inoculation of healthy animals with brain extracts obtained from ill individuals, and the viral RNA is only detected in diseased animals (naturally or inoculated) (99).

Members of the *Avastrovirus* genus are associated with different diseases in different species. Astrovirus isolated from ducks cause fatal hepatitis in ducklings (106), while isolates from chickens are associated with renal and gastrointestinal diseases (107). Turkey astroviruses cause not only enteritis but immunopathology that leads to a disease called poult enteritis mortality syndrome (108–110); in pigeons astrovirus has been related to nephritis (111).

### Immune Response

The existence of several HAstV serotypes suggests that neutralizing antibodies exert an immune selection pressure on the virus. In adult volunteers HAstV seroconversion occurred after inoculation, and, in some cases, the antibodies recognized other serotypes, indicating that cross-neutralizing antibodies can be elicited upon infection (112, 113). The role of antibodies to control a natural infection is not clear, and it is not known if primary infections in childhood

**FIGURE 5** Detection of the capsid protein of HAstV VA-1 in neuronal tissue from immunosuppressed individuals. (A) Immunohistochemistry with an antibody against astrovirus shows extensive staining of cell bodies and processes in the neuropil. Some of the astrovirus-positive cells have the morphology of pyramidal neurons (indicated by an arrow; scale bar, 50  $\mu\text{m}$ ). (B) Electron microscopy of the same patient in (A) showed a rare focus of crystalline material but no viral particles (scale bar, 2  $\mu\text{m}$ ). (C) Indirect immunofluorescence of brain tissue sections from a 15-year-old boy with X-linked agammaglobulinemia and astrovirus encephalitis (patient), and a control patient with astrogliosis not caused by astrovirus infection (control). The sections were stained for the astrocyte marker glial fibrillary acidic protein (GFAP, green) and for viral capsid protein (red); the blue color (DAPI) indicates nuclear counterstaining. Original magnification,  $\times 100$ . (Adapted from references 103 (A and B) and 102, with permission.)

provide heterotypic protection for subsequent infection, although symptomatic infections in elderly patients suggest that antibodies acquired early in life (114) do not provide protection from illness at a late age.

The mucosal immune system could be important in protecting individuals from repeated astrovirus infections. T cells that recognize astrovirus antigens in a human leukocyte antigen (HLA)-restricted manner were found to reside in the intestinal lamina propria of healthy adults (115). These HAstV-specific CD4<sup>+</sup> T cells produced helper T-cell subtype 1 cytokines, interferon gamma and tumor necrosis factor when activated. Recent isolation of murine astrovirus and the use of mice defective in the production of T cells confirmed the role of adaptive immunity in the control of astroviruses, and the use of knockout mice for STAT-1 suggests that the innate immune response can also have a role in the immune control of these viruses (116). HAstVs induce the production of interferon, and viral replication is partially susceptible to it (117). The capsid protein of HAstVs inhibits the complement system (118).

## CLINICAL MANIFESTATIONS

A typical astrovirus infection in humans is characterized by acute gastroenteritis, consisting of watery diarrhea for two to three days that may be accompanied by vomiting, fever, anorexia, abdominal pain, and a variety of constitutional

symptoms that typically last no more than four days (74). Symptoms are similar to those caused by other gastrointestinal viruses like rotavirus and calicivirus, but are usually not severe enough to require hospitalization. Cases of severe astrovirus infections have been reported during infections with serotypes 6 (119) and 3 (120). HAstVs have been detected in children with intussusception, although astrovirus infection does not appear to be associated with increased risk of this problem (121–125). The severity of an astrovirus infection is associated with the immune status of the patient, since immunodeficient patients have shown persistent infections with an extended course of infection and viral shedding (64). Illness due to astrovirus infection may be more severe in the elderly, given the likelihood of general debility and underlying serious medical conditions in many of these patients (59). Death associated with astrovirus infection is extremely rare.

The clinical manifestations of infection with novel HAstVs are not clear, since some studies have associated them with gastroenteritis while others have detected the virus in the absence of gastroenteric symptoms. The patients in whom novel HAstVs have been detected in cerebral tissue had neuropsychiatric manifestations, including irritability, dystonia, reduced consciousness, withdrawal, ataxia, memory loss, headache, and vestibulocochlear dysfunction. Viremia was reported in one case, and the patient developed respiratory and gastrointestinal complications. The capsid

protein or viral RNA was detected in neurons and glial cells (Fig. 5). All encephalitis cases have proven fatal (102–104). One report found classical HAstV-4 in the brain. In this case no detection of viral antigen was reported, but viral RNA was detected in postmortem autopsy tissue from several organs including brain; the patient developed multiorgan dysfunction (105).

## LABORATORY DIAGNOSIS

### Virus Isolation

Caco-2 is the cell line of choice for virus isolation from human fecal samples (35, 126). Trypsin treatment of the sample is necessary to successfully adapt HAstV to cells. Since the cytopathic effect caused by an astrovirus infection is difficult to observe in most cases, especially in the first passages in Caco-2 cells, this technique should be complemented with additional methods to enhance specificity and sensitivity, including immunofluorescence with group-specific antibodies or RT-PCR EM of infected cells, which can also be used to confirm the isolation of astrovirus in culture. Notably, paracrystalline structures around the nucleus are formed by multiple particles (Fig. 1B). As mentioned earlier, T84 and PLC/PRF/5 hepatoma cells may also be used for isolation of human astroviruses directly from fecal specimens. Other cell lines, like HEK-293, HT29, MA104, and LLC-MK2, that have been used to grow cell culture-adapted astrovirus strains, are not easily infected with the virus present in fecal samples. The novel HAstV strains have not yet been grown in cell culture.

### Electron Microscopy

EM has been used to distinguish this virus from other viruses of similar size; however, this technique requires qualified personnel to obtain reliable results, since a low percentage of particles in fecal samples show the star-like morphology. The EM detection method requires  $10^6$  to  $10^7$  particles per gram of stool (127). Sensitivity by EM can be improved by treating the sample with astrovirus-specific antibodies in order to agglutinate viral particles, facilitating detection.

### Antigen Detection

Enzyme immunoassays (EIA) have been developed to detect the classical eight HAstVs in fecal samples. Variations of this assay have used monoclonal antibodies that recognize a group antigen, as well as serotype-specific polyclonal antibodies (128–131). EIA (e.g., ProSpecT Astrovirus Test, Oxoid Microbiological Products, UK) is useful to detect astroviruses in a large number of samples, showing specificities in the range of 90 to 98%. It has been estimated that a positive EIA requires at least  $10^5$  and  $10^6$  viral particles per gram of stool (127). The high antigenic divergence of avian viruses has not permitted the identification of antibodies to common epitopes to be used in immunoassays to detect all AstV that infect flocks. Similarly, no antibodies to common epitopes to detect the novel HAstV and other mammalian astroviruses have been produced.

### Nucleic Acid Detection

Astrovirus nucleic acid can be detected in fecal samples by RT-PCR. The most useful oligonucleotide primers to detect serologically distinct strains of classical HAstVs were selected from highly conserved regions, such as the 5'-terminal region of ORF2, the 3'-end of the genome and the RNA-dependent RNA polymerase gene (132). However, oligo-

nucleotide primers from the hypervariable region of ORF2 have also been used to genotype human isolates, since the amino acid sequence of this region correlates with the serotype (133). The sensitivity of RT-PCR (approximately 10 to 100 particles per gram of stool) (127) is higher than the sensitivity of EIA, although it can depend on several other factors, such as the primers used, the protocol to obtain the viral RNA and the reaction conditions. The sensitivity of RT-PCR to detect HAstV may be enhanced when it is combined with cell culture. This combined method has been successfully used to detect human astroviruses in water samples (134). Sequencing of the amplified DNA fragment by RT-PCR from a fecal sample can be useful to confirm astrovirus presence in that sample and to distinguish genotypes. RT-PCR assays have also been used to confirm the presence of astrovirus in animal samples.

For detection of both classical and novel HAstVs, primers that, in principle, could detect all strains have been designed, although no commercially available assays exist. After RT-PCR genome amplification with these pan-astrovirus primers, positive samples are amplified with specific primers, followed by DNA sequencing of the amplicon to determine the virus genotype (63). More recent developments include several protocols for real-time RT-PCR, several of which are designed as multiplex assays for detection of multiple pathogens (for instance, Astrovirus Assay, CeramTools, France; FilmArray, Biomérieux, France; Diagenode, Belgium; and Seeplex Diarrhea ACE Detection, Seegene, Korea) (9). The detection of astrovirus has also been reported using DNA microarray platforms (135–137). Deep sequencing was used in the identification of MLB and VA HAstVs and is a useful technique for identification of emerging astroviruses (10, 63).

## PREVENTION

Prophylactic measures to avoid astrovirus spreading in the population are important but may be difficult to achieve. Sanitation is particularly important in institutions, such as daycare centers, aged-care centers, and hospitals with children and with immunocompromised patients, where outbreaks can emerge. Since astroviruses are resistant to a number of chemical treatments, appropriate disinfectants should be used. Soapy water and ethanol wipes were shown to reduce diarrhea due to astrovirus in a medical unit attending children with immune disorders (138). Standard water chlorination, although not totally effective, can help to diminish astrovirus viability (46, 47). Universal hygienic procedures must be used to prepare the food. No vaccines are available to prevent astrovirus disease in humans. In chickens, vaccination with the recombinant astrovirus capsid protein induced partial protection against the runting and stunting syndrome (139).

## TREATMENT

As mentioned above, the gastroenteritis caused by astrovirus is not as severe as that caused by other viruses, and it is self-limiting. Generally, astrovirus infections do not require a specific therapy, other than rehydration. However, in immunodeficient patients with persistent infections, intravenous immunoglobulin administration has been used. Immunoglobulin therapy of immunocompromised patients with persistent astrovirus infection has resulted anecdotally in virus clearance and diarrhea elimination (140), but this treatment did not work for bone marrow transplant patients with

chronic diarrhea, even though this preparation was demonstrated to have antibodies to the homologous infecting astrovirus serotype (138). In this group, virus excretion was reduced in two patients when T-cell responses started to be detected after transplantation, suggesting that CD4+ T cells could be important to control virus replication either directly or through activation of B cells to produce antibodies (115, 138). No antiviral agents have been developed to control astrovirus infections, although synthetic flavonoids cause a dose-dependent reduction of viral antigen synthesis (141).

# Coronaviruses

J.S.M. PEIRIS

## 52

The name coronavirus derives from the Latin word “corona,” meaning crown or halo, and this refers to the “crown-like” fringe of projections seen on the surface of virus particles when viewed under the electron microscope (Fig. 1). The first coronavirus to be recovered was infectious bronchitis virus (IBV) from chickens with respiratory disease, reported by Beaudette and Hudson in 1937 (1). Murine hepatitis viruses (MHV) (2) and transmissible gastroenteritis virus (TGEV) in swine (3) were then recognized as causes of other animal diseases. The relationship between these viruses was not appreciated until after the human coronaviruses (HCoVs) were discovered in the 1960s and the *Coronavirus* genus was defined. Tyrrell and Bynoe (4) described the first HCoV, designated as B814, by inoculating specimens from a patient with a “cold” onto organ cultures of human embryonic trachea. Using electron microscopy (EM), the virus was found to resemble avian IBV (5). At about the same time, Hamre and Procknow (6) recovered five HCoV strains from medical students with colds and cultivated them in human embryo kidney cells. The prototype strain HCoV 229E had morphology that was identical to that of B814 and IBV. McIntosh et al. used the organ culture technique to recover six further strains, including the prototype strain HCoV OC43 and three other strains considered antigenically unrelated to either OC43 or 229E (7).

Until 2002, coronaviruses were perceived primarily as causes of the “common cold” and were not generally a subject of major public health or research interest. In the winter of 2002–2003, an unusual and often lethal form of pneumonia, a disease subsequently named severe acute respiratory syndrome (SARS), appeared in the Guangdong Province of China. Within days of this disease spreading to Hong Kong in late February, international air travelers seeded outbreaks in Vietnam, Singapore, Toronto in Canada, and elsewhere. By the end of this brief but global epidemic in July 2003, 8,096 cases had been recorded, 744 of them fatal, in 29 countries across five continents. Transmission within healthcare settings was a notable feature, accounting for 21% of all cases (reviewed in reference 8).

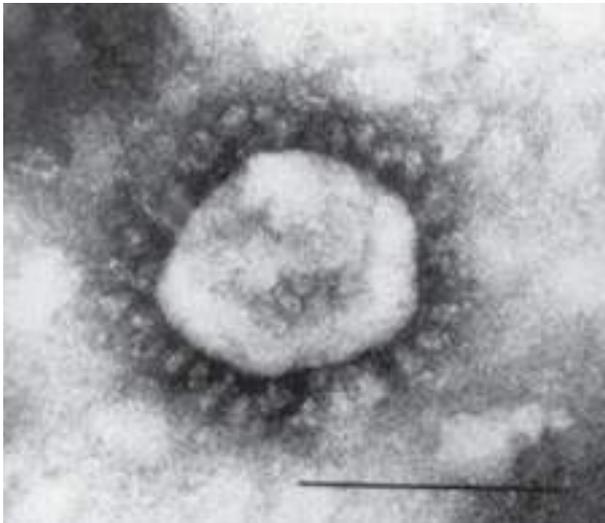

The resurgence of scientific interest in coronaviruses following the emergence of SARS, supplemented in part by the development of new culture-independent molecular methods for detection and identification of viruses, led to the discovery of three other coronaviruses causing disease in

humans: NL63, HKU-1, and in 2012, Middle East respiratory syndrome coronavirus (MERS-CoV) (9–11). HCoVs 229E, OC43, NL-63, and HKU-1 (collectively referred to as endemic HCoVs below) are endemic in the human population and are distributed globally. SARS-CoV is no longer circulating within the human population, but MERS-CoV continues to cause sporadic zoonotic cases, sometimes followed by clusters of transmission between humans, mainly within healthcare facilities or families.

## VIROLOGY

### Classification

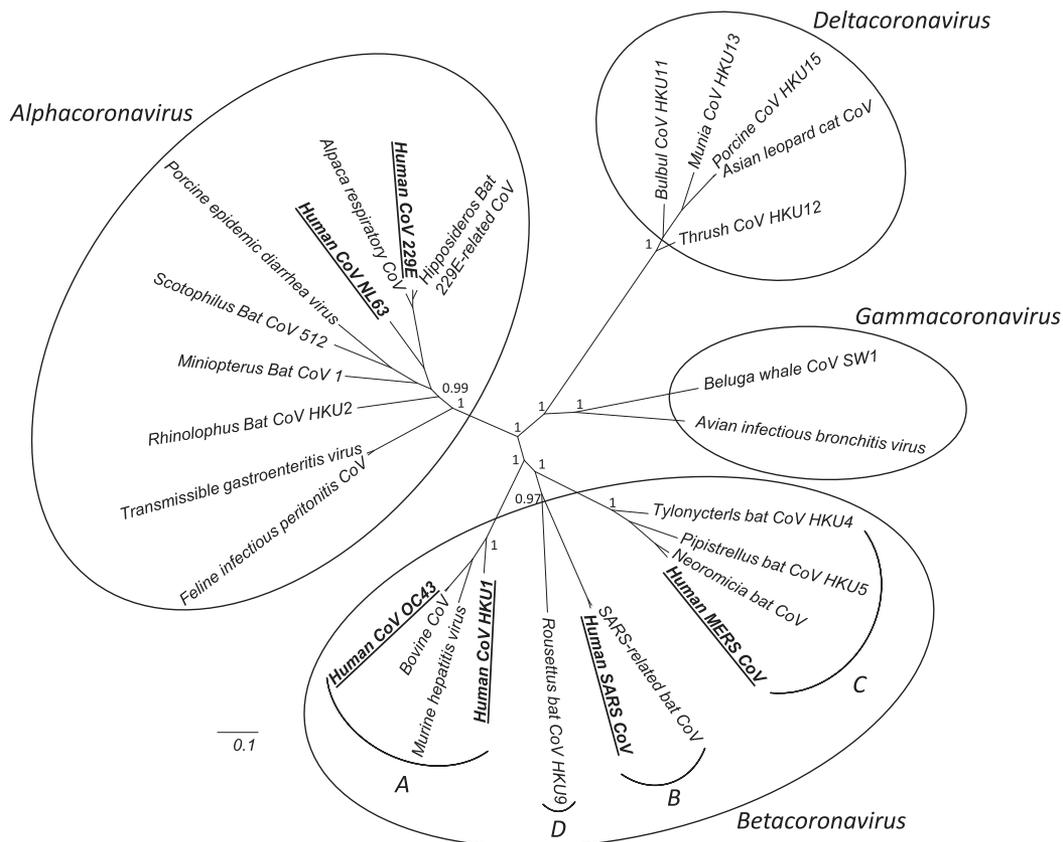

Coronaviruses have been classified as members of the order Nidovirales, positive-sense, single-stranded RNA viruses that replicate using a nested (“nido”) set of mRNAs. The family Coronaviridae contains two genera, *Torovirus* and *Coronavirus*. The original basis for classification of the coronaviruses into a separate genus lay in the distinct morphology of the members (12) (Fig. 1). This classification subsequently has been justified by genetic relatedness and similar strategies of replication. The *Coronavirus* genus is a large one, with representative viruses infecting multiple species, including chickens, turkeys, ducks, geese, other birds, rodents, cats, dogs, rabbits, cattle, horses, antelopes, camelids, pigs, aquatic mammals (dolphins, whales), bats, and humans. Many of the animal coronaviruses are of great economic importance. On the basis of genetic homologies, the coronaviruses are divided into alpha, beta, gamma, and delta coronavirus groups (Fig. 2). As defined by the International Committee on Taxonomy of Viruses, a virus is grouped into a known genus if the genetic sequence of RNA-dependent RNA polymerase, nonstructural protein (nsp) 5, nsp12, nsp13, nsp14, nsp15, and nsp16 share more than 46% nucleotide sequence homology. Previously, alpha-, beta-, and gammacoronaviruses had been designated as group 1, group 2, and group 3 coronaviruses, respectively, with deltacoronaviruses being a more recently defined group. Alphacoronaviruses include HCoV 229E and NL63. Betacoronaviruses are subdivided into groups A–D, with HKU1 and OC43 included in group A, SARS-CoV in group B and MERS-CoV in group C. Gammacoronaviruses are largely avian in origin and include IBV as well as marine mammalian viruses, whereas deltacoronaviruses include

**FIGURE 1** Coronavirus OC16, viewed by EM and negatively stained. The characteristic round or oval shape is seen, along with petal-shaped peplomers. Bar, 100 nm.

viruses of avian species and swine. There is a large diversity of bat coronaviruses within alpha- and betacoronaviruses, and thus bat coronaviruses are believed to be ancestral to all alpha- and betacoronaviruses. Rodent coronaviruses appear to be intermediate ancestors of the betacoronavirus group A. Similarly, avian coronaviruses are believed to be ancestral to gamma- and deltacoronaviruses (13).

Several coronavirus species cause gastroenteritis in newborn or young animals, and it was therefore not surprising when coronavirus-like particles (CVLPs) were found by EM in human feces. The identity of CVLPs in human intestinal contents and their role in disease are still unresolved. Some of the confusion about the role of enteric coronaviruses as causes of diarrhea may be related to the similar appearance of toroviruses in negatively stained stool specimens examined by EM. Toroviruses, belonging to a separate genus within the family Coronaviridae, are well-characterized causes of diarrhea in calves and horses. Human toroviruses, partially purified from stool samples, have been shown to be serologically related to both equine and bovine toroviruses (14, 15) and to contain sequences at the 3' end almost identical to those of equine torovirus (15, 16). With the help of serologic specificity, EM identification, and genetic characterization, differentiation from coronaviruses is possible (16). Likely the distinct roles of toroviruses and enteric coronaviruses will be clarified in the future.

**FIGURE 2** Phylogenetic relationships among coronaviruses. The phylogenetic tree was generated with an RNA-dependent RNA polymerase gene using the maximum likelihood method. Supports for branches were estimated by the Shimodaira-Hasegawa-like method and are shown at major nodes. The four coronavirus genera are indicated in circles. The betacoronavirus lineages A–D are denoted. Human coronaviruses included in the analysis are underlined.

## Composition of Virus

### Virion Structure

Coronavirus virions are round, enveloped, moderately pleomorphic, medium-sized particles measuring 100–150 nm in diameter and covered with a distinctive fringe of widely spaced, club-shaped surface projections (Fig. 1) (17). The projections are about 20 nm in length and represent the spike (S) protein, which aggregates in trimers to form the characteristic peplomers of the virus. Some members of betacoronaviruses, including OC43, also contain a shorter envelope protein, named hemagglutinin esterase (HE).

In EM thin sections of infected cells, virus particles have a diameter of 85 nm, a typical bilayer external membrane, and a coiled nucleic acid core that is, in cross section, 9–11 nm in diameter. These particles have been observed to bud from the membranes of the Golgi apparatus or endoplasmic reticulum (ER) of an infected cell and to accumulate in cytoplasmic vesicles (18) (Fig. 3). Infected cells often have particles on the cell surface that represent virus disgorged from cytoplasmic vesicles, rather than budding of virus at the plasma membrane.

Unlike coronaviruses, which are round in shape, toroviruses have a doughnut shape. They have few 20-nm spikes but have a fringe of smaller spikes, 7–10 nm in length (19, 20).

### Genome

The genome of coronaviruses is the largest known RNA virus genome, 25.4–31.8 kb in size. It is single stranded, positive sense, capped, and adenylated. The order of genes is shown in Fig. 4A and is roughly identical throughout all coronavirus species, namely, 5′-replicase–spike (S)–envelope

(E)–membrane protein (M)–nucleocapsid (N)–3′. In those species containing the HE gene, this is found between the replicase gene and the S protein gene. Many species have additional genes that code for accessory proteins, the presence of which can vary in different viruses (Fig. 4A).

### Major Structural and Regulatory Proteins

The large surface glycoprotein, the S protein, is oriented with its amino terminus facing outward, is N-glycosylated, assembles into trimers, and forms the club-shaped surface projections. The S protein is a prototypical class 1 fusion protein and is involved in receptor binding and fusion functions. Following cleavage by cellular proteases into S1 and S2 subunits, the former is involved in interaction with receptors whereas the latter is involved in fusion of the viral and cellular membranes. Coronavirus cell and tissue tropism, disease pathogenesis, and host range are initially controlled by interactions between the S1 subunit and host cell receptors; however, proteolytic activation of the spike protein by host cell proteases also plays a critical role. A number of host proteases have been shown to process the spike protein proteolytically, including, but not limited to, endosomal cathepsins, cell-surface transmembrane protease/serine (TMPRSS) proteases, furin, and trypsin (21). The spike protein elicits neutralizing antibody responses.

The HE glycoprotein, found on the surface of some betacoronaviruses, is genetically related to a similar protein in influenza C virus. The esterase function may have a role in the release of virus from infected cells. Embedded in the membrane of the virus particle is the M protein, a 20- to 35-kDa glycosylated protein that penetrates the viral envelope three times and has a key role in virus assembly, probably interacting with the RNA–nucleoprotein complex of the virus during the maturation of the particle. Also present in the membrane is a sparsely represented protein, the E protein. The nucleoprotein itself is a 50- to 60-kDa phosphoprotein, which binds to and presumably stabilizes the positive-strand RNA of the virus.

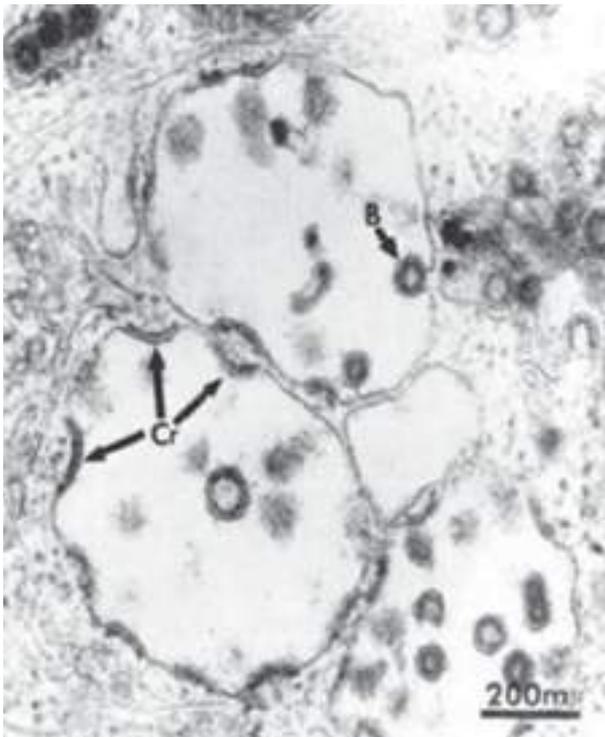

The open reading frame 1a/b (ORF1a/b) of the coronavirus genome encodes a huge polyprotein that is cleaved by cellular and viral proteases into some 16 nonstructural proteins, including an RNA-dependent RNA polymerase, several RNases, several proteases, and several other essential proteins. Unlike other RNA viruses, which lack proofreading mechanisms to correct mutations that occur during replication of RNA, coronavirus nonstructural protein 14 provides proofreading activity (22). Coronaviruses have a number of accessory proteins, some of them not essential for virus replication *in vitro* but important *in vivo*. Some of these, for example, ORF6, ORF3b, and ORF4a, are interferon antagonists that help the virus evade host innate immune responses (reviewed in 23, 24).

The proteins of enteric HCoVs have not been well characterized, although it appears that their size and number are similar to those of other coronaviruses (25).

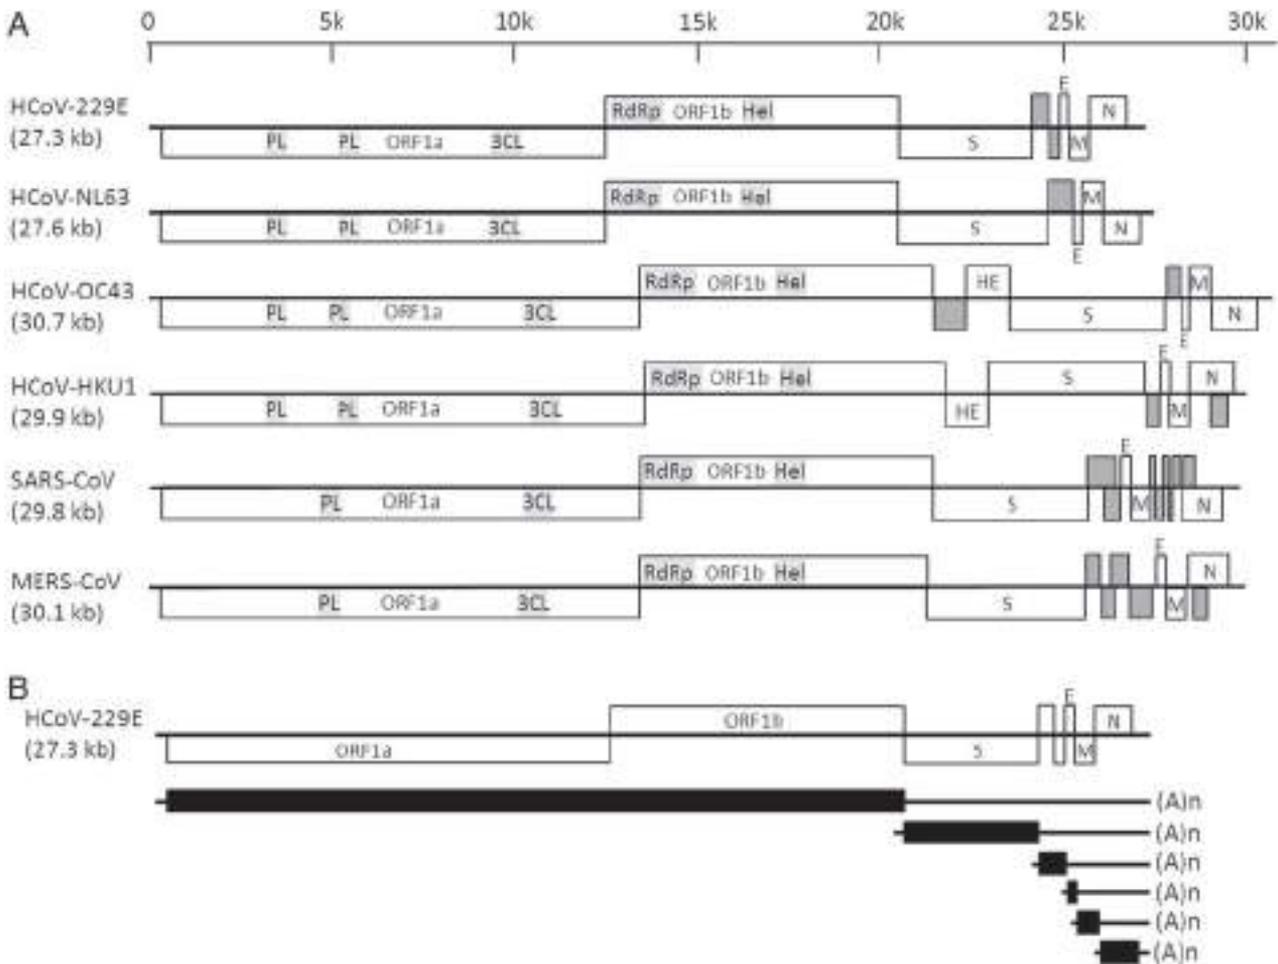

## Biology

### Replication Strategy

The biology of coronaviruses (reviewed in 25, 26) is complex. Coronaviruses bind to cells through receptors, although the details are not presently known for all members of the genus. HCoV 229E binds specifically the metalloprotease human aminopeptidase N (27), whereas the alphacoronavirus HCoV NL63 and betacoronavirus SARS-CoV bind specifically to another metalloprotease, angiotensin-converting

**FIGURE 3** Coronavirus 229E in WI38 cells. Characteristic crescents (Cr) of budding particles (B) are seen, as well as particles that are free in cytoplasmic vesicles.

**FIGURE 4** (A) Genome organization of alphacoronaviruses HCoV 229E and HCoV NL63 and betacoronaviruses HCoV OC43, HCoV HKU1, SARS-CoV, and MERS-CoV. Genes and open reading frames (ORFs) of the genomes are shown, with accessory genes indicated in dark grey boxes. Positions of papain-like proteases (PL), chymotrypsin-like protease (3CL), RNA-dependent RNA polymerase (RdRp), and helicase (Hel) encoded in ORF1a and ORF1b are shown in light grey. (B) The 3' coterminal nested set of coronavirus mRNA is shown for HCoV 229E. The black boxes indicate the region of each mRNA being translated.

enzyme 2 (ACE2) (28, 29). Betacoronavirus MERS-CoV binds to dipeptidyl peptidase-4 (DPP4; CD26), which is found on many human tissues including the respiratory epithelium (30), whereas MHV uses carcinoembryonic antigen-related cell adhesion molecule 1 (CEACAM-1) as a receptor (31). Betacoronaviruses can also use both S protein and (if present) HE to bind to 9-*O*-acetylated neuraminic acid molecules on many biological membranes as an additional receptor. HKU1 binds *O*-acetylated sialic acid residues on glycoproteins to initiate the infection of host cells (32), but this sialic acid is not the 9-*O*-acetylated neuraminic acid molecule that binds OC43 and bovine coronaviruses.

Viral entry is accomplished through fusion of the plasma and viral membranes at the cell surface or by receptor-mediated endocytosis via a clathrin-dependent mechanism. Once in the cytoplasm, the genomic viral RNA is translated by host machinery to produce the polyprotein that is then cleaved by virally encoded papain-like protease and the main protease to produce (among other proteins) an RNA-dependent RNA polymerase. This enzyme helps make a minus-sense copy of the full-length genome and also a set of nested minus-strand RNAs from the genomic RNA, which

serve as templates for mRNA synthesis (Fig. 4B). Each of the nested-set mRNAs begins with a leader sequence, identical to the leader sequence found at the 5' end of the full-length genomic RNA, then an intergenic sequence, then the translated ORF, and then all bases through to the 3'-polyadenylated end. Thus, all of the mRNAs except the smallest, that coding for the N protein, are polycistronic, containing sequences coding for more than one protein, although only the first cistron in line is actually translated during protein synthesis (25, 26).

The various viral proteins are synthesized, processed, and transported by cellular cytoplasmic machinery. Coronaviruses can replicate in enucleated cells. The S protein and HE are cotranslationally N-glycosylated in the ER and processed in the Golgi apparatus where the S protein is oligomerized into a trimer. The S protein undergoes proteolytic cleavage either intra- or extracellularly, as mentioned above. The M protein is inserted into the ER shortly after synthesis and accumulates in the Golgi apparatus.

Assembly takes place when the N protein binds to genomic RNA and recognizes signals on the M protein in the ER or the Golgi apparatus. The S protein and HE are in-

incorporated into the ER and Golgi membranes at the time of budding, and viruses accumulate in large numbers in smooth-walled cytoplasmic vesicles. These fuse with the plasma membrane and virus is released.

### Host Range and Zoonotic Emergence

The host range of coronaviruses is largely determined by the viral spike–host cell receptor interactions and the dependence of viral spike activation by defined host proteases (see above). Coronaviruses rival influenza viruses as a group where human epidemics or pandemics can arise from animal viruses. Four (HCoV 229E, HCoV OC43, MERS-CoV, SARS-CoV) of the six currently known HCoVs originated by zoonotic transmission events within the past few hundred years (33) (Fig. 2). Ancestral viruses to HCoV 229E exist in African bats and camelid species, suggesting that 229E arose from bat viruses with camelids as a potential intermediate host (Fig. 2) (34, 35). This pathway of emergence is reminiscent of zoonotic MERS-CoV infections, which currently appear to be transmitted from dromedary camels (36, 37), but it is possible that the ancestral viruses again reside in bat species (33, 38). HCoV OC43 arose from bovine coronaviruses (BCoVs), which have also crossed to other animal species, including other ruminants and camelids (33). SARS-CoV emerged from *Rhinolophus* bats (39). Intermediate hosts, such as civet cats within game animal markets in Guangdong, served as amplifiers for the virus, and these venues provided the interface for repeated human exposure (40). Other examples of interspecies transmission between animals include the emergence of canine CoV (CCoV) II and feline CoV II from recombination events between canine, feline, and porcine coronaviruses and CCoV II, which led to the emergence of TGEV (reviewed in 23, 41).

There are examples of dramatic changes of tissue tropism, pathogenesis, and virulence associated with genetic changes in the spike protein. TGEV, a cause of a virulent gastrointestinal disease of swine, had tropism for the intestine. Viruses with deletions of the spike protein gene of TGEV emerged spontaneously, leading to a change in the tropism of the virus to the swine respiratory tract. This virus, now called porcine respiratory coronavirus, causes a milder disease (41, 42).

### Experimental Animal Models

Animal models are important for the investigation of viral pathogenesis, transmission, and the efficacy of treatments and vaccines. Successful experimental animal models should mimic the human disease; share comparable disease severity, increased in relevant demographic groups (e.g., age); manifest comparable pathology, virus tropism, and receptor distribution; and mimic the natural route of transmission. Experimental models for the endemic HCoV have not been investigated intensively, whereas experimental animal models for SARS and MERS have been studied (reviewed in 43, 44, 45). Nonhuman primates (NHPs), mice, hamsters, and ferrets have been investigated for this purpose.

Experimental infection of cynomolgus macaques and African green monkeys with SARS-CoV led to variable disease severity. In parallel with the demographics of disease in humans, aged macaques manifest more severe disease (see section on pathogenesis). Common marmosets (*Callithrix jacchus*) develop multiorgan disease. Experimental infection of mice leads to virus replication without overt disease, but disease severity can be increased by using older mice (46), using transgenic mice expressing the human ACE-2 receptor, or adapting the virus to mice by serial virus passage. The

virus replicates to high titers in hamsters without overt disease. SARS-CoV infection of ferrets has been reported with conflicting results.

MERS-CoV infection of macaques is associated with viral replication and lung infiltration but mild disease. Infection of marmosets is associated with higher levels of virus replication and more severe disease; however, the intratracheal route of infection required has led to controversy regarding the biological relevance of this experimental model. Mice are not susceptible to MERS-CoV because mouse DPP4 does not support viral attachment and replication. Transduction of human DPP4 into mouse lung via an adenovirus vector makes mice susceptible to experimental challenge, leading to an interstitial pneumonia, but not to death. Aged mice have more severe disease, but still without virus-associated mortality. Transgenic mice with global expression of human DPP4 are permissive to robust viral replication, leading to severe respiratory and generalized disease and death. Hamsters and ferrets are not susceptible to MERS-CoV infection. Dromedary camels are a natural host for MERS-CoV, and infection causes minimal overt disease. In parallel, experimental intranasal infection of dromedaries is associated with viral replication and shedding in the nasopharynx associated with a mild nasal discharge. There is no evidence of virus dissemination (reviewed in 44).

### Growth in Cell Culture

None of the HCoVs grows easily in cell culture without adaptation by passage. Strains related to 229E can be grown in primary or secondary human embryonic kidney cell lines, in diploid human fibroblast lines, and in a few heteroploid lines (47, 48). The most sensitive cell line for isolation of 229E from clinical specimens appears to be the diploid intestinal cell line MA-177 (48). The hepatoma line HUH7 has been recently used with success for isolation of HKU1, OC43, and 229E from clinical samples (49–51). LLC-MK2 and Vero B4 cells have been helpful in isolation of NL63, although the cytopathic effects (CPE) are somewhat nonspecific (52). The highest titers of both 229E and OC43 have been obtained by growth in human rhabdomyosarcoma cells (53). Plaque assays for HCoV-229E can be performed in human diploid fibroblasts (54), and those for both 229E and OC43 can be performed in rhabdomyosarcoma and fetal tonsil diploid cells (53).

Culture of HKU1 has also been possible in primary human tracheal–bronchial epithelial cells cultured in an air-liquid interface (55). Organ cultures of human embryonic trachea, while a sensitive culture system, are not practical for diagnostic laboratories. Although two strains have been adapted to growth in suckling mice (56), direct isolation in mice from respiratory tract specimens has not been reported.

SARS-CoV was isolated first in Vero E6 or fetal rhesus kidney cell lines with production of CPE (57–59). Vero E6 cells are now routinely used for its growth and also for plaque assays of infectivity (60). In addition, the virus has been adapted for growth in a number of other cell lines that express the ACE2 receptor. MERS-CoV was also initially isolated in Vero E6 cells, which remain a cell line used for growing and titrating this virus (11). There are reports that Caco-2 cells are more efficient for primary isolation (61).

Enteric coronaviruses have been very difficult to propagate *in vitro*, and most strains have only been detected by EM of negatively stained fecal preparations (62–65). Their morphology is sometimes different from that of other coronaviruses (66). On the other hand, several strains have been propagated in intestinal organ cultures (67, 68), and both

antigenic and biophysical studies have been performed (68, 69). Certain strains were related both to bovine diarrhea virus and to OC43 (69, 70). One strain, recovered from infants with outbreak-associated diarrhea and originally isolated in fetal intestinal organ culture, has been adapted to growth in a mouse macrophage line and a mosquito cell line and appears unrelated to other HCoV or animal coronaviruses (71).

#### Inactivation by Physical and Chemical Agents

SARS-CoV and MERS-CoV remain viable for much longer than other HCoV or influenza when dried on surfaces (reviewed in 72). SARS-CoV remains viable up to 9 days in liquid suspension and 6 days in the dried state (73). SARS-CoV dried on smooth surfaces retains its viability for over 5 days at temperatures of 22–25°C and a relative humidity of 40–50% (i.e., typical air-conditioned environments), whereas virus viability is rapidly lost at higher temperatures and higher relative humidity (74). MERS-CoV also retains viability on surfaces for many days and is more stable at low-temperature/low-humidity conditions. Aerosolized MERS-CoV retains viability at low temperature and low humidity (75). MERS-CoV has been isolated from environmental surfaces of patient rooms and anterooms, such as benchtops, bed sheets, bedrails, intravenous fluid hangers, and X-ray devices, for many days (76), indicating the potential for fomite transmission.

Common disinfectants commonly used in hospital and laboratory settings are generally effective in inactivating SARS-CoV. Thermal inactivation at 56°C was highly effective in the absence of protein, reducing the virus titer to below detectability; however, the addition of 20% protein exerted a protective effect resulting in residual infectivity. If protein-containing solutions are to be inactivated, heat treatment at 60°C for at least 30 min must be used (73).

## EPIDEMIOLOGY

### Geographic Distribution

Antibodies to OC43, 229E, NL63, and HKU1 have been detected in human sera worldwide. Seropositivity appears in early childhood and increases rapidly with age (77–79). Similarly, virus RNA from endemic HCoVs has been detected in clinical specimens globally (80–82). Seroprevalence of HKU1 in adults appears to be lower than observed with other endemic HCoV (78). It should be noted that the type of serological assay used may affect estimates of seroprevalence (see Laboratory Diagnosis section, below).

As noted above, SARS emerged in Guangdong Province, China, in late 2002 and spread to 29 countries (8). However, the interruption of human-to-human transmission in July 2003 aborted the outbreak. The virus re-emerged to infect four other persons in contact with live game animals in December 2003 and January 2004, the virus infecting humans being similar to SARS-like viruses circulating in civets and other animals within these markets. These patients had mild disease and no secondary transmission was detected. The closure of these live game animal markets prevented further human zoonotic infections.

Three laboratory-associated infections have subsequently been reported, one of them leading to limited secondary transmission within the community (8, 83). SARS was unusual among respiratory viruses in that asymptomatic infection was uncommon (84). Thus, antibody to SARS-CoV is found only in those who have had clinical SARS, a small

number of contacts who have been asymptotically infected, and a fraction of individuals who work in these live-animal markets and have presumably been exposed to the precursor SARS-CoV-like virus (40). The continued presence of the SARS-like bat virus precursor in *Rhinolophus* bats implies that the re-emergence of SARS remains possible (39).

MERS-CoV still remains zoonotic in origin, all zoonotic infections so far being reported from the Arabian Peninsula or the Middle East region (85). Travel-associated cases have been reported in many other countries in Europe, Africa, and Asia, some of them leading to secondary transmission; the largest such outbreak outside of the Middle East affected 186 persons in the Republic of Korea in 2015 (85, 86). Although dromedary camels are infected endemically in North, East, and Central Africa (87), primary zoonotic infections have not been reported so far in Africa. It is unclear whether this reflects lack of recognition and diagnosis, differences in zoonotic potential of the virus, or other behavioral factors that affect transmission.

The geographic distribution of the gastrointestinal coronaviruses is less clearly delineated. CVLPs have been found in the stools of adults and children in both resource-rich and -poor countries, and it has been common to find them in equal frequencies in both healthy and sick persons.

### Incidence and Prevalence

#### Endemic HCoVs (229E, OC43, NL63, HKU1)

The rate of coronavirus infection among adults with upper respiratory illness varies by respiratory seasons and year. In an early 6-year study of 229E infection among medical students, based solely on rises in neutralizing antibody, only 1% of acute respiratory illnesses in the period from 1964 to 1965 could be attributed to 229E; but from 1966 to 1967, the proportion was 35%, giving an overall average infection attack rate of 15% (88). The proportion of coronavirus-associated minor respiratory illnesses in a general population in Tecumseh, MI, during the same peak year was 34% (89), and a rate of 24% was found in Bethesda, MD (48). Serosurveys of OC43 infection in adults have shown similar proportions. During peak seasons, 25% (89) to 29% (77) of colds could be associated with OC43 infection; overall, 17% of individuals developed antibody rises each year.

In a serologic survey of OC43 infection in high-risk adult populations in Houston, TX, 8–9% of acute respiratory episodes in outpatient adults with underlying chronic obstructive pulmonary disease or asthma were attributable to OC43 infection (90). In England, a study of asthmatic adults with acute respiratory symptoms from 1990 to 1992 showed infection with OC43 or 229E in 16% (91). Serologically documented infections by 229E or OC43 occur at about one-half the frequency of rhinovirus infection and the same as, or somewhat greater than, that of influenza virus and respiratory syncytial virus (RSV) infections (92, 93). Among Finnish adults surveyed by serologic techniques over a 10-month period, 8.5% of colds were associated with infection with either 229E- or OC43-related strains compared to 52.5% rhinoviruses detected by reverse transcriptase PCR (RT-PCR) (94). There are few longitudinal sero-epidemiological studies with HCoVs NL63 or HKU1. In a small cohort (n=13) of newborn babies followed serologically for 18 months using an NL63 and 229E nucleocapsid protein-based enzyme-linked immunosorbent assay (ELISA), all of the babies had maternally acquired antibodies at birth. After clearance of maternal antibody, 7 and 2 of these

13 children became NL63 and 229E seropositive, respectively, during the 18 months of follow-up (95).

Using RT-PCR for detection of 229E and OC43, two community studies of acute respiratory illness have been performed in patients cared for by general practitioners in The Netherlands (96, 97). In adults 60 years or older, during a single respiratory season, these two coronaviruses were found in 17% of 107 elderly subjects with acute respiratory disease, in contrast to only 2% of controls. In the same cohort, 32% of episodes were associated with rhinovirus infection (2% of controls), and 7% were associated with influenza infection (0% of controls) (96). In the second study, subjects of all ages (mean, 35 years) were sampled over 3 years. In contrast to the findings in the exclusively elderly, in this population coronavirus infection was not significantly associated with illness, being found in 6 (3.6%) of 166 influenza-like illnesses, 29 (7.7%) of 376 other respiratory illness, and 21 (3.9%) of 541 controls (97). There have been no systematic, adequately controlled studies of either NL63 or HKU1 in adults or children with outpatient respiratory illness.

Particularly in young children, coronavirus RNA is frequently found in respiratory samples from asymptomatic as well as symptomatic individuals (97–99). Also, multiple viruses may be detected in the same clinical specimen, such that it is often difficult to attribute illness, especially of the lower respiratory tract, in an individual patient. The level of confidence of causality of HCoV for lower respiratory tract infections is enhanced by including an age-matched control group or by detecting the virus in specimens such as bronchoalveolar lavage (BAL), lung biopsy, or autopsy specimens, although the latter are rarely available. Concomitant seroconversion also enhances confidence that the detected virus is of clinical relevance. Infection rates in six studies of outpatient or hospitalized patients with acute respiratory tract disease are summarized in Table 1 (81, 100–104). In outpatient or hospitalized patients with acute respiratory tract disease, in which 229E, OC43, NL63, and HKU1 were sought by RT-PCR, there was evidence of HCoV RNA in 1.7–7.6% of patients, with varying proportions of the four HCoVs being detected. Coinfections with other respiratory viruses were detected in about one-quarter of the HCoV infections, similar rates of coinfections being found for each of the four HCoVs. In a multiple-year study of acute respiratory illness of all ages in Yamagata, Japan, HCoVs were detected in 7.6% of infections overall, all four endemic HCoVs being detected. There was marked winter seasonality, and monthly detection rates of NL63 exceeded 10% in 3 months, with peak monthly detection rates being as high as 28.5% (81). In a study of children hospitalized with acute respiratory symptoms or fever, HCoV-associated hospitalization per 10,000 population was 10.2 [95% confidence interval (CI) 4.3, 17.6], 4.2 (95% CI 1.9, 6.9), and 0 (95% CI 0, 3.7) in children aged <6 months, 6–23 months, and 24–59 months, respectively (105). In an outpatient-based study where all nontrauma acute illnesses were investigated, acute respiratory symptoms were the most common presenting symptom, but diarrhea was noted as a presenting symptom in some (80). Of those patients with HCoV being the only virus detected, 7.7%, 9.0%, and 9.1% of the patients with NL63, 229E, and OC43 required hospital admission. Peaks of activity with one virus often were associated with subsequent periods (years) of low virus activity (80, 81).

Enteric coronaviruses or CVLPs have been most frequently associated with gastrointestinal disease in neonates

and infants less than 12 months of age. Particles have been found in the stools of adults with acquired immunodeficiency syndrome (AIDS), in some studies more frequently in the presence of diarrhea than in its absence (106). Asymptomatic shedding is common, and particles are apparently shed for prolonged periods (65, 107–109).

#### SARS-CoV and MERS-CoV

During the period of the SARS outbreak (from November 2002 to July 2003), 8,096 confirmed cases were reported from 29 countries or administrative regions across five continents, 774 of these being fatal. After the end of the outbreak in July 2003, four laboratory-acquired infections were reported in Singapore, Taiwan, and Beijing in 2003 and 2004, one of these leading to limited community transmission, which was again controlled by public health measures (83). Another four instances of new zoonotic transmission occurred in December 2003 to January 2004 in live-animal markets, in Guangdong Province, China, causing mild disease, and did not result in detectable human-to-human transmission (110).

As of early January 2016, 1,626 cases of confirmed MERS had been reported from 26 countries in Asia, Africa, Europe, and North America, 586 of these being fatal (111). Primary zoonotic infections have so far only been reported from the Arabian Peninsula and the Middle East, with travel associated cases being reported from other countries.

#### Seasonality

In temperate regions, OC43, 229E, and, on the basis of more limited data, also NL63 and HKU1 appear to have peak incidence in the winter and early spring (55, 81, 112, 113), but seasonality may be more variable in tropical and semi-temperate regions (100, 114). Two or three yearly cycles have been observed with each coronavirus, possibly a result of population immunity. Unlike seasonal influenza, in which a given subtype and strain may dominate in multiple countries in any given year, coronavirus outbreaks are more localized geographically (112).

Reported cases of MERS appear to show marked seasonal peaks in the spring-summer period (85). Some of these peaks are due to large outbreaks within hospitals, and longer-term follow-up would be required to establish if such a seasonal pattern does exist. Zoonotic MERS-CoV infections may increase in the spring, following an increase in virus activity in camels associated with the camel calving season, which occurs in the winter and early spring. Higher rates of detection of MERS-CoV are found in camel calves compared with adults (115).

On the basis of the limited data currently available, enteric coronaviruses appear to have little or no seasonality (116).

#### Transmission

##### Endemic HCoVs

Both 229E and OC43, as well as several less-well-characterized strains of coronaviruses (B814, LP, EVS, OC16, OC37, OC38, OC44, and OC48) were transmitted by intranasal inoculation to adult volunteers in the Common Cold Research Unit, Salisbury, UK, and all produced clinical upper respiratory illness (117). Presumably, the respiratory route is the primary mode of infection with these viruses, although the details of their spread have not been studied in a field setting. After infection of adult volunteers, virus was shed beginning 48 hr after inoculation, at about the time

**TABLE 1** Summary of selected epidemiological studies on the prevalence of respiratory coronavirus infection in outpatient and inpatient populations. Data on other respiratory viruses are shown for comparison, where available.

symptoms began, and shedding continued for five days (118). Presumably, infected subjects are themselves infectious during this time. Comparable studies have not been carried out with NL63 or HKU1. Detailed information is lacking on the mode of spread of the endemic respiratory HCoV infections; i.e., the relative importance of small versus large droplets and aerosols or fomite transmission. In community-based settings, there is evidence of clustering of transmission within family groups (112).

#### SARS-CoV

The community transmission patterns for SARS-CoV are very different from endemic HCoVs. Although the majority of cases did not transmit infection at all, a few were responsible for explosive outbreaks, the so-called “super-spreading incidents” (119). In a number of these instances, it

is the overall epidemiological context rather than the nature of the individual index patient that was crucial to such super-spreading events. An unusual transmission event occurred in Amoy Gardens, an apartment complex in Hong Kong, where over 300 people acquired infection within a few days from one index case who had diarrhea as well as mild respiratory illness at that time. It is believed that a faulty sewage system led to aerosolization of infectious fecal matter, which then spread by the airborne route to affect many other residents in this housing complex (120).

The number of secondary cases produced by a single case was estimated to be 2.2 to 3.7, similar to what is estimated for pandemic influenza (121). The success of public health measures in interrupting transmission is that, unlike with many other respiratory viral infections, it predominantly took place later in the illness, usually after day 5 of symp-

toms. This provided a window of opportunity for case detection and isolation prior to maximal transmissibility, allowing public health measures to interrupt transmission in the community (122). In addition, there was extraordinary cooperation and communication between countries and public health workers to control spread. It is interesting to speculate whether SARS-CoV might have become an endemic respiratory infection if not for the determined international global public health efforts implemented in 2003.

### MERS-CoV

MERS-CoV infection in humans has been initiated by zoonotic transmission events, camels being the likely source of such infection (36). Infection in camels is mild, causing a “common cold”-like illness, especially in juveniles (123). The virus is shed primarily from the nose of infected camels, with virus being shed for a few weeks. Virus is less often detected in the feces. Although virus RNA was detected in camel milk, it has so far not been cultured from milk (124). Given that milk is usually rich in maternally transferred antibody to MERS-CoV, it is unclear if such contaminated milk is infectious. However, given the local practice of drinking fresh, unboiled camel milk, this must be considered as a potential route of transmission. Camels become reinfected, resulting in a high prevalence of MERS-CoV shedding in situations where animals from different origins are mixed, such as camel abattoirs. Thus, virus shedding is common in such settings and implies constant exposure of humans to infected animals although disease does not appear to be common.

A large population-based seroepidemiological study of apparently healthy persons older than 15 years of age in Saudi Arabia revealed an overall seroprevalence of 0.2%, increasing to 3.6% in abattoir workers routinely exposed to dromedary camels, implying that there have been many more infections taking place than has been recognized from case diagnosis (125). Whereas nosocomial transmission accounts for most of the transmission occurring between humans (see next section), transmission does occur within family settings (126). There is evidence of asymptomatic infection of humans infected zoonotically (127) as well as nosocomially (128), and transmission possibly occurs from such asymptomatic or mild infections (129). Thus, a likely scenario is that most zoonotic transmission is asymptomatic or mild and unrecognized. Such infections may sometimes lead to transmission to other humans, where infection may be detected only in those in whom severe clinical disease occurs, for example, because of being older in age or having underlying comorbidities. In such epidemiological settings, it may be difficult to identify the initial zoonotic infection.

### Nosocomial Transmission

As with other respiratory viruses, nosocomial transmission of coronaviruses is problematic. One outbreak of respiratory endemic HCoV in a neonatal intensive care unit caused 10 infections, all associated with symptoms of generalized acute illness, among 40 premature infants (130). NL63 infection in hospitalized children has also led to an outbreak in a neonatal intensive care unit (131). Occurrence of infections in closed populations, such as military or children’s institutions, have been reported (112). However, the most dramatic examples of nosocomial transmission of coronaviruses occurred with SARS and MERS.

Both SARS and MERS have been merciless in exploiting lapses in infection control measures within healthcare set-

tings, particularly within modern hospital settings. During the SARS outbreak in 2003, 21% of cases were in healthcare workers, often with severe consequences. The virus spread readily in the hospital environment, particularly early in the epidemic of 2002–2003, when recognition of the disease was poor, confirmatory diagnosis was lacking, and appropriate precautions were not being taken (132). The enforcement of droplet and contact precautions was strongly associated with protection (133). However, in some instances when aerosol-generating procedures were used (e.g., nebulizers, intubation, and high-flow oxygen therapy), transmission also occurred via small-particle aerosols. The unusual stability of the virus also likely predisposed it to spread via direct or indirect contact (see above). Risk factors associated with SARS outbreaks in hospital wards were narrow space between beds, lack of availability of washing or changing facilities for staff, performance of resuscitation in the ward, and the use of oxygen therapy or bilevel positive-airway-pressure ventilation (134).

With MERS-CoV, chains of transmission have led to large outbreaks within healthcare facilities, some involving over 100 persons and often involving healthcare workers (86, 135). Some outbreaks have involved multiple healthcare facilities and have continued for months (136). Outbreaks of MERS-CoV have been associated with failures in consistent application of patient triage and infection control precautions; failure in early recognition, diagnosis, and isolation; crowded emergency rooms; and healthcare workers continuing to work while infected in the early stages with mild illness or asymptotically (129, 136). An outbreak in the Republic of Korea initiated by a returning traveler led to 185 other confirmed infections in 16 hospitals. Some 44.1% of the cases were patients exposed in hospitals, 32.8% were family or paid caregivers, and 13.4% were healthcare personnel (86). Although 91% of cases did not lead to secondary transmission, five “superspreaders,” all of whom had pneumonia at initial presentation and came into contact with large numbers of people prior to diagnosis, led to 83% of the cases. In the Korean outbreak, the practice of seeking healthcare at multiple healthcare facilities, of having paid caregivers within hospitals, and frequent inter-hospital transfers were additional factors that appear to have contributed to spread. Heightened awareness, infection control measures, patient isolation, and quarantine and surveillance of known contacts have so far been able to contain such outbreaks, as illustrated in Saudi Arabia and Korea.

### Risk Factors

#### Endemic HCoVs

In contrast to other respiratory viruses, infection attack rates of HCoV in young adults are not much lower than those in children (89). There is no consistent sex difference in susceptibility, although an excess of females has been noted in some community-based studies (112). Increased susceptibility of females to experimental challenge has been noted (137). HCoV infections (229E, OC43, HKU1, NL63) have been associated with exacerbation of chronic obstructive respiratory illnesses, but it is unclear if this reflects increased susceptibility to infection or more severe illness following infection (138). Susceptibility to experimental infection by 229E (as well as to rhinoviruses) is increased by psychological stress (139). Atopy [as assessed by detectable total immunoglobulin E (IgE) in nasal secretions or higher serum IgE levels] is associated with increased clinical severity following

experimental 229E infection (140). Immunocompromise appears to be associated with severe HCoV disease, although whether because of increased susceptibility, severity, or both is unclear (141, 142).

### SARS and MERS

Increasing age has been associated with increased severity of disease for both SARS and MERS. In Hong Kong, mortality rates in patients with SARS aged 0–24, 25–44, 45–64, or >65 years was 0%, 6%, 15%, and 52%, respectively (reviewed in 8). Severity of MERS also increased with age, but this may reflect the presence of comorbidities as well as age. Of reported cases, 76% of patients with MERS had underlying comorbid conditions (obesity, diabetes, cardiac disease, lung disease, immune-compromised) compared to 10–30% of patients with SARS (143). In the case of MERS, it is likely that the older age of reported cases reflects the fact that younger patients have milder disease and remain undiagnosed. Genetic polymorphisms associated with low serum levels of mannose-binding lectin were associated with increased susceptibility to SARS (144). Genetic factors associated with the risk of MERS remain to be investigated.

The risk of zoonotic MERS is associated with exposure of the patient or family members to dromedary camels (37).

## PATHOGENESIS IN HUMANS

### Patterns of Virus Replication

In volunteers infected experimentally with 229E and OC43 HCoVs, infection was detectable in the respiratory tract from around the time of symptom onset for about five days (145, 146). During acute infection, all six HCoVs replicate primarily within the respiratory tract (see section on Pathogenesis, below). HKU1 has been detected in the feces of patients with gastroenteritis, but its contribution to these symptoms is still unclear (147).

Viral load of SARS-CoV RNA, as quantitated by RT-PCR in the upper respiratory tract (nasopharyngeal aspirates), was low in the first 4–5 days of illness but peaked in the second week, corresponding to the time at which patients were maximally infectious (148). Virus RNA was detectable in the respiratory secretions, feces, and, at lower frequency, in urine, for 3–5 weeks, even though transmission was uncommon after the third week of illness (149). SARS-CoV replicated in the gastrointestinal tract, as demonstrated by EM evidence of viral replication in intestinal epithelium (apical enterocytes) in intestinal biopsies and autopsy tissues (150). Virus RNA was routinely detected in serum and urine, although it was not certain whether this reflected spillover of virus replicating in the respiratory and gastrointestinal tracts. Viral load in nasopharyngeal aspirates and in serum from day 10 to day 15 after onset of symptoms was associated with oxygen desaturation, mechanical ventilation, diarrhea, hepatic dysfunction, and death, whereas stool viral load was associated with diarrhea (151). Furthermore, higher initial viral load was independently associated with worse prognosis in SARS (152).

MERS-CoV RNA has been detected in respiratory specimens, with higher viral load being found in the lower respiratory tract (endotracheal aspirates, sputum) than in upper respiratory specimens (reviewed in 153). The viral load is also higher in fatal cases than in those who survive (154, 155). Although virus RNA has also been detected in the serum, feces, and urine, there is so far no direct evidence that there is active replication at these sites, although such

replication cannot be excluded. Virus RNA can be detected for over 30 days after the onset of illness (156), but the probability of isolating virus from clinical specimens decreased with time after hospital admission and with decreasing viral load (61).

### Pathology

A histopathological study described the nasal mucosa of a young girl with chronic rhinitis and bronchitis who showed the typical EM changes of a coronavirus infection (157). Brush biopsy specimens showed morphologically typical coronavirus particles in large numbers in cytoplasmic vesicles and the Golgi apparatus of ciliated epithelial cells (and not in goblet cells). Interestingly, the infected cells appeared not to show signs of cell death and appeared to have intact synthetic activity. On the other hand, degenerative changes affecting the cilia and loss of cilia were seen, likely indicating decreased ciliary function. It is interesting that EM of SARS-CoV infection of the human gastrointestinal tract seems to reveal a similar pattern, with viral replication and budding occurring with minimal CPE (150, 158).

In SARS, type 1 and type 2 pneumocytes are the key target cells for the virus, and pulmonary histopathology varied according to the duration of illness virus (159–161). Cases of 10 or fewer days' duration demonstrated acute-phase diffuse alveolar damage (DAD), airspace edema, and bronchiolar fibrin. Cases of more than 10 days' duration exhibited organizing-phase DAD, type II pneumocyte hyperplasia, squamous metaplasia, multinucleated giant cells, and acute bronchopneumonia. Multinucleated cells were observed to be pneumocytes or macrophages (159, 160). Immunohistochemistry and *in situ* hybridization studies showed evidence of SARS-CoV infection in the alveolar epithelium and alveolar macrophages in lungs of patients dying within the first 2 weeks of illness, but not at later times after disease onset. Although the virus spreads to other organs (e.g., the gastrointestinal tract) and symptoms of diarrhea were common, disease severity and fatality were due to the respiratory pathology. Pathological studies of MERS are limited. In a 45-year-old man who died on day 8 after onset of illness, the main histopathologic finding in the lungs was diffuse alveolar damage. Pneumocytes and epithelial syncytial cells showed MERS-CoV antigen by immunohistochemistry. There was no evidence of viral antigen in extrapulmonary sites (162).

### Pathogenesis

#### Endemic HCoVs

Little is known of the pathogenesis of the endemic HCoVs. The symptom profile is very similar to that of rhinovirus-induced colds, and likely comparable mechanisms leading to upper respiratory tract illness apply (see Chapter 47).

#### SARS-CoV

The pathology and viral tropism of SARS-CoV have been discussed above (161). Whether and to what extent immunopathology contributes to the disease process is still unresolved (8). Proinflammatory cytokines, such as interleukin 1 (IL-1), IL-6, and IL-12, and chemokines, such as IL-8, chemokine (C-C motif) ligand 2 (CCL-2), and C-X-C motif chemokine 10 (CXCL10), have been found to be elevated in plasma of patients with SARS, but it is not clear whether they drive pathogenesis or are a reflection of virus-induced cell pathology. *In vitro* studies suggest that poor interferon (IFN) induction and signaling occur in SARS-

CoV-infected macrophages and monocyte-derived dendritic cells (reviewed in 8, 163, 164). However, plasmacytoid dendritic cells (pDCs) respond to SARS-CoV infection with potent type I interferon responses (165). Transcriptomic studies of peripheral blood leukocytes from SARS-CoV-infected patients early in the disease process revealed high IFN- $\alpha$ , IFN- $\gamma$ , IFN-stimulated chemokine, and IFN-stimulated gene (ISG) expression. SARS patients who recovered then expressed adaptive immune genes, whereas those with poor clinical outcomes showed deviated ISG expression, immunoglobulin gene expression levels, persistent plasma chemokine levels, and deficient anti-SARS spike antibody production, suggesting a malfunction of the switch from innate immunity to adaptive immunity (166).

Aged macaques infected experimentally with SARS-CoV developed more severe pathology than young adult animals (see above). Although levels of viral replication were similar in both age groups, older animals had pronounced activation of genes associated with inflammation such as nuclear factor- $\kappa$ B (NF- $\kappa$ B)-related pathways while expression of IFN- $\beta$  was reduced. Therapeutic treatment of SARS-CoV-infected aged macaques with type I IFN reduces pathology and diminishes pro-inflammatory gene expression, including IL-8 levels, without affecting virus replication in the lungs (167).

### MERS-CoV

The pathogenesis of MERS is less well studied, and only limited data exist for humans infected with MERS-CoV. Experimental infection of *ex vivo* cultures of human bronchus and lung demonstrate that nonciliated epithelial cells in the bronchus, type 1 and type 2 pneumocytes in the lung, and lung vascular endothelium are infected by the virus, reflecting the distribution of the DPP4 receptor, whereas HCoV 229E did not replicate in human bronchus or lung (168). MERS-CoV infects and replicates in the alveolar epithelial cell line A549, but there are no detectable type I or III IFN responses (168). Human B cells, M1 macrophages, M2 macrophages, and monocyte-derived dendritic cells did not secrete type I or type III IFNs upon inoculation with MERS-CoV *in vitro*. In contrast, human pDCs secreted large amounts of type I and III IFNs upon contact with MERS-CoV (169). MERS-CoV abortively infects CD4 and CD8 T cells, leading to their apoptosis and possibly explaining the lymphopenia observed in MERS (170). In BAL cells of two MERS patients collected in the first week of illness, the patient with a fatal outcome had poor induction of retinoic acid-inducible gene 1 (RIG-1), melanoma differentiation associated protein 5 (MDA-5), interferon regulatory factor 3 (IRF3), IRF7, and type I IFN, whereas the patient who survived had strong type I IFN responses (171).

### Immune Responses

#### Endemic HCoVs

Serum antibody to the major structural antigens of the virus (primarily to the S protein but also to the M and N proteins) is made in adult volunteers in response to inoculation and infection with HCoV 229E and OC43 (172). Antibody titers, as measured by ELISA, rise significantly in volunteers who shed virus (173). In experimental human challenge studies with HCoV 229E, both circulating and mucosal-specific antibodies are associated with protection from infection and disease, but only specific IgA antibodies appear to shorten the period of virus shedding. Total protein in nasal washings also appeared to protect against infection,

indicating that other locally produced proteins, not yet identified, may be associated with resistance (137). Volunteer studies with 229E and 229E-like strains suggest that symptomatic reinfection after a period of 1 year is possible. It is not clear, however, whether this is due to waning immunity or to slight differences in the antigenicities of different virus strains (174). Sequencing of several variants of 229E and OC43 has revealed somewhat contradictory data regarding the genetic diversity of the S protein over time and location, but with consensus regarding the lack of evidence for recombination events (175, 176). Although T cell immunity has been well studied in mice, there are limited data on T-cell responses following human coronavirus infections (reviewed in 177).

### SARS-CoV

The S protein is the predominant target of neutralizing humoral immunity, and the major antibody neutralizing epitopes are in the region from residues 441 to 700 of the S protein of SARS-CoV (8). Neutralizing antibody titers were shown to rise in the second week of the illness, peak between week 5 and week 8 after onset, and decline thereafter, with a half-life of 6.4 weeks (178). All patients who survived >28 days of illness became seropositive. By 36 months after illness, SARS-CoV IgG and neutralizing antibody were undetectable in 25.8% and 16.1% of patients, respectively (179). Contradictory findings have been reported on the association between early antibody responses and disease severity (178, 179), but the use of corticosteroid therapy may have confounded these associations. In patients that have recovered from SARS, T-cell responses have been demonstrated to both the N and S viral proteins in convalescence, and memory T-cell responses have been detectable even 6 years after infection (reviewed in 177).

### MERS-CoV

MERS-CoV infection is associated with robust neutralization and MERS-S1 ELISA antibody responses in most survivors, typically within 3 weeks of the onset of illness, but a few patients have marginal or undetectable antibody responses even after 4 weeks of illness (154, 180). There is yet little information on the longer-term kinetics of antibody responses in MERS-CoV infections. Serum antibody titers correlate inversely with lower respiratory tract viral RNA loads, but virus RNA may remain detectable for weeks despite development of neutralizing antibody responses (154). No systematic studies of T-cell responses in patients with MERS have been reported. The neutralizing antibody responses are directed primarily at the receptor-binding domain of the spike (S1 domain) protein; however, a minor component of neutralizing antibody response binds to other parts of the S1 and S2 domains of the spike protein (181). Although there is genetic diversity in MERS-CoV, all variants appear to be one serotype with efficient cross-neutralization between strains (61, 182).

## CLINICAL MANIFESTATIONS

### Endemic Human Respiratory Coronaviruses

Association of the HCoV strains 229E and OC43 with human disease has been established conclusively by infecting volunteers intranasally with cultured virus and documenting “common cold”-like symptoms correlated with evidence of viral replication in the upper respiratory tract (117, 145, 146, 174, 183). Only 10–30% of inoculated

volunteers developed symptoms, indicating that most HCoV 229E and OC43 infections are asymptomatic in healthy adults. The incubation period of 229E and OC43 infection in volunteers averages 3 days with a range of 2–5 days (145). The peak of respiratory symptoms is not reached until 3 or 4 days after inoculation. The clinical illness consists of general malaise, headache, nasal discharge, sneezing, and a sore throat, symptoms that last for 6–7 days. Cough is seen in about 25% of the subjects and fever only in approximately 10%. The features of coronavirus URTI cannot be differentiated from those produced by rhinoviruses, but fever, chills, and myalgia are less prominent than with influenza. Overall, the character and severity of HCoV illness are somewhat less severe than those of influenza virus and RSV, rarely leading to hospitalization (92, 93, 95). In a study of children with upper and lower respiratory illness that did use a control group for comparison, an association of PCR detection of HCoV 229E and OC43 with upper and lower respiratory disease has been demonstrated (184). Similarly, NL63 has been found preferentially in children hospitalized with croup, even more commonly than parainfluenza viruses, which have been traditionally associated with this disease (101, 185, 186).

A study of 418 patients (mean age 49 years) with community-acquired pneumonia (CAP) in Hong Kong over a 1-year period (2003–2004) yielded HKU1 in 10 (2.4%), 9 of them adults (187), although no control group was studied. The median age of the HKU1-positive patients was 71.5 years (range, 13–96 years); eight of them had underlying comorbidities and two had fatal outcomes. Clinically, these patients were not distinguishable from age-matched CAP patients who were HKU1 negative. Coronavirus infection of marine recruits has been associated with pneumonia and pleural reaction in about 33% (188). A 20-month survey testing all four HCoV types in 540 BAL samples from 279 hospitalized adults identified HCoVs in 29 (5.4%) samples, one-third of all respiratory viruses detected (189). HCoV OC43 was identified in 12, 229E in 7, NL63 in 6, and HKU1 in 4 specimens. Most of the HCoV-positive patients had clinical and radiological evidence of pneumonia and were immune suppressed or were lung transplant recipients.

As with other respiratory viruses, prolonged shedding of virus with or without severe disease can occur in immunocompromised patients (141, 142, 190). Endemic HCoVs are detected in hematopoietic stem cell transplant recipients; the median duration of viral shedding is 3 weeks, but prolonged shedding of at least 3 months can occur. Infection can be asymptomatic or associated with upper respiratory tract symptoms. Progression to lower respiratory tract involvement may occur rarely (191, 192).

Acute lower respiratory tract viral infections in patients after lung transplantation are associated with respiratory viruses in 66%, with coronaviruses (OC43, 229E, and NL63) being the second most common behind rhinoviruses (193). A highly significant association exists between viral infection and decline in 1-sec forced expiratory volume (FEV-1), acute rejection, and likely development of bronchiolitis obliterans syndrome.

In young children with a history of asthma, acute exacerbations were seen during infection by OC43 and 229E (194), although recent studies using PCR have shown that rhinoviruses are by far the most important cause of triggering acute wheezing in children with underlying asthma (195). In adults with chronic pulmonary disease or asthma, several serologic studies have shown significant association between

coronavirus infection and acute exacerbations of respiratory symptoms (90, 91, 96, 196, 197). Infection in the elderly, particularly in those with underlying cardiopulmonary disease, is commonly associated with lower respiratory tract symptoms, although these rarely lead either to hospitalization or to death (92, 93).

The role of respiratory coronaviruses in otitis media has been elucidated by detecting viral RNA in both nasal secretions and middle ear fluids. Among 92 children with acute otitis media, coronavirus sequences were found in 16 children (17%), with 14 children harboring the virus in the nasopharynx and 7 harboring it in the middle ear fluid (198). This incidence was lower than for RSV (28%) and rhinovirus (35%). Coronaviruses were less frequently found in middle ear effusions at the time of tube placement (3 of 100) (199).

Overall, 229E, OC43, NL63, and HKU1 are able to cause upper respiratory tract infections, croup, otitis media, as well as lower respiratory tract infections, the latter being more commonly seen in children, the elderly, or those with comorbidities (80).

More controversially, there is also evidence for the presence and persistence of 229E and OC43 virus RNA in the central nervous system (CNS) in conjunction with chronic neurologic syndromes, particularly multiple sclerosis and acute demyelinating encephalomyelitis (200–203). Human “respiratory” coronaviruses are sometimes capable of entering the CNS. However, assignment of a pathogenic role in demyelinating diseases of humans, so well demonstrated in the murine model, must, however, await further studies.

#### SARS-CoV

The incubation period for SARS-CoV has been estimated to average 4–6 days, with a range of 1–14 days (121, 122). SARS begins with acute onset of fever, myalgia, malaise, and chills and then progresses to cough. Upper respiratory symptoms of rhinorrhea and sore throat are uncommon. Dyspnea and tachypnea develop later in the illness; at this stage, individuals often have scattered ground-glass peripheral lung infiltrates. Over the course of the next several days, they either improve gradually or worsen with increasing oxygen requirements; severe cases progress to acute respiratory distress syndrome (ARDS). A watery diarrhea occurs in some patients, usually associated with clinical deterioration, mainly in the second week of illness. Other extrapulmonary manifestations include hepatic dysfunction and CNS manifestations. Overall mortality is between 9% and 12%, mortality progressively increasing with age (reviewed in 8, 204, 205).

Chest radiographic abnormalities were present in 60–100% of patients, depending on duration of illness, and typically encompass ground-glass opacities or focal consolidation over the periphery and subpleural regions of the lower zones of the lung. Bilateral involvement and shifting opacities are common. High-resolution computed tomography (CT) scanning reveals abnormalities, even in those with initially normal chest radiography.

Laboratory abnormalities include leukopenia (particularly lymphopenia in severe cases) and elevated transaminase levels. In addition to age, the presence of comorbidities, more extensive lung involvement, high neutrophil counts, low CD4 and CD8 counts, and increased lactic dehydrogenase levels are predictors of a poor prognosis. High viral loads in nasopharynx and serum early in the illness and between days 10 and 15 of illness are independent predictors of a poor outcome.

Atypical (sometimes afebrile) presentations can occur in the elderly or immunocompromised patients, leading to delayed recognition, sometimes resulting in nosocomial transmission.

Three months after hospital discharge, patients convalescing from SARS have detectable defects in pulmonary function, but the impairment is mild in almost all cases. Many patients have reduced exercise capacity, not accounted for by impairment of pulmonary function (206).

### MERS-CoV

The median incubation period for MERS is estimated to be approximately 5.5–6.5 days with a maximum 14-day incubation period used for contact tracing and management (85, 86). Clinical features of MERS range from asymptomatic infection to severe pneumonia, often leading to ARDS and death (reviewed in 143, 207–209). The range of illness is broadly similar to that of SARS, but the frequencies of subclinical and mild illness are much higher. Fever (98%), chills or rigors (87%), cough (dry or productive) (83%), and shortness of breath (72%) are common presenting symptoms; diarrhea or vomiting has been reported by around one-third of the patients, whereas sore throat (14%) and rhinorrhea (6%) are uncommon. Common chest radiographic abnormalities include bilateral hilar infiltrates, unilateral or bilateral patchy infiltrates, segmented or lobar opacities, and ground-glass opacities, with the lower lobes being generally more affected than the upper lobes, early in the illness. Small pleural effusions may sometimes be seen. Lymphopenia, thrombocytopenia, and high lactate dehydrogenase levels are seen in around one-third to one-half of patients.

Because mild and asymptomatic infections are more common in MERS, especially in younger persons such as healthcare workers, the case descriptions and case fatality ratios are likely biased by case ascertainment skewed to more severely ill patients. Patients reported with MERS have been older than those with SARS, and the overall disease progression of disease from onset to pneumonia (often within the first week), time to requirement of ventilator support, and time to death appear to be more rapid in MERS. Factors predisposing to fatal outcome include age, underlying comorbidities, and viral load in nasopharyngeal specimens, and, possibly, detection of viral RNA in plasma (155, 210).

### Enteric Coronaviruses

The clinical features of possible enteric infections with coronaviruses have not been clearly described. CVLPs have been detected in stools from healthy subjects as frequently as in stools from those with enteritis (64). On the other hand, studies of disease in neonates and infants in the first year of life have found statistically significant associations between CVLPs and illness, either mild and self-limited (65, 69) or severe, and, in some neonates, requiring surgical intervention (62). One study comparing rotavirus and CVLP-associated diarrhea in children found similar incidences of fever and vomiting, but stools from children excreting CVLPs more often were positive for occult blood (18% versus 0%) and mucoid (32% versus 8%) (109).

## LABORATORY DIAGNOSIS

### Viral Detection

As for other respiratory viral infections, specimen collection should be targeted to the anatomical site predominantly

affected (see Chapter 15). In clinical syndromes involving the upper respiratory tract, nasopharyngeal swabs or aspirates are the specimen of choice, with throat swabs being an alternative. In illnesses where the disease largely involves the lower respiratory tract with minimal involvement of the upper respiratory tract (SARS, MERS), lower respiratory specimens, including BAL, endotracheal aspirates (if the patient is intubated), or sputum, are appropriate. Sputum is not routinely considered a specimen of choice for viral diagnosis, but the experience with MERS suggests that sputum provides a higher diagnostic yield than throat, nasal, or nasopharyngeal specimens (154). However, optimization of methods for RNA extraction from sputum is needed to avoid occasional false-negative results because of high levels of mucus. In the case of suspected SARS or MERS, stool, urine, and blood (serum or plasma) are also useful specimens, although they generally give a lower diagnostic yield than lower respiratory specimens (154).

Primary isolation of respiratory HCoV in cell culture is difficult, and serial passage is frequently required (see above). Respiratory HCoVs can be detected by immunofluorescence of cells shed from the respiratory tract using commercially available reagents (130) or polyclonal (211) or monoclonal (141) reagents developed in individual laboratories. ELISA for coronavirus antigen in nasal swabs or secretions has limited sensitivity (212). ELISA and other antigen detection assays for detecting MERS-CoV in camel swabs have been reported, and more evaluation with human specimens is awaited (213, 214).

RT-PCR, either conventional or real-time, has become the diagnostic method of choice for detection of all HCoV strains. There have been attempts to develop sets of “pancoronavirus” primers and probes (131, 215), and such systems have been used with success (193). However, type-specific primers have greater sensitivity. With HKU1 viruses, there are three genotypes, and it is important that the primers chosen will detect all of these (216). With SARS, the small amount of virus present in all clinical samples obtained in the early phase of the illness has proven to be a diagnostic challenge, even with sensitive RT-PCR methods. The use of multiple specimens (including stool and blood) increases diagnostic yields in the first few days of SARS illness. Diagnostic algorithms for MERS typically involve screening with RT-PCR primers targeting the RNA upstream of the E gene (*upE*) and confirmation with primers targeting ORFs 1b or 1a (217, 218). A single negative result does not exclude a diagnosis of MERS, and repeated testing using lower respiratory specimens must be carried out. Many of the widely used commercially available multiplex assays for detection of endemic respiratory viruses do not detect MERS-CoV; thus, it is important to make a specific request for MERS-CoV diagnosis when clinically indicated.

Genotyping of MERS-CoV can be carried out by primers targeting a 615-base-pair-long region in the S2 domain of the spike gene (219). The full viral genome (or large parts of it) can be sequenced directly from clinical specimens, especially when there is high viral load, and viral genetic analysis can complement epidemiological studies in investigating outbreaks (e.g., within hospitals) (136). Isolation of virus in cell culture often leads to the introduction of amino acid substitutions associated with cell culture adaptation (220). Thus, virus sequence analysis for molecular epidemiology is best based on virus sequence derived directly from the clinical specimen.

The diagnosis of enteric coronavirus infection depends on finding the characteristic particles in stool samples

examined by EM. No culture, antigen detection, or nucleic acid amplification system was available by early 2016.

### Serology

A number of serological assays have been used for detecting coronavirus infections. Historically, complement fixation (CF), hemagglutination inhibition, and virus neutralization tests were used for epidemiological studies and for diagnosis of 229E and OC43 infections. CF antibody responses appeared relatively short lasting and possibly broadly cross-reactive across the then known as well as unknown endemic HCoV, whereas neutralizing antibody was more type specific and lasted many years (112). Neutralization tests (neutralization of CPE or plaque reduction neutralization tests) are thus generally regarded as the most specific and the “gold-standard” serologic tests. ELISA assays and immunofluorescence (IF) tests have also been used.

In IF tests, IgM antibodies in response to SARS remained detectable for more than 6 months after the onset of illness. While SARS CoV infections induce an anamnestic IgG antibody response to the 229E and OC43 viruses, these cross-reactive antibodies remain of high avidity from early (the first month) postinfection. Thus, assays to detect low-avidity antibody may be useful for discriminating early from late antibody responses and also for distinguishing anamnestic cross-reactive antibody responses from primary specific responses (221). Line immunoassays based on nucleoprotein to HCoVs 229E, OC43, NL63, HKU1, and SARS-CoV have been evaluated. There is considerable cross-reactivity between the two betacoronaviruses OC43 and HKU1 and between the betacoronaviruses 229E and NL63 (222). There is, however, no cross-reactivity with SARS-CoV.

For the serodiagnosis of MERS, ELISA or IF assays based on whole virus or virus-infected cells may sometimes detect cross-reacting antibody elicited by other coronaviruses. The S1 region of the spike protein is more specific. ELISA assays to detect MERS-CoV S1 antibody have been developed and commercialized (223). Antibody arrays using the S1 region of multiple human coronaviruses (including MERS-CoV) spotted on a glass slide have also been developed (36). Any sera positive with ELISA, IF, or antibody array tests need to be confirmed by a neutralization test. Conventional neutralization tests with viruses such as SARS-CoV or MERS-CoV require biosafety level-3 (BSL-3) containment because they necessitate the use of live virus. A pseudoparticle neutralization test expressing the MERS-CoV spike protein on the surface of a replication-incompetent human immunodeficiency virus (HIV) backbone with a reporter gene has proved to correlate very well with the plaque reduction neutralization test results (182, 224). This pseudoparticle neutralization test does not require BSL-3 containment and can be performed in BSL-2 laboratories. Kinetics of immune responses of SARS and MERS are discussed in the section on Immune Responses (above).

## PREVENTION

### General

Because MERS can be acquired zoonotically, it is important to educate persons living within MERS-endemic areas and those traveling to such regions to avoid close contact with dromedary camels, drinking fresh camel milk, contact with other camel secretions, and consuming under-cooked camel meat. If contact with these animals becomes unavoidable,

appropriate hygiene measures should be used as soon as possible. The virus is shed mainly from the camel's nose and upper respiratory tract; thus, it is particularly important to avoid contact with these areas. In patients with confirmed MERS, in addition to infection prevention and control measures in healthcare settings, tracing and quarantine (within their homes or in hospital) of close contacts is required (225).

### Infection Control and Prevention

As with other respiratory viruses, infection prevention and control measures for coronaviruses include administrative controls to manage patient flow, with clinical triage of those with acute respiratory infections, prevention of overcrowding in waiting areas, spatial separation of at least 1 meter between patients, adequate environmental ventilation, appropriate hand hygiene, and rational use of personal protective equipment. For patients with acute respiratory infections, standard precautions should be supplemented by the use of a medical mask when in close contact (1 meter) of a patient or when entering the patient room. Consider the use of a mask on the patient to minimize spread of infectious droplets, especially if it becomes essential to move the patient outside of the room. When performing aerosol-generating procedures (e.g., tracheal intubation, tracheotomy, noninvasive ventilation, manual ventilation prior to intubation, etc.), additional precautions (fit-tested particulate respirator, eye protection, long-sleeved gowns, fluid-resistant aprons) are needed (225).

For MERS, specific enquiry needs to be made about travel to MERS-endemic regions, evidence of risk exposures (camel contact, visit to healthcare facility in endemic areas, contact with known MERS patients), contact with an ill returning traveler from affected countries, or work in a laboratory where MERS-CoV exposure may have taken place. When MERS is suspected, additional precautions include the placement of the patient in a single room, preferably with negative pressure ventilation; limiting the number of healthcare workers, caregivers, and family members accessing the patient; sending appropriate specimens for urgent laboratory diagnosis; the use of a particulate respirator, eye protection, gown, gloves, and hand hygiene immediately before and after patient contact or entering the patient area; and the use of disposable or dedicated equipment (stethoscopes, blood pressure cuffs, thermometers, etc.). The use of portable X-ray equipment and other diagnostic equipment, which can minimize movement and transport of patients out of the barrier nursing area, needs to be considered (225). These additional barrier nursing precautions should be in place for the duration of the symptomatic illness and continued for at least 24 hr after symptoms have resolved. Patient information, such as immune status and use of immune-suppressive medication (e.g., corticosteroids), also needs to be considered. MERS-CoV viral load in respiratory specimens would also be useful to monitor in this context. However, it is not clear if low-level MERS-CoV detection by RT-PCR late in the illness necessarily implies that the patient is infectious.

### Vaccines

At present, there is no effective vaccine for any of the human coronaviruses. Antibodies to the S protein of coronaviruses are neutralizing, the critical epitopes being those in the receptor-binding domain. Research on vaccine development for SARS-CoV was initiated after the outbreak in 2003, but there was waning of research funding when no

further cases occurred. Animal studies on vaccine-induced protection, on adoptive transfer, and on T-cell depletion suggest that antibody is necessary and sufficient to confer protection against SARS. Subunit vaccines, whole-virus inactivated vaccines, vaccines that use various live-virus vectors, and DNA vaccines have been tested in various animal model systems, and many of these modalities have shown promise (226). Phase 1 studies with an inactivated SARS-CoV vaccine demonstrated safety and immunogenicity (227). However, the persistence of the antibody responses was not assessed, and, furthermore, volunteers were young and healthy (age range 21–40 years); thus, immunogenicity in older persons remains unclear. Antigenic diversity and lack of cross-neutralization between the human SARS-CoV used for vaccine development and precursor SARS-CoV-like viruses found in small mammals in live-game markets (e.g., civets) and bats, both of which are likely sources of any new SARS outbreak, pose a problem for vaccine development (228). However, some monoclonal antibodies cross-neutralize and cross-protect against both human and animal (palm civet) coronaviruses, but perhaps not those from bats, which is one source of potential SARS re-emergence (229). Vaccines for coronaviruses carry the risk that paradoxical disease enhancement may occur, as has been seen with vaccines for feline peritonitis virus (230). Although such effects were not seen with many of the vaccines studied, there were some examples of vaccine-elicited immunopathology. Mice, ferrets, and macaques immunized with some SARS vaccines led to Th2-mediated immunopathology in the lung upon SARS-CoV challenge, an effect that was more pronounced in vaccines containing only the N protein (231).

Vaccines against MERS-CoV are being developed, primarily based on generating immunity to the spike protein. All MERS-CoV strains tested so far form one serotype with cross-neutralization between strains (see above) (61, 182). Thus, antigenic diversity may not be a problem for vaccine development. Spike DNA and subunit protein vaccines have provided protection in experimental mouse and primate model studies (181). Recombinant vaccines expressing MERS-CoV spike protein in a vaccinia vector have provided protection from experimental challenge in mouse models and in dromedary camels (232). A key remaining question pertains to the duration of such immunity, because there is evidence the natural infection does not prevent reinfection in camels. MERS vaccines are expected to go into Phase 1 human clinical trials soon (e.g., NCT 02670187).

### Chemoprophylaxis

A double-blind, placebo-controlled study of self-administered intranasal recombinant human IFN- $\alpha$  A given both before and after virus challenge reduced incidence of colds, the severity of symptoms and signs, and virus replication as compared with those given placebo (233). Protection by intranasal IFN against HCoV has not been demonstrated under field conditions.

In experimental animal models, MERS-immune antibody can effectively prevent and treat MERS-CoV infections (234, 235). Hence this approach was used as a primary treatment for a patient with MERS-CoV infection and as prophylaxis for his spouse, although it was not possible to assess efficacy in this anecdotal setting (236). Passive immunotherapy with polyclonal MERS-CoV immune serum or humanized MERS-CoV neutralizing monoclonal antibodies is effective in prophylaxis in experimental models of MERS

(237). Thus, this potential option for postexposure prophylaxis of MERS requires study.

## TREATMENT

### Supportive Care

No specific antivirals are proven effective for any coronavirus infection, and good supportive treatment is the mainstay for clinical management. Syndrome-related symptomatic therapy is indicated. In infections leading to severe respiratory illness leading to ARDS, as occurs with SARS and MERS, ventilation using a lung-protective strategy with small tidal volume is advised (238). The use of corticosteroids in viral pneumonia leading to ARDS is in general to be avoided, except in patients with refractory shock or other clinical indication for corticosteroid use. In a retrospective cohort study of patients with SARS, corticosteroid use was associated with worsened outcome and a prolongation of viral shedding (239).

### Antiviral Treatment

Because of the clinical severity and lack of prior data for SARS, various treatments have been attempted for SARS patients. During the outbreak of 2002–2003, many patients were treated with intravenous or oral ribavirin, and those with severe disease also received systemic corticosteroids, often in high doses. A systematic review of different treatments used for SARS found evidence for inhibition of SARS-CoV *in vitro* by ribavirin, lopinavir, and type I IFN (239). Observational trials of convalescent plasma or intravenous immunoglobulin (IVIG), type I IFN, ribavirin, and lopinavir/ritonavir were inconclusive. Corticosteroid therapy worsened clinical outcomes (239) and increased duration of virus shedding. Pegylated IFN had therapeutic efficacy in macaques, and IFN- $\alpha$ 1 may have had some beneficial effect in a preliminary clinical study in humans (240).

Potentially useful drugs for treatment of MERS have been identified on the basis of the *in vitro* experimental animal studies and, where available, any human clinical studies (240–242). MERS-CoV is inhibited by type I IFN *in vitro*, and IFN- $\alpha$ 2b combined with high doses of ribavirin modestly reduced viral titers and lung pathology in experimentally infected rhesus macaques (241). Lopinavir/ritonavir or IFN- $\beta$ 1b treatment improved outcome in common marmosets infected with MERS-CoV, but there are criticisms about the experimental model used (242). One observational study of IFN- $\alpha$ 2b combined with ribavirin treatment in several severely ill patients with MERS found evidence of lower mortality at day 14 but not at day 28, and other observational studies have not yielded encouraging results (210). A number of other compounds (e.g., chloroquine, chlorpromazine, loperamide, lopinavir) have shown inhibitory effects of MERS-CoV *in vitro*, but their effectiveness *in vivo* remains unclear (reviewed by 143).

Passive immunotherapy with neutralizing antibodies from convalescent plasma, equine or camel immune sera, anti-S monoclonal antibodies, and polyclonal human antibodies from transgenic cows have also been identified as potentially beneficial (244). Passive immunotherapy has shown some promise in animal models of SARS (245), and a meta-analysis of clinical trials demonstrated a possible reduction of mortality (244). Clinical trials in MERS patients are anticipated with one or more of these immunotherapeutics.

# Arthropod-Borne Flaviviruses

LYLE R. PETERSEN AND ALAN D.T. BARRETT

## 53

In 1901 the prototype flavivirus disease, yellow fever, was the first human illness shown to be caused by a filterable virus, and, in 1927, it became the first member of the flavivirus family to be isolated. The *Flaviviridae* derive their name from yellow (*flavus*, Latin) fever. From the medical perspective, the flaviviruses are the most important group of arthropod-borne viruses (arboviruses). Dengue fever and dengue hemorrhagic fever (DHF) are major causes of human morbidity worldwide. Yellow fever remains an epidemic threat in Africa and South America. Since its introduction into North America, West Nile virus (WNV) has caused annual outbreaks of encephalitis and febrile illness in North America and has spread throughout the Americas as far south as Argentina; Japanese encephalitis (JE) remains a major cause of viral encephalitis in Asia.

### VIROLOGY

#### Classification

The *Flaviviridae* constitute a structurally unique virus family of positive-sense, single-stranded RNA viruses, divided into the genera *Flavivirus*, *Pegivirus*, *Pestivirus*, and *Hepacivirus*. There are approximately 60 distinct agents in the *Flavivirus* genus, most of which are transmitted by arthropods (mosquitoes or ticks), and more than half are associated with human disease. Classification of viruses within the *Flavivirus* genus has been traditionally based on antigenic distinctions, and each of the 60 virus species represents a distinct "species" or serotype. Using the neutralization test, flaviviruses have been classified into at least eight antigenic complexes, of which six contain human pathogens (1). More recently, nucleotide sequencing has assumed a prominent role in determining relationships among viruses and identifying which are termed "species." The current virus species and their groupings are shown in Table 1. Twelve virus groups have been identified, and an additional group of viruses has been found in insects (insect-specific flaviviruses). Recently a large number of flaviviruses have been identified from either mosquitoes or ticks that do not replicate in vertebrate hosts and have no apparent pathogenic effects in humans (2). While it is clear that these are related to currently identified flaviviruses, it is unclear if they are members of the *Flavivirus* genus. For this reason, they are not considered further in this chapter. The classification of the tick-borne flaviviruses is still being debated (3).

The viruses within the tick-borne, dengue, and Japanese encephalitis serocomplexes are most closely related to each other, sharing up to 77% of their amino acid sequences, whereas homology across the serocomplexes is only 40% to 45%. Immunological cross-protection between viruses is not observed for agents with <70% sequence homology, but incomplete or partial cross-protection may be present across closely related viruses within a serocomplex. Many closely related members of a serocomplex are allopatric species (i.e., subdivided into geographically isolated populations), so that immunological interactions do not occur naturally. Exceptions with overlapping geographic distributions (e.g., dengue serotypes, Japanese encephalitis West Nile) will be noted in the text.

Flaviviruses undergo high rates of mutation characteristic of RNA viruses, and each species consists of multiple genetic variants. Genetic variation is tempered by the requirement to maintain sufficient genetic stability to ensure fitness in hosts and vectors belonging to different phyla. Recombination within species contributes to strain variation of hyper-endemic viruses (such as dengue) that have high rates of co-infection of hosts and vectors (4). An analysis of flavivirus phylogenetic changes by comparing complete E glycoprotein nucleotide sequences showed that the mosquito-borne flaviviruses (like dengue) have undergone explosive genetic diversification within the last 200 years, whereas the more primitive tick-borne viruses evolved slowly (5), probably due, in part, to the different ecologies of the viruses. The recent evolution of dengue viruses is associated with the expanding size and dispersal of human host and vector populations, while the tick-borne agents are transmitted in stable environments between small terrestrial mammal hosts and vectors with a long reproductive cycle.

#### Composition

Flavivirus particles are approximately 50 nm in diameter and have a spherical nucleocapsid surrounded by a lipid-bilayer envelope with small surface projections, comprised of E glycoprotein dimers anchored to the virus membrane. The envelope protects the genome from cellular nucleases. Lipases, organic solvents, and detergents disrupt the virus envelope and inactivate flaviviruses.

The flavivirus genome is a single strand of RNA of positive polarity containing approximately 11,000 nucleotides (6) and is composed of a short 5' noncoding region, a single

long open reading frame containing more than 10,000 nucleotides, and a 3' noncoding region (3'NCR) of variable length that is usually devoid of poly A tracts. The long open reading frame encodes 3 structural proteins at the 5' end, which are the capsid (C), premembrane (prM), and envelope (E) proteins. These are followed downstream by 7 nonstructural (NS) proteins in the sequence NS1, NS2A-NS2B-NS3-NS4A-NS4B-NS5 (Table 2). The structural proteins are incorporated into the mature virion, whereas the NS proteins play various roles in virus replication and

polypeptide processing. The polyprotein is co- and post-translationally cleaved to yield the individual proteins. Translation occurs at the rough endoplasmic reticulum (ER), so that the prM, E, and NS1 proteins are translocated, whereas the others remain on the cytoplasmic side of the host-cell membrane. Cell-associated virions within the ER are morphologically identical to extracellular particles.

The capsid protein interacts with RNA to form the virion nucleocapsid. The prM glycoprotein forms an intracellular heterodimer, stabilizing the E polypeptide during exocytosis.

TABLE 2 Flavivirus proteins and their known or suspected functions

Protein	Location	Mol mass (kDa)	Function	
			Replication	Immunity
C	Capsid	9–12	Associates with RNA in nucleocapsid	T cell epitopes
prM	Premembrane (immature virion)	18–19	Chaperone for E protein; proper folding and stabilization during virus maturation and exocytosis	Protective immunity (minor role, induces low titer neutralizing antibody)
M	Membrane (mature virion)	7–9	Control of fusion events (with E)	T-helper epitope?, induces low titer neutralizing antibody
E	Envelope	55–60	Receptor binding; mediation of membrane fusion in endosome and virus internalization; dissociation of nucleocapsids	Neutralizing (protective) antibody, CTL epitope(s), Th epitopes, immune enhancement, hemagglutination inhibition antibody
NS1	Nonstructural	42–50	Involved in RNA replication and virion assembly/maturation	Antibody, complement-dependent cell lysis; CTL epitopes
NS2A		18–22	Assembly; release	? CTL epitope; interferon antagonist for West Nile virus
NS2B		13–15	Central domain associated with functional NS3 protease	
NS3		67–70	Serine protease (posttranslational processing of viral proteins), helicase, nucleoside triphosphatase, RNA 5'-triphosphatase; RNA capping	Nonneutralizing antibody; CTL epitopes
NS4A		16	Integral membrane protein; induces endoplasmic reticulum membrane rearrangement; regulates ATPase activity of NS3 helicase; part of replication complex	? CTL epitope; induces autophagy
NS4B		27–28	Integral membrane protein; part of replication complex	? CTL epitope; RNA interference; formation of stress granules; unfolded protein response; interferon antagonist for West Nile and dengue-2 viruses, and others?
NS5		104–106	RNA-dependent RNA polymerase, methyltransferase, RNA capping	Nonneutralizing antibody; CTL epitope; interferon antagonist for Langkat and Japanese encephalitis viruses; induction of IL-8

The prM protein is cleaved before virus release from the cell, leaving a small M structural protein anchored in the virus envelope, and releasing the larger 18–19 kDa “pr” glycopeptide segment into the extracellular medium.

The E glycoprotein contains antigenic determinants for hemagglutination and neutralization. Antibodies directed at E and prM determinants also mediate the phenomenon of antibody-dependent enhancement (ADE) of infection in the pathogenesis of dengue hemorrhagic fever (7–9). The E protein is also involved in attachment to cells and fusion of the viral and host-cell membrane during virus entry into the cell, and thus is a major factor in virus virulence. Mutations in the E gene are often responsible for significant alterations in biologic functions of the virus and may affect virulence; however, virulence is multigenic, and evidence suggests that most virus-encoded proteins and 3'NCR contribute to pathogenicity.

The three-dimensional crystallographic structure of the E glycoprotein reveals a head-to-tail dimer composed of a 170-Å-long rod anchored to the membrane at its basal end with

its long axis parallel to the virion surface (10) and is typical of a class II fusion protein characteristic of alphaviruses and flaviviruses. The C-terminus resembles an immunoglobulin constant domain and is connected by a hinge region to a central portion of the molecule (domain I) with up-and-down topology consisting of eight antiparallel strands and containing the N-terminus. Two long loops (domain II) extend outward from this part of the protein and play a role in dimerization of the molecule. A conserved stretch of 14 amino acids at the end of one of the domain II loops is responsible for fusion of the viral envelope and the membrane of the host cell (11). The fusion event is acid-dependent and occurs within endosomal vesicles, releasing the uncoated nucleocapsids into the cytoplasm of the infected cell. The fusion process also results in an irreversible rearrangement of the E protein into a trimeric form. Domain III contains a ligand(s) involved in binding-cell receptors. An Arg-Gly-Asp (RGD) protein sequence in domain III is involved in attachment to glycosaminoglycan receptors (e.g., heparan sulfate) on cell membranes, but other ligand-

receptor interactions probably also occur. To date, no cell receptor has been conclusively proven for any flavivirus. Discontinuous (conformational) neutralization determinants are scattered across all three structural domains but tend to be located on the accessible surface of the E protein, with critical determinants located on domain III and near the fusion peptide region. In addition to infectious virions, several noninfectious subvirus structures are present on, or are released from, infected cells.

The NS1 protein both is released extracellularly and is associated with the plasma membrane of infected cells in the form of a dimeric structure anchored to glycosylphosphatidylinositol (12). The secreted form is antigenic ("soluble complement fixing" antigen), containing both virus-specific and cross-reactive epitopes, and for dengue is also detectable in blood for diagnostic purposes. Antibodies to NS1 do not react with the virion and exhibit no neutralizing activity. Protective immunity is mediated by antibody- and complement-mediated lysis of cells bearing NS1 targets (13).

NS3 functions as a serine protease, involved in post-translational cleavage of the virus polyprotein, and also has RNA helicase, NTP phosphatase, and RNA triphosphatase activities. The protein is present in cell membranes, stimulates virus-specific T-cell responses, and is a target for attack by cytotoxic T cells containing multiple dominant epitopes for CD4+ and CD8+ T lymphocytes in both mice and humans (14). Like NS3, the NS5 protein is also highly conserved; it functions both as the RNA-dependent RNA polymerase in virus replication and as a methyltransferase in 5' cap methylation. The functions of the other NS proteins in replication are poorly defined. NS2A, NS4A, and NS4B function as interferon antagonists for West Nile and dengue-2 viruses (15), while NS5 has the same activity for Langkat and JE viruses.

### Replication Strategy

Flaviviruses enter cells by attachment to heparan sulfate or other, as yet undefined, receptors, followed by uptake of the virus into cells by receptor-mediated endocytosis in clathrin-coated vesicles. Subsequent low-pH-induced fusion of the viral envelope and endosomal membrane involves an acid-mediated change in the configuration of Domain II of the E glycoprotein. The nucleocapsids are released into the cytoplasm, after which the uncoated genomic mRNA is translated into a polyprotein that includes the polymerase, protease, and helicase enzymes (NS5 and NS3) required for continued replication. This genomic RNA also forms the template for synthesis of complementary negative RNA strands, which serve in turn as templates for full-length plus strands. The progeny genomic mRNA serves two functions. First, it synthesizes additional negative strands that serve as templates for more progeny-genomic RNA that will be assembled into virions, and, second, it translates the mRNA to yield additional nonstructural and structural viral proteins required for continued replication and virion assembly. Assembly of virus particles occurs in close association with ER. Virus particles are transported through the ER to the plasma membrane, where they are exocytosed.

### Propagation in Cell Culture

Many cell-culture types of human, monkey, rodent, swine, and avian tissue origins are useful for the replication and assay of flaviviruses (Table 3). Monkey kidney cells (Vero, LLC-MK2), hamster kidney (BHK-21), porcine kidney (PS), human adrenal carcinoma (SW-13), as well as primary chick or duck embryo cells, have been widely used. Virus

titers of  $10^6$  to  $10^8$  tissue-culture-infective doses (TCID<sub>50</sub>), or PFU per milliliter, are readily achievable for most viruses in the genus. Both cytopathic effects (CPE) and plaque/focus formation are observed in these cells, but these vary considerably with the specific virus and host cell (see below). Flavivirus replication in cultured cells may also be measured by detection of antigen or nucleic acid in the cytoplasm of cells by immunocytochemistry or in supernatant fluids by enzyme-linked immunosorbent assay (ELISA), complement fixation (CF), or reverse-transcriptase polymerase chain reaction (RT-PCR).

Mosquito cell cultures, including C6/36 *Ae. albopictus* cells, are widely used for virus isolation or assay. Cytopathic effects (CPE; syncytium formation) and plaque formation occur after infection with some viruses, but others are noncytopathic. Tick-borne flaviviruses replicate in tick cell cultures without causing CPE. The mosquito-borne group viruses replicate well in mosquito, but not tick cell, cultures; the converse is true for the tick-borne group viruses (16), whereas the no-vector group does not replicate in either. While most flaviviruses replicate in vertebrate cell cultures, some flaviviruses replicate in mosquito or tick cells only (2). Some viruses can replicate to some extent both in tick and mosquito cell cultures (e.g., WNV and St. Louis encephalitis [SLE] virus), which correlates with occasional field observations.

Multiplication in cell culture includes a rapid absorption phase, followed by an eclipse phase of approximately 10 to 12 hours, after which infectious virus first appears and enters a log phase of replication lasting 18 to 24 hours. Peak titers in fluid phase cultures may appear after 24 hours at high multiplicities of infection, but multiplication of some flaviviruses is considerably slower. Persistent infection without cytopathology has been demonstrated in a variety of arthropod and vertebrate cell lines. Progeny virus from such cultures may have altered antigenic properties, reduced virulence, or temperature sensitivity.

### Inactivation by Physical and Chemical Agents

Flaviviruses are rapidly inactivated by ionic and nonionic detergents, trypsin, ultraviolet light,  $\gamma$ -irradiation, formaldehyde,  $\beta$ -propiolactone, ethyleneimine, and most disinfectants, including chlorine, iodine, phenol, and alcohol. The viruses are optimally stable at temperatures below  $-70^\circ\text{C}$ , and they are rapidly inactivated in blood or other liquids within 30 min at  $56^\circ\text{C}$ . Flaviviruses are optimally stable at pH 8.4 to 8.8 and, with the exception of some tick-borne viruses, are rapidly degraded at low pH. Sensitivity to acid, bile, lipases, and proteases in the gastrointestinal tract generally precludes infection by the oral route, although tick-borne encephalitis may be acquired by ingestion of milk.

## BIOLOGY

### Host Range and Route of Infection

The host range of specific flaviviruses varies considerably by individual agent (reviewed by Weaver and Barrett) (17). In general, laboratory rodents (mice and hamsters) are susceptible to infection and develop lethal encephalitis after intracerebral inoculation (Table 3). Many hosts that get clinical disease are dead-end hosts due to low viremia such that biting mosquitoes/ticks cannot be infected during feeding (Table 3). Flaviviruses all have transmission cycles involving wild vertebrate species and infect their natural vertebrate hosts via the bite of blood-feeding arthropods.

**TABLE 3** Host range and cell culture systems most useful for isolation and assay of flaviviruses, and vectors demonstrating infection and transmission in the laboratory

<sup>a</sup>Abbreviations: CEE, Central European encephalitis; DEN, dengue; JE, Japanese encephalitis; KFD, Kyasanur Forest disease; OHF, Omsk hemorrhagic fever; MVE, Murray Valley encephalitis; RSSE, Russian spring-summer encephalitis; SLE, St. Louis encephalitis; WN, West Nile; YF, Yellow fever; SM, suckling mouse; SH, suckling hamster; WM, weaned mouse; WH, weaned hamster; GP, guinea pig; i.c., intracerebral route; i.p., intraperitoneal route; i.n., intranasal route; s.c., subcutaneous route; DE, primary duck embryo; CE, primary chicken embryo; BHK, baby hamster kidney; SW13, human adrenal carcinoma; Vero, LLCMK2, MA-104, monkey kidney; PS, porcine kidney; C6/36, *A. albopictus*; AP61, *A. pseudoscutellaris*.

<sup>b</sup>Often requires adaptation by brain serial passage.

<sup>c</sup>Often requires adaptation by liver serial passage.

<sup>d</sup>AG129 and nude mice.

<sup>e</sup>Humans are dead-end hosts due to insufficient viremia for a mosquito/tick to pick up the virus during feeding.

<sup>f</sup>All economically important animals are dead-end hosts.

Several mosquito-borne zoonotic viruses in the JE complex cause central nervous system (CNS) disease in both humans and domesticated livestock, particularly horses. Viruses in this group also infect wild birds, which serve as intermediary hosts in transmission cycles. In a balanced virus ecosystem, wild birds infected with flaviviruses typically do not suffer overt clinical signs of disease (e.g., Japanese encephalitis virus) but sometimes this is not the case (e.g., West Nile virus in American crows). Rodents, insectivores, and birds are involved in transmission of TBE complex viruses, typically without causing disease in these hosts. Tick-borne flaviviruses also cause zoonotic disease in humans and domestic livestock. Kyasanur Forest disease virus (a member of the TBE complex) causes fatal illness in nonhuman primates, and Omsk hemorrhagic fever causes illness and death in an exotic rodent species (muskrats) introduced from North America to Russia. Yellow fever and dengue viruses are principally human pathogens but also infect certain nonhuman primates and, in the case of yellow fever, produce a similar illness (hepatitis) in certain neotropical monkey species.

Arthropod-borne flaviviruses are infectious for mosquito and tick vectors by the oral route and replicate to high titers in arthropod tissues. Of the approximately 60 flaviviruses, 16 have no known arthropod vector and are presumably transmitted directly between specific vertebrate-reservoir host-species, including rodents and bats. Contact infection of these hosts may be transmitted by the respiratory or oral route or by bites. Only isolated cases of human illness caused by a rodent-borne (Modoc virus) or bat-borne virus (Dakar bat virus) have been reported, but this observation may reflect lack of exposure rather than host-range restriction.

### Arthropod Infection

Medically important flaviviruses are transmitted by the bite of infected mosquitoes or ticks, which are true biologic (as opposed to mechanical) vectors. After ingestion of a blood meal containing virus, replication occurs in midgut epithelial cells, and virus is released into the hemolymph, whence it invades the salivary gland. Ultimately virus is secreted in saliva during refeeding on a susceptible vertebrate host. The interval between the ingestion of virus-containing blood and the salivary secretion of virus (extrinsic incubation period) is critical to transmission, because this interval must not exceed the lifespan of the arthropod. Increased temperature shortens the extrinsic incubation period and may thus increase the rate of virus transmission in nature. In general, flaviviruses do not induce pathologic changes in the arthropod vector.

Mosquito-borne flaviviruses are amplified in nature by sequential passage through vectors and vertebrate hosts. Because of the small volume of blood ingested by the vector, the threshold concentration of virus in vertebrate blood required to infect 1% of vectors is quite high ( $\sim 3$  to  $5 \log_{10}$  infectious units/mL). Hosts that do not circulate virus at high titer, the so-called “dead-end hosts,” are excluded from transmission cycles. This is true for human beings in the case of most flaviviruses, notable exceptions being dengue and yellow fever. Ticks imbibe much larger volumes of blood over a long period of time. This adaptation requires down-regulation of the host’s coagulation, inflammatory, and immunological responses by proteins contained in tick saliva (18). TBEVs are transmitted efficiently from infected to uninfected ticks via tick saliva shared during simultaneous feeding on a vertebrate host. WNV can be transmitted from infected to uninfected mosquitoes feeding on birds.

Vertical transmission in arthropods is an important mechanism for overwinter survival of some flaviviruses. Flaviviruses infect the genital tract of male and female mosquitoes, and virus enters the ovum at the time of fertilization. Venereal transmission of flaviviruses from male to female mosquitoes also occurs. The mechanism of trans-ovarial transmission of tick-borne flaviviruses remains to be elucidated.

## PATHOGENESIS

### Virus-Host Interactions

Human disease caused by flaviviruses may be classified syndromically as either (i) CNS infection; (ii) hemorrhagic fever; or (iii) fever-arthritis with or without rash. By contrast, mice develop encephalitis after infection with most flaviviruses, with the exception of mice deficient in both alpha/beta and gamma interferon receptors where some strains of yellow fever and dengue viruses induce viscerotropic disease in this model (19–22), and have been widely used as a model for study of pathogenesis. After the bite of a mosquito or tick, flaviviruses replicate in dendritic cells with subsequent spread to regional lymph nodes, whence they are transported via lymphatics to the thoracic duct and then to the bloodstream. Langerhans’ dendritic cells are important for transport of virus to lymphoid tissues (23, 24). After inoculation of virus in mosquito saliva, replication in local tissues may occur for several hours before vascular dissemination. Components of mosquito or tick saliva appear to facilitate flavivirus transmission by interfering with aspects of both innate and adaptive immunity (25, 26). After dissemination to, and replication in, extraneural tissues, large amounts of virus are shed directly into the blood. Viremia is terminated around 1 week after infection by both innate and adaptive immune responses (27). Depending on the specific agent, extraneural cells and tissues involved in flavivirus replication include macrophages and other lymphoid cells, skeletal muscle and myocardium, smooth muscle, and endocrine and exocrine glands. Major differences have been noted between specific cell types in their ability to sustain infections. Although no comprehensive analysis of flavivirus-cell interactions *in vivo* is possible, the special interaction of dengue viruses with dendritic cells and monocytes/macrophages, of dengue and yellow fever viruses with hepatocytes, and of the encephalitis viruses with neural cells underlie pathogenesis.

Invasion of the CNS appears to be closely linked to virus replication in extraneural sites and to the level of viremia. Factors that impair the blood-brain barrier, including immaturity, traumatic disruption of the barrier, or concurrent infection of the brain with unrelated agents, potentiate neuroinvasion, and encephalitis (28). The mechanism by which flavivirus particles enter the central nervous system during natural infection remains uncertain. Postulated mechanisms include entry via leukocytes, direct entry across the blood-brain barrier, and entry by retrograde axonal transport via the peripheral nervous system (27). In addition, there is evidence that the innate immune response can either contribute to inhibition or promotion of neuroinvasion (29–31). In the mouse, WNV RNA can be detected in the brainstem and spinal cord within the first 2 days of infection, and viral antigen was observed in the cortex, hippocampus, and choroid plexus by the third day, suggesting multiple routes of CNS invasion (32). Although neuroinvasive flaviviruses can be identified from most regions of the central nervous system, a predilection for involvement of the

anterior horn cells of the spinal cord, as well as the thalamus, substantia nigra, pons, and cerebellum, accounts for the acute flaccid paralysis and movement disorders clinically observed following infection in monkeys and humans.

Persistence of immunoglobulin M antibody following acute infection has been noted for some flaviviruses, raising the question of persistent infection (33). Several animal models have demonstrated viral persistence, and chronic infections sometimes associated with progressive neuropathology have been observed (33). In humans, persistent infection with recurrent neurologic disease has been reported in patients following JE and TBE.

Age-related resistance in mice is manifested around 1 to 2 weeks of age with maturity of the blood-brain barrier, at which time parenteral injection of virus elicits inapparent infection, whereas intracerebral inoculation still causes lethal encephalitis. In humans, some flaviviruses (e.g., SLE virus, WNV) cause severe disease principally in the elderly, whereas others have a bimodal distribution with an excess of cases at both age extremes (e.g., JE and Murray Valley encephalitis [MVE]).

The genetic background of the host plays an important role in susceptibility to infection (34). In the mouse, presence of a truncated form of the 2'-5'-oligoadenylate synthetase (OAS) gene located on chromosome 5 increases susceptibility to flavivirus encephalitis (35). Although a similar mutation has not been observed in humans, an increased frequency of an OAS-like allele that contained a splice-enhancer site was observed in patients hospitalized with WNV infection (36). Humans with a deletion in the CCR5 gene may be at higher risk for a poor outcome following WNV infection (37, 38).

### Immune Responses

Innate immune responses, including natural killer (NK) cells, alpha/beta interferon (IFN- $\alpha/\beta$ ), and other cytokines, and nitric oxide production by macrophages, are the first line of defense and also modulate the acquired, virus-specific immune responses that rapidly follow infection (39). In recent years a considerable body of information is being obtained about the innate immune response, particularly to WNV and dengue (40, 41), as a paradigm for the flavivirus genus as a whole. These studies show that once a flavivirus has infected a cell, there is a cascade of intracellular signaling that results in production of IFN- $\alpha/\beta$ . This, in turn, induces intracellular antiviral responses that subsequently initiate the adaptive immune response. Specifically, once the virus uncoats inside the cell, pattern-recognition receptors, such as toll-like receptors (TLRs), recognize double-stranded and single-stranded RNA (e.g., TLR-3, TLR-7, and TLR-8) and result in induction of IFN- $\alpha/\beta$ . Similarly, retinoic-acid-inducible gene I (RIG-I) and melanoma differentiation-associated gene 5 (MDA5) recognize viral dsRNA and lead to induction of IFN- $\beta$ . IFN- $\alpha/\beta$  is secreted by virus-infected cells and triggers an "antiviral state" in surrounding cells via signaling pathways involving Janus Kinase and signal transducer and activation of transcription (JAK/STAT) molecules that lead to expression of a variety of IFN-stimulating genes that have antiviral activity. The situation is complicated because it has been found that various cell types in the body vary in their ability to mount an antiviral response. Not surprisingly, flaviviruses have developed multiple approaches to overcome the intracellular antiviral responses and signaling cascades by utilizing nonstructural proteins in various roles (Table 2), and this "war" between the host's innate immune response and the functions of viral proteins will

ultimately determine whether or not a virus infection results in clinical disease. Abortive (subclinical) infections, which are the norm, are the presumed result of robust innate- and acquired-immune responses that out-pace virus-mediated cell damage, as well as virus-induced apoptotic cell death that limits the progression of infection in the host.

Antibodies appear to play the primary role in protection against reinfection, while both antibodies and cellular immune responses are responsible for clearance of virus-infected cells and recovery from active infection. Neutralizing antibodies directed against determinants on the E glycoprotein provide long-lived, virus-specific protection against reinfection. Thus, infection by one virus gives life-long immunity to that particular virus but not to other flaviviruses. Infection also elicits antibody responses against the NS1 nonstructural protein that decorates the surface of infected cells, and anti-NS1 antibodies may protect against reinfection and play a role in recovery from infection.

Pathologic events *in vivo* are principally the result of direct virus injury, although immunopathologic mechanisms are implicated in some preclinical models. The extent to which the host's immunologic response to infection plays a role in pathogenesis in human infection is uncertain, except in the case of DHF (see below). In flavivirus encephalitis, neuroinvasion and rapid accumulation of viral antigen in the critical target tissues occur late in the course of infection and may potentially elicit inflammatory responses that enhance lesions and accelerate death of infected cells. NK cells and CTLs lyse infected neurons, and CTLs interact with infected astrocytes (42). Infection of these cells in the brain appears to result in an enhanced expression of MHC-I, with increased CTL recognition of infected cells. The increase in MHC-I molecules on the infected cell surface may be induced by interferon or may be a result of flavivirus peptide transport to the ER. In addition to cell-mediated clearance, antibodies can be shown to cause early death in mice infected with yellow fever and MVE viruses (43, 44). This effect is attributed to complement-mediated cytolysis of infected cells. Infiltration of neutrophils into perivascular areas of the infected brain, in response to tumor necrosis factor alpha (TNF- $\alpha$ ) and neutrophil chemotactic factor, results in the expression of inducible nitric oxide synthase activity, which appears to increase pathogenesis (45), possibly by inducing apoptosis. An additional possible immunopathological mechanism is antibody binding to glucosylphosphatidylinositol-anchored NS1, followed by signal transduction, activation of superoxide anions, and apoptosis (12). The relevance of such experimental observations to human disease is an area of active research, including the effects of active and passive immunization against heterologous flaviviruses on the course and outcome of neurologic infection. There is evidence for cross-protection between flaviviruses in humans, whereas cross-reactive immunopathological responses have not been clearly defined except in the case of dengue disease.

The most important example of immunopathologic response in humans is antibody-dependent enhancement (ADE) of flavivirus replication in Fc $\gamma$ -receptor-bearing peripheral blood monocytes (7). This phenomenon is thought to determine the severity of dengue (see section on DHF below), although excessive pro-inflammatory innate immune responses may also contribute to severe dengue disease (46). Antibody attack against molecular mimics has also been postulated to play a role in dengue pathogenesis. The dengue E protein contains a 20-amino-acid region of homology with plasminogen, the mediator of fibrinolysis, and

anti-E antibodies might interfere with fibrinolysis and contribute to disseminated intravascular coagulopathy (47).

Flavivirus NS proteins are processed in a major histocompatibility class I (MHC-I)-dependent fashion resulting in serotype-specific and cross-reactive T-cell clones. Cytotoxic T cells, recognizing NS proteins in infected cells, are involved in postinfection virus clearance. The structural proteins, particularly E and prM, as well as NS1, stimulate MHC-II-restricted responses and generate antibodies protective against subsequent infection. However, the E and NS1 proteins also play a role in the generation of cytotoxic T lymphocytes (CTLs).

### Virus-Specific Factors in Virulence

Differences have often been noted in the expression of disease caused by the same flavivirus among individual patients, among geographic regions, or between the early and late phases of an epidemic. These variations may be due in part to strain-specific differences in virulence genes. Virulence is multigenic, including mutations in the E gene affecting attachment and uncoating, and/or in nonstructural genes and 3'NCR affecting replication rate. Neurovirulence determinants in the E protein genes of yellow fever virus, JE virus, and tick-borne encephalitis virus (TBEV) have been partially mapped by comparing virulent strains and attenuated vaccines derived from wild type virus, or by attenuated neutralization escape mutants and mutants unable to bind brain-membrane receptors (48, 49). E-gene virulence determinants include (i) amino acid residues at the interface of domains I and II involved in reconfiguration of the E protein and trimer formation under acidic conditions in the endosome; (ii) residues (E98 to E120) in the fusion domain at the end of domain II; (iii) residues (E305 to E315) in the upper lateral surface of domain III involved in virus-cell attachment (49); and (iv) residues in the C-terminal stem-anchor region involved in E-protein conformational changes during fusion. Other studies have identified mutations in nonstructural genes, NS1, NS2A, NS3, NS4A, NS4B, and NS5 and in the 5' and 3'UTR that result in a decrease in virulence by downregulating the rate of virus replication.

## FEATURES OF SPECIFIC FLAVIVIRUSES

### Viruses Causing Central Nervous System Infection

#### Japanese Encephalitis Virus

##### Biology

JE virus is the prototype of an antigenic complex that includes SLE and MVE viruses, WNV, and several other flaviviruses of lesser medical importance (Table 1). Although JE virus represents a single antigenic serotype (50), fine distinctions of no recognized clinical importance exist between JE virus strains serologically, genetically, and by biological assays, such as cross-protection in mice and neurovirulence. Five distinct genotypes (genetic clusters) of JE virus exist: genotype I includes isolates from Cambodia and northern Thailand; genotype II includes isolates from Indonesia, southern Thailand, and Malaysia; genotype III includes isolates from temperate regions of Asia: Japan, China, Taiwan, India, Nepal, Sri Lanka, and the Philippines.

Transmission of JEV is epidemic in temperate zones with the majority of cases occurring in summer months, whereas transmission is endemic in tropical zones and occurs year-round at lower rates. Genotypes III and GI-b are found in temperate areas, while GI-a and GII are found in tropical

areas (51). Genotype IV includes certain isolates from Indonesia only. Genotype V has been isolated only on rare occasions and has recently re-emerged after almost 60 years of undetected virus circulation in Korea, China, and Tibet (52, 53, 54). Phylogenetic studies suggest that JE virus originated in Indonesia/Malaysia and spread from there into different parts of Asia with genotype IV being ancestral to the other genotypes. Genotype III was the dominant genotype in Asia until the mid-1990s and has been gradually replaced by genotype I over time, such that genotype I is now the dominant genotype. The mechanism of genotype replacement is not known at the present time.

### Epidemiology

**Distribution and Geography.** JE is transmitted in nearly every country of Asia from the far eastern end of Russia to areas of Pakistan in west Asia (Fig. 1). Approximately 68,000 cases are reported annually from the region, including 13,600 to 20,400 deaths (55) principally from China, Southeast Asia, and India. In most areas, transmission is endemic with annual fluctuations in the number of cases, depending on environmental factors. Within a single country, transmission may be localized to certain regions where appropriate ecologic conditions prevail (in general, in rural areas where rice is grown). In developed countries such as Japan, South Korea, and Taiwan, the low incidence reflects high immunization rates despite the persistence of enzootic virus transmission.

**Incidence and Prevalence.** Estimates of the subclinical/clinical infection ratio usually center around 250:1, although values range from 25:1 to 1,000:1 (56). Exposure to JE virus occurs in childhood, and antibody prevalence approaches 80% by early adulthood. Annual incidence rates in locations of endemicity typically range from 1 to 10 overt cases/100,000, and epidemic attack rates may exceed 100/100,000. Case fatality rates of up to 30% have been reported, with neurologic or psychiatric sequelae in 20 to 30% of survivors. The estimated annual incidence is 5.4 per 100,000 and 0.6 per 100,000 in the 0 to 14- and  $\geq 15$ -year-old age groups, respectively (55). Vaccination has reduced JE incidence in many countries. In Japan and other developed Asian countries, JE risk is highest in the elderly, reflecting high vaccine coverage of children and undefined biological risk factors associated with aging. In areas with overlapping religious and cultural affiliations (e.g., Malaysia and Indonesia), Muslims who eschew pork and do not keep pigs are at lower risk; conversely, Hindu Bali and principally Buddhist Chinese Sarawak have the highest reported JE activity in their respective countries. Household crowding, low socioeconomic status, and lack of air conditioning appear to be risk factors for acquiring JE.

In countries where JE is endemic, JE is mostly a disease of children and young adults due to the fact that most adults are already immune. Increased incidence in the elderly has been reported in several countries, presumably due to waning of seroprotective immunity. Prior anti-flavivirus antibodies do not appear to protect against infection with JE virus but may decrease morbidity (57). Repeated clinical infections have not been reported, but subclinical reinfections are common in areas of endemicity and probably provide natural immunity and boosters to immunization.

**Transmission.** With the rare exception of laboratory-acquired cases, infection is transmitted only by bites of infected mosquitoes. In temperate regions, JE virus is

FIGURE 1 Geographical distribution of JE.

transmitted in the late summer and early fall after the virus has been amplified by vector mosquitoes and pigs, and, in some areas, by a preceding phase of amplification in birds (Fig. 2). Pigs play a central role in virus amplification because they develop high and sustained levels of viremia and because their high body temperature and large hairless body surface area attract thousands of mosquitoes nightly. The ubiquitous place of pigs as backyard or even cohabiting livestock animals in rural Asia has led to high levels of human exposure in rural villages and often in household premises. In developed countries (like Japan), the centralization of pig

rearing and modernized agricultural methods have served to reduce JE virus transmission. On the other hand, deforestation and agricultural development, especially the creation of irrigation schemes, have contributed to an increase in JE and other mosquito-borne diseases in other areas (e.g., central Sri Lanka and the Terai of Nepal).

The principal JE vectors are *Culex* mosquitoes that use ground pools and especially rice paddies for their larval stages. *Culex tritaeniorhynchus* is the principal vector in most areas of Asia; other important vectors include *Culex annulus* in Taiwan and Hong Kong; *Culex vishnui*, *Culex gelidus*,

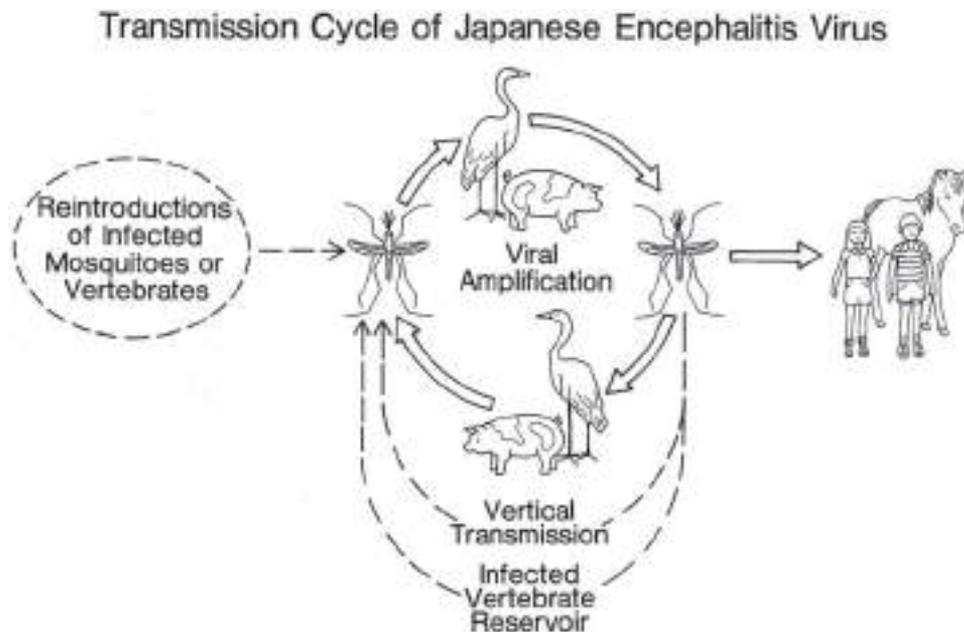

FIGURE 2 Transmission cycle of JE virus. Broken lines indicate speculative portions of the transmission cycle.

*Culex pseudovishnui*, *Culex fuscocephala*, *Culex bitaeniorhynchus*, and *Anopheles hyrcanus* in India and Nepal; *C. gelidus* in Indonesia; *Culex annulirostris* in the Pacific and Australia; and *Aedes togoi* in Russia. Most JE vectors are zoophilic, preferring animals to humans; exophilic, biting outdoors; and crepuscular, most active in the evening and night.

The transmission season is well defined in temperate areas (e.g., northern China), with onset of cases in June, a September peak, and disappearance by October. Farther south, the transmission season begins earlier and ends later. More complex seasonal patterns are observed in tropical areas where mosquito densities are correlated with monsoons. Vector density and infection rates typically increase following the initiation of rice cultivation midyear. Mosquito infection rates are modulated by rising herd immunity in pigs, but high vector abundance in the wet-cool season (October–December) ensures a continued risk of human infection.

### Pathogenesis

The vast majority of infections are cleared before neuroinvasion occurs and are subclinical or lead to mild illnesses without CNS signs. Circulating antibody plays a critical part, and heterologous flavivirus immunity (e.g., from prior dengue virus infection) may limit peripheral virus replication and neuroinvasion. Disruption of the blood-brain barrier may be a risk factor for neuroinvasion, because persons with fatal JE are more likely to have had concurrent neurocysticercosis than persons dying of other causes; dual infections with herpes simplex virus or mumps virus also have been reported. Functional and structural changes due to hypertension, cerebrovascular disease, and head trauma have also been suggested as factors contributing to neuroinvasion.

At autopsy, inflammatory reactions are found in the myocardium, lungs, liver, spleen, lymph nodes, and kidneys. The brain appears swollen, and the ventricles may be narrowed by edema. Herniation of the cerebellar tonsils and hippocampal uncus may occur. The meninges are congested, and inflammatory changes are present. Pathological changes are distributed principally in the thalamus, substantia nigra, brain stem, hippocampus and temporal cortex, cerebellum, and spinal cord. Histopathology shows focal neuronal degeneration, diffuse and focal microglial proliferation, and perivascular cuffing (78). Infected neurons contain antigen in their cell bodies, axons, and dendrites, suggesting that virus spreads from cell to cell within the brain. Antigen-containing neurons may have no associated microglial reaction until cell death has occurred. Small amounts of virus antigen may be present in vascular endothelia.

Infection elicits a broad inflammatory response of macrophages, T and B cells in perivascular cuffs, and predominantly T cells in the brain parenchyma. A greater proportion of CD4<sup>+</sup> T cells are seen in the CNS than in the blood. Degeneration of infected neurons, microglial proliferation, and neuronophagia lead to the formation of gliomesenchymal nodules. Intrathecal antibodies have been associated with a favorable outcome in some series, suggesting an important role for antibody-mediated virus neutralization in the brain. However, others suggest that specific antibodies cannot reach virus spreading directly from cell to cell and that neuronal damage occurs by an immunopathological mechanism. This view is supported by observations of intrathecal neurofilament protein antibodies and myelin basic protein antibodies in 49% of cases and their association with fatal outcome (58). Immune complexes, found in the cere-

brospinal fluid (CSF) of 17% of patients, are associated with death (35). Immune CD4<sup>+</sup> and CD8<sup>+</sup> T cells proliferate in response to JE virus or infected cell lysates, but cellular proliferative and humoral responses are not correlated, and no association between cellular proliferative response and outcome has been found (58). *In vivo* models indicate that activation of microglial cells may produce pro-inflammatory mediators instrumental in inducing neuronal cell death (59).

### Clinical Manifestations

After a mosquito bite, 4 to 14 days elapse before the onset of symptoms. A prodromal illness of fever, headache, lethargy, nausea, and vomiting lasting several days precedes the onset of CNS signs. Neurologic signs reflect damage to the brain stem, thalamus, cerebral cortex, and spinal cord. The central feature is an altered state of consciousness, ranging from mild mental clouding to drowsiness and stupor, or agitation and delirium (60). Some children exhibit personality changes, slurred speech, and mutism. Early-onset seizures occur in at least half of hospitalized children and a quarter of adults. Seizures are usually generalized tonic-clonic but may also be partial motor or with more subtle clinical manifestations, such as twitching of a digit or eyebrow or nystagmus. Patients with subtle seizures are usually in status epilepticus. Extrapyramidal features include dull, expressionless faces, generalized hypertonia, and cogwheel rigidity.

Significant stupor or coma is usual, tremor and involuntary movements are common, and signs of meningeal irritation may be present. Disconjugate gaze and facial and other cranial nerve palsies are found in one-third of cases. Papilledema is seen in fewer than 10% of cases. The muscular tone is usually increased, and hyperreflexia and pathological reflexes may be elicited. Weakness or paralysis may be generalized or asymmetric in distribution and spastic or flaccid in character. Autonomic disturbances, especially hyperpnea, may occur.

A modest peripheral leukocytosis may be present in the first week of illness. The serum sodium often is depressed due to inappropriate ADH secretion. The CSF typically is clear and under normal pressure, with normal or mildly elevated protein and normal glucose concentrations. A pleocytosis of 10 to several hundred white cells is typical in the first week of illness, and the cell count may remain elevated until the third week. EEG tracings show generalized delta-wave slowing, consistent with a thalamic involvement. Computed tomography (CT) scans show diffuse white matter edema and nonenhancing low-density lesions mainly in the thalamus, basal ganglia, and pons. Unilateral or bilateral thalamic hemorrhages are common. Magnetic resonance imaging (MRI) discloses a similar pattern of high-signal-intensity lesions in the thalamus, basal ganglia, cerebellum, pons, midbrain, and spinal cord.

Defervescence occurs during the second week of illness; choreoathetosis and extrapyramidal signs may appear as other neurologic manifestations improve. The substantia nigra is a site of predominant injury in some patients, as detected by MRI (61, 62) and clinical presentation, with cogwheel rigidity and opsoclonus during the acute phase and emergence of typical Parkinsonism during convalescence, from which patients generally recover (63). The illness is fatal in 10 to 35% of cases, most often within the first week, and fatality rates have been decreasing with improved clinical management. Children younger than 10 years are more likely to die and to have serious neurologic sequelae, such as motor weakness and paralysis, abnormal muscular

tone, seizures, blindness, ataxia, and extrapyramidal movement disorders (64). Convalescence is slow; consciousness and motor functions are gradually regained. One-third to one-half of patients surviving the acute illness have such major neurologic sequelae 1 year later, and EEG abnormalities may be present in 50% of recovered children. At 5 years after recovery, 75% have behavioral disorders and subnormal performance on age-standardized psychological tests.

JE acquired during the first and second trimesters of pregnancy has led to fetal death and abortion, with recovery of virus isolates from products of conception (65). It is unknown whether congenital infection causes fetal malformations, as occurs in pigs. The few reported cases of JE in the third trimester have been associated with a normal fetal outcome.

The most common complications are bacterial infections, especially pneumonia, and stasis ulcers. In a few cases, clinical relapse occurred several months after recovery from the acute illness. JE virus–infected peripheral-blood mononuclear cells were demonstrated in these and other asymptomatic recovered patients, implying the persistence of infection. Evidence of subacute JE virus CNS infection has been demonstrated in 5% of cases by detecting JE virus or antigen in CSF 3 weeks after recovery or intrathecal IgM at 50 to 180 days. The clinical significance of these findings is unclear.

### Diagnosis

In Asia, the most important diagnostic considerations in children with signs of acute CNS infection are bacterial meningitis, tuberculosis, malaria, typhoid fever with associated tremors and ataxia, dengue disease with encephalopathy or encephalitis, WNV encephalitis, MVE (in Australia and Papua New Guinea), Nipah virus encephalitis, and enterovirus (particularly enterovirus 71) infection. Other disorders that overlap the clinical presentation of JE are hyperthermia and scrub typhus. JE occasionally may present as Guillain-Barré syndrome (GBS) or acute psychosis. In Asia, the percentage of children presenting with acute encephalitic illness, who had JE, ranged from 23 to 67%. Central hyperpnea and extrapyramidal signs were the best clinical predictors (sensitivity of 41% and specificity of 81%) that the illness was JE (66).

JE virus rarely can be isolated from blood early in the illness, usually no later than 6 to 7 days after infection. Virus is seldom recovered from the CSF except in cases with a poor outcome. RT-PCR of CSF specimens is not a more sensitive technique. Immunofluorescence (IF) staining of CSF mononuclear cells provides laboratory confirmation most rapidly but has a reported sensitivity of only 60% (67).

The standard laboratory diagnostic method is serology by IgM capture ELISA, which has a sensitivity approaching 100% when both CSF and serum samples are tested and samples from 1 to 2 weeks after onset are used. An evaluation of three commercially available IgM capture ELISA kits demonstrated sensitivities of at least 89%; however, specificities ranged from 56 to 99% (68). Specificities were at least 96% when dengue virus IgM-positive samples were excluded. Subsequently, two IgM capture ELISAs were field tested with reasonable sensitivities and excellent specificities and little cross-reaction with dengue (69, 70). Samples taken too early in the illness may be negative. Anti-JE virus IgM was detected in nearly all serum samples collected at least 9 days after symptom onset and in all CSF samples collected at least 7 days after symptom onset (26). This and all serologic tests are limited by the potential for cross-reactions with cocirculating flaviviruses, principally dengue

virus and WNV. Representative flavivirus antigens relevant to the patient's site of exposure should be included in serologic tests. Some laboratories have established diagnostic IgM ELISA absorbance ratios based on comparative reactivities to the respective antigens. Fourfold changes in IF, hemagglutination-inhibiting (HI), CF, and neutralizing antibodies (in order of increasing specificity) may provide a clear diagnosis in patients with their first flavivirus infection, but cross-reactions may be uninterpretable for patients with multiple previous flavivirus infections or immunization with JE and yellow fever vaccines.

### Prevention

In areas of Asia where JE is endemic, childhood vaccination has led to significant declines in disease incidence, and in some countries the near disappearance of the disease. Approximately half of the countries where JE is endemic have routine immunization programs. Formalin-inactivated, mouse-brain-derived vaccine is still produced in a few countries, but manufacture is being phased out in place of Vero-cell-culture-derived inactivated vaccines. The Vero-cell-culture-derived vaccine (IXIARO) was introduced into the United States in 2009 and replaced the mouse-brain-derived vaccine manufactured by BIKEN (Osaka, Japan; licensed as JE-VAX) in 2012. The vaccine is licensed for use in those aged >2 months in the US (and >6 months of age in endemic countries). The vaccine is supplied as a two-dose primary immunization series, given on 0 and 28 days, with children aged 2 months to ≤3 years getting half of the dose used in those 3 years or older. Vaccinees are not to visit JE endemic areas until at least 7 days after receiving the second dose of vaccine. It is approved for HIV-infected and immunocompromised individuals, although the immune response induced may be less than that in healthy individuals. An accelerated 0- to 7-day immunization regimen is non-inferior to the standard 0-, 28-day regimen (71).

A live, attenuated vaccine (SA14-14-2) produced in primary hamster kidney cell culture was licensed in China in 1988, and more than 350 million doses have been administered as a single dose vaccine in those aged 8 months or older. The vaccine was shown to be 96% effective with no evidence of reactogenicity in Nepalese children 5 years after immunization (72). In addition, there is a live, attenuated recombinant-chimeric yellow fever/JE vaccine based on the yellow fever 17D vaccine virus backbone with the structural protein genes (premembrane and envelope protein genes) of SA14-14-2 virus (73). This vaccine has been licensed as a single-dose vaccine for those aged 9 months and older in Australia and some Asian countries.

Exposure to JE mosquito vectors can be reduced by avoiding rural areas and outdoor activity during the evening, staying in air-conditioned or well-screened quarters, using repellents, and wearing long-sleeved clothing and long pants. Specific public health interventions to control vector mosquitoes are implemented in a few locations. These include the addition of larvicides and predatory fish to irrigated fields and periodically changing their water level to interfere with the vectors' aquatic stages. In epidemic emergencies, adulticide applications provide short-term reductions of vector mosquito populations.

### Treatment

No specific antiviral therapy is currently available, and there is little published on candidate antivirals. In a double-blind, placebo-controlled trial, IFN- $\alpha$ 2a did not improve the outcome of patients with JE (74). The introduction of

intensive-care equipment and training has reduced the mortality rate from more than 30 to 5%. Acute coma, seizures, and respiratory failure necessitate rapid anticonvulsive therapy, ventilatory support, and intensive monitoring of fluid and electrolyte balance. Osmotic agents to reduce intracranial pressure may be needed in some cases; a controlled study of early dexamethasone therapy found no clinical benefit (or harm) with its routine use (75). Hyponatremia due to inappropriate ADH secretion is a frequent complication usually responsive to free water restriction alone.

### Murray Valley Encephalitis Virus

#### Biology

MVE virus is a member of the JE antigenic complex and has a close genetic relationship to JE virus. Australian MVE virus strains share a high degree of sequence homogeneity, whereas strains from Papua New Guinea differ, indicating that this area may represent a separate focus of virus activity. The host range of MVE virus and susceptibility of cell cultures are shown in Table 3. Alfuy virus, also found in Australia, is a distinct species from MVE virus (76).

#### Epidemiology

**Distribution and Incidence.** MVE virus occurs in Australia, Papua New Guinea, and probably islands in the eastern part of the Indonesian archipelago (77). Localized seasonal outbreaks or sporadic cases have been reported intermittently from southeastern Australia, the Kimberley region in Western Australia, and the Northern Territory. Although the disease is clinically severe, incidence has been low. The last major outbreak was in 1974 involving 58 cases over a wide geographic area, including Queensland, Northern Territory, South Australia, the Ord River Basin of Western Australia, and Papua New Guinea. In 2011, the largest outbreak since 1974 caused 17 cases (including 3 deaths). Significantly, half of the cases did not live in areas where they were infected (78).

MVE primarily strikes the young and the elderly, with approximately 50% of the cases in infants and children under 10 years old and 25% in persons over 50 years old. An excess of cases among males has been observed. The case fatality rate is 15 to 30% and long-term sequelae in 30 to 50%; only 40% have complete recovery. Subclinical infections are frequent, and it is thought that only one in 150 to 1,000 infections results in clinical illness. Serologic surveys conducted after epidemics have revealed evidence of recent infection in 4.5 to 36% of the residents. Attempts to associate MVE virus with mild febrile illnesses without neurologic signs have not been successful.

Virus circulation is seasonal, occurring during the summer months (January to May), and is associated with periods of abnormally high rainfall over two consecutive years. Ecological factors influencing vector density, such as the development of irrigation projects, have been linked to the emergence of MVE epidemics.

**Transmission.** The primary summertime transmission cycle involves wild avian hosts and *Culex annulirostris* mosquitoes, a species that breeds in temporary pools. Aquatic birds, such as herons, egrets, and pelicans, serve as the major viremic hosts, but mammals (especially rabbits and possibly kangaroos) may also play a role in transmission. *Culex annulirostris* has been implicated in tangential transmission of MVE virus to humans, which are dead-end

hosts. No human-to-human spread is recognized. The overwintering mechanism and the factors responsible for emergence of intermittent epidemics are unknown.

#### Pathogenesis

Like other members of the JE virus complex, MVE virus is highly neurotropic. The virus has been recovered from human brain tissue obtained postmortem. Pathological findings are similar to those in JE (79) and are limited to the CNS.

HI and neutralizing antibodies appear during the first week after onset. IgM antibodies appear early and may persist for weeks. Immunity to reinfection is believed to be lifelong. The presence of closely related flaviviruses in Australia, including Kunjin virus (WNV) and JE, dengue, and Kokobera viruses, complicates serodiagnosis.

#### Clinical Manifestations

The incubation period is 1 to 4 weeks. The clinical features of MVE (80) include a 2- to 5-day nonspecific illness, which precedes CNS involvement, with sudden onset of fever, headache, myalgia, generalized malaise, anorexia, and nausea. This is followed by the onset of nuchal rigidity and neurologic signs. In infants the disease progresses rapidly, and coma and death may occur within 24 hours of onset of neurologic signs, often with clinical signs of involvement of the brain stem and spinal cord. The clinical features are classified by illness severity (81): (i) mild cases with altered levels of consciousness and variable neurologic abnormalities, but without coma or respiratory depression, and stabilization of neurologic signs within 5 to 10 days; (ii) severe cases with seizures, coma, and paralysis, often requiring respiratory assistance; and (iii) fatal cases with spastic quadriplegia and progressive CNS damage or severe disease with superimposed bacterial infection. Seizures and flaccid paralysis are rare in adult patients. The CSF shows pleocytosis, which shifts from polymorphonuclear to mononuclear predominance after a few days of onset; normal or mildly elevated protein; and normal glucose concentration. Neurologic sequelae occur in up to 40% of the mild cases and in all of the severe cases from which patients recover. Abnormalities include cerebral atrophy, paraplegia, impaired gait and motor coordination, and intellectual deterioration. Recovery or death generally occurs within 2 weeks of onset. Respiratory failure, intercurrent bacterial infections, and the residual neuropsychiatric deficits represent the most important complications of MVE.

#### Diagnosis

Viremia is present early in infection, but virus isolation or viral nucleic acid detection from blood (or CSF) has not generally been successful. Serologic diagnosis is based on ELISA or HI, CF, or neutralization tests. IgM antibodies appear to be quite specific and useful for early diagnosis, the test becoming positive around 4 to 9 days after onset and can persist for months. Cross-reactions with Kunjin virus and other flaviviruses may confuse interpretation. An epitope-blocking ELISA with MVE virus monoclonal antibodies distinguished MVE virus infections from those with other flaviviruses. Postmortem diagnosis is possible by examination of brain tissue by virus culture, direct detection of the virus genome by RT-PCR, or detection of virus antigen by immunohistochemistry.

#### Prevention

No vaccine is available. It is unknown whether active immunization with JE vaccine would provide a degree of

cross-protection against MVE. However, mice immunized with inactivated mouse-brain-derived JE vaccine and challenged with MVE were not protected, and, in fact, had accelerated deaths, consistent with an immunopathological process. In contrast, the live chimeric JE vaccines, ChimeriVax-JE [yellow fever 17D vaccine virus backbone with JE premembrane and envelope protein genes], gave complete and durable (>5 months) protective immunity against MVE virus challenge (82). In areas prone to recurrent epidemics (e.g., the Murray-Darling River basin), reduction of *Culex annulirostris* breeding by use of larvicides is practiced. Treatment of MVE is symptomatic.

### Treatment

Treatment of MVE is symptomatic and consists of good general management and nursing care, especially in the semicomatose and comatose patient, and respiratory support as required. No effective antiviral chemotherapeutic agent is available (80). Neither IFN nor ribavirin has been studied.

### Powassan Virus

Powassan virus is related to the eastern hemisphere's TBE viruses and is maintained in a cycle between ticks and rodents (83). Two lineages of Powassan virus exist in North America. Lineage 1 Powassan virus is associated with *Ixodes cookei* ticks and woodchucks and *Ixodes marxi*, ticks and squirrels. These ticks rarely bite humans. Lineage 2 Powassan virus, sometimes called deer tick virus, is associated with *Ixodes scapularis* ticks, the same tick that transmits Lyme disease, babesiosis, and anaplasmosis.

Since its discovery in 1958, Powassan virus has become recognized as an uncommon cause of encephalitis in Russia, eastern Canada, and the north central, northeastern, and upper Midwestern United States. The incidence of Powassan virus infection appears to be increasing from 2004 through 2013, during which 57 cases were reported to the United States Centers for Disease Control and Prevention. Infection mostly occurs from June to September.

The reported incubation periods range from 8 to 34 days (84, 85). However, patients infrequently recall a tick bite, because ixodid ticks are small and can be easily overlooked. Symptomatic patients typically present with fever, weakness, paralysis, somnolence, gastrointestinal complaints, headache, and confusion; seizures can occur. The case-fatality rate is 5 to 10 percent, with a high incidence of residual neurological dysfunction among survivors, including hemiplegia, headaches, minor memory impairment, and persistent ophthalmoplegia (84–86).

The diagnosis of Powassan virus infection can be made by demonstration of IgM antibody by capture immunoassay of CSF, a fourfold rise in serum antibody titers against the virus, or isolation of virus from or demonstration of viral antigen or nucleotide sequences in tissue, blood, or CSF. IgM antibodies alone should be confirmed by demonstration of IgG antibody by another serologic assay (e.g., neutralization).

No specific vaccine or antiviral treatment is available.

Flaviviruses associated with rare and sporadic cases of human disease are shown in Table 4.

### Saint Louis Encephalitis Virus

#### Biology

Saint Louis encephalitis (SLE) virus is a member of the JE antigenic complex. Antigenic cross reactivities between SLE and other members of the complex are demonstrable with polyclonal and monoclonal antibodies. All SLE strains be-

long to a single serotype defined by neutralization, but strain variation occurs at the molecular level. The nucleotide sequence of the SLE E gene shows <10% nucleotide difference among strains spanning a >60-year interval (87, 88). Genomic conservation suggests that the virus is adapted to a highly constrained system of virus maintenance in vectors and vertebrate hosts. SLE virus strains from North America and from Central and South America can be divided into seven lineages, which are predominantly, but not strictly, geographically distinct (88).

Among commonly used laboratory animals, hamsters are most susceptible to lethal infection, followed by mice (Table 3). Young animals are most susceptible to lethal encephalitis. Neurovirulence is greater with epidemic, than with endemic, strains. SLE virus is lethal for chick embryos or after intracerebral inoculation of young hatchling birds, but birds infected naturally develop asymptomatic viremic infections. Birds are the principal hosts, amplifying virus in the transmission cycle. The absence of overt disease associated with SLE infection of birds is due to a long co-evolution of virus strains with their hosts in the Americas. Although various wild and domestic mammals can be infected with SLE virus, these infections are also usually asymptomatic. Antibodies have been found in a wide array of wild mammals in North and South America. Additional information on host range and cell culture susceptibility is given in Table 3.

### Epidemiology

**Distribution and Geography.** SLE virus is widely distributed in the Americas. Although cases have been reported from nearly all US states, incidence is highest in states in the Ohio-Mississippi River basins and on the Gulf Coast (Fig. 3). The geography of SLE in the United States can best be understood in terms of its three enzootic transmission cycles sustained by *Culex pipiens* and *Cx. quinquefasciatus* in the Ohio and Mississippi river basin states and areas farther east; *Cx. nigripalpus* in Florida; and *Cx. tarsalis* in the central and western states, west of, and including, Minnesota, Iowa, Kansas, Oklahoma, and west Texas (Fig. 4). In the east, SLE is transmitted periodically in localized, and sometimes regional, outbreaks occurring at intervals of years and even decades apart but without significant enzootic or endemic transmission in intervening years.

**Incidence and Prevalence.** More than 10,000 SLE cases have been reported in the United States over the last five decades, although only 1 to 12 cases per year were reported from 2004 to 2013, most likely due to competition for the same mosquito vectors by West Nile virus (Fig. 5). However, a concurrent outbreak of SLE and West Nile virus occurred in Phoenix, Arizona, in 2015 (89). Most cases have occurred as sporadic outbreaks, with the largest resulting in 1,967 reported cases from 31 states in 1975. Population seroprevalence rates are generally low, with seroprevalence ranging from 3 to 15% following outbreaks. Only 1 of approximately 300 infections is clinically apparent. Although infections are uniform across the age spectrum, clinical attack rates rise steeply with age, resulting in inapparent/apparent infection ratios ranging from 800:1 in children younger than 10 years to 85:1 in adults.

SLE in eastern states follows an unpredictable pattern of localized outbreaks, usually in urban areas (90). The principal vectors, *Cx. pipiens* and *Cx. quinquefasciatus*, are typically found in peridomestic habitats. Adult mosquitoes

TABLE 4 Flaviviruses causing sporadic human disease<sup>a</sup>

Virus	Human disease			Veterinary disease species affected	Geographic distribution	Transmission cycle
	No. of cases	Clinical features	Severity			
Banzi virus	<10	Nonspecific febrile illness	Self-limited	None known	Southern and East Africa	Mosquitoes ( <i>Culex</i> )-rodents
Bussuquara virus	1	Fever, arthralgia	Self-limited	None known	Brazil, Colombia, Panama	Mosquitoes ( <i>Culex</i> )-rodents
Edge Hill virus	1	Fever, myalgia, arthralgia	Self-limited	None known	Australia	Mosquitoes ( <i>Aedes</i> )-wallabies
Ilheus virus	6	Fever, myalgia, encephalitis <sup>b</sup>	Potentially severe (no deaths)	None known	Brazil, Colombia, Panama, Trinidad	Mosquitoes ( <i>Psorophora</i> )-birds
Kokobera virus	3	Fever, rash, arthralgia	Self-limited	None known	Australia, Papua New Guinea	Mosquitoes ( <i>Culex</i> )-?
Koutango virus	1 <sup>c</sup>	Fever, rash, arthralgia	Self-limited	None known	West Central Africa	Ticks (several genera)-rodents
Kunjin virus	<20	Fever, rash, encephalitis	Potentially severe (no deaths)	Horses (rare) <sup>e</sup>	Australia, Sarawak, Thailand	Mosquitoes ( <i>Culex</i> )-birds
Langat virus	<10	Fever, encephalitis <sup>b</sup>	Potentially severe (no deaths)	None known	Malaysia, Thailand, Russia	Ticks ( <i>Ixodes</i> )-rodents
Louping ill virus	39 <sup>d</sup>	Similar to CEE <sup>f</sup>	Potentially severe (no deaths)	Sheep <sup>g</sup>	United Kingdom, Ireland	Ticks ( <i>Ixodes</i> )-sheep, grouse
Modoc virus	1	Aseptic meningitis	Self-limited	None known	Western United States, Canada	Rodent-rodent <sup>h</sup>
Negishi virus	3+ <sup>i</sup>	Encephalitis	Potentially fatal	None known	Japan, China	Ticks-?
Rio Bravo virus	6 (11)	Febrile illness, meningitis, orchitis	Self-limited	None known	Western United States, Mexico	Bat-bat
Sepik virus	1	Febrile illness (hospitalized)	Self-limited	None known	New Guinea	Mosquitoes ( <i>Mansonia</i> )-?
Spondweni virus	3	Fever, arthralgia, rash	Self-limited	None known	South and West Africa	Mosquitoes ( <i>Aedes</i> )
Usutu virus	1	Fever, rash	Self-limited	None known	South and Central Africa	Mosquitoes ( <i>Culex</i> )-birds
Wesselsbron virus	<20	Fever, arthralgia, rash, encephalitis	Potentially severe (no deaths)	Sheep <sup>h</sup>	Sub-Saharan Africa, Thailand	Mosquitoes ( <i>Aedes</i> )-?

<sup>a</sup>The recognition of these diseases has often occurred in the setting of general virus investigations and surveillance projects. Infection (disease) may be more common than indicated, and the clinical spectrum may differ from that delineated by the few recognized cases.

<sup>b</sup>Includes cancer patients intentionally infected who developed encephalitis.

<sup>c</sup>Laboratory infection.

<sup>d</sup>26 cases were laboratory infections.

<sup>e</sup>Encephalomyelitis.

<sup>f</sup>In one case a hemorrhagic diathesis was described.

<sup>g</sup>Encephalitis (cerebellar syndrome). Sporadic disease also described in dogs, horses, cows, goats, pigs, and deer.

<sup>h</sup>Virus without known intermediate arthropod vector; transmission by contact or aerosol.

<sup>i</sup>Includes a laboratory infection.

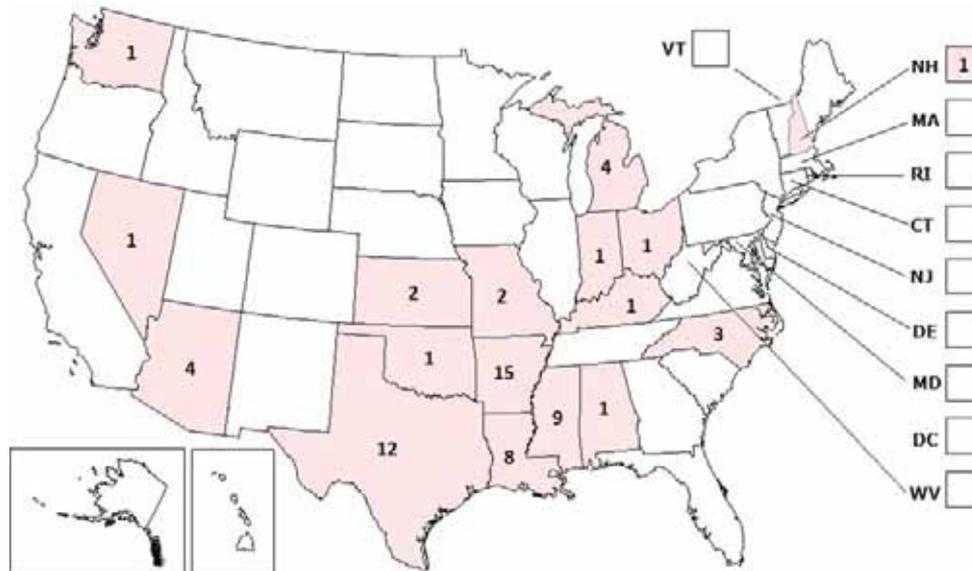

FIGURE 3 SLE neuroinvasive disease cases by state, 2004–2013.

use open house foundations and urban storm sewers as resting sites, and polluted ground water is available for their larval stages. Outbreaks often have occurred in small towns or in older lower socioeconomic sections of cities. Older construction, featuring open foundations, porches, lack of air conditioning, and poor screens, contributes to an increased risk of exposure. Local or regional outbreaks occur infrequently, sometimes separated by decades when, for unknown reasons, virus transmission in the enzootic cycle becomes sufficiently intense to create substantial human infection risk. The overwintering mechanism for SLE virus remains unclear.

SLE transmission in Florida has followed a pattern of periodic focal or widespread outbreaks, but the disease may be absent. Drought conditions might concentrate *Cx. nigripalpus* mosquitoes in relatively moist, densely vegetated “hammock” habitats at a time when nesting birds also make

use of the hammocks (91). This forcing of birds and mosquitoes together fosters epizootic SLE amplification. During subsequent wet periods, infected birds and mosquitoes disperse and carry the virus from the hammocks.

In the west, SLE is transmitted perennially and at a low level in the enzootic transmission cycle; this results in sporadic human infections, a higher level of naturally acquired immunity, and, occasionally, outbreaks that are usually smaller than those occurring in the east.

SLE cases are usually noted no earlier than June and peak in August and September. Transmission may continue as late as December/January in Florida and in parts of southern California. Elevated temperatures enhance multiplication of SLE virus in *Cx. tarsalis*. Rainfall patterns also markedly influence SLE virus transmission. Years of high spring and summer rainfall or excessive runoff from snowmelt favor vector density, and virus amplification in areas where *Cx. nigripalpus* and *Cx. tarsalis* are responsible for transmission. In contrast, mid-summer drought conditions appear to favor amplification in the *Cx. pipiens*-*Cx. quinquefasciatus* transmission cycle, because these vectors breed in stagnant water pools susceptible to being flushed and cleaned by rainfall.

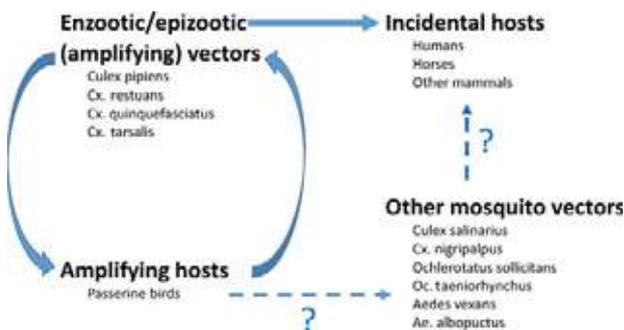

FIGURE 4 Transmission cycle of SLE virus and WNV. Both viruses are transmitted in a cycle between birds and *Culex* mosquitoes. *C. pipiens* is an important vector in the northern United States and Canada. *Culex quinquefasciatus* is important in the southern United States, whereas *C. tarsalis* is important in the western United States. In addition, *C. nigripalpus* is a vector in Florida. Other mosquito species may be “bridge” vectors to horses, humans, and other dead-end hosts, which typically do not develop high-level viremia and do not participate in the transmission cycle. However, bridge vectors likely have a minor role compared to enzootic vectors in viral transmission to dead-end hosts.

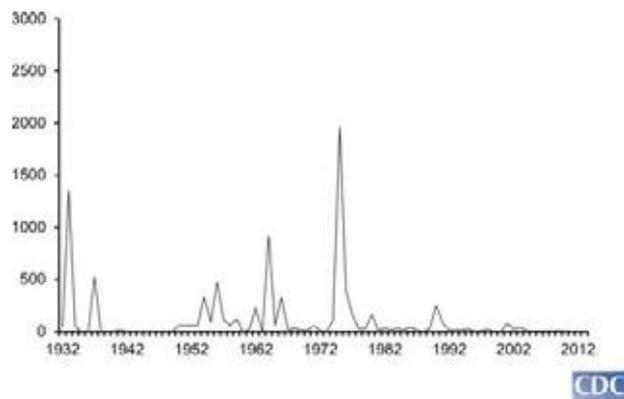

FIGURE 5 Number of reported cases of SLE, 1932–2012.

**Risk Factors Associated with Human Disease.** Risk of exposure and infection are independent of age, but clinical attack rates and severity of illness, as measured by case-fatality ratio, all rise sharply with age. Age-specific rates are approximately 10-fold higher in persons older than 70 years than in young adults and children. Hypertension, arteriosclerosis, and other chronic diseases have been noted in fatal cases. Although such associations with symptomatic illness have not been controlled for age, they suggest that virus neuroinvasion might be facilitated through compromised vascular endothelia.

The principal risk factor for *Cx. tarsalis*-borne SLE is residence in, or outdoor occupational or avocational exposure to, rural areas where the enzootic cycle is maintained. Risk is greatest in persons who are outdoors in the evening when *Cx. tarsalis* is most active. In Florida, a similar pattern holds because *Cx. nigripalpus* has analogous exophilic crepuscular biting habits. In some *Cx. tarsalis*-borne outbreaks, risk has been higher in males, possibly reflecting occupational or avocational exposures. The peridomestic habits of SLE vectors (*Cx. quinquefasciatus* and *Cx. pipiens*) elsewhere in the eastern states have been associated with higher incidence in females in some outbreaks, although this pattern is not consistent. Risk factors, such as lack of air conditioning, poor screens, and sitting on an unscreened porch, suggest that exposure occurs indoors or near residences. In some urban outbreaks, a large proportion of cases have occurred in homeless people.

**Transmission.** Natural infections are transmitted by mosquito bites. Laboratory infection occurred by mucous membrane or respiratory exposure in one reported case. SLE virus antigen has been recovered from nasal secretions of infected mice, and hamsters can be experimentally infected by intranasal inoculation, suggesting the potential for infection via the olfactory apparatus. No nosocomial cases or instances of congenital infection have been reported. One possible transmission via breast milk has been reported.

### Pathogenesis

Pathological changes in humans have been reported only for the CNS; however, SLE virus has been isolated from the vitreous humor, lungs, liver, spleen, kidneys, and blood. In fatal cases, the brain and meninges appear to be congested, but cerebral edema is unusual. Pathological changes are widely distributed in the brain and spinal cord but are most pronounced in the substantia nigra, thalamus, hypothalamus, cerebellar and cerebral cortices, basal ganglia, and the brain stem and cervical spinal cord. Changes are most prevalent in gray matter nuclei, but lesions also are found in the subcortical and deep cerebral white matter and long tracts of the brain stem and spinal cord. Microscopic changes consist of diffuse parenchymal inflammation and substantial perivascular infiltrates with destruction of vessels and extensive microgliosis. The inflammatory infiltrate is a mixture of small lymphocytes, histiocytes, plasma cells, and rare neutrophils. Degenerating neurons may be surrounded by microglial nodules. Axonal destruction and demyelination are not usually present. SLE virions have been identified by electron microscopy and SLE antigen by immunohistochemistry in postmortem brain samples.

### Clinical Manifestations

The incubation period has been estimated to be 4 to 21 days. Illness begins with nonspecific symptoms of malaise, fever, headache, and myalgias, sometimes accompanied by

cough, sore throat, abdominal pain, vomiting, or diarrhea. Dysuria, urgency, and incontinence are early symptoms in some patients. The illness may evolve quickly, with development of meningismus, increased headache, tremulousness, ataxia, and mental clouding. Other patients have a more insidious progression of nonspecific symptoms, especially myalgias, backache, headache, photophobia, and gastrointestinal complaints, followed days later by neurologic symptoms.

Neurologic involvement most frequently results in an altered state of consciousness, which may be clinically subtle, manifested by only mild confusion or decreased cognitive facility. Deep coma occurs in about 15% of cases. Most patients exhibit tremors involving the eyelids, tongue, lips, and extremities. Cranial nerve palsies are present in about 25% and are often asymmetrical or unilateral. Cerebellar signs are also common; ambulatory patients may exhibit an ataxic gait. Involuntary movements, such as myoclonic jerking, nystagmus, and, rarely, opsoclonus, may be present. Convulsions are unusual, occurring mainly in children and, in severe cases, in adults and signal a poor prognosis. Nuchal rigidity is variable and may be more common in children. Presentation with focal weakness or paralysis is unusual. Occasional cases have presented with Guillain-Barré syndrome.

The peripheral white cell count is usually normal or slightly elevated. Proteinuria, microscopic hematuria, and pyuria are found in some patients. More than one-third of cases have hyponatremia due to inappropriate antidiuretic hormone (ADH) secretion. Transaminases may be slightly elevated. Lumbar puncture discloses an elevated opening pressure in the range of 200 to 250 mmHg in about one-third of cases and CSF protein elevated above 45 mg/dL in more than two-thirds of cases. A moderate CSF pleocytosis of five to several hundred cells is typical, with the proportion of mononuclear cells increasing from 50 to 100% during the first week of illness. Electroencephalograms (EEGs) show diffuse generalized slowing and delta-wave activity. Focal discharges and spike activity have been observed occasionally. Neuroimaging may show hyperintensity of the substantia nigra on T2-weighted images.

Defervescence and neurologic improvement are seen over several days, with a rapid reversal of altered sensorium. Overall, 17% of cases are fatal; deaths generally occur within the first or second week of illness. A prolonged convalescence is typical, characterized principally by emotional lability but also by asthenia, forgetfulness, headache, tremor, dizziness, and unsteadiness; such manifestations may persist for months to years after initial recovery. Muscle tremors, asymmetric deep tendon reflexes, and visual disturbances are present in about one-third of patients several months after the acute illness. One patient had postinfectious encephalomyelitis; otherwise, chronic, persistent, or relapsing infections have not been reported.

### Diagnosis

SLE should be considered in patients with onset of acute encephalitis in summer or early fall and with exposure to an endemic or epidemic focus. Clinical features may overlap those of other virus infections, especially WNV, enteroviruses, western and eastern equine encephalitis, and herpesvirus. Mycoplasmal, bacterial, and fungal meningitis, especially partially treated bacterial meningitis, leptospirosis, cat scratch encephalopathy, and listeria encephalitis, may cause a CNS syndrome similar to SLE.

The limited viremia preceding onset of neurologic symptoms precludes virus isolation in most cases with

clinical encephalitis. Virus isolation from CSF is generally unsuccessful, but virus can be recovered from brain and other postmortem tissues. Viral antigen can be detected by IF or immunocytochemical staining in brain tissue, but the sensitivity of this technique is low because of the sparse distribution of infected cells. Antigen detection ELISAs and RT-PCR developed to identify infected mosquitoes have not been evaluated on clinical samples, but they are likely to be less sensitive than serology.

The principal serologic tests in use are IgM capture ELISA and IF. When both CSF and serum samples are examined, sensitivity of the former test approaches 100% by the 10th day after onset. The sensitivity of indirect IF is lower, especially when CSF is examined or if only acute-phase serum is examined. When both IgG and IgM are measured by indirect IF or ELISA in paired serum samples, sensitivity approaches 100%. Cross-reactive antibodies in patients who have had previous flavivirus infections, especially dengue virus and WNV, limit the specificity of serologic tests. More specific serologic tests (e.g., neutralization) are needed to sort out such reactions. Viral RNA detection is usually used for blood donations and transfusions.

### Prevention

Efforts to prevent SLE epidemics are based on mosquito- and bird- or sentinel-chicken surveillance that measures enzootic virus activity in the spring and summer. Early increased transmission in the enzootic cycle signals the possibility of spillover to humans and should trigger emergency mosquito control with insecticides and public health warnings to avoid mosquito exposure. Reduction of larval habitat by improving drainage is a long-term approach to reduce risk. Repairing screens, avoiding outdoor exposure in the evening, and applying mosquito repellents may reduce mosquito exposure. No vaccine is currently available.

### Treatment

No specific antiviral therapy is currently available. As with other flaviviruses, ribavirin is active *in vitro* at relatively high concentrations, but there is no evidence for its clinical efficacy. A nonrandomized, unblinded clinical trial suggested a possible benefit of IFN- $\alpha$ 2b treatment in patients with neuroinvasive disease (92).

### Tick-borne Encephalitis Virus (CEE and RSSE)

Russian spring-summer encephalitis (RSSE) virus was isolated from human brain tissue in the far east of the former Soviet Union in 1937. A similar disease was first described in Czechoslovakia in 1948, and the causative virus (Central European encephalitis [CEE] virus) was shown to be serologically related to RSSE virus. These agents, transmitted by the bite of small ixodid ticks, cause severe neurological infections and represent an important health threat over large areas of Europe and Asia.

### Biology

Originally the TBEV virus complex contained 14 antigenically-related agents, 8 of which were human pathogens (Table 1). Genetic studies have resulted in the TBEV complex being divided into two complexes: mammalian tick-borne virus group and seabird tick-borne virus group. Within the mammalian tick-borne virus group are nine distinct species: Gadgets Gully, Kadam, Kyasanur Forest disease, Langat, Louping ill, Omsk hemorrhagic fever, Powassan, Royal Farm, and TBEV (3). TBEV has three subtypes: central European encephalitis (CEE; also called

western subtype), Russian spring-summer encephalitis (RSSE; also called far eastern subtype), and Siberian (also called Vasilchenko virus) (93, 94). Louping ill has at least five subtypes (British, Greek, Irish, Spanish, and Turkish), and Kyasanur Forest disease virus has Alkhumra virus as a subtype. The close antigenic and genetic relationships of these viruses create difficulty in identifying individual virus species, and, hence, much debate. Indeed, debate remains whether the Turkish subtype is a distinct species. Nonetheless, immunity to CEE and RSSE is cross-protective. Within a subtype, strains are relatively homogeneous, varying by a maximum of 2.2% nucleotide variation, while a maximum difference between subtypes is 5.6%. It is proposed that the TBEVs evolved approximately 2,000 years ago (5). Evolution of this group of viruses is characterized by the emergence of a small number of stable lineages, reflecting the slow rate of transmission of these agents and restricted movements of vectors and terrestrial (rodent) hosts.

The host range and cell culture susceptibility of tick-borne flaviviruses vary substantially (Table 3). Within a subtype, virus strains may vary considerably with respect to virulence (95). Single amino acid changes in the E gene have been shown to alter the virulence of CEE virus (10). Most domestic livestock (cows, goats, and sheep) develop viremia and secrete virus in their milk but do not develop clinical illness. Dogs are susceptible to encephalitis acquired by tick bite.

### Epidemiology

**Distribution and incidence.** TBE occurs in an endemic pattern over a wide area of Russia and the independent states of the former Soviet Union, Central and Eastern Europe, and Scandinavia, Switzerland, Germany, Italy, Greece, Albania, China, and Japan (Fig. 6). Austria, the Czech Republic, Slovakia, Slovenia, and Hungary experience the highest incidences, with several hundred cases each year and morbidity rates between 1 and 20 per 100,000. In Russia, 3,000 to 6,000 cases occur annually, and the highest incidence is in western Siberia, with morbidity rates of 5 to 10 per 100,000. In Japan, sporadic cases of RSSE occur in Hokkaido. Among American military personnel and travelers in Germany, the risk of infection was found to be approximately 1 per 1,000 person-months of exposure (96).

TBEV has relatively constant distribution coinciding with ecologic habitats favorable for tick activity. TBEV is usually found in valleys and nearby rivers with adequate habitats for ticks; however, in recent years, TBEV has also been reported at altitudes up to 2,100 m above sea level (97). The risk of human exposure to ticks largely depends on outdoor activities. Occupations (forestry and farming), mushroom- and berry-picking, and recreational activities in forested and scrub areas are risk factors for infection. Approximately two-thirds of the cases occur in young adults (20 to 40 years of age), and males are at slightly higher risk than females. Serologic surveys indicate that subclinical infections are not uncommon, and the case-infection ratio is between 1:25 and 1:200. Antibody prevalence varies widely with region but is in the range of 10 to 30% in adults living in endemic areas of Eastern Europe.

**Transmission.** RSSE occurs between May and August, whereas CEE cases occur between May and October. The natural transmission cycle involves larval and nymphal ixodid ticks and wild rodents and insectivores (98). *Ixodes ricinus* (the species also responsible for the transmission of

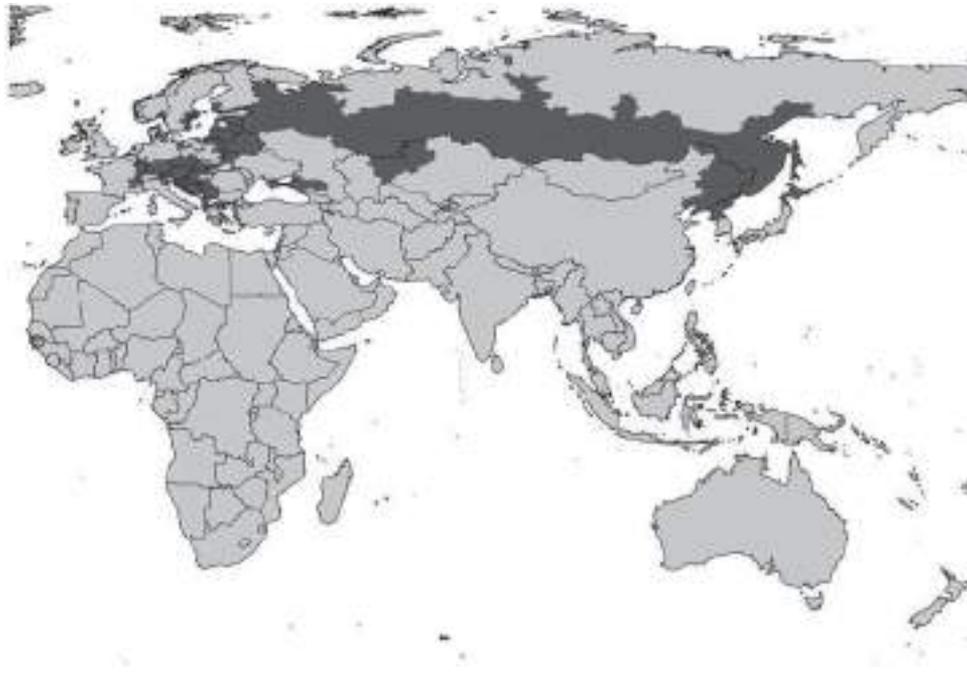

FIGURE 6 Geographical distribution of TBE.

Lyme disease in Europe) and *Ix. persulcatus* are responsible for transmission in Europe and Russia, respectively (Fig. 7). *Ixodes ovatus* is the vector in Hokkaido, Japan. In nature, ixodid vectors may reach high population densities (100–500/m<sup>2</sup>), with up to 20% of the ticks infected with virus. Mixed infections of ticks with *Borrelia burgdorferi* and tick-borne encephalitis viruses are common, and concurrent infection of humans with both diseases have been reported.

The active transmission cycle is initiated in the spring when adult and nymphal ticks emerge from hibernation. Adult ticks feed on large mammals, including domestic livestock, and lay eggs that produce larvae, a small proportion of which are transovarially infected. Goats, sheep, cows, and other large mammals are critical to maintaining vector population, but these hosts are not involved, or are rarely involved, in virus transmission to ticks. Infected overwintering nymphal ticks feed together with larval ticks on small rodents and insectivores. Rodents may develop viremia and infect attached ticks, but direct transmission apparently also occurs between infected and uninfected ticks co-feeding on small mammals in the absence of detectable viremia (99). These mechanisms for passage from nymphal to larval ticks ensure amplification of the virus. CEE and RSSE viruses are passed from larva to nymph and from nymph to adult during tick molting. Human infection occurs on exposure to adult ticks that were infected during the previous or current season.

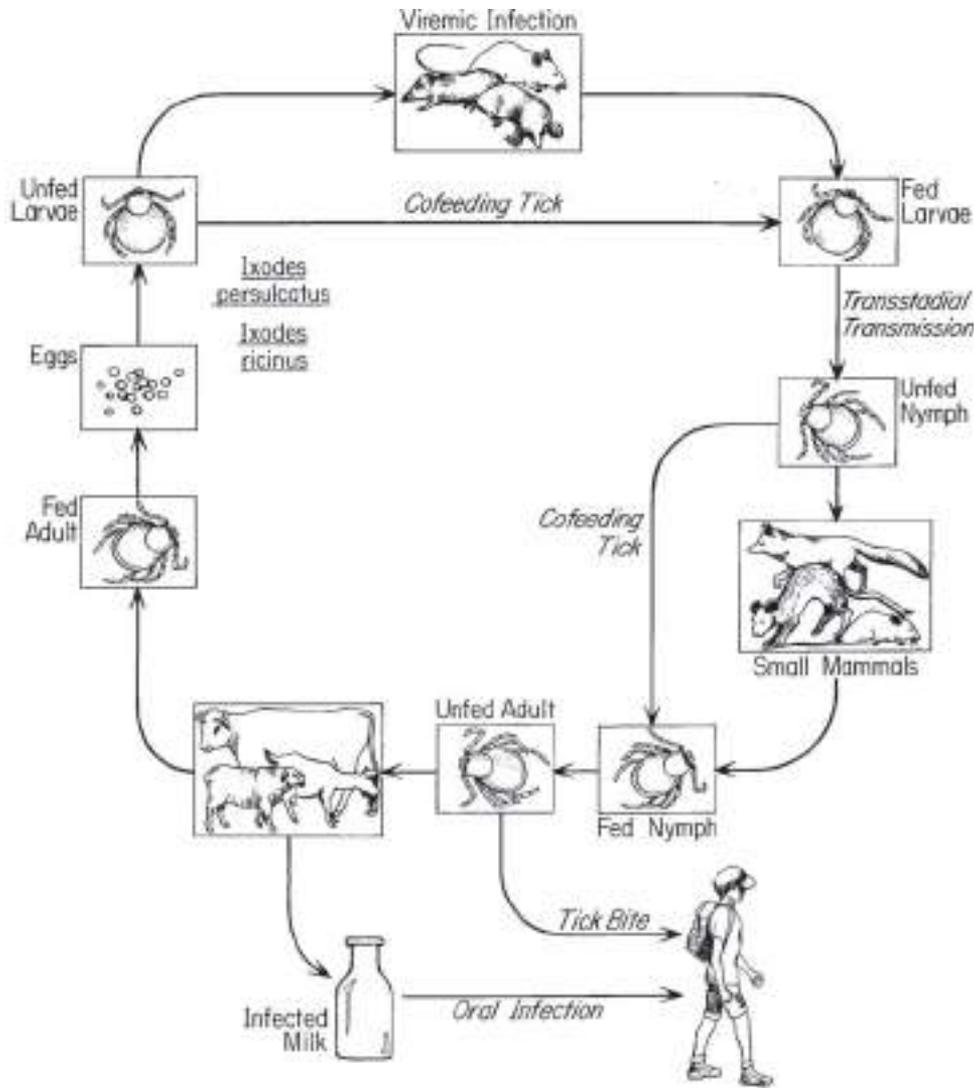

Infected sheep and goats secrete virus, with concentrations as high as 10<sup>5</sup> PFU/ml in milk, and human outbreaks with RSSE or CEE viruses have followed ingestion of unpasteurized sheep's or goat's milk or cheese. Since flaviviruses are inactivated by gastric acid and intestinal bile, it is likely that virus entry occurs in the oropharynx, presumably via tonsillar lymphoid tissue. Laboratory infections with RSSE and CEE viruses occurred frequently, often by the aerosol route, before the use of biological containment procedures and vaccines. Regardless of the route of infection, the patient is not contagious and does not perpetuate transmission by ticks or interhuman contact.

### Pathogenesis

Pathological findings are limited to the CNS and are generally similar to those in other flavivirus encephalitides, with a predilection for damage to brainstem structures. Lymphocytic infiltration of the meninges and perivascular inflammation, neuronal degeneration and necrosis, neurophagia, and glial nodule formation around necrotic neurons are widely scattered throughout cerebral and cerebellar cortices, brain stem, basal ganglia, and spinal cord. The anterior horn cells of the cervical cord are especially affected in RSSE, which explains the lower motor neuron paralysis of the upper extremities, a hallmark of the disease. Indeed, the pathological picture and clinical manifestations (flaccid paralysis) may lead to confusion with poliomyelitis, but, in TBE, the cerebral cortex is more heavily involved. Apoptosis has been proposed as one mechanism of cell death in TBE (100). An interesting feature of members of the TBEV complex is their propensity to cause persistent infections in experimentally infected monkeys, hamsters, and, possibly, humans. Chronic infection in animals is characterized by mutations in the virus (possibly related to evasion of the immune response) and destructive changes to neurons and other cell types in the brain in the absence of significant inflammation. Chronic progressive human encephalitis and seizure disorders in humans (including “Kozhevnikov epilepsy,” a form of *epilepsia partialis continua*) have been associated with RSSE virus (101), and virus has been isolated from the CSF of a patient with a disease clinically resembling amyotrophic lateral sclerosis (102).

### Clinical Manifestations

Up to two-thirds of patients have a history of tick-bite. The incubation period is 7 to 14 days. CEE and TBE-Siberia usually have a biphasic course, with an initial grippelike illness lasting about a week and characterized by fever of 38 to 39° C, chills, malaise, headache, arthralgia, myalgia, and vomiting. This is followed by remission with fatigue but no other symptoms and lasts 1 to 20 days. Most patients

**FIGURE 7** Transmission cycle of TBE. Reprinted with permission from T. P. Monath and E. X. Heinz. 1996. *Flaviviruses*, page 994. In B. N. Fields, D. M. Knipe, and P. M. Howley (eds.), *Fields Virology*, third edition. Lippincott-Raven, Philadelphia, PA.

experience an abortive infection and recover fully without further symptoms. However, up to one-third of patients develop a second phase of the disease, which takes the form of aseptic meningitis in 10 to 50% and encephalitis, myelitis, or radiculitis in the remainder (98). Encephalitic signs include alteration of consciousness, ataxia, paresis or paralysis, and cranial nerve abnormalities. The case-fatality rate is 1 to 3% for CEE and can be as high as 8% for TBE-Siberia. Patients usually die within 1 week of onset of neurological signs. The disease is less severe in children than in adults. Adult patients have higher levels of albumin and specific IgG in the CSF indicating increased virus replication, and they more often require treatment for brain swelling than children. Furthermore adults aged at least 60 years had a more severe initial illness and less favorable outcome than younger adults (103). The CSF changes in TBE are similar to other virus encephalitides. Other clinical laboratory abnormalities include leukocytosis and elevated erythrocyte sedimentation rate. Abnormalities in the EEG and MRI are seen in most patients with encephalitis signs.

About 10 to 30% of patients with acute involvement of brain parenchyma have neuropsychiatric sequelae (98). Postencephalitic signs and symptoms correlate with severity of the acute disease, and patients with coma or a requirement for assisted ventilation have increased sequelae. Objective neurological sequelae (radicular signs and paresis) generally resolve over several months, but inability to work, chronic fatigue, memory and concentration deficits, and other cognitive changes may persist for years. Chronic disease is seen in 1% of TBE-Siberia cases, and these can have evidence of persistent virus infection.

In RSSE the clinical disease is usually monophasic; the onset of illness is more often gradual than acute, with a prodromal phase including fever, headache, anorexia, nausea, vomiting, and photophobia. These symptoms are followed by stiff neck, sensorial changes, visual disturbances, and neurologic dysfunction. The neurologic features in an individual case with encephalitis are highly variable. These include predominantly cerebrocortical forms with obtundation, convulsions, paresis or paralysis, and hyperkinesia; predominant involvement of brain stem with respiratory

depression, cardiac arrhythmia, oculomotor deficits, and paralysis of the shoulder girdle and upper extremities; and myelitic forms with lower motor-neuron paralysis and little alteration of consciousness. Kozhevnikov epilepsy may occur in the acute stage or become part of a chronic postencephalitic syndrome. In fatal cases, death occurs within the first week after onset. Case-fatality rates as high as 20% for RSSE have been reported but may be overestimated by the lack of hospitalization of patients with milder cases. The case fatality rate of the Siberian subtype appears to be similar to that of CEE. Neurologic sequelae, including acute flaccid paralysis of the shoulder girdle and arms, resembling the sequelae of poliomyelitis, occur in as many as 30 to 60% of survivors of RSSE.

### Diagnosis

Diagnosis is most often made by serological testing, especially the detection of serum and CSF IgM antibodies by ELISA. A  $\geq 4$ -fold increase of ELISA antibody titers in paired sera collected two weeks apart is considered a confirmatory diagnosis. IgM antibodies in serum may be detectable for up to 10 months after disease onset. The virus (or viral antigen) may be isolated from the blood during the first phase of illness and from brain tissue of patients dying during the early phase of the disease, but the success rate is less than 10%. RT-PCR on brain tissue may be useful in postmortem diagnosis.

### Prevention and Treatment

Vaccination is warranted in persons living in endemic areas, persons working under high-risk conditions, or travelers engaged in high-risk activities. The latter situation prevails in highly endemic countries in eastern and central Europe and is enhanced with occupational or recreational risk factors.

In Europe, two equivalent, safe, and effective inactivated TBE vaccines, based on CEEV strains, are available in adult and pediatric formulations: FSME-IMMUN (Pfizer) and Encepur (GSK). Three inactivated TBE vaccines, based on RSSEV strains, are available: TBE-Moscow (Chumakov Institute of Poliomyelitis and Viral Encephalitides, Moscow, Russia); EnceVir (Microgen, Tomsk, Russia); and a vaccine produced by Changchun Institute of Biological Products, Changchun, China. The TBE-Moscow vaccine is used domestically and internationally, whereas the other two RSSE-based vaccines are used in domestic markets only. Both European vaccines have a two-dose primary series consisting of immunizations administered intramuscularly, starting on day 0, with the second dose given 1 to 3 months later. A booster dose is administered 5 to 12 months (FSME-IMMUN) or 9 to 12 months (Encepur) after the second immunization. For the European vaccines, subsequent booster doses are recommended every 5 years for persons younger than 60 years and every 3 years for persons 60 years or older. For travelers, an accelerated dosing schedule at 0 and 14 days, followed by a booster dose at 5 to 12 months is available. Both Russian vaccines have a two-dose primary series with two doses administered 1 to 7 months apart with a booster 12 months after the second dose and every 3 years thereafter. Vaccine efficacy for both products is estimated at greater than 95%. No tick-borne encephalitis vaccine is licensed in the United States but FSME-IMMUN is licensed in Canada.

The use of repellents or protective clothing may reduce the risk of tick bite, although this is not a practical prophylactic measure for persons with a permanent risk of exposure.

Permethrin-impregnated clothing is effective in repelling ticks during outdoor exposure (whereas N, N-diethyl-m-toluamide [DEET] is less effective). Treatment is supportive.

### West Nile Virus

WNV was first isolated from the blood of a patient with fever in Uganda in 1937. It is one of the most widely distributed of all arboviruses, but it had not been identified in the New World before its discovery in 1999 in the area of New York, NY (104).

### Biology

WNV, a member of the JE antigenic complex, is represented by a single serotype. Sequence analyses suggest that WNV strains can be categorized into at least five phylogenetic lineages (105); however, only lineage 1- and 2-strains have been associated with significant disease outbreaks in humans. The lineage 1 viruses can be further subdivided into three sublineages (a–c): isolates from the Western Hemisphere, Africa, the Middle East, and Europe constitute lineage 1a; Kunjin virus from Australasia represents lineage 1b; and lineage 1c consists of viruses from India (105, 106). The lineage 1a viruses are the most widely dispersed and epidemiologically important, having caused large outbreaks in Europe, Russia, and North America during the past two decades. Lineage 1a can be further subdivided phylogenetically into several clusters, each with a relatively distinct geographic focus of circulation (105). Nevertheless, all but one cluster contains isolates from Africa, suggesting frequent gene flow from Africa to Europe and Russia, most likely by migrating birds.

The means and origin of the lineage 1a WNV strain (East Coast genotype), brought into North America, are unknown. Recent phylogenetic analysis suggests that this virus, and similar strains causing recent outbreaks in Europe, share a common progenitor from North Africa (105). The WNV strain imported into North America contains a single nucleotide change in the NS3 gene (T249P), which confers avian virulence in otherwise nonvirulent strains (107). Since approximately 2002, the East Coast genotype has largely been displaced by a newly evolved genotype (WN02) encompassing 13 nucleotide changes and one conserved amino acid substitution in the E protein, compared to the East Coast genotype, resulting in enhanced dissemination and transmission of the WN02 virus in North American mosquito vectors (108, 109).

Since 2004, highly pathogenic lineage 2 WNVs have caused both human and animal disease in South Africa (110) and Europe (111). Isolates from lineage 2 viruses have histidine at the 249 locus of the NS3 gene; however, isolates that have caused large outbreaks in Greece since 2010 contain a proline substitution at this locus (112, 113). Like lineage 1 viruses, phylogenetic analysis suggests multiple introductions of lineage 2 viruses into Europe from Africa.

The virus is maintained in an enzootic cycle between birds and *Culex* mosquitoes (Fig. 4). Wild birds develop prolonged high levels of viremia and serve as amplifying hosts (114). The major mosquito vector in Africa and the Middle East is *Cx. univittatus*, with *Cx. poicilipes*, *Cx. neavei*, *Cx. decens*, *Aedes albocephalus*, or *Mimomyia* spp. important in some areas. In Europe, *Cx. pipiens*, *Cx. modestus*, and *Coquilletidia richiardii* are important. In Asia, *Cx. tritaeniorhynchus*, *Cx. vishnui*, and *Cx. quinquefasciatus* predominate.

In the United States, more than 65 mosquito species have been infected with WNV. WNV and SLE virus share the same maintenance vectors: *Cx. pipiens* and *Cx. restuans*

in the northeastern United States and Canada, *Cx. quinquefasciatus* in the southern United States, and *Cx. tarsalis* in the western United States and Canada. *Cx. nigripalpus* may be important in Florida. There is evidence from Texas and California that WNV has displaced SLE virus in *Culex* vectors.

*Culex* mosquitoes are important for their role in overwintering the virus in temperate climates, where they hibernate as adults. The amplification cycle begins when infected overwintering mosquitoes emerge in the spring and infect birds. Amplification within the bird-mosquito-bird cycle continues until late summer and fall, when *Culex* mosquitoes begin diapause and rarely blood feed. The importance of vertical transmission in maintaining the virus is unknown, but it may be an important mechanism of infection of mosquitoes entering diapause.

In the Old World, naturally acquired disease in wild birds is uncommon, suggesting a balanced relationship between virus and hosts. A notable exception was mortality in domestic geese and migrating storks (115) in Israel resulting from infection by a strain similar to the East Coast strain in the United States. WNV has caused lethal infection in more than 320 resident and exotic avian species and marked declines in populations of highly susceptible species, such as American crows, in the United States (116).

WNV grows and produces CPE or plaques in primary chicken embryo cells and in continuous cells of human, primate, swine, and mosquito origin. Mice and hamsters are susceptible to lethal infection by the intracerebral and intraperitoneal routes. Equine encephalitis outbreaks have occurred in many countries. In the United States, equine incidence peaked in 2002 and subsequently decreased after equine WNV vaccines became available. Approximately 10% of experimentally infected horses develop clinical illness. Ill horses experience a 20 to 40% mortality rate. Age, vaccination status, inability to rise, and female gender are associated with the risk of death (117). Viremia in horses is low and of short duration; thus, horses are unlikely to serve as important amplifying hosts for WNV in nature.

## Epidemiology

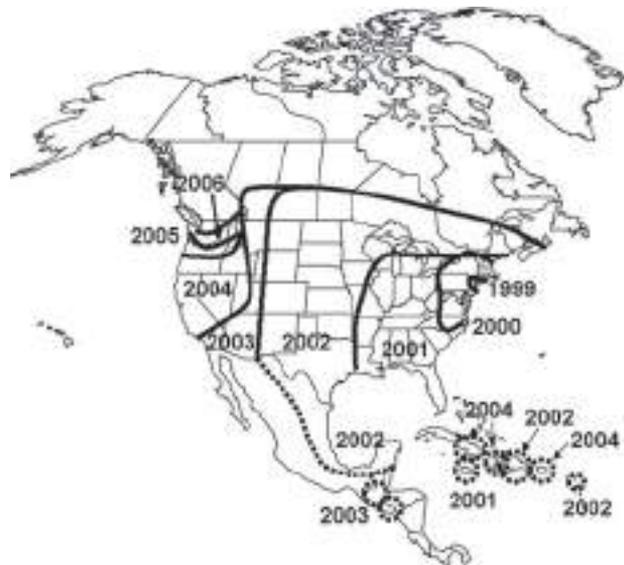

**Distribution and geography.** WNV is present throughout Africa, the Middle East, continental Europe, India, Indonesia, and Australia. Notably, the virus has rarely been identified from JE endemic areas. In the New World, its distribution has expanded from its discovery site in New York City in 1999 to Argentina in 2006. Despite serological evidence of WNV circulation in many countries in the Caribbean and Latin America, human and equine disease has rarely been reported.

Before 1995, human infection with WNV was mainly associated with little or no disease. In the Nile Delta of Egypt, serological data showing 6% seroprevalence in schoolchildren and 40% in young adults suggest that infection is very common (118). In 1974, Cape Province, South Africa experienced an outbreak with a 55% incidence of infection with thousands of clinical cases, yet illness was mild and without encephalitis. Outside of Africa, small outbreaks or sporadic cases of CNS infection had been reported from Israel, India, and several European countries (119). A marked upswing in WNV activity began in the mid-1990s coincident with the emergence of a group of genetically similar lineage-1 viruses of apparent increased pathogenicity (120, 121). Outbreaks associated with a high incidence of severe neuroinvasive disease occurred in Al-

geria (1994), Romania (1996), Tunisia (1997), Russia (1999 to 2001), the United States (1999), Israel (2000), and Sudan (2002) (122). Subsequently, outbreaks of CNS infection from both lineage 1 and 2 viruses have continued in parts of Europe.

**Incidence and Prevalence.** In the New World, significant human morbidity and mortality have been noted only in the United States and Canada. The initial outbreak in New York City caused 62 cases and 7 deaths in Queens and surrounding areas (104). The virus then spread rapidly from its initial locus (Fig. 8). Surveillance systems focus on detection of WNV neuroinvasive disease (encephalitis, meningitis, acute flaccid paralysis) since reporting of these cases is relatively complete. From 1999 to 2014, a total of 41,762 confirmed and probable cases of WNV disease, including 18,810 cases of neuroinvasive disease, were reported to the CDC from 48 states and the District of Columbia. Only 19 human cases of WNV neuroinvasive disease were reported in the United States in 2000 and 64 in 2001. However, from 2002 to 2014, the number of reported neuroinvasive disease cases ranged from 386 to 2,946, with the three largest outbreaks occurring in 2002 (2,946 cases), 2003 (2,866 cases), and 2012 (2,873 cases) (123, 124). Neuroinvasive disease varies considerably across the United States, with the highest-incidence states located in the Midwest. In Canada, 1,030 patients with neuroinvasive disease were reported through 2014.

Serologic surveys and extrapolations from blood-donor screening data indicate that neuroinvasive disease following WNV infection is infrequent, with estimates ranging from 1 in 140 to 1 in 256 infections resulting in meningitis or encephalitis (125–127). By extrapolation, the 18,810 cases of neuroinvasive disease reported in the United States through

**FIGURE 8** Expansion of WNV in North America, Central America, and the Caribbean, 1999 to 2006. Areas demarcated by solid lines confirmed by virological confirmation in mosquitoes or vertebrates. Areas demarcated by dashed lines are those with serological evidence in vertebrates only. Serological evidence of WNV was found in Colombia and Venezuela in 2004, and WNV caused an equine outbreak in Argentina in 2006.

2014 would imply that from 2.6 to 4.8 million persons have been infected. Serological surveys indicate that even in areas experiencing outbreaks, less than 10% of the population has been exposed to the virus (126–129).

Human WNV infection incidence increases in early summer and peaks in August or early September. In the United States, within large regional WNV epidemics, the incidence of human disease varies markedly from county to county, suggesting the importance of local ecological conditions. Urban and agricultural land covers, rural irrigated landscapes, farming activities, and several socioeconomic factors relate to higher WNV incidence in some locations. Males and persons living in a rural area were approximately 1.4 times and 3.4 times (respectively) more likely than females or persons living in suburban or urban locations to have WNV infection (130).

**Risk Factors Associated with Human Disease.** Serologic surveys in Romania (128) and New York City (127, 128), as well as blood-donor screening data (131), indicate that WNV infection incidence is constant across all age groups during outbreaks. Advancing age profoundly increases the risk of neuroinvasive disease, particularly encephalitis (126, 132). The risk may approach one in 50 among persons aged at least 65 years, a rate 16 times higher than that for persons aged 16 to 24 years (126). In addition, a history of cancer, diabetes, hypertension, alcohol abuse, renal disease, and CCR5 deficiency, as well as male sex, may increase the risk of neuroinvasive disease (126, 132–136). Persons infected through transplantation of WNV-infected organs are at extreme risk of developing neuroinvasive disease (137), but conflicting data exist regarding risk among previous organ recipients infected via a mosquito bite (138, 139).

### Transmission

Mosquito bites account for nearly all human WNV infections. West Nile virus can also be transmitted via transfused platelets, red blood cells, and fresh frozen plasma (140), as well as through heart, liver, lung, and kidney transplantation (137). Transmission via organ transplantation has occurred from donors without detectable viremia, suggesting viral sequestration in organs shortly after viremia has cleared.

One possible transplacental transmission following a second trimester WNV infection resulted in an infant with chorioretinitis, lissencephaly, and cerebral white matter loss (141). Fortunately, fetal abnormalities due to intrauterine infection are uncommon; none of 72 live infants born to 71 women infected during pregnancy had malformations linked to WNV infection or had conclusive laboratory evidence of congenital WNV infection (142). Nevertheless, three infants born to women infected within three weeks prepartum developed symptomatic WNV disease at, or shortly after, birth, indicating the possibility of intrauterine infection or infection at the time of delivery. Other rare or suspected modes of transmission include breast milk, percutaneous or conjunctival exposure to laboratory workers, and by unknown means in dialysis-unit patients and workers at a turkey breeder farm (143).

### Pathogenesis

Mosquito salivary components introduced at the site of infection in vertebrates modulate initial infection of target cells like keratinocytes (144) and skin-resident dendritic cells through several mechanisms, including focal suppression of immune effector cell trafficking to the site of inoculation (145). Infected dendritic cells or keratinocytes

migrate to draining lymph nodes from which a serum viremia is generated that then relays infection to visceral organs and potentially to the central nervous system (CNS).

WNV is capable of replicating and eliciting pathology in the brain, but a critical prerequisite to generating neuroinvasive disease in humans is the virus' capacity to gain access to the CNS (i.e., neuroinvasiveness). Postulated WNV neuroinvasive mechanisms include direct viral crossing of the blood-brain barrier (BBB) due to cytokine-mediated increased vascular permeability, a Trojan horse mechanism in which infected tissue macrophages are trafficked across the BBB, direct infection and passage through the endothelium of the BBB, and retrograde axonal transport of the virus to the CNS via infection of olfactory or peripheral neurons (136). Regardless of how WNV enters the CNS, murine models of infection have shown persistent viral replication in various tissues, including the CNS, suggesting a potential etiology for long-term neurological sequelae observed in neuroinvasive-disease patients (136).

WNV could be isolated from lung, heart, skeletal muscle, skin, lymph nodes, liver, small intestine, kidney, thyroid, spinal cord, pons, basal ganglia, cerebellum, and cerebrum in patients who died within one month of receiving WNV for treatment of cancer during the 1950s (146). In one study, all 23 patients who died from WNV encephalomyelitis had glial nodules with variable loss of neurons and perivascular cuffing by mononuclear cells (147). Mononuclear inflammation and loss of neurons were most prominent in the gray matter of the medulla, pons, and midbrain. Inflammation of spinal cord was universally present, particularly in the anterior horns. Glial nodules and lymphocytic perivascular cuffing were usually seen in both anterior and posterior horns. Immunohistochemical assays showed viral antigens in the cytoplasm of neurons and neuronal process.

### Clinical Manifestations

The typical incubation period for infection ranges from 2 to 14 days, although longer incubation periods have been observed among immunosuppressed hosts (140). Most persons infected with WNV are asymptomatic, because symptoms are seen in only about 25 percent of infected patients (148).

**West Nile Fever.** The usual presentation is a self-limited febrile illness, called West Nile fever, which is indistinguishable from dengue and other viral fevers. The illness is characterized by fever, headache, malaise, back pain, myalgias, and anorexia persisting for three to six days. Eye pain, pharyngitis, nausea, vomiting, diarrhea, and abdominal pain can also occur. A rash, which often appears around the time of defervescence, tends to be morbilliform and non-pruritic, predominating over the torso and extremities, but sparing the palms and soles.

Although initially considered a mild, febrile illness, many patients experience a more severe and prolonged course. In a study of 98 patients with West Nile fever, the frequency and median duration of symptoms were as follows: fatigue (96%; 36 days), fever (81%; 5 days), headache (71%; 10 days), muscle weakness (61%; 28 days), and difficulty concentrating (53%; 14 days) (149). Thirty patients required hospitalization for a median of five days, and 79% missed work or school for a median of 10 days. At 30 days, 63% were symptomatic. In a follow-up study of 531 patients with West Nile fever, 53% reported symptoms of at least 30 days in duration, and 79% reported missing work for a median of 16 days (150).

**Neuroinvasive Disease.** Approximately one in 150 to 250 persons infected with WNV develop neuroinvasive disease (127, 151), which is manifested by meningitis, encephalitis, or acute flaccid paralysis. Encephalitis that is associated with muscle weakness and flaccid paralysis is particularly suggestive of WNV infection. West Nile encephalitis ranges in severity from a mild, self-limited confusional state to severe encephalopathy, coma, and death. Fever is present in at least 90%, with weakness, nausea, vomiting, and headache in approximately one-half of patients. Other neurologic manifestations include tremor, myoclonus, and parkinsonian features, such as rigidity, postural instability, and bradykinesia. The case-fatality rate among persons with neuroinvasive disease is approximately 10%.

Although Guillain-Barré syndrome can occur, WNV-associated acute flaccid paralysis most commonly results from destruction of anterior horn cells. Paralysis from WNV myelitis is asymmetric and can occur without overt meningitis or encephalitis (152). Cranial nerve palsies can occur, resulting in facial weakness, vertigo, dysarthria, and dysphagia. Facial paralysis carries a favorable prognosis. Dysarthria and dysphagia accompanied by acute flaccid paralysis indicate a high risk of impending respiratory failure (152). All patients have some improvement in muscle strength, mostly in the first 4 months following acute illness, with about one-third having significant recovery and one-third recovering fully. Patients with respiratory failure experience >50% mortality, although functional recovery is highly variable and complete recovery is possible (153). WNV infection infrequently causes other forms of weakness, including brachial plexopathy, radiculopathy, and a predominantly demyelinating peripheral neuropathy similar to Guillain-Barré syndrome. Other neurologic complications with WNV include seizures, cerebellar ataxia, optic neuritis, and hearing loss.

Total leukocyte counts in peripheral blood are mostly normal or elevated. In cases with signs of CNS involvement, the CSF usually demonstrates a pleocytosis often with a predominance of lymphocytes, as well as an elevated protein concentration. A few patients with meningitis or encephalitis have normal (<5 per mm<sup>3</sup>) CSF cell counts (3 and 5%, respectively). Over 90% of patients had elevated CSF protein levels.

CT of the brain typically shows no evidence of acute disease. MRI shows abnormalities in 20 to 70% of patients (154). Hyperintensity on T2-weighted MR images may be seen in regions such as the basal ganglia, thalami, caudate nuclei, brainstem, and spinal cord. Electroencephalography (EEG) in patients with meningitis or encephalitis typically shows generalized, continuous slowing, which is more prominent in the frontal or temporal regions (155). Patients with acute flaccid paralysis have electrodiagnostic studies showing normal sensory nerve action potentials (SNAPs) with compound motor action potentials (CMAPs) varying between normal and markedly decreased, depending on the degree of paralysis (156).

**Other Complications.** Other manifestations described with WNV infection include multifocal choroiditis, vitritis, myocarditis, pancreatitis, fulminant hepatitis, rhabdomyolysis, stiff-person syndrome, and autonomic instability (143).

#### Diagnosis

WNV should be considered in patients who have unexplained febrile illness, encephalitis, meningitis, or acute

flaccid paralysis during mosquito season. Evidence of WNV enzootic activity or other human cases, either locally or in a region where the patient has traveled, should raise the index of suspicion.

Viremic blood donors develop IgM antibody in plasma within nine days after donation (157). Serum or CSF can be tested with the IgM antibody capture ELISA. Nearly all patients with meningitis or encephalitis have a positive IgM antibody capture ELISA result at clinical presentation, but patients with West Nile fever may not have demonstrable antibody in serum obtained within eight days of clinical onset and can only be documented to have West Nile virus infection after nucleic acid amplification test or convalescent-phase samples demonstrate antibody (158). IgM antibody to WNV may persist for 1 year or longer. False positive ELISA results can occur due to recent immunization with yellow fever or JE vaccines or due to infections with other related flaviviruses, such as SLE or dengue viruses.

WNV can be isolated or viral antigen or nucleic acid detected in CSF, tissue, or other body fluids, although the low sensitivities of these methods preclude their use as routine screening tests. Nucleic acid testing (NAT), such as real-time PCR, has been positive in up to 55% of CSF samples. NAT of plasma from blood donors indicates that viremia is of a low titer and detectable for a median of 6.9 days (159). Among patients with neuroinvasive disease, NAT of plasma has a sensitivity of less than 15% (104, 158). However, patients with West Nile fever have been diagnosed by NAT, serology, or a combined approach of these two methods in 45, 58, and 94% of cases, respectively (158). Thus NAT may complement serologic testing in patients with suspected West Nile fever, particularly if the test is available and urgent diagnosis is required. NAT in serum or CSF may be valuable for severely immunocompromised patients, who may have prolonged viremia or lack IgM antibody.

#### Treatment

Treatment of WNV infection remains supportive. Several investigational therapeutic approaches including immune  $\gamma$ -globulin, WNV-specific neutralizing monoclonal antibodies, corticosteroids, ribavirin, interferon  $\alpha$ -2b, and anti-sense oligomers (160, 161) have failed to document efficacy, in part due to difficulty in recruiting sufficient numbers of patients. Case reports or uncontrolled clinical series suggesting efficacy should be interpreted with extreme caution due to WNV's highly variable clinical course. There is intensive research using structure-function studies of virus-encoded proteins to identify viral targets for drug development, but these are all *in vitro* or small animal models studies. (162–165), including Favipiravir (T-705), which is a broad spectrum RNA virus inhibitor (166).

#### Prevention

The introduction of a vaccine against WNV for use in horses has substantially reduced the incidence of equine WNV disease in the United States (167, 168). Three licensed inactivated vaccines are available in the United States or the European Union (169–173); a DNA vaccine has also been licensed in the United States but is not commercially available (174).

Several human WNV vaccine constructs have been developed, some of which have reached human clinical trials (173). Chimeric vaccines, inserting WNV prM and E protein genes into attenuated yellow fever and dengue 4 virus backbones, have undergone successful phase 2 and 1 clinical

trials, respectively, and have demonstrated safety and immunogenicity, although efficacy trials were not possible (175). A phase 1 WNV DNA vaccine trial has been completed demonstrating safety and immunogenicity (176). Phase-3 efficacy trials have not been attempted due to the unknown market potential of a WNV vaccine and logistical difficulties in conducting phase-3 clinical trials for this sporadic and widely dispersed disease (160).

Personal protection to avoid mosquito exposure and the use of repellents is advised during periods of WNV activity. Public health measures include surveillance for virus activity in birds, mosquitoes, and humans, and the use of pesticides to kill adult infected mosquitoes.

## Flaviviruses Associated Primarily with Febrile Syndromes with Rash

### Dengue Viruses

Dengue disease was first described in the 18th century, but the causative agent was not isolated until 1944. Between 1944 and 1956 it was shown that four distinct viruses, designated dengue types 1 to 4, were responsible for the same clinical syndrome. In 1956, a severe form of the disease, dengue hemorrhagic fever/dengue shock syndrome (DHF/DSS), was described for the first time, although, in retrospect, earlier isolated outbreaks had probably occurred in Australia and South Africa. Both dengue fever and DHF/DSS are increasing in frequency worldwide.

### Biology

Dengue fever is caused by four distinct antigenically and genetically related viruses (dengue virus types 1 to 4) that are distinguished by neutralization tests. Infection with an individual dengue serotype confers lifelong protection to that serotype, but sequential infections with different serotypes occur because cross-protection between serotypes *in vivo* is absent or of short duration. Sequences of strains of dengue virus belonging to the same serotype are >90% homologous, whereas homology across serotypes is approximately 65% (177). Distinct genotypes have evolved in different geographic regions, and genotyping thus provides a means of determining the origin and spread of epidemics (178). In many areas of the world, two or more genotypes of each serotype co-circulate, reflecting either the evolution of autochthonous variants over time, or introduction and spread of a distinct genotype from another region. In addition to mutational events, intertypic recombination appears to play a role in the evolution of variants within dengue serotypes (4) but not between serotypes.

All four dengue virus serotypes cause DHF/DSS, but dengue type 2 is the most important, followed by dengue type 3 (179–181). The sequence of infecting serotypes and strain differences in virulence appear to influence the occurrence of DHF. There is no animal model of DHF disease permitting study of these factors. Epidemiological studies and comparison of nucleotide sequences of strains associated with different disease outcomes have provided clues that virus specified factors may contribute to the pathogenesis of DHF. In the Americas, two distinct genotypes of dengue 2 virus have circulated since 1981, when a strain belonging to the genotype I was introduced from Southeast Asia and superimposed on the endemic “American” genotype V (179). The Asian genotype has caused multiple epidemics of DHF/DSS in populations with prior immunity to dengue 1 (182), whereas the American genotype appears to be less pathogenic and has not caused outbreaks of severe disease in

populations with a similar immunological background (183). A detailed comparison of the nucleotide sequences of multiple dengue 2 strains, representing Southeast Asian genotype I and American genotype V, led to the identification of structural differences at critical determinants that were associated with the potential to cause DHF. These differences were located at E390 (putative cell receptor binding region of the E protein, a region of the 5' noncoding region (NCR) involved in the initiation of translation, and a region of the 3'NCR believed important in the formation of replicative intermediates (184).

The structure and replication strategy of dengue viruses are similar to other flaviviruses, but their host range and growth characteristics *in vitro* are distinctive. Unadapted isolates of dengue virus often do not cause CPE in cell culture and are not pathogenic for infant mice. Neuroadaptation by sequential passage is required to produce consistent pathogenicity. In general, cells of monkey (Vero, LLC-MK2) and mosquito (*A. albopictus* C6/36) origin are most useful for virus isolation and propagation *in vitro* (Table 3). Syncytium formation occurs in mosquito cells. Dengue viruses replicate to high titer in mosquitoes after intrathoracic inoculation.

### Epidemiology

**Distribution and Incidence.** Dengue viruses occur worldwide in tropical regions. Their distribution is determined by the presence of the principal mosquito vector (*Aedes aegypti*) (Fig. 9). Since World War II, dengue has expanded in incidence and geography, due principally to urbanization and the attendant increase in domestic *A. aegypti* populations, and to the increased movement of infected people by airplanes (185). It is estimated that over 3.9 billion people in 128 countries inhabit tropical areas at risk of infection (186) and about 390 million dengue virus infections occur annually throughout the world, resulting in 96 million cases of dengue disease (187).

Dengue infections are most prevalent in Southeast Asia, where all four serotypes are continuously present. In recent years, the Indian subcontinent, southern China, and Taiwan have experienced epidemics. Island nations in Oceania have long been at risk of epidemic spread. All four serotypes have been introduced episodically, but the island outbreaks have generally been caused by a single serotype. Intermittent transmission of dengue has occurred in Queensland, Australia. All four serotypes have been isolated in tropical Africa, but their medical impact remains unclear due to poor surveillance.

Many areas of Central and South America, the Caribbean, and the coastal United States experienced outbreaks throughout the 19th and early 20th centuries. Concerted control programs in the mid-20th century effectively eliminated the *A. aegypti* mosquito from much of the Americas, and dengue activity was reduced to sporadic activity in the Caribbean (188). However, discontinuation of the control program in the 1970s resulted in reinfestation of *A. aegypti* to its former range by the mid-1990s. This has resulted in an increase in annual reported dengue cases from 66,000 in 1980 to more than a million cases in recent years over a widening geographic range (189).

Dengue epidemics have occurred occasionally in the continental United States since the end of World War II (Louisiana in 1945; Texas in 1980, 1986, 1995, 2000, and 2005; Florida 2009, 2010, 2013). The Texas outbreaks resulted from amplified transmission in northern Mexico and

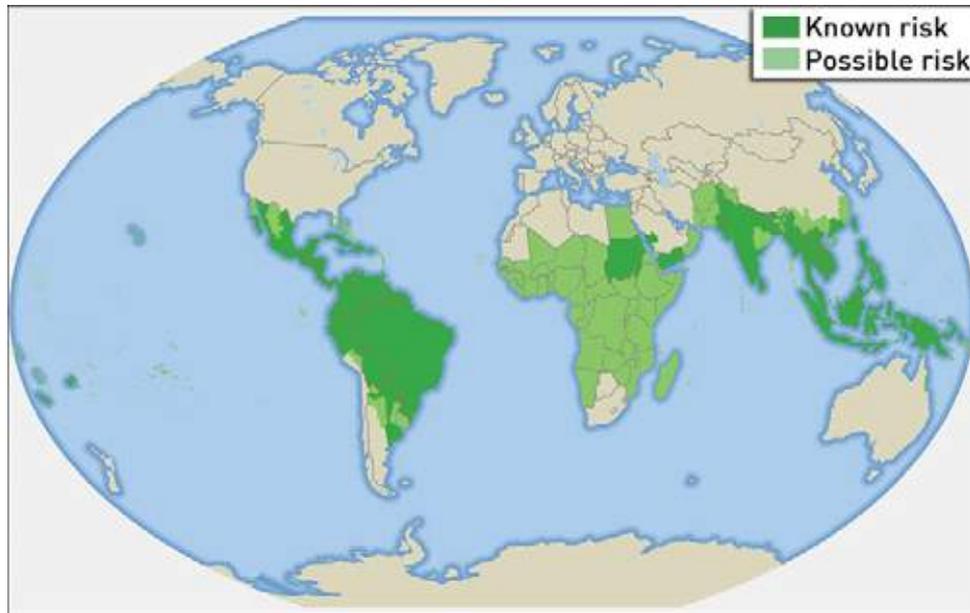

FIGURE 9 Geographical risk map of dengue fever.

included both imported cases and cases derived from secondary spread (190). Following a 56-year hiatus, an outbreak vectored by the *A. albopictus* mosquito occurred in Hawaii from 2001 to 2002 (191).

In hyperendemic areas of Southeast Asia, the annual incidence of infection is 10 to 20%, and most children have experienced at least one dengue infection by the age of 7 years. In these areas, dengue is a childhood disease, and adults are protected by cumulative immunity. In island communities or in naïve populations undergoing virgin-soil epidemics, the incidence of dengue infection has been 70% or higher, with similar attack rates across all age groups. The ratio of inapparent/apparent infections is probably highly variable due to age, other host factors, and virus strain variation. Inapparent-to-apparent infection ratios are between 6:1 and 15:1 for primary infection (187, 192) and 1:1 to 3:1 in adults (193–195). In a dengue-naïve population, the risk of dengue fever following primary infection increases with age (196).

The WHO estimates that 500,000 people with severe dengue require hospitalization annually, with a 2.5% overall mortality. Severe dengue now occurs in many countries every year, with a pattern of increasing incidence, largely as the result of the global transport of dengue viruses resulting in co-circulation of multiple dengue serotypes, permitting secondary infections. Immunity acquired after infection with one serotype confers full (probably lifelong) protection against reinfection with that serotype, but predisposes an individual to more severe disease (DHF) on sequential infection with another dengue serotype. The ratio of inapparent-to-apparent infection is significantly lower in secondary infection.

In the American region, sporadic cases of DHF were reported in the 1970s, and the first epidemic occurred in Cuba in 1981 (10,000 cases, 158 deaths) with the introduction of a dengue 2 Asian genotype virus (182). Subsequently, major outbreaks of severe dengue have been recorded throughout the region as all four dengue genotypes now circulate throughout the Americas.

**Transmission.** *Aedes* spp. mosquitoes transmit dengue virus, and humans are the intermediate host. *A. aegypti* is the most important vector globally. In tropical areas, vectors are active year round and dengue occurs throughout the year, with increased transmission during the rainy season. This is due to higher mean temperatures and the attendant shorter extrinsic incubation period in the vector and to higher humidity and enhanced survival of adult mosquitoes. In temperate zones, transmission is limited to the summer months. Dengue fever is an important travel-associated infection, and hundreds of imported cases of dengue fever are reported each year in travelers returning to the United States, Europe, and Australia.

The period of viremia for blood-feeding adult female vectors, during which humans are infectious, is 3 to 5 days (197). After blood feeding, an extrinsic incubation period of 10 to 14 days must elapse before *A. aegypti* can transmit the virus upon refeeding (197). *A. aegypti* is a domestic species that breeds in artificial containers and bites in and around human habitation. Peak biting activity occurs in the early morning and late afternoon. In tropical areas where storage of drinking water is practiced, 10 to 20 female *A. aegypti* may be found per room, of which 5 to 10% may be infected with dengue virus. However, outbreaks with vector densities of less than 1 female mosquito per house have also been recorded. *A. aegypti* is a furtive mosquito and may probe several persons before completing a blood-meal, enhancing the rate of virus transmission due to the presence of virus in mosquito saliva. The vector population threshold for dengue transmission has not been established, although it is clear from experiences in Cuba and Singapore that very low vector densities must be reached for transmission to cease (see “Prevention” below). In rural areas in some parts of the world, *A. albopictus* plays a secondary role in interhuman transmission of dengue. *A. albopictus* spread from Asia to the New World in the 1980s, and, in 1995, was implicated in dengue transmission for the first time in Mexico (198).

The maintenance of dengue viruses between epidemics has not been clearly defined, especially in rural areas with

relatively sparse human populations. Vertical transmission of dengue virus in *A. aegypti* and in sylvatic *Aedes* spp. occurs, and probably contributes, to virus maintenance. In Southeast Asia and West Africa, a sylvatic cycle of transmission occurs, involving nonhuman primates and tree-hole-breeding *Aedes* spp., similar to the cycle for yellow fever (Fig. 10). However, in Africa, virus strains involved in the sylvatic cycle are distinct from strains associated with human disease outbreaks (199).

Dengue infections have been transmitted by needle stick, from bone marrow transplantation, and blood transfusion.

#### Risk Factors Associated with Severe Dengue

The principal risk factor for DHF/DSS is prior exposure to a heterologous dengue serotype. Approximately 90% of persons with DHF/DSS are secondary infections (i.e., a second dengue infection involving a serotype different from that causing the first infection). The risk of DHF is estimated to be 15 times higher and that of DSS 50–100 times higher in secondary than in primary dengue infection (180).

Age influences disease expression. Unlike classical dengue fever, DHF/DSS is principally a disease of childhood. Two peaks have been noted in age-specific incidence rates: children younger than 1 year old and children 3 to 5 years of age. The disease in infants is rare and is associated with primary infection in the presence of maternal antibody, whereas the vast majority of cases in older children are the result of secondary infections. In Thailand the highest incidence of DHF/DSS is in children 5 to 9 years of age. In the 1981 DHF epidemic in Cuba, children had a higher incidence of severe disease compared to adults with a similar immunologic predisposition (200). However, when dengue 2 reinvaded in 1997, all individuals with prior exposure to dengue 1 had been infected at least 9 years before (dengue 1 struck Cuba in 1977 to 1978) and all patients hospitalized

were >15 years old (201). The case-fatality rate was higher in this outbreak than in 1981 (182). These findings illustrate the importance of age in DHF pathogenesis.

In addition, age, sex, race, and acquired host factors modulate disease expression. The incidence of DHF (but not of dengue infection) is higher in females than in males. It is hypothesized that females may have a more robust immune response to dengue infection or may be more susceptible to cytokine-mediated vascular injury. Malnutrition, which may reduce immune responsiveness, appears to spare children from DHF/DSS. Race influences disease severity; in Cuba, Caucasians and Asians had a significantly higher incidence of DHF/DSS than did blacks (200). Underlying disease or special condition may exacerbate illness. Peptic ulcer disease (202) and menstruation were risk factors for gastrointestinal hemorrhage and menorrhagia, respectively. Underlying diseases (e.g., sickle cell disease, diabetes mellitus, and bronchial asthma) (203, 204) as well as HLA-related and nonrelated host genetics (e.g., Fc $\gamma$  receptor IIA, G6PD deficiency, TNF $\alpha$ , interleukin 10) (205, 206) increase the risk of developing severe disease.

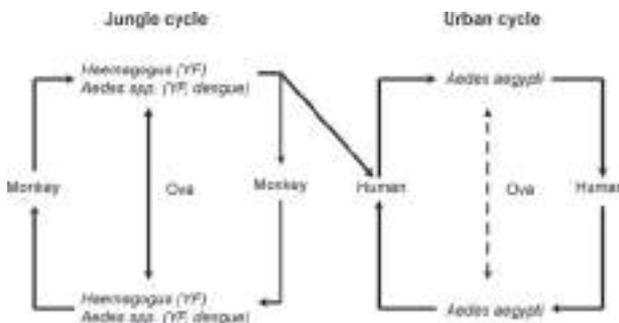

#### Pathogenesis

The primary cells infected after inoculation in mosquito saliva are probably dendritic cells in the skin (207), which subsequently migrate to draining lymph nodes (24). After initial replication in skin and draining lymph nodes, virus appears in blood during the acute febrile phase, generally for 3 to 5 days, and may be recovered from serum and from peripheral blood mononuclear cells (208). Although blood-derived dendritic cells are highly permissive to infection, one study indicated the principal subset of PBMCs infected were CD20+ B cells (209). Dengue virus enters cells via clathrin-dependent receptor-mediated endocytosis, with DC-SIGN serving as a virus attachment factor on dendritic cells.

Both the innate and adaptive immune responses are important for controlling dengue virus infection (210). As with other flaviviral infections, toll-like receptors and intracellular sensors, such as the helicases, melanoma differentiation-associated protein 5 (MDA5), and retinoic acid-inducible gene 1 (RIG-1) are important in recognizing viral RNA, which, in turn, induces strong IFN responses (211). Dengue viruses have developed mechanisms to downregulate the IFN response, which is a powerful inhibitor to dengue virus replication. After primary infection, a strong virion-specific neutralizing antibody response is directed toward epitopes located on domain II of the viral E protein. However, most antibodies are dengue-serotype cross-reactive but have low or no neutralizing activity, with a few high-titer serotype-specific antibodies.

The viremic period is terminated coincident with the appearance of serum antibodies. In most patients, humoral and cellular responses result in recovery from infection and long-lasting protection against reinfection with the homologous serotype. Serotype-specific neutralizing antibodies directed against the E protein and serotype-specific CD4+ and CD8+ cytotoxic lymphocytes directed against structural and nonstructural virus targets on infected cells are responsible for protection and recovery. Cross-protection against other dengue serotypes is short-lived, and severe disease (DHF/DSS) occurs in a subset of individuals experiencing secondary infection with a heterologous serotype.

The genesis of systemic symptoms in dengue fever is uncertain, but the release of cytokines and chemokines, as a result of virus injury to dendritic cells and macrophages and activation of CD4+ and CD8+ T lymphocytes, play an

**FIGURE 10** Simplified transmission cycle of dengue and yellow fever viruses. Both viruses have a jungle cycle involving tree-hole mosquitoes. In the Americas, *Haemagogus* sp. transmits yellow fever, but no jungle cycle for dengue has been discovered. In Africa, both viruses are transmitted in jungle cycles involving *Aedes* spp. Yellow fever does not exist in Asia, but in Malaysia, Sri Lanka, and probably elsewhere, dengue virus is transmitted in a jungle cycle involving *Aedes* spp. The relationship between the jungle cycle of dengue and human infections is not clear. However, the jungle cycle of yellow fever is a source of human infections in the Americas and Africa. Dengue transmission occurs principally in urban environments, where domestic *Ae. aegypti* serves as the vector and humans serve as the viremic host. A similar cycle of yellow fever transmission occurs commonly in West Africa. No urban outbreaks of yellow fever have occurred in the Americas since 1964, except possibly for a very limited outbreak in Bolivia in 1997 to 1998.

important role. In uncomplicated (classical) dengue fever, elevated plasma or blood levels, soluble IL-2 receptor, IL-2, soluble CD4, and interferon- $\gamma$ , and other cytokines like TNF- $\alpha$ , IL-1 $\beta$ , and platelet activating factor in plasma or blood are present. High levels of interferon- $\alpha$  have been documented for a week or more after the onset of illness. Leukopenia, due to transient bone marrow suppression, is a feature of dengue fever and also may be due to the release of soluble factors from infected monocytes. A 43-kDa cytokine produced by T cells and cytotoxic for mouse splenocytes has been demonstrated in mice and humans and may play a role in the abnormalities of hematopoiesis seen in dengue.

**DHF/DSS.** Several factors may predispose individuals to the development of DHF/DSS, including primary versus secondary infection, time interval between infections, host genetics, and viral strain. DHF/DSS is characterized by diffuse capillary leakage and hemorrhage. Increased vascular permeability results in hemoconcentration, decreased effective blood volume, tissue hypoxia, lactic acidosis, and shock. These perturbations in homeostasis are mediated by cytokines, and there are consequently few pathologic findings in fatal human cases. On autopsy, signs of capillary leak (pleural effusions, retroperitoneal edema) and of hemorrhage (petechiae, ecchymoses, and visceral hemorrhages) are evident. Histopathologic examination reveals perivascular edema and hemorrhage, proliferation of lymphoid cells and plasmacytoid elements in spleen and lymph nodes, and necrosis of thymus-dependent areas of the spleen. Central or paracentral focal necrosis of hepatocytes, Councilman bodies, hypertrophy of Kupffer cells, and focal mononuclear cell infiltration may be evident in the liver. Bone marrow changes include maturational arrest of megakaryocytes. Focal dengue virus antigen has been demonstrated in skin, liver, and mononuclear leukocytes.

The precise mechanism of DHF/DSS pathogenesis is not well understood, in part due to the lack of a suitable animal model. Proposed mechanisms include (i) antibody-mediated enhancement of infection of monocyte/macrophages; (ii) activation of dengue-specific lymphocytes, with release of cytokines and activation of complement; and (iii) innate immune response, with immune clearance of infected monocyte/macrophages and release of cytokines and activation of complement.

In the setting of a secondary dengue infection, preexisting nonneutralizing antibodies recognizing antigenic determinants on the E glycoprotein that are shared by the four dengue viruses (sometimes termed "heterologous antibody") bind dengue virus and form infectious immune complexes. Dengue virus bound to IgG antibody gains access to the principal cell targets for replication (monocyte/macrophages) via Fc- $\gamma$  receptors, in particular FcRII. The number of infected cells in the host and the overall virus load is thus enhanced. This phenomenon of antibody-mediated enhancement of virus replication has been demonstrated *in vitro* and in animal models but has been difficult to demonstrate in humans. In addition to a role for the E protein, the NS1 protein may also play a role. NS1 is found in both cell-associated and secreted forms, with the latter associated with viremia in secondary infections. However, studies to date show no correlation between anti-NS1 antibodies and plasma leakage.

Primary infection also induces both serotype-specific and dengue virus cross-reactive CD4<sup>+</sup> and CD8<sup>+</sup> CTLs directed against cross-reactive structural and (especially) nonstructural virion proteins expressed on the surface of infected

monocytes. Activation of dengue-specific T lymphocytes, interacting with infected monocyte/macrophages, causes release of IFN $\gamma$ , IL-2, TNF- $\alpha$ , and TNF- $\beta$ . Interestingly, CD4<sup>+</sup> T cells produce greater quantities of IFN $\gamma$  to the homologous virus causing the primary infection, while the ratio of TNF- $\alpha$  to IFN $\gamma$  is higher following stimulation with heterologous dengue viruses. In terms of secondary infections, it is hypothesized that low-avidity dengue-virus cross-reactive T cells, induced by the primary infecting dengue virus, dominate during a secondary heterologous dengue virus infection. Furthermore, since plasma leakage is relatively short-lived, it suggests a role for the innate immune response, in particular pro-inflammatory mediators, such as IL-6, IL-8, and TNF- $\alpha$ .

The overall numbers of CD4<sup>+</sup> T cells, CD8<sup>+</sup> T cells, natural killer cells, and  $\gamma\delta$  T cells have been found to be decreased in DHF patients compared to those with dengue fever. However, markers of T-cell activation, including elevated levels of soluble CD4 and CD8, IL-2 receptors, and TNF receptors are higher in patients with DHF than with classical dengue fever. Activated CD4<sup>+</sup> and CD8<sup>+</sup> lymphocytes may themselves also be targets for dengue replication. Apoptosis or immune lysis of dengue-infected monocyte/macrophages cells by CD4<sup>+</sup> and CD8<sup>+</sup> CTLs results in the release of a variety of vasoactive mediators and procoagulants. IL-10 and secretory TNF-RII are significantly higher in DHF compared to dengue fever patients, and IFN $\gamma$  levels peak earlier in DHF patients, while IL-6, IL-1r, and macrophage inhibitory factor were higher in fatal DHF cases. The situation is further complicated by evidence of higher levels of secreted NS1 in DHF patients, and complement activation (associated with the NS1 protein) appears to take place at the same time as plasma leakage.

Infection of cell cultures with dengue virus induces production of chemokines, such as IL-8, RANTES, MIP-1 $\alpha$ , and MIP-1 $\beta$ , which is consistent with studies in humans. IFN- $\gamma$  up-regulates both the expression of Fc- $\gamma$  receptors on monocytes (augmenting the infection of these cells by infectious immune complexes) and the expression of MHC class I and II molecules involved in recognition of these cells by cytotoxic T cells, thereby increasing the potential for enhanced dengue replication and release of cytokine mediators. Activation of complement by virus-antibody complexes or by cytokines released during immune clearance of infected cells is probably also involved in endothelial damage. Elevated levels of TNF- $\alpha$ , IL-6, C3a and C5a, and histamine occur in DHF. TNF- $\alpha$  causes capillary endothelial permeability, and increased plasma levels of this cytokine, in particular, have been associated with severe disease and shock. Dengue virus also infects cells of the mast cell/basophil lineage *in vitro*, suggesting that release of histamine from mast cells may contribute to capillary leakage.

A 43-kDa cytokine ("cytotoxic factor") produced by CD4<sup>+</sup> T cells has been demonstrated in sera from DHF patients. When administered to uninfected mice, cytotoxic factor induced vascular and blood-brain barrier permeability and lymphoid cell depletion, mimicking those conditions seen in DHF. Immunization of mice with this cytokine prevented these effects. Although these observations strongly suggest that the disturbances in vascular permeability that account for DHF and DSS are mediated by cytokines, the precise mechanisms remain uncertain and are likely to be complex. Lacking an appropriate animal model, the role of individual cytokines cannot be easily dissected, and the prospects for therapeutic interventions in humans appear to be as, or more, problematic than for bacterial septic shock.

### Clinical Manifestations

Illness starts suddenly after an incubation period of 2 to 7 days and can manifest as undifferentiated fever, dengue fever (with or without hemorrhage), or DHF (with or without shock [DSS]).

**Undifferentiated Fever.** The patient experiences fever with mild nonspecific symptoms that can mimic many acute febrile illnesses. Without specific diagnostic tests, the diagnosis is rarely made since symptoms and physical exam are nonspecific. Patients are typically young children or those experiencing their first infection (primary infection). Full recovery without the need for hospital care is the norm.

**Dengue Fever with or without Hemorrhage.** Dengue fever begins abruptly with high fever ( $\geq 38.5^{\circ}\text{C}$ ), chilliness, headache, retrobulbar pain, lumbosacral aching pain, conjunctival congestion, puffiness of the eyelids, gastrointestinal symptoms, and facial flushing. Myalgia, arthralgia, and deep bone pain (“breakbone fever”) are characteristic features. Fever may be sustained for as many as 6 to 7 days or may have a biphasic (saddle-back) course. Fever is accompanied by generalized malaise, prostration, anorexia, and nausea. There is no increase in pulse rate related to fever. Respiratory symptoms (cough, sore throat, and rhinitis) are not uncommon, especially in children. A transient, generalized macular or mottled rash may appear on the first or second day. Coincident with defervescence on the third to fifth day, a maculopapular or morbilliform rash appears on the trunk and then on the face and limbs, sparing palms and soles. The rash is nonpruritic, lasts 1 to 5 days, and may result in desquamation on healing. Other signs and symptoms may include generalized lymphadenopathy, cutaneous hyperesthesia, and altered (metallic) taste sensation. Minor hemorrhagic signs are noted in some patients (petechiae, epistaxis). Patients do not develop substantial plasma leak, which is a hallmark of DSS (212). Adults may have a greater propensity for low platelet counts and hemorrhage than children (212).

Myocarditis and various neurologic disorders have been associated with dengue fever. Myocarditis is self-limited and does not result in progressive heart failure. Neurologic manifestations include encephalitis, encephalopathy (without evidence of brain infection), transverse myelitis, peripheral mononeuropathy, polyneuritis, Guillain-Barré syndrome, and Bell’s palsy. Reye’s syndrome has also been reported to follow dengue infection. Ocular disturbances are rare but include decreased visual acuity, accompanied by retinal hemorrhage, cotton wool exudates, and macular lesions (213). Convalescence may be prolonged, lasting several weeks, with generalized weakness, psychological depression, bradycardia, and ventricular extrasystoles. Persistent arthritis is not a feature of dengue, and there are no known permanent sequelae of classic dengue infection (214). Hemophagocytic syndrome has been reported in association with dengue fever and dengue shock syndrome (215, 216).

Maternal dengue infection generally results in a normal fetal outcome (217, 218); congenital abnormalities have not been definitively linked to dengue infection. Fetal deaths have been recorded during acute maternal infection, but causality could not be determined. Maternal infection near the time of parturition has been reported to result in hemorrhagic complications and premature delivery (219), as well as transplacental infection and severe dengue in the neonatal period (220), but such events are rare.

The similar clinical presentation of dengue fever and DHF creates difficulties in differentiating them early in the course of illness. Close monitoring, such as monitoring fever, fluid intake, and the presence of warning signs (abdominal pain, persistent vomiting, clinical fluid accumulation, mucosal bleed, lethargy, liver enlargement, increasing hematocrit, decreasing platelet count), is necessary around the time of defervescence so that early and appropriate therapy for DHF/DSS can be initiated.

**DHF.** This clinical condition can be characterized by three phases: (i) the febrile phase, (ii) the critical (plasma leak) phase, and (iii) the convalescent (reabsorption) phase.

During the early febrile phase, which typically lasts 2 to 7 days, patients with DHF can present with symptoms much like those of dengue fever, but they may also have hepatomegaly without jaundice (later in the febrile phase). The hemorrhagic manifestations that occur in the early course of DHF most frequently consist of mild hemorrhagic manifestations as in dengue fever. Less commonly, epistaxis, bleeding of the gums, or frank gastrointestinal bleeding occurs while the patient is still febrile.

The critical (plasma leak) phase, which usually lasts 24 to 48 hours, begins about the time fever abates. At this time, it is vital to watch for evidence of hemorrhage and plasma leak into the pleural and abdominal cavities and to implement appropriate therapies replacing intravascular losses and stabilizing effective volume. If left untreated, this can lead to intravascular volume depletion and cardiovascular compromise. Evidence of plasma leak includes sudden increase in hematocrit ( $\geq 20\%$  increase from baseline), presence of ascites, a new pleural effusion on lateral decubitus chest x-ray, or low serum albumin or protein for the patient’s age and sex. Patients with plasma leak should be monitored for early changes in hemodynamic parameters consistent with compensated shock, such as tachycardia, especially in the absence of fever, weak and thready pulse, cool extremities, narrowing pulse pressure (systolic minus diastolic blood pressure  $< 20$  mmHg), delayed capillary refill ( $> 2$  seconds), and oliguria. Once frank shock is diagnosed, the patient is categorized as having DSS. Prolonged shock is the main factor, associated with complications, that can lead to death, including massive gastrointestinal hemorrhage. Interestingly, many patients with DHF/DSS remain alert and lucid throughout the course of the illness, even at the tipping point of profound shock.

Indicators that a patient has entered the critical phase include sudden change from high to normal or subnormal temperature, rapid decrease in platelet count, and hemocoagulation (hematocrit increased by  $> 20\%$ ), new hypoalbuminemia or hypercholesterolemia, new pleural effusion or ascites, and signs and symptoms of impending or frank shock.

During the recovery phase, which typically lasts 48 to 72 hours, a gradual reabsorption of extravascular compartment fluid takes place. The hematocrit stabilizes or may be lower due to the dilutional effect of reabsorbed fluid. Congestive heart failure and respiratory distress from pleural effusion and ascites may occur if excessive fluids have been administered.

**Dengue Case Classification.** The 1997 WHO dengue case definition was limited in terms of complexity and applicability. According to the new case definitions adopted in 2009, clinical dengue infection is classified as (i) dengue without warning signs, (ii) dengue with warning signs, and (iii) severe dengue (Table 5).

**TABLE 5** Clinical description of the 2009 WHO revised dengue case definitions

<b>Dengue without warning signs</b>
<i>Fever and two of the following:</i>
Nausea, vomiting
Rash
Aches and pains
Leukopenia
Positive tourniquet test
<b>Dengue with warning signs</b>
<i>Dengue as defined above with any of the following:</i>
Abdominal pain or tenderness
Persistent vomiting
Clinical fluid accumulations (ascites, pleural effusion)
Mucosal bleeding
Lethargy, restlessness
Liver enlargement > 2 cm
Increase in hematocrit concurrent with rapid decrease in platelet count
<b>Severe dengue</b>
<i>Dengue with at least one of the following:</i>
Severe plasma leakage leading to
Shock (DSS)
Fluid accumulation with respiratory distress
Severe bleeding as evaluated by a clinician
Severe organ involvement:
Liver: AST or ALT $\geq$ 1000
CNS: impaired consciousness
Failure of heart or other organs

### Diagnosis

Diagnosis depends on the consideration of clinical features and potential exposure, based on residence or travel in dengue-endemic areas, and knowledge about the occurrence of other cases in the community. The disease may resemble influenza, rubella, rubeola, malaria, scrub typhus, leptospirosis, and a variety of other arbovirus infections, especially chikungunya, O'nyong nyong, West Nile, Sindbis, Mayaro, Edge Hill, Kokobera, Spondweni, Barmah Forest, Zika, and Ross River virus diseases. With its rising incidence in tropical areas affected by dengue, leptospirosis, in particular, has caused considerable diagnostic confusion with dengue.

The approach to laboratory diagnosis depends on the timing of sample collection relative to illness onset. Viremia is detectable via culture, PCR, and antigen detection from blood during the first 3 to 5 days of illness before defervescence. *A. albopictus* C6/36 mosquito cell lines are the preferred viral isolation system, but mosquito inoculation is more sensitive. In practice, however, virus isolation is not practical for routine diagnosis, since it requires cell culture facilities and has a long turnaround time and lower sensitivity compared to molecular or immunoassay methods (221).

RT-PCR with type-specific primers is useful for serotype-specific diagnosis. Multiplex RT-PCR can provide a method for detection and typing multiple dengue viruses in clinical samples or cell culture fluids. Viral nucleic acid can be detected in serum, plasma, blood (including that collected on filter paper), saliva, and tissues (including formalin fixed).

Many RT-PCR protocols are available; however, many have not been validated. Several manufacturers offer dengue RT-PCR kits, but an FDA-approved real-time RT-PCR kit available from the CDC allows viral detection in the first 7 days of illness (222).

NS1 antigen can be detected in blood, for as long as 9 days after fever onset, and in tissue samples. Commercial ELISA and rapid tests are available in some countries. These tests are particularly attractive since they can detect dengue virus early during the course of illness when accurate diagnosis is most clinically relevant, have rapid turnaround, and can be conducted in resource-poor settings without specialized equipment for nucleic acid detection. Rapid tests that can detect both NS1 antigen and IgM antibody are also available. In a multicenter study the NS1 ELISA sensitivity was 60 to 75% and specificity was 71 to 80%, while NS1 rapid diagnostic test sensitivity was 38 to 71% and specificity was 76 to 80% (223). Sensitivities were generally higher in primary than secondary dengue infections.

Definitive serologic diagnosis depends on the demonstration of a 4-fold or greater rise (or fall) in antibody titers. The IgM antibody-capture ELISA is a useful diagnostic test, and a positive result on a single serum sample provides a presumptive diagnosis. IgM antibodies appear shortly after defervescence (on days 4 to 6 after onset), are detectable in 50% of patients by 3 to 5 days of illness and in 99% by day 10, and wane after 1 to 2 months. IgM antibodies are found following both primary and secondary infections; however, in secondary infection early convalescent stage IgM levels are significantly lower than in primary infections and may be undetectable in some instances (224). A negative IgM test before the sixth day of onset is not definitive, whereas a negative result after that day suggests another etiology. A small proportion of cases of secondary infection will have no detectable IgM response.

The IgM antibody-capture ELISA is the most common method of serologic diagnosis and can be applied to serum, blood on filter paper, and saliva. In addition, rapid tests for detection of IgM antibody are available. In a multicenter study the IgM ELISA sensitivity was 96 to 98% and specificity was 78 to 91%, while IgM rapid diagnostic test sensitivity was 30 to 96% and specificity was 86 to 92% (223).

The HI, CF, IgG, ELISA, and neutralization tests are useful for diagnosis of recent infection. Preferably an acute sample is obtained as early as possible (in the febrile phase) and a second specimen is obtained 2 to 3 weeks later. Serotype-specific diagnosis by a  $\geq$ 4-fold rise in antibody titer is relatively simple in the case of primary infections, but broad cross-reactions create considerable difficulties in serotype-specific diagnosis in cases of secondary infections. The plaque reduction neutralization test, which is more specific than other tests, or epitope-blocking ELISAs employing monoclonal antibodies, may help to distinguish specific from cross-reactive antibody responses. In the case of sequential dengue infections, the antibody response to the initial infecting virus type may exceed that of the current infecting type ("original antigenic sin"). Secondary dengue infections are characterized by the presence of HI antibodies at titers greater than 20 in the acute phase sample and by high titers (> 1,280) in convalescent sera. The ratio of IgM and IgG antibodies determined by ELISA has been used to distinguish primary from secondary infection; in primary infections the IgM/IgG ratio in acute sera or convalescent sera obtained during the first month after onset generally exceeds 1.5, whereas secondary infections are characterized by an excess of IgG (225).

## Prevention

Prevention of dengue transmission by control or eradication of *A. aegypti* by elimination of breeding sites in contemporary settings has been successful only in a few locales (e.g., Singapore and Cuba) where intensive efforts have been sustainable. However, even in Singapore, dengue has resurged in recent years as a result of decreased herd immunity, virus transmission outside the home, an increase in the age of infection, and adoption of a case-reactive approach to vector control (226). One model, that estimated the *Ae. aegypti* threshold density (expressed as the standing crop of pupae per human inhabitant) required for virus transmission, found that the threshold levels ranged between 0.5 and 1.5, thus illustrating the extreme difficulty in dengue prevention by means of vector-source reduction (227). Unfortunately, epidemic control by use of aerial or ground applications of mosquito adulticides has not been highly successful, in part because *Ae. aegypti* resting places are not reached by aerosols.

New approaches to *A. aegypti* control in development include lethal ovitraps, release of *Wolbachia*-infected mosquitoes, release of male mosquitoes carrying a dominant lethal gene (RIDL), and use of insecticide-treated curtains (228–230). While many of these methods show promise in small-scale field trials, studies have not been conducted on a scale capable of demonstrating reduction in dengue incidence. Epidemiologic investigations of dengue outbreaks on the Texas-Mexico border suggest that the use of air conditioning strongly protects inhabitants from dengue infection (231).

The long-term solution to the control of dengue is the wide-scale use of safe, effective, and inexpensive vaccines against all four dengue serotypes. Challenges to dengue vaccine development include the need for protection against all four serotypes, the possibility that vaccine immunity might predispose to immunopathological events associated with DHF, the lack of understanding of the pathophysiology of infection, and the lack of suitable animal models. Many approaches to dengue vaccines are currently under investigation, including live attenuated, chimeric, DNA, subunit, and inactivated vaccines (232).

A recombinant, live attenuated tetravalent chimeric vaccine (Sanofi Pasteur) has been evaluated in two phase-3 randomized clinical trials in children between the ages of 2 and 14 years in the Asia-Pacific region and between the ages of 9 and 16 years in Latin America (233, 234). This 3-dose (0, 6, and 12 months) vaccine is based on the yellow fever 17D vaccine virus backbone, substituting the dengue envelope genes from each of the four dengue serotypes. The vaccine had a 57% efficacy in the Asia-Pacific trial and a 61% efficacy in the Latin American trial. Efficacy varied among the dengue serotypes, with particularly low efficacy noted for the dengue 2 serotype and among younger children. No evident vaccine safety issues were noted in either trial. In a subsequent 3-year follow-up of children enrolled in these two trials, as well as an earlier phase 2b trial in Thailand, vaccinated children aged 9 years and older at baseline had a lower risk of dengue-related hospitalization (relative risk=0.50, 95% CI: 0.29–0.86) while younger vaccinated children had a higher risk of hospitalization (relative risk=1.58, 95% CI: 0.83–3.02) (235). An overall efficacy of 60% for prevention of symptomatic dengue was similar to that noted in earlier analysis, with higher efficacy noted in older children (66% compared to 45% in younger children). This vaccine is now licensed in several countries (Brazil, El Salvador, Mexico, and the Philippines as of February 2016).

Two other dengue vaccines currently in clinical development demonstrate adequate immunogenicity (i.e., seroconversion demonstrated as a neutralization titer of 1 in 10 or a 4-fold increase in neutralization titers). A 2-dose, live attenuated tetravalent chimeric vaccine (Takeda) engineered the attenuated dengue 2 PDK-53 vaccine strain developed by Mahidol University as a backbone by replacing the dengue serotype 2 virus prM and E structural proteins with the comparable proteins of dengue serotypes 1, 3, and 4. It was well tolerated and immunogenic in phase-1 trials (236). A live attenuated tetravalent vaccine developed at the National Institutes of Health is based on wild-type serotype-1 and -4 viruses, each with an attenuating 30-nucleotide deletion ( $\Delta$ 30) in the 3' untranslated region (rDEN1 $\Delta$ 30 and rDEN4 $\Delta$ 30). The vaccine for the dengue 2 (rDEN2/4 $\Delta$ 3[prME]) component uses the dengue 4 vaccine strain (rDEN4 $\Delta$ 30) backbone and the premembrane and envelope proteins of dengue 2. The genotype 3 vaccine (rDEN3 $\Delta$ 30/31) component is based on a dengue 3 virus with a 30-nucleotide deletion similar to the other strains with an additional 31-nucleotide deletion upstream of the  $\Delta$ 30 mutation. A single dose of this vaccine produced seroconversion rates of 92% or greater for all four dengue genotypes and was well tolerated (237).

## Treatment

The WHO updated its guidelines for the management of dengue in 2009. Initial assessment, including patient history and a full blood count, should determine the dengue phase (febrile, critical, or recovery), whether warning signs (Table 5) are present, hydration and hemodynamic status, and whether the patient requires admission. Ambulatory patients should be reviewed daily for disease progression until they are out of the critical period around defervescence. Uncomplicated dengue fever treatment is supportive and includes bed rest, fluid replacement, antipyretics, and analgesics. Aspirin or nonsteroidal anti-inflammatory agents should be avoided due to the hemorrhagic diathesis and a possible relationship between dengue and Reye's syndrome. Patients with warning signs, or those with co-existing conditions that may complicate dengue treatment, should be hospitalized for observation and fluid management. Patients with evidence of severe plasma leakage, hemorrhage, or organ impairment (hepatic damage, renal impairment, cardiomyopathy, encephalopathy, or encephalitis) require emergency treatment. For these patients, judicious intravenous fluid resuscitation is the essential, and usually sole, intervention required. Detailed algorithms for fluid management are provided in the WHO guidelines. Fluid overload, which will produce pleural effusions, ascites, pulmonary edema, and irreversible shock (heart failure, if in combination with ongoing hypovolemia) should be avoided. Blood transfusion is lifesaving for severe bleeding; however, care must be given to avoid fluid overload. Other aspects of treatment involve monitoring for hyperglycemia or hypoglycemia and electrolyte and acid-base imbalance. Co-infections, such as malaria, typhus, and leptospirosis, should also be considered. Prompt recognition and treatment of DSS can reduce mortality to less than 1% (238–241). Corticosteroids, chloroquine, lovastatin, and the polymerase inhibitor belapiravir have not proven effective in controlled clinical trials (238–240, 242).

There are intense efforts to develop antiviral drugs for dengue. Most are based on structure-function studies that are identifying drug targets. Most focus on the protease, RNA-dependent RNA polymerase, or NS4B. Many show antiviral

activity *in vitro* (162, 243–249) and to date only a few show activity in small animal models. The most advanced was NITD-0008; however, this had toxicity issues and development was discontinued (250). Prochlorperazine, a dopamine D2-receptor antagonist approved for treating nausea and emesis, is inhibitory for dengue replication *in vitro* and in *Stat1*-deficient mice (251). None of these agents has advanced to clinical evaluation.

### Zika Fever

Zika fever is caused by Zika virus, which was first isolated from a rhesus monkey in the Zika Forest, Uganda, in 1947. The virus is thought to exist in an *Aedes* mosquito—monkey cycle. Until recently very few clinical cases of Zika fever were recorded, and the virus was considered to cause sporadic infections in countries in Africa and Asia. However, in 2007, a Zika virus outbreak on Yap Island, Federated States of Micronesia, in the Pacific, involving 108 confirmed cases and a further 72 suspected cases (252), represented the first documented transmission outside of endemic areas in Africa and Asia. Subsequently, the virus was found in the Philippines (2012) and French Polynesia (2013–2014), with subsequent spread across the South Pacific (New Caledonia, Easter Island, and the Cook Islands). During 2015 the virus has greatly expanded its geographic range into the Americas with confirmed reports from Brazil in May 2015 onwards (253, 254), followed by reports from a further 26 countries in the Americas during the second half of 2015 and into early 2016. Zika fever is now considered an important emerging disease, and WHO declared the outbreak to be a Public Health Emergency of International Concern on 1 February 2016 (255). An updated review of the virus has recently been published (256).

The virus is spread by the bite of *Aedes* mosquito species and approximately 20% of infections lead to clinical disease. The incubation period is 3 to 12 days. Clinical symptoms are usually mild, often consisting of fever, rash, joint pain, and red eye, and sometimes muscle pain, headache, retro-orbital pain, and vomiting. Symptoms last up to one week. Hospitalization is rare, and fatalities are infrequent. Sexual transmission has occurred, and virus has been detected for several weeks in semen, sometimes in association with hematospermia (257, 258). Transfusion-mediated transmission appears possible, as 3% of blood donors were RT-PCR positive for Zika virus during the French Polynesia outbreak (259). The French Polynesian epidemic included cases of GBS that are still being investigated (260). While the causal link between Zika virus infection and GBS remains to be confirmed, multiple countries in the Americas have reported increased GBS case numbers in the context of the current outbreak.

Until 2015 there has been one case of virus transmitted to a fetus during the third trimester and one case potentially acquired via sexual contact. However, during 2015 the Brazilian Ministry of Health reported an epidemic of congenital microcephaly (a description of a condition where the occipital frontal circumference of the head of a newborn child is less than that of the normal circumference for gestational age, sex, and race) associated with Zika virus infection. Other reported abnormalities include intracranial calcifications, ventricular dilation, macular lesions, and hearing loss (261, 262). As of January 30, 2016, the Brazilian Ministry of health had reported 4,783 cases of microcephaly or central nervous system malformation, including 476 deaths, in at least 20 states of Brazil. At present, the relationship between Zika virus infection and congenital mi-

crocephaly is primarily ecological, and investigation of the causal link between Zika virus and microcephaly is ongoing (263). However, there are reports of detection of viral RNA by RT-PCR in amniotic fluid samples from pregnant women whose fetuses had microcephaly (264) and detection of viral RNA in blood and tissue samples from a newborn baby with congenital abnormalities. In addition, there has been a recent report of characterization of Zika virus-associated cases of microcephaly (265).

There is no vaccine, and treatment is supportive. Guidelines with regard to infection prevention, including sexual transmission, and evaluation of potentially affected infants and exposed women are available on US CDC (266, 267) and WHO websites.

Other flaviviruses associated with rare and sporadic human disease are listed in Table 4.

## Flaviviruses Causing the Hemorrhagic Fever Syndrome

### Dengue Viruses

Dengue viruses (discussed above) are a leading cause of hemorrhagic fever throughout the tropics.

### Yellow Fever Virus

In 1901 Major Walter Reed, a US Army physician, and colleagues, working in Cuba, proved that yellow fever was transmitted by the bite of an *Aedes aegypti* mosquito rather than by physical contact of clothing or bedding from infected individuals. This groundbreaking research led to studies on epidemiology of infectious diseases. Subsequently, in 1927, Sawyer and colleagues isolated yellow fever virus from a Ghanan named Asibi by passage of Asibi's serum in monkeys. Yellow fever virus, the prototype member of the family *Flaviviridae*, causes a hemorrhagic fever syndrome characterized by high viremia; hepatic, renal, and myocardial injury; hemorrhage; and high lethality.

### Biology

Nucleotide sequencing has placed yellow fever virus within a group of eight other viruses in the *Flavivirus* genus, including Banzi, Edge Hill, Entebbe bat, Jugra, Sepik, Uganda S and Wesselsbron, and Yokose. Analyses of the yellow fever virus nucleotide sequences have distinguished at least 7 genotypes: two in West Africa, with probable subdivisions between western (Senegal) and eastern (Nigeria) strains; one in Central and East Africa; one in East Africa; one in Angola; and two in South America. South American genotype I is present in Brazil, Colombia, and Ecuador, whereas genotype II is found in Peru and Bolivia. Genotype II exhibits a higher degree of microheterogeneity, and a phylogenetic pattern suggesting independent evolution in localized geographic areas (268). Phylogenetic studies of the West African and South American genotype-I strains show genetic relatedness, supporting the notion that yellow fever virus was introduced into the New World from West Africa during the slave trade. Homology across all yellow fever genotypes is >90%, suggesting that the virus is relatively resistant to mutational change either because of gene flow within large geographic regions or because of restrictions on change based on the requirement for specific vectors and vertebrate hosts.

The host range of yellow fever is shown in Table 3. *Aedes pseudoscutellaris* (AP-61) mosquito cells are highly susceptible, with virus replication assessed by CPE, immunofluorescence, or subpassage to mice or mammalian cells.

FIGURE 11 Geographical distribution of yellow fever.

Intrathoracic inoculation of mosquitoes (*Toxorhynchites* or *A. aegypti*) is also a sensitive method for isolation or assay of yellow fever virus. Asian (rhesus and cynomolgus) monkeys, as well as some New World monkeys infected with yellow fever virus, develop fatal hepatitis resembling the human disease, whereas African species, with which the virus has coevolved, are resistant to overt disease.

### Epidemiology

**Distribution and incidence.** Yellow fever occurs only in tropical South America (13 countries), and sub-Saharan Africa (31 countries) (Fig. 11). Yellow fever has never invaded Asia. Possible explanations include (i) cross-protection afforded by dengue immunity and (ii) low vector competence of Asian strains of *A. aegypti* (there is experimental evidence supporting both hypotheses); (iii) occurrence of yellow fever in remote areas; and (iv) exclusion of infected persons from routes of travel. In Africa, where approximately 90% of cases occur, there were an estimated 130,000 (95% CI 51,000–380,000) cases with fever and jaundice or hemorrhage, including 78,000 (95% CI 19,000–180,000) deaths in 2013 (269). In South America, yellow fever occurs in the Amazon, Orinoco, and Araguaia River basins and contiguous areas, and, intermittently, on the island of Trinidad.

The incidence of yellow fever in South America is highest during months with peak rainfall, humidity, and temperature (January to March). In tropical America, jungle yellow fever principally affects young adult males exposed, during forest-clearing activities, to the vector (*Haemagogus* spp.), which inhabits the rain forest canopy. In Africa, transmission peaks during the late rainy season and early dry season. A wider array of vectors is responsible for transmission, and they reach highest densities in savanna habitats. Human infection is endemic, the prevalence of immunity increases with age, and therefore children are at greater risk. There is little difference in incidence by sex.

During epidemics in Africa, the incidence of infection may be as high as 20%, and the incidence of disease may be 3% (270). The infection/case ratio ranges between 2:1 and 20:1, respectively. Immunity to certain heterologous flaviviruses ameliorates the disease and increases this ratio. The case-fatality ratio has varied widely in different epidemics, possibly reflecting virus-strain variation in virulence or sensitivity of case detection. Rates higher than 50% are reported, but the lethality of yellow fever with jaundice usually approximates 20%.

**Transmission.** The virus is transmitted between wild nonhuman primates and diurnally active mosquitoes that breed in tree holes (*Haemagogus* spp. in the Americas, and *Ae. africanus* in Africa) (271) (Fig. 10). Humans are infected when they are exposed to these vectors (“jungle yellow fever”), and epidemic-spread from human to human can be maintained in rural areas by the same mosquitoes. Alternatively, *A. aegypti*, a domestic mosquito that breeds in manmade containers, may transmit yellow fever virus between humans as the sole viremic hosts in this cycle (“urban yellow fever”). In the moist savanna region of Africa, tree-hole-breeding *Aedes* spp. (e.g., *Aedes furcifer* and *Aedes luteocephalus*) are implicated in endemic and epidemic transmission. The virus is maintained over the dry season by vertical transmission in mosquitoes.

### Pathogenesis

The pathophysiology of yellow fever disease is multifactorial, involving direct viral injury, necrotic and apoptotic processes in virus-infected hepatocytes, hypoxia, and induction of a pro-inflammatory innate immune response. Signs of specific organ dysfunction (hepatitis and renal injury) follow onset of illness by several days. The virus initially replicates in regional lymph nodes and then spreads via the bloodstream to other tissues, including liver, spleen, bone marrow, and myocardium. In liver, Kupffer cells are infected first, followed by hepatocytes in the midzone (zone 2) of the liver lobule, which undergo coagulative necrosis, sparing cells bordering the central vein and portal tracts. The reason for this peculiar distribution of hepatic injury is unknown. However, midzonal necrosis has been described in low-flow hypoxia, due to ATP depletion and oxidative stress of marginally oxygenated cells at the border between anoxic and normoxic cells. Yellow fever virus antigen has been observed principally in hepatocytes in the midzone, suggesting a predilection of these cells to virus replication. Injury to hepatocytes is characterized by eosinophilic degeneration (Councilman bodies), rather than by ballooning and rarefaction necrosis typically seen in virus hepatitis. Cytopathic changes (including Councilman bodies) are the result of programmed cell death (apoptosis), which is the dominant mechanism of cell injury in the liver (272). Consistent with apoptotic cell death, only minimal mononuclear inflammation develops in yellow fever. Other hepatic pathologic changes include microvesicular accumulation of fat, ceroid/lipofuscin deposits, and intranuclear (Torres) bodies. The reticulin framework is preserved, and healing occurs without cirrhosis. Renal pathology is

characterized principally by acute tubular necrosis and fatty change, which may represent late-stage injury following shock. Cerebral edema and petechial hemorrhages are common findings. Lymphocytic elements in the spleen and lymph nodes are depleted, and large mononuclear or histiocytic cells accumulate in the splenic follicles.

In addition to hepatic and renal dysfunction, the disease is characterized by hemorrhage and circulatory collapse. Decreased synthesis of vitamin K–dependent coagulation factors by the liver, disseminated intravascular coagulation, and altered platelet function contribute to the hemorrhagic diathesis (273). Direct virus injury to myocardial fibers, which show cloudy swelling and fatty changes, may contribute to shock. However, shock is undoubtedly mediated by cytokine dysregulation. TNF- $\alpha$ , IFN- $\gamma$ , TGF- $\beta$ , and inducible nitric oxide produced by infected/activated Kupffer cells, and splenic macrophages might play a prominent role in cell injury, oxygen radical formation, microvascular damage and microthrombosis, tissue anoxia, and shock. Patients dying of yellow fever show cerebral edema at autopsy, probably the result of microvascular dysfunction.

Yellow fever infection is followed by a rapid immune response. Neutralizing antibodies, cytolytic antibodies against viral proteins on the surface of infected cells, antibody-dependent cell-mediated cytotoxicity, and cytotoxic T cells are presumed to mediate the clearance of primary infection (274). Neutralizing antibodies appear toward the end of the first week after onset, and it is notable that antibody (and presumably cellular) responses occur coincident with the clinical crises; however, it is unclear whether immune mechanisms during the acute stage of disease contribute to pathogenesis. Neutralizing antibodies persist lifelong after yellow fever infection, and provide complete protection against disease on re-exposure to the virus.

### Clinical Manifestations

The incubation period from the bite of an infected mosquito to onset of fever is 3 to 6 days. The clinical expression of disease varies from nonspecific influenza-like illness to life-threatening hemorrhagic fever (274). Onset is abrupt, with fever, chills, malaise, headache, lumbosacral pain, generalized myalgia, nausea, and dizziness. The patient appears toxic, with congestion of the conjunctivae and face, a furred tongue with reddening of the edges, and a relative bradycardia in the face of fever (Faget's sign). Leukopenia with a relative neutropenia is typically present. This "period of infection," during which the patient is viremic and may serve as a source of infection for blood-feeding mosquitoes, lasts up to several days. It is sometimes followed by a distinct "period of remission" with abatement of fever and symptoms lasting 2 to 24 hours. In the abortive case, the patient may simply recover, without further signs or symptoms. In other cases, the illness reappears with fever, nausea, vomiting, epigastric pain, and the onset of jaundice, renal dysfunction, and a hemorrhagic diathesis. During this "period of intoxication," viremia is usually absent. Over the course of 3 to 5 days, jaundice and serum transaminase levels increase. The direct bilirubin level reaches levels between 10 and 15 mg/dL. There is a marked increase in albuminuria, a reduction in urine output, and rising azotemia. Albumin levels in the urine range between 3 and 20 g/L. Variable hemorrhagic phenomena occur, including coffee-grounds hematemesis, melena, metrorrhagia, petechiae, ecchymoses, epistaxis, oozing of blood from the gums, and excessive bleeding at needle-puncture sites. Laboratory abnormalities include thrombocytopenia, prolonged clotting and prothrombin times, and global reductions in

clotting factors. Some patients appear to have a pattern of clotting abnormalities, suggesting disseminated intravascular coagulation. Death occurs on the seventh to tenth day of illness. Preterminal events include hypothermia, agitated delirium, intractable hiccups, hypoglycemia, hyperkalemia, stupor, and coma. The electrocardiogram may show ST-T wave abnormalities. CSF is under increased pressure, with elevated albumin, but contains no increase in cells, findings that are consistent with cerebral edema.

Convalescence may be associated with weakness and fatigability lasting several weeks. Late deaths have occurred weeks after the illness and have been ascribed to cardiac arrhythmia. The duration of icterus in surviving cases is unknown. Elevations of serum transaminase levels have been documented to persist for at least 2 months after onset of yellow fever. The hepatitis resolves eventually without postnecrotic scarring.

### Diagnosis

Diseases that must be differentiated clinically from yellow fever include viral hepatitis, leptospirosis, dengue hemorrhagic fever, Rift Valley fever, Congo-Crimean hemorrhagic fever, severe malaria, Q fever, and typhoid fever. Other virus hemorrhagic fevers, including Lassa, Marburg, and Ebola virus diseases, Bolivian, and Argentine hemorrhagic fevers, are not usually associated with jaundice. The isolated case of yellow fever obviously presents a more difficult diagnostic challenge than do a cluster of similar cases. However, outbreaks of leptospirosis and hepatitis E (with deaths in pregnant women) and delta hepatitis have been confused with yellow fever in the past. The high levels of protein in the urine help distinguish yellow fever from severe malaria (blackwater fever).

The virus is most readily isolated from blood during the first 4 days after onset; it is occasionally isolated at later times. The virus may also be recovered from postmortem liver tissue. However, hepatic biopsy during the illness is contraindicated and has led to fatal hemorrhage in patients in whom this procedure was performed. Virus is isolated by intracerebral inoculation of mice, intrathoracic inoculation of *Toxorhynchites* mosquitoes, or inoculation of mosquito cell cultures, particularly *A. pseudoscutellaris* cells, with detection of virus after 3 to 4 days by immunofluorescence or RT-PCR.

Viral antigen is detectable in serum by immunoassay in a high proportion of cases, and the test may detect noninfectious antigen in poorly handled specimens. RT-PCR may also be used for rapid detection of virus nucleic acid in blood. A definitive postmortem diagnosis is made by detection of yellow fever antigen in liver tissue sections by immunocytochemical staining or RT-PCR. There are no currently available commercial diagnostic tests; the assays described remain special procedures in research and reference laboratories.

The presence of IgM antibodies in a single sample provides a presumptive diagnosis, and confirmation is made by a rise in titer between paired acute- and convalescent-phase samples. Although older methods for serologic methods for diagnosis (HI, CF, indirect immunofluorescence, and neutralization tests) are useful procedures, they have largely been replaced by the ELISA, particularly the IgM capture immunoassay.

### Prevention

The control of *A. aegypti* is discussed above for dengue virus. The control of yellow fever epidemics involving wild vector species is more difficult. Aerial applications of ULV insecticides have been attempted in the past.

The risk of acquiring yellow fever illness among unvaccinated travelers to West Africa during the peak transmission season from July to October was estimated at 50 per 100,000 for a 2-week stay. Measures to avoid mosquito bites are likely to provide incomplete protection, making immunization the best preventive strategy. A valid certificate of vaccination is required under the International Health Regulations for entry into yellow fever endemic countries and for travel from such countries to receptive (*A. aegypti*-infested) countries. Detailed information on these requirements can be obtained from the CDC website.

Yellow fever 17D is a highly effective, generally safe, live attenuated vaccine. Protective immunity (conferred by neutralizing antibodies) occurs in >90% of vaccinees within 10 days and 99% in 30 days after vaccination, and probably provides lifelong protection after a single dose (275). Until recently, booster vaccinations were required every 10 years to maintain protective immunity; however, in June 2013 the World Health Organization recommended that a single dose of yellow fever vaccine was sufficient to induce lifelong protective immunity against yellow fever in healthy individuals (276). Subsequently, in 2015, the Advisory Committee on Immunization Practices (ACIP) concurred that a single dose of yellow fever vaccine provides long-lasting protection and is adequate for most travelers, and, in addition, approved recommendations for certain categories of travelers to receive additional doses of yellow fever vaccine (277).

The vaccine may be simultaneously administered with other vaccines used for childhood immunization (measles, polio, DPT, hepatitis B) or travel (hepatitis A, oral cholera, oral or parenteral typhoid). In practice, few vaccinees complain of local injection inflammation, fever, mild headache, myalgia, and malaise. In clinical trials, where symptoms have been prompted, these reactions are more frequent but are mild and do not interfere with activities. Severe or serious adverse reactions to 17D vaccine are extremely rare. Although over 500 million persons have received the vaccine, there have been 218 cases of vaccine-associated neurologic disease, of which a 3-year-old child in the US and 53-year-old HIV-positive man in Thailand died. Virus recovered from the brain of the child who died contained two amino acid changes in the E gene and exhibited increased neurovirulence in animals (278) suggesting that mutation of the vaccine virus during replication in the patient was responsible for the vaccine accident. The vaccine is thus not recommended for infants younger than 9 months (6 months during epidemic risk) and is contraindicated for infants younger than 5 months.

In an analysis of post-marketing safety data in the US, a higher incidence of severe adverse reactions was noted in elderly persons, with those >75 years having a risk 12 times higher than young adults. The adverse experiences were not well characterized and included multisystem and neurological incidents. Three deaths in elderly persons with multisystem disease, including liver and kidney involvement and shock, occurred in the US in the late 1990s (279) and were linked to yellow fever vaccine; two deaths also occurred in Brazil (280). Pathological examination and case histories in these fatal cases of viscerotropic disease were similar to infection with wild-type yellow fever virus, however, were caused by vaccine virus with no detectable mutations that could explain the wild-type-like clinical disease. To date there have been 72 reported cases of vaccine-associated viscerotropic disease with a case-fatality rate of approximately 50%. All were first-time vaccinees, showed clinical

signs of disease within 2 to 5 days of immunization, and were 4 to 79 years old, with most aged over 60 years. Although extremely rare, it appears that yellow fever vaccine can cause viscerotropic fatal infections resembling yellow fever disease. Evidence to date suggests that this is not due directly to the vaccine virus; rather it appears to be an atypical host response to the vaccine.

The vaccine is manufactured in embryonated chicken eggs and is contraindicated for persons with a history of egg allergy (e.g., oral intolerance to eggs). Travelers who require immunization but who have a history of egg allergy should be skin-tested as directed in the vaccine label; in case a reaction to the vaccine occurs, the full dose should not be administered and a neutralization test should be performed 10 to 14 days later to determine if the patient has seroconverted as a result of the low (skin-test) dose of virus. If seroconversion has occurred, the patient may be reassured that she is protected against natural infection. If not, desensitization before vaccination may be considered (as described in the product label), or, alternatively, personal protection against mosquito bite or avoidance of travel may be recommended. The physician faced with questions of allergy (or other contraindications) should carefully consider the true risk of exposure based on the regions to be visited and may wish to consult an expert in the epidemiology of yellow fever. In persons without egg allergy, systemic allergic reactions occur at a very low rate (approximately 1:131,000 [281]) and may be due to sensitivity to gelatin used to stabilize the vaccine.

The safety of yellow fever vaccination during pregnancy has not been clearly established. In limited studies, congenital infection appears to occur at a low rate (probably 1 to 2%) and has not been clearly associated with fetal abnormalities. An underpowered case-control study of vaccination in early pregnancy indicated a relative risk of spontaneous abortion of 2.3 (282). In another (uncontrolled) analysis (283), the authors concluded that, while spontaneous abortion and congenital anomalies could not be excluded as effects of the vaccine, there was no medical rationale to interrupt pregnancy if inadvertent vaccination in pregnancy is performed. Pregnant women may be reassured that there is no risk to themselves and very low (if any) risk to the fetus from the vaccine. Patients should be followed to determine the outcome of pregnancy, and, if fetal abnormality is noted, cord blood should be obtained for an IgM test to determine whether congenital infection has occurred.

The immune response to yellow fever vaccination during pregnancy is impaired, and revaccination is indicated after parturition (284). Other factors that may impair seroconversion to 17D vaccine include malnutrition, simultaneous administration of injected cholera vaccine, and HIV infection. Asymptomatic HIV-infected travelers with CD4+ cell counts >200/mm<sup>3</sup>, who require the vaccine, should be immunized, but it may be prudent to confirm that they have developed neutralizing antibodies because two studies have shown lower rates of yellow fever virus-specific neutralizing antibodies among HIV-infected persons compared with uninfected controls at 10 to 12 months postvaccination (285, 286). Adverse events do not appear more frequently in HIV-infected subjects, although one case of vaccine-associated neurological disease occurred in an HIV-infected man with a low CD4+ count (108/mm<sup>3</sup>). Immunosuppressed persons who are unable to effectively resist viral infections should not be vaccinated. A history of thymus disease is a contraindication to yellow fever vaccine.

### Treatment

Treatment of yellow fever is symptomatic (273). There is little experience in the management of patients in modern intensive-care settings. Salicylates should be avoided due to the hemorrhagic diathesis. On theoretical grounds, severely ill patients should benefit from supplemental oxygen, fluid and electrolyte management, and circulatory support. In cases with severe hemorrhage, blood replacement may be indicated. ATP depletion of the liver might be countered by administration of glycolytic substrates (fructose). Heparin treatment to reverse disseminated intravascular coagulation has been proposed but should be considered only in cases that have been extensively evaluated and in which consumption of clotting factors and activation of fibrinolytic mechanisms appear to predominate over diminished production. Hemodialysis may be indicated in patients with severe renal impairment. No effective antivirals are currently available, but favipiravir and BCX4430 show activity in animal models (287, 288) and would be candidates for study based on studies in a hamster model. Ivermectin and imidazole-4,5- and pyrazine-2,3-dicarboxamides are inhibitory *in vitro* but have not been evaluated *in vivo* (289, 290). Based on animal studies, interferon or immunoglobulin are not useful after onset of disease. Liver transplantation has not been attempted.

### Kyasanur Forest Disease and Alkhurma Hemorrhagic Fever Viruses

Kyasanur Forest disease virus (KFDV), first isolated in Karnataka (then Mysore) State, India, in 1957 is a member of the TBE virus antigenic complex that has been subsequently termed the mammalian tick-borne virus group. The virus occurs principally in a localized region of western India, but a closely related virus, Alkhurma, has been discovered in Saudi Arabia (291). Subsequent studies have shown that Alkhurma virus is a genetic variant of Kyasanur Forest disease virus. In 2009, Nanjianyin virus was isolated from an acute febrile case in the Yunnan province of China. Nucleotide sequencing revealed the virus was nearly identical in sequence to the prototype strain of KFDV, suggesting potential laboratory contamination (292). However, the same study included a seroepidemiologic investigation of Yunnan Province from 1987 to 1990 indicating others had been infected with the virus.

Thousands of human cases of Kyasanur Forest disease have occurred in India, principally among persons working in the forest in Karnataka State. Several hundred cases occur annually, with higher rates during epidemic years. In 1983, 1,550 cases, including 150 deaths, occurred. The case-fatality rate is 1 to 2%. The transmission cycle involves ixodid ticks (*Haemaphysalis spinigera*) and wild rodents and insectivores. Wild and experimentally infected monkeys become infected and succumb to the disease. Domestic livestock are important as hosts sustaining tick populations, but their role in transmission is uncertain.

The clinical illness in humans is characterized by fever, headache, myalgia, cough, bradycardia, dehydration, gastrointestinal symptoms, leukopenia, and hemorrhagic manifestations with hypotension and shock (293). In some patients, a syndrome resembling Central European encephalitis occurs, with a febrile illness lasting a week or more, followed by remission, and then reappearance of fever and signs of meningoencephalitis. The cause of hemorrhage is unknown, but disseminated intravascular coagulation is suspected. Diagnosis is by virus isolation from blood or serology. Virus is recoverable from blood during the first week

of illness (and occasionally longer). A formalin-inactivated vaccine produced in chick embryo fibroblasts is used in affected regions of India.

Alkhurma virus (ALKV) was first isolated in Jeddah, Saudi Arabia, in the 1990s from the blood of a butcher admitted to the hospital with a severe infectious syndrome. At least 256 cases have been recorded in the last 10 years; nearly all were in Saudi Arabia and involved infection via contaminated goats, sheep, or camels. The tick vectors are *Ornithodoros* spp. and *Hyalomma dromedarii*. In 2010 cases were reported in Egypt near the Egypt-Sudan border. Clinical manifestations include fever, headache, retro-orbital pain, joint pain, generalized muscle pain, anorexia, and vomiting associated with leukopenia, thrombocytopenia, and elevated levels of liver enzymes (294). Some patients have had clinical symptoms of hemorrhagic fever or encephalitis, and this has resulted in the virus sometimes being termed Alkhurma hemorrhagic fever virus. Overall, the case-fatality rate is 1 to 2%. In immunocompetent BALB/c mice, KFDV causes a neurotropic disease, whereas ALKV does not cause clinical signs of disease nor does it invade the brain (295), while, in CBA, C57BL/6J, and A/J mice, both viruses caused clinical signs of disease, but KFDV was much more virulent than ALKV (296). Overall, KFDV appears more virulent than ALKV in mice.

Treatment is supportive, and no vaccines or specific antivirals are currently available.

### Omsk Hemorrhagic Fever Virus

Omsk hemorrhagic fever virus was originally isolated in 1947 from a patient with hemorrhagic fever in Siberia. The virus is a member of the TBE virus complex with a known distribution restricted to western Siberia. Approximately 1,500 cases were reported between 1945 and 1958, and the incidence in the late 1940s was high (500 to 1,400 per 100,000 population). Cases continue to occur but at considerably lower incidence. The transmission cycle involves ixodid ticks (principally *Dermacentor reticulatus*) and rodents, especially water voles (*Arvicola terrestris*). Muskrats develop epizootic illness. Sporadic cases acquired by tick bite occur in spring and summer. Muskrat hunters may become infected by contact with blood and tissues of infected animals and such cases can occur during the winter months. The disease in humans closely resembles Kyasanur Forest disease except that sequelae (hearing loss, hair loss, neuropsychiatric complaints) are relatively frequent. The case-fatality rate is 0.5 to 3%. Laboratory diagnosis is by virus isolation from blood or by serology. No specific Omsk hemorrhagic fever vaccine has been developed, but TBE vaccines apparently provide cross-protective immunity and have been used in high-risk population groups.

# Hepatitis C Virus

CHRISTOPHER KOH, QISHENG LI, AND JAKE LIANG

## 54

Hepatitis C virus (HCV), a member of the genus *Hepacivirus* in the *Flaviviridae* family (1), is a single-stranded RNA virus that infects humans and other higher primates, and has a selective tropism to the liver. Following exposure, HCV is able to evade the host's immune system and establish a chronic, often asymptomatic, infection that may lead to liver failure, hepatocellular carcinoma, and death. Transmitted primarily by exposure to infected blood, but also through sexual and perinatal routes, the virus is estimated to infect 2.8% of the world's population (2). Originally termed non-A, non-B hepatitis, infection with HCV was a frequent cause of transfusion-related hepatitis until discovery of the virus in 1989 (3, 4) and the subsequent development of effective screening methods. Many substantial advances have recently been made in treating HCV infection, and it is now possible to cure over 90% of patients with HCV infection. These advances also provide promising opportunities for future public health efforts to effectively reduce the disease burden of this global infection.

### VIROLOGY

#### Classification

##### Genotypes

Shortly after the identification of HCV, it became apparent that the virus is highly heterogeneous and that widely divergent genetic strains can be identified (5). The driving force for this variability is inherent to the replication strategy of the virus, which is mediated by an error-prone RNA-dependent RNA polymerase with a mutation rate of  $10^{-4}$  to  $10^{-5}$  per nucleotide (6), and a high replication level with an estimated production rate of  $10^{12}$  virions per day (7). This mutagenic propensity is balanced by viral and host constraints. The genetic variability is manifest as genotypic, sub-genotypic, or even quasi-species differences within the same host (8). These different levels of variability probably reflect different sources and selection pressures for heterogeneity. For instance, the hypervariable region 1 (HVR-1) in the E2 gene has remarkable heterogeneity among different isolates, even within patients, probably as a consequence of its antigenicity and selective pressure by the host immune system. Genotypic variability also helps shed light on the evolutionary origin of the virus and its shared history with humans. A suggested model, based on the genotype and

subtype distribution, has been described for persistent, long-term endemic foci of infection in sub-Saharan Africa and South-East Asia. This infection then rapidly spread in the last century to the western world and other countries with the advent of medical practices (blood transfusion, use of syringes) and the epidemic of injection drug abuse (9).

On the basis of phylogenetic analysis, HCV can be classified into six major genotypes, possessing sequence divergence of 30 to 35% across the viral genome (Figure 1) (10). Most genotypes can be further subdivided into subtypes, with a genomic difference of 20 to 25% (9). The viral genotypes differ with respect to geographic origin and global distribution (Figure 2) and respond differently to HCV treatment regimens (11). In general, the question of whether different genotypes are associated with disease severity remains unresolved, although genotype 3 is frequently associated with hepatic steatosis and rapid disease progression (12).

Recently, a number of human viruses have been identified that are genetically related to HCV. These include human pegivirus (HPgV) and a growing spectrum of related viruses now known to infect horses, rodents, bats, and monkeys (13). Of note, virome analysis of blood transfusion recipients has uncovered a novel human virus, human hepegivirus 1 (HHpgV-1), that shares genomic features with HCV and HPgV (14). The identification of HHpgV-1 may result in a reevaluation of the original criteria by which the genera *Hepacivirus* and *Pegivirus* are defined, and expand our knowledge of the spectrum of genome configurations of these viruses (14).

##### Serotypes and Antigenicity

Serotyping of HCV, although not commonly used in clinical practice, is possible. The non-structural protein NS4 has an antigenic region that is highly variable among different viral types. This variability confers type-specific antibodies in infected patients. A commercial serotyping kit, based on detection of antibodies with NS4-derived synthetic peptides, has a reported sensitivity of 77% and specificity of 94% (15). The low sensitivity, combined with the availability of more accurate nucleic acid-based methods, renders this assay less practical. In most clinical settings in the developed world, genotyping assays are preferred, although the serotyping method may be more practical for developing countries.

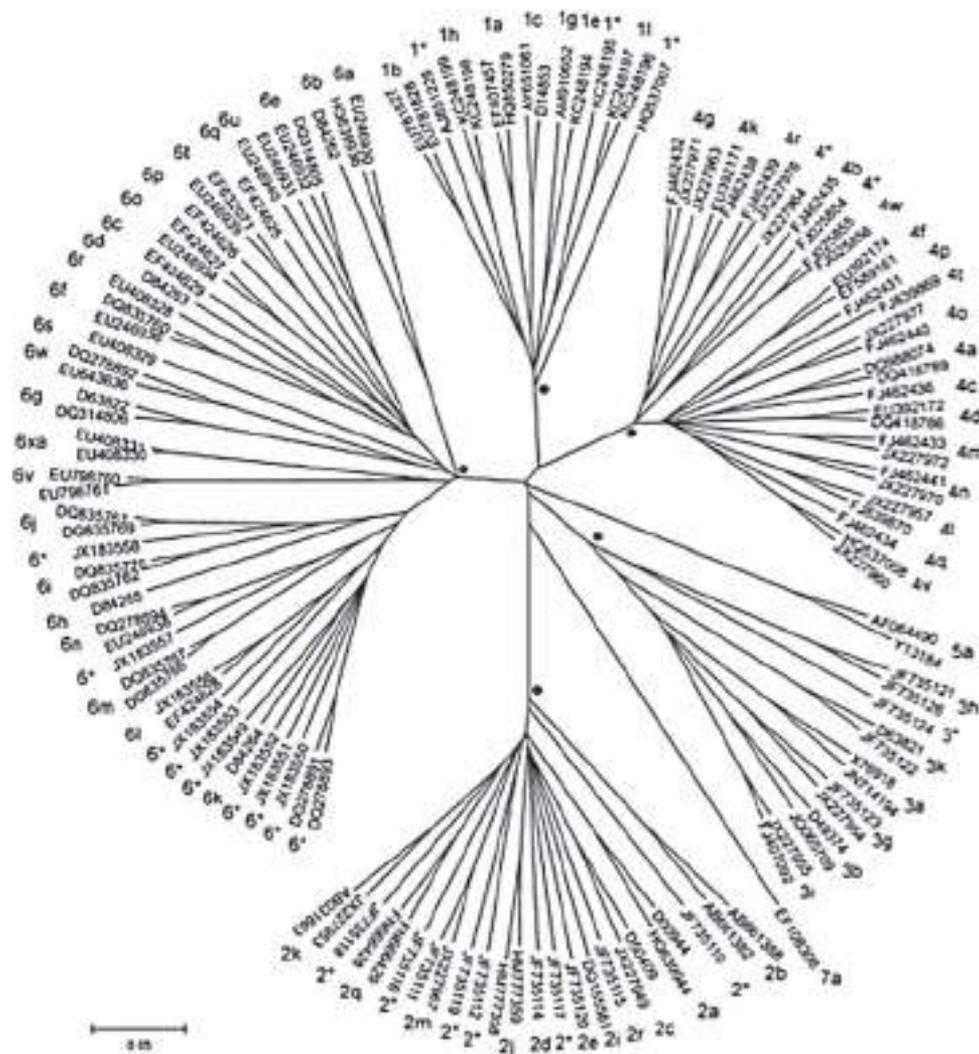

FIGURE 1 Phylogenetic tree of 129 representative complete coding region sequences demonstrating clustering to 7 genotypes and 67 subtypes. For genotypes 1, 2, 3, 4, and 6, the lowest common branch shared by all subtypes and supported by 100% of bootstrap replicates ( $n = 1,000$ ) is indicated by ·. (Reprinted from Smith et al. (10) with permission.)

## Composition of the Virus

### Virion Morphology, Structure and Size

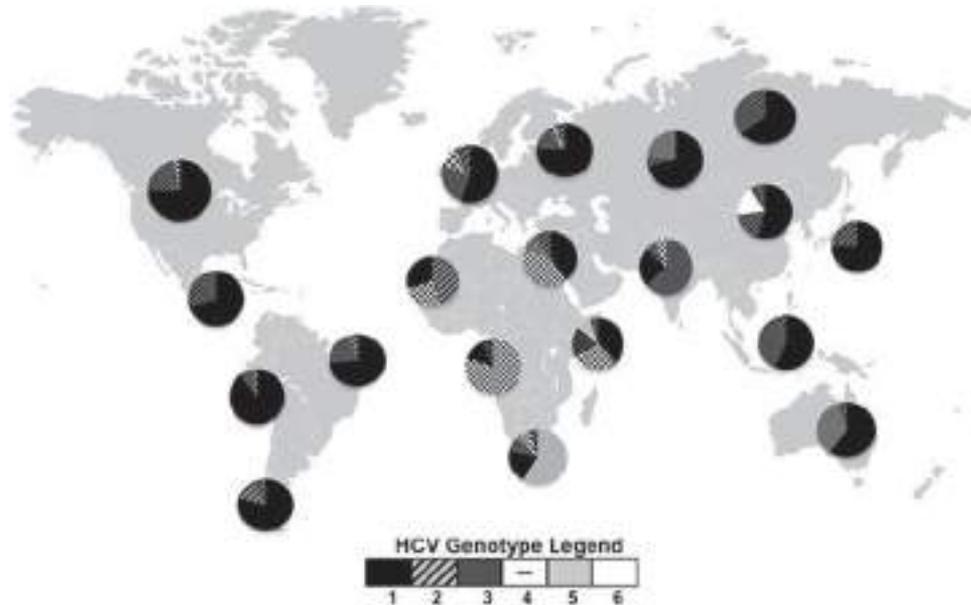

Despite recent progress in developing an efficient HCV *in vitro* cell culture system that enables robust production of infectious viral particles, the biochemical and morphological features of the HCV virion remain elusive. However, even before the virus was successfully identified, inactivation by chloroform was demonstrated, suggesting a lipid-membrane envelope (16) and filtration studies estimated the particle size at 30 to 60 nm. Electron microscopy studies identified HCV particles with sizes of 55 to 65 nm (17) (Figure 3a). The reported density for virus particles has a wide range of <math>1.06</math> to <math>1.3</math> g/ml (18).

Although the HCV virion itself is difficult to visualize, by inference from other *Flaviviridae*, the putative particle is composed of a nucleocapsid composed of the core protein and viral RNA, surrounded by a phospholipid membrane in which the viral envelope proteins are embedded. Apart from lipid-enveloped virions, naked nucleocapsids may also be circulating in the plasma, perhaps playing a role in the viral interaction with the immune system. Another major form of

viral particles circulating in the plasma is the lipo-virion (LVP), which is rich in triglycerides and contains viral RNA, core protein, apolipoprotein B (apoB) apoE, and apoA-I (18). Recent advances in a cell culture system provide a unique opportunity to visualize and study the three-dimensional structural features of HCV virions by cryo-EM (19) (Figure 3b) and cryoelectron tomography (cryo-ET) (20).

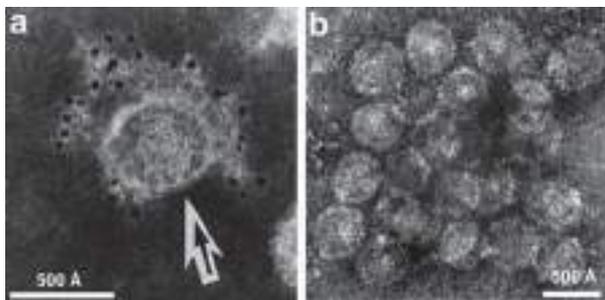

### Inactivation by Physical and Chemical Agents

Although HCV played a major role in iatrogenic infection prior to its discovery, and can be transmitted by invasive procedures, little data have been rigorously gathered on its survival in the environment and methods for inactivation. Some researchers have focused on detection (or the lack thereof) of viral RNA as a surrogate for infectivity (21) while others have examined the effect of various agents on binding of HCV to the Vero cell line (22). Many studies, however, used the related *Pestivirus* bovine viral diarrhea virus (BVDV) as a surrogate. Effectiveness of some agents is inferred from their effect on other lipid-enveloped viruses.

**FIGURE 2** Geographic distribution of HCV genotypes. Genotype 1 is the most prevalent and can be seen worldwide. Genotype 3 is more common in South- and South-East Asia, genotype 4 is seen almost exclusively in patients from Central Africa, Egypt and Saudi Arabia, genotype 5 is mostly confined to South Africa, and genotype 6 to South-East Asia.

HCV is stable in stored serum and plasma samples at 4°C for at least 7 days (23). Even before the identification of HCV, treatment with heat, beta-propiolactone, UV radiation, or chloroform, were all shown to prevent transmission of hepatitis to chimpanzees. Treatment of blood products by solvent-detergents, photochemical methods, or ultrafiltration seems to be sufficient to prevent transmission. The current recommendations for disinfecting reusable endoscopic equipment by mechanical washing with detergent and soaking in glutaraldehyde 2% were shown to be sufficient to eliminate contamination with HCV (24). Alternative methods for cleaning medical instruments, such as the use of acidic electrolyte water or hydrogen peroxide, are also effective. The effectiveness of alcohol and diluted bleach were not formally tested against HCV, but the virus is most likely susceptible to these agents as well (25).

**FIGURE 3** Electron microscopy of viral particles. (a) Immunogold electron microscopy of a viral particle from patient serum. The sample was incubated with Anti E1 polyclonal antibody and a secondary antibody conjugated to colloidal gold particles. An inner core (arrow) seems to be included within the particle. Reprinted from Kaito et al. (17) with permission. (b) Negative stain electron microscopy of HCV harvested from Huh-7.5 cells infected *in vitro* with HCV strain JFH-1. Spherical particles of uniform size with inner cores can be seen.

### Genome Organization and Composition

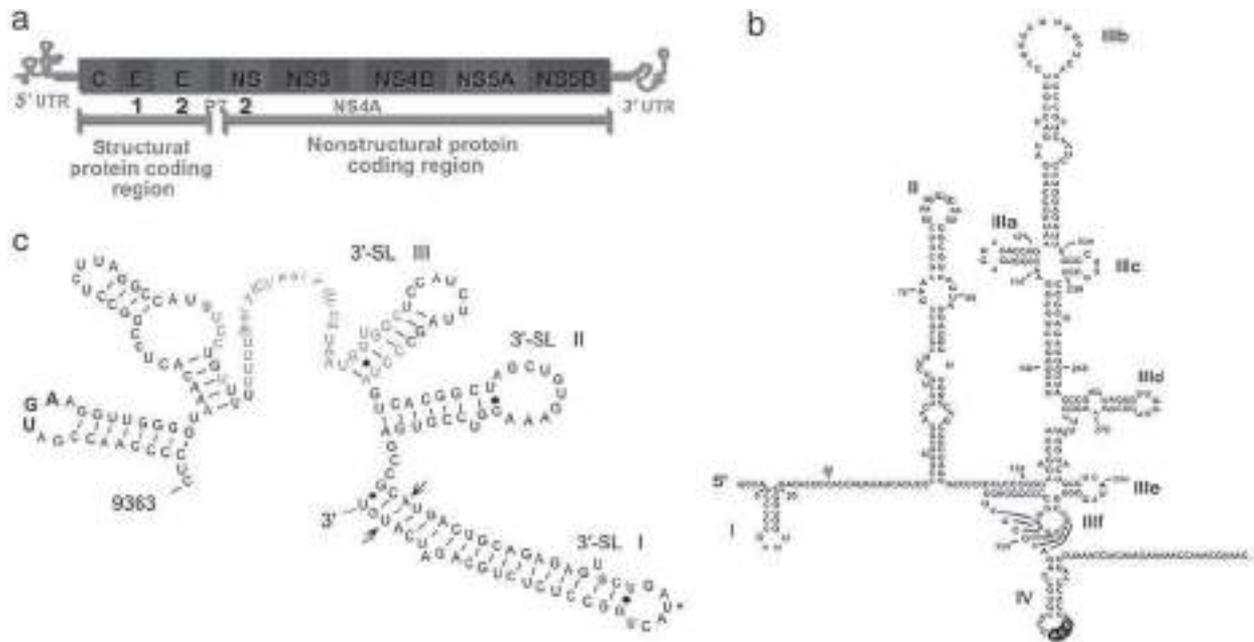

The HCV genome, like that of other members of the *Flaviviridae* family, is a single-strand, positive-sense RNA of approximately 9,600 nucleotides. The genome contains a single, large, open reading frame, coding for a polyprotein of 3,300 amino acids, flanked by 2 highly conserved, untranslated regions at the 5' and 3' ends (Figure 4a).

The 5' UTR (Figure 4b) contains an internal ribosomal entry site (IRES), interacting with the ribosomal machinery to facilitate cap-independent viral protein synthesis (26). The IRES has a conserved secondary structure comprising 3 domains that extend to the N-terminal core coding sequence and are essential for its function. Also contained in this region, upstream of the IRES, is a short sequence, highly conserved among all genotypes, that is recognized by a liver-specific microRNA (miRNA), miR-122 (27). Mutations introduced into this conserved segment significantly reduce viral replication *in vitro*, suggesting this endogenous miRNA enhances viral replication efficiency.

The 3' UTR of the HCV genome is required for replication. This region consists of three distinct domains; a short variable region, a poly(U/C) tract of heterogeneous length, and a highly-conserved, 98 nt-long "X" tail organized into three stem-loop structures (Figure 4c). All of these domains are essential for efficient replication (28, 29). The second (SL II) stem-loop of the X segment is able to base pair with another loop (SL V) in the NS5B coding region, with the poly(U/C) tract probably serving as a flexible linker. As the SLV may be the binding site for the viral RNA polymerase, this closed-loop formation serves to bring the 3' end of the positive-strand RNA into alignment with this site, to facilitate initiation of negative-strand synthesis.

### Structural and Nonstructural Proteins

Translation of the HCV open reading frame produces a single large polyprotein of about 3,300 amino acids. Host viral proteases then cleave this polyprotein to produce three

**FIGURE 4** Genome structure of HCV. (a) The positive-sense single-strand RNA genome of HCV has one long open reading frame, containing genes for 3 structural and 7 nonstructural proteins, and flanked by two untranslated regions. (b) Sequence and secondary structure of the 5' UTR. The AUG start-codon for the open reading frame is highlighted in stem-loop IV. (c) Sequence and secondary structure of the 3' UTR region. Arrows indicate variable base pairs in the stem of SL1 and the asterisk denotes the variable nucleotide in the loop of SL1. UTR—untranslated region.

structural (core, E1, E2) and seven nonstructural proteins (p7, NS2—NS5) (Table 1).

The core protein is a basic, RNA-binding protein that together with the viral genome forms the viral nucleocapsid (30). After translation and cleavage of the first 191 amino acids of the viral polyprotein, it undergoes a series of post-translational modifications, before it becomes functional. Core is able to interact with multiple host proteins and induce host gene expression, being implicated in the development of liver steatosis, carcinogenesis (31), apoptosis, and immune modulation. The association of core with the lipid droplet (LD) and interactions with NS5A are essential for production of infectious viral particles (32, 33). Core protein also recruits viral replication complexes (RCs) to LD-associated membranes and induces the accumulation of LDs in hepatocytes to enhance viral assembly.

Translation from an alternative reading frame of the core encoding region, with a +1 codon frame shift, yields a protein called F-protein or ARFP (34). The reading frame for this protein does not start with the canonical AUG start codon, and translation is probably initiated by a programmed ribosomal frame-shift. The evolutionary conservation of this frame-shift product, and the presence of antibodies to this protein in the sera of infected patients suggest that this protein is produced *in vivo* and probably has a role, yet to be elucidated, in the viral replication cycle and pathogenesis.

The two envelope proteins, E1 and E2, are type I transmembrane glycoproteins with an N-terminal ectodomain. These proteins are associated with the ER membrane after cleavage, where their ectodomain undergoes modification by N-linked glycosylation (35). They form non-covalent heterodimers that function as the building blocks for the assembly of the virion. Although both proteins facilitate cell entry, E2 is probably the major viral protein to interact with host cell-surface molecules and is thought to mediate viral

entry (36). Several highly variable regions (HVRs) have been identified in E2, differing by up to 80% among HCV genotypes. While HVR1 represents an immunodominant region that elicits type-specific neutralizing antibodies, HVR2 may modulate receptor E2 binding and play a structural role in glycoprotein assembly and virion infectivity (37). E1 protein contains a putative fusogenic sequence that may be involved in viral fusion (38).

p7 is a hydrophobic 63 amino acid protein that is associated with endoplasmic reticulum and mitochondrial associated membranes. Considered as a class IIA viroporin, HCV p7 is able to form a multimeric cation channel that can be blocked by amantadine (39). p7 is dispensable for HCV replication *in vitro*, but is essential for the formation and release of infectious HCV particles through its ion channel and pore-like activity (40). It is possible that the pore formed by p7 modulates intra-ER pH to protect viral glycoproteins during maturation and export. Besides its channel activity, p7 also acts in concert with core, envelope proteins, and NS2 to facilitate HCV assembly (41, 42). Several viroporin inhibitors that antagonize p7 ion channel activity are currently under clinical investigation for their anti-HCV effects (43).

The nonstructural 2 (NS2) protein encodes a cysteine protease whose function is stimulated by cofactor domains in NS3 (44). The protease has an autocatalytic activity, cleaving the polyprotein precursor at the NS2/NS3 junction to free, fully functional NS3, and thus promote viral RNA replication. NS2 also acts as a central organizer of HCV assembly that is independent of its protease activity, but may exploit a complex network of interactions with the envelope and various other nonstructural proteins (45, 46).

The next nonstructural protein, NS3, has a chemo-trypsin-like serine protease in the N-terminus (47) followed by an NTPase/RNA helicase in the C-terminus (48). The

**TABLE 1** Viral proteins and their function in the viral replication cycle

Name	Size (amino acids)	Function	Intracellular location	Comment
Core	171	Viral nucleocapsid	ER membranes, membranous webs, lipid droplets	Associates with viral replication complexes (RCs) and LDs for HCV assembly
E1	192	Viral envelope	RER lumen (membrane anchored)	Glycoprotein; Heterodimer formation with E1; Possibly involved in fusion
E2	363	Viral envelope	RER lumen (membrane anchored)	Glycoprotein; Heterodimer formation with E2; Binds to CD81 and other entry factors
p7	63	Cation channel, viroporin	RER membrane, mitochondrial membranes	Inhibited by amantadine & amiloride
NS2	217	Cysteine protease and viral assembly	RER membrane	Protease activity when joined with NS3
NS3	631	N-terminal serine protease, C-terminal RNA helicase	Cytosol (anchored to ER membrane by NS4A)	Protease activity dependent on NS4A co-factor; Cleaves RIG-I adaptor MAVS and mediates viral evasion to innate immunity
NS4A	54	Protease cofactor	ER membrane	HCV RNA replication and virion assembly
NS4B	261	Scaffold for replication complex	ER membrane	Induces the formation of “membranous webs”
NS5A	447	Regulating replication and assembly	ER membrane	Phosphoprotein; RNA-binding
NS5B	591	RNA-dependent RNA polymerase	ER membrane	
F/ARFP		Unknown	Unknown	Product of an alternate reading frame of the core-encoding region

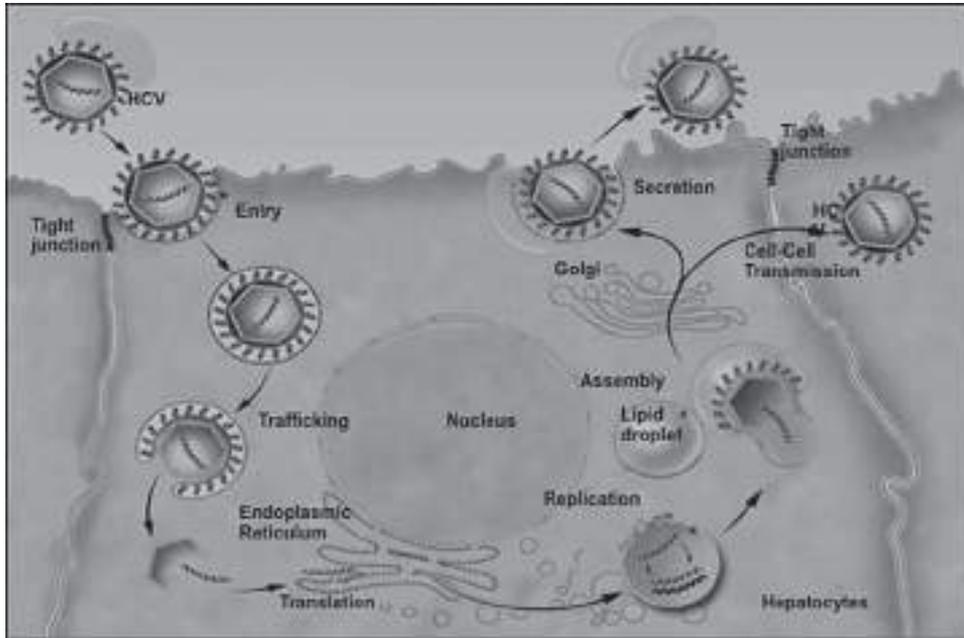

serine protease activity requires NS4A as a cofactor, which anchors the complex to the ER membrane and changes the catalytic site conformation through its N-terminal domain (49). The C-terminal portion of NS4A interacts with other replicase components and contributes to HCV RNA replication and virion assembly (50, 51). The NS3 NTPase/RNA helicase acts as a molecular motor, unwinding double-stranded RNA in an ATP-dependent manner and facilitating the activity of NS5B polymerase. It is required for RNA replication and meanwhile plays a role in viral assembly (52). Interestingly, NS3/4A also targets and cleaves several host cellular proteins, including the RIG-I adaptor MAVS and the TLR3 adaptor TRIF, supporting its role in mediating viral evasion to immune response and HCV persistence (53, 54). The NS3 protease is an attractive target for developing antiviral therapy, and several specific NS3/4A protease inhibitors are approved or being investigated as direct antiviral agents (DAAs) (see below).

The role and structure of NS4B are relatively less known. This hydrophobic 27 kDa protein is an integral membrane protein across the ER membrane, and includes the formation of membranous webs, unique membranous structures that serve as a scaffold for HCV replication complexes. NS4B also interacts with other viral nonstructural proteins, binds to viral RNA, and contains a GTP binding motif that is important for viral replication (55). Sequence variations in the protein have a significant effect on the efficiency of viral replication (56). In addition, NS4B harbors NTPase activity and has been shown to play a role in viral assembly (57).

The 447 amino acid nonstructural protein NS5A is a hydrophilic, proline-rich protein, anchored to the ER membranes by its C-terminus (58). NS5A plays an impor-

tant role in both HCV RNA replication and viral assembly (59). The protein is extensively phosphorylated by host kinases, such as the  $\alpha$  isoform of casein kinase I (CKI $\alpha$ ) (60) and casein kinase II (CKII) (61), and the degree of its phosphorylation is inversely related to the efficiency of viral replication *in vitro*. Adaptive mutations that reduce the degree of hyperphosphorylation are required for efficient replication of HCV replicons in tissue culture; however, the same mutations inhibit infectivity *in vivo*. This inverse relationship between *in vivo* infectivity and *in vitro* replication suggests that NS5A may act as a molecular switch, directing replication or assembly of virions according to the degree of its phosphorylation. Mutations in the interferon sensitivity-determining region (ISDR) within NS5A were initially thought to play a major role in the resistance to interferon of genotype 1 strains, but this was subsequently questioned by other studies (62). NS5A interacts extensively with viral elements and cellular proteins (63). Like core and NS3/4A, NS5A is probably important for the ability of HCV to evade the host's antiviral immune response.

The last protein encoded in the viral polyprotein is NS5B, the RNA-dependent RNA polymerase (64). This 68 kDa enzyme has the ability to initiate RNA synthesis *de novo*. The crystal structure of the catalytic domain demonstrates palm, finger, and thumb subdomains similar to other polymerases, including the conserved GDD sequence. A transmembrane C-terminal domain anchors the catalytic site to the membranous webs discussed below. This protein is responsible for the synthesis of the negative-strand intermediate and then the positive-strand viral genome. This essential role, and the well-defined catalytic activity, makes this enzyme another attractive target for the development of specific HCV inhibitors (see below).

**FIGURE 5** Viral replication cycle. Binding of the virus to the cell surface and internalization are followed by release of the viral RNA, harnessing of the cellular ribosomes, and protein translation and processing. The viral proteins, associated with the ER membrane, promote the formation of replication complexes anchored to lipid membranous webs in which the RNA dependent polymerase NS5B creates copies of the viral RNA through a negative strand RNA intermediate. HCV RNA is then packaged into membrane-covered viral particles and exported from the cell, presumably through the exocytosis pathway.

## Biology

### HCV Replication Cycle and Host Dependencies

The replication cycle of HCV is not fully understood, although great advances have been made since the discovery of the virus. The replication cycle can be divided into multiple stages: viral binding and entry to the cell, post-entry trafficking of viral genome, polyprotein translation and processing, RNA replication, packaging and assembly of the virion, and release or secretion (Figure 5). Each of these steps interacts with, and depends largely on, cellular pathways and host factors (65). Identification of these host dependencies may provide not only potential antiviral targets, but also critical insights into mechanisms of HCV-mediated pathogenesis and chronic liver disease.

### Binding and Entry

Great advances have been achieved in elucidating HCV entry pathway, mechanism, and cellular factors involved in the entry processes. Entry steps play central roles in cell tropism and species specificity. The highly coordinated HCV entry process exploits multiple cellular molecules, including tetraspanin CD81 (66), the tight junction proteins, claudin-1 (CLDN1) (67) and occluding (OCLN) (68), the receptor tyrosine kinases epidermal growth factor receptor (EGFR), and ephrin receptor A2 (EphA2) (69), Niemann-Pick C1-like 1 (NPC1L1) (70), and transferrin receptor 1 (70). The presence of both E1 and E2 in a non-covalent heterodimer formation is essential for viral entry (71). Several cell-surface molecules, mostly identified by screening for the ability to bind a soluble E2 protein, have been suggested as putative receptors that could facilitate virus-cell interaction and cell entry. The process is likely to involve several of these molecules, sequentially or in unison, as none alone was shown to

be sufficient for entry. The 25 kDa tetraspanin CD81, a ubiquitous surface protein, is able to bind E2 (66) and is required for cell entry in a density-dependent manner. E2-CD81 binding sites have been shown to be major targets for broadly neutralizing antibodies, which thereby efficiently inhibit viral binding and entry (72, 73). There is, however, evidence to suggest that CD81 is not required for binding but acts at a post-binding stage.

Another putative viral receptor is scavenger receptor class B type I (SR-BI), an 82 kD, E2-binding protein (74), expressed on hepatocytes, dendritic cells, and steroidogenic tissue (adrenals and ovaries), and involved in binding of HDL, VLDL, and oxidized LDL. SR-BI plays multi-stepwise roles during HCV entry. The initial binding of HCV to SR-BI is mediated by HCV-associated lipoproteins, such as apoE, present on LVPs. The lipid uptake activity of SR-BI may assist the exposure of CD81 binding sites on E2 and transfer of viral particles to CD81. The effect of SR-BI on HCV entry is enhanced by HDL cholesterol and inhibited by oxidized LDL. In addition, SR-BI-E2 interaction enhances HCV infection at a post-binding stage. Indeed, HCV entry employs a complex interplay between lipoproteins, SR-BI, CD81, and HCV envelope glycoproteins.

A few other molecules are involved in this process. Highly sulfated heparin sulfate, a liver-specific form of heparin sulfate, was shown to bind E2 (75), and it may be the initial binding surface molecule. DC-SIGN and L-SIGN, two members of the C-type lectin family, were also shown to bind E2 and HCV particles. However, these proteins are expressed by dendritic cells and liver sinusoidal endothelial cells, respectively, but not by hepatocytes. Thus, they probably promote infection *in trans* by capturing virions and transporting them to the vicinity of hepatocytes (76). The LDL receptor (LDLR) is also involved with the internal-

zation of HCV (77), probably through association of viral particles with lipoproteins, because entry of naked HCV pseudoparticles is not mediated through this receptor (71).

CLDN1, a component of tight junctions that is highly expressed in the liver, was identified as an essential HCV entry factor (67). HCV E1 but not E2 may directly interact with CLDN1 (78). CLDN1 contributes to the post-binding steps of HCV entry by interacting with CD81, forming a complex critical for virus internalization (67, 79). OCLN, another tight junction protein, functions at a post-attachment step during HCV entry (68). Together with CD81, OCLN defines the species tropism of HCV entry (80, 81).

Receptor tyrosine kinases EGFR and EphA2 are also important HCV entry factors (69). EGFR-dependent signaling promotes CD81-CLDN1 association, thus facilitating HCV entry. The cholesterol transporter Niemann-Pick C1-like 1 (NPC1L1) and the iron uptake receptor, transferrin receptor 1 (TfR1), were found to be additional entry factors (70, 82). The precise functions and mechanisms of these cellular factors remain to be addressed.

Entry into the cell is clathrin and pH dependent, suggesting that after binding, the virus is endocytosed and that membrane fusion occurs in the endosome. In summary, although several cell surface molecules have been shown to bind viral proteins or particles and to facilitate cell entry, the process *in vivo* most likely involves multiple molecules, interacting simultaneously or in sequence to bind, attach, endocytose, and internalize the virus.

### Protein Translation and Processing

Following internalization and release of the viral RNA from the capsid, protein translation ensues. The IRES in the 5' UTR is able to harness the 40S ribosomal subunit in the absence of other initiation factors (needed for cap-dependent translation) and direct it to the AUG start codon of the viral polyprotein. The eIF2-Met-tRNA-GTP ternary complex, eIF3, and the 60S subunit are then recruited to form the active 80S ribosome (26).

Following translation, the large polyprotein product is co- and post-translationally cleaved by host (signalase and signal peptide peptidase) and viral (NS2/3 and NS3/4A) proteases to release ten mature HCV proteins (83). Four signal peptides are located in the polyprotein sequence: at the core protein and E1 junction, between E1 and E2, E2 and p7, and at the p7 and NS2 junction. These signal peptides direct the elongating protein to the endoplasmic reticulum membrane and determine the location of the future cleavage products: cytosolic, ER-membrane associated, or intraluminal. Cleavage at the site of the signal peptides is by the ER signal peptidase (84). The NS2/3 junction then undergoes autocatalytic cleavage following dimerization (85). Further downstream processing is dependent upon the NS3/4A protease, which cleaves the NS3/4A, NS4A/4B, NS4B/NS5A, and NS5A/NS5B junctions, with NS4A as a required cofactor (47).

Less is known about cellular proteins involved in HCV IRES-mediated translation. Recent integrative functional genomics studies identified PIAS1, USP11, and several other cellular genes as putative host factors that promote HCV protein translation (65).

### RNA Replication

RNA replication occurs in a membrane-anchored complex of the viral nonstructural proteins and RNA, termed the replication complex or the replicase. Replication *in vitro*,

and perhaps *in vivo* as well, takes place on unique membranous webs, thought to be derived from the ER membranes by the action of NS4B (86).

HCV replication relies on miR-122 (27), a liver-specific host microRNA that recruits Argonaute 2 to the 5' end of the viral genome (87), stimulating viral RNA synthesis, and protecting it from degradation by exonuclease Xrn1 (88). Antagonism of miR-122 with an antisense oligonucleotide results in long-lasting suppression of HCV viremia in chimpanzees and humans, and hence constitutes a novel therapeutic strategy against chronic HCV infection (89, 90).

Taking advantage of RNAi-based screening and mass spectrometry interactome approaches, a large number of HCV host dependencies influencing translation and replication have been identified (91–93). These include cyclophilin A (CypA), a peptidyl-prolyl cis-trans isomerase, and phosphatidylinositol-4-kinase-III- $\alpha$  (PI4KIII $\alpha$ ), a kinase and central player in HCV replication. CypA inhibitors, such as cyclosporine A and nonimmunosuppressive analogs alisporivir (DEBIO-025) (94) and SCY-635 (95), exhibit potent anti-HCV activity and are being developed as host-targeting antivirals (HTAs).

### Assembly and Release

The process of packaging and export of HCV virions is assumed to involve budding of virions into the ER membrane and export through the secretory pathway, but detailed mechanisms involved in HCV assembly and release are yet to be delineated, although an intricate interaction with host cell lipid metabolism has been suggested (96, 97). In the early step of assembly, the core protein recruits non-structural proteins and viral replication complexes to lipid droplet (LD)-associated membranes, but the subsequent steps remain unclear (32, 98). Multiple host factors have been identified to participate in HCV assembly. Most notable is ApoE, which appears to be incorporated into infectious HCV particles through interaction with NS5A (99, 100). Other lipid metabolism genes are also required for HCV assembly, for example MTP, a microsomal triglyceride transfer protein that is essential for VLDL synthesis (101), and DGAT1, a lipogenic enzyme that specifically interacts with and translocates HCV core to the viral assembly sites (102). Recently, the I $\kappa$ B kinase- $\alpha$  (IKK- $\alpha$ ) has also been shown to be a critical host factor mediating HCV assembly (103). HCV, through its 3' UTR, interacts with DEAD box polypeptide 3, X-linked (DDX3X) to activate IKK- $\alpha$ , which translocates to the nucleus and induces a CBP/p300-mediated transcriptional program involving sterol regulatory element-binding proteins (SREBPs). This innate pathway induces lipogenic genes and enhances core-associated lipid droplet formation to facilitate viral assembly (103).

The host dependencies for HCV secretion are largely unknown. The current model suggests a role of VLDL secretory pathway and trans-Golgi network (TGN)-recycling endosomes in the release of HCV particles (101, 104, 105).

### Cell Culture and *In Vitro* Model Systems

Since the discovery of HCV, the lack of a robust cell culture system capable of supporting efficient productive infection of HCV had been a major obstacle to the study of this pathogen and the development of countermeasures. Surrogate model systems, such as production of HCV-like particles and HCV retro-pseudoparticles, provide valuable tools to study virus-cell interactions (106), but none of these *in vitro* model systems produce infectious viral particles. The development of replicon systems, instrumental in creating a

TABLE 2 Virologic model systems

Model system	Method	Proteins expressed	Life cycle stages studied	Infectivity <i>in vivo</i>	Comments
HCV-like particles (HCV-LP)	Assembly of envelope proteins in insect and mammalian cells	E1, E2	Binding and entry	-

system to study viral replication, consist of a bicistronic construct containing the non-structural genome region (NS3-NS5B) downstream of the encephalomyocarditis virus (EMCV) IRES and a selectable marker driven by the HCV IRES (Table 2) (107). Transfection of these subgenomic replicons to human hepatoma Huh7 cells resulted in viral replication. However, efficient viral replication depends on the appearance of adaptive mutations, especially in NS5A (108). This system is naturally limited by the absence of the structural proteins and hence is not amenable to studying the packaging and export process. Further modifications of the replicon system included the production of monocistronic subgenomic replicons and of a full-length replicon. To date, subgenomic replicons have been constructed for six major HCV genotypes, and have greatly contributed to the discovery of DAAs that are currently licensed or under development. A major breakthrough for investigating the process of HCV entry was the development of HCV pseudoparticles (HCVpp)—defective retroviral particles expressing HCV envelope glycoproteins on their surface (71, 109). Using HCVpp system, a variety of viral entry factors and molecular pathways have been uncovered.

Wakita et al. (110) transfected hepatoma cells with a full-length cDNA cloned from a patient with fulminant hepatitis C. This strain, termed JFH-1 and classified to genotype 2a, replicates efficiently in tissue culture without adaptive mutations and produces viral particles that are infectious to hepatoma cells *in vitro* and to chimpanzees *in vivo* (111, 112). Studies utilizing this strain and chimeras derived from it have greatly enhanced our knowledge of the complete viral life cycle. However, the JFH-1 strain is rather unique and information garnered from studying this strain may not be applicable to other more common strains, in particular genotype 1. Similar results have been obtained with a modified genotype 1 virus, but adaptive mutations were required to maintain *in vitro* replication and infectivity (113).

These approaches are all sequence dependent, and thus results are not necessarily generalizable to other viral strains or genotypes. One sequence-independent system (114) involves a viral cDNA inserted between two self-splicing ribozymes and transfected into human hepatoma cells (114).

This system can be applied to different HCV strains and genotypes to produce HCV particles capable of infecting chimpanzees (115). Others have been able to infect non-transformed human fetal hepatocytes in culture with HCV from genotypes 1, 2, 3 from patient sera and demonstrated the release of infectious virions to the medium (116). Recently, a single human cDNA, SEC14L2, enabled replication of diverse HCV genotypes in hepatoma cell lines (117). SEC14L2-expressing Huh7.5 cells also supported HCV replication directly from patient sera. Mechanistically, SEC14L2 enhances HCV infection by facilitating vitamin E-mediated protection against lipid peroxidation (117). This discovery represents an important breakthrough in developing an HCV cell culture (HCVcc) system in which the virus can be propagated without the need for adaptive mutations, thereby opening up new avenues for studying HCV biology, including drug resistant clinical variants that are emerging even in the new era of DAAs.

The HCVcc system enabled for the first time studies of the entire viral replication cycle, and also led to biophysical and ultrastructural characterization of the HCV virion. Importantly, HCVcc is infectious in chimpanzees and human liver-chimeric mice, permitting the evaluation of vaccine candidates *in vivo* and the development of genetically humanized mice (118). In addition, the recently developed chimeric HCVcc models cover a wide range of viral variants, and will potentially be of importance for future tailoring of the optimal regimens that address all HCV genotypes (119).

To date, cells most permissive to HCV infection *in vitro* are a human hepatoma cell line, Huh7, and its derivatives, including the widely used, RIG-I and innate immunity incompetent Huh7.5 cells. A limitation of the Huh7 cell lines lies in the lack of cell polarity. As such, certain aspects of the viral replication cycle and interaction with lipoproteins may not be reproduced in these cells (120). The polarized HepG2 cells, though refractory to HCV infection due to lack of CD81 expression, can be engineered fully permissive to HCV and support the entire HCV replication cycle upon ectopic expression of human CD81 and miR-122 (121). Primary human hepatocytes (PHHs) represent the natural host for HCV, and HCVcc systems based on PHHs may be

optimized to achieve reproducible and sustained infection in a physiologically relevant manner. Differentiated hepatocyte-like cells (HLCs) derived from both human embryonic stem cells (hESCs) and induced pluripotent stem cells (iPSCs) are permissive to infection of HCVcc and HCV-positive sera *in vivo*, providing exciting new models for study of HCV biology, pathogenesis and clinical HCV isolates (122–124).

#### Host Range and *In Vivo* Models

HCV appears to infect only humans. A study in Gabon failed to detect hepatitis C virus infection in 316 wild-born primates of different species (125). As shown even before HCV was identified, chimpanzees can be experimentally infected with HCV. Although chimpanzees can develop a persistent infection like humans and develop similar inflammatory liver lesions, there are some important differences in disease behavior among the species. Persistent infection occurs after inoculation in only 30 to 40% of chimpanzees (as opposed to 85% in humans), and fibrosis and cirrhosis do not occur (126). The limited availability and the endangered status of chimpanzees, in addition to the financial cost, led to a search for other animal models. Tree shrews (*Tupaia belangeri chinensis*), a species distantly related to primates, can be transiently infected with HCV (127). HCV may utilize the tupaia orthologs of CD81, SR-BI, CLDN1, and OCLN to gain entry into tupaia hepatocytes (128) and induces mild hepatitis within the acute phase of infection (129).

The mechanism for the selective liver tropism is not clear but most likely involves selectivity of one or more of the cell surface molecules responsible for cell entry, although the specific molecule has not been identified. The species tropism of CD81 has been investigated. HCV E2 glycoprotein was shown to bind CD81 from tamarins (*Saguinus* sp.), which are not susceptible to HCV infection (130). Similarly, expression of CD81 from African green monkeys and rats in hepatoma cells confers susceptibility to HCV entry (131).

Mice are naturally resistant to HCV infection—both viral entry and replication are fairly limited in murine cells. Intriguingly, transient expression of human CD81 and OCLN by adenoviral gene delivery enables mouse hepatocytes to be infected by HCVcc, and the derived mouse model has been applied for evaluation of vaccine candidates and entry inhibitors (73, 80). Subsequently, transgenic expression of human HCV entry factors combining blunting of the mouse innate immune responses has allowed the recapitulation of the entire HCV replication cycle, albeit at low levels (81). However the level of HCV replication is still much lower in these reconstituted mouse cells, suggesting other unidentified tropic factors are important.

In an attempt to overcome viral selectivity and establish a small animal model, several groups developed immunodeficient mouse strains harboring chimeric human-mouse livers (132, 133). HCV can replicate in the human-derived hepatocytes of these mice, but the absence of an effective immune response limits the value of this model in studying the pathogenesis of hepatitis C.

## EPIDEMIOLOGY

### Geographic Distribution

Infection with HCV is a global problem affecting up to 2.8% of the world population (134). Great variability exists in seroprevalence rates among various countries and geographic regions (Figure 6) reflecting differences in public health practices, transmission patterns, and surveillance schemes (135). In the developed world, injection drug use is currently the most common mode of infection, and overall seroprevalence is generally low, ranging from 0.6% in Germany to 2.2 to 2.3% in Italy and Japan. The seroprevalence in the United States is reported at 1.6% (135). In the developing world, unsafe injections and contaminated medical instruments seem to be a major risk factor (136). Egypt has the highest reported seroprevalence rate, 22%, attributable to

**FIGURE 6** World distribution of HCV seroprevalence. The highest prevalence is in Egypt. Other countries with high prevalence of infection include Mongolia, Bolivia, and several sub-Saharan nations.

mass public health campaigns of parenteral antischistosomal treatment (137). The WHO estimates that in the year 2000, 2 million people worldwide were iatrogenically infected by reused injection equipment (138).

## Transmission

### Routes

The major route of HCV transmission is parenteral. In the past, transfusion of blood or blood products was the most common means of acquiring infection in the developed world. Post-transfusion hepatitis rates in patients undergoing open-heart surgery, for example, were as high as 33%. Products manufactured from pooled donor blood (such as anti-D globulin or coagulation factor concentrates) were implicated in large outbreaks of infection (139). However, changes in donor selection, including elimination of donor remuneration, exclusion of high-risk populations, screening donated blood for ALT elevations, and the use of recombinant clotting factors, greatly reduced the risk of transmission even before HCV was actually identified (140) (Figure 7). With the implementation of specific HCV tests, first serologic and then nucleic acid based, the risk of transfusion-associated HCV decreased further and is now estimated at 1:600,000 per unit.

With the elimination of blood transfusion as a risk factor, most of the parenteral exposure in the developed world is the result of injection drug use (141). Practices like needle sharing, back-loading, and sharing cotton, rinse-water, and other paraphernalia are associated with transmission. The seroprevalence of HCV antibodies increases with drug use duration, reaching a rate of 60 to 85% for persons using drugs for more than 6 years. Snorting cocaine is also a risk factor for acquiring HCV, probably through contamination of shared snorting devices and nasal mucosal injury. Various risk-reduction measures, such as needle exchange programs, have shown some benefit in reducing transmission, but the overall effect is not optimal (142).

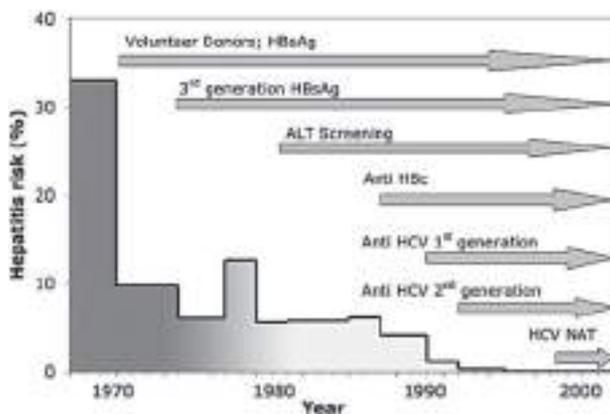

Iatrogenic transmission of hepatitis C virus has been associated with multiple medical and dental procedures (143). Cases of transmission were reported to be associated with

gastrointestinal and pulmonary endoscopy, ambulatory surgical procedures, chemotherapy, administration of anesthesia, radiologic procedures, and in general any procedure involving parenteral access. Patients on hemodialysis are at an especially high risk for nosocomial infection (144) and a large number of outbreaks in dialysis units has been reported. The risk for dialysis patients can be decreased significantly by segregating patients to dedicated rooms and equipment based on HCV serology. In general, most cases of iatrogenic transmission in developed countries are associated with breaches of universal precautions and inadequate infection-control practices, especially with the use of multi-dose vials. The source for most nosocomial outbreaks is a chronically infected patient, although transmission from an infected health-care worker has been documented in rare cases. As previously discussed, in the developing world, iatrogenic infection is associated with reuse of medical instruments, substandard hygienic practices, and treatment by non-professionals.

Healthcare workers are at risk for acquiring HCV infection through needle-stick injuries. The risk is related to the size of the needle, the depth of the injury, intravenous or intra-arterial needles, higher viral load, and male sex (145). Overall, the risk of infection from a needle-stick is usually quoted at 3% based on early reports, although a later analysis suggested the risk is only 0.5% (146).

HCV can be transmitted vertically from mother to child. The risk of transmission is estimated at 2 to 5.5% (147, 148) in HCV mono-infected mothers. The major risk factor for vertical transmission is co-infection with HIV, which increases the transmission risk significantly (149). Other risk factors include maternal viral RNA and ALT level, prolonged labor (more than 6 hours after rupture of the membranes), use of internal fetal monitoring devices during labor, and female sex of the newborn. The risk of transmission with vaginal delivery is not greater than with a caesarean section, and the latter should not be recommended routinely (150). Infection can occur either *in utero* or during delivery; whether postpartum transmission also occurs is not clear. Although HCV has been detected in breast milk from infected mothers, it does not seem to be transmissible by breast feeding and this should not be avoided by HCV positive women (151).

Sexual transmission of HCV was documented in several case reports, but the actual risk for sexual transmission is hard to determine (152). Sexual exposure was found to be the only risk factor in 15% of acute hepatitis C cases (153), and hepatitis C is somewhat more common in high-risk populations for sexually transmitted diseases: HIV infected, sex workers, men who have sex with men, multiple sex partners, and presence of other sexually transmitted diseases. However, studies of long-term monogamous heterosexual spouses of HCV-infected patients demonstrated a relatively low rate of infection, and those studies that utilized detailed analysis found that most infections were associated with other possible risk factors, such as drug abuse, sharing razors, high-risk sexual practices, etc. Moreover, when sequence analysis was used, only a small number of co-infected sexual partners actually harbored the same strains. Two recent studies of low-risk monogamous couples (154, 155) found rates of HCV seropositivity of 2% to 3.8% in spouses of HCV-infected patients, although most infections were attributable to other risk factors. Prospective follow-up at up to 10 years did not identify any new case of interspousal transmission. Thus, sexual transmission is possible but appears to be very inefficient. This observation probably relates to a low titer of the virus in vaginal secretion, semen, and saliva, a lack of

**FIGURE 7** The evolution of screening methods for donated blood and the corresponding decrease in transfusion-related hepatitis. NAT—nucleic acid technology. (Adapted from reference 140.)

target cells in the genital system, and possibly other mechanisms as well.

The efficiency of sexual transmission during acute hepatitis C is less well defined. In a study of Egyptian healthcare workers with documented acute hepatitis C (156), 15% of spouses developed viremia, which spontaneously resolved in half of them. The breadth and magnitude of the polyclonal CD4<sup>+</sup> and CD8<sup>+</sup> T-cell response against HCV was greater in patients who eventually cleared viremia when compared to those who progressed to chronic infection. Interestingly, significant T-cell responses were also seen in some spouses of infected patients, although these spouses never developed viremia or seroconverted. This finding suggests that the host immune system plays a major role in the control of sexually transmitted HCV.

Sexual transmission of HCV by men who have sex with men (MSM) has been well documented in urban areas of North America, Europe, Australia, and Asia (156, 157). In the presence of HIV infection, acute HCV infection has a higher likelihood of chronicity with a more rapid progression to cirrhosis (158). Factors associated with transmission in MSM with HIV include higher viral loads, traumatic sexual practices, the presence of other sexual transmitted infections, and decreased sexual inhibition related illicit drug use in MSM (159–163).

### Risk Factors

Risk factors for infection with HCV stem directly from the routes of transmission discussed above. Thus, in the western world, those at the highest risk for newly acquired infections are individuals who use intravenous drugs and share needles. Among non-drug users, transfusion of blood prior to 1992 or of clotting factors prior to 1987 constitutes a major risk. Patients on hemodialysis, past or present, are also a major risk group. Individuals incarcerated at correctional facilities are at a high risk of exposure to hepatitis C virus, reflecting the prevalence of IV drug use and high-risk sexual behavior in this population. Estimates of HCV seroprevalence in incarcerated inmates range from 16 to 41% with chronic infection detected in 12 to 35% (164). Similarly, homeless persons with severe mental illnesses are also at a high risk for infection.

Promiscuity and high-risk sexual behavior were identified as risk factors for HCV seropositivity in cross-sectional studies (165). Although the prevalence is higher in female sex workers, it seems to be related more to drug-abuse habits than to sexual transmission (166). Similarly, although epidemics of acute hepatitis C were recorded among MSM, this is mostly related to high-risk behavior and drug use (167).

Ethnicity and sex significantly modify the risk for HCV infection. In the United States, men are at a higher risk than women with a prevalence of 2.1% and 1.1%, respectively (135) and African Americans have higher rates than Caucasian Americans. The highest rates were observed in non-Hispanic black males aged 40 to 49 years, for whom the prevalence is a striking 13.6%.

## PATHOGENESIS IN HUMANS

### Incubation Period

Since many acute HCV infections are asymptomatic, it is difficult to define a precise incubation period. However, the relative kinetics of viral levels, liver enzymes, antibody appearance, and symptoms can be described based on obser-

vational studies in humans and experimental infection of chimpanzees. Typically in chimpanzees, HCV RNA is usually detectable in the blood within 2 weeks after HCV inoculation (168). The viral level then quickly rises until onset of hepatitis and activation of host immune response, when viral levels may decrease, fluctuate, or become intermittently positive until either complete viral clearance is achieved or the animal progresses to chronic infection. Once chronicity is established, the viral levels remain relatively stable. Similar patterns are seen in human HCV infection, although viral levels may have much wider fluctuations. Following HCV exposure, patients may have intermittently low-level viremia for a period that may last as long as 2 months but is usually approximately 2 weeks (169). This is followed by a ramp phase lasting 8 to 10 days in which viral levels increase rapidly in an exponential manner with a doubling time of 11 hours. Viral levels then reach a high-titer plateau for about 40 to 60 days. Serum ALT levels, marking liver injury, increase during the plateau phase, typically reaching a peak 7 to 8 weeks after infection. Symptoms and jaundice may appear at that time, although commonly these elevations are asymptomatic and thus often missed. Antibodies against HCV appear shortly after ALT starts to increase and their appearance coincides with a decrease in viremia and either resolution or development of chronicity.

### Patterns of Virus Replication

The selective infection of human hepatocytes by HCV is probably attributable to viral interaction with cell-surface molecules specifically expressed on liver cells. Viral replication in extra-hepatic sites has, on the other hand, been inconsistently demonstrated (170). In peripheral blood mononuclear cells (PBMC), negative strand RNA has been detected (albeit in a minority of cells) in dendritic cells and B-lymphocytes. It has also been suggested that HCV is able to replicate in the central nervous system, possibly in microglia (171).

Quasispecies distribution, and perhaps subgenotypic distribution (172), appears to differ between the hepatic, serum, and the extra-hepatic compartments. PBMC-specific mutations and amino-acid changes occur in the E1-HVR1 region (170) and the IRES region in the 5' UTR (172). Similar findings were reported from clones detected in the central nervous system (171). This may reflect strains with tropism for different organs or emergence of tissue-specific adaptive mutations. The clinical significance of these observations is not clear. The detection of HCV RNA in PBMCs of patients who were treated successfully and are free of viremia and liver disease for a long period, as well as the absence of PBMC-specific strains in the serum of the same patients, all suggest that even if extrahepatic replication occurs in PBMCs, it is associated with low viral replication and perhaps failure to mature or export the virus.

### Factors in Disease Production

The basic histopathologic findings in chronic HCV infection are similar to those of other chronic viral hepatitis (detailed in chapter 5) and can be separated into inflammatory and fibrotic components, thought to reflect the disease activity ("grade") and cumulative damage ("stage"), respectively (173). The characteristic inflammatory component consists of a chronic, predominantly monocytic, cellular infiltration of the portal tracts, which can extend into the limiting plate of hepatocytes bordering the tract ("piecemeal necrosis") and can be accompanied by varying degrees of

necroinflammatory changes in the lobules. Not all components are seen in every biopsy, and these findings probably represent varying degrees of severity. Fibrosis begins by accumulation of extracellular matrix and expansion of the portal tracts. This is followed by formation of septae, which are fibrotic bridges connecting vascular tracts and are mostly porto-portal but also porto-central. Progressive accumulation of these fibrotic bands distorts the liver architecture, and when coupled with regeneration and formation of nodules, is defined as cirrhosis, the end-point of most chronic liver diseases. Various scales have been developed to semi-quantitatively describe those changes. Some histopathologic characteristics, more common in chronic hepatitis C than other chronic viral hepatitis, include the presence of lymphoid aggregates or follicles in the portal tracts (Figure 8a), inflammatory damage to small bile ducts with reactive changes, mild iron overload, and, occasionally, histological

findings similar to autoimmune hepatitis with a predominantly plasma-cell infiltrate.

Steatosis, the accumulation of fat in the hepatocytes, is commonly observed in chronic hepatitis C (Figure 8b), particularly in cases of infection with genotype 3. In non-genotype 3 cases, steatosis mostly reflects the presence of the metabolic syndrome or its components (“metabolic” steatosis), while for genotype 3, steatosis is probably a direct consequence of the viral infection (“viral” steatosis) (174) and appropriately disappears following successful viral eradication (175). The presence of steatosis is associated with accelerated fibrosis and possibly with reduced responsiveness to antiviral therapy.

### Immune Responses

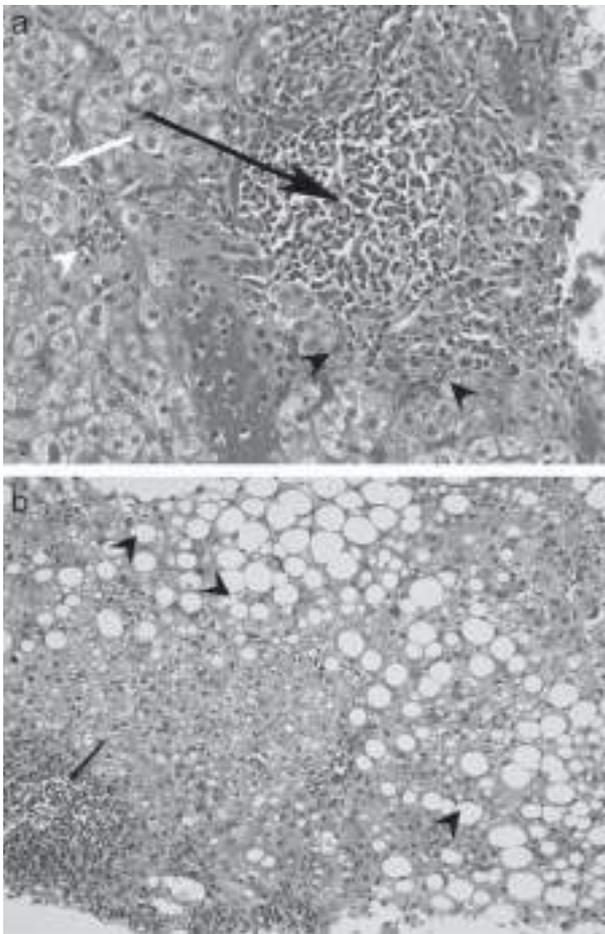

HCV, capable of causing chronic infection in most infected individuals, has multiple mechanisms of evading the immune system. Thus, the discussion of the host’s immune response is coupled here to discussion of viral evasion mechanisms (Figure 9).

### Nonspecific Immune Responses

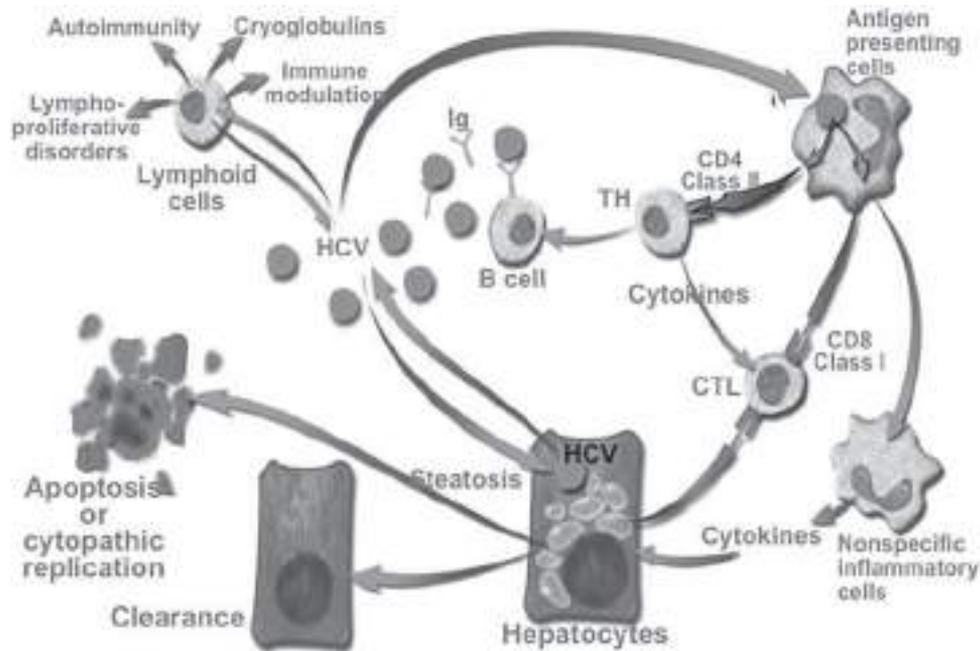

The single-strand RNA genome of hepatitis C contains numerous secondary-structure components. Upon infection of hepatocytes, these secondary structures are detected by toll-like receptor 3 (TLR3) and retinoic-acid inducible gene I (RIG-I), the intracellular detectors of double-stranded RNA (dsRNA). This initiates a cascade of kinase activation that results in induction of interferon- $\beta$  expression and its secretion to the surrounding milieu. Interferon- $\beta$  then acts in an autocrine and paracrine manner, and through dimerization of the type I interferon receptor, activation of Jak1/Tyk2 and of the STAT system induces the transcription of multiple interferon-stimulated genes (ISGs) that confer an antiviral state. HCV has developed several strategies of evading this pathway at multiple levels (176). The afferent arm of the host response, upstream of interferon induction, is effectively blocked by the NS3/4A serine protease, which cleaves and inactivates CARDIF (53) and TRIF (54), the downstream mediators of RIG-I and TLR3, respectively. The interferon-signaling pathway is inhibited by induction of the inhibitory proteins SOCS1 and SOCS3, and by hypomethylation of STAT1, which attenuates its function. Finally, the NS5A and E2 viral proteins inhibit PKR, an interferon-stimulated protein that promotes an antiviral state.

An increased pre-treatment hepatic expression of several ISGs was found in patients who subsequently failed interferon-based treatment (177). Similarly, plasma levels of IP-10 (CXCL-10), another ISG, were higher in patients with a slow response to interferon treatment (178). This observation suggests a maximal, but ineffective, activation of the type 1 interferon pathway in response to HCV infection in some patients. This phenotypic observation has been linked to several single nucleotide polymorphisms in the locus of IFN-lambda genes and point to the importance of this class of interferons in host response to and pathogenesis of HCV infection (179, 180).

Natural killer (NK) cells, the cellular effector arm of the innate immune system, are also important in HCV clearance, chronicity, and pathogenesis of liver damage. NK cells are held under a constant inhibitory influence by interaction of self MHC class I ligands with killer cell immunoglobulin-like receptors (KIRs) on their surface. A specific HLA-C/KIR genotype combination, which has a weaker inhibitory effect on NK cells, increases the rates of clearance of acute HCV infection in patients infected with a small inoculum

**FIGURE 8** Histopathologic findings in chronic hepatitis C. (a) Moderate inflammatory activity. The portal area is expanded by an inflammatory infiltrate and a lymphoid follicle (arrow). The infiltrate disrupts the limiting plate between portal area and hepatic parenchyma (“interface hepatitis”, arrowheads). Foci of lobular inflammation can also be seen (white arrowhead) as well as an acidophil body (white arrow). H&E stain, 400 $\times$  magnification. (b) HCV-associated steatosis. The inflammatory infiltrate (arrow) is accompanied by fat droplets in hepatocytes (arrowheads). H&E stain, 200 $\times$  magnification. **FIGURE 9** The immune response to HCV infection. Hepatitis C infection induces innate and adaptive immune responses. Induction of HCV-specific cytotoxic T-cells by antigen presenting cells is crucial in viral clearance and prevention of chronic infection, through both cytopathic and noncytopathic mechanisms. Antibodies against HCV, secreted by B-cells, appear late and do not seem to have an important role in viral control. Activation of nonspecific inflammatory cells causes liver injury. Chronic stimulation of lymphoid cells can induce autoimmunity and lymphoproliferative disorders including cryoglobulinemia and lymphoma.

(181). This suggests an important role for NK cells in prevention of chronicity. The interaction of NK and dendritic cells is important for dendritic cell (DC) maturation and efficient antigen presentation, which is crucial for recruitment of the adaptive cellular response. The E2 protein of HCV seems to be able to inhibit NK cell activity directly by cross-linking of CD81 receptors on the NK cell surface, and this may be a crucial link in the development of the defective adaptive response discussed below (182).

#### HCV-Specific Humoral and Cellular Immune Responses

The adaptive immune response against HCV tends to be weak and slow in onset as compared to other viral infections (183). Upon acute infection, a specific cellular response appears after 4 to 12 weeks and is correlated with an increase in liver enzymes, marking the cellular immune response as the likely cause of hepatocyte injury, as opposed to viral cytopathicity *per se*. In general, patients who are able to mount a broad and vigorous CD4<sup>+</sup>/CD8<sup>+</sup> response tend to recover spontaneously, while patients who become chronically infected have a late, transient, or narrowly focused and weak response. This defect in cellular immunity is HCV-specific and is not associated with a wider immune deficiency. Moreover, the virus-specific T-cells seem to lose their ability to proliferate and produce cytokines over time during chronic infection (184).

Several mechanisms have been proposed to explain the attenuated cellular response. First, inhibition of NK cells and impaired DC maturation can lead to ineffective antigen presentation to the T-cells. Second, continuous exposure to the persistent viral antigenemia may be the cause of the observed CD8<sup>+</sup> cell functional exhaustion. Third, direct viral inhibition of T-cells may occur; the viral core protein

binds to C1qR on these cells, thereby reducing their function and cytokine secretion. Fourth, escape mutations can develop as a result of the CD8<sup>+</sup> T-cell selective pressure (185). And finally, increased HCV-specific regulatory T-cells in the livers of patients with chronic hepatitis C may be responsible for the down-regulation of T-cell response. Irrespective of the mechanism, it seems that the inability to mount and sustain an efficient CD4<sup>+</sup> response is the hallmark of progression to chronic infection.

HCV-specific antibodies also appear late during the course of acute infection, typically more than 4 weeks after initial infection. Although antibodies against epitopes in the envelope proteins have been demonstrated to protect from infection in a chimpanzee model, these “neutralizing” antibodies are not protective in humans (183). In fact, the titer of these antibodies is highest in patients with chronic HCV infection, and such antibodies are often absent in patients who resolve infection, probably reflecting the rapid emergence of viral escape mutants during active replication (185). In general, anti-HCV antibodies do not seem to play a major role in the pathogenesis, clearance, and chronicity of hepatitis C.

#### Correlates of Immune Protection and Disease Resolution

The presence of cellular and humoral immune responses against HCV does not provide full protection from re-infection. Chimpanzees who recovered from HCV infection can be experimentally re-infected, although the recurrent disease seems to be attenuated in severity. This attenuation is dependent on the presence of both memory CD8<sup>+</sup> (186) and CD4<sup>+</sup> T-cells (187). Re-infection has been reported in human patients in high-risk groups such as active drug users, multi-transfused children with thalassemia and MSM (188,

189). Re-infection is possible after spontaneous recovery, after successful antiviral treatment, and even during treatment. IV drug users who spontaneously cleared viremia are less likely to be infected again upon re-exposure and have lower rates of persistence to chronicity when compared to previously non-exposed controls, as long as they are HIV negative, again suggesting some degree of protection from acquired cellular immunity (190).

Patients who recover from hepatitis C infection have persistent serum antibodies against HCV for a long duration, possibly for life, although a waning titer and sometimes disappearance have been documented after many years. Specific T-cell responses against HCV epitopes also seem to persist for life after spontaneous recovery from acute HCV infection.

## CLINICAL MANIFESTATIONS

### Major Clinical Syndromes: Acute Hepatitis C

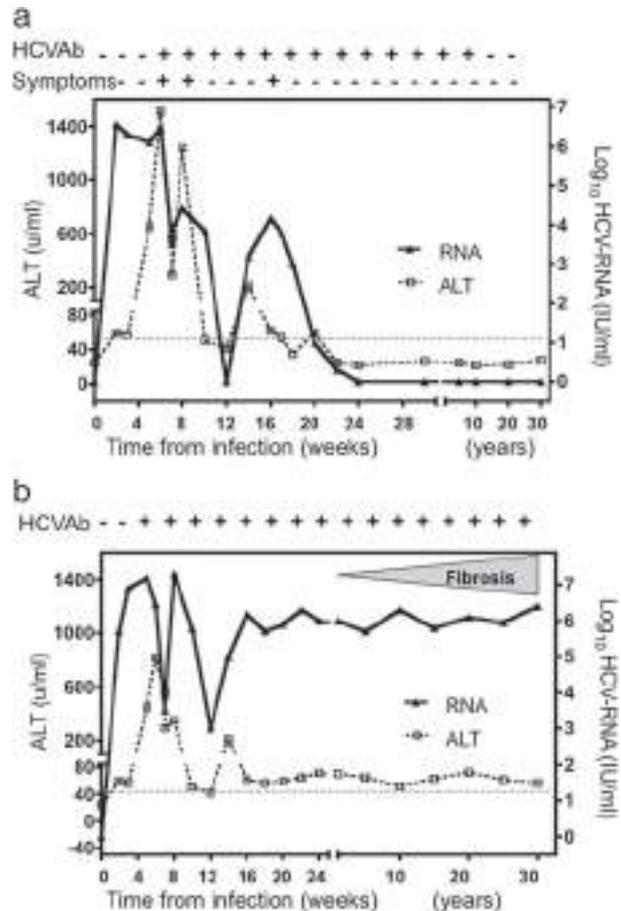

Approximately 3 to 4 million new HCV infections occur worldwide annually (191). Following infection with HCV, most patients develop intermittent viremia and elevated aminotransferases. Symptoms, however, are usually absent or very mild, and thus most cases do not come to medical attention (192). Some patients develop symptoms of hepatitis, which may include nausea, loss of appetite, or jaundice. Only 20 to 50% of patients with acute hepatitis C will resolve, usually within 6 months (median of 16.5 weeks) (Figure 10) (193, 194). In those that do not resolve after 6 months, the chance of spontaneous clearance is low (194). The percentage of resolving cases is a rough estimate, as many cases of acute asymptomatic disease go unnoticed, and is mostly based on serologic cross-sectional studies (195). Young age, female sex, host genetic polymorphisms (especially the IL28B gene), and presence of symptoms seem to be associated with resolution, and so is the vigor and breadth of the immune response (193, 194, 196). Conversely, immune suppression is associated with higher rates of chronicity.

### Chronic Hepatitis C

Approximately 170 million people, or 3% of the world's population, are chronically infected with HCV (197). Chronic hepatitis C (CHC) is usually associated with mild, vague symptoms, if any. The most common symptom reported is fatigue, experienced by 50 to 75% of patients and is associated with age, female sex, and advanced disease (198). A vague, right upper quadrant, pain is sometimes associated with CHC. Other associated symptoms may include arthralgia (23%), paresthesia (17%), myalgia (15%), pruritus, (15%), and sicca syndrome (11%). Some patients present only with symptoms of advanced liver disease, such as jaundice, ascites, or gastrointestinal hemorrhage. Physical findings are usually absent unless cirrhosis is present, in which case, jaundice, splenomegaly, spider angiomas, and other cirrhosis-associated manifestations may be seen.

Mild elevation of aminotransferases is commonly observed, predominantly of alanine aminotransferase (ALT), although up to one-third of asymptomatic patients have persistently normal enzymes (199). Antibodies against HCV, as well as relatively stable levels of serum HCV RNA, are universally present.

As discussed above, liver histology in CHC generally consists of inflammatory infiltrate and some degree of fibrosis, ranging from minimal expansion of portal tracts to cirrhosis. The fibrotic process, driven by liver inflammation, can progress over time, although patients differ greatly in

**FIGURE 10** The clinical course and natural history of HCV infection. (a) Acute, spontaneously resolving hepatitis C. The liver enzyme elevation, symptoms, and appearance of antibodies usually lag behind viremia. Seropositivity persists for years after recovery but may decline after decades. (b) Acute infection progressing to chronic hepatitis C. Viral levels and enzyme elevations are relatively stable in the chronic phase. Accumulation of fibrosis occurs gradually, over many years. The gray dashed line represents the upper limit of the norm for ALT. HCVAb—anti-HCV antibodies. ALT—alanine aminotransferase.

rates of progression. In some patients (non-progressors), no increase in fibrosis is seen over decades of follow-up, while in others, it may progress rapidly to cirrhosis within a few years (200). Since the hepatic complications of CHC are generally limited to cirrhotic patients, defining predictive factors that affect the rate of progression, and thus prognosis, is essential (201). The most important predictors of rapid progression are immune suppression, alcohol consumption, male sex, older age at infection, obesity, and degree of histological activity. Estimates of the percentage of patients who progress to cirrhosis range from 4% to 22% at 20 years of infection, depending on methodology and patient population (202).

### Acute Liver Failure

Few cases of acute liver failure attributable to HCV have been reported (203). Acute HCV infection causing liver failure appears to be very rare; for example, none of the 308

cases observed by the acute liver failure study group in the United States (204) were caused by HCV. A few cases were reported in patients with CHC, developing fulminant liver failure upon withdrawal of immunosuppressive or chemotherapeutic treatment for other disorders. Fulminant liver failure can also be seen in patients chronically infected with HCV who suffer an acute infection with hepatitis A (205) or B (206), although the association with acute hepatitis A has been debated.

### Extrahepatic Manifestations

Although hepatitis C is mostly hepatotropic, extrahepatic manifestations are not uncommon, presenting clinically or solely as laboratory abnormalities. Some are immunologic phenomena while others may reflect actual viral presence in the affected organ. In a large, cross-sectional study (207), 39% of HCV-infected patients had at least one extrahepatic manifestation, most notably various skin disorders, arthralgias, sicca syndrome, and peripheral neuropathy. Autoantibodies, mostly antinuclear antibodies or rheumatic factor, can be detected in 70% of tested sera. Anti-thyroid antibodies are often detected in HCV patients and can be associated with autoimmune thyroid disease,

A common extrahepatic manifestation is HCV-associated mixed cryoglobulinemia (MC, previously termed essential mixed cryoglobulinemia or type II MC). The hallmark of this immunological disorder is the presence in the serum of a cryoprecipitating monoclonal IgM directed against a polyclonal IgG. High concentrations of HCV can be detected within the cryoprecipitate. Low levels of cryoglobulins can be detected in up to 59% of infected patients (208), mostly without clinical manifestations. However, 10% of patients develop small and medium-sized vessel leukocytoclastic vasculitis manifesting as palpable purpura, arthralgias or arthritis, peripheral neuropathy, glomerulonephritis, and occasionally involvement of other organs. The pathogenesis of HCV-associated MC is assumed to be chronic inflammatory stimulation of B-cells with the subsequent formation of a clonal lymphoproliferative disorder and at times, non-Hodgkin's lymphoma (209). Interferon therapy reduces cryoglobulin levels and decreases symptoms during treatment, which is durable only if sustained virological response is achieved. It is currently unknown if the same effect can be achieved with direct-acting antiviral (DAA) therapy for HCV given the mixed case reports and lack of clinical studies (210, 211).

Apart from MC-related purpura, other skin manifestations of chronic hepatitis are pruritus, porphyria cutanea tarda, and lichen planus (208). Autoimmune thyroid disease is also commonly seen. Membranoproliferative glomerulonephritis, with or without cryoglobulins, is the most common renal manifestation of HCV infection. Sjögren-like lymphocytic sialoadenitis is histologically present in three-quarters of patients with hepatitis C, although only a minority have symptoms of the sicca syndrome. Diabetes mellitus type 2 is more frequent in patients with CHC than with control patients or patients with chronic hepatitis B. This may be related to the impaired glucose tolerance seen with cirrhosis, as well as to insulin resistance promoted directly by HCV.

### Disease in Children

Hepatitis C infection in children is usually acquired vertically, and has been reported to occur in 2 to 8% of HCV mono-infected mothers, and perhaps higher in those co-infected with HIV (212, 213). Prior to the era of universal

testing of blood products, transfusion-associated disease accounted for many cases of HCV infection, especially in children with inherited coagulation disorders. Today, it is generally accepted that factors associated with vertical transmission include a high viral load, maternal blood exposure from lacerations during vaginal delivery, prolonged rupture of membranes, and HIV co-infection (212). Current evidence does not support the use of cesarean section to reduce the risk of vertical transmission. In those infected with HCV, during the first 2 decades of life, the disease seems to be mild and asymptomatic, although cirrhosis and complications have been reported (214). Spontaneous clearance of infection in vertically infected children can be seen in 20 to 25% of patients and can occur as late as age 3 years, and occasionally even later. Of the remaining 80%, non-invasive studies suggest mild asymptomatic disease in 50% and active disease in 30% (148). However, liver biopsies, although usually demonstrating mild disease, can also demonstrate progression of fibrosis with prolonged disease duration (215). Thus, although symptomatic disease is not commonly seen in children, it is not clear whether this reflects a true difference in disease behavior from the adult population, or is just reflective of the shorter duration of disease.

### Disease in Immunocompromised Hosts

Immune suppression has a significant effect on the natural history of HCV infection. Co-infection with HIV is common, and it is estimated that 30% of HIV infected patients in the United States and Europe are co-infected with HCV, with even higher rates in hemophiliacs and IV drug abusers (216). Rates of co-infection in Africa appear to be much lower (217), perhaps because the dominant route of transmission for HIV is sexual in these regions. Since the advent of HAART, with prolonged survival of HIV-infected patients, liver disease has emerged as a leading cause of mortality, ranking third only to AIDS-related death and non-AIDS-defining cancers (218). Co-infection is associated with higher serum HCV RNA levels, worse histopathological findings, and accelerated rates of fibrosis. Cirrhosis, HCC, and death from liver disease tend to appear after a shorter duration of infection in co-infected patients. HAART treatment can slow the progression of liver fibrosis, although the rates of drug-hepatotoxicity are increased in co-infected patients. In the past era of interferon-based therapies, treatment success rates were lower in co-infected patients with treatment results directly related to CD4<sup>+</sup> counts (219). However, with direct-acting antiviral (DAA) therapy, co-infected patients now experience similar success rates compared to those who are mono-infected (220).

Organ transplantation, and its associated prolonged immune suppression, can also affect the progression of HCV infection. Patients in need of organ transplantation historically have had higher rates of HCV infection, probably because of the need for blood products and for multiple, invasive, therapeutic, and diagnostic interventions. This is especially true for kidney transplant recipients, for whom hemodialysis is a major risk factor and on whom more data is available. Serum HCV RNA levels increase after kidney transplantation, and this was particularly prominent after a course of anti-lymphocyte antibodies. HCV infection portends worse outcome after kidney transplantation, with decreased graft- and patient-survival, although most deaths are not due to liver disease (221). The limited data on progression of the liver disease in HCV-infected kidney transplant recipients suggest more advanced fibrosis in these patients (222). In hematopoietic stem-cell transplant recipients,

hepatitis C seems to progress more rapidly to cirrhosis compared to non-transplanted patients (223), and pre-existing hepatitis C with elevated enzymes increases the risk for severe veno-occlusive disease, a serious hepatic complication of stem cell transplantation (224). Curiously, cancer chemotherapy and its associated profound immune-suppression may be associated with minor liver enzyme elevations, but rarely with serious flares of hepatitis C.

Liver transplantation for hepatitis C is distinctive, since the infected organ itself is removed and is replaced by an uninfected organ. Re-infection of the graft is universal and is associated with recurrence of hepatitis and cirrhosis in a significant number of patients, resulting in poorer graft and patient survival when compared to patients who had a liver transplantation for indications other than hepatitis C (225). A significant factor affecting survival is the need for immunosuppressive treatment of acute rejection episodes, with bolus steroids, lymphocyte-depleting agents, or anti-IL-2 receptor antibodies. In fact, maintaining a stable immunosuppressive dose and avoiding rapid changes were shown to improve outcome significantly (226).

### Complications

Decompensation and complications may complicate the cirrhosis of CHC. These complications are not unique to infection with HCV and can be seen with other etiologies of cirrhosis. The complications include hypersplenism, bleeding from esophageal or gastric varices, portal hypertensive gastropathy, hepatic encephalopathy, ascites, spontaneous bacterial peritonitis, renal failure, and death. Not all cirrhotic patients are symptomatic or present with complications. Decompensation occurs at an estimated rate of about 4% per year (227, 228).

Hepatocellular carcinoma (HCC) can develop as a complication of cirrhosis, irrespective of the etiology, although some etiologies are associated with a much higher likelihood of HCC. The yearly incidence of HCC in patients with cirrhosis due to HCV infection is estimated at 2 to 8% (229). The risk for non-cirrhotic patients appears to be much lower, although underestimation of the severity of the underlying liver disease may lead to false assurance in these patients. As discussed below, successful eradication of hepatitis C with antiviral treatment significantly reduces, but does not eliminate completely, the risk of HCC.

### Differential Diagnosis

Diagnosis of chronic hepatitis C is straightforward when the appropriate laboratory tests are available. The differential diagnosis of elevated liver enzymes is vast; other causes of infectious hepatitis are discussed in chapter 5. However, a positive serum HCV antibody is almost always a marker of exposure to HCV and a positive serum HCV RNA test is diagnostic for the disease. These tests should be performed on all patients with elevated aminotransferases, and can be used to screen patients with high-risk behaviors (injection drug use or intranasal illicit drug use), high-risk exposures (long-term hemodialysis, healthcare exposures, incarceration, and individuals with HIV), and blood or organ donors. In addition to these patients thought to be at high risk for HCV infection, the Centers for Disease Control and Prevention (CDC) and the United States Preventive Services Task Force recently recommended expansion of risk-based HCV screening guidelines to include a one-time HCV screening in all persons born during 1945–1965, which is a birth cohort that has been demonstrated to have a higher risk of having HCV infection (230, 231).

## LABORATORY DIAGNOSIS

### Virus Detection

Nucleic acid testing is the gold standard for detecting active HCV replication. Detection of viral genome sequence in the plasma, quantitatively or qualitatively, is typically performed using automated assays with sensitivity and specificity nearing 100% (232). Qualitative assays to detect the presence of hepatitis C most commonly utilize reverse transcriptase-polymerase chain reaction (RT-PCR) assays and have a lower detection limit of 50 international units (IU)/ml. Assays based on the transcription-mediated amplification (TMA) method are even more sensitive, with a lower threshold of 5 IU/ml. In most clinical scenarios, a qualitative result is sufficient for the diagnosis and monitoring of patients with chronic and acute hepatitis C. Quantitative measurement of HCV viral load is required before and during treatment of patients to assess their response and can be performed using quantitative real-time RT-PCR. The 2nd quantitative real-time RT-PCR has a high dynamic range and a lower limit of detection of 15 IU/mL. To facilitate standardization, the WHO developed a panel of standard calibration samples and promoted the use of the arbitrary international units. The conversion from copies/ml to IU/ml differs based on the commercial assay used, and ranges from 0.9 to 5.2 copies/ml to 1 IU/ml equivalent.

An assay for detection of an HCV core protein antigen (233) incorporates an immune complex dissociation step (to diminish interference from naturally occurring anti-core antibodies) followed by an enzyme immunoassay (EIA) step. The assay has a detection threshold of 20,000 IU/mL with specificity of more than 99%. Despite the excellent performance of the assay, it is still inferior to nucleic acid detection assays, which becomes positive earlier during the window period.

### Serologic Assays

Serologic assays for detecting HCV infection were rapidly developed and improved following the initial discovery of the virus because of the urgent need to screen blood donors and prevent transmission. The first EIA test contained a single recombinant antigen derived from the NS4 protein and was limited in both sensitivity and specificity. A second generation test, with additional antigens from the core and NS3 proteins, and a third generation test, with reconfigured core- and NS3-based antigen as well as an antigen from NS5, markedly improved test performance and shortened the window period between infection and seroconversion. The currently available third generation assays, especially those utilized in the western world, provide sensitivity of 100% and specificity of nearly 100% when tested against standardized panels. As opposed to their use in diagnosing chronic hepatitis C in a clinically suspected case, the positive predictive value of the EIA tests is lower when they are used for screening of a low-prevalence population, such as blood donors, and often requires a confirmatory test. In the past, a recombinant immunoblot assay (RIBA) could be used to confirm a positive EIA in this setting, although the nucleic acid tests discussed above are superior and RIBA is no longer available. With the current sensitivity and specificity of the EIA assays, a confirmatory test may no longer be necessary in the context of screening a low-risk population (234).

In 2010, the U.S. Food and Drug Administration (FDA) approved the use of a rapid diagnostic test that utilizes immunochromatography to identify HCV antibodies in oral fluid and blood (serum, plasma, or whole blood). This has

facilitated the possibility of point-of-care (POC) testing to improve turnaround time and the making of rapid clinical decisions. While many POC tests are under clinical evaluation, there is currently only one rapid HCV test approved for clinical use by the FDA, which has a >90% sensitivity and >99% specificity for detecting antibodies to HCV. Since these rapid tests are used to identify patients with HCV antibody, they would have limited utility in diagnosis of acute hepatitis C given that HCV antibody can only be detected in 80% of patients after 15 weeks of exposure.

## PREVENTION

### General

Persons infected with HCV should be advised to avoid sharing toothbrushes, razors, nail clippers, and other personal care articles that may become contaminated with blood (235). Patients in a long-term heterosexual monogamous relationship need not alter their sexual practices, although testing the partner for exposure and counseling on the potential risk is advised. Couples may consider the use of barrier protection to reduce the already low risk, or during higher risk sexual practices such as anal sex or intercourse during menses. Persons involved in high-risk sexual behavior (multiple partners, violent sex, sex workers, etc.) should be advised to use barrier protection to prevent HCV transmission and infection with other sexually transmitted diseases (152). Drug users should be counseled to avoid sharing of needles, syringes, and other injection and snorting paraphernalia. Needle-exchange programs have been shown to reduce HCV seroprevalence.

Since alcohol consumption is associated with acceleration of liver injury and fibrosis, minimizing alcohol intake should be recommended for all patients. Routine vaccination against hepatitis A and B viruses should be done to reduce the risk of superinfection and potential liver failure.

### Passive Immunoprophylaxis

Passive immunoprophylaxis against HCV reinfection has been attempted in the context of liver transplantation, in light of the success in the use of hepatitis B immunoglobulin to prevent HBV reinfection of the graft. Anti-HCV-enriched human immunoglobulin preparation failed to prevent re-infection in HCV patients after liver transplantation (236). The use of a monoclonal anti-E2 antibody in this setting in a phase 2, randomized, controlled trial had only a transient effect on viral levels (237). This same antibody demonstrated short-term (less than 48 hours) reduction of viral levels when administered to non-transplanted patients with chronic hepatitis C (238). With further development of broadly neutralizing antibodies, it is possible that passive protection may still be achievable (239–241).

### Active Immunization

Despite remarkable recent advances in the understanding, testing, and treatment of HCV, the field of prophylactic vaccine development for HCV has lagged significantly behind. Although therapies for HCV are rapidly evolving, the development of a vaccine remains paramount given the current global public health burden of HCV, current and projected future cost of care, and lack of accessibility of care in less-industrialized countries. Over the past few decades, many attempts have been made to develop an HCV vaccine; however, all have failed at various stages of clinical development (242). The difficulty in designing an effective HCV

vaccine is multifaceted, including: (i) an incomplete understanding of the mechanisms of protective immunity in HCV infection (242); (ii) design of a vaccine that can encompass the HCVs worldwide genetic diversity (243); (iii) HCVs ability to hide from the antibody response (244); (iv) HCV's ability to alter the activation of T-cells with resultant ineffective cell-mediated immunity (184, 245); and (v) the lack of convenient and authentic experimental animal model systems for vaccine development (246).

Currently, various candidate vaccines are in different stages of clinical development. While many candidate vaccines have utilized various viral vectors including adenovirus, vaccinia virus, modified vaccinia Ankara (MVA), fowl pox viruses, and other viruses with the aim of delivering various HCV structural and nonstructural antigens for induction of T-cell-mediated immunity, the adenoviral vector seems to be the most promising due to their ability to induce robust CD4<sup>+</sup> and CD8<sup>+</sup> T-cell responses with a predominant T<sub>H</sub>1 phenotype (247–250). Other vaccine vehicles include HCV viral proteins, DNA immunization, and virus-like particles (VLPs) that induce both humoral and cellular arms of the immune response and/or peptides that target specific T-cell epitopes and biological adjuvants that hope to have efficacy in humans. With continued efforts in the field of HCV vaccination, the hope is that this field will catch up to the treatment field to provide a two-pronged attack for global eradication of HCV infection in humans.

### Antiviral Chemoprophylaxis

As discussed below, in documented cases of acute HCV infection, antiviral treatment is withheld for 8 to 16 weeks to allow the patient a chance to clear the virus on their own. Because interferon and ribavirin are expensive and fraught with side effects, chemoprophylaxis after exposure or in high-risk populations is not advised. However, with the approval of highly effective oral antivirals against HCV, post-exposure prophylaxis with DAAs has yet to be explored and will be an interesting topic to revisit in the future. Additionally, the use of DAAs as prophylaxis during the anhepatic phase of liver transplantation has only been described in a case report and formal investigation is still lacking (251).

### Management of Outbreaks

Outbreaks of hepatitis C associated with a single source of transmission are often detected late as most cases of acute infection are asymptomatic and go unnoticed. Iatrogenic outbreaks as a result of contaminated medical or dental instruments or contaminated injections/infusions have been reported (137, 139, 252, 253). Recently, outbreaks among communities of MSM and persons who inject drugs (PWID) have been reported to be on the rise and appear to be the major route of HCV transmission in the developed countries (254). When such an outbreak is detected, screening of all potentially affected patients, reviewing of potential breaches of standard care, and offering of treatment to infected individuals should be undertaken.

### Prevention of Perinatal and Congenital Infection

Although HCV can be transmitted vertically, there is no effective method to prevent transmission. Caesarean section was not proven to prevent infection of the newborn and should not be recommended routinely for HIV-negative mothers (150). Invasive fetal monitoring during pregnancy appears to be associated with increased risk of transmission (147). Thus, it is prudent to avoid invasive monitoring if possible without compromising maternal or fetal safety.

## TREATMENT

### Indications for Therapy and Monitoring of Response

In general, antiviral treatment is indicated for all patients with chronic hepatitis C who are viremic, except those with significant co-morbidity due to non-liver related conditions (255). Normal aminotransferase levels should not exclude patients from therapy, as up to one-third of patients may have advanced disease on histopathology. The goal of therapy in those infected with HCV is a reduction in all-cause mortality and liver-related adverse health consequences. A liver biopsy, while invasive, is the diagnostic gold standard and is helpful in determining the degree of disease severity to provide prognostic information. More recently, the use of noninvasive fibrosis biomarkers utilizing indirect (routine tests) or direct (components of extracellular matrix produced by activated hepatic stellate cells) serum biomarkers and vibration-controlled transient elastography has gained popularity and is an acceptable substitute in assessing fibrosis in chronic HCV infection (255, 256). Based on available resources, it is currently recommended that patients with advanced fibrosis, compensated cirrhosis, liver transplant recipients, and those with severe extrahepatic HCV manifestations should be considered as high priority for therapy (255). However, there is emerging evidence that demonstrates a greater benefit in patients who are treated at an earlier stage of hepatic fibrosis (257–259).

Response to therapy, assessed by quantitative RT-PCR, is the standard-of-care during and after therapy. A sustained virological response (SVR) is defined as a negative HCV RNA test after a defined time period after completion of therapy. Achieving an SVR, inherently a virological outcome, is an accepted surrogate marker for beneficial clinical outcomes, and has been equated with “being cured of HCV” in the public domain. Those that are persistently HCV RNA negative post-therapy are less likely to progress to decompensated liver disease, to die from hepatic causes, or to develop hepatocellular carcinoma, even if they already have established cirrhosis (260, 261). In general, the likelihood of relapse later than 6 months after treatment (the currently accepted time point for SVR determination) is very low and re-appearance of HCV viremia more frequently indicated reinfection rather than relapse. Although HCV RNA sequences can occasionally be detected by PCR or TMA in peripheral blood mononuclear cells (PBMCs) or liver tissue (see above), this has not been shown to be associated with enzyme elevation or histological worsening of liver disease and the significance of these findings remains unknown. Historically, a SVR was defined as 24 weeks after the end of treatment; however, a large retrospective analysis from five phase III studies, performed in 2015, described a high rate of concordance between 12 and 24 weeks post-therapy (262). An undetectable HCV RNA 12 weeks after therapy is currently accepted by clinicians and regulatory authorities as a primary endpoint of therapy and an SVR.

### The Historical Era of Interferon-Based Therapy

The first use of interferon for chronic non-A non-B hepatitis was evaluated at the National Institutes of Health Clinical Center in 1984 and the first patient was cured of HCV with interferon therapy shortly thereafter (263, 264). Interferon induces a multitude of host genes that promote an antiviral state. These seminal pilot studies evaluating interferon for HCV led to the initiation of two randomized controlled trials which subsequently led to FDA approval

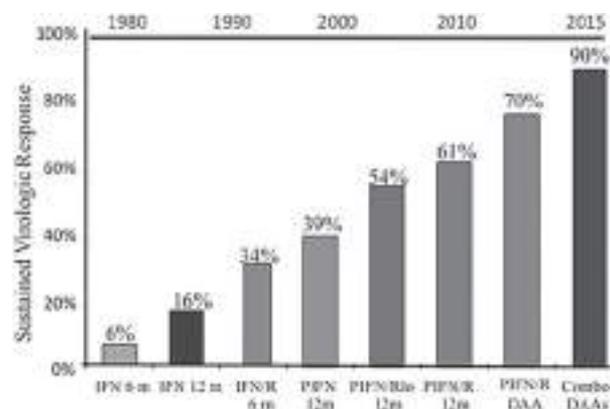

the use of interferon  $\alpha$ -2b for chronic hepatitis C in 1991 (265, 266).

Despite the initial enthusiasm of the use of interferon for chronic HCV infection, this therapeutic modality had an SVR rate of only 6% after 24 weeks of therapy and 13 to 19% with 48 weeks of therapy (267, 268). These SVR rates were even worse when evaluated according to HCV genotype, whereby genotype 1 infection resulted in less than a 2% SVR with 24 weeks of therapy and 7 to 11% SVR rate with 48 weeks of therapy.

The next major improvement with interferon-based therapies occurred in the early 1990s, after ribavirin was noted to have anti-HCV activity (269–272). Subsequent large-scale studies evaluating the combination of interferon- $\alpha$  and ribavirin revealed increased SVR rates to 16% with 24 weeks of therapy and 42% with 48 weeks of therapy (271, 273, 274). Within the next decade, SVRs became associated with favorable long-term clinical outcomes, and the combination of interferon and ribavirin was approved as the standard-of-care for the treatment of chronic HCV.

Thereafter, subsequent improvements to the delivery of interferon were achieved by attaching a polyethylene glycol (PEG) molecule to interferon, thereby prolonging the half-life of interferon and further improving response rates to interferon-based therapies (275, 276). When used in combination with ribavirin, pegylated interferon (peginterferon) induced an SVR in up to 46% of patients with HCV genotype 1 infection and up to 82% in patients infected with genotype 2 and 3 infection (Figure 11) (277, 278). Therefore, peginterferon- $\alpha$  with ribavirin became the standard-of-care for all genotypes of chronic HCV infection only differing by duration of therapy (48 weeks for genotypes 1 and 4 and 24 weeks for genotypes 2 and 3).

Dual therapy with peginterferon and ribavirin (7) demonstrated a biphasic response, with a rapid decline over the first 2 days and a slower, second-phase decline lasting at least up to day 14 of treatment. Mathematical modeling applied to these data suggested that the first phase represented rapid clearance of the virus from serum on the basis of inhibition of replication and of new virion production by interferon. The second phase corresponded to the death and clearance of infected cells in addition to inhibition of viral replication. With this early therapeutic modality, failure to achieve an early virological response (EVR) (defined as negativity or

**FIGURE 11** The evolution of treatment regimens for chronic hepatitis C and the corresponding rates of sustained virological response. IFN—interferon alpha. PIFN—pegylated interferon alpha. R—ribavirin. DAA—direct-acting antiviral therapy.

more than a 2 log decrease in viral load by week 12) or to become HCV-RNA by week 24 of treatment (279), had a very high (>95%) negative predictive value for response and allowed clinicians to terminate the treatment course early for some patients. Aside from the assessment of on-therapy virological response and infecting genotype as predictive factors of response, a high pre-treatment viral load, African-American race, obesity, advanced fibrosis, and a host IL28B TT genotype were all unfavorable factors for interferon-based therapy.

Along with response rates <50% with interferon-based dual therapy for CHC, the side effects of interferon made this therapeutic modality very difficult for patients to tolerate for 24 to 48 weeks (277, 278). Among the various notable side effects of interferon, hematologic toxicity (especially neutropenia (280) and thrombocytopenia) was the most common reason for dose reduction or interruption and occurred in up to 20% of patients. Interestingly, psychiatric side effects of interferon, especially depression, were more common in HCV patients than in patients with chronic hepatitis B treated with the same doses.

In acute HCV infection, treatment indications and regimens are less standardized. Much of this is due to the lack of large-scale studies for acute HCV infection. Currently, treatment should be deferred for 12 to 16 weeks from the time of infection, to allow for possible spontaneous clearance to occur, especially in symptomatic patients. One randomized phase III study with interferon-based therapy demonstrated non-inferiority between starting therapy at the time of diagnosis versus delaying therapy for 12 weeks after identification of acute infection (281). Treatment can be offered using standard or peginterferon monotherapy. Treatment for genotype 1 infection should probably last 24 weeks while for genotypes 2, 3, or 4, a course of 8 to 12 weeks of treatment seems to be sufficient (282). A high likelihood of treatment success, with SVR rates above 90%, was reported in several series, suggesting that, at least for genotype 1 infection, treatment before chronicity develops should be attempted whenever possible (283).

### Ribavirin

Ribavirin (RBV) is a synthetic oral guanosine nucleoside analogue that was initially identified to have broad-spectrum antiviral activity against both DNA and RNA viruses in *in vitro* and *in vivo* models (284). In HCV as monotherapy, it demonstrated improvement in aminotransferase levels but not in decreasing viral load *in vivo* (269, 270, 285–288). However, as discussed in the previous section, when utilized in combination with interferon or pegylated interferon, ribavirin significantly improved SVR rates and became the standard-of-care for over 10 years.

Despite the utility of RBV for HCV, the mechanism of action of ribavirin in HCV has never been fully elucidated. Various mechanistic hypothesis have been proposed, including: (i) RNA viral mutagenesis through incorporation of ribavirin triphosphate into the HCV viral genome resulting in nucleotide transitions; (ii) direct inhibition against HCV RNA dependent RNA polymerases leading to inhibition of genome replication; (iii) alteration of the host adaptive immune response through Th2 response suppression and Th1 response induction leading to increased clearance of infected cells; (iv) inhibition of host inosine monophosphate dehydrogenase resulting in decreased synthesis and lower GTP levels and subsequent inhibition of genome replication; and (v) potentiation of interferon activity through modulation of genes involved in interferon signaling and/or an indirect

mechanism that may act to reset interferon-responsiveness in an HCV-infected liver (289–295).

Before the current era of direct-acting antiviral (DAA) therapy, ribavirin was administered orally twice daily, dosed according to weight and genotype. Patients with genotypes 1 or 4 infection were treated with peginterferon and weight-based ribavirin (1,000 mg in those <75 kg and 1,200 mg in those ≥75 kg) for 48 weeks, while for patients with genotypes 2 or 3, a 24-week course of peginterferon with 800 mg of ribavirin was sufficient (296). In the current era of DAA therapy, weight-based ribavirin therapy still plays a role in certain therapeutic regimens with an improvement in SVR rates (297).

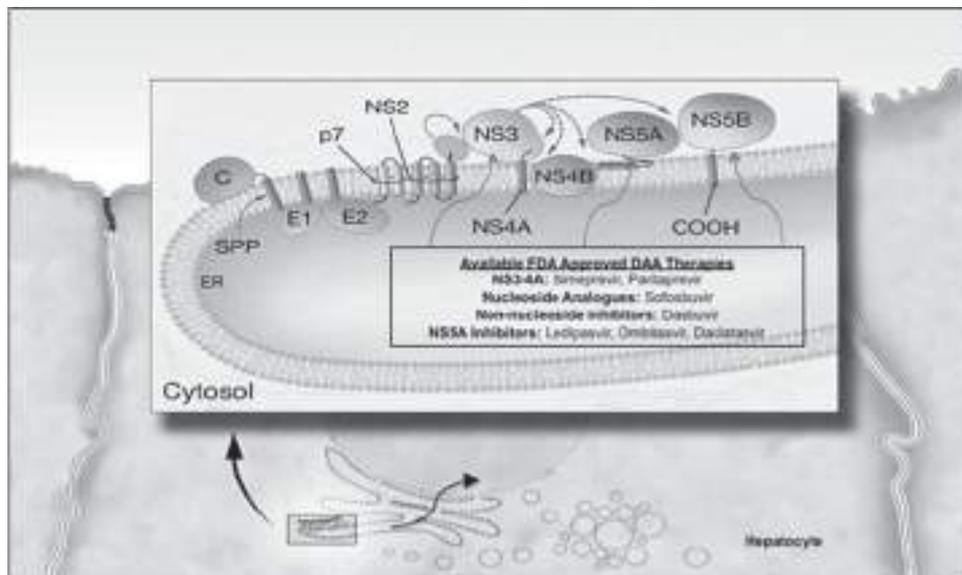

During the era of dual therapy with peginterferon and ribavirin, ribavirin-induced hemolysis played a large role in dosing limitations. The side effects of ribavirin were managed mainly by dose reduction, although this approach was undesirable as significant dose-reduction (>20%) was associated with decreased response rates to treatment (298), especially if dose adjustments were made early in the treatment course.

### The Era of Direct-Acting Antiviral Therapy for HCV

With the less-than-optimal response rates to interferon-based therapies, especially for genotype 1 patients, along with the side effects, different therapeutic strategies were sought. The development of new therapeutic targets was promoted by the development of a genotype 1 subgenomic and genomic replicon system and the identification of a genotype 2a JFH1 clone (299). These new model systems allowed for the identification of the steps of the HCV life cycle, further allowing for the development of new therapeutic targets (Figure 12). As a result, in 2011, the first DAA therapies, boceprevir and telaprevir, were approved by the FDA for use as “triple therapy” in combination with peginterferon and ribavirin in patients with chronic HCV genotype 1 infection (300–304). These first-generation DAAs inhibited the HCV NS3/NS4A protease by binding to the active site, thereby inhibiting HCV replication, and significantly increasing SVR rates in HCV genotype 1 infection to 69 to 75% when used as “triple therapy” with peginterferon and ribavirin (300, 301). These DAA regimens quickly became the standard-of-care for chronic HCV genotype 1 infection in 2011 (305). However, these first generation DAAs have a low barrier to resistance, leading to the rapid selection of resistance-associated variants when used either alone or in combination with peginterferon and ribavirin, and were poorly tolerated, especially when used as triple therapy (with serious adverse events and even death), and had low response rates in prior null responders to peginterferon and ribavirin (306, 307).

The development of HCV DAAs has progressed rapidly, and in 2012, several phase II studies demonstrated that it was possible to cure chronic HCV infection without the use of peginterferon- $\alpha$  (308–310). Subsequent phase III studies have confirmed this finding, especially with improved understanding that therapeutic targets can be directed at blocking different steps in the HCV replicative cycle (311, 312). Currently, the therapeutics under drug development include NS3-4A protease inhibitors, nucleotide analogue and non-nucleoside inhibitors of the HCV RNA-dependent RNA polymerase (RdRp), and inhibitors of the non-structural 5A (NS5A) protein (Table 3).

Simeprevir (a NS3/4A protease inhibitor), which was the third DAA to receive FDA approval in 2013 for use in combination with peginterferon and ribavirin for genotype 1

**FIGURE 12** Currently FDA approved direct-acting antiviral therapy for hepatitis C includes NS3-4A protease inhibitors, nucleotide analogue, and non-nucleoside inhibitors of the HCV RNA-dependent RNA polymerase (RdRp) and inhibitors of the non-structural 5A (NS5A) protein.

infection. This regimen achieved SVR in 80% of treatment-naïve patients and in 79% of treatment-experienced relapsers. Two weeks after simeprevir's approval, the first multi-genotypic DAA sofosbuvir, received FDA approval for use in genotypes 1, 2, 3, and 4 infection. This drug was the first of the nucleotide analogues to be approved for use in CHC. In genotypes 1 and 4, sofosbuvir was approved for use with peginterferon and weight-based ribavirin for 12 weeks. In genotype 2, sofosbuvir was approved for use with weight-based ribavirin without interferon for 12 weeks and in genotype 3 for 24 weeks. This approval heralded a new era of interferon-free therapies.

#### HCV Genotype 1 Therapy

In contrast to interferon-based therapies, the paradigm has shifted and genotype 1 is no longer difficult to treat in the current era of DAAs.

##### Simeprevir and Sofosbuvir Combination Therapy

The combination of simeprevir (a NS3-4A protease inhibitor) and sofosbuvir (a nucleoside analogue) was the second interferon-free DAA regimen approved for use in HCV genotype 1 infection. One phase III study that demonstrated a  $\geq 95\%$  SVR rate in those without cirrhosis regardless of viral subtype (1a or 1b) when treated for 12 weeks (313). Another phase III study demonstrated an overall SVR rate of 83% in cirrhotic patients (88% in treatment-naïve patients and 79% in prior non-responders to peginterferon and ribavirin dual therapy patients) and an SVR rate of 74% in genotype 1a patients with cirrhosis (314). Based on the results from these large studies, the combination of simeprevir and sofosbuvir can be administered for 12 weeks in patients without cirrhosis and 24 weeks with or without ribavirin in those with cirrhosis.

##### Sofosbuvir and Ledipasvir Combination Therapy

In late 2014/early 2015, the combination of the sofosbuvir (a nucleotide analogue) and ledipasvir (an NS5A inhibitor) was approved for use in HCV genotype 1 in the United States and genotypes 1, 3, and 4 in Europe. Phase III

studies demonstrated a  $>90\%$  SVR rate when used with or without ribavirin for 12 to 24 weeks in both treatment-naïve and treatment-experienced patients (315–317). In patients with cirrhosis (compensated and decompensated) and those in the pre- and post-liver transplant setting, SVR rates ranged from 85 to 95% depending on the severity of disease (318–321). The combination of sofosbuvir and ledipasvir for 12 weeks of therapy in treatment-naïve or treatment-experienced patients without cirrhosis, and 24 weeks in treatment-experienced patients with cirrhosis is appropriate.

##### Ombitasvir, Dasabuvir, and Ritonavir-Boosted Paritaprevir Combination Therapy

Shortly after the approval of sofosbuvir and ledipasvir, the DAA combination of ombitasvir (an NS5A inhibitor), dasabuvir (a nonnucleoside NS5B polymerase inhibitor), and ritonavir boosted paritaprevir (an NS3/4A protease inhibitor) received FDA approval for the therapy of HCV genotype 1 infection. Phase III studies demonstrated SVR rates  $>95\%$  in genotype 1a patients when used in combination with weight-based ribavirin and approximately a 90% SVR rate when used without ribavirin. In genotype 1b patients, SVR rates were  $>97\%$  without the use of ribavirin. Thus, this fixed-dose regimen can be used with weight-based ribavirin for 12 weeks in genotype 1a patients without cirrhosis and 24 weeks in those with cirrhosis. For genotype 1b patients, the fixed dose DAA combination is recommended for 12 weeks without ribavirin.

##### Daclatasvir and Sofosbuvir Combination Therapy

In July 2015, the FDA approved the use of daclatasvir (an NS5A inhibitor) for use with sofosbuvir for genotype 3 HCV infection. Although this combination was not yet approved for use in genotype 1 infection, existing data from several studies suggested efficacy in genotype 1 infection (255). In one phase IIB study and two phase III studies evaluating daclatasvir and sofosbuvir for 12 and 24 weeks in various genotype 1a and 1b populations (with and without cirrhosis, co-infected with HIV), SVR rates  $>95\%$  were achieved in genotype 1b infection with 12 weeks of therapy (322–324).

**TABLE 3** Direct-acting antiviral therapeutic targets, mechanisms of action, and approved and investigational therapies

HCV target	Mechanism of action	Drug name	HCV genotype activity	FDA status	Status
NS3-4A protease inhibitors	Bind to the catalytic site of the NS3-4A protease and block post-translational processing of the viral polyprotein	Telaprevir	1	Approved	No longer available
		Boceprevir	1	Approved	No longer available
		Simeprevir	1,2,4	Approved	In use
		Paritaprevir	1,2,4	Approved	In use
		Asunaprevir	1,2,4	Not approved	Under development
		Sovaprevir	1,2,4	Not approved	Under development
		Vaniprevir	1,2,4	Not approved	Under development
		Vedoprevir	1,2,4	Not approved	Under development
		ACH-2684	All	Not approved	Under development
		ABT-493	All	Not approved	Under development
		Ciluprevir	All	Not approved	Under development
		GS-9857	All	Not approved	Under development
		IDX320	All	Not approved	Under development
Grazoprevir	All	Not approved	Under development		
Nucleoside/Nucleotide analogues	Function as false substrates for the HCV RdRp and lead to chain termination after incorporation into synthesized viral RNA	Sofosbuvir	All	Approved	In use
		ACH-3422	All	Not approved	Under development
		AL-335	All	Not approved	Under development
		MK-3682	All	Not approved	Under development
Non-nucleoside inhibitors of the HCV RdRp	Bind to one of four allosteric sites of the enzyme and change the conformation of the RdRp which results in blocking of its catalytic function	Dasabuvir	All	Approved	In Use
		Beclabuvir	All	Not approved	In development
		GS-9669	All	Not approved	In development
NS5A inhibitors	Bind to domain 1 of the NS5A protein, thereby blocking regulation of HCV replication. Also inhibit assembly and release of viral particles	Ledipasvir	1,2,4	Approved	In use
		Ombitasvir	1,2,4		
		Daclatasvir	All		
		Elbasvir	All	Not approved	In development
		ACH-3102	All	Not approved	In development
		ABT-530	All	Not approved	In development
		Odalasvir	All	Not approved	In development
		Velpatasvir	All	Not approved	In development
		MK-8408	All	Not approved	In development
GS-5816	All	Not approved	In development		

However, in those with cirrhosis (genotype 1a or 1b) or genotype 1a infection, SVR rates were only reached in 76% with or without ribavirin. Based on this information, this combination can be administered for 12 weeks in treatment naïve genotype 1b patients without cirrhosis whereas 24 weeks of therapy with or without ribavirin can be instituted in treatment naïve genotype 1b patients with cirrhosis or all patients with genotype 1a infection.

#### HCV Genotype 2 Therapy

With interferon-based therapy, genotype 2 infection was considered as an easy-to-treat genotype. Interferon-free DAA regimens also provide very high response rates; however, some available therapies still require the use of ribavirin.

##### Sofosbuvir with Weight-Based Ribavirin Combination Therapy

One of the earliest approved interferon-free regimens for chronic HCV infection was for the treatment of those with

HCV genotype 2 or 3 infection. Phase II and III studies described an SVR rate of approximately 94% in genotype 2 infection (325–328). Thus, the combination of sofosbuvir plus weight-based ribavirin for 12 weeks has been used in patients with genotype 2 infection with extension to 16 weeks in patients with cirrhosis (255).

##### Daclatasvir and Sofosbuvir Combination Therapy

In 2015, the combination of daclatasvir and sofosbuvir, while not FDA approved for genotype 2 infection, has been utilized as an off-label therapy. Studies have demonstrated SVR rates >92% in treatment naïve patients with both 12 and 24 weeks of therapy (324, 329). Thus, this regimen has been utilized for 12 weeks in treatment naïve patients or those who are unable to tolerate ribavirin therapy.

##### HCV Genotype 3 Therapy

In the era of interferon-free DAA therapy, HCV genotype 3 has become the “difficult-to-treat” population. Many of the

available DAA therapies are significantly less effective in this population and have a high rate of viral resistance. In fact, in 2015, it was the only genotype for which pegylated interferon was still recommended as a first-line therapy to be used in conjunction with a DAA (255).

#### **Peginterferon, Ribavirin, and Sofosbuvir Combination Therapy**

In a phase III, triple-arm, clinical trial, patients treated with the combination of peginterferon, ribavirin, and sofosbuvir for 12 weeks achieved 95% SVR rate compared to rates of 77% for 16 weeks and 88% for 24 weeks of therapy without peginterferon (330). Prior to this study, other studies have described an overall SVR rate of 84%, which was higher in treatment naive (93%), compared to treatment experienced (77%) patients (326, 328, 331). Given these results, in 2015, first-line therapy for genotype 3 infection utilizing sofosbuvir includes the combination of ribavirin plus weekly peginterferon for 12 weeks, and second-line therapy for those who cannot tolerate interferon includes sofosbuvir and weight-based ribavirin for 24 weeks.

#### **Daclatasvir and Sofosbuvir Combination Therapy**

As mentioned above, the combination of daclatasvir with sofosbuvir was approved in 2015 by the FDA for therapy of HCV genotype 3 infection. One phase III study demonstrated a 97% SVR rate in treatment naive patients without cirrhosis, and a 58% SVR rate in those with cirrhosis (332). As such, this regimen has been administered for 12 weeks in those without cirrhosis and 24 weeks with or without weight-based ribavirin in those with cirrhosis (255).

#### **HCV Genotype 4 Therapy**

During the era of interferon-based therapies, treatment recommendations for genotype 4 were identical to that of genotype 1 as both were thought to be “difficult-to-treat” populations. Therefore, dual therapy with peginterferon and ribavirin was administered for 48 weeks. The combination of sofosbuvir with weekly peginterferon and weight-based ribavirin resulted in a 96% SVR rate when administered for 12 weeks (331). In the current DAA era, while there are no FDA approved therapies or phase III studies for genotype 4 infection, data suggest that three DAA combinations may be effective for those infected with this genotype.

#### **Ledipasvir and Sofosbuvir Combination Therapy**

In two small phase II studies, a 95 to 100% SVR rate was seen with the combination of ledipasvir and sofosbuvir for 12 weeks in treatment-naive and treatment-experienced patients regardless of fibrosis stage (333, 334). Therefore, therapy with this combination has been used off-label in genotype 4 patients for 12 weeks.

#### **Ombitasvir, Dasabuvir, and Ritonavir-Boosted Paritaprevir Combination Therapy**

The combination of ombitasvir (an NS5A inhibitor), dasabuvir, and ritonavir-boosted paritaprevir with or without ribavirin was evaluated in a small phase IIb study (335). This study evaluated this therapeutic regimen for 12 weeks in 86 treatment naive patients without cirrhosis and resulted in a 100% SVR rate in those that received weight-based ribavirin, and a 91% SVR rate in those that did not receive ribavirin. Given these results, this combination has been used off-label with weight-based ribavirin for 12 weeks in treatment-naive patients with genotype 4 infection.

#### **Sofosbuvir with Weight-Based Ribavirin Combination Therapy**

The combination of sofosbuvir with weight-based ribavirin (336, 337) given for 24 weeks appears to be better than 12 weeks of therapy, with SVR rates above 90%. However, in HIV/HCV co-infected patients, only 84% achieved an SVR (338). Thus, this combination has been administered for 24 weeks in treatment-naive patients infected with HCV genotype 4.

#### **HCV Genotypes 5 and 6 Therapy**

Historically, there has been a paucity of data in treating patients with HCV genotype 5 or 6 chronic infection, even during the era of combination therapy with peginterferon and ribavirin. Although these genotypes are seen worldwide they are seen in much lower frequencies than genotypes 1 to 4. During the early availability of sofosbuvir, only 7 patients (1 with genotype 5 and 6 with genotype 6) were treated with the combination of sofosbuvir plus peginterferon and weight-based ribavirin for 12 weeks, all of whom achieved an SVR (331).

Ledipasvir and sofosbuvir is the only interferon-free DAA combination that has been evaluated for genotype 5 or 6 infection. In two small open-label studies an SVR rate of approximately 96% has been demonstrated with this regimen when treated for 12 weeks (255, 339).

#### **Future Therapeutic Development**

Aside from the various therapeutic targets identified in the HCV replication cycle, including studies evaluating sofosbuvir and the new NS5a inhibitor velpatasvir, future potential targets of therapy include miR122, HCV p7, immune modulatory agents, and viral entry inhibitors. Micro RNA-122 (miR-122) is highly expressed in the liver and has been shown to be essential in HCV replication, and is therefore a potential therapeutic target (27, 340). HCV p7 is a membrane-associated ion channel protein that is essential for capsid assembly and envelopment (341). Current immunomodulatory drug targets under investigation for HCV include TLR-7 agonists, caspase inhibitors, PD-1 receptor antibody therapy, and others. In an ongoing multi-center phase 1 study targeting miR-122 in HCV infected patients, preliminary results of this target appear promising with pangenotypic activity (342).

Viral binding and entry into the target cell have been areas of active research. Through targeting these mechanisms, one can prevent the initial step of entry of viral genomic material that can persist in infected cells (343). Although the entry of HCV is complex, numerous host receptors and pathways have been identified (344). Current potential targets of entry factors include heparin sulfate proteoglycans, scavenger receptor class B type I (SR-BI), CD81, claudin-1 (CLDN1), occluding (OCLN), Neumann-Pick C1-like 1 (NPC1L1), transferrin receptor 1 (TfR1), epidermal growth factor receptor (EGFR), and ephrin receptor A1 (EphA2). Thus, given these vast targets, the development of HCV entry inhibitors as therapies is a burgeoning field that hopes to yield fruitful results.

Another potential avenue includes the discovery of novel inhibitors of other steps of HCV life cycle. With the recent significant improvements of high-throughput cell culture screening systems, large-scale screening of compound libraries has become feasible along with the identification of new potential therapies for HCV (345). One such recent discovery includes the identification of the first-generation antihistamine chlorcyclizine HCL (CCZ) as a potent in-

hibitor of HCV replication (346, 347). This over-the-counter compound has been described to have the ability to block HCV entry in addition to reducing HCV replication in animal models, while displaying synergy with sofosbuvir, boceprevir, and telaprevir. Thus, with further clinical development, this therapeutic modality may provide low-cost alternative for HCV eradication.

### Contraindications and Side-Effects to Direct-Acting Antiviral Therapy Regimens

Compared to the first approved DAAs, the contraindications and side effects of current DAAs have significantly improved. Contraindications for currently available DAA therapies are few and include pregnancy, breast-feeding, allergy to the specific medication, and intake of other medications that would alter the drugs metabolism. Each DAA has its own unique profile of medications that cannot be co-administered. For example: (i) sofosbuvir should not be administered with P-glycoprotein inducers as this can alter drug concentrations; (ii) sofosbuvir with co-administration of amiodarone can result in symptomatic bradycardia; and (iii) ombitasvir, paritaprevir/ritonavir plus dasbuvir should not be co-administered with drugs that are dependent on CYP3A for clearance, are inducers of CYP3A and CYP2C8, or are strong inhibitors of CYP2C8 (349–352). Thus it is paramount for the prescriber to be aware of potential drug-drug interactions on a case-by-case basis. Side effects of current DAAs are minimal and also drug specific. Taken together, the tolerability of current regimens has vastly improved, which has resulted in improved accessibility to patients, especially for those that are intolerant to interferon-based therapies.

### CONCLUSION

Since the early 1970s, another form of infectious viral hepatitis separate from the hepatitis A and B was known to exist. Today, this virus is known as hepatitis C, which remains the leading cause for liver transplantation. Since its initial cloning and early characterizations in 1989, significant advances in the understanding, characterization, and treatment of HCV have been realized (3). Today, compared to a decade ago, given the multitude of advancements in this field, the possibility of global eradication of HCV appears to be an attainable goal. However, much remains to be done to significantly impact global health with this devastating viral infectious disease.
