BASIC AND CLINICAL PHARMACOLOGY

10TH EDITION

Mc Graw Hill LANGE

Contributors

Editor

Bertram G. Katzung, MD, PhD
Professor Emeritus
Department of Cellular & Molecular Pharmacology
University of California, San Francisco

Contributors

Emmanuel T. Akporiaye, PhD
Professor, Department of Microbiology and Immunology, University of Arizona Health Sciences Center, Tucson

Michael J. Aminoff, MD, DSc, FRCP
Professor, Department of Neurology, University of California, San Francisco

Allan I. Basbaum, PhD
Professor and Chair, Department of Anatomy and W.M. Keck Foundation Center for Integrative Neuroscience, University of California, San Francisco

Neal L. Benowitz, MD
Professor of Medicine, Psychiatry, and Biopharmaceutical Sciences, University of California, San Francisco

Barry A. Berkowitz, PhD
Adjunct Professor, Northeastern University, Boston University; CEO and President, Cetek Corporation, Marlborough, Massachusetts

Daniel D. Bikle, MD, PhD
Professor of Medicine, Department of Medicine, and Co-Director, Special Diagnostic and Treatment Unit, University of California, San Francisco, and Veterans Affairs Medical Center, San Francisco

Henry R. Bourne, MD
Professor, Department of Cellular & Molecular Pharmacology, University of California, San Francisco

Homer A. Boushey, MD
Chief, Asthma Clinical Research Center and Division of Allergy & Immunology; Professor of Medicine, Department of Medicine, University of California, San Francisco

Adrienne D. Briggs, MD
Clinical Director, Bone Marrow Transplant Program, Banner Good Samaritan Hospital, Phoenix

Henry F. Chambers, MD
Professor of Medicine, University of California, San Francisco; Chief of Infectious Diseases, San Francisco General Hospital, San Francisco

Kanu Chatterjee, MB, FRCP, FCCP, FACC, MACP
Ernest Gallo Distinguished Professor of Medicine, University of California, San Francisco

George P. Chrousos, MD

Professor & Chair, First Department of Pediatrics, Athens University Medical School, Athens

Edward Chu, MD
Professor of Medicine and Pharmacology; Director, VACT Cancer Center; Associate Director, Yale Cancer Center; Yale University School of Medicine, New Haven

Robin L. Corelli, PharmD
Associate Clinical Professor, Department of Clinical Pharmacy, School of Pharmacy, University of California, San Francisco

Maria Almira Correia, PhD
Professor of Pharmacology, Pharmaceutical Chemistry and Biopharmaceutical Sciences, Department of Cellular & Molecular Pharmacology, University of California, San Francisco

Cathi E. Dennehy, PharmD
Associate Clinical Professor, Department of Clinical Pharmacy, School of Pharmacy, University of California, San Francisco

Betty J. Dong, PharmD
Professor of Clinical Pharmacy and Clinical Professor of Family and Community Medicine, Department of Clinical Pharmacy and Department of Family and Community Medicine, Schools of Pharmacy and Medicine, University of California, San Francisco

Garret A. FitzGerald, MD
Professor and Chair, Department of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia

Daniel E. Furst, MD
Carl M. Pearson Professor of Rheumatology, Director, Rheumatology Clinical Research Center, Department of Rheumatology, University of California, Los Angeles

Augustus O. Grant, MD, PhD
Professor of Medicine, Cardiovascular Division, Duke University Medical Center, Durham

Francis S. Greenspan, MD, FCAP
Clinical Professor of Medicine and Radiology and Chief, Thyroid Clinic, Division of Endocrinology, Department of Medicine, University of California, San Francisco

Brian B. Hoffman, MD
Visiting Professor of Medicine, Harvard Medical School, Boston; Co-Chief of Medicine, Veterans Administration Boston Health Care System, West Roxbury

Nicholas H. G. Holford, MBChB, MSc, MRCP(UK), FRACP
Professor, Department of Pharmacology and Clinical Pharmacology, University of Auckland Medical School, Auckland

Leo E. Hollister, MD[†]
Professor Emeritus of Psychiatry, University of Texas Medical School, Houston
[†]Deceased

John R. Horn, PharmD
Professor of Pharmacy, School of Pharmacy, University of Washington, Seattle

Joseph R. Hume, PhD
Professor and Chairman, Department of Pharmacology; Adjunct Professor, Department of Physiology and Cell Biology, University of Nevada School of Medicine, Reno

Harlan E. Ives, MD, PhD
Professor of Medicine, Department of Medicine, University of California, San Francisco

Samie R. Jaffrey, MD, PhD
Associate Professor of Pharmacology, Department of Pharmacology, Cornell University Weill Medical College, New York City

John P. Kane, MD, PhD
Professor of Medicine, Department of Medicine; Professor of Biochemistry and Biophysics; Associate Director, Cardiovascular Research Institute, University of California, San Francisco

John H. Karam, MD[†]
Professor Emeritus, Department of Medicine, University of California, San Francisco
[†]Deceased

Bertram G. Katzung, MD, PhD
Professor Emeritus, Department of Cellular & Molecular Pharmacology, University of California, San Francisco

Gideon Koren, MD, FABMT, FRCPC
Professor and Chairman, Ivey Chair in Molecular Toxicology, University of Western Ontario; Director, The Motherisk Program, Professor of Pediatrics, Pharmacology, Pharmacy, Medicine, and Medical Genetics, The University of Toronto; Senior Scientist, The Research Institute, The Hospital for Sick Children, Toronto

Bottom of Form

Preface

This book is designed to provide a complete, authoritative, current, and readable pharmacology textbook for students in the health sciences. It also offers special features that make it useful to house officers and practicing clinicians.

Information is organized according to the sequence used in many pharmacology courses and in integrated organ system curricula: basic principles; autonomic drugs; cardiovascular-renal drugs; drugs with important actions on smooth muscle; central nervous system drugs; drugs used to treat inflammation, gout, and diseases of the blood; endocrine drugs; chemotherapeutic drugs; toxicology; and special topics. This sequence builds new information on a foundation of information already assimilated. For example, early presentation of autonomic pharmacology allows students to integrate the physiology and neuroscience they know with the pharmacology they are learning and prepares them to understand the autonomic effects of other drugs. This is especially important for the cardiovascular and central nervous system drug groups. However, chapters can be used equally well in courses and curricula that present these topics in a different sequence.

Within each chapter, emphasis is placed on discussion of drug groups and prototypes rather than offering repetitive detail about individual drugs. Selection of the subject matter and the order of its presentation are based on the accumulated experience of teaching this material to thousands of medical, pharmacy, dental, podiatry, nursing, and other health science students.

Major features that make this book especially useful to professional students include sections that specifically address the clinical choice and use of drugs in patients and the monitoring of their effects—in other words, *clinical pharmacology* is an integral part of this text. Lists of the commercial preparations available, including trade and generic names and dosage formulations, are provided at the end of each chapter for easy reference by the house officer or practitioner writing a chart order or prescription.

Significant revisions in this edition include the following:

- Major revisions of the chapters on prostaglandins, nitric oxide, anti-inflammatory drugs, hypothalamic and pituitary hormones, antidiabetic drugs, antiviral drugs, and immunopharmacology
- Many new figures, most in color, that help to clarify important concepts in pharmacology
- Many descriptions of important developments based on genetically modified mice ("knockout" and "knockin" mice), a research tool of great importance in pharmacology
- Continuing expansion of the coverage of general concepts relating to receptors and listings of newly discovered drug transporters and receptors
- Descriptions of important new drugs released through August 2006, including numerous new immunopharmacologic agents

An important related source of information is *Katzung & Trevor's Pharmacology: Examination & Board Review, 7th ed* (Trevor AJ, Katzung BG, & Masters SB: McGraw-Hill, 2005). This book provides a succinct review of pharmacology with one of the largest available collections of sample examination questions and answers. It is especially helpful to students preparing for board-type examinations. A more highly condensed source of information suitable for review purposes is *USMLE Road Map: Pharmacology, 2nd ed* (Katzung BG, Trevor AJ: McGraw-Hill, 2006).

This edition marks the 25th year of publication of Basic & Clinical Pharmacology. The widespread acceptance of the first nine editions suggests that this book fills an important need. We believe that the tenth edition will satisfy this need even more successfully. Spanish, Portuguese, Italian, French, Czech, Indonesian, Japanese, and Chinese translations are available. Translations into other languages are under way; the publisher may be contacted for further information.

I wish to acknowledge the prior and continuing efforts of my contributing authors and the major contributions of the staff at Lange Medical Publications, Appleton & Lange, and more recently at McGraw-Hill, and of our editors, Alison Kelley and Donna Frassetto. I also wish to thank my wife, Alice Camp, for her expert proofreading contributions since the first edition.

Special thanks and recognition are due James Ransom, PhD, the long-time Senior Editor at Lange Medical Publications, who provided major inspiration and invaluable guidance through the first eight editions of the book. Without him, this book would not exist.

Suggestions and comments about *Basic & Clinical Pharmacology* are always welcome. They may be sent to me at the Department of Cellular & Molecular Pharmacology, P.O. Box 0450, University of California, San Francisco, CA 94143-0450.

INTRODUCTION TO PHARMACOLOGY: INTRODUCTION

Pharmacology can be defined as the study of substances that interact with living systems through chemical processes, especially by binding to regulatory molecules and activating or inhibiting normal body processes. These substances may be chemicals administered to achieve a beneficial therapeutic effect on some process within the patient or for their toxic effects on regulatory processes in parasites infecting the patient. Such deliberate therapeutic applications may be considered the proper role of **medical pharmacology**, which is often defined as the science of substances used to prevent, diagnose, and treat disease. **Toxicology** is that branch of pharmacology which deals with the undesirable effects of chemicals on living systems, from individual cells to complex ecosystems.

THE HISTORY OF PHARMACOLOGY

Prehistoric people undoubtedly recognized the beneficial or toxic effects of many plant and animal materials. Early written records from China and from Egypt list remedies of many types, including a few still recognized as useful drugs today. Most, however, were worthless or actually harmful. In the 1500 years or so preceding the present, there were sporadic attempts to introduce rational methods into medicine, but none was successful owing to the dominance of systems of thought that purported to explain all of biology and disease without the need for experimentation and observation. These schools promulgated bizarre notions such as the idea that disease was caused by excesses of bile or blood in the body, that wounds could be healed by applying a salve to the weapon that caused the wound, and so on.

Around the end of the 17th century, reliance on observation and experimentation began to replace theorizing in medicine, following the example of the physical sciences. As the value of these methods in the study of disease became clear, physicians in Great Britain and on the Continent began to apply them to the effects of traditional drugs used in their own practices. Thus, **materia medica**—the science of drug preparation and the medical use of drugs—began to develop as the precursor to pharmacology. However, any real understanding of the mechanisms of action of drugs was prevented by the absence of methods for purifying active agents from the crude materials that were available and—even more—by the lack of methods for testing hypotheses about the nature of drug actions.

In the late 18th and early 19th centuries, François Magendie, and later his student Claude Bernard, began to develop the methods of **experimental animal physiology** and **pharmacology**. Advances in chemistry and the further development of physiology in the 18th, 19th, and early 20th centuries laid the foundation needed for understanding how drugs work at the organ and tissue levels. Paradoxically, real advances in basic pharmacology during this time were accompanied by an outburst of unscientific promotion by manufacturers and marketers of worthless "patent medicines." Not until the concepts of rational therapeutics, especially that of the **controlled clinical trial**, were reintroduced into medicine—only about 50 years ago—did it become possible to accurately evaluate therapeutic claims.

Around the same time, a major expansion of research efforts in all areas of biology began. As new concepts and new techniques were introduced, information accumulated about drug action and the biologic substrate of that action, the **drug receptor**. During the last half-century, many fundamentally new drug groups and new members of old groups were introduced. The last three decades have seen an even more rapid growth of information and understanding of the molecular basis for drug action. The molecular mechanisms of action of many drugs have now been identified, and numerous receptors have been isolated, structurally characterized, and cloned. In fact, the use of receptor identification methods (described in Chapter 2) has led to the discovery of many orphan receptors—receptors for which no ligand has been discovered and whose function can only be surmised. Studies of the local molecular environment of receptors have shown that receptors and effectors do not function in isolation; they are strongly influenced by companion regulatory proteins. Decoding of the genomes of many species—from bacteria to humans—has led to the recognition of unsuspected relationships between receptor families and the ways that receptor proteins have evolved. Pharmacogenomics—the relation of the individual's genetic makeup to his or her response to specific drugs—is close to becoming a practical area of therapy (see Pharmacology & Genetics). Much of that progress is summarized in this book.

The extension of scientific principles into everyday therapeutics is still going on, although the medication-consuming public unfortunately is still exposed to vast amounts of inaccurate, incomplete, or unscientific information regarding the pharmacologic effects of chemicals. This has resulted in the faddish use of innumerable expensive, ineffective, and sometimes harmful remedies and the growth of a huge "alternative health care" industry. Conversely, lack of understanding of basic scientific principles in biology and statistics and the absence of critical thinking about public health issues have led to rejection of medical science by a segment of the public and to a common tendency to assume that all adverse drug effects are the result of malpractice.

Two general principles that the student should always remember are, first, that *all* substances can under certain circumstances be toxic; and second, that all dietary supplements and all therapies promoted as health-enhancing should meet the same standards of efficacy and safety, ie, there should be no artificial separation between scientific medicine and "alternative" or "complementary" medicine.

Pharmacology & Genetics

It has been known for centuries that certain diseases are inherited, and we now understand that individuals with such diseases have a heritable abnormality in their DNA. During the last 10 years, the genomes of humans, mice, and many other organisms have been decoded in considerable detail. This has opened the door to a remarkable range of new approaches to research and treatment. It is now possible in the case of some inherited diseases to define exactly which DNA base pairs are anomalous and in which chromosome they appear. In a small number of animal models of such diseases, it has been possible to correct the abnormality by gene therapy, ie, insertion of an appropriate "healthy" gene into somatic cells. Human somatic cell gene therapy has been attempted, but the technical difficulties are great.

Studies of a newly discovered receptor or endogenous ligand are often confounded by incomplete knowledge of the exact role of that receptor or ligand. One of the most powerful of the new genetic techniques is the ability to breed animals (usually mice) in which the gene for the receptor or its endogenous ligand has been "knocked out," ie, mutated so that the gene product is absent or nonfunctional. Homozygous knockout mice usually have complete suppression of that function, whereas heterozygous animals usually have partial suppression. Observation of the behavior, biochemistry, and physiology of the knockout mice often defines the role of the missing gene product very clearly. When the products of a particular gene are so essential that even heterozygotes do not survive to birth, it is sometimes possible to breed "knockdown" versions with only limited suppression of function. Conversely, "knockin" mice have been bred, which overexpress certain proteins of interest.

Some patients respond to certain drugs with greater than usual sensitivity to standard doses. It is now clear that such increased sensitivity is often due to a very small genetic modification that results in decreased activity of a particular enzyme responsible for eliminating that drug. (Such variations are discussed in Chapter 4.) Pharmacogenomics (or pharmacogenetics) is the study of the genetic variations that cause differences in drug response among individuals or populations. Future clinicians may screen every patient for a variety of such differences before prescribing a drug.

PHARMACOLOGY & THE PHARMACEUTICAL INDUSTRY

Much of the recent progress in the application of drugs to disease problems can be ascribed to the pharmaceutical industry and specifically to "big pharma," the multibillion-dollar corporations that specialize in drug discovery and development. These entities deserve great credit for making possible many of the therapeutic advances that we enjoy today. As described in Chapter 5, these companies are uniquely skilled in exploiting discoveries from academic and governmental laboratories and translating these basic findings into commercially successful therapeutic breakthroughs.

Such breakthroughs come at a price, however, and the escalating cost of drugs has become a significant contributor to the inflationary increase in the cost of health care. Development of new drugs is enormously expensive and to survive and prosper, big pharma must pay the costs of drug development and marketing and return a profit to its shareholders. At present, considerable controversy surrounds drug pricing. Critics claim that the costs of development and marketing are grossly inflated by marketing procedures, which may consume as much as 25% or more of a company's budget in advertising and other promotional efforts. Furthermore, profit margins for big pharma have historically exceeded all other industries by a significant factor. Finally, pricing schedules for many drugs vary dramatically from country to country and even within countries, where large organizations can negotiate favorable prices and small ones cannot. Some countries have already addressed these problems, and it seems likely that all countries will have to do so during the next few decades.

GENERAL PRINCIPLES OF PHARMACOLOGY

The Nature of Drugs

In the most general sense, a drug may be defined as any substance that brings about a change in biologic function through its chemical actions. In the great majority of cases, the drug molecule interacts with a specific molecule in the biologic system that plays a regulatory role. This molecule is called a receptor. The nature of receptors is discussed more fully in Chapter 2. In a very small number of cases, drugs known as chemical antagonists may interact directly with other drugs, whereas a few drugs (osmotic agents) interact almost exclusively with water molecules. Drugs may be synthesized within the body (eg, hormones) or may be chemicals *not* synthesized in the body, ie, xenobiotics (from the Greek *xenos,* meaning "stranger"). Poisons are drugs that have almost exclusively harmful effects. However, Paracelsus (1493–1541) famously stated that "the dose makes the poison," meaning that almost all substances can be harmful if taken in the wrong dosage. Toxins are usually defined as poisons of biologic origin, ie, synthesized by plants or animals, in contrast to inorganic poisons such as lead and arsenic.

To interact chemically with its receptor, a drug molecule must have the appropriate size, electrical charge, shape, and atomic composition. Furthermore, a drug is often administered at a location distant from its intended site of action, eg, a pill given orally to relieve a headache. Therefore, a useful drug must have the necessary properties to be transported from its site of administration to its site of action. Finally, a practical drug should be inactivated or excreted from the body at a reasonable rate so that its actions will be of appropriate duration.

THE PHYSICAL NATURE OF DRUGS

Drugs may be solid at room temperature (eg, aspirin, atropine), liquid (eg, nicotine, ethanol), or gaseous (eg, nitrous oxide). These factors often determine the best route of administration. The most common routes of administration are described in Chapter 3. The various classes of organic compounds—carbohydrates, proteins, lipids, and their constituents—are all represented in pharmacology.

A number of useful or dangerous drugs are inorganic elements, eg, lithium, iron, and heavy metals. Many organic drugs are weak acids or bases. This fact has important implications for the way they are handled by the body, because pH differences in the various compartments of the body may alter the degree of ionization of such drugs (see below).

DRUG SIZE

The molecular size of drugs varies from very small (lithium ion, MW 7) to very large (eg, alteplase [t-PA], a protein of MW 59,050). However, most drugs have molecular weights between 100 and 1000. The lower limit of this narrow range is probably set by the requirements for specificity of action. To have a good "fit" to only one type of receptor, a drug molecule must be sufficiently unique in shape, charge, and other properties, to prevent its binding to other receptors. To achieve such selective binding, it appears that a molecule should in most cases be at least 100 MW units in size. The upper limit in molecular weight is determined primarily by the requirement that drugs be able to move within the body (eg, from site of administration to site of action). Drugs much larger than MW 1000 do not diffuse readily between compartments of the body (see Permeation, below). Therefore, very large drugs (usually proteins) must often be administered directly into the compartment where they have their effect. In the case of alteplase, a clot-dissolving enzyme, the drug is administered directly into the vascular compartment by intravenous or intra-arterial infusion.

DRUG REACTIVITY AND DRUG-RECEPTOR BONDS

Drugs interact with receptors by means of chemical forces or bonds. These are of three major types: covalent, electrostatic, and hydrophobic. Covalent bonds are very strong and in many cases not reversible under biologic conditions. Thus, the covalent bond formed between the acetyl group of aspirin and its enzyme target in platelets, cyclooxygenase, is not readily broken. The platelet aggregation–blocking effect of aspirin lasts long after free acetylsalicylic acid has disappeared from the bloodstream (about 15 minutes) and is reversed only by the synthesis of new enzyme in new platelets, a process that takes about 7 days. Other examples of highly reactive, covalent bond-forming drugs are the DNA-alkylating agents used in cancer chemotherapy to disrupt cell division in the tumor.

Electrostatic bonding is much more common than covalent bonding in drug-receptor interactions. Electrostatic bonds vary from relatively strong linkages between permanently charged ionic molecules to weaker hydrogen bonds and very weak induced dipole interactions such as van der Waals forces and similar phenomena. Electrostatic bonds are weaker than covalent bonds.

Hydrophobic bonds are usually quite weak and are probably important in the interactions of highly lipid-soluble drugs with the lipids of cell membranes and perhaps in the interaction of drugs with the internal walls of receptor "pockets."

The specific nature of a particular drug-receptor bond is of less practical importance than the fact that drugs that bind through weak bonds to their receptors are generally more selective than drugs that bind by means of very strong bonds. This is because weak bonds require a very precise fit of the drug to its receptor if an interaction is to occur. Only a few receptor types are likely to provide such a precise fit for a particular drug structure. Thus, if we wished to design a highly selective short-acting drug for a particular receptor, we would avoid highly reactive molecules that form covalent bonds and instead choose molecules that form weaker bonds.

A few substances that are almost completely inert in the chemical sense nevertheless have significant pharmacologic effects. For example, xenon, an "inert" gas, has anesthetic effects at elevated pressures.

DRUG SHAPE

The shape of a drug molecule must be such as to permit binding to its receptor site via the bonds just described. Optimally, the drug's shape is complementary to that of the receptor site in the same way that a key is complementary to a lock. Furthermore, the phenomenon of chirality (stereoisomerism) is so common in biology that more than half of all useful drugs are chiral molecules; that is, they exist as enantiomeric pairs. Drugs with two asymmetric centers have four diastereomers, eg, ephedrine, a sympathomimetic drug. In most cases, one of these enantiomers is much more potent than its mirror image enantiomer, reflecting a better fit to the receptor molecule. For example, the (*S*)(+) enantiomer of methacholine, a parasympathomimetic drug, is over 250 times more potent than the (*R*)(–) enantiomer. If one imagines the receptor site to be like a glove into which the drug molecule must fit to bring about its effect, it is clear why a "left-oriented" drug is more effective in binding to a left-hand receptor than its "right-oriented" enantiomer.

The more active enantiomer at one type of receptor site may not be more active at another type, eg, a receptor type that may be responsible for some other effect. For example, carvedilol, a drug that interacts with adrenoceptors, has a single chiral center and thus two enantiomers (Table 1–1). One of these enantiomers, the (*S*)(–) isomer, is a potent β-receptor blocker. The (*R*)(+) isomer is 100-fold weaker at the βreceptor. However, the isomers are approximately equipotent as α-receptor blockers. Ketamine is an intravenous anesthetic. The (+) enantiomer is a more potent anesthetic and is less toxic than the (–) enantiomer. Unfortunately, the drug is still used as the racemic mixture.

Table 1–1. Dissociation Constants (K_d) of the Enantiomers and Racemate of Carvedilol.		
Form of Carvedilol	Inverse of Affinity for α Receptors (K_d, nmol/L)	Inverse of Affinity for β Receptors (K_d, nmol/L)
R(+) enantiomer	14	45
S(–) enantiomer	16	0.4
R,S(+/–) enantiomers	11	0.9

Note: The K_d is the concentration for 50% saturation of the receptors and is inversely proportionate to the affinity of the drug for the receptors.

Data from Ruffolo RR et al: The pharmacology of carvedilol. Eur J Pharmacol 1990;38:S82.

Finally, because enzymes are usually stereoselective, one drug enantiomer is often more susceptible than the other to drug-metabolizing enzymes. As a result, the duration of action of one enantiomer may be quite different from that of the other.

Unfortunately, most studies of clinical efficacy and drug elimination in humans have been carried out with racemic mixtures of drugs rather than with the separate enantiomers. At present, only about 45% of the chiral drugs used clinically are marketed as the active isomer—the rest are available only as racemic mixtures. As a result, many patients are receiving drug doses of which 50% or more is less active, inactive, or actively toxic. However, there is increasing interest at both the scientific and the regulatory levels in making more chiral drugs available as their active enantiomers.

RATIONAL DRUG DESIGN

Rational design of drugs implies the ability to predict the appropriate molecular structure of a drug on the basis of information about its biologic receptor. Until recently, no receptor was known in sufficient detail to permit such drug design. Instead, drugs were developed through random testing of chemicals or modification of drugs already known to have some effect (see Chapter 5). However, during the past three decades, many receptors have been isolated and characterized. A few drugs now in use were developed through molecular design based on a knowledge of the three-dimensional structure of the receptor site. Computer programs are now available that can iteratively optimize drug structures to fit known receptors. As more becomes known about receptor structure, rational drug design will become more common.

RECEPTOR NOMENCLATURE

The spectacular success of newer, more efficient ways to identify and characterize receptors (see Chapter 2) has resulted in a variety of differing systems for naming them. This in turn has led to a number of suggestions regarding more rational methods of naming them. The interested reader is referred for details to the efforts of the International Union of Pharmacology (IUPHAR) *Committee on*

Receptor Nomenclature and Drug Classification (reported in various issues of *Pharmacological Reviews*) and to Alexander SPH, Mathie A, Peters JA: Guide to receptors and channels. Br J Pharmacol 2006;147(Suppl 3):S1–S180. The chapters in this book mainly use these sources for naming receptors.

Drug-Body Interactions

The interactions between a drug and the body are conveniently divided into two classes. The actions of the drug on the body are termed pharmacodynamic processes; the principles of pharmacodynamics are presented in greater detail in Chapter 2. These properties determine the group in which the drug is classified and play the major role in deciding whether that group is appropriate therapy for a particular symptom or disease. The actions of the body on the drug are called pharmacokinetic processes and are described in Chapters 3 and 4. Pharmacokinetic processes govern the absorption, distribution, and elimination of drugs and are of great practical importance in the choice and administration of a particular drug for a particular patient, eg, a patient with impaired renal function. The following paragraphs provide a brief introduction to pharmacodynamics and pharmacokinetics.

Pharmacodynamic Principles

Most drugs must bind to a receptor to bring about an effect. However, at the molecular level, drug binding is only the first in what is often a complex sequence of steps.

TYPES OF DRUG-RECEPTOR INTERACTIONS

Agonist drugs bind to and *activate* the receptor in some fashion, which directly or indirectly brings about the effect. Some receptors incorporate effector machinery in the same molecule, so that drug binding brings about the effect directly, eg, opening of an ion channel or activation of enzyme activity. Other receptors are linked through one or more intervening coupling molecules to a separate effector molecule. The five major types of drug-receptor-effector coupling systems are discussed in Chapter 2. Pharmacologic antagonist drugs, by binding to a receptor, *prevent* binding by other molecules. For example, acetylcholine receptor blockers such as atropine are antagonists because they prevent access of acetylcholine and similar agonist drugs to the acetylcholine receptor and they stabilize the receptor in its inactive state. These agents reduce the effects of acetylcholine and similar molecules in the body.

AGONISTS THAT *INHIBIT* THEIR BINDING MOLECULES AND PARTIAL AGONISTS

Some drugs mimic agonist drugs by inhibiting the molecules responsible for terminating the action of an endogenous agonist. For example, acetylcholinesterase *inhibitors*, by slowing the destruction of endogenous acetylcholine, cause cholinomimetic effects that closely resemble the actions of cholinoceptor *agonist* molecules even though cholinesterase inhibitors do not bind or only incidentally bind to cholinoceptors (see Chapter 7, Cholinoceptor-Activating & Cholinesterase-Inhibiting Drugs). Other drugs bind to receptors and activate them but do not evoke as great a response as so-called full agonists. Thus, pindolol, a β adrenoceptor "partial agonist," may act as either an agonist (if no full agonist is present) or as an antagonist (if a full agonist such as epinephrine is present). (See Chapter 2.)

DURATION OF DRUG ACTION

Termination of drug action at the receptor level results from one of several processes. In some cases, the effect lasts only as long as the drug occupies the receptor, so that dissociation of drug from the receptor automatically terminates the effect. In many cases, however, the action may persist after the drug has dissociated, because, for example, some coupling molecule is still present in activated form. In the case of drugs that bind covalently to the receptor site, the effect may persist until the drug-receptor complex is destroyed and new receptors or enzymes are synthesized, as described previously for aspirin. Finally, many receptor-effector systems incorporate desensitization mechanisms for preventing excessive activation when agonist molecules continue to be present for long periods. See Chapter 2 for additional details.

RECEPTORS AND INERT BINDING SITES

To function as a receptor, an endogenous molecule must first be *selective* in choosing ligands (drug molecules) to bind; and second, it must *change its function* upon binding in such a way that the function of the biologic system (cell, tissue, etc) is altered. The first characteristic is required to avoid constant activation of the receptor by promiscuous binding of many different ligands. The second characteristic is clearly necessary if the ligand is to cause a pharmacologic effect. The body contains many molecules that are capable of binding drugs, however, and not all of these endogenous molecules are regulatory molecules. Binding of a drug to a nonregulatory molecule such as plasma albumin will result in no detectable change in the function of the biologic system, so this endogenous molecule can be called an inert binding site. Such binding is not completely without significance, however, because it affects the distribution of drug within the body and determines the amount of free drug in the circulation. Both of these factors are of pharmacokinetic importance (see below and Chapter 3).

Pharmacokinetic Principles

In practical therapeutics, a drug should be able to reach its intended site of action after administration by some convenient route. In some cases, a chemical that is readily absorbed and distributed is administered and then converted to the active drug by biologic processes—inside the body. Such a chemical is called a *prodrug*.

In only a few situations is it possible to directly apply a drug to its target tissue, eg, by topical application of an anti-inflammatory agent to inflamed skin or mucous membrane. Most often, a drug is administered into one body compartment, eg, the gut, and must move to its site of action in another compartment, eg, the brain. This requires that the drug be *absorbed* into the blood from its site of administration and *distributed* to its site of action, *permeating* through the various barriers that separate these compartments. For a drug given orally to produce an effect in the central nervous system, these barriers include the tissues that make up the wall of the intestine, the walls of the capillaries that perfuse the gut, and the "blood-brain barrier," the walls of the capillaries that perfuse the brain. Finally, after bringing about its effect, a drug should be *eliminated* at a reasonable rate by metabolic inactivation, by excretion from the body, or by a combination of these processes.

PERMEATION

Drug permeation proceeds by several mechanisms. Passive diffusion in an aqueous or lipid medium is common, but active processes play a role in the movement of many drugs, especially those whose molecules are too large to diffuse readily.

Aqueous Diffusion

Aqueous diffusion occurs within the larger aqueous compartments of the body (interstitial space, cytosol, etc) and across epithelial membrane tight junctions and the endothelial lining of blood vessels through aqueous pores that—in some tissues—permit the passage of molecules as large as MW 20,000–30,000.*

Aqueous diffusion of drug molecules is usually driven by the concentration gradient of the permeating drug, a downhill movement described by Fick's law (see below). Drug molecules that are bound to large plasma proteins (eg, albumin) do not permeate most vascular aqueous pores. If the drug is charged, its flux is also influenced by electrical fields (eg, the membrane potential and—in parts of the nephron—the transtubular potential).

*The capillaries of the brain, the testes, and some other tissues are characterized by the absence of pores that permit aqueous diffusion. They may also contain high concentrations of drug export pumps (MDR pumps; see text). These tissues are therefore protected or "sanctuary" sites from many circulating drugs.

Lipid Diffusion

Lipid diffusion is the most important limiting factor for drug permeation because of the large number of lipid barriers that separate the compartments of the body. Because these lipid barriers separate aqueous compartments, the lipid:aqueous partition coefficient of a drug determines how readily the molecule moves between aqueous and lipid media. In the case of weak acids and weak bases (which gain or lose electrical charge-bearing protons, depending on the pH), the ability to move from aqueous to lipid or vice versa varies with the pH of the medium, because charged molecules attract water molecules. The ratio of lipid-soluble form to water-soluble form for a weak acid or weak base is expressed by the Henderson-Hasselbalch equation (see below).

Special Carriers

Special carrier molecules exist for certain substances that are important for cell function and too large or too insoluble in lipid to diffuse passively through membranes, eg, peptides, amino acids, glucose. These carriers bring about movement by active transport or facilitated diffusion and, unlike passive diffusion, are saturable and inhibitable. Because many drugs are or resemble such naturally occurring peptides, amino acids, or sugars, they can use these carriers to cross membranes.

Many cells also contain less selective membrane carriers that are specialized for expelling foreign molecules. One large family of such transporters bind adenosine triphosphate (ATP) and is called the ABC (ATP-binding cassette) family. This family includes the P-glycoprotein or multidrug-resistance type 1 (MDR1) transporter found in the brain, testes, and other tissues, and in some drug-resistant neoplastic cells. Similar transport molecules from the ABC family, the multidrug resistance-associated protein (MRP1 through MRP5) transporters, play important roles in excretion of some drugs or their metabolites into urine and bile and in resistance of some tumors to chemotherapeutic drugs. Several other transporter families have been identified that do not bind ATP but use ion gradients for transport energy. Some of these are particularly important in the uptake of neurotransmitters across nerve ending membranes.

Endocytosis and Exocytosis

A few substances are so large or impermeant that they can enter cells only by endocytosis, the process by which the substance is engulfed by the cell membrane and carried into the cell by pinching off of the newly formed vesicle inside the membrane. The substance can then be released inside the cytosol by breakdown of the vesicle membrane. This process is responsible for the transport of vitamin B_{12}, complexed with a binding protein (intrinsic factor) across the wall of the gut into the blood. Similarly, iron is transported into hemoglobin-synthesizing red blood cell precursors in association with the protein transferrin. Specific receptors for the transport proteins must be present for this process to work.

The reverse process (exocytosis) is responsible for the secretion of many substances from cells. For example, many neurotransmitter substances are stored in membrane-bound vesicles in nerve endings to protect them from metabolic destruction in the cytoplasm. Appropriate activation of the nerve ending causes fusion of the storage vesicle with the cell membrane and expulsion of its contents into the extracellular space (see Chapter 6).

FICK'S LAW OF DIFFUSION

The passive flux of molecules down a concentration gradient is given by Fick's law:

$$\text{Flux (molecules per unit time)} = (C_1 - C_2) \times \frac{\text{Area} \times \text{Permeability coefficient}}{\text{Thickness}}$$

where C_1 is the higher concentration, C_2 is the lower concentration, area is the area across which diffusion is occurring, permeability coefficient is a measure of the mobility of the drug molecules in the medium of the diffusion path, and thickness is the thickness (length) of the diffusion path. In the case of lipid diffusion, the lipid:aqueous partition coefficient is a major determinant of mobility of the drug, because it determines how readily the drug enters the lipid membrane from the aqueous medium.

IONIZATION OF WEAK ACIDS AND WEAK BASES; THE HENDERSON-HASSELBALCH EQUATION

The electrostatic charge of an ionized molecule attracts water dipoles and results in a polar, relatively water-soluble and lipid-insoluble complex. Because lipid diffusion depends on relatively high lipid solubility, ionization of drugs may markedly reduce their ability to permeate membranes. A very large fraction of the drugs in use are weak acids or weak bases (Table 1–2). For drugs, a weak acid is best defined as a neutral molecule that can reversibly dissociate into an anion (a negatively charged molecule) and a proton (a hydrogen ion). For example, aspirin dissociates as follows:

$$\underset{\text{Neutral aspirin}}{C_8H_7O_2COOH} \rightleftharpoons \underset{\text{Aspirin anion}}{C_8H_7O_2COO^-} + \underset{\text{Proton}}{H^+}$$

Table 1–2. Ionization Constants of Some Common Drugs.

Drug	pK_a[1]	Drug	pK_a[1]	Drug	pK_a[1]
Weak acids		Weak bases		Weak bases (cont'd)	
Acetaminophen	9.5	Albuterol (salbutamol)	9.3	Isoproterenol	8.6
Acetazolamide	7.2	Allopurinol	9.4, 12.3[2]	Lidocaine	7.9
Ampicillin	2.5	Alprenolol	9.6	Metaraminol	8.6
Aspirin	3.5	Amiloride	8.7	Methadone	8.4

Drug	pK_a[1]	Drug	pK_a[1]	Drug	pK_a[1]
Chlorothiazide	6.8, 9.4[2]	Amiodarone	6.56	Methamphetamine	10.0
Chlorpropamide	5.0	Amphetamine	9.8	Methyldopa	10.6
Ciprofloxacin	6.1, 8.7[2]	Atropine	9.7	Metoprolol	9.8
Cromolyn	2.0	Bupivacaine	8.1	Morphine	7.9
Ethacrynic acid	2.5	Chlordiazepoxide	4.6	Nicotine	7.9, 3.1[2]
Furosemide	3.9	Chloroquine	10.8, 8.4	Norepinephrine	8.6
Ibuprofen	4.4, 5.2[2]	Chlorpheniramine	9.2	Pentazocine	7.9
Levodopa	2.3	Chlorpromazine	9.3	Phenylephrine	9.8
Methotrexate	4.8	Clonidine	8.3	Physostigmine	7.9, 1.8[2]
Methyldopa	2.2, 9.2[2]	Cocaine	8.5	Pilocarpine	6.9, 1.4[2]
Penicillamine	1.8	Codeine	8.2	Pindolol	8.6
Pentobarbital	8.1	Cyclizine	8.2	Procainamide	9.2
Phenobarbital	7.4	Desipramine	10.2	Procaine	9.0
Phenytoin	8.3	Diazepam	3	Promethazine	9.1
Propylthiouracil	8.3	Diphenhydramine	8.8	Propranolol	9.4
Salicylic acid	3.0	Diphenoxylate	7.1	Pseudoephedrine	9.8
Sulfadiazine	6.5	Ephedrine	9.6	Pyrimethamine	7.0
Sulfapyridine	8.4	Epinephrine	8.7	Quinidine	8.5, 4.4[2]
Theophylline	8.8	Ergotamine	6.3	Scopolamine	8.1

Drug	pK_a[1]	Drug	pK_a[1]	Drug	pK_a[1]
Tolbutamide	5.3	Fluphenazine	8.0, 3.9[2]	Strychnine	8.0, 2.3[2]
Warfarin	5.0	Hydralazine	7.1	Terbutaline	10.1
		Imipramine	9.5	Thioridazine	9.5

[1]The pK_a is that pH at which the concentrations of the ionized and un-ionized forms are equal.

[2]More than one ionizable group.

A drug that is a weak base can be defined as a neutral molecule that can form a cation (a positively charged molecule) by combining with a proton. For example, pyrimethamine, an antimalarial drug, undergoes the following association-dissociation process:

$$\underset{\text{Pyrimethamine cation}}{C_{12}H_{11}ClN_3NH_3^+} \rightleftharpoons \underset{\text{Neutral pyrimethamine}}{C_{12}H_{11}ClN_3NH_2} + \underset{\text{Proton}}{H^+}$$

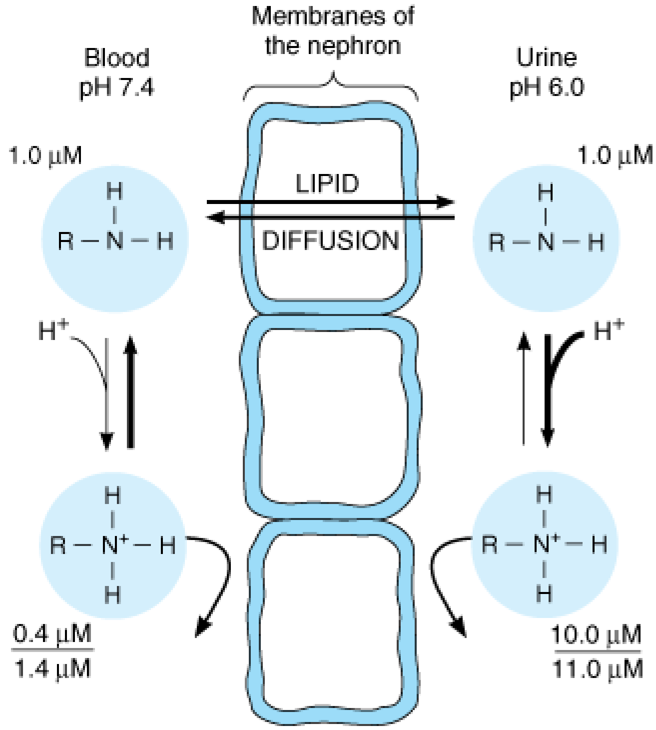
Note that the protonated form of a weak acid is the neutral, more lipid-soluble form, whereas the unprotonated form of a weak base is the neutral form. The law of mass action requires that these reactions move to the left in an acid environment (low pH, excess protons available) and to the right in an alkaline environment. The Henderson-Hasselbalch equation relates the ratio of protonated to unprotonated weak acid or weak base to the molecule's pK_a and the pH of the medium as follows:

$$\log \frac{(\text{Protonated})}{(\text{Unprotonated})} = pK_a - pH$$

This equation applies to both acidic and basic drugs. Inspection confirms that the lower the pH relative to the pK_a, the greater will be the fraction of drug in the protonated form. Because the uncharged form is the more lipid-soluble, more of a weak acid will be in the lipid-soluble form at acid pH, whereas more of a basic drug will be in the lipid-soluble form at alkaline pH.

Application of this principle is made in the manipulation of drug excretion by the kidney. Almost all drugs are filtered at the glomerulus. If a drug is in a lipid-soluble form during its passage down the renal tubule, a significant fraction will be reabsorbed by simple passive diffusion. If the goal is to accelerate excretion of the drug (eg, in a case of drug overdose), it is important to prevent its reabsorption from the tubule. This can often be accomplished by adjusting urine pH to make certain that most of the drug is in the ionized state, as shown in Figure 1–1. As a result of this partitioning effect, the drug will be "trapped" in the urine. Thus, weak acids are usually excreted faster in alkaline urine; weak bases are usually excreted faster in acidic urine. Other body fluids in which pH differences from blood pH may cause trapping or reabsorption are the contents of the stomach and small intestine; breast milk; aqueous humor; and vaginal and prostatic secretions (Table 1–3).

Figure 1–1.



Trapping of a weak base (pyrimethamine) in the urine when the urine is more acidic than the blood. In the hypothetical case illustrated, the diffusible uncharged form of the drug has equilibrated across the membrane, but the total concentration (charged plus uncharged) in the urine is almost eight times higher than in the blood.

Table 1–3. Body Fluids with Potential for Drug "Trapping" Through the pH-Partitioning Phenomenon.

Body Fluid	Range of pH	Total Fluid: Blood Concentration Ratios for Sulfadiazine (acid, pK_a 6.5)[1]	Total Fluid: Blood Concentration Ratios for Pyrimethamine (base, pK_a 7.0)[1]
Urine	5.0–8.0	0.12–4.65	72.24–0.79
Breast milk	6.4–7.6[2]	0.2–1.77	3.56–0.89

Body Fluid	Range of pH	Total Fluid: Blood Concentration Ratios for Sulfadiazine (acid, pK_a 6.5)[1]	Total Fluid: Blood Concentration Ratios for Pyrimethamine (base, pK_a 7.0)[1]
Jejunum, ileum contents	7.5–8.0[3]	1.23–3.54	0.94–0.79
Stomach contents	1.92–2.59[2]	0.11[4]	85,993–18,386
Prostatic secretions	6.45–7.4[2]	0.21	3.25–1.0
Vaginal secretions	3.4–4.2[3]	0.11[4]	2848–452

[1]Body fluid protonated-to-unprotonated drug ratios were calculated using each of the pH extremes cited; a blood pH of 7.4 was used for blood:drug ratio. For example, the steady-state urine:blood ratio for sulfadiazine is 0.12 at a urine pH of 5.0; this ratio is 4.65 at a urine pH of 8.0. Thus, sulfadiazine is much more effectively trapped and excreted in alkaline urine.

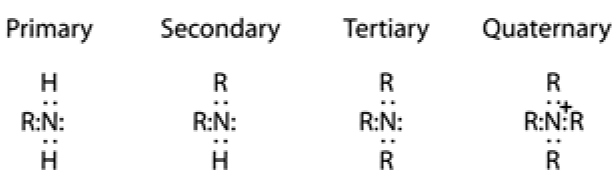
[4]Insignificant change in ratios over the physiologic pH range.

As suggested by Table 1–2, a large number of drugs are weak bases. Most of these bases are amine-containing molecules. The nitrogen of a neutral amine has three atoms associated with it plus a pair of unshared electrons (see the display that follows). The three atoms may consist of one carbon (designated "R") and two hydrogens (a *primary* amine), two carbons and one hydrogen (a *secondary* amine), or three carbon atoms (a *tertiary* amine). Each of these three forms may reversibly bind a proton with the unshared electrons. Some drugs have a fourth carbon-nitrogen bond; these are *quaternary* amines. However, the quaternary amine is permanently charged and has no unshared electrons with which to reversibly bind a proton. Therefore, primary, secondary, and tertiary amines may undergo reversible protonation and vary their lipid solubility with pH, but quaternary amines are always in the poorly lipid-soluble charged form.



Drug Groups

To learn each pertinent fact about each of the many hundreds of drugs mentioned in this book would be an impractical goal and, fortunately, is unnecessary. Almost all of the several thousand drugs currently available can be arranged in about 70 groups. Many of the drugs within each group are very similar in pharmacodynamic actions and often in their pharmacokinetic properties as well. For most groups, one or more **prototype drugs** can be identified that typify the most important characteristics of the group. This permits classification of other important drugs in the group as variants of the prototype, so that only the prototype must be learned in detail and, for the remaining drugs, only the differences from the prototype.

Sources of Information

Students who wish to review the field of pharmacology in preparation for an examination are referred to *Pharmacology: Examination and Board Review,* by Trevor, Katzung, and Masters (McGraw-Hill, 2005) or *USMLE Road Map: Pharmacology,* by Katzung and Trevor (McGraw-Hill, 2006).

The references at the end of each chapter in this book were selected to provide reviews, or classic publications, of information specific to those chapters. Specific questions relating to basic or clinical research are best answered by referring to the journals covering general pharmacology and clinical specialties. For the student and the physician, three periodicals can be recommended as especially useful sources of current information about drugs: *The New England Journal of Medicine,* which publishes much original drug-related clinical research as well as frequent reviews of topics in pharmacology; *The Medical Letter on Drugs and Therapeutics,* which publishes brief critical reviews of new and old therapies, mostly pharmacologic; and *Drugs,* which publishes extensive reviews of drugs and drug groups.

Other sources of information pertinent to the USA should be mentioned as well. The "package insert" is a summary of information that the manufacturer is required to place in the prescription sales package; *Physicians' Desk Reference (PDR*) is a compendium of package inserts published annually with supplements twice a year. The *USP DI* (vol 1, *Drug Information for the Health Care Professional*) is a large annual drug compendium with monthly Internet updates published by the Micromedex Corporation. The package insert consists of a brief description of the pharmacology of the product. While this brochure contains much practical information, it is also used as a means of shifting liability for untoward drug reactions from the manufacturer onto the practitioner. Therefore, the manufacturer typically lists every toxic effect ever reported, no matter how rare. A useful and objective quarterly handbook that presents information on drug toxicity and interactions is *Drug Interactions: Analysis and Management.* Finally, the Food and Drug Administration (FDA) has an Internet website that carries news regarding recent drug approvals, withdrawals, warnings, etc. It can be reached using a personal computer equipped with Internet browser software at http://www.fda.gov.

The following addresses are provided for the convenience of readers wishing to obtain any of the publications mentioned above:

DRUG RECEPTORS & PHARMACODYNAMICS: INTRODUCTION

Therapeutic and toxic effects of drugs result from their interactions with molecules in the patient. Most drugs ac by associating with specific macromolecules in ways that alter the macromolecules' biochemical or biophysical activities. This idea, more than a century old, is embodied in the term *receptor*: the component of a cell or organism that interacts with a drug and initiates the chain of events leading to the drug's observed effects.

Receptors have become the central focus of investigation of drug effects and their mechanisms of action (pharmacodynamics). The receptor concept, extended to endocrinology, immunology, and molecular biology, h proved essential for explaining many aspects of biologic regulation. Many drug receptors have been isolated an characterized in detail, thus opening the way to precise understanding of the molecular basis of drug action.

The receptor concept has important practical consequences for the development of drugs and for arriving at therapeutic decisions in clinical practice. These consequences form the basis for understanding the actions and clinical uses of drugs described in almost every chapter of this book. They may be briefly summarized as follows

(1) *Receptors largely determine the quantitative relations between dose or concentration of drug ar pharmacologic effects.* The receptor's affinity for binding a drug determines the concentration of drug require to form a significant number of drug-receptor complexes, and the total number of receptors may limit the maximal effect a drug may produce.

(2) *Receptors are responsible for selectivity of drug action.* The molecular size, shape, and electrical charge of a drug determine whether—and with what affinity—it will bind to a particular receptor among the vas array of chemically different binding sites available in a cell, tissue, or patient. Accordingly, changes in the chemical structure of a drug can dramatically increase or decrease a new drug's affinities for different classes o receptors, with resulting alterations in therapeutic and toxic effects.

(3) *Receptors mediate the actions of both pharmacologic agonists and antagonists.* Some drugs and many natural ligands, such as hormones and neurotransmitters, regulate the function of receptor macromolecu as agonists; ie, they activate the receptor to signal as a direct result of binding to it. Some agonists activate a single kind of receptor to produce all of their biologic functions, whereas others selectively promote one recepto function more than another.

Other drugs act as pharmacologic antagonists; ie, they bind to receptors but do not activate generation of a signal; consequently, they interfere with the ability of an agonist to activate the receptor. The effect of a so-cal "pure" antagonist on a cell or in a patient depends entirely on its preventing the binding of agonist molecules ar blocking their biologic actions. Other antagonists, in addition to preventing agonist binding, suppress the basal signaling ("constitutive") activity of receptors. Some of the most useful drugs in clinical medicine are pharmacologic antagonists.

MACROMOLECULAR NATURE OF DRUG RECEPTORS

Most receptors are proteins, presumably because the structures of polypeptides provide both the necessary diversity and the necessary specificity of shape and electrical charge. Receptors vary greatly in structure and ca be identified in many ways. Traditionally, drug binding was used to identify or purify receptors from tissue extracts; consequently, receptors were discovered more recently than the drugs that bind to them. However, advances in molecular biology and genome sequencing have begun to reverse this order. Now receptors are be discovered by predicted structure or sequence homology to other (known) receptors, and drugs that bind to th are developed later using chemical screening methods. This effort has revealed, for many known drugs, a large diversity of receptors than previously anticipated. It has also identified a number of "orphan" receptors, so-calle because their ligands are presently unknown, which may prove to be useful targets for the development of new drugs.

The best-characterized drug receptors are **regulatory proteins**, which mediate the actions of endogenous chemical signals such as neurotransmitters, autacoids, and hormones. This class of receptors mediates the effe of many of the most useful therapeutic agents. The molecular structures and biochemical mechanisms of these regulatory receptors are described in a later section entitled Signaling Mechanisms & Drug Action.

Other classes of proteins that have been clearly identified as drug receptors include **enzymes**, which may be inhibited (or, less commonly, activated) by binding a drug (eg, dihydrofolate reductase, the receptor for the antineoplastic drug methotrexate); **transport proteins** (eg, Na^+/K^+ ATPase, the membrane receptor for cardioactive digitalis glycosides); and **structural proteins** (eg, tubulin, the receptor for colchicine, an anti-inflammatory agent).

This chapter deals with three aspects of drug receptor function, presented in increasing order of complexity: (1 Receptors as determinants of the quantitative relation between the concentration of a drug and the pharmacolo response. (2) Receptors as regulatory proteins and components of chemical signaling mechanisms that provide targets for important drugs. (3) Receptors as key determinants of the therapeutic and toxic effects of drugs in patients.

RELATION BETWEEN DRUG CONCENTRATION & RESPONSE

The relation between dose of a drug and the clinically observed response may be complex. In carefully controlle in vitro systems, however, the relation between concentration of a drug and its effect is often simple and can b described with mathematical precision. This idealized relation underlies the more complex relations between do and effect that occur when drugs are given to patients.

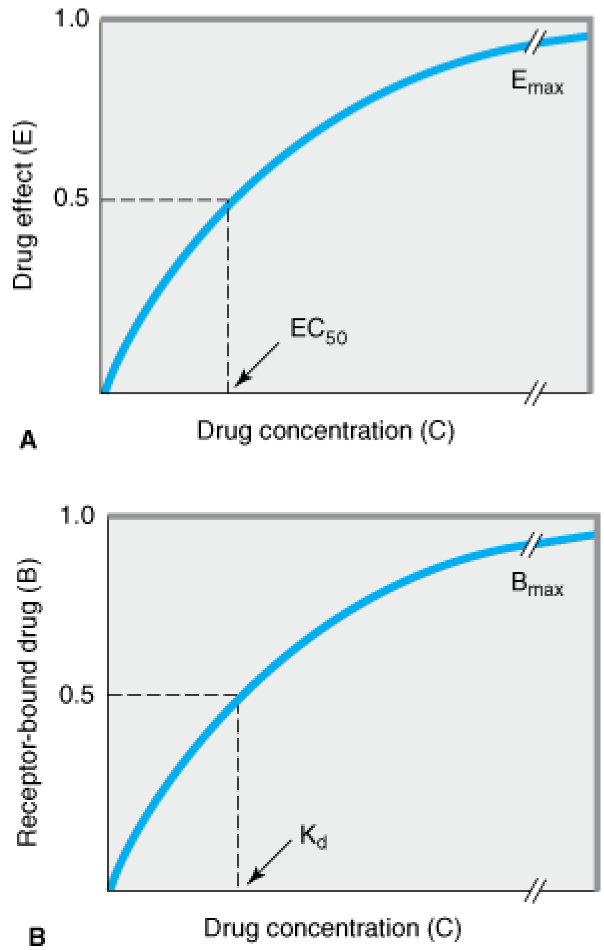
Concentration-Effect Curves & Receptor Binding of Agonists

Even in intact animals or patients, responses to low doses of a drug usually increase in direct proportion to dos As doses increase, however, the response increment diminishes; finally, doses may be reached at which no further increase in response can be achieved. In idealized or in vitro systems, the relation between drug concentration and effect is described by a hyperbolic curve (Figure 2–1A) according to the following equation:

$$E = \frac{E_{max} \times C}{C + EC_{50}}$$

where E is the effect observed at concentration C, E_{max} is the maximal response that can be produced by the drug, and EC_{50} is the concentration of drug that produces 50% of maximal effect.

Figure 2–1.



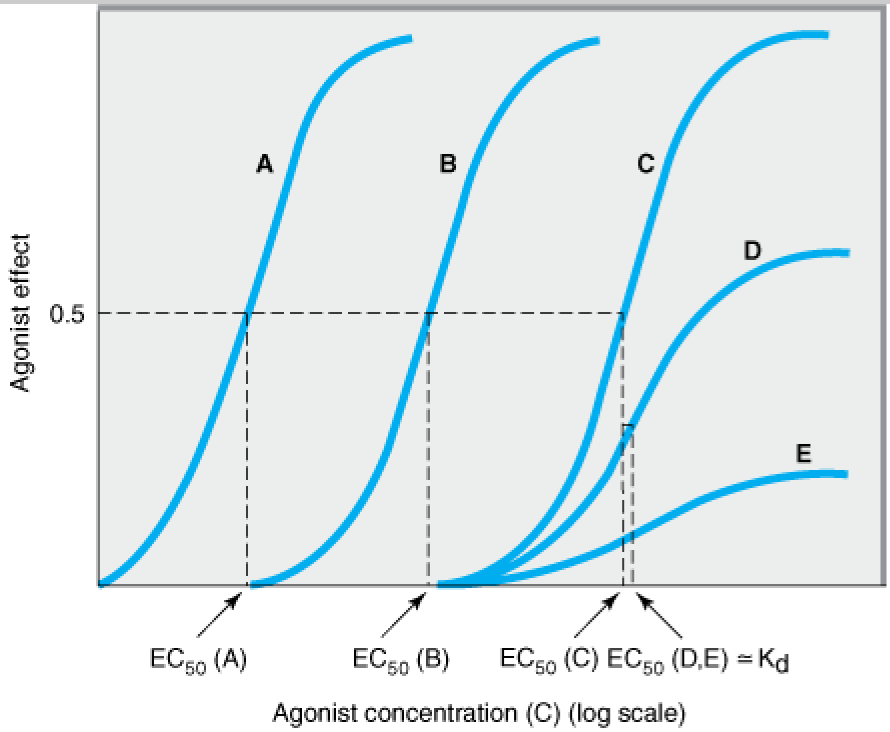
Relations between drug concentration and drug effect (panel A) or receptor-bound drug (panel B). The drug concentrations which effect or receptor occupancy is half-maximal are denoted EC_{50} and K_d , respectively.

This hyperbolic relation resembles the mass action law, which describes association between two molecules of a given affinity. This resemblance suggests that drug agonists act by binding to ("occupying") a distinct class of biologic molecules with a characteristic affinity for the drug receptor. Radioactive receptor ligands have been us to confirm this occupancy assumption in many drug-receptor systems. In these systems, drug bound to recepto (B) relates to the concentration of free (unbound) drug (C) as depicted in Figure 2–1B and as described by an analogous equation:

$$B = \frac{B_{max} \times C}{C + K_d}$$

in which B_{max} indicates the total concentration of receptor sites (ie, sites bound to the drug at infinitely high concentrations of free drug). K_d (the equilibrium dissociation constant) represents the concentration of free dru at which half-maximal binding is observed. This constant characterizes the receptor's affinity for binding the dru in a reciprocal fashion: If the K_d is low, binding affinity is high, and vice versa. The EC_{50} and K_d may be identical but need not be, as discussed below. Dose-response data are often presented as a plot of the drug effect (ordinate) against the *logarithm* of the dose or concentration (abscissa). This mathematical maneuver transforr the hyperbolic curve of Figure 2–1 into a sigmoid curve with a linear midportion (eg, Figure 2–2). This expands the scale of the concentration axis at low concentrations (where the effect is changing rapidly) and compresses at high concentrations (where the effect is changing slowly), but has no special biologic or pharmacologic significance.

Figure 2–2.



Logarithmic transformation of the dose axis and experimental demonstration of spare receptors, using different concentratio of an irreversible antagonist. Curve A shows agonist response in the absence of antagonist. After treatment with a low concentration of antagonist (curve B), the curve is shifted to the right; maximal responsiveness is preserved, however, because the remaining available receptors are still in excess of the number required. In curve C, produced after treatment w a larger concentration of antagonist, the available receptors are no longer "spare"; instead, they are just sufficient to mediat an undiminished maximal response. Still higher concentrations of antagonist (curves D and E) reduce the number of availab receptors to the point that maximal response is diminished. The apparent EC_{50} of the agonist in curves D and E may approximate the K_d that characterizes the binding affinity of the agonist for the receptor.

Receptor-Effector Coupling & Spare Receptors

When a receptor is occupied by an agonist, the resulting conformational change is only the first of many steps usually required to produce a pharmacologic response. The transduction process that links drug occupancy of receptors and pharmacologic response is often termed **coupling**. The relative efficiency of occupancy-response coupling is partially determined by the initial conformational change in the receptor; thus, the effects of full agonists can be considered more efficiently coupled to receptor occupancy than can the effects of partial agonis as described below. Coupling efficiency is also determined by the biochemical events that transduce receptor occupancy into cellular response. Sometimes the biologic effect of the drug is linearly related to the number of receptors bound. This is often true for drug-regulated ion channels, eg, where the ion current produced by the drug is directly proportional to the number of receptors (ion channels) bound. In other cases the biologic respoı is a more complex function of drug binding to receptors. This is often true for receptors linked to enzymatic sigı transduction cascades, eg, where the biologic response often increases disproportionately to the number of receptors occupied by drug.

Many factors can contribute to nonlinear occupancy-response coupling, and often these factors are only partiall understood. The concept of "spare" receptors, irrespective of the precise biochemical mechanism involved, can help us to think about these effects. Receptors are said to be "spare" for a given pharmacologic response if it is possible to elicit a maximal biologic response at a concentration of agonist that does not result in occupancy of full complement of available receptors. Experimentally, spare receptors may be demonstrated by using irreversible antagonists to prevent binding of agonist to a proportion of available receptors and showing that hi concentrations of agonist can still produce an undiminished maximal response (Figure 2–2). Thus, the same maximal inotropic response of heart muscle to catecholamines can be elicited even under conditions where 90% of the β-adrenoceptors are occupied by a quasi-irreversible antagonist. Accordingly, myocardial cells are said t contain a large proportion of spare β-adrenoceptors.

How can we account for the phenomenon of spare receptors? In the example of the β-adrenoceptor, receptor activation promotes binding of guanosine triphosphate (GTP) to an intermediate signaling protein, and activatio of the signaling intermediate may greatly outlast the agonist-receptor interaction (see the following section on Proteins & Second Messengers). In such a case, the "spareness" of receptors is *temporal* . Maximal response ca be elicited by activation of relatively few receptors because the response initiated by an individual ligand-recep binding event persists longer than the binding event itself.

In other cases, where the biochemical mechanism is not understood, we imagine that the receptors might be *spare in number.* If the concentration or amount of cellular components other than the receptors limits the coupling of receptor occupancy to response, then a maximal response can occur without occupancy of all receptors. Thus, the sensitivity of a cell or tissue to a particular concentration of agonist depends not only on th *affinity* of the receptor for binding the agonist (characterized by the K_d) but also on the *degree of spareness*— total number of receptors present compared with the number actually needed to elicit a maximal biologic response.

The concept of spare receptors is very useful clinically because it allows one to think precisely about the effects drug dosage, without needing to consider biochemical details of the signaling response. The K_d of the agonist-receptor interaction determines what fraction (B/B_{max}) of total receptors will be occupied at a given free concentration (C) of agonist regardless of the receptor concentration:

$$\frac{B}{B_{max}} = \frac{C}{C + K_d}$$

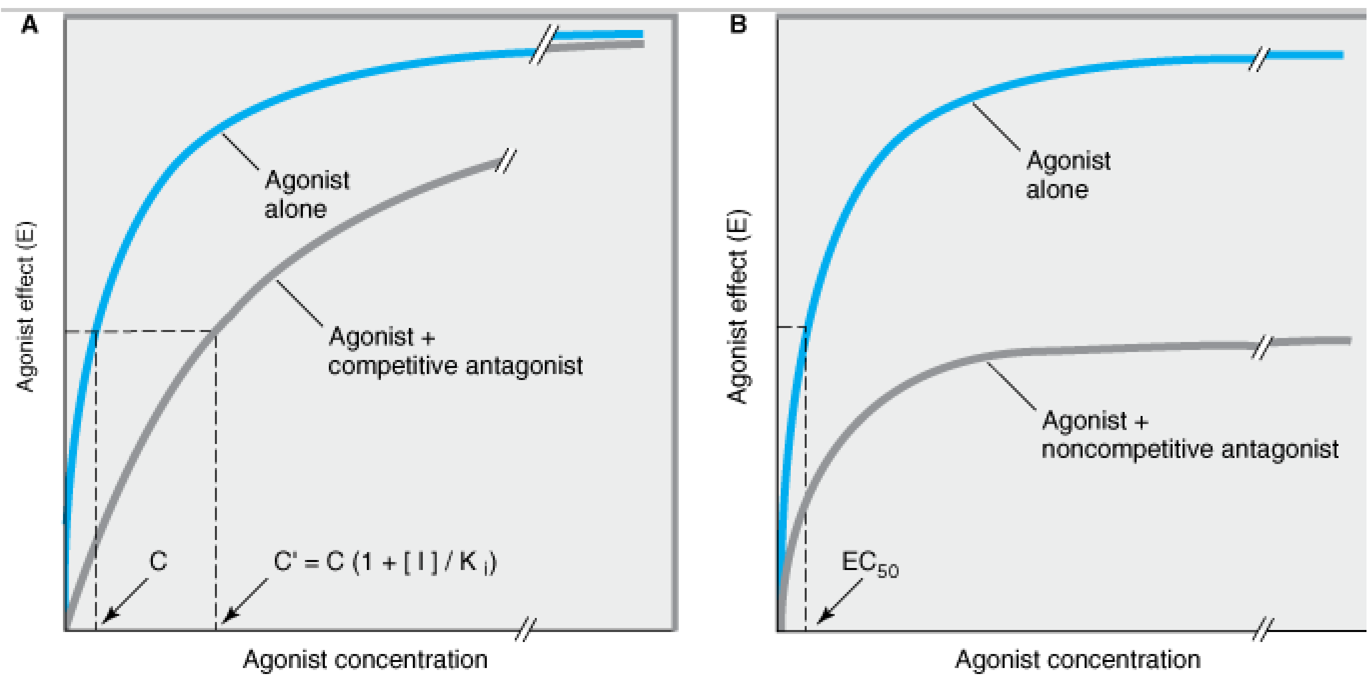
Imagine a responding cell with four receptors and four effectors. Here the number of effectors does not limit th maximal response, and the receptors are *not* spare in number. Consequently, an agonist present at a concentration equal to the K_d will occupy 50% of the receptors, and half of the effectors will be activated, producing a half-maximal response (ie, two receptors stimulate two effectors). Now imagine that the number o receptors increases 10-fold to 40 receptors but that the total number of effectors remains constant. Most of the receptors are now spare in number. As a result, a much lower concentration of agonist suffices to occupy two o the 40 receptors (5% of the receptors), and this same low concentration of agonist is able to elicit a half-maxim response (two of four effectors activated). Thus, it is possible to change the sensitivity of tissues with spare receptors by changing the receptor concentration.

Competitive & Irreversible Antagonists

Receptor antagonists bind to receptors but do not activate them. The primary action of antagonists is to preven agonists (other drugs or endogenous regulatory molecules) from activating receptors. Some antagonists (so-called "inverse agonists"), also reduce receptor activity below basal levels observed in the absence of bound ligand. Antagonists are divided into two classes depending on whether or not they *reversibly compete* with agonists for binding to receptors.

In the presence of a fixed concentration of agonist, increasing concentrations of a reversible competitive antagonist progressively inhibit the agonist response; high antagonist concentrations prevent response completely. Conversely, sufficiently high concentrations of agonist can completely surmount the effect of a give concentration of the antagonist; that is, the E_{max} for the agonist remains the same for any fixed concentration c antagonist (Figure 2–3A). Because the antagonism is competitive, the presence of antagonist increases the agonist concentration required for a given degree of response, and so the agonist concentration-effect curve is shifted to the right.

Figure 2–3.



Changes in agonist concentration-effect curves produced by a competitive antagonist (Panel A) or by an irreversible antago (Panel B). In the presence of a competitive antagonist, higher concentrations of agonist are required to produce a given eff thus the agonist concentration (C') required for a given effect in the presence of concentration [I] of an antagonist is shifted the right, as shown. High agonist concentrations can overcome inhibition by a competitive antagonist. This is not the case w an irreversible (or noncompetitive) antagonist, which reduces the maximal effect the agonist can achieve, although it may n change its EC_{50} .

The concentration (C') of an agonist required to produce a given effect in the presence of a fixed concentration ([I]) of competitive antagonist is greater than the agonist concentration (C) required to produce the same effec in the absence of the antagonist. The ratio of these two agonist concentrations (the "dose ratio") is related to tl dissociation constant (K_i) of the antagonist by the Schild equation:

$$\frac{C'}{C} = 1 + \frac{[I]}{K_i}$$

Pharmacologists often use this relation to determine the K_i of a competitive antagonist. Even without knowledge of the relationship between agonist occupancy of the receptor and response, the K_i can be determined simply a accurately. As shown in Figure 2–3, concentration response curves are obtained in the presence and in the absence of a fixed concentration of competitive antagonist; comparison of the agonist concentrations required t produce identical degrees of pharmacologic effect in the two situations reveals the antagonist's K_i . If C' is twice C, for example, then [I] = K_i .

For the clinician, this mathematical relation has two important therapeutic implications:

(1) The degree of inhibition produced by a competitive antagonist depends on the concentration of antagonist. Different patients receiving a fixed dose of propranolol, for example, exhibit a wide range of plasma concentrations, owing to differences in clearance of the drug. As a result, the effects of a fixed dose of this competitive antagonist of norepinephrine may vary widely in patients, and the dose must be adjusted accordin

(2) Clinical response to a competitive antagonist depends on the concentration of agonist that is competing for binding to receptors. Here also propranolol provides a useful example: When this competitive β-adrenoceptor antagonist is administered in doses sufficient to block the effect of basal levels of the neurotransmitter norepinephrine, resting heart rate is decreased. However, the increase in release of norepinephrine and epinephrine that occurs with exercise, postural changes, or emotional stress may suffice to overcome competiti antagonism by propranolol and increase heart rate, and thereby can influence therapeutic response.

Some receptor antagonists bind to the receptor in an *irreversible* or nearly irreversible fashion, either by form a covalent bond with the receptor or by binding so tightly that, for practical purposes, the receptor is unavailab for binding of agonist. After occupancy of some proportion of receptors by such an antagonist, the number of remaining unoccupied receptors may be too low for the agonist (even at high concentrations) to elicit a respons comparable to the previous maximal response (Figure 2–3B). If spare receptors are present, however, a lower dose of an irreversible antagonist may leave enough receptors unoccupied to allow achievement of maximum response to agonist, although a higher agonist concentration will be required (Figures 2–2B and C; see Recepto Effector Coupling and Spare Receptors, above).

Therapeutically, irreversible antagonists present distinctive advantages and disadvantages. Once the irreversibl antagonist has occupied the receptor, it need not be present in unbound form to inhibit agonist responses. Consequently, the duration of action of such an irreversible antagonist is relatively independent of its own rate elimination and more dependent on the rate of turnover of receptor molecules.

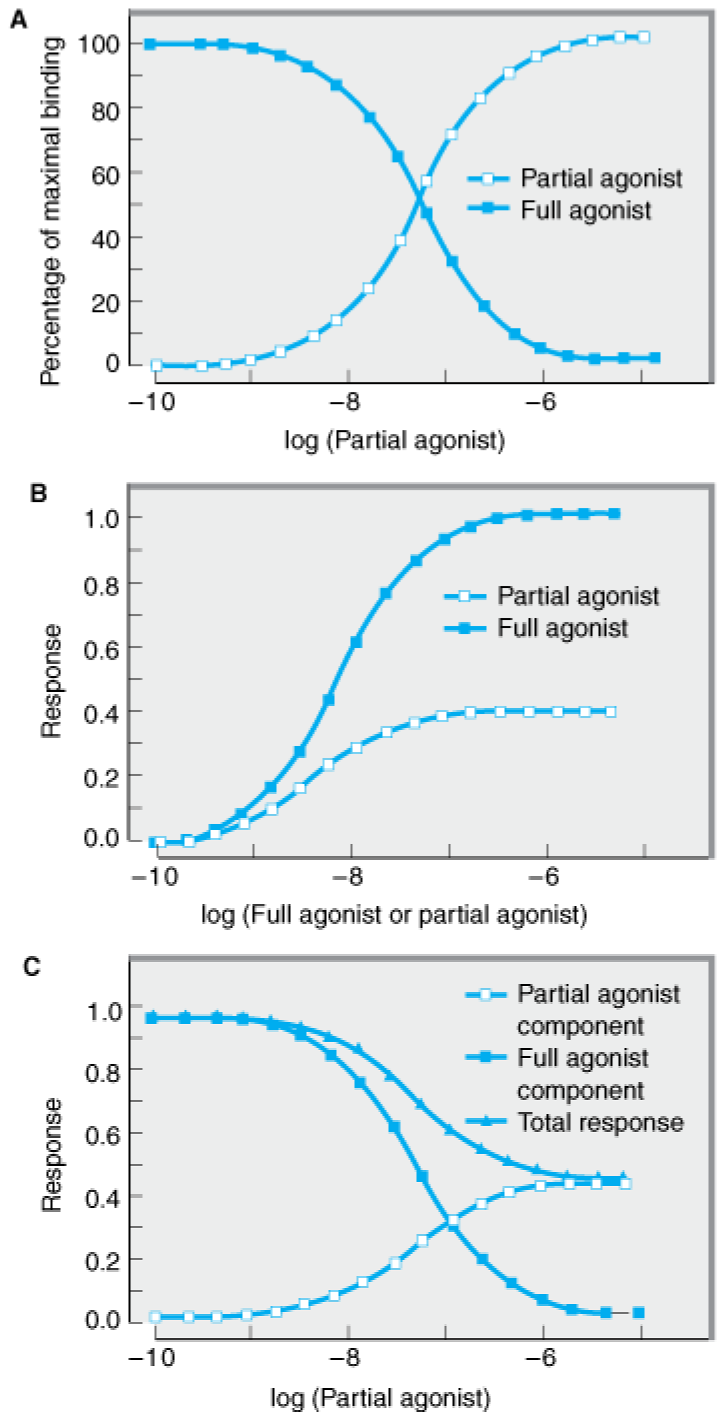
Phenoxybenzamine, an irreversible α-adrenoceptor antagonist, is used to control the hypertension caused by catecholamines released from pheochromocytoma, a tumor of the adrenal medulla. If administration of phenoxybenzamine lowers blood pressure, blockade will be maintained even when the tumor episodically releas very large amounts of catecholamine. In this case, the ability to prevent responses to varying and high concentrations of agonist is a therapeutic advantage. If overdose occurs, however, a real problem may arise. If the α-adrenoceptor blockade cannot be overcome, excess effects of the drug must be antagonized "physiologically," ie, by using a pressor agent that does not act via α receptors.

Antagonists can function noncompetitively in a different way; that is, by binding to a site on the receptor protei separate from the agonist binding site and thereby preventing receptor activation without blocking agonist binding. Although these drugs act noncompetitively, their actions are reversible if they do not bind covalently. Some drugs, often called *allosteric modulators* , bind to a separate site on the receptor protein and alter recept function without inactivating the receptor. For example, benzodiazepines bind noncompetitively to ion channels activated by the neurotransmitter γ-aminobutyric acid (GABA), enhancing the net activating effect of GABA on channel conductance.

Partial Agonists

Based on the maximal pharmacologic response that occurs when all receptors are occupied, agonists can be divided into two classes: partial agonists produce a lower response, at full receptor occupancy, than do full agonists. Partial agonists produce concentration-effect curves that resemble those observed with full agonists the presence of an antagonist that irreversibly blocks some of the receptor sites (compare Figures 2–2 [curve D and 2–4B). It is important to emphasize that the failure of partial agonists to produce a maximal response is nc due to decreased affinity for binding to receptors. Indeed, a partial agonist's inability to cause a maximal pharmacologic response, even when present at high concentrations that saturate binding to all receptors, is indicated by the fact that partial agonists competitively inhibit the responses produced by full agonists (Figure 2–4C). Many drugs used clinically as antagonists are in fact weak partial agonists.

Figure 2–4.



Panel A: The percentage of receptor occupancy resulting from full agonist (present at a single concentration) binding to receptors in the presence of increasing concentrations of a partial agonist. Because the full agonist (filled squares) and the partial agonist (open squares) compete to bind to the same receptor sites, when occupancy by the partial agonist increases, binding of the full agonist decreases. Panel B: When each of the two drugs is used alone and response is measured, occupai of all the receptors by the partial agonist produces a lower maximal response than does similar occupancy by the full agonis Panel C: Simultaneous treatment with a single concentration of full agonist and increasing concentrations of the partial agon produces the response patterns shown in the bottom panel. The fractional response caused by a single high concentration of the full agonist (filled squares) decreases as increasing concentrations of the partial agonist compete to bind to the receptor with increasing success; at the same time the portion of the response caused by the partial agonist (open squares) increase while the total response—ie, the sum of responses to the two drugs (filled triangles)—gradually decreases, eventually reachi the value produced by partial agonist alone (compare panel B).

Other Mechanisms of Drug Antagonism

Not all of the mechanisms of antagonism involve interactions of drugs or endogenous ligands at a single type of receptor, and some types of antagonism do not involve a receptor at all. For example, protamine, a protein tha positively charged at physiologic pH, can be used clinically to counteract the effects of heparin, an anticoagulan that is negatively charged; in this case, one drug acts as a **chemical antagonist** of the other simply by ionic binding that makes the other drug unavailable for interactions with proteins involved in blood clotting.

Another type of antagonism is **physiologic antagonism** between endogenous regulatory pathways mediated b different receptors. For example, several catabolic actions of the glucocorticoid hormones lead to increased bloo sugar, an effect that is physiologically opposed by insulin. Although glucocorticoids and insulin act on quite disti receptor-effector systems, the clinician must sometimes administer insulin to oppose the hyperglycemic effects a glucocorticoid hormone, whether the latter is elevated by endogenous synthesis (eg, a tumor of the adrenal cortex) or as a result of glucocorticoid therapy.

In general, use of a drug as a physiologic antagonist produces effects that are less specific and less easy to control than are the effects of a receptor-specific antagonist. Thus, for example, to treat bradycardia caused by increased release of acetylcholine from vagus nerve endings, the physician could use isoproterenol, a β-adrenoceptor agonist that increases heart rate by mimicking sympathetic stimulation of the heart. However, us of this physiologic antagonist would be less rational—and potentially more dangerous—than would use of a receptor-specific antagonist such as atropine (a competitive antagonist at the receptors at which acetylcholine slows heart rate).

SIGNALING MECHANISMS & DRUG ACTION

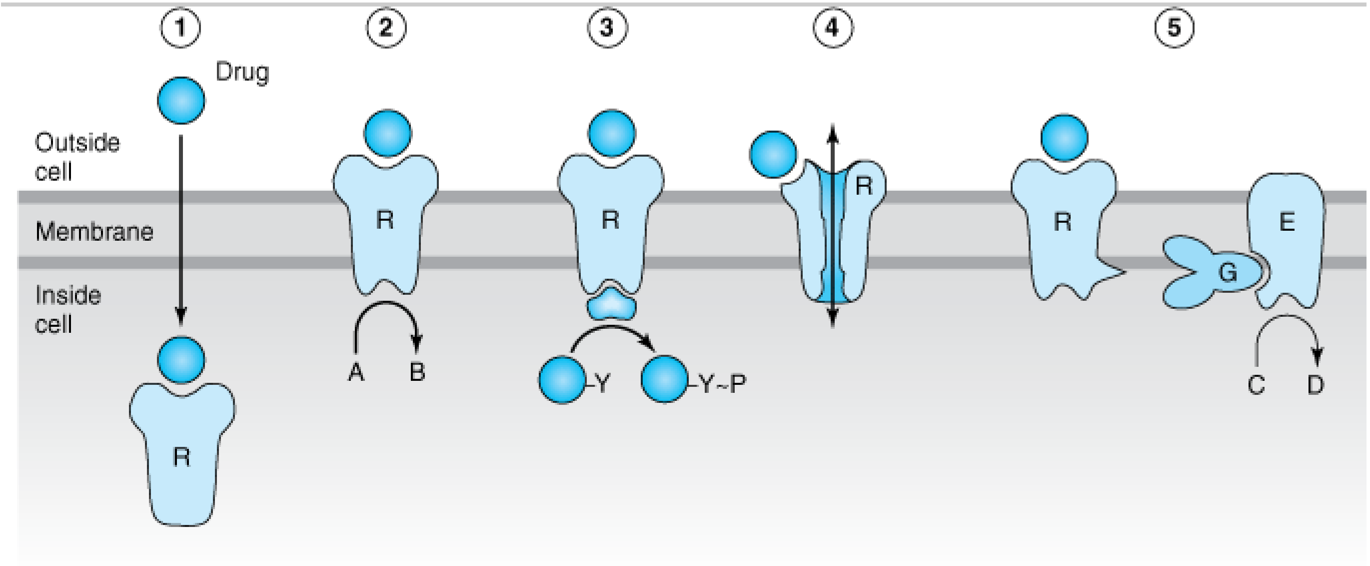
Until now we have considered receptor interactions and drug effects in terms of equations and concentration-effect curves. We must also understand the molecular mechanisms by which a drug acts. Such understanding allows us to ask basic questions with important clinical implications:

- Why do some drugs produce effects that persist for minutes, hours, or even days after the drug is no longer present?
- Why do responses to other drugs diminish rapidly with prolonged or repeated administration?
- How do cellular mechanisms for amplifying external chemical signals explain the phenomenon of spar receptors?
- Why do chemically similar drugs often exhibit extraordinary selectivity in their actions?
- Do these mechanisms provide targets for developing new drugs?

Most transmembrane signaling is accomplished by a small number of different molecular mechanisms. Each typ of mechanism has been adapted, through the evolution of distinctive protein families, to transduce many differe signals. These protein families include receptors on the cell surface and within the cell, as well as enzymes and other components that generate, amplify, coordinate, and terminate postreceptor signaling by chemical second messengers in the cytoplasm. This section first discusses the mechanisms for carrying chemical information across the plasma membrane and then outlines key features of cytoplasmic second messengers.

Five basic mechanisms of transmembrane signaling are well understood (Figure 2–5). Each uses a different strategy to circumvent the barrier posed by the lipid bilayer of the plasma membrane. These strategies use (1) lipid-soluble ligand that crosses the membrane and acts on an intracellular receptor; (2) a transmembrane receptor protein whose intracellular enzymatic activity is allosterically regulated by a ligand that binds to a site the protein's extracellular domain; (3) a transmembrane receptor that binds and stimulates a protein tyrosine kinase; (4) a ligand-gated transmembrane ion channel that can be induced to open or close by the binding of a ligand; or (5) a transmembrane receptor protein that stimulates a GTP-binding signal transducer protein (G protein), which in turn modulates production of an intracellular second messenger.

Figure 2–5.



Known transmembrane signaling mechanisms: 1: A lipid-soluble chemical signal crosses the plasma membrane and acts on intracellular receptor (which may be an enzyme or a regulator of gene transcription); 2: the signal binds to the extracellular domain of a transmembrane protein, thereby activating an enzymatic activity of its cytoplasmic domain; 3: the signal binds the extracellular domain of a transmembrane receptor bound to a protein tyrosine kinase, which it activates; 4: the signal bi to and directly regulates the opening of an ion channel; 5: the signal binds to a cell-surface receptor linked to an effector enzyme by a G protein. (A, C, substrates; B, D, products; R, receptor; G, G protein; E, effector [enzyme or ion channel]; Y, tyrosine; P, phosphate.)

While the five established mechanisms do not account for all the chemical signals conveyed across cell membranes, they do transduce many of the most important signals exploited in pharmacotherapy.

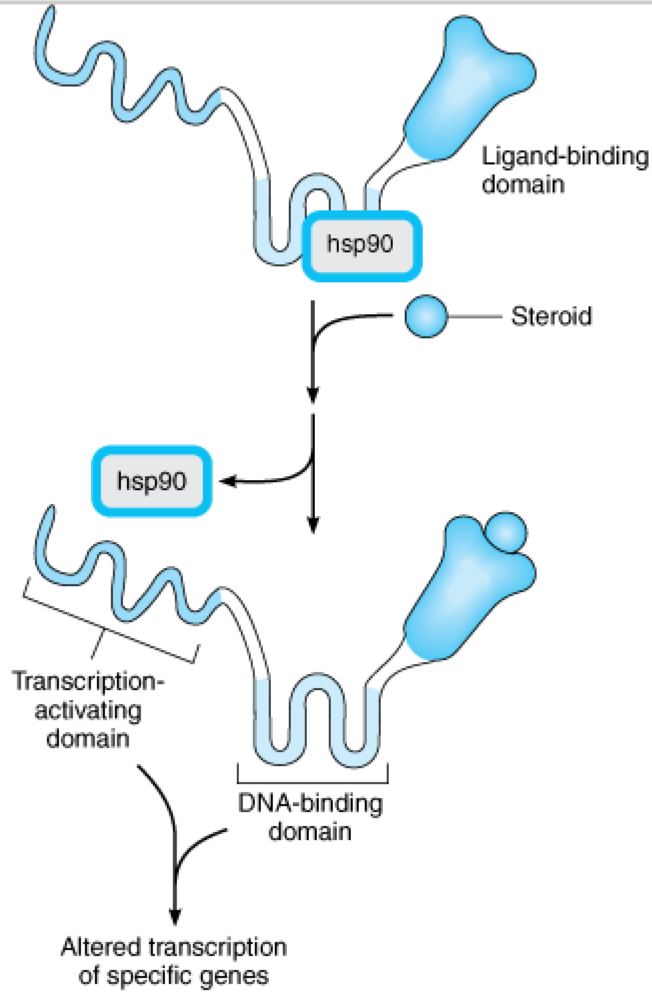
Intracellular Receptors for Lipid-Soluble Agents

Several biologic ligands are sufficiently lipid-soluble to cross the plasma membrane and act on intracellular receptors. One class of such ligands includes steroids (corticosteroids, mineralocorticoids, sex steroids, vitamin

D), and thyroid hormone, whose receptors stimulate the transcription of genes by binding to specific DNA sequences near the gene whose expression is to be regulated. Many of the target DNA sequences (called response elements) have been identified.

These "gene-active" receptors belong to a protein family that evolved from a common precursor. Dissection of receptors by recombinant DNA techniques has provided insights into their molecular mechanism. For example, binding of glucocorticoid hormone to its normal receptor protein relieves an inhibitory constraint on the transcription-stimulating activity of the protein. Figure 2–6 schematically depicts the molecular mechanism of glucocorticoid action: In the absence of hormone, the receptor is bound to hsp90, a protein that appears to prevent normal folding of several structural domains of the receptor. Binding of hormone to the ligand-binding domain triggers release of hsp90. This allows the DNA-binding and transcription-activating domains of the receptor to fold into their functionally active conformations, so that the activated receptor can initiate transcript of target genes.

Figure 2–6.



Mechanism of glucocorticoid action. The glucocorticoid receptor polypeptide is schematically depicted as a protein with three distinct domains. A heat-shock protein, hsp90, binds to the receptor in the absence of hormone and prevents folding into th active conformation of the receptor. Binding of a hormone ligand (steroid) causes dissociation of the hsp90 stabilizer and permits conversion to the active configuration.

The mechanism used by hormones that act by regulating gene expression has two therapeutically important consequences:

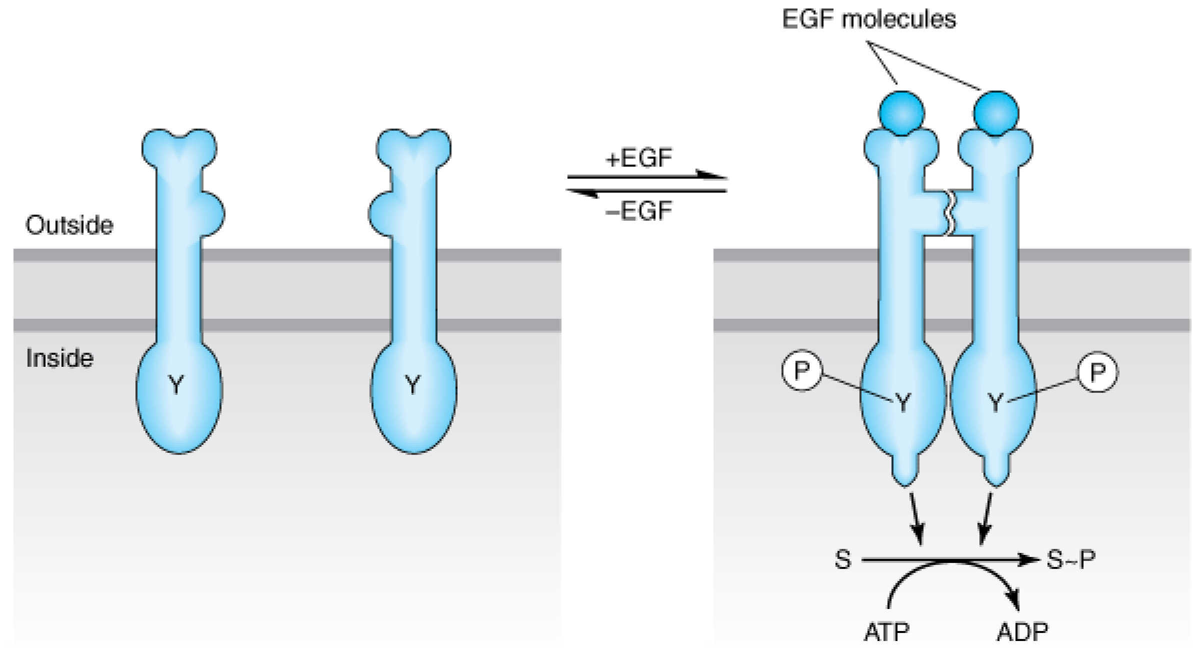
(1) All of these hormones produce their effects after a characteristic lag period of 30 minutes to several hours—the time required for the synthesis of new proteins. This means that the gene-active hormones cannot I expected to alter a pathologic state within minutes (eg, glucocorticoids will not immediately relieve the sympto of acute bronchial asthma).

(2) The effects of these agents can persist for hours or days after the agonist concentration has been reduced t zero. The persistence of effect is primarily due to the relatively slow turnover of most enzymes and proteins, which can remain active in cells for hours or days after they have been synthesized. Consequently, it means th the beneficial (or toxic) effects of a gene-active hormone will usually decrease slowly when administration of th hormone is stopped.

Ligand-Regulated Transmembrane Enzymes Including Receptor Tyrosine Kinases

This class of receptor molecules mediates the first steps in signaling by insulin, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), atrial natriuretic peptide (ANP), transforming growth factor-β (TGF-β), a many other trophic hormones. These receptors are polypeptides consisting of an extracellular hormone-binding domain and a cytoplasmic enzyme domain, which may be a protein tyrosine kinase, a serine kinase, or a guany cyclase (Figure 2–7). In all these receptors, the two domains are connected by a hydrophobic segment of the polypeptide that crosses the lipid bilayer of the plasma membrane.

Figure 2–7.



Mechanism of activation of the epidermal growth factor (EGF) receptor, a representative receptor tyrosine kinase. The recep polypeptide has extracellular and cytoplasmic domains, depicted above and below the plasma membrane. Upon binding of E((circle), the receptor converts from its inactive monomeric state (left) to an active dimeric state (right), in which two recepto polypeptides bind noncovalently. The cytoplasmic domains become phosphorylated (P) on specific tyrosine residues (Y) and their enzymatic activities are activated, catalyzing phosphorylation of substrate proteins (S).

The receptor tyrosine kinase signaling pathway begins with binding of ligand, typically a polypeptide hormone o growth factor, to the receptor's extracellular domain. The resulting change in receptor conformation causes receptor molecules to bind to one another, which in turn brings together the tyrosine kinase domains, which become enzymatically active, and phosphorylate one another as well as additional downstream signaling protei Activated receptors catalyze phosphorylation of tyrosine residues on different target signaling proteins, thereby allowing a single type of activated receptor to modulate a number of biochemical processes.

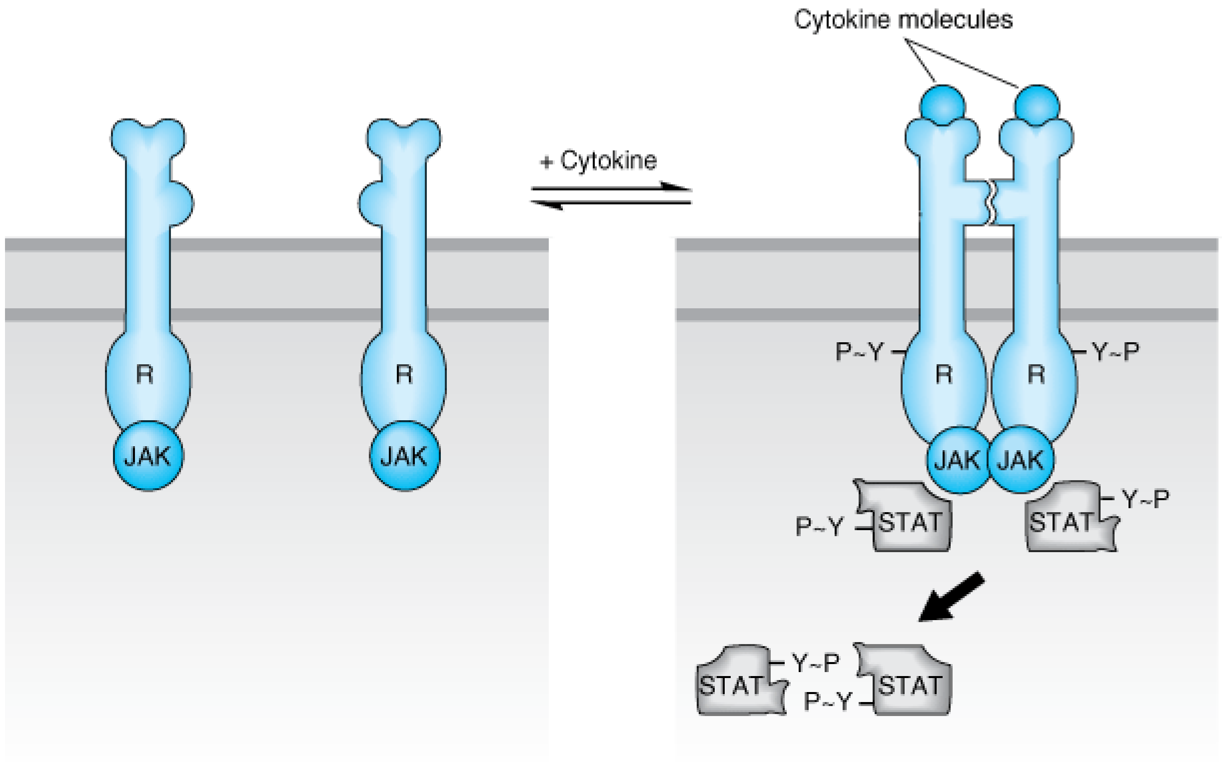
Insulin, for example, uses a single class of receptors to trigger increased uptake of glucose and amino acids, ar to regulate metabolism of glycogen and triglycerides in the cell. Similarly, each of the growth factors initiates in specific target cells a complex program of cellular events ranging from altered membrane transport of ions and metabolites to changes in the expression of many genes. Inhibitors of receptor tyrosine kinases are finding increased use in neoplastic disorders where excessive growth factor signaling is often involved. Some of these inhibitors are monoclonal antibodies (eg, trastuzumab, cetuximab), which bind to the extracellular domain of a particular receptor and interfere with binding of growth factor. Other inhibitors are membrane-permeant "small molecule" chemicals (eg, gefitinib, erlotinib), which inhibit the receptor's kinase activity in the cytoplasm.

The intensity and duration of action of EGF, PDGF, and other agents that act via receptor tyrosine kinases are limited by a process called receptor down-regulation. Ligand binding often induces accelerated endocytosis o receptors from the cell surface, followed by the degradation of those receptors (and their bound ligands). Wher this process occurs at a rate faster than de novo synthesis of receptors, the total number of cell-surface recept is reduced (down-regulated) and the cell's responsiveness to ligand is correspondingly diminished. A well-understood example is the EGF receptor tyrosine kinase, which undergoes rapid endocytosis and is trafficked tc lysosomes after EGF binding; genetic mutations that interfere with this process cause excessive growth factor–induced cell proliferation and are associated with an increased susceptibility to certain types of cancer. Endocytosis of other receptor tyrosine kinases, most notably receptors for nerve growth factor, serves a very different function. Internalized nerve growth factor receptors are not rapidly degraded and are translocated in endocytic vesicles from the distal axon, where receptors are activated by nerve growth factor released from the innervated tissue, to the cell body. In the cell body the growth factor signal is transduced to transcription factor regulating the expression of genes controlling cell survival. This process effectively transports a critical survival signal from its site of release to its site of signaling effect, and does so over a remarkably long distance—more than 1 meter in certain sensory neurons. A number of regulators of growth and differentiation, including TGF-β, act on another class of transmembrane receptor enzymes that phosphorylate serine and threonine residues. AN an important regulator of blood volume and vascular tone, acts on a transmembrane receptor whose intracellul domain, a guanylyl cyclase, generates cGMP (see below). Receptors in both groups, like the receptor tyrosine kinases, are active in their dimeric forms.

Cytokine Receptors

Cytokine receptors respond to a heterogeneous group of peptide ligands that includes growth hormone, erythropoietin, several kinds of interferon, and other regulators of growth and differentiation. These receptors u a mechanism (Figure 2–8) closely resembling that of receptor tyrosine kinases, except that in this case, the protein tyrosine kinase activity is not intrinsic to the receptor molecule. Instead, a separate protein tyrosine kinase, from the Janus-kinase (JAK) family, binds noncovalently to the receptor. As in the case of the EGF-receptor, cytokine receptors dimerize after they bind the activating ligand, allowing the bound JAKs to become activated and to phosphorylate tyrosine residues on the receptor. Tyrosine phosphates on the receptor then set motion a complex signaling dance by binding another set of proteins, called STATs (signal transducers and activators of transcription). The bound STATs are themselves phosphorylated by the JAKs, two STAT molecules dimerize (attaching to one another's tyrosine phosphates), and finally the STAT/STAT dimer dissociates from th receptor and travels to the nucleus, where it regulates transcription of specific genes.

Figure 2–8.



Cytokine receptors, like receptor tyrosine kinases, have extracellular and intracellular domains and form dimers. However, a activation by an appropriate ligand, separate mobile protein tyrosine kinase molecules (JAK) are activated, resulting in phosphorylation of signal transducers and activation of transcription (STAT) molecules. STAT dimers then travel to the nucle where they regulate transcription.

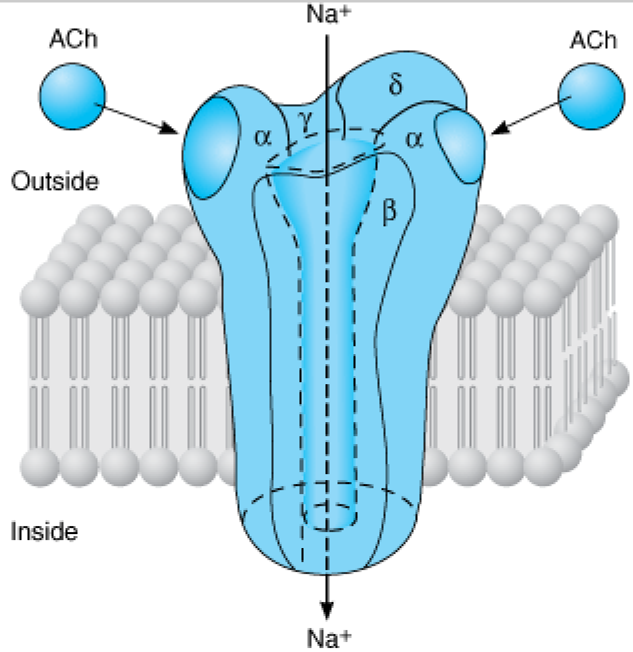
Ligand-Gated Channels

Many of the most useful drugs in clinical medicine act by mimicking or blocking the actions of endogenous ligan that regulate the flow of ions through plasma membrane channels. The natural ligands include acetylcholine, serotonin, GABA, and glutamate. All of these agents are synaptic transmitters.

Each of their receptors transmits its signal across the plasma membrane by increasing transmembrane conductance of the relevant ion and thereby altering the electrical potential across the membrane. For example acetylcholine causes the opening of the ion channel in the nicotinic acetylcholine receptor (AChR), which allows Na^+ to flow down its concentration gradient into cells, producing a localized excitatory postsynaptic potential—a depolarization.

The AChR (Figure 2–9) is one of the best-characterized of all cell-surface receptors for hormones or neurotransmitters. One form of this receptor is a pentamer made up of four polypeptide subunits (eg, two αcha plus one β, one γ, and one δchain, all with molecular weights ranging from 43,000 to 50,000). These polypeptides, each of which crosses the lipid bilayer four times, form a cylindric structure 8 nm in diameter. Wh acetylcholine binds to sites on the αsubunits, a conformational change occurs that results in the transient openi of a central aqueous channel through which sodium ions penetrate from the extracellular fluid into the cell.

Figure 2–9.



The nicotinic acetylcholine receptor, a ligand-gated ion channel. The receptor molecule is depicted as embedded in a rectangular piece of plasma membrane, with extracellular fluid above and cytoplasm below. Composed of five subunits (two one β, one γ, and one δ), the receptor opens a central transmembrane ion channel when acetylcholine (ACh) binds to sites the extracellular domain of its α subunits.

The time elapsed between the binding of the agonist to a ligand-gated channel and the cellular response can of be measured in milliseconds. The rapidity of this signaling mechanism is crucially important for moment-to-moment transfer of information across synapses. Ligand-gated ion channels can be regulated by multiple mechanisms, including phosphorylation and endocytosis. In the central nervous system, these mechanisms contribute to synaptic plasticity involved in learning and memory.

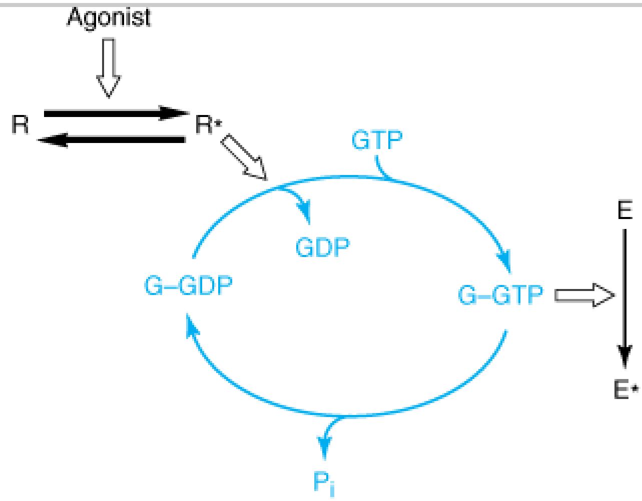
G Proteins & Second Messengers

Many extracellular ligands act by increasing the intracellular concentrations of second messengers such as cycli adenosine-3',5'-monophosphate (cAMP), calcium ion, or the phosphoinositides (described below). In most case they use a transmembrane signaling system with three separate components. First, the extracellular ligand is specifically detected by a cell-surface receptor. The receptor in turn triggers the activation of a G protein locate on the cytoplasmic face of the plasma membrane. The activated G protein then changes the activity of an effec element, usually an enzyme or ion channel. This element then changes the concentration of the intracellular second messenger. For cAMP, the effector enzyme is adenylyl cyclase, a membrane protein that converts intracellular adenosine triphosphate (ATP) to cAMP. The corresponding G protein, G_S , stimulates adenylyl cycla after being activated by hormones and neurotransmitters that act via specific G_S -coupled receptors. There are many examples of such receptors including β-adrenoceptors, glucagon receptors, thyrotropin receptors, and certain subtypes of dopamine and serotonin receptors.

G_S and other G proteins use a molecular mechanism that involves binding and hydrolysis of GTP (Figure 2–10).

This mechanism allows the transduced signal to be amplified. For example, a neurotransmitter such as norepinephrine may encounter its membrane receptor for only a few milliseconds. When the encounter generat a GTP-bound G_S molecule, however, the duration of activation of adenylyl cyclase depends on the longevity of G binding to G_S rather than on the receptor's affinity for norepinephrine. Indeed, like other G proteins, GTP-bounc G_S may remain active for tens of seconds, enormously amplifying the original signal. This mechanism also helps explain how signaling by G proteins produces the phenomenon of spare receptors (described above). The famil of G proteins contains several functionally diverse subfamilies (Table 2–1), each of which mediates effects of a particular set of receptors to a distinctive group of effectors. Note that an endogenous ligand (eg, norepinephri acetylcholine, serotonin, many others not listed in Table 2–1) may bind and stimulate receptors that couple to different subsets of G proteins. The apparent promiscuity of such a ligand allows it to elicit different G protein-dependent responses in different cells. For instance, the body responds to danger by using catecholamines (norepinephrine and epinephrine) both to increase heart rate and to induce constriction of blood vessels in the skin, by acting on G_S -coupled β-adrenoceptors and G_q -coupled α_1 -adrenoceptors, respectively. Ligand promiscuity also offers opportunities in drug development (see Receptor Classes & Drug Development, below).

Figure 2–10.



The guanine nucleotide-dependent activation-inactivation cycle of G proteins. The agonist activates the receptor (R→R*), wh promotes release of GDP from the G protein (G), allowing entry of GTP into the nucleotide binding site. In its GTP-bound sta (G-GTP), the G protein regulates activity of an effector enzyme or ion channel (E). The signal is terminated by hydrolysis of GTP, followed by return of the system to the basal unstimulated state. Open arrows denote regulatory effects. (P_i , inorganic phosphate.)

Table 2–1. G Proteins and Their Receptors and Effectors.

G Protein	Receptors for:	Effector/Signaling Pathway
G_S		

β-Adrenergic amines, glucagon, histamine, serotonin, and many other hormones

↑Adenylyl cyclase →↑cAMP

G_{i1} , G_{i2} , G_{i3}

α_2 -Adrenergic amines, acetylcholine (muscarinic), opioids, serotonin, and many others

Several, including:

↓ Adenylyl cyclase →↓cAMP

Open cardiac K^+ channels →↓heart rate

G_{olf}

Odorants (olfactory epithelium)

↑Adenylyl cyclase →↑cAMP

G_o

Neurotransmitters in brain (not yet specifically identified)

Not yet clear

G_q

Acetylcholine (muscarinic), bombesin, serotonin (5-HT_{1C}), and many others

↑Phospholipase C →↑IP_3 , diacylglycerol, cytoplasmic Ca^{2+}

G_{t1} , G_{t2}

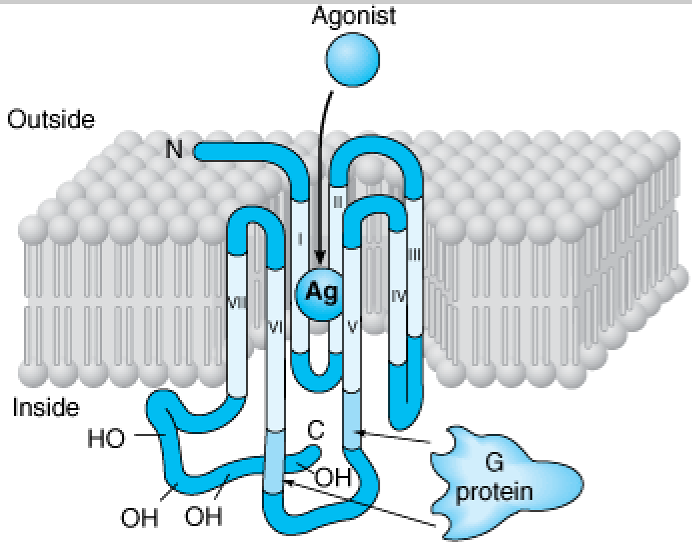
Photons (rhodopsin and color opsins in retinal rod and cone cells)

↑cGMP phosphodiesterase →↓cGMP (phototransduction)

Key: cAMP = cyclic adenosine monophosphate; cGMP = cyclic guanosine monophosphate.

Receptors coupled to G proteins comprise a family of "seven-transmembrane" (7-TM) or "serpentine" receptors so called because the receptor polypeptide chain "snakes" across the plasma membrane seven times (Figure 2–11). Receptors for adrenergic amines, serotonin, acetylcholine (muscarinic but not nicotinic), many peptide hormones, odorants, and even visual receptors (in retinal rod and cone cells) all belong to the serpentine family All were derived from a common evolutionary precursor. Several serpentine receptors exist as dimers or larger complexes. Serpentine receptors signal by a different mechanism than receptor tyrosine kinases and cytokine receptors, however, and it is thought that dimerization is not essential for activation of many serpentine receptors.

Figure 2–11.



Transmembrane topology of a typical serpentine receptor. The receptor's amino (N) terminal is extracellular (above the plan the membrane), and its carboxyl (C) terminal intracellular. The terminals are connected by a polypeptide chain that traverse the plane of the membrane seven times. The hydrophobic transmembrane segments (light color) are designated by roman numerals (I–VII). The agonist (Ag) approaches the receptor from the extracellular fluid and binds to a site surrounded by th transmembrane regions of the receptor protein. G proteins interact with cytoplasmic regions of the receptor, especially with portions of the third cytoplasmic loop between transmembrane regions V and VI. The receptor's cytoplasmic terminal tail contains numerous serine and threonine residues whose hydroxyl (–OH) groups can be phosphorylated. This phosphorylatio may be associated with diminished receptor-G protein interaction.

All serpentine receptors transduce signals across the plasma membrane in essentially the same way. Often the agonist ligand—eg, a catecholamine, acetylcholine, or the photon-activated chromophore of retinal photoreceptors—is bound in a pocket enclosed by the transmembrane regions of the receptor (as in Figure 2–1 The resulting change in conformation of these regions is transmitted to cytoplasmic loops of the receptor, which turn activate the appropriate G protein by promoting replacement of GDP by GTP, as described above. Amino acids in the third cytoplasmic loop of the serpentine receptor polypeptide are generally thought to play a key ro in mediating receptor interaction with G proteins (shown by arrows in Figure 2–11).

Receptor Regulation

G protein-mediated responses to drugs and hormonal agonists often attenuate with time (Figure 2–12, top). Af reaching an initial high level, the response (eg, cellular cAMP accumulation, Na^+ influx, contractility, etc) diminishes over seconds or minutes, even in the continued presence of the agonist. This "desensitization" is oft rapidly reversible; a second exposure to agonist, if provided a few minutes after termination of the first exposu results in a response similar to the initial response.

Rapid desensitization and longer-term down-regulation of β-adrenoceptors. Panel A: Response to a β-adrenoceptor agonist (ordinate) versus time (abscissa). Temporal duration of exposure to a constant concentration of agonist is indicated by the light-colored bar. The break in the time axis indicates passage of time in the absence of agonist. Desensitization refers to the reduced cAMP response after several minutes in the continued presence of agonist; restored response is observed after a br period (typically several more minutes) in the absence of agonist. Panel B: Agonist-induced phosphorylation (P) by a G protein–coupled receptor kinase (GRK) of carboxyl terminal hydroxyl groups (–OH) of the β-adrenoceptor. This phosphorylation induces binding of a protein, β-arrestin (β-arr), which prevents the receptor from interacting with G_s . Removal of agonist for a short period of time (on the order of several minutes) allows dissociation of β-arr, removal of phosphate (Pi) from the receptor by phosphatases (P'ase), and restoration of the receptor's normal responsiveness to agoni Panel C: Agonist-induced endocytosis and endocytic membrane trafficking of receptors. Beta-arrestin promotes receptor binding to endocytotic structures in the plasma membrane called coated pits. After short-term agonist exposure, receptors primarily undergo dephosphorylation by phosphatases (P'ase) and recycling, promoting rapid recovery of signaling responsiveness. After longer-term agonist exposure, receptors that have undergone endocytosis traffic to lysosomes, promoting the process of receptor down-regulation.

The mechanism mediating rapid desensitization of G protein–coupled receptors often involves receptor phosphorylation, as illustrated by rapid desensitization of the β-adrenoceptor (Figure 2–12, top). The agonist-induced change in conformation of the receptor causes it to bind, activate, and serve as a substrate for a family specific receptor kinases, called G protein-coupled receptor kinases (GRKs). The activated GRK then phosphorylates serine residues in the receptor's carboxyl terminal tail. The presence of phosphoserines increas the receptor's affinity for binding a third protein, β-arrestin. Binding of β-arrestin to cytoplasmic loops of the receptor diminishes the receptor's ability to interact with G_s , thereby reducing the agonist response (ie, stimulation of adenylyl cyclase). Upon removal of agonist, GRK activation is terminated and the desensitization process can be reversed by cellular phosphatases.

For the β-adrenoceptor, and many other serpentine receptors, β-arrestin binding also accelerates endocytosis o receptors from the plasma membrane. Endocytosis of receptors promotes their dephosphorylation, by a recepto phosphatase that is present at high concentration on endosome membranes, and receptors then return to the plasma membrane. This helps explain the ability of cells to recover receptor-mediated signaling responsiveness very efficiently after agonist-induced desensitization. Several serpentine receptors—including the β-adrenocepto if it is persistently activated—instead traffic to lysosomes after endocytosis and are degraded. This process effectively attenuates (rather than restores) cellular responsiveness, similar to the process of down-regulation described above for the epidermal growth factor receptor. Thus, depending on the particular receptor and duration of activation, endocytosis can contribute to either rapid recovery or prolonged attenuation of cellular responsiveness (Figure 2–12).

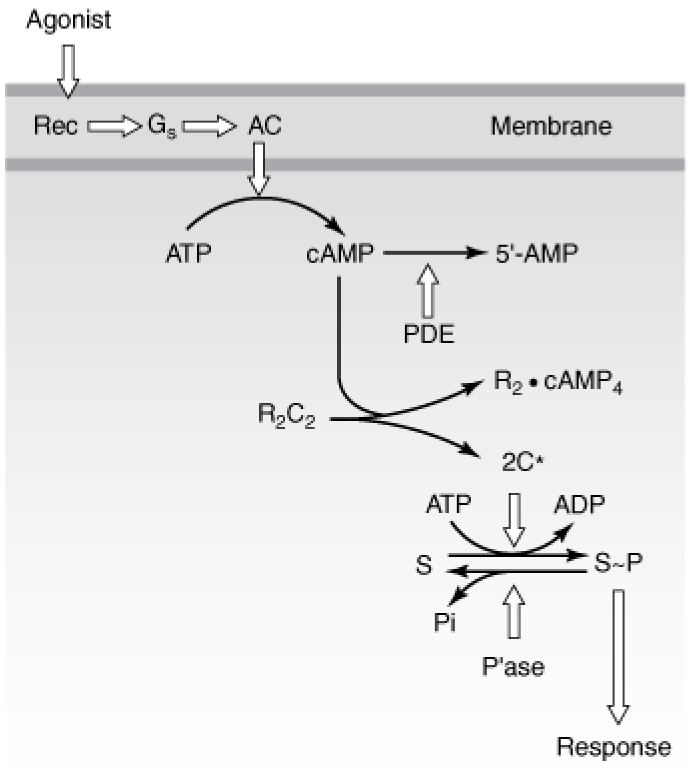
Well-Established Second Messengers

CYCLIC ADENOSINE MONOPHOSPHATE (CAMP)

Acting as an intracellular second messenger, cAMP mediates such hormonal responses as the mobilization of stored energy (the breakdown of carbohydrates in liver or triglycerides in fat cells stimulated by β-adrenomime catecholamines), conservation of water by the kidney (mediated by vasopressin), Ca^{2+} homeostasis (regulated parathyroid hormone), and increased rate and contractile force of heart muscle (β-adrenomimetic catecholamines). It also regulates the production of adrenal and sex steroids (in response to corticotropin or follicle-stimulating hormone), relaxation of smooth muscle, and many other endocrine and neural processes.

cAMP exerts most of its effects by stimulating cAMP-dependent protein kinases (Figure 2–13). These kinases ar composed of a cAMP-binding regulatory (R) dimer and two catalytic (C) chains. When cAMP binds to the R dime active C chains are released to diffuse through the cytoplasm and nucleus, where they transfer phosphate from ATP to appropriate substrate proteins, often enzymes. The specificity of cAMP's regulatory effects resides in the distinct protein substrates of the kinases that are expressed in different cells. For example, liver is rich in phosphorylase kinase and glycogen synthase, enzymes whose reciprocal regulation by cAMP-dependent phosphorylation governs carbohydrate storage and release.

Figure 2–13.



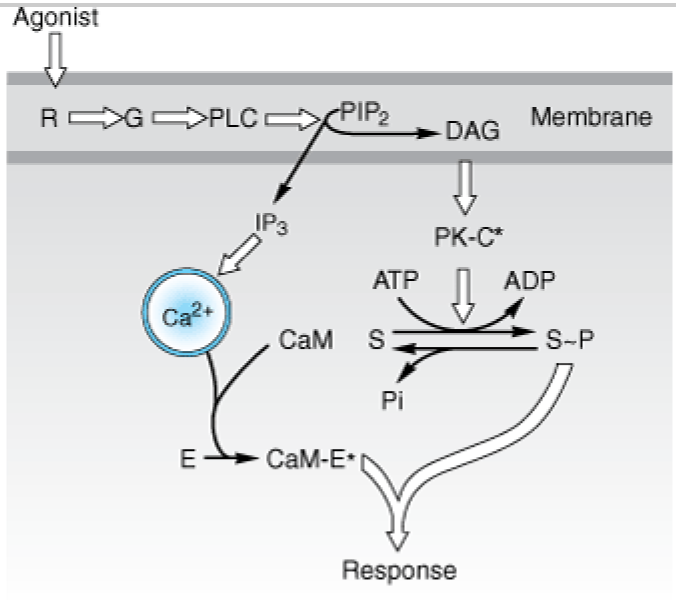
The cAMP second messenger pathway. Key proteins include hormone receptors (Rec), a stimulatory G protein (G_s), catalytic adenylyl cyclase (AC), phosphodiesterases (PDE) that hydrolyze cAMP, cAMP-dependent kinases, with regulatory (R) and catalytic (C) subunits, protein substrates (S) of the kinases, and phosphatases (P'ase), which remove phosphates from substrate proteins. Open arrows denote regulatory effects.

When the hormonal stimulus stops, the intracellular actions of cAMP are terminated by an elaborate series of enzymes. cAMP-stimulated phosphorylation of enzyme substrates is rapidly reversed by a diverse group of spec and nonspecific phosphatases. cAMP itself is degraded to 5'-AMP by several cyclic nucleotide phosphodiesterase (PDE, Figure 2–13). Competitive inhibition of cAMP degradation is one way caffeine, theophylline, and other methylxanthines produce their effects (see Chapter 20).

CALCIUM AND PHOSPHOINOSITIDES

Another well-studied second messenger system involves hormonal stimulation of phosphoinositide hydrolysis (Figure 2–14). Some of the hormones, neurotransmitters, and growth factors that trigger this pathway bind to receptors linked to G proteins, while others bind to receptor tyrosine kinases. In all cases, the crucial step is stimulation of a membrane enzyme, phospholipase C (PLC), which splits a minor phospholipid component of the plasma membrane, phosphatidylinositol-4,5-bisphosphate (PIP_2), into two second messengers, diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP_3 or $InsP_3$). Diacylglycerol is confined to the membrane where it activates a phospholipid- and calcium-sensitive protein kinase called protein kinase C. IP_3 is water-soluble and diffuses through the cytoplasm to trigger release of Ca^{2+} from internal storage vesicles. Elevated cytoplasmic Ca^{2+} concentration promotes the binding of Ca^{2+} to the calcium-binding protein calmodulin, which regulates activities of other enzymes, including calcium-dependent protein kinases.

Figure 2–14.



The Ca^{2+} -phosphoinositide signaling pathway. Key proteins include hormone receptors (R), a G protein (G), a phosphoinositide-specific phospholipase C (PLC), protein kinase C substrates of the kinase (S), calmodulin (CaM), and calmodulin-binding enzymes (E), including kinases, phosphodiesterases, etc. (PIP_2 , phosphatidylinositol-4,5-bisphosphate; DAG, diacylglycerol; IP_3 , inositol trisphosphate. Asterisk denotes activated state. Open arrows denote regulatory effects.)

With its multiple second messengers and protein kinases, the phosphoinositide signaling pathway is much more complex than the cAMP pathway. For example, different cell types may contain one or more specialized calcium and calmodulin-dependent kinases with limited substrate specificity (eg, myosin light chain kinase) in addition t general calcium- and calmodulin-dependent kinase that can phosphorylate a wide variety of protein substrates. Furthermore, at least nine structurally distinct types of protein kinase C have been identified.

As in the cAMP system, multiple mechanisms damp or terminate signaling by this pathway. IP_3 is inactivated by dephosphorylation; diacylglycerol is either phosphorylated to yield phosphatidic acid, which is then converted b into phospholipids, or it is deacylated to yield arachidonic acid; Ca^{2+} is actively removed from the cytoplasm by Ca^{2+} pumps.

These and other nonreceptor elements of the calcium-phosphoinositide signaling pathway are now becoming targets for drug development. For example, the therapeutic effects of lithium ion, an established agent for treating manic-depressive disorder, may be mediated by effects on the metabolism of phosphoinositides (see Chapter 29).

CYCLIC GUANOSINE MONOPHOSPHATE (CGMP)

Unlike cAMP, the ubiquitous and versatile carrier of diverse messages, cGMP has established signaling roles in only a few cell types. In intestinal mucosa and vascular smooth muscle, the cGMP-based signal transduction mechanism closely parallels the cAMP-mediated signaling mechanism. Ligands detected by cell surface receptor stimulate membrane-bound guanylyl cyclase to produce cGMP, and cGMP acts by stimulating a cGMP-dependen protein kinase. The actions of cGMP in these cells are terminated by enzymatic degradation of the cyclic nucleotide and by dephosphorylation of kinase substrates.

Increased cGMP concentration causes relaxation of vascular smooth muscle by a kinase-mediated mechanism t results in dephosphorylation of myosin light chains (Figure 12–2). In these smooth muscle cells, cGMP synthes can be elevated by two different transmembrane signaling mechanisms utilizing two different guanylyl cyclases Atrial natriuretic peptide, a blood-borne peptide hormone, stimulates a transmembrane receptor by binding to i extracellular domain, thereby activating the guanylyl cyclase activity that resides in the receptor's intracellular domain. The other mechanism mediates responses to nitric oxide (NO; see Chapter 19), which is generated in vascular endothelial cells in response to natural vasodilator agents such as acetylcholine and histamine. After entering the target cell, NO binds to and activates a cytoplasmic guanylyl cyclase. A number of useful vasodilati drugs, such as nitroglycerin and sodium nitroprusside used in treating cardiac ischemia and acute hypertension act by generating or mimicking NO. Other drugs produce vasodilation by inhibiting specific phosphodiesterases, thereby interfering with the metabolic breakdown of cGMP. One such drug is sildenafil, used in treating erectile dysfunction (see Chapter 12).

Interplay among Signaling Mechanisms

The calcium-phosphoinositide and cAMP signaling pathways oppose one another in some cells and are complementary in others. For example, vasopressor agents that contract smooth muscle act by IP_3 -mediated mobilization of Ca^{2+} , whereas agents that relax smooth muscle often act by elevation of cAMP. In contrast, cAN and phosphoinositide second messengers act together to stimulate glucose release from the liver.

Phosphorylation: A Common Theme

Almost all second messenger signaling involves reversible phosphorylation, which performs two principal functio in signaling: amplification and flexible regulation. In *amplification*, rather like GTP bound to a G protein, the attachment of a phosphoryl group to a serine, threonine, or tyrosine residue powerfully amplifies the initial regulatory signal by recording a molecular memory that the pathway has been activated; dephosphorylation erases the memory, taking a longer time to do so than is required for dissociation of an allosteric ligand. In *flexible regulation*, differing substrate specificities of the multiple protein kinases regulated by second messengers provide branch points in signaling pathways that may be independently regulated. In this way, cAN Ca^{2+} , or other second messengers can use the presence or absence of particular kinases or kinase substrates produce quite different effects in different cell types. Inhibitors of protein kinases have great potential as therapeutic agents, particularly in neoplastic diseases. Trastuzumab, an antibody that antagonizes growth facto receptor signaling, was discussed earlier and is a useful therapeutic agent for breast cancer. Another example o this general approach is imatinib, a small molecule inhibitor of the cytoplasmic tyrosine kinase Abl, which is activated by growth factor signaling pathways. Imatinib appears to be very effective for treating chronic myelogenous leukemia, which is caused by a chromosomal translocation event that produces an active Bcr/Abl fusion protein in hematopoietic cells.

RECEPTOR CLASSES & DRUG DEVELOPMENT

The existence of a specific drug receptor is usually inferred from studying the *structure-activity relationship* a group of structurally similar congeners of the drug that mimic or antagonize its effects. Thus, if a series of related agonists exhibits identical relative potencies in producing two distinct effects, it is likely that the two effects are mediated by similar or identical receptor molecules. In addition, if identical receptors mediate both effects, a competitive antagonist will inhibit both responses with the same K_i ; a second competitive antagonist will inhibit both responses with its own characteristic K_i . Thus, studies of the relation between structure and activity of a series of agonists and antagonists can identify a species of receptor that mediates a set of pharmacologic responses.

Exactly the same experimental procedure can show that observed effects of a drug are mediated by *different* receptors. In this case, effects mediated by different receptors may exhibit different orders of potency among agonists and different K_i values for each competitive antagonist.

Wherever we look, evolution has created many different receptors that function to mediate responses to any individual chemical signal. In some cases, the same chemical acts on completely different structural receptor classes. For example, acetylcholine uses ligand-gated ion channels (nicotinic AChRs) to initiate a fast excitatory postsynaptic potential (EPSP) in postganglionic neurons. Acetylcholine also activates a separate class of G prote coupled receptors (muscarinic AChRs), which modulate responsiveness of the same neurons to the fast EPSP. I addition, each structural class usually includes multiple subtypes of receptor, often with significantly different signaling or regulatory properties. For example, many biogenic amines (eg, norepinephrine, acetylcholine, and serotonin) activate more than one receptor, each of which may activate a different G protein, as described abov (see also Table 2–1). The existence of multiple receptor classes and subtypes for the same endogenous ligand created important opportunities for drug development. For example, propranolol, a selective antagonist of β-adrenoceptors, can reduce an accelerated heart rate without preventing the sympathetic nervous system from causing vasoconstriction, an effect mediated by α_1 receptors.

The principle of drug selectivity may even apply to structurally identical receptors expressed in different cells, e receptors for steroids such as estrogen (Figure 2–6). Different cell types express different accessory proteins, which interact with steroid receptors and change the functional effects of drug-receptor interaction. For exampl tamoxifen acts as an *antagonist* on estrogen receptors expressed in mammary tissue but as an *agonist* on estrogen receptors in bone. Consequently, tamoxifen may be useful not only in the treatment and prophylaxis c breast cancer but also in the prevention of osteoporosis by increasing bone density (see Chapters 40 and 42). Tamoxifen may also create complications in postmenopausal women, however, by exerting an agonist action in the uterus, stimulating endometrial cell proliferation.

New drug development is not confined to agents that act on receptors for extracellular chemical signals. Pharmaceutical chemists are now determining whether elements of signaling pathways distal to the receptors m also serve as targets of selective and useful drugs. For example, clinically useful agents might be developed tha act selectively on specific G proteins, kinases, phosphatases, or the enzymes that degrade second messengers.

RELATION BETWEEN DRUG DOSE & CLINICAL RESPONSE

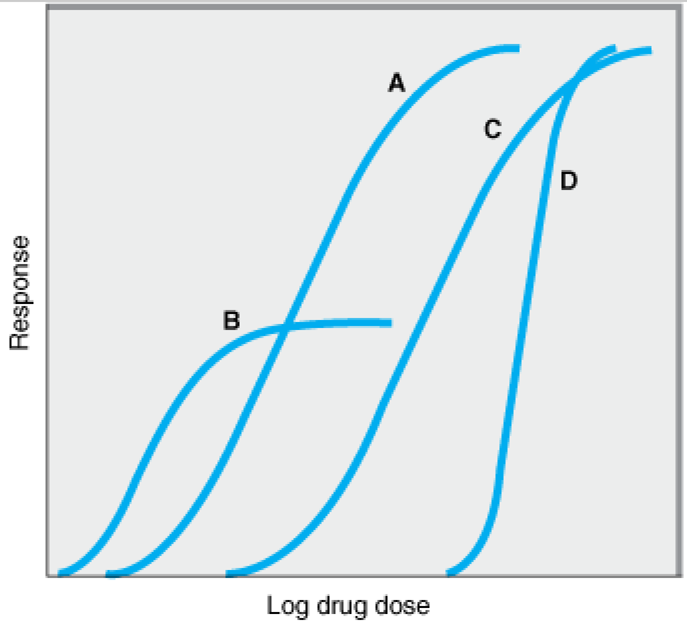
We have dealt with receptors as molecules and shown how receptors can quantitatively account for the relation between dose or concentration of a drug and pharmacologic responses, at least in an idealized system. When faced with a patient who needs treatment, the prescriber must make a choice among a variety of possible drug and devise a dosage regimen that is likely to produce maximal benefit and minimal toxicity. In order to make rational therapeutic decisions, the prescriber must understand how drug-receptor interactions underlie the relations between dose and response in patients, the nature and causes of variation in pharmacologic responsiveness, and the clinical implications of selectivity of drug action.

Dose & Response in Patients

GRADED DOSE-RESPONSE RELATIONS

To choose among drugs and to determine appropriate doses of a drug, the prescriber must know the relative pharmacologic potency and maximal efficacy of the drugs in relation to the desired therapeutic effect. The: two important terms, often confusing to students and clinicians, can be explained by referring to Figure 2–15, which depicts graded dose-response curves that relate dose of four different drugs to the magnitude of a particular therapeutic effect.

Figure 2–15.



Graded dose-response curves for four drugs, illustrating different pharmacologic potencies and different maximal efficacies. (See text.)

Potency

Drugs A and B are said to be more potent than drugs C and D because of the relative positions of their dose-response curves along the dose axis of Figure 2–15. Potency refers to the concentration (EC_{50}) or dose (ED_{50} of a drug required to produce 50% of that drug's maximal effect. Thus, the pharmacologic potency of drug A in Figure 2–15 is less than that of drug B, a partial agonist, because the EC_{50} of A is greater than the EC_{50} of B. Potency of a drug depends in part on the affinity (K_d) of receptors for binding the drug and in part on the efficiency with which drug-receptor interaction is coupled to response. Note that some doses of drug A can produce larger effects than any dose of drug B, despite the fact that we describe drug B as pharmacologically more potent. The reason for this is that drug A has a larger maximal efficacy, as described below.

For clinical use, it is important to distinguish between a drug's potency and its efficacy. The clinical effectivenes of a drug depends not on its potency (EC_{50}), but on its maximal efficacy (see below) and its ability to reach the relevant receptors. This ability can depend on its route of administration, absorption, distribution through the body, and clearance from the blood or site of action. In deciding which of two drugs to administer to a patient, prescriber must usually consider their relative effectiveness rather than their relative potency. Pharmacologic potency can largely determine the administered dose of the chosen drug.

For therapeutic purposes, the potency of a drug should be stated in dosage units, usually in terms of a particula therapeutic end point (eg, 50 mg for mild sedation, 1 mcg/kg/min for an increase in heart rate of 25 beats/min Relative potency, the ratio of equi-effective doses (0.2, 10, etc), may be used in comparing one drug with another.

Maximal Efficacy

This parameter reflects the limit of the dose-response relation on the response axis. Drugs A, C, and D in Figu 2–15 have equal maximal efficacy, while all have greater maximal efficacy than drug B. The maximal efficacy (sometimes referred to simply as efficacy) of a drug is obviously crucial for making clinical decisions when a larg response is needed. It may be determined by the drug's mode of interactions with receptors (as with partial agonists, described above)* or by characteristics of the receptor-effector system involved.

Thus, diuretics that act on one portion of the nephron may produce much greater excretion of fluid and electrolytes than diuretics that act elsewhere. In addition, the practical efficacy of a drug for achieving a therapeutic end point (eg, increased cardiac contractility) may be limited by the drug's propensity to cause a to effect (eg, fatal cardiac arrhythmia) even if the drug could otherwise produce a greater therapeutic effect.

*Note that "maximal efficacy," used in a therapeutic context, does not have exactly the same meaning the term denotes in the more specialized context of drug-receptor interactions described earlier in this chapter. In an idealized in vitro system, efficacy denotes the relative maximal efficacy of agonists and partial agonists that act via the same receptor. In therapeutics, efficacy denotes the extent or degree of an effect that can be achieved the intact patient. Thus, therapeutic efficacy may be affected by the characteristics of a particular drug-recepto interaction, but it also depends on a host of other factors as noted in the text.

SHAPE OF DOSE-RESPONSE CURVES

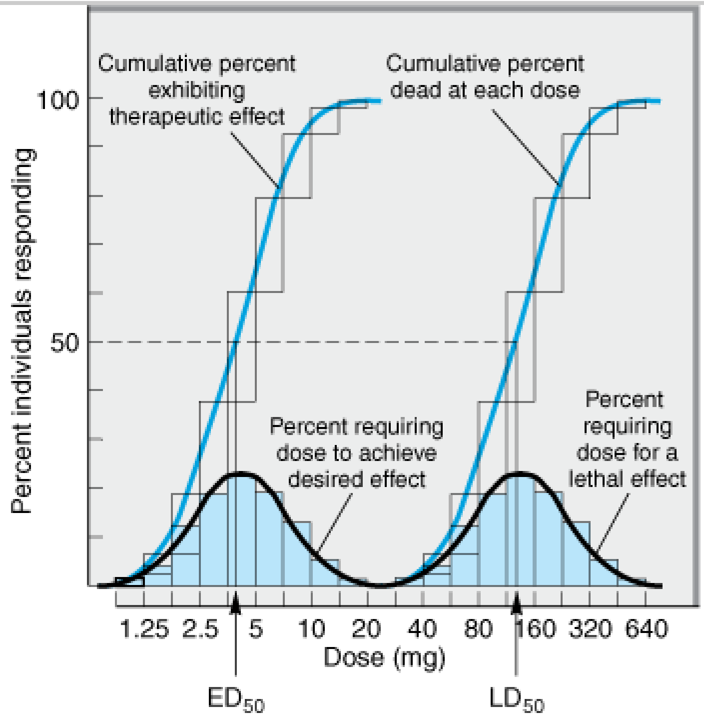
While the responses depicted in curves A, B, and C of Figure 2–15 approximate the shape of a simple Michaelis Menten relation (transformed to a logarithmic plot), some clinical responses do not. Extremely steep dose-response curves (eg, curve D) may have important clinical consequences if the upper portion of the curve represents an undesirable extent of response (eg, coma caused by a sedative-hypnotic). Steep dose-response curves in patients can result from cooperative interactions of several different actions of a drug (eg, effects on brain, heart, and peripheral vessels, all contributing to lowering of blood pressure).

QUANTAL DOSE-EFFECT CURVES

Graded dose-response curves of the sort described above have certain limitations in their application to clinical decision making. For example, such curves may be impossible to construct if the pharmacologic response is an either-or (quantal) event, such as prevention of convulsions, arrhythmia, or death. Furthermore, the clinical relevance of a quantitative dose-response relationship in a single patient, no matter how precisely defined, may be limited in application to other patients, owing to the great potential variability among patients in severity of disease and responsiveness to drugs.

Some of these difficulties may be avoided by determining the dose of drug required to produce a specified magnitude of effect in a large number of individual patients or experimental animals and plotting the cumulativ frequency distribution of responders versus the log dose (Figure 2–16). The specified quantal effect may be chosen on the basis of clinical relevance (eg, relief of headache) or for preservation of safety of experimental subjects (eg, using low doses of a cardiac stimulant and specifying an increase in heart rate of 20 beats/min as the quantal effect), or it may be an inherently quantal event (eg, death of an experimental animal). For most drugs, the doses required to produce a specified quantal effect in individuals are lognormally distributed; that is frequency distribution of such responses plotted against the log of the dose produces a gaussian normal curve variation (colored area, Figure 2–16). When these responses are summated, the resulting cumulative frequency distribution constitutes a quantal dose-effect curve (or dose-percent curve) of the proportion or percentage of individuals who exhibit the effect plotted as a function of log dose (Figure 2–16).

Figure 2–16.



Quantal dose-effect plots. Shaded boxes (and the accompanying black curves) indicate the frequency distribution of doses of drug required to produce a specified effect; that is, the percentage of animals that required a particular dose to exhibit the effect. The open boxes (and the corresponding colored curves) indicate the cumulative frequency distribution of responses, which are lognormally distributed.

The quantal dose-effect curve is often characterized by stating the **median effective dose** (ED_{50}), the dose at which 50% of individuals exhibit the specified quantal effect. (Note that the abbreviation ED_{50} has a different meaning in this context from its meaning in relation to graded dose-effect curves, described above.) Similarly, the dose required to produce a particular toxic effect in 50% of animals is called the **median toxic dose** (TD_{50}). If the toxic effect is death of the animal, a **median lethal dose** (LD_{50}) may be experimentally defined. Such values provide a convenient way of comparing the potencies of drugs in experimental and clinical settings: Thus the ED_{50}s of two drugs for producing a specified quantal effect are 5 and 500 mg, respectively, then the first drug can be said to be 100 times more potent than the second for that particular effect. Similarly, one can obtain a valuable index of the selectivity of a drug's action by comparing its ED_{50}s for two different quantal effects in a population (eg, cough suppression versus sedation for opioid drugs).

Quantal dose-effect curves may also be used to generate information regarding the margin of safety to be expected from a particular drug used to produce a specified effect. One measure, which relates the dose of a d required to produce a desired effect to that which produces an undesired effect, is the **therapeutic index**. In animal studies, the therapeutic index is usually defined as the ratio of the TD_{50} to the ED_{50} for some therapeutically relevant effect. The precision possible in animal experiments may make it useful to use such a therapeutic index to estimate the potential benefit of a drug in humans. Of course, the therapeutic index of a d in humans is almost never known with real precision; instead, drug trials and accumulated clinical experience often reveal a range of usually effective doses and a different (but sometimes overlapping) range of possibly to doses. The clinically acceptable risk of toxicity depends critically on the severity of the disease being treated. Fo example, the dose range that provides relief from an ordinary headache in the great majority of patients should be very much lower than the dose range that produces serious toxicity, even if the toxicity occurs in a small minority of patients. However, for treatment of a lethal disease such as Hodgkin's lymphoma, the acceptable difference between therapeutic and toxic doses may be smaller.

Finally, note that the quantal dose-effect curve and the graded dose-response curve summarize somewhat different sets of information, although both appear sigmoid in shape on a semilogarithmic plot (compare Figure 2–15 and 2–16). Critical information required for making rational therapeutic decisions can be obtained from ea type of curve. Both curves provide information regarding the **potency** and **selectivity** of drugs; the graded dos response curve indicates the **maximal efficacy** of a drug, and the quantal dose-effect curve indicates the potential **variability** of responsiveness among individuals.

Variation in Drug Responsiveness

Individuals may vary considerably in their responsiveness to a drug; indeed, a single individual may respond differently to the same drug at different times during the course of treatment. Occasionally, individuals exhibit a unusual or **idiosyncratic** drug response, one that is infrequently observed in most patients. The idiosyncratic responses are usually caused by genetic differences in metabolism of the drug or by immunologic mechanisms, including allergic reactions.

Quantitative variations in drug response are in general more common and more clinically important. An individu patient is **hyporeactive** or **hyperreactive** to a drug in that the intensity of effect of a given dose of drug is diminished or increased in comparison to the effect seen in most individuals. (*Note:* The term **hypersensitivit** usually refers to allergic or other immunologic responses to drugs.) With some drugs, the intensity of response a given dose may change during the course of therapy; in these cases, responsiveness usually decreases as a consequence of continued drug administration, producing a state of relative **tolerance** to the drug's effects. When responsiveness diminishes rapidly after administration of a drug, the response is said to be subject to **tachyphylaxis**.

Even before administering the first dose of a drug, the prescriber should consider factors that may help in predicting the direction and extent of possible variations in responsiveness. These include the propensity of a particular drug to produce tolerance or tachyphylaxis as well as the effects of age, sex, body size, disease state genetic factors, and simultaneous administration of other drugs.

Four general mechanisms may contribute to variation in drug responsiveness among patients or within an individual patient at different times.

ALTERATION IN CONCENTRATION OF DRUG THAT REACHES THE RECEPTOR

Patients may differ in the rate of absorption of a drug, in distributing it through body compartments, or in cleari the drug from the blood (see Chapter 3). By altering the concentration of drug that reaches relevant receptors, such pharmacokinetic differences may alter the clinical response. Some differences can be predicted on the bas of age, weight, sex, disease state, liver and kidney function, and by testing specifically for genetic differences t may result from inheritance of a functionally distinctive complement of drug-metabolizing enzymes (see Chapte 3 and 4). Another important mechanism influencing drug availability is active transport of drug from the cytoplasm, mediated by a family of membrane transporters encoded by the so-called multidrug resistance (*MD* genes. For example, up-regulation of *MDR* gene–encoded transporter expression is a major mechanism by whic tumor cells develop resistance to anticancer drugs.

VARIATION IN CONCENTRATION OF AN ENDOGENOUS RECEPTOR LIGAND

This mechanism contributes greatly to variability in responses to pharmacologic antagonists. Thus, propranolol, β-adrenoceptor antagonist, will markedly slow the heart rate of a patient whose endogenous catecholamines a elevated (as in pheochromocytoma) but will not affect the resting heart rate of a well-trained marathon runner. partial agonist may exhibit even more dramatically different responses: Saralasin, a weak partial agonist at angiotensin II receptors, lowers blood pressure in patients with hypertension caused by increased angiotensin I production and raises blood pressure in patients who produce small amounts of angiotensin.

ALTERATIONS IN NUMBER OR FUNCTION OF RECEPTORS

Experimental studies have documented changes in drug responsiveness caused by increases or decreases in th number of receptor sites or by alterations in the efficiency of coupling of receptors to distal effector mechanism In some cases, the change in receptor number is caused by other hormones; for example, thyroid hormones increase both the number of βreceptors in rat heart muscle and cardiac sensitivity to catecholamines. Similar changes probably contribute to the tachycardia of thyrotoxicosis in patients and may account for the usefulness propranolol, a β-adrenoceptor antagonist, in ameliorating symptoms of this disease.

In other cases, the agonist ligand itself induces a decrease in the number (eg, down-regulation) or coupling efficiency (eg, desensitization) of its receptors. These mechanisms (discussed above, under Signaling Mechanis & Drug Actions) may contribute to two clinically important phenomena: first, tachyphylaxis or tolerance to the effects of some drugs (eg, biogenic amines and their congeners), and second, the "overshoot" phenomena that follow withdrawal of certain drugs. These phenomena can occur with either agonists or antagonists. An antagor may increase the number of receptors in a critical cell or tissue by preventing down-regulation caused by an endogenous agonist. When the antagonist is withdrawn, the elevated number of receptors can produce an exaggerated response to physiologic concentrations of agonist. Potentially disastrous withdrawal symptoms can result for the opposite reason when administration of an agonist drug is discontinued. In this situation, the number of receptors, which has been decreased by drug-induced down-regulation, is too low for endogenous agonist to produce effective stimulation. For example, the withdrawal of clonidine (a drug whose α_2 -adrenocep agonist activity reduces blood pressure) can produce hypertensive crisis, probably because the drug down-regulates α_2 -adrenoceptors (see Chapter 11).

Genetic factors also can play an important role in altering the number or function of specific receptors. For example, a specific genetic variant of the α_{2C} -adrenoceptor—when inherited together with a specific variant of the α_1 -adrenoceptor—confers increased risk for developing heart failure, which may be reduced by early intervention using antagonist drugs. The identification of such genetic factors, part of the rapidly developing fie of pharmacogenetics, holds promise for clinical diagnosis and in the future may help physicians design the mos appropriate pharmacologic therapy for individual patients. Another interesting example of genetic effects on dr response is seen in the treatment of cancers involving excessive growth factor signaling. Somatic mutations affecting the tyrosine kinase domain of the epidermal growth factor receptor confer enhanced sensitivity to kin inhibitors such as gefitinib in certain lung cancers. This effect enhances the antineoplastic effect of the drug anc because the somatic mutation is specific to the tumor and not present in the host, the therapeutic index of thes drugs can be significantly enhanced in patients whose tumors harbor such somatic mutations.

CHANGES IN COMPONENTS OF RESPONSE DISTAL TO THE RECEPTOR

Although a drug initiates its actions by binding to receptors, the response observed in a patient depends on the functional integrity of biochemical processes in the responding cell and physiologic regulation by interacting org systems. Clinically, changes in these postreceptor processes represent the largest and most important class of mechanisms that cause variation in responsiveness to drug therapy.

Before initiating therapy with a drug, the prescriber should be aware of patient characteristics that may limit th clinical response. These characteristics include the age and general health of the patient and—most importantly—the severity and pathophysiologic mechanism of the disease. The most important potential cause failure to achieve a satisfactory response is that the diagnosis is wrong or physiologically incomplete. Drug therapy will always be most successful when it is accurately directed at the pathophysiologic mechanism responsible for the disease.

When the diagnosis is correct and the drug is appropriate, an unsatisfactory therapeutic response can often be traced to compensatory mechanisms in the patient that respond to and oppose the beneficial effects of the dru Compensatory increases in sympathetic nervous tone and fluid retention by the kidney, for example, can contribute to tolerance to antihypertensive effects of a vasodilator drug. In such cases, additional drugs may be required to achieve a useful therapeutic result.

Clinical Selectivity: Beneficial versus Toxic Effects of Drugs

Although we classify drugs according to their principal actions, it is clear that *no drug causes only a single, spec effect.* Why is this so? It is exceedingly unlikely that any kind of drug molecule will bind to only a single type of receptor molecule, if only because the number of potential receptors in every patient is astronomically large. Ev if the chemical structure of a drug allowed it to bind to only one kind of receptor, the biochemical processes controlled by such receptors would take place in multiple cell types and would be coupled to many other biochemical functions; as a result, the patient and the prescriber would probably perceive more than one drug effect. Accordingly, drugs are only *selective* —rather than specific—in their actions, because they bind to one or few types of receptor more tightly than to others and because these receptors control discrete processes that result in distinct effects.

It is only because of their selectivity that drugs are useful in clinical medicine. Selectivity can be measured by comparing binding affinities of a drug to different receptors or by comparing ED_{50} s for different effects of a dru in vivo. In drug development and in clinical medicine, selectivity is usually considered by separating effects into two categories: beneficial or therapeutic effects versus toxic effects. Pharmaceutical advertisements and prescribers occasionally use the term side effect, implying that the effect in question is insignificant or occurs a pathway that is to one side of the principal action of the drug; such implications are frequently erroneous.

BENEFICIAL AND TOXIC EFFECTS MEDIATED BY THE SAME RECEPTOR-EFFECTOR MECHANISM

Much of the serious drug toxicity in clinical practice represents a direct pharmacologic extension of the therape actions of the drug. In some of these cases (eg, bleeding caused by anticoagulant therapy; hypoglycemic coma due to insulin), toxicity may be avoided by judicious management of the dose of drug administered, guided by careful monitoring of effect (measurements of blood coagulation or serum glucose) and aided by ancillary measures (avoiding tissue trauma that may lead to hemorrhage; regulation of carbohydrate intake). In still oth cases, the toxicity may be avoided by not administering the drug at all, if the therapeutic indication is weak or i other therapy is available.

In certain situations, a drug is clearly necessary and beneficial but produces unacceptable toxicity when given in doses that produce optimal benefit. In such situations, it may be necessary to add another drug to the treatme regimen. In treating hypertension, for example, administration of a second drug often allows the prescriber to reduce the dose and toxicity of the first drug (see Chapter 11).

BENEFICIAL AND TOXIC EFFECTS MEDIATED BY IDENTICAL RECEPTORS BUT IN DIFFERENT TISSUE OR BY DIFFERENT EFFECTOR PATHWAYS

Many drugs produce both their desired effects and adverse effects by acting on a single receptor type in differe tissues. Examples discussed in this book include: digitalis glycosides, which act by inhibiting Na^+ /K^+ ATPase in cell membranes; methotrexate, which inhibits the enzyme dihydrofolate reductase; and glucocorticoid hormone

Three therapeutic strategies are used to avoid or mitigate this sort of toxicity. First, the drug should always be administered at the lowest dose that produces acceptable benefit. Second, adjunctive drugs that act through different receptor mechanisms and produce different toxicities may allow lowering the dose of the first drug, th limiting its toxicity (eg, use of other immunosuppressive agents added to glucocorticoids in treating inflammato disorders). Third, selectivity of the drug's actions may be increased by manipulating the concentrations of drug available to receptors in different parts of the body, for example, by aerosol administration of a glucocorticoid t the bronchi in asthma.

BENEFICIAL AND TOXIC EFFECTS MEDIATED BY DIFFERENT TYPES OF RECEPTORS

Therapeutic advantages resulting from new chemical entities with improved receptor selectivity were mentione earlier in this chapter and are described in detail in later chapters. Such drugs include the α- and β-selective adrenoceptor agonists and antagonists, the H_1 and H_2 antihistamines, nicotinic and muscarinic blocking agents and receptor-selective steroid hormones. All of these receptors are grouped in functional families, each respons to a small class of endogenous agonists. The receptors and their associated therapeutic uses were discovered b analyzing effects of the physiologic chemical signals—catecholamines, histamine, acetylcholine, and corticosteroids.

Several other drugs were discovered by exploiting therapeutic or toxic effects of chemically similar agents observed in a clinical context. Examples include quinidine, the sulfonylureas, thiazide diuretics, tricyclic antidepressants, opioid drugs, and phenothiazine antipsychotics. Often the new agents turn out to interact with receptors for endogenous substances (eg, opioids and phenothiazines for endogenous opioid and dopamine receptors, respectively). It is likely that other new drugs will be found to do so in the future, perhaps leading to the discovery of new classes of receptors and endogenous ligands for future drug development.

Thus, the propensity of drugs to bind to different classes of receptor sites is not only a potentially vexing proble in treating patients, it also presents a continuing challenge to pharmacology and an opportunity for developing new and more useful drugs.

PHARMACOKINETICS & PHARMACODYNAMICS: RATIONAL DOSING & THE TIME COURSE OF DRUG ACTION: INTRODUCTION

The goal of therapeutics is to achieve a desired beneficial effect with minimal adverse effects. When a medicine has been selected for a patient, the clinician must determine the dose that most closely achieves this goal. A rational approach to this objective combines the principles of pharmacokinetics with pharmacodynamics to clarify the dose-effect relationship (Figure 3–1). Pharmacodynamics governs the concentration-effect part of the interaction, whereas pharmacokinetics deals with the dose-concentration part. The pharmacokinetic processes of absorption, distribution, and elimination determine how rapidly and for how long the drug will appear at the target organ. The pharmacodynamic concepts of maximum response and sensitivity determine the magnitude of the effect at a particular concentration (see the definitions of E_{max} and EC_{50} , Chapter 2).

Figure 3–1.

The relationship between dose and effect can be separated into pharmacokinetic (dose-concentration) and pharmacodynamic (concentration-effect) components. Concentration provides the link between pharmacokinetics and pharmacodynamics and is the focus of the target concentration approach to rational dosing. The three primary processes of pharmacokinetics are absorption, distribution, and elimination.

Figure 3–1 illustrates a fundamental hypothesis of pharmacology, namely, that a relationship exists between a beneficial or toxic effect of a drug and the concentration of the drug. This hypothesis has been documented for many drugs, as indicated by the Target Concentrations and Toxic Concentrations columns in Table 3–1. The apparent lack of such a relationship for some drugs does not weaken the basic hypothesis but points to the need to consider the time course of concentration at the actual site of pharmacologic effect (see below).

Table 3–1. Pharmacokinetic and Pharmacodynamic Parameters for Selected Drugs.

[1] Convert to mL/min by multiplying the number given by 16.6.

[2] Varies with concentration.

[3] Target area under the concentration time curve after a single dose.

[4] Can be estimated from measured C_p using $CL = V_{max}/(K_m + C_p)$; V_{max} = 415 mg/d, K_m = 5 mg/L. See text.

[5] Varies because of concentration-dependent clearance.

See Speight & Holford, 1997, for a more comprehensive listing.

Knowing the relationship between dose, drug concentration, and effects allows the clinician to take into account the various pathologic and physiologic features of a particular patient that make him or her different from the average individual in responding to a drug. The importance of pharmacokinetics and pharmacodynamics in patient care thus rests upon the improvement in therapeutic benefit and reduction in toxicity that can be achieved by application of these principles.

PHARMACOKINETICS

The "standard" dose of a drug is based on trials in healthy volunteers and patients with average ability to absorb, distribute, and eliminate the drug (see Clinical Trials: The IND & NDA in Chapter 5). This dose will not be suitable for every patient. Several physiologic processes (eg, maturation of organ function in infants) and pathologic processes (eg, heart failure, renal failure) dictate dosage adjustment in individual patients. These processes modify specific pharmacokinetic parameters. The two basic parameters are **clearance**, the measure of the ability of the body to eliminate the drug; and **volume of distribution**, the measure of the apparent space in the body available to contain the drug. These parameters are illustrated schematically in Figure 3–2, where the volume of the compartments into which the drugs diffuse represents the volume of distribution and the size of the outflow "drain" in Figures 3–2B and 3–2D represents the clearance.

Figure 3–2.

Models of drug distribution and elimination. The effect of adding drug to the blood by rapid intravenous injection is represented by expelling a known amount of the agent into a beaker. The time course of the amount of drug in the beaker is shown in the graphs at the right. In the first example (A), there is no movement of drug out of the beaker, so the graph shows only a steep rise to maximum followed by a plateau. In the second example (B), a route of elimination is present, and the graph shows a slow decay after a sharp rise to a maximum. Because the level of material in the beaker falls, the "pressure" driving the elimination process also falls, and the slope of the curve decreases. This is an exponential decay curve. In the third model (C), drug placed in the first compartment ("blood") equilibrates rapidly with the second compartment ("extravascular volume") and the amount of drug in "blood" declines exponentially to a new steady state. The fourth model (D) illustrates a more realistic combination of elimination mechanism and extravascular equilibration. The resulting graph shows an early distribution phase followed by the slower elimination phase.

Volume of Distribution

Volume of distribution (V_d) relates the amount of drug in the body to the concentration of drug (C) in blood or plasma:

The volume of distribution may be defined with respect to blood, plasma, or water (unbound drug), depending on the concentration used in equation (1) ($C = C_b$, C_p, or C_u).

That the V_d calculated from equation (1) is an *apparent* volume may be appreciated by comparing the volumes of distribution of drugs such as digoxin or chloroquine (Table 3–1) with some of the physical volumes of the body (Table 3–2). Volume of distribution can vastly exceed any physical volume in the body because it is the volume apparently necessary to contain the amount of drug *homogeneously* at the concentration found in the blood, plasma, or water. Drugs with very high volumes of distribution have much higher concentrations in extravascular tissue than in the vascular compartment; that is, they are *not* homogeneously distributed. Drugs that are completely retained within the vascular compartment, on the other hand, have a minimum possible volume of distribution equal to the blood component in which they are distributed, eg, 0.04 L/kg body weight or 2.8 L/70 kg (Table 3–2) for a drug that is restricted to the plasma compartment.

Table 3–2. Physical Volumes (in L/kg Body Weight) of Some Body Compartments into Which Drugs May Be Distributed.

Compartment and Volume	Examples of Drugs
Water	
Total body water (0.6 L/kg[1])	Small water-soluble molecules: eg, ethanol.
Extracellular water (0.2 L/kg)	Larger water-soluble molecules: eg, gentamicin.
Blood (0.08 L/kg); plasma (0.04 L/kg)	Strongly plasma protein-bound molecules and very large molecules: eg, heparin.
Fat (0.2–0.35 L/kg)	Highly lipid-soluble molecules: eg, DDT.
Bone (0.07 L/kg)	Certain ions: eg, lead, fluoride.

[1] An average figure. Total body water in a young lean man might be 0.7 L/kg; in an obese woman, 0.5 L/kg.

Clearance

Drug clearance principles are similar to the clearance concepts of renal physiology. Clearance of a drug is the factor that predicts the rate of elimination in relation to the drug concentration:

Clearance, like volume of distribution, may be defined with respect to blood (CL_b), plasma (CL_p), or unbound in water (CL_u), depending on the concentration measured.

It is important to note the additive character of clearance. Elimination of drug from the body may involve processes occurring in the kidney, the lung, the liver, and other organs. Dividing the rate of elimination at each organ by the concentration of drug presented to it yields the respective clearance at that organ. Added together, these separate clearances equal total systemic clearance:

"Other" tissues of elimination could include the lungs and additional sites of metabolism, eg, blood or muscle.

The two major sites of drug elimination are the kidneys and the liver. Clearance of unchanged drug in the urine represents renal clearance. Within the liver, drug elimination occurs via biotransformation of parent drug to one or more metabolites, or excretion of unchanged drug into the bile, or both. The pathways of biotransformation are discussed in Chapter 4. For most drugs, clearance is constant over the concentration range encountered in clinical settings, ie, elimination is not saturable, and the rate of drug elimination is directly proportional to concentration (rearranging equation [2]):

This is usually referred to as *first-order elimination*. When clearance is first-order, it can be estimated by calculating the *area under the curve* (AUC) of the time-concentration profile after a dose. Clearance is calculated from the dose divided by the AUC.

CAPACITY-LIMITED ELIMINATION

For drugs that exhibit capacity-limited elimination (eg, phenytoin, ethanol), clearance will vary depending on the concentration of drug that is achieved (Table 3–1). Capacity-limited elimination is also known as saturable, dose- or concentration-dependent, nonlinear, and Michaelis-Menten elimination.

Most drug elimination pathways will become saturated if the dose is high enough. When blood flow to an organ does not limit elimination (see below), the relation between elimination rate and concentration (C) is expressed mathematically in equation (5):

The maximum elimination capacity is V_{max}, and K_m is the drug concentration at which the rate of elimination is 50% of V_{max}. At concentrations that are high relative to the K_m, the elimination rate is almost independent of concentration—a state of "pseudo-zero order" elimination. If dosing rate exceeds elimination capacity, steady state cannot be achieved: The concentration will keep on rising as long as dosing continues. This pattern of capacity-limited elimination is important for three drugs in common use: ethanol, phenytoin, and aspirin. Clearance has no real meaning for drugs with capacity-limited elimination, and AUC cannot be used to describe the elimination of such drugs.

FLOW-DEPENDENT ELIMINATION

In contrast to capacity-limited drug elimination, some drugs are cleared very readily by the organ of elimination, so that at any clinically realistic concentration of the drug, most of the drug in the blood perfusing the organ is eliminated on the first pass of the drug through it. The elimination of these drugs will thus depend primarily on the rate of drug delivery to the organ of elimination. Such drugs (see Table 4–7) can be called "high-extraction" drugs since they are almost completely extracted from the blood by the organ. Blood flow to the organ is the main determinant of drug delivery, but plasma protein binding and blood cell partitioning may also be important for extensively bound drugs that are highly extracted.

Half-Life

Half-life ($t_{1/2}$) is the time required to change the amount of drug in the body by one-half during elimination (or during a constant infusion). In the simplest case—and the most useful in designing drug dosage regimens—the body may be considered as a single compartment (as illustrated in Figure 3–2B) of a size equal to the volume of distribution (V_d). The time course of drug in the body will depend on both the volume of distribution and the clearance:

Half-life is useful because it indicates the time required to attain 50% of steady state—or to decay 50% from steady-state conditions—after a change in the rate of drug administration. Figure 3–3 shows the time course of drug accumulation during a constant-rate drug infusion and the time course of drug elimination after stopping an infusion that has reached steady state.

Figure 3–3.

The time course of drug accumulation and elimination. *Solid line*: Plasma concentrations reflecting drug accumulation during a constant rate infusion of a drug. Fifty percent of the steady-state concentration is reached after one half-life, 75% after two half-lives, and over 90% after four half-lives. *Dashed line*: Plasma concentrations reflecting drug elimination after a constant rate infusion of a drug had reached steady state. Fifty percent of the drug is lost after one half-life, 75% after two half-lives, etc. The "rule of thumb" that four half-lives must elapse after starting a drug-dosing regimen before full effects will be seen is based on the approach of the accumulation curve to over 90% of the final steady-state concentration.

Disease states can affect both of the physiologically related primary pharmacokinetic parameters: volume of distribution and clearance. A change in half-life will not necessarily reflect a change in drug elimination. For example, patients with chronic renal failure have decreased renal clearance of digoxin but also a decreased volume of distribution; the increase in digoxin half-life is not as great as might be expected based on the change in renal function. The decrease in volume of distribution is due to the decreased renal and skeletal muscle mass and consequent decreased tissue binding of digoxin to Na^+ /K^+ ATPase.

Many drugs will exhibit multicompartment pharmacokinetics (as illustrated in Figures 3–2C and 3–2D). Under these conditions, the "true" terminal half-life, as given in Table 3–1, will be greater than that calculated from equation (6).

*The constant 0.7 in equation (6) is an approximation to the natural logarithm of 2. Because drug elimination can be described by an exponential process, the time taken for a twofold decrease can be shown to be proportional to ln(2).

Drug Accumulation

Whenever drug doses are repeated, the drug will accumulate in the body until dosing stops. This is because it takes an infinite time (in theory) to eliminate all of a given dose. In practical terms, this means that if the dosing interval is shorter than four half-lives, accumulation will be detectable.

Accumulation is inversely proportional to the fraction of the dose lost in each dosing interval. The fraction lost is 1 minus the fraction remaining just before the next dose. The fraction remaining can be predicted from the dosing interval and the half-life. A convenient index of accumulation is the *accumulation factor*.

For a drug given once every half-life, the accumulation factor is 1/0.5, or 2. The accumulation factor predicts the ratio of the steady-state concentration to that seen at the same time following the first dose. Thus, the peak concentrations after intermittent doses at steady state will be equal to the peak concentration after the first dose multiplied by the accumulation factor.

Bioavailability

Bioavailability is defined as the fraction of unchanged drug reaching the systemic circulation following administration by any route (Table 3–3). The area under the blood concentration-time curve (AUC) is a common measure of the extent of bioavailability for a drug given by a particular route (Figure 3–4). For an intravenous dose of the drug, bioavailability is assumed to be equal to unity. For a drug administered orally, bioavailability may be less than 100% for two main reasons—incomplete extent of absorption and first-pass elimination.

Table 3–3. Routes of Administration, Bioavailability, and General Characteristics.

Route	Bioavailability (%)	Characteristics
Intravenous (IV)	100 (by definition)	Most rapid onset
Intramuscular (IM)	75 to □100	Large volumes often feasible; may be painful
Subcutaneous (SC)	75 to □100	Smaller volumes than IM; may be painful
Oral (PO)	5 to <100	Most convenient; first-pass effect may be significant
Rectal (PR)	30 to <100	Less first-pass effect than oral

Inhalation	5 to <100	Often very rapid onset
Transdermal	80 to □100	Usually very slow absorption; used for lack of first-pass effect; prolonged duration of action

Figure 3–4.

Blood concentration-time curves, illustrating how changes in the rate of absorption and extent of bioavailability can influence both the duration of action and the effectiveness of the same total dose of a drug administered in three different formulations. The dashed line indicates the target concentration (TC) of the drug in the blood.

EXTENT OF ABSORPTION

After oral administration, a drug may be incompletely absorbed, eg, only 70% of a dose of digoxin reaches the systemic circulation. This is mainly due to lack of absorption from the gut. Other drugs are either too hydrophilic (eg, atenolol) or too lipophilic (eg, acyclovir) to be absorbed easily, and their low bioavailability is also due to incomplete absorption. If too hydrophilic, the drug cannot cross the lipid cell membrane; if too lipophilic, the drug is not soluble enough to cross the water layer adjacent to the cell. Drugs may not be absorbed because of a reverse transporter associated with P-glycoprotein. This process actively pumps drug out of gut wall cells back into the gut lumen. Inhibition of P-glycoprotein and gut wall metabolism, eg, by grapefruit juice, may be associated with substantially increased drug absorption.

FIRST-PASS ELIMINATION

Following absorption across the gut wall, the portal blood delivers the drug to the liver prior to entry into the systemic circulation. A drug can be metabolized in the gut wall (eg, by the CYP3A4 enzyme system) or even in the portal blood, but most commonly it is the liver that is responsible for metabolism before the drug reaches the systemic circulation. In addition, the liver can excrete the drug into the bile. Any of these sites can contribute to this reduction in bioavailability, and the overall process is known as first-pass elimination. The effect of first-pass hepatic elimination on bioavailability is expressed as the extraction ratio (ER):

where Q is hepatic blood flow, normally about 90 L/h in a person weighing 70 kg.

The systemic bioavailability of the drug (F) can be predicted from the extent of absorption (f) and the extraction ratio (ER):

A drug such as morphine is almost completely absorbed (f = 1), so that loss in the gut is negligible. However, the hepatic extraction ratio for morphine is 0.67, so (1 – ER) is 0.33. The bioavailability of morphine is therefore expected to be about 33%, which is close to the observed value (Table 3–1).

RATE OF ABSORPTION

The distinction between rate and extent of absorption is shown in Figure 3–4. The rate of absorption is determined by the site of administration and the drug formulation. Both the rate of absorption and the extent of input can influence the clinical effectiveness of a drug. For the three different dosage forms depicted in Figure 3–4, there would be significant differences in the intensity of clinical effect. Dosage form B would require twice the dose to attain blood concentrations equivalent to those of dosage form A. Differences in rate of availability may become important for drugs given as a single dose, such as a hypnotic used to induce sleep. In this case, drug from dosage form A would reach its target concentration earlier than drug from dosage form C; concentrations from A would also reach a higher level and remain above the target concentration for a longer period. In a multiple dosing regimen, dosage forms A and C would yield the same average blood level concentrations, although dosage form A would show somewhat greater maximum and lower minimum concentrations.

The mechanism of drug absorption is said to be zero-order when the rate is independent of the amount of drug remaining in the gut, eg, when it is determined by the rate of gastric emptying or by a controlled-release drug formulation. In contrast, when the full dose is dissolved in gastrointestinal fluids, the rate of absorption is usually proportional to the gastrointestinal concentration and is said to be first-order.

Extraction Ratio & the First-Pass Effect

Systemic clearance is not affected by bioavailability. However, clearance can markedly affect the extent of availability because it determines the extraction ratio (equation [8a]). Of course, therapeutic blood concentrations may still be reached by the oral route of administration if larger doses are given. However, in this case, the concentrations of the drug *metabolites* will be increased significantly over those that would occur following intravenous administration. Lidocaine and verapamil are both used to treat cardiac arrhythmias and have bioavailability less than 40%, but lidocaine is never given orally because its metabolites are believed to contribute to central nervous system toxicity. Other drugs that are highly extracted by the liver include morphine, propranolol, verapamil, and several tricyclic antidepressants (Table 3–1) as well as isoniazid.

Drugs with high extraction ratios will show marked variations in bioavailability between subjects because of differences in hepatic function and blood flow. These differences can explain the marked variation in drug concentrations that occurs among individuals given similar doses of highly extracted drugs. For drugs that are highly extracted by the liver, shunting of blood past hepatic sites of elimination will result in substantial increases in drug availability, whereas for drugs that are poorly extracted by the liver (for which the difference between entering and exiting drug concentration is small), shunting of blood past the liver will cause little change in availability. Drugs in Table 3–1 that are poorly extracted by the liver include chlorpropamide, diazepam, phenytoin, theophylline, tolbutamide, and warfarin.

Alternative Routes of Administration & the First-Pass Effect

There are several reasons for different routes of administration used in clinical medicine (Table 3–3)—for convenience (eg, oral), to maximize concentration at the site of action and minimize it elsewhere (eg, topical), to prolong the duration of drug absorption (eg, transdermal), or to avoid the first-pass effect.

The hepatic first-pass effect can be avoided to a great extent by use of sublingual tablets and transdermal preparations and to a lesser extent by use of rectal suppositories. Sublingual absorption provides direct access to systemic—not portal—veins. The transdermal route offers the same advantage. Drugs absorbed from suppositories in the lower rectum enter vessels that drain into the inferior vena cava, thus bypassing the liver. However, suppositories tend to move upward in the rectum into a region where veins that lead to the liver predominate. Thus, only about 50% of a rectal dose can be assumed to bypass the liver.

Although drugs administered by inhalation bypass the hepatic first-pass effect, the lung may also serve as a site of first-pass loss by excretion and possibly metabolism for drugs administered by nongastrointestinal ("parenteral") routes.

THE TIME COURSE OF DRUG EFFECT

The principles of pharmacokinetics (discussed in this chapter) and those of pharmacodynamics (discussed in Chapter 2; Holford & Sheiner, 1981) provide a framework for understanding the time course of drug effect.

Immediate Effects

In the simplest case, drug effects are directly related to plasma concentrations, but this does not necessarily mean that effects simply parallel the time course of concentrations. Because the relationship between drug concentration and effect is not linear (recall the E_{max} model described in Chapter 2), the effect will not usually be linearly proportional to the concentration.

Consider the effect of an angiotensin-converting enzyme (ACE) inhibitor, such as enalapril, on plasma ACE. The half-life of enalapril is about 3 hours. After an oral dose of 10 mg, the plasma concentration at 3 hours is about 50 ng/mL. Enalapril is usually given once a day, so seven half-lives will elapse from the time of peak concentration to the end of the dosing interval. The concentration of enalapril after each half-life and the corresponding extent of ACE inhibition are shown in Figure 3–5. The extent of inhibition of ACE is calculated using the E_{max} model, where E_{max}, the maximum extent of inhibition, is 100% and the EC_{50} is about 1 ng/mL.

Figure 3–5.

Time course of angiotensin-converting enzyme (ACE) inhibitor concentrations and effects. The black line shows the plasma enalapril concentrations in nanograms per milliliter after a single oral dose. The colored line indicates the percentage inhibition of its target, ACE. Note the different shapes of the concentration-time course (exponentially decreasing) and the effect-time course (linearly decreasing in its central portion).

Note that plasma concentrations of enalapril change by a factor of 16 over the first 12 hours (four half-lives) after the peak, but ACE inhibition has only decreased by 20%. Because the concentrations over this time are so high in relation to the EC_{50}, the effect on ACE is almost constant. After 24 hours, ACE is still 33% inhibited. This explains why a drug with a short half-life can be given once a day and still maintain its effect throughout the day. The key factor is a high initial concentration in relation to the EC_{50}. Even though the plasma concentration at 24 hours is less than 1% of its peak, this low concentration is still half the EC_{50}. This is very common for drugs that act on enzymes (eg, ACE inhibitors) or compete at receptors (eg, propranolol).

When concentrations are in the range between one fourth and four times the EC_{50}, the time course of effect is essentially a linear function of time—13% of the effect is lost every half-life over this concentration range. At concentrations below one fourth the EC_{50}, the effect becomes almost directly proportional to concentration and the time course of drug effect will follow the exponential decline of concentration. It is only when the concentration is low in relation to the EC_{50} that the concept of a "half-life of drug effect" has any meaning.

Delayed Effects

Changes in drug effects are often delayed in relation to changes in plasma concentration. This delay may reflect the time required for the drug to distribute from plasma to the site of action. This will be the case for almost all drugs. The delay due to distribution is a pharmacokinetic phenomenon that can account for delays of a few minutes. This distributional delay can account for the lag of effects after rapid intravenous injection of central nervous system (CNS)–active agents such as thiopental.

A common reason for more delayed drug effects—especially those that take many hours or even days to occur—is the slow turnover of a physiologic substance that is involved in the expression of the drug effect. For example, warfarin works as an anticoagulant by inhibiting vitamin K epoxidase in the liver. This action of warfarin occurs rapidly, and inhibition of the enzyme is closely related to plasma concentrations of warfarin. The clinical effect of warfarin, eg, on the prothrombin time, reflects a decrease in the concentration of the prothrombin complex of clotting factors. Inhibition of vitamin K epoxidase decreases the synthesis of these clotting factors, but the complex has a long half-life (about 14 hours), and it is this half-life that determines how long it takes for the concentration of clotting factors to reach a new steady state and for a drug effect to become manifest that reflects the warfarin plasma concentration.

Cumulative Effects

Some drug effects are more obviously related to a cumulative action than to a rapidly reversible one. The renal toxicity of aminoglycoside antibiotics (eg, gentamicin) is greater when administered as a constant infusion than with intermittent dosing. It is the accumulation of aminoglycoside in the renal cortex that is thought to cause renal damage. Even though both dosing schemes produce the same average steady-state concentration, the intermittent dosing scheme produces much higher peak concentrations, which saturate an uptake mechanism into the cortex; thus, total aminoglycoside accumulation is less. The difference in toxicity is a predictable consequence of the different patterns of concentration and the saturable uptake mechanism.

The effect of many drugs used to treat cancer also reflects a cumulative action—eg, the extent of binding of a drug to DNA is proportional to drug concentration and is usually irreversible. The effect on tumor growth is therefore a consequence of cumulative exposure to the drug. Measures of cumulative exposure, such as AUC, provide a means to individualize treatment.

THE TARGET CONCENTRATION APPROACH TO DESIGNING A RATIONAL DOSAGE REGIMEN

A rational dosage regimen is based on the assumption that there is a *target concentration* that will produce the desired therapeutic effect. By considering the pharmacokinetic factors that determine the dose-concentration relationship, it is possible to individualize the dose regimen to achieve the target concentration. The effective concentration ranges shown in Table 3–1 are a guide to the concentrations measured when patients are being effectively treated. The initial target concentration should usually be chosen from the lower end of this range. In some cases, the target concentration will also depend on the specific therapeutic objective—eg, the control of atrial fibrillation by digoxin often requires a target concentration of 2 ng/mL, while heart failure is usually adequately managed with a target concentration of 1 ng/mL.

Maintenance Dose

In most clinical situations, drugs are administered in such a way as to maintain a steady state of drug in the body, ie, just enough drug is given in each dose to replace the drug eliminated since the preceding dose. Thus, calculation of the appropriate maintenance dose is a primary goal. Clearance is the most important pharmacokinetic term to be considered in defining a rational steady-state drug dosage regimen. At steady state, the dosing rate ("rate in") must equal the rate of elimination ("rate out"). Substitution of the target concentration (TC) for concentration (C) in equation (4) predicts the maintenance dosing rate:

Thus, if the desired target concentration is known, the clearance in that patient will determine the dosing rate. If the drug is given by a route that has a bioavailability less than 100%, then the dosing rate predicted by equation (9) must be modified. For oral dosing:

If intermittent doses are given, the maintenance dose is calculated from:

(See Example: Maintenance Dose Calculation.)

Note that the steady-state concentration achieved by continuous infusion or the *average* concentration following intermittent dosing depends only on clearance. The volume of distribution and the half-life need not be known in order to determine the average plasma concentration expected from a given dosing rate or to predict the dosing rate for a desired target concentration. Figure 3–6 shows that at different dosing intervals, the concentration time curves will have different maximum and minimum values even though the average level will always be 10 mg/L.

Figure 3–6.

Relationship between frequency of dosing and maximum and minimum plasma concentrations when a steady-state theophylline plasma level of 10 mg/L is desired. The smoothly rising line (solid black) shows the plasma concentration achieved with an intravenous infusion of 28 mg/h. The doses for 8-hourly administration (light color) are 224 mg; for 24-hourly administration (dark color), 672 mg. In each of the three cases, the mean steady-state plasma concentration is 10 mg/L.

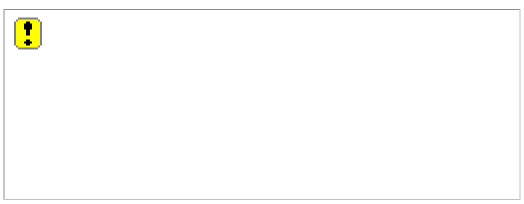
Estimates of dosing rate and average steady-state concentrations, which may be calculated using clearance, are independent of any specific pharmacokinetic model. In contrast, the determination of maximum and minimum steady-state concentrations requires further assumptions about the pharmacokinetic model. The accumulation factor (equation [7]) assumes that the drug follows a one-compartment body model (Figure 3–2B), and the peak concentration prediction assumes that the absorption rate is much faster than the elimination rate. For the calculation of estimated maximum and minimum concentrations in a clinical situation, these assumptions are usually reasonable.

EXAMPLE: MAINTENANCE DOSE CALCULATION

A target plasma theophylline concentration of 10 mg/L is desired to relieve acute bronchial asthma in a patient. If the patient is a nonsmoker and otherwise normal except for asthma, we may use the mean clearance given in Table 3–1, ie, 2.8 L/h/70 kg. Since the drug will be given as an intravenous infusion, F = 1.

Therefore, in this patient, the proper infusion rate would be 28 mg/h/70 kg.

If the asthma attack is relieved, the clinician might want to maintain this plasma level using oral theophylline, which might be given every 12 hours using an extended-release formulation to approximate a continuous intravenous infusion. According to Table 3–1, F_{oral} is 0.96. When the dosing interval is 12 hours, the size of each maintenance dose would be:



A tablet or capsule size close to the ideal dose of 350 mg would then be prescribed at 12-hourly intervals. If an 8-hour dosing interval was used, the ideal dose would be 233 mg; and if the drug was given once a day, the dose would be 700 mg. In practice, F could be omitted from the calculation since it is so close to 1.

Loading Dose

When the time to reach steady state is appreciable, as it is for drugs with long half-lives, it may be desirable to administer a loading dose that promptly raises the concentration of drug in plasma to the target concentration. In theory, only the amount of the loading dose need be computed—not the rate of its administration—and, to a first approximation, this is so. The volume of distribution is the proportionality factor that relates the total amount of drug in the body to the concentration in the plasma (C_p); if a loading dose is to achieve the target concentration, then from equation (1):

For the theophylline example given in Example: Maintenance Dose Calculation, the loading dose would be 350 mg (35 L x 10 mg/L) for a 70 kg person. For most drugs, the loading dose can be given as a single dose by the chosen route of administration.

Up to this point, we have ignored the fact that some drugs follow more complex multicompartment pharmacokinetics, eg, the distribution process illustrated by the two-compartment model in Figure 3–2. This is justified in the great majority of cases. However, in some cases the distribution phase may not be ignored, particularly in connection with the calculation of loading doses. If the rate of absorption is rapid relative to distribution (this is always true for intravenous bolus administration), the concentration of drug in plasma that results from an appropriate loading dose—calculated using the apparent volume of distribution—can initially be considerably higher than desired. Severe toxicity may occur, albeit transiently. This may be particularly important, for example, in the administration of antiarrhythmic drugs such as lidocaine, where an almost immediate toxic response may occur. Thus, while the estimation of the *amount* of a loading dose may be quite correct, the *rate of administration* can sometimes be crucial in preventing excessive drug concentrations, and slow administration of an intravenous drug (over minutes rather than seconds) is almost always prudent practice. For intravenous doses of theophylline, initial injections should be given over a 20-minute period to reduce the possibility of high plasma concentrations during the distribution phase.

When intermittent doses are given, the loading dose calculated from equation (12) will only reach the average steady-state concentration and will not match the peak steady-state concentration (Figure 3–6). To match the peak steady-state concentration, the loading dose can be calculated from equation (13):

THERAPEUTIC DRUG MONITORING: RELATING PHARMACOKINETICS & PHARMACODYNAMICS

The basic principles outlined above can be applied to the interpretation of clinical drug concentration measurements on the basis of three major pharmacokinetic variables: absorption, clearance, and volume of distribution (and the derived variable, half-life); and two pharmacodynamic variables: maximum effect attainable in the target tissue and the sensitivity of the tissue to the drug. Diseases may modify all of these parameters, and the ability to predict the effect of disease states on pharmacokinetic parameters is important in properly adjusting dosage in such cases. (See The Target Concentration Strategy.)

The Target Concentration Strategy

Recognition of the essential role of concentration in linking pharmacokinetics and pharmacodynamics leads naturally to the target concentration strategy. Pharmacodynamic principles can be used to predict the concentration required to achieve a particular degree of therapeutic effect. This target concentration can then be achieved by using pharmacokinetic principles to arrive at a suitable dosing regimen. The target concentration strategy is a process for optimizing the dose in an individual on the basis of a measured surrogate response such as drug concentration:

1. Choose the target concentration, TC.
2. Predict volume of distribution (V_d) and clearance (CL) based on standard population values (eg, Table 3–1) with adjustments for factors such as weight and renal function.
3. Give a loading dose or maintenance dose calculated from TC, V_d , and CL.
4. Measure the patient's response and drug concentration.
5. Revise V_d and/or CL based on the measured concentration.
6. Repeat steps 3–5, adjusting the predicted dose to achieve TC.

Pharmacokinetic Variables

ABSORPTION

The amount of drug that enters the body depends on the patient's compliance with the prescribed regimen and on the rate and extent of transfer from the site of administration to the blood.

Overdosage and underdosage relative to the prescribed dosage—both aspects of failure of compliance—can frequently be detected by concentration measurements when gross deviations from expected values are obtained. If compliance is found to be adequate, absorption abnormalities in the small bowel may be the cause of abnormally low concentrations. Variations in the extent of bioavailability are rarely caused by irregularities in the manufacture of the particular drug formulation. More commonly, variations in bioavailability are due to metabolism during absorption.

CLEARANCE

Abnormal clearance may be anticipated when there is major impairment of the function of the kidney, liver, or heart. Creatinine clearance is a useful quantitative indicator of renal function. Conversely, drug clearance may be a useful indicator of the functional consequences of heart, kidney, or liver failure, often with greater precision than clinical findings or other laboratory tests. For example, when renal function is changing rapidly, estimation of the clearance of aminoglycoside antibiotics may be a more accurate indicator of glomerular filtration than serum creatinine.

Hepatic disease has been shown to reduce the clearance and prolong the half-life of many drugs. However, for many other drugs known to be eliminated by hepatic processes, no changes in clearance or half-life have been noted with similar hepatic disease. This reflects the fact that hepatic disease does not always affect the hepatic intrinsic clearance. At present, there is no reliable marker of hepatic drug-metabolizing function that can be used to predict changes in liver clearance in a manner analogous to the use of creatinine clearance as a marker of renal drug clearance.

VOLUME OF DISTRIBUTION

The apparent volume of distribution reflects a balance between binding to tissues, which decreases plasma concentration and makes the apparent volume larger, and binding to plasma proteins, which increases plasma concentration and makes the apparent volume smaller. Changes in either tissue or plasma binding can change the apparent volume of distribution determined from plasma concentration measurements. Older people have a relative decrease in skeletal muscle mass and tend to have a smaller apparent volume of distribution of digoxin (which binds to muscle proteins). The volume of distribution may be overestimated in obese patients if based on body weight and the drug does not enter fatty tissues well, as is the case with digoxin. In contrast, theophylline has a volume of distribution similar to that of total body water. Adipose tissue has almost as much water in it as other tissues, so that the apparent total volume of distribution of theophylline is proportional to body weight even in obese patients.

Abnormal accumulation of fluid—edema, ascites, pleural effusion—can markedly increase the volume of distribution of drugs such as gentamicin that are hydrophilic and have small volumes of distribution.

HALF-LIFE

The differences between clearance and half-life are important in defining the underlying mechanisms for the effect of a disease state on drug disposition. For example, the half-life of diazepam increases with age. When clearance is related to age, it is found that clearance of this drug does not change with age. The increasing half-life for diazepam actually results from changes in the volume of distribution with age; the metabolic processes responsible for eliminating the drug are fairly constant.

Pharmacodynamic Variables

MAXIMUM EFFECT

All pharmacologic responses must have a maximum effect (E_{max}). No matter how high the drug concentration goes, a point will be reached beyond which no further increment in response is achieved.

If increasing the dose in a particular patient does not lead to a further clinical response, it is possible that the maximum effect has been reached. Recognition of maximum effect is helpful in avoiding ineffectual increases of dose with the attendant risk of toxicity.

SENSITIVITY

The sensitivity of the target organ to drug concentration is reflected by the concentration required to produce 50% of maximum effect, the EC_{50}. Failure of response due to diminished sensitivity to the drug can be detected by measuring—in a patient who is not getting better—drug concentrations that are usually associated with therapeutic response. This may be a result of abnormal physiology—eg, hyperkalemia diminishes responsiveness to digoxin—or drug antagonism—eg, calcium channel blockers impair the inotropic response to digoxin.

Increased sensitivity to a drug is usually signaled by exaggerated responses to small or moderate doses. The pharmacodynamic nature of this sensitivity can be confirmed by measuring drug concentrations that are low in relation to the observed effect.

INTERPRETATION OF DRUG CONCENTRATION MEASUREMENTS

Clearance

Clearance is the single most important factor determining drug concentrations. The interpretation of measurements of drug concentrations depends on a clear understanding of three factors that may influence clearance: the dose, the organ blood flow, and the intrinsic function of the liver or kidneys. Each of these factors should be considered when interpreting clearance estimated from a drug concentration measurement. It must also be recognized that changes in protein binding may lead the unwary to believe there is a change in clearance when in fact drug elimination is not altered (see Plasma Protein Binding: Is It Important?). Factors affecting protein binding include the following:

(1) Albumin concentration: Drugs such as phenytoin, salicylates, and disopyramide are extensively bound to plasma albumin. Albumin levels are low in many disease states, resulting in lower total drug concentrations.

(2) Alpha$_1$ -acid glycoprotein concentration: □$_1$ -acid glycoprotein is an important binding protein with binding sites for drugs such as quinidine, lidocaine, and propranolol. It is increased in acute inflammatory disorders and causes major changes in total plasma concentration of these drugs even though drug elimination is unchanged.

(3) Capacity-limited protein binding: The binding of drugs to plasma proteins is capacity-limited. Therapeutic concentrations of salicylates and prednisolone show concentration-dependent protein binding. Because unbound drug concentration is determined by dosing rate and clearance—which is not altered, in the case of these low-extraction-ratio drugs, by protein binding—increases in dosing rate will cause corresponding changes in the pharmacodynamically important unbound concentration. Total drug concentration will increase less rapidly than the dosing rate would suggest as protein binding approaches saturation at higher concentrations.

PLASMA PROTEIN BINDING: IS IT IMPORTANT?

Plasma protein binding is often mentioned as a factor playing a role in pharmacokinetics, pharmacodynamics, and drug interactions. However, there are no clinically relevant examples of changes in drug disposition or effects that can be clearly ascribed to changes in plasma protein binding (Benet & Hoener 2002). The idea that if a drug is displaced from plasma proteins it would increase the unbound drug concentration and increase the drug effect and, perhaps, produce toxicity seems a simple and obvious mechanism. Unfortunately, this simple theory, which is appropriate for a test tube, does not work in the body, which is an open system capable of eliminating unbound drug.

First, a seemingly dramatic change in the unbound fraction from 1% to 10% releases less than 5% of the total amount of drug in the body into the unbound pool because less than one third of the drug in the body is bound to plasma proteins even in the most extreme cases, eg, warfarin. Drug displaced from plasma protein will of course distribute throughout the volume of distribution, so that a 5% increase in the amount of unbound drug in the body produces at most a 5% increase in pharmacologically active unbound drug at the site of action.

Second, when the amount of unbound drug in plasma increases, the rate of elimination will increase (if unbound clearance is unchanged), and after four half-lives the unbound concentration will return to its previous steady-state value. When drug interactions associated with protein binding displacement and clinically important effects have been studied, it has been found that the displacing drug is also an inhibitor of clearance, and it is the change in *clearance* of the *unbound* drug that is the relevant mechanism explaining the interaction.

The clinical importance of plasma protein binding is only to help interpretation of measured drug concentrations. When plasma proteins are lower than normal, then total drug concentrations will be lower but unbound concentrations will not be affected.

Dosing History

An accurate dosing history is essential if one is to obtain maximum value from a drug concentration measurement. In fact, if the dosing history is unknown or incomplete, a drug concentration measurement loses all predictive value.

Timing of Samples for Concentration Measurement

Information about the rate and extent of drug absorption in a particular patient is rarely of great clinical importance. However, absorption usually occurs during the first 2 hours after a drug dose and varies according to food intake, posture, and activity. Therefore, it is important to avoid drawing blood until absorption is complete (about 2 hours after an oral dose). Attempts to measure peak concentrations early after oral dosing are usually unsuccessful and compromise the validity of the measurement, because one cannot be certain that absorption is complete.

Some drugs such as digoxin and lithium take several hours to distribute to tissues. Digoxin samples should be taken at least 6 hours after the last dose and lithium just before the next dose (usually 24 hours after the last dose). Aminoglycosides distribute quite rapidly, but it is still prudent to wait 1 hour after giving the dose before taking a sample.

Clearance is readily estimated from the dosing rate and mean steady-state concentration. Blood samples should be appropriately timed to estimate steady-state concentration. Provided steady state has been approached (at least three half-lives of constant dosing), a sample obtained near the midpoint of the dosing interval will usually be close to the mean steady-state concentration.

Initial Predictions of Volume of Distribution & Clearance

VOLUME OF DISTRIBUTION

Volume of distribution is commonly calculated for a particular patient using body weight (70 kg body weight is assumed for the values in Table 3–1). If a patient is obese, drugs that do not readily penetrate fat (eg, gentamicin and digoxin) should have their volumes calculated from ideal body weight as shown below:

Patients with edema, ascites, or pleural effusions offer a larger volume of distribution to the aminoglycoside antibiotics (eg, gentamicin) than is predicted by body weight. In such patients, the weight should be corrected as follows: Subtract an estimate of the weight of the excess fluid accumulation from the measured weight. Use the resultant "normal" body weight to calculate the normal volume of distribution. Finally, this normal volume should be increased by 1 L for each estimated kilogram of excess fluid. This correction is important because of the relatively small volumes of distribution of these water-soluble drugs.

CLEARANCE

Drugs cleared by the renal route often require adjustment of clearance in proportion to renal function. This can be conveniently estimated from the creatinine clearance, calculated from a single serum creatinine measurement and the predicted creatinine production rate.

The predicted creatinine production rate in women is 85% of the calculated value, because they have a smaller muscle mass per kilogram and it is muscle mass that determines creatinine production. Muscle mass as a fraction of body weight decreases with age, which is why age appears in the Cockcroft-Gault equation.*

The decrease of renal function with age is independent of the decrease in creatinine production. Because of the difficulty of obtaining complete urine collections, creatinine clearance calculated in this way is at least as reliable as estimates based on urine collections. Ideal body weight should be used for obese patients, and correction should be made for muscle wasting in severely ill patients.

*The Cockcroft-Gault equation is given in Chapter 61.

Revising Individual Estimates of Volume of Distribution & Clearance

The commonsense approach to the interpretation of drug concentrations compares predictions of pharmacokinetic parameters and expected concentrations to measured values. If measured concentrations differ by more than 20% from predicted values, revised estimates of V_d or CL for that patient should be calculated using equation (1) or equation (2). If the change calculated is more than a 100% increase or 50% decrease in either V_d or CL, the assumptions made about the timing of the sample and the dosing history should be critically examined.

For example, if a patient is taking 0.25 mg of digoxin a day, a clinician may expect the digoxin concentration to be about 1 ng/mL. This is based on typical values for bioavailability of 70% and total clearance of about 7 L/h (CL_{renal} 4 L/h, $CL_{nonrenal}$ 3 L/h). If the patient has heart failure, the nonrenal (hepatic) clearance might be halved because of hepatic congestion and hypoxia, so the expected clearance would become 5.5 L/h. The concentration is then expected to be about 1.3 ng/mL. Suppose that the concentration actually measured is 2 ng/mL. Commonsense would suggest halving the daily dose to achieve a target concentration of 1 ng/mL. This approach implies a revised clearance of 3.5 L/h. The smaller clearance compared with the expected value of 5.5 L/h may reflect additional renal functional impairment due to heart failure.

This technique will often be misleading if steady state has not been reached. At least a week of regular dosing (three to four half-lives) must elapse before the implicit method will be reliable.

Bottom of Form

Top of Form

DRUG BIOTRANSFORMATION: INTRODUCTION

Humans are exposed daily to a wide variety of foreign compounds called xenobiotics—substances absorbed across the lungs or skin or, more commonly, ingested either unintentionally as compounds present in food and drink or deliberately as drugs for therapeutic or "recreational" purposes. Exposure to environmental xenobiotics may be inadvertent and accidental or—when they are present as components of air, water, and food—inescapable. Some xenobiotics are innocuous, but many can provoke biologic responses. Such biologic responses often depend on conversion of the absorbed substance into an active metabolite. The discussion that follows is applicable to xenobiotics in general (including drugs) and to some extent to endogenous compounds.

WHY IS DRUG BIOTRANSFORMATION NECESSARY?

Renal excretion plays a pivotal role in terminating the biologic activity of some drugs, particularly those that have small molecular volumes or possess polar characteristics such as functional groups that are fully ionized at physiologic pH. However, many drugs do not possess such physicochemical properties. Pharmacologically active organic molecules tend to be lipophilic and remain un-ionized or only partially ionized at physiologic pH; these are readily reabsorbed from the glomerular filtrate in the nephron. Certain lipophilic compounds are often strongly bound to plasma proteins and may not be readily filtered at the glomerulus. Consequently, most drugs would have a prolonged duration of action if termination of their action depended solely on renal excretion.

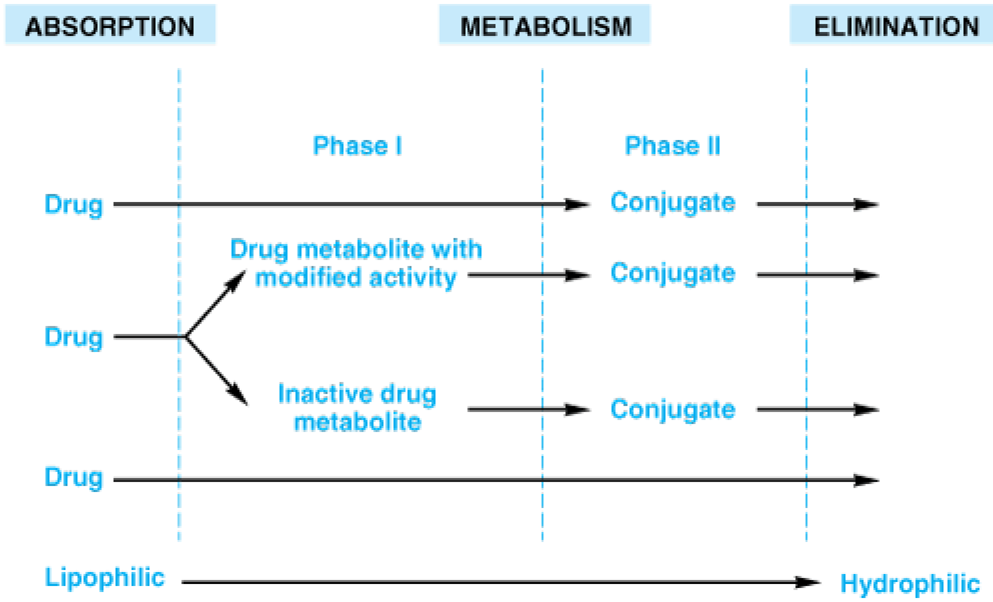
An alternative process that can lead to the termination or alteration of biologic activity is metabolism. In general, lipophilic xenobiotics are transformed to more polar and hence more readily excreted products. The role metabolism plays in the inactivation of lipid-soluble drugs can be quite dramatic. For example, lipophilic barbiturates such as thiopental and pentobarbital would have extremely long half-lives if it were not for their metabolic conversion to more water-soluble compounds.

Metabolic products are often less pharmacodynamically active than the parent drug and may even be inactive. However, some biotransformation products have *enhanced* activity or toxic properties. It is noteworthy that the synthesis of endogenous substrates such as steroid hormones, cholesterol, active vitamin D congeners, and bile acids involves many pathways catalyzed by enzymes associated with the metabolism of xenobiotics. Finally, drug-metabolizing enzymes have been exploited in the design of pharmacologically inactive prodrugs that are converted to active molecules in the body.

THE ROLE OF BIOTRANSFORMATION IN DRUG DISPOSITION

Most metabolic biotransformations occur at some point between absorption of the drug into the general circulation and its renal elimination. A few transformations occur in the intestinal lumen or intestinal wall. In general, all of these reactions can be assigned to one of two major categories called phase I and phase II reactions (Figure 4–1).

Figure 4–1.

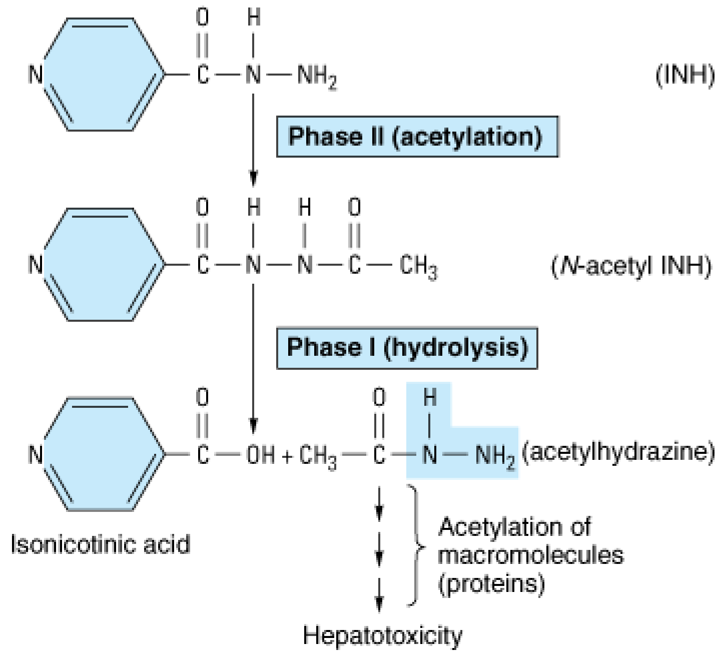


Phase I and phase II reactions, and direct elimination, in drug biodisposition. Phase II reactions may also precede phase I reactions.

Phase I reactions usually convert the parent drug to a more polar metabolite by introducing or unmasking a functional group (–OH, $-NH_2$, –SH). Often these metabolites are inactive, although in some instances activity is only modified or even enhanced.

If phase I metabolites are sufficiently polar, they may be readily excreted. However, many phase I products are not eliminated rapidly and undergo a subsequent reaction in which an endogenous substrate such as glucuronic acid, sulfuric acid, acetic acid, or an amino acid combines with the newly incorporated functional group to form a highly polar conjugate. Such conjugation or synthetic reactions are the hallmarks of phase II metabolism. A great variety of drugs undergo these sequential biotransformation reactions, although in some instances the parent drug may already possess a functional group that may form a conjugate directly. For example, the hydrazide moiety of isoniazid is known to form an *N*-acetyl conjugate in a phase II reaction. This conjugate is then a substrate for a phase I type reaction, namely, hydrolysis to isonicotinic acid (Figure 4–2). Thus, phase II reactions may actually precede phase I reactions.

Figure 4–2.



Phase II activation of isoniazid (INH) to a hepatotoxic metabolite.

WHERE DO DRUG BIOTRANSFORMATIONS OCCUR?

Although every tissue has some ability to metabolize drugs, the liver is the principal organ of drug metabolism. Other tissues that display considerable activity include the gastrointestinal tract, the lungs, the skin, and the kidneys. Following oral administration, many drugs (eg, isoproterenol, meperidine, pentazocine, morphine) are absorbed intact from the small intestine and transported first via the portal system to the liver, where they undergo extensive metabolism. This process is called the first-pass effect (see Chapter 3). Some orally administered drugs (eg, clonazepam, chlorpromazine, cyclosporine) are more extensively metabolized in the intestine than in the liver, whereas others (eg, midazolam) undergo significant (50%) intestinal metabolism. Thus, intestinal metabolism can contribute to the overall first-pass effect, and individuals with compromised liver function may increasingly rely on such intestinal metabolism for drug elimination. First-pass effects may so greatly limit the bioavailability of orally administered drugs (eg, lidocaine) that alternative routes of administration must be used to achieve therapeutically effective blood levels. Furthermore, the lower gut harbors intestinal microorganisms that are capable of many biotransformation reactions. In addition, drugs may be metabolized by gastric acid (eg, penicillin), by digestive enzymes (eg, polypeptides such as insulin), or by enzymes in the wall of the intestine (eg, sympathomimetic catecholamines).

Although drug biotransformation in vivo can occur by spontaneous, noncatalyzed chemical reactions, the vast majority of transformations are catalyzed by specific cellular enzymes. At the subcellular level, these enzymes may be located in the endoplasmic reticulum (ER), mitochondria, cytosol, lysosomes, or even the nuclear envelope or plasma membrane.

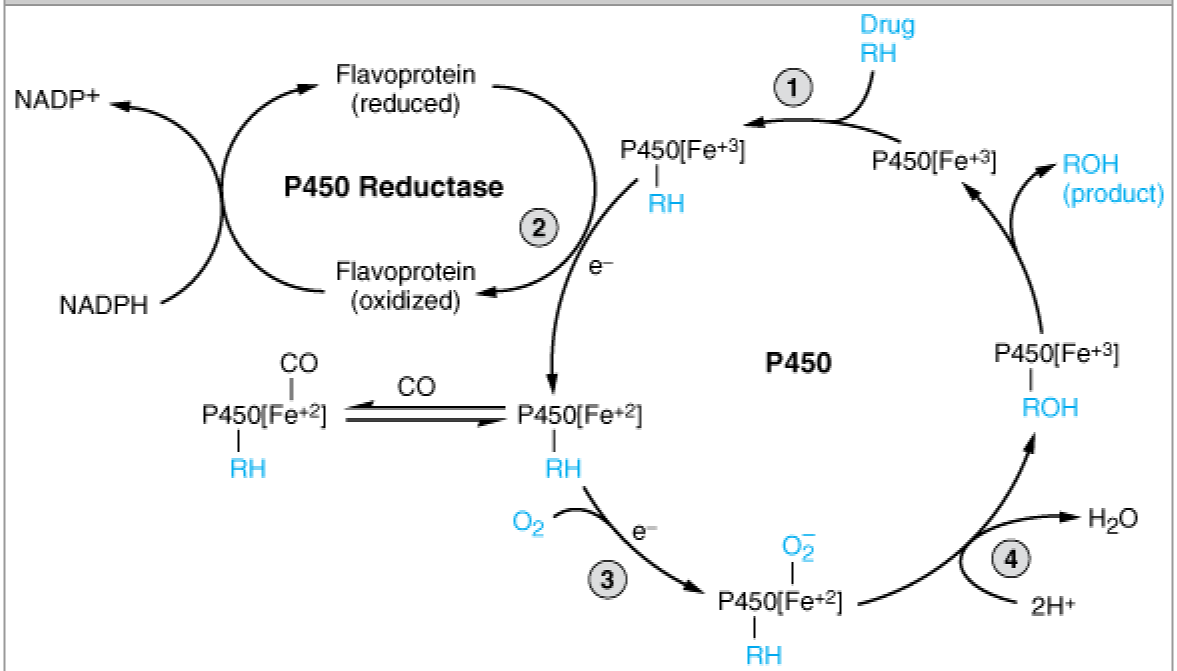
MICROSOMAL MIXED FUNCTION OXIDASE SYSTEM & PHASE I REACTIONS

Many drug-metabolizing enzymes are located in the lipophilic ER membranes of the liver and other tissues. When these lamellar membranes are isolated by homogenization and fractionation of the cell, they re-form into vesicles called *microsomes*. Microsomes retain most of the morphologic and functional characteristics of the intact membranes, including the rough and smooth surface features of the rough (ribosome-studded) and smooth (no ribosomes) ER. Whereas the rough microsomes tend to be dedicated to protein synthesis, the smooth microsomes are relatively rich in enzymes responsible for oxidative drug metabolism. In particular, they contain the important class of enzymes known as the *mixed function oxidases* (MFOs), or *monooxygenases*. The activity of these enzymes requires both a reducing agent (nicotinamide adenine dinucleotide phosphate [NADPH]) and molecular oxygen; in a typical reaction, one molecule of oxygen is consumed (reduced) per substrate molecule, with one oxygen atom appearing in the product and the other in the form of water.

In this oxidation-reduction process, two microsomal enzymes play a key role. The first of these is a flavoprotein, *NADPH-cytochrome P450 reductase*. One mole of this enzyme contains 1 mol each of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). The second microsomal enzyme is a hemoprotein called *cytochrome P450*, which serves as the terminal oxidase. In fact, the microsomal membrane harbors multiple forms of this hemoprotein, and this multiplicity is increased by repeated administration of exogenous chemicals (see below). The name cytochrome P450 (abbreviated as CYP or *P450*) is derived from the spectral properties of this hemoprotein. In its reduced (ferrous) form, it binds carbon monoxide to give a complex that absorbs light maximally at 450 nm. The relative abundance of P450s, compared with that of the reductase in the liver, contributes to making P450 heme reduction a rate-limiting step in hepatic drug oxidations.

Microsomal drug oxidations require P450, P450 reductase, NADPH, and molecular oxygen. A simplified scheme of the oxidative cycle is presented in Figure 4–3. Briefly, oxidized (Fe^{3+}) P450 combines with a drug substrate to form a binary complex (step 1). NADPH donates an electron to the flavoprotein P450 reductase, which in turn reduces the oxidized P450-drug complex (step 2). A second electron is introduced from NADPH via the same P450 reductase, which serves to reduce molecular oxygen and to form an "activated oxygen"-P450-substrate complex (step 3). This complex in turn transfers activated oxygen to the drug substrate to form the oxidized product (step 4).

Figure 4–3.



Cytochrome P450 cycle in drug oxidations. (RH, parent drug; ROH, oxidized metabolite; e−, electron.)

The potent oxidizing properties of this activated oxygen permit oxidation of a large number of substrates. Substrate specificity is very low for this enzyme complex. High lipid solubility is the only common structural feature of the wide variety of structurally unrelated drugs and chemicals that serve as substrates in this system (Table 4–1).

Table 4–1. Phase I Reactions

Reaction Class	Structural Change	Drug Substrates
Oxidations		
Cytochrome P450-dependent oxidations:		

Reaction Class	Structural Change	Drug Substrates
Aromatic hydroxylations		Acetanilide, propranolol, phenobarbital, phenytoin, phenylbutazone, amphetamine, warfarin, 17α-ethinyl estradiol, naphthalene, benzpyrene
Aliphatic hydroxylations	$RCH_2CH_3 \rightarrow RCH_2CH_2OH$ $RCH_2CH_3 \rightarrow RCH(OH)CH_3$	Amobarbital, pentobarbital, secobarbital, chlorpropamide, ibuprofen, meprobamate, glutethimide, phenylbutazone, digitoxin
Epoxidation		Aldrin
Oxidative dealkylation	$RNHCH_3 \rightarrow RNH_2 + CH_2O$	Morphine, ethylmorphine, benzphetamine, aminopyrine, caffeine, theophylline
N-Dealkylation		
O-Dealkylation	$ROCH_3 \rightarrow ROH + CH_2O$	Codeine, *p*-nitroanisole
S-Dealkylation	$RSCH_3 \rightarrow RSH + CH_2O$	6-Methylthiopurine, methitural
N-Oxidation	$RNH_2 \rightarrow RNHOH$	
Primary amines		Aniline, chlorphentermine
Secondary amines		2-Acetylaminofluorene, acetaminophen

Reaction Class	Structural Change	Drug Substrates
Tertiary amines		Nicotine, methaqualone
S-Oxidation		Thioridazine, cimetidine, chlorpromazine
Deamination		Amphetamine, diazepam
Desulfuration		Thiopental
		Parathion
Dechlorination	$CCl_4 \rightarrow [CCl_3^{\cdot}] \rightarrow CHCl_3$	Carbon tetrachloride
Cytochrome P450-independent oxidations:		
Flavin monooxygenase (Ziegler's enzyme)	$R_3N \longrightarrow R_3N^+ \rightarrow O^- \xrightarrow{H^+} R_3N^+OH$	Chlorpromazine, amitriptyline, benzphetamine

Reaction Class	Structural Change	Drug Substrates
	$RCH_2N(H)—CH_2R \rightarrow RCH_2—N(OH)—CH_2R \rightarrow RCH{=}N(O^-)—CH_2R$	Desipramine, nortriptyline
		Methimazole, propylthiouracil
Amine oxidases	$RCH_2NH_2 \rightarrow RCHO + NH_3$	Phenylethylamine, epinephrine
Dehydrogenations	$RCH_2OH \rightarrow RCHO$	Ethanol
Reductions		
Azo reductions	$RN{=}NR_1 \rightarrow RNH—NHR_1 \rightarrow RNH_2 + R_1NH_2$	Prontosil, tartrazine
Nitro reductions	$RNO_2 \rightarrow RNO \rightarrow RNHOH \rightarrow RNH_2$	Nitrobenzene, chloramphenicol, clonazepam, dantrolene
Carbonyl reductions	$RC(=O)R' \rightarrow RCH(OH)R'$	Metyrapone, methadone, naloxone
Hydrolyses		
Esters	$R_1COOR_2 \rightarrow R_1COOH + R_2OH$	Procaine, succinylcholine, aspirin, clofibrate, methylphenidate
Amides	$RCONHR_1 \rightarrow RCOOH + R_1NH_2$	Procainamide, lidocaine, indomethacin

Human Liver P450 Enzymes

Immunoblotting analyses, combined with the use of relatively selective functional markers and selective P450 inhibitors, have identified numerous P450 isoforms (CYP: 1A2, 2A6, 2B6, 2C8, 2C9, 2C18, 2C19, 2D6, 2E1, 3A4, 3A5, 4A11, and 7) in human liver microsomal preparations. Of these, CYP1A2, CYP2A6, CYP2C9, CYP2D6, CYP2E1, and CYP3A4 appear to be the most important forms, accounting for approximately, 15%, 4%, 20%, 5%, 10%, and 30%, respectively, of the total human liver P450 content. Together, they are responsible for catalyzing the bulk of the hepatic drug and xenobiotic metabolism (Table 4–2).

Table 4–2. Human Liver P450s (CYPs), and Some of the Drugs Metabolized (Substrates), Inducers, and Selective Inhibitors.

CYP	Substrates	Inducers	Inhibitors
1A2	Acetaminophen, antipyrine, caffeine, clomipramine, phenacetin, tacrine, tamoxifen, theophylline, warfarin	Smoking, charcoal-broiled foods, cruciferous vegetables, omeprazole	Galangin, furafylline, fluvoxamine
2A6	Coumarin, tobacco nitrosamines, nicotine (to cotinine and 2'-hydroxynicotine)	Rifampin, phenobarbital	Tranylcypromine, menthofuran, methoxsalen
2B6	Artemisinin, bupropion, *S*-mephobarbital, cyclophosphamide, *S*-mephenytoin (*N*-demethylation to nirvanol), propofol, selegiline, sertraline	Phenobarbital, cyclophosphamide	Ticlopidine, clopidogrel
2C8	Taxol, all-*trans*-retinoic acid	Rifampin, barbiturates	Trimethoprim
2C9	Celecoxib, flurbiprofen, hexobarbital, ibuprofen, losartan, phenytoin, tolbutamide, trimethadione, sulfaphenazole, *S*-warfarin, ticrynafen	Barbiturates, rifampin	Tienilic acid, sulfaphenazole
2C18	Tolbutamide	Phenobarbital	
2C19	Diazepam, *S*-mephenytoin, naproxen, nirvanol, omeprazole, propranolol	Barbiturates, rifampin	*N*3-benzylnirvanol, *N*3-benzylphenobarbital, fluconazole
2D6	Bufuralol, bupranolol, clomipramine, clozapine, codeine, debrisoquin, dextromethorphan, encainide, flecainide, fluoxetine, guanoxan, haloperidol, hydrocodone, 4-methoxy-amphetamine, metoprolol, mexiletine, oxycodone, paroxetine, phenformin, propafenone, propoxyphene, risperidone, selegiline	St. John's wort, rifampin	Quinidine, paroxetine

CYP	Substrates	Inducers	Inhibitors
	(deprenyl), sparteine, thioridazine, timolol, tricyclic antidepressants		
2E1	Acetaminophen, chlorzoxazone, enflurane, halothane, ethanol (a minor pathway)	Ethanol, isoniazid	4-Methylpyrazole, disulfiram
3A4[1]	Acetaminophen, alfentanil, amiodarone, astemizole, cisapride, cocaine, cortisol, cyclosporine, dapsone, diazepam, dihydroergotamine, dihydropyridines, diltiazem, erythromycin, ethinyl estradiol, gestodene, indinavir, lidocaine, lovastatin, macrolides, methadone, miconazole, midazolam, mifepristone (RU 486), nifedipine, paclitaxel, progesterone, quinidine, rapamycin, ritonavir, saquinavir, spironolactone, sulfamethoxazole, sufentanil, tacrolimus, tamoxifen, terfenadine, testosterone, tetrahydrocannabinol, triazolam, troleandomycin, verapamil	Barbiturates, carbamazepine, glucocorticoids, macrolide antibiotics, pioglitazone, phenytoin, rifampin	Azamulin, diltiazam, erythromycin, fluconazole, grapefruit juice (furanocoumarins), itraconazole, ketoconazole, ritonavir, troleandomycin

[1]CYP3A5 has similar substrate and inhibitor profiles, but except for a few drugs is generally less active than CYP3A4.

It is noteworthy that CYP3A4 alone is responsible for the metabolism of over 50% of the clinically prescribed drugs metabolized by the liver. The involvement of individual P450s in the metabolism of a given drug may be screened in vitro by means of selective functional markers, selective chemical P450 inhibitors, and anti-P450 antibodies. In vivo, such screening may be accomplished by means of relatively selective noninvasive markers, which include breath tests or urinary analyses of specific metabolites after administration of a P450-selective substrate probe.

Enzyme Induction

Some of the chemically dissimilar P450 substrate drugs, on repeated administration, *induce* P450 by enhancing the rate of its synthesis or reducing its rate of degradation (Table 4–2). Induction results in an acceleration of substrate metabolism and usually in a decrease in the pharmacologic action of the inducer and also of coadministered drugs. However, in the case of drugs metabolically transformed to reactive metabolites, enzyme induction may exacerbate metabolite-mediated toxicity.

Various substrates induce P450 isoforms having different molecular masses and exhibiting different substrate specificities and immunochemical and spectral characteristics.

Environmental pollutants are also capable of inducing P450 enzymes. As noted above, exposure to benzo[*a*]pyrene and other polycyclic aromatic hydrocarbons, which are present in tobacco smoke, charcoal-broiled meat, and other organic pyrolysis products, is known to induce CYP1A enzymes and to alter the rates of drug metabolism. Other environmental chemicals known to induce specific P450s include the polychlorinated biphenyls (PCBs), which were once used widely in industry as insulating materials and plasticizers, and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (dioxin, TCDD), a trace byproduct of the chemical synthesis of the defoliant 2,4,5-T (see Chapter 57).

Increased P450 synthesis requires enhanced transcription and translation. A cytoplasmic receptor (termed AhR) for polycyclic aromatic hydrocarbons (eg, benzo[*a*]pyrene, dioxin) has been identified, and the translocation of the inducer-receptor complex into the nucleus and subsequent activation of regulatory elements of genes have been documented. A pregnane X receptor (PXR), a member of the steroid-retinoid-thyroid hormone receptor family, has recently been shown to mediate CYP3A induction by various chemicals (dexamethasone, rifampin) in the liver and intestinal mucosa. A similar receptor, the constitutive androstane receptor (CAR) has been identified for the phenobarbital class of inducers.

P450 enzymes may also be induced by substrate stabilization, ie, decreased degradation, as is the case with troleandomycin- or clotrimazole-mediated induction of CYP3A enzymes and the ethanol-mediated induction of CYP2E1.

Enzyme Inhibition

Certain drug substrates inhibit cytochrome P450 enzyme activity (Table 4–2). Imidazole-containing drugs such as cimetidine and ketoconazole bind tightly to the P450 heme iron and effectively reduce the metabolism of endogenous substrates (eg, testosterone) or other coadministered drugs through competitive inhibition. However, macrolide antibiotics such as troleandomycin, erythromycin, and erythromycin derivatives are metabolized, apparently by CYP3A, to metabolites that complex the cytochrome P450 heme-iron and render it catalytically inactive. Another compound that acts through this mechanism is the inhibitor proadifen (SKF-525-A, used in research), which binds tightly to the heme iron and quasi-irreversibly inactivates the enzyme, thereby inhibiting the metabolism of potential substrates.

Some substrates irreversibly inhibit P450s via covalent interaction of a metabolically generated reactive intermediate that may react with the P450 apoprotein or heme moiety or even cause the heme to fragment and irreversibly modify the apoprotein. The antibiotic chloramphenicol is metabolized by CYP2B1 to a species that modifies its protein and thus also inactivates the enzyme. A growing list of such suicide inhibitors—inactivators that attack the heme or the protein moiety—includes certain steroids (ethinyl estradiol, norethindrone, and spironolactone); fluroxene; allobarbital; the analgesic sedatives allylisopropylacetylurea, diethylpentenamide, and ethchlorvynol; carbon disulfide; grapefruit furanocoumarins; deprenyl; phencyclidine; ticlopidine and clopidogrel; ritonavir, and propylthiouracil. On the other hand, the barbiturate secobarbital is found to inactivate CYP2B1 by modification of *both* its heme and protein moieties. Other metabolically activated drugs whose P450 inactivation mechanism is not fully elucidated include mifepristone (RU-486), troglitazone, raloxifene, and tamoxifen.

PHASE II REACTIONS

Parent drugs or their phase I metabolites that contain suitable chemical groups often undergo coupling or conjugation reactions with an endogenous substance to yield drug conjugates (Table 4–3). In general, conjugates are polar molecules that are readily excreted and often inactive. Conjugate formation involves high-energy intermediates and specific transfer enzymes. Such enzymes (transferases) may be located in microsomes or in the cytosol. They catalyze the coupling of an activated endogenous substance (such as the uridine 5'-diphosphate [UDP] derivative of glucuronic acid) with a drug (or endogenous compound), or of an activated drug (such as the *S*-CoA derivative of benzoic acid) with an endogenous substrate. Because the endogenous substrates originate in the diet, nutrition plays a critical role in the regulation of drug conjugations.

Table 4–3. Phase II Reactions.

Type of Conjugation	Endogenous Reactant	Transferase (Location)	Types of Substrates	Examples
Glucuronidation	UDP glucuronic acid	UDP glucuronosyl-transferase (microsomes)	Phenols, alcohols, carboxylic acids, hydroxylamines, sulfonamides	Nitrophenol, morphine, acetaminophen, diazepam, *N*-hydroxydapsone, sulfathiazole, meprobamate, digitoxin, digoxin
Acetylation	Acetyl-CoA	*N*-Acetyltransferase (cytosol)	Amines	Sulfonamides, isoniazid, clonazepam, dapsone, mescaline
Glutathione conjugation	Glutathione (GSH)	GSH-*S*-transferase (cytosol, microsomes)	Epoxides, arene oxides, nitro groups, hydroxylamines	Acetminphen, ethacrynic acid, bromobenzene
Glycine conjugation	Glycine	Acyl-CoA glycinetransferase (mitochondria)	Acyl-CoA derivatives of carboxylic acids	Salicylic acid, benzoic acid, nicotinic acid, cinnamic acid, cholic acid, deoxycholic acid
Sulfation	Phosphoadenosyl phosphosulfate	Sulfotransferase (cytosol)	Phenols, alcohols, aromatic amines	Estrone, aniline, phenol, 3-hydroxy-coumarin, acetaminophen, methyldopa
Methylation	*S*-Adenosyl-methionine	Transmethylases (cytosol)	Catecholamines, phenols, amines	Dopamine, epinephrine, pyridine, histamine, thiouracil
Water conjugation	Water	Epoxide hydrolase (microsomes)	Arene oxides, *cis*-disubstituted and monosubstituted	Benzopyrene 7,8-epoxide, styrene 1,2-oxide,

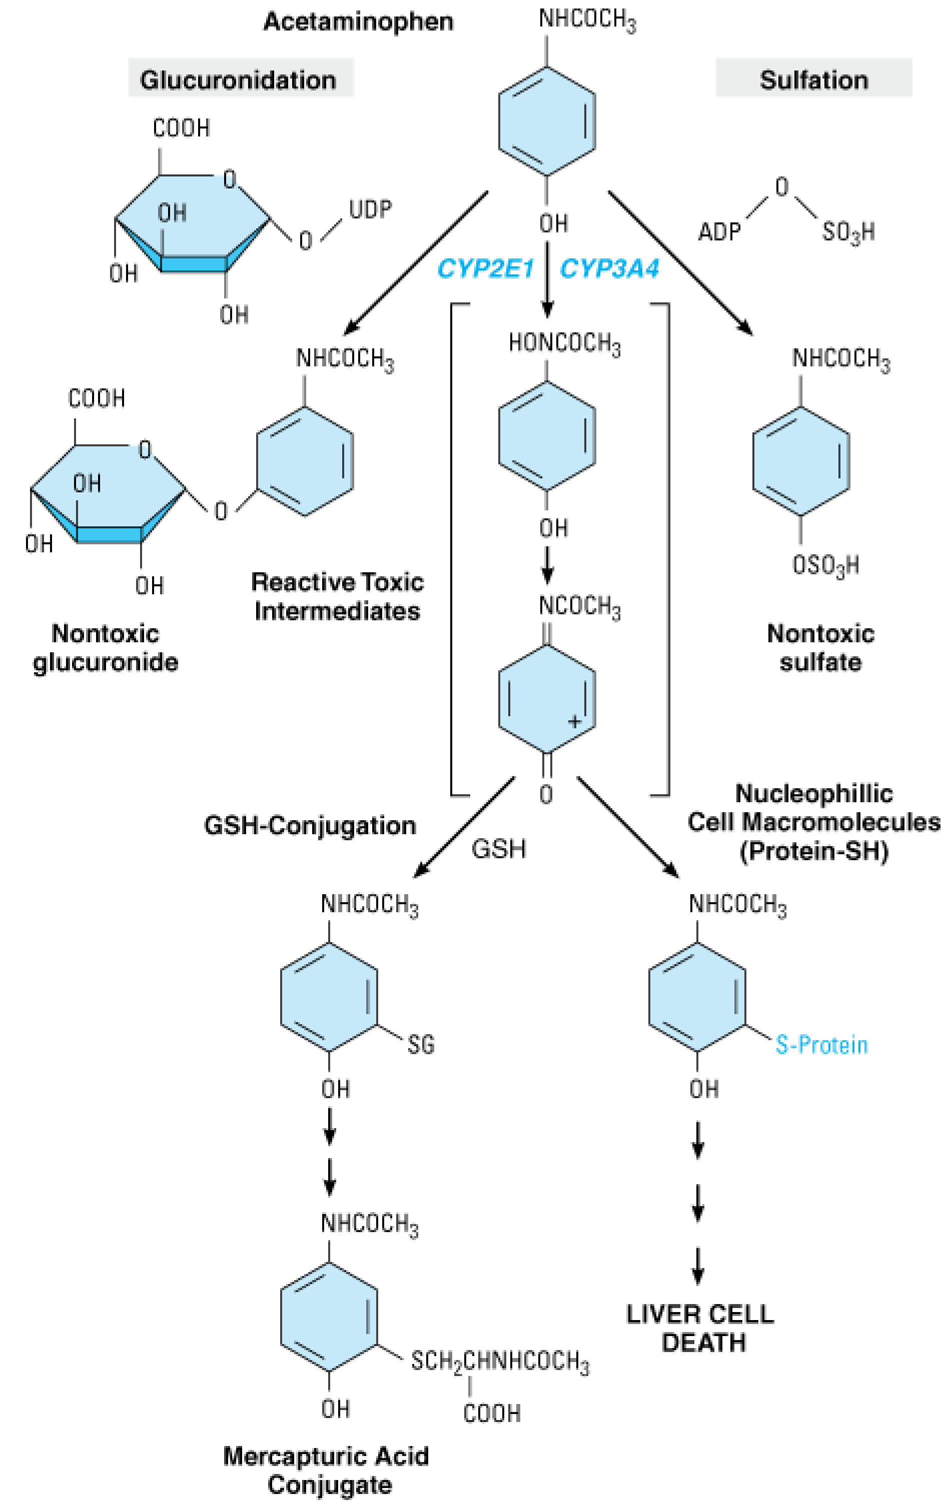
Type of Conjugation	Endogenous Reactant	Transferase (Location)	Types of Substrates	Examples
			oxiranes	carbamazepine epoxide
		(cytosol)	Alkene oxides, fatty acid epoxides	Leukotriene A_4

Drug conjugations were once believed to represent terminal inactivation events and as such have been viewed as "true detoxification" reactions. However, this concept must be modified, because it is now known that certain conjugation reactions (acyl glucuronidation of nonsteroidal anti-inflammatory drugs, *O*-sulfation of *N*-hydroxyacetylaminofluorene, and *N*-acetylation of isoniazid) may lead to the formation of reactive species responsible for the toxicity of the drugs. Furthermore, sulfation is known to activate the orally active prodrug minoxidil into a very efficacious vasodilator and morphine-6-glucuronide is more potent than morphine itself.

METABOLISM OF DRUGS TO TOXIC PRODUCTS

Metabolism of drugs and other foreign chemicals may not always be an innocuous biochemical event leading to detoxification and elimination of the compound. Indeed, as noted above, several compounds have been shown to be metabolically transformed to reactive intermediates that are toxic to various organs. Such toxic reactions may not be apparent at low levels of exposure to parent compounds when alternative detoxification mechanisms are not yet overwhelmed or compromised and the availability of endogenous detoxifying cosubstrates (glutathione [GSH], glucuronic acid, sulfate) is not limited. However, when these resources are exhausted, the toxic pathway may prevail, resulting in overt organ toxicity or carcinogenesis. The number of specific examples of such drug-induced toxicity is expanding rapidly. An example is acetaminophen (paracetamol)-induced hepatotoxicity (Figure 4–4). This analgesic antipyretic drug is quite safe in therapeutic doses (1.2 g/d for an adult). It normally undergoes glucuronidation and sulfation to the corresponding conjugates, which together comprise 95% of the total excreted metabolites. The alternative P450-dependent GSH conjugation pathway accounts for the remaining 5%. When acetaminophen intake far exceeds therapeutic doses, the glucuronidation and sulfation pathways are saturated, and the P450-dependent pathway becomes increasingly important. Little or no hepatotoxicity results as long as GSH is available for conjugation. However, with time, hepatic GSH is depleted faster than it can be regenerated, and a reactive, toxic metabolite accumulates. In the absence of intracellular nucleophiles such as GSH, this reactive metabolite (*N*-acetylbenzoiminoquinone) reacts with nucleophilic groups of cellular proteins, resulting in hepatotoxicity.

Figure 4–4.



Metabolism of acetaminophen (top center) to hepatotoxic metabolites. (GSH, glutathione; SG, glutathione moiety).

The chemical and toxicologic characterization of the electrophilic nature of the reactive acetaminophen metabolite has led to the development of effective antidotes—cysteamine and *N*-acetylcysteine. Administration of *N*-acetylcysteine (the safer of the two) within 8–16 hours following acetaminophen overdosage has been shown to protect victims from fulminant hepatotoxicity and death (see Chapter 59). Administration of GSH is not effective because it does not cross cell membranes readily.

CLINICAL RELEVANCE OF DRUG METABOLISM

The dose and frequency of administration required to achieve effective therapeutic blood and tissue levels vary in different patients because of individual differences in drug distribution and rates of drug metabolism and elimination. These differences are determined by genetic factors and nongenetic variables such as age, sex, liver size, liver function, circadian rhythm, body temperature, and nutritional and environmental factors such as concomitant exposure to inducers or inhibitors of drug metabolism. The discussion that follows summarizes the most important of these variables.

Individual Differences

Individual differences in metabolic rate depend on the nature of the drug itself. Thus, within the same population, steady-state plasma levels may reflect a 30-fold variation in the metabolism of one drug and only a two-fold variation in the metabolism of another.

Genetic Factors

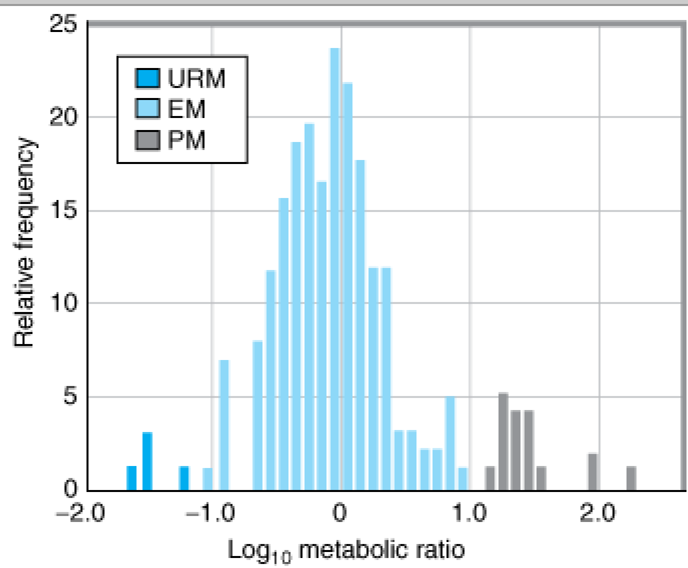
Genetic factors that influence enzyme levels account for some of these differences. Succinylcholine, for example, is metabolized only half as rapidly in persons with genetically determined defects in pseudocholinesterase as in persons with normally functioning pseudocholinesterase. Analogous pharmacogenetic differences are seen in the acetylation of isoniazid and the hydroxylation of warfarin. The defect in slow acetylators (of isoniazid and similar amines) appears to be caused by the synthesis of less of the enzyme rather than of an abnormal form of it. Inherited as an autosomal recessive trait, the slow acetylator phenotype occurs in about 50% of blacks and whites in the USA, more frequently in Europeans living in high northern latitudes, and much less commonly in Asians and Inuits (Eskimos). Similarly, genetically determined defects in the oxidative metabolism of debrisoquin, phenacetin, guanoxan, sparteine, phenformin, warfarin, and others have been reported (Table 4–4). The defects are apparently transmitted as autosomal recessive traits and may be expressed at any one of the multiple metabolic transformations that a chemical might undergo.

Table 4–4. Some Examples of Genetic Polymorphisms in Drug Metabolism.			
Defect	Enzyme Involved	Drug and Therapeutic Use	Clinical Consequences[1]
Oxidation	CYP2D6	Bufuralol (β-adrenoceptor blocker)	Exacerbation of β-blockade, nausea
Oxidation	CYP2D6	Codeine (analgesic)	Reduced analgesia
Oxidation	CYP2D6	Debrisoquin (antihypertensive)	Orthostatic hypotension
Oxidation	Aldehyde dehydrogenase	Ethanol (recreational drug)	Facial flushing, hypotension, tachycardia, nausea, vomiting
N-Acetylation	*N*-acetyl transferase	Hydralazine (antihypertensive)	Lupus erythematosus-like syndrome
N-Acetylation	*N*-acetyl transferase	Isoniazid (antitubercular)	Peripheral neuropathy
Oxidation	CYP2C19	Mephenytoin (antiepileptic)	Overdose toxicity
S-Methylation	Thiopurine methyl-transferase	Mercaptopurines (cancer chemotherapeutic)	Myelotoxicity
Oxidation	CYP2A6	Nicotine (stimulant)	Lesser toxicity
Oxidation	CYP2D6	Nortriptyline (antidepressant)	Toxicity
O-Demethylation	CYP2C19	Omeprazole (proton pump inhibitor)	Increased therapeutic efficacy
Oxidation	CYP2D6	Sparteine	Oxytocic symptoms
Ester hydrolysis	Plasma cholinesterase	Succinylcholine (neuromuscular blocker)	Prolonged apnea
Oxidation	CYP2C9	S-warfarin (anticoagulant)	Bleeding
Oxidation	CYP2C9	Tolbutamide (hypoglycemic)	Cardiotoxicity

[1]Observed or predictable.

Of the several recognized genetic varieties of drug metabolism polymorphisms, three have been particularly well characterized and afford some insight into possible underlying mechanisms. First is the debrisoquin-sparteine oxidation type of polymorphism, which apparently occurs in 3–10% of whites and is inherited as an autosomal recessive trait. In affected individuals, the CYP2D6-dependent oxidations of debrisoquin and other drugs (see Table 4–2; Figure 4–5) are impaired. These defects in oxidative drug metabolism are probably coinherited. The precise molecular basis for the defect appears to be faulty expression of the P450 protein, resulting in little or no isoform-catalyzed drug metabolism. More recently, however, another polymorphic genotype has been reported that results in ultrarapid metabolism of relevant drugs due to the presence of 2D6 allelic variants with up to 13 gene copies in tandem. This genotype is most common in Ethiopians and Saudi Arabians, populations that display it in up to one third of individuals. As a result, these subjects require twofold to threefold higher daily doses of nortriptyline (a 2D6 substrate) to achieve therapeutic plasma levels. Conversely, in these ultrarapidly metabolizing populations, the prodrug codeine (another 2D6 substrate) is metabolized much faster to morphine, often resulting in undesirable adverse effects of morphine, such as abdominal pain.

Figure 4–5.



Genetic polymorphism in debrisoquin 4-hydroxylation by CYP2D6 in a Caucasian population. The semilog frequency distribution histogram of the metabolic ratio (MR; defined as percent of dose excreted as unchanged debrisoquin divided by the percent of dose excreted as 4-hydroxydebrisoquin metabolite) in the 8-hour urine collected after oral ingestion of 12.8 mg debrisoquin sulfate (equivalent to 10 mg free debrisoquin base). Individuals with MR values > 12.6 were phenotyped as poor metabolizers (PM, *dark gray bars*), and those with MR values < 12.6 but > 0.2 were designated extensive metabolizers (EM, *light color bars*). Those with MR values < 0.2 were designated as ultrarapid metabolizers (URM, *dark color bars*) based on the MR values (0.01–0.1) of individuals with documented multiple copies of CYP2D6 allelic variants resulting from inherited amplification of this gene. (Data from Woolhouse et al: Debrisoquin hydroxylation polymorphism among Ghanians and Caucasians. Clin Pharmacol Ther 1979;26:584.)

A second well-studied genetic drug polymorphism involves the stereoselective aromatic (4)-

hydroxylation of the anticonvulsant mephenytoin, catalyzed by CYP2C19. This polymorphism, which is also inherited as an autosomal recessive trait, occurs in 3–5% of Caucasians and 18–23% of Japanese populations. It is genetically independent of the debrisoquin-sparteine polymorphism. In normal "extensive metabolizers," (*S*)-mephenytoin is extensively hydroxylated by CYP2C19 at the 4 position of the phenyl ring before its glucuronidation and rapid excretion in the urine, whereas (*R*)-mephenytoin is slowly *N*-demethylated to nirvanol, an active metabolite. "Poor metabolizers," however, appear to totally lack the stereospecific (*S*)-mephenytoin hydroxylase activity, so both (*S*)- and (*R*)-mephenytoin enantiomers are *N*-demethylated to nirvanol, which accumulates in much higher concentrations. Thus, poor metabolizers of mephenytoin show signs of profound sedation and ataxia after doses of the drug that are well tolerated by normal metabolizers. The molecular basis for this defect is a single base pair mutation in exon 5 of the CYP2C19 gene that creates an aberrant splice site, a correspondingly altered reading frame of the mRNA, and, finally, a truncated, nonfunctional protein. It is clinically important to recognize that the safety of a drug may be severely reduced in individuals who are poor metabolizers.

The third recently characterized genetic polymorphism is that of CYP2C9. Two well-characterized variants of this enzyme exist, each with amino acid mutations that result in altered metabolism. The CYP2C9*2 allele encodes an Arg144Cys mutation, exhibiting impaired functional interactions with P450 reductase. The other allelic variant, CYP2C9*3, encodes an enzyme with an Ile359Leu mutation that has lowered affinity for many substrates. For example, individuals displaying the CYP2C9*3 phenotype have greatly reduced tolerance for the anticoagulant warfarin. The warfarin clearance in CYP2C9*3-homozygous individuals is about 10% of normal values, and these people have a much lower tolerance for the drug than those who are homozygous for the normal wild-type allele. These individuals also have a much higher risk of adverse effects with warfarin (eg, bleeding) and with other CYP2C9 substrates such as phenytoin, losartan, tolbutamide, and some NSAIDs.

Allelic variants of CYP3A4 have also been reported but their contribution to its well-known interindividual variability in drug metabolism apparently is limited. On the other hand, the expression of CYP3A5, another human liver isoform, is markedly polymorphic, ranging from 0% to 100% of the total hepatic CYP3A content. This CYP3A5 protein polymorphism is now known to result from a single nucleotide polymorphism (SNP) within intron 3, which enables normally spliced CYP3A5 transcripts in 5% of Caucasians, 29% of Japanese, 27% of Chinese, 30% of Koreans, and 73% of African Americans. Thus, it can significantly contribute to interindividual differences in the metabolism of preferential CYP3A5 substrates such as midazolam.

Additional genetic polymorphisms in drug metabolism (eg, CYP2B6) that are inherited independently from those already described are being discovered. Studies of theophylline metabolism in monozygotic and dizygotic twins that included pedigree analysis of various families have revealed that a distinct polymorphism may exist for this drug and may be inherited as a recessive genetic trait. Genetic drug metabolism polymorphisms also appear to occur for aminopyrine and carbocysteine oxidations. Regularly updated information on human P450-polymorphisms is available at www.imm.ki.se/CYPalleles/.

Although genetic polymorphisms in drug oxidations often involve specific P450 enzymes, such genetic variations can also occur in other enzymes. Recent descriptions of a polymorphism in the oxidation of trimethylamine, believed to be metabolized largely by the flavin monooxygenase (Ziegler's enzyme), suggest that genetic variants of other non-P450-dependent oxidative enzymes may also contribute to such polymorphisms.

Diet & Environmental Factors

Diet and environmental factors contribute to individual variations in drug metabolism. Charcoal-broiled foods and cruciferous vegetables are known to induce CYP1A enzymes, whereas grapefruit juice is known to inhibit the CYP3A metabolism of coadministered drug substrates (Table 4–2). Cigarette smokers metabolize some drugs more rapidly than nonsmokers because of enzyme induction (see previous section). Industrial workers exposed to some pesticides metabolize certain drugs more rapidly than nonexposed individuals. Such differences make it difficult to determine effective and safe doses of drugs that have narrow therapeutic indices.

Age & Sex

Increased susceptibility to the pharmacologic or toxic activity of drugs has been reported in very young and very old patients compared with young adults (see Chapters 60 and 61). Although this may reflect differences in absorption, distribution, and elimination, differences in drug metabolism also play a role. Slower metabolism could be due to reduced activity of metabolic enzymes or reduced availability of essential endogenous cofactors.

Sex-dependent variations in drug metabolism have been well documented in rats but not in other rodents. Young adult male rats metabolize drugs much faster than mature female rats or prepubertal male rats. These differences in drug metabolism have been clearly associated with androgenic hormones. Clinical reports suggest that similar sex-dependent differences in drug metabolism also exist in humans for ethanol, propranolol, some benzodiazepines, estrogens, and salicylates.

Drug-Drug Interactions during Metabolism

Many substrates, by virtue of their relatively high lipophilicity, are retained not only at the active site of the enzyme but remain nonspecifically bound to the lipid ER membrane. In this state, they may induce microsomal enzymes, particularly after repeated use. Acutely, depending on the residual drug levels at the active site, they also may competitively inhibit metabolism of a simultaneously administered drug.

Enzyme-inducing drugs include various sedative-hypnotics, antipsychotics, anticonvulsants, the antitubercular drug rifampin, and insecticides (Table 4–5). Patients who routinely ingest barbiturates, other sedative-hypnotics, or certain antipsychotic drugs may require considerably higher doses of warfarin to maintain a therapeutic effect. On the other hand, discontinuance of the sedative inducer may result in reduced metabolism of the anticoagulant and bleeding—a toxic effect of the ensuing enhanced plasma levels of the anticoagulant. Similar interactions have been observed in individuals receiving various combinations of drug regimens such as rifampin, antipsychotics, or sedatives with contraceptive agents, sedatives with anticonvulsant drugs, and even alcohol with hypoglycemic drugs (tolbutamide).

Table 4–5. Partial List of Drugs That Enhance Drug Metabolism in Humans.	
Inducer	**Drug Whose Metabolism Is Enhanced**
Benzo[*a*]pyrene	Theophylline
Carbamazepine	Carbamazepine, clonazepam, itraconazole
Chlorcyclizine	Steroid hormones
Ethchlorvynol	Warfarin
Glutethimide	Antipyrine, glutethimide, warfarin
Griseofulvin	Warfarin
Phenobarbital and other barbiturates[1]	Barbiturates, chloramphenicol, chlorpromazine, cortisol, coumarin anticoagulants, desmethylimipramine, digitoxin, doxorubicin, estradiol, itraconazole, phenylbutazone, phenytoin, quinine, testosterone
Phenylbutazone	Aminopyrine, cortisol, digitoxin
Phenytoin	Cortisol, dexamethasone, digitoxin, itraconazole, theophylline
Rifampin	Coumarin anticoagulants, digitoxin, glucocorticoids, itraconazole, methadone, metoprolol, oral contraceptives, prednisone, propranolol, quinidine, saquinavir
Ritonavir[2]	Midazolam
St. John's wort	Alprazolam, cyclosporine, digoxin, indinavir, oral contraceptives, ritonavir, simvastatin, tacrolimus, warfarin

[1]Secobarbital is an exception. See Table 4–6 and text.

[2]With chronic (repeated) administration; acutely, ritonavir is a potent CYP3A4 *inhibitor/inactivator*.

It must also be noted that an inducer may enhance not only the metabolism of other drugs but also its own metabolism. Thus, continued use of some drugs may result in a pharmacokinetic type of tolerance—progressively reduced therapeutic effectiveness due to enhancement of their own metabolism.

Conversely, simultaneous administration of two or more drugs may result in impaired elimination of the more slowly metabolized drug and prolongation or potentiation of its pharmacologic effects (Table 4–6). Both competitive substrate inhibition and irreversible substrate-mediated enzyme inactivation may augment plasma drug levels and lead to toxic effects from drugs with narrow therapeutic indices. Indeed, such acute interactions of terfenadine (a second-generation antihistamine) with a CYP3A4 substrate-inhibitor (ketoconazole, erythromycin, or grapefruit juice) resulted in fatal cardiac arrhythmias (torsade de pointes) requiring its withdrawal from the market. Similar drug-drug interactions with CYP3A4 substrate-inhibitors (such as the antibiotics erythromycin and clarithromycin, the antidepressant nefazodone, the antifungals itraconazole and ketoconazole, and the HIV protease inhibitors indinavir and ritonavir), and consequent cardiotoxicity led to withdrawal or restricted use of the 5-HT_4 agonist, cisapride. Similarly, allopurinol both prolongs the duration and enhances the chemotherapeutic and toxic actions of mercaptopurine by competitive inhibition of xanthine oxidase. Consequently, to avoid bone marrow toxicity, the dose of mercaptopurine must be reduced in patients receiving allopurinol. Cimetidine, a drug used in the treatment of peptic ulcer, has been shown to potentiate the pharmacologic actions of anticoagulants and sedatives. The metabolism of the sedative chlordiazepoxide has been shown to be inhibited by 63% after a single dose of cimetidine; such effects are reversed within 48 hours after withdrawal of cimetidine.

Table 4–6. Partial List of Drugs That Inhibit Drug Metabolism in Humans.

Inhibitor[1]	Drug Whose Metabolism Is Inhibited
Allopurinol, chloramphenicol, isoniazid	Antipyrine, dicumarol, probenecid, tolbutamide
Chlorpromazine	Propranolol
Cimetidine	Chlordiazepoxide, diazepam, warfarin, others
Dicumarol	Phenytoin
Diethylpentenamide	Diethylpentenamide
Disulfiram	Antipyrine, ethanol, phenytoin, warfarin
Ethanol	Chlordiazepoxide (?), diazepam (?), methanol
Grapefruit juice[2]	Alprazolam, atorvastatin, cisapride, cyclosporine, midazolam, triazolam
Itraconazole	Alfentanil, alprazolam, astemizole, atorvastin, buspirone, cisapride, cyclosporine, delavirdine, diazepam, digoxin, felodipine, indinavir, loratidine, lovastatin, midazolam, nisoldipine, phenytoin, quinidine, ritonavir, saquinavir, sildenafil, simvastatin, sirolimus, tacrolimus, triazolam, verapamil, warfarin
Ketoconazole	Astemizole, cyclosporine, terfenadine
Nortriptyline	Antipyrine

Inhibitor[1]	Drug Whose Metabolism Is Inhibited
Oral contraceptives	Antipyrine
Phenylbutazone	Phenytoin, tolbutamide
Ritonavir	Amiodarone, cisapride, itraconazole, midazolam, triazolam
Saquinavir	Cisapride, ergot derivatives, midazolam, triazolam
Secobarbital	Secobarbital
Spironolactone	Digoxin
Troleandomycin	Theophylline, methylprednisolone

[1]While some inhibitors are selective for a given P450 enzyme, others are more general and can inhibit several P450s concurrently.

[2]Active components in grapefruit juice include furanocoumarins such as 6', 7'-dihydroxybergamottin (which inactivates both intestinal and liver CYP3A4) as well as other unknown components that inhibit P-glycoprotein-mediated intestinal drug efflux and consequently further enhance the bioavailability of certain drugs such as cyclosporine.

Impaired metabolism may also result if a simultaneously administered drug irreversibly inactivates a common metabolizing enzyme. These inhibitors, in the course of their metabolism by cytochrome P450, inactivate the enzyme and result in impairment of their own metabolism and that of other cosubstrates.

Interactions between Drugs & Endogenous Compounds

As noted previously, some drugs require conjugation with endogenous substrates such as glutathione, glucuronic acid, or sulfate for their inactivation. Consequently, different drugs may compete for the same endogenous substrates, and the faster-reacting drug may effectively deplete endogenous substrate levels and impair the metabolism of the slower-reacting drug. If the latter has a steep dose-response curve or a narrow margin of safety, potentiation of its pharmacologic and toxic effects may result.

Diseases Affecting Drug Metabolism

Acute or chronic diseases that affect liver architecture or function markedly affect hepatic metabolism of some drugs. Such conditions include alcoholic hepatitis, active or inactive alcoholic cirrhosis, hemochromatosis, chronic active hepatitis, biliary cirrhosis, and acute viral or drug-induced hepatitis. Depending on their severity, these conditions may significantly impair hepatic drug-metabolizing enzymes, particularly microsomal oxidases, and thereby markedly affect drug elimination. For example, the half-lives of chlordiazepoxide and diazepam in patients with liver cirrhosis or acute viral hepatitis are greatly increased, with a corresponding prolongation of their effects. Consequently, these drugs may cause coma in patients with liver disease when given in ordinary doses.

Some drugs are metabolized so readily that even marked reduction in liver function does not significantly prolong their action. However, cardiac disease, by limiting blood flow to the liver, may impair disposition of those drugs whose metabolism is flow-limited (Table 4–7). These drugs are so readily metabolized by the liver that hepatic clearance is essentially equal to liver blood flow. Pulmonary disease may also affect drug metabolism as indicated by the impaired hydrolysis of procainamide and procaine in patients with chronic respiratory insufficiency and the increased half-life of antipyrine in patients with lung cancer. The impaired enzyme activity or defective formation of enzymes associated with heavy metal poisoning or porphyria also results in reduced hepatic drug metabolism.

Table 4–7. Rapidly Metabolized Drugs Whose Hepatic Clearance Is Blood Flow-Limited.

Alprenolol	Lidocaine
Amitriptyline	Meperidine
Clomethiazole	Morphine
Desipramine	Pentazocine
Imipramine	Propoxyphene
Isoniazid	Propranolol
Labetalol	Verapamil

Although the effects of endocrine dysfunction on drug metabolism have been well explored in experimental animal models, corresponding data for humans with endocrine disorders are scanty. Thyroid dysfunction has been associated with altered metabolism of some drugs and of some endogenous compounds as well. Hypothyroidism increases the half-life of antipyrine, digoxin, methimazole, and some beta blockers, whereas hyperthyroidism has the opposite effect. A few clinical studies in diabetic patients indicate no apparent impairment of drug metabolism, although impairment has been noted in diabetic rats. Malfunctions of the pituitary, adrenal cortex, and gonads markedly reduce hepatic drug metabolism in rats. On the basis of these findings, it may be supposed that such disorders could significantly affect drug metabolism in humans. However, until sufficient evidence is obtained from clinical studies in patients, such extrapolations must be considered tentative.

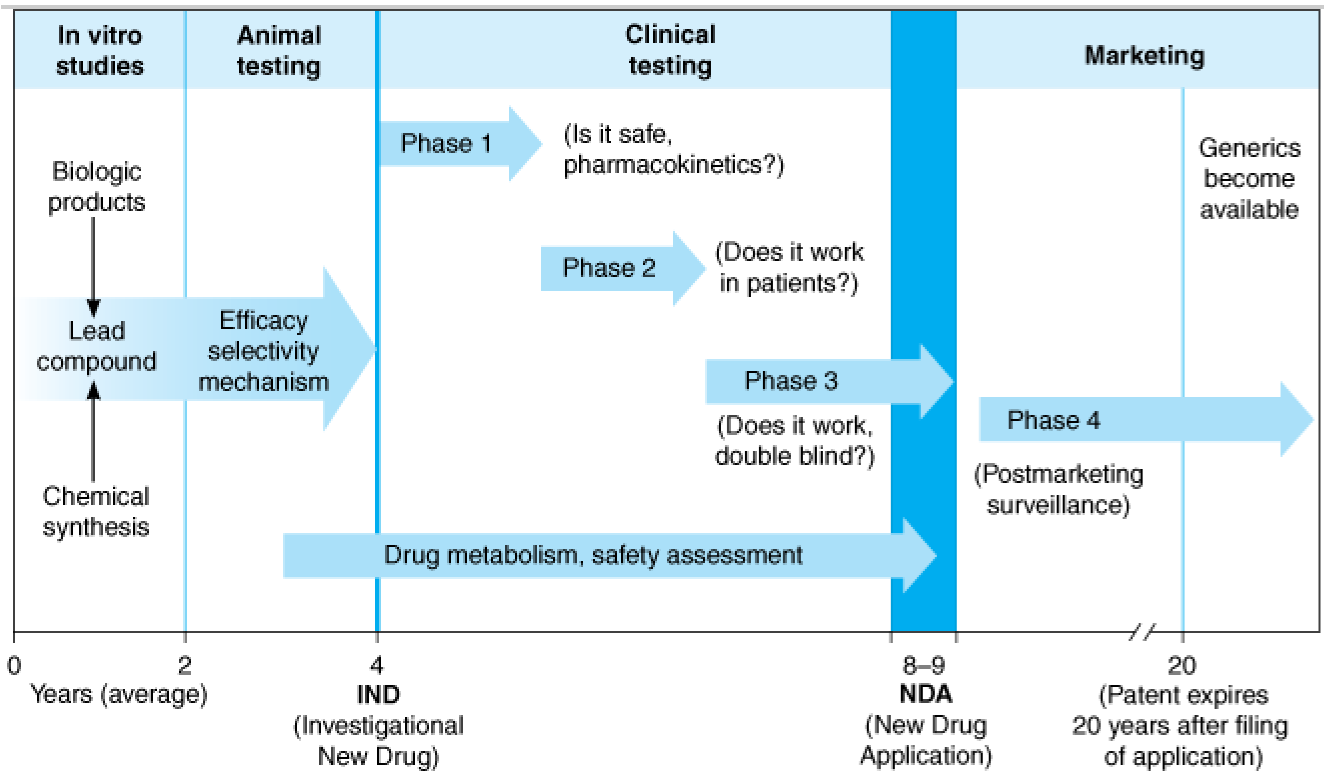
DEVELOPMENT & REGULATION OF DRUGS: INTRODUCTION

New drugs have revolutionized the practice of medicine, converting many once fatal or debilitating diseases into manageable therapeutic exercises. For example, deaths from cardiovascular disease, the main cause of death in the USA, and from stroke have decreased by more than 50% in the USA over the past 30 years. This decline is due—in part—to the discovery and increased use of antihypertensives, cholesterol synthesis inhibitors, drugs that prevent or dissolve blood clots, medical devices, and drug-releasing stents.

Among the first steps in the development of a new drug is the discovery or synthesis of a potential new drug molecule and seeking an understanding of its interaction (mechanism) with the appropriate biologic targets. Repeated application of this approach leads to compounds with increased potency and selectivity (Figure 5–1). By law, the safety and efficacy of drugs must be defined before marketing. In addition to in vitro studies, relevant biologic effects, drug metabolism, and pharmacokinetic profiles and particularly an assessment of the relative safety of the drug must be characterized in animals before human drug trials can be started. With regulatory approval, human testing can then go forward in three phases before the drug can be considered for approval for general use. A fourth phase of data gathering and safety monitoring is becoming increasingly important and follows after approval for general use.

Figure 5–1.



The development and testing process required to bring a drug to market in the USA. Some of the requirements may be different for drugs used in life-threatening diseases.

Enormous and increasing costs, with estimates from $150 million to $900 million, are involved in the research and development of a single new drug that reaches the marketplace. Only 3 of 10 marketed drugs return their research and development (R&D) investments, thus providing considerable motivation to develop "blockbusters." Thousands of compounds may be synthesized and hundreds of thousands tested from libraries of compounds for each successful new drug lead, which then generally needs to be further optimized for reasons of potency, selectivity, drug metabolism, and dosing convenience before each drug reaches the market. Because of the economic investment required and the need to efficiently access multiple technologies, most new drugs are developed in pharmaceutical companies.

At the same time, the incentives to succeed in drug development can be equally enormous. The global market for pharmaceuticals in 2006 is estimated at about $640 billion. The 2004 sales of the top-selling drug worldwide (Lipitor) exceeded $10 billion. During the second half of the 20th century, estimates indicate that medications produced by the pharmaceutical industry saved more than 1.5 million lives and $140 billion in the costs of treatment for tuberculosis, poliomyelitis, coronary artery disease, and cerebrovascular disease alone. New drugs played a key role in the post-1995 decline in HIV mortality and the social returns for HIV drug innovation appear to be extremely large. In the USA, approximately 10% of the health care dollar is presently spent on prescription drugs.

DRUG DISCOVERY

Most new drugs or drug products are discovered or developed through one or more of six approaches:

1. Identification or elucidation of a new drug target

2. Rational drug design of a new drug based on an understanding of biologic mechanisms, drug receptor structure, and drug structure

3. Chemical modification of a known molecule

4. Screening for biologic activity of large numbers of natural products, banks of previously discovered chemical entities, and large libraries of peptides, nucleic acids, and other organic molecules

5. Biotechnology and cloning using genes to produce peptides and proteins. Efforts continue to focus on the discovery of new targets and approaches, from studies with genomics, proteomics, nucleic acids and molecular pharmacology for drug therapy. Significantly increasing the number of useful disease targets should be a positive driver for new and improved drugs.

6. Combinations of known drugs to obtain additive or synergistic effects or a repositioning of a known drug for a new therapeutic use.

Drug Screening

Regardless of the source or the key idea leading to a drug candidate molecule, testing it involves a sequence of iterative experimentation and characterization called **drug screening**. A variety of biologic assays at the molecular, cellular, organ system, and whole animal levels are used to define the activity and selectivity of the drug (Table 5–1). The type and number of initial screening tests depend on the pharmacologic and therapeutic goal. Anti-infective drugs may be tested against a variety of infectious organisms some of which are resistant to standard agents, hypoglycemic drugs for their ability to lower blood sugar, etc. In addition, the molecule will also be studied for a broad array of other actions to establish the mechanism of action and selectivity of the drug. This has the advantage of demonstrating both suspected and unsuspected toxic effects. Occasionally, an unsuspected therapeutic action is serendipitously discovered by the careful observer. The selection of molecules for further study is most efficiently conducted in animal models of human disease. Where good predictive preclinical models exist (eg, antibacterials, hypertension or thrombotic disease), we generally have adequate drugs. Good drugs or breakthough improvements are conspicuously lacking and slow for diseases for which pre-clinical models are poor, or not yet available, eg, Alzheimer's disease.

Table 5–1. Pharmacologic Profile Tests.

Experimental Method or Target Organ	Species or Tissue	Measurement
Molecular		
Receptor binding (example: β-adrenoceptors)	Cell membrane fractions from organs or cultured cells; cloned receptors	Receptor affinity and selectivity
Enzyme activity (examples: tyrosine hydroxylase, dopamine-3-hydroxylase, monoamine oxidase)	Sympathetic nerves; adrenal glands; purified enzymes	Enzyme inhibition and selectivity
Cytochrome P450	Liver	Enzyme inhibition; effects on drug metabolism
Cellular		
Cell function	Cultured cells	Evidence for receptor activity—agonism or antagonism (example: effects on cyclic nucleotides)
Isolated tissue	Blood vessels, heart, lung, ileum (rat or guinea pig)	Effects on vascular contraction and relaxation; selectivity for vascular receptors; effects on other smooth muscles
Systems/disease models		

Blood pressure

Dog, cat (anesthetized)

Systolic-diastolic changes

Rat, hypertensive (conscious)

Antihypertensive effects

Cardiac effects

Dog (conscious)

Electrocardiography

Dog (anesthetized)

Inotropic, chronotropic effects, cardiac output, total peripheral resistance

Peripheral autonomic nervous system

Dog (anesthetized)

Effects on response to known drugs and electrical stimulation of central and peripheral autonomic nerves

Respiratory effects

Dog, guinea pig

Effects on respiratory rate and amplitude, bronchial tone

Diuretic activity

Dog

Natriuresis, kaliuresis, water diuresis, renal blood flow, glomerular filtration rate

Gastrointestinal effects

Rat

Gastrointestinal motility and secretions

Circulating hormones, cholesterol, blood sugar

Rat, dog

Serum concentration

Blood coagulation

Rabbit

Coagulation time, clot retraction, prothrombin time

Central nervous system

Mouse, rat

Degree of sedation, muscle relaxation, locomotor activity, stimulation

Studies are performed during drug screening to define the *pharmacologic profile* of the drug at the molecular, cellular, system, organ, and organism levels. For example, a broad range of tests would be performed on a drug designed to act as an antagonist at vascular α-adrenoceptors for the treatment of hypertension.

At the molecular level, the compound would be screened for receptor binding affinity to cell membranes containing α receptors (if possible on human receptors), other receptors, and binding sites on enzymes. If crystal structures of the drug and target are available, structural biology analyses or computer-assisted virtual screening might be done to better understand the drug receptor interaction. Early studies would be done to predict effects that might later cause undesired drug metabolism or toxicologic complications. For example, studies on liver cytochrome P450 enzymes would be performed to determine whether the drug of interest is likely to be a substrate or inhibitor of these enzymes or to interfere with the metabolism of other drugs. Effects on cardiac ion channels such as the hERG potassium channel, possibly predictive of life threatening arrhythmias, would be considered.

Effects on cell function would be studied to determine whether the drug is an agonist, partial agonist, or antagonist at α receptors. Isolated tissues, especially vascular smooth muscle, would be utilized to characterize the pharmacologic activity and selectivity of the new compound in comparison with reference compounds. Comparison with other drugs would also be undertaken in other in vitro preparations such as gastrointestinal and bronchial smooth muscle. At each step in this process, the compound would have to meet specific performance criteria to be carried further.

Whole animal studies are generally necessary to determine the effect of the drug on organ systems and disease models. Cardiovascular and renal function studies of all new drugs are generally first performed in normal animals. Where appropriate, studies on disease models would be performed. For a candidate antihypertensive drug, animals with hypertension would be treated to see if blood pressure was lowered in a dose-related manner and to characterize other effects of the compound. Evidence would be collected on duration of action and efficacy following oral and parenteral administration. If the agent possessed useful activity, it would be further studied for possible adverse effects on other major organ systems, including the respiratory, gastrointestinal, endocrine, and central nervous systems.

These studies might suggest the need for further chemical modification to achieve more desirable pharmacokinetic or pharmacodynamic properties. For example, oral administration studies might show that the drug was poorly absorbed or rapidly metabolized in the liver; modification to improve bioavailability might be indicated. If the drug was to be administered long-term, an assessment of tolerance development would be made. For drugs related to or having mechanisms of action similar to those known to cause physical dependence, abuse potential would also be studied. For each major action found, a pharmacologic mechanism would be sought.

The desired result of this screening procedure (which may have to be repeated several times with analogs or congeners of the original molecules) is called a *lead compound*, ie, a leading candidate for a successful new drug. A patent application would generally be filed for a novel compound (a composition of matter patent) that is efficacious, or for a new and nonobvious therapeutic use (a use patent) for a previously known chemical entity.

PRECLINICAL SAFETY & TOXICITY TESTING

All drugs are toxic at some dose . Seeking to correctly define the limiting toxicities of drugs and the therapeutic index comparing benefits and risks of a new drug might be argued as the most essential part of the new drug development process. Most drug candidates fail to reach the market, but the art of drug discovery and development is the effective assessment and management of risk and not total risk avoidance.

Candidate drugs that survive the initial screening and profiling procedures must be carefully evaluated for potential risks before and during clinical testing. Depending on the proposed use of the drug, preclinical toxicity testing includes most or all of the procedures shown in Table 5–2. Although no chemical can be certified as completely "safe" (free of risk), the objective is to estimate the risk associated with exposure to the drug candidate and to consider this in the context of therapeutic needs and duration of likely drug use.

Table 5–2. Safety Tests.

Type of Test	Approach
Acute toxicity	Acute dose that is lethal in approximately 50% of animals and the maximum tolerated dose. Usually two species, two routes, single dose.
Subacute toxicity	Three doses, two species. 4 weeks to 3 months may be necessary prior to clinical trial. The longer the duration of expected clinical use, the longer the subacute test.
Chronic toxicity	Rodent and non-rodent species. 6 months or longer. Required when drug is intended to be used in humans for prolonged periods. Usually run concurrently with clinical trial.
Effect on reproductive performance	Effects on animal mating behavior, reproduction, parturition, progeny, birth defects, postnatal development.
Carcinogenic potential	Two years, two species. Required when drug is intended to be used in humans for prolonged periods.
Mutagenic potential	Effects on genetic stability and mutations in bacteria (Ames test) or mammalian cells in culture; dominant lethal test and clastogenicity in mice.
Investigative toxicology	Determine sequence and mechanisms of toxic action. Discover the genes, proteins, pathways involved. Develop new methods for assessing toxicity.

The goals of preclinical toxicity studies include identifying potential human toxicities; designing tests to further define the toxic mechanisms; and predicting the specific and the most relevant toxicities to be monitored in clinical trials. In addition to the studies shown in Tables 5–1 and 5–2, several quantitative estimates are desirable. These include the "*no-effect" dose* —the maximum dose at which a specified toxic effect is not seen; the *minimum lethal dose* —the smallest dose that is observed to kill any experimental animal; and, if necessary, the *median lethal dose* (LD_{50})— the dose that kills approximately 50% of the animals. Presently, the LD_{50} is estimated from the smallest number of animals possible. These doses are used to calculate the initial dose to be tried in humans, usually taken as one hundredth to one tenth of the no-effect dose in animals.

It is important to recognize the limitations of preclinical testing. These include the following:

1. Toxicity testing is time-consuming and expensive. Two to 6 years may be required to collect and analyze data on toxicity and estimates of therapeutic index (a comparison of the amount that causes the desired therapeutic effect to the amount that causes toxic effects, see Chapter 2) before the drug can be considered ready for testing in humans.

2. Large numbers of animals may be needed to obtain valid preclinical data. Scientists are properly concerned about this situation, and progress has been made toward reducing the numbers required while still obtaining valid data. Cell and tissue culture in vitro methods are increasingly being used, but their predictive value is still severely limited. Nevertheless, some segments of the public attempt to halt all animal testing in the unfounded belief that it has become unnecessary.

3. Extrapolations of therapeutic index and toxicity data from animals to humans are reasonably predictive for many but not for all toxicities. Seeking an improved process, a Predictive Safety Testing Consortium of five of America's largest pharmaceutical companies with an advisory role by the Food and Drug Administration (FDA) has been formed to share internally developed laboratory methods to predict the safety of new treatments before they are tested in humans.

4. For statistical reasons, rare adverse effects are unlikely to be detected.

EVALUATION IN HUMANS

Less than one third of the drugs tested in clinical trials reach the marketplace. Federal law in the USA and ethical considerations require that the study of new drugs in humans be conducted in accordance with stringent guidelines. Scientifically valid results are not guaranteed simply by conforming to government regulations, however, and the design and execution of a good clinical trial require interdisciplinary personnel including basic scientists, clinical pharmacologists, clinician specialists, statisticians, and frequently others. The need for careful design and execution is based on three major confounding factors inherent in the study of any drug in humans.

Confounding Factors in Clinical Trials

THE VARIABLE NATURAL HISTORY OF MOST DISEASES

Many diseases tend to wax and wane in severity; some disappear spontaneously, even, on occasion, malignant neoplasms. A good experimental design takes into account the natural history of the disease by evaluating a large enough population of subjects over a sufficient period of time. Further protection against errors of interpretation caused by disease fluctuations is provided by using a crossover design, which consists of alternating periods of administration of test drug, placebo preparation (the control), and the standard treatment (positive control), if any, in each subject. These sequences are systematically varied, so that different subsets of patients receive each of the possible sequences of treatment.

THE PRESENCE OF OTHER DISEASES AND RISK FACTORS

Known and unknown diseases and risk factors (including lifestyles of subjects) may influence the results of a clinical study. For example, some diseases alter the pharmacokinetics of drugs (see Chapters 3 and 4). Concentrations of a blood or tissue component being monitored as a measure of the effect of the new agent may be influenced by other diseases or other drugs. Attempts to avoid this hazard usually involve the crossover technique (when feasible) and proper selection and assignment of patients to each of the study groups. This requires obtaining accurate medical and pharmacologic histories (including use of recreational drugs) and the use of statistically valid methods of randomization in assigning subjects to particular study groups.

SUBJECT AND OBSERVER BIAS

Most patients tend to respond in a positive way to any therapeutic intervention by interested, caring, and enthusiastic medical personnel. The manifestation of this phenomenon in the subject is the placebo response (Latin, "I shall please") and may involve objective physiologic and biochemical changes as well as changes in subjective complaints associated with the disease. The placebo response is usually quantitated by administration of an inert material, with exactly the same physical appearance, odor, consistency, etc, as the active dosage form. The magnitude of the response varies considerably from patient to patient and may also be influenced by the duration of the study. Placebo adverse effects and "toxicity" also occur but usually involve subjective effects: stomach upset, insomnia, sedation, etc.

Subject bias effects can be quantitated—and minimized relative to the response measured during active therapy—by the single-blind design. This involves use of a placebo as described above, administered to the same subjects in a crossover design, if possible, or to a separate control group of subjects. Observer bias can be taken into account by disguising the identity of the medication being used—placebo or active form—from both the subjects and the personnel evaluating the subjects' responses (double-blind design). In this design, a third party holds the code identifying each medication packet, and the code is not broken until all of the clinical data have been collected.

The Food & Drug Administration (FDA)

It is the responsibility of those seeking to market a drug to test it and submit evidence on its relative safety and effectiveness. The FDA is the administrative body that oversees the drug evaluation process in the USA and grants approval for marketing of new drug products.

Outside the USA, the regulatory and drug approval for marketing process is generally similar to that in the USA. For example, the European Agency for the Evaluation of Medical Products (EMEA) is responsible for biologicals and optional for synthetic drugs. In Japan, the marketing and manufacture of drugs is regulated by the Ministry of Health, Labor and Welfare (MHLW) and advised by the Central Pharmaceutical Affairs Council (CPAC), which evaluates scientific data.

The FDA's authority to regulate drugs derives from specific legislation (Table 5–3). If a drug has not been shown through adequately controlled testing to be "safe and effective" for a specific use, it cannot be marketed in interstate commerce for this use.*

Table 5–3. Major Legislation Pertaining to Drugs in the United States.

Law	Purpose and Effect

Pure Food and Drug Act of 1906

Prohibited mislabeling and adulteration of drugs.

Opium Exclusion Act of 1909

Prohibited importation of opium.

Amendment (1912) to the Pure Food and Drug Act

Prohibited false or fraudulent advertising claims.

Harrison Narcotic Act of 1914

Established regulations for use of opium, opiates, and cocaine (marijuana added in 1937).

Food, Drug, and Cosmetic Act of 1938

Required that new drugs be safe as well as pure (but did not require proof of efficacy). Enforcement by FDA.

Durham-Humphrey Act of 1952

Vested in the FDA the power to determine which products could be sold without prescription.

Kefauver-Harris Amendments (1962) to the Food, Drug, and Cosmetic Act

Required proof of efficacy as well as safety for new drugs and for drugs released since 1938; established guidelines for reporting of information about adverse reactions, clinical testing, and advertising of new drugs.

Comprehensive Drug Abuse Prevention and Control Act (1970)

Outlined strict controls in the manufacture, distribution, and prescribing of habit-forming drugs; established programs to prevent and treat drug addiction.

Orphan Drug Amendments of 1983

Amended Food, Drug, and Cosmetic Act of 1938, providing incentives for development of drugs that treat diseases with less than 200,000 patients in USA.

Drug Price Competition and Patent Restoration Act of 1984

Abbreviated new drug applications for generic drugs. Required bioequivalence data. Patent life extended by amount of time drug delayed by FDA review process. Cannot exceed 5 extra years or extend to more than 14 years post-NDA approval.

Expedited Drug Approval Act (1992)

Allowed accelerated FDA approval for drugs of high medical need. Required detailed postmarketing patient surveillance.

Prescription Drug User Fee Act (1992)

Manufacturers pay user fees for certain new drug applications. FDA review time for new chemical entities dropped from 30 months in 1992 to 20 months in 1994.

Reauthorized 1997 and 2002

Dietary Supplement Health and Education Act (1994)

Amended the Federal Food, Drug, and Cosmetic Act of 1938 to establish standards with respect to dietary supplements. Required the establishment of specific ingredient and nutrition information labeling that defines dietary supplements and classifies them as part of the food supply.

Bioterrorism Act of 2002

Enhanced controls on dangerous biologic agents and toxins. Seeks to protect safety of food, water, and drug supply.

Unfortunately, "safe" can mean different things to the patient, the physician, and society. As noted above, complete absence of risk is impossible to demonstrate, but this fact is not well understood by the average member of the public, who frequently assume that any medication sold with the approval of the FDA should indeed be free of serious "side effects." This confusion is a major factor in litigation and dissatisfaction with aspects of drugs and medical care.

The history of drug regulation reflects several medical and public health events that precipitated major shifts in public opinion. The Pure Food and Drug Act of 1906 (Table 5–3) became law mostly in response to revelations of unsanitary and unethical practices in the meat-packing industry. The Federal Food, Drug, and Cosmetic Act of 1938 was largely a reaction to deaths associated with the use of a preparation of sulfanilamide marketed before it and its vehicle were adequately tested. Thalidomide is another example of a drug that altered drug testing methods and stimulated drug regulating legislation. This agent was introduced in Europe in 1957–1958 and, based on animal tests then commonly used, was marketed as a "nontoxic" hypnotic and for morning sickness treatment during pregnancy. In 1961, reports were published suggesting that thalidomide was responsible for a dramatic increase in the incidence of a rare birth defect called phocomelia, a condition involving shortening or complete absence of the limbs. Epidemiologic studies provided strong evidence for the association of this defect with thalidomide use by women during the first trimester of pregnancy, and the drug was withdrawn from sale worldwide. An estimated 10,000 children were born with birth defects because of maternal exposure to this one agent. The tragedy led to the requirement for more extensive testing of new drugs for teratogenic effects and played an important role in stimulating passage of the Kefauver-Harris Amendments of 1962, even though the drug was not then approved for use in the USA. In spite of its disastrous fetal toxicity and effects in pregnancy, thalidomide is a relatively safe drug for humans other than the fetus. Even the most serious risk of toxicities may be avoided or managed if understood, and despite its toxicity thalidomide is now allowed by the FDA for limited use as a potent immunoregulatory agent and to treat certain forms of leprosy.

It is impossible to certify that a drug is absolutely safe, ie, free of all risk. It is possible, however, to identify most of the hazards likely to be associated with use of a new drug and to place some statistical limits on frequency of occurrence of such events in the population under study. As a result, an operational and pragmatic definition of "safety" can usually be reached that is based on the nature and incidence of drug-associated hazards compared with the hazard of nontherapy of the target disease.

*Although the FDA does not directly control drug commerce within states, a variety of state and federal laws control interstate production and marketing of drugs.

Clinical Trials: The IND & NDA

Once a drug is judged ready to be studied in humans, a Notice of Claimed Investigational Exemption for a New Drug (IND) must be filed with the FDA (Figure 5–1). The IND includes (1) information on the composition and source of the drug, (2) chemical and manufacturing information, (3) all data from animal studies, (4) proposed clinical plans and protocols, (5) the names and credentials of physicians who will conduct the clinical trials, and (6) a compilation of the key data relevant to study the drug in man made available to investigators and their institutional review boards.

It often requires 4–6 years of clinical testing to accumulate and analyze all required data. Testing in humans is begun after sufficient acute and subacute animal toxicity studies have been completed. Chronic safety testing in animals, including carcinogenicity studies, is usually done concurrently with clinical trials. In each of the three formal phases of clinical trials, volunteers or patients must be informed of the investigational status of the drug as well as the possible risks and must be allowed to decline or to consent to participate and receive the drug. These regulations are based on the ethical principles set forth in the Declaration of Helsinki. In addition to the approval of the sponsoring organization and the FDA, an interdisciplinary institutional review board (IRB) at the facility where the clinical drug trial will be conducted must review and approve the plans and ethics for testing in humans.

In phase 1, the effects of the drug as a function of dosage are established in a small number (25–50) of healthy volunteers. Although a goal is to find the maximum tolerated dose, the study is designed to avoid severe toxicity. If the drug is *expected* to have significant toxicity, as is often the case in cancer and AIDS therapy, volunteer patients with the disease are used in phase 1 rather than normal volunteers. Phase 1 trials are done to determine whether humans and animals show significantly different responses to the drug and to establish the probable limits of the safe clinical dosage range. These trials are nonblind or "open"; that is, both the investigators and the subjects know what is being given. Many predictable toxicities are detected in this phase. Pharmacokinetic measurements of absorption, half-life, and metabolism are often done in phase 1. Phase 1 studies are usually performed in research centers by specially trained clinical pharmacologists.

In phase 2, the drug is studied in patients with the target disease to determine its efficacy. A modest number of patients (100–200) are studied in detail. A single-blind design is often used, with an inert placebo medication and an established active drug (positive control) in addition to the investigational agent. Phase 2 trials are usually done in special clinical centers (eg, university hospitals). A broader range of toxicities may be detected in this phase.

In phase 3, the drug is evaluated in much larger numbers of patients with the target disease—sometimes thousands—to further establish safety and efficacy. Using information gathered in phases 1 and 2, phase 3 trials are designed to minimize errors caused by placebo effects, variable course of the disease, etc. Therefore, double-blind and crossover techniques are frequently used. Phase 3 trials are usually performed in settings similar to those anticipated for the ultimate use of the drug. Phase 3 studies can be difficult to design and execute and are usually expensive because of the large numbers of patients involved and the masses of data that must be collected and analyzed. The investigators are usually specialists in the disease being treated. Certain toxic effects, especially those caused by immunologic processes, may first become apparent in phase 3.

If phase 3 results meet expectations, application is made for permission to market the new agent. Marketing approval requires submission of a New Drug Application (NDA) to the FDA. The application contains, often in hundreds of volumes, full reports of all preclinical and clinical data pertaining to the drug under review. The number of subjects studied in support of the NDA has been increasing and currently averages more than 5000 patients for new drugs of novel structure (new molecular entities). The duration of the FDA review leading to approval (or denial) of the NDA may vary from months to years. Priority approvals are designated for products that represent significant improvements compared with marketed products; in 2004, the median priority approval time was 6 months. Standard approvals, which take longer, are designated for products judged similar to those on the market—in 2004, the median standard approval time was 12.9 months. In cases in which an urgent need is perceived (eg, cancer chemotherapy), the process of preclinical and clinical testing and FDA review may be accelerated. For serious diseases, the FDA may permit extensive but controlled marketing of a new drug before phase 3 studies are completed; for life-threatening diseases, it may permit controlled marketing even before phase 2 studies have been completed.

Once approval to market a drug has been obtained, phase 4 begins. This constitutes monitoring the safety of the new drug under actual conditions of use in large numbers of patients. The importance of careful and complete reporting of toxicity by physicians after marketing begins can be appreciated by noting that many important drug-induced effects have an incidence of 1 in 10,000 or less and that some side effects may become more apparent after chronic dosing. The sample size required to disclose drug-induced events or toxicities is very large for such rare events. For example, several hundred thousand patients may have to be exposed before the first case is observed of a toxicity that occurs with an average incidence of 1 in 10,000 (see Case Study: Aspirin to COX-2 Inhibitors—From Discovery to Recall). Therefore, low-incidence drug effects are not generally detected before phase 4 no matter how carefully the studies are executed. Phase 4 has no fixed duration.

The time from the filing of a patent application to approval for marketing of a new drug may be 5 years or considerably longer. Since the lifetime of a patent is 20 years in the USA, the owner of the patent (usually a pharmaceutical company) has exclusive rights for marketing the product for only a limited time after approval of the NDA. Because the FDA review process can be lengthy, the time consumed by the review is sometimes added to the patent life. However, the extension (up to 5 years) cannot increase the total life of the patent to more than 14 years after NDA approval. After expiration of the patent, any company may produce the drug, file an ANDA (abbreviated NDA), demonstrate required equivalence, and, with FDA approval, market the drug as a generic product without paying license fees to the original patent owner. However, a trademark (the drug's proprietary trade name) may be legally protected indefinitely. Therefore, pharmaceutical companies are motivated to give their new drugs easily remembered trade names. Generic prescribing is described in Chapter 66.

The FDA drug approval process is one of the rate-limiting factors in the time it takes for a drug to be marketed and to reach patients. The Prescription Drug User Fee Act (PDUFA) of 1992, reauthorized in 1997 and 2002, attempts to make more FDA resources available to the drug approval process and increase efficiency through use of fees collected from the drug companies that produce certain human drugs and biologic products. Current PDUFA fees for a new chemical entity are about $1 million.

CASE STUDY: ASPIRIN TO COX-2 INHIBITORS—FROM DISCOVERY TO RECALL*

The idea. The pain-relieving and fever-reducing effects of willow bark and its extracts have been known for millennia; its main active component, salicin, was identified in 1828. The synthesis of the salicin derivative, aspirin (acetylsalicylic acid) in 1897 and recognition of its anti-inflammatory effect constituted a landmark event. Determining how aspirin worked and might be improved would take another 70 years.

The clinical need. Aspirin has broad therapeutic actions. However, it also has significant adverse effects including stomach pain and gastrointestinal (GI) bleeding. Corticosteroids are too toxic for chronic use. The need and opportunity for improved nonsteroidal anti-inflammatory drugs (NSAIDs) became confluent with improved understanding of mediators of inflammation, especially prostaglandins (PGs) as drug targets. From the 1950s through the 1980s, many NSAIDs were developed that were more potent than aspirin but had similar toxicities, especially GI adverse effects.

The biologic hypothesis. Vane and his colleagues demonstrated that aspirin had a key role in inhibiting PG synthesis. Needleman and others found that the enzyme cyclooxygenase (COX) involved in the synthesis of specific PGs was increased in inflamed tissue and stimulated by certain cytokines. Needleman provided evidence for an inducible COX (COX-2) that is up-regulated in inflammation, which could be differentiated from the other, constitutive, isoform (COX-1) that maintains the integrity of the lining of the stomach. COX-1 also helps maintain normal platelet and kidney functions. Could COX-2 be a new drug target?

The chemical hypothesis. In 1991, scientists cloned and expressed COX-2. Using both screening and rational drug design, an inhibitor much more selective for COX-2 than for COX-1 was discovered and named celecoxib (Celebrex). Soon thereafter, the COX-2-selective drug rofecoxib (Vioxx) was discovered, followed by a third valdecoxib (Bextra).

Development. Celecoxib was approved in December 1998 for treatment of osteoarthritis and rheumatoid arthritis.

The NDA for rofecoxib was filed in 1998. At about the same time, its manufacturer began two large clinical trials with rofecoxib in an attempt to discover whether the drug also protected against colonic polyps and against Alzheimer's disease. In 1999, the FDA approved the rofecoxib NDA for the relief of osteoarthritis symptoms, management of acute pain, and painful menstruation. About 1 year later, the results of the first large comparison trial became available. These showed the benefits of rofecoxib in protecting the stomach, but also showed a fourfold higher risk of heart attacks compared with a nonselective COX inhibitor. In 2002, the FDA approved changes to the rofecoxib label, including noting cardiovascular risks, GI benefits, and a new use to treat rheumatoid arthritis. In 2004, the second large trial showed twice the risk of heart attacks among patients taking rofecoxib for 18 months compared with those who took placebos. The manufacturer then decided to voluntarily withdraw rofecoxib, ceasing marketing and sales.

Postscript. The discovery, development, and marketing of celecoxib and the recall of rofecoxib (and subsequently valdecoxib) are representative of the opportunities, mistakes, and issues facing health care companies and practitioners. However, it is clear that vigorous phase 4 and follow-up drug surveillance efforts are now an increasingly important aspect of the drug R&D process.

*Case studies are illustrative and highly condensed. They present key events, but not necessarily all events, contributions, or contributors are noted.

Orphan Drugs & Treatment of Rare Diseases

Drugs for rare diseases—so-called orphan drugs—can be difficult to research, develop, and market. Proof of drug safety and efficacy in small populations must be established, but doing so is a complex process. For example, for ethical and legal reasons, clinical testing of drugs in children is severely restricted, but a number of rare diseases affect the very young. Furthermore, because basic research in the pathophysiology and mechanisms of rare diseases receives relatively little attention or funding in both academic and industrial settings, recognized rational targets for drug action may be few. In addition, the cost of developing a drug can greatly influence priorities when the target population is relatively small.

The Orphan Drug Act of 1983, which amended the 1938 Federal Food, Drug, and Cosmetic Act, provides incentives for the development of drugs for treatment of a rare disease or condition defined as "any disease or condition which (a) affects less than 200,000 persons in the U.S. or (b) affects more than 200,000 persons in the U.S. but for which there is no reasonable expectation that the cost of developing and making available in the U.S. a drug for such disease or condition will be recovered from sales in the U.S. of such drug." Since 1983, the FDA has approved for marketing 268 orphan drugs to treat more than 82 rare diseases.

Adverse Drug Reactions (ADRs)

An adverse reaction to a drug is a harmful or unintended response. ADRs are claimed to be the 4th leading cause of death, exceeding pulmonary disease, AIDS, accidents, and automobile deaths. The FDA has further estimated that 300,000 preventable adverse events occur in hospitals, many as a result of confusing medical information. Some adverse reactions, such as overdose, excessive effects, and drug interactions, may occur in anyone. Adverse reactions occurring only in susceptible patients include intolerance, idiosyncrasy (frequently genetic in origin), and allergy (usually immunologically mediated). During the IND and clinical phase 1–3 trials and before FDA approval, all adverse events (serious, life-threatening, disabling, reasonably drug-related, or unexpected) must be reported. Following FDA approval to market, surveillance, evaluation, and reporting must continue for any adverse events in patients that are related to use of the drug, including overdose, accident, failure of expected action, events occurring from drug withdrawal, and unexpected events not listed in labeling. Events that are both serious and unexpected must be reported to the FDA within 15 days. In January 2006, the FDA announced a new prescription drug information format to improve patient safety by implementing improvements in prescription drug labels and inserts so they are less confusing and more concise with respect to prescribing information aiding both patients and health care professionals.

INTRODUCTION TO AUTONOMIC PHARMACOLOGY: INTRODUCTION

The motor (efferent) portion of the nervous system can be divided into two major subdivisions: autonomic and somatic. The autonomic nervous system (ANS) is largely autonomous (independent) in that its activities are not under direct conscious control. It is concerned primarily with visceral functions such as cardiac output, blood flow to various organs, and digestion, which are necessary for life. The somatic division is largely concerned with consciously controlled functions such as movement, respiration, and posture. Both systems have important afferent (sensory) inputs that provide information regarding the internal and external environments and modify motor output through reflex arcs of varying size and complexity.

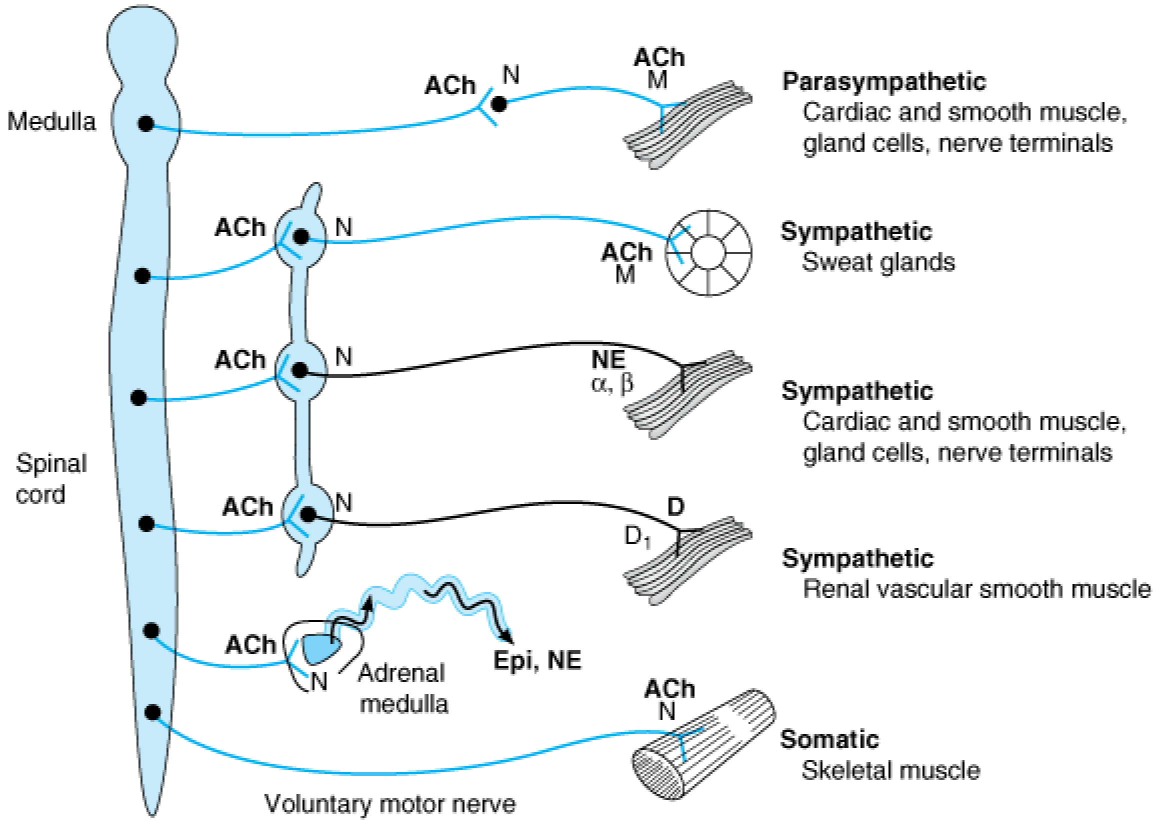
The nervous system has several properties in common with the endocrine system, which is the other major system for control of body function. These include high-level integration in the brain, the ability to influence processes in distant regions of the body, and extensive use of negative feedback. Both systems use chemicals for the transmission of information. In the nervous system, chemical transmission occurs between nerve cells and their effector cells. Chemical transmission takes place through the release of small amounts of transmitter substances from the nerve terminals into the synaptic cleft. The transmitter crosses the cleft by diffusion and activates or inhibits the postsynaptic cell by binding to a specialized receptor molecule.

By using drugs that mimic or block the actions of chemical transmitters, we can selectively modify many autonomic functions. These functions involve a variety of effector tissues, including cardiac muscle, smooth muscle, vascular endothelium, exocrine glands, and presynaptic nerve terminals. Autonomic drugs are useful in many clinical conditions. However, a very large number of drugs used for other purposes have unwanted effects on autonomic function.

ANATOMY OF THE AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system lends itself to division on anatomic grounds into two major portions: the sympathetic (thoracolumbar) division and the parasympathetic (craniosacral) division (Figure 6–1). Both divisions originate in nuclei within the central nervous system and give rise to preganglionic efferent fibers that exit from the brain stem or spinal cord and terminate in motor ganglia. The sympathetic preganglionic fibers leave the central nervous system through the thoracic and lumbar spinal nerves. The parasympathetic preganglionic fibers leave the central nervous system through the cranial nerves (especially the third, seventh, ninth, and tenth) and the third and fourth sacral spinal roots.

Figure 6–1.



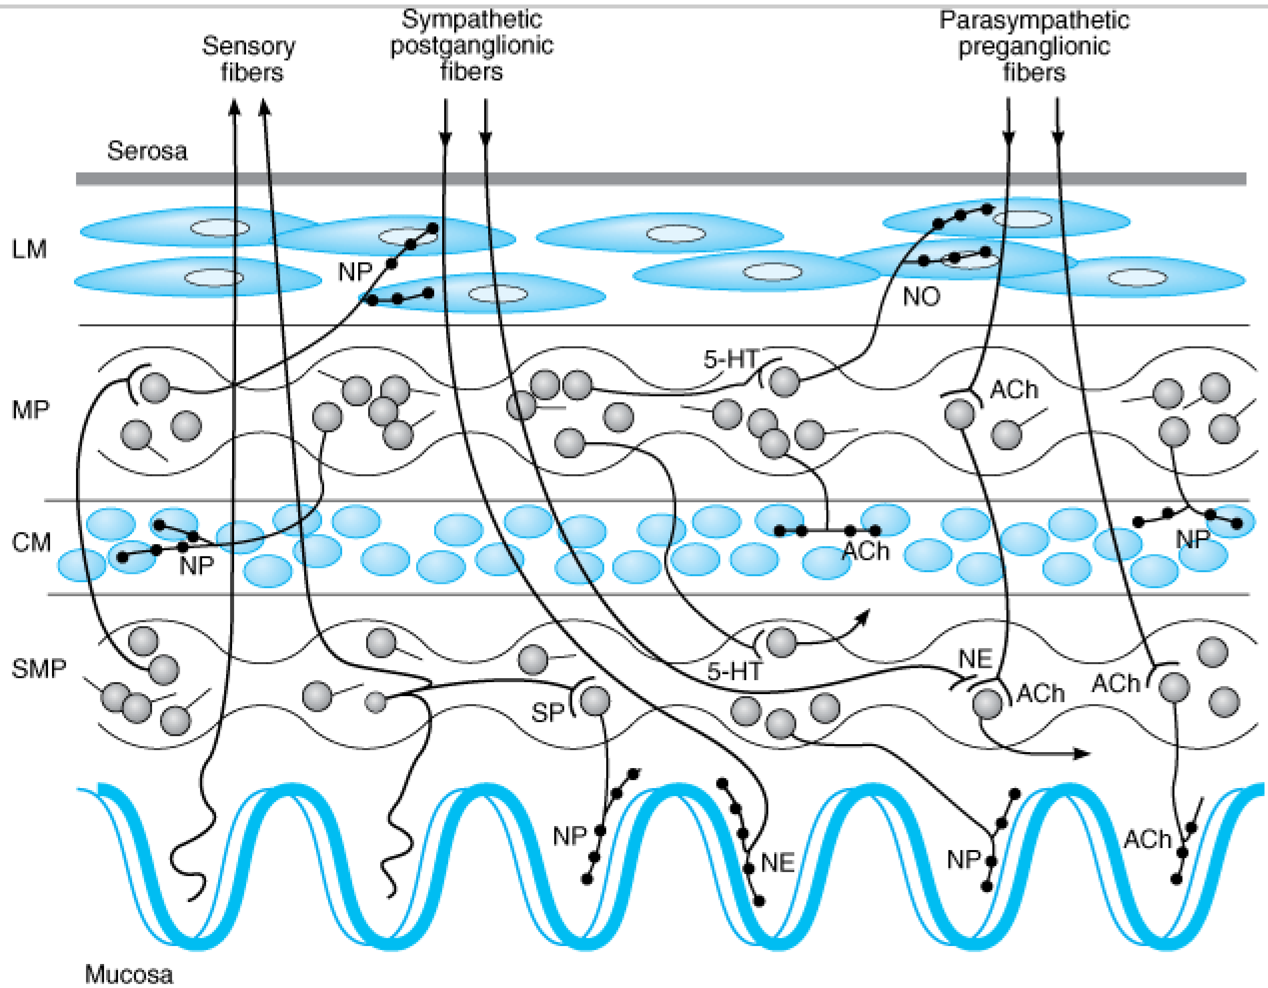
Schematic diagram comparing some anatomic and neurotransmitter features of autonomic and somatic motor nerves. Only the primary transmitter substances are shown. Parasympathetic ganglia are not shown because most are in or near the wall of the organ innervated. Cholinergic nerves are shown in color. Note that some sympathetic postganglionic fibers release acetylcholine or dopamine rather than norepinephrine. The adrenal medulla, a modified sympathetic ganglion, receives sympathetic preganglionic fibers and releases epinephrine and norepinephrine into the blood. (ACh, acetylcholine; D, dopamine; Epi, epinephrine; NE, norepinephrine; N, nicotinic receptors; M, muscarinic receptors.)

Most of the sympathetic preganglionic fibers terminate in ganglia located in the paravertebral chains that lie on either side of the spinal column. The remaining sympathetic preganglionic fibers terminate in prevertebral ganglia, which lie in front of the vertebrae, usually on the surface of the aorta. From the ganglia, postganglionic sympathetic fibers run to the tissues innervated. Some preganglionic parasympathetic fibers terminate in parasympathetic ganglia located outside the organs innervated: the ciliary, pterygopalatine, submandibular, otic, and several pelvic ganglia. The majority of parasympathetic preganglionic fibers terminate on ganglion cells distributed diffusely or in networks in the walls of the innervated organs. Note that the terms "sympathetic" and "parasympathetic" are anatomic designations and do not depend on the type of transmitter chemical released from the nerve endings nor on the kind of effect—excitatory or inhibitory—evoked by nerve activity.

In addition to these clearly defined peripheral motor portions of the ANS, large numbers of afferent fibers run from the periphery to integrating centers, including the enteric plexuses in the gut, the autonomic ganglia, and the central nervous system. Many of the sensory neurons that end in the central nervous system terminate in the integrating centers of the hypothalamus and medulla and evoke reflex motor activity that is carried to the effector cells by the efferent fibers described above. There is increasing evidence that some of these sensory fibers also have peripheral motor functions (see Nonadrenergic, Noncholinergic Neurons, below).

The enteric nervous system (ENS) is a large and highly organized collection of neurons located in the walls of the gastrointestinal system (Figure 6–2). It is sometimes considered a third division of the ANS. The ENS includes the myenteric plexus (the plexus of Auerbach) and the submucous plexus (the plexus of Meissner). These neuronal networks receive preganglionic fibers from the parasympathetic system and postganglionic sympathetic axons. They also receive sensory input from within the wall of the gut. Fibers from the cell bodies in these plexuses travel to the smooth muscle of the gut to control motility and to secretory cells in the mucosa. Sensory fibers transmit information from the mucosa and from stretch receptors to motor neurons in the plexuses and to postganglionic neurons in the sympathetic ganglia. The parasympathetic and sympathetic fibers that synapse on enteric plexus neurons appear to play a modulatory role, as indicated by the observation that deprivation of input from both ANS divisions does not completely halt activity in the plexuses nor in the smooth muscle and glands innervated by them.

Figure 6–2.



A highly simplified diagram of the intestinal wall and some of the circuitry of the enteric nervous system (ENS). The ENS receives input from both the sympathetic and the parasympathetic systems and sends afferent impulses to sympathetic ganglia and to the central nervous system. Many transmitter or neuromodulator substances have been identified in the ENS; see Table 6–1. (LM, longitudinal muscle layer; MP, myenteric plexus; CM, circular muscle layer; SMP, submucosal plexus; ACh, acetylcholine; NE, norepinephrine; NO, nitric oxide; NP, neuropeptides; SP, substance P; 5-HT, serotonin.)

NEUROTRANSMITTER CHEMISTRY OF THE AUTONOMIC NERVOUS SYSTEM

An important traditional classification of autonomic nerves is based on the primary transmitter molecules—acetylcholine or norepinephrine—released from their terminal boutons and varicosities. A large number of peripheral ANS fibers synthesize and release acetylcholine; they are cholinergic fibers, ie, they act by releasing acetylcholine. As shown in Figure 6–1, these include all preganglionic efferent autonomic fibers and the somatic (nonautonomic) motor fibers to skeletal muscle as well. Thus, almost all efferent fibers leaving the central nervous system are cholinergic. In addition, most parasympathetic postganglionic and a few sympathetic postganglionic fibers are cholinergic. A significant number of parasympathetic postganglionic neurons utilize nitric oxide or peptides for transmission. Most postganglionic sympathetic fibers release norepinephrine (also known as noradrenaline); they are noradrenergic (often called simply "adrenergic") fibers; that is, they act by releasing norepinephrine. These transmitter characteristics are presented schematically in Figure 6–1. As noted above, a few sympathetic fibers release acetylcholine. Dopamine is a very important transmitter in the central nervous system, and there is evidence that it may be released by some peripheral sympathetic fibers. Adrenal medullary cells, which are embryologically analogous to postganglionic sympathetic neurons, release a mixture of epinephrine and norepinephrine. Finally, most autonomic nerves also release several transmitter substances, or *cotransmitters,* in addition to the primary transmitters described above.

Five key features of neurotransmitter function provide potential targets for pharmacologic therapy: synthesis, storage, release, and termination of action of the transmitter, and functions of the receptor. These processes are discussed in detail below.

Cholinergic Transmission

The terminals of cholinergic neurons contain large numbers of small membrane-bound vesicles concentrated near the synaptic portion of the cell membrane (Figure 6–3) as well as a smaller number of large dense-cored vesicles located farther from the synaptic membrane. The large vesicles contain a high concentration of peptide cotransmitters (Table 6–1), whereas the smaller clear vesicles contain most of the acetylcholine. Vesicles are initially synthesized in the neuron soma and transported to the terminal. They may also be recycled several times within the terminal. Vesicles are provided with vesicle-associated membrane proteins (VAMPs), which serve to align them with release sites on the inner neuronal cell membrane and participate in triggering the release of transmitter. The corresponding release site on the inner surface of the nerve terminal membrane contains synaptosomal nerve-associated proteins (SNAPs).

Schematic illustration of a generalized cholinergic junction (not to scale). Choline is transported into the presynaptic nerve terminal by a sodium-dependent choline transporter (CHT). This transporter can be inhibited by hemicholinium drugs. In the cytoplasm, acetylcholine is synthesized from choline and acetyl Co-A (AcCoA) by the enzyme choline acetyltransferase (ChAT). ACh is then transported into the storage vesicle by a second carrier, the vesicle-associated transporter (VAT), which can be inhibited by vesamicol. Peptides (P), adenosine triphosphate (ATP), and proteoglycan are also stored in the vesicle. Release of transmitter occurs when voltage-sensitive calcium channels in the terminal membrane are opened, allowing an influx of calcium. The resulting increase in intracellular calcium causes fusion of vesicles with the surface membrane and exocytotic expulsion of ACh and cotransmitters into the junctional cleft (see text). This step can be blocked by botulinum toxin. Acetylcholine's action is terminated by metabolism by the enzyme acetylcholinesterase. Receptors on the presynaptic nerve ending regulate transmitter release. (SNAPs, synaptosome-associated proteins; VAMPs, vesicle-associated membrane proteins.)

Table 6–1. Some of the Transmitter Substances Found in Autonomic Nervous System (ANS), Enteric Nervous System (ENS), and Nonadrenergic, Noncholinergic Neurons.[1]

Substance	Probable Roles
Acetylcholine (ACh)	The primary transmitter at ANS ganglia, at the somatic neuromuscular junction, and at parasympathetic postganglionic nerve endings. A primary excitatory transmitter to smooth muscle and secretory cells in the ENS. Probably also the major neuron-to-neuron ("ganglionic") transmitter in the ENS.
Adenosine triphosphate (ATP)	Acts as a transmitter or cotransmitter at many ANS-effector synapses.
Calcitonin gene-related peptide (CGRP)	Found with substance P in cardiovascular sensory nerve fibers. Present in some secretomotor ENS neurons and interneurons. A cardiac stimulant.
Cholecystokinin (CCK)	May act as a cotransmitter in some excitatory neuromuscular ENS neurons.
Dopamine	A modulatory transmitter in some ganglia and the ENS. Probably a postganglionic sympathetic transmitter in renal blood vessels.
Enkephalin and related opioid peptides	Present in some secretomotor and interneurons in the ENS. Appear to inhibit ACh release and thereby inhibit peristalsis. May *stimulate* secretion.
Galanin	Present in secretomotor neurons; may play a role in appetite-satiety mechanisms.
GABA (γ-aminobutyric acid)	May have presynaptic effects on excitatory ENS nerve terminals. Has some relaxant effect on the gut. Probably not a major transmitter in the ENS.

Gastrin-releasing peptide (GRP)

Extremely potent excitatory transmitter to gastrin cells. Also known as mammalian bombesin.

Neuropeptide Y (NPY)

Found in many noradrenergic neurons. Present in some secretomotor neurons in the ENS and may inhibit secretion of water and electrolytes by the gut. Causes long-lasting vasoconstriction. It is also a cotransmitter in some parasympathetic postganglionic neurons.

Nitric oxide (NO)

A cotransmitter at inhibitory ENS neuromuscular junctions; may be especially important at sphincters.

Norepinephrine (NE)

The primary transmitter at most sympathetic postganglionic nerve endings.

Serotonin (5-HT)

An important transmitter or cotransmitter at excitatory neuron-to-neuron junctions in the ENS.

Substance P (and related "tachykinins")

Substance P is an important sensory neuron transmitter in the ENS and elsewhere. Tachykinins appear to be excitatory cotransmitters with ACh at ENS neuromuscular junctions. Found with CGRP in cardiovascular sensory neurons. Substance P is a vasodilator (probably via release of nitric oxide).

Vasoactive intestinal peptide (VIP)

Excitatory secretomotor transmitter in the ENS; may also be an inhibitory ENS neuromuscular cotransmitter. A probable cotransmitter in many cholinergic neurons. A vasodilator (found in many perivascular neurons) and cardiac stimulant.

---

[1] See Chapter 21 for transmitters found in the central nervous system.

Acetylcholine is synthesized in the cytoplasm from acetyl-CoA and choline through the catalytic action of the enzyme choline acetyltransferase (ChAT). Acetyl-CoA is synthesized in mitochondria, which are present in large numbers in the nerve ending. Choline is transported from the extracellular fluid into the neuron terminal by a sodium-dependent membrane **choline transporter** (Figure 6–3, CHT). This symporter can be blocked by a group of research drugs called **hemicholiniums**. Once synthesized, acetylcholine is transported from the cytoplasm into the vesicles by a **vesicle-associated transporter** that is driven by proton efflux (Figure 6–3, carrier VAT). This antiporter can be blocked by the research drug **vesamicol**. Acetylcholine synthesis is a rapid process capable of supporting a very high rate of transmitter release. Storage of acetylcholine is accomplished by the packaging of "quanta" of acetylcholine molecules (usually 1000–50,000 molecules in each vesicle).

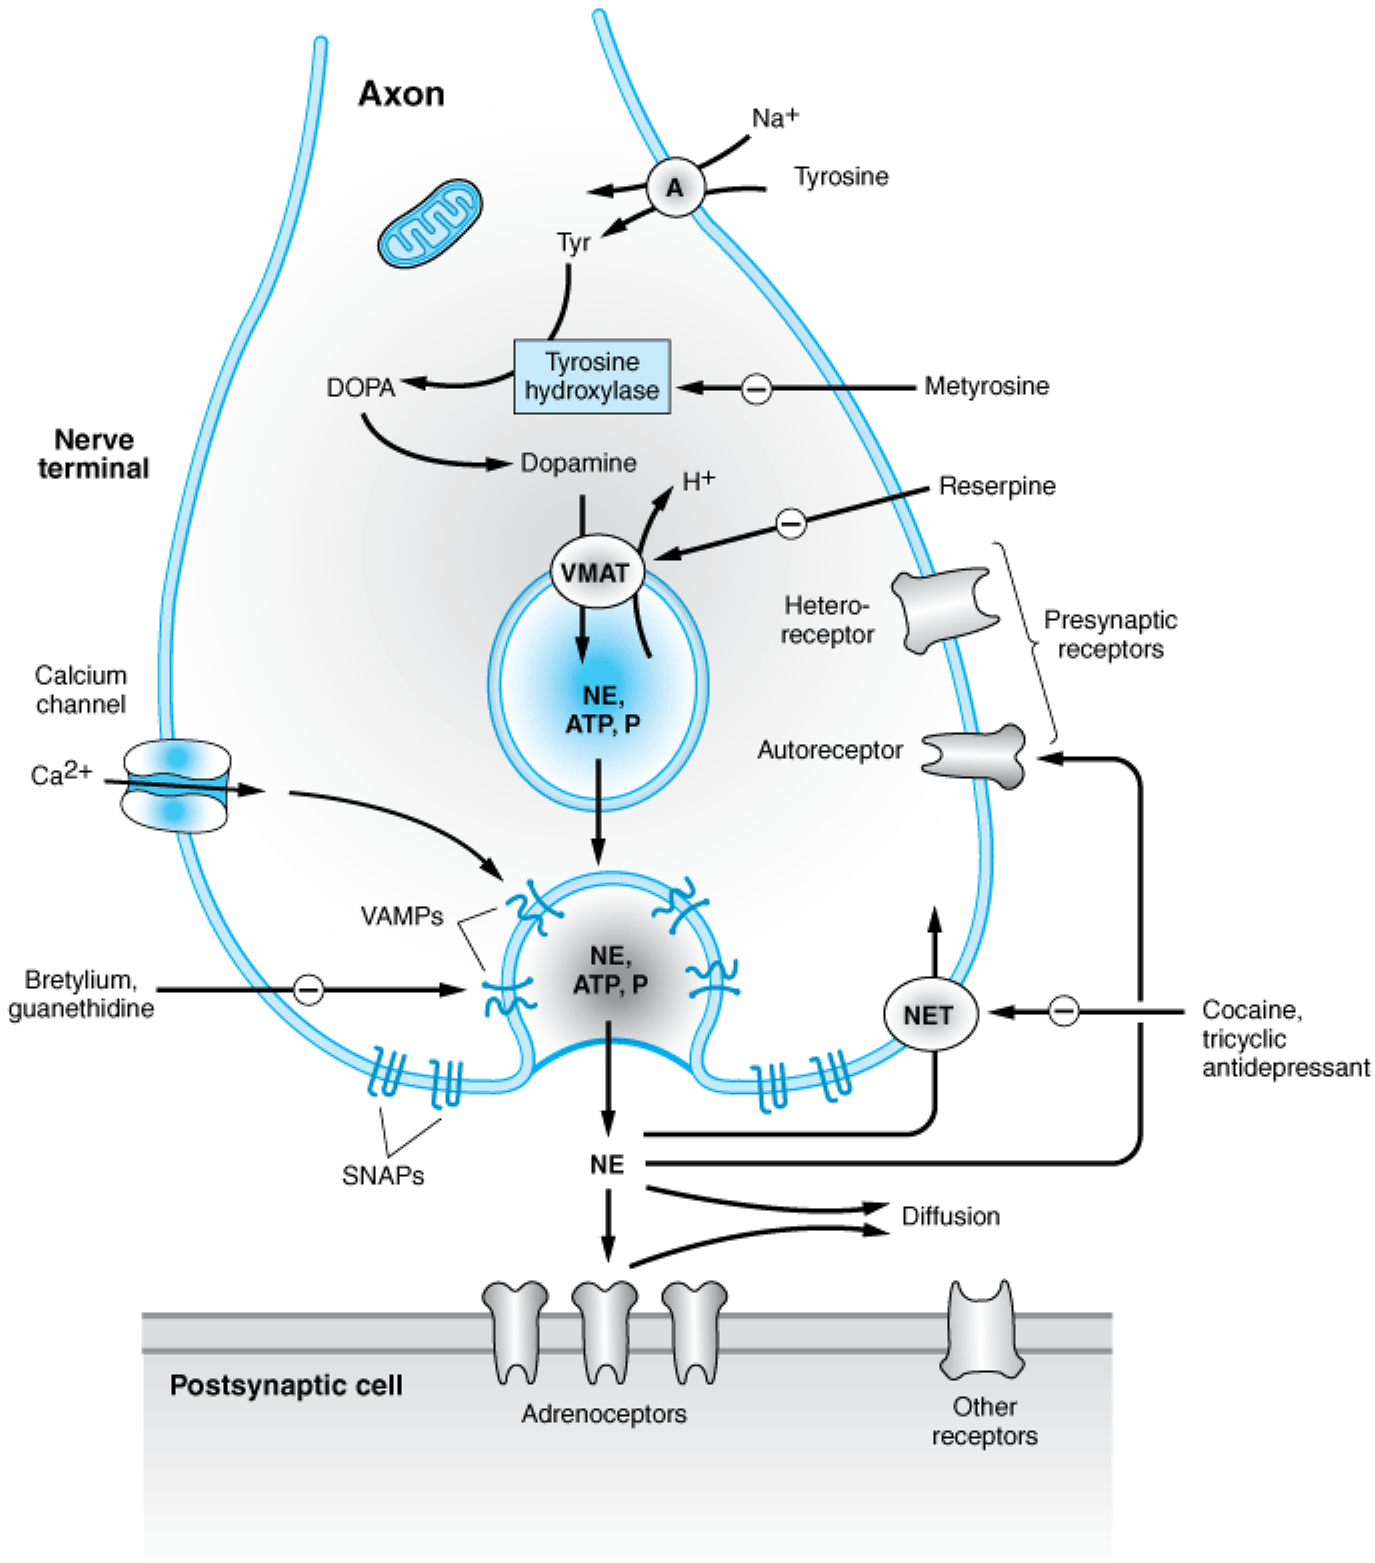
Vesicles are concentrated on the inner surface of the nerve terminal facing the synapse through the interaction of so-called SNARE proteins on the vesicle (VAMPs called v-SNAREs, especially synaptobrevin) and on the inside of the neuronal cell membrane (SNAPs called t-SNAREs, especially syntaxin and SNAP-25). Release of transmitter from the vesicles is dependent on extracellular calcium and occurs when an action potential reaches the terminal and triggers sufficient influx of calcium ions. Calcium interacts with the VAMP synaptotagmin on the vesicle membrane and triggers fusion of the vesicle membrane with the terminal membrane and opening of a pore into the synapse. The opening of the pore results in exocytotic expulsion—in the case of somatic motor nerves—of several hundred quanta of acetylcholine into the synaptic cleft. The amount of transmitter released by one depolarization of an autonomic postganglionic nerve terminal is probably smaller. In addition to acetylcholine, several cotransmitters are released at the same time (Table 6–1). The acetylcholine vesicle release process is blocked by botulinum toxin through the enzymatic removal of two amino acids from one or more of the fusion proteins.

After release from the presynaptic terminal, acetylcholine molecules may bind to and activate an acetylcholine receptor (cholinoceptor). Eventually (and usually very rapidly), all of the acetylcholine released diffuses within range of an acetylcholinesterase (AChE) molecule. AChE very efficiently splits acetylcholine into choline and acetate, neither of which has significant transmitter effect, and thereby terminates the action of the transmitter (Figure 6–3). Most cholinergic synapses are richly supplied with acetylcholinesterase; the half-life of acetylcholine in the synapse is therefore very short (seconds). Acetylcholinesterase is also found in other tissues, eg, red blood cells. (Another cholinesterase with a lower specificity for acetylcholine, butyrylcholinesterase [pseudocholinesterase], is found in blood plasma, liver, glia, and many other tissues.)

Adrenergic Transmission

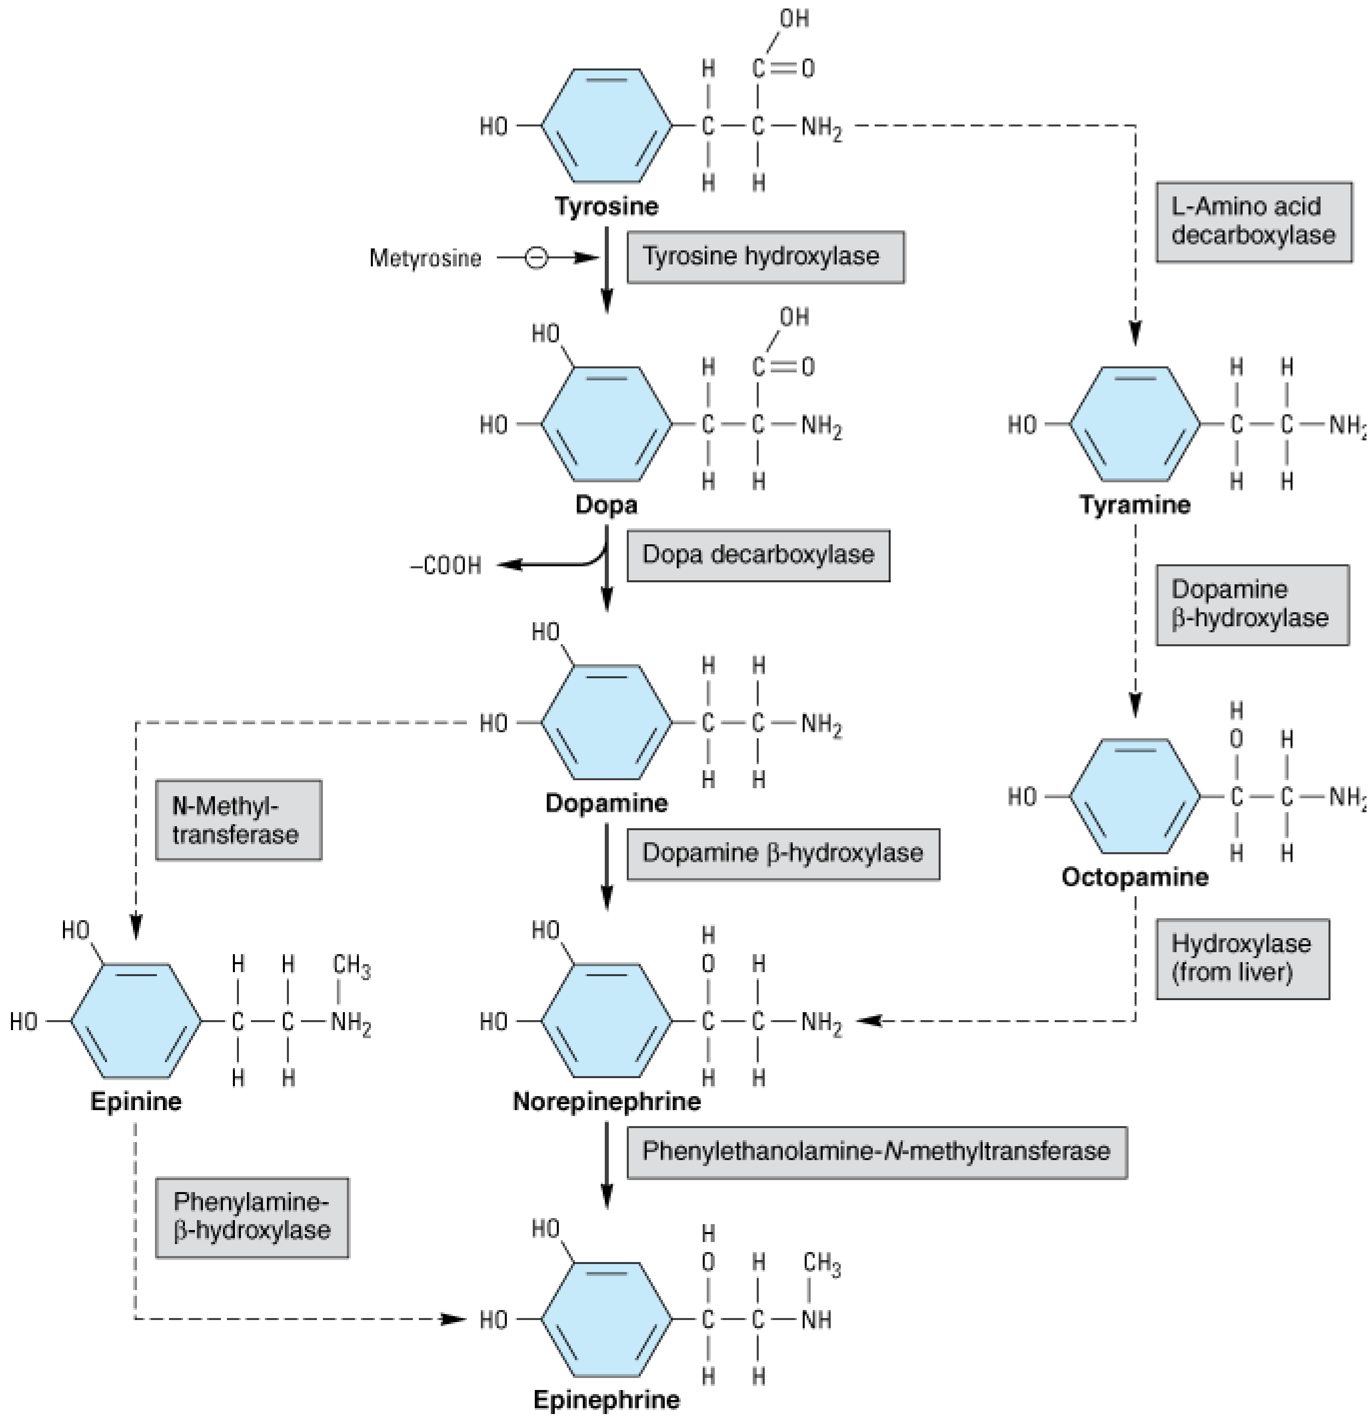
Adrenergic neurons (Figure 6–4) also transport a precursor molecule into the nerve ending, then synthesize the catecholamine transmitter, and finally store it in membrane-bound vesicles, but, as indicated in Figure 6–5, the synthesis of the catecholamine transmitters is more complex than that of acetylcholine. In most sympathetic postganglionic neurons, norepinephrine is the final product. In the adrenal medulla and certain areas of the brain, norepinephrine is further converted to epinephrine. In dopaminergic neurons, synthesis terminates with dopamine. Several processes in these nerve terminals are potential sites of drug action. One of these, the conversion of tyrosine to dopa, is the rate-limiting step in catecholamine transmitter synthesis. It can be inhibited by the tyrosine analog metyrosine (Figure 6–4). A high-affinity carrier for catecholamines located in the wall of the storage vesicle (vesicular monoamine transporter, VMAT) can be inhibited by the reserpine alkaloids (Figure 6–4, carrier VMAT). Reserpine causes depletion of transmitter stores. Another transporter (norepinephrine transporter, NET) carries norepinephrine and similar molecules back into the cell cytoplasm from the synaptic cleft (Figure 6–4, NET). NET is also commonly called uptake 1 or reuptake 1. NET can be inhibited by cocaine and tricyclic antidepressant drugs, resulting in an increase of transmitter activity in the synaptic cleft. Similar transporters (DAT, SERT) are responsible for the reuptake of dopamine and 5-HT (serotonin), respectively, into the neurons that release these transmitters.

Figure 6–4.



Schematic diagram of a generalized noradrenergic junction (not to scale). Tyrosine is transported into the noradrenergic ending or varicosity by a sodium-dependent carrier (A). Tyrosine is converted to dopamine (see Figure 6–5 for details), which is transported into the vesicle by the vesicular monoamine transporter (VMAT), which can be blocked by reserpine. The same carrier transports norepinephrine (NE) and several other amines into these granules. Dopamine is converted to NE in the vesicle by dopamine-β-hydroxylase. Physiologic release of transmitter occurs when an action potential opens voltage-sensitive calcium channels and increases intracellular calcium. Fusion of vesicles with the surface membrane results in expulsion of norepinephrine, cotransmitters, and dopamine-β-hydroxylase. Release can be blocked by drugs such as guanethidine and bretylium. After release, norepinephrine diffuses out of the cleft or is transported into the cytoplasm of the terminal by the norepinephrine transporter (NET), which can be blocked by cocaine and tricyclic antidepressants, or into postjunctional or perijunctional cells. Regulatory receptors are present on the presynaptic terminal. (SNAPs, synaptosome-associated proteins; VAMPs, vesicle-associated membrane proteins.)

Figure 6–5.

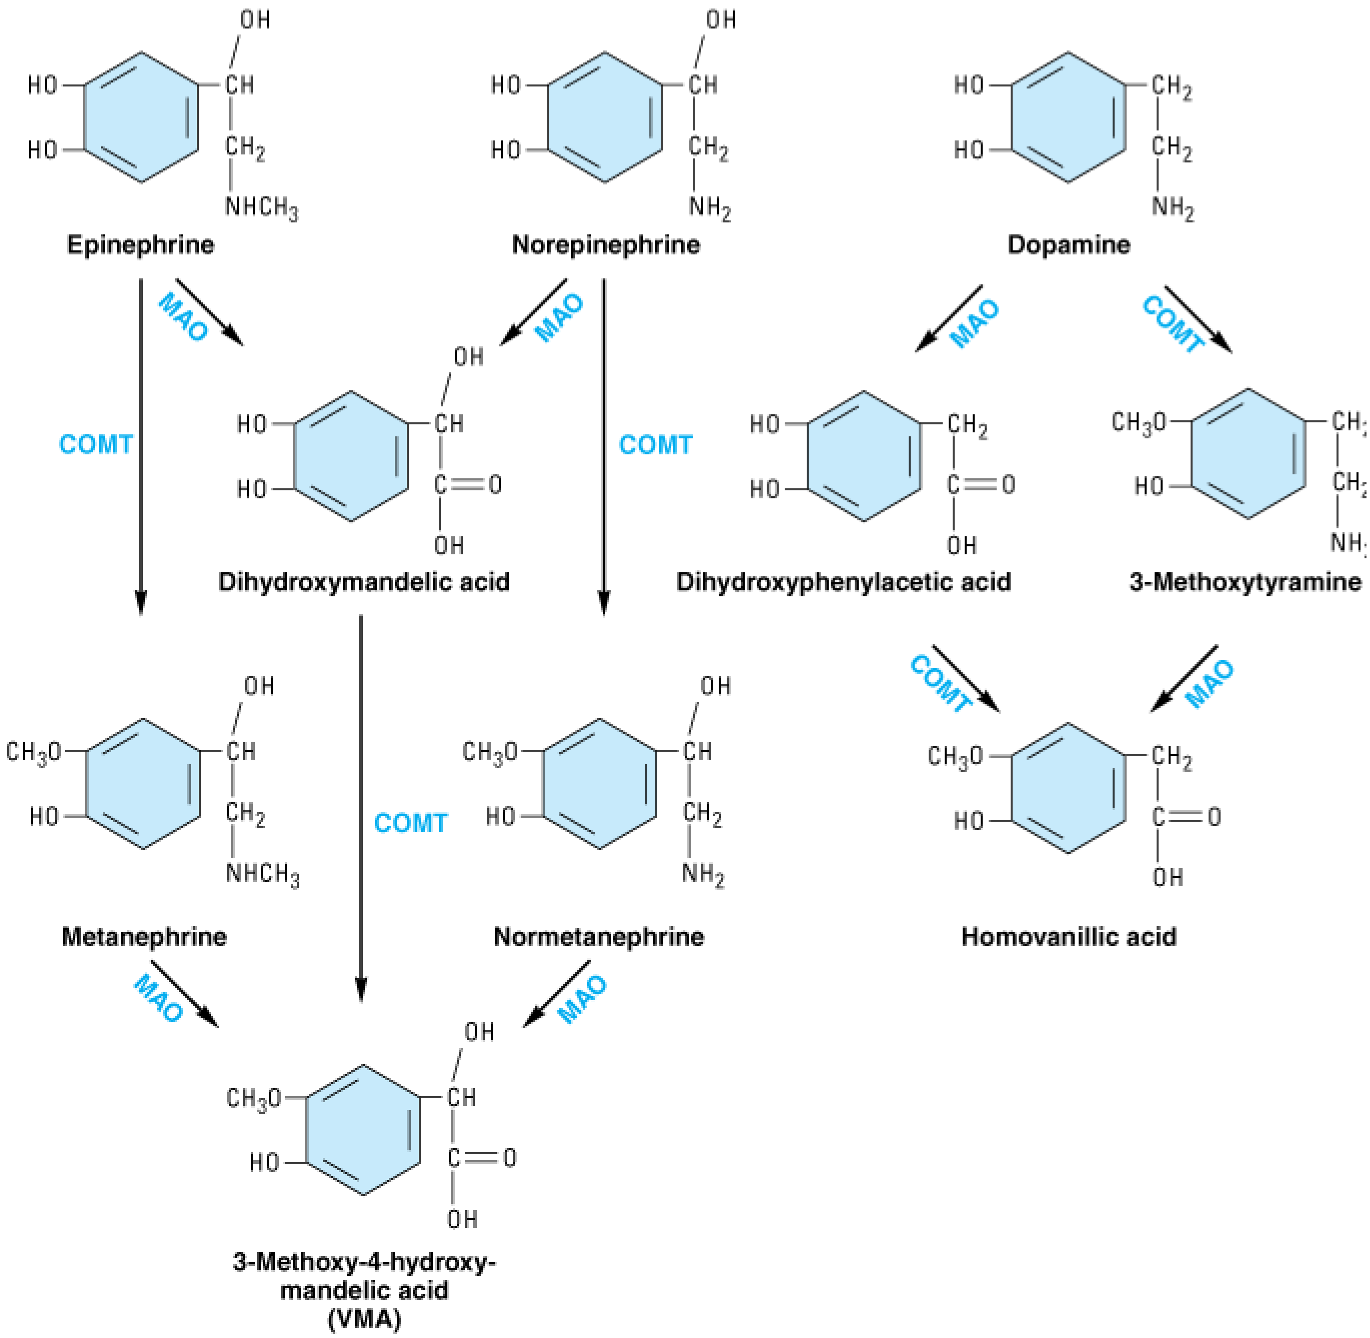


Biosynthesis of catecholamines. The rate-limiting step, conversion of tyrosine to dopa, can be inhibited by metyrosine (α-methyltyrosine). The alternative pathways shown by the dashed arrows have not been found to be of physiologic significanc in humans. However, tyramine and octopamine may accumulate in patients treated with monoamine oxidase inhibitors. (Reproduced, with permission, from Greenspan FS, Gardner DG (editors): *Basic and Clinical Endocrinology,* 7th ed. McGraw-Hill, 2003.)

Release of the vesicular transmitter store from noradrenergic nerve endings is similar to the calcium-dependent process described above for cholinergic terminals. In addition to the primary transmitter (norepinephrine), adenosine triphosphate (ATP), dopamine-β-hydroxylase, and peptide cotransmitters are also released into the synaptic cleft. Indirectly acting and mixed sympathomimetics, eg, tyramine, amphetamines, and ephedrine are capable of releasing stored transmitter from noradrenergic nerve endings by a calcium-independent process. These drugs are poor agonists (some are inactive) at adrenoceptors, but they are excellent substrates for monoamine transporters. As a result, they are avidly taken up into noradrenergic nerve endings by NET. In the nerve ending, they are then transported by VMAT into the vesicles, displacing norepinephrine, which is subsequently expelled into the synaptic space by reverse transport via NET. Amphetamines also inhibit monoamine oxidase and have other effects that result in increased norepinephrine activity in the synapse. Thei action does not require vesicle exocytosis.

Norepinephrine and epinephrine can be metabolized by several enzymes, as shown in Figure 6–6. Because of the high activity of monoamine oxidase in the mitochondria of the nerve terminal, there is significant turnover of norepinephrine even in the resting terminal. Since the metabolic products are excreted in the urine, an estimate of catecholamine turnover can be obtained from laboratory analysis of total metabolites (sometimes referred to as "VMA and metanephrines") in a 24-hour urine sample. However, metabolism is not the primary mechanism for termination of action of norepinephrine physiologically released from noradrenergic nerves. Termination of noradrenergic transmission results from two processes, simple diffusion away from the receptor site (with eventual metabolism in the plasma or liver), and reuptake into the nerve terminal by NET (Figure 6–4) or into perisynaptic glia or other cells.

Figure 6–6.



Metabolism of catecholamines by catechol-*O*- methyltransferase (COMT) and monoamine oxidase (MAO). (Modified and reproduced, with permission, from Greenspan FS, Gardner DG (editors): *Basic and Clinical Endocrinology,* 7th ed. McGraw-Hill, 2003.)

Cotransmitters in Cholinergic & Adrenergic Nerves

As previously noted, the vesicles of both cholinergic and adrenergic nerves contain other substances in addition to the primary transmitter. Some of the substances identified to date are listed in Table 6–1. Many of these substances are also *primary* transmitters in the nonadrenergic, noncholinergic nerves described in the text that follows. Their roles in the function of nerves that release acetylcholine or norepinephrine are not yet fully understood. In some cases, they provide a faster or slower action to supplement or modulate the effects of the primary transmitter. They also participate in feedback inhibition of the same and nearby nerve terminals.

AUTONOMIC RECEPTORS

Historically, structure-activity analyses, with careful comparisons of the potency of series of autonomic agonist and antagonist analogs, led to the definition of different autonomic receptor subtypes, including muscarinic and nicotinic cholinoceptors, and α, β, and dopamine adrenoceptors (Table 6–2). Subsequently, binding of isotope-labeled ligands permitted the purification and characterization of several of the receptor molecules. Molecular biology now provides techniques for the discovery and expression of genes that code for related receptors within these groups (see Chapter 2).

Table 6–2. Major Autonomic Receptor Types.

Receptor Name	Typical Locations	Result of Ligand Binding
Cholinoceptors		
Muscarinic M_1	CNS neurons, sympathetic postganglionic neurons, some presynaptic sites	Formation of IP_3 and DAG, increased intracellular calcium
Muscarinic M_2	Myocardium, smooth muscle, some presynaptic sites; CNS neurons	Opening of potassium channels, inhibition of adenylyl cyclase
Muscarinic M_3	Exocrine glands, vessels (smooth muscle and endothelium); CNS neurons	Like M_1 receptor-ligand binding
Muscarinic M_4	CNS neurons; possibly vagal nerve endings	Like M_2 receptor-ligand binding

Muscarinic M_5

Vascular endothelium, especially cerebral vessels; CNS neurons

Like M_1 receptor-ligand binding

Nicotinic N_N

Postganglionic neurons, some presynaptic cholinergic terminals

Opening of Na^+ , K^+ channels, depolarization

Nicotinic N_M

Skeletal muscle neuromuscular endplates

Opening of Na^+ , K^+ channels, depolarization

Adrenoceptors

Alpha$_1$

Postsynaptic effector cells, especially smooth muscle

Formation of IP_3 and DAG, increased intracellular calcium

Alpha$_2$

Presynaptic adrenergic nerve terminals, platelets, lipocytes, smooth muscle

Inhibition of adenylyl cyclase, decreased cAMP

Beta$_1$

Postsynaptic effector cells, especially heart, lipocytes, brain; presynaptic adrenergic and cholinergic nerve terminals, juxtaglomerular apparatus of renal tubules, ciliary body epithelium

Stimulation of adenylyl cyclase, increased cAMP

Beta$_2$

Postsynaptic effector cells, especially smooth muscle and cardiac muscle

Stimulation of adenylyl cyclase and increased cAMP. Activates cardiac G_i under some conditions.

Beta$_3$

Postsynaptic effector cells, especially lipocytes; heart

Stimulation of adenylyl cyclase and increased cAMP[1]

Dopamine receptors

D_1 (DA_1), D_5

Brain; effector tissues, especially smooth muscle of the renal vascular bed

Stimulation of adenylyl cyclase and increased cAMP

D_2 (DA_2)

Brain; effector tissues, especially smooth muscle; presynaptic nerve terminals

Inhibition of adenylyl cyclase; increased potassium conductance

D_3

Brain

Inhibition of adenylyl cyclase

D_4

Brain, cardiovascular system

Inhibition of adenylyl cyclase

[1] Cardiac beta$_3$ -receptor function is poorly understood, but activation does *not* appear to result in stimulation of rate or force.

The primary acetylcholine receptor subtypes were named after the alkaloids originally used in their identification: muscarine and nicotine. These nouns are readily converted into adjectives—thus, muscarinic and nicotinic receptors. In the case of receptors associated with noradrenergic nerves, the coining of simple adjectives from the names of the agonists (noradrenaline, phenylephrine, isoproterenol, etc) was not practicable. Therefore, the term adrenoceptor is widely used to describe receptors that respond to catecholamines such as norepinephrine. By analogy, the term cholinoceptor denotes receptors (both muscarinic and nicotinic) that respond to acetylcholine. In North America, receptors were colloquially named after the nerves that usually innervate them; thus, adrenergic (or noradrenergic) receptors and cholinergic receptors. The general class of adrenoceptors can be further subdivided into α-adrenoceptor, β-adrenoceptor, and dopamine-receptor types on the basis of both agonist and antagonist selectivity and on genomic grounds. Development of more selective blocking drugs has led to the naming of subclasses within these major types; for example, within the α-adrenoceptor class, α_1 and α_2 receptors differ in both agonist and antagonist selectivity. Specific examples of such selective drugs are given in the chapters that follow.

NONADRENERGIC, NONCHOLINERGIC (NANC) NEURONS

It has been known for many years that autonomic effector tissues (eg, gut, airways, bladder) contain nerve fibers that do not show the histochemical characteristics of either cholinergic or adrenergic fibers. Both motor and sensory nonadrenergic, noncholinergic fibers are present. Although peptides are the most common transmitter substances found in these nerve endings, other substances, eg, nitric oxide synthase and purines, are also present in many nerve terminals (Table 6–1). Capsaicin, a neurotoxin derived from chili peppers, can cause the release of transmitter (especially substance P) from such neurons and, if given in high doses, destruction of the neuron.

The enteric system in the gut wall (Figure 6–2) is the most extensively studied system containing nonadrenergic, noncholinergic neurons in addition to cholinergic and adrenergic fibers. In the small intestine, for example, these neurons contain one or more of the following: nitric oxide synthase, calcitonin gene-related peptide, cholecystokinin, dynorphin, enkephalins, gastrin-releasing peptide, 5-hydroxytryptamine (serotonin), neuropeptide Y, somatostatin, substance P, and vasoactive intestinal peptide. Some neurons contain as many as five different transmitters. The ENS functions in a semiautonomous manner, utilizing input from the motor outflow of the ANS for modulation of gastrointestinal activity and sending sensory information back to the central nervous system. The ENS provides the necessary synchronization of impulses that, for example, ensures forward, not backward, propulsion of gut contents and relaxation of sphincters when the gut wall contracts.

The sensory fibers in the nonadrenergic, noncholinergic systems are probably better termed "sensory-efferent" or "sensory-local effector" fibers because, when activated by a sensory input, they are capable of releasing transmitter peptides from the sensory ending itself, from local axon branches, and from collaterals that terminate in the autonomic ganglia. These peptides are potent agonists at many autonomic effector tissues.

FUNCTIONAL ORGANIZATION OF AUTONOMIC ACTIVITY

A basic understanding of the interactions of autonomic nerves with each other and with their effector organs is essential for an appreciation of the actions of autonomic drugs, especially because of the significant reflex (compensatory) effects that may be evoked by these agents.

Central Integration

At the highest level—midbrain and medulla—the two divisions of the ANS and the endocrine system are integrated with each other, with sensory input, and with information from higher central nervous system centers. These interactions are such that early investigators called the parasympathetic system a trophotropic one (ie, leading to growth) used to "rest and digest" and the sympathetic system an ergotropic one (ie, leading to energy expenditure), which is activated for "fight or flight." Although such terms offer little insight into the mechanisms involved, they do provide simple descriptions applicable to many of the actions of the systems (Table 6–3). For example, slowing of the heart and stimulation of digestive activity are typical energyconserving actions of the parasympathetic system. In contrast, cardiac stimulation, increased blood sugar, and cutaneous vasoconstriction are responses produced by sympathetic discharge that are suited to fighting or surviving attack.

[1] Less important actions are shown in brackets.

[2] Specific receptor type: α = alpha, β = beta, M = muscarinic.

[3] Vascular smooth muscle in skeletal muscle has sympathetic cholinergic dilator fibers.

[4] The endothelium of most blood vessels releases EDRF (endothelium-derived relaxing factor), which causes marked vasodilation, in response to muscarinic stimuli. However, unlike the receptors innervated by sympathetic cholinergic fibers in skeletal muscle blood vessels, these muscarinic receptors are not innervated and respond only to circulating muscarinic agonists.

[5] Cerebral blood vessels dilate in response to M_5 receptor activation.

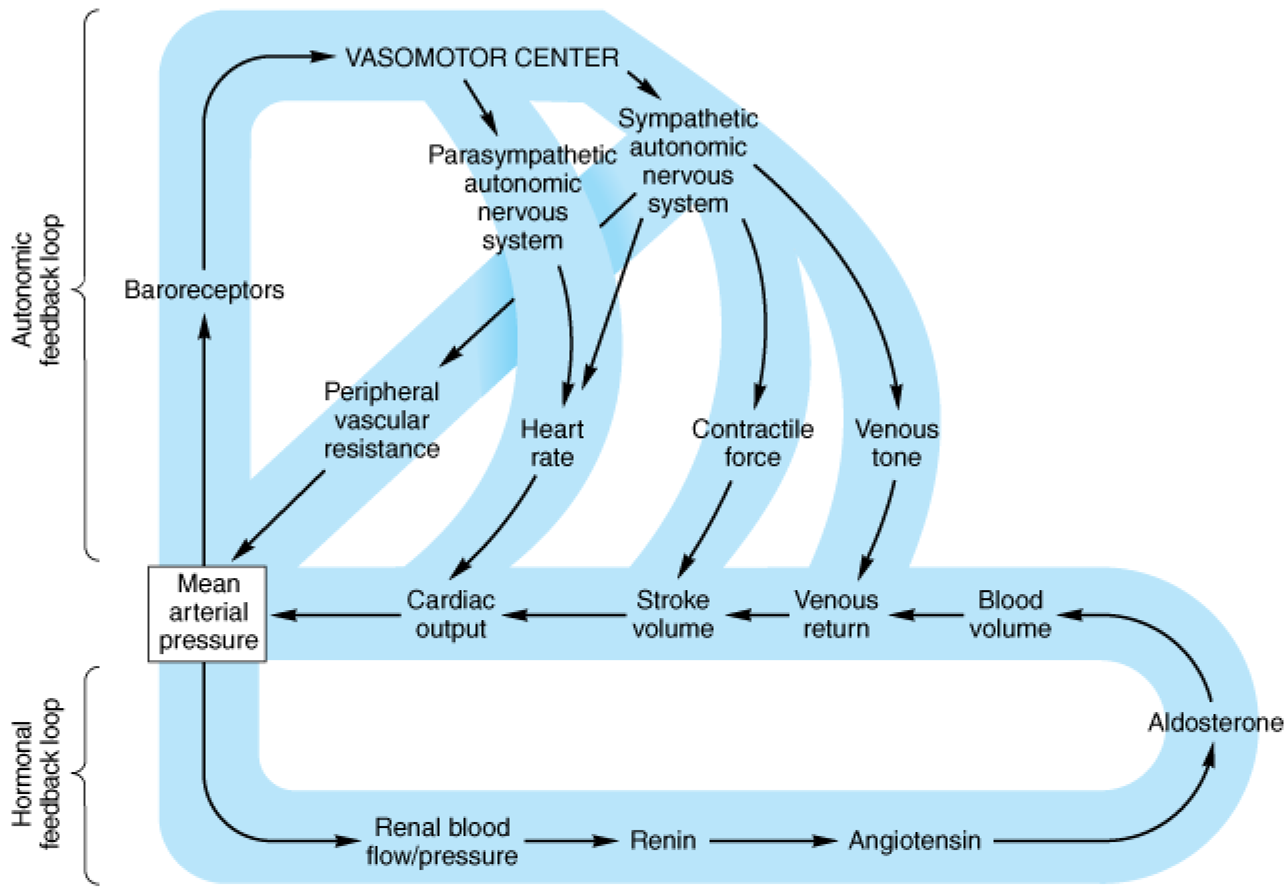
[6] Probably through presynaptic inhibition of parasympathetic activity.

At a more subtle level of interactions in the brain stem, medulla, and spinal cord, there are important cooperative interactions between the parasympathetic and sympathetic systems. For some organs, sensory fibers associated with the parasympathetic system exert reflex control over motor outflow in the sympathetic system. Thus, the sensory carotid sinus baroreceptor fibers in the glossopharyngeal nerve have a major influence on sympathetic outflow from the vasomotor center. This example is described in greater detail below. Similarly, parasympathetic sensory fibers in the wall of the urinary bladder significantly influence sympathetic inhibitory outflow to that organ. Within the enteric nervous system, sensory fibers from the wall of the gut synapse on both preganglionic and postganglionic motor cells that control intestinal smooth muscle and secretory cells (Figure 6–2).

Integration of Cardiovascular Function

Autonomic reflexes are particularly important in understanding cardiovascular responses to autonomic drugs. A indicated in Figure 6–7, the primary controlled variable in cardiovascular function is mean arterial pressure. Changes in any variable contributing to mean arterial pressure (eg, a drug-induced increase in peripheral vascular resistance) evoke powerful homeostatic secondary responses that tend to compensate for the directl evoked change. The homeostatic response may be sufficient to reduce the change in mean arterial pressure and to reverse the drug's effects on heart rate. A slow infusion of norepinephrine provides a useful example. This agent produces direct effects on both vascular and cardiac muscle. It is a powerful vasoconstrictor and, by increasing peripheral vascular resistance, increases mean arterial pressure. In the absence of reflex control—in a patient who has had a heart transplant, for example—the drug's effect on the heart is also stimulatory; that is, it increases heart rate and contractile force. However, in a subject with intact reflexes, the negative feedback baroreceptor response to increased mean arterial pressure causes decreased sympathetic outflow to the heart and a powerful increase in parasympathetic (vagus nerve) discharge at the cardiac pacemaker. As a result, the *net* effect of ordinary pressor doses of norepinephrine in a normal subject is to produce a marked increase in peripheral vascular resistance, an increase in mean arterial pressure, and a consistent *slowing* of heart rate. Bradycardia, the reflex compensatory response elicited by this agent, is the *exact opposite* of the drug's direct action; yet it is completely predictable if the integration of cardiovascular function by the ANS is understood.

Figure 6–7.



Autonomic and hormonal control of cardiovascular function. Note that two feedback loops are present: the autonomic nervous system loop and the hormonal loop. The sympathetic nervous system directly influences four major variables: peripheral vascular resistance, heart rate, force, and venous tone. It also directly modulates renin production (not shown). The parasympathetic nervous system directly influences heart rate. In addition to its role in stimulating aldosterone secretion, angiotensin II directly increases peripheral vascular resistance and facilitates sympathetic effects (not shown). The net feedback effect of each loop is to compensate for changes in arterial blood pressure. Thus, decreased blood pressure due to blood loss would evoke increased sympathetic outflow and renin release. Conversely, elevated pressure due to the administration of a vasoconstrictor drug would cause reduced sympathetic outflow, reduced renin release, and increased parasympathetic (vagal) outflow.

Presynaptic Regulation

The principle of negative feedback control is also found at the presynaptic level of autonomic function. Important presynaptic feedback inhibitory control mechanisms have been shown to exist at most nerve endings. A well-documented mechanism involves the α_2 receptor located on noradrenergic nerve terminals. This receptor is activated by norepinephrine and similar molecules; activation diminishes further release of norepinephrine from these nerve endings (Table 6–4). Conversely, a presynaptic β receptor appears to facilitate the release of norepinephrine from some adrenergic neurons. Presynaptic receptors that respond to the primary transmitter substance released by the nerve ending are called *autoreceptors*. Autoreceptors are usually inhibitory, but many cholinergic fibers, especially somatic motor fibers, have excitatory nicotinic autoreceptors.

[1] A provisional list. The number of transmitters and locations will undoubtedly increase with additional research

Control of transmitter release is not limited to modulation by the transmitter itself. Nerve terminals also carry regulatory receptors that respond to many other substances. Such **heteroreceptors** may be activated by substances released from other nerve terminals that synapse with the nerve ending. For example, some vagal fibers in the myocardium synapse on sympathetic noradrenergic nerve terminals and inhibit norepinephrine release. Alternatively, the ligands for these receptors may diffuse to the receptors from the blood or from nearby tissues. Some of the transmitters and receptors identified to date are listed in Table 6–4. Presynaptic regulation by a variety of endogenous chemicals probably occurs in all nerve fibers.

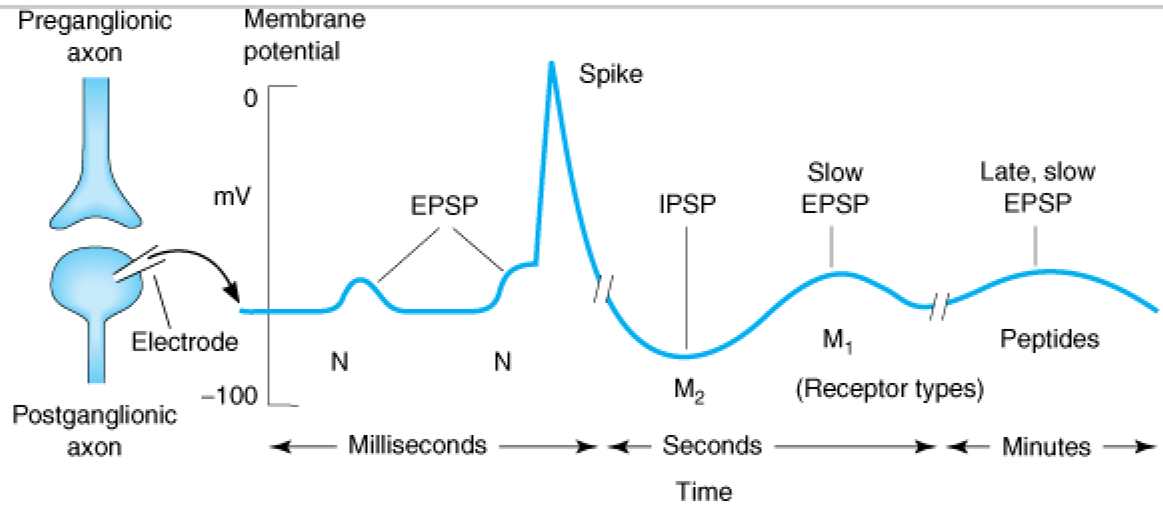
Postsynaptic Regulation

Postsynaptic regulation can be considered from two perspectives: modulation by the history of activity at the primary receptor (which may up- or down-regulate receptor number or desensitize receptors; see Chapter 2) and modulation by other temporally associated events.

The first mechanism has been well documented in several receptor-effector systems. Up- and down-regulation are known to occur in response to decreased or increased activation, respectively, of the receptors. An extreme form of up-regulation occurs after denervation of some tissues, resulting in **denervation supersensitivity** of the tissue to activators of that receptor type. In skeletal muscle, for example, nicotinic receptors are normally restricted to the end plate regions underlying somatic motor nerve terminals. Surgical denervation results in marked proliferation of nicotinic cholinoceptors over all parts of the fiber, including areas not previously associated with any motor nerve junctions. A pharmacologic supersensitivity related to denervation supersensitivity occurs in autonomic effector tissues after administration of drugs that deplete transmitter stores and prevent activation of the postsynaptic receptors for a sufficient period of time. For example, prolonged administration of large doses of reserpine, a norepinephrine depleter, can cause increased sensitivity of the smooth muscle and cardiac muscle effector cells served by the depleted sympathetic fibers.

The second mechanism involves modulation of the primary transmitter-receptor event by events evoked by the same or other transmitters acting on different postsynaptic receptors. Ganglionic transmission is a good example of this phenomenon (Figure 6–8). The postganglionic cells are activated (depolarized) as a result of binding of an appropriate ligand to a neuronal nicotinic (N_N) acetylcholine receptor. The resulting fast excitatory postsynaptic potential (EPSP) evokes a propagated action potential if threshold is reached. This event is often followed by a small and slowly developing but longer-lasting hyperpolarizing afterpotential—a slow inhibitory postsynaptic potential (IPSP). The hyperpolarization involves opening of potassium channels by M_2 cholinoceptors. The IPSP is followed by a small, slow excitatory postsynaptic potential caused by closure of potassium channels linked to M_1 cholinoceptors. Finally, a late, very slow EPSP may be evoked by peptides released from other fibers. These slow potentials serve to modulate the responsiveness of the postsynaptic cell to subsequent primary excitatory presynaptic nerve activity. (See Chapter 21 for additional examples.)

Figure 6–8.



Excitatory and inhibitory postsynaptic potentials (EPSP and IPSP) in an autonomic ganglion cell. The postganglionic neuron shown at the left with a recording electrode might undergo the membrane potential changes shown schematically in the recording. The response begins with two EPSP responses to nicotinic (N) receptor activation, the first not reaching threshold. The action potential is followed by an IPSP, probably evoked by M_2 receptor activation (with possible participation from dopamine receptor activation). The IPSP is, in turn, followed by a slower, M_1 -dependent EPSP, and this is sometimes followed by a still slower peptide-induced excitatory postsynaptic potential.

PHARMACOLOGIC MODIFICATION OF AUTONOMIC FUNCTION

Because transmission involves different mechanisms in different segments of the ANS, some drugs produce highly specific effects, whereas others are much less selective in their actions. A summary of the steps in transmission of impulses, from the central nervous system to the autonomic effector cells, is presented in Table 6–5. Drugs that block action potential propagation (local anesthetics) are very nonselective in their action, since they act on a process that is common to all neurons. On the other hand, drugs that act on the biochemical processes involved in transmitter synthesis and storage are more selective, since the biochemistry of adrenergic transmission is very different from that of cholinergic transmission. Activation or blockade of effector cell receptors offers maximum flexibility and selectivity of effect: adrenoceptors are easily distinguished from cholinoceptors. Furthermore, individual subgroups can often be selectively activated or blocked within each major type. Some examples are given in Pharmacology of the Eye.

Table 6–5. Steps in Autonomic Transmission: Effects of Drugs.

Process Affected	Drug Example	Site	Action
Action potential propagation	Local anesthetics, tetrodotoxin,[1] saxitoxin[2]	Nerve axons	Block sodium channels; block conduction
Transmitter synthesis	Hemicholinium	Cholinergic nerve terminals: membrane	Blocks uptake of choline and slows synthesis
	α-Methyltyrosine (metyrosine)	Adrenergic nerve terminals and adrenal medulla: cytoplasm	Blocks synthesis
Transmitter storage	Vesamicol	Cholinergic terminals vesicles	Prevents storage, depletes
	Reserpine	Adrenergic terminals vesicles	

Prevents storage, depletes

Transmitter release

Many[3]

Nerve terminal membrane receptors

Modulate release

ω-Conotoxin GVIA[4]

Nerve terminal calcium channels

Reduces transmitter release

Botulinum toxin

Cholinergic vesicles

Prevents release

α-Latrotoxin[5]

Cholinergic and adrenergic vesicles

Causes explosive transmitter release

Tyramine, amphetamine

Adrenergic nerve terminals

Promote transmitter release

Transmitter uptake after release

Cocaine, tricyclic antidepressants

Adrenergic nerve terminals

Inhibit uptake; increase transmitter effect on postsynaptic receptors

Receptor activation or blockade

Norepinephrine

Receptors at adrenergic junctions

Binds α-receptors; causes contraction

Phentolamine

Receptors at adrenergic junctions

Binds α-receptors; prevents activation

Isoproterenol

Receptors at adrenergic junctions

Binds β receptors; activates adenylyl cyclase

Propranolol

Receptors at adrenergic junctions

Binds β receptors; prevents activation

Nicotine

Receptors at nicotinic cholinergic junctions (autonomic ganglion, neuromuscular end plates)

Binds nicotinic receptors; opens ion channel in postsynaptic membrane

Tubocurarine

Neuromuscular end plates

Prevents activation

Bethanechol

Receptors, parasympathetic effector cells (smooth muscle, glands)

Binds and activates muscarinic receptors

Atropine

Receptors, parasympathetic effector cells

Binds muscarinic receptors; prevents activation

Enzymatic inactivation of transmitter

Neostigmine

Cholinergic synapses (acetylcholinesterase)

Inhibits enzyme; prolongs and intensifies transmitter action

Tranylcypromine

Adrenergic nerve terminals (monoamine oxidase)

Inhibits enzyme; increases stored transmitter pool

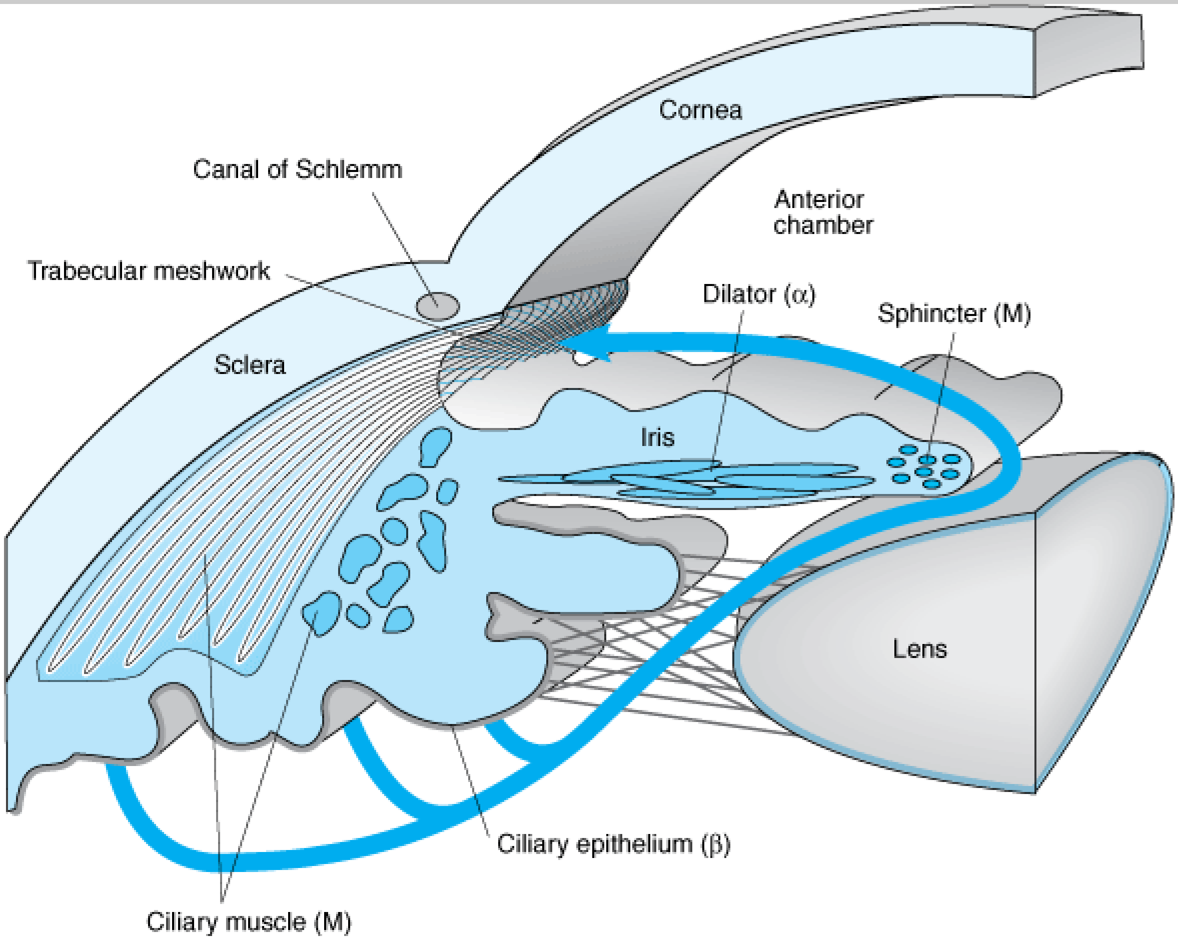
[5] Black widow spider venom.

The next four chapters provide many more examples of this useful diversity of autonomic control processes.

Pharmacology of the Eye

The eye is a good example of an organ with multiple autonomic nervous system (ANS) functions, controlled by several different autonomic receptors. As shown in Figure 6–9, the anterior chamber is the site of several tissues controlled by the ANS. These tissues include three different muscles (pupillary dilator and constrictor muscles in the iris and the ciliary muscle) and the secretory epithelium of the ciliary body.

Figure 6–9.



Structures of the anterior chamber of the eye. Tissues with significant autonomic functions and the associated ANS receptors are shown in this schematic diagram. Aqueous humor is secreted by the epithelium of the ciliary body, flows into the space in front of the iris, through the trabecular meshwork, and exits via the canal of Schlemm (arrow). Blockade of the β adrenoceptors associated with the ciliary epithelium causes decreased secretion of aqueous. Blood vessels (not shown) in the sclera are also under autonomic control and influence aqueous drainage.

Parasympathetic nerve activity and muscarinic cholinomimetics mediate contraction of the circular pupillary constrictor muscle and of the ciliary muscle. Contraction of the pupillary constrictor muscle causes **miosis**, a reduction in pupil size. Miosis is usually present in patients exposed to large systemic or small topical doses of cholinomimetics, especially organophosphate cholinesterase inhibitors. Ciliary muscle contraction causes **accommodation** of focus for near vision. Marked contraction of the ciliary muscle, which often occurs with cholinesterase inhibitor intoxication, is called *cyclospasm.* Ciliary muscle contraction also puts tension on the trabecular meshwork, opening its pores and facilitating outflow of the aqueous humor into the canal of Schlemm. Increased outflow reduces intraocular pressure, a very useful result in patients with glaucoma. All of these effects are prevented or reversed by muscarinic blocking drugs such as atropine.

Alpha adrenoceptors mediate contraction of the radially oriented pupillary dilator muscle fibers in the iris and result in mydriasis. This occurs during sympathetic discharge and when alpha agonist drugs such as phenylephrine are placed in the conjunctival sac. Beta-adrenoceptors on the ciliary epithelium facilitate the secretion of aqueous humor. Blocking these receptors (with β-blocking drugs) reduces the secretory activity and reduces intraocular pressure, providing another therapy for glaucoma.

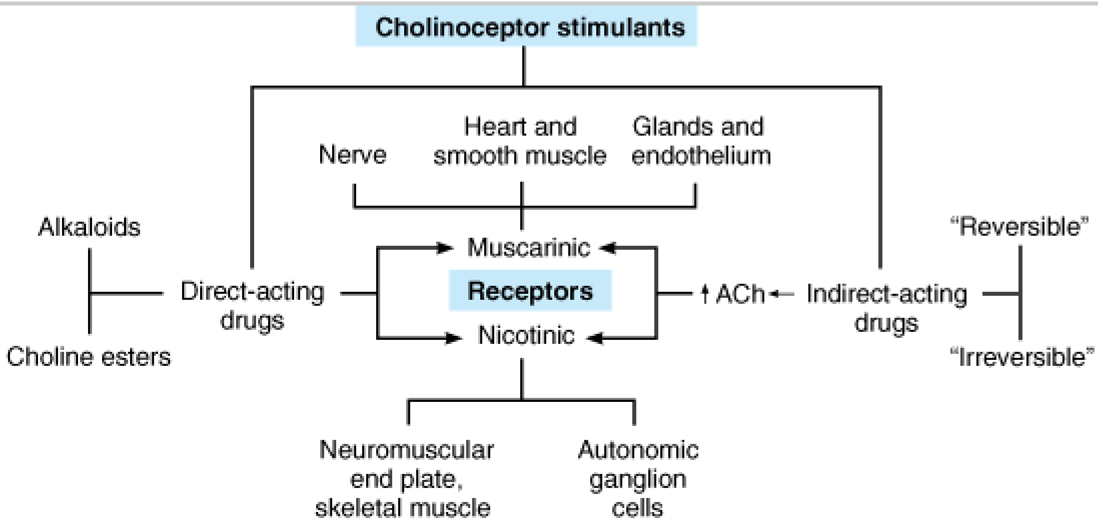
CHOLINOCEPTOR-ACTIVATING & CHOLINESTERASE-INHIBITING DRUGS: INTRODUCTION

Acetylcholine receptor stimulants and cholinesterase inhibitors together comprise a large group of drugs that mimic acetylcholine (cholinomimetic agents) (Figure 7–1). Cholinoceptor stimulants are classified pharmacologically by their spectrum of action depending on the type of receptor—muscarinic or nicotinic—that is activated. They are also classified by their mechanism of action because some cholinomimetic drugs bind directly to (and activate) cholinoceptors while others act indirectly by inhibiting the hydrolysis of endogenous acetylcholine.

Figure 7–1.



The major groups of cholinoceptor-activating drugs, receptors, and target tissues.

SPECTRUM OF ACTION OF CHOLINOMIMETIC DRUGS

Early studies of the parasympathetic nervous system showed that the alkaloid muscarine mimicked the effects of parasympathetic nerve discharge, ie, the effects were parasympathomimetic. Application of muscarine to ganglia and to autonomic effector tissues (smooth muscle, heart, exocrine glands) showed that the parasympathomimetic action of the alkaloid occurred through an action on receptors at effector cells, not those in ganglia. The effects of acetylcholine itself and of other cholinomimetic drugs at autonomic neuroeffector junctions are called parasympathomimetic effects, and are mediated by muscarinic receptors. In contrast, low concentrations of the alkaloid nicotine stimulated autonomic ganglia and skeletal muscle neuromuscular junctions but not autonomic effector cells. The ganglion and skeletal muscle receptors were therefore labeled nicotinic. When acetylcholine was later identified as the physiologic transmitter at both muscarinic and nicotinic receptors, both receptors were recognized as cholinoceptor subtypes.

Cholinoceptors are members of either G protein–linked (muscarinic) or ion channel (nicotinic) families on the basis of their transmembrane signaling mechanisms. Muscarinic receptors contain seven transmembrane domains whose third cytoplasmic loop is coupled to G proteins that function as transducers (see Figure 2–11). These receptors regulate the production of intracellular second messengers and modulate certain ion channels via their G proteins. Agonist selectivity is determined by the subtypes of muscarinic receptors and G proteins that are present in a given cell (Table 7–1). Muscarinic receptors are located on plasma membranes of cells in the central nervous system, in organs innervated by parasympathetic nerves as well as on some tissues that are not innervated by these nerves, eg, endothelial cells (Table 7–1), and on those tissues innervated by postganglionic sympathetic cholinergic nerves.

Table 7–1. Subtypes and Characteristics of Cholinoceptors.

Receptor Type	Other Names	Location	Structural Features	Postreceptor Mechanism
M_1		Nerves	Seven transmembrane segments, $G_{q/11}$ protein-linked	IP_3 , DAG cascade
M_2	Cardiac M_2	Heart, nerves, smooth muscle	Seven transmembrane segments, $G_{i/o}$ protein-linked	Inhibition of cAMP production, activation of K^+ channels
M_3		Glands, smooth muscle, endothelium	Seven transmembrane segments, $G_{q/11}$ protein-linked	IP_3 , DAG cascade

M_4

---

[1] Structure in *Torpedo* electric organ and fetal mammalian muscle. In adult muscle, the γ subunit is replaced by an ε subunit. Several different α and β subunits have been identified in different mammalian tissues (Lukas et al, 1999).

Nicotinic receptors are part of a transmembrane polypeptide whose subunits form cation-selective ion channels (see Figure 2–9). These receptors are located on plasma membranes of postganglionic cells in all autonomic ganglia, of muscles innervated by somatic motor fibers, and of some central nervous system neurons (see Figure 6–1).

Unselective cholinoceptor stimulants in sufficient dosage can produce very diffuse and marked alterations in organ system function because acetylcholine has multiple sites of action where it initiates both excitatory and inhibitory effects. Fortunately, drugs are available that have a degree of selectivity, so that desired effects can often be achieved while avoiding or minimizing adverse effects. Selectivity of action is based on several factors. Some drugs stimulate either muscarinic receptors or nicotinic receptors selectively. Some agents stimulate nicotinic receptors at neuromuscular junctions preferentially and have less effect on nicotinic receptors in ganglia. Organ selectivity can also be achieved by using appropriate routes of administration ("pharmacokinetic selectivity"). For example, muscarinic stimulants can be administered topically to the surface of the eye to modify ocular function while minimizing systemic effects.

MODE OF ACTION OF CHOLINOMIMETIC DRUGS

Direct-acting cholinomimetic agents bind to and activate muscarinic or nicotinic receptors (Figure 7–1). Indirect-acting agents produce their primary effects by inhibiting acetylcholinesterase, which hydrolyzes acetylcholine to choline and acetic acid (see Figure 6–3). By inhibiting acetylcholinesterase, the indirect-acting drugs increase the endogenous acetylcholine concentration in synaptic clefts and neuroeffector junctions. The excess acetylcholine, in turn, stimulates cholinoceptors to evoke increased responses. These drugs act primarily where acetylcholine is physiologically released and are thus *amplifiers* of endogenous acetylcholine.

Some cholinesterase inhibitors also inhibit butyrylcholinesterase (pseudocholinesterase). However, inhibition of butyrylcholinesterase plays little role in the action of indirect-acting cholinomimetic drugs because this enzyme is not important in the physiologic termination of synaptic acetylcholine action. Some quaternary cholinesterase inhibitors also have a modest direct action as well, eg, neostigmine, which activates neuromuscular nicotinic cholinoceptors directly in addition to blocking cholinesterase.

BASIC PHARMACOLOGY OF THE DIRECT-ACTING CHOLINOCEPTOR STIMULANTS

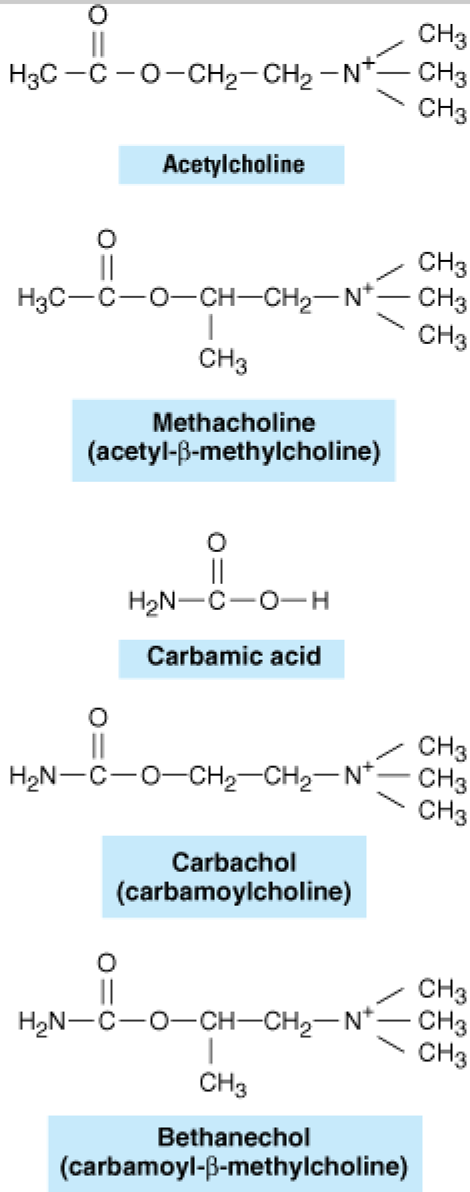
The direct-acting cholinomimetic drugs can be divided on the basis of chemical structure into esters of choline (including acetylcholine) and alkaloids (such as muscarine and nicotine). A few of these drugs are highly selective for the muscarinic or for the nicotinic receptor. Many have effects on both receptors; acetylcholine is typical.

Chemistry & Pharmacokinetics

STRUCTURE

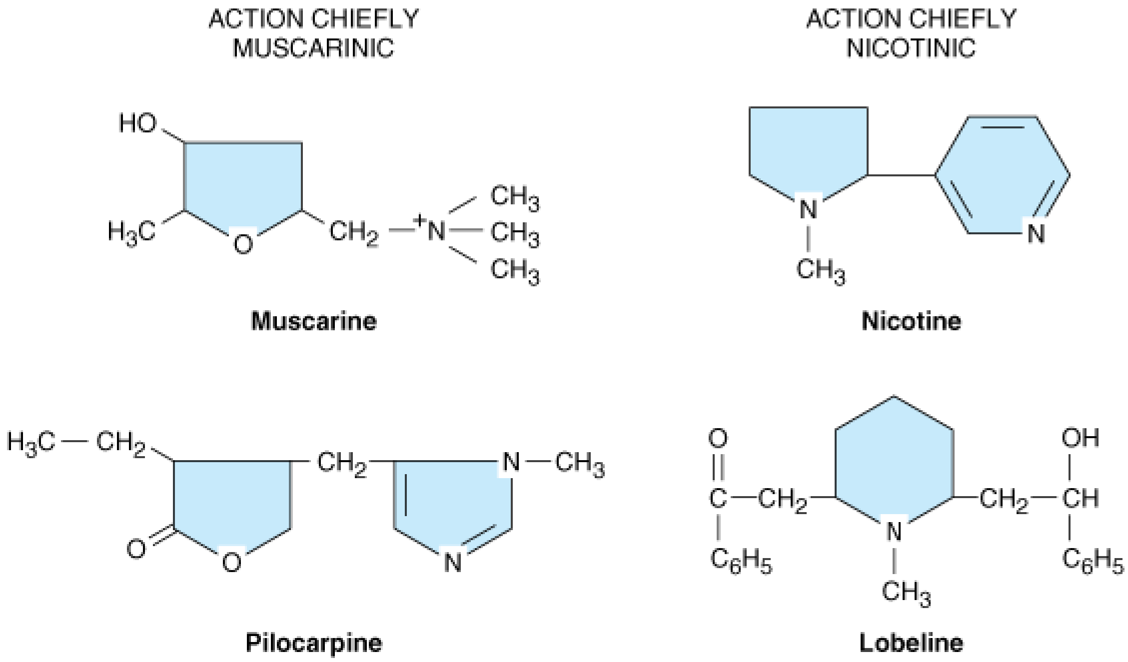
Four important choline esters that have been studied extensively are shown in Figure 7–2. Their permanently charged quaternary ammonium group renders them relatively insoluble in lipids. Many naturally occurring and synthetic cholinomimetic drugs that are not choline esters have been identified; a few of these are shown in Figure 7–3. The muscarinic receptor is strongly stereoselective: *(S)* -bethanechol is almost 1000 times more potent than *(R)* -bethanechol.

Figure 7–2.



Molecular structures of four choline esters and carbamic acid. Acetylcholine and methacholine are acetic acid esters of choline and β-methylcholine, respectively. Carbachol and bethanechol are carbamic acid esters of the same alcohols.

Figure 7–3.



Structures of some cholinomimetic alkaloids.

ABSORPTION, DISTRIBUTION, AND METABOLISM

Choline esters are poorly absorbed and poorly distributed into the central nervous system because they are hydrophilic. Although all are hydrolyzed in the gastrointestinal tract (and less active by the oral route), they differ markedly in their susceptibility to hydrolysis by cholinesterase. Acetylcholine is very rapidly hydrolyzed (see Chapter 6); large amounts must be infused intravenously to achieve concentrations sufficient to produce detectable effects. A large intravenous bolus injection has a brief effect, typically 5–20 seconds, whereas intramuscular and subcutaneous injections produce only local effects. Methacholine is more resistant to hydrolysis, and the carbamic acid esters carbachol and bethanechol are still more resistant to hydrolysis by cholinesterase and have correspondingly longer durations of action. The β-methyl group (methacholine, bethanechol) reduces the potency of these drugs at nicotinic receptors (Table 7–2).

Table 7–2. Properties of Choline Esters.

++

None

The tertiary natural cholinomimetic alkaloids (pilocarpine, nicotine, lobeline; Figure 7–3) are well absorbed from most sites of administration. Nicotine, a liquid, is sufficiently lipid-soluble to be absorbed across the skin. Muscarine, a quaternary amine, is less completely absorbed from the gastrointestinal tract than the tertiary amines but is nevertheless toxic when ingested, eg, in certain mushrooms, and even enters the brain. Lobeline is a plant derivative similar to nicotine. These amines are excreted chiefly by the kidneys. Acidification of the urine accelerates clearance of the tertiary amines.

Pharmacodynamics

MECHANISM OF ACTION

Activation of the parasympathetic nervous system modifies organ function by two major mechanisms. First, acetylcholine released from parasympathetic nerves activates muscarinic receptors on effector cells to alter organ function directly. Second, acetylcholine released from parasympathetic nerves interacts with muscarinic receptors on nerve terminals to inhibit the release of their neurotransmitter. By this mechanism, acetylcholine release and circulating muscarinic agonists indirectly alter organ function by modulating the effects of the parasympathetic and sympathetic nervous systems and perhaps nonadrenergic, noncholinergic (NANC) systems.

As indicated in Chapter 6, muscarinic receptor subtypes have been characterized by binding studies and cloned. Several cellular events occur when muscarinic receptors are activated, one or more of which might serve as second messengers for muscarinic activation. All muscarinic receptors appear to be of the G-protein coupled type (see Chapter 2 and Table 7–1). Muscarinic agonist binding activates the inositol trisphosphate (IP_3), diacylglycerol (DAG) cascade. Some evidence implicates DAG in the opening of smooth muscle calcium channels; IP_3 releases calcium from endoplasmic and sarcoplasmic reticulum. Muscarinic agonists also increase cellular cGMP concentrations. Activation of muscarinic receptors also increases potassium flux across cardiac cell membranes and decreases it in ganglion and smooth muscle cells. This effect is mediated by the binding of an activated G protein directly to the channel. Finally, muscarinic receptor activation in some tissues (eg, heart, intestine) inhibits adenylyl cyclase activity. Moreover, muscarinic agonists attenuate the activation of adenylyl cyclase and modulate the increase in cAMP levels induced by hormones such as catecholamines. These muscarinic effects on cAMP generation reduce the physiologic response of the organ to stimulatory hormones.

The mechanism of nicotinic receptor activation has been studied in great detail, taking advantage of three factors: (1) the receptor is present in extremely high concentration in the membranes of the electric organs of electric fish; (2) α-bungarotoxin, a component of certain snake venoms, binds tightly to the receptors and is readily labeled as a marker for isolation procedures; and (3) receptor activation results in easily measured electrical and ionic changes in the cells involved. The nicotinic receptor in muscle tissues is a pentamer of four types of glycoprotein subunits (one monomer occurs twice) with a total molecular weight of about 250,000 (see Figure 2–9). The neuronal nicotinic receptor consists of α and β subunits only (Table 7–1). Each subunit has four transmembrane segments. Each α subunit has a receptor site that, when occupied by a nicotinic agonist, causes a conformational change in the protein (channel opening) that allows sodium and potassium ions to diffuse rapidly down their concentration gradients. Binding of an agonist molecule by one of the two α subunit receptor sites only modestly increases the probability of channel opening; simultaneous binding of agonist by both of the receptor sites greatly enhances opening probability. Nicotinic receptor activation causes depolarization of the nerve cell or neuromuscular end plate membrane.

Prolonged agonist occupancy of the nicotinic receptor abolishes the effector response; that is, the postganglionic neuron stops firing (ganglionic effect), and the skeletal muscle cell relaxes (neuromuscular end plate effect). Furthermore, the continued presence of the nicotinic agonist prevents electrical recovery of the postjunctional membrane. Thus, a state of "depolarizing blockade" is induced that is refractory to reversal by other agonists. As noted below, this effect can be exploited for producing muscle paralysis.

ORGAN SYSTEM EFFECTS

Most of the direct organ system effects of muscarinic cholinoceptor stimulants are readily predicted from a knowledge of the effects of parasympathetic nerve stimulation (see Table 6–3) and the distribution of muscarinic receptors. Effects of a typical agent such as acetylcholine are listed in Table 7–3. The effects of nicotinic agonists are similarly predictable from a knowledge of the physiology of the autonomic ganglia and skeletal muscle motor end plate.

Table 7–3. Effects of Direct-Acting Cholinoceptor Stimulants. Only the Direct Effects Are Indicated; Homeostatic Responses to These Direct Actions May Be Important (See Text).

Organ	Response
Eye	
Sphincter muscle of iris	Contraction (miosis)
Ciliary muscle	Contraction for near vision
Heart	

Sinoatrial node

Decrease in rate (negative chronotropy)

Atria

Decrease in contractile strength (negative inotropy). Decrease in refractory period

Atrioventricular node

Decrease in conduction velocity (negative dromotropy). Increase in refractory period

Ventricles

Small decrease in contractile strength

Blood vessels

Arteries

Dilation (via EDRF). Constriction (high-dose direct effect)

Veins

Dilation (via EDRF). Constriction (high-dose direct effect)

Lung

Bronchial muscle

Contraction

Trigone and sphincter

Relaxation

Glands

Sweat, salivary, lacrimal, nasopharyngeal

Secretion

Eye

Muscarinic agonists instilled into the conjunctival sac cause contraction of the smooth muscle of the iris sphincter (resulting in miosis) and of the ciliary muscle (resulting in accommodation). As a result, the iris is pulled away from the angle of the anterior chamber, and the trabecular meshwork at the base of the ciliary muscle is opened. Both effects facilitate aqueous humor outflow into the canal of Schlemm, which drains the anterior chamber.

Cardiovascular System

The primary cardiovascular effects of muscarinic agonists are reduction in peripheral vascular resistance and changes in heart rate. The direct effects listed in Table 7–3 are modified by important homeostatic reflexes, as described in Chapter 6 and depicted in Figure 6–7. Intravenous infusions of minimally effective doses of acetylcholine in humans (eg, 20–50 mcg/min) cause vasodilation, resulting in a reduction in blood pressure, often accompanied by a reflex increase in heart rate. Larger doses of acetylcholine produce bradycardia and decrease atrioventricular node conduction velocity in addition to hypotension.

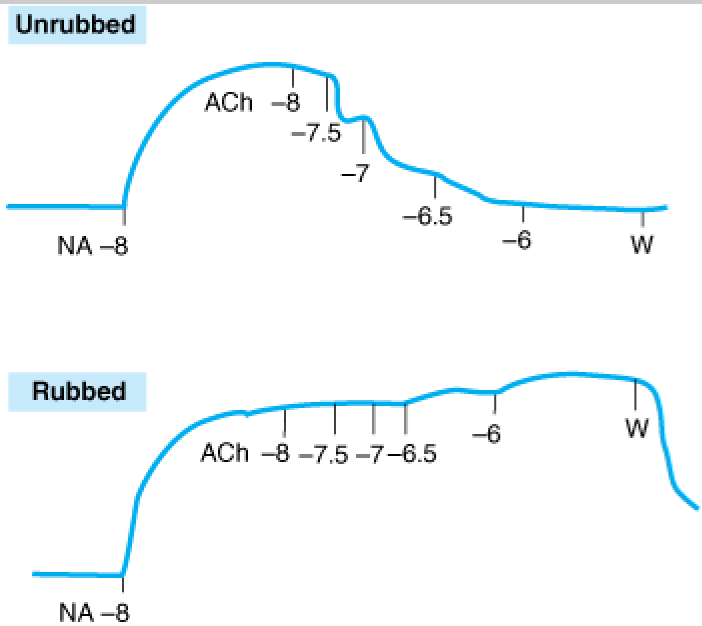
The direct cardiac actions of muscarinic stimulants include the following: (1) an increase in a potassium current ($I_{K(ACh)}$) in atrial muscle cells and in the cells of the sinoatrial and atrioventricular nodes as well; (2) a decrease in the slow inward calcium current (I_{Ca}) in heart cells; and (3) a reduction in the hyperpolarization-activated current (I_f) that underlies diastolic depolarization. All of these actions are mediated by M_2 receptors and contribute to slowing the pacemaker rate. Effects (1) and (2) cause hyperpolarization and decrease the contractility of atrial cells. Predictably, carbachol does not inhibit sinoatrial rate in animals with mutated M_2 receptors.

The direct slowing of sinoatrial rate and atrioventricular conduction that is produced by muscarinic agonists is often opposed by reflex sympathetic discharge, elicited by the decrease in blood pressure. The resultant sympathetic-parasympathetic interaction is complex because of the muscarinic modulation of sympathetic influences that occurs by inhibition of norepinephrine release and by postjunctional cellular effects. Muscarinic receptors that are present on postganglionic parasympathetic nerve terminals allow neurally released acetylcholine to inhibit its own secretion. The neuronal muscarinic receptors need not be the same subtype as found on effector cells. Therefore, the net effect on heart rate depends on local concentrations of the agonist in the heart and in the vessels and on the level of reflex responsiveness.

Parasympathetic innervation of the ventricles is much less extensive than that of the atria; activation of ventricular muscarinic receptors causes much less physiologic effect than that seen in atria. However, during sympathetic nerve stimulation, the effects of muscarinic agonists on ventricular function are clearly evident because of muscarinic modulation of sympathetic effects ("accentuated antagonism").

In the intact organism, muscarinic agonists produce marked vasodilation. However, earlier studies of isolated blood vessels often showed a contractile response to these agents. It is now known that acetylcholine-induced vasodilation requires the presence of intact endothelium (Figure 7–4). Muscarinic agonists release endothelium-derived relaxing factor (EDRF) from the endothelial cells that relaxes smooth muscle. Isolated vessels prepared with the endothelium preserved consistently reproduce the vasodilation seen in the intact organism. EDRF appears to be largely nitric oxide (NO). This substance activates guanylyl cyclase and increases cGMP in smooth muscle, resulting in relaxation (see Figure 12–2).

Figure 7–4.



Activation of endothelial cell muscarinic receptors by acetylcholine releases endothelium-derived relaxing factor (nitric oxide) (EDRF [NO]), which causes relaxation of vascular smooth muscle precontracted with norepinephrine. Removal of the endothelium by rubbing eliminates the relaxant effect and reveals contraction caused by direct action of acetylcholine on vascular smooth muscle. (NA, noradrenaline [norepinephrine]; ACh, acetylcholine. Numbers indicate the log concentration applied at the time indicated.) (Modified and reproduced, with permission, from Furchgott RF, Zawadzki JV: The obligatory role of endothelial cells in the relaxation of arterial smooth muscle by acetylcholine. Nature 1980;288:373.)

The cardiovascular effects of all of the choline esters are similar to those of acetylcholine, the main difference being in their potency and duration of action. Because of the resistance of methacholine, carbachol, and bethanechol to acetylcholinesterase, lower doses given intravenously are sufficient to produce effects similar to those of acetylcholine, and the duration of action of these synthetic choline esters is longer. The cardiovascular effects of most of the cholinomimetic natural alkaloids and the synthetic analogs are also generally similar to those of acetylcholine.

Pilocarpine is an interesting exception to the above statement. If given intravenously (an experimental exercise), it may produce hypertension after a brief initial hypotensive response. The longer-lasting hypertensive effect can be traced to sympathetic ganglionic discharge caused by activation of postganglionic cell membrane M_1 receptors, which close K^+ channels and elicit slow excitatory (depolarizing) postsynaptic potentials. This effect, like the hypotensive effect, can be blocked by atropine, an antimuscarinic drug.

Respiratory System

Muscarinic stimulants contract the smooth muscle of the bronchial tree. In addition, the glands of the tracheobronchial mucosa are stimulated to secrete. This combination of effects can occasionally cause symptoms, especially in individuals with asthma.

Gastrointestinal Tract

Administration of muscarinic agonists, like parasympathetic nervous system stimulation, increases the secretory and motor activity of the gut. The salivary and gastric glands are strongly stimulated; the pancreas and small intestinal glands less so. Peristaltic activity is increased throughout the gut, and most sphincters are relaxed. Stimulation of contraction in this organ system involves depolarization of the smooth muscle cell membrane and increased calcium influx. Muscarinic agonists do not cause contraction of the ileum in mutant mice lacking M_2 and M_3 receptors. The M_3 receptor is required for direct activation of smooth muscle contraction while the M_2 receptor reduces cAMP formation and relaxation caused by sympathomimetic drugs.

Genitourinary Tract

Muscarinic agonists stimulate the detrusor muscle and relax the trigone and sphincter muscles of the bladder, thus promoting voiding. The function of M_2 and M_3 receptors in the urinary bladder appears to be the same as in intestinal smooth muscle. The human uterus is not notably sensitive to muscarinic agonists.

Miscellaneous Secretory Glands

Muscarinic agonists stimulate secretion by thermoregulatory sweat, lacrimal, and nasopharyngeal glands.

Central Nervous System

The central nervous system contains both muscarinic and nicotinic receptors, the brain being relatively richer in muscarinic sites and the spinal cord containing a preponderance of nicotinic sites. The physiologic roles of these receptors are discussed in Chapter 21.

The role of muscarinic receptors in the central nervous system has been confirmed by experiments in knockout mice. The central nervous system effects of the synthetic muscarinic agonist oxotremorine (tremor, hypothermia, and antinociception) were also lacking in mice with homozygously mutated M_2 receptors. Animals lacking M_3 receptors, especially those in the hypothalamus, had reduced appetite and diminished body fat mass. Knockout of M_1 receptors was associated with different changes in the peripheral and central nervous systems. Oxotremorine did not suppress M current in sympathetic ganglia, and pilocarpine did not induce epileptic seizures in M_1 mutant mice.

In spite of the smaller ratio of nicotinic to muscarinic receptors in the brain, nicotine and lobeline (Figure 7–3) have important effects on the brainstem and cortex. The mild alerting action of nicotine absorbed from inhaled tobacco smoke is the best-known of these effects. In high concentrations, nicotine induces tremor, emesis, and stimulation of the respiratory center. At still higher levels, nicotine causes convulsions, which may terminate in fatal coma. The lethal effects on the central nervous system and the fact that nicotine is readily absorbed form the basis for the use of nicotine as an insecticide.

Peripheral Nervous System

Autonomic ganglia are important sites of nicotinic synaptic action. The nicotinic agents shown in Figure 7–3 cause marked activation of these nicotinic receptors and initiate action potentials in postganglionic neurons (see Figure 6–8). Nicotine itself has a somewhat greater affinity for neuronal than for skeletal muscle nicotinic receptors. The action is the same on both parasympathetic and sympathetic ganglia. The initial response therefore often resembles simultaneous discharge of both the parasympathetic and the sympathetic nervous systems. In the case of the cardiovascular system, the effects of nicotine are chiefly sympathomimetic. Dramatic hypertension is produced by parenteral injection of nicotine; sympathetic tachycardia may alternate with a bradycardia mediated by vagal discharge. In the gastrointestinal and urinary tracts, the effects are largely parasympathomimetic: nausea, vomiting, diarrhea, and voiding of urine are commonly observed. Prolonged exposure may result in depolarizing blockade of the ganglia.

Neuronal nicotinic receptors are present on sensory nerve endings—especially afferent nerves in coronary arteries and the carotid and aortic bodies as well as on the glomus cells of the latter. Activation of these receptors by nicotinic stimulants and of muscarinic receptors on glomus cells by muscarinic stimulants elicits complex medullary responses, including respiratory alterations and vagal discharge.

Neuromuscular Junction

The nicotinic receptors on the neuromuscular end plate apparatus are similar but not identical to the receptors in the autonomic ganglia (Table 7–1). Both types respond to acetylcholine and nicotine. (However, as discussed in Chapter 8, the receptors differ in their structural requirements for nicotinic blocking drugs.) When a nicotinic agonist is applied directly (by iontophoresis or by intra-arterial injection), an immediate depolarization of the end plate results, caused by an increase in permeability to sodium and potassium ions. The contractile response varies from disorganized fasciculations of independent motor units to a strong contraction of the entire muscle depending on the synchronization of depolarization of end plates throughout the muscle. Depolarizing nicotinic agents that are not rapidly hydrolyzed (like nicotine itself) cause rapid development of depolarization blockade; transmission blockade persists even when the membrane has repolarized (discussed further in Chapters 8 and 27). This block is manifested as flaccid paralysis in the case of skeletal muscle.

BASIC PHARMACOLOGY OF THE INDIRECT-ACTING CHOLINOMIMETICS

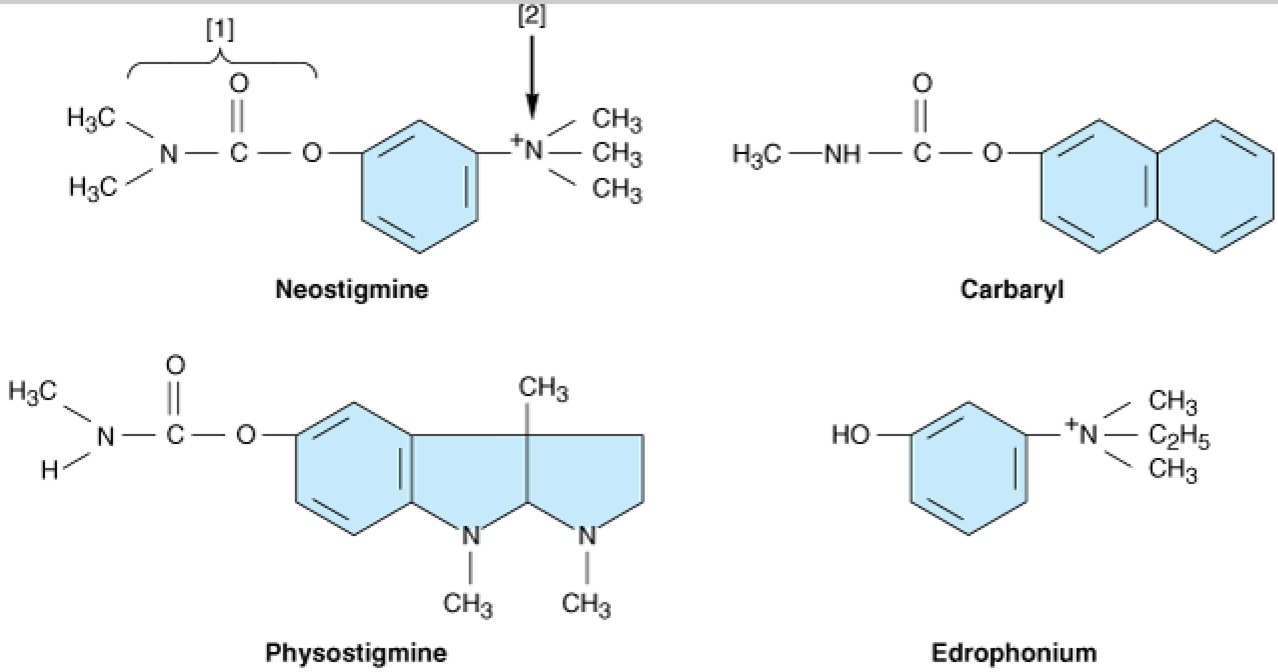
The actions of acetylcholine released from autonomic and somatic motor nerves are terminated by enzymatic hydrolysis of the molecule. Hydrolysis is accomplished by the action of acetylcholinesterase, which is present in high concentrations in cholinergic synapses. The indirect-acting cholinomimetics have their primary effect at the active site of this enzyme, although some also have direct actions at nicotinic receptors. The chief differences between members of the group are chemical and pharmacokinetic—their pharmacodynamic properties are almost identical.

Chemistry & Pharmacokinetics

STRUCTURE

There are three chemical groups of cholinesterase inhibitors: (1) simple alcohols bearing a quaternary ammonium group, eg, edrophonium; (2) carbamic acid esters of alcohols bearing quaternary or tertiary ammonium groups (carbamates, eg, neostigmine); and (3) organic derivatives of phosphoric acid (organophosphates, eg, echothiophate). Examples of the first two groups are shown in Figure 7–5 . Edrophonium, neostigmine, and pyridostigmine are synthetic quaternary ammonium agents used in medicine. Physostigmine (eserine) is a naturally occurring tertiary amine of greater lipid solubility that is also used in therapeutics. Carbaryl (carbaril) is typical of a large group of carbamate insecticides designed for very high lipid solubility, so that absorption into the insect and distribution to its central nervous system are very rapid.

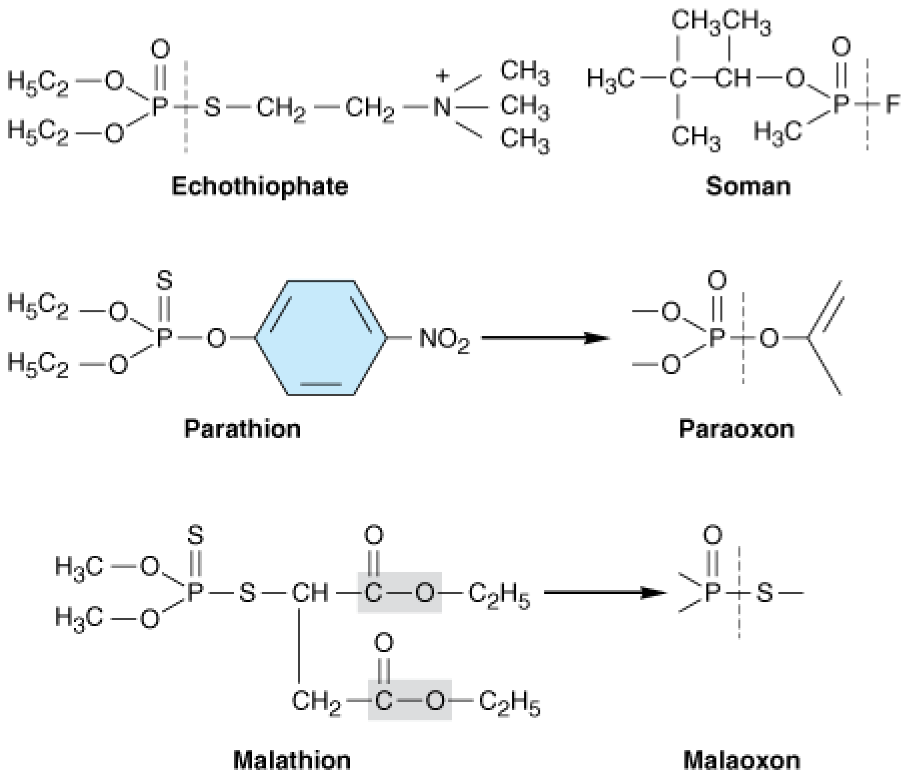
Figure 7–5.



Cholinesterase inhibitors. Neostigmine exemplifies the typical ester composed of carbamic acid ([1]) and a phenol bearing a quaternary ammonium group ([2]). Physostigmine, a naturally occurring carbamate, is a tertiary amine. Edrophonium is not an ester but binds to the active site of the enzyme.

A few of the estimated 50,000 organophosphates are shown in Figure 7–6. Many of the organophosphates (echothiophate is an exception) are highly lipid-soluble liquids. Echothiophate, a thiocholine derivative, is of clinical value because it retains the very long duration of action of other organophosphates but is more stable in aqueous solution. Soman is an extremely potent "nerve gas." Parathion and malathion are thiophosphate prodrugs that are inactive as such; they are converted to the phosphate derivatives in animals and plants and are used as insecticides.

Figure 7–6.



Structures of some organophosphate cholinesterase inhibitors. The dashed lines indicate the bond that is hydrolyzed in binding to the enzyme. The shaded ester bonds in malathion represent the points of detoxification of the molecule in mammals and birds.

ABSORPTION, DISTRIBUTION, AND METABOLISM

Absorption of the quaternary carbamates from the conjunctiva, skin, and lungs is predictably poor, since their permanent charge renders them relatively insoluble in lipids. Thus, much larger doses are required for oral administration than for parenteral injection. Distribution into the central nervous system is negligible. Physostigmine, in contrast, is well absorbed from all sites and can be used topically in the eye (see Table 7–4). It is distributed into the central nervous system and is more toxic than the more polar quaternary carbamates. The carbamates are relatively stable in aqueous solution but can be metabolized by nonspecific esterases in the body as well as by cholinesterase. However, the duration of their effect is determined chiefly by the stability of the inhibitor-enzyme complex (see Mechanism of Action, below), not by metabolism or excretion.

Table 7–4. Therapeutic Uses and Durations of Action of Cholinesterase Inhibitors.

Uses
Approximate Duration of Action

Alcohols

Edrophonium

Myasthenia gravis, ileus, arrhythmias

Ambenonium

Myasthenia gravis

4–8 hours

Demecarium

Glaucoma

4–6 hours

Organophosphates

Echothiophate

Glaucoma

100 hours

The organophosphate cholinesterase inhibitors (except for echothiophate) are well absorbed from the skin, lung, gut, and conjunctiva—thereby making them dangerous to humans and highly effective as insecticides. They are relatively less stable than the carbamates when dissolved in water and thus have a limited half-life in the environment (compared with the other major class of insecticides, the halogenated hydrocarbons, eg, DDT). Echothiophate is highly polar and more stable than most other organophosphates. When prepared in aqueous solution for ophthalmic use, it retains activity for weeks.

The thiophosphate insecticides (parathion, malathion, and related compounds) are quite lipid-soluble and are rapidly absorbed by all routes. They must be activated in the body by conversion to the oxygen analogs (Figure 7–6), a process that occurs rapidly in both insects and vertebrates. Malathion and a few other organophosphate insecticides are also rapidly metabolized by other pathways to inactive products in birds and mammals but not in insects; these agents are therefore considered safe enough for sale to the general public. Unfortunately, fish cannot detoxify malathion, and significant numbers of fish have died from the heavy use of this agent on and near waterways. Parathion is not detoxified effectively in vertebrates; thus, it is considerably more dangerous than malathion to humans and livestock and is not available for general public use.

All of the organophosphates except echothiophate are distributed to all parts of the body, including the central nervous system. Poisoning with these agents therefore includes an important component of central nervous system toxicity.

Pharmacodynamics

MECHANISM OF ACTION

Acetylcholinesterase is the primary target of these drugs, but butyrylcholinesterase is also inhibited. Acetylcholinesterase is an extremely active enzyme. In the initial catalytic step, acetylcholine binds to the enzyme's active site and is hydrolyzed, yielding free choline and the acetylated enzyme. In the second step, the covalent acetylenzyme bond is split, with the addition of water (hydration). The entire process takes place in approximately 150 microseconds.

All of the cholinesterase inhibitors increase the concentration of endogenous acetylcholine at cholinoceptors by inhibiting acetylcholinesterase. However, the molecular details of their interaction with the enzyme vary according to the three chemical subgroups mentioned above.

The first group, of which edrophonium is the major example, consists of quaternary alcohols. These agents reversibly bind electrostatically and by hydrogen bonds to the active site, thus preventing access of acetylcholine. The enzyme-inhibitor complex does not involve a covalent bond and is correspondingly short-lived (on the order of 2–10 minutes). The second group consists of carbamate esters, eg, neostigmine and physostigmine. These agents undergo a two-step hydrolysis sequence analogous to that described for acetylcholine. However, the covalent bond of the *carbamoylated* enzyme is considerably more resistant to the second (hydration) process, and this step is correspondingly prolonged (on the order of 30 minutes to 6 hours). The third group consists of the organophosphates. These agents also undergo initial binding and hydrolysis by the enzyme, resulting in a *phosphorylated* active site. The covalent phosphorus-enzyme bond is extremely stable and hydrolyzes in water at a very slow rate (hundreds of hours). After the initial binding-hydrolysis step, the phosphorylated enzyme complex may undergo a process called aging. This process apparently involves the breaking of one of the oxygen-phosphorus bonds of the inhibitor and further strengthens the phosphorus-enzyme bond. The rate of aging varies with the particular organophosphate compound. If given before aging has occurred, strong nucleophiles like pralidoxime are able to break the phosphorus-enzyme bond and can be used as "cholinesterase regenerator" drugs for organophosphate insecticide poisoning (see Chapter 8). Once aging has occurred, the enzyme-inhibitor complex is even more stable and is more difficult to break, even with oxime regenerator compounds.

The organophosphate inhibitors are sometimes referred to as "irreversible" cholinesterase inhibitors, and edrophonium and the carbamates are considered "reversible" inhibitors because of the marked differences in duration of action. However, the molecular mechanisms of action of the three groups do not support this simplistic description.

ORGAN SYSTEM EFFECTS

The most prominent pharmacologic effects of cholinesterase inhibitors are on the cardiovascular and gastrointestinal systems, the eye, and the skeletal muscle neuromuscular junction. Because the primary action is to amplify the actions of endogenous acetylcholine, the effects are similar (but not always identical) to the effects of the direct-acting cholinomimetic agonists.

Central Nervous System

In low concentrations, the lipid-soluble cholinesterase inhibitors cause diffuse activation on the electroencephalogram and a subjective alerting response. In higher concentrations, they cause generalized convulsions, which may be followed by coma and respiratory arrest.

Eye, Respiratory Tract, Gastrointestinal Tract, Urinary Tract

The effects of the cholinesterase inhibitors on these organ systems, all of which are well innervated by the parasympathetic nervous system, are qualitatively quite similar to the effects of the direct-acting cholinomimetics (Table 7–3).

Cardiovascular System

The cholinesterase inhibitors can increase activity in both sympathetic and parasympathetic ganglia supplying the heart and at the acetylcholine receptors on neuroeffector cells (cardiac and vascular smooth muscles) that receive cholinergic innervation.

In the heart, the effects on the parasympathetic limb predominate. Thus, cholinesterase inhibitors such as edrophonium, physostigmine, or neostigmine mimic the effects of vagal nerve activation on the heart. Negative chronotropic, dromotropic, and inotropic effects are produced, and cardiac output falls. The fall in cardiac output is attributable to bradycardia, decreased atrial contractility, and some reduction in ventricular contractility. The latter effect occurs as a result of prejunctional inhibition of norepinephrine release as well as inhibition of postjunctional cellular sympathetic effects.

Cholinesterase inhibitors have less marked effects on vascular smooth muscle and on blood pressure than direct-acting muscarinic agonists. This is because indirect-acting drugs can modify the tone of only those vessels that are innervated by cholinergic nerves and because the net effects on vascular tone may reflect activation of both the parasympathetic and sympathetic nervous systems. The cholinomimetic effect at the smooth muscle effector tissue is minimal since few vascular beds receive cholinergic innervation. Activation of sympathetic ganglia may increase vascular resistance.

The *net* cardiovascular effects of moderate doses of cholinesterase inhibitors therefore consist of modest bradycardia, a fall in cardiac output, and no change or a modest fall in blood pressure. Large (toxic) doses of these drugs cause more marked bradycardia (occasionally tachycardia) and hypotension.

Neuromuscular Junction

The cholinesterase inhibitors have important therapeutic and toxic effects at the skeletal muscle neuromuscular junction. Low (therapeutic) concentrations moderately prolong and intensify the actions of physiologically released acetylcholine. This increases strength of contraction, especially in muscles weakened by curare-like neuromuscular blocking agents or by myasthenia gravis. At higher concentrations, the accumulation of acetylcholine may result in fibrillation of muscle fibers. Antidromic firing of the motor neuron may also occur, resulting in fasciculations that involve an entire motor unit. With marked inhibition of acetylcholinesterase, depolarizing neuromuscular blockade occurs and that may be followed by a phase of nondepolarizing blockade as seen with succinylcholine (see Table 27–2 and Figure 27–7).

Some quaternary carbamate cholinesterase inhibitors, eg, neostigmine, have an additional *direct* nicotinic agonist effect at the neuromuscular junction. This may contribute to the effectiveness of these agents as therapy for myasthenia.

CLINICAL PHARMACOLOGY OF THE CHOLINOMIMETICS

The major therapeutic uses of the cholinomimetics are for diseases of the eye (glaucoma, accommodative esotropia), the gastrointestinal and urinary tracts (postoperative atony, neurogenic bladder), the neuromuscular junction (myasthenia gravis, curare-induced neuromuscular paralysis), and very rarely, the heart (certain atrial arrhythmias). Cholinesterase inhibitors are occasionally used in the treatment of atropine overdosage. Several newer cholinesterase inhibitors are being used to treat patients with Alzheimer's disease.

Clinical Uses

THE EYE

Glaucoma is a disease characterized by increased intraocular pressure. Muscarinic stimulants and cholinesterase inhibitors reduce intraocular pressure by causing contraction of the ciliary body so as to facilitate outflow of aqueous humor and perhaps also by diminishing the rate of its secretion (see Figure 6–9). In the past, glaucoma was treated with either direct agonists (pilocarpine, methacholine, carbachol) or cholinesterase inhibitors (physostigmine, demecarium, echothiophate, isoflurophate). For chronic glaucoma, these drugs have been largely replaced by topical β-blockers and prostaglandin derivatives.

Acute angle-closure glaucoma is a medical emergency that is frequently treated initially with drugs but usually requires surgery for permanent correction. Initial therapy often consists of a combination of a direct muscarinic agonist and a cholinesterase inhibitor (eg, pilocarpine plus physostigmine) as well as other drugs. Once the intraocular pressure is controlled and the danger of vision loss is diminished, the patient can be prepared for corrective surgery (iridectomy). Open-angle glaucoma and some cases of secondary glaucoma are chronic diseases that are not amenable to traditional surgical correction although newer laser techniques appear to be useful. Other treatments for glaucoma are described in Treatment of Glaucoma in Chapter 10 .

Accommodative esotropia (strabismus caused by hypermetropic accommodative error) in young children is sometimes diagnosed and treated with cholinomimetic agonists. Dosage is similar to or higher than that used for glaucoma.

GASTROINTESTINAL AND URINARY TRACTS

In clinical disorders that involve depression of smooth muscle activity without obstruction, cholinomimetic drugs with direct or indirect muscarinic effects may be helpful. These disorders include postoperative ileus (atony or paralysis of the stomach or bowel following surgical manipulation) and congenital megacolon. Urinary retention may occur postoperatively or postpartum or may be secondary to spinal cord injury or disease (neurogenic bladder). Cholinomimetics are also sometimes used to increase the tone of the lower esophageal sphincter in patients with reflux esophagitis. Of the choline esters, bethanechol is the most widely used for these disorders. For gastrointestinal problems, it is usually administered orally in a dose of 10–25 mg three or four times daily. In patients with urinary retention, bethanechol can be given subcutaneously in a dose of 5 mg and repeated in 30 minutes if necessary. Of the cholinesterase inhibitors, neostigmine is the most widely used for these applications. For paralytic ileus or atony of the urinary bladder, neostigmine can be given subcutaneously in a dose of 0.5–1 mg. If patients are able to take the drug by mouth, neostigmine can be given orally in a dose of 15 mg. In all of these situations, the clinician must be certain that there is no mechanical obstruction to outflow prior to using the cholinomimetic. Otherwise, the drug may exacerbate the problem and may even cause perforation as a result of increased pressure.

Pilocarpine has long been used to increase salivary secretion. Cevimeline, a quinuclidine derivative of acetylcholine, is a new direct-acting muscarinic agonist used for the treatment of dry mouth associated with Sjögren's syndrome.

NEUROMUSCULAR JUNCTION

Myasthenia gravis is a disease affecting skeletal muscle neuromuscular junctions. An autoimmune process causes production of antibodies that bind to the α subunits of the nicotinic receptor. This effect causes accelerated degradation of the receptor and blockade of acetylcholine binding to receptors on muscle end plates. Frequent findings are ptosis, diplopia, difficulty in speaking and swallowing, and extremity weakness. Severe disease may affect all the muscles, including those necessary for respiration. The disease resembles the neuromuscular paralysis produced by *d* -tubocurarine and similar nondepolarizing neuromuscular blocking drugs (see Chapter 27). Patients with myasthenia are exquisitely sensitive to the action of curariform drugs and other drugs that interfere with neuromuscular transmission, eg, aminoglycoside antibiotics.

Cholinesterase inhibitors—but not direct-acting acetylcholine receptor agonists—are extremely valuable as therapy for myasthenia. Almost all patients are also treated with immunosuppressant drugs and some with thymectomy.

Edrophonium is sometimes used as a diagnostic test for myasthenia. A 2 mg dose is injected intravenously after baseline measurements of muscle strength have been obtained. If no reaction occurs after 45 seconds, an additional 8 mg may be injected. If the patient has myasthenia gravis, an improvement in muscle strength that lasts about 5 minutes will usually be observed.

Edrophonium is also used to assess the adequacy of treatment with the longer-acting cholinesterase inhibitors in patients with myasthenia gravis. If excessive amounts of cholinesterase inhibitor have been used, patients may become paradoxically weak because of nicotinic depolarizing blockade of the motor end plate. These patients may also exhibit symptoms of excessive stimulation of muscarinic receptors (abdominal cramps, diarrhea, increased salivation, excessive bronchial secretions, miosis, bradycardia). Small doses of edrophonium (1–2 mg intravenously) will produce no relief or even worsen weakness if the patient is receiving excessive cholinesterase inhibitor therapy. On the other hand, if the patient improves with edrophonium, an increase in cholinesterase inhibitor dosage may be indicated. Clinical situations in which severe myasthenia (myasthenic crisis) must be distinguished from excessive drug therapy (cholinergic crisis) usually occur in very ill myasthenic patients and must be managed in hospital with adequate emergency support systems (eg, mechanical ventilators) available.

Long-term therapy for myasthenia gravis is usually accomplished with pyridostigmine; neostigmine or ambenonium are alternatives. The doses are titrated to optimum levels based on changes in muscle strength. These agents are relatively short-acting and therefore require frequent dosing (every 6 hours for pyridostigmine and ambenonium and every 4 hours for neostigmine; Table 7–4). Sustained-release preparations are available but should be used only at night and if needed. Longer-acting cholinesterase inhibitors such as the organophosphate agents are not used, because the dose requirement in this disease changes too rapidly to permit smooth control with long-acting drugs.

If muscarinic effects of such therapy are prominent, they can be controlled by the administration of antimuscarinic drugs such as atropine. Frequently, tolerance to the muscarinic effects of the cholinesterase inhibitors develops, so atropine treatment is not required.

Neuromuscular blockade is frequently produced as an adjunct to surgical anesthesia, using nondepolarizing neuromuscular relaxants such as pancuronium and newer agents (see Chapter 27). Following surgery, it is usually desirable to reverse this pharmacologic paralysis promptly. This can be easily accomplished with cholinesterase inhibitors; neostigmine and edrophonium are the drugs of choice. They are given intravenously or intramuscularly for prompt effect.

HEART

The short-acting cholinesterase inhibitor edrophonium was used to treat supraventricular tachyarrhythmias, particularly paroxysmal supraventricular tachycardia. In this application, edrophonium has been replaced by newer drugs (adenosine and the calcium channel blockers verapamil and diltiazem).

ANTIMUSCARINIC DRUG INTOXICATION

Atropine intoxication is potentially lethal in children (see Chapter 8) and may cause prolonged severe behavioral disturbances and arrhythmias in adults. The tricyclic antidepressants, when taken in overdosage (often with suicidal intent), also cause severe muscarinic blockade (see Chapter 30). The muscarinic receptor blockade produced by all these agents is competitive in nature and can be overcome by increasing the amount of endogenous acetylcholine present at the neuroeffector junctions. Theoretically, a cholinesterase inhibitor could be used to reverse these effects. Physostigmine has been used for this application, because it enters the central nervous system and reverses the central as well as the peripheral signs of muscarinic blockade. However, as noted previously, physostigmine itself can produce dangerous central nervous system effects, and such therapy is therefore used only in patients with dangerous elevation of body temperature or very rapid supraventricular tachycardia.

CENTRAL NERVOUS SYSTEM

Tacrine is a drug with anticholinesterase and other cholinomimetic actions that has been used for the treatment of mild to moderate Alzheimer's disease. Tacrine's efficacy is modest and hepatic toxicity is significant. Donepezil, galantamine, and rivastigmine are newer, more selective acetylcholinesterase inhibitors that appear to have the same modest clinical benefit as tacrine in treatment of cognitive dysfunction in Alzheimer's patients. Donepezil may be given once daily because of its long half-life, and it lacks the hepatotoxic effect of tacrine. However, no comparative trials of these newer drugs and tacrine have been reported. These drugs are discussed in Chapter 61.

Varenicline is a new direct-acting nicotinic agonist that is approved for use in smoking cessation treatment. It appears to have some selectivity for the $\alpha_4\beta_2$ isoform of the N_N receptor. It is orally active and has a half-life of 14–20 hours. Toxicity includes nausea, headache, and sleep disturbances.

Toxicity

The toxic potential of the cholinoceptor stimulants varies markedly depending on their absorption, access to the central nervous system, and metabolism.

DIRECT-ACTING MUSCARINIC STIMULANTS

Drugs such as pilocarpine and the choline esters cause predictable signs of muscarinic excess when given in overdosage. These effects include nausea, vomiting, diarrhea, urinary urgency, salivation, sweating, cutaneous vasodilation, and bronchial constriction. The effects are all blocked competitively by atropine and its congeners.

Certain mushrooms, especially those of the genus *Inocybe,* contain muscarinic alkaloids. Ingestion of these mushrooms causes typical signs of muscarinic excess within 15–30 minutes. Treatment is with atropine, 1–2 mg parenterally. (*Amanita muscaria,* the first source of muscarine, contains very low concentrations of the alkaloid.)

DIRECT-ACTING NICOTINIC STIMULANTS

Nicotine itself is the only common cause of this type of poisoning. The acute toxicity of the alkaloid is well-defined but much less important than the chronic effects associated with smoking. In addition to tobacco products, nicotine is also used in insecticides.

Acute Toxicity

The fatal dose of nicotine is approximately 40 mg, or 1 drop of the pure liquid. This is the amount of nicotine in two regular cigarettes. Fortunately, most of the nicotine in cigarettes is destroyed by burning or escapes via the "sidestream" smoke. Ingestion of nicotine insecticides or of tobacco by infants and children is usually followed by vomiting, limiting the amount of the alkaloid absorbed.

The toxic effects of a large dose of nicotine are simple extensions of the effects described previously. The most dangerous are (1) central stimulant actions, which cause convulsions and may progress to coma and respiratory arrest; (2) skeletal muscle end plate depolarization, which may lead to depolarization blockade and respiratory paralysis; and (3) hypertension and cardiac arrhythmias.

Treatment of acute nicotine poisoning is largely symptom-directed. Muscarinic excess resulting from parasympathetic ganglion stimulation can be controlled with atropine. Central stimulation is usually treated with parenteral anticonvulsants such as diazepam. Neuromuscular blockade is not responsive to pharmacologic treatment and may require mechanical respiration.

Fortunately, nicotine is metabolized and excreted relatively rapidly. Patients who survive the first 4 hours usually recover completely if hypoxia and brain damage have not occurred.

Chronic Nicotine Toxicity

The health costs of tobacco smoking to the smoker and its socioeconomic costs to the general public are still incompletely understood. However, the 1979 *Surgeon General's Report on Health Promotion and Disease Prevention* stated that "cigarette smoking is clearly the largest single preventable cause of illness and premature death in the United States." This statement has been supported by numerous subsequent studies. Unfortunately, the fact that the most important of the tobacco-associated diseases are delayed in onset reduces the health incentive to stop smoking.

Clearly, the addictive power of cigarettes is directly related to their nicotine content. It is not known to what extent nicotine per se contributes to the other well-documented adverse effects of chronic tobacco use. It appears highly probable that nicotine contributes to the increased risk of vascular disease and sudden coronary death associated with smoking. Also, nicotine probably contributes to the high incidence of ulcer recurrences in smokers with peptic ulcer.

CHOLINESTERASE INHIBITORS

The acute toxic effects of the cholinesterase inhibitors, like those of the direct-acting agents, are direct extensions of their pharmacologic actions. The major source of such intoxications is pesticide use in agriculture and in the home. Approximately 100 organophosphate and 20 carbamate cholinesterase inhibitors are available in pesticides and veterinary vermifuges used in the USA.

Acute intoxication must be recognized and treated promptly in patients with heavy exposure. The dominant initial signs are those of muscarinic excess: miosis, salivation, sweating, bronchial constriction, vomiting, and diarrhea. Central nervous system involvement usually follows rapidly, accompanied by peripheral nicotinic effects, especially depolarizing neuromuscular blockade. Therapy always includes (1) maintenance of vital signs—respiration in particular may be impaired; (2) decontamination to prevent further absorption—this may require removal of all clothing and washing of the skin in cases of exposure to dusts and sprays; and (3) atropine parenterally in large doses, given as often as required to control signs of muscarinic excess. Therapy often also includes treatment with pralidoxime as described in Chapter 8.

Chronic exposure to certain organophosphate compounds, including some organophosphate cholinesterase inhibitors, causes neuropathy associated with demyelination of axons. Triorthocresylphosphate, an additive in lubricating oils, is the prototype agent of this class. The effects are not caused by cholinesterase inhibition.

PREPARATIONS AVAILABLE

Direct-Acting Cholinomimetics

Acetylcholine (Miochol-E)

Ophthalmic: 1% intraocular solution

Bethanechol (generic, Urecholine)

Oral: 5, 10, 25, 50 mg tablets

Parenteral: 5 mg/mL for SC injection

Carbachol

Ophthalmic (topical, Isopto Carbachol, Carboptic): 0.75, 1.5, 2.25, 3% solution

Ophthalmic (intraocular, Miostat, Carbastat): 0.01% solution

Cevimeline (Evoxac)

Oral: 30 mg capsules

Pilocarpine (generic, Isopto Carpine)

Ophthalmic (topical): 0.5, 1, 2, 3, 4, 6, 8, 10% solutions, 4% gel

Ophthalmic sustained-release inserts (Ocusert Pilo-20, Ocusert Pilo-40): release 20 and 40 mcg pilocarpine per hour for 1 week, respectively

Oral (Salagen): 5 mg tablets

Varenicline (Chantix)

Oral: 0.5, 1 mg tablets

Cholinesterase Inhibitors

Ambenonium (Mytelase)

Oral: 10 mg tablets

Demecarium (Humorsol)

Ophthalmic: 0.125, 0.25% drops

Donepezil (Aricept)

Oral: 5, 10 mg tablets

Echothiophate (Phospholine)

Ophthalmic: 1.5 mg (0.03%) powder to reconstitute for solution; 0.06, 0.125, 0.25% drops

Edrophonium (generic, Tensilon)

Parenteral: 10 mg/mL for IM or IV injection

Galantamine (Reminyl)

Oral: 4, 8, 12 mg tablets; 4 mg/mL solution

Neostigmine (generic, Prostigmin)

Oral: 15 mg tablets

Parenteral: 0.2, 0.5, 1, 2.5 mg/mL solution

Physostigmine, eserine (generic)

Ophthalmic: 0.25% ointment; 0.25, 0.5% solution

Parenteral: 1 mg/mL for IM or slow IV injection

Pyridostigmine (Mestinon, Regonol)

Oral: 30, 60 mg tablets; 180 mg sustained-release tablets; 12 mg/mL syrup

Parenteral: 5 mg/mL for IM or slow IV injection

Rivastigmine (Exelon)

Oral: 1.5, 3, 4.5, 6 mg tablets; 2 mg/mL solution

Tacrine (Cognex)

Oral: 10, 20, 30, 40 mg tablets

CHOLINOCEPTOR-BLOCKING DRUGS: INTRODUCTION

Cholinoceptor antagonists, like agonists, are divided into muscarinic and nicotinic subgroups on the basis of their specific receptor affinities. Ganglion-blockers and neuromuscular junction blockers comprise the antinicotinic drugs. The ganglion-blocking drugs have little clinical use and are discussed at the end of this chapter. The neuromuscular blockers are discussed in Chapter 27. This chapter emphasizes drugs that block muscarinic cholinoceptors.

Five subtypes of muscarinic receptors have been identified, primarily on the basis of data from ligand-binding and cDNA-cloning experiments (see Chapters 6 and 7). A standard terminology (M_1 through M_5) for these subtypes is now in common use, and evidence, based mostly on selective agonists and antagonists, indicates that functional differences exist between several of these subtypes.

As suggested in Chapter 6, the M_1 receptor subtype is located on central nervous system neurons, sympathetic postganglionic cell bodies, and many presynaptic sites. M_2 receptors are located in the myocardium, smooth muscle organs, and some neuronal sites. M_3 receptors are most common on effector cell membranes, especially glandular and smooth muscle cells.

BASIC PHARMACOLOGY OF THE MUSCARINIC RECEPTOR-BLOCKING DRUGS

Muscarinic antagonists are sometimes called parasympatholytic because they block the effects of parasympathetic autonomic discharge. However, they do not "lyse" parasympathetic nerves, and they have some effects that are not predictable from block of the parasympathetic nervous system. For these reasons, the term "antimuscarinic" is preferable.

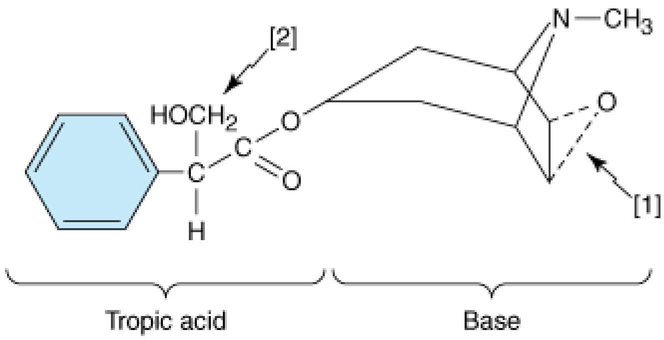
Naturally occurring compounds with antimuscarinic effects have been known and used for millennia as medicines, poisons, and cosmetics. Atropine is the prototype of these drugs. Many similar plant alkaloids are known, and hundreds of synthetic antimuscarinic compounds have been prepared.

Chemistry & Pharmacokinetics

SOURCE AND CHEMISTRY

Atropine and its naturally occurring congeners are tertiary amine alkaloid esters of tropic acid (Figure 8–1). Atropine (hyoscyamine) is found in the plant *Atropa belladonna,* or deadly nightshade, and in *Datura stramonium,* also known as jimsonweed (Jamestown weed), sacred Datura, or thorn apple. Scopolamine (hyoscine) occurs in *Hyoscyamus niger,* or henbane, as the *l* (–) stereoisomer. Naturally occurring atropine is *l* (–)-hyoscyamine, but the compound readily racemizes, so the commercial material is racemic *d,l* -hyoscyamine. The *l* (–) isomers of both alkaloids are at least 100 times more potent than the *d* (+) isomers.

Figure 8–1.

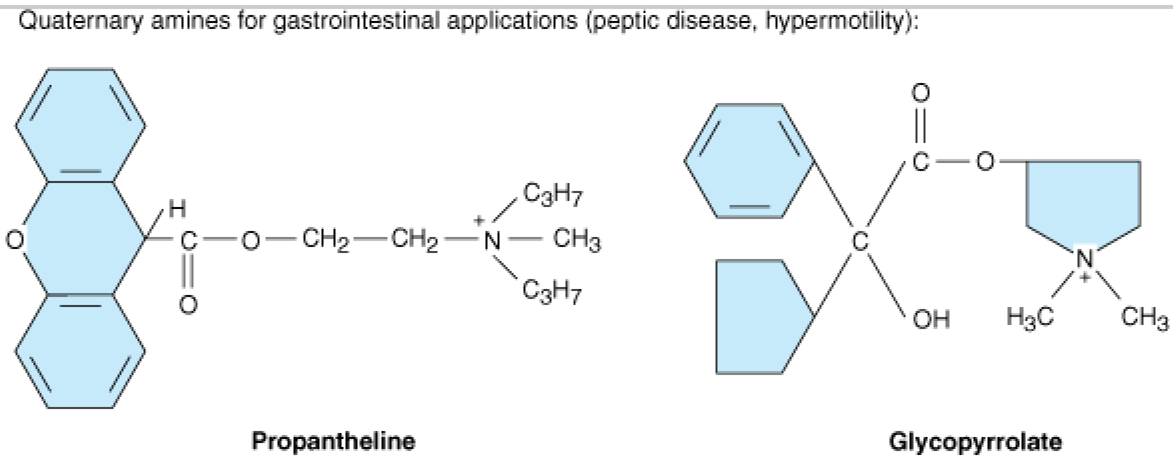


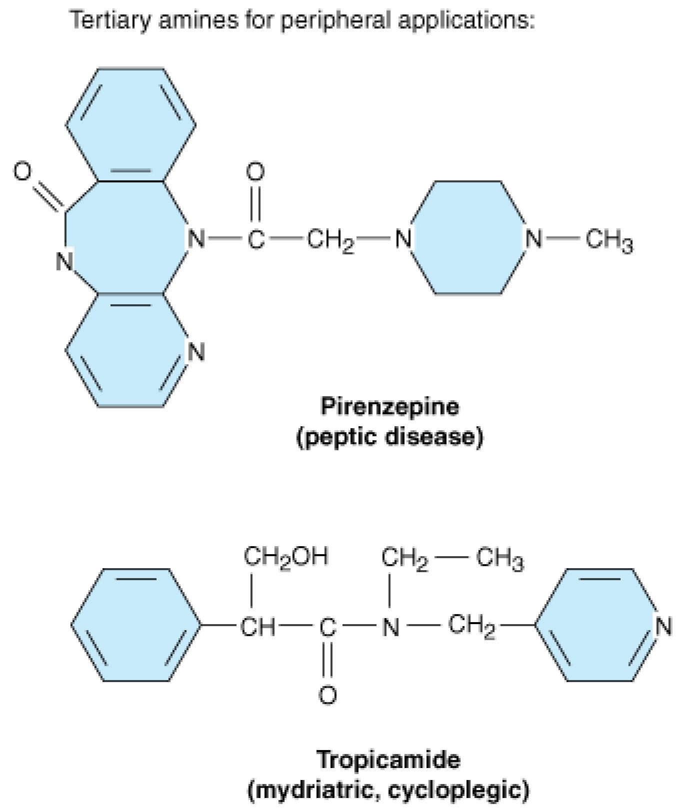
The structure of atropine (oxygen at *[1]* is missing) or scopolamine (oxygen present). In homatropine, the hydroxymethyl at *[2]* is replaced by a hydroxyl group, and the oxygen at *[1]* is absent.

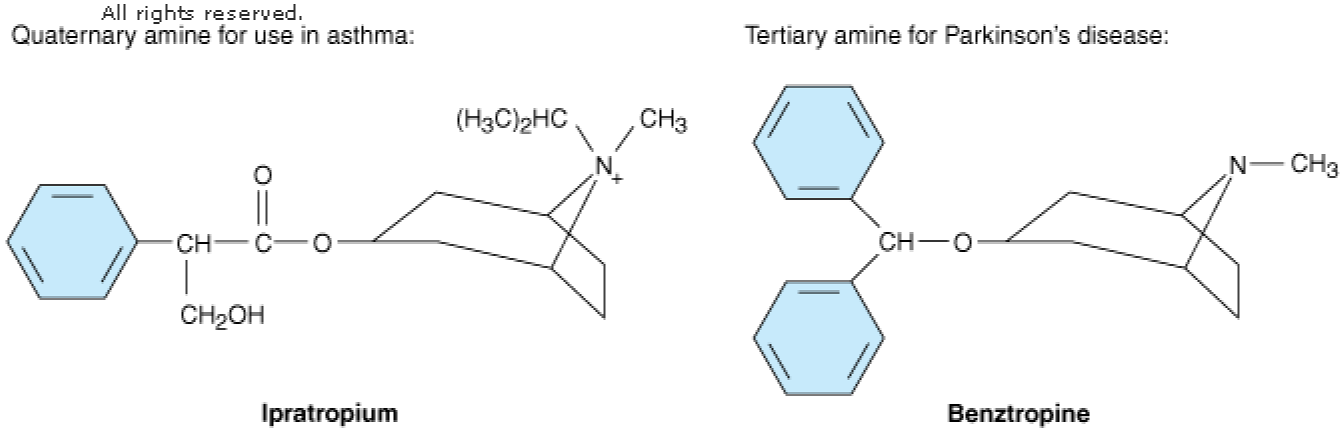
A variety of semisynthetic and fully synthetic molecules have antimuscarinic effects.

The tertiary members of these classes (Figure 8–2) are often used for their effects on the eye or the central nervous system. Many antihistaminic (see Chapter 16), antipsychotic (see Chapter 29), and antidepressant (see Chapter 30) drugs have similar structures and, predictably, significant antimuscarinic effects.

Figure 8–2.







Structures of some semisynthetic and synthetic antimuscarinic drugs.

Quaternary amine antimuscarinic agents (Figure 8–2) have been developed to produce more peripheral effects with reduced central nervous system effects.

ABSORPTION

The natural alkaloids and most tertiary antimuscarinic drugs are well absorbed from the gut and conjunctival membranes. When applied in a suitable vehicle, some (eg, scopolamine) are even absorbed across the skin (transdermal route). In contrast, only 10–30% of a dose of a quaternary antimuscarinic drug is absorbed after oral administration, reflecting the decreased lipid solubility of the charged molecule.

DISTRIBUTION

Atropine and the other tertiary agents are widely distributed in the body. Significant levels are achieved in the central nervous system within 30 minutes to 1 hour, and this can limit the dose tolerated when the drug is taken for its peripheral effects. Scopolamine is rapidly and fully distributed into the central nervous system where it has greater effects than most other antimuscarinic drugs. In contrast, the quaternary derivatives are poorly taken up by the brain and therefore are relatively free—at low doses—of central nervous system effects.

METABOLISM AND EXCRETION

After administration, atropine disappears rapidly from the blood with a half-life of 2 hours. About 60% of the dose is excreted unchanged in the urine. Most of the rest appears in the urine as hydrolysis and conjugation products. The drug's effect on parasympathetic function declines rapidly in all organs except the eye. Effects on the iris and ciliary muscle persist for ≥72 hours.

Pharmacodynamics

MECHANISM OF ACTION

Atropine causes reversible (surmountable) blockade (see Chapter 2) of cholinomimetic actions at muscarinic receptors—ie, blockade by a small dose of atropine can be overcome by a larger concentration of acetylcholine or equivalent muscarinic agonist. Mutation experiments suggest that aspartate in the receptor forms the characteristic bond with the nitrogen atom of acetylcholine; this amino acid is also required for binding of antimuscarinic drugs. When atropine binds to the muscarinic receptor, it prevents actions such as the release of inositol trisphosphate (IP_3) and the inhibition of adenylyl cyclase that are caused by muscarinic agonists (see Chapter 7).

The effectiveness of antimuscarinic drugs varies with the tissue and with the source of agonist. Tissues most sensitive to atropine are the salivary, bronchial, and sweat glands. Secretion of acid by the gastric parietal cells is the least sensitive. In most tissues, antimuscarinic agents block exogenously administered cholinoceptor agonists more effectively than endogenously released acetylcholine.

Atropine is highly selective for muscarinic receptors. Its potency at nicotinic receptors is much lower, and actions at nonmuscarinic receptors are generally undetectable clinically.

Atropine does not distinguish between the M_1, M_2, and M_3 subgroups of muscarinic receptors. In contrast, other antimuscarinic drugs are moderately selective for one or another of these subgroups (Table 8–1). Most synthetic antimuscarinic drugs are considerably less selective than atropine in interactions with nonmuscarinic receptors. For example, some quaternary amine antimuscarinic agents have significant ganglion-blocking actions, and others are potent histamine receptor blockers. The antimuscarinic effects of other agents, eg, antipsychotic and antidepressant drugs, have been mentioned. Their relative selectivity for muscarinic receptor subtypes has not been defined.

ORGAN SYSTEM EFFECTS

Central Nervous System

In the doses usually used, atropine has minimal stimulant effects on the central nervous system, especially the parasympathetic medullary centers, and a slower, longer-lasting sedative effect on the brain. Scopolamine has more marked central effects, producing drowsiness when given in recommended dosages and amnesia in sensitive individuals. In toxic doses, scopolamine and to a lesser degree atropine can cause excitement, agitation, hallucinations, and coma.

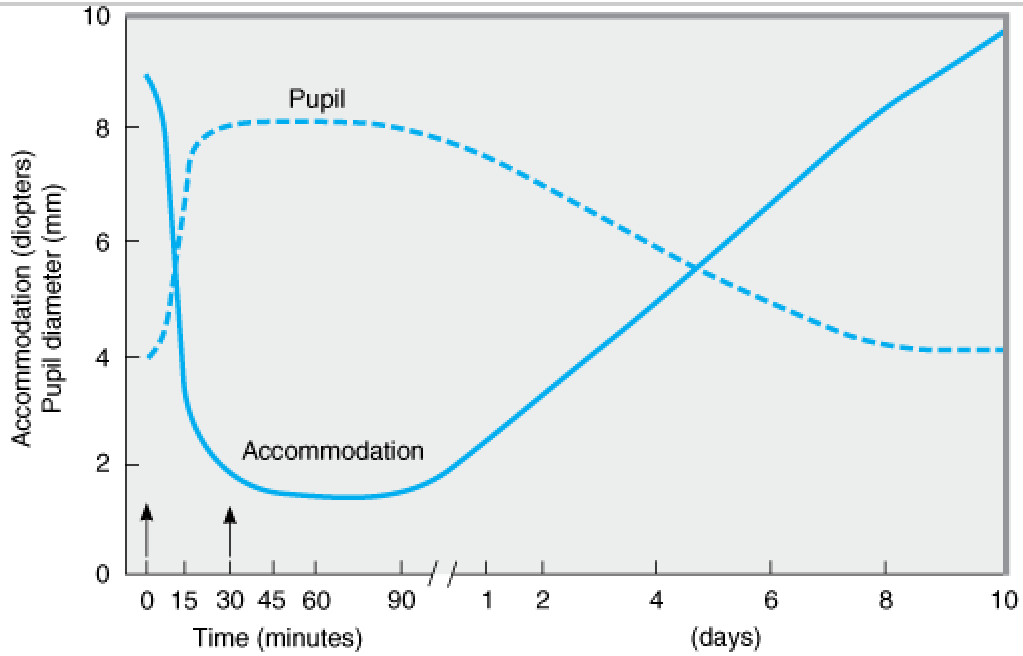
The tremor of Parkinson's disease is reduced by centrally acting antimuscarinic drugs, and atropine—in the form of belladonna extract—was one of the first drugs used in the therapy of this disease. As discussed in Chapter 28, parkinsonian tremor and rigidity seem to result from a *relative* excess of cholinergic activity because of a deficiency of dopaminergic activity in the basal ganglia-striatum system. The combination of an antimuscarinic agent with a dopamine precursor drug (levodopa) can sometimes provide more effective therapy than either drug alone.

Vestibular disturbances, especially motion sickness, appear to involve muscarinic cholinergic transmission. Scopolamine is often effective in preventing or reversing these disturbances.

Eye

The pupillary constrictor muscle (see Figure 6–9) depends on muscarinic cholinoceptor activation. This activation is blocked by topical atropine and other tertiary antimuscarinic drugs and results in unopposed sympathetic dilator activity and mydriasis (Figure 8–3). Dilated pupils were considered cosmetically desirable during the Renaissance and account for the name belladonna (Italian, "beautiful lady") applied to the plant and its active extract because of the use of the extract as eye drops during that time.

Figure 8–3.



Effects of topical scopolamine drops on pupil diameter (mm) and accommodation (diopters) in the normal human eye. One drop of 0.5% solution of drug was applied at zero time, and a second drop was administered at 30 minutes (*arrows*). The responses of 42 eyes were averaged. Note the extremely slow recovery. (Redrawn from Marron J: Cycloplegia and mydriasis by use of atropine, scopolamine, and homatropine-paredrine. Arch Ophthalmol 1940;23:340.)

The second important ocular effect of antimuscarinic drugs is to weaken contraction of the ciliary muscle, or **cycloplegia**. Cycloplegia results in loss of the ability to accommodate; the fully atropinized eye cannot focus for near vision (Figure 8–3).

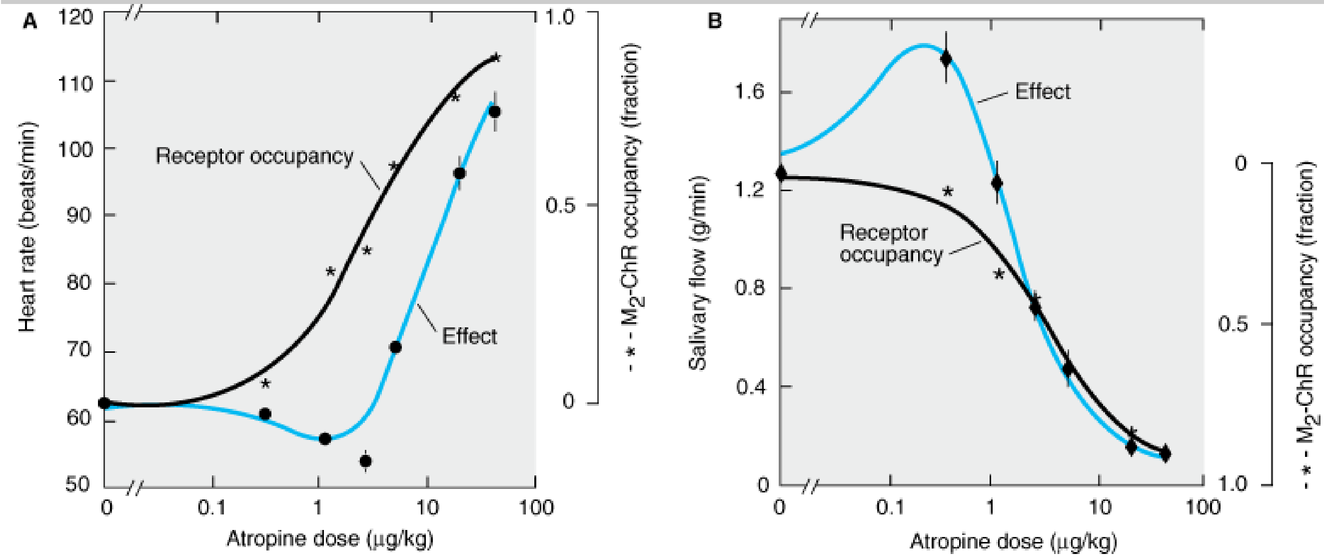
Both mydriasis and cycloplegia are useful in ophthalmology. They are also potentially hazardous, since acute glaucoma may be induced in patients with a narrow anterior chamber angle.

A third ocular effect of antimuscarinic drugs is to reduce lacrimal secretion. Patients occasionally complain of dry or "sandy" eyes when receiving large doses of antimuscarinic drugs.

Cardiovascular System

The sinoatrial node is very sensitive to muscarinic receptor blockade. Moderate to high therapeutic doses of atropine cause tachycardia in the innervated and spontaneously beating heart by blockade of vagal slowing. However, lower doses often result in initial bradycardia before the effects of peripheral vagal block become manifest (Figure 8–4). This slowing may be due to block of prejunctional M_1 receptors (autoreceptors, see Chapter 6) on vagal postganglionic fibers that normally limit acetylcholine release in the sinus node and other tissues. The same mechanisms operate in the atrioventricular node; in the presence of high vagal tone, atropine can significantly reduce the PR interval of the electrocardiogram by blocking muscarinic receptors in the atrioventricular node. Muscarinic effects on atrial muscle are similarly blocked, but these effects are of no clinical significance except in atrial flutter and fibrillation. The ventricles are less affected by antimuscarinic drugs at therapeutic levels because of a lesser degree of muscarinic control. In toxic concentrations, the drugs can cause intraventricular conduction block that has been attributed to a local anesthetic action.

Figure 8–4.



Effects of increasing doses of atropine on heart rate (A) and salivary flow (B) compared with muscarinic receptor occupancy in humans. The parasympathomimetic effect of low-dose atropine is attributed to blockade of prejunctional muscarinic receptors that suppress acetylcholine release. (Modified and reproduced, with permission, from Wellstein A, Pitschner HF: Complex dose-response curves of atropine in man explained by different functions of M_1 and M_2 cholinoceptors. Naunyn Schmiedebergs Arch Pharmacol 1988;338:19.)

Most blood vessels receive no direct innervation from the parasympathetic system. However, parasympathetic nerve stimulation dilates coronary arteries, and sympathetic cholinergic nerves cause vasodilation in the skeletal muscle vascular bed (see Chapter 6). Atropine can block this vasodilation. Furthermore, almost all vessels contain endothelial muscarinic receptors that mediate vasodilation (see Chapter 7). These receptors are readily blocked by antimuscarinic drugs. At toxic doses, and in some individuals at normal doses, antimuscarinic agents cause cutaneous vasodilation, especially in the upper portion of the body. The mechanism is unknown.

The net cardiovascular effects of atropine in patients with normal hemodynamics are not dramatic: tachycardia may occur, but there is little effect on blood pressure. However, the cardiovascular effects of administered direct-acting muscarinic agonists are easily prevented.

Respiratory System

Both smooth muscle and secretory glands of the airway receive vagal innervation and contain muscarinic receptors. Even in normal individuals, administration of atropine can cause some bronchodilation and reduce secretion. The effect is more significant in patients with airway disease, although the antimuscarinic drugs are not as useful as the β-adrenoceptor stimulants in the treatment of asthma (see Chapter 20). The effectiveness of unselective antimuscarinic drugs in treating chronic obstructive pulmonary disease (COPD) is limited because block of autoinhibitory M_2 receptors on postganglionic parasympathetic nerves can oppose the bronchodilation caused by block of M_3 receptors on airway smooth muscle. Nevertheless, antimuscarinic agents are valuable in some patients with asthma or COPD.

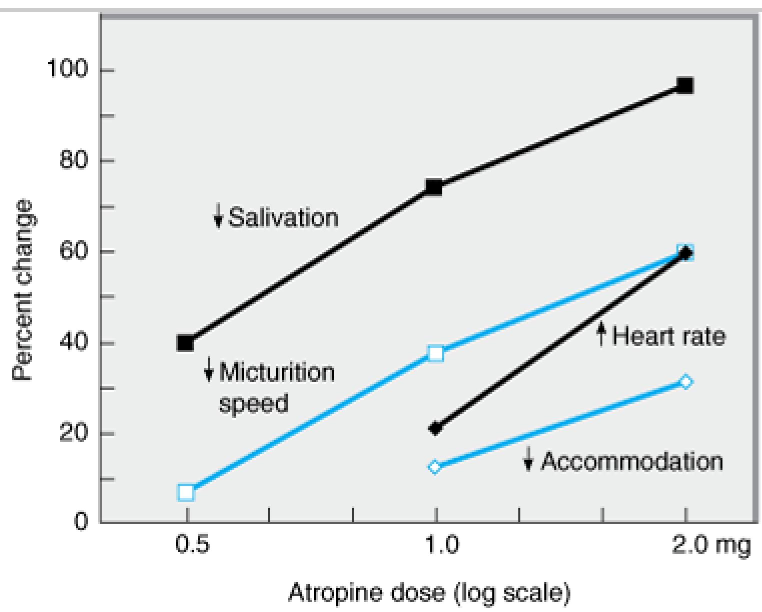
Antimuscarinic drugs are frequently used prior to administration of inhalant anesthetics to reduce the accumulation of secretions in the trachea and the possibility of laryngospasm.

Gastrointestinal Tract

Blockade of muscarinic receptors has dramatic effects on motility and some of the secretory functions of the gut. However, even complete muscarinic block cannot totally abolish activity in this organ system since local hormones and noncholinergic neurons in the enteric nervous system (see Chapters 6 and 63) also modulate gastrointestinal function. As in other tissues, exogenously administered muscarinic stimulants are more effectively blocked than the effects of parasympathetic (vagal) nerve activity. The removal of autoinhibition, a negative feedback mechanism by which neural acetylcholine suppresses its own release, might explain the greater efficacy of antimuscarinic drugs against exogenous muscarinic stimulants.

Antimuscarinic drugs have marked effects on salivary secretion; dry mouth occurs frequently in patients taking antimuscarinic drugs for Parkinson's disease or urinary conditions (Figure 8–5). Gastric secretion is blocked less effectively: the volume and amount of acid, pepsin, and mucin are all reduced, but large doses of atropine may be required. Basal secretion is blocked more effectively than that stimulated by food, nicotine, or alcohol. Pirenzepine and a more potent analog, telenzepine, reduce gastric acid secretion with fewer adverse effects than atropine and other less selective agents. This results from a selective blockade of presynaptic excitatory muscarinic receptors on vagal nerve endings as suggested by their high ratio of M_1 to M_3 affinity (Table 8–1). Pirenzepine and telenzepine are investigational in the USA. Pancreatic and intestinal secretion are little affected by atropine; these processes are primarily under hormonal rather than vagal control.

Figure 8–5.



Effects of subcutaneous injection of atropine on salivation, speed of micturition (voiding), heart rate, and accommodation in normal adults. Note that salivation is the most sensitive of these variables, accommodation the least. (Data from Herxheimer A: Br J Pharmacol 1958;13:184.)

Gastrointestinal smooth muscle motility is affected from the stomach to the colon. In general, the walls of the viscera are relaxed, and both tone and propulsive movements are diminished. Therefore, gastric emptying time is prolonged, and intestinal transit time is lengthened. Diarrhea due to overdosage with parasympathomimetic agents is readily stopped, and even that caused by nonautonomic agents can usually be temporarily controlled. However, intestinal "paralysis" induced by antimuscarinic drugs is temporary; local mechanisms within the enteric nervous system will usually reestablish at least some peristalsis after 1–3 days of antimuscarinic drug therapy.

Genitourinary Tract

The antimuscarinic action of atropine and its analogs relaxes smooth muscle of the ureters and bladder wall and slows voiding (Figure 8–5). This action is useful in the treatment of spasm induced by mild inflammation, surgery, and certain neurologic conditions, but it can precipitate urinary retention in men who have prostatic hyperplasia (see following section, Clinical Pharmacology of the Muscarinic Receptor-Blocking Drugs). The antimuscarinic drugs have no significant effect on the uterus.

Sweat Glands

Atropine suppresses thermoregulatory sweating. Sympathetic cholinergic fibers innervate eccrine sweat glands, and their muscarinic receptors are readily accessible to antimuscarinic drugs. In adults, body temperature is elevated by this effect only if large doses are administered, but in infants and children even ordinary doses may cause "atropine fever."

CLINICAL PHARMACOLOGY OF THE MUSCARINIC RECEPTOR-BLOCKING DRUGS

Therapeutic Applications

CENTRAL NERVOUS SYSTEM DISORDERS

Parkinson's Disease

As described in Chapter 28, the treatment of Parkinson's disease is often an exercise in polypharmacy, since no single agent is fully effective over the course of the disease. Most antimuscarinic drugs promoted for this application (see Table 28–1) were developed before levodopa became available. Their use is accompanied by all of the adverse effects described below, but the drugs remain useful as adjunctive therapy in some patients.

Motion Sickness

Certain vestibular disorders respond to antimuscarinic drugs (and to antihistaminic agents with antimuscarinic effects). Scopolamine is one of the oldest remedies for seasickness and is as effective as any more recently introduced agent. It can be given by injection, by mouth, or as a transdermal patch. The patch formulation produces significant blood levels over 48–72 hours. Unfortunately, useful doses by any route usually cause significant sedation and dry mouth.

OPHTHALMOLOGIC DISORDERS

Accurate measurement of refractive error in uncooperative patients, eg, young children, requires ciliary paralysis. Also, ophthalmoscopic examination of the retina is greatly facilitated by mydriasis. Therefore, antimuscarinic agents, administered topically as eye drops or ointment, are very helpful in doing a complete examination. For adults and older children, the shorter-acting drugs are preferred (Table 8–2). For younger children, the greater efficacy of atropine is sometimes necessary, but the possibility of antimuscarinic poisoning is correspondingly increased. Drug loss from the conjunctival sac via the nasolacrimal duct into the nasopharynx can be diminished by the use of the ointment form instead of drops. Formerly, ophthalmic antimuscarinic drugs were selected from the tertiary amine subgroup to ensure good penetration after conjunctival application. Recent experiments in animals, however, suggest that glycopyrrolate, a quaternary agent, is as rapid in onset and as long-lasting as atropine.

Table 8–2. Antimuscarinic Drugs Used in Ophthalmology.

Drug	Duration of Effect (days)	Usual Concentration (%)
Atropine	7–10	0.5–1
Scopolamine	3–7	0.25
Homatropine	1–3	2–5
Cyclopentolate	1	0.5–2
Tropicamide	0.25	0.5–1

Antimuscarinic drugs should never be used for mydriasis unless cycloplegia or prolonged action is required. Alpha-adrenoceptor stimulant drugs, eg, phenylephrine, produce a short-lasting mydriasis that is usually sufficient for funduscopic examination (see Chapter 9).

A second ophthalmologic use is to prevent synechia (adhesion) formation in uveitis and iritis. The longer-lasting preparations, especially homatropine, are valuable for this indication.

RESPIRATORY DISORDERS

The use of atropine became part of routine preoperative medication when anesthetics such as ether were used, because these irritant anesthetics markedly increased airway secretions and were associated with frequent episodes of laryngospasm. Preanesthetic injection of atropine or scopolamine could prevent these hazardous effects. Scopolamine also produces significant amnesia for the events associated with surgery and obstetric delivery, a side effect that was considered desirable. On the other hand, urinary retention and intestinal hypomotility following surgery were often exacerbated by antimuscarinic drugs. Newer inhalational anesthetics are far less irritating to the airways.

As described in Chapter 20, the hyperactive neural bronchoconstrictor reflex present in most individuals with asthma is mediated by the vagus, acting on muscarinic receptors on bronchial smooth muscle cells. Ipratropium (Figure 8–2), a synthetic analog of atropine, is used as an inhalational drug in asthma. The aerosol route of administration has the advantages of maximal concentration at the bronchial target tissue with reduced systemic effects. This application is discussed in greater detail in Chapter 20. Ipratropium has also proved useful in COPD, a condition that occurs with higher frequency in older patients, particularly chronic smokers. Patients with COPD benefit from bronchodilators, especially antimuscarinic agents such as ipratropium and the recently approved tiotropium. In contrast to ipratropium, tiotropium has a longer bronchodilator action and can be given once daily. Tiotropium reduces the incidence of COPD exacerbations and is a useful adjunct to pulmonary rehabilitation in increasing exercise tolerance.

CARDIOVASCULAR DISORDERS

Marked reflex vagal discharge sometimes accompanies the pain of myocardial infarction (eg, vasovagal attack) and may depress sinoatrial or atrioventricular node function sufficiently to impair cardiac output. Parenteral atropine or a similar antimuscarinic drug is appropriate therapy in this situation. Rare individuals without other detectable cardiac disease have hyperactive carotid sinus reflexes and may experience faintness or even syncope as a result of vagal discharge in response to pressure on the neck, eg, from a tight collar. Such individuals may benefit from the judicious use of atropine or a related antimuscarinic agent.

Pathophysiology can influence muscarinic activity in other ways as well. Circulating autoantibodies against the second extracellular loop of cardiac muscarinic receptors have been detected in some patients with idiopathic dilated cardiomyopathy. These antibodies exert parasympathomimetic actions on the heart that are prevented by atropine. Although their role in the pathology of heart failure is unknown, they should provide clues to the molecular basis of receptor activation.

GASTROINTESTINAL DISORDERS

Antimuscarinic agents are now rarely used for peptic ulcer disease in the USA (see Chapter 63). Antimuscarinic agents can provide some relief in the treatment of common traveler's diarrhea and other mild or self-limited conditions of hypermotility. They are often combined with an opioid antidiarrheal drug, an extremely effective therapy. In this combination, however, the very low dosage of the antimuscarinic drug functions primarily to discourage abuse of the opioid agent. The classic combination of atropine with diphenoxylate, a nonanalgesic congener of meperidine, is available under many names (eg, Lomotil) in both tablet and liquid form (see Chapter 63).

URINARY DISORDERS

Atropine and other antimuscarinic drugs have been used to provide symptomatic relief in the treatment of urinary urgency caused by minor inflammatory bladder disorders (Table 8–3). However, specific antimicrobial therapy is essential in bacterial cystitis. In the human urinary bladder, M_2 and M_3 receptors are expressed predominantly with the M_3 subtype mediating direct activation of contraction. As in intestinal smooth muscle, the M_2 subtype appears to act indirectly by inhibiting relaxation by norepinephrine and epinephrine.

Table 8–3. Antimuscarinic Drugs Used in Gastrointestinal and Genitourinary Conditions.

Drug	Usual Dosage
Quaternary amines	
Anisotropine	50 mg tid
Clidinium	2.5 mg tid–qid
Glycopyrrolate	1 mg bid–tid
Isopropamide	5 mg bid
Mepenzolate	25–50 mg qid
Methantheline	50–100 mg qid
Methscopolamine	2.5 mg qid
Oxyphenonium	5–10 mg qid
Propantheline	15 mg qid
Tridihexethyl	25–50 mg tid–qid
Trospium	20 mg bid
Tertiary amines	
Atropine	0.4 mg tid–qid

Darifenacin	7.5 mg qd
Dicyclomine	10–20 mg qid
Oxybutynin	5 mg tid
Oxyphencyclimine	10 mg bid
Propiverine	15 mg bid–tid
Scopolamine	0.4 mg tid
Solifenacin	5 mg qd
Tolterodine	2 mg bid

Oxybutynin, which is somewhat selective for M_3 receptors, is used to relieve bladder spasm after urologic surgery, eg, prostatectomy. It is also valuable in reducing involuntary voiding in patients with neurologic disease, eg, children with meningomyelocele. Oral oxybutynin or instillation of the drug by catheter into the bladder in such patients appears to improve bladder capacity and continence and to reduce infection and renal damage. Trospium, an unselective antagonist, has recently been approved and is comparable in efficacy and side effects with oxybutynin. Darifenacin and solifenacin are recently approved antagonists that have greater selectivity for M_3 receptors than oxybutynin or trospium. Their advantages include once daily dosing because of their long half-lives and a reduced incidence of xerostomia and constipation. Tolterodine, another M_3 -selective antimuscarinic, is available for use in adults with urinary incontinence. It has many of the qualities of darifenacin and solifenacin. The reason for the reduced incidence of dry mouth with these drugs as compared with oxybutynin is not known.

Imipramine, a tricyclic antidepressant drug with strong antimuscarinic actions, has long been used to reduce incontinence in institutionalized elderly patients. It is moderately effective but causes significant central nervous system toxicity. Propiverine, a newer antimuscarinic agent, has been approved for this purpose.

Antimuscarinic agents have also been used in urolithiasis to relieve the painful ureteral smooth muscle spasm caused by passage of the stone. However, their usefulness in this condition is debatable.

CHOLINERGIC POISONING

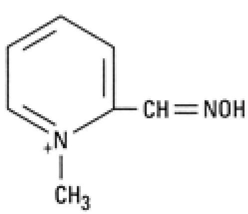
Severe cholinergic excess is a medical emergency, especially in rural communities where cholinesterase inhibitor insecticides are commonly used and in cultures where wild mushrooms are commonly eaten. The potential use of cholinesterase inhibitors as chemical warfare "nerve gases" also requires an awareness of the methods for treating acute poisoning (see Chapter 59).

Antimuscarinic Therapy

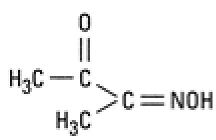
As noted in Chapter 7, both the nicotinic and the muscarinic effects of the cholinesterase inhibitors can be life-threatening. Unfortunately, there is no effective method for directly blocking the nicotinic effects of cholinesterase inhibition, because nicotinic agonists *and* antagonists cause blockade of transmission (see Chapter 27). To reverse the muscarinic effects, a tertiary (not quaternary) amine drug must be used (preferably atropine) to treat the central nervous system effects as well as the peripheral effects of the organophosphate inhibitors. Large doses of atropine may be needed to oppose the muscarinic effects of extremely potent agents like parathion and chemical warfare nerve gases: 1–2 mg of atropine sulfate may be given intravenously every 5–15 minutes until signs of effect (dry mouth, reversal of miosis) appear. The drug may have to be repeated many times, since the acute effects of the anticholinesterase agent may last for 24–48 hours or longer. In this life-threatening situation, as much as 1 g of atropine per day may be required for as long as 1 month for full control of muscarinic excess.

Cholinesterase Regenerator Compounds

A second class of compounds, capable of regenerating active enzyme from the organophosphorus-cholinesterase complex, is also available to treat organophosphorus poisoning. These oxime agents include pralidoxime (PAM), diacetylmonoxime (DAM), and others.



Pralidoxime



Diacetylmonoxime

The oxime group (=NOH) has a very high affinity for the phosphorus atom, and these drugs can hydrolyze the phosphorylated enzyme if the complex has not "aged" (see Chapter 7). Pralidoxime is the most extensively studied—in humans—of the agents shown and the only one available for clinical use in the USA. It is most effective in regenerating the cholinesterase associated with skeletal muscle neuromuscular junctions. Pralidoxime is ineffective in reversing the central effects of organophosphate poisoning because its positive charge prevents entry into the central nervous system. Diacetylmonoxime, on the other hand, crosses the blood-brain barrier and, in experimental animals, can regenerate some of the central nervous system cholinesterase.

Pralidoxime is administered by intravenous infusion, 1–2 g given over 15–30 minutes. In spite of the likelihood of aging of the phosphate-enzyme complex, recent reports suggest that administration of multiple doses of pralidoxime over several days may be useful in severe poisoning. In excessive doses, pralidoxime can induce neuromuscular weakness and other adverse effects. Pralidoxime is *not* recommended for the reversal of inhibition of acetylcholinesterase by carbamate inhibitors. Further details of treatment of anticholinesterase toxicity are given in Chapter 59.

A third approach to protection against excessive AChE inhibition is *pretreatment* with reversible enzyme inhibitors to prevent binding of the irreversible organophosphate inhibitor. This prophylaxis can be achieved with pyridostigmine or physostigmine but is reserved for situations in which possibly lethal poisoning is anticipated, eg, chemical warfare. Simultaneous use of atropine is required to control muscarinic excess.

Mushroom poisoning has traditionally been divided into rapid-onset and delayed-onset types. The rapid-onset type is usually apparent within 15–30 minutes following ingestion of the mushrooms. It is often characterized entirely by signs of muscarinic excess: nausea, vomiting, diarrhea, urinary urgency, vasodilation, reflex tachycardia (occasionally bradycardia), sweating, salivation, and sometimes bronchoconstriction. Although *Amanita muscaria* contains muscarine (the alkaloid was named after the mushroom), numerous other alkaloids, including antimuscarinic agents, are found in this fungus. In fact, ingestion of *A muscaria* may produce signs of atropine poisoning, not muscarine excess. Other mushrooms, especially those of the *Inocybe* genus, cause rapid-onset poisoning of the muscarinic excess type. Parenteral atropine, 1–2 mg, is effective treatment in such intoxications.

Delayed-onset mushroom poisoning, usually caused by *Amanita phalloides, A virosa, Galerina autumnalis,* or *G marginata,* manifests its first symptoms 6–12 hours after ingestion. Although the initial symptoms usually include nausea and vomiting, the major toxicity involves hepatic and renal cellular injury by amatoxins that inhibit RNA polymerase. Atropine is of no value in this form of mushroom poisoning (see Chapter 59).

OTHER APPLICATIONS

Hyperhidrosis (excessive sweating) is sometimes reduced by antimuscarinic agents. However, relief is incomplete at best, probably because apocrine rather than eccrine glands are usually involved.

Adverse Effects

Treatment with atropine or its congeners directed at one organ system almost always induces undesirable effects in other organ systems. Thus, mydriasis and cycloplegia are adverse effects when an antimuscarinic agent is used to reduce gastrointestinal secretion or motility, even though they are therapeutic effects when the drug is used in ophthalmology.

At higher concentrations, atropine causes block of all parasympathetic functions. However, atropine is a remarkably safe drug *in adults.* Atropine poisoning has occurred as a result of attempted suicide, but most cases are due to attempts to induce hallucinations. Poisoned individuals manifest dry mouth, mydriasis, tachycardia, hot and flushed skin, agitation, and delirium for as long as a week. Body temperature is frequently elevated. These effects are memorialized in the adage, "dry as a bone, blind as a bat, red as a beet, mad as a hatter."

Unfortunately, children, especially infants, are very sensitive to the hyperthermic effects of atropine. Although accidental administration of over 400 mg has been followed by recovery, deaths have followed doses as small as 2 mg. Therefore, atropine should be considered a highly dangerous drug when overdose occurs in infants or children.

Overdoses of atropine or its congeners are generally treated symptomatically (see Chapter 59). In the past, physostigmine or another cholinesterase inhibitor was recommended, but most poison control experts now consider physostigmine more dangerous and no more effective in most patients than symptomatic management. When physostigmine is deemed necessary, *small* doses are given *slowly* intravenously (1–4 mg in adults, 0.5–1 mg in children). Symptomatic treatment may require temperature control with cooling blankets and seizure control with diazepam.

Poisoning caused by high doses of quaternary antimuscarinic drugs is associated with all of the peripheral signs of parasympathetic blockade but few or none of the central nervous system effects of atropine. These more polar drugs may cause significant ganglionic blockade, however, with marked orthostatic hypotension (see below). Treatment of the antimuscarinic effects, if required, can be carried out with a quaternary cholinesterase inhibitor such as neostigmine. Control of hypotension may require the administration of a sympathomimetic drug such as phenylephrine.

Contraindications

Contraindications to the use of antimuscarinic drugs are relative, not absolute. Obvious muscarinic excess, especially that caused by cholinesterase inhibitors, can always be treated with atropine.

Antimuscarinic drugs are contraindicated in patients with glaucoma, especially angle-closure glaucoma. Even systemic use of moderate doses may precipitate angle closure (and acute glaucoma) in patients with shallow anterior chambers.

In elderly men, antimuscarinic drugs should always be used with caution and should be avoided in those with a history of prostatic hyperplasia.

Because the antimuscarinic drugs slow gastric emptying, they may *increase* symptoms in patients with gastric ulcer. Nonselective antimuscarinic agents should never be used to treat acid-peptic disease (see Chapter 63).

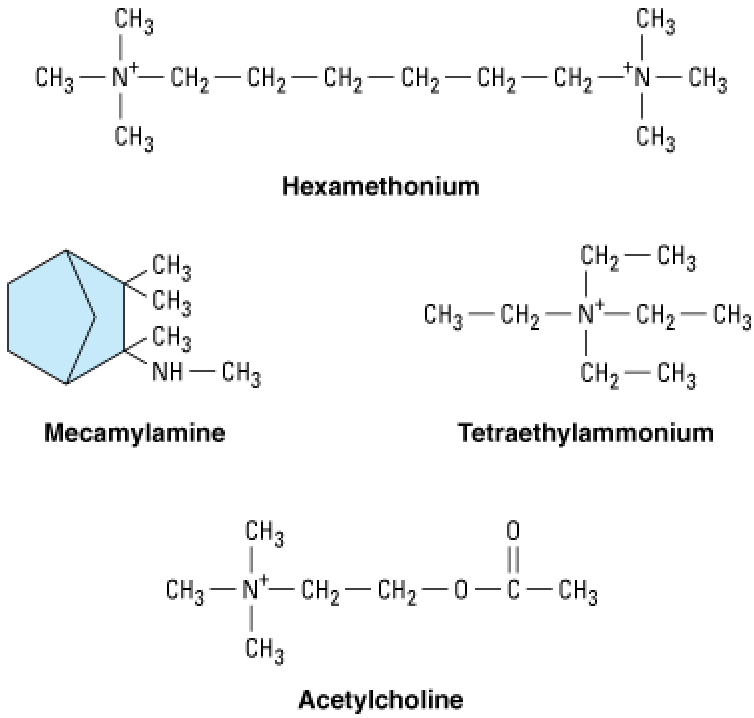
BASIC & CLINICAL PHARMACOLOGY OF THE GANGLION-BLOCKING DRUGS

These agents competitively block the action of acetylcholine and similar agonists at nicotinic receptors of both parasympathetic and sympathetic autonomic ganglia. Some members of the group also block the ion channel that is gated by the nicotinic cholinoceptor. The ganglion-blocking drugs are important and used in pharmacologic and physiologic research because they can block all autonomic outflow. However, their lack of selectivity confers such a broad range of undesirable effects that they have limited clinical use.

Chemistry & Pharmacokinetics

All ganglion-blocking drugs of interest are synthetic amines. **Tetraethylammonium** (TEA), the first to be recognized as having this action, has a very short duration of action. **Hexamethonium** ("C6") was developed and was introduced clinically as the first drug effective for management of hypertension. As shown in Figure 8–6, there is an obvious relationship between the structures of the agonist acetylcholine and the nicotinic antagonists tetraethylammonium and hexamethonium. Decamethonium, the "C10" analog of hexamethonium, is a depolarizing neuromuscular blocking agent.

Figure 8–6.



Some ganglion-blocking drugs. Acetylcholine is shown for reference.

Mecamylamine, a secondary amine, was developed to improve the degree and extent of absorption from the gastrointestinal tract because the quaternary amine ganglion-blocking compounds were poorly and erratically absorbed after oral administration. Trimethaphan, a short-acting ganglion blocker, is inactive orally and is given by intravenous infusion.

Pharmacodynamics

MECHANISM OF ACTION

Ganglionic nicotinic receptors, like those of the skeletal muscle neuromuscular junction, are subject to both depolarizing and nondepolarizing blockade (see Chapters 7 and 27). Nicotine itself, carbamoylcholine, and even acetylcholine (if amplified with a cholinesterase inhibitor) can produce depolarizing ganglion block.

Drugs now used as ganglion blockers are classified as nondepolarizing competitive antagonists. However, hexamethonium actually produces most of its blockade by occupying sites in or on the nicotinic ion channel, not by occupying the cholinoceptor itself. In contrast, trimethaphan appears to block the nicotinic receptor, not the channel. Blockade can be surmounted by increasing the concentration of an agonist, eg, acetylcholine.

ORGAN SYSTEM EFFECTS

Central Nervous System

Mecamylamine, unlike the quaternary amine agents and trimethaphan, crosses the blood-brain barrier and readily enters the central nervous system. Sedation, tremor, choreiform movements, and mental aberrations have been reported as effects of mecamylamine.

Eye

The ganglion-blocking drugs cause a predictable cycloplegia with loss of accommodation because the ciliary muscle receives innervation primarily from the parasympathetic nervous system. The effect on the pupil is not so easily predicted, since the iris receives both sympathetic innervation (mediating pupillary dilation) and parasympathetic innervation (mediating pupillary constriction). Ganglionic blockade often causes moderate dilation of the pupil because parasympathetic tone usually dominates this tissue.

Cardiovascular System

Blood vessels receive chiefly vasoconstrictor fibers from the sympathetic nervous system; therefore, ganglionic blockade causes a marked decrease in arteriolar and venomotor tone. The blood pressure may fall precipitously, because both peripheral vascular resistance and venous return are decreased (see Figure 6–7). Hypotension is especially marked in the upright position (orthostatic or postural hypotension), because postural reflexes that normally prevent venous pooling are blocked.

Cardiac effects include diminished contractility and, because the sinoatrial node is usually dominated by the parasympathetic nervous system, a moderate tachycardia.

Gastrointestinal Tract

Secretion is reduced, although not enough to effectively treat peptic disease. Motility is profoundly inhibited, and constipation can be marked.

Other Systems

Genitourinary smooth muscle is partially dependent on autonomic innervation for normal function. Therefore, ganglionic blockade causes hesitancy in urination and may precipitate urinary retention in men with prostatic hyperplasia. Sexual function is impaired in that both erection and ejaculation may be prevented by moderate doses.

Thermoregulatory sweating is reduced by the ganglion-blocking drugs. However, hyperthermia is not a problem except in very warm environments, because cutaneous vasodilation is usually sufficient to maintain a normal body temperature.

Response to Autonomic Drugs

Patients receiving ganglion-blocking drugs are fully responsive to autonomic drugs acting on muscarinic, α-, and β-adrenergic receptors because these effector cell receptors are not blocked. In fact, responses may be exaggerated or even reversed (eg, norepinephrine may cause tachycardia rather than bradycardia), because homeostatic reflexes, which normally moderate autonomic responses, are absent.

Clinical Applications & Toxicity

Use of the ganglion blockers is infrequent because more selective autonomic blocking agents are available. Mecamylamine is being studied for possible use in reducing nicotine craving in patients attempting to quit smoking and for some other central indications. Trimethaphan is occasionally used in the treatment of hypertensive emergencies and dissecting aortic aneurysm; to produce controlled hypotension, which can be of value in neurosurgery to reduce bleeding in the operative field; and in patients undergoing electroconvulsive therapy. The toxicity of the ganglion-blocking drugs is limited to the autonomic effects already described. For most patients, these effects are intolerable except for acute use.

PREPARATIONS AVAILABLE

Antimuscarinic Anticholinergic Drugs*

Atropine (generic)

Oral: 0.4, 0.6 mg tablets

Parenteral: 0.05, 0.1, 0.3, 0.4, 0.5, 0.8, 1 mg/mL for injection

Ophthalmic (generic, Isopto Atropine): 0.5, 1, 2% drops; 0.5, 1% ointments

Belladonna alkaloids, extract or tincture (generic)

Oral: 0.27–0.33 mg/mL liquid

Clidinium (generic, Quarzan, others)

Oral: 2.5, 5 mg capsules

Cyclopentolate (generic, Cyclogyl, others)

Ophthalmic: 0.5, 1, 2% drops

Darifenacin (Enablex)

Oral: 7.5, 15 mg tablets (extended release)

Dicyclomine (generic, Bentyl, others)

Oral: 10, 20 mg capsules; 20 mg tablets; 10 mg/5 mL syrup

Parenteral: 10 mg/mL for injection

Flavoxate (Urispas)

Oral: 100 mg tablets

Glycopyrrolate (generic, Robinul)

Oral: 1, 2 mg tablets

Parenteral: 0.2 mg/mL for injection

Homatropine (generic, Isopto Homatropine, others)

Ophthalmic: 2, 5% drops

l-Hyoscyamine (Anaspaz, Cystospaz-M, Levsinex)

Oral: 0.125, 0.15 mg tablets; 0.375 mg timed-release capsules; 0.125 mg/5 mL oral elixir and solution

Parenteral: 0.5 mg/mL for injection

Ipratropium (generic, Atrovent)

Aerosol: 200 dose metered-dose inhaler

Solution for nebulizer: 0.02%

Nasal spray: 0.03, 0.06%

Mepenzolate (Cantil)

Oral: 25 mg tablets

Methantheline (Banthine)

Oral: 50 mg tablets

Methscopolamine (Pamine)

Oral: 2.5 mg tablets

Oxybutynin (generic, Ditropan)

Oral: 5 mg tablets; 5, 10, 15 mg extended-release tablets; 5 mg/5 mL syrup

Propantheline (generic, Pro-Banthine, others)

Oral: 7.5, 15 mg tablets

Scopolamine (generic)

Oral: 0.25 mg tablets

Parenteral: 0.3, 0.4, 0.86, 1 mg/mL for injection

Ophthalmic (Isopto Hyoscine): 0.25% solution

Transdermal (Transderm Scop): 1.5 mg (delivers 0.5 mg) patch

Solifenacin (Vesicare)

Oral: 5, 10 mg tablets

Tiotropium (Spiriva)

Aerosol: 18 mcg tablet for inhaler

Tolterodine (Detrol)

Oral: 1, 2 mg tablets; 2, 4 mg extended-release capsules

Tridihexethyl (Pathilon)

Oral: 25 mg tablets

Tropicamide (generic, Mydriacyl Ophthalmic, others)

Ophthalmic: 0.5, 1% drops

Trospium (Spasmex)

Oral: 5, 15, 30 mg tablets

Suppository: 0.75, 1.0 mg

Parenteral: 0.6 mg/mL

Ganglion Blockers

Mecamylamine (Inversine)

Oral: 2.5 mg tablets

Trimethaphan (Arfonad)

Parenteral: 50 mg/mL

Cholinesterase Regenerator

Pralidoxime (generic, Protopam)

Parenteral: 1 g vial with 20 mL diluent for IV administration; 600 mg in 2 mL autoinjector

*Antimuscarinic drugs used in parkinsonism are listed in Chapter 28.

ADRENOCEPTOR-ACTIVATING & OTHER SYMPATHOMIMETIC DRUGS: INTRODUCTION

The sympathetic nervous system is an important regulator of the activities of organs such as the heart and peripheral vasculature, especially in responses to stress (see Chapter 6). The ultimate effects of sympathetic stimulation are mediated by release from nerve terminals of norepinephrine that serves to activate the adrenoceptors on postsynaptic sites. Also, in response to a variety of stimuli such as stress, the adrenal medulla releases epinephrine, which is transported in the blood to target tissues; in other words, epinephrine acts as a hormone. Drugs that mimic the actions of epinephrine or norepinephrine—sympathomimetic drugs —would be expected to have a wide range of effects. An understanding of the pharmacology of these agents is thus a logical extension of what we know about the physiologic role of the catecholamines.

The Mode & Spectrum of Action of Sympathomimetic Drugs

Like the cholinomimetic drugs, the sympathomimetics can be grouped by mode of action and by the spectrum of receptors that they activate. Some of these drugs (eg, norepinephrine and epinephrine) act by a *direct* mode; that is, they directly interact with and activate adrenoceptors. Others act *indirectly* ; their actions are dependent on the release of endogenous catecholamines. These indirect agents may have either of two different mechanisms: (1) displacement of stored catecholamines from the adrenergic nerve ending (eg, amphetamine and tyramine) or (2) inhibition of reuptake of catecholamines already released (eg, cocaine and tricyclic antidepressants). Some drugs have both direct and indirect actions. Both types of sympathomimetics, direct and indirect, ultimately cause activation of adrenoceptors, leading to some or all of the characteristic effects of endogenous catecholamines. The selectivity of different sympathomimetics for various types of adrenoceptors is discussed below.

BASIC PHARMACOLOGY OF SYMPATHOMIMETIC DRUGS

IDENTIFICATION OF ADRENOCEPTORS

The effort to understand the molecular mechanisms by which catecholamines act has a long and rich history. A great conceptual debt is owed to the work done by John Langley and Paul Ehrlich 100 years ago in developing the hypothesis that drugs have their effects by interacting with specific "receptive" substances. Raymond Ahlquist in 1948 rationalized a large body of observations by his conjecture that catecholamines acted via two principal receptors. He termed these receptors α and β. Alpha receptors are those that have the comparative potencies epinephrine $\geq$ norepinephrine >> isoproterenol. Beta receptors have the comparative potencies isoproterenol > epinephrine $\geq$ norepinephrine. Ahlquist's hypothesis was dramatically confirmed by the development of drugs that selectively antagonize β receptors but not α receptors (see Chapter 10). More recent evidence suggests that α receptors comprise two major families. At present, therefore, it appears appropriate to classify adrenoceptors into three major groups, namely, β, α_1, and α_2 receptors. Each of these major groups of receptors also has three subtypes. Considerable effort has been expended in elucidating structure-function relationships that determine ligand binding properties and the molecular signaling characteristics of the various adrenergic receptors.

BETA ADRENOCEPTORS

Soon after the demonstration of separate α and β receptors, it was found that there were at least two *subtypes* of β receptors, designated β_1 and β_2. These subtypes are operationally defined by their affinities for epinephrine and norepinephrine: β_1 receptors have approximately equal affinity for epinephrine and norepinephrine, whereas β_2 receptors have a higher affinity for epinephrine than for norepinephrine. Subsequently, β_3 receptors were identified as a novel and distinct third β-adrenoceptor subtype. These receptor types are listed in Table 9–1.

ALPHA ADRENOCEPTORS

Following the demonstration of the β subtypes, two major groups of α receptors were found: α_1 and α_2 . These receptors were originally identified with antagonist drugs that distinguished between α_1 and α_2 receptors. For example, α adrenoceptors were identified in a variety of tissues by measuring the binding of radiolabeled antagonist compounds that are considered to have a high affinity for these receptors, eg, dihydroergocryptine (α_1 and α_2), prazosin (α_1), and yohimbine (α_2). These radioligands were used to measure the number of receptors in tissues and to determine the affinity (by displacement of the radiolabeled ligand) of other drugs that interact with the receptors.

The concept of subtypes *within* the α_1 group emerged out of pharmacologic experiments that demonstrated complex shapes of agonist dose-response curves of smooth muscle contraction as well as differences in antagonist affinities in inhibiting contractile responses in various tissues. These experiments demonstrated the existence of two subtypes of α_1 receptor that could be distinguished on the basis of their reversible affinities for a variety of drugs and experimental compounds. A third α_1 -receptor subtype was subsequently identified by molecular cloning techniques. These α_1 receptors are termed α_{1A} , α_{1B} , and α_{1D} receptors. There is evidence that the α_{1A} receptor has splice variants. A major current area of investigation is determining the importance of each of these various subtypes in mediating α_1 -receptor responses in a variety of organs.

The hypothesis that there are subtypes of α_2 receptors emerged from pharmacologic experiments and molecular cloning. It is now known that there are three subtypes of α_2 receptors, termed α_{2A} , α_{2B} , and α_{2C} , which are products of distinct genes.

DOPAMINE RECEPTORS

The endogenous catecholamine dopamine produces a variety of biologic effects that are mediated by interactions with specific dopamine receptors (Table 9–1). These receptors are distinct from α and β receptors and are particularly important in the brain (see Chapters 21 and 29) and in the splanchnic and renal vasculature. There is now considerable evidence for the existence of at least five subtypes of dopamine receptors. Pharmacologically distinct dopamine receptor subtypes, termed D_1 and D_2, have been known for some time. Molecular cloning has identified several distinct genes encoding each of these subtypes. Further complexity occurs because of the presence of introns within the coding region of the D_2-like receptor genes, which allows for alternative splicing of the exons in this major subtype. There is extensive polymorphic variation in the D_4 human receptor gene. The terminology of the various subtypes is D_1, D_2, D_3, D_4, and D_5. They comprise two D_1-like receptors (D_1 and D_5) and three D_2-like (D_2, D_3, and D_4). These subtypes may have importance for understanding the efficacy and adverse effects of novel antipsychotic drugs (see Chapter 29).

Receptor Selectivity

Examples of clinically useful sympathomimetic agonists that are relatively selective for α_1-, α_2-, and β-adrenoceptor subgroups are compared with some nonselective agents in Table 9–2. Selectivity means that a drug may preferentially bind to one subgroup of receptors at concentrations too low to interact extensively with another subgroup. For example, norepinephrine preferentially activates β_1 receptors compared with β_2 receptors. However, selectivity is not usually absolute (nearly absolute selectivity has been termed "specificity"), and at higher concentrations related classes of receptor may also interact with the drug. As a result, the "numeric" subclassification of adrenoceptors is clinically important mainly for drugs that have relatively marked selectivity. Given interpatient variations in drug kinetics and dynamics, the extent of a drug's selectivity should be kept in mind if this property is viewed as clinically important in the treatment of an individual patient.

Table 9–2. Relative Selectivity of Adrenoceptor Agonists.

	Relative Receptor Affinities

[1] See text.

The exact number of adrenoceptor subtypes that are actually expressed in human tissues is uncertain, but expression of subtypes has been demonstrated in tissues in which the physiologic or pharmacologic importance of the subtype is not yet known. These results suggest the possibility of designing novel drugs to exploit the expression of a particular receptor subtype in a single target tissue. For example, determining which blood vessels express which subtypes of α_1 and α_2 receptors could lead to design of drugs having selectivity for certain vascular beds such as the splanchnic or coronary vessels. Similarly, there has been extensive investigation into the α_1 -receptor subtypes mediating pharmacologic responses in the human prostate (see Receptor Selectivity and Physiologic Functions of Adrenoceptor Subtypes).

Receptor Selectivity and Physiologic Functions of Adrenoceptor Subtypes: Lessons from Knockout Mice

Since pharmacologic tools used to evaluate the function of adrenoceptor subtypes have some limitations, a number of knockout mice have been developed with one or more adrenoceptor genes subjected to loss of function mutations, as described in Chapter 1 (see Pharmacology & Genetics). These models have their own complexities and extrapolations from mice to humans may be uncertain. Nonetheless, these studies have yielded some novel insights. For example, α-adrenoceptor subtypes play an important role in cardiac responses, the α_{2A} -adrenoceptor subtype is critical in transducing the effects of α_2 agonists on blood pressure control, and β_1 receptors play a predominant role in directly increasing heart rate in mouse heart.

MOLECULAR MECHANISMS OF SYMPATHOMIMETIC ACTION

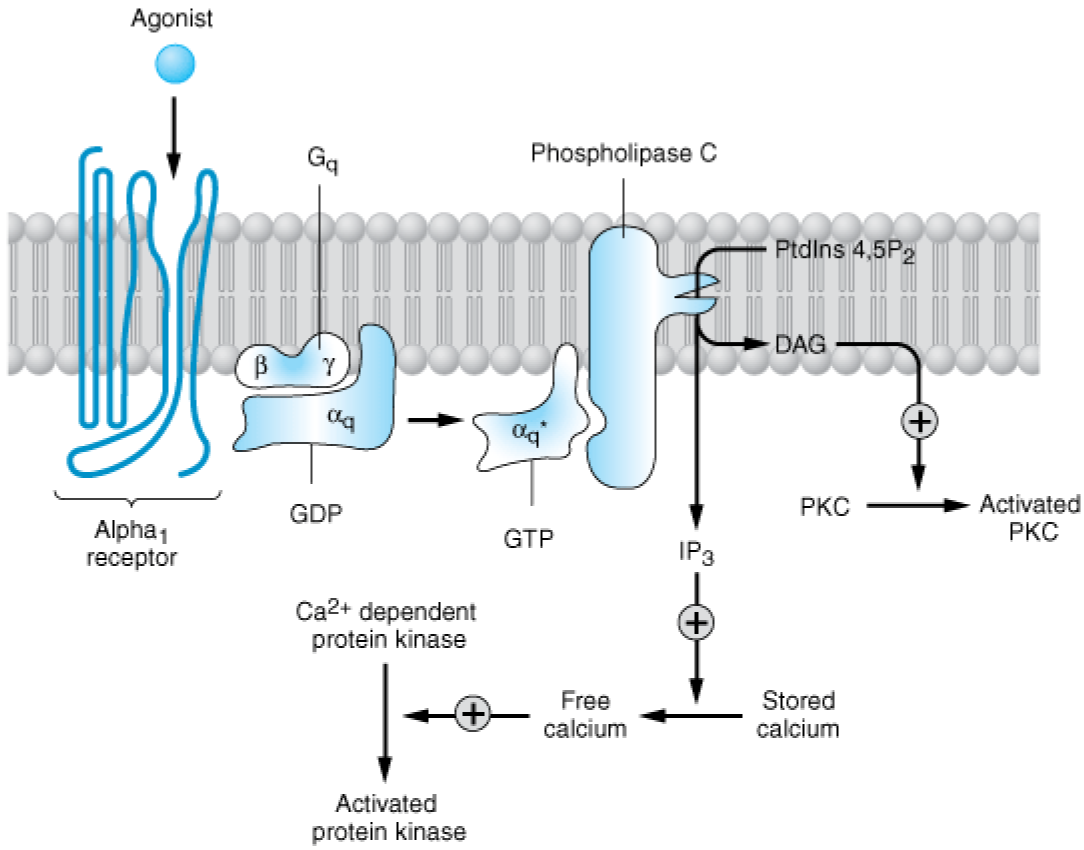
The effects of catecholamines are mediated by cell surface receptors. As described in Chapter 2, these GPCRs (G protein-coupled receptors) are coupled by G proteins to the various effector proteins whose activities are regulated by those receptors. Each G protein is a heterotrimer consisting of α, β, and γ subunits. G proteins are classified on the basis of their distinctive α subunits. G proteins of particular importance for adrenoceptor function include G_s , the stimulatory G protein of adenylyl cyclase; G_i , the inhibitory G protein of adenylyl cyclase; and G_q , the protein coupling α receptors to phospholipase C. The activation of G protein-coupled receptors by catecholamines promotes the dissociation of GDP from the α subunit of the appropriate G protein. GTP then binds to this G protein, and the α subunit dissociates from the β-γ unit. The activated GTP-bound α subunit then regulates the activity of its effector. Effectors of adrenoceptor-activated α subunits include adenylyl cyclase, cGMP phosphodiesterase, phospholipase C, and ion channels. The α subunit is inactivated by hydrolysis of the bound GTP to GDP and phosphate, and the subsequent reassociation of the α subunit with the β-γ subunit. The β-γ subunits have additional independent effects, acting on a variety of effectors such as ion channels and enzymes.

Receptor Types

ALPHA RECEPTORS

Alpha$_1$ receptors are coupled to polyphosphoinositide hydrolysis, leading to the formation of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) (Table 9–1, Figure 9–1). G proteins in the G_q family couple α_1 receptors to phospholipase C. IP_3 promotes the release of sequestered Ca^{2+} from intracellular stores, which increases the cytoplasmic concentration of free Ca^{2+} and the activation of various calcium-dependent protein kinases. Activation of these receptors may also increase influx of calcium across the cell's plasma membrane. IP_3 is sequentially dephosphorylated, which ultimately leads to the formation of free inositol. DAG activates protein kinase C, which modulates activity of many signaling pathways. In addition, α_1 receptors activate signal transduction pathways that were originally described for peptide growth factor receptors that activate tyrosine kinases. For example, α_1 receptors have been found to activate mitogen-activated kinases (MAP kinases) and polyphosphoinositol-3-kinase (PI-3-kinase). These pathways may have importance for the α_1 -receptor-mediated stimulation of cell growth and proliferation through the regulation of gene expression. The physiologic significance of this "cross talk" between major signaling pathways remains to be determined.

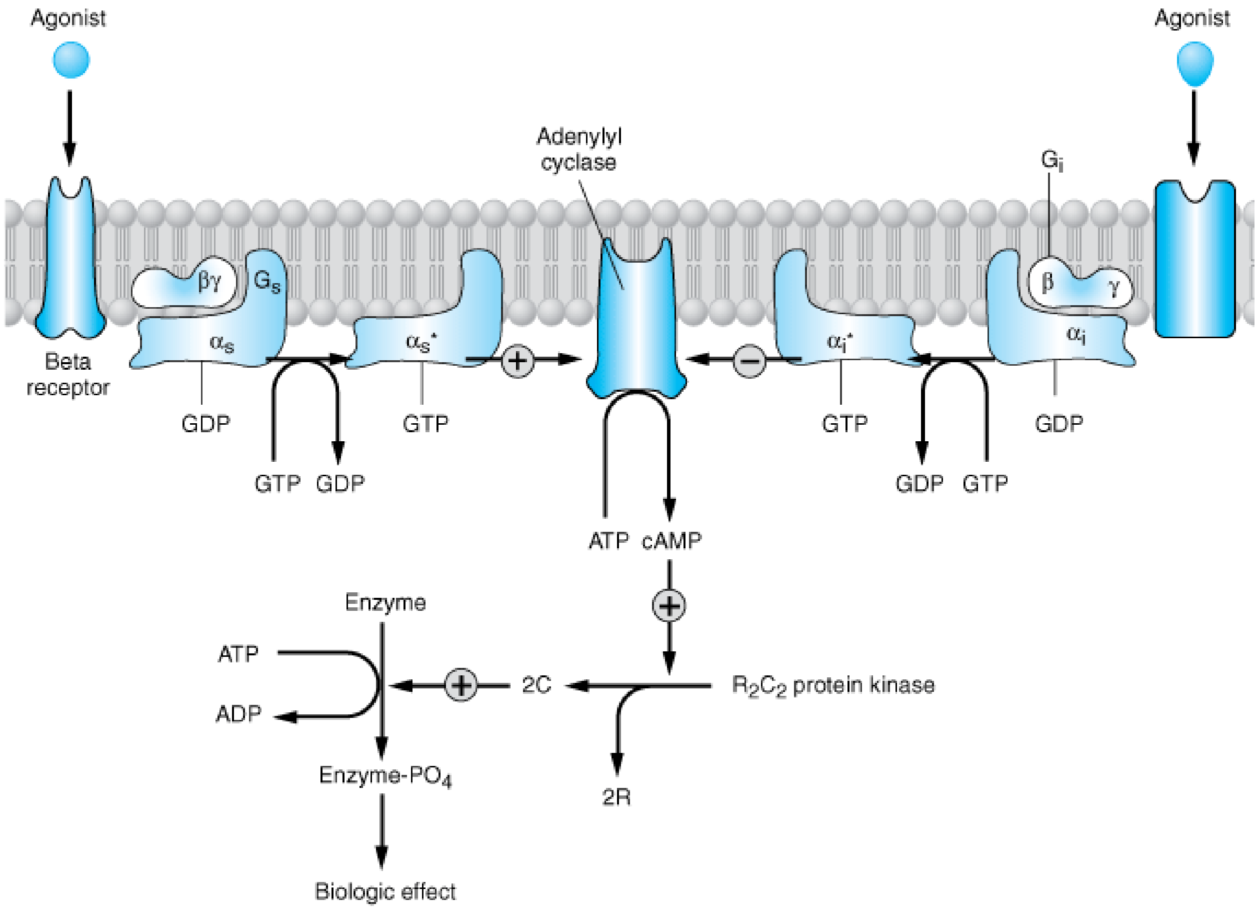
Figure 9–1.



Activation of α_1 responses. Stimulation of α_1 receptors by catecholamines leads to the activation of a G_q -coupling protein. The activated α subunit (α_q *) of this G protein activates the effector, phospholipase C, which leads to the release of IP_3 (inositol 1,4,5-trisphosphate) and DAG (diacylglycerol) from phosphatidylinositol 4,5-bisphosphate *(PtdIns 4,5-P $_2$)* . IP_3 stimulates the release of sequestered stores of calcium, leading to an increased concentration of cytoplasmic Ca^{2+} . Ca^{2+} may then activate Ca^{2+} -dependent protein kinases, which in turn phosphorylate their substrates. DAG activates protein kinase C (PKC). See text for additional effects of α_1 -receptor activation.

Alpha$_2$ receptors inhibit adenylyl cyclase activity and cause intracellular cyclic adenosine monophosphate (cAMP) levels to decrease. In addition to this well-documented effect, α_2 receptors utilize other signaling pathways, including regulation of ion channel activities and the activities of important enzymes involved in signal transduction. α_2 -receptor–mediated inhibition of adenylyl cyclase activity is transduced by the inhibitory regulatory protein, G_i (Figure 9–2). How the activation of G_i leads to the inhibition of adenylyl cyclase is unclear, but it is likely that both α and the β-γ subunits of G_i contribute to this response. In addition, some of the effects of α_2 adrenoceptors are independent of their ability to inhibit adenylyl cyclase; for example, α_2 -receptor agonists cause platelet aggregation and a decrease in platelet cAMP levels, but it is not clear whether aggregation is the result of the decrease in cAMP or other mechanisms involving G_i -regulated effectors.

Figure 9–2.



Activation and inhibition of adenylyl cyclase by agonists that bind to catecholamine receptors. Binding to βadrenoceptors stimulates adenylyl cyclase by activating the stimulatory G protein, G_s , which leads to the dissociation of its αsubunit charged with GTP. This activated α_s subunit directly activates adenylyl cyclase, resulting in an increased rate of synthesis of cAMP. Alpha$_2$ -adrenoceptor ligands inhibit adenylyl cyclase by causing dissociation of the inhibitory G protein, G_i , into its subunits; ie, an activated α_i subunit charged with GTP and a βγunit. The mechanism by which these subunits inhibit adenylyl cyclase is uncertain. cAMP binds to the regulatory subunit *(R)* of cAMP-dependent protein kinase, leading to the liberation of active catalytic subunits *(C)* that phosphorylate specific protein substrates and modify their activity. These catalytic units also phosphorylate the cAMP response element binding protein (CREB), which modifies gene expression. See text for other actions of βand α_2 adrenoceptors.

BETA RECEPTORS

The mechanism of action of βagonists has been studied in considerable detail. Activation of all three receptor subtypes (β_1 , β_2 , and β_3) results in activation of adenylyl cyclase and increased conversion of adenosine triphosphate (ATP) to cAMP (Table 9–1, Figure 9–2). Activation of the cyclase enzyme is mediated by the stimulatory coupling protein G_s . cAMP is the major second messenger of β-receptor activation. For example, in the liver of many species, β-receptor activation increases cAMP synthesis, which leads to a cascade of events culminating in the activation of glycogen phosphorylase. In the heart, β-receptor activation increases the influx of calcium across the cell membrane and its sequestration inside the cell. Beta-receptor activation also promotes the relaxation of smooth muscle. Although the mechanism of the smooth muscle effect is uncertain, it may involve the phosphorylation of myosin light-chain kinase to an inactive form (see Figure 12–1). Beta adrenoceptors may activate voltage-sensitive calcium channels in the heart via G_s -mediated enhancement independently of changes in cAMP concentration. Under certain circumstances, β_2 receptors may couple to G_q proteins. These receptors have been demonstrated to activate additional kinases, such as MAP kinases, by forming multi-subunit complexes within cells, which contain multiple signaling molecules. In addition, recent evidence suggests that formation of dimers of β receptors themselves (both homodimers and heterodimers of β_1 and β_2 receptors) is prominently involved in their signaling mechanisms. Moreover, agonist activation of β receptors promotes the association of several different proteins with these receptors, leading to activation of novel, additional signal pathways that regulate complex intracellular functions. Similarly, additional proteins interact directly with α_1 and α_2 receptors, leading to further physiologic responses at a cellular level.

DOPAMINE RECEPTORS

The D_1 receptor is typically associated with the stimulation of adenylyl cyclase (Table 9–1); for example, D_1 -receptor-induced smooth muscle relaxation is presumably due to cAMP accumulation in the smooth muscle of those vascular beds in which dopamine is a vasodilator. D_2 receptors have been found to inhibit adenylyl cyclase activity, open potassium channels, and decrease calcium influx.

Receptor Regulation

Responses mediated by adrenoceptors are not fixed and static. The number and function of adrenoceptors on the cell surface and their responses may be regulated by catecholamines themselves, other hormones and drugs, age, and a number of disease states (see Chapter 2). These changes may modify the magnitude of a tissue's physiologic response to catecholamines and can be important clinically during the course of treatment. One of the best-studied examples of receptor regulation is the desensitization of adrenoceptors that may occur after exposure to catecholamines and other sympathomimetic drugs. After a cell or tissue has been exposed for a period of time to an agonist, that tissue often becomes less responsive to further stimulation by that agent. Other terms such as tolerance, refractoriness, and tachyphylaxis have also been used to denote desensitization. This process has potential clinical significance because it may limit the therapeutic response to sympathomimetic agents.

Many mechanisms have been found to contribute to desensitization. Operating at transcriptional, translational, and protein levels, some mechanisms function relatively slowly—over the course of hours or days. Other mechanisms of desensitization occur quickly, within minutes. Rapid modulation of receptor function in desensitized cells may involve critical covalent modification of the receptor, especially by phosphorylation on specific amino acid residues, association of these receptors with other proteins, or changes in their subcellular location.

There are two major categories of desensitization of responses mediated by G protein-coupled receptors. Homologous desensitization refers to loss of responsiveness exclusively of the receptors that have been exposed to repeated or sustained activation by a drug. Heterologous desensitization refers to loss of responsiveness of some cell surface receptors that have not been directly activated by the drug in question.

A major mechanism of desensitization that occurs rapidly involves phosphorylation of receptors by members of the G protein-coupled receptor kinase (GRK) family, of which there are at least seven members. Specific adrenoceptors are substrates for these kinases only when they are bound to an agonist. This mechanism is an example of homologous desensitization because it specifically involves only agonist-occupied receptors.

Phosphorylation of these receptors enhances their affinity for β arrestins; upon binding of a β-arrestin molecule, the capacity of the receptor to activate G proteins is blunted, presumably due to steric hindrance (see Figure 2–12). Arrestins constitute another large family of widely expressed proteins. Receptor phosphorylation followed by β-arrestin binding has been linked to subsequent endocytosis of the receptor. This response may be facilitated by the capacity of β arrestins to bind to the structural protein clathrin. In addition to blunting responses requiring the presence of the receptor on the cell surface, these regulatory processes may also contribute to novel mechanisms of receptor signaling via intracellular pathways.

Receptor desensitization may also be mediated by second-messenger feedback. For example, β adrenoceptors stimulate cAMP accumulation, which leads to activation of protein kinase A; protein kinase A can phosphorylate residues on β receptors, resulting in inhibition of receptor function. For the β_2 receptor, phosphorylation occurs on serine residues both in the third cytoplasmic loop and in the carboxyl terminal tail of the receptor. Similarly, activation of protein kinase C by G_q -coupled receptors may lead to phosphorylation of this class of G protein-coupled receptors. This second-messenger feedback mechanism has been termed heterologous desensitization because activated protein kinase A or protein kinase C may phosphorylate any structurally similar receptor with the appropriate consensus sites for phosphorylation by these enzymes.

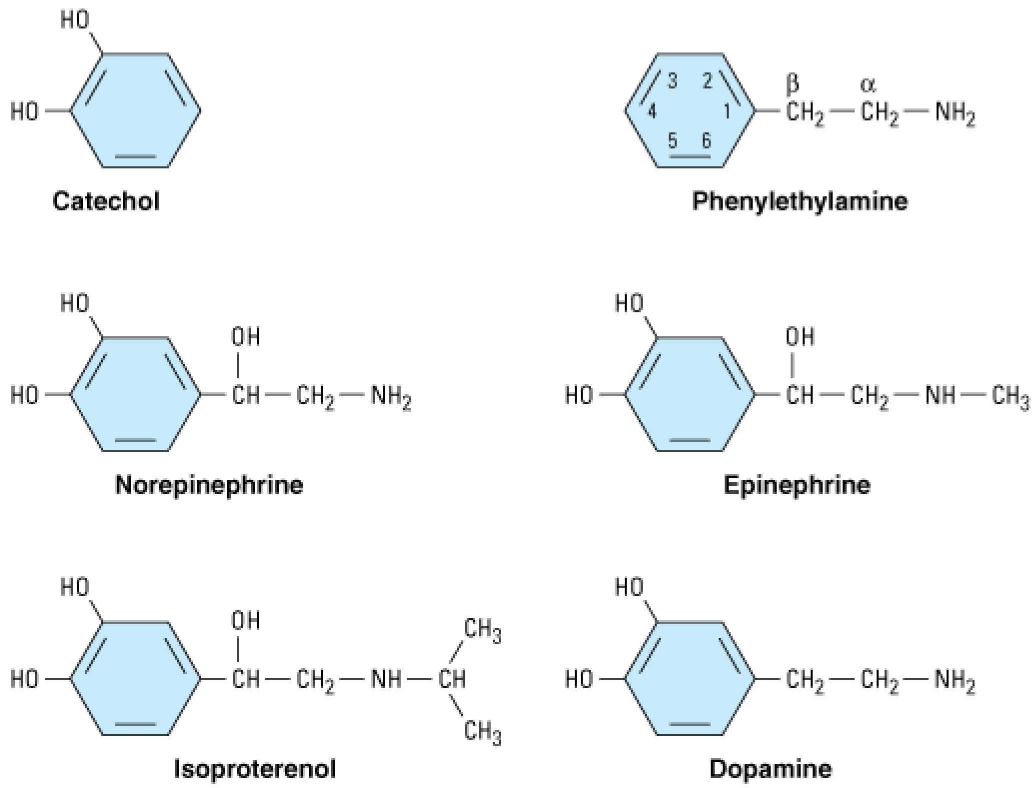
ADRENOCEPTOR POLYMORPHISMS

Since elucidation of the sequences of the genes encoding the α_1 , α_2 , and β subtypes of adrenoceptors, it has become clear that there are relatively common genetic polymorphisms for many of these receptor subtypes in humans. Some of these may lead to changes in critical amino acid sequences that have pharmacologic importance. There is evidence that some of these polymorphisms may change the susceptibility to diseases such as heart failure, alter the propensity of a receptor to desensitize, and alter therapeutic responses to drugs in diseases such as asthma.

CHEMISTRY & PHARMACOKINETICS OF SYMPATHOMIMETIC DRUGS

Phenylethylamine may be considered the parent compound from which sympathomimetic drugs are derived (Figure 9–3). This compound consists of a benzene ring with an ethylamine side chain. Substitutions may be made (1) on the terminal amino group, (2) on the benzene ring, and (3) on the α or β carbons. Substitution by –OH groups at the 3 and 4 positions yields sympathomimetic drugs collectively known as catecholamines. The effects of modification of phenylethylamine are to change the affinity of the drugs for α and β receptors as well as to influence the intrinsic ability to activate the receptors. In addition, chemical structure determines the pharmacokinetic properties of these molecules. Sympathomimetic drugs may activate both α and β receptors; however, the relative α-receptor versus β-receptor activity spans the range from almost pure α activity (methoxamine) to almost pure β activity (isoproterenol).

Figure 9–3.



Phenylethylamine and some important catecholamines. Catechol is shown for reference.

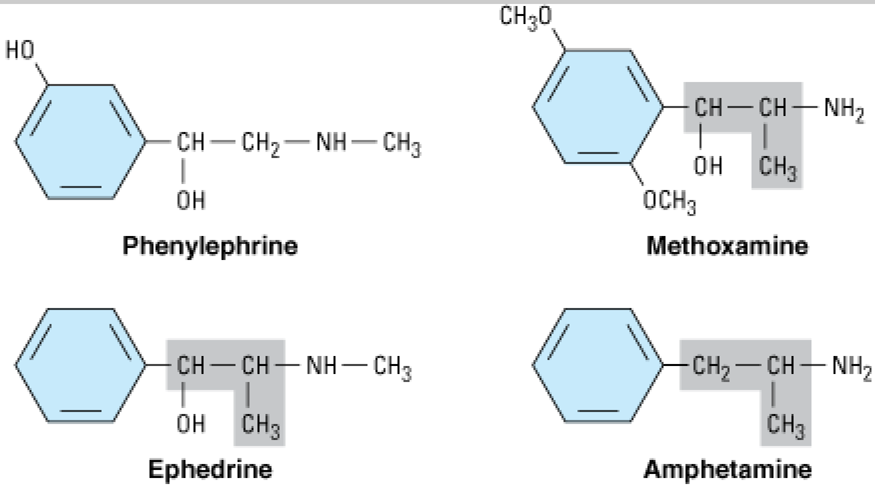
SUBSTITUTION ON THE AMINO GROUP

Increasing the size of alkyl substituents on the amino group tends to increase β-receptor activity. For example, methyl substitution on norepinephrine, yielding epinephrine, enhances activity at β_2 receptors. Beta activity is further enhanced with isopropyl substitution at the amino nitrogen (isoproterenol). $Beta_2$ -selective agonists generally require a large amino substituent group. The larger the substituent on the amino group, the lower the activity at α receptors; for example, isoproterenol is very weak at α receptors.

SUBSTITUTION ON THE BENZENE RING

Maximal α and β activity is found with catecholamines (drugs having –OH groups at the 3 and 4 positions). The absence of one or the other of these groups, particularly the hydroxyl at C_3 , without other substitutions on the ring may dramatically reduce the potency of the drugs. For example, phenylephrine (Figure 9–4) is much less potent than epinephrine; indeed, α-receptor affinity is decreased about 100-fold and β activity is almost negligible except at very high concentrations. However, catecholamines are subject to inactivation by catechol-*O*- methyltransferase (COMT), an enzyme found in gut and liver (see Chapter 6). Therefore, absence of one or both –OH groups on the phenyl ring increases the bioavailability after oral administration and prolongs the duration of action. Furthermore, absence of ring –OH groups tends to increase the distribution of the molecule to the central nervous system. For example, ephedrine and amphetamine (Figure 9–4) are orally active, have a prolonged duration of action, and produce central nervous system effects not typically observed with the catecholamines.

Figure 9–4.



Some examples of noncatecholamine sympathomimetic drugs. The isopropyl group is shown in gray.

SUBSTITUTION ON THE ALPHA CARBON

Substitutions at the α carbon block oxidation by monoamine oxidase (MAO) and prolong the action of such drugs, particularly the noncatecholamines. Ephedrine and amphetamine are examples of α-substituted compounds (Figure 9–4). Alpha-methyl compounds are also called phenylisopropylamines. In addition to their resistance to oxidation by MAO, some phenylisopropylamines have an enhanced ability to displace catecholamines from storage sites in noradrenergic nerves (see Chapter 6). Therefore, a portion of their activity is dependent on the presence of normal norepinephrine stores in the body; they are indirectly acting sympathomimetics.

SUBSTITUTION ON THE BETA CARBON

Direct-acting agonists typically have a β-hydroxyl group, though dopamine does not. In addition to facilitating activation of adrenoceptors, this hydroxyl group may be important for storage of sympathomimetic amines in neural vesicles.

ORGAN SYSTEM EFFECTS OF SYMPATHOMIMETIC DRUGS

General outlines of the cellular actions of sympathomimetics are presented in Tables 6–3 and 9–3. The net effect of a given drug in the intact organism depends on its relative receptor affinity (α or β), intrinsic activity, and the compensatory reflexes evoked by its direct actions.

Cardiovascular System

BLOOD VESSELS

Vascular smooth muscle tone is regulated by adrenoceptors; consequently, catecholamines are important in controlling peripheral vascular resistance and venous capacitance. Alpha receptors increase arterial resistance, whereas β_2 receptors promote smooth muscle relaxation. There are major differences in receptor types in the various vascular beds (Table 9–4). The skin vessels have predominantly α receptors and constrict in response to epinephrine and norepinephrine, as do the splanchnic vessels. Vessels in skeletal muscle may constrict or dilate depending on whether α or β receptors are activated. Consequently, the overall effects of a sympathomimetic drug on blood vessels depend on the relative activities of that drug at α and β receptors and the anatomic sites of the vessels affected. In addition, D_1 receptors promote vasodilation of renal, splanchnic, coronary, cerebral, and perhaps other resistance vessels. Activation of the D_1 receptors in the renal vasculature may play a major role in the natriuresis induced by pharmacologic administration of dopamine.

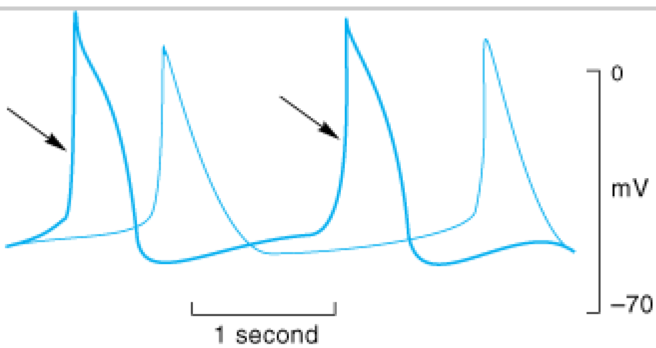
[2] Small doses decrease, large doses increase.

HEART

Direct effects on the heart are determined largely by β_1 receptors, although β_2 and to a lesser extent α receptors are also involved, especially in heart failure. Beta-receptor activation results in increased calcium influx in cardiac cells. This has both electrical (Figure 9–5) and mechanical consequences. Pacemaker activity, both normal (sinoatrial node) and abnormal (eg, Purkinje fibers), is increased (positive chronotropic effect). Conduction velocity in the atrioventricular node is increased, and the refractory period is decreased. Intrinsic contractility is increased (positive inotropic effect), and relaxation is accelerated. As a result, the twitch response of isolated cardiac muscle is increased in tension but abbreviated in duration. In the intact heart, intraventricular pressure rises and falls more rapidly, and ejection time is decreased. These direct effects are easily demonstrated in the absence of reflexes evoked by changes in blood pressure, eg, in isolated myocardial preparations and in patients with ganglionic blockade. In the presence of normal reflex activity, the direct effects on heart rate may be dominated by a reflex response to blood pressure changes. Physiologic stimulation of the heart by catecholamines tends to increase coronary blood flow.

Figure 9–5.

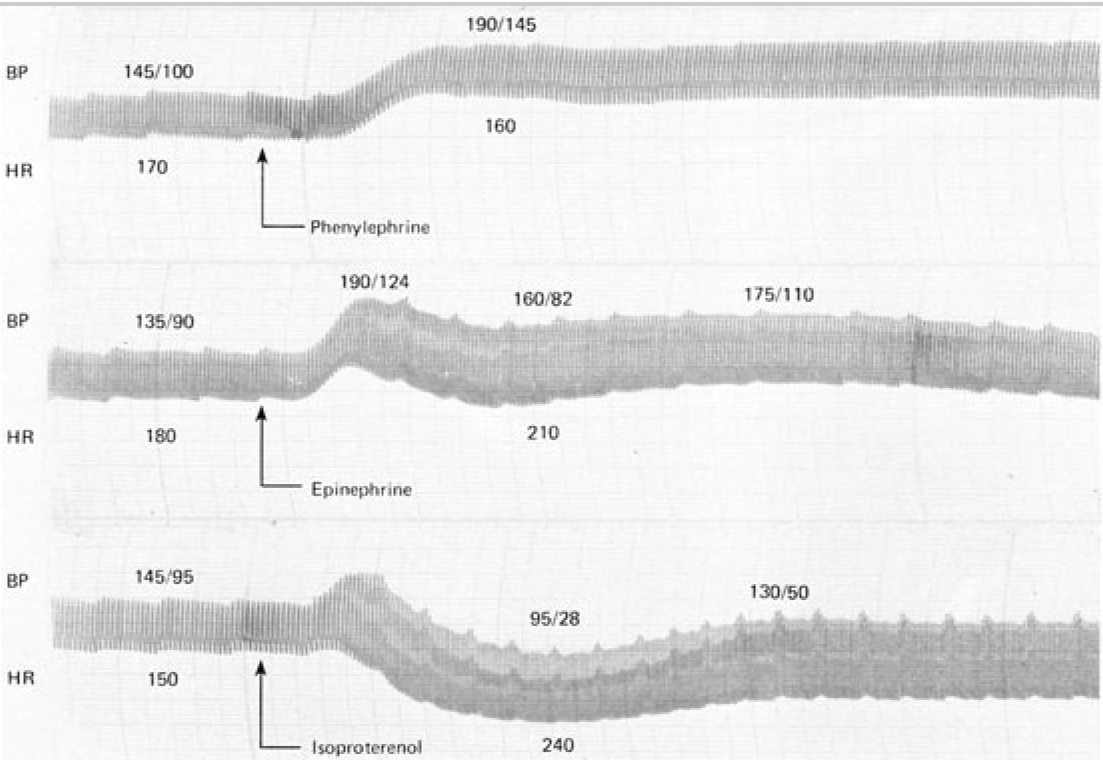


Effect of epinephrine on the transmembrane potential of a pacemaker cell in the frog heart. The arrowed trace was recorded after the addition of epinephrine. Note the increased slope of diastolic depolarization and decreased interval between action potentials. This pacemaker acceleration is typical of β_1 -stimulant drugs. (Modified and reproduced, with permission, from Brown H, Giles W, Noble S: Membrane currents underlying rhythmic activity in frog sinus venosus. In: Bonke FIM [editor]: *The Sinus Node: Structure, Function, and Clinical Relevance.* Martinus Nijhoff, 1978.)

BLOOD PRESSURE

The effects of sympathomimetic drugs on blood pressure can be explained on the basis of their effects on the heart, the peripheral vascular resistance, and the venous return (see Figure 6–7 and Table 9–4). A relatively pure α agonist such as phenylephrine increases peripheral arterial resistance and decreases venous capacitance. The enhanced arterial resistance usually leads to a dose-dependent rise in blood pressure (Figure 9–6). In the presence of normal cardiovascular reflexes, the rise in blood pressure elicits a baroreceptor-mediated increase in vagal tone with slowing of the heart rate, which may be quite marked. However, cardiac output may not diminish in proportion to this reduction in rate, since increased venous return may increase stroke volume. Furthermore, direct α-adrenoceptor stimulation of the heart may have a modest positive inotropic action. While these are the expected effects of pure α agonists in normal subjects, their use in hypotensive patients usually does not lead to brisk reflex responses because in this situation blood pressure is returning to normal, not exceeding normal.

Figure 9–6.



Effects of an α-selective (phenylephrine), β-selective (isoproterenol), and nonselective (epinephrine) sympathomimetic, given as an intravenous bolus injection to a dog. (BP, blood pressure; HR, heart rate.) Reflexes are blunted but not eliminated in this anesthetized animal.

The blood pressure response to a pure β-adrenoceptor agonist is quite different. Stimulation of β receptors in the heart increases cardiac output. A relatively pure β agonist such as isoproterenol also decreases peripheral resistance by activating β_2 receptors, leading to vasodilation in certain vascular beds (Table 9–4). The net effect is to maintain or slightly increase systolic pressure while permitting a fall in diastolic pressure owing to enhanced diastolic runoff (Figure 9–6). The actions of drugs with both α and β effects (eg, epinephrine and norepinephrine) are discussed below.

Eye

The radial pupillary dilator muscle of the iris contains α receptors; activation by drugs such as phenylephrine causes mydriasis (see Figure 6–9). Alpha stimulants also have important effects on intraocular pressure. Present evidence suggests that α agonists increase the outflow of aqueous humor from the eye and reduce intraocular pressure. In contrast, β agonists have little effect, but β *antagonists* decrease the production of aqueous humor. These effects are important in the treatment of glaucoma (see Chapter 10), a leading cause of blindness. Beta stimulants relax the ciliary muscle to a minor degree, causing an insignificant decrease in accommodation. In addition, adrenergic drugs may directly protect neuronal cells in the retina.

Respiratory Tract

Bronchial smooth muscle contains β_2 receptors that cause relaxation. Activation of these receptors results in bronchodilation (see Chapter 20 and Table 9–3). The blood vessels of the upper respiratory tract mucosa contain α receptors; the decongestant action of adrenoceptor stimulants is clinically useful (see Clinical Pharmacology).

Table 9–3. Distribution of Adrenoceptor Subtypes.

Type	Tissue	Actions
α_1	Most vascular smooth muscle (innervated)	Contraction
	Pupillary dilator muscle	Contraction (dilates pupil)
	Pilomotor smooth muscle	Erects hair
	Prostate	Contraction
	Heart	Increases force of contraction
α_2		

Postsynaptic CNS adrenoceptors

Probably multiple

Platelets

Aggregation

Adrenergic and cholinergic nerve terminals

Inhibition of transmitter release

Some vascular smooth muscle

Contraction

Fat cells

Inhibition of lipolysis

β_1

Heart

Increases force and rate of contraction

β_2

Respiratory, uterine, and vascular smooth muscle

Promotes smooth muscle relaxation

Skeletal muscle

Promotes potassium uptake

Human liver

Activates glycogenolysis

β_3

Fat cells

Activates lipolysis

D_1

Smooth muscle

Dilates renal blood vessels

D_2

Nerve endings

Modulates transmitter release

Gastrointestinal Tract

Relaxation of gastrointestinal smooth muscle can be brought about by both α- and β-stimulant agents. Beta receptors appear to be located directly on the smooth muscle cells and mediate relaxation via hyperpolarization and decreased spike activity in these cells. Alpha stimulants, especially α_2 -selective agonists, decrease muscle activity *indirectly* by presynaptically reducing the release of acetylcholine and possibly other stimulants within the enteric nervous system (see Chapter 6). The α-receptor-mediated response is probably of greater pharmacologic significance than the β-stimulant response. Alpha$_2$ receptors may also decrease salt and water flux into the lumen of the intestine.

Genitourinary Tract

The human uterus contains $\alpha$and β_2 receptors. The fact that the βreceptors mediate relaxation may be clinically useful in pregnancy (see Clinical Pharmacology). The bladder base, urethral sphincter, and prostate contain αreceptors that mediate contraction and therefore promote urinary continence. The specific subtype of α_1 receptor involved in mediating constriction of the bladder base and prostate is uncertain, but α_{1A} receptors probably play an important role. The β_2 receptors of the bladder wall mediate relaxation. Ejaculation depends on normal α-receptor (and possibly purinergic receptor) activation in the ductus deferens, seminal vesicles, and prostate. The detumescence of erectile tissue that normally follows ejaculation is also brought about by norepinephrine (and possibly neuropeptide Y) released from sympathetic nerves. Alpha activation appears to have a similar detumescent effect on erectile tissue in female animals.

Exocrine Glands

The salivary glands contain adrenoceptors that regulate the secretion of amylase and water. However, certain sympathomimetic drugs, eg, clonidine, produce symptoms of dry mouth. The mechanism of this effect is uncertain; it is likely that central nervous system effects are responsible, though peripheral effects may contribute.

The apocrine sweat glands, located on the palms of the hands and a few other areas, respond to adrenoceptor stimulants with increased sweat production. These are the apocrine nonthermoregulatory glands usually associated with psychologic stress. (The diffusely distributed thermoregulatory eccrine sweat glands are regulated by *sympathetic cholinergic* postganglionic nerves that activate muscarinic cholinoceptors; see Chapter 6.)

Metabolic Effects

Sympathomimetic drugs have important effects on intermediary metabolism. Activation of βadrenoceptors in fat cells leads to increased lipolysis with enhanced release of free fatty acids and glycerol into the blood. Beta$_3$ adrenoceptors play a role in mediating this response. There is considerable interest in developing β_3 -receptor-selective agonists, which could be useful in some metabolic disorders. Human lipocytes also contain α_2 receptors that inhibit lipolysis by decreasing intracellular cAMP. Sympathomimetic drugs enhance glycogenolysis in the liver, which leads to increased glucose release into the circulation. In the human liver, the effects of catecholamines are probably mediated mainly by βreceptors, though α_1 receptors may also play a role. Catecholamines in high concentration may also cause metabolic acidosis. Activation of β_2

adrenoceptors by endogenous epinephrine or by sympathomimetic drugs promotes the uptake of potassium into cells, leading to a fall in extracellular potassium. This may lead to a fall in the plasma potassium concentration during stress or protect against a rise in plasma potassium during exercise. Blockade of these receptors may accentuate the rise in plasma potassium that occurs during exercise. Beta receptors and α_2 receptors that are expressed in pancreatic islets tend to increase and decrease, respectively, insulin secretion, although the major regulator of insulin release is the plasma concentration of glucose.

Effects on Endocrine Function & Leukocytosis

Catecholamines are important endogenous regulators of hormone secretion from a number of glands. As mentioned above, insulin secretion is stimulated by β receptors and inhibited by α_2 receptors. Similarly, renin secretion is stimulated by β_1 and inhibited by α_2 receptors; indeed, β-receptor antagonist drugs may lower plasma renin and blood pressure in patients with hypertension at least in part by this mechanism. Adrenoceptors also modulate the secretion of parathyroid hormone, calcitonin, thyroxine, and gastrin; however, the physiologic significance of these control mechanisms is probably limited. In high concentrations, epinephrine and related agents cause leukocytosis, in part by promoting demargination of white blood cells sequestered away from the general circulation.

Effects on the Central Nervous System

The action of sympathomimetics on the central nervous system varies dramatically, depending on their ability to cross the blood-brain barrier. The catecholamines are almost completely excluded by this barrier, and subjective central nervous system effects are noted only at the highest rates of infusion. These effects have been described as ranging from "nervousness" to "a feeling of impending disaster," sensations that are undesirable. Furthermore, peripheral effects of β-adrenoceptor agonists such as tachycardia and tremor are similar to the somatic manifestations of anxiety. In contrast, noncatecholamines with indirect actions, such as amphetamines, which readily enter the central nervous system from the circulation, produce qualitatively very different central nervous system effects. These actions vary from mild alerting, with improved attention to boring tasks; through elevation of mood, insomnia, euphoria, and anorexia; to full-blown psychotic behavior. These effects are not readily assigned to either α- or β-mediated actions and may represent enhancement of dopamine-mediated processes or other effects of these drugs in the central nervous system.

SPECIFIC SYMPATHOMIMETIC DRUGS

Catecholamines

Epinephrine (adrenaline) is a very potent vasoconstrictor and cardiac stimulant. The rise in systolic blood pressure that occurs after epinephrine release or administration is caused by its positive inotropic and chronotropic actions on the heart (predominantly β_1 receptors) and the vasoconstriction induced in many vascular beds (α receptors). Epinephrine also activates β_2 receptors in some vessels (eg, skeletal muscle blood vessels), leading to their dilation. Consequently, total peripheral resistance may actually fall, explaining the fall in diastolic pressure that is sometimes seen with epinephrine injection (Figure 9–6; Table 9–4). Activation of these β_2 receptors in skeletal muscle contributes to increased blood flow during exercise. Under physiologic conditions, epinephrine functions largely as a hormone; after release from the adrenal medulla into the blood, it acts on distant cells.

Norepinephrine (levarterenol, noradrenaline) and epinephrine have similar effects on β_1 receptors in the heart and similar potency at α receptors. Norepinephrine has relatively little effect on β_2 receptors. Consequently, norepinephrine increases peripheral resistance and both diastolic and systolic blood pressure. Compensatory vagal reflexes tend to overcome the direct positive chronotropic effects of norepinephrine; however, the positive inotropic effects on the heart are maintained (Table 9–4).

Isoproterenol (isoprenaline) is a very potent β-receptor agonist and has little effect on α receptors. The drug has positive chronotropic and inotropic actions; because isoproterenol activates β receptors almost exclusively, it is a potent vasodilator. These actions lead to a marked increase in cardiac output associated with a fall in diastolic and mean arterial pressure and a lesser decrease or a slight increase in systolic pressure (Table 9–4; Figure 9–6).

Dopamine, the immediate metabolic precursor of norepinephrine, activates D_1 receptors in several vascular beds, which leads to vasodilation. The effect this has on renal blood flow can be of clinical value. The activation of presynaptic D_2 receptors, which suppress norepinephrine release, contributes to these effects to an unknown extent. In addition, dopamine activates β_1 receptors in the heart. At low doses, peripheral resistance may decrease. At higher rates of infusion, dopamine activates vascular α receptors, leading to vasoconstriction, including in the renal vascular bed. Consequently, high rates of infusion of dopamine may mimic the actions of epinephrine.

Fenoldopam is a D_1 -receptor agonist that selectively leads to peripheral vasodilation in some vascular beds. The primary indication for fenoldopam is in the intravenous treatment of severe hypertension (Chapter 11). Continuous infusions of the drug have prompt effects on blood pressure.

Dopamine agonists with central actions are of considerable value for the treatment of Parkinson's disease and prolactinemia. These agents are discussed in Chapters 28 and 37.

Dobutamine is a relatively β_1 -selective synthetic catecholamine. As discussed below, dobutamine also activates α_1 receptors.

Other Sympathomimetics

These agents are of interest because of pharmacokinetic features (oral activity, distribution to the central nervous system) or because of relative selectivity for specific receptor subclasses.

Phenylephrine was previously described as an example of a relatively pure α agonist (Table 9–2). It acts directly on the receptors. Because it is not a catechol derivative (Figure 9–4), it is not inactivated by COMT and has a much longer duration of action than the catecholamines. It is an effective mydriatic and decongestant and can be used to raise the blood pressure (Figure 9–6).

Methoxamine acts pharmacologically like phenylephrine, since it is predominantly a direct-acting α_1 -receptor agonist. It may cause a prolonged increase in blood pressure due to vasoconstriction; it also causes a vagally mediated bradycardia. Methoxamine is available for parenteral use, but clinical applications are rare and limited to hypotensive states.

Midodrine is a prodrug that is enzymatically hydrolyzed to desglymidodrine, an α_1 -receptor-selective agonist. The peak concentration of desglymidodrine is achieved about 1 hour after midodrine is administered. The primary indication for midodrine is the treatment of postural hypotension, typically due to impaired autonomic nervous system function. Although the drug has efficacy in diminishing the fall of blood pressure when the patient is standing, it may cause hypertension when the subject is supine.

Ephedrine occurs in various plants and has been used in China for over 2000 years; it was introduced into Western medicine in 1924 as the first orally active sympathomimetic drug. It is found in ma-huang, a popular herbal medication (see Chapter 65). Ma-huang contains multiple ephedrine-like alkaloids in addition to ephedrine. Because ephedrine is a noncatechol phenylisopropylamine (Figure 9–4), it has high bioavailability and a relatively long duration of action—hours rather than minutes. As is the case with many other phenylisopropylamines, a significant fraction of the drug is excreted unchanged in the urine. Since it is a weak base, its excretion can be accelerated by acidification of the urine.

Ephedrine has not been extensively studied in humans in spite of its long history of use. Its ability to activate β receptors probably accounted for its earlier use in asthma. Because it gains access to the central nervous system, it is a mild stimulant. Ingestion of ephedrine alkaloids contained in ma-huang has raised important safety concerns. Pseudoephedrine, one of four ephedrine enantiomers, has been available over the counter as a component of many decongestant mixtures. However, the use of pseudoephedrine as a precursor in the illicit manufacture of methamphetamine has led to restrictions on its sale.

Xylometazoline and oxymetazoline are direct-acting α agonists. These drugs have been used as topical decongestants because of their ability to promote constriction of the nasal mucosa. When taken in large doses, oxymetazoline may cause hypotension, presumably because of a central clonidine-like effect (Chapter 11). Oxymetazoline has significant affinity for α_{2A} receptors.

Amphetamine is a phenylisopropylamine (Figure 9–4) that is important chiefly because of its use and misuse as a central nervous system stimulant (see Chapter 32). Its pharmacokinetics are similar to those of ephedrine; however, amphetamine even more readily enters the central nervous system, where it has marked stimulant effects on mood and alertness and a depressant effect on appetite. Its peripheral actions are mediated primarily through the release of catecholamines. Methamphetamine (*N*-methylamphetamine) is very similar to amphetamine with an even higher ratio of central to peripheral actions. Phenmetrazine is a variant phenylisopropylamine with amphetamine-like effects. It has been promoted as an anorexiant and is also a popular drug of abuse. Methylphenidate and pemoline are amphetamine variants whose major pharmacologic effects and abuse potential are similar to those of amphetamine. These two drugs appear to have efficacy in some children with attention deficit hyperactivity disorder (see Clinical Pharmacology). Pemoline has been withdrawn from use in the USA because of an association with life-threatening hepatic failure. Modafinil is a new drug with both similarities to and differences from amphetamine. It has significant effects on central α_{1B} receptors but in addition appears to affect GABAergic, glutaminergic, and serotonergic synapses (see Clinical Pharmacology).

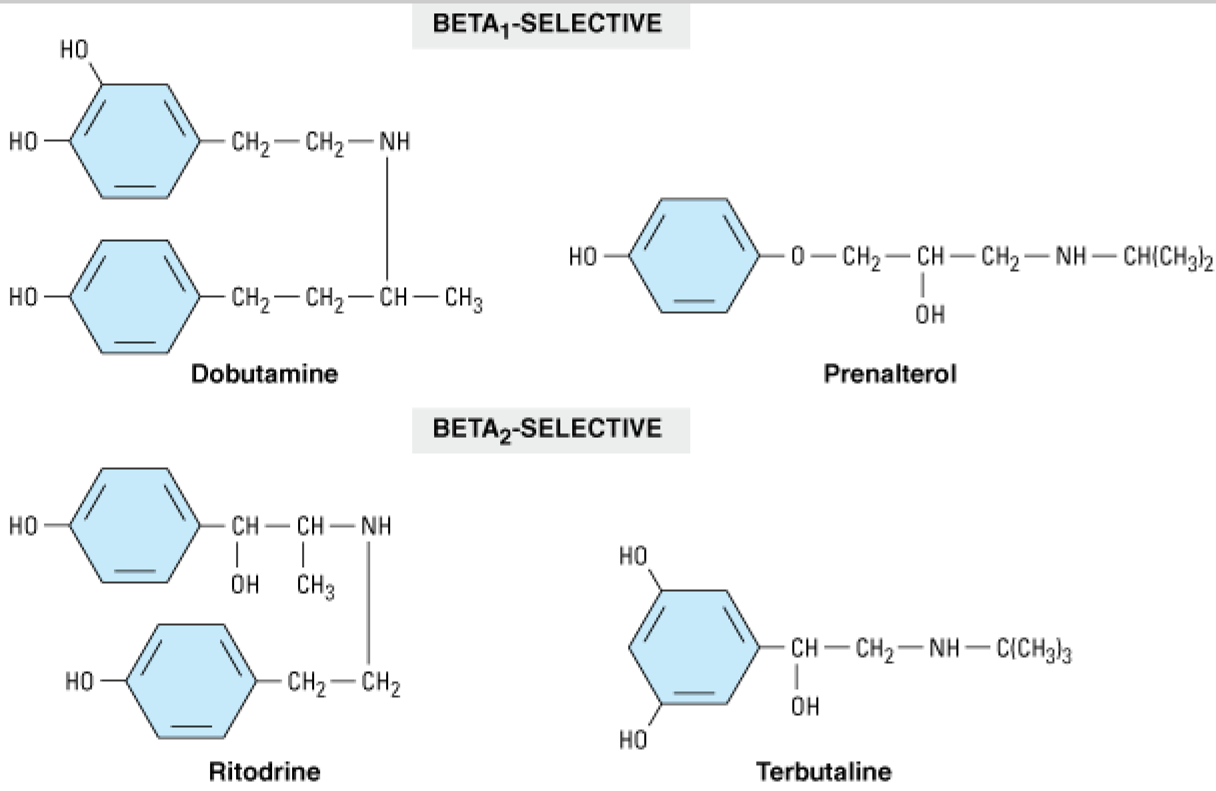
Receptor-Selective Sympathomimetic Drugs

$Alpha_2$ -selective agonists have an important ability to decrease blood pressure through actions in the central nervous system even though direct application to a blood vessel may cause vasoconstriction. Such drugs (eg, clonidine, methyldopa, guanfacine, guanabenz) are useful in the treatment of hypertension (and some other conditions) and are discussed in Chapter 11. Dexmedetomidine is a centrally acting α_2 -selective agonist that is indicated for sedation of initially intubated and mechanically ventilated patients during treatment in an intensive care setting.

Beta-selective agonists are very important because of the separation of β_1 and β_2 effects that has been achieved (Table 9–2). Although this separation is incomplete, it is sufficient to reduce adverse effects in several clinical applications.

Beta$_1$ -selective agents include dobutamine and a partial agonist, prenalterol (Figure 9–7). Because they are less effective in activating vasodilator β_2 receptors, they may increase cardiac output with less reflex tachycardia than occurs with nonselective β agonists such as isoproterenol. Dobutamine consists of two isomers, administered as a racemic mixture. The (+) isomer is a potent β_1 agonist and an α_1 receptor antagonist. The (–) isomer is a potent α_1 agonist, capable of causing significant vasoconstriction when given alone. This action tends to reduce vasodilation and may also contribute to the positive inotropic action caused by the isomer with predominantly β-receptor activity. A major limitation with these drugs—as with other direct-acting sympathomimetic agents—is that tolerance to their effects may develop with prolonged use and the likelihood that chronic cardiac stimulation in patients with heart failure may worsen long-term outcome.

Figure 9–7.



Examples of β_1 - and β_2 -selective agonists.

Beta$_2$ -selective agents have achieved an important place in the treatment of asthma and are discussed in Chapter 20. An additional application is to achieve uterine relaxation in premature labor (ritodrine; see below). Some examples of β_2 -selective drugs currently in use are shown in Figures 9–7 and 20–4; many more are available or under investigation.

Special Sympathomimetics

Cocaine is a local anesthetic with a peripheral sympathomimetic action that results from inhibition of transmitter reuptake at noradrenergic synapses (see Chapter 6). It readily enters the central nervous system and produces an amphetamine-like effect that is shorter lasting and more intense. The major action of cocaine in the central nervous system is to inhibit dopamine reuptake into neurons in the "pleasure centers" of the brain. These properties and the fact that it can be smoked, "snorted" into the nose, or injected for rapid onset of effect have made it a heavily abused drug (see Chapter 32). Interestingly, dopamine-transporter knockout mice still self-administer cocaine, suggesting that cocaine may have additional pharmacologic targets.

Tyramine (see Figure 6–5) is a normal by-product of tyrosine metabolism in the body and is also found in high concentrations in some fermented foods such as cheese (Table 9–5). It is readily metabolized by MAO in the liver and is normally inactive when taken orally because of a very high first-pass effect, ie, low bioavailability. If administered parenterally, it has an indirect sympathomimetic action caused by the release of stored catecholamines. Consequently, its spectrum of action is similar to that of norepinephrine. In patients treated with MAO inhibitors—particularly inhibitors of the MAO-A isoform—this effect of tyramine may be greatly intensified, leading to marked increases in blood pressure. This occurs because of increased bioavailability of tyramine and increased neuronal stores of catecholamines. Patients taking MAO inhibitors must be very careful to avoid tyramine-containing foods. There are differences in the effects of various MAO inhibitors on tyramine bioavailability, and isoform-specific or reversible enzyme antagonists may be safer (see Chapters 28 and 30).

Table 9–5. Foods Reputed to Have a High Content of Tyramine or Other Sympathomimetic Agents.

Food	Tyramine Content of an Average Serving
Beer	(No data)
Broad beans, fava beans	Negligible (but contains dopamine)
Cheese, natural or aged	Nil to 130 mg (cheddar, Gruyère, and Stilton especially high)
Chicken liver	Nil to 9 mg
Chocolate	Negligible (but contains phenylethylamine)
Sausage, fermented (eg, salami, pepperoni, summer sausage)	Nil to 74 mg
Smoked or pickled fish (eg, pickled herring)	Nil to 198 mg
Snails	

(No data)

Wine (red)

Nil to 3 mg

Yeast (eg, dietary brewer's yeast supplements)

2–68 mg

Note: In a patient taking an irreversible MAO inhibitor drug, 20–50 mg of tyramine in a meal may increase the blood pressure significantly (see also Chapter 30: Antidepressant Agents). Note that only cheese, sausage, pickled fish, and yeast supplements contain sufficient tyramine to be consistently dangerous. This does not rule out the possibility that some preparations of other foods might contain significantly greater than average amounts of tyramine.

CLINICAL PHARMACOLOGY OF SYMPATHOMIMETIC DRUGS

The rationale for the use of sympathomimetic drugs in therapy rests on a knowledge of the physiologic effects of catecholamines on tissues. Selection of a particular sympathomimetic drug from the host of compounds available depends upon such factors as whether activation of α, β_1 , or β_2 receptors is desired; the duration of action desired; and the preferred route of administration. Sympathomimetic drugs are very potent and can have profound effects on a variety of organ systems, particularly the heart and peripheral circulation. Therefore, great caution is indicated when these agents are used parenterally. In most cases, rather than using fixed doses of the drugs, careful monitoring of pharmacologic response is required to determine the appropriate dosage, especially if the drug is being infused. Generally, it is desirable to use the minimum dose required to achieve the desired response. The adverse effects of these drugs are generally understandable in terms of their known physiologic effects.

Cardiovascular Applications

CONDITIONS IN WHICH BLOOD FLOW OR PRESSURE IS TO BE ENHANCED

Hypotension may occur in a variety of settings such as decreased blood volume, cardiac arrhythmias, neurologic disease or accidents, adverse reactions to medications such as antihypertensive drugs, and infection. If cerebral, renal, cardiac perfusion is maintained, hypotension itself does not usually require vigorous direct treatment. Rather, placing the patient in the recumbent position and ensuring adequate fluid volume, while the primary problem is determined and treated, is usually the correct course of action. The use of sympathomimetic drugs merely to elevate a blood pressure that is not an immediate threat to the patient may increase morbidity (see Toxicity of Sympathomimetic Drugs, below). Sympathomimetic drugs may be used in a hypotensive emergency to preserve cerebral and coronary blood flow. Such situations might arise in severe hemorrhage, spinal cord injury, or overdoses of antihypertensive or central nervous system depressant medications. The treatment is usually of short duration while the appropriate intravenous fluid or blood is being administered. Direct-acting α agonists such as norepinephrine, phenylephrine, or methoxamine have been utilized in this setting if vasoconstriction is desired. For the treatment of chronic orthostatic hypotension, oral ephedrine has been the traditional therapy. Midodrine, an orally active α agonist, may be the preferred sympathomimetic in this application if further studies confirm its long-term safety and efficacy.

Shock is a complex acute cardiovascular syndrome that results in a critical reduction in perfusion of vital tissues and a wide range of systemic effects. Shock is usually associated with hypotension, an altered mental state, oliguria, and metabolic acidosis. If untreated, shock usually progresses to a refractory deteriorating state and death. The three major mechanisms responsible for shock are hypovolemia, cardiac insufficiency, and altered vascular resistance. Volume replacement and treatment of the underlying disease are the mainstays of the treatment of shock. Although sympathomimetic drugs have been used in the treatment of virtually all forms of shock, their efficacy is unclear.

In most forms of shock, vasoconstriction mediated by the sympathetic nervous system is already intense. Indeed, efforts aimed at reducing rather than increasing peripheral resistance may be more fruitful if cerebral, coronary, and renal perfusion are improved. A decision to use vasoconstrictors or vasodilators is best made on the basis of information about the underlying cause, which may require invasive monitoring.

Cardiogenic shock, usually due to massive myocardial infarction, has a poor prognosis. Mechanically assisted perfusion and emergency cardiac surgery have been utilized in some settings. Optimal fluid replacement requires monitoring of pulmonary capillary wedge pressure and other parameters of cardiac function. Positive inotropic agents such as dopamine or dobutamine may have a role in this situation. In low to moderate doses, these drugs may increase cardiac output and, compared with norepinephrine, cause relatively little peripheral vasoconstriction. Isoproterenol increases heart rate and work more than either dopamine or dobutamine. See Chapter 13 and Table 13–4 for a discussion of shock associated with myocardial infarction.

Unfortunately, the patient with shock may not respond to any of these therapeutic maneuvers; the temptation is then great to use vasoconstrictors to maintain adequate blood pressure. Coronary perfusion may be improved, but this gain may be offset by increased myocardial oxygen demands as well as more severe vasoconstriction in blood vessels to the abdominal viscera. Therefore, the goal of therapy in shock should be to optimize tissue perfusion, not blood pressure.

CONDITIONS IN WHICH BLOOD FLOW IS TO BE REDUCED

Reduction of local or regional blood flow is desirable for achieving hemostasis in surgery, for reducing diffusion of local anesthetics away from the site of administration, and for reducing mucous membrane congestion. In each instance, α-receptor activation is desired, and the choice of agent depends upon the maximal efficacy required, the desired duration of action, and the route of administration.

Effective pharmacologic hemostasis, often necessary for facial, oral, and nasopharyngeal surgery, requires drugs of high efficacy that can be administered in high concentration by local application. Epinephrine is usually applied topically in nasal packs (for epistaxis) or in a gingival string (for gingivectomy). Cocaine is still sometimes used for nasopharyngeal surgery, because it combines a hemostatic effect with local anesthesia. Occasionally, cocaine is mixed with epinephrine for maximum hemostasis and local anesthesia.

Combining α agonists with some local anesthetics greatly prolongs the duration of infiltration nerve block; the total dose of local anesthetic (and the probability of toxicity) can therefore be reduced. Epinephrine, 1:200,000, is the favored agent for this application, but norepinephrine, phenylephrine, and other α agonists have also been used. Systemic effects on the heart and peripheral vasculature may occur even with local drug administration.

Mucous membrane decongestants are α agonists that reduce the discomfort of hay fever and, to a lesser extent, the common cold by decreasing the volume of the nasal mucosa. These effects are probably mediated by α_1 receptors. Unfortunately, rebound hyperemia may follow the use of these agents, and repeated topical use of high drug concentrations may result in ischemic changes in the mucous membranes, probably as a result of vasoconstriction of nutrient arteries. Constriction of these vessels may involve activation of α_2 receptors. For example, phenylephrine is often used in nasal decongestant sprays. A longer duration of action—at the cost of much lower local concentrations and greater potential for cardiac and central nervous system effects—can be achieved by the oral administration of agents such as ephedrine or one of its isomers, pseudoephedrine. Long-acting topical decongestants include xylometazoline and oxymetazoline. Most of these mucous membrane decongestants are available as over-the-counter products.

CARDIAC APPLICATIONS

Catecholamines such as isoproterenol and epinephrine have been used in the temporary emergency management of complete heart block and cardiac arrest. Epinephrine may be useful in cardiac arrest in part by redistributing blood flow during cardiopulmonary resuscitation to coronaries and to the brain. However, electronic pacemakers are both safer and more effective in heart block and should be inserted as soon as possible if there is any indication of continued high-degree block.

Heart failure may respond to the positive inotropic effects of drugs such as dobutamine. These applications are discussed in Chapter 13. The development of tolerance or desensitization is a major limitation to the use of catecholamines in heart failure.

Pulmonary Applications

One of the most important uses of sympathomimetic drugs is in the therapy of bronchial asthma. This use is discussed in Chapter 20. Nonselective drugs (epinephrine), β-selective agents (isoproterenol), and β_2 -selective agents (metaproterenol, terbutaline, albuterol) are all available for this indication. Sympathomimetics other than the β_2 -selective drugs are now rarely used because they are likely to have more adverse effects than the selective drugs.

Anaphylaxis

Anaphylactic shock and related immediate (type I) IgE-mediated reactions affect both the respiratory and the cardiovascular systems. The syndrome of bronchospasm, mucous membrane congestion, angioedema, and severe hypotension usually responds rapidly to the parenteral administration of epinephrine, 0.3–0.5 mg (0.3–0.5 mL of 1:1000 epinephrine solution). Intramuscular injection may be the preferred route of administration, since skin blood flow (and hence systemic drug absorption from subcutaneous injection) is unpredictable in hypotensive patients. In some patients with impaired cardiovascular function, intravenous injection of epinephrine may be required. Extensive experimental and clinical experience with the drug in anaphylaxis supports epinephrine as the agent of choice, presumably because epinephrine activates α, β_1 , and β_2 receptors, all of which may be important in reversing the pathophysiologic processes underlying anaphylaxis. Glucocorticoids and antihistamines (both H_1 - and H_2 -receptor antagonists) may be useful as secondary therapy in anaphylaxis; however, epinephrine is the initial treatment.

Ophthalmic Applications

Phenylephrine is an effective mydriatic agent frequently used to facilitate examination of the retina. It is also a useful decongestant for minor allergic hyperemia and itching of the conjunctival membranes. Sympathomimetics administered as ophthalmic drops are also useful in localizing the lesion in Horner's syndrome. (See An Application of Basic Pharmacology to a Clinical Problem.)

Glaucoma responds to a variety of sympathomimetic and sympathoplegic drugs. (See Chapter 10: The Treatment of Glaucoma.) Epinephrine and its prodrug dipivefrin are now rarely used, but β-blocking agents are among the most important therapies. Apraclonidine and brimonidine are α_2 -selective agonists that also lower intraocular pressure and are approved for use in glaucoma. The mechanism of action of these drugs in treating glaucoma is still uncertain; direct neuroprotective effects may be involved in addition to the benefits of lowering intraocular pressure.

AN APPLICATION OF BASIC PHARMACOLOGY TO A CLINICAL PROBLEM

Horner's syndrome is a condition—usually unilateral—that results from interruption of the sympathetic nerves to the face. The effects include vasodilation, ptosis, miosis, and loss of sweating on the side affected. The syndrome can be caused by either a preganglionic or a postganglionic lesion, such as a tumor. Knowledge of the location of the lesion (preganglionic or postganglionic) helps determine the optimal therapy.

An understanding of the effects of denervation on neurotransmitter metabolism permits the clinician to use drugs to localize the lesion. In most situations, a localized lesion in a nerve causes degeneration of the distal portion of that fiber and loss of transmitter contents from the degenerated nerve ending—without affecting neurons innervated by the fiber. Therefore, a preganglionic lesion leaves the postganglionic adrenergic neuron intact, whereas a postganglionic lesion results in degeneration of the adrenergic nerve endings and loss of stored catecholamines from them. Because indirectly acting sympathomimetics require normal stores of catecholamines, such drugs can be used to test for the presence of normal adrenergic nerve endings. The iris, because it is easily visible and responsive to topical sympathomimetics, is a convenient assay tissue in the patient.

If the lesion of Horner's syndrome is postganglionic, indirectly acting sympathomimetics (eg, cocaine, hydroxyamphetamine) will not dilate the abnormally constricted pupil because catecholamines have been lost from the nerve endings in the iris. In contrast, the pupil dilates in response to phenylephrine, which acts directly on the α receptors on the smooth muscle of the iris. A patient with a preganglionic lesion, on the other hand, shows a normal response to both drugs, since the postganglionic fibers and their catecholamine stores remain intact in this situation.

Genitourinary Applications

As noted above, β_2 -selective agents relax the pregnant uterus. Ritodrine, terbutaline, and similar drugs have been used to suppress premature labor. The goal is to defer labor long enough to ensure adequate maturation of the fetus. These drugs may delay labor for several days. This may afford time to administer corticosteroid drugs, which decrease the incidence of neonatal respiratory distress syndrome. However, meta-analysis of older trials and a randomized study suggest that β-agonist therapy may have no significant benefit on perinatal infant mortality and may increase maternal morbidity.

Oral sympathomimetic therapy is occasionally useful in the treatment of stress incontinence. Ephedrine or pseudoephedrine may be tried.

Central Nervous System Applications

The amphetamines have a mood-elevating (euphoriant) effect; this effect is the basis for the widespread abuse of this drug and some of its analogs (see Chapter 32). The amphetamines also have an alerting, sleep-deferring action that is manifested by improved attention to repetitive tasks and by acceleration and desynchronization of the electroencephalogram. A therapeutic application of this effect is in the treatment of narcolepsy. Modafinil, a new amphetamine substitute, is approved for use in narcolepsy and is claimed to have fewer disadvantages (excessive mood changes, insomnia, abuse potential) than amphetamine in this condition. The appetite-suppressing effect of these agents is easily demonstrated in experimental animals. In obese humans, an encouraging initial response may be observed, but there is no evidence that long-term improvement in weight control can be achieved with amphetamines alone, especially when administered for a relatively short course. A final application of the CNS-active sympathomimetics is in the attention-deficit hyperactivity disorder (ADHD) of children, a poorly defined and overdiagnosed behavioral syndrome consisting of short attention span, hyperkinetic physical behavior, and learning problems. Some patients with this syndrome respond well to low doses of methylphenidate and related agents or to clonidine. Extended-release formulations of methylphenidate may simplify dosing regimens and increase adherence to therapy, especially in school-age children. Evidence from several clinical trials suggests that modafinil may also be useful in ADHD.

Additional Therapeutic Uses

Although the primary use of the α_2 agonist clonidine is in the treatment of hypertension (Chapter 11), the drug has been found to have efficacy in the treatment of diarrhea in diabetics with autonomic neuropathy, perhaps because of its ability to enhance salt and water absorption from the intestines. In addition, clonidine has efficacy in diminishing craving for narcotics and alcohol during withdrawal and may facilitate cessation of cigarette smoking. Clonidine has also been used to diminish menopausal hot flushes and is being used experimentally to reduce hemodynamic instability during general anesthesia. Dexmedetomidine is indicated for sedation under intensive care circumstances.

TOXICITY OF SYMPATHOMIMETIC DRUGS

The adverse effects of adrenoceptor agonists are primarily extensions of their pharmacologic effects in the cardiovascular and central nervous systems.

Adverse cardiovascular effects seen with intravenously infused pressor agents include marked elevations in blood pressure that cause increased cardiac work, which may precipitate cardiac ischemia and failure. Systemically administered β-receptor-stimulant drugs may cause sinus tachycardia and may even provoke serious ventricular arrhythmias. Sympathomimetic drugs may lead to myocardial damage, particularly after prolonged infusion. Special caution is indicated in elderly patients and those with hypertension or coronary artery disease. To avoid excessive pharmacologic responses, it is essential to monitor the blood pressure when administering sympathomimetic drugs parenterally.

If an adverse sympathomimetic effect requires urgent reversal, a specific adrenoceptor antagonist can be used (see Chapter 10).

Central nervous system toxicity is rarely observed with catecholamines or drugs such as phenylephrine. In moderate doses, amphetamines commonly cause restlessness, tremor, insomnia, and anxiety; in high doses, a paranoid state may be induced. Cocaine may precipitate convulsions, cerebral hemorrhage, arrhythmias, or myocardial infarction. Therapy is discussed in Chapter 59.

PREPARATIONS AVAILABLE[1]

Amphetamine, racemic mixture (generic)

Oral: 5, 10 mg tablets

Oral (Adderall): 1:1:1:1 mixtures of amphetamine sulfate, amphetamine aspartate, dextroamphetamine sulfate, and dextroamphetamine saccharate, formulated to contain a total of 5, 7.5, 10, 12.5, 15, 20, or 30 mg in tablets; or 10, 20, or 30 mg in capsules

Apraclonidine (Iopidine)

Topical: 0.5, 1% solutions

Brimonidine (Alphagan)

Topical: 0.15, 0.2% solution

Dexmedetomidine (Precedex)

Parenteral: 100 mcg/mL

Dexmethylphenidate (Focalin)

Oral: 2.5, 5, 10 mg tablets

Dextroamphetamine (generic, Dexedrine)

Oral: 5, 10 mg tablets

Oral sustained-release: 5, 10, 15 mg capsules

Oral mixtures with amphetamine: see Amphetamine (Adderall)

Dipivefrin (generic, Propine)

Topical: 0.1% ophthalmic solution

Dobutamine (generic, Dobutrex)

Parenteral: 12.5 mg/mL in 20 mL vials for injection

Dopamine (generic, Intropin)

Parenteral: 40, 80, 160 mg/mL for injection; 80, 160, 320 mg/100 mL in 5% D/W for injection

Ephedrine (generic)

Oral: 25 mg capsules

Parenteral: 50 mg/mL for injection

Epinephrine (generic, Adrenalin Chloride, others)

Parenteral: 1:1000 (1 mg/mL), 1:2000 (0.5 mg/mL), 1:10,000 (0.1 mg/mL), 1:100,000 (0.01 mg/mL) for injection

Parenteral autoinjector (Epipen): 1:1000 (1 mg/mL), 1:2000 (0.5 mg/mL)

Ophthalmic: 0.1, 0.5, 1, 2% drops

Nasal: 0.1% drops and spray

Aerosol for bronchospasm (Primatene Mist, Bronkaid Mist): 0.22 mg/spray

Solution for aerosol: 1:100

Fenoldopam (Corlopam)

Parenteral: 10 mg/mL for IV infusion

Hydroxyamphetamine (Paredrine)

Ophthalmic: 1% drops

Isoproterenol (generic, Isuprel)

Parenteral: 1:5000 (0.2 mg/mL), 1:50,000 (0.02 mg/mL) for injection

Mephentermine (Wyamine Sulfate)

Parenteral: 15, 30 mg/mL for injection

Metaraminol (Aramine)

Parenteral: 10 mg/mL for injection

Methamphetamine (Desoxyn)

Oral: 5 mg tablets

Methoxamine (Vasoxyl)

Parenteral: 20 mg/mL for injection

Methylphenidate (generic, Ritalin, Ritalin-SR)

Oral: 5, 10, 20 mg tablets

Oral sustained-release: 10, 18, 20, 27, 36, 54 mg tablets; 20, 30, 40 mg capsules

Midodrine (ProAmatine)

Oral: 2.5, 5, 10 mg tablets

Modafinil (Provigil)

Oral: 100, 200 mg tablets

Naphazoline (generic, Privine)

Nasal: 0.05% drops and spray

Ophthalmic: 0.012, 0.02, 0.03, 0.1% drops

Norepinephrine (generic, Levophed)

Parenteral: 1 mg/mL for injection

Oxymetazoline (generic, Afrin, Neo-Synephrine 12 Hour, Visine LR)

Nasal: 0.05% spray

Ophthalmic: 0.025% drops

Phenylephrine (generic, Neo-Synephrine)

Oral: 10 mg chewable tablets

Parenteral: 10 mg/mL for injection

Nasal: 0.125, 0.16, 0.25, 0.5, 1% drops and spray

Ophthalmic: 0.12, 2.5, 10% solution

Pseudoephedrine (generic, Sudafed)

Oral: 30, 60 mg tablets; 30, 60 mg capsules; 15, 30 mg/5 mL syrups; 7.5 mg/0.8 mL drops

Oral extended-release: 120, 240 mg tablets, capsules

Tetrahydrozoline (generic, Tyzine)

Nasal: 0.05, 0.1% drops

Ophthalmic: 0.05% drops

Xylometazoline (generic, Otrivin)

Nasal: 0.05, 0.1% drops

[1] α_2 -Agonists used in hypertension are listed in Chapter 11. β_2 -Agonists used in asthma are listed in Chapter 20.

ADRENOCEPTOR ANTAGONIST DRUGS: INTRODUCTION

Since catecholamines play a role in a variety of physiologic and pathophysiologic responses, drugs that block adrenoceptors have important effects, some of which are of great clinical value. These effects vary dramatically according to the drug's selectivity for α and β receptors. The classification of adrenoceptors into α_1, α_2, and β subtypes and the effects of activating these receptors are discussed in Chapters 6 and 9. Blockade of peripheral dopamine receptors is of no recognized clinical importance at present. In contrast, blockade of central nervous system dopamine receptors is very important; drugs that act on these receptors are discussed in Chapters 21 and 29. This chapter deals with pharmacologic antagonist drugs whose major effect is to occupy either α_1, α_2, or β receptors outside the central nervous system and prevent their activation by catecholamines and related agonists.

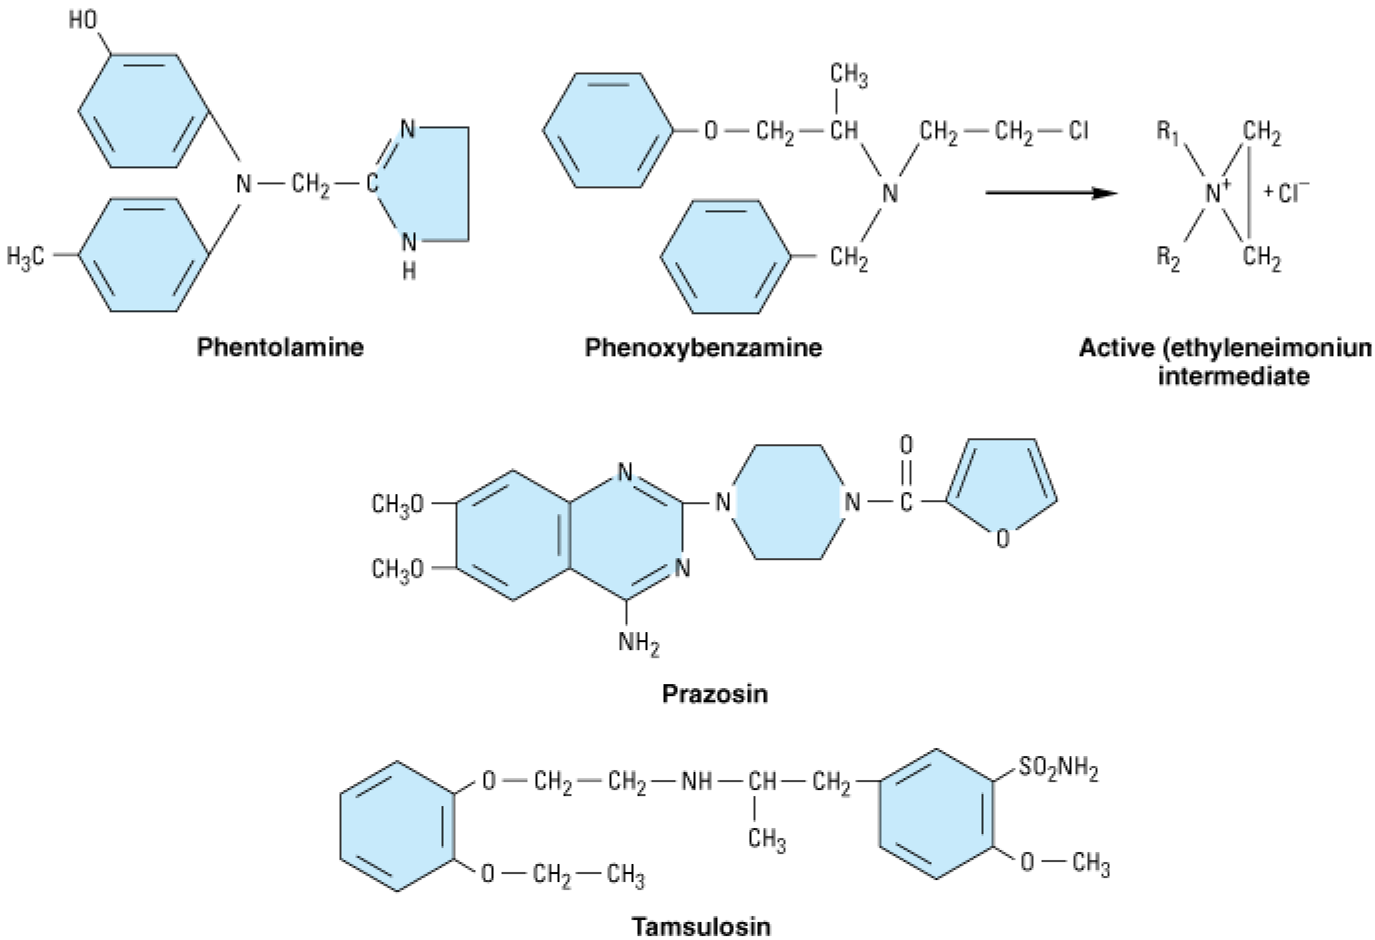
For pharmacologic research, α_1- and α_2-adrenoceptor antagonist drugs have been very useful in the experimental exploration of autonomic nervous system function. In clinical therapeutics, nonselective α antagonists are used in the treatment of pheochromocytoma (tumors that secrete catecholamines), and α_1-selective antagonists are used in primary hypertension and benign prostatic hyperplasia. Beta-receptor antagonist drugs have been found useful in a much wider variety of clinical conditions and are firmly established in the treatment of hypertension, ischemic heart disease, arrhythmias, endocrinologic and neurologic disorders, glaucoma, and other conditions.

BASIC PHARMACOLOGY OF THE ALPHA-RECEPTOR ANTAGONIST DRUGS

Mechanism of Action

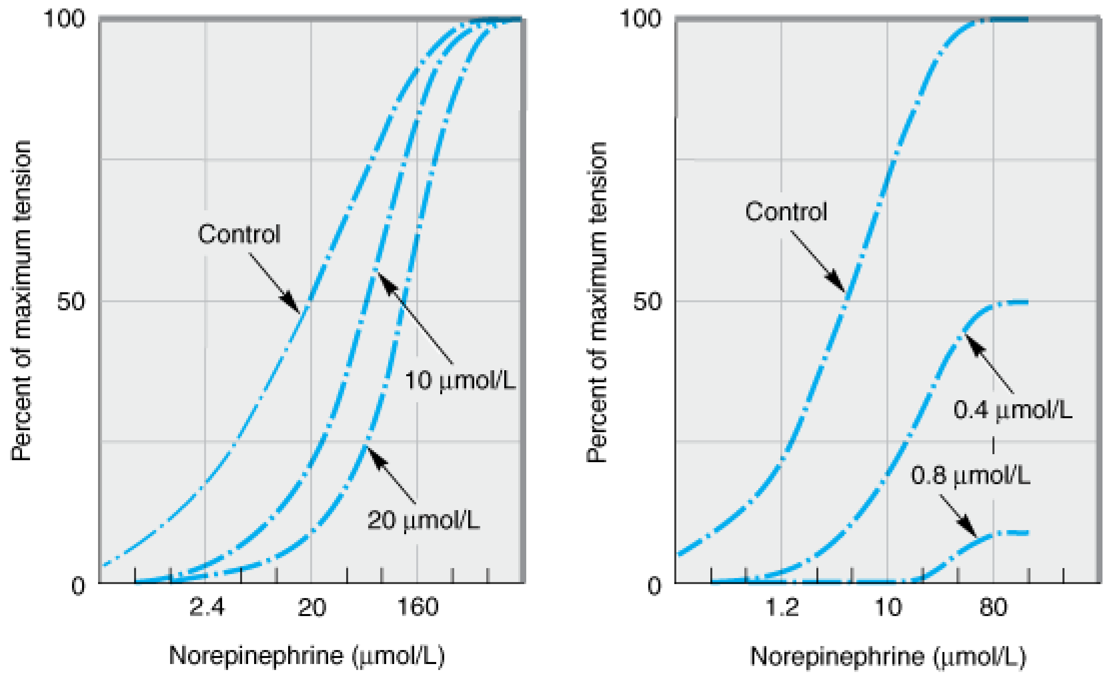
Alpha-receptor antagonists may be reversible or irreversible in their interaction with these receptors. Reversible antagonists dissociate from receptors and the block can be surmounted with sufficiently high concentrations of agonists; irreversible drugs do not dissociate and cannot be surmounted. Phentolamine (Figure 10–1) and prazosin are examples of reversible antagonists. Prazosin (and analogs) and labetalol—drugs used primarily for their antihypertensive effects—as well as several ergot derivatives (see Chapter 16) are also reversible α-adrenoceptor antagonists or partial agonists. Phenoxybenzamine, an agent related to the nitrogen mustards, forms a reactive ethyleneimonium intermediate (Figure 10–1) that covalently binds to a receptors, resulting in irreversible blockade. Figure 10–2 illustrates the effects of a reversible drug in comparison with those of an irreversible agent.

Figure 10–1.



Structure of several α-receptor-blocking drugs.

Figure 10–2.



Dose-response curves to norepinephrine in the presence of two different α-adrenoceptor-blocking drugs. The tension produced in isolated strips of cat spleen, a tissue rich in α receptors, was measured in response to graded doses of norepinephrine. Left: Tolazoline, a reversible blocker, shifted the curve to the right without decreasing the maximum response when present at concentrations of 10 and 20 µmol/L. Right: Dibenamine, an analog of phenoxybenzamine and irreversible in its action, reduced the maximum response attainable at both concentrations tested. (Modified and reproduced with permission, from Bickerton RK: The response of isolated strips of cat spleen to sympathomimetic drugs and their antagonists. J Pharmacol Exp Ther 1963;142:99.)

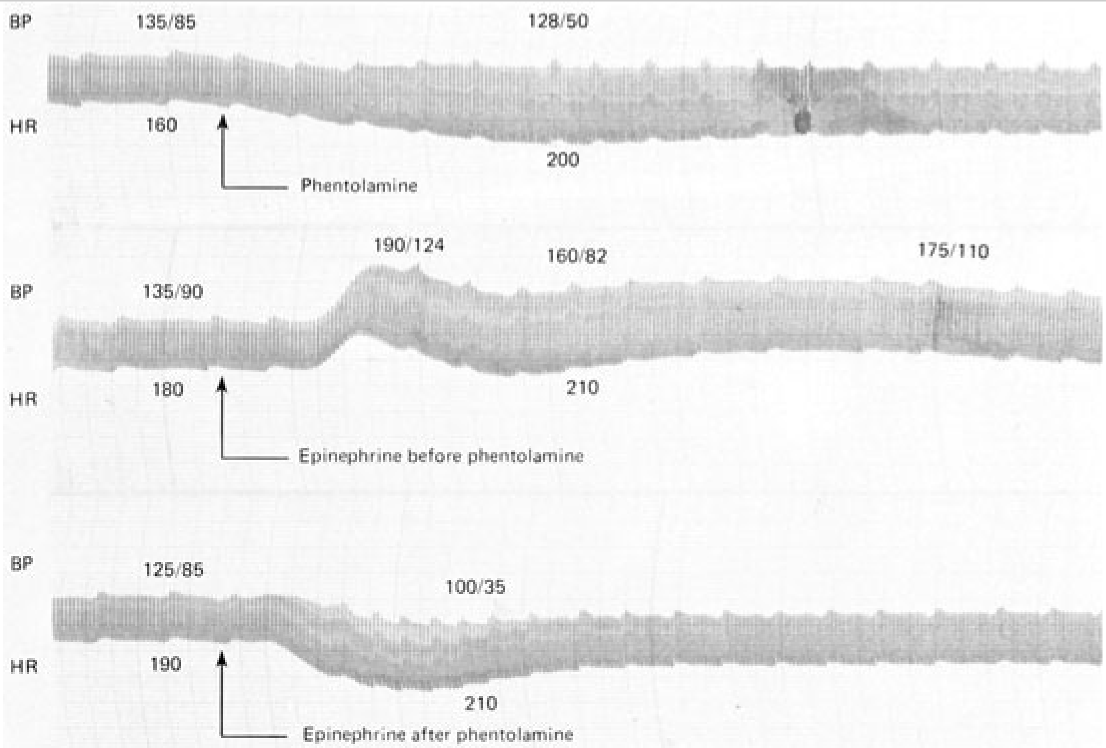
As discussed in Chapters 1 and 2, the duration of action of a reversible antagonist is largely dependent on the half-life of the drug in the body and the rate at which it dissociates from its receptor: The shorter the half-life of the drug in the body, the less time it takes for the effects of the drug to dissipate. In contrast, the effects of an irreversible antagonist may persist long after the drug has been cleared from the plasma. In the case of phenoxybenzamine, the restoration of tissue responsiveness after extensive α-receptor blockade is dependent on synthesis of new receptors, which may take several days. The rate of return of α_1 -adrenoceptor responsiveness may be particularly important in patients having a sudden cardiovascular event or who become candidates for urgent surgery.

Pharmacologic Effects

CARDIOVASCULAR EFFECTS

Because arteriolar and venous tone are determined to a large extent by α receptors on vascular smooth muscle α-receptor antagonist drugs cause a lowering of peripheral vascular resistance and blood pressure (Figure 10–3). These drugs can prevent the pressor effects of usual doses of α agonists; indeed, in the case of agonists with both α and β_2 effects (eg, epinephrine), selective α-receptor antagonism may convert a pressor to a depressor response (Figure 10–3). This change in response is called *epinephrine reversal*; it illustrates how the activation of both α and β receptors in the vasculature may lead to opposite responses. Alpha-receptor antagonists often cause postural hypotension and reflex tachycardia; nonselective ($\alpha_1 = \alpha_2$, Table 10–1) blockers usually cause significant tachycardia if blood pressure is lowered below normal. Postural hypotension is due to antagonism of sympathetic nervous system stimulation of α_1 receptors in venous smooth muscle; contraction of veins is an important component of the normal capacity to maintain blood pressure in the upright position since it decreases venous pooling in the periphery. Constriction of arterioles in the legs may also contribute to the postural response. Tachycardia may be more marked with agents that block α_2 -presynaptic receptors in the heart, since the augmented release of norepinephrine will further stimulate β receptors in the heart.

Figure 10–3.



Top: Effects of phentolamine, an α-receptor-blocking drug, on blood pressure in an anesthetized dog. Epinephrine reversal is demonstrated by tracings showing the response to epinephrine before (middle) and after (bottom) phentolamine. All drugs given intravenously. (BP, blood pressure; HR, heart rate.)

Table 10–1. Relative Selectivity of Antagonists for Adrenoceptors.

Receptor Affinity

α Antagonists

Prazosin, terazosin, doxazosin

α_1 >>>> α_2

Phenoxybenzamine

$\alpha_1 > \alpha_2$

Phentolamine

$\alpha_1 = \alpha_2$

Rauwolscine, yohimbine, tolazoline

$\alpha_2 >> \alpha_1$

Mixed antagonists

Labetalol, carvedilol

$\beta_1 = \beta_2 \geq \alpha_1 > \alpha_2$

β Antagonists

Metoprololol, acebutolol, alprenolol, atenolol, betaxolol, celiprolol, esmolol

$\beta_1 >>> \beta_2$

Propranolol, carteolol, penbutolol, pindolol, timolol

$\beta_1 = \beta_2$

Butoxamine

$\beta_2 >>> \beta_1$

OTHER EFFECTS

Minor effects that signal the blockade of α receptors in other tissues include miosis and nasal stuffiness. Alpha$_1$ -receptor blockade of the base of the bladder and the prostate is associated with decreased resistance to the flow of urine. Individual agents may have other important effects in addition to α-receptor antagonism (see below).

SPECIFIC AGENTS

Phentolamine, an imidazoline derivative, is a potent competitive antagonist at both α_1 and α_2 receptors (Table 10–1). Phentolamine causes a reduction in peripheral resistance through blockade of α_1 receptors and possibly α_2 receptors on vascular smooth muscle. The cardiac stimulation induced by phentolamine is due to sympatheti stimulation of the heart resulting from baroreflex mechanisms. Furthermore, since phentolamine potently block α_2 receptors, antagonism of presynaptic α_2 receptors may lead to enhanced release of norepinephrine from sympathetic nerves. In addition to being an α_1 - and α_2 -receptor antagonist, phentolamine also has minor inhibitory effects at serotonin receptors and agonist effects at muscarinic and H_1 and H_2 histamine receptors.

Phentolamine has limited absorption after oral administration. Its pharmacokinetic properties are not well known; it may reach peak concentrations within an hour after oral administration and has a half-life of 5–7 hours. The principal adverse effects are related to cardiac stimulation, which may cause severe tachycardia, arrhythmias, and myocardial ischemia, especially after intravenous administration. With oral administration, adverse effects include tachycardia, nasal congestion, and headache.

Phentolamine has been used in the treatment of pheochromocytoma—especially intraoperatively—as well as fo male erectile dysfunction by injection intracavernosally and when taken orally (see below).

Phenoxybenzamine binds covalently to α receptors, causing irreversible blockade of long duration (14–48 hours or longer). It is somewhat selective for α_1 receptors but less so than prazosin (Table 10–1). The drug als inhibits reuptake of released norepinephrine by presynaptic adrenergic nerve terminals. Phenoxybenzamine blocks histamine (H_1), acetylcholine, and serotonin receptors as well as α receptors (see Chapter 16).

The pharmacologic actions of phenoxybenzamine are primarily related to antagonism of α-receptor–mediated events. Most significant is that phenoxybenzamine attenuates catecholamine-induced vasoconstriction. While phenoxybenzamine causes relatively little fall in blood pressure in normal supine individuals, it reduces blood pressure when sympathetic tone is high, eg, as a result of upright posture or because of reduced blood volume Cardiac output may be increased because of reflex effects and because of some blockade of presynaptic α_2 receptors in cardiac sympathetic nerves.

Phenoxybenzamine is absorbed after oral administration, although bioavailability is low and its kinetic propertie are not well known. The drug is usually given orally, starting with low doses of 10–20 mg/d and progressively increasing the dose until the desired effect is achieved. A dosage of less than 100 mg/d is usually sufficient to achieve adequate α-receptor blockade. The major use of phenoxybenzamine is in the treatment of pheochromocytoma (see below).

Many of the adverse effects of phenoxybenzamine derive from its α-receptor–blocking action; the most important are postural hypotension and tachycardia. Nasal stuffiness and inhibition of ejaculation also occur. Since phenoxybenzamine enters the central nervous system, it may cause less specific effects, including fatigue sedation, and nausea. Because phenoxybenzamine is an alkylating agent, it may have other adverse effects tha have not yet been characterized. Phenoxybenzamine causes tumors in animals, but the clinical implications of this observation are unknown.

Tolazoline is an obsolete agent similar to phentolamine. **Ergot derivatives**, eg, ergotamine, dihydroergotamine, cause reversible α-receptor blockade, probably via a partial agonist action (Chapter 16).

Prazosin is a piperazinyl quinazoline effective in the management of hypertension (see Chapter 11). It is highl selective for α_1 receptors and typically 1000-fold less potent at α_2 receptors. This may partially explain the relative absence of tachycardia seen with prazosin compared with that reported with phentolamine and phenoxybenzamine. Prazosin leads to relaxation of both arterial and venous vascular smooth muscle, as well as smooth muscle in the prostate, due to blockade of α_1 receptors. Prazosin is extensively metabolized in humans; because of metabolic degradation by the liver, only about 50% of the drug is available after oral administration

The half-life is normally about 3 hours.

Terazosin is another reversible α_1 -selective antagonist that is effective in hypertension (Chapter 11); it is also approved for use in men with urinary symptoms due to benign prostatic hyperplasia (BPH). Terazosin has high bioavailability but is extensively metabolized in the liver, with only a small fraction of unchanged drug excreted in the urine. The half-life of terazosin is 9–12 hours.

Doxazosin is efficacious in the treatment of hypertension and BPH. It differs from prazosin and terazosin in having a longer half-life of about 22 hours. It has moderate bioavailability and is extensively metabolized, with very little parent drug excreted in urine or feces. Doxazosin has active metabolites, although their contribution to the drug's effects is probably small.

Tamsulosin is a competitive α_1 antagonist with a structure quite different from that of most other α_1 -receptor blockers. It has high bioavailability and a long half-life of 9–15 hours. It is metabolized extensively in the liver. Tamsulosin has higher affinity for α_{1A} and α_{1D} receptors than for the α_{1B} subtype. Evidence suggests that tamsulosin has relatively greater potency in inhibiting contraction in *prostate* smooth muscle versus *vascular* smooth muscle compared with other α_1 -selective antagonists. The drug's efficacy in BPH suggests that the α_{1A} subtype may be the most important α subtype mediating prostate smooth muscle contraction. Furthermore, compared with other antagonists, tamsulosin has less effect on standing blood pressure in patients. Nevertheless, caution is appropriate in using any α antagonist in patients with diminished sympathetic nervous system function.

OTHER ALPHA-ADRENOCEPTOR ANTAGONISTS

Alfuzosin is an α_1 -selective quinazoline derivative that is approved for use in BPH. It has a bioavailability of about 60%, is extensively metabolized, and has an elimination half-life of about 5 hours. Indoramin is another α_1 -selective antagonist that also has efficacy as an antihypertensive. Urapidil is an α_1 antagonist (its primary effect) that also has weak α_2 -agonist and 5-HT_{1A} -agonist actions and weak antagonist action at β_1 receptors. It is used in Europe as an antihypertensive agent and for benign prostatic hyperplasia. Labetalol has both α_1 -selective and β-antagonistic effects; it is discussed below. Neuroleptic drugs such as chlorpromazine and haloperidol are potent dopamine receptor antagonists but are also antagonists at α receptors. Their antagonism of α receptors probably contributes to some of their adverse effects, particularly hypotension. Similarly, the antidepressant trazodone has the capacity to block α_1 receptors.

Yohimbine, an indole alkaloid, is an α_2 -selective antagonist. It has no established clinical role. Theoretically, i could be useful in autonomic insufficiency by promoting neurotransmitter release through blockade of presynaptic α_2 receptors. It has been suggested that yohimbine improves male sexual function; however, evidence for this effect in humans is limited. Yohimbine can abruptly reverse the antihypertensive effects of an $_2$ -adrenoceptor agonist such as clonidine—a potentially serious adverse drug interaction.

CLINICAL PHARMACOLOGY OF THE ALPHA-RECEPTOR–BLOCKING DRUGS

Pheochromocytoma

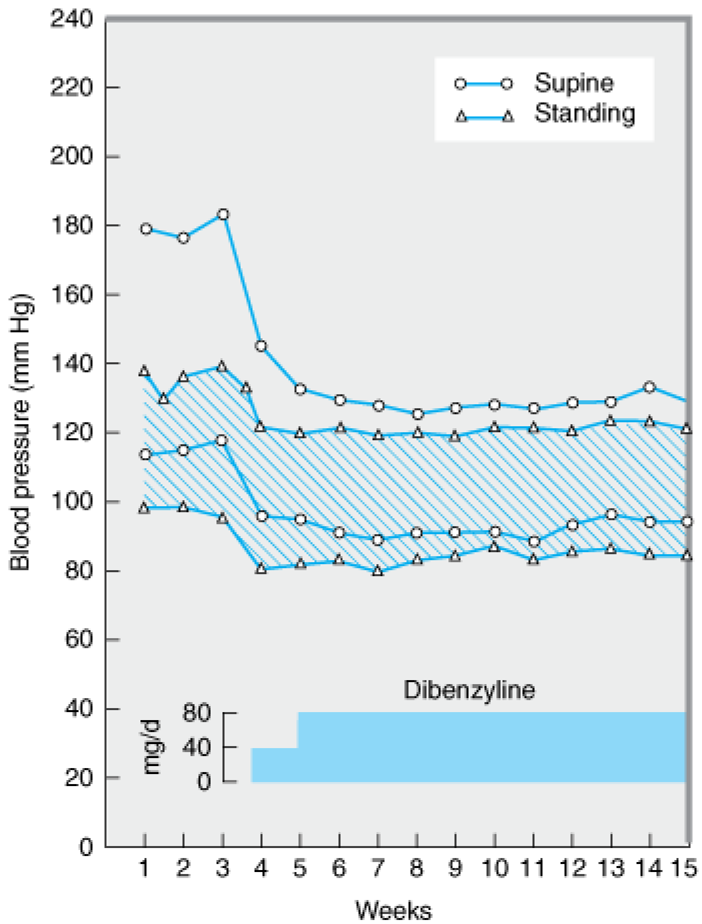
The major clinical use of both phenoxybenzamine and phentolamine is in the management of pheochromocytoma. This tumor is usually found in the adrenal medulla; it typically releases a mixture of epinephrine and norepinephrine. Patients have many symptoms and signs of catecholamine excess, including intermittent or sustained hypertension, headaches, palpitations, and increased sweating.

The diagnosis of pheochromocytoma is usually made on the basis of chemical assay of circulating catecholamines and urinary excretion of catecholamine metabolites, especially 3-hydroxy-4-methoxymandelic acid, metanephrine, and normetanephrine (see Chapter 6). Measurement of plasma metanephrines is also an effective diagnostic tool. A variety of diagnostic techniques are available to localize a pheochromocytoma diagnosed biochemically, including CT and MRI scans as well as scanning with various radioisotopes.

Unavoidable release of stored catecholamines sometimes occurs during operative manipulation of pheochromocytoma; the resulting hypertension may be controlled with phentolamine or nitroprusside. Nitroprusside has many advantages, particularly since its effects can be more readily titrated and it has a shorter duration of action.

Alpha-receptor antagonists are most useful in the preoperative management of patients with pheochromocytoma (Figure 10–4). Administration of phenoxybenzamine in the preoperative period will help control hypertension and will tend to reverse chronic changes resulting from excessive catecholamine secretion such as plasma volume contraction, if present. Furthermore, the patient's operative course may be simplified. Oral doses of 10–20 mg/d can be increased at intervals of several days until hypertension is controlled. Some physicians give phenoxybenzamine to patients with pheochromocytoma for 1–3 weeks before surgery. Other surgeons prefer to operate on patients in the absence of treatment with phenoxybenzamine, counting on modern anesthetic techniques to control blood pressure and heart rate during surgery. Phenoxybenzamine can be very useful in the chronic treatment of inoperable or metastatic pheochromocytoma. Although there is less experience with alternative drugs, hypertension in patients with pheochromocytoma may also respond to reversible α_1 -selective antagonists or to conventional calcium channel antagonists. Beta-receptor antagonists may be required after α-receptor blockade has been instituted to reverse the cardiac effects of excessive catecholamines. Beta antagonists should not be used prior to establishing effective α-receptor blockade, since unopposed β-receptor blockade could theoretically cause blood pressure elevation from increased vasoconstriction.

Figure 10–4.



Effects of phenoxybenzamine (Dibenzyline) on blood pressure in a patient with pheochromocytoma. Dosage of the drug was begun in the third week as shown by the shaded bar. Supine systolic and diastolic pressures are indicated by the circles, the standing pressures by triangles and the hatched area. Note that the α-blocking drug dramatically reduced blood pressure. The reduction in orthostatic hypotension, which was marked before treatment, is probably due to normalization of blood volume, a variable that is sometimes markedly reduced in patients with long-standing pheochromocytoma-induced hypertension. (Redrawn and reproduced, with permission, from Engelman E, Sjoerdsma A: Chronic medical therapy for pheochromocytoma. Ann Intern Med 1961;61:229.)

Pheochromocytoma is rarely treated with **metyrosine** (α-methyltyrosine), the α-methyl analog of tyrosine. This agent is a competitive inhibitor of tyrosine hydroxylase and interferes with synthesis of dopamine, norepinephrine, and epinephrine (see Figure 6–5). Metyrosine is especially useful in symptomatic patients with inoperable or metastatic pheochromocytoma.

Hypertensive Emergencies

The α-adrenoceptor antagonist drugs have limited application in the management of hypertensive emergencies although labetalol has been used in this setting (see Chapter 11). In theory, α-adrenoceptor antagonists are most useful when increased blood pressure reflects excess circulating concentrations of α agonists, eg, in pheochromocytoma, overdosage of sympathomimetic drugs, or clonidine withdrawal. However, other drugs are generally preferable, since considerable experience is necessary to use phentolamine safely in these settings and few physicians have such experience.

Chronic Hypertension

Members of the prazosin family of α_1 -selective antagonists are efficacious drugs in the treatment of mild to moderate systemic hypertension (see Chapter 11). They are generally well tolerated by most patients. Howeve their efficacy in preventing heart failure when used as monotherapy for hypertension has been questioned in th ALLHAT study. Their major adverse effect is postural hypotension, which may be severe after the first doses bu is otherwise uncommon. Nonselective α antagonists are not used in primary systemic hypertension. Prazosin an related drugs may also be associated with feelings of dizziness. This symptom may not be due to a fall in blood pressure, but postural changes in blood pressure should be checked routinely in any patient being treated for hypertension.

It is interesting that the use of α-adrenoceptor antagonists such as prazosin has been found to be associated with either no changes in plasma lipids or increased concentrations of high-density lipoproteins (HDL), which could be a favorable alteration. The mechanism for this effect is not known.

Peripheral Vascular Disease

Although α-receptor-blocking drugs have been tried in the treatment of peripheral vascular occlusive disease, there is no evidence that the effects are significant when morphologic changes limit flow in the vessels. Occasionally, individuals with Raynaud's phenomenon and other conditions involving excessive reversible vasospasm in the peripheral circulation do benefit from phentolamine, prazosin, or phenoxybenzamine, althoug calcium channel blockers may be preferable for many patients.

Local Vasoconstrictor Excess

Phentolamine has been used to reverse the intense local vasoconstriction caused by inadvertent infiltration of α agonists (eg, norepinephrine) into subcutaneous tissue during intended intravenous administration. The α antagonist is administered by local infiltration into the ischemic tissue.

Urinary Obstruction

Benign prostatic hyperplasia is a prevalent disorder in elderly men. A variety of surgical treatments are effectiv in relieving the urinary symptoms of BPH; however, drug therapy is efficacious in many patients. The mechanism of action in improving urine flow involves partial reversal of smooth muscle contraction in the enlarged prostate and in the bladder base. It has been suggested that some α_1 -receptor antagonists may hav additional effects on cells in the prostate that help improve symptoms.

A number of well-controlled studies have demonstrated reproducible efficacy of several α_1 -receptor antagonist in patients with BPH. Prazosin, doxazosin, and terazosin are efficacious. These drugs are particularly useful in patients who also have hypertension. Considerable interest has focused on which α_1 -receptor subtype is most important for smooth muscle contraction in the prostate: *subtype-selective* α_{1A} -receptor antagonists might lea to improved efficacy and safety in treating this disease. As indicated above, tamsulosin is also efficacious in BP and has little if any effect on blood pressure at a low dose. This drug may be preferred in patients who have experienced postural hypotension with other α_1 -receptor antagonists.

Erectile Dysfunction

A combination of phentolamine with the nonspecific smooth muscle relaxant papaverine, when injected directly into the penis, may cause erections in men with sexual dysfunction. Fibrotic reactions may occur, especially wit long-term administration. Systemic absorption may lead to orthostatic hypotension; priapism may require direc treatment with an α-adrenoceptor agonist such as phenylephrine. Alternative therapies include prostaglandins (see Chapter 18), sildenafil and other cGMP phosphodiesterase inhibitors (see Chapter 12), and apomorphine.

Applications of Alpha$_2$ Antagonists

Alpha$_2$ antagonists have relatively little clinical usefulness. There has been experimental interest in the development of highly selective antagonists for use in Raynaud's phenomenon to inhibit smooth muscle contraction, for treatment of type 2 diabetes (α_2 receptors inhibit insulin secretion), and for treatment of psychiatric depression. It is not known to what extent the recognition of multiple subtypes of α_2 receptors will lead to development of clinically useful subtype-selective new drugs.

BASIC PHARMACOLOGY OF THE BETA-RECEPTOR ANTAGONIST DRUGS

Beta-receptor antagonists share the common feature of antagonizing the effects of catecholamines at β adrenoceptors. Beta-blocking drugs occupy β receptors and competitively reduce receptor occupancy by catecholamines and other β agonists. (A few members of this group, used only for experimental purposes, bind irreversibly to β receptors.) Most β-blocking drugs in clinical use are pure antagonists; that is, the occupancy of a β receptor by such a drug causes no activation of the receptor. However, some are partial agonists; that is, they cause partial activation of the receptor, albeit less than that caused by the full agonists epinephrine and isoproterenol. As described in Chapter 2, partial agonists inhibit the activation of β receptors in the presence of high catecholamine concentrations but moderately activate the receptors in the absence of endogenous agonists. Finally, evidence suggests that some β blockers (eg, betaxolol, metoprolol) are *inverse agonists*—drugs that reduce constitutive activity of β receptors—in some tissues. The clinical significance of this property is not known.

Another major difference among the many β-receptor-blocking drugs concerns their relative affinities for β_1 and β_2 receptors (Table 10–1). Some of these antagonists have a higher affinity for β_1 than for β_2 receptors, and this selectivity may have important clinical implications. Since none of the clinically available β-receptor antagonists are absolutely specific for β_1 receptors, the selectivity is dose-related; it tends to diminish at higher drug concentrations. Other major differences among β antagonists relate to their pharmacokinetic characteristic and local anesthetic membrane-stabilizing effects.

Chemically, the β-receptor-antagonist drugs (Figure 10–5) resemble isoproterenol (see Figure 9–3), a potent β receptor agonist.

Figure 10–5.

Pharmacokinetic Properties of the Beta-Receptor Antagonists

ABSORPTION

Most of the drugs in this class are well absorbed after oral administration; peak concentrations occur 1–3 hours after ingestion. Sustained-release preparations of propranolol and metoprolol are available.

BIOAVAILABILITY

Propranolol undergoes extensive hepatic (first-pass) metabolism; its bioavailability is relatively low (Table 10–2). The proportion of drug reaching the systemic circulation increases as the dose is increased, suggesting that hepatic extraction mechanisms may become saturated. A major consequence of the low bioavailability of propranolol is that oral administration of the drug leads to much lower drug concentrations than are achieved after intravenous injection of the same dose. Because the first-pass effect varies among individuals, there is great individual variability in the plasma concentrations achieved after oral propranolol. For the same reason, bioavailability is limited to varying degrees for most β antagonists with the exception of betaxolol, penbutolol, pindolol, and sotalol.

DISTRIBUTION AND CLEARANCE

The β antagonists are rapidly distributed and have large volumes of distribution. Propranolol and penbutolol are quite lipophilic and readily cross the blood-brain barrier (Table 10–2). Most β antagonists have half-lives in the range of 3–10 hours. A major exception is esmolol, which is rapidly hydrolyzed and has a half-life of approximately 10 minutes. Propranolol and metoprolol are extensively metabolized in the liver, with little unchanged drug appearing in the urine. The cytochrome P450 2D6 (CYP2D6) genotype is a major determinant of interindividual differences in metoprolol plasma clearance (see Chapter 4). Poor metabolizers exhibit threefol to tenfold higher plasma concentrations after administration of metoprolol than extensive metabolizers. Atenolol, celiprolol, and pindolol are less completely metabolized. Nadolol is excreted unchanged in the urine and has the longest half-life of any available β antagonist (up to 24 hours). The half-life of nadolol is prolonged i renal failure. The elimination of drugs such as propranolol may be prolonged in the presence of liver disease, diminished hepatic blood flow, or hepatic enzyme inhibition. It is notable that the pharmacodynamic effects of these drugs are often prolonged well beyond the time predicted from half-life data.

Pharmacodynamics of the Beta-Receptor-Antagonist Drugs

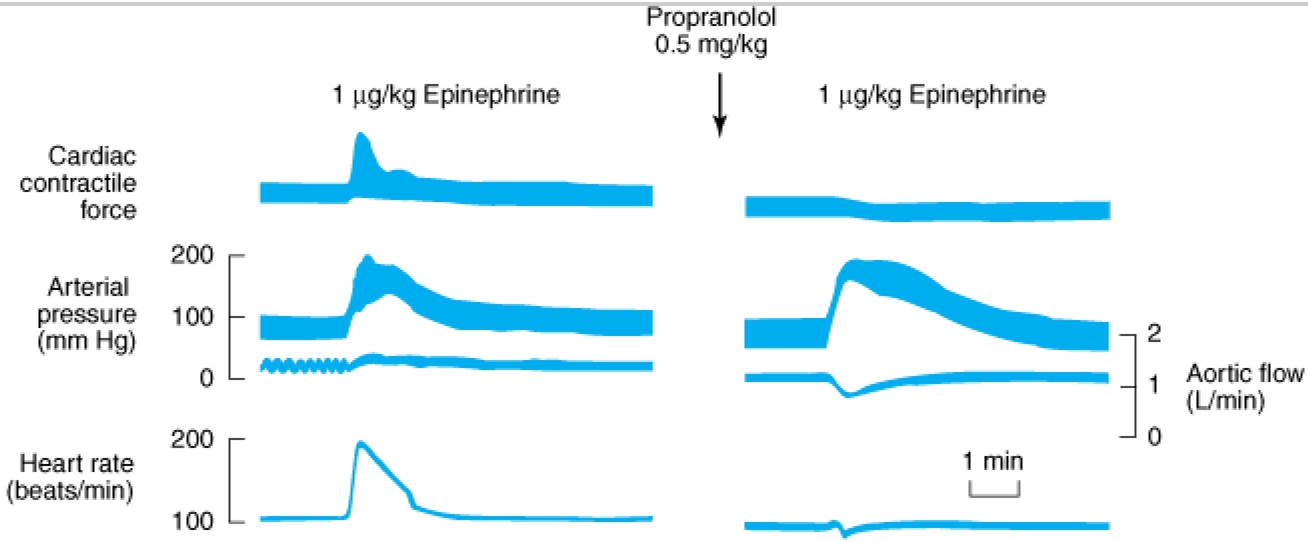
Most of the effects of these drugs are due to occupancy and blockade of β receptors. However, some actions may be due to other effects, including partial agonist activity at β receptors and local anesthetic action, which differ among the β blockers (Table 10–2).

EFFECTS ON THE CARDIOVASCULAR SYSTEM

Beta-blocking drugs given chronically lower blood pressure in patients with hypertension (see Chapter 11). The mechanisms involved are not fully understood but probably include effects on the heart and blood vessels, suppression of the renin-angiotensin system, and perhaps effects in the central nervous system or elsewhere. I contrast, conventional doses of these drugs do *not* usually cause hypotension in healthy individuals with norma blood pressure.

Beta-receptor antagonists have prominent effects on the heart (Figure 10–6) and are very valuable in the treatment of angina (see Chapter 12) and chronic heart failure (see Chapter 13) and following myocardial infarction (see Chapter 14). The negative inotropic and chronotropic effects are predictable from the role of adrenoceptors in regulating these functions. Slowed atrioventricular conduction with an increased PR interval is a related result of adrenoceptor blockade in the atrioventricular node. In the vascular system, β-receptor blockade opposes β_2 -mediated vasodilation. This may acutely lead to a rise in peripheral resistance from unopposed α-receptor-mediated effects as the sympathetic nervous system discharges in response to lowered blood pressure due to the fall in cardiac output. Nonselective and β_1 -blocking drugs antagonize the release of renin caused by the sympathetic nervous system.

Figure 10–6.



The effect in an anesthetized dog of the injection of epinephrine before and after propranolol. In the presence of a β-receptor–blocking agent, epinephrine no longer augments the force of contraction (measured by a strain gauge attached to the ventricular wall) nor increases cardiac rate. Blood pressure is still elevated by epinephrine because vasoconstriction is nc blocked. (Reproduced, with permission, from Shanks RG: The pharmacology of βsympathetic blockade. Am J Cardiol 1966;18:312.)

Overall, although the acute effects of these drugs may include a rise in peripheral resistance, chronic drug administration leads to a fall in peripheral resistance in patients with hypertension. How this adjustment occurs is not yet clear.

EFFECTS ON THE RESPIRATORY TRACT

Blockade of the β_2 receptors in bronchial smooth muscle may lead to an increase in airway resistance, particularly in patients with asthma. $Beta_1$ -receptor antagonists such as metoprolol and atenolol may have some advantage over nonselective βantagonists when blockade of β_1 receptors in the heart is desired and β_2 -receptor blockade is undesirable. However, no currently available β_1 -selective antagonist is sufficiently specific to *completely* avoid interactions with β_2 adrenoceptors. Consequently, these drugs should generally be avoided in patients with asthma. On the other hand, many patients with chronic obstructive pulmonary disease (COPD) may tolerate these drugs quite well and the benefits, for example in patients with concomitant ischemic heart disease, may outweigh the risks.

EFFECTS ON THE EYE

Several β-blocking agents reduce intraocular pressure, especially in glaucomatous eyes. The mechanism usuall reported is decreased aqueous humor production. (See Clinical Pharmacology and The Treatment of Glaucoma.

The Treatment of Glaucoma

Glaucoma is a major cause of blindness and of great pharmacologic interest because the chronic form often responds to drug therapy. The primary manifestation is increased intraocular pressure not initially associated with symptoms. Without treatment, increased intraocular pressure results in damage to the retina and optic nerve, with restriction of visual fields and, eventually, blindness. Intraocular pressure is easily measured as par of the routine ophthalmologic examination. Two major types of glaucoma are recognized: open-angle and closed-angle (or narrow-angle). The closed-angle form is associated with a shallow anterior chamber, in which a dilated iris can occlude the outflow drainage pathway at the angle between the cornea and the ciliary body (see Figure 6–9). This form is associated with acute and painful increases of pressure, which must be controlled on an emergency basis with drugs or prevented by surgical removal of part of the iris (iridectomy). The open-angle form of glaucoma is a chronic condition, and treatment is largely pharmacologic. Because intraocular pressure i a function of the balance between fluid input and drainage out of the globe, the strategies for the treatment of open-angle glaucoma fall into two classes: reduction of aqueous humor secretion and enhancement of aqueous outflow. Five general groups of drugs—cholinomimetics, α agonists, β blockers, prostaglandin F_2 analogs, and diuretics—have been found to be useful in reducing intraocular pressure and can be related to these strategies as shown in Table 10–3. Of the five drug groups listed in Table 10–3, the prostaglandin analogs and the β blockers are the most popular. This popularity results from convenience (once- or twice-daily dosing) and relative lack of adverse effects (except, in the case of β blockers, in patients with asthma or cardiac pacemaker or conduction pathway disease). Other drugs that have been reported to reduce intraocular pressure include prostaglandin E_2 and marijuana. The use of drugs in acute closed-angle glaucoma is limited to cholinomimetics, acetazolamide, and osmotic agents preceding surgery. The onset of action of the other agents is too slow in thi situation.

Table 10–3. Drugs Used in Open-Angle Glaucoma.

Mechanism

Methods of Administration

Cholinomimetics

Pilocarpine, carbachol, physostigmine, echothiophate, demecarium

Ciliary muscle contraction, opening of trabecular meshwork; increased outflow

Topical drops or gel; plastic film slow-release insert

Alpha agonists

Unselective

Increased outflow

Topical drops

Epinephrine, dipivefrin

$Alpha_2$ -selective

Decreased aqueous secretion

Topical

Beta-blockers

Timolol, betaxolol, carteolol, levobunolol, metipranolol

Decreased aqueous secretion from the ciliary epithelium

Topical drops

Diuretics

Dorzolamide, brinzolamide

Decreased aqueous secretion due to lack of HCO_3^-

Topical

Acetazolamide, dichlorphenamide, methazolamide

Oral

Prostaglandins

Latanoprost, bimatoprost, travoprost, unoprostone

Increased outflow

Topical

METABOLIC AND ENDOCRINE EFFECTS

Beta-receptor antagonists such as propranolol inhibit sympathetic nervous system stimulation of lipolysis. The effects on carbohydrate metabolism are less clear, though glycogenolysis in the human liver is at least partially inhibited after β_2 -receptor blockade. However, glucagon is the primary hormone used to combat hypoglycemia It is unclear to what extent βantagonists impair recovery from hypoglycemia, but they should be used with caution in insulin-dependent diabetic patients. This may be particularly important in diabetic patients with inadequate glucagon reserve and in pancreatectomized patients since catecholamines may be the major factors in stimulating glucose release from the liver in response to hypoglycemia. $Beta_1$ -receptor–selective drugs may be less prone to inhibit recovery from hypoglycemia. Beta-receptor antagonists are much safer in those type 2 diabetic patients who do not have hypoglycemic episodes.

The chronic use of β-adrenoceptor antagonists has been associated with increased plasma concentrations of very-low-density lipoproteins (VLDL) and decreased concentrations of HDL cholesterol. Both of these changes are potentially unfavorable in terms of risk of cardiovascular disease. Although low-density lipoprotein (LDL) concentrations generally do not change, there is a variable decline in the HDL cholesterol/LDL cholesterol ratio that may increase the risk of coronary artery disease. These changes tend to occur with both selective and nonselective β-blockers, though they are perhaps less likely to occur with β-blockers possessing intrinsic sympathomimetic activity (partial agonists). The mechanisms by which β-receptor antagonists cause these changes are not understood, though changes in sensitivity to insulin action may contribute.

EFFECTS NOT RELATED TO BETA-BLOCKADE

Partial β-agonist activity was significant in the first β-blocking drug synthesized, dichloroisoproterenol. It has been suggested that retention of some intrinsic sympathomimetic activity is desirable to prevent untoward effects such as precipitation of asthma or excessive bradycardia. Pindolol and other partial agonists are noted in Table 10–2. It is not yet clear to what extent partial agonism is clinically valuable. Furthermore, these drugs may not be as effective as the pure antagonists in secondary prevention of myocardial infarction. However, they may be useful in patients who develop symptomatic bradycardia or bronchoconstriction in response to pure antagonist β-adrenoceptor drugs, but only if they are strongly indicated for a particular clinical indication.

Local anesthetic action, also known as "membrane-stabilizing" action, is a prominent effect of several βblockers (Table 10–2). This action is the result of typical local anesthetic blockade of sodium channels and can be demonstrated experimentally in isolated neurons, heart muscle, and skeletal muscle membrane. However, it is unlikely that this effect is important after systemic administration of these drugs, since the concentration in plasma usually achieved by these routes is too low for the anesthetic effects to be evident. These membrane-stabilizing β-blockers are not used topically on the eye, where local anesthesia of the cornea would be highly undesirable. Sotalol is a nonselective β-receptor antagonist that lacks local anesthetic action but has marked class III antiarrhythmic effects, reflecting potassium channel blockade (see Chapter 14).

SPECIFIC AGENTS

(See Table 10–2.) Propranolol is the prototypical β-blocking drug. As noted above, it has low and dose-dependent bioavailability. A long-acting form of propranolol is available; prolonged absorption of the drug may occur over a 24-hour period. The drug has negligible effects at $\alpha$and muscarinic receptors; however, it may block some serotonin receptors in the brain, though the clinical significance is unclear. It has no detectable partial agonist action at βreceptors.

Metoprolol, atenolol, and several other drugs (see Table 10–2) are members of the β_1 -selective group. These agents may be safer in patients who experience bronchoconstriction in response to propranolol. Since their β_1

selectivity is rather modest, they should be used with great caution, if at all, in patients with a history of asthma. However, in selected patients with chronic obstructive lung disease the benefits may exceed the risks, eg, in patients with myocardial infarction. $Beta_1$ -selective antagonists may be preferable in patients with diabetes or peripheral vascular disease when therapy with a βblocker is required, since β_2 receptors are probably important in liver (recovery from hypoglycemia) and blood vessels (vasodilation).

Nadolol is noteworthy for its very long duration of action; its spectrum of action is similar to that of timolol. Timolol is a nonselective agent with no local anesthetic activity. It has excellent ocular hypotensive effects when administered topically in the eye. Levobunonol (nonselective) and betaxolol (β_1 -selective) are also used for topical ophthalmic application in glaucoma; the latter drug may be less likely to induce bronchoconstriction than nonselective antagonists. Carteolol is a nonselective β-receptor antagonist.

Pindolol, acebutolol, carteolol, bopindolol, * oxprenolol, * celiprolol,* and penbutolol are of interest because they have partial β-agonist activity.

They are effective in the major cardiovascular applications of the β-blocking group (hypertension and angina). Although these partial agonists may be less likely to cause bradycardia and abnormalities in plasma lipids than are antagonists, the overall clinical significance of intrinsic sympathomimetic activity remains uncertain. Pindolol perhaps as a result of actions on serotonin signaling, may potentiate the action of traditional antidepressant medications. Celiprolol is a β_1 -selective antagonist with a modest capacity to activate β_2 receptors.

There is limited evidence suggesting that celiprolol may have less adverse bronchoconstrictor effect in asthma and may even promote bronchodilation. Acebutolol is also a β_1 -selective antagonist.

Labetalol is a reversible adrenoceptor antagonist available as a racemic mixture of two pairs of chiral isomers (the molecule has two centers of asymmetry). The *(S,S)* - and *(R,S)* -isomers are nearly inactive, *(S,R)* - is a potent αblocker, and the *(R,R)* -isomer is a potent βblocker. Labetalol's affinity for αreceptors is less than that of phentolamine, but labetalol is α_1 -selective. Its β-blocking potency is somewhat lower than that of propranolol. Hypotension induced by labetalol is accompanied by less tachycardia than occurs with phentolamine and similar αblockers.

Carvedilol, medroxalol, * and bucindolol * are nonselective β-receptor antagonists with some capacity to block α_1 -adrenergic receptors.

Carvedilol antagonizes the actions of catecholamines more potently at βreceptors than at αreceptors. The drug has a half-life of 6–8 hours. It is extensively metabolized in the liver, and stereoselective metabolism of its two isomers is observed. Since metabolism of *(R)*- carvedilol is influenced by polymorphisms in cytochrome P450 2D6 activity and by drugs that inhibit this enzyme's activity (such as quinidine and fluoxetine), drug interactions may occur. Carvedilol also appears to attenuate oxygen free radical–initiated lipid peroxidation and to inhibit vascular smooth muscle mitogenesis independently of adrenoceptor blockade. These effects may contribute to the clinical benefits of the drug in chronic heart failure (see Chapter 13).

Esmolol is an ultra-short–acting β_1 -selective adrenoceptor antagonist. The structure of esmolol contains an ester linkage; esterases in red blood cells rapidly metabolize esmolol to a metabolite that has a low affinity for β receptors. Consequently, esmolol has a short half-life (about 10 minutes). Therefore, during continuous infusions of esmolol, steady-state concentrations are achieved quickly, and the therapeutic actions of the drug are terminated rapidly when its infusion is discontinued. Esmolol is potentially safer to use than longer-acting antagonists in critically ill patients who require a β-adrenoceptor antagonist. Esmolol is useful in controlling supraventricular arrhythmias, arrhythmias associated with thyrotoxicosis, perioperative hypertension, and myocardial ischemia in acutely ill patients.

Butoxamine is a research drug selective for β_2 receptors. Selective β_2 -blocking drugs have not been actively sought because there is no obvious clinical application for them; none is available for clinical use.

*Not available in the USA.

CLINICAL PHARMACOLOGY OF THE BETA-RECEPTOR–BLOCKING DRUGS

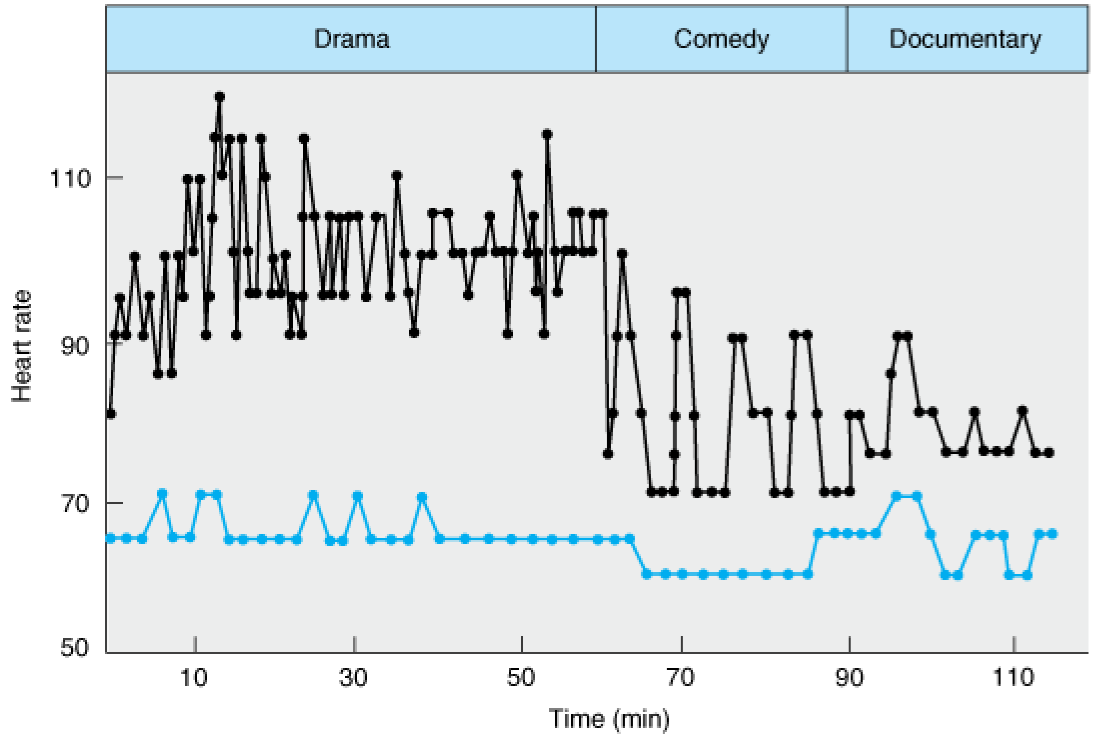
Hypertension

The β-adrenoceptor-blocking drugs have proved to be effective and well tolerated in hypertension. Although many hypertensive patients respond to a βblocker used alone, the drug is often used with either a diuretic or a vasodilator. In spite of the short half-life of many βantagonists, these drugs may be administered once or twice daily and still have an adequate therapeutic effect. Labetalol, a competitive $\alpha$and βantagonist, is effective in hypertension, though its ultimate role is yet to be determined. Use of these agents is discussed in detail in Chapter 11. There is some evidence that drugs in this class may be less effective in blacks and the elderly. However, these differences are relatively small and may not apply to an individual patient. Indeed, since effects on blood pressure are easily measured, the therapeutic outcome for this indication can be readily detected in any patient.

Ischemic Heart Disease

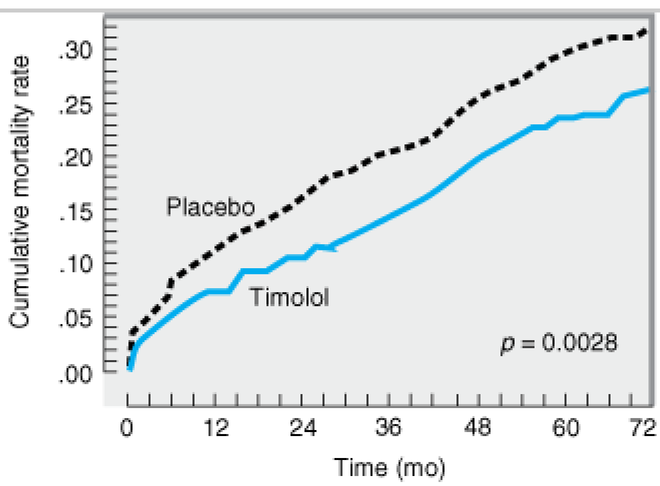
Beta-adrenoceptor blockers reduce the frequency of anginal episodes and improve exercise tolerance in many patients with angina (see Chapter 12). These actions relate to the blockade of cardiac βreceptors, resulting in decreased cardiac work and reduction in oxygen demand. Slowing and regularization of the heart rate may contribute to clinical benefits (Figure 10–7). Multiple large-scale prospective studies indicate that the long-term use of timolol, propranolol, or metoprolol in patients who have had a myocardial infarction prolongs survival (Figure 10–8). At the present time, data are less compelling for the use of other than the three mentioned β-adrenoceptor antagonists for this indication. It is significant that surveys in many populations have indicated that β-receptor antagonists are underused, leading to unnecessary morbidity and mortality. In addition, β-adrenoceptor antagonists are strongly indicated in the acute phase of a myocardial infarction. In this setting, relative contraindications include bradycardia, hypotension, moderate or severe left ventricular failure, shock, heart block, and active airways disease. It has been suggested that certain polymorphisms in β_2 -adrenoceptor genes may influence survival among patients receiving antagonists after acute coronary syndromes.

Figure 10–7.



Heart rate in a patient with ischemic heart disease measured by telemetry while watching television. Measurements were begun 1 hour after receiving placebo (upper line, black) or 40 mg of oxprenolol (color), a nonselective β-antagonist with partial agonist activity. Not only was the heart rate decreased by the drug under the conditions of this experiment; it also varied much less in response to stimuli. (Modified and reproduced, with permission, from Taylor SH: Oxprenolol in clinical practice. Am J Cardiol 1983;52:34D.)

Figure 10–8.



Effects of β-blocker therapy on life-table cumulated rates of mortality from all causes over 6 years among 1884 patients surviving myocardial infarctions. Patients were randomly assigned to treatment with placebo (dashed line) or timolol (color). (Reproduced, with permission, from Pederson TR: Six-year follow-up of the Norwegian multicenter study on timolol after acute myocardial infarction. N Engl J Med 1985;313:1055.)

Cardiac Arrhythmias

Beta antagonists are often effective in the treatment of both supraventricular and ventricular arrhythmias (see Chapter 14). It has been suggested that the improved survival following myocardial infarction in patients using βantagonists (Figure 10–8) is due to suppression of arrhythmias, but this has not been proved. By increasing the atrioventricular nodal refractory period, βantagonists slow ventricular response rates in atrial flutter and fibrillation. These drugs can also reduce ventricular ectopic beats, particularly if the ectopic activity has been precipitated by catecholamines. Sotalol has additional antiarrhythmic effects involving ion channel blockade in addition to its β-blocking action; these are discussed in Chapter 14.

Heart Failure

Clinical trials have demonstrated that at least three βantagonists—metoprolol, bisoprolol, and carvedilol—are effective in treating chronic heart failure in selected patients. Although administration of these drugs may worsen acute congestive heart failure, cautious long-term use with gradual dose increments in patients who tolerate them may prolong life. Although mechanisms are uncertain, there appear to be beneficial effects on myocardial remodeling and in decreasing the risk of sudden death (see Chapter 13).

Other Cardiovascular Disorders

Beta-receptor antagonists have been found to increase stroke volume in some patients with obstructive cardiomyopathy. This beneficial effect is thought to result from the slowing of ventricular ejection and decrease outflow resistance. Beta antagonists are useful in dissecting aortic aneurysm to decrease the rate of development of systolic pressure. Beta antagonists are also useful in selected at-risk patients in the prevention of adverse cardiovascular outcomes resulting from noncardiac surgery.

Glaucoma

Systemic administration of β-blocking drugs for other indications was found serendipitously to reduce intraocula pressure in patients with glaucoma (see The Treatment of Glaucoma). Subsequently, it was found that topical administration also reduces intraocular pressure. The mechanism appears to involve reduced production of aqueous humor by the ciliary body, which is physiologically activated by cAMP. Timolol and related βantagonists are suitable for local use in the eye because they lack local anesthetic properties. Beta antagonists appear to have an efficacy comparable to that of epinephrine or pilocarpine in open-angle glaucoma and are far better tolerated by most patients. While the maximal daily dose applied locally (1 mg) is small compared with the systemic doses commonly used in the treatment of hypertension or angina (10–60 mg), sufficient timolol may be absorbed from the eye to cause serious adverse effects on the heart and airways in susceptible individuals. Topical timolol may interact with orally administered verapamil and increase the risk of heart block.

Betaxolol, carteolol, levobunolol, and metipranolol are β-receptor antagonists approved for the treatment of glaucoma. Betaxolol has the potential advantage of being β_1 -selective; to what extent this potential advantage might diminish systemic adverse effects remains to be determined. The drug apparently has caused worsening of pulmonary symptoms in some patients.

Hyperthyroidism

Excessive catecholamine action is an important aspect of the pathophysiology of hyperthyroidism, especially in relation to the heart (see Chapter 38). The β antagonists have salutary effects in this condition. These beneficia effects presumably relate to blockade of adrenoceptors and perhaps in part to the inhibition of peripheral conversion of thyroxine to triiodothyronine. The latter action may vary from one β antagonist to another. Propranolol has been used extensively in patients with thyroid storm (severe hyperthyroidism); it is used cautiously in patients with this condition to control supraventricular tachycardias that often precipitate heart failure.

Neurologic Diseases

Several studies show a beneficial effect of propranolol in reducing the frequency and intensity of migraine headache. Other β-receptor antagonists with preventive efficacy include metoprolol and probably also atenolol, timolol, and nadolol. The mechanism is not known. Since sympathetic activity may enhance skeletal muscle tremor, it is not surprising that β antagonists have been found to reduce certain tremors (see Chapter 28). The somatic manifestations of anxiety may respond dramatically to low doses of propranolol, particularly when take prophylactically. For example, benefit has been found in musicians with performance anxiety ("stage fright"). Propranolol may contribute to the symptomatic treatment of alcohol withdrawal in some patients.

Miscellaneous

Beta-receptor antagonists have been found to diminish portal vein pressure in patients with cirrhosis. There is evidence that both propranolol and nadolol decrease the incidence of the first episode of bleeding from esophageal varices and decrease the mortality rate associated with bleeding in patients with cirrhosis. Nadolol i combination with isosorbide mononitrate appears to be more efficacious than sclerotherapy in preventing re-bleeding in patients who have previously bled from esophageal varices. Variceal band ligation in combination with a β antagonist may be more efficacious.

CHOICE OF A BETA-ADRENOCEPTOR ANTAGONIST DRUG

Propranolol is the standard against which newer β antagonists developed for systemic use have been compared. In many years of very wide use, propranolol has been found to be a safe and effective drug for many indications. Since it is possible that some actions of a β-receptor antagonist may relate to some other effect of the drug, these drugs should not be considered interchangeable for all applications. For example, only β antagonists known to be effective in stable heart failure or in prophylactic therapy after myocardial infarction should be used for those indications. It is possible that the beneficial effects of one drug in these settings might not be shared by another drug in the same class. The possible advantages and disadvantages of β-receptor antagonists that are partial agonists have not been clearly defined in clinical settings, although current evidenc suggests that they are probably less efficacious in secondary prevention after a myocardial infarction compared to pure antagonists.

CLINICAL TOXICITY OF THE BETA-RECEPTOR ANTAGONIST DRUGS

A variety of minor toxic effects have been reported for propranolol. Rash, fever, and other manifestations of drug allergy are rare. Central nervous system effects include sedation, sleep disturbances, and depression. Rarely, psychotic reactions may occur. Discontinuing the use of β blockers in any patient who develops a depression should be seriously considered if clinically feasible. It has been claimed that β-receptor antagonist drugs with low lipid solubility are associated with a lower incidence of central nervous system adverse effects than compounds with higher lipid solubility (see Table 10–2). Further studies designed to compare the central nervous system adverse effects of various drugs are required before specific recommendations can be made, though it seems reasonable to try the hydrophilic drugs nadolol or atenolol in a patient who experiences unpleasant central nervous system effects with other β blockers.

The major adverse effects of β-receptor antagonist drugs relate to the predictable consequences of β blockade. $Beta_2$ -receptor blockade associated with the use of nonselective agents commonly causes worsening of preexisting asthma and other forms of airway obstruction without having these consequences in normal individuals. Indeed, relatively trivial asthma may become severe after β blockade. However, because of their life saving possibilities in cardiovascular disease, strong consideration should be given to individualized therapeutic trials in some classes of patients, eg, those with chronic obstructive pulmonary disease who have appropriate indications for β blockers. While β_1 -selective drugs may have less effect on airways than nonselective β antagonists, they must be used very cautiously, if at all, in patients with reactive airways. $Beta_1$ -selective antagonists are generally well tolerated in patients with mild to moderate peripheral vascular disease, but caution is required in patients with severe peripheral vascular disease or vasospastic disorders.

Beta-receptor blockade depresses myocardial contractility and excitability. In patients with abnormal myocardia function, cardiac output may be dependent on sympathetic drive. If this stimulus is removed by β blockade, cardiac decompensation may ensue. Thus, caution must be exercised in starting a β-receptor antagonist in patients with compensated heart failure even though long-term use of these drugs in these patients may prolong life. A life-threatening adverse cardiac effect of a β antagonist may be overcome directly with isoproterenol or with glucagon (glucagon stimulates the heart via glucagon receptors, which are not blocked by β antagonists), but neither of these methods is without hazard. A very small dose of a β antagonist (eg, 10 mg o propranolol) may provoke severe cardiac failure in a susceptible individual. Beta blockers may interact with the calcium antagonist verapamil; severe hypotension, bradycardia, heart failure, and cardiac conduction abnormalities have all been described. These adverse effects may even arise in susceptible patients taking a topical (ophthalmic) β blocker and oral verapamil.

Some hazards are associated with abruptly discontinuing β-antagonist therapy after chronic use. Evidence suggests that patients with ischemic heart disease may be at increased risk if β blockade is suddenly interrupted. The mechanism of this effect is uncertain but might involve up-regulation of the number of β receptors. Until better evidence is available regarding the magnitude of the risk, prudence dictates the gradual tapering rather than abrupt cessation of dosage when these drugs are discontinued, especially drugs with short half-lives, such as propranolol and metoprolol.

The incidence of hypoglycemic episodes in diabetics that are exacerbated by β-blocking agents is unknown. Nevertheless, it is inadvisable to use β antagonists in insulin-dependent diabetic patients who are subject to frequent hypoglycemic reactions if alternative therapies are available. $Beta_1$ -selective antagonists offer some advantage in these patients, since the rate of recovery from hypoglycemia may be faster compared with diabetics receiving nonselective β-adrenoceptor antagonists. There is considerable potential benefit from these drugs in diabetics after a myocardial infarction, so the balance of risk versus benefit must be evaluated in individual patients.

PREPARATIONS AVAILABLE

Alpha Blockers

Alfuzosin (Uroxatral)

Oral: 10 mg tablets (extended-release)

Doxazosin (generic, Cardura)

Oral: 1, 2, 4, 8 mg tablets

Phenoxybenzamine (Dibenzyline)

Oral: 10 mg capsules

Phentolamine (generic, Regitine)

Parenteral: 5 mg/vial for injection

Prazosin (generic, Minipress)

Oral: 1, 2, 5 mg capsules

Tamsulosin (Flomax)

Oral: 0.4 mg capsule

Terazosin (generic, Hytrin)

Oral: 1, 2, 5, 10 mg tablets, capsules

Tolazoline (Priscoline)

Parenteral: 25 mg/mL for injection

Beta Blockers

Acebutolol (generic, Sectral)

Oral: 200, 400 mg capsules

Atenolol (generic, Tenormin)

Oral: 25, 50, 100 mg tablets

Parenteral: 0.5 mg/mL for IV injection

Betaxolol

Oral (Kerlone): 10, 20 mg tablets

Ophthalmic (generic, Betoptic): 0.25%, 0.5% drops

Bisoprolol (Zebeta)

Oral: 5, 10 mg tablets

Carteolol

Oral (Cartrol): 2.5, 5 mg tablets

Ophthalmic (generic, Ocupress): 1% drops

Carvedilol (Coreg)

Oral: 3.125, 6.25, 12.5, 25 mg tablets

Esmolol (Brevibloc)

Parenteral: 10 mg/mL for IV injection; 250 mg/mL for IV infusion

Labetalol (generic, Normodyne, Trandate)

Oral: 100, 200, 300 mg tablets

Parenteral: 5 mg/mL for injection

Levobunolol (Betagan Liquifilm, others)

Ophthalmic: 0.25, 0.5% drops

Metipranolol (Optipranolol)

Ophthalmic: 0.3% drops

Metoprolol (generic, Lopressor, Toprol)

Oral: 50, 100 mg tablets

Oral sustained-release: 25, 50, 100, 200 mg tablets

Parenteral: 1 mg/mL for injection

Nadolol (generic, Corgard)

Oral: 20, 40, 80, 120, 160 mg tablets

Penbutolol (Levatol)

Oral: 20 mg tablets

Pindolol (generic, Visken)

Oral: 5, 10 mg tablets

Propranolol (generic, Inderal)

Oral: 10, 20, 40, 60, 80, 90 mg tablets; 4, 8, 80 mg/mL solutions

Oral sustained-release: 60, 80, 120, 160 mg capsules

Parenteral: 1 mg/mL for injection

Sotalol (generic, Betapace)

Oral: 80, 120, 160, 240 mg tablets

Timolol

Oral (generic, Blocadren): 5, 10, 20 mg tablets

Ophthalmic (generic, Timoptic): 0.25, 0.5% drops, gel

Synthesis Inhibitor

Metyrosine (Demser)

Oral: 250 mg capsules

ANTIHYPERTENSIVE AGENTS: INTRODUCTION

Hypertension is the most common cardiovascular disease. In a survey carried out in 2000, hypertension was found in 28% of American adults. According to a Framingham study of blood pressure trends in middle-aged and older individuals, approximately 90% of Caucasian Americans will develop hypertension in their lifetime. The prevalence varies with age, race, education, and many other variables. Sustained arterial hypertension damages blood vessels in kidney, heart, and brain and leads to an increased incidence of renal failure, coronary disease, cardiac failure, and stroke. Effective pharmacologic lowering of blood pressure has been shown to prevent damage to blood vessels and to substantially reduce morbidity and mortality rates. Unfortunately, several surveys indicate that only one third of Americans with hypertension have adequate blood pressure control. Many effective drugs are available. Knowledge of their antihypertensive mechanisms and sites of action allows accurate prediction of efficacy and toxicity. As a result, rational use of these agents, alone or in combination, can lower blood pressure with minimal risk of serious toxicity in most patients.

Hypertension & Regulation of Blood Pressure

Diagnosis

The diagnosis of hypertension is based on repeated, reproducible measurements of elevated blood pressure. The diagnosis serves primarily as a prediction of consequences for the patient; it seldom includes a statement about the cause of hypertension.

Epidemiologic studies indicate that the risks of damage to kidney, heart, and brain are directly related to the extent of blood pressure elevation. Even mild hypertension (blood pressure 140/90 mm Hg) increases the risk of eventual end organ damage. Starting at 115/75 mm Hg cardiovascular disease risk doubles with each increment of 20/10 mm Hg throughout the blood pressure range. The risks—and therefore the urgency of instituting therapy—increase in proportion to the magnitude of blood pressure elevation. The risk of end organ damage at any level of blood pressure or age is greater in African-Americans and relatively less in premenopausal women than in men. Other positive risk factors include smoking, hyperlipidemia, diabetes, manifestations of end organ damage at the time of diagnosis, and a family history of cardiovascular disease.

It should be noted that the diagnosis of hypertension depends on measurement of blood pressure and not on symptoms reported by the patient. In fact, hypertension is usually asymptomatic until overt end organ damage is imminent or has already occurred.

Etiology of Hypertension

A specific cause of hypertension can be established in only 10–15% of patients. It is important to consider specific causes in each case, however, because some of them are amenable to definitive surgical treatment: renal artery constriction, coarctation of the aorta, pheochromocytoma, Cushing's disease, and primary aldosteronism.

Patients in whom no specific cause of hypertension can be found are said to have essential hypertension. *

In most cases, elevated blood pressure is associated with an overall increase in resistance to flow of blood through arterioles, while cardiac output is usually normal. Meticulous investigation of autonomic nervous system function, baroreceptor reflexes, the renin-angiotensin-aldosterone system, and the kidney has failed to identify a primary abnormality as the cause of increased peripheral vascular resistance in essential hypertension.

Elevated blood pressure is usually caused by a combination of several (multifactorial) abnormalities. Epidemiologic evidence points to genetic inheritance, psychological stress, and environmental and dietary factors (increased salt and decreased potassium or calcium intake) as perhaps contributing to the development of hypertension. Increase in blood pressure with aging does not occur in populations with low daily sodium intake. Patients with labile hypertension appear more likely than normal controls to have blood pressure elevations after salt loading.

The heritability of essential hypertension is estimated to be about 30%. Mutations in several genes have been linked to various rare causes of hypertension. Functional variations of the genes for angiotensinogen, angiotensin-converting enzyme (ACE), the β_2 adrenoceptor, and α adducin (a cytoskeletal protein) appear to contribute to some cases of essential hypertension.

*The adjective originally was intended to convey the now abandoned idea that blood pressure elevation was essential for adequate perfusion of diseased tissues.

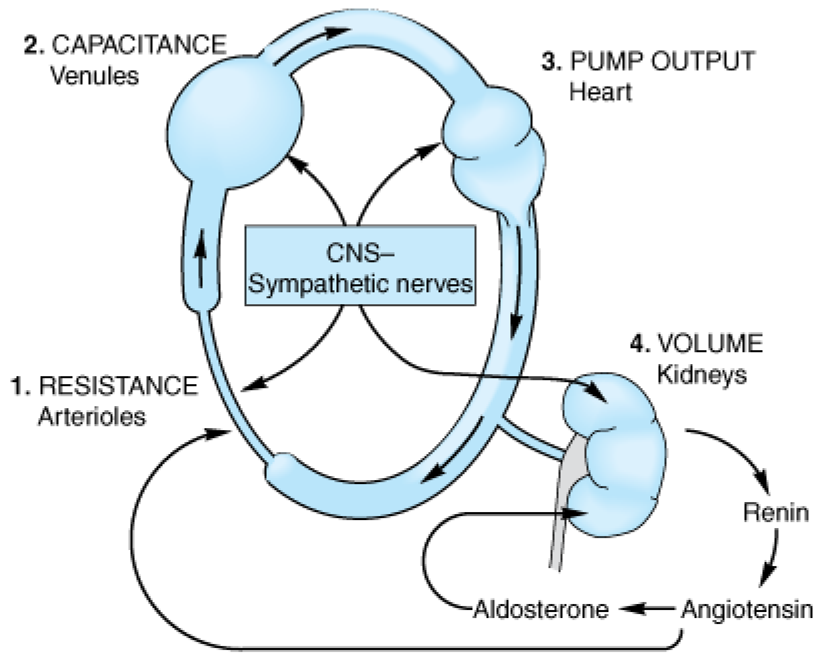
Normal Regulation of Blood Pressure

According to the hydraulic equation, arterial blood pressure (BP) is directly proportionate to the product of the blood flow (cardiac output, CO) and the resistance to passage of blood through precapillary arterioles (peripheral vascular resistance, PVR):

$$BP = CO \times PVR$$

Physiologically, in both normal and hypertensive individuals, blood pressure is maintained by moment-to-moment regulation of cardiac output and peripheral vascular resistance, exerted at three anatomic sites (Figure 11–1): arterioles, postcapillary venules (capacitance vessels), and heart. A fourth anatomic control site, the kidney, contributes to maintenance of blood pressure by regulating the volume of intravascular fluid. Baroreflexes, mediated by autonomic nerves, act in combination with humoral mechanisms, including the renin-angiotensin-aldosterone system, to coordinate function at these four control sites and to maintain normal blood pressure. Finally, local release of vasoactive substances from vascular endothelium may also be involved in the regulation of vascular resistance. For example, endothelin-1 (see Chapter 17) constricts and nitric oxide (see Chapter 19) dilates blood vessels.

Figure 11–1.



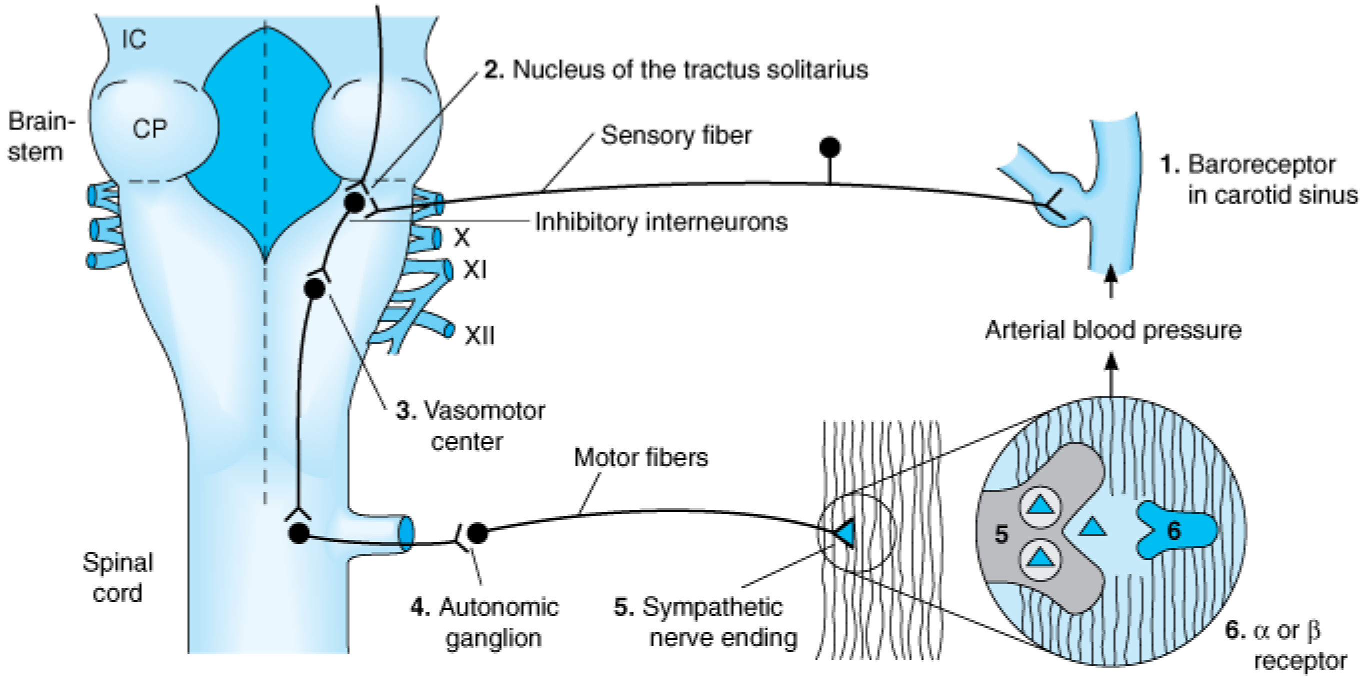
Anatomic sites of blood pressure control.

Blood pressure in a hypertensive patient is controlled by the same mechanisms that are operative in normotensive subjects. Regulation of blood pressure in hypertensive patients differs from healthy patients in that the baroreceptors and the renal blood volume-pressure control systems appear to be "set" at a higher level of blood pressure. All antihypertensive drugs act by interfering with these normal mechanisms, which are reviewed below.

POSTURAL BAROREFLEX

(Figure 11–2) Baroreflexes are responsible for rapid, moment-to-moment adjustments in blood pressure, such as in transition from a reclining to an upright posture. Central sympathetic neurons arising from the vasomotor area of the medulla are tonically active. Carotid baroreceptors are stimulated by the stretch of the vessel walls brought about by the internal pressure (arterial blood pressure). Baroreceptor activation inhibits central sympathetic discharge. Conversely, reduction in stretch results in a reduction in baroreceptor activity. Thus, in the case of a transition to upright posture, baroreceptors sense the reduction in arterial pressure that results from pooling of blood in the veins below the level of the heart as reduced wall stretch, and sympathetic discharge is disinhibited. The reflex increase in sympathetic outflow acts through nerve endings to increase peripheral vascular resistance (constriction of arterioles) and cardiac output (direct stimulation of the heart and constriction of capacitance vessels, which increases venous return to the heart), thereby restoring normal blood pressure. The same baroreflex acts in response to any event that lowers arterial pressure, including a primary reduction in peripheral vascular resistance (eg, caused by a vasodilating agent) or a reduction in intravascular volume (eg, due to hemorrhage or to loss of salt and water via the kidney).

Figure 11–2.



Baroreceptor reflex arc.

RENAL RESPONSE TO DECREASED BLOOD PRESSURE

By controlling blood volume, the kidney is primarily responsible for long-term blood pressure control. A reduction in renal perfusion pressure causes intrarenal redistribution of blood flow and increased reabsorption of salt and water. In addition, decreased pressure in renal arterioles as well as sympathetic neural activity (via β adrenoceptors) stimulates production of renin, which increases production of angiotensin II (see Figure 11–1 and Chapter 17). Angiotensin II causes (1) direct constriction of resistance vessels and (2) stimulation of aldosterone synthesis in the adrenal cortex, which increases renal sodium absorption and intravascular blood volume. Vasopressin released from the posterior pituitary gland also plays a role in maintenance of blood pressure through its ability to regulate water reabsorption by the kidney (see Chapters 15 and 17).

BASIC PHARMACOLOGY OF ANTIHYPERTENSIVE AGENTS

All antihypertensive agents act at one or more of the four anatomic control sites depicted in Figure 11–1 and produce their effects by interfering with normal mechanisms of blood pressure regulation. A useful classification of these agents categorizes them according to the principal regulatory site or mechanism on which they act (Figure 11–3). Because of their common mechanisms of action, drugs within each category tend to produce a similar spectrum of toxicities. The categories include the following:

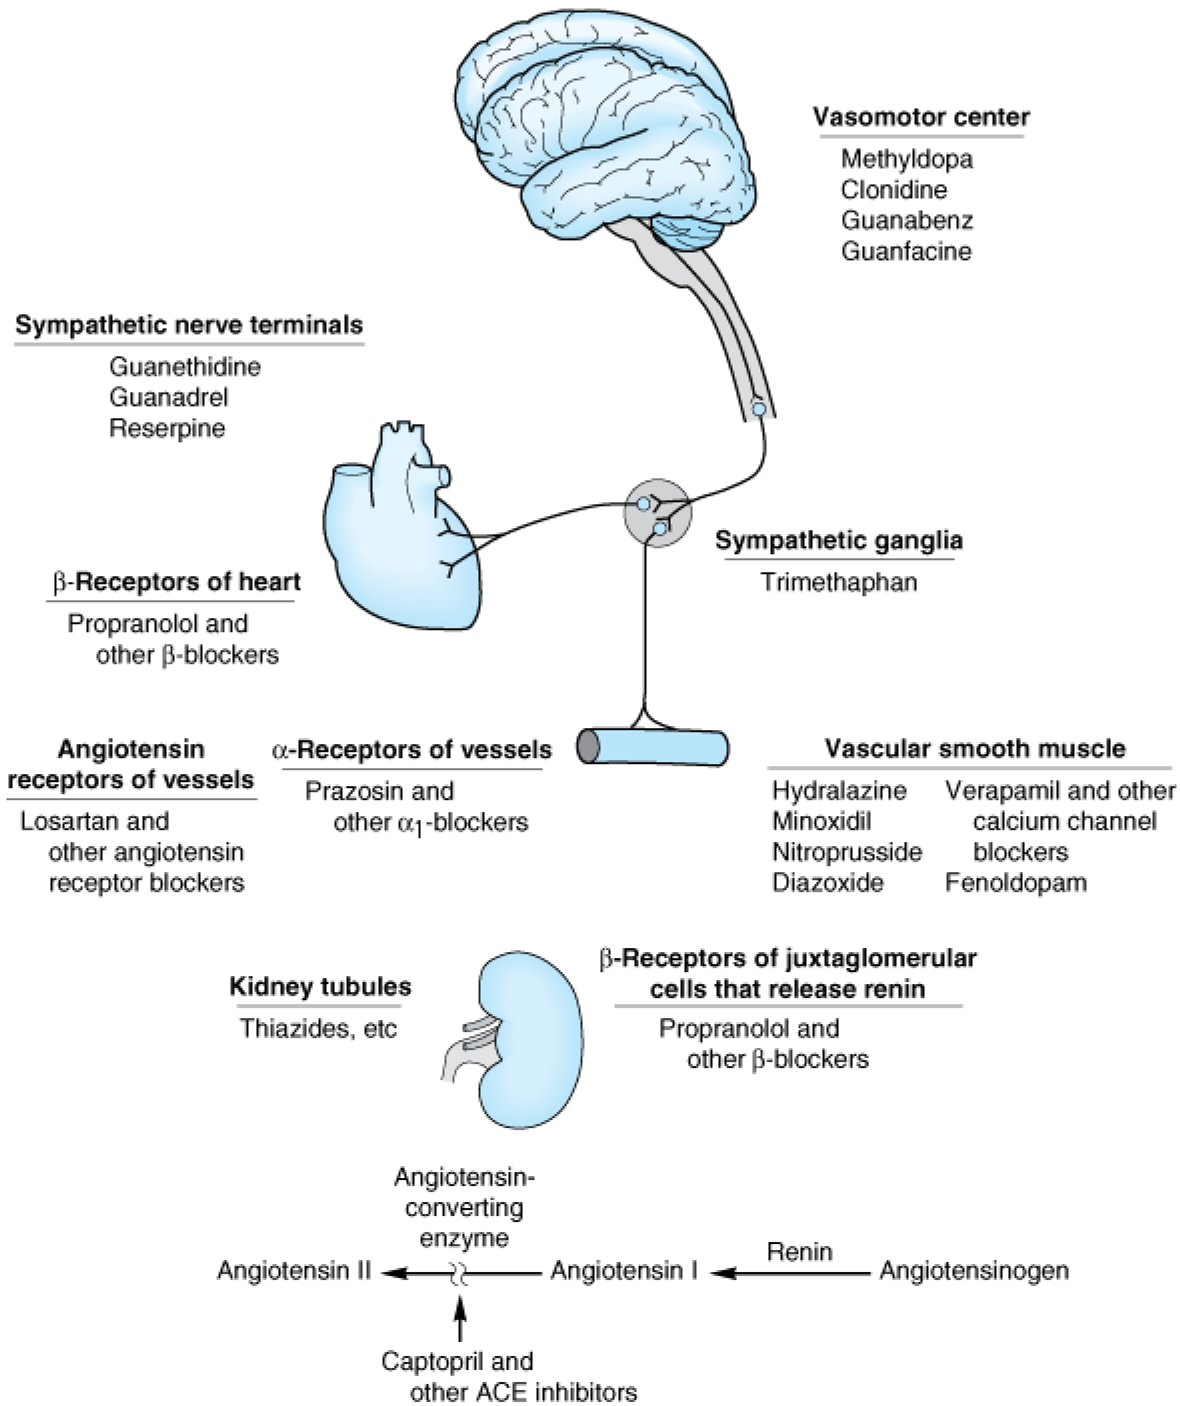
(1) Diuretics, which lower blood pressure by depleting the body of sodium and reducing blood volume and perhaps by other mechanisms.

(2) Sympathoplegic agents, which lower blood pressure by reducing peripheral vascular resistance, inhibiting cardiac function, and increasing venous pooling in capacitance vessels. (The latter two effects reduce cardiac output.) These agents are further subdivided according to their putative sites of action in the sympathetic reflex arc (see below).

(3) Direct vasodilators, which reduce pressure by relaxing vascular smooth muscle, thus dilating resistance vessels and—to varying degrees—increasing capacitance as well.

(4) Agents that block production or action of angiotensin and thereby reduce peripheral vascular resistance and (potentially) blood volume.

Figure 11–3.



Sites of action of the major classes of antihypertensive drugs.

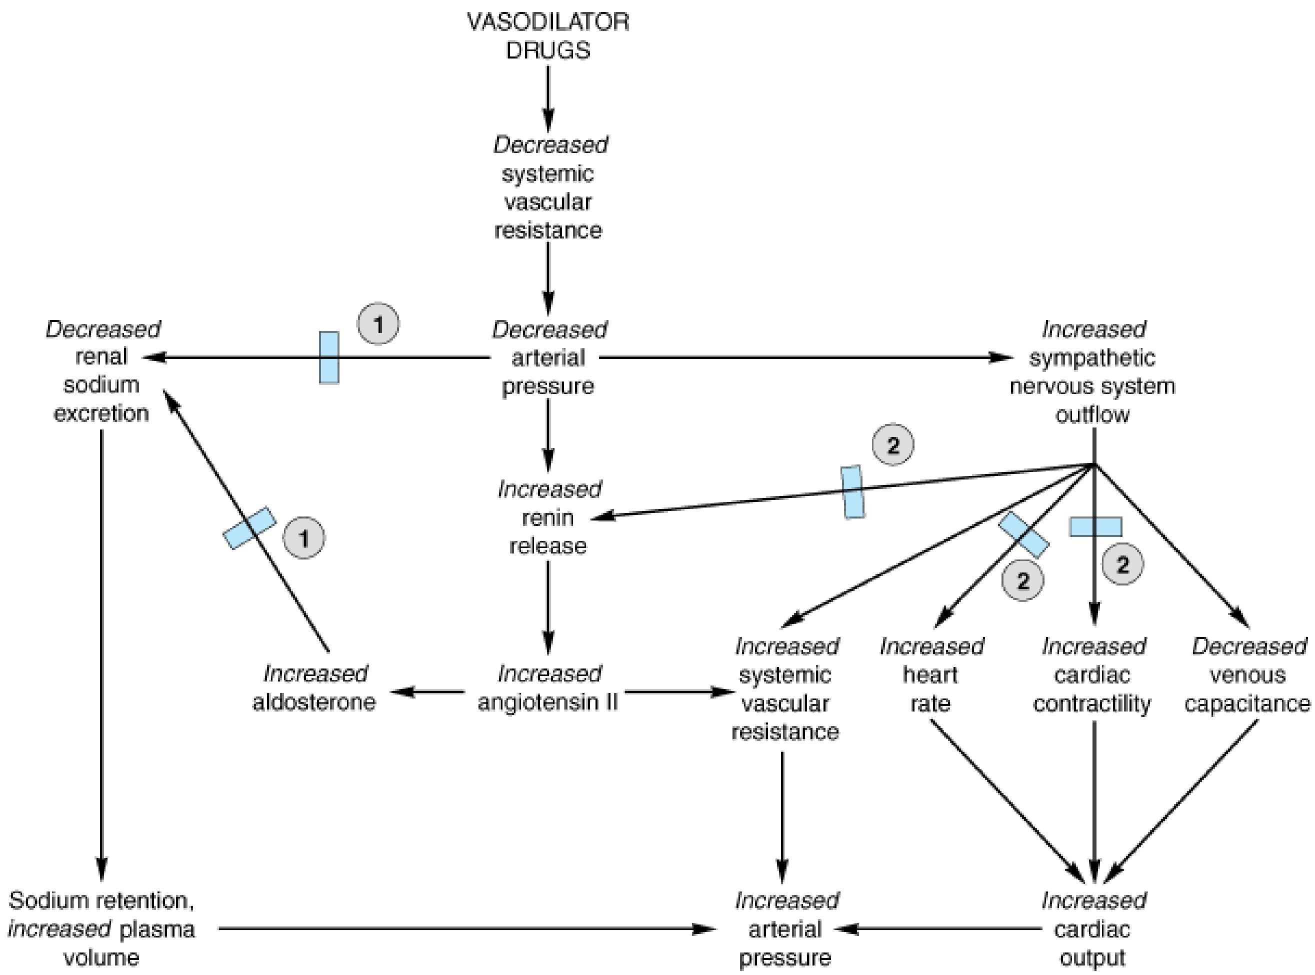
The fact that these drug groups act by different mechanisms permits the combination of drugs from two or more groups with increased efficacy and, in some cases, decreased toxicity. (See Monotherapy Versus Polypharmacy in Hypertension.)

Monotherapy versus Polypharmacy in Hypertension

Monotherapy of hypertension (treatment with a single drug) is desirable because compliance is likely to be better, cost is lower, and because in some cases adverse effects are fewer. However, most patients with hypertension require two or more drugs, each acting by a different mechanism (polypharmacy). The rationale for polypharmacy is that each of the drugs acts on one of a set of interacting, mutually compensatory regulatory mechanisms for maintaining blood pressure (see Figures 6–7 and 11–1).

For example, because an adequate dose of hydralazine causes a significant decrease in peripheral vascular resistance, there will initially be a drop in mean arterial blood pressure, evoking a strong response in the form of compensatory tachycardia and salt and water retention (Figure 11–4). The result is an increase in cardiac output that is capable of almost completely reversing the effect of hydralazine. The addition of a βblocker prevents the tachycardia; addition of a diuretic (eg, hydrochlorothiazide) prevents the salt and water retention. In effect, all three drugs increase the sensitivity of the cardiovascular system to each other's actions. Thus, partial impairment of one regulatory mechanism (sympathetic discharge to the heart) increases the antihypertensive effect of impairing regulation by another mechanism (peripheral vascular resistance). Finally, in some circumstances, a normal compensatory response accounts for the toxicity of an antihypertensive agent, and the toxic effect can be prevented by administering a second type of drug. In the case of hydralazine, compensatory tachycardia and increased cardiac output may precipitate angina in patients with coronary atherosclerosis. Addition of the βblocker and diuretic can prevent this toxicity in many patients.

Figure 11–4.



Compensatory responses to vasodilators; basis for combination therapy with β blockers and diuretics. 1 Effect blocked by diuretics. 2 Effect blocked by β blockers.

In practice, when hypertension does not respond adequately to a regimen of one drug, a second drug from a different class with a different mechanism of action and different pattern of toxicity is added. If the response is still inadequate and compliance is known to be good, a third drug may be added. The drugs least likely to be successful as monotherapy are the vasodilators hydralazine and minoxidil. It is not completely clear why other vasodilators such as calcium channel blockers cause less marked compensatory responses for the same amount of blood pressure lowering.

Drugs That Alter Sodium & Water Balance

Dietary sodium restriction has been known for many years to decrease blood pressure in hypertensive patients. With the advent of diuretics, sodium restriction was thought to be less important. However, there is now general agreement that dietary control of blood pressure is a relatively nontoxic therapeutic measure and may even be preventive. Several studies have shown that even modest dietary sodium restriction lowers blood pressure (although to varying extents) in many hypertensive individuals.

Mechanisms of Action & Hemodynamic Effects of Diuretics

Diuretics lower blood pressure primarily by depleting body sodium stores. Initially, diuretics reduce blood pressure by reducing blood volume and cardiac output; peripheral vascular resistance may increase. After 6–8 weeks, cardiac output returns toward normal while peripheral vascular resistance declines. Sodium is believed to contribute to vascular resistance by increasing vessel stiffness and neural reactivity, possibly related to increased sodium-calcium exchange with a resultant increase in intracellular calcium. These effects are reversed by diuretics or sodium restriction.

Some diuretics have direct vasodilating effects in addition to their diuretic action. Indapamide is a nonthiazide sulfonamide diuretic with both diuretic and vasodilator activity. As a consequence of vasodilation, cardiac output remains unchanged or increases slightly. Amiloride inhibits smooth muscle responses to contractile stimuli, probably through effects on transmembrane and intracellular calcium movement that are independent of its action on sodium excretion.

Diuretics are effective in lowering blood pressure by 10–15 mm Hg in most patients, and diuretics alone often provide adequate treatment for mild or moderate essential hypertension. In more severe hypertension, diuretics are used in combination with sympathoplegic and vasodilator drugs to control the tendency toward sodium retention caused by these agents. Vascular responsiveness—ie, the ability to either constrict or dilate—is diminished by sympathoplegic and vasodilator drugs, so that the vasculature behaves like an inflexible tube. As a consequence, blood pressure becomes exquisitely sensitive to blood volume. Thus, in severe hypertension, when multiple drugs are used, blood pressure may be well controlled when blood volume is 95% of normal but much too high when blood volume is 105% of normal.

Use of Diuretics

The sites of action within the kidney and the pharmacokinetics of various diuretic drugs are discussed in Chapter 15. Thiazide diuretics are appropriate for most patients with mild or moderate hypertension and normal renal and cardiac function. More powerful diuretics (eg, those acting on the loop of Henle) are necessary in severe hypertension, when multiple drugs with sodium-retaining properties are used; in renal insufficiency, when glomerular filtration rate is less than 30 or 40 mL/min; and in cardiac failure or cirrhosis, where sodium retention is marked.

Potassium-sparing diuretics are useful both to avoid excessive potassium depletion, particularly in patients taking digitalis, and to enhance the natriuretic effects of other diuretics. Aldosterone receptor antagonists in particular also have a favorable effect on cardiac function in people with heart failure.

Some pharmacokinetic characteristics and the initial and usual maintenance dosages of hydrochlorothiazide are listed in Table 11–1. Although thiazide diuretics are more natriuretic at higher doses (up to 100–200 mg of hydrochlorothiazide), when used as a single agent, lower doses (25–50 mg) exert as much antihypertensive effect as do higher doses. In contrast to thiazides, the blood pressure response to loop diuretics continues to increase at doses many times greater than the usual therapeutic dose.

[3] The active metabolite of losartan has a half-life of 3–4 hours.

Toxicity of Diuretics

In the treatment of hypertension, the most common adverse effect of diuretics (except for potassium-sparing diuretics) is potassium depletion. Although mild degrees of hypokalemia are tolerated well by many patients, hypokalemia may be hazardous in persons taking digitalis, those who have chronic arrhythmias, or those with acute myocardial infarction or left ventricular dysfunction. Potassium loss is coupled to reabsorption of sodium, and restriction of dietary sodium intake will therefore minimize potassium loss. Diuretics may also cause magnesium depletion, impair glucose tolerance, and increase serum lipid concentrations. Diuretics increase uric acid concentrations and may precipitate gout. The use of low doses minimizes these adverse metabolic effects without impairing the antihypertensive action. Several case-control studies have reported a small but significant excess risk of renal cell carcinoma associated with diuretic use. Potassium-sparing diuretics may produce hyperkalemia, particularly in patients with renal insufficiency and those taking ACE inhibitors or angiotension receptor blockers; spironolactone (a steroid) is associated with gynecomastia.

Drugs That Alter Sympathetic Nervous System Function

In patients with moderate to severe hypertension, most effective drug regimens include an agent that inhibits function of the sympathetic nervous system. Drugs in this group are classified according to the site at which they impair the sympathetic reflex arc (Figure 11–2). This neuroanatomic classification explains prominent differences in cardiovascular effects of drugs and allows the clinician to predict interactions of these drugs with one another and with other drugs.

Most importantly, the subclasses of drugs exhibit different patterns of potential toxicity. Drugs that lower blood pressure by actions on the central nervous system tend to cause sedation and mental depression and may produce disturbances of sleep, including nightmares. Drugs that act by inhibiting transmission through autonomic ganglia produce toxicity from inhibition of parasympathetic regulation, in addition to profound sympathetic blockade. Drugs that act chiefly by reducing release of norepinephrine from sympathetic nerve endings cause effects that are similar to those of surgical sympathectomy, including inhibition of ejaculation, and hypotension that is increased by upright posture and after exercise. Drugs that block postsynaptic adrenoceptors produce a more selective spectrum of effects depending on the class of receptor to which they bind.

Finally, one should note that *all* of the agents that lower blood pressure by altering sympathetic function can elicit compensatory effects through mechanisms that are not dependent on adrenergic nerves. Thus, the antihypertensive effect of any of these agents used alone may be limited by retention of sodium by the kidney and expansion of blood volume. For these reasons, sympathoplegic antihypertensive drugs are most effective when used concomitantly with a diuretic.

CENTRALLY ACTING SYMPATHOPLEGIC DRUGS

Mechanisms & Sites of Action

These agents reduce sympathetic outflow from vasopressor centers in the brainstem but allow these centers to retain or even increase their sensitivity to baroreceptor control. Accordingly, the antihypertensive and toxic actions of these drugs are generally less dependent on posture than are the effects of drugs that act directly on peripheral sympathetic neurons.

Methyldopa (L-α-methyl-3,4-dihydroxyphenylalanine) is an analog of L-dopa and is converted to α-methyldopamine and α-methylnorepinephrine; this pathway directly parallels the synthesis of norepinephrine from dopa illustrated in Figure 6–5. Alpha-methylnorepinephrine is stored in adrenergic nerve vesicles, where it stoichiometrically replaces norepinephrine, and is released by nerve stimulation to interact with postsynaptic adrenoceptors. However, this replacement of norepinephrine by a false transmitter in peripheral neurons is *not* responsible for methyldopa's antihypertensive effect, because the α-methylnorepinephrine released is an effective agonist at the α adrenoceptors that mediate peripheral sympathetic constriction of arterioles and venules. Direct electrical stimulation of sympathetic nerves in methyldopa-treated animals produces sympathetic responses similar to those observed in untreated animals.

In fact, methyldopa's antihypertensive action appears to be due to stimulation of *central* αadrenoceptors by α-methylnorepinephrine or α-methyldopamine, based on the following evidence: (1) Much lower doses of methyldopa are required to lower blood pressure in animals when the drug is administered centrally by injection into the cerebral ventricles rather than intravenously. (2) Alpha-receptor antagonists, especially α_2-selective antagonists, administered centrally, block the antihypertensive effect of methyldopa, whether the latter is given centrally or intravenously. (3) Potent inhibitors of dopa decarboxylase, administered centrally, block methyldopa's antihypertensive effect, thus showing that metabolism of the parent drug in the central nervous system is necessary for its action.

The antihypertensive action of clonidine, a 2-imidazoline derivative, was discovered in the course of testing the drug for use as a topically applied nasal decongestant.

After intravenous injection, clonidine produces a brief rise in blood pressure followed by more prolonged hypotension. The pressor response is due to direct stimulation of αadrenoceptors in arterioles. The drug is classified as a partial agonist at αreceptors because it also inhibits pressor effects of other αagonists.

Considerable evidence indicates that the hypotensive effect of clonidine is exerted at αadrenoceptors in the medulla of the brain. In animals, the hypotensive effect of clonidine is prevented by central administration of αantagonists. Clonidine reduces sympathetic and increases parasympathetic tone, resulting in blood pressure lowering and bradycardia. The reduction in pressure is accompanied by a decrease in circulating catecholamine levels. These observations suggest that clonidine sensitizes brainstem pressor centers to inhibition by baroreflexes.

Thus, studies of clonidine and methyldopa suggest that normal regulation of blood pressure involves central adrenergic neurons that modulate baroreceptor reflexes. Clonidine and α-methylnorepinephrine bind more tightly to α_2 than to α_1 adrenoceptors. As noted in Chapter 6, α_2 receptors are located on presynaptic adrenergic neurons as well as some postsynaptic sites. It is possible that clonidine and α-methylnorepinephrine act in the brain to reduce norepinephrine release onto relevant receptor sites. Alternatively, these drugs may act on postsynaptic α_2 adrenoceptors to inhibit activity of appropriate neurons. Finally, clonidine also binds to a nonadrenoceptor site, the imidazoline receptor, which may also mediate antihypertensive effects.

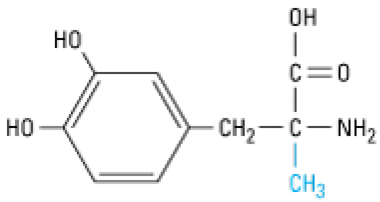
Methyldopa and clonidine produce slightly different hemodynamic effects: clonidine lowers heart rate and cardiac output more than does methyldopa. This difference suggests that these two drugs do not have identical sites of action. They may act primarily on different populations of neurons in the vasomotor centers of the brainstem.

Guanabenz and guanfacine are centrally active antihypertensive drugs that share the central α-adrenoceptor-stimulating effects of clonidine. They do not appear to offer any advantages over clonidine.

METHYLDOPA

Methyldopa is useful in the treatment of mild to moderately severe hypertension. It lowers blood pressure chiefly by reducing peripheral vascular resistance, with a variable reduction in heart rate and cardiac output.

Most cardiovascular reflexes remain intact after administration of methyldopa, and blood pressure reduction is not markedly dependent on maintenance of upright posture. Postural (orthostatic) hypotension sometimes occurs, particularly in volume-depleted patients. One potential advantage of methyldopa is that it causes reduction in renal vascular resistance.



α-Methyldopa
(α-methyl group in color)

Pharmacokinetics & Dosage

Pharmacokinetic characteristics of methyldopa are listed in Table 11–1. Methyldopa enters the brain via an aromatic amino acid transporter. The usual oral dose of methyldopa produces its maximal antihypertensive effect in 4–6 hours, and the effect can persist for up to 24 hours. Because the effect depends on accumulation and storage of a metabolite (α-methylnorepinephrine) in the vesicles of nerve endings, the action persists after the parent drug has disappeared from the circulation.

Toxicity

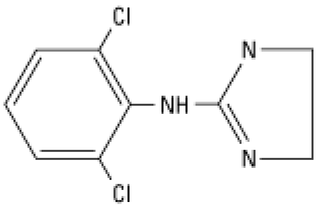
The most frequent undesirable effect of methyldopa is overt sedation, particularly at the onset of treatment. With long-term therapy, patients may complain of persistent mental lassitude and impaired mental concentration. Nightmares, mental depression, vertigo, and extrapyramidal signs may occur but are relatively infrequent. Lactation, associated with increased prolactin secretion, can occur both in men and in women treated with methyldopa. This toxicity is probably mediated by inhibition of dopaminergic mechanisms in the hypothalamus.

Other important adverse effects of methyldopa are development of a positive Coombs test (occurring in 10–20% of patients undergoing therapy for longer than 12 months), which sometimes makes cross-matching blood for transfusion difficult and rarely is associated with hemolytic anemia, as well as hepatitis and drug fever. Discontinuation of the drug usually results in prompt reversal of these abnormalities.

CLONIDINE

Hemodynamic studies indicate that blood pressure lowering by clonidine results from reduction of cardiac output due to decreased heart rate and relaxation of capacitance vessels, with a reduction in peripheral vascular resistance, particularly when patients are upright (when sympathetic tone is normally increased).

Reduction in arterial blood pressure by clonidine is accompanied by decreased renal vascular resistance and maintenance of renal blood flow. As with methyldopa, clonidine reduces blood pressure in the supine position and only rarely causes postural hypotension. Pressor effects of clonidine are not observed after ingestion of therapeutic doses of clonidine, but severe hypertension can complicate a massive overdose.



Clonidine

Pharmacokinetics & Dosage

Typical pharmacokinetic characteristics are listed in Table 11–1.

Clonidine is lipid-soluble and rapidly enters the brain from the circulation. Because of its relatively short half-life and the fact that its antihypertensive effect is directly related to blood concentration, oral clonidine must be given twice a day (or as a patch, below) to maintain smooth blood pressure control. However, as is not the case with methyldopa, the dose-response curve of clonidine is such that increasing doses are more effective (but also more toxic).

A transdermal preparation of clonidine that reduces blood pressure for 7 days after a single application is also available. This preparation appears to produce less sedation than clonidine tablets but is often associated with local skin reactions.

Toxicity

Dry mouth and sedation are frequent and may be severe. Both effects are centrally mediated and dose-dependent and coincide temporally with the drug's antihypertensive effect.

The drug should not be given to patients who are at risk for mental depression and should be withdrawn if depression occurs during therapy. Concomitant treatment with tricyclic antidepressants may block the antihypertensive effect of clonidine. The interaction is believed to be due to α-adrenoceptor-blocking actions of the tricyclics.

Withdrawal of clonidine after protracted use, particularly with high dosages (greater than 1 mg/d), can result in life-threatening hypertensive crisis mediated by increased sympathetic nervous activity. Patients exhibit nervousness, tachycardia, headache, and sweating after omitting one or two doses of the drug. Although the incidence of severe hypertensive crisis is unknown, it is high enough to require that all patients who take clonidine be carefully warned of the possibility. If the drug must be stopped, this should be done gradually while other antihypertensive agents are being substituted. Treatment of the hypertensive crisis consists of reinstitution of clonidine therapy or administration of α- and β-adrenoceptor–blocking agents.

GANGLION-BLOCKING AGENTS

Historically, drugs that block stimulation of postganglionic autonomic neurons by acetylcholine were among the first agents used in the treatment of hypertension. Most such drugs are no longer available clinically because of intolerable toxicities related to their primary action (see below).

Ganglion blockers competitively block nicotinic cholinoceptors on postganglionic neurons in both sympathetic and parasympathetic ganglia. In addition, these drugs may directly block the nicotinic acetylcholine channel, in the same fashion as neuromuscular nicotinic blockers (see Figure 27–6).

The adverse effects of ganglion blockers are direct extensions of their pharmacologic effects. These effects include both sympathoplegia (excessive orthostatic hypotension and sexual dysfunction) and parasympathoplegia (constipation, urinary retention, precipitation of glaucoma, blurred vision, dry mouth, etc). These severe toxicities are the major reason for the abandonment of ganglion blockers for the therapy of hypertension.

ADRENERGIC NEURON–BLOCKING AGENTS

These drugs lower blood pressure by preventing normal physiologic release of norepinephrine from postganglionic sympathetic neurons.

GUANETHIDINE

In high enough doses, guanethidine can produce profound sympathoplegia. The resulting high maximal efficacy of this agent made it the mainstay of outpatient therapy of severe hypertension for many years. For the same reason, guanethidine can produce all of the toxicities expected from "pharmacologic sympathectomy," including marked postural hypotension, diarrhea, and impaired ejaculation. Because of these adverse effects, guanethidine is now rarely used.

Guanethidine is too polar to enter the central nervous system. As a result, this drug has none of the central effects seen with many of the other antihypertensive agents described in this chapter.

Guanadrel is a guanethidine-like drug that is available in the USA. Bethanidine and debrisoquin, antihypertensive agents not available for clinical use in the USA, are similar to guanethidine in mechanism of antihypertensive action.

Mechanism & Sites of Action

Guanethidine inhibits the release of norepinephrine from sympathetic nerve endings (see Figure 6–4). This effect is probably responsible for most of the sympathoplegia that occurs in patients. Guanethidine is transported across the sympathetic nerve membrane by the same mechanism that transports norepinephrine itself (NET, uptake 1), and uptake is essential for the drug's action. Once guanethidine has entered the nerve, it is concentrated in transmitter vesicles, where it replaces norepinephrine. Because it replaces norepinephrine, the drug causes a gradual depletion of norepinephrine stores in the nerve ending.

Inhibition of norepinephrine release is probably caused by guanethidine's local anesthetic properties on sympathetic nerve terminals. Although the drug does not impair axonal conduction in sympathetic fibers, local blockade of membrane electrical activity may occur in nerve endings because the nerve endings specifically take up and concentrate the drug.

Because neuronal uptake is necessary for the hypotensive activity of guanethidine, drugs that block the catecholamine uptake process or displace amines from the nerve terminal (see Chapter 6) block its effects. These include cocaine, amphetamine, tricyclic antidepressants, phenothiazines, and phenoxybenzamine.

Guanethidine increases sensitivity to the hypertensive effects of exogenously administered sympathomimetic amines. This results from inhibition of neuronal uptake of such amines and, after long-term therapy with guanethidine, supersensitivity of effector smooth muscle cells, in a fashion analogous to the process that follows surgical sympathectomy (see Chapter 6).

The hypotensive action of guanethidine early in the course of therapy is associated with reduced cardiac output, due to bradycardia and relaxation of capacitance vessels. With long-term therapy, peripheral vascular resistance decreases. Compensatory sodium and water retention may be marked during guanethidine therapy.

Pharmacokinetics & Dosage

Because of its long half-life (5 days) the onset of sympathoplegia is gradual (maximal effect in 1–2 weeks), and sympathoplegia persists for a comparable period after cessation of therapy. The dose should not ordinarily be increased at intervals shorter than 2 weeks.

Toxicity

Therapeutic use of guanethidine is often associated with symptomatic postural hypotension and hypotension following exercise, particularly when the drug is given in high doses, and may produce dangerously decreased blood flow to heart and brain or even overt shock. Guanethidine-induced sympathoplegia in men may be associated with delayed or retrograde ejaculation (into the bladder). Guanethidine commonly causes diarrhea, which results from increased gastrointestinal motility due to parasympathetic predominance in controlling the activity of intestinal smooth muscle.

Interactions with other drugs may complicate guanethidine therapy. Sympathomimetic agents, at doses available in over-the-counter cold preparations, can produce hypertension in patients taking guanethidine. Similarly, guanethidine can produce hypertensive crisis by releasing catecholamines in patients with pheochromocytoma. When tricyclic antidepressants are administered to patients taking guanethidine, the drug's antihypertensive effect is attenuated, and severe hypertension may follow.

RESERPINE

Reserpine, an alkaloid extracted from the roots of an Indian plant, *Rauwolfia serpentina,* was one of the first effective drugs used on a large scale in the treatment of hypertension. At present, it is considered an effective and relatively safe drug for treating mild to moderate hypertension.

Mechanism & Sites of Action

Reserpine blocks the ability of aminergic transmitter vesicles to take up and store biogenic amines, probably by interfering with the vesicular membrane-associated transporter (VMAT, see Figure 6–4). This effect occurs throughout the body, resulting in depletion of norepinephrine, dopamine, and serotonin in both central and peripheral neurons. Chromaffin granules of the adrenal medulla are also depleted of catecholamines, although to a lesser extent than are the vesicles of neurons. Reserpine's effects on adrenergic vesicles appear irreversible; trace amounts of the drug remain bound to vesicular membranes for many days. Although sufficiently high doses of reserpine in animals can reduce catecholamine stores to zero, lower doses cause inhibition of neurotransmission that is roughly proportionate to the degree of amine depletion.

Depletion of peripheral amines probably accounts for much of the beneficial antihypertensive effect of reserpine, but a central component cannot be ruled out. The effects of low but clinically effective doses resemble those of centrally acting agents (eg, methyldopa) in that sympathetic reflexes remain largely intact, blood pressure is reduced in supine as well as in standing patients, and postural hypotension is mild. Reserpine readily enters the brain, and depletion of cerebral amine stores causes sedation, mental depression, and parkinsonism symptoms.

At lower doses used for treatment of mild hypertension, reserpine lowers blood pressure by a combination of decreased cardiac output and decreased peripheral vascular resistance.

Pharmacokinetics & Dosage

See Table 11–1.

Toxicity

At the low doses usually administered, reserpine produces little postural hypotension. Most of the unwanted effects of reserpine result from actions on the brain or gastrointestinal tract.

High doses of reserpine characteristically produce sedation, lassitude, nightmares, and severe mental depression; occasionally, these occur even in patients receiving low doses (0.25 mg/d). Much less frequently, ordinary low doses of reserpine produce extrapyramidal effects resembling Parkinson's disease, probably as a result of dopamine depletion in the corpus striatum. Although these central effects are uncommon, it should be stressed that they may occur at any time, even after months of uneventful treatment. Patients with a history of mental depression should not receive reserpine, and the drug should be stopped if depression appears.

Reserpine rather often produces mild diarrhea and gastrointestinal cramps and increases gastric acid secretion. The drug should probably not be given to patients with a history of peptic ulcer.

ADRENOCEPTOR ANTAGONISTS

The pharmacology of α- and β-adrenoceptor blockers is presented in Chapter 10. This chapter will concentrate on two prototypical drugs, propranolol and prazosin, primarily in relation to their use in treatment of hypertension. Other adrenoceptor antagonists will be considered only briefly.

PROPRANOLOL

Propranolol was the first βblocker shown to be effective in hypertension and ischemic heart disease. It is now clear that all β-adrenoceptor-blocking agents are very useful for lowering blood pressure in mild to moderate hypertension. In severe hypertension, βblockers are especially useful in preventing the reflex tachycardia that often results from treatment with direct vasodilators. Beta blockers have been shown to reduce mortality in patients with heart failure, and they are particularly advantageous for treating hypertension in that population (see Chapter 13).

Mechanism & Sites of Action

Propranolol's efficacy in treating hypertension as well as most of its toxic effects result from nonselective β blockade. Propranolol decreases blood pressure primarily as a result of a decrease in cardiac output. Other β blockers may decrease cardiac output or decrease peripheral vascular resistance to various degrees, depending on cardioselectivity and partial agonist activities.

Beta blockade in brain, kidney, and peripheral adrenergic neurons has been proposed as contributing to the antihypertensive effect observed with β-receptor blockers. In spite of conflicting evidence, the brain appears unlikely to be the primary site of the hypotensive action of these drugs, because some βblockers that do not readily cross the blood-brain barrier (eg, nadolol, described below) are nonetheless effective antihypertensive agents.

Propranolol inhibits the stimulation of renin production by catecholamines (mediated by β_1 receptors). It is likely that propranolol's effect is due in part to depression of the renin-angiotensin-aldosterone system. Although most effective in patients with high plasma renin activity, propranolol also reduces blood pressure in hypertensive patients with normal or even low renin activity. Beta blockers might also act on peripheral presynaptic β adrenoceptors to reduce sympathetic vasoconstrictor nerve activity.

In mild to moderate hypertension, propranolol produces a significant reduction in blood pressure without prominent postural hypotension.

Pharmacokinetics & Dosage

See Table 11–1. Resting bradycardia and a reduction in the heart rate during exercise are indicators of propranolol's β-blocking effect. Measures of these responses may be used as guides in regulating dosage. Propranolol can be administered once or twice daily and slow-release preparations are available.

Toxicity

The principal toxicities of propranolol result from blockade of cardiac, vascular, or bronchial β receptors and are described in more detail in Chapter 10. The most important of these predictable extensions of the β-blocking action occur in patients with bradycardia or cardiac conduction disease, asthma, peripheral vascular insufficiency, and diabetes.

When propranolol is discontinued after prolonged regular use, some patients experience a withdrawal syndrome, manifested by nervousness, tachycardia, increased intensity of angina, or increase of blood pressure. Myocardial infarction has been reported in a few patients. Although the incidence of these complications is probably low, propranolol should not be discontinued abruptly. The withdrawal syndrome may involve up-regulation or supersensitivity of β adrenoceptors.

OTHER BETA-ADRENOCEPTOR–BLOCKING AGENTS

Of the large number of β blockers tested, most have been shown to be effective in lowering blood pressure. The pharmacologic properties of several of these agents differ from those of propranolol in ways that may confer therapeutic benefits in certain clinical situations.

Metoprolol

Metoprolol is approximately equipotent to propranolol in inhibiting stimulation of β_1 adrenoceptors such as those in the heart but 50- to 100-fold less potent than propranolol in blocking β_2 receptors. Although metoprolol is in other respects very similar to propranolol, its relative cardioselectivity may be advantageous in treating hypertensive patients who also suffer from asthma, diabetes, or peripheral vascular disease. Studies of small numbers of asthmatic patients have shown that metoprolol causes less bronchial constriction than propranolol at doses that produce equal inhibition of β_1 adrenoceptor responses. The cardioselectivity is not complete, however, and asthmatic symptoms have been exacerbated by metoprolol. See Table 11–1.

Nadolol, Carteolol, Atenolol, Betaxolol, & Bisoprolol

Nadolol and carteolol, nonselective β-receptor antagonists, and atenolol, a β_1 -selective blocker, are not appreciably metabolized and are excreted to a considerable extent in the urine. Betaxolol and bisoprolol are β_1 -selective blockers that are primarily metabolized in the liver but have long half-lives. Because of these relatively long half-lives, these drugs can be administered once daily. Nadolol is usually begun at a dosage of 40 mg/d, atenolol at 50 mg/d, carteolol at 2.5 mg/d, betaxolol at 10 mg/d, and bisoprolol at 5 mg/d. Increases in dosage to obtain a satisfactory therapeutic effect should take place no more often than every 4 or 5 days. Patients with reduced renal function should receive correspondingly reduced doses of nadolol, carteolol, and atenolol. It is claimed that atenolol produces fewer central nervous system-related effects than other more lipid-soluble β antagonists.

Pindolol, Acebutolol, & Penbutolol

Pindolol, acebutolol, and penbutolol are partial agonists, ie, βblockers with some intrinsic sympathomimetic activity. They lower blood pressure by decreasing vascular resistance and appear to depress cardiac output or heart rate less than other βblockers, perhaps because of significantly greater agonist than antagonist effects at β_2 receptors. This may be particularly beneficial for patients with bradyarrhythmias or peripheral vascular disease. Daily doses of pindolol start at 10 mg; of acebutolol, at 400 mg; and of penbutolol, at 20 mg.

Labetalol & Carvedilol

Labetalol is formulated as a racemic mixture of four isomers (it has two centers of asymmetry). Two of these isomers—the *(S,S)* - and *(R,S)* -isomers—are relatively inactive, a third *(S,R)* - is a potent αblocker, and the last *(R,R)* - is a potent βblocker. The β-blocking isomer is thought to have selective β_2 agonist and nonselective βantagonist action. Labetalol has a 3:1 ratio of β:α antagonism after oral dosing. Blood pressure is lowered by reduction of systemic vascular resistance without significant alteration in heart rate or cardiac output. Because of its combined α- and β-blocking activity, labetalol is useful in treating the hypertension of pheochromocytoma and hypertensive emergencies. Oral daily doses of labetalol range from 200 to 2400 mg/d. Labetalol is given as repeated intravenous bolus injections of 20–80 mg to treat hypertensive emergencies.

Carvedilol, like labetalol, is administered as a racemic mixture. The *S* (–) isomer is a nonselective β-adrenoceptor blocker, but both *S* (–) and *R* (+) isomers have approximately equal α-blocking potency. The isomers are stereoselectively metabolized in the liver, which means that their elimination half-lives may differ. The average half-life is 7–10 hours. The usual starting dosage of carvedilol for ordinary hypertension is 6.25 mg twice daily.

Esmolol

Esmolol is a β_1 -selective blocker that is rapidly metabolized via hydrolysis by red blood cell esterases. It has a short half-life (9–10 minutes) and is administered by constant intravenous infusion. Esmolol is generally administered as a loading dose (0.5–1 mg/kg), followed by a constant infusion. The infusion is typically started at 50–150 mcg/kg/min, and the dose increased every 5 minutes, up to 300 mcg/kg/min, as needed to achieve the desired therapeutic effect. Esmolol is used for management of intraoperative and postoperative hypertension, and sometimes for hypertensive emergencies, particularly when hypertension is associated with tachycardia.

PRAZOSIN & OTHER ALPHA$_1$ BLOCKERS

Mechanism & Sites of Action

Prazosin, terazosin, and doxazosin produce most of their antihypertensive effect by selectively blocking α_1 receptors in arterioles and venules. These agents produce less reflex tachycardia when lowering blood pressure than do nonselective αantagonists such as phentolamine. Alpha$_1$ receptor selectivity allows norepinephrine to exert unopposed negative feedback (mediated by presynaptic α_2 receptors) on its own release (see Chapter 6); in contrast, phentolamine blocks both presynaptic and postsynaptic αreceptors, with the result that reflex activation of sympathetic neurons produces greater release of transmitter onto β receptors and correspondingly greater cardioacceleration.

Alpha blockers reduce arterial pressure by dilating both resistance and capacitance vessels. As expected, blood pressure is reduced more in the upright than in the supine position. Retention of salt and water occurs when these drugs are administered without a diuretic. The drugs are more effective when used in combination with other agents, such as a β-blocker and a diuretic, than when used alone.

Pharmacokinetics & Dosage

Pharmacokinetic characteristics of prazosin are listed in Table 11–1. Terazosin is also extensively metabolized but undergoes very little first-pass metabolism and has a half-life of 12 hours. Doxazosin has an intermediate bioavailability and a half-life of 22 hours.

Terazosin can often be given once daily, with doses of 5–20 mg/d. Doxazosin is usually given once daily starting at 1 mg/d and progressing to 4 mg/d or more as needed. Although long-term treatment with these α-blockers causes relatively little postural hypotension, a precipitous drop in standing blood pressure develops in some patients shortly after the first dose is absorbed. For this reason, the first dose should be small and should be administered at bedtime. While the mechanism of this first-dose phenomenon is not clear, it occurs more commonly in patients who are salt- and volume-depleted.

Aside from the first-dose phenomenon, the reported toxicities of the α_1 blockers are relatively infrequent and mild. These include dizziness, palpitations, headache, and lassitude. Some patients develop a positive test for antinuclear factor in serum while on prazosin therapy, but this has not been associated with rheumatic symptoms. The α_1 blockers do not adversely and may even beneficially affect plasma lipid profiles but this action has not been shown to confer any benefit on clinical outcomes.

OTHER ALPHA-ADRENOCEPTOR–BLOCKING AGENTS

The nonselective agents, phentolamine and phenoxybenzamine, are useful in diagnosis and treatment of pheochromocytoma and in other clinical situations associated with exaggerated release of catecholamines (eg, phentolamine may be combined with propranolol to treat the clonidine withdrawal syndrome, described above). Their pharmacology is described in Chapter 10.

Vasodilators

Mechanism & Sites of Action

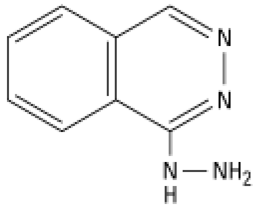
Within this class of drugs are the oral vasodilators, hydralazine and minoxidil, which are used for long-term outpatient therapy of hypertension; the parenteral vasodilators, nitroprusside, diazoxide, and fenoldopam, which are used to treat hypertensive emergencies; and the calcium channel blockers, which are used in both circumstances.

Chapter 12 contains a general discussion of vasodilators. All of the vasodilators useful in hypertension relax smooth muscle of arterioles, thereby decreasing systemic vascular resistance. Sodium nitroprusside also relaxes veins. Decreased arterial resistance and decreased mean arterial blood pressure elicit compensatory responses, mediated by baroreceptors and the sympathetic nervous system (Figure 11–4), as well as renin, angiotensin, and aldosterone. Because sympathetic reflexes are intact, vasodilator therapy does not cause orthostatic hypotension or sexual dysfunction.

Vasodilators work best in combination with other antihypertensive drugs that oppose the compensatory cardiovascular responses. (See Monotherapy Versus Polypharmacy in Hypertension.)

HYDRALAZINE

Hydralazine, a hydrazine derivative, dilates arterioles but not veins. It has been available for many years, although it was initially thought not to be particularly effective because tachyphylaxis to its antihypertensive effects developed rapidly. The benefits of combination therapy are now recognized, and hydralazine may be used more effectively, particularly in severe hypertension.



Hydralazine

Pharmacokinetics & Dosage

Hydralazine is well absorbed and rapidly metabolized by the liver during the first pass, so that bioavailability is low (averaging 25%) and variable among individuals. It is metabolized in part by acetylation at a rate that appears to be bimodally distributed in the population (see Chapter 4). As a consequence, rapid acetylators have greater first-pass metabolism, lower bioavailability, and less antihypertensive benefit from a given dose than do slow acetylators. The half-life of hydralazine ranges from 1.5 to 3 hours, but vascular effects persist longer than do blood concentrations, possibly due to avid binding to vascular tissue.

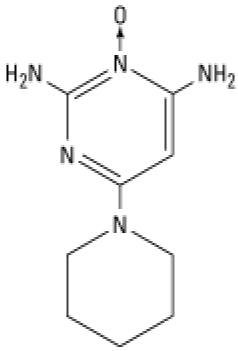
Usual dosage ranges from 40 mg/d to 200 mg/d. The higher dosage was selected as the dose at which there is a small possibility of developing the lupus erythematosus-like syndrome described in the next section. However, higher dosages result in greater vasodilation and may be used if necessary. Dosing two or three times daily provides smooth control of blood pressure.

Toxicity

The most common adverse effects of hydralazine are headache, nausea, anorexia, palpitations, sweating, and flushing. In patients with ischemic heart disease, reflex tachycardia and sympathetic stimulation may provoke angina or ischemic arrhythmias. With dosages of 400 mg/d or more, there is a 10–20% incidence—chiefly in persons who slowly acetylate the drug—of a syndrome characterized by arthralgia, myalgia, skin rashes, and fever that resembles lupus erythematosus. The syndrome is not associated with renal damage and is reversed by discontinuance of hydralazine. Peripheral neuropathy and drug fever are other serious but uncommon adverse effects.

MINOXIDIL

Minoxidil is a very efficacious orally active vasodilator. The effect results from the opening of potassium channels in smooth muscle membranes by minoxidil sulfate, the active metabolite. Increased potassium permeability stabilizes the membrane at its resting potential and makes contraction less likely. Like hydralazine, minoxidil dilates arterioles but not veins. Because of its greater potential antihypertensive effect, minoxidil should replace hydralazine when maximal doses of the latter are not effective or in patients with renal failure and severe hypertension, who do not respond well to hydralazine.



Minoxidil

Pharmacokinetics & Dosage

Pharmacokinetic parameters of minoxidil are listed in Table 11–1. Even more than with hydralazine, the use of minoxidil is associated with reflex sympathetic stimulation and sodium and fluid retention. Minoxidil must be used in combination with a β-blocker and a loop diuretic.

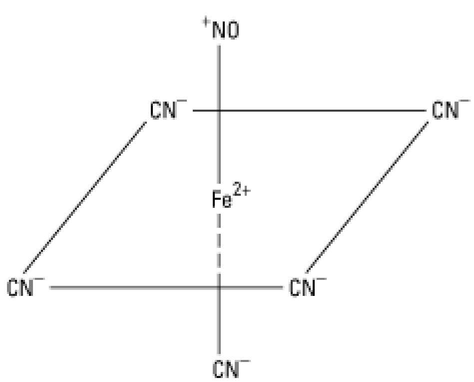
Toxicity

Tachycardia, palpitations, angina, and edema are observed when doses of β-blockers and diuretics are inadequate. Headache, sweating, and hirsutism, which is particularly bothersome in women, are relatively common. Minoxidil illustrates how one person's toxicity may become another person's therapy. Topical minoxidil (as Rogaine) is used as a stimulant to hair growth for correction of baldness.

SODIUM NITROPRUSSIDE

Sodium nitroprusside is a powerful parenterally administered vasodilator that is used in treating hypertensive emergencies as well as severe heart failure. Nitroprusside dilates both arterial and venous vessels, resulting in reduced peripheral vascular resistance and venous return. The action occurs as a result of activation of guanylyl cyclase, either via release of nitric oxide or by direct stimulation of the enzyme. The result is increased intracellular cGMP, which relaxes vascular smooth muscle (see Figure 12-2).

In the absence of heart failure, blood pressure decreases, owing to decreased vascular resistance, while cardiac output does not change or decreases slightly. In patients with heart failure and low cardiac output, output often increases owing to afterload reduction.



Nitroprusside

Pharmacokinetics & Dosage

Nitroprusside is a complex of iron, cyanide groups, and a nitroso moiety. It is rapidly metabolized by uptake into red blood cells with liberation of cyanide. Cyanide in turn is metabolized by the mitochondrial enzyme rhodanase, in the presence of a sulfur donor, to the less toxic thiocyanate. Thiocyanate is distributed in extracellular fluid and slowly eliminated by the kidney.

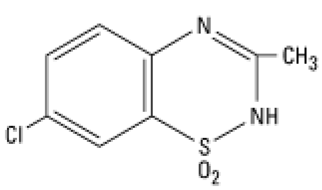
Nitroprusside rapidly lowers blood pressure, and its effects disappear within 1–10 minutes after discontinuation. The drug is given by intravenous infusion. Sodium nitroprusside in aqueous solution is sensitive to light and must therefore be made up fresh before each administration and covered with opaque foil. Infusion solutions should be changed after several hours. Dosage typically begins at 0.5 mcg/kg/min and may be increased up to 10 mcg/kg/min as necessary to control blood pressure. Higher rates of infusion, if continued for more than an hour, may result in toxicity. Because of its efficacy and rapid onset of effect, the drug should be administered by infusion pump and arterial blood pressure continuously monitored via intra-arterial recording.

Toxicity

Other than excessive blood pressure lowering, the most serious toxicity is related to accumulation of cyanide; metabolic acidosis, arrhythmias, excessive hypotension, and death have resulted. In a few cases, toxicity after relatively low doses of nitroprusside suggested a defect in cyanide metabolism. Administration of sodium thiosulfate as a sulfur donor facilitates metabolism of cyanide. Hydroxocobalamin combines with cyanide to form the nontoxic cyanocobalamin. Both have been advocated for prophylaxis or treatment of cyanide poisoning during nitroprusside infusion. Thiocyanate may accumulate over the course of prolonged administration, usually several days or more, particularly in patients with renal insufficiency who do not excrete thiocyanate at a normal rate. Thiocyanate toxicity is manifested as weakness, disorientation, psychosis, muscle spasms, and convulsions, and the diagnosis is confirmed by finding serum concentrations greater than 10 mg/dL. Rarely, delayed hypothyroidism occurs, owing to thiocyanate inhibition of iodide uptake by the thyroid. Methemoglobinemia during infusion of nitroprusside has also been reported.

DIAZOXIDE

Diazoxide is an effective and relatively long-acting parenterally administered arteriolar dilator that is occasionally used to treat hypertensive emergencies. Injection of diazoxide results in a rapid fall in systemic vascular resistance and mean arterial blood pressure associated with substantial tachycardia and increase in cardiac output. Studies of its mechanism suggest that it prevents vascular smooth muscle contraction by opening potassium channels and stabilizing the membrane potential at the resting level.



Diazoxide

Pharmacokinetics & Dosage

Diazoxide is similar chemically to the thiazide diuretics but has no diuretic activity. It is bound extensively to serum albumin and to vascular tissue. Diazoxide is partially metabolized; its metabolic pathways are not well characterized. The remainder is excreted unchanged. Its half-life is approximately 24 hours, but the relationship between blood concentration and hypotensive action is not well established. The blood pressure-lowering effect after a rapid injection is established within 5 minutes and lasts for 4–12 hours.

When diazoxide was first marketed, a dose of 300 mg by rapid injection was recommended. It appears, however, that excessive hypotension can be avoided by beginning with smaller doses (50–150 mg). If necessary, doses of 150 mg may be repeated every 5 minutes until blood pressure is lowered satisfactorily. Nearly all patients respond to a maximum of three or four doses. Alternatively, diazoxide may be administered by intravenous infusion at rates of 15–30 mg/min. Because of reduced protein binding, hypotension occurs after smaller doses in persons with chronic renal failure, and smaller doses should be administered to these patients. The hypotensive effects of diazoxide are also greater if patients are pretreated with β-blockers to prevent the reflex tachycardia and associated increase in cardiac output.

Toxicity

The most significant toxicity from diazoxide has been excessive hypotension, resulting from the recommendation to use a fixed dose of 300 mg in all patients. Such hypotension has resulted in stroke and myocardial infarction. The reflex sympathetic response can provoke angina, electrocardiographic evidence of ischemia, and cardiac failure in patients with ischemic heart disease, and diazoxide should be avoided in this situation.

Diazoxide inhibits insulin release from the pancreas (probably by opening potassium channels in the β-cell membrane) and is used to treat hypoglycemia secondary to insulinoma. Occasionally, hyperglycemia complicates diazoxide use, particularly in persons with renal insufficiency.

In contrast to the structurally related thiazide diuretics, diazoxide causes renal salt and water *retention.* However, because the drug is used for short periods only, this is rarely a problem.

FENOLDOPAM

Fenoldopam is a peripheral arteriolar dilator used for hypertensive emergencies and postoperative hypertension. It acts primarily as an agonist of dopamine D_1 receptors, resulting in dilation of peripheral arteries and natriuresis. The commercial product is a racemic mixture with the *(R)* -isomer mediating the pharmacologic activity.

Fenoldopam is rapidly metabolized, primarily by conjugation. Its half-life is 10 minutes. The drug is administered by continuous intravenous infusion. Fenoldopam is initiated at a low dosage (0.1 mcg/kg/min), and the dose is then titrated upward every 15 or 20 minutes up to a maximum dose of 1.6 mcg/kg/min or until the desired blood pressure reduction is achieved.

As with other direct vasodilators, the major toxicities are reflex tachycardia, headache, and flushing. Fenoldopam also increases intraocular pressure and should be avoided in patients with glaucoma.

CALCIUM CHANNEL BLOCKERS

In addition to their antianginal (see Chapter 12) and antiarrhythmic effects (see Chapter 14), calcium channel blockers also reduce peripheral resistance and blood pressure. The mechanism of action in hypertension (and, in part, in angina) is inhibition of calcium influx into arterial smooth muscle cells.

Verapamil, diltiazem, and the dihydropyridine family (amlodipine, felodipine, isradipine, nicardipine, nifedipine, and nisoldipine) are all equally effective in lowering blood pressure, and many formulations are currently approved for this use in the USA. Hemodynamic differences among calcium channel blockers may influence the choice of a particular agent. Nifedipine and the other dihydropyridine agents are more selective as vasodilators and have less cardiac depressant effect than verapamil and diltiazem. Reflex sympathetic activation with slight tachycardia maintains or increases cardiac output in most patients given dihydropyridines. Verapamil has the greatest depressant effect on the heart and may decrease heart rate and cardiac output. Diltiazem has intermediate actions. The pharmacology and toxicity of these drugs is discussed in more detail in Chapter 12. Doses of calcium channel blockers used in treating hypertension are similar to those used in treating angina. Some epidemiologic studies reported an increased risk of myocardial infarction or mortality in patients receiving short-acting nifedipine for hypertension. It is therefore recommended that short-acting dihydropyridines not be used for hypertension. Sustained-release calcium blockers or calcium blockers with long half-lives provide smoother blood pressure control and are more appropriate for treatment of chronic hypertension. Intravenous nicardipine is available for the treatment of hypertension when oral therapy is not feasible, although parenteral verapamil and diltiazem could be used for the same indication. Nicardipine is typically infused at rates of 2–15 mg/h. Oral short-acting nifedipine has been used in emergency management of severe hypertension.

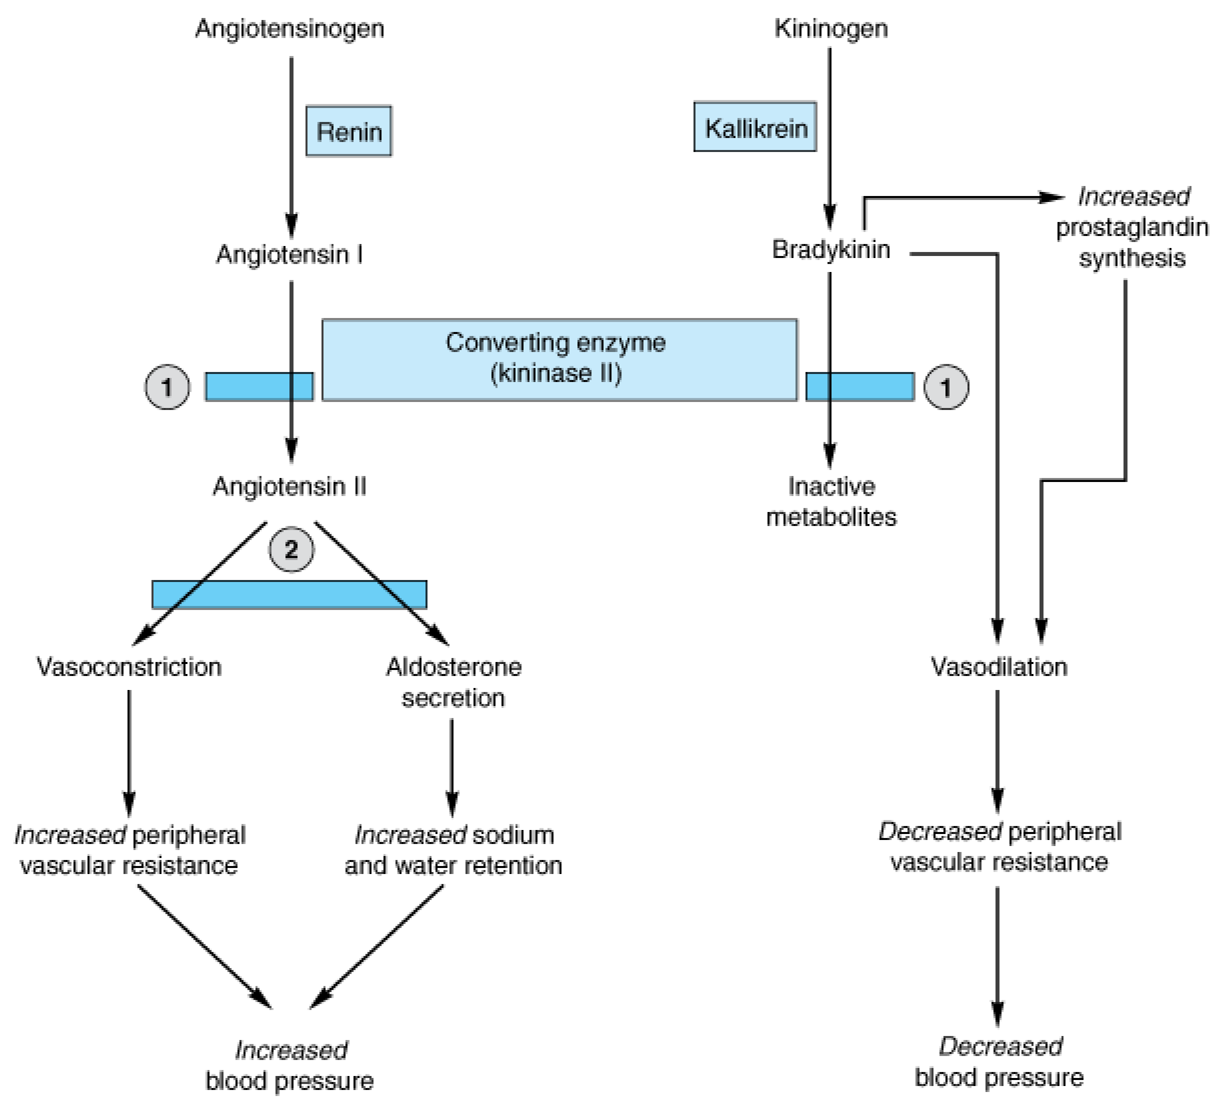
Inhibitors of Angiotensin

Renin, angiotensin, and aldosterone play important roles in at least some individuals with essential hypertension. Approximately 20% of patients with essential hypertension have inappropriately low and 20% have inappropriately high plasma renin activity. Blood pressure of patients with high-renin hypertension responds well to β-adrenoceptor blockers, which lower plasma renin activity, and to angiotensin inhibitors—supporting a role for excess renin and angiotensin in this population.

Mechanism & Sites of Action

Renin release from the kidney cortex is stimulated by reduced renal arterial pressure, sympathetic neural stimulation, and reduced sodium delivery or increased sodium concentration at the distal renal tubule (see Chapter 17). Renin acts upon angiotensinogen to split off the inactive precursor decapeptide angiotensin I. Angiotensin I is then converted, primarily by endothelial ACE, to the arterial vasoconstrictor octapeptide angiotensin II (Figure 11–5), which is in turn converted in the adrenal gland to angiotensin III. Angiotensin II has vasoconstrictor and sodium-retaining activity. Angiotensin II and III both stimulate aldosterone release. Angiotensin may contribute to maintaining high vascular resistance in hypertensive states associated with high plasma renin activity, such as renal arterial stenosis, some types of intrinsic renal disease, and malignant hypertension, as well as in essential hypertension after treatment with sodium restriction, diuretics, or vasodilators. However, even in low-renin hypertensive states, these drugs can lower blood pressure (see below).

Figure 11–5.



Sites of action of ACE inhibitors and angiotensin II receptor blockers. 1 Site of angiotensin-converting enzyme blockade. 2 Site of receptor blockade.

A parallel system for angiotensin generation exists in several other tissues (eg, heart) and may be responsible for trophic changes such as cardiac hypertrophy. The converting enzyme involved in tissue angiotensin II synthesis is also inhibited by the ACE inhibitors.

Two classes of drugs act specifically on the renin-angiotensin system: the ACE inhibitors and the competitive inhibitors of angiotensin at its receptors, including losartan and other nonpeptide antagonists, and the peptide saralasin. (Saralasin is no longer in clinical use.) An orally active renin antagonist (aliskiren, see Chapter 17) is currently under study.

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS

Captopril (see Figure 17–2) and other drugs in this class inhibit the converting enzyme peptidyl dipeptidase that hydrolyzes angiotensin I to angiotensin II and (under the name plasma kininase) inactivates bradykinin, a potent vasodilator, which works at least in part by stimulating release of nitric oxide and prostacyclin. The hypotensive activity of captopril results both from an inhibitory action on the renin-angiotensin system and a stimulating action on the kallikrein-kinin system (Figure 11–5). The latter mechanism has been demonstrated by showing that a bradykinin receptor antagonist, icatibant (see Chapter 17), blunts the blood pressure-lowering effect of captopril.

Enalapril (see Figure 17–3) is an oral prodrug that is converted by hydrolysis to a converting enzyme inhibitor, enalaprilat, with effects similar to those of captopril. Enalaprilat itself is available only for intravenous use, primarily for hypertensive emergencies. Lisinopril is a lysine derivative of enalaprilat. Benazepril, fosinopril, moexipril, perindopril, quinapril, ramipril, and trandolapril are other long-acting members of the class. All are prodrugs, like enalapril, and are converted to the active agents by hydrolysis, primarily in the liver.

Angiotensin II inhibitors lower blood pressure principally by decreasing peripheral vascular resistance. Cardiac output and heart rate are not significantly changed. Unlike direct vasodilators, these agents do not result in reflex sympathetic activation and can be used safely in persons with ischemic heart disease. The absence of reflex tachycardia may be due to downward resetting of the baroreceptors or to enhanced parasympathetic activity.

Although converting enzyme inhibitors are most effective in conditions associated with high plasma renin activity, there is no good correlation among subjects between plasma renin activity and antihypertensive response. Accordingly, renin profiling is unnecessary.

ACE inhibitors have a particularly useful role in treating patients with chronic kidney disease because they diminish proteinuria and stabilize renal function (even in the absence of lowering of blood pressure). These benefits probably result from improved intrarenal hemodynamics, with decreased glomerular efferent arteriolar resistance and a resulting reduction of intraglomerular capillary pressure. ACE inhibitors have also proved to be extremely useful in the treatment of heart failure, and after myocardial infarction, and there is recent evidence that ACE inhibitors reduce the incidence of diabetes in patients with high cardiovascular risk (see Chapter 13).

Pharmacokinetics & Dosage

Captopril's pharmacokinetic parameters and dosing recommendations are set forth in Table 11–1. Peak concentrations of enalaprilat, the active metabolite, occur 3–4 hours after dosing with enalapril. The half-life of enalaprilat is about 11 hours. Typical doses of enalapril are 10–20 mg once or twice daily. Lisinopril has a half-life of 12 hours. Doses of 10–80 mg once daily are effective in most patients. All of the ACE inhibitors except fosinopril and moexipril are eliminated primarily by the kidneys; doses of these drugs should be reduced in patients with renal insufficiency.

Toxicity

Severe hypotension can occur after initial doses of any ACE inhibitor in patients who are hypovolemic due to diuretics, salt restriction, or gastrointestinal fluid loss. Other adverse effects common to all ACE inhibitors include acute renal failure (particularly in patients with bilateral renal artery stenosis or stenosis of the renal artery of a solitary kidney), hyperkalemia, dry cough sometimes accompanied by wheezing, and angioedema. Hyperkalemia is more likely to occur in patients with renal insufficiency or diabetes. Bradykinin and substance P seem to be responsible for the cough and angioedema seen with ACE inhibition.

The use of ACE inhibitors is contraindicated during the second and third trimesters of pregnancy because of the risk of fetal hypotension, anuria, and renal failure, sometimes associated with fetal malformations or death. Recent evidence also implicates first trimester exposure to ACE inhibitors in increased teratogenic risk. Captopril, particularly when given in high doses to patients with renal insufficiency, may cause neutropenia or proteinuria. Minor toxic effects seen more typically include altered sense of taste, allergic skin rashes, and drug fever, which may occur in as many as 10% of patients.

Important drug interactions include those with potassium supplements or potassium-sparing diuretics, which can result in hyperkalemia. Nonsteroidal anti-inflammatory drugs may impair the hypotensive effects of ACE inhibitors by blocking bradykinin-mediated vasodilation, which is at least in part, prostaglandin mediated.

ANGIOTENSIN RECEPTOR–BLOCKING AGENTS

Losartan and valsartan were the first marketed blockers of the angiotensin II type 1 (AT_1) receptor. More recently, candesartan, eprosartan, irbesartan, and telmisartan have been released. They have no effect on bradykinin metabolism and are therefore more selective blockers of angiotensin effects than ACE inhibitors. They also have the potential for more complete inhibition of angiotensin action compared with ACE inhibitors because there are enzymes other than ACE that are capable of generating angiotensin II. Angiotensin receptor blockers provide benefits similar to those of ACE inhibitors in patients with heart failure and chronic kidney disease. Losartan's pharmacokinetic parameters are listed in Table 11–1. The adverse effects are similar to those described for ACE inhibitors, including the hazard of use during pregnancy. Cough and angioedema can occur but are less common with angiotensin receptor blockers than with ACE inhibitors.

CLINICAL PHARMACOLOGY OF ANTIHYPERTENSIVE AGENTS

Hypertension presents a unique problem in therapeutics. It is usually a lifelong disease that causes few symptoms until the advanced stage. For effective treatment, medicines that may be expensive and often produce adverse effects must be consumed daily. Thus, the physician must establish with certainty that hypertension is persistent and requires treatment and must exclude secondary causes of hypertension that might be treated by definitive surgical procedures. Persistence of hypertension, particularly in persons with mild elevation of blood pressure, should be established by finding an elevated blood pressure on at least three different office visits. Ambulatory blood pressure monitoring may be the best predictor of risk and therefore of need for therapy in mild hypertension. Isolated systolic hypertension and hypertension in the elderly also benefit from therapy.

Once the presence of hypertension is established, the question of whether or not to treat and which drugs to use must be considered. The level of blood pressure, the age and sex of the patient, the severity of organ damage (if any) due to high blood pressure, and the presence of cardiovascular risk factors must all be considered. At this stage, the patient must be educated about the nature of hypertension and the importance of treatment so that he or she can make an informed decision regarding therapy.

Once the decision is made to treat, a therapeutic regimen must be developed. Selection of drugs is dictated by the level of blood pressure, the presence and severity of end organ damage, and the presence of other diseases. Severe high blood pressure with life-threatening complications requires more rapid treatment with more efficacious drugs. Most patients with essential hypertension, however, have had elevated blood pressure for months or years, and therapy is best initiated in a gradual fashion.

Education about the natural history of hypertension and the importance of treatment compliance as well as potential side effects of drugs is essential. Follow-up visits should be frequent enough to convince the patient that the physician thinks the illness is serious. With each follow-up visit, the importance of treatment should be reinforced and questions concerning dosing or side effects of medication encouraged. Other factors that may improve compliance are simplifying dosing regimens and having the patient monitor blood pressure at home.

OUTPATIENT THERAPY OF HYPERTENSION

The initial step in treating hypertension may be nonpharmacologic. As discussed previously, sodium restriction may be effective treatment for many patients with mild hypertension. The average American diet contains about 200 mEq of sodium per day. A reasonable dietary goal in treating hypertension is 70–100 mEq of sodium per day, which can be achieved by not salting food during or after cooking and by avoiding processed foods that contain large amounts of sodium. Eating a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat, and moderation of alcohol intake (no more than two drinks per day) also lower blood pressure.

Weight reduction even without sodium restriction has been shown to normalize blood pressure in up to 75% of overweight patients with mild to moderate hypertension. Regular exercise has been shown in some but not all studies to lower blood pressure in hypertensive patients.

For pharmacologic management of mild hypertension, blood pressure can be normalized in many patients with a single drug. However, most patients with hypertension require two or more antihypertensive medications. Thiazide diuretics, βblockers, ACE inhibitors, angiotensin receptor blockers, and calcium channel blockers have all been shown to reduce complications of hypertension and may be used for initial drug therapy. There has been concern that diuretics, by adversely affecting the serum lipid profile or impairing glucose tolerance, may add to the risk of coronary disease, thereby offsetting the benefit of blood pressure reduction. However a recent large clinical trial comparing different classes of antihypertensive mediations for initial therapy found that chlorthalidone (a thiazide diuretic) was as effective as other agents in reducing coronary heart disease death and nonfatal myocardial infarction, and was superior to amlodipine in preventing heart failure and superior to lisinopril in preventing stroke.

The presence of concomitant disease should influence selection of antihypertensive drugs because two diseases may benefit from a single drug. For example, ACE inhibitors are particularly useful in patients with evidence of chronic kidney disease. Beta blockers or calcium channel blockers are useful in patients who also have angina; diuretics, ACE inhibitors, angiotension receptor blockers, or βblockers in patients who also have heart failure; and α_1 blockers in men who have benign prostatic hyperplasia. Race may also affect drug selection: African-Americans respond better to diuretics and calcium channel blockers than to βblockers and ACE inhibitors. Chinese are more sensitive to the effects of βblockers and may require lower doses.

If a single drug does not adequately control blood pressure, drugs with different sites of action can be combined to effectively lower blood pressure while minimizing toxicity ("stepped care"). If a diuretic is not used initially, it is often selected as the second drug. If three drugs are required, combining a diuretic, a sympathoplegic agent or an ACE inhibitor, and a direct vasodilator (eg, hydralazine or a calcium channel blocker) is often effective. In the USA, fixed-dose drug combinations containing a βblocker, an ACE inhibitor, or an angiotensin receptor blocker plus a thiazide, and a calcium channel blocker plus an ACE inhibitor are available. Fixed-dose combinations have the drawback of not allowing for titration of individual drug doses but have the advantage of allowing fewer pills to be taken, potentially enhancing compliance.

Assessment of blood pressure during office visits should include measurement of recumbent, sitting, and standing pressures. An attempt should be made to normalize blood pressure in the posture or activity level that is customary for the patient. The recent large Hypertension Optimal Treatment study suggests that the optimal blood pressure end point is 138/83 mm Hg. Lowering blood pressure below this level produces no further benefit. In diabetic patients, however, there is a continued reduction of event rates with progressively lower blood pressures. Systolic hypertension (> 140 mm Hg in the presence of normal diastolic blood pressure) is a strong cardiovascular risk factor in people older than 50 years of age and should be treated. In addition to noncompliance with medication, causes of failure to respond to drug therapy include excessive sodium intake and inadequate diuretic therapy with excessive blood volume (this can be measured directly), and drugs such as tricyclic antidepressants, nonsteroidal anti-inflammatory drugs, over-the-counter sympathomimetics, abuse of stimulants (amphetamine or cocaine), or excessive doses of caffeine and oral contraceptives that can interfere with actions of some antihypertensive drugs or directly raise blood pressure.

MANAGEMENT OF HYPERTENSIVE EMERGENCIES

Despite the large number of patients with chronic hypertension, hypertensive emergencies are relatively rare. Marked or sudden elevation of blood pressure may be a serious threat to life, however, and prompt control of blood pressure is indicated. Most commonly, hypertensive emergencies occur in patients whose hypertension is severe and poorly controlled and in those who suddenly discontinue antihypertensive medications.

Clinical Presentation & Pathophysiology

Hypertensive emergencies include hypertension associated with vascular damage (termed malignant hypertension) and hypertension associated with hemodynamic complications such as heart failure, stroke, or dissecting aneurysm. The underlying pathologic process in malignant hypertension is a progressive arteriopathy with inflammation and necrosis of arterioles. Vascular lesions occur in the kidney, which releases renin, which in turn stimulates production of angiotensin and aldosterone, which further increase blood pressure.

Hypertensive encephalopathy is a classic feature of malignant hypertension. Its clinical presentation consists of severe headache, mental confusion, and apprehension. Blurred vision, nausea and vomiting, and focal neurologic deficits are common. If untreated, the syndrome may progress over a period of 12–48 hours to convulsions, stupor, coma, and even death.

Treatment of Hypertensive Emergencies

The general management of hypertensive emergencies requires monitoring the patient in an intensive care unit with continuous recording of arterial blood pressure. Fluid intake and output must be monitored carefully and body weight measured daily as an indicator of total body fluid volume during the course of therapy.

Parenteral antihypertensive medications are used to lower blood pressure rapidly (within a few hours); as soon as reasonable blood pressure control is achieved, oral antihypertensive therapy should be substituted, because this allows smoother long-term management of hypertension. The goal of treatment in the first few hours or days is not complete normalization of blood pressure because chronic hypertension is associated with autoregulatory changes in cerebral blood flow. Thus, rapid normalization of blood pressure may lead to cerebral hypoperfusion and brain injury. Rather, blood pressure should be lowered by about 25%, maintaining diastolic blood pressure at no less than 100–110 mm Hg. Subsequently, blood pressure can be reduced to normal levels using oral medications over several weeks. The drug most commonly used to treat hypertensive emergencies is the vasodilator sodium nitroprusside. Other parenteral drugs that may be effective include fenoldopam, nitroglycerin, labetalol, calcium channel blockers, diazoxide, and hydralazine. Esmolol is often used to manage intraoperative and postoperative hypertension. Diuretics such as furosemide are administered to prevent the volume expansion that typically occurs during administration of powerful vasodilators.

PREPARATIONS AVAILABLE

BETA-ADRENOCEPTOR BLOCKERS

Acebutolol (generic, Sectral)

Oral: 200, 400 mg capsules

Atenolol (generic, Tenormin)

Oral: 25, 50, 100 mg tablets

Parenteral: 0.5 mg/mL for injection

Betaxolol (Kerlone)

Oral: 10, 20 mg tablets

Bisoprolol (Zebeta)

Oral: 5, 10 mg tablets

Carteolol (Cartrol)

Oral: 2.5, 5 mg tablets

Carvedilol (Coreg)

Oral: 3.125, 6.25, 12.5, 25 mg tablets

Esmolol (BreviBloc)

Parenteral: 10, 250 mg/mL for injection

Labetalol (generic, Normodyne, Trandate)

Oral: 100, 200, 300 mg tablets

Parenteral: 5 mg/mL for injection

Metoprolol (generic, Lopressor)

Oral: 50, 100 mg tablets

Oral extended-release (Toprol-XL): 25, 50, 100, 200 mg tablets

Parenteral: 1 mg/mL for injection

Nadolol (generic, Corgard)

Oral: 20, 40, 80, 120, 160 mg tablets

Penbutolol (Levatol)

Oral: 20 mg tablets

Pindolol (generic, Visken)

Oral: 5, 10 mg tablets

Propranolol (generic, Inderal)

Oral: 10, 20, 40, 60, 80, 90 mg tablets; 4, 8 mg/mL oral solution; Intensol, 80 mg/mL solution

Oral sustained-release (generic, Inderal LA): 60, 80, 120, 160 mg capsules

Parenteral: 1 mg/mL for injection

Timolol (generic, Blocadren)

Oral: 5, 10, 20 mg tablets

Centrally Acting Sympathoplegic Drugs

Clonidine (generic, Catapres)

Oral: 0.1, 0.2, 0.3 mg tablets

Transdermal (Catapres-TTS): patches that release 0.1, 0.2, 0.3 mg/24 h

Guanabenz (generic, Wytensin)

Oral: 4, 8 mg tablets

Guanfacine (Tenex)

Oral: 1, 2 mg tablets

Methyldopa (generic)

Oral: 250, 500 mg tablets

Parenteral (Methyldopate HCl): 50 mg/mL for injection

Postganglionic Sympathetic Nerve Terminal Blockers

Guanadrel (Hylorel)

Oral: 10, 25 mg tablets

Guanethidine (Ismelin)

Oral: 10, 25 mg tablets

Reserpine (generic)

Oral: 0.1, 0.25 mg tablets

Alpha $_1$-Selective Adrenoceptor Blockers

Doxazosin (generic, Cardura)

Oral: 1, 2, 4, 8 mg tablets

Prazosin (generic, Minipress)

Oral: 1, 2, 5 mg capsules

Terazosin (generic, Hytrin)

Oral: 1, 2, 5, 10 mg capsules and tablets

Ganglion-Blocking Agents

Mecamylamine (Inversine)

Oral: 2.5 mg tablets

Vasodilators Used in Hypertension

Diazoxide (Hyperstat IV)

Parenteral: 15 mg/mL ampule

Oral (Proglycem): 50 mg capsule; 50 mg/mL oral suspension (for insulinoma)

Fenoldopam (Corlopam)

Parenteral: 10 mg/mL for IV infusion

Hydralazine (generic, Apresoline)

Oral: 10, 25, 50, 100 mg tablets

Parenteral: 20 mg/mL for injection

Minoxidil (generic, Loniten)

Oral: 2.5, 10 mg tablets

Topical (generic, Rogaine): 2% lotion

Nitroprusside (generic, Nitropress)

Parenteral: 50 mg/vial

Calcium Channel Blockers

Amlodipine (Amvaz, Norvasc)

Oral 2.5, 5, 10 mg tablets

Diltiazem (generic, Cardizem)

Oral: 30, 60, 90, 120 mg tablets (unlabeled in hypertension)

Oral sustained-release (Cardizem CD, Cardizem SR, Dilacor XL): 60, 90, 120, 180, 240, 300, 360, 420 mg capsules

Parenteral: 5 mg/mL for injection

Felodipine (Plendil)

Oral extended-release: 2.5, 5, 10 mg tablets

Isradipine (DynaCirc)

Oral: 2.5, 5 mg capsules; 5, 10 mg controlled-release tablets

Nicardipine (generic, Cardene)

Oral: 20, 30 mg capsules

Oral sustained-release (Cardene SR): 30, 45, 60 mg capsules

Parenteral (Cardene I.V.): 2.5 mg/mL for injection

Nisoldipine (Sular)

Oral extended-release: 10, 20, 30, 40 mg tablets

Nifedipine (generic, Adalat, Procardia)

Oral: 10, 20 mg capsules (unlabeled in hypertension)

Oral extended-release (Adalat CC, Procardia-XL): 30, 60, 90 mg tablets

Verapamil (generic, Calan, Isoptin)

Oral: 40, 80, 120 mg tablets

Oral sustained-release (generic, Calan SR, Verelan): 120, 180, 240 mg tablets; 100, 120, 180, 200, 240, 300, 360 mg capsules

Parenteral: 2.5 mg/mL for injection

Angiotensin-Converting Enzyme Inhibitors

Benazepril (generic, Lotensin)

Oral: 5, 10, 20, 40 mg tablets

Captopril (generic, Capoten)

Oral: 12.5, 25, 50, 100 mg tablets

Enalapril (generic, Vasotec)

Oral: 2.5, 5, 10, 20 mg tablets

Parenteral (Enalaprilat): 1.25 mg/mL for injection

Fosinopril (generic, Monopril)

Oral: 10, 20, 40 mg tablets

Lisinopril (generic, Prinivil, Zestril)

Oral: 2.5, 5, 10, 20, 40 mg tablets

Moexipril (generic, Univasc)

Oral: 7.5, 15 mg tablets

Perindopril (Aceon)

Oral: 2, 4, 8 mg tablets

Quinapril (Accupril)

Oral: 5, 10, 20, 40 mg tablets

Ramipril (Altace)

Oral: 1.25, 2.5, 5, 10 mg capsules

Trandolapril (Mavik)

Oral: 1, 2, 4 mg tablets

Angiotensin Receptor Blockers

Candesartan (Atacand)

Oral: 4, 8, 16, 32 mg tablets

Eprosartan (Teveten)

Oral: 400, 600 mg tablets

Irbesartan (Avapro)

Oral; 75, 150, 300 mg tablets

Losartan (Cozaar)

Oral: 25, 50, 100 mg tablets

Olmesartan (Benicar)

Oral: 5, 20, 40 mg tablets

Telmisartan (Micardis)

Oral: 20, 40, 80 mg tablets

Valsartan (Diovan)

Oral: 40, 80, 160, 320 mg tablet

VASODILATORS & THE TREATMENT OF ANGINA PECTORIS: INTRODUCTION

Angina pectoris is the most common condition involving tissue ischemia in which vasodilator drugs are used. The name denotes chest pain caused by accumulation of metabolites resulting from myocardial ischemia. The organic nitrates, eg, nitroglycerin, are the mainstay of therapy for the immediate relief of angina. Another group of vasodilators, the calcium channel blockers, is also important, especially for prophylaxis, and the β blockers, which are *not* vasodilators, are also useful in prophylaxis. New groups of drugs under investigation include fatty acid oxidation inhibitors and selective cardiac rate inhibitors.

Ischemic heart disease is the most common serious health problem in many Western societies. By far the most frequent cause of angina is atheromatous obstruction of the large coronary vessels (atherosclerotic angina, classic angina). However, transient spasm of localized portions of these vessels, which is usually associated with underlying atheromas, can also cause significant myocardial ischemia and pain (vasospastic or variant angina).

The primary cause of angina pectoris is an imbalance between the oxygen requirement of the heart and the oxygen supplied to it via the coronary vessels. In classic angina, the imbalance occurs when the myocardial oxygen requirement increases, as during exercise, and coronary blood flow does not increase proportionately. The resulting ischemia usually leads to pain. Classic angina is therefore "angina of effort." (In some individuals, the ischemia is not always accompanied by pain, resulting in "silent" or "ambulatory" ischemia.) In variant angina, oxygen delivery decreases as a result of reversible coronary vasospasm. Variant angina is also called Prinzmetal's angina.

In theory, the imbalance between oxygen delivery and myocardial oxygen demand can be corrected by decreasing oxygen demand or by increasing delivery (by increasing coronary flow). In effort angina, oxygen demand can be reduced by decreasing cardiac work or, according to recent studies, by shifting myocardial metabolism to substrates that require less oxygen per unit of ATP produced. In variant angina, on the other hand, spasm of coronary vessels can be reversed by nitrates or calcium channel blockers. Lipid-lowering drugs, especially the "statins," have become extremely important in the long-term treatment of atherosclerotic disease (see Chapter 35).

Unstable angina, an acute coronary syndrome, is said to be present when there are episodes of angina at rest and when there is a change in the character, frequency, and duration of chest pain as well as precipitating factors in patients with previously stable angina. Unstable angina is caused by episodes of increased epicardial coronary artery tone or small platelet clots occurring in the vicinity of an atherosclerotic plaque. In most cases, formation of labile nonocclusive thrombi at the site of a fissured or ulcerated plaque is the mechanism for reduction in flow. The course and the prognosis of unstable angina are variable, but this subset of acute coronary syndrome is associated with a high risk of myocardial infarction and death.

Pathophysiology of Angina

Determinants of Myocardial Oxygen Demand

The major determinants of myocardial oxygen requirement are set forth in Table 12–1. As a consequence of its continuous activity, the heart's oxygen needs are relatively high, and it extracts approximately 75% of the available oxygen even in the absence of stress. The myocardial oxygen requirement increases when there is an increase in heart rate, contractility, arterial pressure, or ventricular volume. These hemodynamic alterations frequently occur during physical exercise and sympathetic discharge, which often precipitate angina in patients with obstructive coronary artery disease.

Table 12–1. Determinants of Myocardial Oxygen Consumption.
Wall stress
Intraventricular pressure
Ventricular radius (volume)
Wall thickness
Heart rate
Contractility

The heart favors fatty acids as a substrate for energy production. However, oxidation of fatty acids requires more oxygen per unit of ATP generated than oxidation of carbohydrates. Therefore, drugs that shift myocardial metabolism toward greater use of glucose (fatty acid oxidation inhibitors) have the potential of reducing the oxygen demand without altering hemodynamics.

Determinants of Coronary Blood Flow & Myocardial Oxygen Supply

Increased myocardial demands for oxygen in the normal heart are met by augmenting coronary blood flow. Coronary blood flow is directly related to the perfusion pressure (aortic diastolic pressure) and the duration of diastole. Because coronary flow drops to negligible values during systole, the duration of diastole becomes a limiting factor for myocardial perfusion during tachycardia. Coronary blood flow is inversely proportional to coronary vascular bed resistance. Resistance is determined mainly by intrinsic factors—including metabolic products and autonomic activity—and by various pharmacologic agents. Damage to the endothelium of coronary vessels has been shown to alter their ability to dilate and to increase coronary vascular resistance.

Determinants of Vascular Tone

Arteriolar and venous tone (smooth muscle tension) both play a role in determining myocardial wall stress (Table 12–1). Arteriolar tone directly controls peripheral vascular resistance and thus arterial blood pressure. In systole, intraventricular pressure must exceed aortic pressure to eject blood; arterial blood pressure thus determines the *systolic* wall stress in an important way. Venous tone determines the capacity of the venous circulation and controls the amount of blood sequestered in the venous system versus the amount returned to the heart. Venous tone thereby determines the *diastolic* wall stress.

The regulation of smooth muscle contraction and relaxation is shown schematically in Figure 12–1. As shown in Figures 12–1 and 12–2, drugs may relax vascular smooth muscle in several ways:

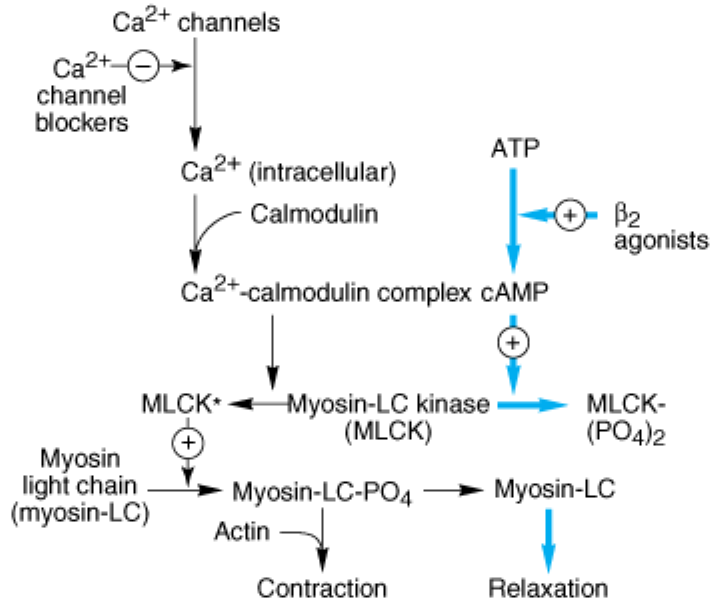
(1) Increasing cGMP: As indicated in Figure 12–2, cGMP facilitates the dephosphorylation of myosin light chains, preventing the interaction of myosin with actin. Nitric oxide is an effective activator of soluble guanylyl cyclase and acts mainly through this mechanism. Important molecular donors of nitric oxide include nitroprusside (see Chapter 11) and the organic nitrates used in angina.

(2) Decreasing intracellular Ca^{2+}: Calcium channel blockers predictably cause vasodilation because they reduce intracellular Ca^{2+}, a major modulator of the activation of myosin light chain kinase. (Beta blockers and calcium channel blockers reduce Ca^{2+} influx in cardiac muscle, thereby reducing rate, contractility, and oxygen requirement unless reversed by compensatory responses.)

(3) Stabilizing or preventing depolarization of the vascular smooth muscle cell membrane: The membrane potential of excitable cells is stabilized near the resting potential by increasing potassium permeability. Potassium channel openers, such as minoxidil sulfate, (see Chapter 11) increase the permeability of K^+ channels, probably ATP-dependent K^+ channels. Certain newer agents under investigation for use in angina (eg, nicorandil) may act, in part, by this mechanism.

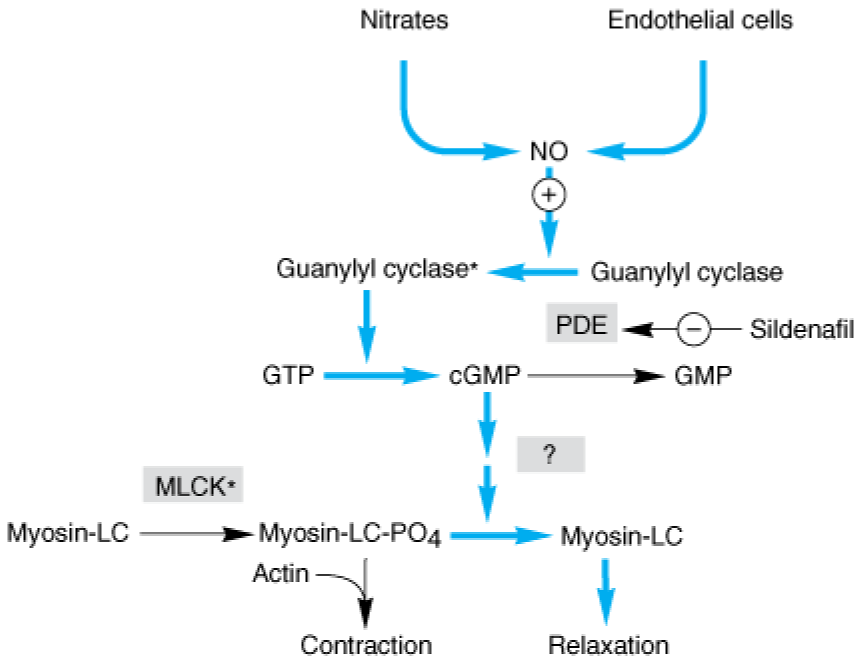
(4) Increasing cAMP in vascular smooth muscle cells: As shown in Figure 12–1, an increase in cAMP increases the rate of inactivation of myosin light chain kinase, the enzyme responsible for triggering the interaction of actin with myosin in these cells. This appears to be the mechanism of vasodilation caused by β_2 agonists, drugs that are *not* used in angina.

Figure 12–1.



Control of smooth muscle contraction and site of action of calcium channel-blocking drugs. Contraction is triggered by influx of calcium (which can be blocked by calcium channel blockers) through transmembrane calcium channels. The calcium combines with calmodulin to form a complex that converts the enzyme myosin light chain kinase to its active form (*MLCK**). The latter phosphorylates the myosin light chains, thereby initiating the interaction of myosin with actin. Beta$_2$ agonists (and other substances that increase cAMP) may cause relaxation in smooth muscle by accelerating the inactivation of MLCK (heavy arrows) and by facilitating the expulsion of calcium from the cell (not shown).

Figure 12–2.



Mechanism of action of nitrates, nitrites, and other substances that increase the concentration of nitric oxide (NO) in smooth muscle cells. (MLCK*, activated myosin light chain kinase [see Figure 12–1]; guanylyl cyclase*, activated guanylyl cyclase; ?, unknown intermediate steps. Steps leading to relaxation are shown with heavy arrows.)

BASIC PHARMACOLOGY OF DRUGS USED TO TREAT ANGINA

Drug Action in Angina

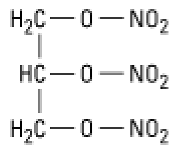
Three of the four drug groups currently approved for use in angina (organic nitrates, calcium channel blockers, and β blockers) *decrease myocardial oxygen requirement* by decreasing the determinants of oxygen demand (heart rate, ventricular volume, blood pressure, and contractility). In some patients, a redistribution of coronary flow may increase oxygen delivery to ischemic tissue. In variant angina, the nitrates and the calcium channel blockers may also *increase myocardial oxygen delivery* by reversing coronary arterial spasm. The fourth group, represented by ranolazine, is discussed later.

NITRATES & NITRITES

Chemistry

These agents are simple nitric and nitrous acid esters of polyalcohols. Nitroglycerin may be considered the prototype of the group. Although nitroglycerin is used in the manufacture of dynamite, the formulations used in medicine are not explosive. The conventional sublingual tablet form of nitroglycerin may lose potency when stored as a result of volatilization and adsorption to plastic surfaces. Therefore, it should be kept in tightly closed glass containers. It is not sensitive to light.

All therapeutically active agents in the nitrate group have identical mechanisms of action and similar toxicities. Therefore, pharmacokinetic factors govern the choice of agent and mode of therapy when using the nitrates.



Nitroglycerin (glyceryl trinitrate)

Pharmacokinetics

The liver contains a high-capacity organic nitrate reductase that removes nitrate groups in a stepwise fashion from the parent molecule and ultimately inactivates the drug. Therefore, oral bioavailability of the traditional organic nitrates (eg, nitroglycerin and isosorbide dinitrate) is very low (typically < 10–20%). For this reason, the sublingual route, which avoids the first-pass effect, is preferred for achieving a therapeutic blood level rapidly. Nitroglycerin and isosorbide dinitrate are both absorbed efficiently by this route and reach therapeutic blood levels within a few minutes. However, the total dose administered by this route must be limited to avoid excessive effect; therefore, the total duration of effect is brief (15–30 minutes). When much longer duration of action is needed, oral preparations can be given that contain an amount of drug sufficient to result in sustained systemic blood levels of the parent drug plus active metabolites. Other routes of administration available for nitroglycerin include transdermal and buccal absorption from slow-release preparations; these are described below.

Amyl nitrite and related nitrites are highly volatile liquids. Amyl nitrite is available in fragile glass ampules packaged in a protective cloth covering. The ampule can be crushed with the fingers, resulting in rapid release of inhalable vapors through the cloth covering. The inhalation route provides very rapid absorption and, like the sublingual route, avoids the hepatic first-pass effect. Because of its unpleasant odor and short duration of action, amyl nitrite is now obsolete for angina.

Once absorbed, the unchanged nitrate compounds have half-lives of only 2–8 minutes. The partially denitrated metabolites have much longer half-lives (up to 3 hours). Of the nitroglycerin metabolites (two dinitroglycerins and two mononitro forms), the dinitro derivatives have significant vasodilator efficacy; they probably provide most of the therapeutic effect of orally administered nitroglycerin. The 5-mononitrate metabolite of isosorbide dinitrate is an active metabolite of the latter drug and is available for clinical use as isosorbide mononitrate. It has a bioavailability of 100%.

Excretion, primarily in the form of glucuronide derivatives of the denitrated metabolites, is largely by way of the kidney.

Pharmacodynamics

MECHANISM OF ACTION IN SMOOTH MUSCLE

Nitroglycerin is denitrated by glutathione *S*-transferase. Free nitrite ion is released, which is then converted to nitric oxide (see Chapter 19). A different unknown enzymatic reaction releases nitric oxide directly from the parent drug molecule. As shown in Figure 12–2, nitric oxide (or an *S*-nitrosothiol derivative) causes activation of guanylyl cyclase and an increase in cGMP, which are the first steps toward smooth muscle relaxation. The production of prostaglandin E or prostacyclin (PGI_2) and membrane hyperpolarization may also be involved. There is no evidence that autonomic receptors are involved in the primary nitrate response (although autonomic *reflex* responses are evoked when hypotensive doses are given).

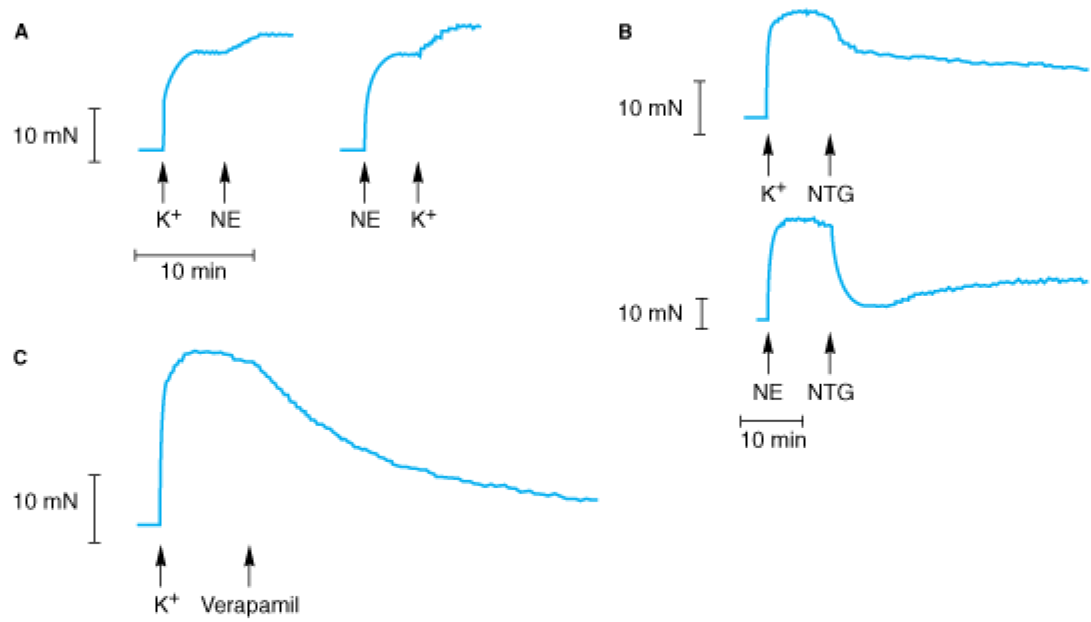
As described below, tolerance is an important consideration in the use of nitrates. While tolerance may be caused in part by a decrease in tissue sulfhydryl groups, it can be only partially prevented or reversed with a sulfhydryl-regenerating agent. Increased generation of oxygen free radicals during nitrate therapy may be another important mechanism of tolerance.

Nicorandil and several other investigational antianginal agents appear to combine the activity of nitric oxide release with potassium channel-opening action, thus providing an additional mechanism for causing vasodilation.

ORGAN SYSTEM EFFECTS

Nitroglycerin relaxes all types of smooth muscle irrespective of the cause of the preexisting muscle tone (Figure 12–3). It has practically no direct effect on cardiac or skeletal muscle.

Figure 12–3.



Effects of vasodilators on contractions of human vein segments studied in vitro. Panel A shows contractions induced by two vasoconstrictor agents, norepinephrine (NE) and potassium (K^+). Panel B shows the relaxation induced by nitroglycerin (NTG), 4 μmol/L. The relaxation is prompt. Panel C shows the relaxation induced by verapamil, 2.2 μmol/L. The relaxation is slower but more sustained. (Modified and reproduced, with permission, from Mikkelsen E, Andersson KE, Bengtsson B: Effects of verapamil and nitroglycerin on contractile responses to potassium and noradrenaline in isolated human peripheral veins. Acta Pharmacol Toxicol 1978;42:14.)

Vascular Smooth Muscle

All segments of the vascular system from large arteries through large veins relax in response to nitroglycerin. Veins respond at the lowest concentrations, arteries at slightly higher ones. Arterioles and precapillary sphincters are dilated less than the large arteries and the veins, partly because of reflex responses and partly because different vessels vary in their ability to release nitric oxide. The primary direct result of an effective dose of nitroglycerin is marked relaxation of veins with increased venous capacitance and decreased ventricular preload. Pulmonary vascular pressures and heart size are significantly reduced. In the absence of heart failure, cardiac output is reduced. Because venous capacitance is increased, orthostatic hypotension may be marked and syncope can result. Dilation of some large arteries (including the aorta) may be significant because of their large increase in compliance. Temporal artery pulsations and a throbbing headache associated with meningeal artery pulsations are frequent effects of nitroglycerin and amyl nitrite. In heart failure, preload is often abnormally high; the nitrates and other vasodilators, by reducing preload, may have a beneficial effect on cardiac output in this condition (see Chapter 13).

The indirect effects of nitroglycerin consist of those compensatory responses evoked by baroreceptors and hormonal mechanisms responding to decreased arterial pressure (see Figure 6–7); this consistently results in tachycardia and increased cardiac contractility. Retention of salt and water may also be significant, especially with intermediate- and long-acting nitrates. These compensatory responses contribute to the development of tolerance.

In normal subjects without coronary disease, nitroglycerin can induce a significant, if transient, increase in total coronary blood flow. In contrast, there is no evidence that total coronary flow is increased in patients with angina due to atherosclerotic obstructive coronary artery disease. However, some studies suggest that *redistribution* of coronary flow from normal to ischemic regions may play a role in nitroglycerin's therapeutic effect. Nitroglycerin also exerts a weak negative inotropic effect via nitric oxide.

Other Smooth Muscle Organs

Relaxation of smooth muscle of the bronchi, gastrointestinal tract (including biliary system), and genitourinary tract has been demonstrated experimentally. Because of their brief duration, these actions of the nitrates are rarely of any clinical value. During recent years, the use of amyl nitrite and isobutyl nitrite by inhalation as purported recreational (sex-enhancing) drugs has become popular with some segments of the population. Nitrites release nitric oxide in erectile tissue as well as vascular smooth muscle and activate guanylyl cyclase. The resulting increase in cGMP causes dephosphorylation of myosin light chains and relaxation (Figure 12–2), which enhances erection. Drugs used in the treatment of erectile dysfunction are discussed in Drugs Used in the Treatment of Erectile Dysfunction.

Action on Platelets

Nitric oxide released from nitroglycerin stimulates guanylyl cyclase in platelets as in smooth muscle. The increase in cGMP that results is responsible for a decrease in platelet aggregation. Unfortunately, recent prospective trials have established no survival benefit when nitroglycerin is used in acute myocardial infarction.

Other Effects

Nitrite ion reacts with hemoglobin (which contains ferrous iron) to produce methemoglobin (which contains ferric iron). Because methemoglobin has a very low affinity for oxygen, large doses of nitrites can result in pseudocyanosis, tissue hypoxia, and death. Fortunately, the plasma level of *nitrite* resulting from even large doses of organic and inorganic *nitrates* is too low to cause significant methemoglobinemia in adults. However, sodium nitrite is used as a curing agent for meats. In nursing infants, the intestinal flora is capable of converting significant amounts of inorganic nitrate, eg, from well water, to nitrite ion. Thus, inadvertent exposure to large amounts of nitrite ion can occur and may produce serious toxicity.

One therapeutic application of this otherwise toxic effect of nitrite has been discovered. Cyanide poisoning results from complexing of cytochrome iron by the CN^- ion. Methemoglobin iron has a very high affinity for CN^-; thus, administration of sodium nitrite ($NaNO_2$) soon after cyanide exposure will regenerate active cytochrome. The cyanmethemoglobin produced can be further detoxified by the intravenous administration of sodium thiosulfate ($Na_2S_2O_3$); this results in formation of thiocyanate ion (SCN^-), a less toxic ion that is readily excreted. Methemoglobinemia, if excessive, can be treated by giving methylene blue intravenously.

Drugs Used in the Treatment of Erectile Dysfunction

Erectile dysfunction in men has long been the subject of research (by both amateur and professional scientists). Among the substances used in the past and generally discredited are "Spanish Fly" (a bladder and urethral irritant), yohimbine (an α_2 antagonist; see Chapter 10), nutmeg, and mixtures containing lead, arsenic, or strychnine. Substances currently favored by practitioners of herbal medicine include ginseng and kava.

Scientific studies of the process have shown that erection requires *relaxation* of the nonvascular smooth muscle of the corpora cavernosa. This relaxation permits inflow of blood at nearly arterial pressure into the sinuses of the cavernosa, and it is the pressure of the blood that causes erection. Physiologic erection occurs in response to the release of nitric oxide from nonadrenergic-noncholinergic nerves (see Chapter 6) associated with parasympathetic discharge. Thus, parasympathetic innervation must be intact and nitric oxide synthesis must be active. (It appears that a similar process occurs in female erectile tissues.) Certain other smooth muscle relaxants—eg, PGE_1 analogs or α antagonists—if present in high enough concentration, can independently cause sufficient cavernosal relaxation to result in erection. As noted in the text, nitric oxide activates guanylyl cyclase, which increases the concentration of cGMP, and the latter messenger stimulates the dephosphorylation of myosin light chains (see Figure 12–2) and relaxation of the smooth muscle. Thus, any drug that increases cGMP might be of value in erectile dysfunction if normal innervation is present. Sildenafil (Viagra) acts to increase cGMP by inhibiting its breakdown by phosphodiesterase isoform 5. The drug has been very successful in the marketplace because it can be taken orally. However, sildenafil is of little or no value in men with loss of potency due to cord injury or other damage to innervation and in men lacking libido. Furthermore, sildenafil potentiates the action of nitrates used for angina, and severe hypotension and a few myocardial infarctions have been reported in men taking both drugs. It is recommended that at least 6 hours pass between use of a nitrate and the ingestion of sildenafil. Sildenafil also has effects on color vision, causing difficulty in blue-green discrimination. Two similar PDE-5 inhibitors, tadalafil and vardenafil, are available.

The drug most commonly used in patients who do not respond to sildenafil is alprostadil, a PGE_1 analog (see Chapter 18) that can be injected directly into the cavernosa or placed in the urethra as a minisuppository, from which it diffuses into the cavernosal tissue. Phentolamine can be used by injection into the cavernosa. These drugs will cause erection in most men who do not respond to sildenafil.

Toxicity & Tolerance

ACUTE ADVERSE EFFECTS

The major acute toxicities of organic nitrates are direct extensions of therapeutic vasodilation: orthostatic hypotension, tachycardia, and throbbing headache. Glaucoma, once thought to be a contraindication, does not worsen, and nitrates can be used safely in the presence of increased intraocular pressure. Nitrates are contraindicated, however, if intracranial pressure is elevated.

TOLERANCE

With continuous exposure to nitrates, isolated smooth muscle may develop complete tolerance (tachyphylaxis), and the intact human becomes progressively more tolerant when long-acting preparations (oral, transdermal) or continuous intravenous infusions are used for more than a few hours without interruption.

Continuous exposure to high levels of nitrates can occur in the chemical industry, especially where explosives are manufactured. When contamination of the workplace with volatile organic nitrate compounds is severe, workers find that upon starting their work week (Monday), they suffer headache and transient dizziness. After a day or so, these symptoms disappear owing to the development of tolerance. Over the weekend, when exposure to the chemicals is reduced, tolerance disappears, so symptoms recur each Monday. Other hazards of industrial exposure, including dependence, have been reported. There is no evidence that physical dependence develops as a result of the therapeutic use of short-acting nitrates for angina, even in large doses.

The mechanisms by which tolerance develops are not completely understood. As noted above, diminished release of nitric oxide resulting from depletion of tissue thiol compounds may be partly responsible for tolerance to nitroglycerin. Systemic compensation also plays a role in tolerance in the intact human. Initially, significant sympathetic discharge occurs and after one or more days of therapy with long-acting nitrates, retention of salt and water may reverse the favorable hemodynamic changes normally caused by nitroglycerin.

CARCINOGENICITY OF NITRATE AND NITRATE DERIVATIVES

Nitrosamines are small molecules with the structure R_2–N–NO formed from the combination of nitrates and nitrites with amines. Some nitrosamines are powerful carcinogens in animals, apparently through conversion to reactive derivatives. While there is no direct proof that these agents cause cancer in humans, there is a strong epidemiologic correlation between the incidence of esophageal and gastric carcinoma and the nitrate content of food in different cultures. Nitrosamines are also found in tobacco and in cigarette smoke. There is no evidence that the small doses of nitrates used in the treatment of angina result in significant body levels of nitrosamines.

Mechanisms of Clinical Effect

The beneficial and deleterious effects of nitrate-induced vasodilation are summarized in Table 12–2.

Table 12–2. Beneficial and Deleterious Effects of Nitrates in the Treatment of Angina.	
Effect	**Result**
Potential beneficial effects	
Decreased ventricular volume	Decreased myocardial oxygen requirement
Decreased arterial pressure	
Decreased ejection time	
Vasodilation of epicardial coronary arteries	Relief of coronary artery spasm
Increased collateral flow	Improved perfusion to ischemic myocardium
Decreased left ventricular diastolic pressure	Improved subendocardial perfusion
Potential deleterious effects	
Reflex tachycardia	Increased myocardial oxygen requirement
Reflex increase in contractility	
Decreased diastolic perfusion time due to tachycardia	Decreased coronary perfusion

NITRATE EFFECTS IN ANGINA OF EFFORT

Decreased venous return to the heart and the resulting reduction of intracardiac volume are the principal hemodynamic effects. Arterial pressure also decreases. Decreased intraventricular pressure and left ventricular volume are associated with decreased wall tension (Laplace relation) and decreased myocardial oxygen requirement. In rare instances, a paradoxical increase in myocardial oxygen demand may occur as a result of excessive reflex tachycardia and increased contractility.

Intracoronary, intravenous, or sublingual nitrate administration consistently increases the caliber of the large epicardial coronary arteries. Coronary arteriolar resistance tends to decrease, although to a lesser extent. However, nitrates administered by the usual systemic routes also consistently *decrease* overall coronary blood flow and myocardial oxygen consumption. The reduction in oxygen consumption is the major mechanism for the relief of effort angina.

NITRATE EFFECTS IN VARIANT ANGINA

Nitrates benefit patients with variant angina by relaxing the smooth muscle of the epicardial coronary arteries and relieving coronary artery spasm.

NITRATE EFFECTS IN UNSTABLE ANGINA

Nitrates are also useful in the treatment of this acute coronary syndrome, but the precise mechanism for their beneficial effects is not clear. Because both increased coronary vascular tone and increased myocardial oxygen demand can precipitate rest angina in these patients, nitrates may exert their beneficial effects both by dilating the epicardial coronary arteries and by simultaneously reducing myocardial oxygen demand. As noted above, nitroglycerin also decreases platelet aggregation, and this effect may be of importance in unstable angina.

Clinical Use of Nitrates

Some of the forms of nitroglycerin and its congeners are listed in Table 12–3. Because of its rapid onset of action (1–3 minutes), sublingual nitroglycerin is the most frequently used agent for the immediate treatment of angina. Because its duration of action is short (not exceeding 20–30 minutes), it is not suitable for maintenance therapy. The onset of action of intravenous nitroglycerin is also rapid (minutes), but its hemodynamic effects are quickly reversed by stopping its infusion. Clinical application of intravenous nitroglycerin, therefore, is restricted to the treatment of severe, recurrent rest angina. Slowly absorbed preparations of nitroglycerin include a buccal form, oral preparations, and several transdermal forms. These formulations have been shown to provide blood concentrations for long periods but, as noted above, this leads to the development of tolerance.

Table 12–3. Nitrate and Nitrite Drugs Used in the Treatment of Angina.

Drug	Dose	Duration of Action
"Short-acting"		
Nitroglycerin, sublingual	0.15–1.2 mg	10–30 minutes
Isosorbide dinitrate, sublingual	2.5–5 mg	10–60 minutes
Amyl nitrite, inhalant	0.18–0.3 mL	3–5 minutes
"Long-acting"		
Nitroglycerin, oral sustained-action	6.5–13 mg per 6–8 hours	6–8 hours
Nitroglycerin, 2% ointment, transdermal	1–1.5 inches per 4 hours	3–6 hours
Nitroglycerin, slow-release, buccal	1–2 mg per 4 hours	3–6 hours
Nitroglycerin, slow-release patch, transdermal	10–25 mg per 24 hours (one patch per day)	8–10 hours
Isosorbide dinitrate, sublingual	2.5–10 mg per 2 hours	1.5–2 hours
Isosorbide dinitrate, oral	10–60 mg per 4–6 hours	4–6 hours
Isosorbide dinitrate, chewable oral	5–10 mg per 2–4 hours	2–3 hours

Drug	Dose	Duration of Action
Isosorbide mononitrate, oral	20 mg per 12 hours	6–10 hours

The hemodynamic effects of sublingual or chewable isosorbide dinitrate and other organic nitrates are similar to those of nitroglycerin. The recommended dosage schedules for commonly used long-acting nitrate preparations, along with their durations of action, are listed in Table 12–3. Although transdermal administration may provide blood levels of nitroglycerin for 24 hours or longer, the full hemodynamic effects usually do not persist for more than 6–8 hours. The clinical efficacy of slow-release forms of nitroglycerin in maintenance therapy of angina is thus limited by the development of significant tolerance. Therefore, a nitrate-free period of at least 8 hours between doses should be observed to reduce or prevent tolerance.

OTHER NITRO-VASODILATORS

Nicorandil is a nicotinamide nitrate ester that has vasodilating properties in normal coronary arteries but more complex effects in patients with angina. Clinical studies suggest that it reduces both preload and afterload. It also provides some myocardial protection via preconditioning by activation of cardiac K_{ATP} channels. One large trial showed a significant reduction in relative risk of fatal and nonfatal coronary events in patients receiving the drug. Nicorandil is currently approved for use in the treatment of angina in Europe and Japan and has been submitted for approval in the USA.

CALCIUM CHANNEL-BLOCKING DRUGS

It has been known since the late 1800s that calcium influx was necessary for the contraction of smooth and cardiac muscle. The discovery of a calcium channel in cardiac muscle was followed by the finding of several different types of calcium channels in different tissues (Table 12–4). The discovery of these channels made possible the development of clinically useful blocking drugs. Although the successful therapeutic blockers developed to date have been exclusively L-type channel blockers, selective blockers of other types of calcium channels are under intensive investigation.

Table 12–4. Properties of Several Recognized Voltage-Activated Calcium Channels.

Type	Channel Name	Where Found	Properties of the Calcium Current	Blocked By
L	CaV1.1–CaV1.3	Muscle, neurons (CaV1.4 is found in retina)	Long, large, high threshold	Verapamil, DHPs, Cd^{2+}

Type	Channel Name	Where Found	Properties of the Calcium Current	Blocked By
T	CaV3.1–CaV3.3	Heart, neurons	Short, small, low threshold	sFTX, flunarizine, Ni^{2+}
N	CaV2.2	Neurons	Short, high threshold	ω-CTX-GVIA, Cd^{2+}
P/Q	CaV2.1	Cerebellar Purkinje neurons	Long, high threshold	ω-CTX-MVIIC, ω-Aga-IVA
R	CaV2.3	Neurons	Pacemaking	SNX-482

DHPs, dihydropyridines (eg, nifedipine); sFTX, synthetic funnel web spider toxin; ω-CTX, conotoxins extracted from several marine snails of the genus *Conus;* ω-Aga-IVA, a toxin of the funnel web spider, *Agelenopsis aperta*; SNX-482, a toxin of the African tarantula, *Hysterocrates gigas*.

Chemistry & Pharmacokinetics

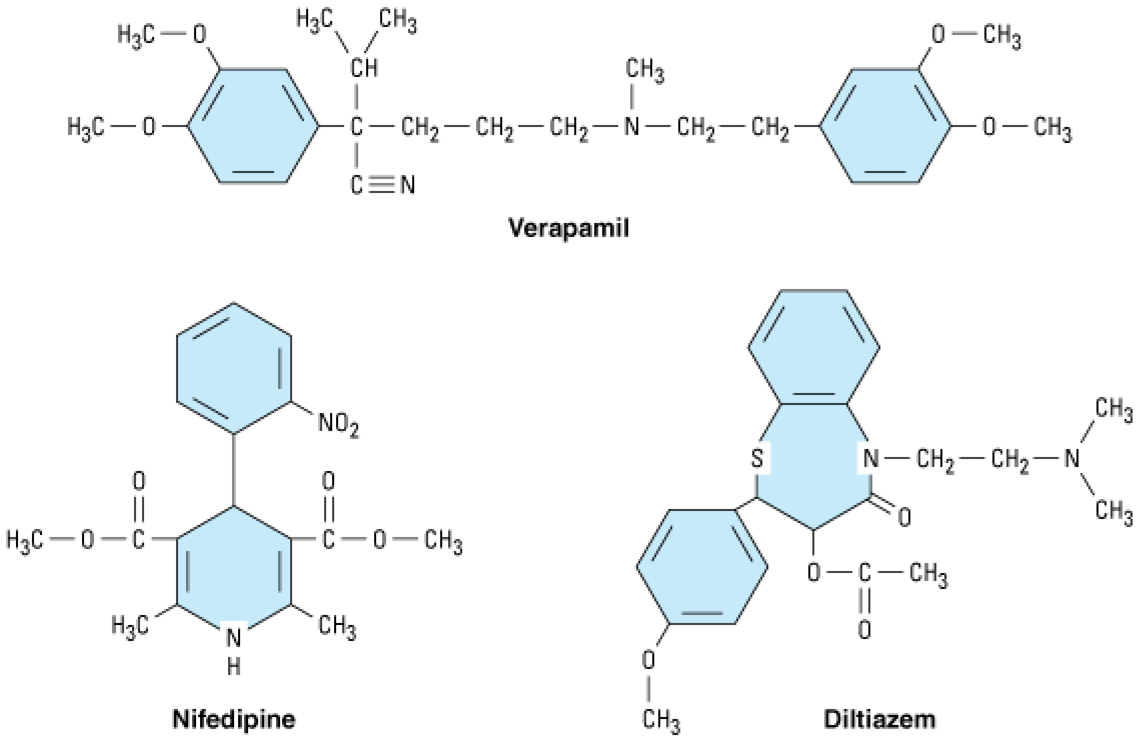
Verapamil, the first clinically useful member of this group, was the result of attempts to synthesize more active analogs of papaverine, a vasodilator alkaloid found in the opium poppy. Since then, dozens of agents of varying structure have been found to have the same fundamental pharmacologic action (Table 12–5). Three chemically dissimilar calcium channel blockers are shown in Figure 12–4. Nifedipine is the prototype of the dihydropyridine family of calcium channel blockers; dozens of molecules in this family have been investigated, and seven are currently approved in the USA for angina and other indications. Nifedipine is the most extensively studied of this group, but the properties of the other dihydropyridines can be assumed to be similar to it unless otherwise noted.

Table 12–5. Clinical Pharmacology of Some Calcium Channel-Blocking Drugs.

Drug	Oral Bioavailability (%)	Half-Life (hours)	Indication	Dosage
Dihydropyridines				
Amlodipine	65–90	30–50	Angina, hypertension	5–10 mg orally once daily
Felodipine	15–20	11–16	Hypertension, Raynaud's phenomenon	5–10 mg orally once daily

Drug	Oral Bioavailability (%)	Half-Life (hours)	Indication	Dosage
Isradipine	15–25	8	Hypertension	2.5–10 mg orally twice daily
Nicardipine	35	2–4	Angina, hypertension	20–40 mg orally every 8 hours
Nifedipine	45–70	4	Angina, hypertension, Raynaud's phenomenon	3–10 mcg/kg IV; 20–40 mg orally every 8 hours
Nimodipine	13	1–2	Subarachnoid hemorrhage	40 mg orally every 4 hours
Nisoldipine	< 10	6–12	Hypertension	20–40 mg orally once daily
Nitrendipine	10–30	5–12	Investigational	20 mg orally once or twice daily
Miscellaneous				
Diltiazem	40–65	3–4	Angina, hypertension, Raynaud's phenomenon	75–150 mcg/kg IV; 30–80 mg orally every 6 hours
Verapamil	20–35	6	Angina, hypertension, arrhythmias, migraine	75–150 mcg/kg IV; 80–160 mg orally every 8 hours

Figure 12–4.



Chemical structures of several calcium channel-blocking drugs.

The calcium channel blockers are orally active agents and are characterized by high first-pass effect, high plasma protein binding, and extensive metabolism. Verapamil and diltiazem are also used by the intravenous route.

Pharmacodynamics

MECHANISM OF ACTION

The L-type calcium channel is the dominant type in cardiac and smooth muscle and is known to contain several drug receptors. It has been demonstrated that nifedipine and other dihydropyridines bind to one site, while verapamil and diltiazem appear to bind to closely related but not identical receptors in another region. Binding of a drug to the verapamil or diltiazem receptors also affects dihydropyridine binding. These receptor regions are stereoselective, since marked differences in both stereoisomer-binding affinity and pharmacologic potency are observed for enantiomers of verapamil, diltiazem, and optically active nifedipine congeners.

Blockade by these drugs resembles that of sodium channel blockade by local anesthetics (see Chapters 14 and 26). The drugs act from the inner side of the membrane and bind more effectively to channels in depolarized membranes. Binding of the drug reduces the frequency of opening in response to depolarization. The result is a marked decrease in transmembrane calcium current, resulting in smooth muscle with a long-lasting relaxation (Figure 12–3), and in cardiac muscle with a reduction in contractility throughout the heart and decreases in sinus node pacemaker rate and in atrioventricular node conduction velocity.*

Smooth muscle responses to calcium influx through *receptor*-operated calcium channels are also reduced by these drugs but not as markedly. The block can be partially reversed by elevating the concentration of calcium, although the levels of calcium required are not easily attainable. Block can also be partially reversed by the use of drugs that increase the transmembrane flux of calcium, such as sympathomimetics.

Other types of calcium channels are less sensitive to blockade by these calcium channel blockers (Table 12–4). Therefore, tissues in which these other channel types play a major role—neurons and most secretory glands—are much less affected by these drugs than are cardiac and smooth muscle.

*At very low doses and under certain circumstances, some dihydropyridines *increase* calcium influx. Some special dihydropyridines, eg, Bay K 8644, actually increase calcium influx over most of their dose range.

ORGAN SYSTEM EFFECTS

Smooth Muscle

Most types of smooth muscle are dependent on transmembrane calcium influx for normal resting tone and contractile responses. These cells are relaxed by the calcium channel blockers (Figure 12–3). Vascular smooth muscle appears to be the most sensitive, but similar relaxation can be shown for bronchiolar, gastrointestinal, and uterine smooth muscle. In the vascular system, arterioles appear to be more sensitive than veins; orthostatic hypotension is not a common adverse effect. Blood pressure is reduced with all calcium channel blockers. Women may be more sensitive than men to the hypotensive action of diltiazem. The reduction in peripheral vascular resistance is one mechanism by which these agents may benefit the patient with angina of effort. Reduction of coronary arterial tone has been demonstrated in patients with variant angina.

Important differences in vascular selectivity exist among the calcium channel blockers. In general, the dihydropyridines have a greater ratio of vascular smooth muscle effects relative to cardiac effects than do diltiazem and verapamil. Furthermore, the dihydropyridines may differ in their potency in different vascular beds. For example, nimodipine is claimed to be particularly selective for cerebral blood vessels.

Cardiac Muscle

Cardiac muscle is highly dependent upon calcium influx for normal function. Impulse generation in the sinoatrial node and conduction in the atrioventricular node—so-called slow response, or calcium-dependent, action potentials—may be reduced or blocked by all of the calcium channel blockers. Excitation-contraction coupling in all cardiac cells requires calcium influx, so these drugs reduce cardiac contractility in a dose-dependent fashion. In some cases, cardiac output may also decrease. This reduction in cardiac mechanical function is another mechanism by which the calcium channel blockers can reduce the oxygen requirement in patients with angina.

Important differences between the available calcium channel blockers arise from the details of their interactions with cardiac ion channels and, as noted above, differences in their relative smooth muscle versus cardiac effects. Sodium channel block is modest with verapamil and still less marked with diltiazem. It is negligible with nifedipine and other dihydropyridines. Verapamil and diltiazem interact kinetically with the calcium channel receptor in a different manner than the dihydropyridines; they block tachycardias in calcium-dependent cells, eg, the atrioventricular node, more selectively than do the dihydropyridines. (See Chapter 14 for additional details.) On the other hand, the dihydropyridines appear to block smooth muscle calcium channels at concentrations below those required for significant cardiac effects; they are therefore less depressant on the heart than verapamil or diltiazem.

Skeletal Muscle

Skeletal muscle is not depressed by the calcium channel blockers because it uses intracellular pools of calcium to support excitation-contraction coupling and does not require as much transmembrane calcium influx.

Cerebral Vasospasm and Infarct Following Subarachnoid Hemorrhage

Nimodipine, a member of the dihydropyridine group of calcium channel blockers, has a high affinity for cerebral blood vessels and appears to reduce morbidity following a subarachnoid hemorrhage. Nimodipine is therefore labeled for use in patients who have had a hemorrhagic stroke. Although evidence suggests that calcium channel blockers may also reduce cerebral damage following thromboembolic stroke in experimental animals, there is no evidence that this occurs in humans.

Other Effects

Calcium channel blockers minimally interfere with stimulus-secretion coupling in glands and nerve endings because of differences between calcium channels in different tissues, as noted above. Verapamil has been shown to inhibit insulin release in humans, but the dosages required are greater than those used in management of angina.

A significant body of evidence suggests that the calcium channel blockers may interfere with platelet aggregation in vitro and prevent or attenuate the development of atheromatous lesions in animals. Clinical studies have not established their role in human blood clotting and atherosclerosis.

Verapamil has been shown to block the P-glycoprotein responsible for the transport of many foreign drugs out of cancer (and other) cells; other calcium channel blockers appear to have a similar effect. This action is not stereospecific. Verapamil has been shown to partially reverse the resistance of cancer cells to many chemotherapeutic drugs in vitro. Some clinical results suggest similar effects in patients (see Chapter 55).

Toxicity

The most important toxic effects reported for the calcium channel blockers are direct extensions of their therapeutic action. Excessive inhibition of calcium influx can cause serious cardiac depression, including cardiac arrest, bradycardia, atrioventricular block, and heart failure. These effects have been rare in clinical use.

Retrospective case control studies reported that immediate-acting nifedipine increased the risk of myocardial infarction in patients with hypertension. Slow-release and long-acting vasoselective calcium channel blockers are usually well tolerated. However, dihydropyridines, compared with angiotensin-converting enzyme inhibitors, have been reported to increase the risk of adverse cardiac events in patients with hypertension with or without diabetes. These results suggest that relatively short-acting calcium channel blockers have the potential to enhance the risk of adverse cardiac events and should be avoided. Patients receiving β-adrenoceptor-blocking drugs are more sensitive to the cardiodepressant effects of calcium channel blockers. Minor toxicity (troublesome but not usually requiring discontinuance of therapy) includes flushing, dizziness, nausea, constipation, and peripheral edema.

Mechanisms of Clinical Effects

Calcium channel blockers decrease myocardial contractile force, which reduces myocardial oxygen requirements. Inhibition of calcium entry into arterial smooth muscle is associated with decreased arteriolar tone and systemic vascular resistance, resulting in decreased arterial and intraventricular pressure. Some of these drugs (eg, verapamil, diltiazem) also possess a nonspecific antiadrenergic effect, which may contribute to peripheral vasodilation. As a result of all of these effects, left ventricular wall stress declines, which reduces myocardial oxygen requirements. Decreased heart rate with the use of verapamil or diltiazem causes a further decrease in myocardial oxygen demand. Calcium channel-blocking agents also relieve and prevent the primary cause of variant angina—focal coronary artery spasm. Use of these agents has thus emerged as the most effective prophylactic treatment for this form of angina pectoris.

Sinoatrial and atrioventricular nodal tissues, which are mainly composed of calcium-dependent, slow response cells, are affected markedly by verapamil, moderately by diltiazem, and much less by dihydropyridines. Thus, verapamil and diltiazem decrease atrioventricular nodal conduction and are effective in the management of supraventricular reentry tachycardia and in decreasing ventricular responses in atrial fibrillation or flutter. Nifedipine does not affect atrioventricular conduction. Nonspecific sympathetic antagonism is most marked with diltiazem and much less with verapamil. Nifedipine does not appear to have this effect. Thus, significant reflex tachycardia in response to hypotension occurs most frequently with nifedipine and less so with diltiazem and verapamil. These differences in pharmacologic effects should be considered in selecting calcium channel-blocking agents for the management of angina.

Clinical Uses of Calcium Channel–Blocking Drugs

In addition to angina, calcium channel blockers have well-documented efficacy in hypertension (see Chapter 11) and supraventricular tachyarrhythmias (see Chapter 14). They also show promise in a variety of other conditions, including hypertrophic cardiomyopathy, migraine, and Raynaud's phenomenon.

The pharmacokinetic properties of these drugs are set forth in Table 12–5. The choice of a particular calcium channel-blocking agent should be made with knowledge of its specific potential adverse effects as well as its pharmacologic properties. Nifedipine does not decrease atrioventricular conduction and therefore can be used more safely than verapamil or diltiazem in the presence of atrioventricular conduction abnormalities. A combination of verapamil or diltiazem with β blockers may produce atrioventricular block and depression of ventricular function. In the presence of overt heart failure, all calcium channel blockers can cause further worsening of heart failure as a result of their negative inotropic effect. Amlodipine, however, does not increase the mortality of patients with heart failure due to left ventricular systolic dysfunction and can be used safely in these patients. In the presence of relatively low blood pressure, dihydropyridines can cause further deleterious lowering of pressure. Verapamil and diltiazem appear to produce less hypotension and may be better tolerated in these circumstances. In patients with a history of atrial tachycardia, flutter, and fibrillation, verapamil and diltiazem provide a distinct advantage because of their antiarrhythmic effects. In the patient receiving digitalis, verapamil should be used with caution, because it may increase digoxin blood levels through a pharmacokinetic interaction. Although increases in digoxin blood level have also been demonstrated with diltiazem and nifedipine, such interactions are less consistent than with verapamil.

In patients with unstable angina, immediate-release short-acting calcium channel blockers can increase the risk of adverse cardiac events and therefore are contraindicated (see Toxicity, above). However, in patients with non-Q-wave myocardial infarction, diltiazem can decrease the frequency of postinfarction angina and may be used.

BETA-ADRENORECEPTOR–BLOCKING DRUGS

Although they are not vasodilators, β-blocking drugs (see Chapter 10) are extremely useful in the management of angina pectoris associated with effort. The beneficial effects of β-blocking agents are related primarily to their hemodynamic effects—decreased heart rate, blood pressure, and contractility—which decrease myocardial oxygen requirements at rest and during exercise. Lower heart rate is also associated with an increase in diastolic perfusion time that may increase coronary perfusion. However, reduction of heart rate and blood pressure and consequently decreased myocardial oxygen consumption appear to be the most important mechanisms for relief of angina and improved exercise tolerance. Beta blockers may also be valuable in treating silent or ambulatory ischemia. Because this condition causes no pain, it is usually detected by the appearance of typical electrocardiographic signs of ischemia. The total amount of "ischemic time" per day is reduced by long-term therapy with a βblocker. Beta-blocking agents decrease mortality of patients with recent myocardial infarction and improve survival and prevent stroke in patients with hypertension. Randomized trials in patients with stable angina have shown better outcome and symptomatic improvement with βblockers compared with calcium channel blockers.

Undesirable effects of β-blocking agents in angina include an increase in end-diastolic volume and an increase in ejection time. Increased myocardial oxygen requirements associated with increased diastolic volume partially offset the beneficial effects of β-blocking agents. These potentially deleterious effects of β-blocking agents can be balanced by the concomitant use of nitrates as described below.

The contraindications to the use of βblockers are asthma and other bronchospastic conditions, severe bradycardia, atrioventricular blockade, bradycardia-tachycardia syndrome, and severe unstable left ventricular failure. Potential complications include fatigue, impaired exercise tolerance, insomnia, unpleasant dreams, worsening of claudication, and erectile dysfunction.

NEWER ANTIANGINAL DRUGS

Because of the high incidence of angina, new drugs are actively sought for its treatment. Some of the drugs or drug groups currently under investigation are listed in Table 12–6.

Table 12–6. Drugs or Drug Groups under Investigation for Use in Angina.
Metabolic modulators, eg, ranolazine
Direct bradycardic agents, eg, ivabradine
Potassium channel activators, eg, nicorandil
Rho-kinase inhibitors, eg, fasudil
Sulfonylureas, eg, glibenclamide
Thiazolidinediones
Vasopeptidase inhibitors
Nitric oxide donors, eg, L-arginine
Capsaicin
Amiloride

The metabolic modulators (eg, ranolazine, trimetazidine) are known as pFOX inhibitors because they partially inhibit the fatty acid oxidation pathway in myocardium. Because metabolism shifts to oxidation of fatty acids in ischemic myocardium, the oxygen requirement per unit of ATP produced increases. Partial inhibition of the enzyme required for fatty acid oxidation (long chain 3-ketoacyl thiolase, LC-3KAT) appears to improve the metabolic status of ischemic tissue. However, blockade of a late sodium current that facilitates calcium entry may play a larger role in the action of ranolazine.

So-called bradycardic drugs, relatively selective I_f sodium channel blockers (eg, ivabradine), reduce cardiac rate by inhibiting the hyperpolarization-activated sodium channel in the sinoatrial node. No other significant hemodynamic effects have been reported. Ivabradine appears to reduce anginal attacks with an efficacy similar to that of calcium channel blockers and blockers.

CLINICAL PHARMACOLOGY OF DRUGS USED TO TREAT ANGINA

Because the most common cause of angina is atheroclerotic disease of the coronaries (CAD), therapy must address the underlying causes of CAD as well as the immediate symptoms of angina. In addition to reducing the need for antianginal therapy, such primary management has been shown to reduce major cardiac events such as myocardial infarction.

First-line therapy of CAD depends on modification of risk factors such as smoking, hypertension (Chapter 11), hyperlipidemia (Chapter 35), obesity, and clinical depression. In addition, antiplatelet drugs (Chapter 34) are very important.

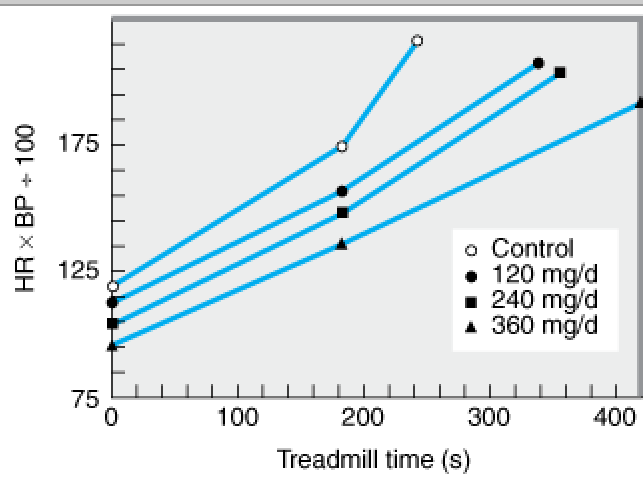
Specific pharmacologic therapy to prevent myocardial infarction and death consists of antiplatelet agents (aspirin, clopidogrel) and lipid-lowering agents, especially statins. Aggressive therapy with statins has been shown to reduce the incidence and severity of ischemia in patients during exercise testing and the incidence of cardiac events (including infarction and death) in clinical trials. Angiotensin-converting enzyme inhibitors also reduce the risk of adverse cardiac events in patients at high risk for CAD although they have not been consistently shown to exert antianginal effects. In patients with unstable angina and non-ST-segment elevation myocardial infarction, aggressive therapy consisting of coronary stenting, antilipid drugs, heparin, and antiplatelet agents is recommended.

The treatment of established angina and other manifestations of myocardial ischemia includes the corrective measures described above as well as treatment to prevent or relieve symptoms. Treatment of symptoms is based on reduction of myocardial oxygen demand and increase of coronary blood flow to the potentially ischemic myocardium to restore the balance between myocardial oxygen supply and demand.

Angina of Effort

Many studies have demonstrated that nitrates, calcium channel blockers, and β blockers increase time to onset of angina and ST depression during treadmill tests in patients with angina of effort (Figure 12–5). Although exercise tolerance increases, there is usually no change in the angina threshold, ie, the rate-pressure product at which symptoms occur.

Figure 12–5.



Effects of diltiazem on the double product (heart rate times systolic blood pressure) in a group of 20 patients with angina of effort. In a double-blind study using a standard protocol, patients were tested on a treadmill during treatment with placebo and three doses of the drug. Heart rate (HR) and systolic blood pressure (BP) were recorded at 180 seconds of exercise (midpoints of lines) and at the time of onset of anginal symptoms (rightmost points). Note that the drug treatment decreased the double product at all times during exercise and prolonged the time to appearance of symptoms. (Data from Lindenberg BS et al: Efficacy and safety of incremental doses of diltiazem for the treatment of angina. J Am Coll Cardiol 1983;2:1129. Used with permission of the American College of Cardiology.)

For maintenance therapy of chronic stable angina, long-acting nitrates, calcium channel-blocking agents, or β-blockers may be chosen; the best choice of drug will depend on the individual patient's response. In hypertensive patients, monotherapy with either slow-release or long-acting calcium channel blockers or β-blockers may be adequate. In normotensive patients, long-acting nitrates may be suitable. The combination of a β-blocker with a calcium channel blocker (eg, propranolol with nifedipine) or two different calcium channel blockers (eg, nifedipine and verapamil) has been shown to be more effective than individual drugs used alone. If response to a single drug is inadequate, a drug from a different class should be added to maximize the beneficial reduction of cardiac work while minimizing undesirable effects (Table 12–7). Some patients may require therapy with all three drug groups.

Table 12–7. Effects of Nitrates Alone and with β-Blockers or Calcium Channel Blockers in Angina Pectoris. (Undesirable Effects Are Shown in Italics.)

	Nitrates Alone	Beta Blockers or Calcium Channel Blockers	Combined Nitrates with Beta Blockers or Calcium Channel Blockers
Heart rate	*Reflex[1] increase*	Decrease	Decrease
Arterial pressure	Decrease	Decrease	Decrease
End-diastolic volume	Decrease	*Increase*	None or decrease
Contractility	*Reflex[1] increase*	Decrease	None
Ejection time	Decrease[1]	*Increase*	None

[1] Baroreceptor reflex.

Surgical revascularization (ie, coronary artery bypass grafting [CABG]) and catheter-based revascularization (ie, percutaneous coronary intervention [PCI]) are the primary methods for promptly restoring coronary blood flow and increasing oxygen supply to the myocardium.

Vasospastic Angina

Nitrates and the calcium channel blockers are effective drugs for relieving and preventing ischemic episodes in patients with variant angina. In approximately 70% of patients treated with nitrates plus calcium channel blockers, angina attacks are completely abolished; in another 20%, marked reduction of frequency of anginal episodes is observed. Prevention of coronary artery spasm (in the presence or absence of fixed atherosclerotic coronary artery lesions) is the principal mechanism for this beneficial response. All presently available calcium channel blockers appear to be equally effective, and the choice of a particular drug should depend on the patient, as indicated above. Surgical revascularization and angioplasty are not indicated in patients with variant angina.

Unstable Angina & Acute Coronary Syndromes

In patients with unstable angina with recurrent ischemic episodes at rest, recurrent platelet-rich nonocclusive thrombus formation is the principal mechanism. Aggressive antiplatelet therapy with a combination of aspirin and clopidigrel is indicated. Intravenous heparin or subcutaneous low-molecular-weight heparin is also indicated in most patients. If PCI with stenting is required, glycoprotein IIb/IIIa inhibitors such as abciximab should be added. In addition, therapy with nitroglycerin and β blockers should be considered; calcium channel blockers should be added in refractory cases for relief of myocardial ischemia. Primary lipid-lowering and ACE-inhibitor therapy should also be initiated.

PREPARATIONS AVAILABLE

NITRATES & NITRITES

Amyl nitrite (generic)

Inhalant: 0.3 mL capsules

Isosorbide dinitrate (generic, Isordil)

Oral: 5, 10, 20, 30, 40 mg tablets; 5, 10 mg chewable tablets

Oral sustained-release (Isochron, Dilatrate SR): 40 mg tablets and capsules

Sublingual: 2.5, 5 mg sublingual tablets

Isosorbide mononitrate (Ismo, others)

Oral: 10, 20 mg tablets; extended-release 30, 60, 120 mg tablets

Nitroglycerin

Sublingual or buccal: 0.3, 0.4, 0.6 mg tablets; 0.4 mg/metered dose aerosol spray

Oral sustained-release (generic, Nitro-Time): 2.5, 6.5, 9 mg capsules

Parenteral (generic): 5 mg/mL for IV administration; 100, 200, 400 mcg/mL in dextrose for IV infusion

Transdermal patches (generic, Nitrek, Nitro-Dur, Transderm-Nitro): to release at rates of 0.1, 0.2, 0.3, 0.4, 0.6, or 0.8 mg/h

Topical ointment (generic, Nitro-Bid): 20 mg/mL ointment (1 inch, or 25 mm, of ointment contains about 15 mg nitroglycerin)

CALCIUM CHANNEL BLOCKERS

Amlodipine (Norvasc, Amvaz)

Oral: 2.5, 5, 10 mg tablets

Diltiazem (Cardizem, generic)

Oral: 30, 60, 90, 120 mg tablets

Oral sustained-release (Cardizem SR, Dilacor XL, others): 60, 90, 120, 180, 240, 300, 360, 420 mg capsules, tablets

Parenteral: 5 mg/mL for injection

Felodipine (Plendil)

Oral extended-release: 2.5, 5, 10 mg tablets

Isradipine (DynaCirc)

Oral: 2.5, 5 mg capsules

Oral controlled-release: 5, 10 mg tablets

Nicardipine (Cardene, others)

Oral: 20, 30 mg capsules

Oral sustained-release (Cardene SR): 30, 45, 60 mg capsules)

Parenteral (Cardene I.V.): 2.5 mg/mL

Nifedipine (Adalat, Procardia, others)

Oral: 10, 20 mg capsules

Oral extended-release (Procardia XL, Adalat CC): 30, 60, 90 mg tablets

Nimodipine (Nimotop)

Oral: 30 mg capsules. (Labeled for use in subarachnoid hemorrhage, not angina.)

Nisoldipine (Sular)

Oral extended-release: 10, 20, 30, 40 mg tablets

Verapamil (generic, Calan, Isoptin)

Oral: 40, 80, 120 mg tablets

Oral sustained-release: 100, 120, 180, 240 mg tablets or capsules

Parenteral: 2.5 mg/mL for injection

BETA BLOCKERS

See Chapter 10.

METABOLISM MODIFIERS

Ranolazine (Ranexa)

Oral: 500 mg extended-release tablets

Top of Form

DRUGS USED IN HEART FAILURE: INTRODUCTION

Heart failure occurs when cardiac output is inadequate to provide the oxygen needed by the body. It is a highly lethal condition, with a 5-year mortality rate conventionally said to be about 50%. The most common cause of heart failure in the USA is coronary artery disease. Two major types of failure may be distinguished. In *systolic failure*, the mechanical pumping action (contractility) and the ejection fraction of the heart are reduced. In *diastolic failure* stiffening and loss of adequate relaxation plays a major role in reducing cardiac output and ejection fraction may be normal. Because other cardiovascular conditions are now being treated more effectively (especially myocardial infarction), more patients are surviving long enough for heart failure to develop, making this one of the cardiovascular conditions that is actually increasing in prevalence.

Although it is believed that the primary defect in early heart failure resides in the excitation-contraction coupling machinery of the heart, the clinical condition also involves many other processes and organs, including the baroreceptor reflex, the sympathetic nervous system, the kidneys, angiotensin II and other peptides, aldosterone, and apoptosis of cardiac cells. Recognition of these factors has resulted in evolution of a variety of treatment strategies (Table 13–1).

Table 13–1. Drug Groups Commonly Used in Heart Failure.

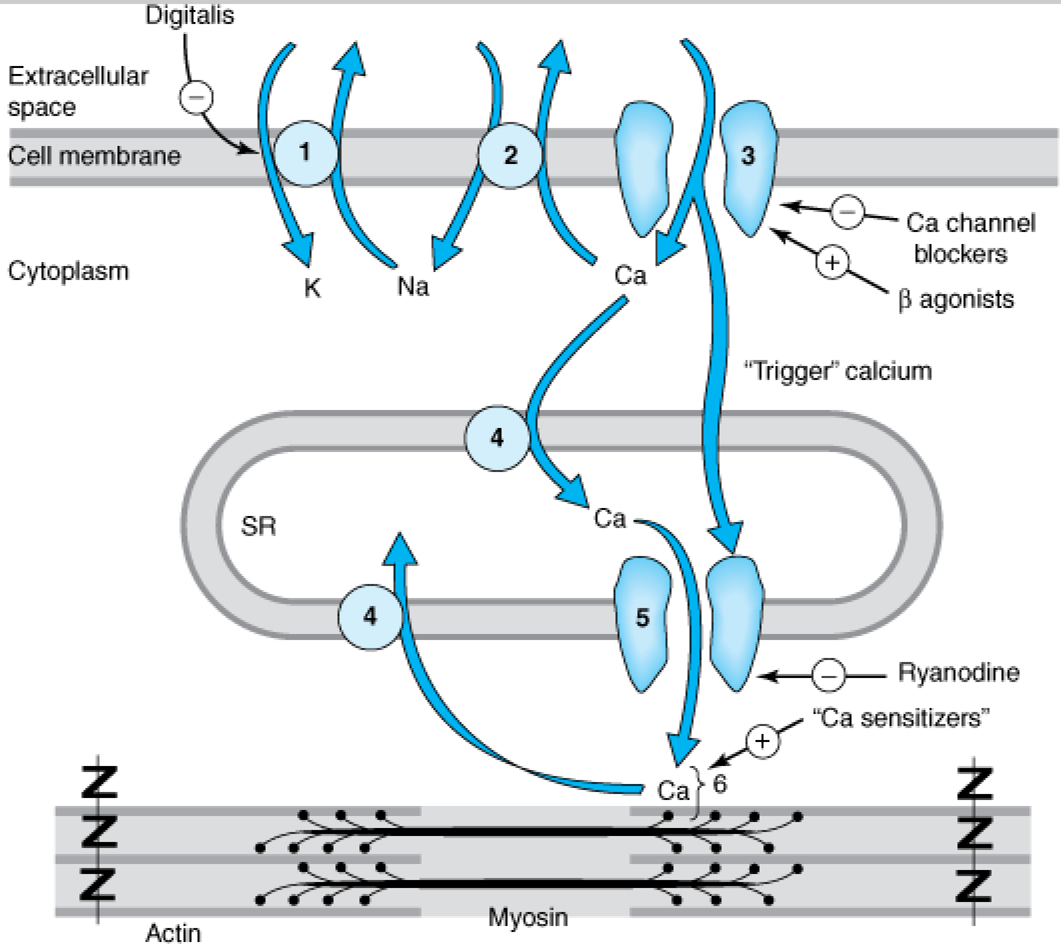
Diuretics
Aldosterone receptor antagonists
Angiotensin-converting enzyme inhibitors
Angiotensin receptor blockers
Beta blockers
Cardiac glycosides
Vasodilators
Beta agonists, dopamine
Bipyridines
Natriuretic peptide

Clinical research has shown that therapy directed at noncardiac targets is more valuable in the long-term treatment of heart failure than traditional positive inotropic agents (cardiac glycosides [digitalis]). Careful clinical trials have shown that angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, β-blockers, aldosterone receptor antagonists, and combined hydralazine-nitrate therapy are the only agents in current use that actually prolong life in patients with chronic heart failure. Positive inotropic drugs, on the other hand, can be very helpful in acute failure. They also reduce symptoms in chronic failure.

Control of Normal Cardiac Contractility

The vigor of contraction of heart muscle is determined by several processes that lead to the movement of actin and myosin filaments in the cardiac sarcomere (Figure 13–1). Ultimately, contraction results from the interaction of *activator* calcium (during systole) with the actin-troponin-tropomyosin system, thereby releasing the actin-myosin interaction. This calcium is released from the sarcoplasmic reticulum (SR). The amount released depends on the amount stored in the SR and on the amount of *trigger* calcium that enters the cell during the plateau of the action potential.

Figure 13–1.



Schematic diagram of a cardiac muscle sarcomere, with sites of action of several drugs that alter contractility (numbered structures). Site *1* is Na^+ /K^+ ATPase, the sodium pump. Site *2* (NaxC) is the sodium/calcium exchanger. Site *3* is the voltage-gated calcium channel. Site *4* (SERCA) is a calcium transporter that pumps calcium into the sarcoplasmic reticulum (SR). Site *5* (RyR) is a calcium channel in the membrane of the SR that is triggered to release stored calcium by activator calcium. Site *6* is the actin-troponin-tropomyosin complex at which activator calcium brings about the contractile interaction of actin and myosin.

SENSITIVITY OF THE CONTRACTILE PROTEINS TO CALCIUM

The determinants of calcium sensitivity, ie, the curve relating the shortening of cardiac myofibrils to the cytoplasmic calcium concentration, are incompletely understood, but several types of drugs can be shown to affect it in vitro. Levosimendan is the most recent example of a drug that increases calcium sensitivity (it may also inhibit phosphodiesterase) and reduces symptoms in models of heart failure.

THE AMOUNT OF CALCIUM RELEASED FROM THE SARCOPLASMIC RETICULUM

A small rise in free cytoplasmic calcium, brought about by calcium influx during the action potential, triggers the opening of ryanodine-sensitive calcium channels (RyR2) in the membrane of the cardiac SR and the rapid release of a large amount of the ion into the cytoplasm in the vicinity of the actin-troponin-tropomyosin complex. The amount released is proportional to the amount stored in the SR and the amount of trigger calcium that enters the cell through the cell membrane. (Ryanodine is a potent negative inotropic plant alkaloid that interferes with the release of calcium through cardiac SR channels.)

THE AMOUNT OF CALCIUM STORED IN THE SARCOPLASMIC RETICULUM

The SR membrane contains a very efficient calcium uptake transporter, known as the sarcoplasmic endoplasmic reticulum Ca^{2+} -ATPase (SERCA). This pump maintains free cytoplasmic calcium at very low levels during diastole by pumping calcium into the SR. The amount of calcium sequestered in the SR is thus determined, in part, by the amount accessible to this transporter. This in turn is dependent on the balance of calcium influx (primarily through the voltage-gated membrane calcium channels) and calcium efflux, the amount removed from the cell (primarily via the sodium-calcium exchanger, a transporter in the cell membrane).

THE AMOUNT OF TRIGGER CALCIUM

The amount of trigger calcium that enters the cell depends on the availability of membrane calcium channels (primarily the L type) and the duration of their opening. As described in Chapters 6 and 9, sympathomimetics cause an increase in calcium influx through an action on these channels. Conversely, the calcium channel blockers (see Chapter 12) reduce this influx and depress contractility.

ACTIVITY OF THE SODIUM-CALCIUM EXCHANGER

This antiporter uses the sodium gradient to move calcium against its concentration gradient from the cytoplasm to the extracellular space. Extracellular concentrations of these ions are much less labile than intracellular concentrations under physiologic conditions. The sodium-calcium exchanger's ability to carry out this transport is thus strongly dependent on the intracellular concentrations of both ions, especially sodium.

INTRACELLULAR SODIUM CONCENTRATION AND ACTIVITY OF NA^+ /K^+ ATPASE

Na^+ /K^+ ATPase, by removing intracellular sodium, is the major determinant of sodium concentration in the cell. The sodium influx through voltage-gated channels, which occurs as a normal part of almost all cardiac action potentials, is another determinant although the amount of sodium that enters with each action potential is much less than 1% of the total intracellular sodium. As described below, Na^+ /K^+ ATPase appears to be the primary target of cardiac glycosides.

Pathophysiology of Heart Failure

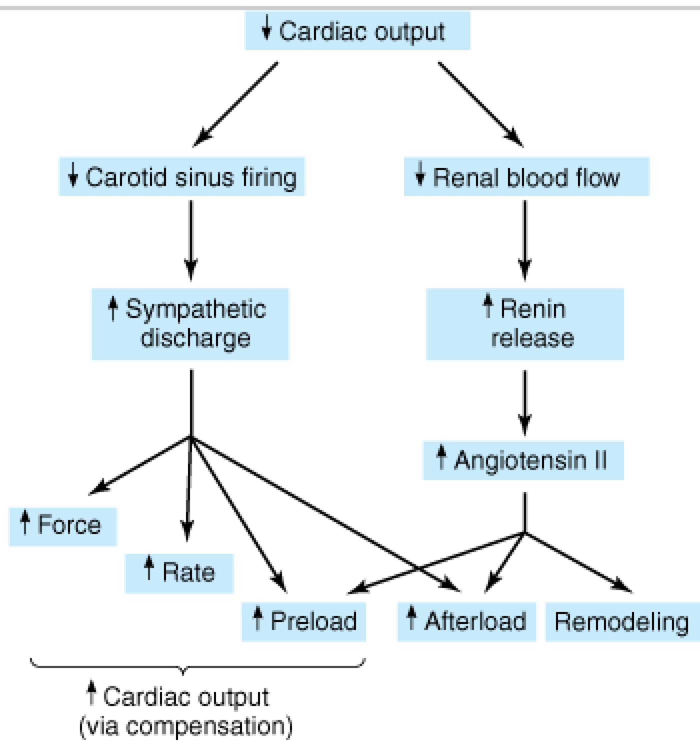
Heart failure is a syndrome with multiple causes that may involve the right ventricle, the left ventricle, or both. Cardiac output in heart failure is usually below the normal range. Systolic dysfunction, with reduced cardiac output and significantly reduced ejection fraction (< 45%), is typical of acute failure, especially that resulting from myocardial infarction. Diastolic dysfunction often occurs as a result of hypertrophy and stiffening of the myocardium, and although cardiac output is reduced, ejection fraction may be normal. Heart failure due to diastolic dysfunction does not usually respond optimally to positive inotropic drugs.

Rarely, "high-output" failure may occur. In this condition, the demands of the body are so great that even increased cardiac output is insufficient. High-output failure can result from hyperthyroidism, beriberi, anemia, and arteriovenous shunts. This form of failure responds poorly to the drugs discussed in this chapter and should be treated by correcting the underlying cause.

The primary signs and symptoms of all types of heart failure include tachycardia, decreased exercise tolerance, shortness of breath, peripheral and pulmonary edema, and cardiomegaly. Decreased exercise tolerance with rapid muscular fatigue is the major direct consequence of diminished cardiac output. The other manifestations result from the attempts by the body to compensate for the intrinsic cardiac defect.

Neurohumoral (extrinsic) compensation involves two major mechanisms previously presented in Figure 6–7: the sympathetic nervous system and the renin-angiotensin-aldosterone hormonal response. Some of the pathologic as well as beneficial features of these compensatory responses are illustrated in Figure 13–2. The baroreceptor reflex appears to be reset, with a lower sensitivity to arterial pressure, in patients with heart failure. As a result, baroreceptor sensory input to the vasomotor center is reduced even at normal pressures; sympathetic outflow is increased, and parasympathetic outflow is decreased. Increased sympathetic outflow causes tachycardia, increased cardiac contractility, and increased vascular tone.

Figure 13–2.



Some compensatory responses that occur during congestive heart failure. In addition to the effects shown, angiotensin II increases sympathetic effects by facilitating norepinephrine release.

While the increased preload, force, and heart rate initially increase cardiac output, increased arterial tone results in increased afterload and decreased ejection fraction, cardiac output, and renal perfusion. After a relatively short time, complex down-regulatory changes in the β_1 -adrenoceptor-G protein-effector system take place that result in diminished stimulatory effects. Beta$_2$ receptors are *not* down-regulated and may develop increased coupling to the IP_3 -DAG cascade. It has also been suggested that cardiac β_3 receptors (which do not appear to be down-regulated in failure) may mediate negative inotropic effects. Excessive beta activation can lead to leakage of calcium from the SR via RyR2 channels and contributes to stiffening of the ventricles and arrhythmias. Increased angiotensin II production leads to increased aldosterone secretion (with sodium and water retention), to increased afterload, and to remodeling of both heart and vessels (discussed below). Other hormones may also be released, including natriuretic peptide and endothelin (see Chapter 17).

The most important intrinsic compensatory mechanism is myocardial hypertrophy. This increase in muscle mass helps maintain cardiac performance. However, after an initial beneficial effect, hypertrophy can lead to ischemic changes, impairment of diastolic filling, and alterations in ventricular geometry. Remodeling is the term applied to dilation (other than that due to passive stretch) and other slow structural changes that occur in the stressed myocardium. It may include proliferation of connective tissue cells as well as abnormal myocardial cells with some biochemical characteristics of fetal myocytes. Ultimately, myocytes in the failing heart die at an accelerated rate through apoptosis, leaving the remaining myocytes subject to even greater stress.

The severity of heart failure is usually described according to a scale devised by the New York Heart Association. Class I failure is associated with no limitations on ordinary activities and symptoms that occur only with greater than ordinary exercise. Class II is characterized by slight limitation of ordinary activities, which result in fatigue and palpitations with ordinary physical activity. Class III failure results in no symptoms at rest, but fatigue, etc, with less than ordinary physical activity. Class IV is associated with symptoms even when the patient is at rest.

Pathophysiology of Cardiac Performance

Cardiac performance is a function of four primary factors:

(1) Preload: When some measure of left ventricular performance such as stroke volume or stroke work is plotted as a function of left ventricular filling pressure or end-diastolic fiber length, the resulting curve is termed the left ventricular function curve (Figure 13–3). The ascending limb (< 15 mm Hg filling pressure) represents the classic Frank-Starling relation. Beyond approximately 15 mm Hg, there is a plateau of performance. Preloads greater than 20–25 mm Hg result in pulmonary congestion. As noted above, preload is usually increased in heart failure because of increased blood volume and venous tone. Because the curve of the failing heart is lower, the plateau is reached at much lower values of stroke work or output. Increased fiber length or filling pressure increases oxygen demand in the myocardium. Reduction of high filling pressure is the goal of salt restriction and diuretic therapy in heart failure. Venodilator drugs (eg, nitroglycerin) also reduce preload by redistributing blood away from the chest into peripheral veins.

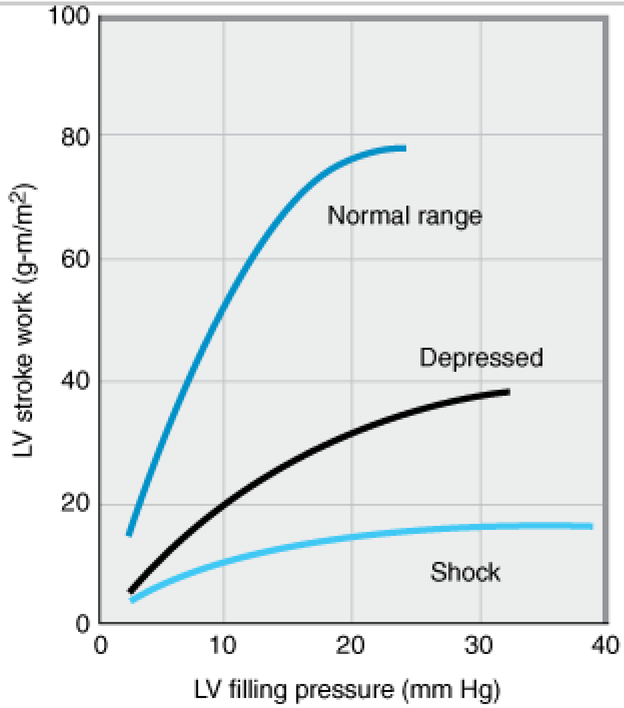
(2) Afterload: Afterload is the resistance against which the heart must pump blood and is represented by aortic impedance and systemic vascular resistance. As cardiac output falls in chronic failure, there is a reflex increase in systemic vascular resistance, mediated in part by increased sympathetic outflow and circulating catecholamines and in part by activation of the renin-angiotensin system. Endothelin, a potent

vasoconstrictor peptide, may also be involved. This sets the stage for the use of drugs that reduce arteriolar tone in heart failure.

(3) Contractility: Heart muscle obtained by biopsy from patients with chronic low-output failure demonstrates a reduction in intrinsic contractility. As contractility decreases in the patient, there is a reduction in the velocity of muscle shortening, the rate of intraventricular pressure development (dP/dt), and the stroke output achieved (Figure 13–3). However, the heart is still capable of some increase in all of these measures of contractility in response to inotropic drugs.

(4) Heart rate: The heart rate is a major determinant of cardiac output. As the intrinsic function of the heart decreases in failure and stroke volume diminishes, an increase in heart rate—through sympathetic activation of βadrenoceptors—is the first compensatory mechanism that comes into play to maintain cardiac output.

Figure 13–3.



Relation of left ventricular (LV) performance to filling pressure in patients with acute myocardial infarction, an important cause of heart failure. The upper line indicates the range for normal, healthy individuals. If acute heart failure occurs, function is shifted down and to the right. Similar depression is observed in patients with chronic heart failure. (Modified and reproduced with permission, from Swan HJC, Parmley WW: Congestive heart failure. In: Sodeman WA Jr, Sodeman TM [editors]. *Pathologic Physiology.* Saunders, 1979.)

BASIC PHARMACOLOGY OF DRUGS USED IN HEART FAILURE

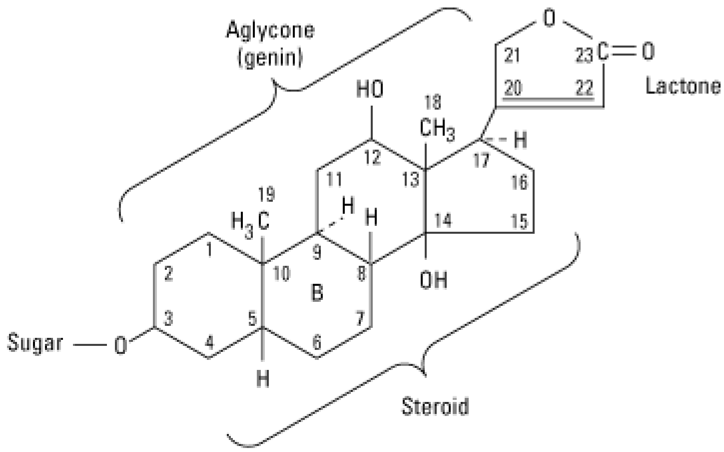
Although digitalis is not the first drug and never the only drug used in heart failure, we begin our discussion with this group because other drugs are discussed in more detail in other chapters. For a more detailed discussion of the cardiac glycosides the reader is referred to earlier editions of this book.

DIGITALIS

Digitalis is the genus name for the family of plants that provide most of the medically useful cardiac glycosides, eg, digoxin. Such plants have been known for thousands of years but were used erratically and with variable success until 1785, when William Withering, an English physician and botanist, published a monograph describing the clinical effects of an extract of the purple foxglove plant (*Digitalis purpurea* , a major source of these agents).

Chemistry

All of the cardiac glycosides, or cardenolides—of which digoxin is the prototype—combine a steroid nucleus linked to a lactone ring at the 17 position and a series of sugars at carbon 3 of the nucleus. Because they lack an easily ionizable group, their solubility is not pH-dependent. Digoxin is obtained from *Digitalis lanata* , the white foxglove, but many common plants contain cardiac glycosides.



Pharmacokinetics

ABSORPTION AND DISTRIBUTION

Digoxin, the only cardiac glycoside used in the USA, is 65–80% absorbed after oral administration. Absorption of other glycosides varies from zero to nearly 100%. Once present in the blood, all cardiac glycosides are widely distributed to tissues, including the central nervous system.

METABOLISM AND EXCRETION

Digoxin is not extensively metabolized in humans; almost two thirds is excreted unchanged by the kidneys. Its renal clearance is proportionate to creatinine clearance. Equations and nomograms are available for adjusting digoxin dosage in patients with renal impairment.

Pharmacodynamics

Digoxin has multiple direct and indirect cardiovascular effects, with both therapeutic and toxic consequences. In addition, it has undesirable effects on the central nervous system and gut.

At the molecular level, all therapeutically useful cardiac glycosides inhibit Na^+/K^+ ATPase, the membrane-bound transporter often called the *sodium pump.* Inhibition of this transporter over most of the dose range has been extensively documented in all tissues studied. It is probable that this inhibitory action is largely responsible for the therapeutic effect (positive inotropy) as well as a major portion of the toxicity of digitalis. Other molecular-level effects of digitalis have been studied in the heart and are discussed below. The fact that a receptor for cardiac glycosides exists on the sodium pump has prompted some investigators to propose that an endogenous "digitalis-like" steroid, possibly ouabain, must exist.

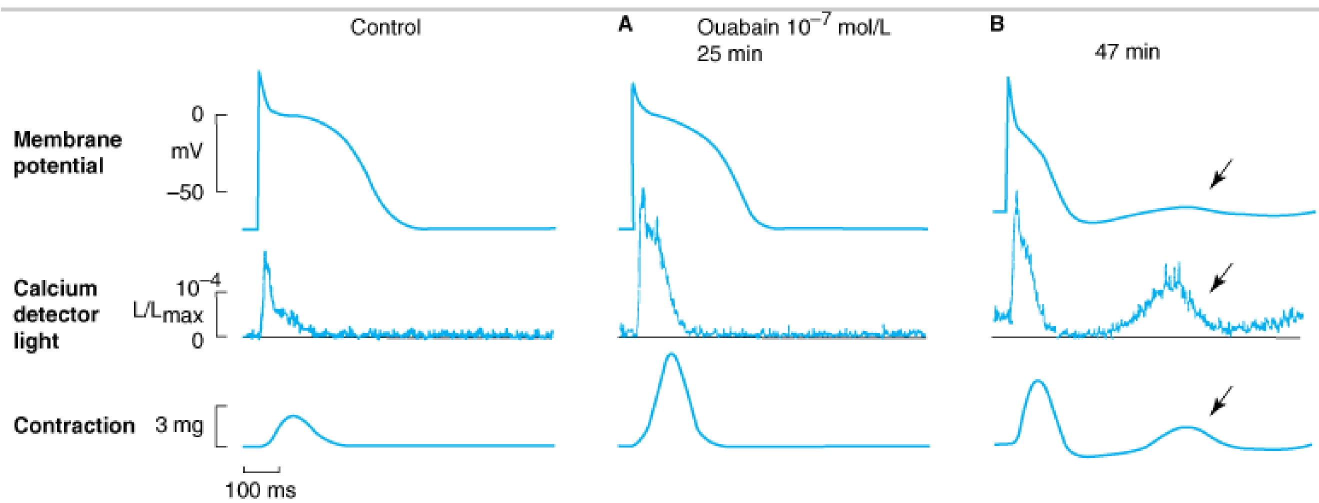
CARDIAC EFFECTS

Mechanical Effects

Cardiac glycosides increase contraction of the cardiac sarcomere (Figure 13–1) by increasing the free calcium concentration in the vicinity of the contractile proteins during systole. The increase in calcium concentration is the result of a two-step process: first, an increase of intracellular sodium concentration because of Na^+ /K^+ ATPase inhibition (*1* in Figure 13–1); and second, a relative reduction of calcium expulsion from the cell by the sodium-calcium exchanger (NaxC in Figure 13–1) caused by the increase in intracellular sodium. The increased cytoplasmic calcium is sequestered by the SERCA in the SR for later release. Other mechanisms have been proposed but are not well supported.

The net result of the action of therapeutic concentrations of a cardiac glycoside is a distinctive increase in cardiac contractility (Figure 13–4, bottom trace). In isolated myocardial preparations, the rate of development of tension and of relaxation are both increased, with little or no change in time to peak tension. This effect occurs in both normal and failing myocardium, but in the intact animal or patient the responses are modified by cardiovascular reflexes and the pathophysiology of heart failure.

Figure 13–4.



Effects of a cardiac glycoside, ouabain, on isolated cardiac tissue. The top tracing shows action potentials evoked during the control period, early in the "therapeutic" phase, and later, when toxicity is present. The middle tracing shows the light (L) emitted by the calcium-detecting protein aequorin (relative to the maximum possible, L_{max}) and is roughly proportionate to the free intracellular calcium concentration. The bottom tracing records the tension elicited by the action potentials. The early phase of ouabain action (A) shows a slight shortening of action potential and a marked increase in free intracellular calcium concentration and contractile tension. The toxic phase (B) is associated with depolarization of the resting potential, a marked shortening of the action potential, and the appearance of an oscillatory depolarization, calcium increment, and contraction (*arrows*). (Unpublished data kindly provided by P Hess and H Gil

Wier.)

Electrical Effects

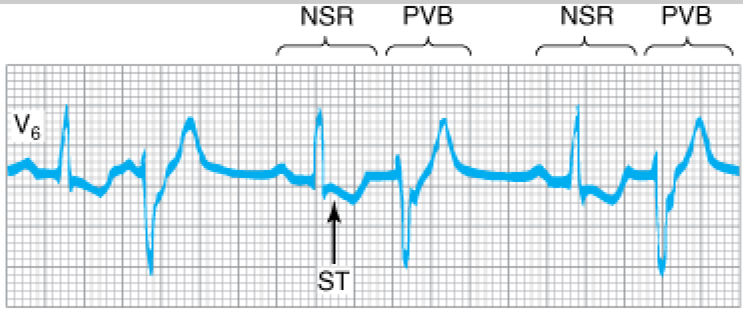
The effects of digitalis on the electrical properties of the heart are a mixture of direct and autonomic actions. Direct actions on the membranes of cardiac cells follow a well-defined progression: an early, brief prolongation of the action potential, followed by shortening (especially the plateau phase). The decrease in action potential duration is probably the result of increased potassium conductance that is caused by increased intracellular calcium (see Chapter 14). All of these effects can be observed at therapeutic concentrations in the absence of overt toxicity (Table 13–2).

Table 13–2. Effects of Digoxin on Electrical Properties of Cardiac Tissues.

Tissue or Variable	Effects at Therapeutic Dosage	Effects at Toxic Dosage
Sinus node	↓Rate	↓Rate
Atrial muscle	↓Refractory period	↓Refractory period, arrhythmias
Atrioventricular node	↓Conduction velocity, ↑refractory period	↑Refractory period, arrhythmias
Purkinje system, ventricular muscle	Slight ↓refractory period	Extrasystoles, tachycardia, fibrillation
Electrocardiogram	↑PR interval, ↓QT interval	Tachycardia, fibrillation, arrest at extremely high dosage

At higher concentrations, resting membrane potential is reduced (made less negative) as a result of inhibition of the sodium pump and reduced intracellular potassium. As toxicity progresses, oscillatory depolarizing afterpotentials appear following normally evoked action potentials (Figure 13–4, panel B). The afterpotentials (also known as *delayed afterdepolarizations, DADs*) are associated with overloading of the intracellular calcium stores and oscillations in the free intracellular calcium ion concentration. When afterpotentials reach threshold, they elicit action potentials (premature depolarizations or ectopic "beats") that are coupled to the preceding normal action potentials. If afterpotentials in the Purkinje conducting system regularly reach threshold in this way, bigeminy will be recorded on the electrocardiogram (Figure 13–5). With further intoxication, each afterpotential-evoked action potential will itself elicit a suprathreshold afterpotential, and a self-sustaining tachycardia will be established. If allowed to progress, such a tachycardia may deteriorate into fibrillation; in the case of ventricular fibrillation, the arrhythmia will be rapidly fatal unless corrected.

Figure 13–5.



Electrocardiographic record showing digitalis-induced bigeminy. The complexes marked NSR are normal sinus rhythm beats; an inverted T wave and depressed ST segment are present. The complexes marked PVB are premature ventricular beats and are the electrocardiographic manifestations of depolarizations evoked by delayed oscillatory afterpotentials as shown in Figure 13–4. (Modified and reproduced, with permission, from Goldman MJ: *Principles of Clinical Electrocardiography,* 12th ed. Lange, 1986.)

Autonomic actions of cardiac glycosides on the heart involve both the parasympathetic and the sympathetic systems. In the lower portion of the dose range, cardioselective parasympathomimetic effects predominate. In fact, these atropine-blockable effects account for a significant portion of the early electrical effects of digitalis (Table 13–2). This action involves sensitization of the baroreceptors, central vagal stimulation, and facilitation of muscarinic transmission at the cardiac muscle cell. Because cholinergic innervation is much richer in the atria, these actions affect atrial and atrioventricular nodal function more than Purkinje or ventricular function. Some of the cholinomimetic effects are useful in the treatment of certain arrhythmias. At toxic levels, sympathetic outflow is increased by digitalis. This effect is not essential for typical digitalis toxicity but sensitizes the myocardium and exaggerates all the toxic effects of the drug.

The most common cardiac manifestations of digitalis toxicity include atrioventricular junctional rhythm, premature ventricular depolarizations, bigeminal rhythm, and second-degree atrioventricular blockade. However, it is claimed that digitalis can cause virtually any arrhythmia.

EFFECTS ON OTHER ORGANS

Cardiac glycosides affect all excitable tissues, including smooth muscle and the central nervous system. The gastrointestinal tract is the most common site of digitalis toxicity outside the heart. The effects include anorexia, nausea, vomiting, and diarrhea. This toxicity may be partially caused by direct effects on the gastrointestinal tract but is also the result of central nervous system actions.

Central nervous system effects include vagal and chemoreceptor trigger zone stimulation. Less often, disorientation and hallucinations—especially in the elderly—and visual disturbances are noted. The latter effect may include aberrations of color perception. Gynecomastia is a rare effect reported in men taking digitalis.

INTERACTIONS WITH POTASSIUM, CALCIUM, AND MAGNESIUM

Potassium and digitalis interact in two ways. First, they inhibit each other's binding to Na^+ /K^+ ATPase; therefore, hyperkalemia reduces the enzyme-inhibiting actions of cardiac glycosides, whereas hypokalemia facilitates these actions. Second, abnormal cardiac automaticity is inhibited by hyperkalemia (see Chapter 14). Moderately increased extracellular K^+ therefore reduces the effects of digitalis, especially the toxic effects.

Calcium ion facilitates the toxic actions of cardiac glycosides by accelerating the overloading of intracellular calcium stores that appears to be responsible for digitalis-induced abnormal automaticity. Hypercalcemia therefore increases the risk of a digitalis-induced arrhythmia. The effects of magnesium ion appear to be opposite to those of calcium. These interactions mandate careful evaluation of serum electrolytes in patients with digitalis-induced arrhythmias.

Other Positive Inotropic Drugs Used in Heart Failure

Drugs that inhibit **phosphodiesterases**, the family of enzymes that inactivate cAMP and cGMP, have long been used in therapy of heart failure. Although they have positive inotropic effects, most of their benefits appear to derive from vasodilation, as discussed below. The bipyridines **inamrinone** and **milrinone** are the most successful of these agents found to date, but their usefulness is quite limited. Levosimendan, an investigational drug that sensitizes the troponin system to calcium, also appears to inhibit phosphodiesterase and cause some vasodilation in addition to its inotropic effects. Some early clinical trials suggest that this drug may be useful in patients with heart failure. A group of β-adrenoceptor stimulants has also been used as digitalis substitutes, but they may increase mortality (see below).

BIPYRIDINES

Inamrinone (previously called amrinone) and milrinone are bipyridine compounds that inhibit phosphodiesterase isozyme 3 (PDE-3). They are active orally as well as parenterally but are only available in parenteral forms. They have elimination half-lives of 3–6 hours, with 10–40% being excreted in the urine.

Pharmacodynamics

The bipyridines increase myocardial contractility by increasing inward calcium flux in the heart during the action potential; they may also alter the intracellular movements of calcium by influencing the sarcoplasmic reticulum. They also have an important vasodilating effect. Inhibition of phosphodiesterase results in an increase in cAMP and the increase in contractility and vasodilation.

The toxicity of inamrinone includes nausea and vomiting; arrhythmias, thrombocytopenia, and liver enzyme changes have also been reported in a significant number of patients. This drug has been withdrawn in some countries. Milrinone appears less likely to cause bone marrow and liver toxicity than inamrinone, but it does cause arrhythmias. Inamrinone and milrinone are now used only intravenously and only for acute heart failure or for severe exacerbation of chronic heart failure.

BETA-ADRENOCEPTOR STIMULANTS

The general pharmacology of these agents is discussed in Chapter 9. The selective β_1 agonist that has been most widely used in patients with heart failure is **dobutamine**. This parenteral drug produces an increase in cardiac output together with a decrease in ventricular filling pressure. Some tachycardia and an increase in myocardial oxygen consumption have been reported. Therefore, the potential for producing angina or arrhythmias in patients with coronary artery disease must be considered, as well as the tachyphylaxis that accompanies the use of any β-stimulant. Intermittent dobutamine infusion may benefit some patients with chronic heart failure.

Dopamine has also been used in acute heart failure and may be particularly helpful if there is a need to raise blood pressure.

Drugs Without Positive Inotropic Effects Used in Heart Failure

Paradoxically, these agents—not positive inotropic drugs—are the first-line therapies for chronic heart failure. The drugs most commonly used are diuretics, ACE inhibitors, angiotensin receptor antagonists, and β-blockers (see Table 13–1). In acute failure, diuretics and vasodilators play important roles.

DIURETICS

The diuretics are discussed in detail in Chapter 15. Their major mechanism of action in heart failure is to reduce venous pressure and ventricular preload. This results in reduction of edema and its symptoms, and reduction of cardiac size, which leads to improved pump efficiency. Spironolactone and eplerenone, the aldosterone antagonist diuretics (see Chapter 15), have the additional benefit of decreasing morbidity and mortality in patients with severe heart failure who are also receiving ACE inhibitors and other standard therapy. One possible mechanism for this benefit lies in accumulating evidence that aldosterone may also cause myocardial and vascular fibrosis and baroreceptor dysfunction in addition to its renal effects.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS, ANGIOTENSIN RECEPTOR BLOCKERS, & RELATED AGENTS

The ACE inhibitors such as captopril are introduced in Chapter 11 and discussed again in Chapter 17. These versatile drugs reduce peripheral resistance and thereby reduce afterload; they also reduce salt and water retention (by reducing aldosterone secretion) and in that way reduce preload. The reduction in tissue angiotensin levels also reduces sympathetic activity, probably through diminution of angiotensin's presynaptic effects on norepinephrine release. Finally, these drugs reduce the long-term remodeling of the heart and vessels, an effect that may be responsible for the observed reduction in mortality and morbidity (see Clinical Pharmacology).

Angiotensin AT_1 receptor-blockers such as losartan (see Chapters 11 and 17) appear to have similar but more limited beneficial effects. Angiotensin receptor blockers should be considered in patients intolerant of ACE inhibitors. In some trials, candesartan was beneficial when *added* to an ACE inhibitor.

VASODILATORS

The vasodilators are effective in acute heart failure because they provide a reduction in preload (through venodilation), or reduction in afterload (through arteriolar dilation), or both. Some evidence suggests that long-term use of hydralazine and isosorbide dinitrate can also reduce damaging remodeling of the heart.

A synthetic form of the endogenous peptide brain natriuretic peptide (BNP) is approved for use in acute cardiac failure as nesiritide. This recombinant product increases cGMP in smooth muscle cells and reduces venous and arteriolar tone in experimental preparations. It also causes diuresis. The peptide has a short half-life of about 18 minutes and is administered as a bolus intravenous dose followed by continuous infusion. Excessive hypotension is the most common adverse effect. Reports of significant renal damage and deaths have resulted in application of extra warnings regarding this agent and it should be used with great caution.

Measurement of *endogenous* BNP has been proposed as a diagnostic test because plasma concentrations rise in most patients with heart failure.

Bosentan, an orally active competitive inhibitor of endothelin (see Chapter 17), has been shown to have some benefits in experimental animal models of heart failure, but results in human trials have been disappointing. This drug is approved for use in pulmonary hypertension (see Chapter 11). It has significant teratogenic and hepatotoxic effects.

BETA-ADRENOCEPTOR BLOCKERS

Most patients with chronic heart failure respond favorably to certain β-blockers in spite of the fact that these drugs can precipitate acute decompensation of cardiac function (see Chapter 10). Studies with bisoprolol, carvedilol, and metoprolol showed a reduction in mortality in patients with stable severe heart failure but this effect was not observed with another β-blocker, bucindolol. A full understanding of the beneficial action of β-blockade is lacking, but suggested mechanisms include attenuation of the adverse effects of high concentrations of catecholamines (including apoptosis), up-regulation of β-receptors, decreased heart rate, and reduced remodeling through inhibition of the mitogenic activity of catecholamines.

CLINICAL PHARMACOLOGY OF DRUGS USED IN HEART FAILURE

In the past, prescription of a diuretic plus digitalis was almost automatic in every case of chronic heart failure, and other drugs were rarely considered. At present, diuretics are still considered as first-line therapy, but digitalis is reserved for patients who do not respond adequately to diuretics, ACE inhibitors, and β-blockers (see Table 13–1).

Management of Chronic Heart Failure

The major steps in the management of patients with chronic heart failure are outlined in Table 13–3. Reduction of cardiac workload is helpful in most cases. This can be accomplished by reducing activity and weight, and—especially important—control of hypertension.

Table 13–3. Steps in the Treatment of Chronic Heart Failure.

1. Reduce workload of the heart
   a. Limit activity, put on bed rest
   b. Reduce weight
   c. Control hypertension
2. Restrict sodium intake
3. Restrict water (rarely required)
4. Give diuretics
5. Give ACE inhibitor or angiotensin receptor blocker
6. Give digitalis if systolic dysfunction with 3rd heart sound or atrial fibrillation is present

7. Give β-blockers to patients with stable class II–IV heart failure

8. Give vasodilators

9. Cardiac resynchronization if wide QRS interval is present in normal sinus rhythm

SODIUM REMOVAL

Sodium removal is the next important step—by dietary salt restriction or a diuretic—especially if edema is present. In mild failure, it is reasonable to start with a thiazide diuretic, switching to agents such as furosemide as required. Sodium loss causes secondary loss of potassium, which is particularly hazardous if the patient is to be given digitalis. Hypokalemia can be treated with potassium supplementation or through the addition of an ACE inhibitor or a potassium-sparing diuretic such as spironolactone. As noted above, spironolactone or eplerenone should probably be considered in all patients with moderate or severe heart failure since they appear to reduce both morbidity and mortality. Serum potassium should be monitored in patients receiving any of these agents.

ACE INHIBITORS & ANGIOTENSIN RECEPTOR BLOCKERS

In patients with left ventricular dysfunction but no edema, an ACE inhibitor should be used first. Several large studies have compared ACE inhibitors with digoxin or with other traditional therapies for chronic heart failure. The results show clearly that ACE inhibitors are superior to both placebo and to vasodilators and must be considered, along with diuretics, as first-line therapy for chronic failure. However, ACE inhibitors cannot replace digoxin in patients already receiving that drug because patients withdrawn from the cardiac glycoside deteriorate while on ACE inhibitor therapy.

By reducing preload and afterload in asymptomatic patients, ACE inhibitors appear to slow the progress of ventricular dilation and thus delay the onset of clinical heart failure. Thus, ACE inhibitors are beneficial in all subsets of patients, from those who are asymptomatic to those in severe chronic failure. This benefit appears to be a class effect, ie, all ACE inhibitors appear to be effective.

The angiotensin II AT_1 receptor blockers (ARBs, eg, losartan, candesartan, etc) produce beneficial hemodynamic effects similar to those of the ACE inhibitors. However, large clinical trials suggest that the angiotensin receptor blockers should only be used in patients who are intolerant of ACE inhibitors (usually because of cough).

VASODILATORS

Vasodilator drugs can be divided into selective arteriolar dilators, venous dilators, and drugs with nonselective vasodilatory effects. For this purpose, the ACE inhibitors may be considered nonselective arteriolar and venous dilators. The choice of agent should be based on the patient's signs and symptoms and hemodynamic measurements. Thus, in patients with high filling pressures in whom the principal symptom is dyspnea, venous dilators such as long-acting nitrates will be most helpful in reducing filling pressures and the symptoms of pulmonary congestion. In patients in whom fatigue due to low left ventricular output is a primary symptom, an arteriolar dilator such as hydralazine may be helpful in increasing forward cardiac output. In most patients with severe chronic failure that responds poorly to other therapy, the problem usually involves both elevated filling pressures and reduced cardiac output. In these circumstances, dilation of both arterioles and veins is required. In a trial in African-American patients already receiving ACE inhibitors, addition of hydralazine and isosorbide dinitrate reduced mortality.

BETA BLOCKERS & CALCIUM CHANNEL BLOCKERS

Trials of β-blocker therapy in patients with heart failure are based on the hypothesis that excessive tachycardia and adverse effects of high catecholamine levels on the heart contribute to the downward course of heart failure patients. The results clearly indicate that such therapy is beneficial if initiated very cautiously at low doses, even though acutely blocking the supportive effects of catecholamines can worsen heart failure. Several months of therapy may be required before improvement is noted; this usually consists of a slight rise in ejection fraction, slower heart rate, and reduction in symptoms. As noted above, bisoprolol, carvedilol, and metoprolol have been shown to reduce mortality.

In contrast, the calcium-blocking drugs appear to have no role in the treatment of patients with heart failure. Their depressant effects on the heart may worsen heart failure.

DIGITALIS

Digoxin is indicated in patients with heart failure and atrial fibrillation. It is also most helpful in patients with a dilated heart and third heart sound. It is usually given only if diuretics and ACE inhibitors have failed to control symptoms. Only about 50% of patients with normal sinus rhythm (usually those with documented systolic dysfunction) will have documentable relief of heart failure from digitalis. Better results are obtained in patients with atrial fibrillation. If the decision is made to use a cardiac glycoside, digoxin is the one chosen in the great majority of cases (and the only one available in the USA). When symptoms are mild, slow loading (digitalization) with 0.125–0.25 mg per day is safer and just as effective as the rapid method (0.5–0.75 mg every 8 hours for 3 doses, followed by 0.125–0.25 mg per day).

Determining the optimal level of digitalis effect may be difficult. In patients with atrial fibrillation, reduction of ventricular rate is the best measure of glycoside effect. In patients in normal sinus rhythm, symptomatic improvement and reductions in heart size, heart rate during exercise, venous pressure, or edema may signify optimum drug levels in the myocardium. Unfortunately, toxic effects may occur before the therapeutic end point is detected. If digitalis is being loaded slowly, simple omission of one dose and halving the maintenance dose will often bring the patient to the narrow range between suboptimal and toxic concentrations. Measurement of plasma digoxin levels is useful in patients who appear unusually resistant or sensitive; a level of 1 ng/mL or less is appropriate.

Because it has a moderate but persistent positive inotropic effect, digitalis can, in theory, reverse all the signs and symptoms of heart failure. Although the drug has no net effect on mortality, it reduces hospitalization and deaths from progressive heart failure at the expense of an increase in sudden death. It is important to note that the mortality rate is reduced in patients with serum digoxin concentrations of less than 0.9 ng/mL but increased in those with digoxin levels greater than 1.5 ng/mL.

Other Clinical Uses of Digitalis

Digitalis is useful in the management of atrial arrhythmias because of its cardioselective parasympathomimetic effects. In atrial flutter and fibrillation, the depressant effect of the drug on atrioventricular conduction will help control an excessively high ventricular rate. Digitalis has also been used in the control of paroxysmal atrial and atrioventricular nodal tachycardia. At present, calcium channel blockers and adenosine are preferred for this application.

Digitalis should be avoided in the therapy of arrhythmias associated with Wolff-Parkinson-White syndrome because it increases the probability of conduction of arrhythmic atrial impulses through the alternative rapidly conducting atrioventricular pathway. It is explicitly contraindicated in patients with Wolff-Parkinson-White syndrome and atrial fibrillation (see Chapter 14).

Toxicity

In spite of its limited benefits and recognized hazards, digitalis is still heavily used and toxicity is common. Therapy of toxicity manifested as visual changes or gastrointestinal disturbances generally requires no more than reducing the dose of the drug. If cardiac arrhythmia is present and can definitely be ascribed to digitalis, more vigorous therapy may be necessary. Serum digitalis and potassium levels and the electrocardiogram should always be monitored during therapy of significant digitalis toxicity. Electrolyte status should be corrected if abnormal (see above).

In severe digitalis intoxication, serum potassium will already be elevated at the time of diagnosis (because of potassium loss from the intracellular compartment of skeletal muscle and other tissues). Furthermore, automaticity is usually depressed, and antiarrhythmic agents administered in this setting may lead to cardiac arrest. Such patients are best treated with prompt insertion of a temporary cardiac pacemaker catheter and administration of digitalis antibodies (digoxin immune fab). These antibodies recognize digitoxin and cardiac glycosides from many other plants in addition to digoxin. They are extremely useful in reversing severe intoxication with most glycosides.

Digitalis-induced arrhythmias are frequently made worse by cardioversion; this therapy should be reserved for ventricular fibrillation if the arrhythmia is glycoside-induced.

Cardiac Resynchronization Therapy

Patients with normal sinus rhythm and a wide QRS interval have some dyssynchronization of ventricular contraction. Poor synchronization of left ventricular contraction results in diminished cardiac output. Resynchronization, with left ventricular or biventricular pacing, has been shown to reduce mortality in patients with chronic heart failure who were already receiving optimal medical therapy.

MANAGEMENT OF ACUTE HEART FAILURE

Acute heart failure occurs frequently in patients with chronic failure. Such episodes are usually associated with increased exertion, emotion, salt in the diet, noncompliance with medical therapy, or increased metabolic demand occasioned by fever, anemia, etc. A particularly common and important cause of acute failure—with or without chronic failure—is acute myocardial infarction.

Patients with acute myocardial infarction are best treated with emergency revascularization using either coronary angioplasty and a stent or a thrombolytic agent. Even with revascularization, acute failure may develop in such patients. Many of the signs and symptoms of acute and chronic failure are identical, but their therapies diverge because of the need for more rapid response and the relatively greater frequency and severity of pulmonary vascular congestion in the acute form.

Measurements of arterial pressure, cardiac output, stroke work index, and pulmonary capillary wedge pressure are particularly useful in patients with acute myocardial infarction and acute heart failure. Such patients can be usefully characterized on the basis of three hemodynamic measurements: arterial pressure, left ventricular filling pressure, and cardiac index. One such classification and therapies that have proved most effective are set forth in Table 13–4. When filling pressure is greater than 15 mm Hg and stroke work index is less than 20 gm/m^2 , the mortality rate is high. Intermediate levels of these two variables imply a much better prognosis.

Table 13–4. Therapeutic Classification of Subsets in Acute Myocardial Infarction.

Subset	Systolic Arterial Pressure (mm Hg)	Left Ventricular Filling Pressure (mm Hg)	Cardiac Index (L/min/m^2)	Therapy
1. Hypovolemia	< 100	< 10	< 2.5	Volume replacement
2. Pulmonary congestion	100–150	> 20	> 2.5	Diuretics
3. Peripheral vasodilation	< 100	10–20	> 2.5	None or vasoactive drugs
4. Power failure	< 100	> 20	< 2.5	Vasodilators, inotropic drugs
5. Severe shock	< 90	> 20	< 2.0	Vasoactive drugs, inotropic drugs, circulatory assist devices

6. Right ventricular infarct

< 100

RVFP > 10

< 2.5

Volume replacement for LVFP, inotropic drugs. Avoid diuretics.

LVFP < 15

7. Mitral regurgitation, ventricular septal defect

< 100

> 20

< 2.5

Vasodilators, inotropic drugs, circulatory assist, surgery

The numeric values are intended to serve as general guidelines and not as absolute cutoff points. Arterial pressures apply to patients who were previously normotensive and should be adjusted upward for patients who were previously hypertensive. (RVFP and LVFP = right and left ventricular filling pressures.)

Among patients with acute decompensation, a small subset is found to have hyponatremia, presumably due to increased vasopressin activity. A new V_{1a} and V_2 receptor antagonist, conivaptan, has recently been approved for the parenteral treatment of euvolemic hyponatremia. Several clinical trials have indicated that this drug and related V_2 antagonists may have a beneficial effect in some patients with acute heart failure and hyponatremia.

PREPARATIONS AVAILABLE

DIURETICS

See Chapter 15.

DIGITALIS

Digoxin (generic, Lanoxicaps, Lanoxin)

Oral: 0.125, 0.25 mg tablets; 0.05, 0.1, 0.2 mg capsules*; 0.05 mg/mL elixir

Parenteral: 0.1, 0.25 mg/mL for injection

*Digoxin capsules (Lanoxicaps) have greater bioavailability than digoxin tablets.

DIGITALIS ANTIBODY

Digoxin immune fab (ovine) (digibind, digifab)

Parenteral: 38 or 40 mg per vial with 75 mg sorbitol lyophilized powder to reconstitute for IV injection. Each vial will bind approximately 0.5 mg digoxin or digitoxin.

SYMPATHOMIMETICS MOST COMMONLY USED IN CONGESTIVE HEART FAILURE

Dobutamine (generic, Dobutrex)

Parenteral: 12.5 mg/mL for IV infusion

Dopamine (generic, Intropin)

Parenteral: 40, 80, 160 mg/mL for IV injection; 80, 160, 320 mg/dL in 5% dextrose for IV infusion

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Benazepril (generic, Lotensin)

Oral: 5, 10, 20, 40 mg tablets

Captopril (generic, Capoten)

Oral: 12.5, 25, 50, 100 mg tablets

Enalapril (Vasotec, Vasotec I.V.)

Oral: 2.5, 5, 10, 20 mg tablets

Parenteral: 1.25 mg enalaprilat/mL

Fosinopril (generic, Monopril)

Oral: 10, 20, 40 mg tablets

Lisinopril (generic, Prinivil, Zestril)

Oral: 2.5, 5, 10, 20, 30, 40 mg tablets

Moexipril (generic, Univasc)

Oral: 7.5, 15 mg tablets

Perindopril (Aceon)

Oral: 2, 4, 8 mg tablets

Quinapril (Accupril)

Oral: 5, 10, 20, 40 mg tablets

Ramipril (Altace)

Oral: 1.25, 2.5, 5, 10 mg capsules

Trandolapril (Mavik)

Oral: 1, 2, 4 mg tablets

ANGIOTENSIN RECEPTOR BLOCKERS

Candesartan (Atacand)

Oral: 4, 8, 16, 32 mg tablets

Eprosartan (Teveten)

Oral: 400, 800 mg tablets

Irbesartan (Avapro)

Oral: 75, 150, 300 mg tablets

Losartan (Cozaar)

Oral: 25, 50, 100 mg tablets

Olmesartan (Benicar)

Oral: 5, 20, 40 mg tablets

Telmisartan (Micardis)

Oral: 20, 40, 80 mg tablets

Valsartan (Diovan)

Oral: 40, 80, 160, 320 mg tablets

BETA BLOCKERS THAT HAVE REDUCED MORTALITY IN HEART FAILURE

Bisoprolol (Zebeta, unlabeled use)

Oral: 5, 10 mg tablets

Carvedilol (Coreg)

Oral: 3.125, 6.25, 12.5, 25 mg tablets

Metoprolol (Lopressor, Toprol XL)

Oral: 50, 100 mg tablets; 25, 50, 100, 200 mg extended-release tablets

Parenteral: 1 mg/mL for IV injection

OTHER DRUGS

Inamrinone

Parenteral: 5 mg/mL for IV injection

Milrinone (generic, Primacor)

Parenteral: 1 mg/mL for IV injection; 200 mcg/mL premixed for IV infusion

Nesiritide (Natrecor)

Parenteral: 1.58 mg powder for IV injection

Bosentan (Tracleer)

Oral: 62.5, 125 mg tablets

AGENTS USED IN CARDIAC ARRHYTHMIAS: INTRODUCTION

Cardiac arrhythmias are a frequent problem in clinical practice, occurring in up to 25% of patients treated with digitalis, 50% of anesthetized patients, and over 80% of patients with acute myocardial infarction. Arrhythmias may require treatment because rhythms that are too rapid, too slow, or asynchronous can reduce cardiac output. Some arrhythmias can precipitate more serious or even lethal rhythm disturbances—eg, early premature ventricular depolarizations can precipitate ventricular fibrillation. In such patients, antiarrhythmic drugs may be lifesaving. On the other hand, the hazards of antiarrhythmic drugs—and in particular the fact that they can *precipitate* lethal arrhythmias in some patients—has led to a reevaluation of their relative risks and benefits. In general, treatment of asymptomatic or minimally symptomatic arrhythmias should be avoided for this reason.

Arrhythmias can be treated with the drugs discussed in this chapter and with nonpharmacologic therapies such as pacemakers, cardioversion, catheter ablation, and surgery. This chapter describes the pharmacology of drugs that suppress arrhythmias by a direct action on the cardiac cell membrane. Other modes of therapy are discussed briefly (see The Nonpharmacologic Therapy of Cardiac Arrhythmias).

THE NONPHARMACOLOGIC THERAPY OF CARDIAC ARRHYTHMIAS

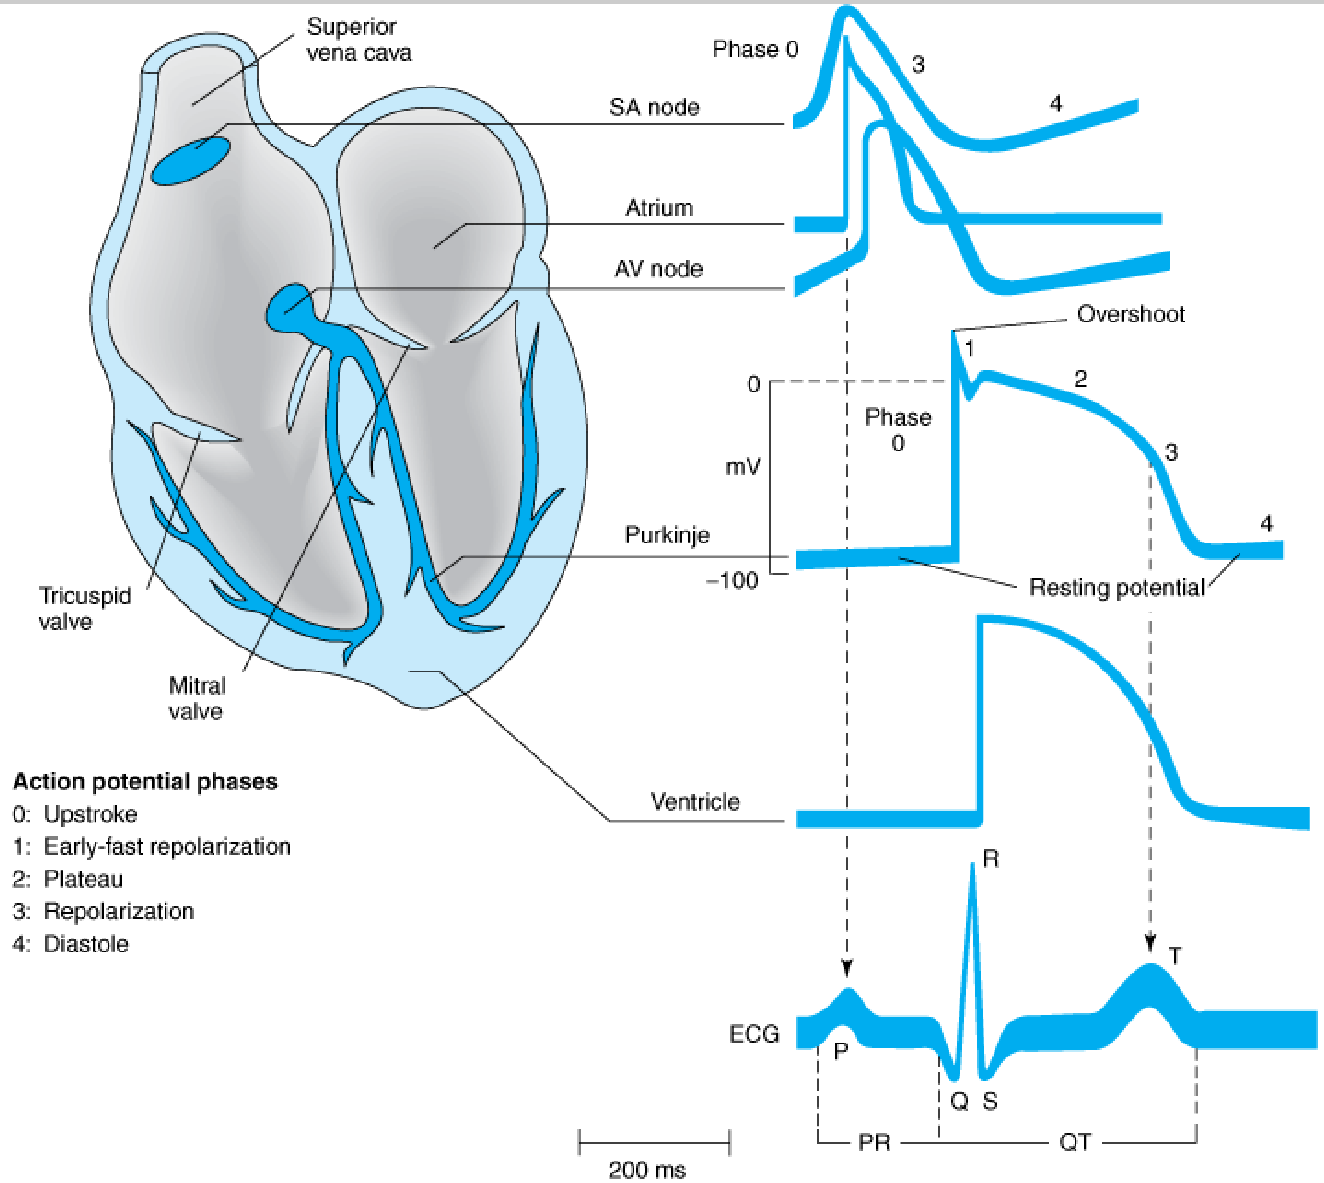
It was recognized over 100 years ago that reentry in simple in vitro models (eg, rings of conducting tissues) was permanently interrupted by transecting the reentry circuit. This concept is now applied in cardiac arrhythmias with defined anatomic pathways—eg, atrioventricular reentry using accessory pathways, atrioventricular node reentry, atrial flutter, and some forms of ventricular tachycardia—by treatment with radiofrequency catheter ablation. Recent studies have shown that paroxysmal and persistent atrial fibrillation may arise from one of the pulmonary veins. Both forms of atrial fibrillation can be cured by electrically isolating the pulmonary veins by radiofrequency catheter ablation or during concomitant cardiac surgery.

Another form of nonpharmacologic therapy is the implantable cardioverter-defibrillator (ICD), a device that can automatically detect and treat potentially fatal arrhythmias such as ventricular fibrillation. ICDs are now widely used in patients who have been resuscitated from such arrhythmias, and several trials have shown that ICD treatment reduces mortality in patients with coronary artery disease who have an ejection fraction ≤ 30% and in patients with class 2 or 3 heart failure and no prior history of arrhythmias. The increasing use of nonpharmacologic antiarrhythmic therapies reflects both advances in the relevant technologies and an increasing appreciation of the dangers of long-term therapy with currently available drugs.

ELECTROPHYSIOLOGY OF NORMAL CARDIAC RHYTHM

The electrical impulse that triggers a normal cardiac contraction originates at regular intervals in the sinoatrial node (Figure 14–1), usually at a frequency of 60–100 beats per minute. This impulse spreads rapidly through the atria and enters the atrioventricular node, which is normally the only conduction pathway between the atria and ventricles. Conduction through the atrioventricular node is slow, requiring about 0.15 s. (This delay provides time for atrial contraction to propel blood into the ventricles.) The impulse then propagates over the His-Purkinje system and invades all parts of the ventricles, beginning with the endocardial surface near the apex and ending with the epicardial surface at the base of the heart. Ventricular activation is complete in less than 0.1 s; therefore, contraction of all of the ventricular muscle is normally synchronous and hemodynamically effective.

Figure 14–1.



Schematic representation of the heart and normal cardiac electrical activity (intracellular recordings from areas indicated and ECG). Sinoatrial node, atrioventricular node, and Purkinje cells display pacemaker activity (phase 4 depolarization). The ECG is the body surface manifestation of the depolarization and repolarization waves of the heart. The P wave is generated by atrial depolarization, the QRS by ventricular muscle depolarization, and the T wave by ventricular repolarization. Thus, the PR interval is a measure of conduction time from atrium to ventricle, and the QRS duration indicates the time required for all of the ventricular cells to be activated (ie, the intraventricular conduction time). The QT interval reflects the duration of the ventricular action potential.

Arrhythmias consist of cardiac depolarizations that deviate from the above description in one or more aspects— ie, there is an abnormality in the site of origin of the impulse, its rate or regularity, or its conduction.

Ionic Basis of Membrane Electrical Activity

The transmembrane potential of cardiac cells is determined by the concentrations of several ions—chiefly sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and chloride (Cl^-)—on either side of the membrane and the permeability of the membrane to each ion. These water-soluble ions are unable to freely diffuse across the lipid cell membrane in response to their electrical and concentration gradients; they require aqueous channels (specific pore-forming proteins) for such diffusion. Thus, ions move across cell membranes in response to their gradients only at specific times during the cardiac cycle when these ion channels are open. The movements of the ions produce currents that form the basis of the cardiac action potential. Individual channels are relatively ion-specific, and the flux of ions through them is thought to be controlled by "gates" (probably flexible peptide chains or energy barriers). Each type of channel has its own type of gate (sodium, calcium, and some potassium channels are each thought to have two types of gates), and each type of gate is opened and closed by specific transmembrane voltage, ionic, or metabolic conditions.

At rest, most cells are not significantly permeable to sodium, but at the start of each action potential, they become quite permeable (see below). In electrophysiologic terms, the conductance of the fast sodium channel suddenly increases in response to a depolarizing stimulus. Similarly, calcium enters and potassium leaves the cell with each action potential. Therefore, in addition to ion channels, the cell must have mechanisms to maintain stable transmembrane ionic conditions by establishing and maintaining ion gradients. The most important of these active mechanisms is the sodium pump, Na^+/K^+ ATPase, described in Chapter 13. This pump and other active ion carriers contribute indirectly to the transmembrane potential by maintaining the gradients necessary for diffusion through channels. In addition, some pumps and exchangers produce net current flow (eg, by exchanging three Na^+ for two K^+ ions) and hence are termed "electrogenic."

When the cardiac cell membrane becomes permeable to a specific ion (ie when the channels selective for that ion are open), movement of that ion across the cell membrane is determined by Ohm's law: current = voltage ÷ resistance, or current = voltage x conductance. Conductance is determined by the properties of the individual ion channel protein. The voltage term is the difference between the actual membrane potential and the reversal potential for that ion (the membrane potential at which no current would flow even if channels were open). For example, in the case of sodium in a cardiac cell at rest, there is a substantial concentration gradient (140 mmol/L Na^+ outside; 10–15 mmol/L Na^+ inside) and an electrical gradient (0 mV outside; –90 mV inside) that would drive Na^+ into cells. Sodium does not enter the cell at rest because sodium channels are closed; when sodium channels open, the very large influx of Na^+ ions accounts for phase 0 depolarization. The situation for K^+ ions in the resting cardiac cell is quite different. Here, the concentration gradient (140 mmol/L inside; 4 mmol/L outside) would drive the ion out of the cell, but the electrical gradient would drive it in; that is, the inward gradient is in equilibrium with the outward gradient. In fact, certain potassium channels ("inward rectifier" channels) are open in the resting cell, but little current flows through them because of this balance. The equilibrium, or reversal potential, for ions is determined by the Nernst equation:

$$E_{ion} = 61 \times \log\left(\frac{C_e}{C_i}\right)$$

where C_e and C_i are the extracellular and intracellular concentrations, respectively, multiplied by their activity coefficients. Note that raising extracellular potassium makes E_K less negative. When this occurs, the membrane depolarizes until the new E_K is reached. Thus, extracellular potassium concentration and inward rectifier channel function are the major factors determining the membrane potential of the resting cardiac cell. The conditions required for application of the Nernst equation are approximated at the peak of the overshoot (using sodium concentrations) and during rest (using potassium concentrations) in most nonpacemaker cardiac cells. If the permeability is significant for both potassium and sodium, the Nernst equation is not a good predictor of membrane potential, but the Goldman-Hodgkin-Katz equation may be used:

$$E_{mem} = 61 \times \log\left(\frac{P_K \times K_e + P_{Na} \times Na_e}{P_K \times K_i + P_{Na} \times Na_i}\right)$$

In pacemaker cells (whether normal or ectopic), spontaneous depolarization (the pacemaker potential) occurs during diastole (phase 4, Figure 14–1). This depolarization results from a gradual increase of depolarizing current through special hyperpolarization-activated ion channels in pacemaker cells. The effect of changing extracellular potassium is more complex in a pacemaker cell than it is in a nonpacemaker cell because the effect on permeability to potassium is much more important in a pacemaker (see Effects of Potassium). In a pacemaker—especially an ectopic one—the end result of an increase in extracellular potassium will usually be to slow or stop the pacemaker. Conversely, hypokalemia will often facilitate ectopic pacemakers.

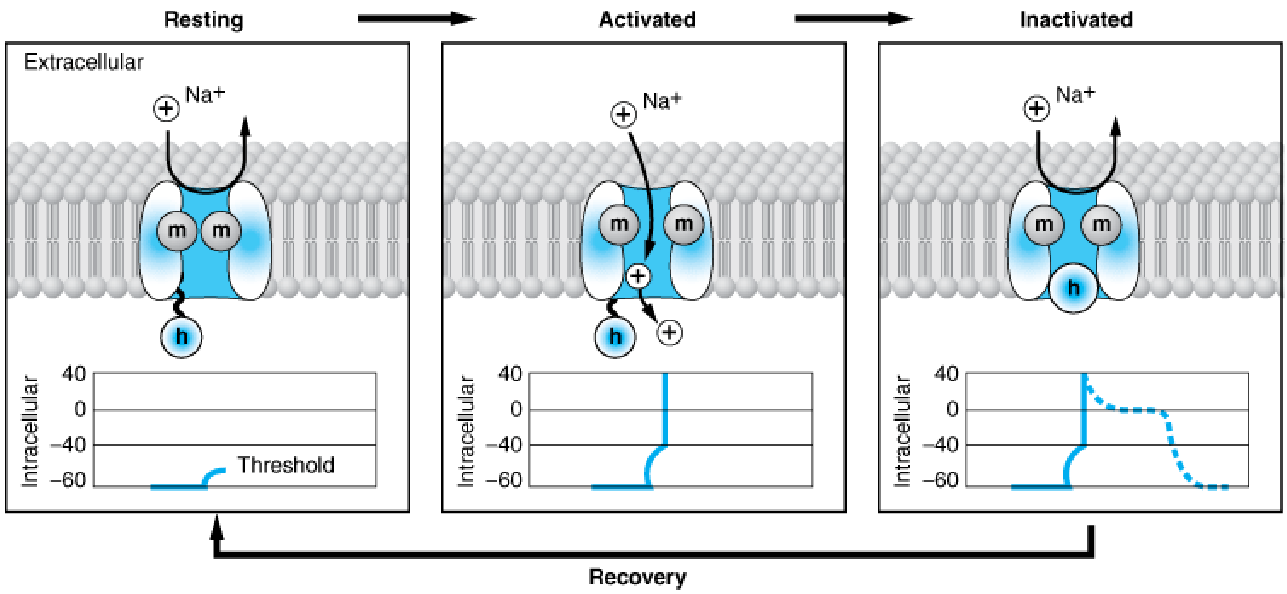
EFFECTS OF POTASSIUM

The effects of changes in serum potassium on cardiac action potential duration, pacemaker rate, and arrhythmias can appear somewhat paradoxical if changes are predicted based solely on a consideration of changes in the potassium *electrochemical gradient.* In the heart, however, changes in serum potassium concentration have the additional effect of altering potassium *conductance* (increased extracellular potassium increases potassium conductance) independent of simple changes in electrochemical driving force, and this effect often predominates. As a result, the actual observed effects of *hyperkalemia* include reduced action potential duration, slowed conduction, decreased pacemaker rate, and decreased pacemaker arrhythmogenesis. Conversely, the actual observed effects of *hypokalemia* include prolonged action potential duration, increased pacemaker rate, and increased pacemaker arrhythmogenesis. Furthermore, pacemaker rate and arrhythmias involving ectopic pacemaker cells appear to be more sensitive to changes in serum potassium concentration, compared with cells of the sinoatrial node. These effects of serum potassium on the heart probably contribute to the observed increased sensitivity to potassium channel-blocking antiarrhythmic agents (quinidine or sotalol) during hypokalemia, eg, accentuated action potential prolongation and tendency to cause torsade de pointes.

The Active Cell Membrane

In normal atrial, Purkinje, and ventricular cells, the action potential upstroke (phase 0) is dependent on sodium current. From a functional point of view, it is convenient to describe the behavior of the sodium current in terms of three channel states (Figure 14–2). The cardiac sodium channel protein has been cloned, and it is now recognized that these channel states actually represent different protein conformations. In addition, regions of the protein that confer specific behaviors, such as voltage sensing, pore formation, and inactivation, are now being identified. The gates described below and in Figure 14–2 represent such regions.

Figure 14–2.



A schematic representation of Na^+ channels cycling through different conformational states during the cardiac action potential. Transitions between resting, activated, and inactivated states are dependent on membrane potential and time. The activation gate is shown as *m* and the inactivation gate as *h.* Potentials typical for each state are shown under each channel schematic as a function of time. The dashed line indicates that part of the action potential during which most Na^+ channels are completely or partially inactivated and unavailable for reactivation.

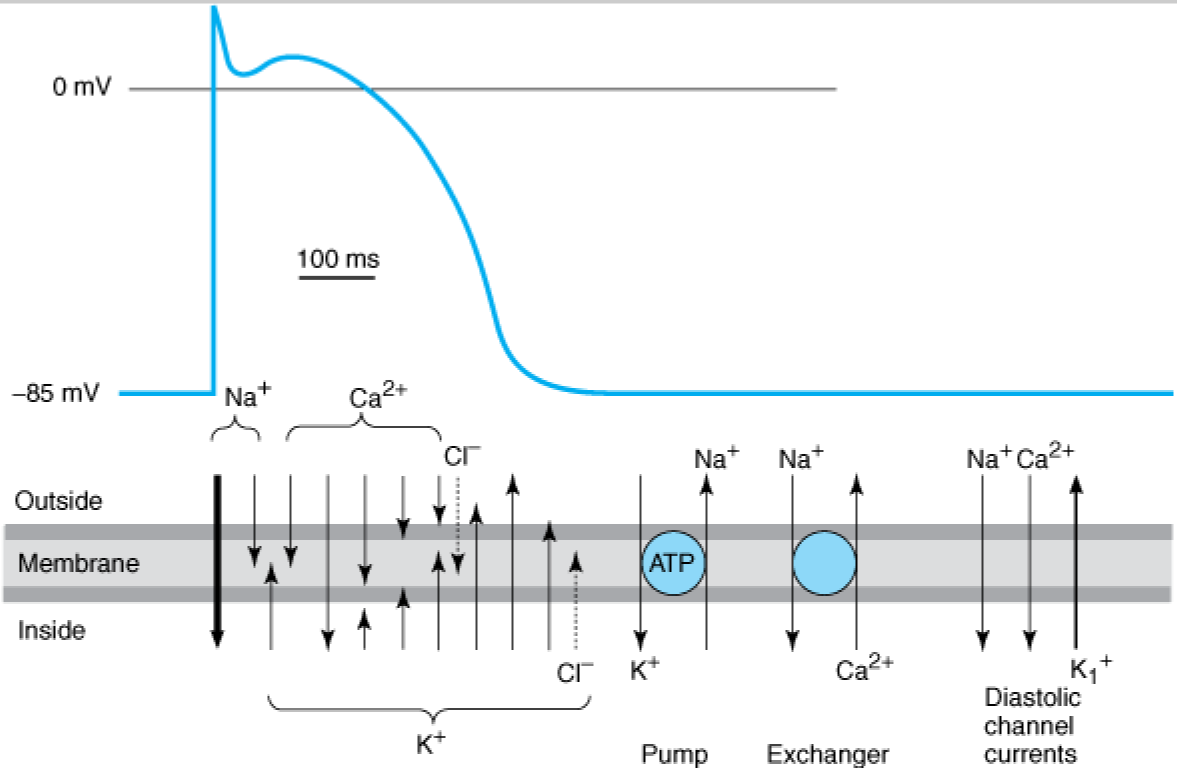
Depolarization to the threshold voltage results in opening of the activation *(m)* gates of sodium channels (Figure 14–2, middle). If the inactivation *(h)* gates of these channels have not already closed, the channels are now open or activated, and sodium permeability is markedly increased, greatly exceeding the permeability for any other ion. Extracellular sodium therefore diffuses down its electrochemical gradient into the cell, and the membrane potential very rapidly approaches the sodium equilibrium potential, E_{Na} (about +70 mV when Na_e = 140 mmol/L and Na_i = 10 mmol/L). This intense sodium current is very brief because opening of the *m* gates upon depolarization is promptly followed by closure of the *h* gates and inactivation of the sodium channels (Figure 14–2, right).

Most calcium channels become activated and inactivated in what appears to be the same way as sodium channels, but in the case of the most common type of cardiac calcium channel (the "L" type), the transitions occur more slowly and at more positive potentials. The action potential plateau (phases 1 and 2) reflects the turning off of most of the sodium current, the waxing and waning of calcium current, and the slow development of a repolarizing potassium current.

Final repolarization (phase 3) of the action potential results from completion of sodium and calcium channel inactivation and the growth of potassium permeability, so that the membrane potential once again approaches the potassium equilibrium potential. The major potassium currents involved in phase 3 repolarization include a rapidly activating potassium current (I_{Kr}) and a slowly activating potassium current (I_{Ks}). These two potassium currents are sometimes discussed together as "I_K ." These processes are diagrammed in Figure 14–3. It is noteworthy that a different potassium current, distinct from I_{Kr} and I_{Ks} , may control repolarization in sinoatrial nodal cells. This explains why some drugs that block either I_{Kr} or I_{Ks} may prolong repolarization in

Purkinje and ventricular cells, but have little effect on sinoatrial nodal repolarization (see Molecular & Genetic Basis of Cardiac Arrhythmias).

Figure 14–3.

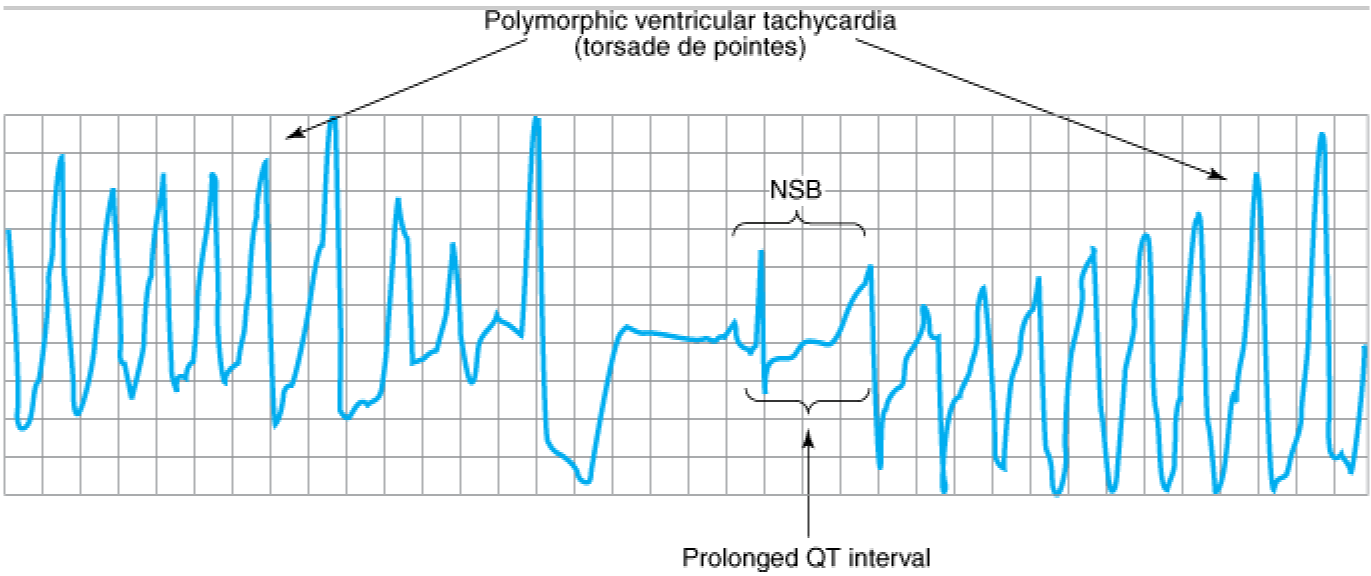


Schematic diagram of the ion permeability changes and transport processes that occur during an action potential and the diastolic period following it. The size and weight of the arrows indicate approximate magnitudes of the ion channel currents; arrows pointing down indicate inward (depolarizing) membrane currents, arrows pointing up indicate outward (repolarizing) membrane currents. Multiple subtypes of potassium and calcium currents, with different sensitivities to blocking drugs, have been identified. Chloride currents (dotted arrows) produce both inward and outward membrane currents during the cardiac action potential.

MOLECULAR & GENETIC BASIS OF CARDIAC ARRHYTHMIAS

It is now possible to define the molecular basis of several congenital and acquired cardiac arrhythmias. The best example is the polymorphic ventricular tachycardia known as torsade de pointes (shown in Figure 14–7), which is associated with prolongation of the QT interval (especially at the onset of the tachycardia), syncope, and sudden death. This must represent prolongation of the action potential of at least some ventricular cells (Figure 14–1). The effect can, in theory, be attributed either to increased inward current (gain of function) or decreased outward current (loss of function) during the plateau of the action potential. In fact, recent molecular genetic studies have identified up to 300 different mutations in at least eight ion channel genes that produce the congenital long QT (LQT) syndrome (Table 14–1), and each mutation may have different clinical implications. Loss of function mutations in potassium channel genes produce decreases in outward repolarizing current and are responsible for LQT subtypes 1, 2, 5, 6, and 7. *HERG* and *KCNE2* (*MiRP1*) genes encode subunits of the the rapid delayed rectifier potassium current (I_{Kr}), whereas *KCNQ1* and *KCNE1* (*minK*) encode subunits of the slow delayed rectifier potassium current (I_{Ks}). *KCNJ2* encodes an inwardly rectifying potassium current (I_{Kir}). In contrast, gain of function mutations in the sodium channel gene (*SCN5A*) or calcium channel gene (*CACNA1c*) cause increases in inward plateau current and are responsible for LQT subtypes 3 and 8, respectively.

Figure 14–7.



Electrocardiogram from a patient with the long QT syndrome during two episodes of torsade de pointes. The polymorphic ventricular tachycardia is seen at the start of this tracing and spontaneously halts at the middle of the panel. A single normal sinus beat (NSB) with an extremely prolonged QT interval follows, succeeded immediately by another episode of ventricular tachycardia of the torsade type. The usual symptoms would be dizziness or transient loss of consciousness.

[1] LF, loss of function; GF, gain of function.

[2] LQT, long QT syndrome.

[3] Ankyrins are intracellular proteins that associate with a variety of transport proteins including Na^+ channels, Na^+ /K^+ ATPase, Na^+ /Ca^{2+} exchange, Ca^{2+} release channels.

[4] Also known as Andersen syndrome.

[5] Also known as Timothy syndrome; multiple organ dysfunction, including autism.

[6] SQT, short QT syndrome.

[7] CPVT, catecholaminergic polymorphic ventricular tachycardia; mutations in intracellular ryanodine Ca^{2+} release channel or the Ca^{2+} buffer protein, calsequestrin, may result in enhanced sarcoplasmic reticulum Ca^{2+} leakage or enhanced Ca^{2+} release during adrenergic stimulation, causing triggered arrhythmogenesis.

[8] *HCN4* encodes a pacemaker current in sinoatrial nodal cells; mutations in sodium channel gene (*SCN5A*) cause conduction defects.

[9] PCCD, progressive cardiac conduction disorder.

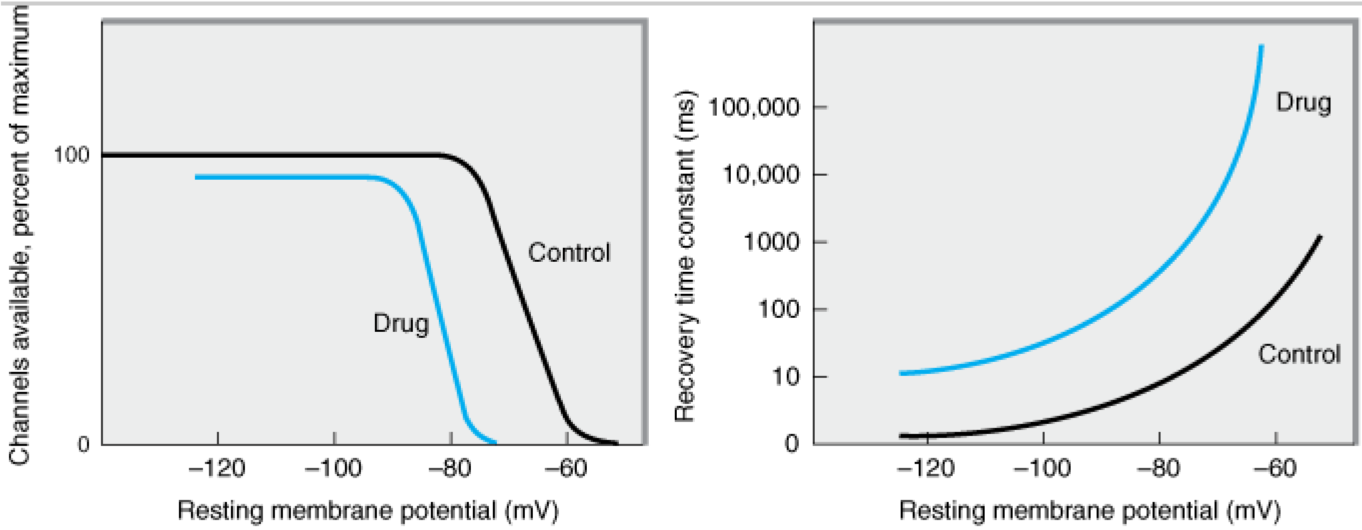
Molecular genetic studies have identified the reason why congenital and acquired cases of torsades de pointes can be so strikingly similar. The potassium channel I_{Kr} (encoded by *HERG*) is blocked or modified by many drugs (eg, quinidine, sotalol) or electrolyte abnormalities (hypokalemia, hypomagnesemia, hypocalcemia) that also produce torsades de pointes. Thus, the identification of the precise molecular mechanisms underlying various forms of the LQT syndromes now raises the possibility that specific therapies may be developed for individuals with defined molecular abnormalities. Indeed, preliminary reports suggest that the sodium channel blocker mexiletine can correct the clinical manifestations of congenital LQT subtype 3 syndrome. It is likely that torsade de pointes originates from triggered upstrokes arising from early afterdepolarizations (Figure 14–5). Thus, therapy is directed at correcting hypokalemia, eliminating triggered upstrokes (eg, by using β-blockers or magnesium), or shortening the action potential (eg, by increasing heart rate with isoproterenol or pacing)—or all of these.

The molecular basis of several other congenital cardiac arrhythmias associated with sudden death has also recently been identified. Three forms of short QT syndrome have been identified that are linked to gain of function mutations in three different potassium channel genes (*KCNH2, KCNQ1,* and *KCNJ2*). Catecholaminergic polymorphic ventricular tachycardia, a disease that is characterized by stress- or emotion-induced syncope, can be caused by genetic mutations in two different proteins in the sarcoplasmic reticulum that control intracellular calcium homeostasis. Mutations in two different ion channel genes (*HCN4* and *SCN5A*) have been linked to congenital forms of sick sinus syndrome. The Brugada syndrome, which is characterized by ventricular fibrillation associated with persistent ST-segment elevation, and progressive cardiac conduction disorder (PCCD), characterized by impaired conduction in the His-Purkinje system and right or left bundle block leading to complete atrioventricular block, have both been linked to several loss-of-function mutations in the sodium channel gene, *SCN5A* . At least one form of familial atrial fibrillation is caused by a gain-of-function mutation in the potassium channel gene, *KCNQ1* .

The Effect of Resting Potential on Action Potentials

A key factor in the pathophysiology of arrhythmias and the actions of antiarrhythmic drugs is the relationship between the resting potential of a cell and the action potentials that can be evoked in it (Figure 14–4, left panel). Because the inactivation gates of sodium channels in the resting membrane close over the potential range –75 to –55 mV, fewer sodium channels are "available" for diffusion of sodium ions when an action potential is evoked from a resting potential of –60 mV than when it is evoked from a resting potential of –80 mV. Important consequences of the reduction in peak sodium permeability include reduced maximum upstroke velocity (called $\dot{V}_{max}$, for maximum rate of change of membrane voltage), reduced action potential amplitude, reduced excitability, and reduced conduction velocity.

Figure 14–4.



Dependence of sodium channel function on the membrane potential preceding the stimulus. Left: The fraction of sodium channels available for opening in response to a stimulus is determined by the membrane potential immediately preceding the stimulus. The decrease in the fraction available when the resting potential is depolarized in the absence of a drug (control curve) results from the voltage-dependent closure of *h* gates in the channels. The curve labeled *Drug* illustrates the effect of a typical local anesthetic antiarrhythmic drug. Most sodium channels are inactivated during the plateau of the action potential. Right: The time constant for recovery from inactivation after repolarization also depends on the resting potential. In the absence of drug, recovery occurs in less than 10 ms at normal resting potentials (–85 to –95 mV). Depolarized cells recover more slowly (note logarithmic scale). In the presence of a sodium channel-blocking drug, the time constant of recovery is increased, but the increase is far greater at depolarized potentials than at more negative ones.

During the plateau of the action potential, most sodium channels are inactivated. Upon repolarization, recovery from inactivation takes place (in the terminology of Figure 14–2, the *h* gates reopen), making the channels again available for excitation. The time between phase 0 and sufficient recovery of sodium channels in phase 3 to permit a new propagated response to an external stimulus is the refractory period. Changes in refractoriness (determined by either altered recovery from inactivation or altered action potential duration) can be important in the genesis or suppression of certain arrhythmias. Another important effect of less negative resting potential is prolongation of this recovery time, as shown in Figure 14–4 (right panel). The prolongation of recovery time is reflected in an increase in the effective refractory period.

A brief, sudden, depolarizing stimulus, whether caused by a propagating action potential or by an external electrode arrangement, causes the opening of large numbers of activation gates before a significant number of inactivation gates can close. In contrast, slow reduction (depolarization) of the resting potential, whether brought about by hyperkalemia, sodium pump blockade, or ischemic cell damage, results in depressed sodium currents during the upstrokes of action potentials. Depolarization of the resting potential to levels positive to

–55 mV abolishes sodium currents, since all sodium channels are inactivated. However, such severely depolarized cells have been found to support special action potentials under circumstances that increase calcium permeability or decrease potassium permeability. These "slow responses"—slow upstroke velocity and slow conduction—depend on a calcium inward current and constitute the normal electrical activity in the sinoatrial and atrioventricular nodes, since these tissues have a normal resting potential in the range of –50 to –70 mV. Slow responses may also be important for certain arrhythmias. Modern techniques of molecular biology and electrophysiology can identify multiple subtypes of calcium and potassium channels. One way in which such subtypes may differ is in sensitivity to drug effects, so drugs targeting specific channel subtypes may be developed in the future.

MECHANISMS OF ARRHYTHMIAS

Many factors can precipitate or exacerbate arrhythmias: ischemia, hypoxia, acidosis or alkalosis, electrolyte abnormalities, excessive catecholamine exposure, autonomic influences, drug toxicity (eg, digitalis or antiarrhythmic drugs), overstretching of cardiac fibers, and the presence of scarred or otherwise diseased tissue. However, all arrhythmias result from (1) disturbances in impulse formation, (2) disturbances in impulse conduction, or (3) both.

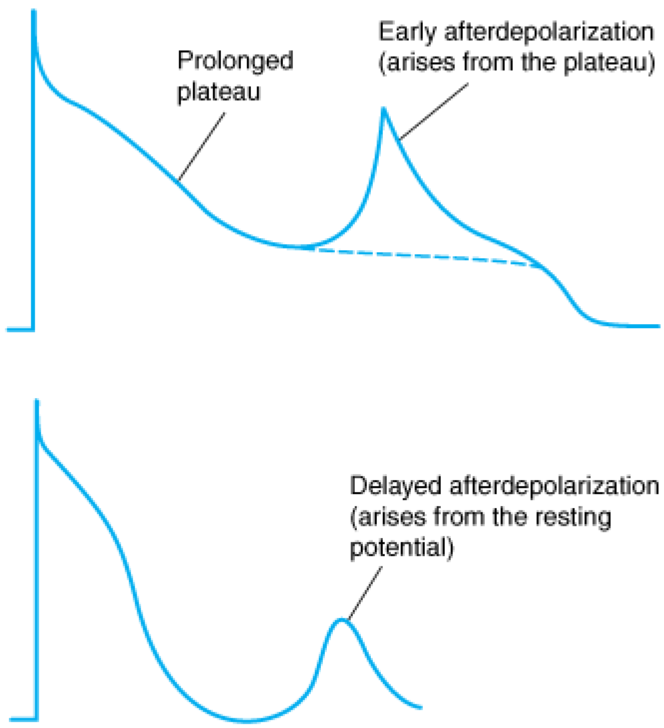
Disturbances of Impulse Formation

The interval between depolarizations of a pacemaker cell is the sum of the duration of the action potential and the duration of the diastolic interval. Shortening of either duration results in an increase in pacemaker rate. The more important of the two, diastolic interval, is determined primarily by the slope of phase 4 depolarization (pacemaker potential). Vagal discharge and β-receptor-blocking drugs slow normal pacemaker rate by reducing the phase 4 slope (acetylcholine also makes the maximum diastolic potential more negative). Acceleration of pacemaker discharge is often brought about by increased phase 4 depolarization slope, which can be caused by hypokalemia, β-adrenoceptor stimulation, positive chronotropic drugs, fiber stretch, acidosis, and partial depolarization by currents of injury.

Latent pacemakers (cells that show slow phase 4 depolarization even under normal conditions, eg, some Purkinje fibers) are particularly prone to acceleration by the above mechanisms. However, all cardiac cells, including normally quiescent atrial and ventricular cells, may show repetitive pacemaker activity when depolarized under appropriate conditions, especially if hypokalemia is also present.

Afterdepolarizations (Figure 14–5) are depolarizations that interrupt phase 3 (early afterdepolarizations, EADs) or phase 4 (delayed afterdepolarizations, DADs). EADs are usually exacerbated at slow heart rates and are thought to contribute to the development of long QT-related arrhythmias (see Molecular & Genetic Basis of Cardiac Arrhythmias). DADs on the other hand, discussed in Chapter 13, often occur when intracellular calcium is increased. They are exacerbated by fast heart rates and are thought to be responsible for some arrhythmias related to digitalis excess, to catecholamines, and to myocardial ischemia.

Figure 14–5.

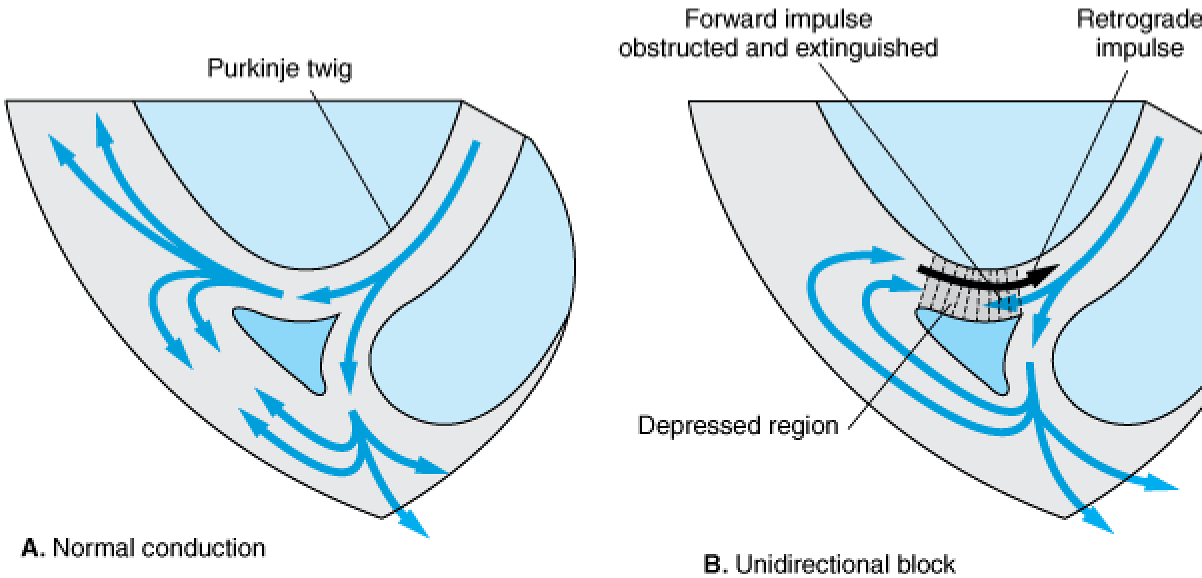


Two forms of abnormal activity, early (top) and delayed after depolarizations (bottom). In both cases, abnormal depolarizations arise during or after a normally evoked action potential. They are therefore often referred to as "triggered" automaticity; that is, they require a normal action potential for their initiation.

Disturbances of Impulse Conduction

Severely depressed conduction may result in simple block, eg, atrioventricular nodal block or bundle branch block. Because parasympathetic control of atrioventricular conduction is significant, partial atrioventricular block is sometimes relieved by atropine. Another common abnormality of conduction is reentry (also known as "circus movement"), in which one impulse reenters and excites areas of the heart more than once (Figure 14–6). The path of the reentering impulse may be confined to very small areas, eg, within or near the atrioventricular node, or it may involve large portions of the atrial or ventricular walls. Some forms of reentry are strictly anatomically determined; for example, in the Wolff-Parkinson-White syndrome, the reentry circuit consists of atrial tissue, the AV node, ventricular tissue, and an accessory atrioventricular connection (a "bypass tract"). In other cases (eg, atrial or ventricular fibrillation), multiple reentry circuits, determined by the properties of the cardiac tissue, may meander through the heart in apparently random paths. Furthermore, the circulating impulse often gives off "daughter impulses" that can spread to the rest of the heart. Depending on how many round trips through the pathway the impulse makes before dying out, the arrhythmia may be manifest as one or a few extra beats or as a sustained tachycardia.

Figure 14–6.



Schematic diagram of a reentry circuit that might occur in small bifurcating branches of the Purkinje system where they enter the ventricular wall. A: Normally, electrical excitation branches around the circuit, is transmitted to the ventricular branches, and becomes extinguished at the other end of the circuit due to collision of impulses. B: An area of unidirectional block develops in one of the branches, preventing anterograde impulse transmission at the site of block, but the retrograde impulse may be propagated through the site of block if the impulse finds excitable tissue; that is, the refractory period is shorter than the conduction time. This impulse will then reexcite tissue it had previously passed through, and a reentry arrhythmia will be established.

In order for reentry to occur, three conditions must coexist, as indicated in Figure 14–6: (1) There must be an obstacle (anatomic or physiologic) to homogeneous conduction, thus establishing a circuit around which the reentrant wavefront can propagate; (2) there must be unidirectional block at some point in the circuit, ie conduction must die out in one direction but continue in the opposite direction (as shown in Figure 14–6 , the impulse can gradually decrease as it invades progressively more depolarized tissue until it finally blocks—a process known as decremental conduction); and (3) conduction time around the circuit must be long enough so that the retrograde impulse does not enter refractory tissue as it travels around the obstacle, ie the conduction time must exceed the effective refractory period. Importantly, reentry depends on conduction that has been depressed by some critical amount, usually as a result of injury or ischemia. If conduction velocity is too slow, bidirectional block rather than unidirectional block occurs; if the reentering impulse is too weak, conduction may fail, or the impulse may arrive so late that it collides with the next regular impulse. On the other hand, if conduction is too rapid, ie almost normal, bidirectional conduction rather than unidirectional block will occur. Even in the presence of unidirectional block, if the impulse travels around the obstacle too rapidly, it will reach tissue that is still refractory.

Slowing of conduction may be due to depression of sodium current, depression of calcium current (the latter especially in the atrioventricular node), or both. Drugs that abolish reentry usually work by further slowing depressed conduction (by blocking the sodium or calcium current) and causing bidirectional block. In theory, accelerating conduction (by increasing sodium or calcium current) would also be effective, but only under unusual circumstances does this mechanism explain the action of any available drug.

Lengthening (or shortening) of the refractory period may also make reentry less likely. The longer the refractory period in tissue near the site of block, the greater the chance that the tissue will still be refractory when reentry is attempted. (Alternatively, the shorter the refractory period in the depressed region, the less likely it is that unidirectional block will occur.) Thus, increased dispersion of refractoriness is one contributor to reentry, and drugs may suppress arrhythmias by reducing such dispersion.

BASIC PHARMACOLOGY OF THE ANTIARRHYTHMIC AGENTS

Mechanisms of Action

Arrhythmias are caused by abnormal pacemaker activity or abnormal impulse propagation. Thus, the aim of therapy of the arrhythmias is to reduce ectopic pacemaker activity and modify conduction or refractoriness in reentry circuits to disable circus movement. The major mechanisms currently available for accomplishing these goals are (1) sodium channel blockade, (2) blockade of sympathetic autonomic effects in the heart, (3) prolongation of the effective refractory period, and (4) calcium channel blockade.

Antiarrhythmic drugs decrease the automaticity of ectopic pacemakers more than that of the sinoatrial node. They also reduce conduction and excitability and increase the refractory period to a greater extent in depolarized tissue than in normally polarized tissue. This is accomplished chiefly by selectively blocking the sodium or calcium channels of depolarized cells (Figure 14–8). Therapeutically useful channel-blocking drugs bind readily to activated channels (ie, during phase 0) or inactivated channels (ie, during phase 2) but bind poorly or not at all to rested channels. Therefore, these drugs block electrical activity when there is a fast tachycardia (many channel activations and inactivations per unit time) or when there is significant loss of resting potential (many inactivated channels during rest). This type of drug action is often described as *use-dependent* or *state-dependent*; that is, channels that are being used frequently, or in an inactivated state, are more susceptible to block. Channels in normal cells that become blocked by a drug during normal activation-inactivation cycles will rapidly lose the drug from the receptors during the resting portion of the cycle (Figure 14–8). Channels in myocardium that is chronically depolarized (ie, has a resting potential more positive than –75 mV) will recover from block very slowly if at all (see also right panel, Figure 14–4).

Figure 14–8.

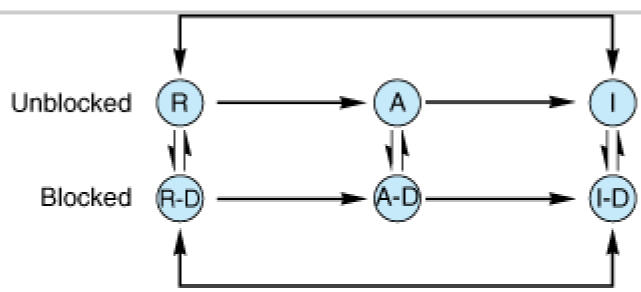


Diagram of a mechanism for the selective depressant action of antiarrhythmic drugs on sodium channels. The upper portion of the figure shows the population of channels moving through a cycle of activity during an action potential in the absence of drugs: R (rested) →A (activated) →I (inactivated). Recovery takes place via the I →R pathway. Antiarrhythmic drugs (D) that act by blocking sodium channels can bind to their receptors in the channels, as shown by the vertical arrows, to form drug-channel complexes, indicated as R-D, A-D, and I-D. Binding of the drugs to the receptor varies with the state of the channel. The data available for a variety of sodium channel blockers indicate that the binding of the drugs to the active and inactivated channel receptor is much greater than the binding to the rested channel. Furthermore, recovery from the I-D state to the R-D state is much slower than from I to R. As a result, rapid activity (more activations and inactivations) and depolarization of the resting potential (more channels in the I state) will favor blockade of the channels and selectively suppress arrhythmic cells.

In cells with abnormal automaticity, most of these drugs reduce the phase 4 slope by blocking either sodium or calcium channels, thereby reducing the ratio of sodium (or calcium) permeability to potassium permeability. As a result, the membrane potential during phase 4 stabilizes closer to the potassium equilibrium potential. In addition, some agents may increase the threshold (make it more positive). Beta-adrenoceptor–blocking drugs indirectly reduce the phase 4 slope by blocking the positive chronotropic action of norepinephrine in the heart.

In reentry arrhythmias, which depend on critically depressed conduction, most antiarrhythmic agents slow conduction further by one or both of two mechanisms: (1) steady-state reduction in the number of available unblocked channels, which reduces the excitatory currents to a level below that required for propagation (Figure 14–4, left); and (2) prolongation of recovery time of the channels still able to reach the rested and available state, which increases the effective refractory period (Figure 14–4, right). As a result, early extrasystoles are unable to propagate at all; later impulses propagate more slowly and are subject to bidirectional conduction block.

By these mechanisms, antiarrhythmic drugs can suppress ectopic automaticity and abnormal conduction occurring in depolarized cells—rendering them electrically silent—while minimally affecting the electrical activity in normally polarized parts of the heart. However, as dosage is increased, these agents also depress conduction in normal tissue, eventually resulting in *drug-induced* arrhythmias. Furthermore, a drug concentration that is therapeutic (antiarrhythmic) under the initial circumstances of treatment may become "proarrhythmic" (arrhythmogenic) during fast heart rates (more development of block), acidosis (slower recovery from block for most drugs), hyperkalemia, or ischemia.

SPECIFIC ANTIARRHYTHMIC AGENTS

The most widely used scheme for the classification of antiarrhythmic drug actions recognizes four classes:

1. Class 1 action is sodium channel blockade. Subclasses of this action reflect effects on the action potential duration (APD) and the kinetics of sodium channel blockade. Drugs with class 1A action prolong the APD and dissociate from the channel with intermediate kinetics; drugs with class 1B action shorten the APD in some tissues of the heart and dissociate from the channel with rapid kinetics; and drugs with class 1C action have minimal effects on the APD and dissociate from the channel with slow kinetics.

2. Class 2 action is sympatholytic. Drugs with this action reduce β-adrenergic activity in the heart.

3. Class 3 action is manifest by prolongation of the APD. Most drugs with this action block the rapid component of the delayed rectifier potassium current, I_{Kr} .

4. Class 4 action is blockade of the cardiac calcium current. This action slows conduction in regions where the action potential upstroke is calcium dependent, eg, the sinoatrial and atrioventricular nodes.

A given drug may have multiple classes of action as indicated by its membrane and electrocardiographic (ECG) effects (Tables 14–2 and 14–3). For example, amiodarone shares all four classes of action. Drugs are usually discussed according to the predominant class of action. Certain antiarrhythmic agents, eg, adenosine and magnesium, do not fit readily into this scheme and are described separately.

Table 14–2. Membrane Actions of Antiarrhythmic Drugs.

1 May suppress diseased sinus nodes.

2 Initial stimulation by release of endogenous norepinephrine followed by depression.

3 Anticholinergic effect and direct depressant action.

4 Especially in Wolff-Parkinson-White syndrome.

5 May be effective in atrial arrhythmias caused by digitalis.

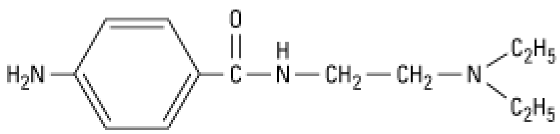
[6] Half-life of active metabolites much longer.

Sodium Channel-Blocking Drugs (Class 1)

PROCAINAMIDE (SUBGROUP 1A)

Cardiac Effects

By blocking sodium channels, procainamide slows the upstroke of the action potential, slows conduction, and prolongs the QRS duration of the ECG. The drug also prolongs the action potential duration by nonspecific blockade of potassium channels. The drug may be somewhat less effective than quinidine (see below) in suppressing abnormal ectopic pacemaker activity but more effective in blocking sodium channels in depolarized cells.



Procainamide

Procainamide has directly depressant actions on sinoatrial and atrioventricular nodes that are only slightly counterbalanced by drug-induced vagal block.

Extracardiac Effects

Procainamide has ganglion-blocking properties. This action reduces peripheral vascular resistance and can cause hypotension, particularly with intravenous use. However, in therapeutic concentrations, its peripheral vascular effects are less prominent than those of quinidine. Hypotension is usually associated with excessively rapid procainamide infusion or the presence of severe underlying left ventricular dysfunction.

Toxicity

CARDIAC

Procainamide's cardiotoxic effects include excessive action potential prolongation, QT interval prolongation, and induction of torsade de pointes arrhythmia and syncope. Excessive slowing of conduction can also occur. New arrhythmias can be precipitated.

EXTRACARDIAC

The most troublesome adverse effect of long-term procainamide therapy is a syndrome resembling lupus erythematosus and usually consisting of arthralgia and arthritis. In some patients, pleuritis, pericarditis, or parenchymal pulmonary disease also occurs. Renal lupus is rarely induced by procainamide. During long-term therapy, serologic abnormalities (eg, increased antinuclear antibody titer) occur in nearly all patients, and in the absence of symptoms these are not an indication to stop drug therapy. Approximately one third of patients receiving long-term procainamide therapy develop these reversible lupus-related symptoms.

Other adverse effects include nausea and diarrhea (about 10% of cases), rash, fever, hepatitis (< 5%), and agranulocytosis (approximately 0.2%).

Pharmacokinetics & Dosage

Procainamide can be administered safely by the intravenous and intramuscular routes and is well absorbed orally. A metabolite (*N* -acetylprocainamide, NAPA) has class 3 activity. Excessive accumulation of NAPA has been implicated in torsade de pointes during procainamide therapy, especially in patients with renal failure. Some individuals rapidly acetylate procainamide and develop high levels of NAPA. The lupus syndrome appears to be less common in these patients.

Procainamide is eliminated by hepatic metabolism to NAPA and by renal elimination. Its half-life is only 3–4 hours, which necessitates frequent dosing or use of a slow-release formulation (the usual practice). NAPA is eliminated by the kidneys. Thus, procainamide dosage must be reduced in patients with renal failure. The reduced volume of distribution and renal clearance associated with heart failure also require reduction in dosage. The half-life of NAPA is considerably longer than that of procainamide, and it therefore accumulates more slowly. Thus, it is important to measure plasma levels of both procainamide and NAPA, especially in patients with circulatory or renal impairment.

If a rapid procainamide effect is needed, an intravenous loading dose of up to 12 mg/kg can be given at a rate of 0.3 mg/kg/min or less rapidly. This dose is followed by a maintenance dosage of 2–5 mg/min, with careful monitoring of plasma levels. The risk of gastrointestinal or cardiac toxicity rises at plasma concentrations greater than 8 mcg/mL or NAPA concentrations greater than 20 mcg/mL.

In order to control ventricular arrhythmias, a total procainamide dosage of 2–5 g/d is usually required. In an occasional patient who accumulates high levels of NAPA, less frequent dosing may be possible. This is also possible in renal disease, where procainamide elimination is slowed.

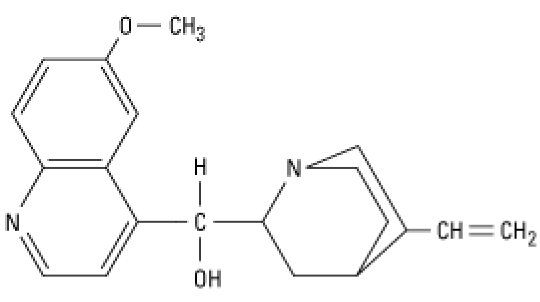
Therapeutic Use

Procainamide is effective against most atrial and ventricular arrhythmias. However, many clinicians attempt to avoid long-term therapy because of the requirement for frequent dosing and the common occurrence of lupus-related effects. Procainamide is the drug of second choice (after lidocaine) in most coronary care units for the treatment of sustained ventricular arrhythmias associated with acute myocardial infarction.

QUINIDINE (SUBGROUP 1A)

Cardiac Effects

Quinidine has actions similar to those of procainamide: it slows the upstroke of the action potential and conduction, and prolongs the QRS duration of the ECG, by blockade of sodium channels. The drug also prolongs the action potential duration by nonspecific blockade of potassium channels. It has more pronounced cardiac antimuscarinic effects than procainamide. Its toxic cardiac effects include excessive QT interval prolongation and induction of torsade de pointes arrhythmia. Toxic concentrations of quinidine also produce excessive sodium channel blockade with slowed conduction throughout the heart.



Quinidine

Extracardiac Effects

Gastrointestinal side effects of diarrhea, nausea, and vomiting are observed in one third to one half of patients. A syndrome of headache, dizziness, and tinnitus (cinchonism) is observed at toxic drug concentrations. Idiosyncratic or immunologic reactions, including thrombocytopenia, hepatitis, angioneurotic edema, and fever, are observed rarely.

Pharmacokinetics

Quinidine is absorbed readily following oral administration, bound to albumin and α_1 -acid glycoprotein, and eliminated primarily by hepatic metabolism. The elimination half-life is 6–8 hours. Quinidine is usually administered in a slow release formulation, eg, that of the gluconate salt.

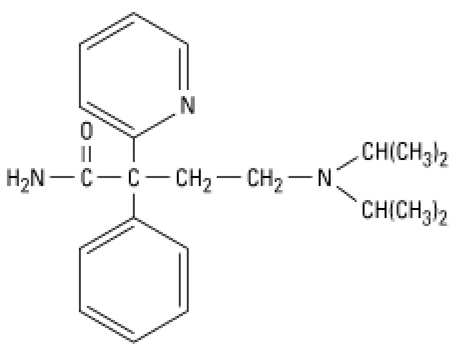
Therapeutic Use

Quinidine is used only occasionally to maintain normal sinus rhythm in patients with atrial flutter/fibrillation. Because of its cardiac and extracardiac side effects, its use is now largely restricted to patients with normal (but arrhythmic) hearts. In randomized, controlled clinical trials, quinidine-treated patients are twice as likely to remain in normal sinus rhythm compared with controls, but the risk of death is increased two- to threefold. Quinidine is used rarely in patients with ventricular tachycardia. Quinidine is the optical isomer of quinine and is sometimes used intravenously for the treatment of acute, severe malaria (see Chapter 53).

DISOPYRAMIDE (SUBGROUP 1A)

Cardiac Effects

The effects of disopyramide are very similar to those of procainamide and quinidine. Its cardiac antimuscarinic effects are even more marked than those of quinidine. Therefore, a drug that slows atrioventricular conduction should be administered with disopyramide when treating atrial flutter or fibrillation.



Disopyramide

Toxicity

CARDIAC

Toxic concentrations of disopyramide can precipitate all of the electrophysiologic disturbances described under quinidine. As a result of its negative inotropic effect, disopyramide may precipitate heart failure de novo or in patients with preexisting depression of left ventricular function. Because of this effect, disopyramide is not used as a first-line antiarrhythmic agent in the USA. It should not be used in patients with heart failure.

EXTRACARDIAC

Disopyramide's atropine-like activity accounts for most of its symptomatic adverse effects: urinary retention (most often, but not exclusively, in male patients with prostatic hyperplasia), dry mouth, blurred vision, constipation, and worsening of preexisting glaucoma. These effects may require discontinuation of the drug.

Pharmacokinetics & Dosage

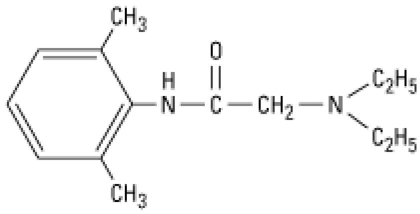
In the USA, disopyramide is only available for oral use. The usual oral dosage of disopyramide is 150 mg three times a day, but as much as 1 g/d has been used. In patients with renal impairment, dosage must be reduced. Because of the danger of precipitating heart failure, the use of loading doses is not recommended.

Therapeutic Use

Although disopyramide has been shown to be effective in a variety of supraventricular arrhythmias, in the USA it is approved only for the treatment of ventricular arrhythmias.

LIDOCAINE (SUBGROUP 1B)

Lidocaine has a low incidence of toxicity and a high degree of effectiveness in arrhythmias associated with acute myocardial infarction. It is used only by the intravenous route.

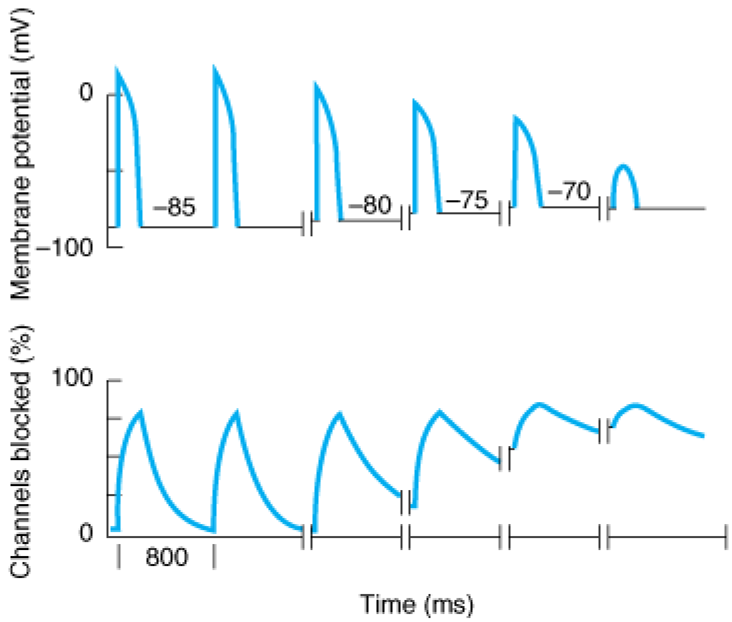


Lidocaine

Cardiac Effects

Lidocaine blocks activated and inactivated sodium channels with rapid kinetics (Figure 14–9); the inactivated state block ensures greater effects on cells with long action potentials such as Purkinje and ventricular cells, compared with atrial cells. The rapid kinetics at normal resting potentials result in recovery from block between action potentials and no effect on conduction. The increased inactivation and slower unbinding kinetics result in the selective depression of conduction in depolarized cells.

Figure 14–9.



Computer simulation of the effect of resting membrane potential on the blocking and unblocking of sodium channels by lidocaine. Upper tracing: Action potentials in a ventricular muscle cell. Lower tracing: Percentage of channels blocked by the drug. As the membrane depolarizes through -80, -75, and -70 mV, an 800 ms time segment is shown. Extra passage of time is indicated by breaks in the traces. Left side: At the normal resting potential of -85 mV, the drug combines with open (activated) and inactivated channels during each action potential, but block is rapidly reversed during diastole because the affinity of the drug for its receptor is so low when the channel recovers to the resting state at -85 mV. Middle: Metabolic injury has occurred, eg, ischemia due to coronary occlusion, that causes gradual depolarization over time. With subsequent action potentials arising from more depolarized potentials, the fraction of channels blocked increases because more channels remain in the inactivated state at less negative potentials (Figure 14–4, left), and the time constant for unblocking during diastole rapidly increases at less negative resting potentials (Figure 14–4, right). Right: Because of marked drug binding, conduction block and loss of excitability in this tissue result; that is, the "sick" (depolarized) tissue is selectively suppressed.

Toxicity

CARDIAC

Lidocaine is one of the least cardiotoxic of the currently used sodium channel blockers. Proarrhythmic effects, including sinoatrial node arrest, worsening of impaired conduction, and ventricular arrhythmias, are uncommon with lidocaine use. In large doses, especially in patients with preexisting heart failure, lidocaine may cause hypotension—partly by depressing myocardial contractility.

EXTRACARDIAC

Lidocaine's most common adverse effects—like those of other local anesthetics—are neurologic: paresthesias, tremor, nausea of central origin, lightheadedness, hearing disturbances, slurred speech, and convulsions. These occur most commonly in elderly or otherwise vulnerable patients or when a bolus of the drug is given too rapidly. The effects are dose-related and usually short-lived; seizures respond to intravenous diazepam. In general, if plasma levels above 9 mcg/mL are avoided, lidocaine is well tolerated.

Pharmacokinetics & Dosage

Because of its extensive first-pass hepatic metabolism, only 3% of orally administered lidocaine appears in the plasma. Thus, lidocaine must be given parenterally. Lidocaine has a half-life of 1–2 hours. In adults, a loading dose of 150–200 mg administered over about 15 minutes (as a single infusion or as a series of slow boluses) should be followed by a maintenance infusion of 2–4 mg/min to achieve a therapeutic plasma level of 2–6 mcg/mL. Determination of lidocaine plasma levels is of great value in adjusting the infusion rate. Occasional patients with myocardial infarction or other acute illness require (and tolerate) higher concentrations. This may be due to increased plasma α_1 -acid glycoprotein, an acute phase reactant protein that binds lidocaine, making less free drug available to exert its pharmacologic effects.

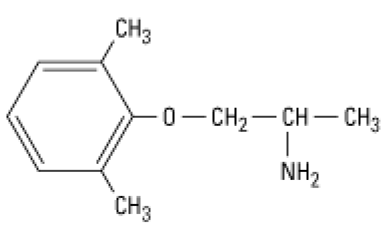
In patients with heart failure, lidocaine's volume of distribution and total body clearance may both be decreased. Thus, both loading and maintenance doses should be decreased. Since these effects counterbalance each other, the half-life may not be increased as much as predicted from clearance changes alone. In patients with liver disease, plasma clearance is markedly reduced and the volume of distribution is often increased; the elimination half-life in such cases may be increased threefold or more. In liver disease, the maintenance dose should be decreased, but usual loading doses can be given. Elimination half-life determines the time to steady state. Thus, while steady-state concentrations may be achieved in 8–10 hours in normal patients and patients with heart failure, 24–36 hours may be required in those with liver disease. Drugs that decrease liver blood flow (eg, propranolol, cimetidine) reduce lidocaine clearance and so increase the risk of toxicity unless infusion rates are decreased. With infusions lasting more than 24 hours, clearance falls and plasma concentrations rise. Renal disease has no major effect on lidocaine disposition.

Therapeutic Use

Lidocaine is the agent of choice for termination of ventricular tachycardia and prevention of ventricular fibrillation after cardioversion in the setting of acute ischemia. However, routine *prophylactic* use of lidocaine in this setting may actually increase total mortality, possibly by increasing the incidence of asystole, and is not the standard of care. Most physicians administer IV lidocaine only to patients with arrhythmias.

MEXILETINE (SUBGROUP 1B)

Mexiletine is an orally active congener of lidocaine. Its electrophysiologic and antiarrhythmic actions are similar to those of lidocaine. (The anticonvulsant phenytoin [see Chapter 24] also exerts similar electrophysiologic effects and has been used as an antiarrhythmic.) Mexiletine is used in the treatment of ventricular arrhythmias. The elimination half-life is 8–20 hours and permits administration two or three times a day. The usual daily dosage of mexiletine is 600–1200 mg/d. Dose-related adverse effects are seen frequently at therapeutic dosage. These are predominantly neurologic, including tremor, blurred vision, and lethargy. Nausea is also a common effect.

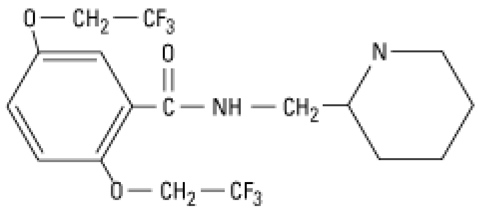


Mexiletine

Mexiletine has also shown significant efficacy in relieving chronic pain, especially pain due to diabetic neuropathy and nerve injury. The usual dosage is 450–750 mg/d orally. This application is unlabeled.

FLECAINIDE (SUBGROUP 1C)

Flecainide is a potent blocker of sodium and potassium channels with slow unblocking kinetics. (Note that although it does block certain potassium channels, it does not prolong the action potential or the QT interval.) It is currently used for patients with otherwise normal hearts who have supraventricular arrhythmias. It has no antimuscarinic effects.



Flecainide

Flecainide is very effective in suppressing premature ventricular contractions. However, it may cause severe exacerbation of arrhythmia even when normal doses are administered to patients with preexisting ventricular tachyarrhythmias and those with a previous myocardial infarction and ventricular ectopy. This was dramatically demonstrated in the Cardiac Arrhythmia Suppression Trial (CAST), which was terminated prematurely because of a two and one-half-fold increase in mortality in the patients receiving flecainide and similar Group 1c drugs. Flecainide is well absorbed and has a half-life of approximately 20 hours. Elimination is both by hepatic metabolism and by the kidney. The usual dosage of flecainide is 100–200 mg twice a day.

PROPAFENONE (SUBGROUP 1C)

Propafenone has some structural similarities to propranolol and possesses weak β-blocking activity. Its spectrum of action is very similar to that of quinidine. Its sodium channel blocking kinetics are similar to that of flecainide. Propafenone is metabolized in the liver, with an average half-life of 5–7 hours. The usual daily dosage of propafenone is 450–900 mg in three doses. The drug is used primarily for supraventricular arrhythmias. The most common adverse effects are a metallic taste and constipation; arrhythmia exacerbation can occur.

MORICIZINE (SUBGROUP 1C)

Moricizine is an antiarrhythmic phenothiazine derivative that is used for treatment of ventricular arrhythmias. It is a relatively potent sodium channel blocker that does not prolong action potential duration.

Moricizine has multiple metabolites, some of which are probably active and have long half-lives. Its most common adverse effects are dizziness and nausea. Like other potent sodium channel blockers, it can exacerbate arrhythmias. The usual dosage of moricizine is 200–300 mg by mouth three times a day.

Beta-Adrenoceptor–Blocking Drugs (Class 2)

Cardiac Effects

Propranolol and similar drugs have antiarrhythmic properties by virtue of their β-receptor–blocking action and direct membrane effects. As described in Chapter 10, some of these drugs have selectivity for cardiac β_1 receptors, some have intrinsic sympathomimetic activity, some have marked direct membrane effects, and some prolong the cardiac action potential. The relative contributions of the β-blocking and direct membrane effects to the antiarrhythmic effects of these drugs are not fully known. Although βblockers are fairly well tolerated, their efficacy for suppression of ventricular ectopic depolarizations is lower than that of sodium channel blockers. However, there is good evidence that these agents can prevent recurrent infarction and sudden death in patients recovering from acute myocardial infarction (see Chapter 10).

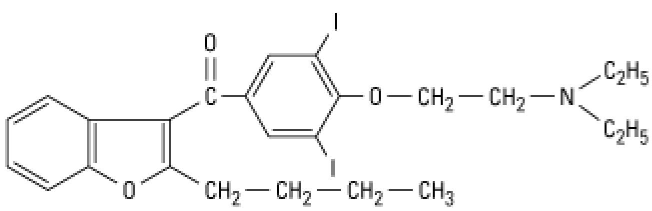
Esmolol is a short-acting β-blocker used primarily as an antiarrhythmic drug for intraoperative and other acute arrhythmias. See Chapter 10 for more information. Sotalol is a nonselective β-blocking drug that prolongs the action potential (class 3 action).

Drugs That Prolong Effective Refractory Period by Prolonging Action Potential (Class 3)

These drugs prolong action potentials, usually by blocking potassium channels in cardiac muscle or by enhancing inward current, eg, through sodium channels. Action potential prolongation by most of these drugs often exhibits the undesirable property of "reverse use-dependence": action potential prolongation is least marked at fast rates (where it is desirable) and most marked at slow rates, where it can contribute to the risk of torsade de pointes.

AMIODARONE

In the USA, amiodarone is approved for oral and intravenous use to treat serious ventricular arrhythmias. However, the drug is also highly effective for the treatment of supraventricular arrhythmias such as atrial fibrillation. Amiodarone has a broad spectrum of cardiac actions, unusual pharmacokinetics, and important extracardiac adverse effects.



Amiodarone

Cardiac Effects

Amiodarone markedly prolongs the action potential duration (and the QT interval on the ECG) by blockade of I_{Kr} . During chronic administration, I_{Ks} is also blocked. The action potential duration is prolonged uniformly over a wide range of heart rates; that is, the drug does not have reverse use-dependent action. In spite of its present classification as a class 3 agent, amiodarone also significantly blocks inactivated sodium channels. Its action potential prolonging action reinforces this effect. Amiodarone also has weak adrenergic and calcium channel blocking actions. Consequences of these actions include slowing of the heart rate and atrioventricular node conduction. The broad spectrum of actions may account for its relatively high efficacy and low incidence of torsade de pointes despite significant QT interval prolongation.

Extracardiac Effects

Amiodarone causes peripheral vasodilation. This action is prominent following intravenous administration and may be related to the action of the vehicle.

Toxicity

CARDIAC

Amiodarone may produce symptomatic bradycardia and heart block in patients with preexisting sinus or atrioventricular node disease.

EXTRACARDIAC

Amiodarone accumulates in many tissues, including the heart (10–50 times greater than plasma), lung, liver, and skin, and is concentrated in tears. Dose-related pulmonary toxicity is the most important adverse effect. Even on a low dose of ≤200 mg/d, fatal pulmonary fibrosis may be observed in 1% of patients. Abnormal liver function tests and hepatitis may develop during amiodarone treatment. The skin deposits result in a photodermatitis and a gray-blue skin discoloration in sun-exposed areas, eg, the malar regions. After a few weeks of treatment, asymptomatic corneal microdeposits are present in virtually all patients treated with amiodarone. Halos develop in the peripheral visual fields of some patients. Drug discontinuation is usually not required. Rarely, an optic neuritis may progress to blindness.

Amiodarone blocks the peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3). It is also a potential source of large amounts of inorganic iodine. Amiodarone may result in hypothyroidism or hyperthyroidism. Thyroid function should be evaluated prior to initiation of treatment and monitored periodically. Because effects have been described in virtually every organ system, amiodarone treatment should be reevaluated whenever new symptoms develop in a patient, including arrhythmia aggravation.

Pharmacokinetics

Amiodarone is variably absorbed with a bioavailability of 35–65%. It undergoes hepatic metabolism, and the major metabolite, desethylamiodarone, is bioactive. The elimination half-life is complex, with a rapid component of 3–10 days (50% of the drug) and a slower component of several weeks. Following discontinuation of the drug, effects are maintained for 1–3 months. Measurable tissue levels may be observed up to 1 year after discontinuation. A total loading dose of 10 g is usually achieved with 0.8–1.2 g daily doses. The maintenance dose is 200–400 mg daily. Pharmacologic effects may be achieved rapidly by intravenous loading. QT-prolonging effect is modest with this route of administration, whereas bradycardia and atrioventricular block may be significant.

Amiodarone has many important drug interactions and all medications should be reviewed during drug initiation or dose adjustments. Amiodarone is a substrate for the liver cytochrome metabolizing enzyme CYP3A4 and its levels are increased by drugs that inhibit this enzyme, eg, the histamine H_2 blocker cimetidine. Drugs that induce CYP3A4, eg, rifampin, decrease amiodarone concentration when coadministered. Amiodarone inhibits the other liver cytochrome metabolizing enzymes and may result in high levels of drugs that are substrates for these enzymes, eg, digoxin and warfarin.

Therapeutic Use

Low doses (100–200 mg/d) of amiodarone are effective in maintaining normal sinus rhythm in patients with atrial fibrillation. The drug is effective in the prevention of recurrent ventricular tachycardia. Its use is not associated with an increase in mortality in patients with coronary artery disease or heart failure. In many centers, the implanted cardioverter-defibrillator (ICD) has succeeded drug therapy as the primary treatment modality for ventricular tachycardia, but amiodarone may be used for ventricular tachycardia as adjuvant therapy to decrease the frequency of uncomfortable ICD discharges. The drug increases the pacing and defibrillation threshold and these devices require retesting after a maintenance dose has been achieved.

BRETYLIUM

Bretylium was first introduced as an antihypertensive agent. It interferes with the neuronal release of catecholamines but also has direct antiarrhythmic properties.

Cardiac & Extracardiac Effects

Bretylium lengthens the ventricular (but not the atrial) action potential duration and effective refractory period. This effect is most pronounced in ischemic cells, which have shortened action potential durations. Thus, bretylium may reverse the shortening of action potential duration caused by ischemia.

Since bretylium causes an initial release of catecholamines, it has some positive inotropic actions when first administered. This action may also *precipitate* ventricular arrhythmias and must be watched for at the onset of therapy with the drug.

The drug's sympathoplegic actions may result in postural hypotension. This effect can be almost totally prevented by concomitant administration of a tricyclic antidepressant agent such as protriptyline. Nausea and vomiting may occur after the intravenous administration of a bolus of bretylium.

Pharmacokinetics & Dosage

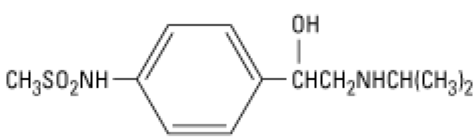
Bretylium is available only for intravenous use in the USA. In adults, an intravenous bolus of bretylium tosylate, 5 mg/kg, is administered over a 10-minute period. This dosage may be repeated after 30 minutes. Maintenance therapy is achieved by a similar bolus every 4–6 hours or by a constant infusion of 0.5–2 mg/min.

Therapeutic Use

Bretylium is rarely used and then only in an emergency setting, often during attempted resuscitation from ventricular fibrillation when lidocaine and cardioversion have failed. In most centers amiodarone is preferred for this indication.

SOTALOL

Sotalol has both β-adrenergic receptor-blocking (class 2) and action potential prolonging (class 3) actions. The drug is formulated as a racemic mixture of *d* - and *l* -sotalol. All the β-adrenergic blocking activity resides in the *l* -isomer; the *d* - and *l* -isomers share action potential prolonging actions. Beta-adrenergic blocking action is not cardioselective and is maximal at doses below those required for action potential prolongation.



Sotalol

Sotalol is well absorbed orally with bioavailability of approximately 100%. It is not metabolized in the liver and it is not bound to plasma proteins. Excretion is predominantly by the kidneys in the unchanged form with a half-life of approximately 12 hours. Because of its relatively simple pharmacokinetics, it exhibits few direct drug interactions. Its most significant cardiac adverse effect is an extension of its pharmacologic action: a dose-related incidence of torsade de pointes that approaches 6% at the highest recommended daily dose. Patients with overt heart failure may experience further depression of left ventricular function during treatment with sotalol.

Sotalol is approved for the treatment of life-threatening ventricular arrhythmias and the maintenance of sinus rhythm in patients with atrial fibrillation. It is also approved for treatment of supraventricular and ventricular arrhythmias in the pediatric age group. Sotalol decreases the threshold for cardiac defibrillation.

DOFETILIDE

Dofetilide has class 3 action potential prolonging action. This action is effected by a dose-dependent blockade of the rapid component of the delayed rectifier potassium current, I_{Kr} . Dofetilide block of I_{Kr} increases in hypokalemia. Dofetilide produces no relevant blockade of the other potassium channels or the sodium channel. Because of the slow rate of recovery from blockade, the extent of blockade shows little dependence on stimulation frequency. However, dofetilide does show less action potential prolongation at rapid rates because of the increased importance of other potassium channels such as I_{Ks} at higher frequencies.

Dofetilide is 100% bioavailable. Verapamil increases peak plasma dofetilide concentration by increasing intestinal blood flow. Eighty percent of an oral dose is eliminated by the kidneys unchanged; the remainder is eliminated in the urine as inactive metabolites. Inhibitors of the renal cation secretion mechanism, eg, cimetidine, prolong the half-life of dofetilide. Since the QT-prolonging effects and risks of ventricular proarrhythmia are directly related to plasma concentration, dofetilide dosage must be based on the estimated creatinine clearance. Treatment with dofetilide should be initiated in hospital after baseline measurement of the rate-corrected QT interval (QT_C) and serum electrolytes. A baseline QT_C of > 450 ms (500 ms in the presence of an intraventricular conduction delay), bradycardia of < 50 beats/min, and hypokalemia are relative contraindications to its use.

Dofetilide is approved for the maintenance of normal sinus rhythm in patients with atrial fibrillation. It is also effective in restoring normal sinus rhythm in patients with atrial fibrillation.

IBUTILIDE

Ibutilide slows cardiac repolarization by blockade of the rapid component of the delayed rectifier potassium current. Activation of slow inward sodium current has also been suggested as an additional mechanism of action. After intravenous administration, ibutilide is rapidly cleared from the plasma by hepatic metabolism. The metabolites are excreted by the kidney. The elimination half-life averages 6 hours.

Intravenous ibutilide is used for the acute conversion of atrial flutter and atrial fibrillation to normal sinus rhythm. The drug is more effective in atrial flutter than fibrillation, with a mean time to termination of 20 minutes. The most important adverse effect is excessive QT interval prolongation and torsade de pointes. Patients require continuous ECG monitoring for 4 hours following ibutilide infusion or until QT_C returns to baseline.

Calcium Channel–Blocking Drugs (Class 4)

These drugs, of which verapamil is the prototype, were first introduced as antianginal agents and are discussed in greater detail in Chapter 12. Verapamil and diltiazem also have antiarrhythmic effects.

VERAPAMIL

Cardiac Effects

Verapamil blocks both activated and inactivated L-type calcium channels. Thus, its effect is more marked in tissues that fire frequently, those that are less completely polarized at rest, and those in which activation depends exclusively on the calcium current, such as the sinoatrial and atrioventricular nodes. Atrioventricular nodal conduction time and effective refractory period are invariably prolonged by therapeutic concentrations. Verapamil usually slows the sinoatrial node by its direct action, but its hypotensive action may occasionally result in a small reflex increase of sinoatrial nodal rate.

Verapamil can suppress both early and delayed afterdepolarizations and may antagonize slow responses arising in severely depolarized tissue.

Extracardiac Effects

Verapamil causes peripheral vasodilation, which may be beneficial in hypertension and peripheral vasospastic disorders. Its effects upon smooth muscle produce a number of extracardiac effects (see Chapter 12).

Toxicity

CARDIAC

Verapamil's cardiotoxic effects are dose-related and usually avoidable. A common error has been to administer intravenous verapamil to a patient with ventricular tachycardia misdiagnosed as supraventricular tachycardia. In this setting, hypotension and ventricular fibrillation can occur. Verapamil's negative inotropic effects may limit its clinical usefulness in diseased hearts (see Chapter 12). Verapamil can induce atrioventricular block when used in large doses or in patients with atrioventricular nodal disease. This block can be treated with atropine and β-receptor stimulants. In patients with sinus node disease, verapamil can precipitate sinus arrest.

EXTRACARDIAC

Adverse effects include constipation, lassitude, nervousness, and peripheral edema.

Pharmacokinetics & Dosage

The half-life of verapamil is approximately 7 hours. It is extensively metabolized by the liver; after oral administration, its bioavailability is only about 20%. Therefore, verapamil must be administered with caution in patients with hepatic dysfunction.

In adult patients without heart failure or sinoatrial or atrioventricular nodal disease, parenteral verapamil can be used to terminate supraventricular tachycardia, although adenosine is the agent of first choice. Verapamil dosage is an initial bolus of 5 mg administered over 2–5 minutes, followed a few minutes later by a second 5 mg bolus if needed. Thereafter, doses of 5–10 mg can be administered every 4–6 hours, or a constant infusion of 0.4 mcg/kg/min may be used.

Effective oral dosages are higher than intravenous dosage because of first-pass metabolism and range from 120 to 640 mg daily, divided into three or four doses.

Therapeutic Use

Supraventricular tachycardia is the major arrhythmia indication for verapamil. Adenosine or verapamil are preferred over older treatments (propranolol, digoxin, edrophonium, vasoconstrictor agents, and cardioversion) for termination. Verapamil can also reduce the ventricular rate in atrial fibrillation and flutter. It only rarely converts atrial flutter and fibrillation to sinus rhythm. Verapamil is occasionally useful in ventricular arrhythmias. However, the use of intravenous verapamil in a patient with sustained ventricular tachycardia can cause hemodynamic collapse.

DILTIAZEM

Diltiazem appears to be similar in efficacy to verapamil in the management of supraventricular arrhythmias, including rate control in atrial fibrillation. An intravenous form of diltiazem is available for the latter indication and causes hypotension or bradyarrhythmias relatively infrequently.

MISCELLANEOUS ANTIARRHYTHMIC AGENTS

Certain agents used for the treatment of arrhythmias do not fit the conventional class 1–4 organization. These include digitalis (discussed in Chapter 13), adenosine, magnesium, and potassium.

ADENOSINE

Mechanism & Clinical Use

Adenosine is a nucleoside that occurs naturally throughout the body. Its half-life in the blood is less than 10 seconds. Its mechanism of action involves activation of an inward rectifier K^+ current and inhibition of calcium current. The results of these actions are marked hyperpolarization and suppression of calcium-dependent action potentials. When given as a bolus dose, adenosine directly inhibits atrioventricular nodal conduction and increases the atrioventricular nodal refractory period but has lesser effects on the sinoatrial node. Adenosine is currently the drug of choice for prompt conversion of paroxysmal supraventricular tachycardia to sinus rhythm because of its high efficacy (90–95%) and very short duration of action. It is usually given in a bolus dose of 6 mg followed, if necessary, by a dose of 12 mg. An uncommon variant of ventricular tachycardia is adenosine sensitive. The drug is less effective in the presence of adenosine receptor blockers such as theophylline or caffeine, and its effects are potentiated by adenosine uptake inhibitors such as dipyridamole.

Toxicity

Adenosine causes flushing in about 20% of patients and shortness of breath or chest burning (perhaps related to bronchospasm) in over 10%. Induction of high-grade atrioventricular block may occur but is very short-lived. Atrial fibrillation may occur. Less common toxicities include headache, hypotension, nausea, and paresthesias.

MAGNESIUM

Originally used for patients with digitalis-induced arrhythmias who were hypomagnesemic, magnesium infusion has been found to have antiarrhythmic effects in some patients with normal serum magnesium levels. The mechanisms of these effects are not known, but magnesium is recognized to influence Na^+ /K^+ ATPase, sodium channels, certain potassium channels, and calcium channels. Magnesium therapy appears to be indicated in patients with digitalis-induced arrhythmias if hypomagnesemia is present; it is also indicated in some patients with torsade de pointes even if serum magnesium is normal. The usual dosage is 1 g (as sulfate) given intravenously over 20 minutes and repeated once if necessary. A full understanding of the action and indications of magnesium as an antiarrhythmic drug awaits further investigation.

POTASSIUM

The significance of the potassium ion concentrations inside and outside the cardiac cell membrane has been discussed earlier in this chapter. The effects of increasing serum K^+ can be summarized as (1) a resting potential depolarizing action and (2) a membrane potential stabilizing action, the latter caused by increased potassium permeability. Hypokalemia results in an increased risk of early and delayed afterdepolarizations, and ectopic pacemaker activity, especially in the presence of digitalis; hyperkalemia depresses ectopic pacemakers (severe hyperkalemia is required to suppress the sinoatrial node) and slows conduction. Because both insufficient and excess potassium are potentially arrhythmogenic, potassium therapy is directed toward normalizing potassium gradients and pools in the body.

PRINCIPLES IN THE CLINICAL USE OF ANTIARRHYTHMIC AGENTS

The margin between efficacy and toxicity is particularly narrow for antiarrhythmic drugs. Risks and benefits must be carefully considered (see Antiarrhythmic Drug-Use Principles Applied to Atrial Fibrillation).

Antiarrhythmic Drug-Use Principles Applied to Atrial Fibrillation

Atrial fibrillation is the most common sustained arrhythmia observed clinically. Its prevalence increases from ~ 0.5% in individuals younger than 65 years of age to 10% in individuals older than 80. Diagnosis is usually straightforward by means of an ECG. The ECG may also enable the identification of a prior myocardial infarction, left ventricular hypertrophy, and ventricular pre-excitation. Hyperthyroidism is an important treatable cause of atrial fibrillation, and a thyroid panel should be obtained at the time of diagnosis to exclude this possibility. With the clinical history and physical examination as a guide, the presence and extent of the underlying heart disease should be evaluated, preferably using noninvasive techniques such as echocardiography.

Treatment of atrial fibrillation is initiated to relieve patient symptoms and prevent the complications of thromboembolism and tachycardia-induced heart failure, the result of prolonged uncontrolled heart rates. The initial treatment objective is control of the ventricular response. This is usually achieved by use of a calcium channel blocking drug alone or in combination with a β-adrenergic blocker. Digoxin may be of value in the presence of heart failure. A second objective is a restoration and maintenance of normal sinus rhythm. Several studies show that rate control (maintenance of ventricular rate in the range of 60–80 beats/min) has a better benefit-to-risk outcome than rhythm control (conversion to normal sinus rhythm) in the long-term health of patients with atrial fibrillation. If rhythm control is deemed desirable, sinus rhythm is usually restored by DC cardioversion in the USA; in some countries, a class 1 antiarrhythmic drug is used initially. For patients with paroxysmal atrial fibrillation, normal sinus rhythm may be restored with a single large oral dose of propafenone or flecainide, provided that safety is initially documented in a monitored setting. Intravenous ibutilide can restore sinus rhythm promptly. For restoration of sinus rhythm in an emergency, eg, atrial fibrillation associated with hypotension or angina, DC cardioversion is the preferred modality. A class 1 or class 3 antiarrhythmic drug is used to maintain normal sinus rhythm.

Pretreatment Evaluation

Several important determinations must be made prior to initiation of any antiarrhythmic therapy:

(1) Eliminate the cause if possible. Precipitating factors must be recognized and eliminated if possible. These include not only abnormalities of internal homeostasis, such as hypoxia or electrolyte abnormalities (especially hypokalemia or hypomagnesemia), but also drug therapy and underlying disease states such as hyperthyroidism or underlying cardiac disease. It is important to separate this abnormal substrate from triggering factors, such as myocardial ischemia or acute cardiac dilation, which may be treatable and reversible.

(2) Make a firm diagnosis. A firm arrhythmia diagnosis should be established. For example, the misuse of verapamil in patients with ventricular tachycardia mistakenly diagnosed as supraventricular tachycardia can lead to catastrophic hypotension and cardiac arrest. As increasingly sophisticated methods to characterize

underlying arrhythmia mechanisms become available and are validated, it may be possible to direct certain drugs toward specific arrhythmia mechanisms.

(3) Determine the baseline condition. A reliable baseline should be established against which to judge the efficacy of any subsequent antiarrhythmic intervention. Several methods are now available for such baseline quantitation. These include prolonged ambulatory monitoring, electrophysiologic studies that reproduce a target arrhythmia, reproduction of a target arrhythmia by treadmill exercise, or the use of transtelephonic monitoring for recording of sporadic but symptomatic arrhythmias.

(4) Question the need for therapy. The mere identification of an abnormality of cardiac rhythm does not necessarily require that the arrhythmia be treated. An excellent justification for conservative treatment was provided by the Cardiac Arrhythmia Suppression Trial (CAST) referred to earlier.

Benefits & Risks

The benefits of antiarrhythmic therapy are actually relatively difficult to establish. Two types of benefits can be envisioned: reduction of arrhythmia-related symptoms, such as palpitations, syncope, or cardiac arrest; or reduction in long-term mortality in asymptomatic patients. Among drugs discussed here, only β blockers have been definitely associated with reduction of mortality in relatively asymptomatic patients, and the mechanism underlying this effect is not established (see Chapter 10).

Antiarrhythmic therapy carries with it a number of risks. In some cases, the risk of an adverse reaction is clearly related to high dosages or plasma concentrations. Examples include lidocaine-induced tremor or quinidine-induced cinchonism. In other cases, adverse reactions are unrelated to high plasma concentrations (eg, procainamide-induced agranulocytosis). For many serious adverse reactions to antiarrhythmic drugs, the *combination* of drug therapy and the underlying heart disease appears important.

Several specific syndromes of arrhythmia provocation by antiarrhythmic drugs have also been identified, each with its underlying pathophysiologic mechanism and risk factors. Drugs such as quinidine, sotalol, ibutilide, and dofetilide, which act—at least in part—by slowing repolarization and prolonging cardiac action potentials, can result in marked QT prolongation and torsade de pointes. Treatment of torsade de pointes requires recognition of the arrhythmia, withdrawal of any offending agent, correction of hypokalemia, and treatment with maneuvers to increase heart rate (pacing or isoproterenol); intravenous magnesium also appears effective, even in patients with normal magnesium levels.

Drugs that markedly slow conduction, such as flecainide, or high concentrations of quinidine, can result in an increased frequency of reentry arrhythmias, notably ventricular tachycardia in patients with prior myocardial infarction in whom a potential reentry circuit may be present. Treatment here consists of recognition, withdrawal of the offending agent, and intravenous sodium.

Conduct of Antiarrhythmic Therapy

The urgency of the clinical situation determines the route and rate of drug initiation. When immediate drug action is required, the intravenous route is preferred. Therapeutic drug levels can be achieved by administration of multiple intravenous boluses. Drug therapy can be considered effective when the target arrhythmia is suppressed (according to the measure used to quantify at baseline) and toxicities are absent. Conversely, drug therapy should not be considered ineffective unless toxicities occur at a time when arrhythmias are not suppressed.

Monitoring plasma drug concentrations can be a useful adjunct to managing antiarrhythmic therapy. Plasma drug concentrations are also important in establishing compliance during long-term therapy as well as in detecting drug interactions that may result in very high concentrations at low drug dosages or very low concentrations at high dosages.

PREPARATIONS AVAILABLE

SODIUM CHANNEL BLOCKERS

Disopyramide (generic, Norpace)

Oral: 100, 150 mg capsules

Oral controlled-release (generic, Norpace CR): 100, 150 capsules

Flecainide (Tambocor)

Oral: 50, 100, 150 mg tablets

Lidocaine (generic, Xylocaine)

Parenteral: 100 mg/mL for IM injection; 10, 20 mg/mL for IV injection; 40, 100, 200 mg/mL for IV admixtures; 2, 4, 8 mg/mL premixed IV (5% D/W) solution

Mexiletine (Mexitil)

Oral: 150, 200, 250 mg capsules

Moricizine (Ethmozine)

Oral: 200, 250, 300 mg tablets

Procainamide (generic, Pronestyl, others)

Oral: 250, 375, 500 mg tablets and capsules

Oral sustained-release (generic, Procan-SR): 250, 500, 750, 1000 mg tablets

Parenteral: 100, 500 mg/mL for injection

Propafenone (Rythmol)

Oral: 150, 225, 300 mg tablets

Quinidine sulfate [83% quinidine base] (generic)

Oral: 200, 300 mg tablets

Oral sustained-release (Quinidex Extentabs): 300 mg tablets

Quinidine gluconate [62% quinidine base] (generic)

Oral sustained-release: 324 mg tablets

Parenteral: 80 mg/mL for injection

Quinidine polygalacturonate [60% quinidine base] (Cardioquin)

Oral: 275 mg tablets

β-BLOCKERS LABELED FOR USE AS ANTIARRHYTHMICS

Acebutolol (generic, Sectral)

Oral: 200, 400 mg capsules

Esmolol (Brevibloc)

Parenteral: 10 mg/mL, 250 mg/mL for IV injection

Propranolol (generic, Inderal)

Oral: 10, 20, 40, 60, 80, 90 mg tablets

Oral sustained-release: 60, 80, 120, 160 mg capsules

Oral solution: 4, 8 mg/mL

Parenteral: 1 mg/mL for injection

ACTION POTENTIAL–PROLONGING AGENTS

Amiodarone (Cordarone)

Oral: 200, 400 mg tablets

Parenteral: 150 mg/3 mL for IV infusion

Bretylium (generic)

Parenteral: 2, 4, 50 mg/mL for injection

Dofetilide (Tikosyn)

Oral: 125, 250, 500 mcg capsules

Ibutilide (Corvert)

Parenteral: 0.1 g/mL solution for IV infusion

Sotalol (generic, Betapace)

Oral: 80, 120, 160, 240 mg capsules

CALCIUM CHANNEL BLOCKERS

Diltiazem (generic, Cardizem, Dilacor)

Oral: 30, 60, 90, 120 mg tablets; 60, 90, 120, 180, 240, 300, 340, 420 mg extended- or sustained-release capsules (*not labeled for use in arrhythmias*)

Parenteral: 5 mg/mL for IV injection

Verapamil (generic, Calan, Isoptin)

Oral: 40, 80, 120 mg tablets

Oral sustained-release (Calan SR, Isoptin SR): 100, 120, 180, 240 mg capsules

Parenteral: 5 mg/2 mL for injection

MISCELLANEOUS

Adenosine (Adenocard)

Parenteral: 3 mg/mL for injection

Magnesium sulfate

Parenteral: 125, 500 mg/mL for IV infusion

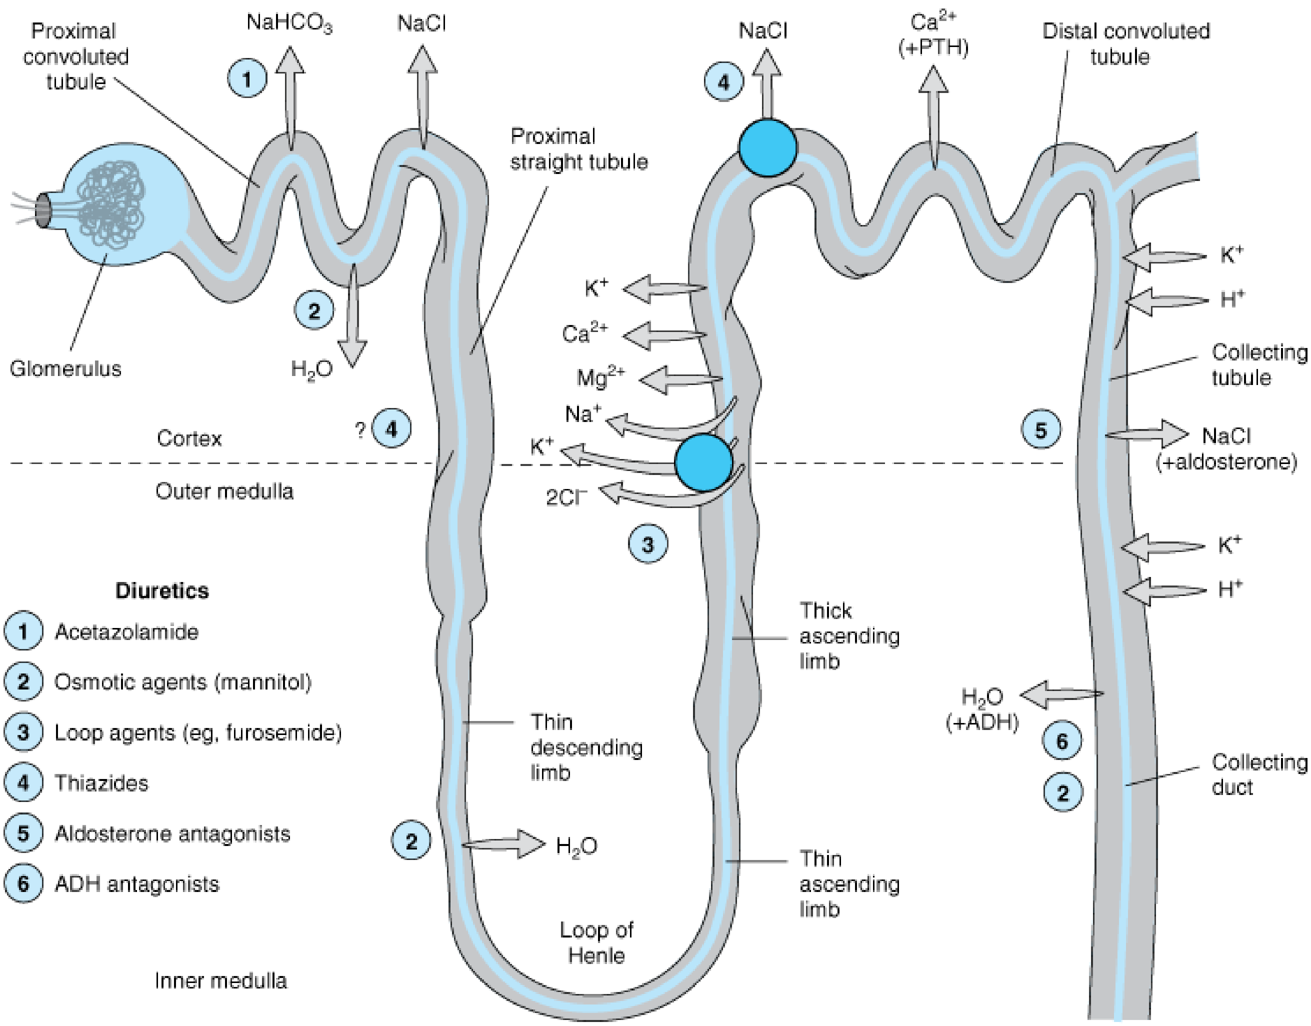
DIURETIC AGENTS: INTRODUCTION

Abnormalities in fluid volume and electrolyte composition are common and important clinical disorders. Drugs that block specific transport functions of the renal tubules are valuable clinical tools in the treatment of these disorders. Although various agents that increase urine volume (diuretics) have been described since antiquity, it was not until 1957 that a practical and powerful diuretic agent (chlorothiazide) became available for widespread use.

Technically, a "diuretic" is an agent that increases urine volume, while a "natriuretic" causes an increase in renal sodium excretion. Because natriuretics almost always also increase water excretion, they are usually called diuretics.

The nephron is divided structurally and functionally into several segments (Figure 15–1, Table 15–1), which are discussed in the first part of this chapter. Many diuretics exert their effects on specific membrane transport proteins in renal tubular epithelial cells. Other diuretics exert osmotic effects that prevent water reabsorption (mannitol), inhibit enzymes (acetazolamide), or interfere with hormone receptors in renal epithelial cells (aldosterone receptor blockers). These effects are discussed in the second part of the chapter. The physiology of each segment is closely linked to the pharmacology of the drugs acting there.

Figure 15–1.



Tubule transport systems and sites of action of diuretics.

Table 15–1. Major Segments of the Nephron and Their Functions.

Segment	Functions	Water Permeability	Primary Transporters and Drug Targets at Apical Membrane	Diuretic with Major Action
Glomerulus	Formation of glomerular filtrate	Extremely high	None	

None

Proximal convoluted tubule (PCT)

Reabsorption of 65% of filtered Na^+ , K^+ , CA^{2+} , and Mg^+ ; 85% of $NaHCO_3$, and nearly 100% of glucose and amino acids. Isosmotic reabsorption of water.

Very high

Na/H^1 (NHE3), carbonic anhydrase

Carbonic anhydrase inhibitors

Proximal tubule, straight segments

Secretion and reabsorption of organic acids and bases, including uric acid and most diuretics

Very high

Acid (eg, uric acid) and base transporters

None

Thin descending limb of Henle's loop

Passive reabsorption of water

High

Aquaporins

None

Thick ascending limb of Henle's loop (TAL)

Active reabsorption of 15–25% of filtered Na^+ , K^+ , Cl^- ; secondary reabsorption of Ca^{2+} and Mg^+

Very low

Na/K/2Cl (NKCC2)

Loop diuretics

Distal convoluted tubule (DCT)

Active reabsorption of 4–8% of filtered Na^+ and Cl^- ; Ca^{2+} reabsorption under parathyroid hormone control

Very low

Na/Cl (NCC)

Thiazides

Cortical collecting tubule (CCT)

Na^+ reabsorption (2–5%) coupled to K^+ and H^+ secretion

Variable[2]

Na channels (ENaC), K channels,[1] H transporter, [1] aquaporins

K^+ -sparing diuretics

Medullary collecting duct

Water reabsorption under vasopressin control

Variable[2]

Aquaporins

Vasopressin antagonist

[2] Controlled by vasopressin activity.

RENAL TUBULE TRANSPORT MECHANISMS

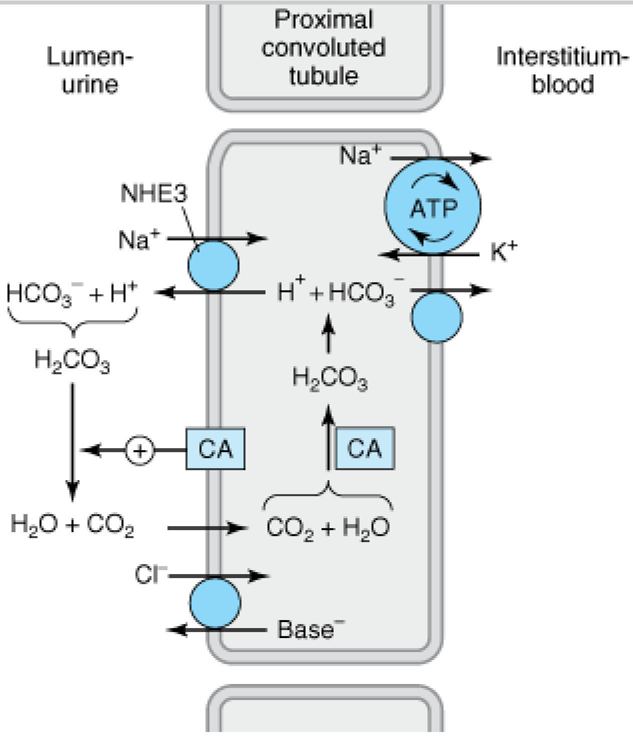
PROXIMAL TUBULE

Sodium bicarbonate ($NaHCO_3$), sodium chloride (NaCl), glucose, amino acids, and other organic solutes are reabsorbed via specific transport systems in the early proximal tubule (proximal convoluted tubule, PCT). Potassium ions (K^+) are reabsorbed via the paracellular pathway. Water is reabsorbed passively, maintaining the osmolality of proximal tubular fluid at a nearly constant level. As tubule fluid is processed along the length of the proximal tubule, the luminal concentrations of these solutes decrease relative to the concentration of inulin, a marker that is filtered but neither secreted nor absorbed by renal tubules. Approximately 66% of total sodium ions (Na^+ , but 85% of the filtered $NaHCO_3$), 65% of the K^+ , 60% of the water, and virtually all of the filtered glucose and amino acids are reabsorbed in the proximal tubule.

Of the various solutes reabsorbed in the proximal tubule, the most relevant to diuretic action are $NaHCO_3$ and NaCl. Of the currently available diuretics, only one group (carbonic anhydrase inhibitors, which block $NaHCO_3$ reabsorption) acts predominantly in the PCT. In view of the large quantity of NaCl absorbed in this segment, a drug that specifically blocked proximal tubular absorption of NaCl would be a particularly powerful diuretic. No such drug is currently available.

Sodium bicarbonate reabsorption by the PCT is initiated by the action of a Na^+ /H^+ exchanger (NHE3) located in the luminal membrane of the proximal tubule epithelial cell (Figure 15–2). This transport system allows Na^+ to enter the cell from the tubular lumen in exchange for a proton (H^+) from inside the cell. As in all portions of the nephron, Na^+ /K^+ ATPase in the basolateral membrane pumps the reabsorbed Na^+ into the interstitium so as to maintain a low intracellular Na^+ concentration. The H^+ secreted into the lumen combines with bicarbonate (HCO_3^-) to form H_2CO_3 (carbonic acid), which is rapidly dehydrated to CO_2 and H_2O by carbonic anhydrase. Carbon dioxide produced by dehydration of H_2CO_3 enters the proximal tubule cell by simple diffusion where it is then rehydrated back to H_2CO_3, facilitated by intracellular carbonic anhydrase. After dissociation of H_2CO_3, the H^+ is available for transport by the Na^+ /H^+ exchanger, and the HCO_3^- is transported out of the cell by a basolateral membrane transporter (Figure 15–2). Bicarbonate reabsorption by the proximal tubule is thus dependent on carbonic anhydrase. This enzyme can be inhibited by acetazolamide and related agents.

Figure 15–2.



Apical membrane Na^+ /H^+ exchange (via NHE3) and bicarbonate reabsorption in the proximal convoluted tubule cell. Na^+ /K^+ ATPase is present in the basolateral membrane to maintain intracellular sodium and potassium levels within the normal range. Because of rapid equilibration, concentrations of the solutes are approximately equal in the interstitial fluid and the blood. Carbonic anhydrase (CA) is found in other locations in addition to the brush border of the luminal membrane.

In the late proximal tubule, as HCO_3^- and organic solutes have been largely removed from the tubular fluid, the residual luminal fluid contains predominantly NaCl. Under these conditions, Na^+ reabsorption continues, but the H^+ secreted by the Na^+ /H^+ exchanger can no longer bind to HCO_3^-. Free H^+ causes luminal pH to fall, activating a still poorly defined Cl^- /base exchanger (Figure 15–2). The net effect of parallel Na^+ /H^+ exchange and Cl^- /base exchange is NaCl reabsorption. As yet, there are no diuretic agents that are known to act on this conjoint process.

Because water is reabsorbed in direct proportion to salt reabsorption in the proximal tubule, luminal fluid osmolality remains nearly constant along its length and an impermeant solute like inulin rises in concentration as water is reabsorbed. If large amounts of an impermeant solute such as mannitol (an osmotic diuretic, see below) are present in the tubular fluid, water reabsorption causes the concentration of the solute and osmolality of tubular fluid to rise, eventually preventing further water reabsorption.

Organic acid secretory systems are located in the middle third of the straight part of the proximal tubule (S_2 segment). These systems secrete a variety of organic acids (uric acid, nonsteroidal anti-inflammatory drugs [NSAIDs], diuretics, antibiotics, etc) into the luminal fluid from the blood. These systems thus help deliver diuretics to the luminal side of the tubule, where most of them act. Organic base secretory systems (creatinine, choline, etc) are also present, in the early (S_1) and middle (S_2) segments of the proximal tubule.

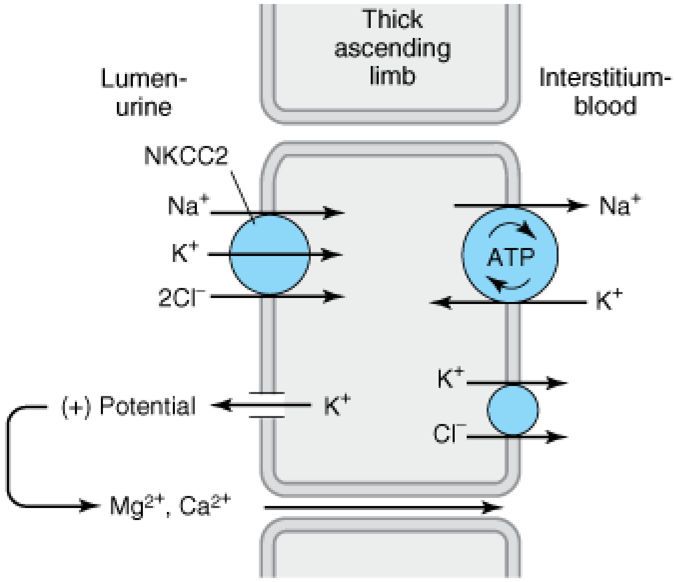
LOOP OF HENLE

At the boundary between the inner and outer stripes of the outer medulla, the proximal tubule empties into the thin descending limb of Henle's loop. Water is extracted from the descending limb of this loop by osmotic forces found in the hypertonic medullary interstitium. As in the proximal tubule, impermeant luminal solutes such as mannitol oppose this water extraction. The thin *ascending* limb is relatively water-impermeable.

The thick ascending limb (TAL) of the loop of Henle actively reabsorbs NaCl from the lumen (about 25% of the filtered sodium), but unlike the proximal tubule and the thin limb of Henle's loop, it is nearly impermeable to water. Salt reabsorption in the TAL therefore dilutes the tubular fluid, and it is called a "diluting segment." Medullary portions of the thick ascending limb contribute to medullary hypertonicity and thereby also play an important role in concentration of urine by the collecting duct.

The NaCl transport system in the luminal membrane of the TAL is a Na^+ /K^+ /2Cl^- cotransporter (called NKCC2 or NK2CL) (Figure 15–3). This transporter is selectively blocked by diuretic agents known as "loop" diuretics (see below). Although the Na^+ /K^+ /2Cl^- transporter is itself electrically neutral (two cations and two anions are cotransported), the action of the transporter contributes to excess K^+ accumulation within the cell. Back diffusion of this K^+ into the tubular lumen causes a lumen-positive electrical potential that provides the driving force for reabsorption of cations—including magnesium and calcium—via the paracellular pathway. Thus, inhibition of salt transport in the thick ascending limb by loop diuretics, which reduces the lumen-positive potential, causes an increase in urinary excretion of divalent cations in addition to NaCl.

Figure 15–3.

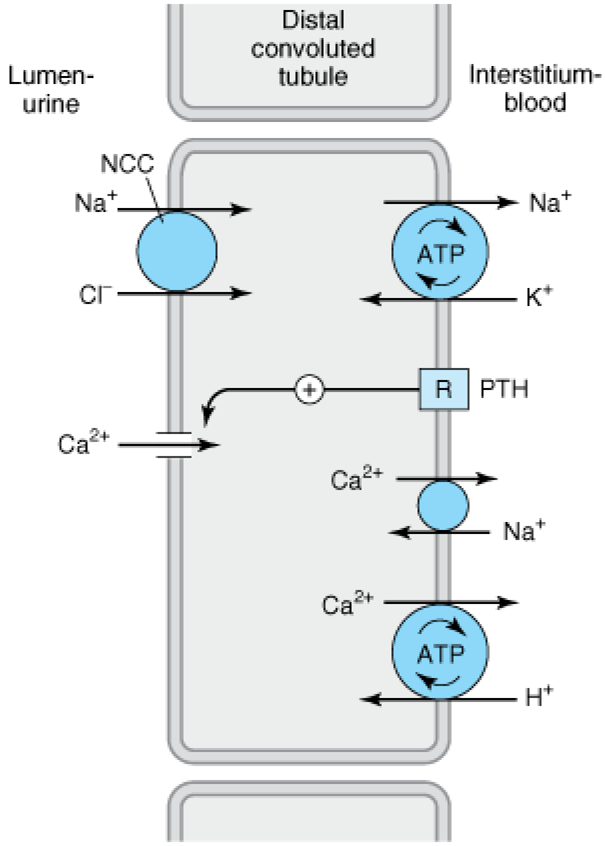


Ion transport pathways across the luminal and basolateral membranes of the thick ascending limb cell. The lumen positive electrical potential created by K^+ back diffusion drives divalent (and monovalent) cation reabsorption via the paracellular pathway. NKCC2 is the primary transporter in the luminal membrane.

DISTAL CONVOLUTED TUBULE

Only about 10% of the filtered NaCl is reabsorbed in the distal convoluted tubule (DCT). Like the thick ascending limb of Henle's loop, this segment is relatively impermeable to water and NaCl reabsorption further dilutes the tubular fluid. The mechanism of NaCl transport in the DCT is an electrically neutral thiazide-sensitive Na^+ and Cl^- cotransporter (NCC, Figure 15–4).

Figure 15–4.



Ion transport pathways across the luminal and basolateral membranes of the distal convoluted tubule cell. As in all tubular cells, Na^+ /K^+ ATPase is present in the basolateral membrane. NCC is the primary sodium and chloride transporter in the luminal membrane. (R, parathyroid hormone [PTH] receptor.)

Because K^+ does not recycle across the apical membrane of the DCT as it does in the TAL, there is no lumen-positive potential in this segment, and Ca^{2+} and Mg^{2+} are not driven out of the tubular lumen by electrical forces. Instead, Ca^{2+} is actively reabsorbed by the DCT epithelial cell via an apical Ca^{2+} channel and basolateral Na^+ /Ca^{2+} exchanger (Figure 15–4). This process is regulated by parathyroid hormone.

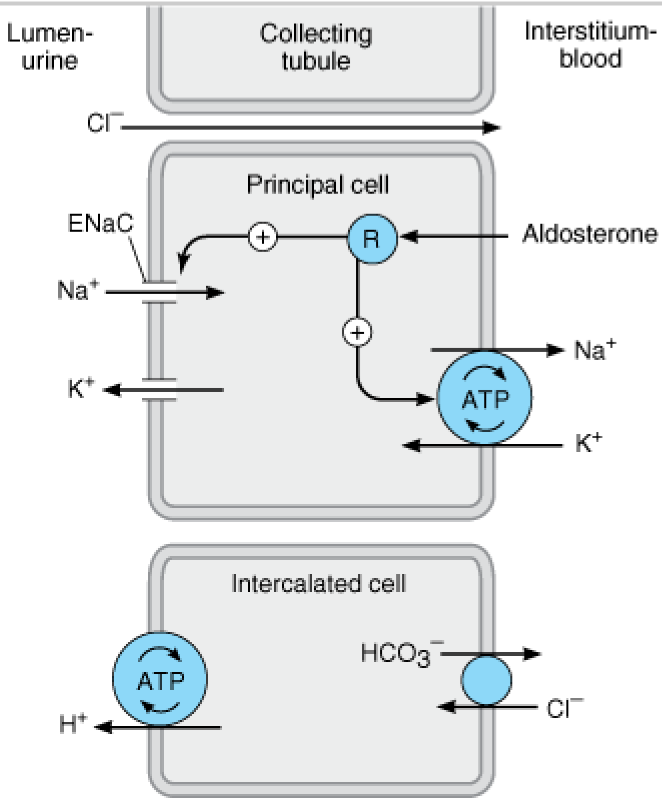
COLLECTING TUBULE

The collecting tubule (CCT) is responsible for only 2–5% of NaCl reabsorption by the kidney. Despite this small contribution, the CCT plays an important role in renal physiology and in diuretic action. As the final site of NaCl reabsorption, the collecting tubule is responsible for tight regulation of body fluid volume and for determining the final Na^+ concentration of the urine. Furthermore, the collecting tubule is a site at which mineralocorticoids exert a significant influence. Lastly, the collecting tubule is the most important site of K^+ secretion by the kidney and the site at which virtually all diuretic-induced changes in K^+ balance occur.

The mechanism of NaCl reabsorption in the CCT is distinct from the mechanisms found in other tubule segments. The *principal* cells are the major sites of Na^+ , K^+ , and water transport (Figure 15–5), and the *intercalated* cells are the primary sites of H^+ secretion. Unlike cells in other nephron segments, the principal cells do not contain cotransport systems for Na^+ and other ions in their apical membranes.

Principal cell membranes exhibit separate ion channels for Na^+ and K^+ . Since these channels exclude anions, transport of Na^+ or K^+ leads to a net movement of charge across the membrane. Because Na^+ entry into the principal cell predominates over K^+ secretion, a 10–50 mV lumen-negative electrical potential develops. Na^+ that enters the principal cell from the tubular fluid is then transported back to the blood via the basolateral Na^+ /K^+ ATPase (Figure 15–5). The 10–50 mV lumen-negative electrical potential drives the transport of Cl^- back to the blood via the paracellular pathway and draws K^+ out of cells through the apical membrane K^+ channel. Thus, there is an important relationship between Na^+ delivery to the CCT and the resulting secretion of K^+ . Diuretics that act upstream of the CCT will increase Na^+ delivery to this site and will enhance K^+ secretion. If the Na^+ is delivered with an anion that cannot be reabsorbed as readily as Cl^- (eg, $HCO_3{}^-$), the lumen-negative potential is increased, and K^+ secretion will be enhanced. This mechanism, combined with enhanced aldosterone secretion due to volume depletion, is the basis for most diuretic-induced K^+ wasting.

Figure 15–5.

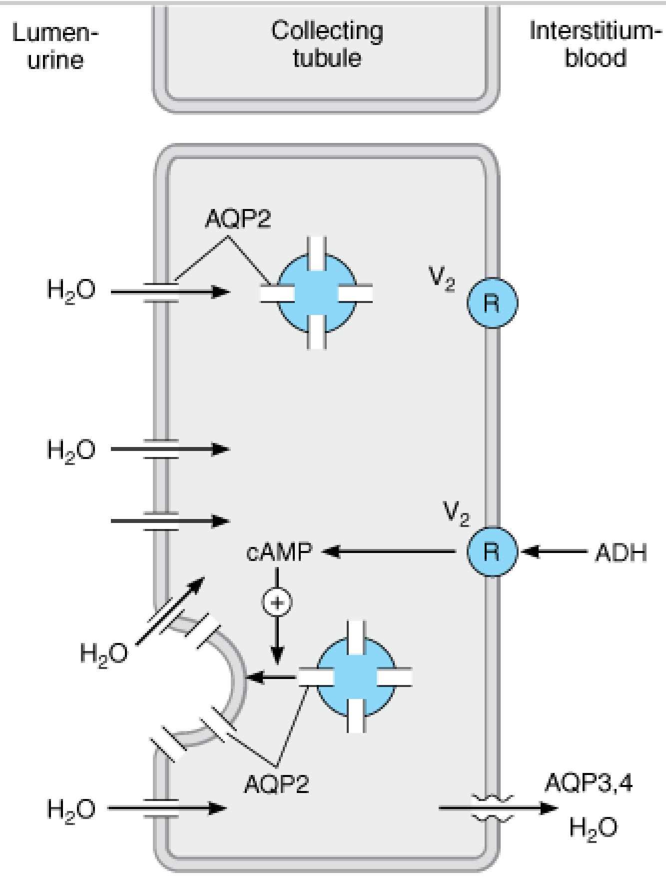


Ion transport pathways across the luminal and basolateral membranes of collecting tubule and collecting duct cells. Inward diffusion of Na^+ via the epithelial sodium channel (ENaC) leaves a lumen-negative potential, which drives reabsorption of Cl^- and efflux of K^+ . (R, aldosterone receptor; ADH, antidiuretic hormone.)

Reabsorption of Na^+ via the epithelial Na channel (ENaC) and its coupled secretion of K^+ is regulated by aldosterone. This steroid hormone, through its actions on gene transcription, increases the activity of both apical membrane channels and the basolateral Na^+ /K^+ ATPase. This leads to an increase in the transepithelial electrical potential and a dramatic increase in both Na^+ reabsorption and K^+ secretion.

The collecting tubule is also the site at which the final urine concentration is determined. Antidiuretic hormone (ADH, also called arginine vasopressin, AVP) controls the permeability of this segment to water by regulating the insertion of preformed water channels (aquaporin-2, AQP2) into the apical membrane via a G protein-coupled cAMP-mediated process (Figure 15–6). In the absence of ADH, the collecting tubule (and duct) is impermeable to water and dilute urine is produced. ADH markedly increases water permeability and this leads to the formation of a more concentrated final urine. ADH also stimulates the insertion of urea transporter UT1 molecules into the apical membranes of medullary collecting tubule cells. Urea concentration in the medulla plays an important role maintaining the high osmolarity of the medulla and in the concentration of urine. ADH secretion is regulated by serum osmolality and by volume status.

Figure 15–6.



Water transport across the luminal and basolateral membranes of collecting duct cells. Above, low water permeability exists in the absence of antidiuretic hormone (ADH). Below, in the presence of ADH, aquaporins are inserted into the apical membrane, greatly increasing water permeability. (V_2 , vasopressin V_2 receptor; AQP2, apical aquaporin water channels; AQP3, 4, basolateral aquaporin water channels.)

BASIC PHARMACOLOGY OF DIURETIC AGENTS

CARBONIC ANHYDRASE INHIBITORS

Carbonic anhydrase is present in many nephron sites, but the predominant location of this enzyme is the luminal membrane of the PCT (Figure 15–2), where it catalyzes the dehydration of H_2CO_3 as described above. By blocking carbonic anhydrase, inhibitors block $NaHCO_3$ reabsorption and cause diuresis.

Carbonic anhydrase inhibitors were the forerunners of modern diuretics. They were discovered when it was found that bacteriostatic sulfonamides caused an alkaline diuresis and hyperchloremic metabolic acidosis. With the development of newer agents, carbonic anhydrase inhibitors are now rarely used as diuretics, but they still have several specific applications that are discussed below. The prototypical carbonic anhydrase inhibitor is acetazolamide.

Pharmacokinetics

The carbonic anhydrase inhibitors are well absorbed after oral administration. An increase in urine pH from the HCO_3^- diuresis is apparent within 30 minutes, maximal at 2 hours, and persists for 12 hours after a single dose. Excretion of the drug is by secretion in the proximal tubule S_2 segment. Therefore, dosing must be reduced in renal insufficiency.

Pharmacodynamics

Inhibition of carbonic anhydrase activity profoundly depresses HCO_3^- reabsorption in the PCT. At its maximal safely administered dosage, 85% of the HCO_3^- reabsorptive capacity of the superficial PCT is inhibited. Some HCO_3^- can still be absorbed at other nephron sites by carbonic anhydrase–independent mechanisms, so the overall effect of maximal acetazolamide dosage is only about 45% inhibition of whole kidney HCO_3^- reabsorption. Nevertheless, carbonic anhydrase inhibition causes significant HCO_3^- losses and hyperchloremic metabolic acidosis (Table 15–2). Because of reduced HCO_3^- in the glomerular filtrate and the fact that HCO_3^- depletion leads to enhanced NaCl reabsorption by the remainder of the nephron, the diuretic efficacy of acetazolamide decreases significantly with use over several days.

Table 15–2. Changes in Urinary Electrolyte Patterns and Body pH in Response to Diuretic Drugs.

Group	Urinary Electrolytes			Body pH
	NaCl	$NaHCO_3$	K^+	
Carbonic anhydrase inhibitors	+	+++	+	–

Loop agents	++++	0	+	+
Thiazides	++	+	+	+
Loop agents plus thiazides	+++++	+	++	+
K^+ -sparing agents	+	(+)	–	–

+, increase; –, decrease; 0, no change.

At present, the major clinical applications of acetazolamide involve carbonic anhydrase–dependent HCO_3^- and fluid transport at sites other than the kidney. The ciliary body of the eye secretes HCO_3^- from the blood into the aqueous humor. Likewise, formation of cerebrospinal fluid by the choroid plexus involves HCO_3^- secretion. Although these processes remove HCO_3^- from the blood (the direction opposite to that in the proximal tubule), they are similarly inhibited by carbonic anhydrase inhibitors.

Clinical Indications & Dosage

GLAUCOMA

(Table 15–3) The reduction of aqueous humor formation by carbonic anhydrase inhibitors decreases the intraocular pressure. This effect is valuable in the management of glaucoma, making it the most common indication for use of carbonic anhydrase inhibitors. Topically active carbonic anhydrase inhibitors (dorzolamide, brinzolamide) are also available. These topical compounds reduce intraocular pressure, but plasma levels are undetectable. Thus, diuretic and systemic metabolic effects are eliminated for the topical agents.

Table 15–3. Carbonic Anhydrase Inhibitors Used Orally in the Treatment of Glaucoma.

Drug	Usual Oral Dosage
Acetazolamide	250 mg 1–4 times daily
Dichlorphenamide	50 mg 1–3 times daily
Methazolamide	50–100 mg 2–3 times daily

URINARY ALKALINIZATION

Uric acid, cystine, and other weak acids are most easily reabsorbed from acidic urine. Therefore, renal excretion of cystine (in cystinuria) and other weak acids can be enhanced by increasing urinary pH with carbonic anhydrase inhibitors. In the absence of continuous HCO_3^- administration, these effects of acetazolamide last only 2–3 days. Prolonged therapy requires HCO_3^- administration.

METABOLIC ALKALOSIS

Metabolic alkalosis is generally treated by correction of abnormalities in total body K^+, intravascular volume, or mineralocorticoid levels. However, when the alkalosis is due to excessive use of diuretics in patients with severe heart failure, replacement of intravascular volume may be contraindicated. In these cases, acetazolamide can be useful in correcting the alkalosis as well as producing a small additional diuresis for correction of volume overload. Acetazolamide can also be used to rapidly correct the metabolic alkalosis that may develop in the setting of respiratory acidosis.

ACUTE MOUNTAIN SICKNESS

Weakness, dizziness, insomnia, headache, and nausea can occur in mountain travelers who rapidly ascend above 3000 m. The symptoms are usually mild and last for a few days. In more serious cases, rapidly progressing pulmonary or cerebral edema can be life-threatening. By decreasing cerebrospinal fluid formation and by decreasing the pH of the cerebrospinal fluid and brain, acetazolamide can increase ventilation and diminish symptoms of mountain sickness.

OTHER USES

Carbonic anhydrase inhibitors have been used as adjuvants in the treatment of epilepsy, in some forms of hypokalemic periodic paralysis, and to increase urinary phosphate excretion during severe hyperphosphatemia.

Toxicity

HYPERCHLOREMIC METABOLIC ACIDOSIS

Acidosis predictably results from chronic reduction of body HCO_3^- stores by carbonic anhydrase inhibitors

(Table 15–2) and limits the diuretic efficacy of these drugs to 2 or 3 days. Unlike the diuretic effect, acidosis persists as long as the drug is continued.

RENAL STONES

Phosphaturia and hypercalciuria occur during the bicarbonaturic response to inhibitors of carbonic anhydrase. Renal excretion of solubilizing factors (eg, citrate) may also decline with chronic use. Calcium salts are relatively insoluble at alkaline pH, which means that the potential for renal stone formation from these salts is enhanced.

RENAL POTASSIUM WASTING

Potassium wasting can occur because Na^+ presented to the collecting tubule is partially reabsorbed, increasing the lumen-negative electrical potential in that segment and enhancing K^+ secretion. This effect can be counteracted by simultaneous administration of potassium chloride.

OTHER TOXICITIES

Drowsiness and paresthesias are common following large doses of acetazolamide. Carbonic anhydrase inhibitors may accumulate in patients with renal failure, leading to nervous system toxicity. Hypersensitivity reactions (fever, rashes, bone marrow suppression, and interstitial nephritis) may also occur.

Contraindications

Carbonic anhydrase inhibitor-induced alkalinization of the urine will decrease urinary excretion of NH_4^+ and may contribute to the development of hyperammonemia and hepatic encephalopathy in patients with cirrhosis.

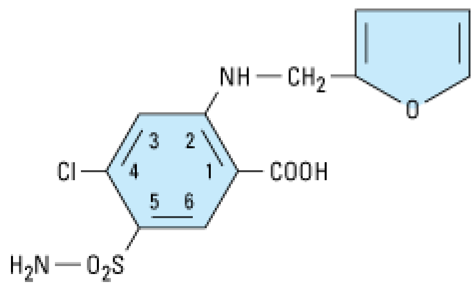
LOOP DIURETICS

Loop diuretics selectively inhibit NaCl reabsorption in the TAL. Due to the large NaCl absorptive capacity of this segment and the fact that the diuretic action of these drugs is not limited by development of acidosis, as is the case with the carbonic anhydrase inhibitors, loop diuretics are among the most efficacious diuretic agents available.

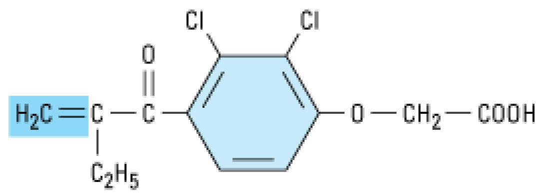
Chemistry

The two prototypical drugs of this group are furosemide and ethacrynic acid. The structures of these diuretics are shown in Figure 15–7. In addition to furosemide, bumetanide and torsemide are sulfonamide loop diuretics.

Figure 15–7.



Furosemide



Ethacrynic acid

Two loop diuretics. The shaded methylene group on ethacrynic acid is reactive and may combine with free sulfhydryl groups.

Ethacrynic acid—not a sulfonamide derivative—is a phenoxyacetic acid derivative containing an adjacent ketone and methylene group (Figure 15–7). The methylene group (shaded) forms an adduct with the free sulfhydryl group of cysteine. The cysteine adduct appears to be an active form of the drug.

Organic mercurial diuretics also inhibit salt transport in the TAL but are no longer used because of their toxicity.

Pharmacokinetics

The loop diuretics are rapidly absorbed. They are eliminated by the kidney by glomerular filtration and tubular secretion. Absorption of oral torsemide is more rapid (1 hour) than that of furosemide (2–3 hours) and is nearly as complete as with intravenous administration. The duration of effect for furosemide is usually 2–3 hours and that of torsemide is 4–6 hours. Half-life depends on renal function. Since loop agents act on the luminal side of the tubule, their diuretic activity correlates with their secretion by the proximal tubule. Reduction in the secretion of loop diuretics may result from simultaneous administration of agents such as NSAIDs or probenecid, which compete for weak acid secretion in the proximal tubule. Metabolites of ethacrynic acid and furosemide have been identified, but it is not known if they have any diuretic activity. Torsemide has at least one active metabolite with a half-life considerably longer than that of the parent compound.

Pharmacodynamics

These drugs inhibit NKCC2, the luminal Na^+ /K^+ /$2Cl^-$ transporter in the thick ascending limb of Henle's loop. By inhibiting this transporter, the loop diuretics reduce the reabsorption of NaCl and also diminish the lumen-positive potential that comes from K^+ recycling (Figure 15–3). This positive potential normally drives divalent cation reabsorption in the loop (Figure 15–3), and by reducing this potential, loop diuretics cause an increase in Mg^{2+} and Ca^{2+} excretion. Prolonged use can cause significant hypomagnesemia in some patients. Since vitamin D-induced intestinal absorption of Ca^{2+} can be increased and Ca^{2+} is actively reabsorbed in the DCT, loop diuretics do not generally cause hypocalcemia. However, in disorders that cause *hypercalcemia* , Ca^{2+} excretion can be usefully enhanced by treatment with loop diuretics combined with saline infusions.

Loop diuretics induce synthesis of renal prostaglandins, which participate in the renal actions of these diuretics. NSAIDs (eg, indomethacin) can interfere with the actions of the loop diuretics by reducing prostaglandin synthesis in the kidney. This interference is minimal in otherwise normal subjects but may be significant in patients with nephrotic syndrome or hepatic cirrhosis.

In addition to their diuretic activity, loop agents have direct effects on blood flow through several vascular beds. Furosemide increases renal blood flow. Both furosemide and ethacrynic acid have also been shown to reduce pulmonary congestion and left ventricular filling pressures in heart failure before a measurable increase in urinary output occurs, and in anephric patients.

Clinical Indications & Dosage

(Table 15–4) The most important indications for the use of the loop diuretics include acute pulmonary edema, other edematous conditions, and acute hypercalcemia. The use of loop diuretics in these conditions is discussed in Clinical Pharmacology. Other indications for loop diuretics include hyperkalemia, acute renal failure, and anion overdose.

Table 15–4. Typical Dosages of Loop Diuretics.

Drug	Total Daily Oral Dose[1]
Bumetanide	0.5–2 mg
Ethacrynic acid	50–200 mg
Furosemide	20–80 mg
Torsemide	5–20 mg

[1] As single dose or in two divided doses.

HYPERKALEMIA

In mild hyperkalemia—or after acute management of severe hyperkalemia by other measures—loop diuretics can significantly enhance urinary excretion of K^+ . This response is enhanced by simultaneous NaCl and water administration.

ACUTE RENAL FAILURE

Loop agents can increase the rate of urine flow and enhance K^+ excretion in acute renal failure. However, they do not shorten the duration of renal failure. If a large pigment load has precipitated acute renal failure (or threatens to), loop agents may help flush out intratubular casts and ameliorate intratubular obstruction. On the other hand, loop agents can theoretically worsen cast formation in myeloma and light chain nephropathy.

ANION OVERDOSE

Loop diuretics are useful in treating toxic ingestions of bromide, fluoride, and iodide, which are reabsorbed in the thick ascending limb. Saline solution must be administered to replace urinary losses of Na^+ and to provide Cl^- , so as to avoid extracellular fluid volume depletion.

Toxicity

HYPOKALEMIC METABOLIC ALKALOSIS

By inhibiting salt reabsorption in the TAL, loop diuretics increase delivery to the collecting duct. Increased delivery leads to increased secretion of K^+ and H^+ by the duct, causing hypokalemic metabolic alkalosis (Table 15–2). This toxicity is a function of the magnitude of the diuresis and can be reversed by K^+ replacement and correction of hypovolemia.

OTOTOXICITY

Loop diuretics occasionally cause dose-related hearing loss that is usually reversible. It is most common in patients who have diminished renal function or who are also receiving other ototoxic agents such as aminoglycoside antibiotics.

HYPERURICEMIA

Loop diuretics can cause hyperuricemia and precipitate attacks of gout. This is caused by hypovolemia-associated enhancement of uric acid reabsorption in the proximal tubule. It may be prevented by using lower doses to avoid development of hypovolemia.

HYPOMAGNESEMIA

Magnesium depletion is a predictable consequence of the chronic use of loop agents and occurs most often in patients with dietary magnesium deficiency. It can be reversed by administration of oral magnesium preparations.

ALLERGIC & OTHER REACTIONS

Except for ethacrynic acid, the loop diuretics are sulfonamides. Therefore skin rash, eosinophilia and, less often, interstitial nephritis are occasional side effects of these drugs. This toxicity usually resolves rapidly after drug withdrawal. Allergic reactions are much less common with ethacrynic acid.

Because Henle's loop is normally responsible for so much salt and water reabsorption, loop diuretics can cause severe dehydration. Hyponatremia is less common than with the thiazides (see below), but patients who increase water intake in response to hypovolemia-induced thirst can become severely hyponatremic with loop agents. Loop agents are sometimes used for their calciuric effect, but hypercalcemia can occur in volume-depleted patients who have another—previously occult—cause for hypercalcemia, such as metastatic breast or squamous cell lung carcinoma.

Contraindications

Furosemide, bumetanide, and torsemide may exhibit allergic cross-reactivity in patients who are sensitive to other sulfonamides but this appears to be very rare. Overzealous use of any diuretic is dangerous in hepatic cirrhosis, borderline renal failure, or heart failure (see below).

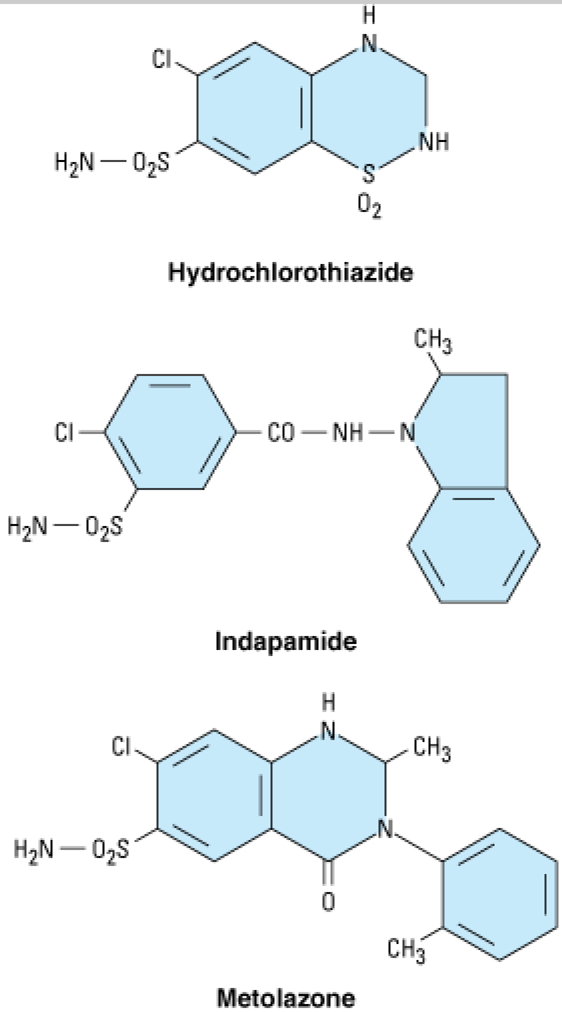
THIAZIDES

The thiazide diuretics emerged from efforts to synthesize more potent carbonic anhydrase inhibitors. It subsequently became clear that the thiazides inhibit NaCl transport predominantly in the DCT. However, some members of this group retain significant carbonic anhydrase inhibitory activity. The prototypical thiazide is hydrochlorothiazide.

Chemistry & Pharmacokinetics

Like carbonic anhydrase inhibitors and many loop diuretics, all of the thiazides have an unsubstituted sulfonamide group (Figure 15–8).

Figure 15–8.



Hydrochlorothiazide and related agents.

All of the thiazides can be administered orally, but there are differences in their metabolism. Chlorothiazide, the parent of the group, is not very lipid-soluble and must be given in relatively large doses. It is the only thiazide available for parenteral administration. Chlorthalidone is slowly absorbed and has a longer duration of action. Although indapamide is excreted primarily by the biliary system, enough of the active form is cleared by the kidney to exert its diuretic effect in the DCT.

All of the thiazides are secreted by the organic acid secretory system in the proximal tubule and compete with the secretion of uric acid by that system. As a result, thiazide use may blunt uric acid secretion and elevate serum uric acid level.

Pharmacodynamics

Thiazides inhibit NaCl reabsorption from the luminal side of epithelial cells in the DCT by blocking the Na^+/Cl^- transporter (NCC). In contrast to the situation in the TAL, where loop diuretics inhibit Ca^{2+} reabsorption, thiazides actually enhance Ca^{2+} reabsorption. This enhancement has been postulated to result from effects in both the proximal and distal convoluted tubules. In the proximal tubule, thiazide-induced volume depletion leads to enhanced Na^+ and passive Ca^{2+} reabsorption. In the DCT, lowering of intracellular Na^+ by thiazide-induced blockade of Na^+ entry enhances Na^+/Ca^{2+} exchange in the basolateral membrane (Figure 15–4), and increases overall reabsorption of Ca^{2+}. While thiazides rarely cause hypercalcemia as the result of this enhanced reabsorption, they can unmask hypercalcemia due to other causes (eg, hyperparathyroidism, carcinoma, sarcoidosis). Thiazides are useful in the treatment of kidney stones caused by hypercalciuria.

The action of thiazides depends in part on renal prostaglandin production. As described above for the loop diuretics, the actions of thiazides can also be inhibited by NSAIDs under certain conditions.

Clinical Indications & Dosage

(Table 15–5) The major indications for thiazide diuretics are (1) hypertension, (2) heart failure, (3) nephrolithiasis due to idiopathic hypercalciuria, and (4) nephrogenic diabetes insipidus. Use of the thiazides in each of these conditions is described in Clinical Pharmacology.

Table 15–5. Thiazides and Related Diuretics.

Drug	Total Daily Oral Dose	Frequency of Administration
Bendroflumethiazide	2.5–10 mg	Single dose
Chlorothiazide	0.5–2 g	Two divided doses
Chlorthalidone[1]	25–50 mg	Single dose

Hydrochlorothiazide	25–100 mg	Single dose
Hydroflumethiazide	12.5–50 mg	Two divided doses
Indapamide[1]	2.5–10 mg	Single dose
Methyclothiazide	2.5–10 mg	Single dose
Metolazone[1]	2.5–10 mg	Single dose
Polythiazide	1–4 mg	Single dose
Quinethazone[1]	25–100 mg	Single dose
Trichlormethiazide	1–4 mg	Single dose

[1] Not a thiazide but a sulfonamide qualitatively similar to the thiazides.

Toxicity

HYPOKALEMIC METABOLIC ALKALOSIS AND HYPERURICEMIA

These toxicities are similar to those observed with loop diuretics (see above and Table 15–2).

IMPAIRED CARBOHYDRATE TOLERANCE

Hyperglycemia may occur in patients who are overtly diabetic or who have even mildly abnormal glucose tolerance tests. The effect is due to both impaired pancreatic release of insulin and diminished tissue utilization of glucose. Hyperglycemia may be partially reversible with correction of hypokalemia.

HYPERLIPIDEMIA

Thiazides cause a 5–15% increase in total serum cholesterol and low-density lipoproteins (LDL). These levels may return toward baseline after prolonged use.

HYPONATREMIA

Hyponatremia is an important adverse effect of thiazide diuretics. It is due to a combination of hypovolemia-induced elevation of ADH, reduction in the diluting capacity of the kidney, and increased thirst. It can be prevented by reducing the dose of the drug or limiting water intake.

ALLERGIC REACTIONS

The thiazides are sulfonamides and share cross-reactivity with other members of this chemical group. Photosensitivity or generalized dermatitis occurs rarely. Serious allergic reactions are extremely rare but do include hemolytic anemia, thrombocytopenia, and acute necrotizing pancreatitis.

OTHER TOXICITIES

Weakness, fatigability, and paresthesias similar to those of carbonic anhydrase inhibitors may occur. Impotence has been reported but is probably related to volume depletion.

Contraindications

Excessive use of any diuretic is dangerous in hepatic cirrhosis, borderline renal failure, or heart failure (see below).

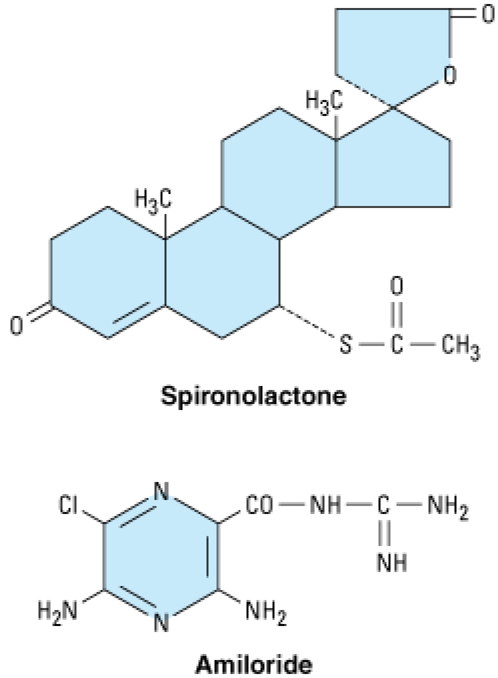
POTASSIUM-SPARING DIURETICS

These diuretics prevent K^+ secretion by antagonizing the effects of aldosterone at the late distal and cortical collecting tubules. Inhibition may occur by direct pharmacologic antagonism of mineralocorticoid receptors (spironolactone, eplerenone) or by inhibition of Na^+ influx through ion channels in the luminal membrane (amiloride, triamterene).

Chemistry & Pharmacokinetics

The structures of spironolactone and amiloride are shown in Figure 15–9.

Figure 15–9.



Potassium-sparing diuretics.

Spironolactone is a synthetic steroid that acts as a competitive antagonist to aldosterone. Onset and duration of its action are determined by the kinetics of the aldosterone response in the target tissue. Substantial inactivation of spironolactone occurs in the liver. Overall, spironolactone has a rather slow onset of action, requiring several days before full therapeutic effect is achieved. Eplerenone is a spironolactone analog with greater selectivity for the aldosterone receptor.

Amiloride and triamterene are direct inhibitors of Na^+ influx in the CCT. Triamterene is metabolized in the liver, but renal excretion is a major route of elimination for the active form and the metabolites. Because triamterene is extensively metabolized, it has a shorter half-life and must be given more frequently than amiloride (which is not metabolized).

Pharmacodynamics

Potassium-sparing diuretics reduce Na^+ absorption in the collecting tubules and ducts. Na^+ absorption (and K^+ secretion) at this site is regulated by aldosterone, as described above. Aldosterone antagonists interfere with this process. Similar effects are observed with respect to H^+ handling by the intercalated cells of the collecting tubule, in part explaining the metabolic acidosis seen with aldosterone antagonists (Table 15–2).

Spironolactone and eplerenone bind to aldosterone receptors and may also reduce the intracellular formation of active metabolites of aldosterone. Amiloride and triamterene do not block the aldosterone receptor but instead directly interfere with Na^+ entry through the epithelial sodium ion channels (ENaC) in the apical membrane of the collecting tubule. Since K^+ secretion is coupled with Na^+ entry in this segment, these agents are also effective potassium-sparing diuretics.

The actions of the aldosterone antagonists depend on renal prostaglandin production. As described above for loop diuretics and thiazides, the actions of K^+ -sparing diuretics can be inhibited by NSAIDs under certain conditions.

Clinical Indications & Dosage

(Table 15–6) Potassium-sparing diuretics are most useful in states of mineralocorticoid excess or hyperaldosteronism (also called aldosteronism), due either to primary hypersecretion (Conn's syndrome, ectopic adrenocorticotropic hormone production) or to secondary hyperaldosteronism (evoked by heart failure, hepatic cirrhosis, nephrotic syndrome, or other conditions associated with diminished effective intravascular volume). Use of diuretics such as thiazides or loop agents can cause or exacerbate volume contraction and may cause secondary hyperaldosteronism. In the setting of enhanced mineralocorticoid secretion and excessive delivery of Na^+ to distal nephron sites, renal K^+ wasting occurs. Potassium-sparing diuretics of either type may be used in this setting to blunt the K^+ secretory response.

Table 15–6. Potassium-Sparing Diuretics and Combination Preparations.

Trade Name	Potassium-Sparing Agent	Hydrochlorothiazide
Aldactazide	Spironolactone 25 mg	50 mg
Aldactone	Spironolactone 25, 50, or 100 mg	. . .
Dyazide	Triamterene 37.5 mg	25 mg

Toxicity

HYPERKALEMIA

Unlike other diuretics, K^+ -sparing diuretics can cause mild, moderate, or even life-threatening hyperkalemia (Table 15–2). The risk of this complication is greatly increased by renal disease (in which maximal K^+ excretion may be reduced) or by the use of other drugs that reduce renin (β blockers, NSAIDs) or angiotensin II activity (angiotensin-converting enzyme inhibitors, angiotensin receptor inhibitors). Since most other diuretic agents lead to K^+ losses, hyperkalemia is more common when K^+ -sparing diuretics are used as the sole diuretic agent, especially in patients with renal insufficiency. With fixed-dosage combinations of K^+ -sparing and thiazide diuretics, the thiazide-induced hypokalemia and metabolic alkalosis are ameliorated. However, owing to variations in the bioavailability of the components of fixed-dosage forms, the thiazide-associated adverse effects often predominate. Therefore, it is generally preferable to adjust the doses of the two drugs separately.

HYPERCHLOREMIC METABOLIC ACIDOSIS

By inhibiting H^+ secretion in parallel with K^+ secretion, the K^+ -sparing diuretics can cause acidosis similar to that seen with type IV renal tubular acidosis.

GYNECOMASTIA

Synthetic steroids may cause endocrine abnormalities by actions on other steroid receptors. Gynecomastia, impotence, and benign prostatic hyperplasia have all been reported with spironolactone. Such effects have not been reported with eplerenone.

ACUTE RENAL FAILURE

The combination of triamterene with indomethacin has been reported to cause acute renal failure. This has not been reported with other K^+ -sparing diuretics.

KIDNEY STONES

Triamterene is only slightly soluble and may precipitate in the urine, causing kidney stones.

Contraindications

These agents can cause severe, even fatal hyperkalemia in susceptible patients. Oral K^+ administration should be discontinued if K^+ -sparing diuretics are administered. Patients with chronic renal insufficiency are especially vulnerable and should rarely be treated with these diuretics. Concomitant use of other agents that blunt the renin-angiotensin system (β blockers or ACE inhibitors) increases the likelihood of hyperkalemia. Patients with liver disease may have impaired metabolism of triamterene and spironolactone, so dosing must be carefully adjusted. Strong CYP3A4 inhibitors (eg, ketoconazole, itraconazole) can markedly increase blood levels of eplerenone.

AGENTS THAT ALTER WATER EXCRETION

Osmotic Diuretics

The proximal tubule and descending limb of Henle's loop are freely permeable to water (Table 15–1). Any osmotically active agent that is filtered by the glomerulus but not reabsorbed causes water to be retained in these segments and promotes a water diuresis. Such agents can be used to reduce intracranial pressure and to promote prompt removal of renal toxins. The prototypic osmotic diuretic is **mannitol**.

Pharmacokinetics

Osmotic diuretics are poorly absorbed, which means that they must be given parenterally. If administered orally, mannitol causes osmotic diarrhea. Mannitol is not metabolized and is excreted by glomerular filtration within 30–60 minutes, without any important tubular reabsorption or secretion.

Pharmacodynamics

Osmotic diuretics have their major effect in the proximal tubule and the descending limb of Henle's loop. Through osmotic effects, they also oppose the action of ADH in the collecting tubule. The presence of a nonreabsorbable solute such as mannitol prevents the normal absorption of water by interposing a countervailing osmotic force. As a result, urine volume increases. The increase in urine flow rate decreases the contact time between fluid and the tubular epithelium, thus reducing Na^+ as well as water reabsorption. The resulting natriuresis is of lesser magnitude than the water diuresis, leading eventually to excessive water loss and hypernatremia.

Clinical Indications & Dosage

TO INCREASE URINE VOLUME

Osmotic diuretics are used to increase water excretion in preference to sodium excretion. This effect can be useful when avid Na^+ retention limits the response to conventional agents. It can be used to maintain urine volume and to prevent anuria that might otherwise result from presentation of large pigment loads to the kidney (eg, from hemolysis or rhabdomyolysis). Some oliguric patients do not respond to osmotic diuretics. Therefore, a test dose of mannitol (12.5 g intravenously) should be given prior to starting a continuous infusion. Mannitol should not be continued unless there is an increase in urine flow rate to more than 50 mL/h during the 3 hours following the test dose. Mannitol (12.5–25 g) can be repeated every 1–2 hours to maintain urine flow rate greater than 100 mL/h. Prolonged use of mannitol is not advised.

REDUCTION OF INTRACRANIAL AND INTRAOCULAR PRESSURE

Osmotic diuretics alter Starling forces so that water leaves cells and reduces intracellular volume. This effect is used to reduce intracranial pressure in neurologic conditions and to reduce intraocular pressure before ophthalmologic procedures. A dose of 1–2 g/kg mannitol is administered intravenously. Intracranial pressure, which must be monitored, should fall in 60–90 minutes.

Toxicity

EXTRACELLULAR VOLUME EXPANSION

Mannitol is rapidly distributed in the extracellular compartment and extracts water from cells. Prior to the diuresis, this leads to expansion of the extracellular volume and hyponatremia. This effect can complicate heart failure and may produce florid pulmonary edema. Headache, nausea, and vomiting are commonly observed in patients treated with osmotic diuretics.

DEHYDRATION, HYPERKALEMIA, AND HYPERNATREMIA

Excessive use of mannitol without adequate water replacement can ultimately lead to severe dehydration, free water losses, and hypernatremia. As water is extracted from cells, intracellular K^+ concentration rises, leading to cellular losses and hyperkalemia. These complications can be avoided by careful attention to serum ion composition and fluid balance.

Antidiuretic Hormone (ADH) Agonists

Vasopressin and **desmopressin** are used in the treatment of central diabetes insipidus. They are discussed in Chapter 37. Their renal action appears to be mediated primarily via V_2 receptors although V_{1a} receptors may also be involved.

Antidiuretic Hormone (ADH) Antagonists

A variety of medical conditions, including congestive heart failure and syndrome of inappropriate ADH (SIADH), cause water retention as the result of ADH excess. Dangerous hyponatremia can result. Several nonpeptide ADH receptor antagonists (vaptans) have been studied, with encouraging clinical results, but only **conivaptan** has been approved for use. Two nonselective agents, lithium and demeclocycline (a tetracycline antimicrobial drug), also have anti-ADH effects.

Pharmacokinetics

Conivaptan, lithium, and demeclocycline are orally active. Conivaptan and demeclocycline have half-lives of 5–10 hours. Lithium (discussed in detail in Chapter 29) is never used as an ADH antagonist.

Pharmacodynamics

Antidiuretic hormone antagonists inhibit the effects of ADH in the collecting tubule. Conivaptan is a pharmacologic antagonist at V_{1a} and V_2 receptors. Both lithium and demeclocycline appear to reduce the formation of cyclic adenosine monophospate (cAMP) in response to ADH and also to interfere with the actions of cAMP in the collecting tubule cells, but the mechanisms of these effects is not known.

Clinical Indications & Dosage

SYNDROME OF INAPPROPRIATE ADH SECRETION (SIADH)

Antidiuretic hormone antagonists are used to manage SIADH when water restriction has failed to correct the abnormality. This generally occurs in the outpatient setting, where water restriction cannot be enforced, or in the hospital when large quantities of intravenous fluid are needed for other purposes. Lithium carbonate has been used to treat this syndrome, but the response is unpredictable. Demeclocycline, in dosages of 600–1200 mg/d, yields a more predictable result and is less toxic. Appropriate plasma levels (2 mcg/mL) should be maintained by monitoring. Unlike demeclocycline, conivaptan is administered by IV injection, so it is not suitable for chronic use in outpatients.

OTHER CAUSES OF ELEVATED ANTIDIURETIC HORMONE (ADH)

Antidiuretic hormone is also elevated in response to diminished effective circulating blood volume, as often occurs in congestive heart failure. When treatment by volume replacement is not desirable, hyponatremia may result. As for SIADH, water restriction is the treatment of choice, but if it is not successful, demeclocycline or conivaptan may be used.

Toxicity

NEPHROGENIC DIABETES INSIPIDUS

If serum Na^+ is not monitored closely, ADH antagonists can cause severe hypernatremia and nephrogenic diabetes insipidus. If lithium is being used for a psychiatric disorder, nephrogenic diabetes insipidus can be treated with a thiazide diuretic or amiloride (see below).

RENAL FAILURE

Both lithium and demeclocycline have been reported to cause acute renal failure. Long-term lithium therapy may also cause chronic interstitial nephritis.

OTHER

Adverse effects associated with lithium therapy are discussed in Chapter 29. Demeclocycline should be avoided in patients with liver disease (see Chapter 44) and in children younger than 12 years.

Diuretic Combinations

LOOP AGENTS & THIAZIDES

Some patients are refractory to the usual dose of loop diuretics or become refractory after an initial response. Since these agents have a short half-life (2–6 hrs), refractoriness may be due to an excessive interval between doses. Renal Na^+ retention may be greatly increased during the time period when the drug is no longer active. After the dosing interval for loop agents is minimized or the dose is maximized, the use of two drugs acting at different nephron sites may exhibit dramatic synergy. Loop agents and thiazides in combination will often produce diuresis when neither agent acting alone is even minimally effective. There are several reasons for this phenomenon. First, salt and water reabsorption in either the TAL or the DCT can increase when the other is blocked. Inhibition of both can therefore produce more than an additive diuretic response. Second, thiazide diuretics often produce a mild natriuresis in the proximal tubule that is usually masked by increased reabsorption in the TAL. The combination of loop diuretics and thiazides can therefore block Na^+ reabsorption, to some extent, from all three segments.

Metolazone is the usual thiazide-like drug used in patients refractory to loop agents alone, but it is likely that other thiazides would be as effective as metolazone. Moreover, metolazone is available only in an oral preparation, while chlorothiazide can be given parenterally.

The combination of loop diuretics and thiazides can mobilize large amounts of fluid, even in patients who have not responded to single agents. Therefore, close hemodynamic monitoring is essential. Routine outpatient use is not recommended. Furthermore, K^+ -wasting is extremely common and may require parenteral K^+ administration with careful monitoring of fluid and electrolyte status.

POTASSIUM-SPARING DIURETICS & LOOP AGENTS OR THIAZIDES

Hypokalemia eventually develops in many patients who are placed on loop diuretics or thiazides. This can usually be managed with dietary NaCl restriction or with dietary KCl supplements. When hypokalemia cannot be managed in this way, the addition of a K^+ -sparing diuretic can significantly lower K^+ excretion. While this approach is generally safe, it should be avoided in patients with renal insufficiency and in those receiving angiotensin antagonists such as ACE inhibitors, in whom life-threatening hyperkalemia can develop in response to K^+ -sparing diuretics.

CLINICAL PHARMACOLOGY OF DIURETIC AGENTS

A summary of the effects of diuretics on urinary electrolyte excretion is shown in Table 15–2.

Edematous States

A common reason for diuretic use is for reduction of peripheral or pulmonary edema that has accumulated as a result of cardiac, renal, or vascular diseases that reduce blood delivery to the kidney. This reduction is sensed as insufficient "effective" arterial blood volume and leads to salt and water retention and edema formation. Judicious use of diuretics can mobilize this interstitial edema without significant reductions in plasma volume. However, excessive diuretic therapy may lead to further compromise of the effective arterial blood volume with reduction in perfusion of vital organs. Therefore, the use of diuretics to mobilize edema requires careful monitoring of the patient's hemodynamic status and an understanding of the pathophysiology of the underlying illness.

HEART FAILURE

When cardiac output is reduced by heart failure, the resultant changes in blood pressure and blood flow to the kidney are sensed as hypovolemia and lead to renal retention of salt and water. This physiologic response initially increases intravascular volume and venous return to the heart and may partially restore the cardiac output toward normal (see Chapter 13).

If the underlying disease causes cardiac output to deteriorate despite expansion of plasma volume, the kidney continues to retain salt and water, which then leaks from the vasculature and becomes interstitial or pulmonary edema. At this point, diuretic use becomes necessary to reduce the accumulation of edema, particularly in the lungs. Reduction of pulmonary vascular congestion with diuretics may actually improve oxygenation and thereby improve myocardial function. Reduction of preload can reduce the size of the heart, allowing it to work at a more efficient fiber length. Edema associated with heart failure is generally managed with loop diuretics. In some instances, salt and water retention may become so severe that a combination of thiazides and loop diuretics is necessary.

In treating the heart failure patient with diuretics, it must always be remembered that cardiac output in these patients is being maintained in part by high filling pressures and that excessive use of diuretics may diminish venous return and further impair cardiac output. This is especially critical in right ventricular heart failure. Systemic, rather than pulmonary vascular, congestion is the hallmark of this disorder. Diuretic-induced volume contraction will predictably reduce venous return and can severely compromise cardiac output if left ventricular filling pressure is reduced below 15 mm Hg (see Chapter 13).

Diuretic-induced metabolic alkalosis is another adverse effect that may further compromise cardiac function. While this complication can be treated with replacement of K^+ and restoration of intravascular volume with saline, severe heart failure may preclude the use of saline even in patients who have received excessive diuretic therapy. In these cases, adjunctive use of acetazolamide will help correct the alkalosis.

Another serious toxicity of diuretic use, particularly in the cardiac patient, is hypokalemia. Hypokalemia can exacerbate underlying cardiac arrhythmias and contribute to digitalis toxicity. This can usually be avoided by having the patient reduce Na^+ intake, thus decreasing Na^+ delivery to the K^+ -secreting collecting tubule. Patients who are noncompliant with a low Na^+ diet must take oral KCl supplements or a K^+ -sparing diuretic.

KIDNEY DISEASE

A variety of renal diseases interfere with the kidney's critical role in volume homeostasis. Although some renal disorders cause salt wasting, most kidney diseases cause retention of salt and water. When loss of renal function is severe, diuretic agents are of little benefit, because there is insufficient glomerular filtration to sustain a natriuretic response. However, a large number of patients with milder degrees of renal insufficiency can be treated with diuretics when they retain sodium.

Many glomerular diseases, such as those associated with diabetes mellitus or systemic lupus erythematosus, exhibit renal retention of salt and water. The cause of this sodium retention is not precisely known, but it probably involves disordered regulation of the renal microcirculation and tubular function through release of vasoconstrictors, prostaglandins, cytokines, and other mediators. When edema or hypertension develops in these patients, diuretic therapy can be very effective. If heart failure is also present, see the warnings mentioned above.

Certain forms of renal disease, particularly diabetic nephropathy, are frequently associated with development of hyperkalemia at a relatively early stage of renal failure. In these cases, a thiazide or loop diuretic will enhance K^+ excretion by increasing delivery of salt to the K^+ -secreting collecting tubule.

Patients with renal diseases leading to the nephrotic syndrome often present complex problems in volume management. These patients may exhibit fluid retention in the form of ascites or edema but have reduced plasma volume due to reduced plasma oncotic pressures. This is very often the case in patients with "minimal change" nephropathy. In these patients, diuretic use may cause further reductions in plasma volume that can impair glomerular filtration rate and may lead to orthostatic hypotension. Most other causes of nephrotic syndrome are associated with primary retention of salt and water by the kidney, leading to expanded plasma volume and hypertension despite the low plasma oncotic pressure. In these cases, diuretic therapy may be beneficial in controlling the volume-dependent component of hypertension.

In choosing a diuretic for the patient with kidney disease, there are a number of important limitations. Acetazolamide must usually be avoided because it can exacerbate acidosis. Potassium-sparing diuretics may cause hyperkalemia. Thiazide diuretics are generally ineffective when glomerular filtration rate falls below 30 mL/min. Thus, loop diuretics are often the best choice in treating edema associated with kidney failure. Lastly, although excessive use of diuretics can impair renal function in all patients, the consequences are more serious in those with underlying renal disease.

HEPATIC CIRRHOSIS

Liver disease is often associated with edema and ascites in conjunction with elevated portal hydrostatic pressures and reduced plasma oncotic pressures. Mechanisms for retention of Na^+ by the kidney in this setting include diminished renal perfusion (from systemic vascular alterations), diminished plasma volume (due to ascites formation), and diminished oncotic pressure (hypoalbuminemia). In addition, there may be primary Na^+ retention due to elevated plasma aldosterone levels.

When ascites and edema become severe, diuretic therapy can be very useful. However, cirrhotic patients are often resistant to loop diuretics because of decreased secretion of the drug into the tubular fluid and because of high aldosterone levels. In contrast, cirrhotic edema is unusually responsive to spironolactone and eplerenone. The combination of loop diuretics and an aldosterone receptor antagonist may be useful in some patients.

It is important to note that, even more than in heart failure, overly aggressive use of diuretics in this setting can be disastrous. Vigorous diuretic therapy can cause marked depletion of intravascular volume, hypokalemia, and metabolic alkalosis. Hepatorenal syndrome and hepatic encephalopathy are the unfortunate consequences of excessive diuretic use in the cirrhotic patient.

IDIOPATHIC EDEMA

Despite intensive study, the pathophysiology of this disorder (fluctuating salt retention and edema) still remains obscure. Some studies, but not all, suggest that intermittent diuretic use may actually contribute to the syndrome. Idiopathic edema should probably be managed with moderate salt restriction alone if possible.

Nonedematous States

HYPERTENSION

The diuretic and mild vasodilator actions of the thiazides are useful in treating virtually all patients with essential hypertension, and may be sufficient in many. Loop diuretics are usually reserved for patients with renal insufficiency or heart failure. Moderate restriction of dietary Na^+ intake (60–100 mEq/d) has been shown to potentiate the effects of diuretics in essential hypertension and to lessen renal K^+ wasting.

A recent very large study (over 30,000 participants) has shown that inexpensive diuretics like thiazides result in similar or superior outcomes to those found with ACE inhibitor or calcium channel blocker therapy. This important result reinforces the importance of thiazide therapy in hypertension.

Although diuretics are often successful as monotherapy, they also play an important role in patients who require multiple drugs to control blood pressure. Diuretics enhance the efficacy of many agents, particularly the ACE inhibitors. Patients being treated with powerful vasodilators such as hydralazine or minoxidil usually require simultaneous diuretics because the vasodilators cause significant salt and water retention.

NEPHROLITHIASIS

Approximately two thirds of kidney stones contain Ca^{2+} phosphate or Ca^{2+} oxalate. Many patients with such stones exhibit a defect in proximal tubular Ca^{2+} reabsorption that causes hypercalciuria. This can be treated with thiazide diuretics, which enhance Ca^{2+} reabsorption in the distal convoluted tubule and thus reduce the urinary Ca^{2+} concentration. Salt intake must be reduced in this setting, as excess dietary NaCl will overwhelm the hypocalciuric effect of thiazides. Calcium stones may also be caused by increased intestinal absorption of Ca^{2+} , or they may be idiopathic. In these situations, thiazides are also effective, but should be used as adjunctive therapy with decreased Ca^{2+} intake and other measures.

HYPERCALCEMIA

Hypercalcemia can be a medical emergency. Because loop diuretics reduce Ca^{2+} reabsorption significantly, they can be quite effective in promoting Ca^{2+} diuresis. However, loop diuretics alone can cause marked volume contraction. If this occurs, loop diuretics are ineffective (and potentially counterproductive) because Ca^{2+} reabsorption in the proximal tubule would be enhanced. Thus, saline must be administered simultaneously with loop diuretics if an effective Ca^{2+} diuresis is to be maintained. The usual approach is to infuse normal saline and furosemide (80–120 mg) intravenously. Once the diuresis begins, the rate of saline infusion can be matched with the urine flow rate to avoid volume depletion. Potassium chloride may be added to the saline infusion as needed.

DIABETES INSIPIDUS

Diabetes insipidus is due either to deficient production of ADH (neurogenic or central diabetes insipidus) or inadequate responsiveness to ADH (nephrogenic diabetes insipidus). Administration of supplementary ADH or one of its analogs is only effective in central diabetes insipidus. Thiazide diuretics can reduce polyuria and polydipsia in both types of diabetes insipidus. This seemingly paradoxic beneficial effect is mediated through plasma volume reduction, with an associated fall in glomerular filtration rate, enhanced proximal reabsorption of NaCl and water, and decreased delivery of fluid to the downstream diluting segments. Thus, the maximum volume of dilute urine that can be produced is lowered and thiazides can significantly reduce urine flow in the polyuric patient. Dietary sodium restriction can potentiate the beneficial effects of thiazides on urine volume in this setting. Lithium (Li^+), used in the treatment of manic-depressive disorder, is a common cause of nephrogenic diabetes insipidus and thiazide diuretics have been found to be helpful in treating it. Serum Li^+ levels must be carefully monitored in these patients, because diuretics may *reduce* renal clearance of Li^+ and raise plasma Li^+ levels into the toxic range (see Chapter 29). Lithium-induced polyuria can also be partially reversed by amiloride, which blocks Li^+ entry into collecting duct cells, much as it blocks Na^+ entry.

PREPARATIONS AVAILABLE

Acetazolamide (generic, Diamox)

Oral: 125, 250 mg tablets

Oral sustained-release: 500 mg capsules

Parenteral: 500 mg powder for injection

Amiloride (generic, Midamor, combination drugs)

Oral: 5 mg tablets

Bendroflumethiazide (Naturetin, combination drugs)

Oral: 5, 10 mg tablets

Brinzolamide (Azopt) (For ocular conditions)

Ophthalmic: 1% suspension

Bumetanide (generic, Bumex)

Oral: 0.5, 1, 2 mg tablets

Parenteral: 0.5 mg/2 mL ampule for IV or IM injection

Chlorothiazide (generic, Diuril)

Oral: 250, 500 mg tablets; 250 mg/5 mL oral suspension

Parenteral: 500 mg for injection

Chlorthalidone (generic, Hygroton, Thalitone, combination drugs)

Oral: 25, 50, 100 mg tablets

Conivaptan (Vaprisol)

Parenteral: 5 mg/mL for IV injection

Demeclocycline (Declomycin)

Oral: 150 mg tablets and capsules; 300 mg tablets

Dichlorphenamide (Daranide)

Oral: 50 mg tablets

Dorzolamide (Trusopt) (For ocular conditions)

Ophthalmic: 2% solution

Eplerenone (Inspra)

Oral: 25, 50 mg tablets

Ethacrynic acid (Edecrin)

Oral: 25, 50 mg tablets

Parenteral: 50 mg IV injection

Furosemide (generic, Lasix, others)

Oral: 20, 40, 80 mg tablets; 8, 10 mg/mL oral solutions

Parenteral: 10 mg/mL for IM or IV injection

Hydrochlorothiazide (generic, Esidrix, Hydro-DIURIL, combination drugs)

Oral: 12.5 mg capsules; 25, 50, 100 mg tablets; 10, 100 mg/mL solution

Hydroflumethiazide (generic, Saluron)

Oral: 50 mg tablets

Indapamide (generic, Lozol)

Oral: 1.25, 2.5 mg tablets

Mannitol (generic, Osmitrol)

Parenteral: 5, 10, 15, 20, for injection

Methazolamide (generic, Neptazane) (For ocular conditions)

Oral: 25, 50 mg tablets

Methyclothiazide (generic, Aquatensen, Enduron)

Oral: 2.5, 5 mg tablets

Metolazone (Mykrox, Zaroxolyn) (Note: Bioavailability of Mykrox is greater than that of Zaroxolyn.)

Oral: 0.5 (Mykrox); 2.5, 5, 10 mg (Zaroxolyn) tablets

Polythiazide (Renese, combination drugs)

Oral: 1, 2, 4 mg tablets

Quinethazone (Hydromox)

Oral: 50 mg tablets

Spironolactone (generic, Aldactone)

Oral: 25, 50, 100 mg tablets

Torsemide (Demadex)

Oral: 5, 10, 20, 100 mg tablets

Parenteral: 10 mg/mL for injection

Triamterene (Dyrenium)

Oral: 50, 100 mg capsules

Trichlormethiazide (generic, Diurese, Naqua, others)

Oral: 2, 4 mg tablets

HISTAMINE, SEROTONIN, & THE ERGOT ALKALOIDS: INTRODUCTION

Histamine and serotonin (5-hydroxytryptamine) are biologically active amines that function as neurotransmitters and are found in non-neural tissues, have complex physiologic and pathologic effects through multiple receptor subtypes, and are often released locally. Together with endogenous peptides (see Chapter 17), prostaglandins and leukotrienes (see Chapter 18), and cytokines (see Chapter 56), they are sometimes called *autacoids* (Greek, "self-remedy") or local hormones in recognition of these properties.

Because of their broad and largely undesirable effects, neither histamine nor serotonin has any clinical application in the treatment of disease. However, compounds that *selectively* activate certain receptor subtypes or selectively antagonize the actions of these amines are of considerable clinical usefulness. This chapter therefore emphasizes the basic pharmacology of the agonist amines and the clinical pharmacology of the more selective agonist and antagonist drugs. The ergot alkaloids, compounds with partial agonist activity at serotonin and several other receptors, are discussed at the end of the chapter.

HISTAMINE

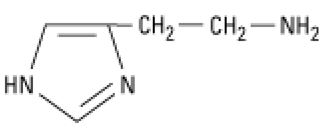
Histamine was synthesized in 1907 and later isolated from mammalian tissues. Early hypotheses concerning the possible physiologic roles of tissue histamine were based on similarities between the effects of intravenously administered histamine and the symptoms of anaphylactic shock and tissue injury. Marked species variation is observed, but in humans histamine is an important mediator of immediate allergic and inflammatory reactions, although it plays only a modest role in anaphylaxis. Histamine plays an important role in gastric acid secretion (see Chapter 63) and functions as a neurotransmitter and neuromodulator (see Chapters 6, 21). Newer evidence indicates that histamine also plays a role in chemotaxis of white blood cells.

BASIC PHARMACOLOGY OF HISTAMINE

Chemistry & Pharmacokinetics

Histamine occurs in plants as well as in animal tissues and is a component of some venoms and stinging secretions.

Histamine is formed by decarboxylation of the amino acid *l* -histidine, a reaction catalyzed in mammalian tissues by the enzyme histidine decarboxylase. Once formed, histamine is either stored or rapidly inactivated. Very little histamine is excreted unchanged. The major metabolic pathways involve conversion to *N*-methylhistamine, methylimidazoleacetic acid, and imidazoleacetic acid (IAA). Certain neoplasms (systemic mastocytosis, urticaria pigmentosa, gastric carcinoid, and occasionally myelogenous leukemia) are associated with increased numbers of mast cells or basophils and with increased excretion of histamine and its metabolites.



Histamine

Most tissue histamine is sequestered and bound in granules (vesicles) in mast cells or basophils; the histamine content of many tissues is directly related to their mast cell content. The bound form of histamine is biologically inactive, but many stimuli, as noted below, can trigger the release of mast cell histamine, allowing the free amine to exert its actions on surrounding tissues. Mast cells are especially rich at sites of potential tissue injury—nose, mouth, and feet; internal body surfaces; and blood vessels, particularly at pressure points and bifurcations.

Non-mast cell histamine is found in several tissues, including the brain, where it functions as a neurotransmitter. Endogenous neurotransmitter histamine may play a role in many brain functions such as neuroendocrine control, cardiovascular regulation, thermal and body weight regulation, and arousal (see Chapter 21).

A second important nonneuronal site of histamine storage and release is the enterochromaffin-like (ECL) cells of the fundus of the stomach. ECL cells release histamine, one of the primary gastric acid secretagogues, to activate the acid-producing parietal cells of the mucosa (see Chapter 63).

Storage & Release of Histamine

The stores of histamine in mast cells can be released through several mechanisms.

IMMUNOLOGIC RELEASE

Immunologic processes account for the most important pathophysiologic mechanism of mast cell and basophil histamine release. These cells, if sensitized by IgE antibodies attached to their surface membranes, degranulate "explosively" when exposed to the appropriate antigen (see Figure 56–5, effector phase). This type of release also requires energy and calcium. Degranulation leads to the simultaneous release of histamine, adenosine triphosphate (ATP), and other mediators that are stored together in the granules. Histamine released by this mechanism is a mediator in immediate (type I) allergic reactions. Substances released during IgG- or IgM-mediated immune reactions that activate the complement cascade also release histamine from mast cells and basophils.

By a negative feedback control mechanism mediated by H_2 receptors, histamine appears to modulate its own release and that of other mediators from sensitized mast cells in some tissues. In humans, mast cells in skin and basophils show this negative feedback mechanism; lung mast cells do not. Thus, histamine may act to limit the intensity of the allergic reaction in the skin and blood.

Endogenous histamine has a modulating role in a variety of inflammatory and immune responses. Upon injury to a tissue, released histamine causes local vasodilation and leakage of plasma containing mediators of acute inflammation (complement, C-reactive protein), and antibodies. Histamine has an active chemotactic attraction for inflammatory cells (neutrophils, eosinophils, basophils, monocytes, and lymphocytes). Histamine inhibits the release of lysosome contents and several T- and B-lymphocyte functions. Most of these actions are mediated by H_2 or H_4 receptors. Release of peptides from nerves in response to inflammation is also probably modulated by histamine, in this case acting through presynaptic H_3 receptors.

CHEMICAL AND MECHANICAL RELEASE

Certain amines, including drugs such as morphine and tubocurarine, can displace histamine from the heparin-protein complex within cells. This type of release does not require energy and is not associated with mast cell injury or degranulation. Loss of granules from the mast cell also releases histamine, since sodium ions in the extracellular fluid rapidly displace the amine from the complex. Chemical and mechanical mast cell injury causes degranulation and histamine release. Compound 48/80, an experimental drug, selectively releases histamine from tissue mast cells by an exocytotic degranulation process requiring energy and calcium.

Pharmacodynamics

MECHANISM OF ACTION

Histamine exerts its biologic actions by combining with specific cellular receptors located on the surface membrane. The four different histamine receptors thus far characterized are designated H_1 –H_4 and are described in Table 16–1. Unlike the other amine transmitter receptors discussed previously, no subfamilies have been found within these major types, although different splice variants of several receptor types have been found.

Table 16–1. Histamine Receptor Subtypes.

Receptor Subtype	Distribution	Postreceptor Mechanism	Partially Selective Agonists	Partially Selective Antagonists
H_1	Smooth muscle, endothelium, brain	G_q , ↑IP_3 , DAG	Histaprodifen	Mepyramine, triprolidine
H_2	Gastric mucosa, cardiac muscle, mast cells, brain	G_s , ↑cAMP	Amthamine	Ranitidine, tiotidine
H_3	Presynaptic: brain, myenteric plexus, other neurons	G_i , ↓cAMP	*R* -α-Methylhistamine, imetit, immepip	Thioperamide, iodophenpropit, clobenpropit[1]
H_4				

Eosinophils, neutrophils, CD4 T cells

G_i , ↓cAMP

Clobenpropit, imetit, clozapine

Thioperamide

---

[1] Inverse agonist.

All four receptor types have been cloned and belong to the large superfamily of receptors having seven membrane-spanning regions and coupled with G proteins (GPCR). The structures of the H_1 and H_2 receptors differ significantly and appear to be more closely related to muscarinic and 5-HT_1 receptors, respectively, than to each other. The H_4 receptor has about 40% homology with the H_3 receptor but does not seem to be closely related to any other histamine receptor. All four histamine receptors have been shown to have constitutive activity in some systems; thus, some "antihistamines" previously considered to be traditional pharmacologic antagonists must now be considered to be possible inverse agonists (Chapter 2). Indeed, many first- and second-generation H_1 blockers (see below) are probably inverse agonists. Furthermore, a single molecule may be an agonist at one histamine receptor and an antagonist at another. For example, clobenprobit, an agonist at H_4 receptors, is an antagonist or inverse agonist at H_3 receptors (Table 16–1).

In the brain, H_1 and H_2 receptors are located on postsynaptic membranes, whereas H_3 receptors are predominantly presynaptic. Activation of H_1 receptors, which are present in endothelium, smooth muscle cells, and nerve endings, usually elicits an increase in phosphoinositol hydrolysis and an increase in intracellular calcium. Activation of H_2 receptors, present in gastric mucosa, cardiac muscle cells, and some immune cells, increases intracellular cyclic adenosine monophosphate (cAMP) via G_s . Like the β_2 adrenoceptor, under certain circumstances the H_2 receptor may couple to G_q , activating the IP_3 -DAG (inositol 1,4,5-trisphosphate-diacylglycerol) cascade. Activation of H_3 receptors decreases transmitter release from histaminergic and other neurons, probably mediated by a decrease in calcium influx through N-type calcium channels in nerve endings. H_4 receptors are mainly found on leukocytes in the bone marrow and circulating blood. H_4 receptors appear to have very important chemotactic effects on eosinophils and mast cells. In this role, they may play an important part in inflammation and allergy. They may also modulate production of these cell types and they may mediate, in part, the previously recognized effects of histamine on cytokine production.

TISSUE AND ORGAN SYSTEM EFFECTS OF HISTAMINE

Histamine exerts powerful effects on smooth and cardiac muscle, on certain endothelial and nerve cells, and on the secretory cells of the stomach. However, sensitivity to histamine varies greatly among species. Guinea pigs are exquisitely sensitive, humans, dogs, and cats somewhat less so, and mice and rats very much less so.

Nervous System

Histamine is a powerful stimulant of sensory nerve endings, especially those mediating pain and itching. This H_1 -mediated effect is an important component of the urticarial response and reactions to insect and nettle stings. Some evidence suggests that local high concentrations can also depolarize efferent (axonal) nerve endings (see The "Triple Response," below). In the mouse, and probably in humans, respiratory neurons signaling inspiration and expiration are modulated by H_1 receptors. Presynaptic H_3 receptors play important roles in modulating transmitter release in the nervous system. H_3 agonists reduce the release of acetylcholine, amine, and peptide transmitters in various areas of the brain and in peripheral nerves.

Cardiovascular System

In humans, injection or infusion of histamine causes a decrease in systolic and diastolic blood pressure and an increase in heart rate. The blood pressure changes are caused by the direct vasodilator action of histamine on arterioles and precapillary sphincters; the increase in heart rate involves both stimulatory actions of histamine on the heart and a reflex tachycardia. Flushing, a sense of warmth, and headache may also occur during histamine administration, consistent with the vasodilation. Vasodilation elicited by small doses of histamine is caused by H_1 -receptor activation and is mediated primarily by release of nitric oxide from the endothelium (see Chapter 19). The decrease in blood pressure is usually accompanied by a reflex tachycardia. Higher doses of histamine activate the H_2 -mediated cAMP process of vasodilation and direct cardiac stimulation. In humans, the cardiovascular effects of small doses of histamine can usually be antagonized by H_1 -receptor antagonists alone.

Histamine-induced edema results from the action of the amine on H_1 receptors in the vessels of the microcirculation, especially the postcapillary vessels. The effect is associated with the separation of the endothelial cells, which permits the transudation of fluid and molecules as large as small proteins into the perivascular tissue. This effect is responsible for the urticaria (hives) that signals the release of histamine in the skin. Studies of endothelial cells suggest that actin and myosin within these cells contract, resulting in separation of the endothelial cells and increased permeability.

Direct cardiac effects of histamine include both increased contractility and increased pacemaker rate. These effects are mediated chiefly by H_2 receptors. In human atrial muscle, histamine can also decrease contractility; this effect is mediated by H_1 receptors. The physiologic significance of these cardiac actions is not clear. Some of the cardiovascular signs and symptoms of anaphylaxis are due to released histamine, though several other mediators are involved and appear to be more important than histamine in humans.

Bronchiolar Smooth Muscle

In both humans and guinea pigs, histamine causes bronchoconstriction mediated by H_1 receptors. In the guinea pig, this effect is the cause of death from histamine toxicity, but in humans with normal airways, bronchoconstriction following small doses of histamine is not marked. However, patients with asthma are very sensitive to histamine. The bronchoconstriction induced in these patients probably represents a hyperactive neural response, since such patients also respond excessively to many other stimuli, and the response to histamine can be blocked by autonomic blocking drugs such as ganglionic blocking agents as well as by H_1 -receptor antagonists (see Chapter 20). Although methacholine provocation is more commonly used, tests using increasing doses of inhaled histamine have been used in the diagnosis of bronchial hyperreactivity in patients with suspected asthma or cystic fibrosis. Such individuals may be 100- to 1000-fold more sensitive to histamine (and methacholine) than are normal subjects. Curiously, a few species (eg, rabbit) respond to histamine with broncho*dilation* , reflecting the dominance of the H_2 receptor in their airways.

Gastrointestinal Tract Smooth Muscle

Histamine causes contraction of intestinal smooth muscle, and histamine-induced contraction of guinea pig ileum is a standard bioassay for this amine. The human gut is not as sensitive as that of the guinea pig, but large doses of histamine may cause diarrhea, partly as a result of this effect. This action of histamine is mediated by H_1 receptors.

Other Smooth Muscle Organs

In humans, histamine generally has insignificant effects on the smooth muscle of the eye and genitourinary tract. However, pregnant women suffering anaphylactic reactions may abort as a result of histamine-induced contractions, and in some species the sensitivity of the uterus is sufficient to form the basis for a bioassay.

Secretory Tissue

Histamine has long been recognized as a powerful stimulant of gastric acid secretion and, to a lesser extent, of gastric pepsin and intrinsic factor production. The effect is caused by activation of H_2 receptors on gastric parietal cells and is associated with increased adenylyl cyclase activity, cAMP concentration, and intracellular Ca^{2+} concentration. Other stimulants of gastric acid secretion such as acetylcholine and gastrin do not increase cAMP even though their maximal effects on acid output can be reduced—but not abolished—by H_2 -receptor antagonists. These actions are discussed in detail in Chapter 63. Histamine also stimulates secretion in the small and large intestine. In contrast, H_3 -selective histamine agonists *inhibit* acid secretion stimulated by food or pentagastrin in several species.

Histamine has much smaller effects on the activity of other glandular tissue at ordinary concentrations. Very high concentrations can cause adrenal medullary discharge.

Metabolic Effects

Recent studies of H_3 -receptor knockout mice demonstrate that absence of this receptor results in animals with increased food intake, decreased energy expenditure, and obesity. They also show insulin resistance and increased blood levels of leptin and insulin. It is not yet known whether the H_3 receptor has a similar role in humans.

The "Triple Response"

Intradermal injection of histamine causes a characteristic red spot, edema, and flare response that was first described over 60 years ago. The effect involves three separate cell types: smooth muscle in the microcirculation, capillary or venular endothelium, and sensory nerve endings. At the site of injection, a reddening appears owing to dilation of small vessels, followed soon by an edematous wheal at the injection site and a red irregular flare surrounding the wheal. The flare is said to be caused by an axon reflex. A sensation of itching may accompany these effects.

Similar local effects may be produced by injecting histamine liberators (compound 48/80, morphine, etc) intradermally or by applying the appropriate antigens to the skin of a sensitized person. Although most of these local effects can be blocked by prior administration of an H_1 -receptor-blocking agent, H_2 and H_3 receptors may also be involved.

Other Effects Possibly Mediated by Histamine Receptors

In addition to the local stimulation of peripheral pain nerve endings via H_3 and H_1 receptors, histamine may play a role in nociception in the central nervous system. Burimamide, an early candidate for H_2 blocking action, and newer analogs with no effect on H_1 , H_2 , or H_3 receptors, have been shown to have significant analgesic action in rodents when administered into the central nervous system. The analgesia is said to be comparable to that produced by opioids, but tolerance, respiratory depression, and constipation have not been reported. Although the mechanism of this action is not known, these compounds may represent an important new class of analgesics.

Other Histamine Agonists

Small substitutions on the imidazole ring of histamine significantly modify the selectivity of the compounds for the histamine receptor subtypes. Some of these are listed in Table 16–1.

CLINICAL PHARMACOLOGY OF HISTAMINE

Clinical Uses

In pulmonary function laboratories, histamine aerosol has been used as a provocative test of bronchial hyperreactivity. Histamine has no other current clinical applications.

Toxicity & Contraindications

Adverse effects of histamine release, like those following administration of histamine, are dose-related. Flushing, hypotension, tachycardia, headache, wheals, bronchoconstriction, and gastrointestinal upset are noted. These effects are also observed after the ingestion of spoiled fish (scombroid fish poisoning), and there is evidence that histamine produced by bacterial action in the flesh of the fish is the major causative agent.

Histamine should not be given to patients with asthma (except as part of a carefully monitored test of pulmonary function) or to patients with active ulcer disease or gastrointestinal bleeding.

HISTAMINE ANTAGONISTS

The effects of histamine released in the body can be reduced in several ways. Physiologic antagonists, especially epinephrine, have smooth muscle actions opposite to those of histamine, but they act at different receptors. This is important clinically because injection of epinephrine can be lifesaving in systemic anaphylaxis and in other conditions in which massive release of histamine—and other mediators—occurs.

Release inhibitors reduce the degranulation of mast cells that results from immunologic triggering by antigen-IgE interaction. Cromolyn and nedocromil appear to have this effect (see Chapter 20) and are used in the treatment of asthma, though the molecular mechanism underlying their action is presently unknown. $Beta_2$ -adrenoceptor agonists also appear capable of reducing histamine release.

Histamine receptor antagonists represent a third approach to the reduction of histamine-mediated responses. For over 60 years, compounds have been available that competitively antagonize many of the actions of histamine on smooth muscle. However, not until the H_2 -receptor antagonist burimamide was described in 1972 was it possible to antagonize the gastric acid-stimulating activity of histamine. The development of selective H_2 -receptor antagonists has led to more effective therapy for peptic disease (see Chapter 63). Selective H_3 and H_4 antagonists are not yet available for clinical use. However, potent and selective experimental H_3 -receptor antagonists, thioperamide and clobenpropit, have been developed.

H_1 -RECEPTOR ANTAGONISTS

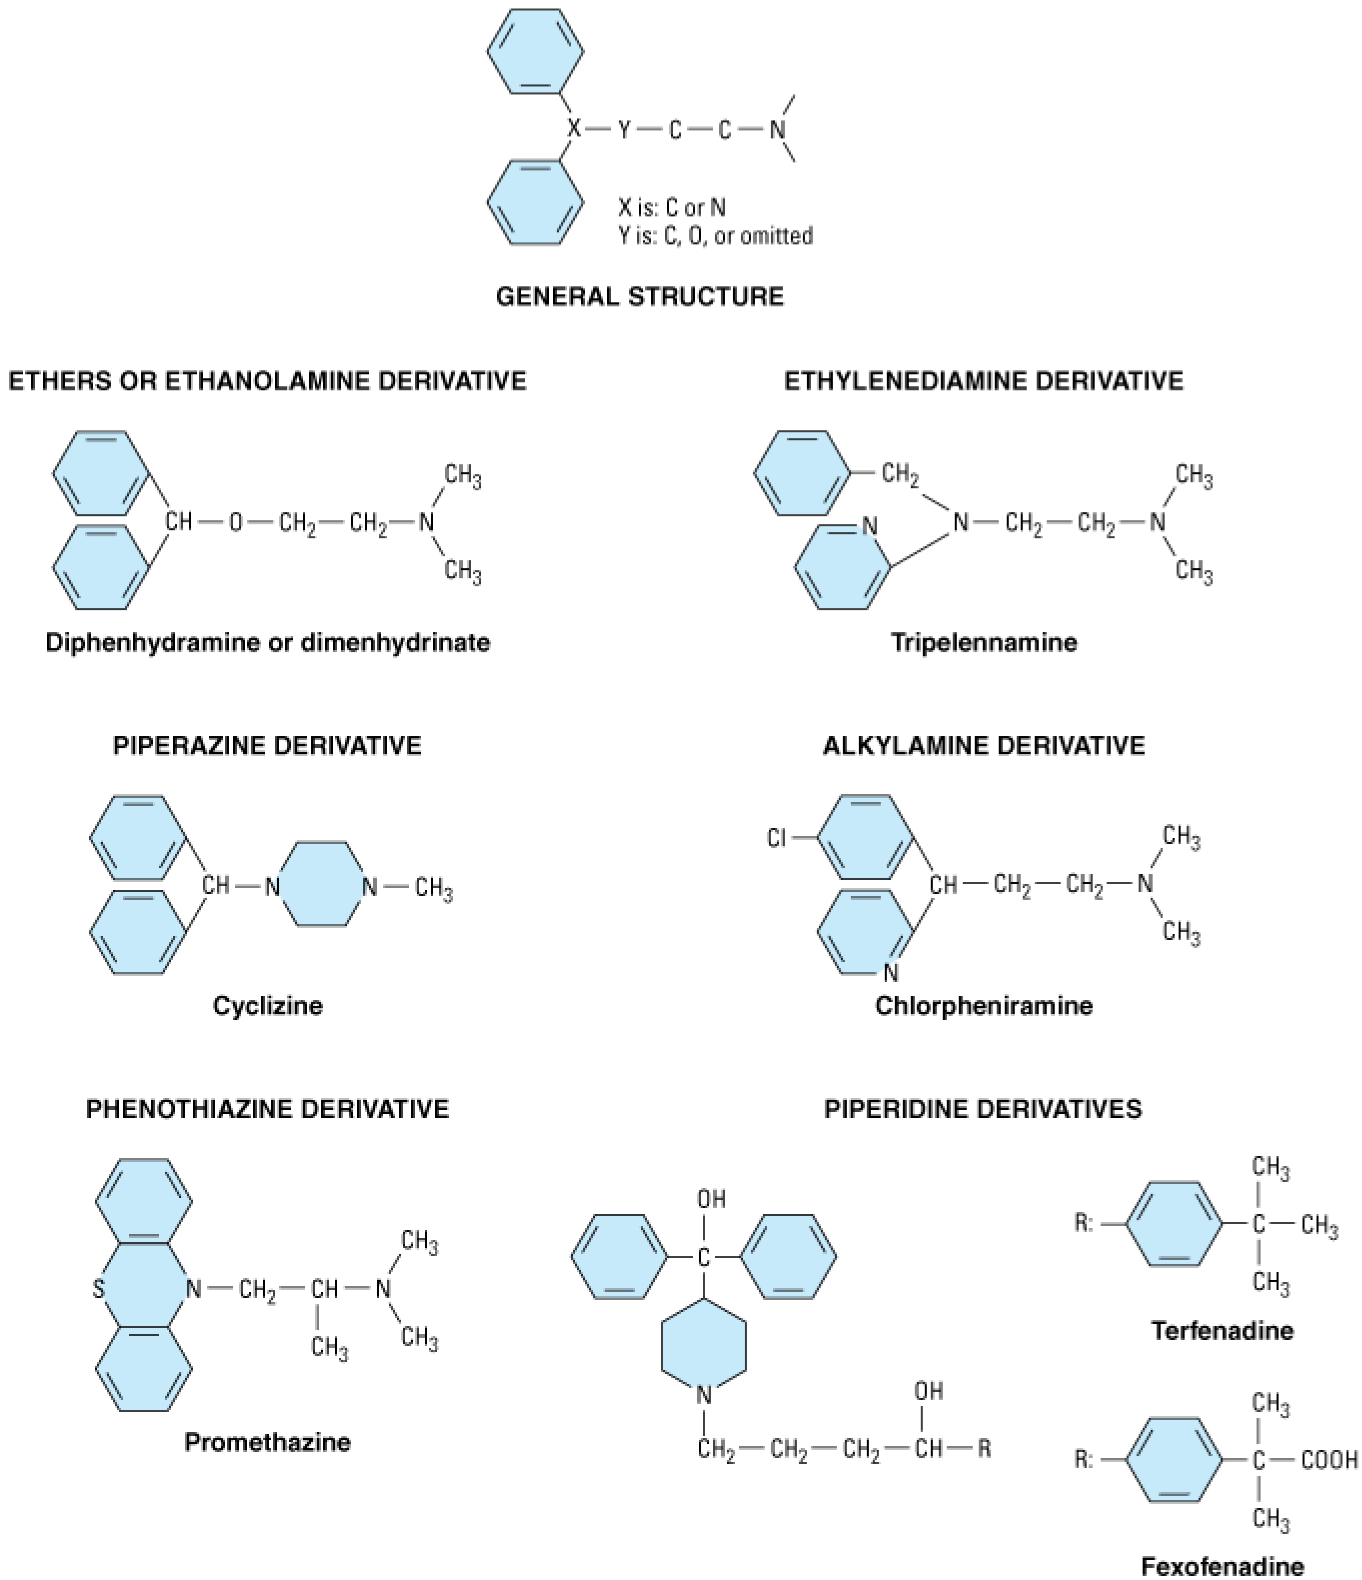
Compounds that competitively block histamine at H_1 receptors have been used in the treatment of allergic conditions for many years, and many H_1 antagonists are currently marketed in the USA. Many are available without prescription, both alone and in combination formulations such as "cold pills" and sleep aids (see Chapter 64).

BASIC PHARMACOLOGY OF H_1 -RECEPTOR ANTAGONISTS

Chemistry & Pharmacokinetics

The H_1 antagonists are conveniently divided into first-generation and second-generation agents. These groups are distinguished by the relatively strong sedative effects of most of the first-generation drugs. The first-generation agents are also more likely to block autonomic receptors. The relatively less sedating characteristic of the second-generation H_1 blockers is due in part to their less complete distribution into the central nervous system. All of the H_1 antagonists are stable amines with the general structure illustrated in Figure 16–1. Several chemical subgroups, and the structures of compounds representing different subgroups are shown in the figure. Doses of some of these drugs are given in Table 16–2.

Figure 16–1.



General structure of H_1 antagonist drugs and examples of the major subgroups.

Table 16–2. Some H_1 Antihistaminic Drugs in Clinical Use.

Drugs	Usual Adult Dose	Anticholinergic Activity	Comments
FIRST-GENERATION ANTIHISTAMINES			
Ethanolamines			
Carbinoxamine (Clistin)	4–8 mg	+++	Slight to moderate sedation
Dimenhydrinate (salt of diphenhydramine) (Dramamine)	50 mg	+++	Marked sedation; anti-motion sickness activity
Diphenhydramine (Benadryl, etc)	25–50 mg	+++	Marked sedation; anti-motion sickness activity
Ethylaminediamine			
Tripelennamine (PBZ, etc)	25–50 mg	+	Moderate sedation
Piperazine derivatives			

Hydroxyzine (Atarax, etc)

15–100 mg

nd

Marked sedation

Cyclizine (Marezine)

25–50 mg

–

Slight sedation; anti-motion sickness activity

Meclizine (Bonine, etc)

25–50 mg

–

Slight sedation; anti-motion sickness activity

Alkylamines

Brompheniramine (Dimetane, etc)

4–8 mg

+

Slight sedation

Chlorpheniramine (Chlor-Trimeton, etc)

4–8 mg

+

Slight sedation; common component of OTC "cold" medication

Phenothiazine derivative

Promethazine (Phenergan, etc)

10–25 mg

+++

Marked sedation; antiemetic; α-block

Miscellaneous

Cyproheptadine (Periactin, etc)

4 mg

+

Moderate sedation; also has antiserotonin activity

SECOND-GENERATION ANTIHISTAMINES

Piperidine

Fexofenadine (Allegra)

60 mg

–

Miscellaneous

Loratadine (Claritin)

10 mg

–

Longer action

Cetirizine (Zyrtec)

5–10 mg

–

nd, no data found.

These agents are rapidly absorbed following oral administration, with peak blood concentrations occurring in 1–2 hours. They are widely distributed throughout the body, and the first-generation drugs enter the central nervous system readily. Some of them are extensively metabolized, primarily by microsomal systems in the liver. Several of the second-generation agents are metabolized by the CYP3A4 system and thus are subject to important interactions when other drugs (such as ketoconazole) inhibit this subtype of P450 enzymes. Most of the drugs have an effective duration of action of 4–6 hours following a single dose, but meclizine and several second-generation agents are longer-acting, with a duration of action of 12–24 hours. The newer agents are considerably less lipid-soluble than the first-generation drugs and are substrates of the P-glycoprotein transporter in the blood-brain barrier; as a result they enter the central nervous system with difficulty or not at all. Many H_1 antagonists have active metabolites. The active metabolites of hydroxyzine, terfenadine, and loratadine are available as drugs (cetirizine, fexofenadine, and desloratadine, respectively).

Pharmacodynamics

HISTAMINE-RECEPTOR BLOCKADE

H_1 -receptor antagonists block the actions of histamine by reversible competitive antagonism at the H_1 receptor. They have negligible potency at the H_2 receptor and little at the H_3 receptor. For example, histamine-induced contraction of bronchiolar or gastrointestinal smooth muscle can be completely blocked by these agents, but the effects on gastric acid secretion and the heart are unmodified.

ACTIONS NOT CAUSED BY HISTAMINE RECEPTOR BLOCKADE

The first-generation H_1 -receptor antagonists have many actions not ascribable to blockade of the actions of histamine. The large number of these actions probably results from the similarity of the general structure (Figure 16–1) to the structure of drugs that have effects at muscarinic cholinoceptor, α-adrenoceptor, serotonin, and local anesthetic receptor sites. Some of these actions are of therapeutic value and some are undesirable.

Sedation

A common effect of first-generation H_1 antagonists is sedation, but the intensity of this effect varies among chemical subgroups (Table 16–2) and among patients as well. The effect is sufficiently prominent with some agents to make them useful as "sleep aids" (see Chapter 64) and unsuitable for daytime use. The effect resembles that of some antimuscarinic drugs and is considered very unlike the disinhibited sedation produced by sedative-hypnotic drugs. Compulsive use has not been reported. At ordinary dosages, children occasionally (and adults rarely) manifest excitation rather than sedation. At very high toxic dose levels, marked stimulation, agitation, and even convulsions may precede coma. Second-generation H_1 antagonists have little or no sedative or stimulant actions. These drugs (or their active metabolites) also have far fewer autonomic effects than the first-generation antihistamines.

Antinausea and Antiemetic Actions

Several first-generation H_1 antagonists have significant activity in preventing motion sickness (Table 16–2). They are less effective against an episode of motion sickness already present. Certain H_1 antagonists, notably doxylamine (in Bendectin), were used widely in the past in the treatment of nausea and vomiting of pregnancy (see below).

Antiparkinsonism Effects

Some of the H_1 antagonists, especially diphenhydramine, have significant acute suppressant effects on the extrapyramidal symptoms associated with certain antipsychotic drugs. This drug is given parenterally for acute dystonic reactions to antipsychotics.

Anticholinoceptor Actions

Many of the first-generation agents, especially those of the ethanolamine and ethylenediamine subgroups, have significant atropine-like effects on peripheral muscarinic receptors. This action may be responsible for some of the (uncertain) benefits reported for nonallergic rhinorrhea but may also cause urinary retention and blurred vision.

Adrenoceptor-Blocking Actions

Alpha-receptor–blocking effects can be demonstrated for many H_1 antagonists, especially those in the phenothiazine subgroup, eg, promethazine. This action may cause orthostatic hypotension in susceptible individuals. Beta-receptor blockade is not observed.

Serotonin-Blocking Action

Strong blocking effects at serotonin receptors have been demonstrated for some first-generation H_1 antagonists, notably cyproheptadine. This drug is promoted as an antiserotonin agent and is discussed with that drug group. Nevertheless, its structure resembles that of the phenothiazine antihistamines, and it is a potent H_1 -blocking agent.

Local Anesthesia

Several first-generation H_1 antagonists are potent local anesthetics. They block sodium channels in excitable membranes in the same fashion as procaine and lidocaine. Diphenhydramine and promethazine are actually more potent than procaine as local anesthetics. They are occasionally used to produce local anesthesia in patients allergic to conventional local anesthetic drugs. A small number of these agents also block potassium channels; this action is discussed below (see Toxicity).

Other Actions

Certain H_1 antagonists, eg, cetirizine, inhibit mast cell release of histamine and some other mediators of inflammation. This action is not due to H_1 -receptor blockade. The mechanism is not understood but could play a role in the beneficial effects of these drugs in the treatment of allergies such as rhinitis. A few H_1 antagonists (eg, terfenadine, acrivastine) have been shown to inhibit the P-glycoprotein transporter found in cancer cells, the epithelium of the gut, and the capillaries of the brain. The significance of this effect is not known.

CLINICAL PHARMACOLOGY OF H_1 -RECEPTOR ANTAGONISTS

Clinical Uses

ALLERGIC REACTIONS

The H_1 antihistaminic agents are often the first drugs used to prevent or treat the symptoms of allergic reactions. In allergic rhinitis and urticaria, in which histamine is the primary mediator, the H_1 antagonists are the drugs of choice and are often quite effective. However, in bronchial asthma, which involves several mediators, the H_1 antagonists are largely ineffective.

Angioedema may be precipitated by histamine release but appears to be maintained by peptide kinins that are not affected by antihistaminic agents. For atopic dermatitis, antihistaminic drugs such as diphenhydramine are used mostly for their sedative side effect, which reduces awareness of itching.

The H_1 antihistamines used for treating allergic conditions such as hay fever are usually selected with the goal of minimizing sedative effects; in the USA, the drugs in widest use are the alkylamines and the second-generation nonsedating agents. However, the sedative effect and the therapeutic efficacy of different agents vary widely among individuals. In addition, the clinical effectiveness of one group may diminish with continued use, and switching to another group may restore drug effectiveness for as yet unexplained reasons.

The second-generation H_1 antagonists are used mainly for the treatment of allergic rhinitis and chronic urticaria. Several double-blind comparisons with older agents (such as chlorpheniramine) indicated about equal therapeutic efficacy. However, sedation and interference with safe operation of machinery, which occur in about 50% of subjects taking first-generation antihistamines, occurred in only about 7% of subjects taking second-generation agents. The newer drugs are much more expensive.

MOTION SICKNESS AND VESTIBULAR DISTURBANCES

Scopolamine (Chapter 8) and certain first-generation H_1 antagonists are the most effective agents available for the prevention of motion sickness. The antihistaminic drugs with the greatest effectiveness in this application are diphenhydramine and promethazine. Dimenhydrinate, which is promoted almost exclusively for the treatment of motion sickness, is a salt of diphenhydramine. The piperazines (cyclizine and meclizine) also have significant activity in preventing motion sickness and are less sedating than diphenhydramine in most patients. Dosage is the same as that recommended for allergic disorders (Table 16–2). Both scopolamine and the H_1 antagonists are more effective in preventing motion sickness when combined with ephedrine or amphetamine.

It has been claimed that the antihistaminic agents effective in prophylaxis of motion sickness are also useful in Ménière's syndrome, but efficacy in the latter application is not established.

NAUSEA AND VOMITING OF PREGNANCY

Several H_1 -antagonist drugs have been studied for possible use in treating "morning sickness." The piperazine derivatives were withdrawn from such use when it was demonstrated that they have teratogenic effects in rodents. Doxylamine, an ethanolamine H_1 antagonist, was promoted for this application as a component of Bendectin, a prescription medication that also contained pyridoxine. Possible teratogenic effects of doxylamine were widely publicized in the lay press after 1978 as a result of a few case reports of fetal malformation associated with maternal ingestion of Bendectin. However, several large prospective studies involving over 60,000 pregnancies, of which more than 3000 involved maternal Bendectin ingestion, disclosed no increase in the incidence of birth defects. However, because of the continuing controversy, adverse publicity, and lawsuits, the manufacturer of Bendectin withdrew the product from the market.

Toxicity

The wide spectrum of nonantihistaminic effects of the H_1 antihistamines is described in the previous text. Several of these effects (sedation, antimuscarinic action) have been used for therapeutic purposes, especially in over-the-counter (OTC) remedies (see Chapter 64). Nevertheless, these two effects constitute the most common undesirable actions when these drugs are used to block histamine receptors.

Less common toxic effects of systemic use include excitation and convulsions in children, postural hypotension, and allergic responses. Drug allergy is relatively common after topical use of H_1 antagonists. The effects of severe systemic overdosage of the older agents resemble those of atropine overdosage and are treated in the same way (see Chapters 8 and 59). Overdosage of astemizole or terfenadine may induce cardiac arrhythmias, but these drugs are no longer marketed in the USA; the same effect may be caused at normal dosage by interaction with enzyme inhibitors (see Drug Interactions, below).

Drug Interactions

Lethal ventricular arrhythmias occurred in several patients taking either of the early second-generation agents, terfenadine or astemizole, in combination with ketoconazole, itraconazole, or macrolide antibiotics such as erythromycin. These antimicrobial drugs inhibit the metabolism of many drugs by CYP3A4 and cause significant increases in blood concentrations of the antihistamines. The mechanism of this toxicity involves blockade of the HERG (I_{Kr}) potassium channels in the heart that are responsible for repolarization of the action potential (see Chapter 14). The result is prolongation of the action potential, and excessive prolongation leads to arrhythmias. Both terfenadine and astemizole were withdrawn from the United States market in recognition of these problems. Where still available, terfenadine and astemizole should be considered to be contraindicated in patients taking ketoconazole, itraconazole, or macrolides and in patients with liver disease. Grapefruit juice also inhibits CYP3A4 and has been shown to increase terfenadine's blood levels significantly.

For those H_1 antagonists that cause significant sedation, concurrent use of other drugs that cause central nervous system depression produces additive effects and is contraindicated while driving or operating machinery. Similarly, the autonomic blocking effects of older antihistamines are additive with those of muscarinic and α-blocking drugs.

H_2 -RECEPTOR ANTAGONISTS

The development of H_2 -receptor antagonists was based on the observation that H_1 antagonists had no effect on histamine-induced acid secretion in the stomach. Molecular manipulation of the histamine molecule resulted in drugs that blocked acid secretion and had no H_1 -agonist or antagonist effects. The high incidence of peptic ulcer disease and related gastrointestinal complaints created great interest in the therapeutic potential of these H_2 -receptor antagonists. Because of the ability of this class of drugs to reduce gastric acid secretion and their low toxicity, they are now among the most frequently used drugs in the USA and have become OTC items. These drugs are discussed in Chapter 63.

H_3 - & H_4 -RECEPTOR ANTAGONISTS

Although no selective H_3 or H_4 ligands are presently available for clinical use, there is great interest in their therapeutic potential. H_3 -selective ligands may be of value in sleep disorders, obesity, and cognitive and psychiatric disorders. H_4 blockers have potential in chronic inflammatory conditions such as asthma, in which eosinophils and mast cells play a prominent role.

SEROTONIN (5-HYDROXYTRYPTAMINE)

Before the identification of 5-hydroxytryptamine (5-HT), it was known that when blood is allowed to clot, a vasoconstrictor (tonic) substance is released from the clot into the serum; this substance was called serotonin. Independent studies established the existence of a smooth muscle stimulant in intestinal mucosa; this was called enteramine. The synthesis of 5-hydroxytryptamine in 1951 permitted the identification of serotonin and enteramine as the same metabolite of 5-hydroxytryptophan.

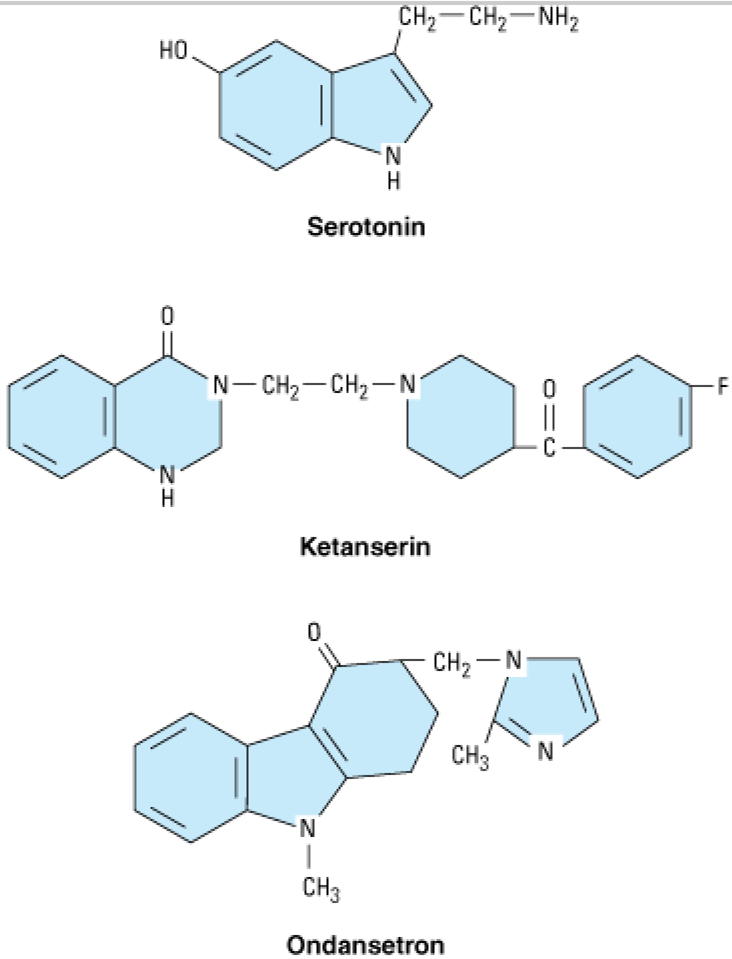
Serotonin is an important neurotransmitter, a local hormone in the gut, a component of the platelet clotting process, and is thought to play a role in migraine headache. Serotonin is also one of the mediators of the signs and symptoms of *carcinoid syndrome* , an unusual manifestation of carcinoid tumor, a neoplasm of enterochromaffin cells. In patients whose tumor is not operable, a serotonin antagonist may constitute a useful treatment.

BASIC PHARMACOLOGY OF SEROTONIN

Chemistry & Pharmacokinetics

Like histamine, serotonin is widely distributed in nature, being found in plant and animal tissues, venoms, and stings. It is an indoleethylamine formed in biologic systems from the amino acid L -tryptophan by hydroxylation of the indole ring followed by decarboxylation of the amino acid (Figure 16–2). Hydroxylation at C5 is the rate-limiting step and can be blocked by *p*- chlorophenylalanine (PCPA; fenclonine) and by *p*- chloroamphetamine. These agents have been used experimentally to reduce serotonin synthesis in carcinoid syndrome but are too toxic for clinical use.

Figure 16–2.



Structures of serotonin and two 5-HT-receptor blockers.

After synthesis, the free amine is stored or is rapidly inactivated, usually by oxidation catalyzed by the enzyme monoamine oxidase. In the pineal gland, serotonin serves as a precursor of melatonin, a melanocyte-stimulating hormone. In mammals (including humans), over 90% of the serotonin in the body is found in enterochromaffin cells in the gastrointestinal tract. In the blood, serotonin is found in platelets, which are able to concentrate the amine by means of an active serotonin transporter mechanism (SERT) similar to that in the membrane of serotonergic nerve endings. Once transported into the platelet or nerve ending, 5-HT is concentrated in vesicles by a vesicle-associated transporter (VAT) that is blocked by reserpine. Serotonin is also found in the raphe nuclei of the brainstem, which contain cell bodies of serotonergic neurons that synthesize, store, and release serotonin as a transmitter. Brain serotonergic neurons are involved in numerous diffuse functions such as mood, sleep, appetite, and temperature regulation, as well as the perception of pain, the regulation of blood pressure, and vomiting (see Chapter 21). Serotonin also appears to be involved in clinical conditions such as depression, anxiety, and migraine. Serotonergic neurons are also found in the enteric nervous system of the gastrointestinal tract and around blood vessels. In rodents (but not in humans), serotonin is found in mast cells.

The function of serotonin in enterochromaffin cells is not fully understood. These cells synthesize serotonin, store the amine in a complex with ATP and with other substances in granules, and release serotonin in response to mechanical and neuronal stimuli. Some of the released serotonin diffuses into blood vessels and is taken up and stored in platelets.

Stored serotonin can be depleted by reserpine in much the same manner as this drug depletes catecholamines from vesicles in adrenergic nerves (see Chapter 6).

Serotonin is metabolized by monoamine oxidase, and the intermediate product, 5-hydroxyindoleacetaldehyde, is further oxidized by aldehyde dehydrogenase to 5-hydroxyindoleacetic acid (5-HIAA). In humans consuming a normal diet, the excretion of 5-HIAA is a measure of serotonin synthesis. Therefore, the 24-hour excretion of 5-HIAA can be used as a diagnostic test for tumors that synthesize excessive quantities of serotonin, especially carcinoid tumor. A few foods (eg, bananas) contain large amounts of serotonin or its precursors and must be prohibited during such diagnostic tests.

Pharmacodynamics

MECHANISMS OF ACTION

Serotonin exerts many actions and, like histamine, has many species differences, making generalizations difficult. The actions of serotonin are mediated through a remarkably large number of cell membrane receptors. The serotonin receptors that have been characterized thus far are listed in Table 16–3. Seven families of 5-HT-receptor subtypes (those given numeric subscripts 1 through 7) have been identified, six involving G protein-coupled receptors of the usual 7-transmembrane serpentine type and one a ligand-gated ion channel. Among these receptor subtypes, a few still lack a well-documented physiologic function. Discovery of these functions awaits the development of more subtype-selective drugs or the knockout mutation of genes encoding these receptors from the mouse genome.

TISSUE AND ORGAN SYSTEM EFFECTS

Nervous System

Serotonin is present in a variety of sites in the brain. Its role as a neurotransmitter and its relation to the actions of drugs acting in the central nervous system are discussed in Chapters 21 and 30. Serotonin is also a precursor of melatonin in the pineal gland (see Melatonin Pharmacology, and Chapter 65).

MELATONIN PHARMACOLOGY

Melatonin is *N* -acetyl-5-methoxytryptamine, a simple methoxylated and *N* -acetylated product of serotonin found in the pineal gland. It is produced and released primarily at night and has long been suspected of playing a role in diurnal cycles of animals and the sleep-wake behavior of humans.

Melatonin receptors have been characterized in the central nervous system and several peripheral tissues. In the brain, MT_1 and MT_2 receptors are found in membranes of neurons in the suprachiasmatic nucleus of the hypothalamus, an area associated—from lesioning experiments—with circadian rhythm. MT_1 and MT_2 are seven-transmembrane G_i protein-coupled receptors. The result of receptor binding is inhibition of adenylyl cyclase. A third receptor, MT_3 , is an enzyme; binding to this site has a poorly defined physiologic role, possibly related to intraocular pressure. Activation of the MT_1 receptor results in sleepiness, whereas the MT_2 receptor may be related to the light-dark synchronization of the biologic circadian clock.

Melatonin itself is promoted commercially as a sleep aid by the food supplement industry (see Chapter 65). Ramelteon is a selective MT_1 and MT_2 agonist that has recently been approved for the medical treatment of insomnia. This drug has no addiction liability (it is not a controlled substance), and it appears to be distinctly more efficacious than melatonin (but less efficacious than benzodiazepines) as a hypnotic. It is metabolized by P450 enzymes and should not be used in individuals taking CYP1A2 inhibitors. It has a half-life of 1–3 hours and an active metabolite with a half-life of up to 5 hours. The toxicity of ramelteon is as yet poorly defined, but prolactin levels were elevated in one clinical trial.

5-HT_3 receptors in the gastrointestinal tract and in the vomiting center of the medulla participate in the vomiting reflex (see Chapter 63). They are particularly important in vomiting caused by chemical triggers such as cancer chemotherapy drugs. 5-HT_{1P} and 5-HT_4 receptors also play a role in enteric nervous system function.

Like histamine, serotonin is a potent stimulant of pain and itch sensory nerve endings and is responsible for some of the symptoms caused by insect and plant stings. In addition, serotonin is a powerful activator of chemosensitive endings located in the coronary vascular bed. Activation of 5-HT_3 receptors on these afferent vagal nerve endings is associated with the chemoreceptor reflex (also known as the Bezold-Jarisch reflex). The reflex response consists of marked bradycardia and hypotension. The bradycardia is mediated by vagal outflow to the heart and can be blocked by atropine. The hypotension is a consequence of the decrease in cardiac output that results from bradycardia. A variety of other agents can activate the chemoreceptor reflex. These include nicotinic cholinoceptor agonists and some cardiac glycosides, eg, ouabain.

Respiratory System

Serotonin has a small direct stimulant effect on bronchiolar smooth muscle in normal humans. It also appears to facilitate acetylcholine release from bronchial vagal nerve endings. In patients with carcinoid syndrome, episodes of bronchoconstriction occur in response to elevated levels of the amine or peptides released from the tumor. Serotonin may also cause hyperventilation as a result of the chemoreceptor reflex or stimulation of bronchial sensory nerve endings.

Cardiovascular System

Serotonin directly causes the contraction of vascular smooth muscle, mainly through 5-HT_2 receptors. In humans, serotonin is a powerful vasoconstrictor except in skeletal muscle and heart, where it dilates blood vessels. At least part of this 5-HT-induced vasodilation requires the presence of vascular endothelial cells. When the endothelium is damaged, coronary vessels constrict. As noted previously, serotonin can also elicit reflex bradycardia by activation of 5-HT_3 receptors on chemoreceptor nerve endings. A triphasic blood pressure response is often seen following injection of serotonin in experimental animals. Initially, there is a decrease in heart rate, cardiac output, and blood pressure caused by the chemoreceptor response. Following this decrease, blood pressure increases as a result of vasoconstriction. The third phase is again a decrease in blood pressure attributed to vasodilation in vessels supplying skeletal muscle. Pulmonary and renal vessels seem especially sensitive to the vasoconstrictor action of serotonin.

Serotonin also constricts veins, and venoconstriction with a resulting increased capillary filling appears to be responsible for the flush that is observed following serotonin administration or release from a carcinoid tumor. Serotonin has small direct positive chronotropic and inotropic effects on the heart, which are probably of no clinical significance. However, prolonged elevation of the blood level of serotonin (which occurs in carcinoid syndrome) is associated with pathologic alterations in the endocardium (subendocardial fibroplasia), which may result in valvular or electrical malfunction.

Serotonin causes blood platelets to aggregate by activating surface 5-HT_2 receptors. This response, in contrast to aggregation induced during clot formation, is not accompanied by the release of serotonin stored in the platelets. The physiologic role of this effect is unclear.

Gastrointestinal Tract

Serotonin is a powerful stimulant of gastrointestinal smooth muscle, increasing tone and facilitating peristalsis. This action is caused by the direct action of serotonin on 5-HT_2 smooth muscle receptors plus a stimulating action on ganglion cells located in the enteric nervous system (see Chapter 6). Activation of 5-HT_4 receptors in the enteric nervous system causes increased acetylcholine release and thereby mediates a motility-enhancing or "prokinetic" effect of selective serotonin agonists such as cisapride. These agents are useful in several gastrointestinal disorders (see Chapter 63). Overproduction of serotonin (and other substances) in carcinoid tumor is associated with severe diarrhea. Serotonin has little effect on secretions, and what effects it has are generally inhibitory.

Skeletal Muscle

5-HT_2 receptors are present on skeletal muscle membranes, but their physiologic role is not understood. Serotonin syndrome is a condition precipitated when MAO inhibitors are given with serotonin agonists, especially antidepressants of the selective serotonin reuptake inhibitor class (SSRIs; see Chapter 30). Although associated with skeletal muscle contractions and the hyperthermia resulting from excessive muscle contraction, serotonin syndrome is probably the result of a central nervous system effect of these drugs (see Table 16–4 and Serotonin Syndrome and Similar Syndromes).

Table 16–4. Characteristics of Serotonin Syndrome and Other Hyperthermic Syndromes.

Syndrome	Precipitating Drugs	Clinical Presentation	Therapy[1]
Serotonin syndrome	SSRIs, second generation antidepressants, MAOIs, linezolid, tramadol, meperidine, fentanyl, ondansetron, sumatriptan, MDMA, LSD, St. John's wort, ginseng	Hypertension, hyperreflexia, tremor, clonus, hyperthermia, hyperactive bowel sounds, diarrhea, mydriasis, agitation, coma; onset within hours	Sedation (benzodiazepines), paralysis, intubation and ventilation; consider 5-HT_2 block with cyproheptadine or chlorpromazine

Neuroleptic malignant syndrome

D_2 -blocking antipsychotics

Acute severe parkinsonism; hypertension, hyperthermia, normal or reduced bowel sounds, onset over 1–3 days

Diphenhydramine (parenteral), cooling if temperature is very high, sedation with benzodiazepines

Malignant hyperthermia

Volatile anesthetics, succinylcholine

Hyperthermia, muscle rigidity, hypertension, tachycardia; onset within minutes

Dantrolene, cooling

---

[1] Precipitating drugs should be discontinued immediately. First-line therapy is in **bold** font.

MAOIs, monoamine oxidase inhibitors; MDMA, methylenedioxy-methamphetamine (ecstasy); SSRIs, selective serotonin reuptake inhibitors.

SEROTONIN SYNDROME AND SIMILAR SYNDROMES

Excess synaptic serotonin causes a serious, potentially fatal syndrome that is diagnosed on the basis of a history of administration of a serotonergic drug within recent weeks and physical findings (Table 16–4). It has some characteristics in common with neuroleptic malignant syndrome (NMS) and malignant hyperthermia (MH), but its pathophysiology and management are quite different.

As suggested by the drugs that precipitate it, serotonin syndrome occurs when overdose with a single drug, or concurrent use of several drugs, results in excess serotonergic activity in the central nervous system. It is predictable and not idiosyncratic, but milder forms may easily be misdiagnosed. In experimental animal models, many of the signs of the syndrome can be reversed by administration of 5-HT_2 antagonists; however, other 5-HT receptors may be involved as well. Dantrolene is of no value, unlike the treatment of MH. NMS is idiosyncratic rather than predictable and appears to be associated with hypersensitivity to the parkinsonism-inducing effects of D_2 -blocking antipsychotics in certain individuals. MH is associated with a genetic defect in the RyR1 calcium channel of skeletal muscle sarcoplasmic reticulum that permits uncontrolled calcium release from the SR when precipitating drugs are given (Chapter 27).

CLINICAL PHARMACOLOGY OF SEROTONIN

Serotonin Agonists

Serotonin has no clinical applications as a drug. However, several receptor subtype-selective agonists have proved to be of value. **Buspirone**, a 5-HT_{1A} agonist, has received wide attention for its usefulness as an effective nonbenzodiazepine anxiolytic (see Chapter 22). **Dexfenfluramine**, another selective 5-HT agonist, was widely used as an appetite suppressant but was withdrawn because of toxicity. Appetite suppression appears to be associated with agonist action at 5-HT_{2C} receptors in the central nervous system. **Sumatriptan** and its congeners are agonists effective in the treatment of acute migraine and cluster headache attacks (see below).

5-$HT_{1D/1B}$ Agonists & Migraine Headache

The 5-$HT_{1D/1B}$ agonists (triptans) are used almost exclusively in migraine headache. Migraine in its "classic" form is characterized by an aura of variable duration that may involve nausea, vomiting, and visual scotomas or even hemianopsia and speech abnormalities; followed by a severe throbbing unilateral headache that lasts for a few hours to 1–2 days. "Common" migraine lacks the aura phase, but the headache is similar. Although the symptom pattern varies among patients, the severity of migraine headache justifies vigorous therapy in the great majority of cases.

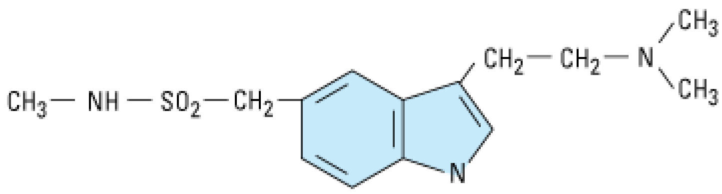
Migraine involves the trigeminal nerve distribution to intracranial (and possibly extracranial) arteries. These nerves release peptide neurotransmitters, especially calcitonin gene-related peptide (CGRP; see Chapter 17), an extremely powerful vasodilator. Substance P and neurokinin A may also be involved. Extravasation of plasma and plasma proteins into the perivascular space appears to be a common feature of animal migraine models and biopsy specimens from migraine patients and probably represents the effect of the neuropeptides on the vessels. The mechanical stretching caused by this perivascular edema may be the immediate cause of activation of pain nerve endings in the dura. The onset of headache is sometimes associated with a marked increase in amplitude of temporal artery pulsations, and relief of pain by administration of effective therapy is sometimes accompanied by diminution of the arterial pulsations.

The mechanisms of action of drugs used in migraine are poorly understood, in part because they include such a wide variety of drug groups and actions. In addition to the triptans, these include ergot alkaloids, nonsteroidal anti-inflammatory analgesic agents, β-adrenoceptor blockers, calcium channel blockers, tricyclic antidepressants and SSRIs, and several antiseizure agents. Furthermore, some of these drug groups are effective only for prophylaxis and not for the acute attack.

Two primary hypotheses have been proposed to explain the actions of these drugs. First, the triptans, the ergot alkaloids, and antidepressants may activate 5-$HT_{1D/1B}$ receptors on presynaptic trigeminal nerve endings to inhibit the release of vasodilating peptides, and antiseizure agents may suppress excessive firing of these nerve endings. Second, the vasoconstrictor actions of direct 5-HT agonists (the triptans and ergot) may prevent vasodilation and stretching of the pain endings. It is possible that both mechanisms contribute in the case of some drugs. Sumatriptan and its congeners are currently first-line therapy for acute severe migraine attacks in most patients. However, they should not be used in patients at risk for coronary artery disease. Anti-inflammatory analgesics such as aspirin and ibuprofen are often helpful in controlling the pain of migraine. Rarely, parenteral opioids may be needed in refractory cases. For patients with very severe nausea and vomiting, parenteral metoclopramide may be helpful.

Propranolol, amitriptyline, and some calcium channel blockers have been found to be effective for the prophylaxis of migraine in some patients. They are of no value in the treatment of acute migraine. The anticonvulsants valproic acid and topiramate (see Chapter 24) have recently been found to have good prophylactic efficacy in many migraine patients. Flunarizine, a calcium channel blocker used in Europe, has been reported in clinical trials to effectively reduce the severity of the acute attack and to prevent recurrences. Verapamil appears to have modest efficacy as prophylaxis against migraine.

Sumatriptan and the other triptans are selective agonists for 5-HT_{1D} and 5-HT_{1B} receptors; the similarity of the triptan structure to that of 5-HT can be seen in the structure below. These receptor types are found in cerebral and meningeal vessels and mediate vasoconstriction. They are also found on neurons and probably function as presynaptic inhibitory receptors.



Sumatriptan

The efficacy of triptan 5-HT_1 agonists in migraine is equal to or greater than that of other acute drug treatments, eg, parenteral, oral, or rectal ergot alkaloids. The pharmacokinetics of the triptans are set forth in Table 16–5. Most adverse effects are mild and include altered sensations (tingling, warmth, etc), dizziness, muscle weakness, neck pain, and for parenteral sumatriptan, injection site reactions. Chest discomfort occurs in 1–5% of patients, and chest pain has been reported, probably because of the ability of these drugs to cause coronary vasospasm. They are therefore contraindicated in patients with coronary artery disease and in patients with angina. Another disadvantage is the fact that their duration of effect (especially that of almotriptan, sumatriptan, rizatriptan, and zolmitriptan, Table 16–5) is often shorter than the duration of the headache. As a result, several doses may be required during a prolonged migraine attack, but their adverse effects limit the maximum safe daily dosage. In addition, these drugs are extremely expensive. Naratriptan and eletriptan are contraindicated in patients with severe hepatic or renal impairment or peripheral vascular syndromes; frovatriptan in patients with peripheral vascular disease; and zolmitriptan in patients with Wolff-Parkinson-White syndrome.

Other Serotonin Agonists in Clinical Use

Cisapride, a 5-HT_4 agonist, was used in the treatment of gastroesophageal reflux and motility disorders. Because of toxicity, it is now available only for compassionate use in the USA. Tegaserod, a newer 5-HT_4 partial agonist, is used for irritable bowel syndrome with constipation. These drugs are discussed in Chapter 63.

Compounds such as fluoxetine and other SSRIs, which modulate serotonergic transmission by blocking reuptake of the transmitter, are among the most widely prescribed drugs for the management of depression and similar disorders. These drugs are discussed in Chapter 30.

SEROTONIN ANTAGONISTS

The actions of serotonin, like those of histamine, can be antagonized in several ways. Such antagonism is clearly desirable in those rare patients who have carcinoid tumor and may also be valuable in certain other conditions.

As noted above, serotonin synthesis can be inhibited by *p*- chlorophenylalanine and *p*- chloroamphetamine. However, these agents are too toxic for general use. Storage of serotonin can be inhibited by the use of reserpine, but the sympatholytic effects of this drug (see Chapter 11) and the high levels of circulating serotonin that result from release prevent its use in carcinoid. Therefore, receptor blockade is the major approach to therapeutic limitation of serotonin effects.

SEROTONIN-RECEPTOR ANTAGONISTS

A wide variety of drugs with actions at other receptors (α adrenoceptors, H_1 -histamine receptors, etc) are also serotonin receptor-blocking agents. Phenoxybenzamine (see Chapter 10) has a long-lasting blocking action at 5-HT_2 receptors. In addition, the ergot alkaloids discussed in the last portion of the chapter are partial agonists at serotonin receptors.

Cyproheptadine resembles the phenothiazine antihistaminic agents in chemical structure and has potent H_1 -receptor-blocking as well as 5-HT_2 -blocking actions. The actions of cyproheptadine are predictable from its H_1 histamine and serotonin receptor affinities. It prevents the smooth muscle effects of both amines but has no effect on the gastric secretion stimulated by histamine. It also has significant antimuscarinic effects and causes sedation.

The major clinical applications of cyproheptadine are in the treatment of the smooth muscle manifestations of carcinoid tumor and in cold-induced urticaria. The usual dosage in adults is 12–16 mg/d in three or four divided doses. It is of some value in serotonin syndrome, but because it is available only in tablet form, it must be crushed and administered by stomach tube in unconscious patients.

Ketanserin (Figure 16–2) blocks 5-HT_{1c} and 5-HT_2 receptors and has little or no reported antagonist activity at other 5-HT or H_1 receptors. However, this drug potently blocks vascular α_1 adrenoceptors. The drug blocks 5-HT_2 receptors on platelets and antagonizes platelet aggregation promoted by serotonin. The mechanism involved in ketanserin's hypotensive action is not clear but probably involves α_1 adrenoceptors more than 5-HT_2 receptor blockade. Ketanserin is available in Europe for the treatment of hypertension and vasospastic conditions but has not been approved in the USA.

Ritanserin, another 5-HT_2 antagonist, has little or no α-blocking action. It has been reported to alter bleeding time and to reduce thromboxane formation, presumably by altering platelet function.

Ondansetron (Figure 16–2) is the prototypical 5-HT_3 antagonist. This drug and its analogs are very important in the prevention of nausea and vomiting associated with surgery and cancer chemotherapy. They are discussed in Chapter 63.

Considering the diverse effects attributed to serotonin and the heterogeneous nature of 5-HT receptors, other selective 5-HT antagonists may prove to be clinically useful.

THE ERGOT ALKALOIDS

Ergot alkaloids are produced by *Claviceps purpurea,* a fungus that infects grain—especially rye—under damp growing or storage conditions. This fungus synthesizes histamine, acetylcholine, tyramine, and other biologically active products in addition to a score or more of unique ergot alkaloids. These alkaloids affect α adrenoceptors, dopamine receptors, 5-HT receptors, and perhaps other receptor types. Similar alkaloids are produced by fungi parasitic to a number of other grass-like plants.

The accidental ingestion of ergot alkaloids in contaminated grain can be traced back more than 2000 years from descriptions of epidemics of ergot poisoning (ergotism). The most dramatic effects of poisoning are dementia with florid hallucinations; prolonged vasospasm, which may result in gangrene; and stimulation of uterine smooth muscle, which in pregnancy may result in abortion. In medieval times, ergot poisoning was called St. Anthony's fire after the saint whose help was sought in relieving the burning pain of vasospastic ischemia. Identifiable epidemics have occurred sporadically up to modern times (see Ergot Poisoning: Not Just an Ancient Disease) and mandate continuous surveillance of all grains used for food. Poisoning of grazing animals is common in many areas because the fungi may grow on pasture grasses.

In addition to the effects noted above, the ergot alkaloids produce a variety of other central nervous system and peripheral effects. Detailed structure-activity analysis and appropriate semisynthetic modifications have yielded a large number of agents with documented or potential clinical value.

ERGOT POISONING: NOT JUST AN ANCIENT DISEASE

As noted in the text, epidemics of ergotism, or poisoning by ergot-contaminated grain, are known to have occurred sporadically in ancient times and through the Middle Ages. It is easy to imagine the social chaos that might result if fiery pain, gangrene, hallucinations, convulsions, and abortions occurred simultaneously throughout a community in which all or most of the people believed in witchcraft, demonic possession, and the visitation of supernatural punishments upon humans for their misdeeds. Such beliefs are uncommon in most cultures today. However, ergotism has not disappeared. A most convincing demonstration of ergotism occurred in the small French village of Pont-Saint-Esprit in 1951. It was described in the *British Medical Journal* in 1951 (Gabbai et al, 1951) and in a later book-length narrative account (Fuller, 1968). Several hundred individuals suffered symptoms of hallucinations, convulsions, and ischemia—and several died—after eating bread made from contaminated flour. Similar events have occurred even more recently when poverty, famine, or incompetence resulted in the consumption of contaminated grain. Ergot toxicity caused by excessive self-medication with pharmaceutical ergot preparations is still occasionally reported.

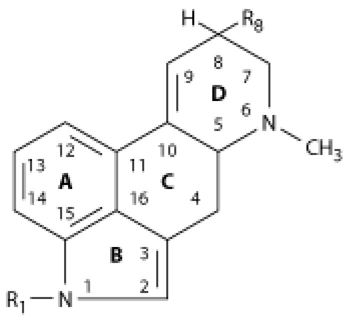
BASIC PHARMACOLOGY OF ERGOT ALKALOIDS

Chemistry & Pharmacokinetics

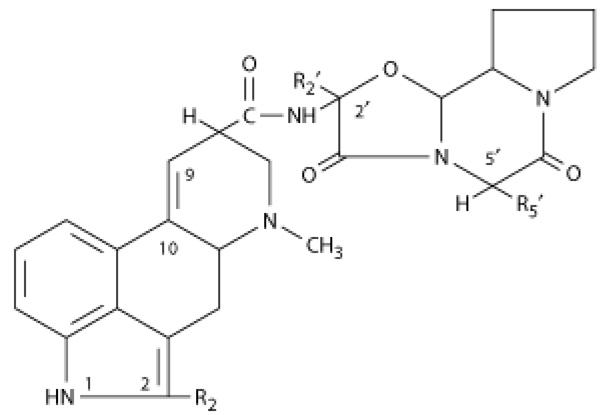
Two major families of compounds that incorporate the tetracyclic ergoline nucleus may be identified; the amine alkaloids and the peptide alkaloids (Table 16–6). Drugs of therapeutic and toxicologic importance are found in both groups.

Table 16–6. Major Ergoline Derivatives (Ergot Alkaloids).

Amine alkaloids



Peptide alkaloids



Amine alkaloids	R_1	R_8
6-Methylergoline	—H	—H
Lysergic acid	—H	—COOH
Lysergic acid diethylamide (LSD)	—H	$—C(=O)—N(CH_2—CH_3)_2$
Ergonovine (ergometrine)	—H	$—C(=O)—NHCH(CH_2OH)CH_3$
Methysergide[2]	$—CH_3$	$—C(=O)—NH—CH(CH_2OH)—CH_2—CH_3$

Peptide alkaloids	R_2	R_2'	R_5'
Ergotamine[1]	—H	$—CH_3$	$—CH_2—$ α-Ergocryptine	—H	$—CH(CH_3)_2$	$—CH_2—CH(CH_3)_2$
Bromocriptine	—Br	$—CH(CH_3)_2$	$—CH_2—CH(CH_3)_2$

[1]Dihydroergotamine lacks the double bond between carbons 9 and 10.
[2]Methysergide withdrawn in the USA.

The ergot alkaloids are variably absorbed from the gastrointestinal tract. The oral dose of ergotamine is about ten times larger than the intramuscular dose, but the speed of absorption and peak blood levels after oral administration can be improved by administration with caffeine (see below). The amine alkaloids are also absorbed from the rectum and the buccal cavity and after administration by aerosol inhaler. Absorption after intramuscular injection is slow but usually reliable. Bromocriptine and the amine derivative cabergoline are well absorbed from the gastrointestinal tract.

The ergot alkaloids are extensively metabolized in the body. The primary metabolites are hydroxylated in the A ring, and peptide alkaloids are also modified in the peptide moiety.

Pharmacodynamics

MECHANISM OF ACTION

As suggested, the ergot alkaloids act on several types of receptors. Their effects include agonist, partial agonist, and antagonist actions at α-adrenoceptors and serotonin receptors (especially 5-HT_{1A} and 5-HT_{1D} ; less for 5-HT_{1C} , 5-HT_2 , and 5-HT_3); and agonist or partial agonist actions at central nervous system dopamine receptors (Table 16–7). Furthermore, some members of the ergot family have a high affinity for presynaptic receptors, whereas others are more selective for postjunctional receptors. There is a powerful stimulant effect on the uterus that seems to be most closely associated with agonist or partial agonist effects at 5-HT_2 receptors. Structural variations increase the selectivity of certain members of the family for specific receptor types.

Table 16–7. Effects of Ergot Alkaloids at Several Receptors.[1]

Ergot Alkaloid	α Adrenoceptor	Dopamine Receptor	Serotonin Receptor (5-HT_2)	Uterine Smooth Muscle Stimulation
Bromocriptine	–	+++	–	0

[1] Agonist effects are indicated by +, antagonist by –, no effect by 0. Relative affinity for the receptor is indicated by the number of + or – signs. PA means partial agonist (both agonist and antagonist effects can be detected).

ORGAN SYSTEM EFFECTS

Central Nervous System

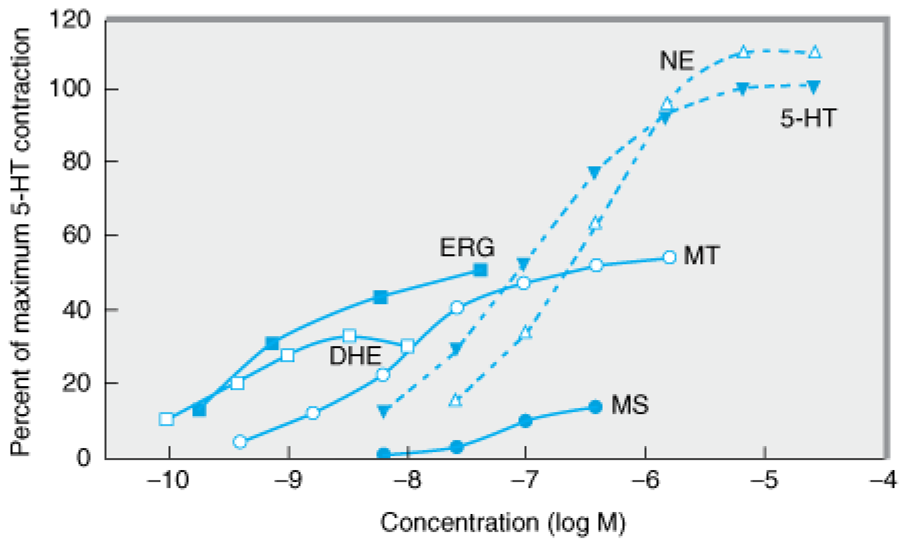
As indicated by traditional descriptions of ergotism, certain of the naturally occurring alkaloids are powerful hallucinogens. Lysergic acid diethylamide (LSD; "acid") is a synthetic ergot compound that clearly demonstrates this action. The drug has been used in the laboratory as a potent peripheral 5-HT_2 antagonist, but good evidence suggests that its behavioral effects are mediated by *agonist* effects at prejunctional or postjunctional 5-HT_2 receptors in the central nervous system. In spite of extensive research, no clinical value has been discovered for LSD's dramatic central nervous system effects. Abuse of this drug has waxed and waned but is still widespread. It is discussed in Chapter 32.

Dopamine receptors in the central nervous system play important roles in extrapyramidal motor control and the regulation of pituitary prolactin release. The actions of the peptide ergoline **bromocriptine** on the extrapyramidal system are discussed in Chapter 28. Of all the currently available ergot derivatives, bromocriptine, **cabergoline**, and **pergolide** have the highest selectivity for the pituitary dopamine receptors. These drugs directly suppress prolactin secretion from pituitary cells by activating regulatory dopamine receptors (Chapter 37). They compete for binding to these sites with dopamine itself and with other dopamine agonists such as apomorphine.

Vascular Smooth Muscle

The action of ergot alkaloids on vascular smooth muscle is drug-, species-, and vessel-dependent, so few generalizations are possible. Ergotamine and related compounds potently constrict most human blood vessels in a predictable, and prolonged manner (Figure 16–3). This response is partially blocked by conventional α-blocking agents. However, ergotamine's effect is also associated with "epinephrine reversal" (see Chapter 10) and with *blockade* of the response to other α agonists. This dual effect represents partial agonist action (Table 16–7). Because ergotamine dissociates very slowly from the α receptor, it produces very long-lasting agonist and antagonist effects at this receptor. There is little or no effect at β adrenoceptors.

Figure 16–3.



Effects of ergot derivatives on contraction of isolated segments of human basilar artery strips removed at surgery. All of the ergot derivatives are partial agonists, and all are more potent than the full agonists, norepinephrine and serotonin. (NE, norepinephrine; 5-HT, serotonin; ERG, ergotamine; MT, methylergometrine; DHE, dihydroergotamine; MS, methysergide.) (Modified and reproduced, with permission, from Müller-Schweinitzer E. In: *5-Hydroxytryptamine Mechanisms in Primary Headaches.* Oleson J, Saxena PR [editors]. Raven Press, 1992.)

While much of the vasoconstriction elicited by ergot alkaloids can be ascribed to partial agonist effects at α adrenoceptors, some may be the result of effects at 5-HT receptors. Ergotamine, ergonovine, and methysergide all have partial agonist effects at 5-HT_2 vascular receptors. The remarkably specific antimigraine action of the ergot derivatives was originally thought to be related to their actions on vascular serotonin receptors. Current hypotheses, however, emphasize their action on prejunctional neuronal 5-HT receptors.

After overdosage with ergotamine and similar agents, vasospasm is severe and prolonged (see Toxicity, below). This vasospasm is not easily reversed by α antagonists, serotonin antagonists, or combinations of both.

Ergotamine is typical of the ergot alkaloids that have a strong vasoconstrictor spectrum of action. The hydrogenation of ergot alkaloids at the 9 and 10 positions (Table 16–6) yields dihydro derivatives that have reduced serotonin partial agonist effects and increased selective α receptor-blocking actions.

Uterine Smooth Muscle

The stimulant action of ergot alkaloids on the uterus, as on vascular smooth muscle, appears to combine α agonist, serotonin, and other effects. Furthermore, the sensitivity of the uterus to the stimulant effects of ergot increases dramatically during pregnancy, perhaps because of increasing dominance of α_1 receptors as pregnancy progresses. As a result, the uterus at term is more sensitive to ergot than earlier in pregnancy and far more sensitive than the nonpregnant organ.

In very small doses, ergot preparations can evoke rhythmic contraction and relaxation of the uterus. At higher concentrations, these drugs induce powerful and prolonged contracture. Ergonovine is more selective than other ergot alkaloids in affecting the uterus and is the agent of choice in obstetric applications of these drugs.

Other Smooth Muscle Organs

In most patients, the ergot alkaloids have little or no significant effect on bronchiolar or urinary smooth muscle. The gastrointestinal tract, on the other hand, is quite sensitive in most patients. Nausea, vomiting, and diarrhea may be induced even by low doses in some patients. The effect is consistent with action on the central nervous system emetic center and on gastrointestinal serotonin receptors.

CLINICAL PHARMACOLOGY OF ERGOT ALKALOIDS

Clinical Uses

MIGRAINE

Ergot derivatives are highly specific for migraine pain; they are not analgesic for any other condition. Although the triptan drugs discussed above are preferred by most clinicians and patients, traditional therapy with ergotamine can also be quite effective when given during the prodrome of an attack; it becomes progressively less effective if delayed. Ergotamine tartrate is available for oral, sublingual, rectal suppository, and inhaler use. It is often combined with caffeine (100 mg caffeine for each 1 mg ergotamine tartrate) to facilitate absorption of the ergot alkaloid.

The vasoconstriction induced by ergotamine is long-lasting and cumulative when the drug is taken repeatedly, as in a severe migraine attack. Therefore, patients must be carefully informed that no more than 6 mg of the oral preparation may be taken for each attack and no more than 10 mg per week. For very severe attacks, ergotamine tartrate, 0.25–0.5 mg, may be given intravenously or intramuscularly. Dihydroergotamine, 0.5–1 mg intravenously, is favored by some clinicians for treatment of intractable migraine. Intranasal dihydroergotamine may also be effective.

HYPERPROLACTINEMIA

Increased serum levels of the anterior pituitary hormone prolactin are associated with secreting tumors of the gland and also with the use of centrally acting dopamine antagonists, especially the D_2 -blocking antipsychotic drugs. Because of negative feedback effects, hyperprolactinemia is associated with amenorrhea and infertility in women as well as galactorrhea in both sexes.

Bromocriptine is extremely effective in reducing the high levels of prolactin that result from pituitary tumors and has even been associated with regression of the tumor in some cases. The usual dosage of bromocriptine is 2.5 mg two or three times daily. Cabergoline is similar but more potent. Bromocriptine has also been used in the same dosage to suppress physiologic lactation. However, serious postpartum cardiovascular toxicity has been reported in association with the latter use of bromocriptine or pergolide, and this application is discouraged (Chapter 37).

POSTPARTUM HEMORRHAGE

The uterus at term is extremely sensitive to the stimulant action of ergot, and even moderate doses produce a prolonged and powerful spasm of the muscle quite unlike natural labor. Therefore, ergot derivatives should be used only for control of late uterine bleeding and should never be given before delivery. Oxytocin is the preferred agent for control of postpartum hemorrhage, but if this peptide agent is ineffective, ergonovine maleate, 0.2 mg usually given intramuscularly, can be tried. It is usually effective within 1–5 minutes and is less toxic than other ergot derivatives for this application. It is given at the time of delivery of the placenta or immediately afterward if bleeding is significant.

DIAGNOSIS OF VARIANT ANGINA

Ergonovine given intravenously produces prompt vasoconstriction during coronary angiography to diagnose variant angina if reactive segments of the coronaries are present.

SENILE CEREBRAL INSUFFICIENCY

Dihydroergotoxine, a mixture of dihydro-α-ergocryptine and three similar dihydrogenated peptide ergot alkaloids (ergoloid mesylates), has been promoted for many years for the relief of senility and more recently for the treatment of Alzheimer's dementia. There is no useful evidence that this drug has significant benefit.

Toxicity & Contraindications

The most common toxic effects of the ergot derivatives are gastrointestinal disturbances, including diarrhea, nausea, and vomiting. Activation of the medullary vomiting center and of the gastrointestinal serotonin receptors is involved. Since migraine attacks are often associated with these symptoms before therapy is begun, these adverse effects are rarely contraindications to the use of ergot.

A more dangerous toxic effect of overdosage with agents like ergotamine and ergonovine is prolonged vasospasm. As described above, this sign of vascular smooth muscle stimulation may result in gangrene and require amputation. Bowel infarction has also been reported and may require resection. Peripheral vascular vasospasm caused by ergot is refractory to most vasodilators, but infusions of large doses of nitroprusside or nitroglycerin have been successful in some cases.

Chronic therapy with methysergide was associated with connective tissue proliferation in the retroperitoneal space, the pleural cavity, and the endocardial tissue of the heart. These changes occurred insidiously over months and presented as hydronephrosis (from obstruction of the ureters) or a cardiac murmur (from distortion of the valves of the heart). In some cases, valve damage required surgical replacement. As a result, this drug was withdrawn. Similar fibrotic change has resulted from the chronic use of 5-HT agonists promoted in the past for weight loss (fenfluramine, desfenfluramine).

Other toxic effects of the ergot alkaloids include drowsiness and, in the case of methysergide, occasional instances of central stimulation and hallucinations. In fact, methysergide was sometimes used as a substitute for LSD by members of the "drug culture."

Contraindications to the use of ergot derivatives consist of the obstructive vascular diseases and collagen diseases.

There is no evidence that ordinary use of ergotamine for migraine is hazardous in pregnancy. However, most clinicians counsel restraint in the use of the ergot derivatives by pregnant patients.

PREPARATIONS AVAILABLE

ANTIHISTAMINES (H_1 BLOCKERS)*

Azelastine

Nasal (Astelin): 137 mcg/puff nasal spray

Ophthalmic (Optivar): 0.5 mg/mL solution

Brompheniramine (generic, Brovex)

Oral: 6, 12 mg extended release tablets; 12 mg chewable tablets; 8, 12 mg/5 mL suspension

Buclizine (Bucladin-S Softabs)

Oral: 50 mg tablets

Carbinoxamine (Histex, Pediatex)

Oral: 4 mg tablets; 8 mg timed-release tablets; 10 mg extended release capsules; 1.5, 4 mg/5 mL liquid; 3.6 mg/5 mL oral suspension

Cetirizine (Zyrtec)

Oral: 5, 10 mg tablets; 5, 10 mg chewable tablets; 5 mg/5 mL syrup

Chlorpheniramine (generic, Chlor-Trimeton)

Oral: 2 mg chewable tablets; 4 mg tablets; 2 mg/5 mL syrup

Oral sustained-release: 8, 12, 16 mg tablets; 8, 12 mg capsules

Clemastine (generic, Tavist)

Oral: 1.34, 2.68 mg tablets; 0.67 mg/5 mL syrup

Cyclizine (Marezine)

Oral: 50 mg tablets

Cyproheptadine (generic)

Oral: 4 mg tablets; 2 mg/5 mL syrup

Desloratadine (Clarinex)

Oral: 5 mg regular or rapidly disintegrating tablets; 2.5 mg/5 mL syrup

Dexchlorpheniramine (generic)

Oral: 4, 6 mg extended release tablets; 2 mg/5 mL syrup

Dimenhydrinate (Dramamine, others)

Oral: 50 mg tablets; 50 mg chewable tablets; 12.5/5 mL, 12.5 mg/4 mL, 15.62 mg/5 mL liquid

Parenteral: 50 mg/mL for IM or IV injection

Diphenhydramine (generic, Benadryl)

Oral: 12.5 mg chewable tablets; 25, 50 mg tablets, capsules; 12.5 mg/5 mL elixir and syrup

Parenteral: 50 mg/mL for injection

Emedastine (Emadine)

Ophthalmic: 0.05% solution

Epinastine (Elestat)

Ophthalmic: 0.05% solution

Fexofenadine (Allegra)

Oral: 30, 60, 180 mg tablets; 60 mg capsules

Hydroxyzine (generic, Vistaril)

Oral: 10, 25, 50 mg tablets; 25, 50, 100 mg capsules; 10 mg/5 mL syrup; 25 mg/5 mL suspension
Parenteral: 25, 50 mg/mL for injection

Ketotifen (Zaditor)

Ophthalmic: 0.025% solution

Levocabastine (Livostin)

Ophthalmic: 0.05% solution

Loratadine (generic, Claritin, Tavist)

Oral: 10 mg tablets; 10 mg rapidly disintegrating tablets; 1 mg/mL syrup

Meclizine (generic, Antivert)

Oral: 12.5, 25, 50 mg tablets; 25 mg capsules; 25 mg chewable tablets

Olopatadine (Patanol)

Ophthalmic: 0.1% solution

Phenindamine (Nolahist)

Oral: 25 mg tablets

Promethazine (generic, Phenergan)

Oral: 25, 50 mg tablets; 6.25 mg/5 mL syrups

Parenteral: 25, 50 mg/mL for injection

Rectal: 12.5, 25, 50 mg suppositories

Triprolidine (Zymine)

Oral: 1.25 mg/5 mL liquid

H_2 BLOCKERS

See Chapter 63.

5-HT AGONISTS

Almotriptan (Axert)

Oral: 6.25, 12.5 mg tablets

Eletriptan (Relpax)

Oral: 24.2, 48.5 mg tablets (equivalent to 20, 40 mg base)

Frovatriptan (Frova)

Oral: 2.5 mg tablets

Naratriptan (Amerge)

Oral: 1, 2.5 mg tablets

Rizatriptan

Oral: 5, 10 mg tablets (Maxalt); 5, 10 mg orally disintegrating tablets (Maxalt-MLT)

Sumatriptan (Imitrex)

Oral: 25, 50, 100 mg tablets

Nasal: 5, 20 mg unit dose spray devices

Parenteral: 6 mg/0.5 mL in SELFdose autoinjection units for subcutaneous injection

Zolmitriptan (Zomig)

Oral: 2.5, 5 mg tablets

Nasal: 5 mg

5-HT ANTAGONISTS

See Chapter 63.

MELATONIN RECEPTOR AGONISTS

Ramelteon (Rozarem)

Oral: 8 mg tablets

ERGOT ALKALOIDS

Dihydroergotamine

Nasal (Migranal): 4 mg/mL nasal spray

Parenteral (D.H.E. 45): 1 mg/mL for injection

Ergonovine (Ergotrate)

Parenteral: 0.2 mg/mL for injection

Oral: 0.2 mg tablets

Ergotamine mixtures (generic, Cafergot)

Oral: 1 mg ergotamine/100 mg caffeine tablets

Rectal: 2 mg ergotamine/100 mg caffeine suppositories

Ergotamine tartrate (Ergomar)

Sublingual: 2 mg sublingual tablets

Methylergonovine (Methergine)

Oral: 0.2 mg tablets

Parenteral: 0.2 mg/mL for injection

*Several other antihistamines are available only in combination products with, for example, phenylephrine.

Dimenhydrinate is the chlorotheophylline salt of diphenhydramine.

Top of Form

VASOACTIVE PEPTIDES: INTRODUCTION

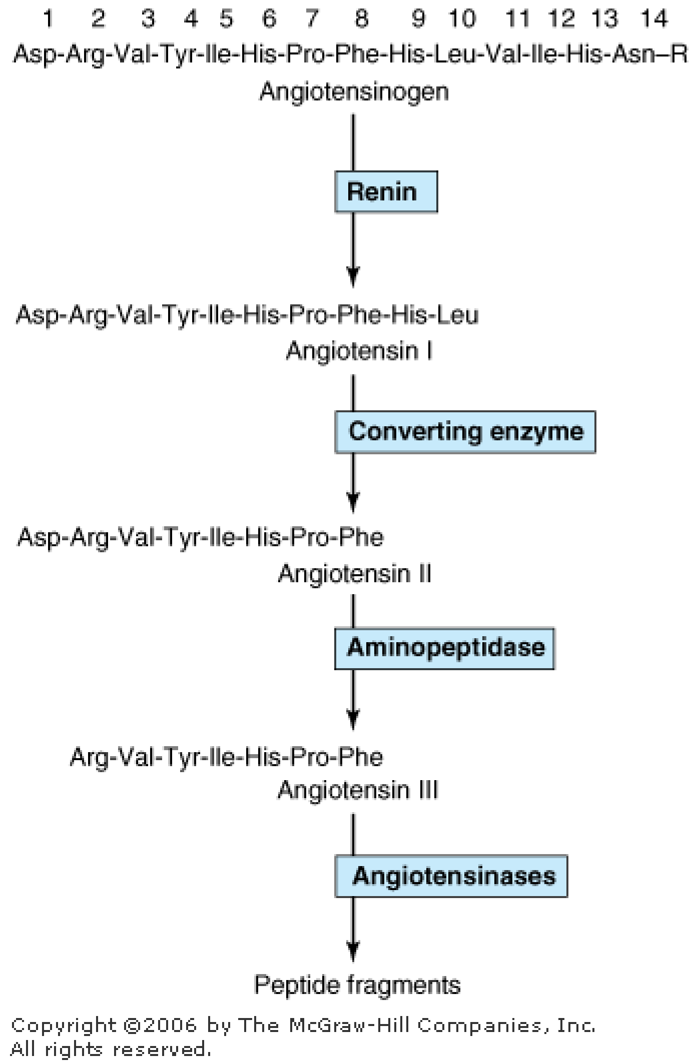
Peptides are used by most tissues for cell-to-cell communication. As noted in Chapters 6 and 21, they play important roles in the autonomic and central nervous systems. Several peptides exert important direct effects on vascular and other smooth muscles. These peptides include vasoconstrictors (angiotensin II, vasopressin, endothelins, neuropeptide Y, and urotensin) and vasodilators (bradykinin and related kinins, natriuretic peptides, vasoactive intestinal peptide, substance P, neurotensin, calcitonin gene-related peptide, and adrenomedullin). This chapter focuses on the smooth muscle actions of the peptides.

ANGIOTENSIN

BIOSYNTHESIS OF ANGIOTENSIN

The pathway for the formation and metabolism of angiotensin II is summarized in Figure 17–1. The principal steps include enzymatic cleavage of angiotensin I from angiotensinogen by renin, conversion of angiotensin I to angiotensin II by converting enzyme, and degradation of angiotensin II by several peptidases.

Figure 17–1.



Chemistry of the renin-angiotensin system. The amino acid sequence of the amino terminal of human angiotensinogen is shown. R denotes the remainder of the protein molecule. See text for additional steps in the formation and metabolism of angiotensin peptides.

Renin & Factors Controlling Renin Secretion

Renin is an aspartyl protease that specifically catalyzes the hydrolytic release of the decapeptide angiotensin I from angiotensinogen. It is synthesized as a preprohormone that is processed to prorenin, which is inactive, and then to active renin, a glycoprotein consisting of 340 amino acids.

Renin in the circulation originates in the kidneys. Enzymes with renin-like activity are present in several extrarenal tissues, including blood vessels, uterus, salivary glands, and adrenal cortex, but no physiologic role for these enzymes has been established. Within the kidney, renin is synthesized and stored in the juxtaglomerular apparatus of the nephron. Specialized granular cells called juxtaglomerular cells are the site of synthesis, storage, and release of renin. The macula densa is a specialized segment of the nephron that is closely associated with the vascular components of the juxtaglomerular apparatus. The vascular and tubular components of the juxtaglomerular apparatus, including the juxtaglomerular cells, are innervated by noradrenergic neurons.

The rate at which renin is secreted by the kidney is the primary determinant of activity of the renin-angiotensin system. Active renin is released immediately upon stimulation of the juxtaglomerular apparatus. Prorenin is released constitutively and, for unknown reasons, circulates at levels that can be considerably higher than those of active renin. Active renin secretion is controlled by a variety of factors, including a renal vascular receptor, the macula densa, the sympathetic nervous system, and angiotensin II.

RENAL VASCULAR RECEPTOR

The renal vascular receptor functions as a stretch receptor, with decreased stretch leading to increased renin release and vice versa. The receptor is apparently located in the afferent arteriole, possibly in the juxtaglomerular cells. Stretch-induced changes in renin release are mediated by changes in Ca^{2+} concentration in the juxtaglomerular cells.

MACULA DENSA

The macula densa contains a different type of receptor, sensitive to changes in the rate of delivery of sodium or chloride to the distal tubule. Decreases in distal delivery result in stimulation of renin secretion and vice versa. Potential candidates for signal transmission between the macula densa and the juxtaglomerular cells include adenosine, prostaglandins, and nitric oxide.

SYMPATHETIC NERVOUS SYSTEM

Maneuvers that increase renal nerve activity cause stimulation of renin secretion, whereas renal denervation results in suppression of renin secretion. Norepinephrine stimulates renin secretion by a direct action on the juxtaglomerular cells. In humans, this effect is mediated by β_1 adrenoceptors.

Circulating epinephrine and norepinephrine may act via the same mechanisms as the norepinephrine released locally from the renal sympathetic nerves, but there is evidence that a major component of the renin secretory response to circulating catecholamines is mediated by extrarenal β receptors.

ANGIOTENSIN

Angiotensin II inhibits renin secretion. The inhibition, which results from a direct action of the peptide on the juxtaglomerular cells, forms the basis of a short-loop negative feedback mechanism controlling renin secretion. Interruption of this feedback with inhibitors of the renin-angiotensin system (see below) results in stimulation of renin secretion.

PHARMACOLOGIC ALTERATION OF RENIN RELEASE

The release of renin is altered by a wide variety of pharmacologic agents. Renin release is stimulated by vasodilators (hydralazine, minoxidil, nitroprusside), β-adrenoceptor agonists (isoproterenol), α-adrenoceptor antagonists, phosphodiesterase inhibitors (theophylline, milrinone, rolipram), and most diuretics and anesthetics. This stimulation can be accounted for by the control mechanisms just described. Drugs that inhibit renin release are discussed below in the section on Inhibition of the Renin-Angiotensin System.

Angiotensinogen

Angiotensinogen is the circulating protein substrate from which renin cleaves angiotensin I. It is synthesized in the liver. Human angiotensinogen is a glycoprotein with a molecular weight of approximately 57,000. The 14 amino acids at the amino terminal of the molecule are shown in Figure 17–1. In humans, the concentration of angiotensinogen in the circulation is less than the K_m of the renin-angiotensinogen reaction and is therefore an important determinant of the rate of formation of angiotensin.

The production of angiotensinogen is increased by corticosteroids, estrogens, thyroid hormones, and angiotensin II. It is also elevated during pregnancy and in women taking estrogen-containing oral contraceptives. The increased plasma angiotensinogen concentration is thought to contribute to the hypertension that may occur in these situations.

Angiotensin I

Although angiotensin I contains the peptide sequences necessary for all of the actions of the renin-angiotensin system, it has little or no biologic activity. Instead, it must be converted to angiotensin II by converting enzyme (Figure 17–1). Angiotensin I may also be acted on by plasma or tissue aminopeptidases to form [des-Asp^1]angiotensin I; this in turn is converted to [des-Asp^1]angiotensin II (commonly known as angiotensin III) by converting enzyme.

Converting Enzyme (ACE, Peptidyl Dipeptidase, Kininase II)

Converting enzyme is a dipeptidyl carboxypeptidase that catalyzes the cleavage of dipeptides from the carboxyl terminal of certain peptides. Its most important substrates are angiotensin I, which it converts to angiotensin II, and bradykinin, which it inactivates (see below). It also cleaves enkephalins and substance P, but the physiologic significance of these effects has not been established. The action of converting enzyme is prevented by a penultimate prolyl residue, and angiotensin II is therefore not hydrolyzed by converting enzyme. Converting enzyme is distributed widely in the body. In most tissues, converting enzyme is located on the luminal surface of vascular endothelial cells and is thus in close contact with the circulation.

A homolog of converting enzyme known as ACE2 was recently discovered. ACE2 is highly expressed in vascular endothelial cells of the kidneys, heart, and testes. Unlike converting enzyme, ACE2 has only one active site and functions as a carboxypeptidase rather than a dipeptidyl carboxypeptidase. It removes a single amino acid from the C-terminal of angiotensin I and II forming angiotensin (1-9), which has no known function, and angiotensin (1-7), which has vasodilator activity and may serve to counteract the vasoconstrictor activity of angiotensin II. ACE2 also differs from converting enzyme in that it does not hydrolyze bradykinin and is not inhibited by converting enzyme inhibitors (see below). Thus, the enzyme might better be regarded as an angiotensinase rather than a converting enzyme. (An interesting recent finding is that ACE2 is a functional receptor for coronaviruses including the virus that causes severe acute respiratory syndrome.)

Angiotensinase

Angiotensin II, which has a plasma half-life of 15–60 seconds, is removed rapidly from the circulation by a variety of peptidases collectively referred to as angiotensinase. It is metabolized during passage through most vascular beds (a notable exception being the lung). Most metabolites of angiotensin II are biologically inactive, but the initial product of aminopeptidase action—[des-Asp^1]angiotensin II—retains considerable biologic activity.

ACTIONS OF ANGIOTENSIN II

Angiotensin II exerts important actions at vascular smooth muscle, adrenal cortex, kidney, heart, and brain. Through these actions, the renin-angiotensin system plays a key role in the regulation of fluid and electrolyte balance and arterial blood pressure. Excessive activity of the renin-angiotensin system can result in hypertension and disorders of fluid and electrolyte homeostasis.

Blood Pressure

Angiotensin II is a very potent pressor agent—on a molar basis, approximately 40 times more potent than norepinephrine. The pressor response to intravenous angiotensin II is rapid in onset (10–15 seconds) and sustained during long-term infusions. A large component of the pressor response is due to direct contraction of vascular—especially arteriolar—smooth muscle. In addition, however, angiotensin II can also increase blood pressure through actions on the brain and autonomic nervous system. The pressor response to angiotensin is usually accompanied by little or no reflex bradycardia because the peptide acts on the brain to reset the baroreceptor reflex control of heart rate to a higher pressure.

Angiotensin II also interacts with the autonomic nervous system. It stimulates autonomic ganglia, increases the release of epinephrine and norepinephrine from the adrenal medulla, and—what is most important—facilitates sympathetic transmission by an action at adrenergic nerve terminals. The latter effect involves both increased release and reduced reuptake of norepinephrine. Angiotensin II also has a less important direct positive inotropic action on the heart.

Adrenal Cortex

Angiotensin II acts directly on the zona glomerulosa of the adrenal cortex to stimulate aldosterone biosynthesis. At higher concentrations, angiotensin II also stimulates glucocorticoid biosynthesis.

Kidney

Angiotensin II acts on the kidney to cause renal vasoconstriction, increase proximal tubular sodium reabsorption, and inhibit the secretion of renin.

Central Nervous System

In addition to its central effects on blood pressure, angiotensin II acts on the central nervous system to stimulate drinking (dipsogenic effect) and increase the secretion of vasopressin and adrenocorticotropic hormone (ACTH). The physiologic significance of the effects of angiotensin II on drinking and pituitary hormone secretion is not known.

Cell Growth

Angiotensin II is mitogenic for vascular and cardiac muscle cells and may contribute to the development of cardiovascular hypertrophy. It also exerts a variety of important effects on the vascular endothelium. Considerable evidence now indicates that ACE inhibitors and angiotensin II receptor antagonists (see below) slow or prevent morphologic changes (remodeling) following myocardial infarction that would otherwise lead to heart failure.

ANGIOTENSIN RECEPTORS & MECHANISM OF ACTION

Angiotensin II receptors are widely distributed in the body. Like the receptors for other peptide hormones, angiotensin II receptors are located on the plasma membrane of target cells, and this permits rapid onset of the various actions of angiotensin II.

Two distinct subtypes of angiotensin II receptors, termed AT_1 and AT_2, have been identified on the basis of their differential affinity for antagonists, and their sensitivity to sulfhydryl-reducing agents. AT_1

receptors have a high affinity for losartan and a low affinity for PD 123177 (an experimental nonpeptide antagonist), whereas AT_2 receptors have a high affinity for PD 123177 and a low affinity for losartan. Angiotensin II and saralasin (see below) bind equally to both subtypes. The relative proportion of the two subtypes varies from tissue to tissue: AT_1 receptors predominate in vascular smooth muscle.

Most of the known actions of angiotensin II are mediated by the AT_1 receptor, a G_q protein-coupled receptor. Binding of angiotensin II to AT_1 receptors in vascular smooth muscle results in activation of phospholipase C and generation of inositol trisphosphate and diacylglycerol (see Chapter 2). These events, which occur within seconds, result in smooth muscle contraction.

The stimulation of vascular and cardiac growth by angiotensin II is mediated by other pathways, probably receptor and nonreceptor tyrosine kinases such as the Janus tyrosine kinase Jak2 and increased transcription of specific genes (see Chapter 2).

The AT_2 receptor has a structure and affinity for angiotensin II similar to those of the AT_1 receptor. In contrast, however, stimulation of AT_2 receptors causes vasodilation that may serve to counteract the vasoconstriction resulting from AT_1 receptor stimulation. AT_2 receptor-mediated vasodilation appears to be nitric oxide (NO)-dependent and may involve the bradykinin B_2 receptor-NO-cGMP pathway.

AT_2 receptors are present at high density in all tissues during fetal development, but they are much less abundant in the adult where they are expressed at high concentration only in the adrenal medulla, reproductive tissues, vascular endothelium, and parts of the brain. AT_2 receptors are up-regulated in pathologic conditions including heart failure and myocardial infarction. The functions of the AT_2 receptor appear to include fetal tissue development, inhibition of growth and proliferation, cell differentiation, apoptosis, and vasodilation.

INHIBITION OF THE RENIN-ANGIOTENSIN SYSTEM

A wide variety of agents are now available that block the formation or actions of angiotensin II. These drugs block renin secretion, the enzymatic action of renin, the conversion of angiotensin I to angiotensin II, or angiotensin II receptors.

Drugs That Block Renin Secretion

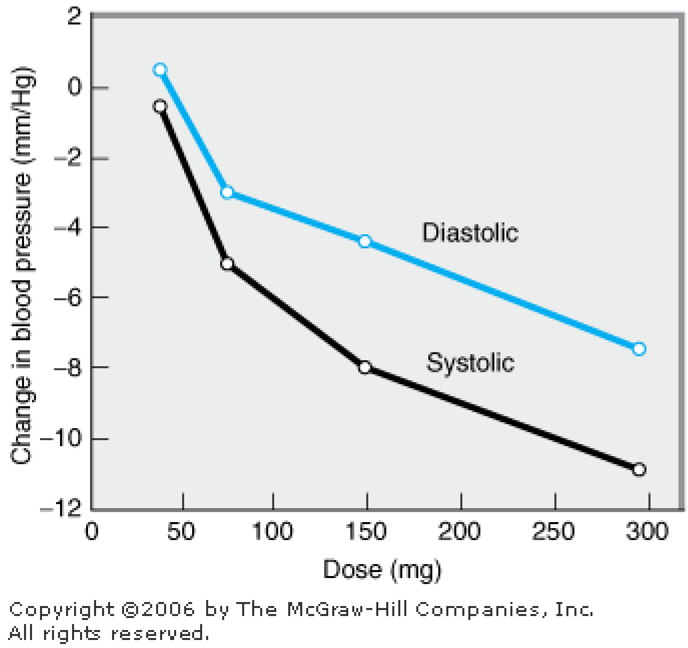
Several drugs that interfere with the sympathetic nervous system inhibit the secretion of renin. Examples are clonidine and propranolol. Clonidine inhibits renin secretion by causing a centrally mediated reduction in renal sympathetic nerve activity, and it may also exert a direct intrarenal action. Propranolol and other β-adrenoceptor–blocking drugs act by blocking the intrarenal and extrarenal β receptors involved in the neural control of renin secretion.

Renin Inhibitors

Drugs that inhibit renin have been available for many years but have been limited by low potency, bioavailability, and duration of action. However, a new class of nonpeptide, low-molecular weight, orally active inhibitors has recently been developed.

Aliskiren is the most advanced of these. In healthy subjects, aliskiren produces a dose-dependent reduction in plasma renin activity and angiotensin I and II and aldosterone concentrations. In patients with essential hypertension, aliskiren suppresses plasma renin activity and causes dose-related reductions in blood pressure similar to those produced by angiotensin II receptor antagonists (Figure 17–2). The safety and tolerability of aliskiren appear to be comparable to angiotensin antagonists and placebo. Renin inhibition thus has considerable promise for the treatment of hypertension and other cardiovascular and renal diseases.

Figure 17–2.

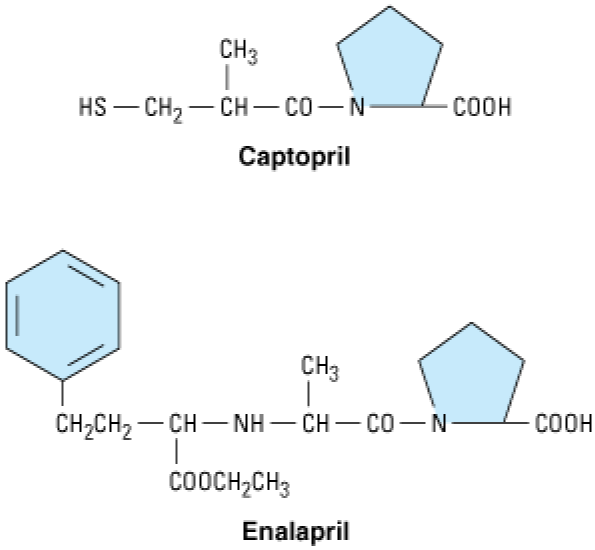


Effect of the renin inhibitor aliskiren on blood pressure in patients with essential hypertension. (Data from Stanton A et al: Blood pressure lowering in essential hypertension with an oral renin inhibitor, aliskiren. Hypertension 2003;42:1137.)

Angiotensin-Converting Enzyme Inhibitors

An important class of orally active ACE inhibitors, directed against the active site of ACE, is now extensively used. Captopril and enalapril (Figure 17–3) are examples of the many potent ACE inhibitors that are available. These drugs differ in their structure and pharmacokinetics, but in clinical use, they are interchangeable. ACE inhibitors decrease systemic vascular resistance without increasing heart rate, and they promote natriuresis. As described in Chapters 11 and 13, they are effective in the treatment of hypertension, decrease morbidity and mortality in heart failure and left ventricular dysfunction after myocardial infarction, and delay the progression of diabetic nephropathy.

Figure 17–3.



Two orally active converting enzyme inhibitors. Enalapril is a prodrug ethyl ester that is hydrolyzed in the body.

ACE inhibitors not only block the conversion of angiotensin I to angiotensin II but also inhibit the degradation of other substances, including bradykinin, substance P, and enkephalins. The action of ACE inhibitors to inhibit bradykinin metabolism contributes significantly to their hypotensive action (see Figure 11–5) and is apparently responsible for some adverse side effects, including cough and angioedema.

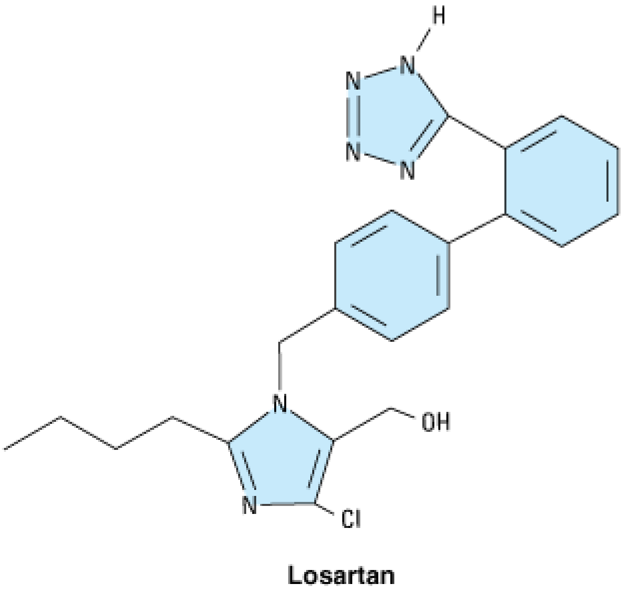
Recent evidence suggests that some of the beneficial effects of ACE inhibitors can be attributed to activation of a distinct ACE-signaling cascade in addition to the changes in angiotensin II and bradykinin levels.

Angiotensin Receptor Antagonists

Potent peptide antagonists of the action of angiotensin II have been developed. The best-known of these is the partial agonist, saralasin. Saralasin lowers blood pressure in hypertensive patients but may elicit pressor responses, particularly when circulating angiotensin II levels are low. Because it must be administered intravenously, saralasin is used only for investigation of renin-dependent hypertension and other hyperreninemic states.

The *non*peptide angiotensin II antagonists are of much greater interest. Losartan (Figure 17–4), valsartan, eprosartan, irbesartan, candesartan, olmesartan, and telmesartan are orally active, potent, and specific competitive antagonists of angiotensin AT_1 receptors. The efficacy of these drugs in hypertension is similar to that of ACE inhibitors, but they are associated with a lower incidence of cough. Like ACE inhibitors, *non*peptide angiotensin II antagonists slow the progression of diabetic nephropathy. The antagonists are also effective in the treatment of heart failure and provide a useful alternative when ACE inhibitors are not well tolerated. Like ACE inhibitors, they are well tolerated but should not be used by patients with nondiabetic renal disease or in pregnancy.

Figure 17–4.



Structure of an angiotensin AT_1 receptor antagonist.

The current angiotensin II receptor antagonists are selective for the AT_1 receptor. Since prolonged treatment with the drugs disinhibits renin secretion and increases circulating angiotensin II levels, there may be increased stimulation of AT_2 receptors. This may be significant in view of the evidence that activation of the AT_2 receptor causes vasodilation and other beneficial effects. AT_2 receptor antagonists such as PD 123177 are available for research but have no clinical applications at this time.

The clinical benefits of AT_1 receptor antagonists are similar to those of ACE inhibitors, and it is not clear if one group of drugs has significant advantages over the other. Combination therapy with both an ACE inhibitor and an angiotensin receptor antagonist has a number of potential advantages and is currently being investigated.

KININS

BIOSYNTHESIS OF KININS

Kinins are potent vasodilator peptides formed enzymatically by the action of enzymes known as kallikreins or kininogenases acting on protein substrates called kininogens. The kallikrein-kinin system has several features in common with the renin-angiotensin system.

Kallikreins

Kallikreins are present in plasma and in several tissues, including the kidneys, pancreas, intestine, sweat glands, and salivary glands. Plasma prekallikrein can be activated to kallikrein by trypsin, Hageman factor, and possibly kallikrein itself. In general, the biochemical properties of tissue kallikreins are different from those of plasma kallikreins. Kallikreins can convert prorenin to active renin, but the physiologic significance of this action has not been established.

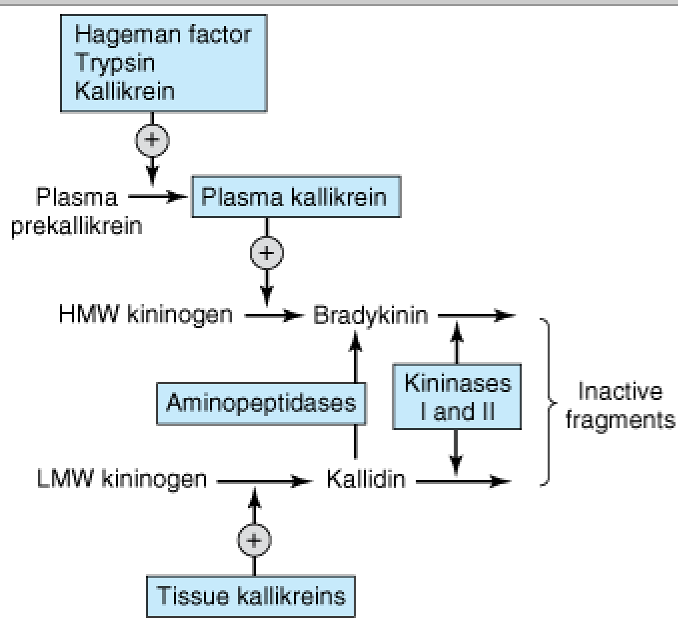
Kininogens

Kininogens—the precursors of kinins and substrates of kallikreins—are present in plasma, lymph, and interstitial fluid. Two kininogens are known to be present in plasma: a low-molecular-weight form (LMW kininogen) and a high-molecular-weight form (HMW kininogen). About 15–20% of the total plasma kininogen is in the HMW form. It is thought that LMW kininogen crosses capillary walls and serves as the substrate for tissue kallikreins, whereas HMW kininogen is confined to the bloodstream and serves as the substrate for plasma kallikrein.

FORMATION OF KININS IN PLASMA & TISSUES

The pathway for the formation and metabolism of kinins is shown in Figure 17–5. Three kinins have been identified in mammals: bradykinin, lysylbradykinin (also known as kallidin), and methionyllysylbradykinin. Each contains bradykinin in its structure.

Figure 17–5.



The kallikrein-kinin system. Kininase II is identical to converting enzyme peptidyl dipeptidase.

Each kinin is formed from a kininogen by the action of a different enzyme. Bradykinin is released by plasma kallikrein, lysylbradykinin by tissue kallikrein, and methionyllysylbradykinin by pepsin and pepsin-like enzymes. The three kinins have been found in plasma and urine. Bradykinin is the predominant kinin in plasma, whereas lysylbradykinin is the major urinary form.

ACTIONS OF KININS

Effects on the Cardiovascular System

Kinins produce marked vasodilation in several vascular beds, including the heart, kidney, intestine, skeletal muscle, and liver. In this respect, kinins are approximately 10 times more potent on a molar basis than histamine. The vasodilation may result from a direct inhibitory effect of kinins on arteriolar smooth muscle or may be mediated by the release of nitric oxide or vasodilator prostaglandins such as PGE_2 and PGI_2. In contrast, the predominant effect of kinins on veins is contraction; again, this may result from direct stimulation of venous smooth muscle or from the release of venoconstrictor prostaglandins such as PGF_2 . Kinins also produce contraction of most visceral smooth muscle.

When injected intravenously, kinins produce a rapid but brief fall in blood pressure that is due to their arteriolar vasodilator action. Intravenous infusions of the peptide fail to produce a sustained decrease in blood pressure; prolonged hypotension can only be produced by progressively increasing the rate of infusion. The rapid reversibility of the hypotensive response to kinins is due primarily to reflex increases in heart rate, myocardial contractility, and cardiac output. In some species, bradykinin produces a biphasic change in blood pressure—an initial hypotensive response followed by an increase above the preinjection level. The increase in blood pressure may be due to a reflex activation of the sympathetic nervous system, but under some conditions, bradykinin can directly release catecholamines from the adrenal medulla and stimulate sympathetic ganglia. Bradykinin also increases blood pressure when injected into the central nervous system, but the physiologic significance of this effect is not clear, since it is unlikely that kinins cross the blood-brain barrier. Kinins have no consistent effect on sympathetic or parasympathetic nerve endings.

The arteriolar dilation produced by kinins causes an increase in pressure and flow in the capillary bed, thus favoring efflux of fluid from blood to tissues. This effect may be facilitated by increased capillary permeability resulting from contraction of endothelial cells and widening of intercellular junctions, and by increased venous pressure secondary to constriction of veins. As a result of these changes, water and solutes pass from the blood to the extracellular fluid, lymph flow increases, and edema may result.

Effects on Endocrine & Exocrine Glands

As noted earlier, prekallikreins and kallikreins are present in several glands, including the pancreas, kidney, intestine, salivary glands, and sweat glands, and they can be released into the secretory fluids of these glands. The function of the enzymes in these tissues is not known. The enzymes (or active kinins) may diffuse from the organs to the blood and act as local modulators of blood flow. Since kinins have such marked effects on smooth muscle, they may also modulate the tone of salivary and pancreatic ducts and help regulate gastrointestinal motility. Kinins also influence the transepithelial transport of water, electrolytes, glucose, and amino acids, and may regulate the transport of these substances in the gastrointestinal tract and kidney. Finally, kallikreins may play a role in the physiologic activation of various prohormones, including proinsulin and prorenin.

Role in Inflammation

Kinins play an important role in the inflammatory process. Kallikreins and kinins can produce redness, local heat, swelling, and pain, and the production of kinins is increased in inflammatory lesions produced by a variety of methods.

Effects on Sensory Nerves

Kinins are potent pain-producing substances when applied to a blister base or injected intradermally. They elicit pain by stimulating nociceptive afferents in the skin and viscera.

KININ RECEPTORS & MECHANISMS OF ACTION

The biologic actions of kinins are mediated by specific receptors located on the membranes of the target tissues. Two types of kinin receptors, termed B_1 and B_2, have been defined based on the rank orders of agonist potencies. (Note that *B* here stands for bradykinin, not for β-adrenoceptor.) Bradykinin displays the highest affinity in most B_2 receptor systems, followed by Lys-bradykinin and then by Met-Lys-bradykinin. One exception is the B_2 receptor that mediates contraction of venous smooth muscle; this appears to be most sensitive to Lys-bradykinin. Recent evidence suggests the existence of two B_2-receptor subtypes, which have been termed B_{2A} and B_{2B}.

B_1 receptors appear to have a very limited distribution in mammalian tissues and have few known functional roles. Studies with knockout mice that lack functional B_1 receptors suggest that these receptors participate in the inflammatory response and may also be important in long-lasting kinin effects such as collagen synthesis and cell multiplication. By contrast, B_2 receptors have a widespread distribution that is consistent with the multitude of biologic effects that are mediated by this receptor type. B_2 receptors are G protein–coupled and agonist binding sets in motion multiple signal transduction events, including calcium mobilization, chloride transport, formation of nitric oxide, and activation of phospholipase C, phospholipase A_2, and adenylyl cyclase.

METABOLISM OF KININS

Kinins are metabolized rapidly (half-life < 15 seconds) by nonspecific exopeptidases or endopeptidases, commonly referred to as kininases. Two plasma kininases have been well characterized. Kininase I, apparently synthesized in the liver, is a carboxypeptidase that releases the carboxyl terminal arginine residue. Kininase II is present in plasma and vascular endothelial cells throughout the body. It is identical to angiotensin-converting enzyme (ACE, peptidyl dipeptidase), discussed above. Kininase II inactivates kinins by cleaving the carboxyl terminal dipeptide phenylalanyl-arginine. Like angiotensin I, bradykinin is almost completely hydrolyzed during a single passage through the pulmonary vascular bed.

DRUGS AFFECTING THE KALLIKREIN-KININ SYSTEM

Drugs that modify the activity of the kallikrein-kinin system are available, though none are in wide clinical use. Considerable effort has been directed toward developing kinin receptor antagonists, since such drugs have considerable therapeutic potential as anti-inflammatory and antinociceptive agents. Competitive antagonists of both B_1 and B_2 receptors are available for research use. Examples of B_1 receptor antagonists are the peptides [Leu^8-des-Arg^9]bradykinin and Lys[Leu^8-des Arg^9]bradykinin. Nonpeptide B_1 receptor antagonists are not yet available. The first B_2 receptor antagonists to be discovered were also peptide derivatives of bradykinin. These first-generation antagonists were used extensively in animal studies of kinin receptor pharmacology. However, their half-life is short, and they are almost inactive on the human B_2 receptor.

Icatibant is a second-generation B_2 receptor antagonist. It is orally active, potent, and selective, has a long duration of action (> 60 minutes), and displays high B_2-receptor affinity in humans and all other species in which it has been tested. Icatibant has been used extensively in animal studies to block exogenous and endogenous bradykinin and in human studies to evaluate the role of kinins in pain, hyperalgesia, and inflammation.

Recently, a third generation of B_2-receptor antagonists was developed; examples are FR 173657, FR 172357, and NPC 18884. These antagonists block both human and animal B_2 receptors and are orally active. They have been reported to inhibit bradykinin-induced bronchoconstriction in guinea pigs, carrageenin-induced inflammatory responses in rats, and capsaicin-induced nociception in mice. These antagonists have promise for the treatment of inflammatory pain in humans.

SSR240612 is a new, potent, and orally active selective antagonist of B_1 receptors in humans and several animal species. It exhibits analgesic and anti-inflammatory activities in mice and rats and is currently in preclinical development for the treatment of inflammatory and neurogenic pain.

The synthesis of kinins can be inhibited with the kallikrein inhibitor aprotinin. Actions of kinins mediated by prostaglandin generation can be blocked nonspecifically with inhibitors of prostaglandin synthesis such as aspirin. Conversely, the actions of kinins can be enhanced with ACE inhibitors, which block the degradation of the peptides. Indeed, as noted above, inhibition of bradykinin metabolism by ACE inhibitors contributes significantly to their antihypertensive action.

There is evidence that by acting on B_2 receptors, bradykinin may play a beneficial, protective role in cardiovascular disease. Selective B_2 agonists are available and have been shown to be effective in some animal models of human cardiovascular disease. These drugs may have potential for the treatment of hypertension and myocardial hypertrophy.

VASOPRESSIN

Vasopressin (antidiuretic hormone, ADH) plays an important role in the long-term control of blood pressure through its action on the kidney to increase water reabsorption. This and other aspects of the physiology of vasopressin are discussed in Chapters 15 and 37 and will not be reviewed here.

Vasopressin also plays an important role in the short-term regulation of arterial pressure by its vasoconstrictor action. It increases total peripheral resistance when infused in doses less than those required to produce maximum urine concentration. Such doses do not normally increase arterial pressure because the vasopressor activity of the peptide is buffered by a reflex decrease in cardiac output. When the influence of this reflex is removed, eg, in shock, pressor sensitivity to vasopressin is greatly increased. Pressor sensitivity to vasopressin is also enhanced in patients with idiopathic orthostatic hypotension. Higher doses of vasopressin increase blood pressure even when baroreceptor reflexes are intact.

VASOPRESSIN RECEPTORS & ANTAGONISTS

Three subtypes of vasopressin receptors have been identified. V_{1a} receptors mediate the vasoconstrictor action of vasopressin; V_{1b} receptors potentiate the release of ACTH by pituitary corticotropes; and V_2 receptors mediate the antidiuretic action. V_{1a} effects are mediated by activation of phospholipase C, formation of inositol trisphosphate, and increased intracellular calcium concentration. V_2 effects are mediated by activation of adenylyl cyclase.

Vasopressin-like peptides selective for either vasoconstrictor or antidiuretic activity have been synthesized. The most specific V_1 vasoconstrictor agonist synthesized to date is [Phe^2, Ile^3, Orn^{8}]vasotocin. Selective V_2 antidiuretic analogs include 1-deamino[D-Arg^{8}]arginine vasopressin (dDAVP) and 1-deamino[Val^{4},D-Arg^{8}]arginine vasopressin (dVDAVP).

Specific antagonists of the vasoconstrictor action of vasopressin are also available. The peptide antagonist [1-(β-mercapto-β,β-cyclopentamethylenepropionic acid)-2-(*O*-methyl)tyrosine] arginine vasopressin also has antioxytocic activity but does not antagonize the antidiuretic action of vasopressin. Recently, nonpeptide, orally active V_{1a} receptor antagonists have been discovered, examples being OPC-21268 and SR49059.

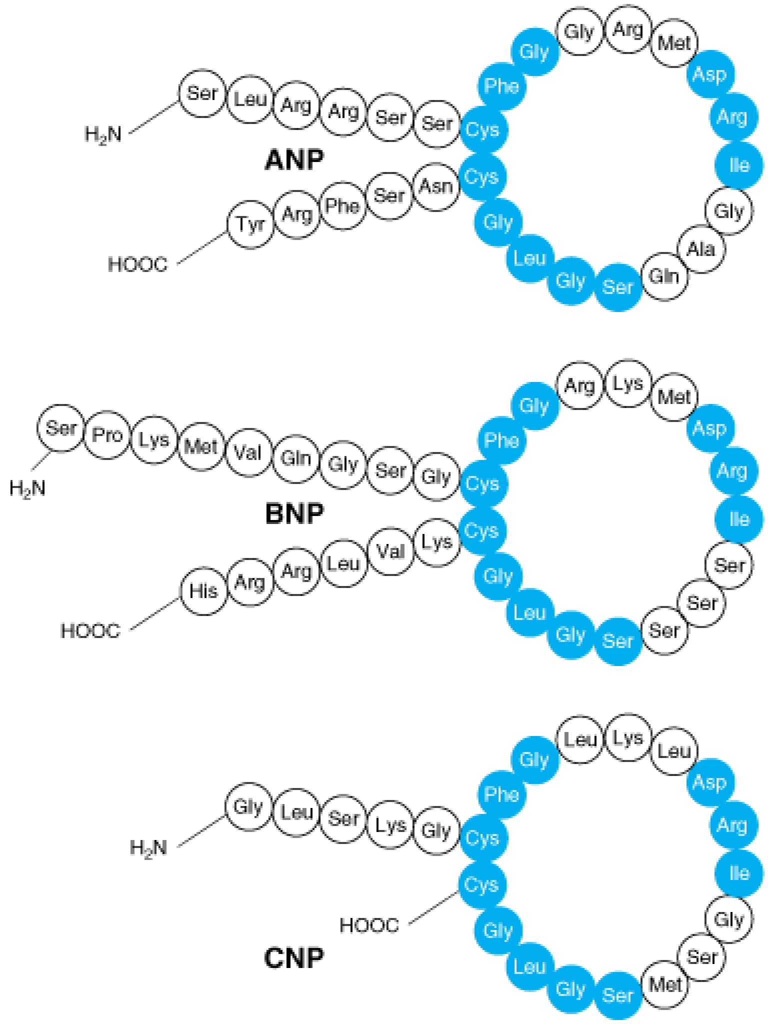
The vasopressor antagonists of vasopressin have been particularly useful in revealing the important role that vasopressin plays in blood pressure regulation in situations such as dehydration and hemorrhage. They have potential for the treatment of hypertension and heart failure. To date, most studies have focused on heart failure in which promising results have been obtained with V_2 antagonists. However, V_{1a} antagonists also have potential, and conivaptan (YM087), a drug with both V_{1a} and V_2 antagonist effects, has been approved for treatment of hyponatremia (see Chapter 15).

NATRIURETIC PEPTIDES

Synthesis & Structure

The atria and other tissues of mammals contain a family of peptides with natriuretic, diuretic, vasorelaxant, and other properties. The family consists of atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP) and C-type natriuretic peptide (CNP). The structures of the three peptides are similar (Figure 17–6), but there are differences in their biologic effects. ANP is derived from the carboxyl terminal end of a common precursor termed preproANP. ANP is synthesized primarily in cardiac atrial cells, but small amounts are synthesized in ventricular cells. It is also synthesized by neurons in the central and peripheral nervous systems and in the lungs. ANP circulates as a 28-amino-acid peptide with a single disulfide bridge that forms a 17-residue ring.

Figure 17–6.



Structures of atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP). Sequences common to the peptides are indicated in blue.

Several factors increase the release of ANP from the heart, but the most important one appears to be atrial stretch via mechanosensitive ion channels. ANP release is also increased by volume expansion, head-out water immersion, changing from the standing to the supine position, and exercise. ANP release can also be increased by sympathetic stimulation via α_{1A}-adrenoceptors, endothelins (see below) via the ET_A-receptor subtype, glucocorticoids, and vasopressin. Finally, plasma ANP concentration increases in various pathologic states, including heart failure, primary aldosteronism, chronic renal failure, and inappropriate ADH secretion syndrome.

Administration of ANP produces prompt and marked increases in sodium excretion and urine flow. Glomerular filtration rate increases, with little or no change in renal blood flow, so that the filtration fraction increases. The ANP-induced natriuresis is apparently due to both the increase in glomerular filtration rate and a decrease in proximal tubular sodium reabsorption. ANP also inhibits the secretion of renin, aldosterone, and vasopressin; these changes may also increase sodium and water excretion.

Finally, ANP decreases arterial blood pressure. This hypotensive action is due to vasodilation, which results from stimulated particulate guanylyl cyclase activity, increased cGMP levels, and decreased cytosolic free calcium concentration. ANP also reduces sympathetic tone to the peripheral vasculature and antagonizes the vasoconstrictor action of angiotensin II and other vasoconstrictors. These actions may contribute to the hypotensive action of the peptide.

There is considerable evidence that ANP participates in the physiologic regulation of sodium excretion and blood pressure. For example, suppression of ANP production or blockade of its action impairs the natriuretic response to volume expansion, and increases blood pressure.

BNP was originally isolated from porcine brain but, like ANP, it is synthesized primarily in the heart. It exists in two forms, having either 26 or 32 amino acids (Figure 17–6). Like ANP, the release of BNP appears to be volume-related; indeed, the two peptides may be co-secreted. BNP exhibits natriuretic, diuretic, and hypotensive activities similar to those of ANP but circulates at a lower concentration.

CNP consists of 22 amino acids (Figure 17–6). It is located predominantly in the central nervous system but is also present in several other tissues including the vascular endothelium, kidneys, and intestine. It has not been found in significant concentrations in the circulation. CNP has less natriuretic and diuretic activity than ANP and BNP but is a potent vasodilator. Its physiologic role is unclear.

Pharmacodynamics & Pharmacokinetics

The biologic actions of the natriuretic peptides are mediated through association with specific high-affinity receptors located on the surface of the target cells. Three receptor subtypes termed ANP_A, ANP_B, and ANP_C have been identified. The ANP_A receptor consists of a 120 kDa protein; its primary ligands are ANP and BNP. The ANP_B receptor is similar in structure to the ANP_A receptor, but its primary ligand appears to be CNP. The ANP_A and ANP_B receptors, but not the ANP_C receptor, are coupled to guanylyl cyclase.

The natriuretic peptides have a short half-life in the circulation. They are metabolized in the kidneys, liver, and lungs by the neutral endopeptidase NEP 24.11. Inhibition of this endopeptidase results in increases in circulating levels of the natriuretic peptides, natriuresis, and diuresis. The peptides are also removed from the circulation by binding to ANP_C receptors in the vascular endothelium. This receptor binds the three natriuretic peptides with equal affinity. The receptor and bound peptide are internalized, the peptide is degraded enzymatically, and the receptor is returned to the cell surface.

Administration of BNP as nesiritide (see Chapter 13) in patients with severe heart failure increases sodium excretion and improves hemodynamics. However, the peptide has to be given by constant intravenous infusion and has caused fatal renal damage. A more promising approach may be the use of drugs that inhibit the neutral endopeptidase responsible for the breakdown of ANP. This is discussed below under Vasopeptidase Inhibitors. Patients with heart failure have high plasma levels of ANP and BNP; the latter has emerged as a diagnostic and prognostic marker in this condition.

VASOPEPTIDASE INHIBITORS

Vasopeptidase inhibitors are a new class of cardiovascular drugs that inhibit two metalloprotease enzymes, NEP 24.11 and ACE. They thus simultaneously increase the levels of natriuretic peptides and decrease the formation of angiotensin II. As a result, they enhance vasodilation, reduce vasoconstriction, and increase sodium excretion, in turn reducing peripheral vascular resistance and blood pressure.

Recently developed vasopeptidase inhibitors include omapatrilat, sampatrilat, and fasidotrilat. Omapatrilat, which has received the most attention, lowers blood pressure in animal models of hypertension as well as in hypertensive patients, and improves cardiac function in patients with heart failure. Unfortunately, omapatrilat causes a significant incidence of angioedema in addition to cough and dizziness and has not been approved for clinical use.

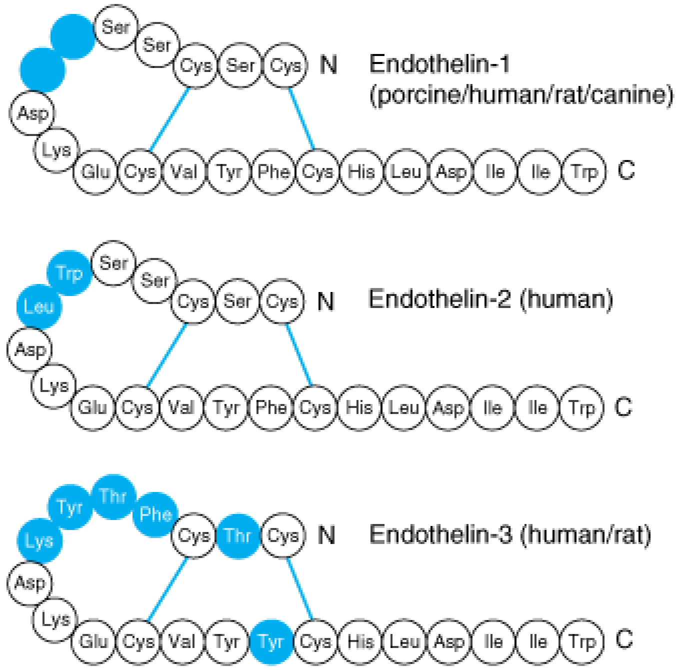
ENDOTHELINS

The endothelium is the source of a variety of substances with vasodilator (PGI_2 and nitric oxide) and vasoconstrictor activities. The latter include the endothelin family, potent vasoconstrictor peptides that were first isolated from aortic endothelial cells.

Biosynthesis, Structure, & Clearance

Three isoforms of endothelin have been identified: the originally described endothelin (ET-1) and two similar peptides, ET-2 and ET-3. Each isoform is a product of a different gene and is synthesized as a prepro form that is processed to a propeptide and then to the mature peptide. Processing to the mature peptides occurs through the action of endothelin-converting enzyme. Each endothelin is a 21-amino-acid peptide containing two disulfide bridges (Figure 17–7).

Figure 17–7.



Structures of the endothelin peptides endothelin-1, endothelin-2, and endothelin-3. Sequences different in the three peptides are shown in blue.

Endothelins are widely distributed in the body. ET-1 is the predominant endothelin secreted by the vascular endothelium. It is also produced by neurons and astrocytes in the central nervous system and in endometrial, renal mesangial, Sertoli, breast epithelial, and other cells. ET-2 is produced predominantly in the kidneys and intestine, whereas ET-3 is found in highest concentration in the brain but is also present in the gastrointestinal tract, lungs, and kidneys. Endothelins are present in the blood but in low concentration; they apparently act locally in a paracrine or autocrine fashion rather than as circulating hormones.

The expression of the ET-1 gene is increased by growth factors and cytokines, including transforming growth factor-β (TGF-β) and interleukin 1 (IL-1), vasoactive substances including angiotensin II and vasopressin, and mechanical stress. Expression is inhibited by nitric oxide, prostacyclin, and atrial natriuretic peptide.

Clearance of endothelins from the circulation is rapid and involves both enzymatic degradation by NEP 24.11 and clearance by the ET_B receptor.

Actions

Endothelins exert widespread actions in the body. In particular, they cause dose-dependent vasoconstriction in most vascular beds. Intravenous administration of ET-1 causes a rapid and transient decrease in arterial blood pressure followed by a prolonged increase. The depressor response results from release of prostacyclin and nitric oxide from the vascular endothelium, whereas the pressor response is due to direct contraction of vascular smooth muscle. Endothelins also exert direct positive inotropic and chronotropic actions on the heart and are potent coronary vasoconstrictors. They act on the kidneys to cause vasoconstriction and decrease glomerular filtration rate and sodium and water excretion. In the respiratory system, they cause potent contraction of tracheal and bronchial smooth muscle. Endothelins interact with several endocrine systems, increasing the secretion of renin, aldosterone, vasopressin, and atrial natriuretic peptide. They exert a variety of actions on the central and peripheral nervous systems, the gastrointestinal system, the liver, the urinary tract, the male and female reproductive systems, the eye, the skeletal system, and the skin. Finally, ET-1 is a potent mitogen for vascular smooth muscle cells, cardiac myocytes, and glomerular mesangial cells.

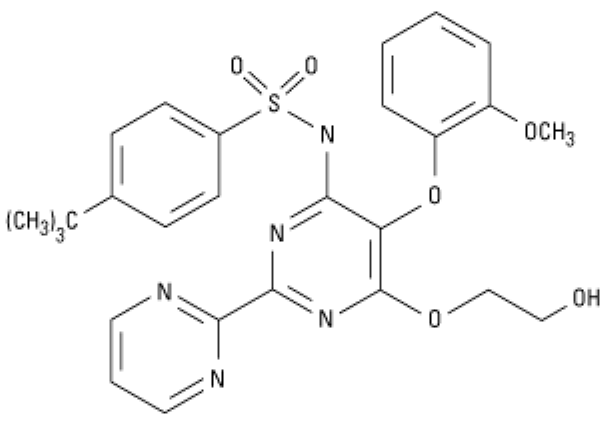
Endothelin receptors are widespread in the body. Two endothelin receptor subtypes, termed ET_A and ET_B, have been cloned and sequenced. ET_A receptors have a high affinity for ET-1 and a low affinity for ET-3 and are located on smooth muscle cells, where they mediate vasoconstriction. ET_B receptors have approximately equal affinities for ET-1 and ET-3 and are located on vascular endothelial cells, where they mediate release of PGI_2 and nitric oxide. Both receptor subtypes belong to the G protein-coupled seven-transmembrane domain family of receptors.

The signal transduction mechanisms triggered by binding of ET-1 to its receptors include stimulation of phospholipase C, formation of inositol trisphosphate, and release of calcium from the endoplasmic reticulum, which results in vasoconstriction. Stimulation of PGI_2 and nitric oxide synthesis results in decreased intracellular calcium concentration and vasodilation.

INHIBITORS OF ENDOTHELIN SYNTHESIS & ACTION

The endothelin system can be blocked with receptor antagonists and drugs that block endothelin-converting enzyme. Endothelin ET_A or ET_B receptors can be blocked selectively, or both can be blocked with nonselective ET_A-ET_B antagonists.

Bosentan is a nonselective antagonist. This drug is active intravenously and orally, and blocks both the initial transient depressor (ET_B) and the prolonged pressor (ET_A) responses to intravenous endothelin. Many orally active endothelin receptor antagonists with increased selectivity have been developed and are available for research use.



Bosentan

The formation of endothelins can be blocked by inhibiting endothelin-converting enzyme with phosphoramidon. Phosphoramidon is not specific for endothelin-converting enzyme, but several potent and more selective inhibitors are now available. The therapeutic potential of these drugs may be similar to that of the endothelin receptor antagonists (see below).

PHYSIOLOGIC & PATHOLOGIC ROLES OF ENDOTHELIN: EFFECTS OF ENDOTHELIN ANTAGONISTS

Systemic administration of endothelin receptor antagonists or endothelin-converting enzyme inhibitors causes vasodilation and decreases arterial pressure in humans and experimental animals. Intra-arterial administration of the drugs also causes slow-onset forearm vasodilation in humans. These observations provide evidence that the endothelin system participates in the regulation of vascular tone, even under resting conditions.

There is increasing evidence that endothelins participate in a variety of cardiovascular diseases, including hypertension, cardiac hypertrophy, heart failure, atherosclerosis, coronary artery disease, and myocardial infarction. Endothelins have also been implicated in pulmonary diseases, including asthma and pulmonary hypertension, as well as in several renal diseases.

Endothelin antagonists have considerable potential in the treatment of these diseases. In clinical trials, bosentan and other nonselective antagonists as well as ET_A-selective antagonists (sitaxentan, ambrisentan) have produced beneficial effects on hemodynamics and other symptoms in heart failure, pulmonary hypertension, and essential hypertension. Bosentan is currently approved for use in pulmonary hypertension (see Chapter 11), and a related antagonist, tezosentan, is under investigation for the treatment of acute heart failure.

Endothelin antagonists occasionally cause systemic hypotension, increased heart rate, facial flushing or edema, and headaches. Potential gastrointestinal effects include nausea, vomiting, and constipation. Because of their teratogenic effects, ET antagonists are contraindicated in pregnancy. Bosentan has been associated with fatal hepatotoxicity, and patients taking this drug must have monthly liver function tests. Negative pregnancy test results are required for women of child-bearing age to take this drug.

VASOACTIVE INTESTINAL PEPTIDE

Vasoactive intestinal peptide (VIP) is a 28-amino-acid peptide related structurally to secretin and glucagon. VIP is widely distributed in the central and peripheral nervous systems, where it functions as a neurotransmitter or neuromodulator. It is also present in the gastrointestinal tract, heart, lungs, kidneys, and thyroid gland. Many blood vessels are innervated by VIP neurons. VIP is found in blood but does not appear to function as a hormone.

VIP exerts significant effects on the cardiovascular system. It produces marked vasodilation in most vascular beds and in this regard is more potent on a molar basis than acetylcholine. In the heart, VIP causes coronary vasodilation and exerts positive inotropic and chronotropic effects. It may thus participate in the regulation of coronary blood flow, cardiac contraction, and heart rate.

The effects of VIP are mediated by G protein-coupled receptors; two subtypes, VPAC1 and VPAC2, have been cloned from human tissues. Both subtypes are widely distributed in the central nervous system and in the heart, blood vessels, and other tissues. Binding of VIP to its receptors results in activation of adenylyl cyclase and formation of cAMP, which is responsible for the vasodilation and many other effects of the peptide. Other actions may be mediated by nitric oxide and cGMP.

Specific VIP receptor agonists and antagonists are currently available for research use.

SUBSTANCE P

Substance P belongs to the tachykinin family of peptides, which share the common carboxyl terminal sequence Phe-X-Gly-Leu-Met. Other members of this family are neurokinin A and neurokinin B. Substance P is an undecapeptide, while neurokinins A and B are decapeptides.

Substance P is present in the central nervous system, where it is a neurotransmitter (see Chapter 21), and in the gastrointestinal tract, where it may play a role as a transmitter in the enteric nervous system and as a local hormone (see Chapter 6).

Substance P exerts a variety of incompletely understood central actions that implicate the peptide in behavior, anxiety, depression, nausea, and emesis. It is a potent arteriolar vasodilator, producing marked hypotension in humans and several animal species. The vasodilation is mediated by release of nitric oxide from the endothelium. Conversely, substance P causes contraction of venous, intestinal, and bronchial smooth muscle. It also stimulates secretion by the salivary glands and causes diuresis and natriuresis by the kidneys.

The actions of substance P and neurokinins A and B are mediated by three G protein-coupled tachykinin receptors designated NK_1, NK_2, and NK_3. Substance P is the preferred ligand for the NK_1 receptor, the predominant tachykinin receptor in the human brain. However, neurokinins A and B also possess considerable affinity for this receptor. In humans, most of the central and peripheral effects of substance P are mediated by NK_1 receptors.

Several nonpeptide NK_1 receptor antagonists have been developed. These compounds are highly selective and orally active, and enter the brain. Recent clinical trials have shown that these antagonists may be useful in treating depression and other disorders and in preventing chemotherapy-induced emesis. The first of these to be approved for the prevention of chemotherapy-induced nausea and vomiting is aprepitant (Chapter 63).

NEUROTENSIN

Neurotensin is a tridecapeptide that was first isolated from the central nervous system but subsequently was found to be present in the gastrointestinal tract and in the circulation. It is synthesized as part of a larger precursor that also contains neuromedin N, a six-amino-acid neurotensin-like peptide.

In the brain, processing of the precursor leads primarily to the formation of neurotensin and neuromedin N; these are released together from nerve endings. In the gut, processing leads mainly to the formation of neurotensin and a larger peptide that contains the neuromedin N sequence at the carboxyl terminal. Both peptides are secreted into the circulation after ingestion of food.

Like many other neuropeptides, neurotensin serves a dual function as a neurotransmitter or neuromodulator in the central nervous system and as a local hormone in the periphery. When administered centrally, neurotensin exerts potent effects including hypothermia, antinociception, and modulation of dopamine neurotransmission. When administered into the peripheral circulation, it causes vasodilation, hypotension, increased vascular permeability, increased secretion of several anterior pituitary hormones, hyperglycemia, inhibition of gastric acid and pepsin secretion, and inhibition of gastric motility.

In the central nervous system, there are close associations between neurotensin and dopamine systems, and neurotensin may be involved in clinical disorders involving dopamine pathways such as schizophrenia, Parkinson's disease, and drug abuse. Consistent with this, it has been shown that central administration of neurotensin produces effects in rodents similar to those produced by antipsychotic drugs.

Three subtypes of neurotensin receptors, designated NT_1, NT_2, and NT_3, have been cloned. NT_1 and NT_2 receptors belong to the G protein-coupled superfamily with seven transmembrane domains; the NT_3 receptor is a single transmembrane domain protein that belongs to a family of sorting proteins.

Neurotensin agonists that cross the blood-brain barrier have been developed and may have potential as therapeutic agents for diseases such as schizophrenia and Parkinson's disease.

Neurotensin receptors can be blocked with the nonpeptide antagonists SR142948A and SR48692. SR142948A is a potent antagonist of the hypothermia and analgesia produced by centrally administered neurotensin. It also blocks the cardiovascular effects of systemic neurotensin.

CALCITONIN GENE–RELATED PEPTIDE

Calcitonin gene–related peptide (CGRP) is a member of the calcitonin family of peptides, which also includes calcitonin, adrenomedullin and amylin. CGRP consists of 37 amino acids and displays approximately 30% structural homology with salmon calcitonin.

Like calcitonin, CGRP is present in large quantities in the C cells of the thyroid gland. It is also distributed widely in the central and peripheral nervous systems, in the cardiovascular system, the gastrointestinal tract, and the urogenital system. CGRP is found with substance P (see above) in some of these regions and with acetylcholine in others.

When CGRP is injected into the central nervous system, it produces a variety of effects, including hypertension and suppression of feeding. When injected into the systemic circulation, the peptide causes hypotension and tachycardia. The hypotensive action of CGRP results from the potent vasodilator action of the peptide; indeed, CGRP is the most potent vasodilator yet discovered. It dilates multiple vascular beds, but the coronary circulation is particularly sensitive.

The actions of CGRP are mediated by two receptors named $CGRP_1$ and $CGRP_2$. Peptide and nonpeptide antagonists of these receptors have been developed. Of the nonpeptide antagonists now available, the best characterized is BIBN4096BS, which has a high affinity and specificity for the human CGRP receptor.

Evidence is accumulating that release of CGRP from trigeminal nerves plays a central role in the pathophysiology of migraine. The peptide is released during migraine attacks, and successful treatment of migraine with a selective serotonin agonist normalizes cranial CGRP levels. BIBN4096BS has recently been shown to be an effective, well-tolerated treatment for migraine.

ADRENOMEDULLIN

Adrenomedullin was first discovered in human adrenal medullary pheochromocytoma tissue. It is a 52-amino acid peptide with a six-amino acid ring and a C-terminal amidation sequence. Like CGRP, adrenomedullin is a member of the calcitonin family of peptides.

Adrenomedullin is widely distributed in the body. The highest concentrations are found in the adrenal glands, hypothalamus, and anterior pituitary, but high levels are also present in the kidneys, lungs, cardiovascular system, and gastrointestinal tract. Adrenomedullin in plasma apparently originates in the heart and vasculature.

In animals, adrenomedullin dilates resistance vessels in the kidney, brain, lung, hind limbs, and mesentery, resulting in a marked, long-lasting hypotension. The hypotension in turn causes reflex increases in heart rate and cardiac output. These responses also occur during intravenous infusion of the peptide in healthy human subjects. Adrenomedullin also acts on the kidneys to increase sodium excretion, and it exerts several endocrine effects including inhibition of aldosterone and insulin secretion. Finally, it acts on the central nervous system to increase sympathetic outflow.

The diverse actions of adrenomedullin are mediated both by CGRP receptors and by specific adrenomedullin receptors termed AM_1 and AM_2. The major second messenger for both receptors is cAMP.

Circulating adrenomedullin levels increase during intense exercise. They also increase in a number of pathologic states, including essential hypertension, cardiac and renal failure, and septic shock. The roles of adrenomedullin in these states remain to be defined, but it is currently thought that the peptide functions as a physiologic antagonist of the actions of vasoconstrictors including endothelin 1 and angiotensin II. By virtue of these actions, adrenomedullin may protect against cardiovascular overload and injury.

NEUROPEPTIDE Y

Neuropeptide Y is a member of the family that also includes peptide YY and pancreatic polypeptide. Each peptide consists of 36 amino acids.

Neuropeptide Y is one of the most abundant neuropeptides in both the central and peripheral nervous systems. In the sympathetic nervous system, neuropeptide Y is frequently localized in noradrenergic neurons and apparently functions both as a vasoconstrictor and as a cotransmitter with norepinephrine. Peptide YY and pancreatic polypeptide are both gut endocrine peptides.

Neuropeptide Y produces a variety of central nervous system effects, including increased feeding (it is one of the most potent orexigenic molecules in the brain), hypotension, hypothermia, and respiratory depression. Other effects include vasoconstriction of cerebral blood vessels, positive chronotropic and inotropic actions on the heart, and hypertension. The peptide is a potent renal vasoconstrictor and suppresses renin secretion, but can cause diuresis and natriuresis. Prejunctional neuronal actions include inhibition of transmitter release from sympathetic and parasympathetic nerves. Vascular actions include direct vasoconstriction, potentiation of the action of vasoconstrictors, and inhibition of the action of vasodilators.

These diverse effects are mediated by multiple receptors designated Y_1 through Y_6. All receptors except Y_3 have been cloned and shown to be G protein-coupled receptors linked to mobilization of Ca^{2+} and inhibition of adenylyl cyclase. Y_1 and Y_2 receptors are of major importance in the cardiovascular and other peripheral effects of the peptide. Y_4 receptors have a high affinity for pancreatic polypeptide and may be a receptor for the pancreatic peptide rather than for neuropeptide Y. Y_5 receptors are found mainly in the central nervous system and may be involved in the control of food intake. Y_6 receptors do not appear to contribute significantly to the physiologic effects of neuropeptide Y in humans.

Selective nonpeptide neuropeptide Y receptor antagonists are now available for research. The first nonpeptide Y_1 receptor antagonist, BIBP3226, is also the most thoroughly studied. It has a short half-life in vivo. In animal models, it blocks the vasoconstrictor and pressor responses to neuropeptide Y. Structurally related Y_1 antagonists include BIB03304, and H409/22, which has been tested in humans. SR120107A and SR120819A are orally active Y_1 antagonists and have a long duration of action. BIIE0246 is the first nonpeptide antagonist selective for the Y_2 receptor.

These antagonists have been useful in analyzing the role of neuropeptide Y in cardiovascular regulation. It now appears that the peptide is not important in the regulation of hemodynamics under normal resting conditions, but may be of increased importance in cardiovascular disorders including hypertension and heart failure. Other studies have implicated neuropeptide Y in feeding disorders, seizures, anxiety, and diabetes, and Y_1 and Y_5 receptor antagonists have potential as anti-obesity agents.

UROTENSIN

Urotensin II was originally identified in fish, but isoforms are now known to be present in mammalian species including the human, mouse, rat and pig. Human urotensin II is an 11-amino acid peptide. Major sites of urotensin II expression in humans include the brain, spinal cord, and kidneys. Urotensin II is also present in plasma, and the kidneys may be a major source of this circulating peptide.

In vitro, urotensin II is a potent constrictor of vascular smooth muscle; its activity depends on the type of blood vessel and the species from which it was obtained. Vasoconstriction occurs primarily in arterial vessels, where urotensin II can be more potent than endothelin 1, making it the most potent known vasoconstrictor. However, under some conditions, urotensin II may cause vasodilation. In vivo, urotensin II has complex hemodynamic effects, the most prominent being regional vasoconstriction and cardiac depression. In some ways, these effects resemble those produced by endothelin 1. Nevertheless, the extent to which the peptide is involved in the regulation of vascular tone and blood pressure in humans is not clear; recent studies have produced conflicting results.

The actions of urotensin II are mediated by a G protein-coupled receptor referred to as the UT receptor. UT receptors are widely distributed in the brain, spinal cord, heart, vascular smooth muscle, skeletal muscle, and pancreas. Some effects of the peptide including vasoconstriction are mediated by the phospholipase C, IP_3-DAG signal transduction pathway.

Modifications of the disulfide bridge of urotensin II have yielded UT-receptor antagonists. A nonpeptide antagonist, palosuran, has also been developed.

Evidence is accumulating that urotensin II is involved in cardiovascular and other diseases. In particular, it has been reported that plasma urotensin II levels are increased in hypertension, heart failure, diabetes mellitus, and renal failure. UT-receptor antagonists will be valuable in studies of the pathophysiologic role of this peptide.

PREPARATIONS AVAILABLE[1]

Aprepitant (Emend)

Oral: 80, 125 mg capsules

Bosentan (Tracleer)

Oral: 62.5, 125 mg tablets

[1]Preparations of angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists are found in Chapter 11; preparations of vasopressin are found in Chapter 37.

THE EICOSANOIDS: PROSTAGLANDINS, THROMBOXANES, LEUKOTRIENES, & RELATED COMPOUNDS: INTRODUCTION

Abbreviations

COX

Cyclooxygenase

DHET

Dihydroxyeicosatrienoic acid

EET

Epoxyeicosatrienoic acid

HETE

Hydroxyeicosatetraenoic acid

HPETE

Hydroxyperoxyeicosatetraenoic acid

LTB, LTC

Leukotriene B, C, etc

LOX

Lipoxygenase

LXA, LXB

Lipoxin A, B

NSAID

Nonsteroidal anti-inflammatory drug

PGE, PGF

Prostaglandin E, F, etc

PLA, PLC

Phospholipase A, C

TXA, TXB

Thromboxane A, B, etc

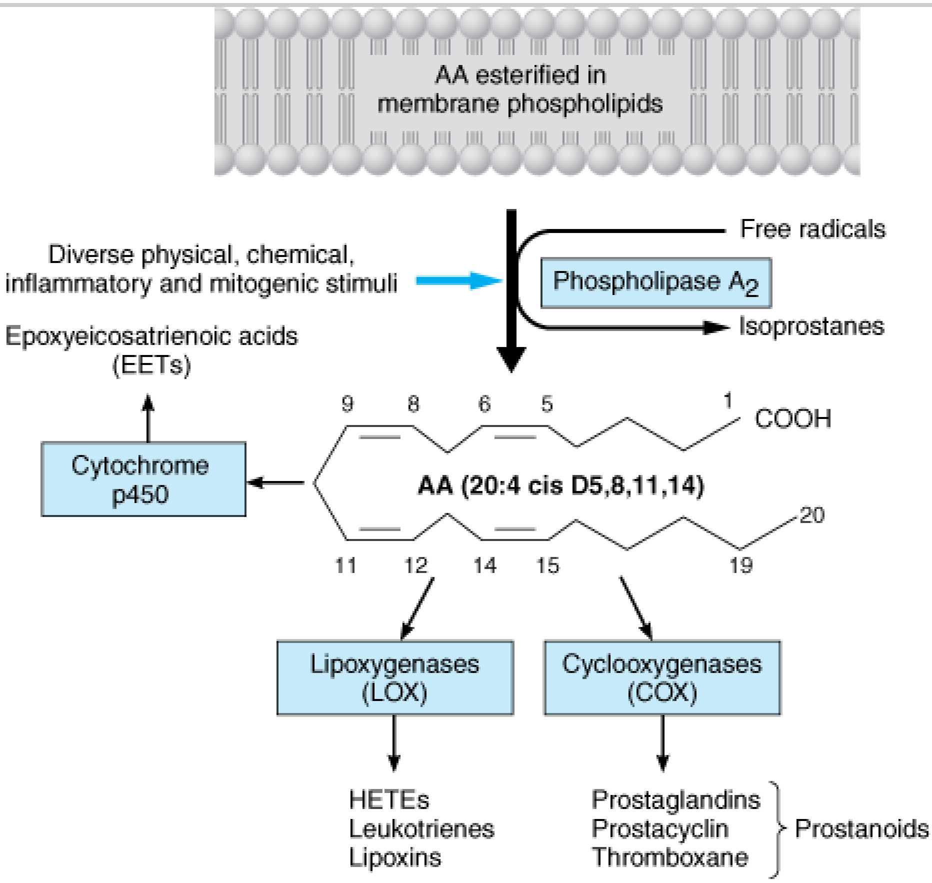
The eicosanoids are oxygenation products of polyunsaturated long-chain fatty acids. They are ubiquitous in the animal kingdom and are also found—together with their precursors—in a variety of plants. They constitute a very large family of compounds that are highly potent and display an extraordinarily wide spectrum of biologic activity. Because of their biologic activity, the eicosanoids, their specific receptor antagonists and enzyme inhibitors, and their plant and fish oil precursors have great therapeutic potential. Their short half-lives, which are seconds to minutes, make special delivery systems or synthesis of stable analogs mandatory for their clinical use.

*The authors acknowledge the contributions of the previous authors of this chapter, Drs. Marie L. Foegh and Peter W. Ramwell.

ARACHIDONIC ACID & OTHER POLYUNSATURATED PRECURSORS

Arachidonic acid, the most abundant and important of the eicosanoid precursors, is a 20-carbon (C20) fatty acid that contains four double bonds beginning at the omega-6 position to yield a 5,8,11,14-eicosatetraenoic acid (designated C20:4–6). For eicosanoid synthesis to occur, arachidonate must first be released or mobilized from membrane phospholipids by one or more lipases of the phospholipase A_2 (PLA_2) type (Figure 18–1). At least three phospholipases mediate arachidonate release from membrane lipids: cytosolic (c) PLA_2, secretory (s) PLA_2, and calcium-independent (i) PLA_2. In addition, arachidonate is also released by a combination of phospholipase C and diglyceride lipase.

Figure 18–1.



Pathways of arachidonic acid (AA) release and metabolism.

Following mobilization, arachidonic acid is oxygenated by four separate routes: the cyclooxygenase (COX), lipoxygenase, P450 epoxygenase, and isoprostane pathways (Figure 18–1). A number of factors determine the type of eicosanoid synthesized: (1) the species, (2) the type of cell, and (3) the cell's particular phenotype. The pattern of eicosanoids synthesized also frequently reflects (4) the manner in which the cell is stimulated. Finally, an important factor governing the pattern of eicosanoid release is (5) the nature of the precursor polyunsaturated fatty acid that has been esterified in specific membrane phospholipids. For example, homo-γ-linoleic acid (C20:3–6), which is trienoic, yields products that differ from those derived from arachidonate (C20:4–6), which has four double bonds. Similarly, the products derived from eicosapentaenoic acid (C20:5–3), which has five double bonds, are also quantitatively different. This is the basis for using as nutritional supplements in humans the structurally different fatty acids obtained from cold water fish or from plants. An example of the significance of the polyunsaturated fatty acid precursors is evident when one considers thromboxane A (TXA) derived from the COX pathway. TXA_2 is synthesized from arachidonate, a tetraenoic acid, and is a powerful vasoconstrictor and aggregator of platelets. However 5,8,11,14,17-eicosapentaenoic acid yields TXA_3 , which is relatively inactive. In theory, dietary eicosapentaenoate substitution for arachidonate should minimize thrombotic events due to the displacement of tetraenoic arachidonate in the membrane by a pentaenoic acid.

SYNTHESIS OF EICOSANOIDS

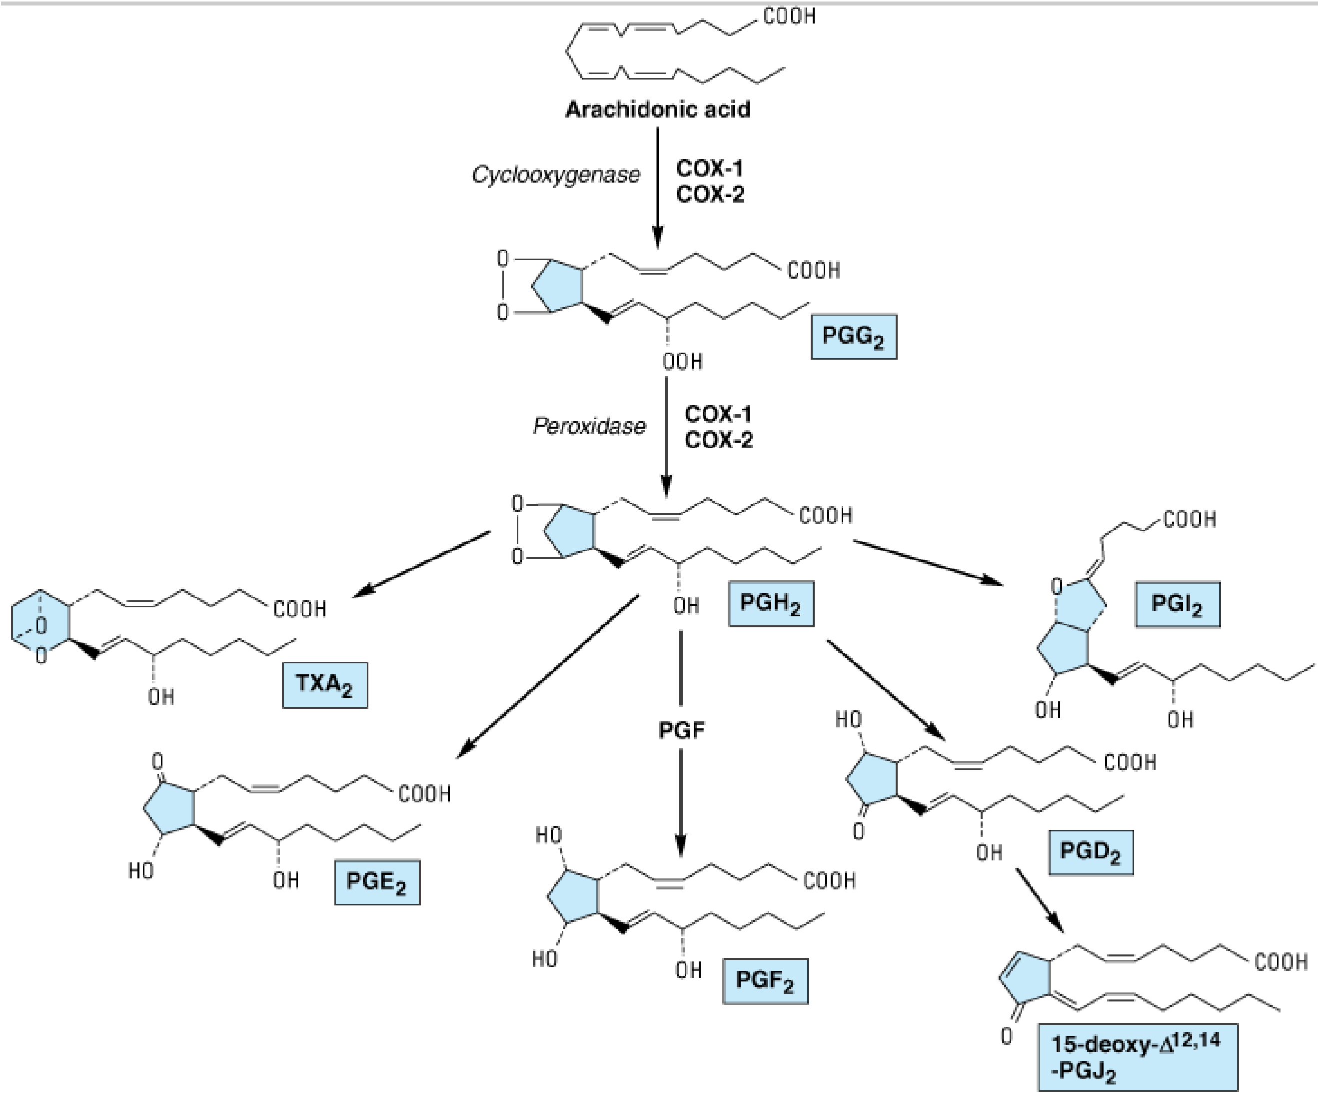
Products of Prostaglandin Endoperoxide Synthases (Cyclooxygenases)

Two unique COX isozymes convert arachidonic acid into prostaglandin endoperoxide. PGH synthase-1 (COX-1) is expressed constitutively in most cells. In contrast, PGH synthase-2 (COX-2) is inducible; its expression varies markedly depending on the stimulus. COX-2 is an immediate early-response gene product that is markedly up-regulated by shear stress, growth factors, tumor promoters, and cytokines. COX-1 generates prostanoids for "housekeeping" such as gastric epithelial cytoprotection, whereas COX-2 is the major source of prostanoids in inflammation and cancer. This distinction is overly simplistic, however; there are both physiologic and pathophysiologic processes in which each enzyme is uniquely involved and others in which they function coordinately. For example, endothelial COX-2 is the primary source of vascular prostacyclin, whereas renal COX-2-derived prostanoids are important for normal renal development and maintenance of function. An additional COX-1 variant termed "COX-3" has been described in dogs, but it does not appear functionally relevant in other species.

The synthases are important because it is at this step that the nonsteroidal anti-inflammatory drugs (NSAIDs) exert their therapeutic effects (see Chapter 36). Indomethacin and sulindac are slightly selective for COX-1. Meclofenamate and ibuprofen are approximately equipotent on COX-1 and COX-2, whereas celecoxib, diclofenac, rofecoxib, lumiracoxib, and etoricoxib inhibit COX-2 with increasing selectivity. Aspirin acetylates and inhibits both enzymes covalently. Low doses (< 100 mg/day) inhibit preferentially, but not exclusively, COX-1, whereas higher doses inhibit both COX-1 and COX-2.

Both COX-1 and COX-2 promote the uptake of two molecules of oxygen by cyclization of arachidonic acid to yield a C_9 –C_{11} endoperoxide C_{15} hydroperoxide (Figure 18–2). This product is PGG_2 , which is then rapidly modified by the peroxidase moiety of the COX enzyme to add a 15-hydroxyl group that is essential for biologic activity. This product is PGH_2 . Both endoperoxides are highly unstable. Analogous families—PGH_1 and PGH_3 and all their subsequent products—are derived from homo-γ-linolenic acid and eicosapentaenoic acid, respectively.

Figure 18–2.



Prostanoid biosynthesis. Compound names are enclosed in boxes

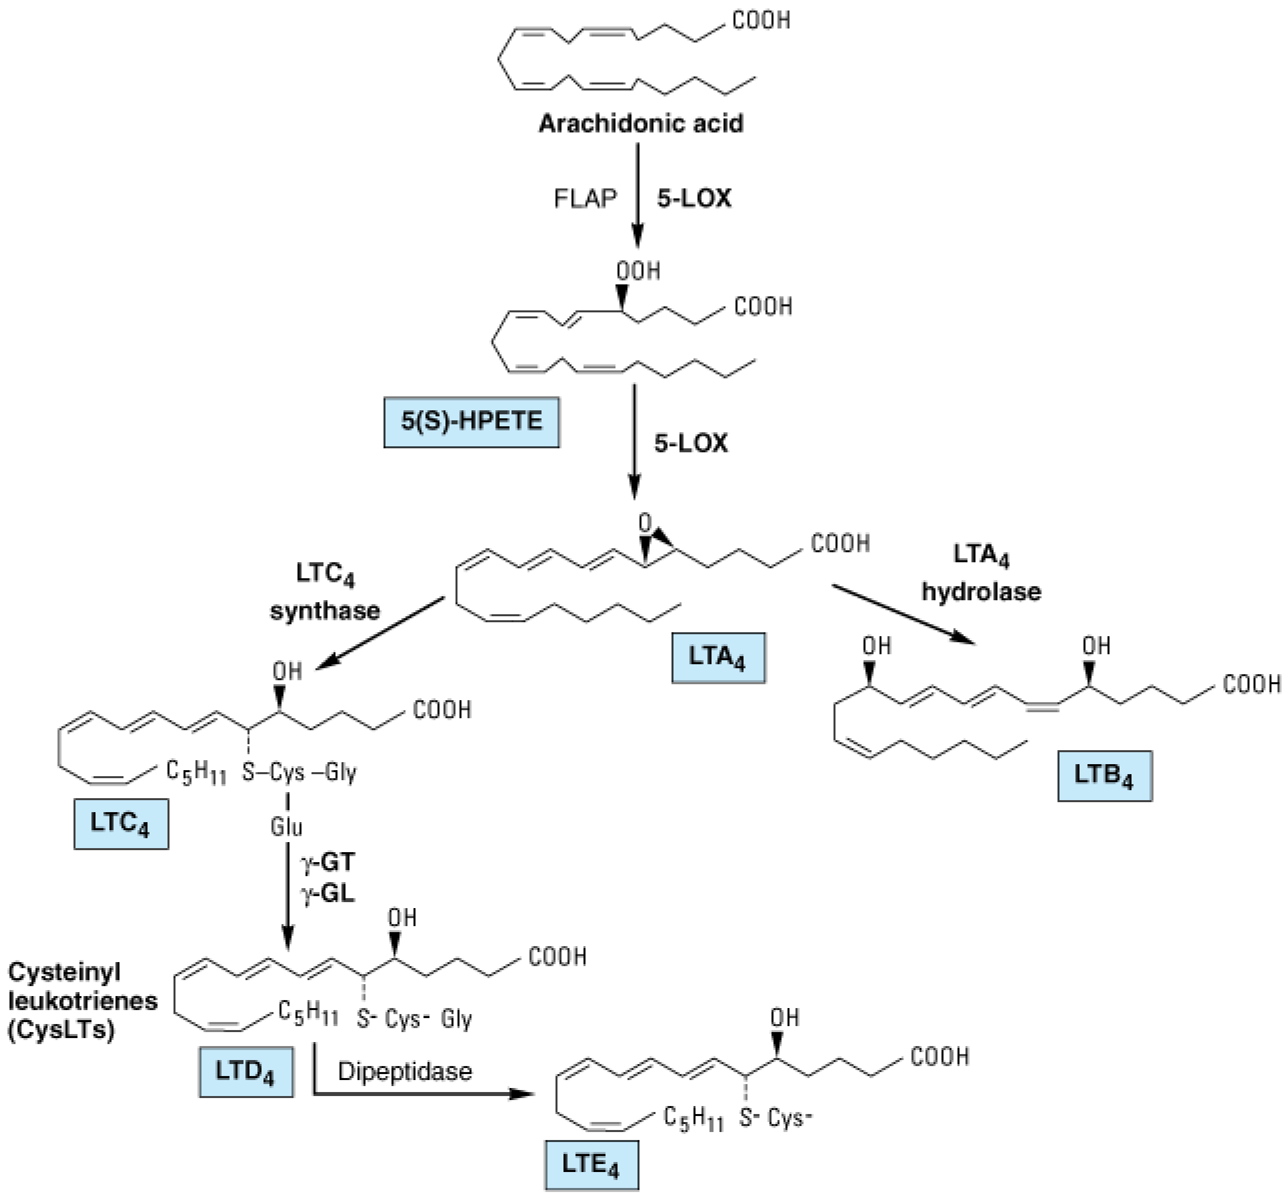
The prostaglandins, thromboxane, and prostacyclin, collectively termed the prostanoids, are generated from PGH_2 through the action of isomerases and synthases. These terminal enzymes are expressed in a relatively cell-specific fashion, such that most cells make one or two dominant prostanoids. The prostaglandins differ from each other in two ways: (1) in the substituents of the pentane ring (indicated by the last letter, eg, E and F in PGE and PGF) and (2) in the number of double bonds in the side chains (indicated by the subscript, eg, PGE_1 , PGE_2). Several products of the arachidonate series are of current clinical importance. Alprostadil (PGE_1) may be used for its smooth muscle relaxing effects to maintain the ductus arterosus patent in some neonates awaiting cardiac surgery and in the treatment of impotence. Misoprostol, a PGE_1 derivative, is a cytoprotective prostaglandin used in preventing peptic ulcer and in combination with mifepristone (RU486) for terminating early pregnancies. PGE_2 and PGF_2 are used in obstetrics to induce labor. Latanoprost and several similar compounds are topically active PGF_2 derivatives used in ophthalmology to treat open angle glaucoma. Prostacyclin (PGI_2 , epoprostenol) is synthesized mainly by the vascular endothelium and is a powerful vasodilator and inhibitor of platelet aggregation. It is used clinically to treat pulmonary hypertension and portopulmonary hypertension. In contrast, thromboxane (TXA_2) has undesirable properties (aggregation of platelets, vasoconstriction). Therefore TXA_2 -receptor antagonists and synthesis inhibitors have been developed for cardiovascular indications, although these (except for aspirin) have yet to establish a place in clinical usage.

All the naturally occurring COX products undergo rapid metabolism either initially by hydration to inactive products, which are then metabolized (PGI_2 , TXA_2), or by oxidation of the key 15-hydroxyl group to the corresponding ketone by prostaglandin 15-OH dehydrogenase. Further metabolism is by Δ^{13} reduction, β-oxidation, and ω-oxidation. The inactive metabolites can be determined in blood and urine by immunoassay or mass spectrometry as a measure of the in vivo synthesis of their parent compounds.

Products of Lipoxygenase

The metabolism of arachidonic acid by the 5-, 12-, and 15-lipoxygenases (LOX) results in the production of hydroperoxyeicosatetraenoic acids (HPETEs), which rapidly convert to hydroxy derivatives (HETEs) and leukotrienes (Figure 18–3). The most actively investigated leukotrienes are those produced by the 5-lipoxygenase present in inflammatory cells (polymorphonuclear leukocytes [PMNs], basophils, mast cells, eosinophils, macrophages). This pathway is of great interest since it is associated with asthma, anaphylactic shock, and cardiovascular disease. Stimulation of these cells elevates intracellular Ca^{2+} and releases arachidonate; incorporation of moleular oxygen by 5-LOX, in association with 5-LOX-activating protein (FLAP), then yields the unstable epoxide leukotriene A_4 (LTA_4). This intermediate either converts to the dihydroxy leukotriene B_4 (LTB_4) or conjugates with glutathione to yield leukotriene C_4 (LTC_4), which undergoes sequential degradation of the glutathione moiety by peptidases to yield LTD_4 and LTE_4 . These three products are called cysteinyl leukotrienes or peptidoleukotrienes.

Figure 18–3.



Leukotriene (LT) biosynthesis. LTC_4 , LTD_4 and LTE_4 are known collectively as the Cysteinyl (Cys) LTs. GT, glutamyl transpeptidase; GL, glutamyl leukotrienase.

LTC_4 and LTD_4 are potent bronchoconstrictors and are recognized as the primary components of the slow-reacting substance of anaphylaxis (SRS-A) that is secreted in asthma and anaphylaxis. There are four current approaches to anti-leukotriene drug development: 5-lipoxygenase enzyme inhibitors, leukotriene-receptor antagonists, inhibitors of FLAP, and phospholipase A_2 inhibitors. Selective leukotriene-receptor antagonists (zafirlukast, montelukast, and pranlukast) are currently used or in trials for treatment of asthma.

LTA_4 , the primary product of 5-LOX, can be converted via 12-LOX in platelets to the lipoxins LXA_4 and LXB_4 . These mediators can also arise through 5-LOX metabolism of 15-HETE, the product of 15-LOX-2 metabolism of arachidonic acid. 15-LOX-1 prefers linoleic acid as a substrate forming 15*S* -hydroxyoctadecadienoic acid. The stereochemical isomer, 15*R* -HETE, may be derived from the action of aspirin-acetylated COX-2 and further transformed in leukocytes by 5-LOX to 15-epi-LXA_4 or 15-epi-LXB_4 , the so-called aspirin-triggered lipoxins. 12-HETE can also undergo a catalyzed molecular rearrangement to epoxy-hydroxyeicosatrienoic acids called **hepoxilins**. The biologic roles of these mediators remain ill-defined.

The LOX located in epidermal cells are distinct from "conventional" enzymes—arachidonic acid and linoleic acid are apparently not the natural substrates for epidermal LOX. Epidermal accumulation of 12*R* -HETE is a feature of psoriasis and ichthyosis and inhibitors of 12*R* -LOX are under investigation for the treatment of these proliferative skin disorders.

Epoxygenase Products

Specific isozymes of microsomal cytochrome P450 monooxygenases convert arachidonic acid to four epoxyeicosatrienoic acids (EETs) (Figure 18–1). These are the 5,6-, 6,9-, 11,12-, and 14,15-oxido products. Each EET has two stereoisomers (*R* and *S*). Their biosynthesis can be altered by pharmacologic, nutritional, and genetic factors that affect P450 expression. These epoxides are unstable and rapidly form the corresponding dihydroxyeicosatrienoic (DHET) acid, eg, 5,6-DHET. Unlike the prostaglandins, both the EETs and the DHETs can be incorporated into phospholipids, which then act as storage sites. Intracellular fatty acid-binding proteins may differentially bind EETs and DHETs, thus modulating their metabolism, activities, and targeting. The epoxygenase products are synthesized in endothelial cells, and cause vasodilation in a number of vascular beds by activating the smooth muscle large conductance Ca^{2+} -activated K^+ channels. This results in smooth muscle cell hyperpolarization and vasodilation, leading to reduced blood pressure. Substantial evidence indicates that EETs may function as endothelium-derived hyperpolarizing factors, particularly in the coronary circulation.

Isoprostanes

The generation of isoprostanes from arachidonic acid is another potentially important pathway. The isoprostanes are prostaglandin stereoisomers. Because prostaglandins have many asymmetric centers, they have a large number of potential stereoisomers. COX is not needed for the formation of the isoprostanes, and its inhibition with aspirin or other NSAIDs should not affect the isoprostane pathway. The primary epimerization mechanism is peroxidation of arachidonate by free radicals. Peroxidation occurs while arachidonic acid is still esterified to the membrane phospholipids. Thus, unlike prostaglandins, these stereoisomers are "stored" as part of the membrane. They are then cleaved, presumably by phospholipases, circulate, and are excreted in urine. Isoprostanes are present in relatively large amounts (ten-fold greater in blood and urine than the COX-derived prostaglandins). They have potent vasoconstrictor effects when infused into renal and other vascular beds and may activate prostanoid receptors. It has been speculated that they may contribute to the pathophysiology of inflammatory responses in a manner insensitive to COX inhibitors.

BASIC PHARMACOLOGY OF EICOSANOIDS

MECHANISMS & EFFECTS OF EICOSANOIDS

Receptor Mechanisms

As a result of their short half-lives, the eicosanoids act in an autocrine and paracrine fashion, ie, close to the site of their synthesis. These ligands bind to receptors on the cell surface, and pharmacologic specificity is determined by receptor density and type on different cells. A single gene product has been identified for the PGI_2 receptor (IP receptor), PGF_2 (FP), and TXA_2 (TP), while four distinct PGE_2 receptors (EPs 1-4) and two PGD_2 receptors (DP_1 and DP_2) have been cloned. Additional isoforms of the TP (α and β), FP (A and B), and EP_3 (A-D) receptors can arise through differential mRNA splicing. Two receptors exist for both LTB_4 (BLT_1 and BLT_2) and the cysteinyl-leukotrienes ($cysLT_1$ and $cysLT_2$). A single lipoxin receptor termed ALX was found to be the same as the formyl peptide (fMPL)-1 receptor. All of these receptors are G protein-coupled; properties of the best-studied receptors are listed in Table 18–1.

Table 18–1. Eicosanoid Receptors.

Receptor	Endogenous Ligand	Secondary Ligands	G protein, Second Messenger	Major Phenotype(s) in Knockout Mice

Splice variants for the eicosanoid receptors are indicated where appropriate.

$Ca^{2+}{}_i$, intracellular calcium; cAMP, adenosine 3',5'-monophosphate; PLC, phospholipase C; isoPs, isoprostanes; 15d-PGJ_2 , 15-deoxy-$\Delta^{12,14}$ -PGJ_2 .

EP_2 , EP_4 , IP and DP_1 receptors activate adenylyl cyclase via G_s . This leads to increased intracellular cAMP levels, which in turn activates specific protein kinases (see Chapter 2). These kinases phosphorylate internal calcium pump proteins, an action that decreases free intracellular calcium concentration. In contrast, EP_1 , FP, and TP receptors activate phosphatidylinositol metabolism, leading to the formation of $InsP_3$ (IP_3), with subsequent mobilization of Ca^{2+} stores and an increase of free intracellular calcium. Activation of the TP-receptor isoforms may activate or inhibit adenylyl cyclase via G_s (TP) or G_i (TP), respectively, and signal via G_q and related proteins to membrane associated protein (MAP) kinase signaling pathways. EP_3 receptors can couple to both elevation of intracellular calcium and a decrease in cAMP. The DP_2 receptor, which is unrelated to the other prostanoid receptors, is a member of the fMLP receptor superfamily. This receptor couples through to a G_i -type G protein and leads to inhibition of cAMP synthesis and increases in intracellular calcium in a variety of cell types.

LTB_4 also generates $InsP_3$ release via the BLT_1 receptor, causing activation, degranulation, and superoxide anion generation in PMNs. The BLT_2 receptor, the low-affinity receptor for LTB_4 , is bound with reasonable affinity by 12*S*- and 12*R* -HETE, although the biologic relevance of this observation is not clear. $CysLT_1$ receptors couple to G_q , leading to increased intracellular Ca^{2+} .

The contractile effects of eicosanoids on smooth muscle are mediated by the release of calcium, while their relaxing effects are mediated by the generation of cAMP. The effects of eicosanoids on many target systems, including the immune system, can be similarly explained (see below). Many of the eicosanoids' contractile effects on smooth muscle can be inhibited by lowering extracellular calcium or by using calcium channel blocking drugs.

Although prostanoids can activate peroxisome proliferator-activated receptors (PPARs) if added in sufficient concentration in vitro, it is questionable whether these compounds attain concentrations sufficient to function as endogenous nuclear-receptor ligands in vivo.

Effects of Prostaglandins & Thromboxanes

The prostaglandins and thromboxanes have major effects on four types of smooth muscle: vascular, gastrointestinal, airway, and reproductive. Other important targets include platelets and monocytes, kidneys, the central nervous system, autonomic presynaptic nerve terminals, sensory nerve endings, endocrine organs, adipose tissue, and the eye (the effects on the eye may involve smooth muscle).

SMOOTH MUSCLE

Vascular

TXA_2 is a potent vasoconstrictor. It is also a smooth muscle cell mitogen and is the only eicosanoid that has convincingly been shown to have this effect. The mitogenic effect is potentiated by exposure of smooth muscle cells to testosterone, which up-regulates smooth muscle cell TP receptors. PGF_2 is also a vasoconstrictor but is not a mitogen for smooth muscle cells. Another vasoconstrictor is the isoprostane 8-*iso-* PGF_2 , also known as iPF_2 III, which may act via the TP receptor. In patients with cirrhosis, it is produced in large amounts in the liver and is thought to play a pathophysiologic role as an important vasoconstrictor substance in the hepatorenal syndrome.

Vasodilator prostaglandins, especially PGI_2 and PGE_2 , promote vasodilation by increasing cAMP and decreasing smooth muscle intracellular calcium, primarily via IP and EP_4 receptors. Vascular prostacyclin is synthesized by both smooth muscle and endothelial cells, with the latter being the major contributor. In the microcirculation, PGE_2 is a vasodilator produced by endothelial cells.

Gastrointestinal Tract

Most of the prostaglandins and thromboxanes activate gastrointestinal smooth muscle. Longitudinal muscle is contracted by PGE_2 (via EP_3) and PGF_2 (via FP receptors), whereas circular muscle is contracted strongly by PGF_2 and weakly by PGI_2 , and relaxed by PGE_2 (via EP_4 receptors). Administration of either PGE_2 or PGF_2 results in colicky cramps (see Clinical Pharmacology of Eicosanoids, below). The leukotrienes also have powerful contractile effects.

Airways

Respiratory smooth muscle is relaxed by PGE_2 and PGI_2 and contracted by PGD_2 , TXA_2 , and PGF_2 . Studies of DP_1 knockout mice suggest an important role of this receptor in asthma. The cysteinyl leukotrienes are bronchoconstrictors. They act principally on smooth muscle in peripheral airways and are a thousand times more potent than histamine both in vitro and in vivo. They also stimulate bronchial mucus secretion and cause mucosal edema. Bronchospasm occurs in about 10% of people taking NSAIDs, probably because of a shift in arachidonate metabolism from COX-1 metabolism to leukotriene formation.

Reproductive

The actions of prostaglandins on reproductive smooth muscle are discussed below under Reproductive Organs.

PLATELETS

Platelet aggregation is markedly affected by eicosanoids. Low concentrations of PGE_2 enhance, whereas higher concentrations inhibit, platelet aggregation. Both PGD_2 and PGI_2 inhibit aggregation. TXA_2 is the major product of platelet COX-1, is a platelet aggregator, and amplifies the effects of other more potent platelet agonists such as thrombin. The platelet actions of TXA_2 are restrained in vivo by PGI_2 , which inhibits platelet aggregation by all recognized agonists. Platelets release TXA_2 during activation and aggregation. Urinary metabolites of TXA_2 increase in patients experiencing a myocardial infarction; this increment is suppressed substantially by low-dosage aspirin, but a variable contribution, presumably from macrophage COX-2, may be insensitive to such a regimen. Comparative trials of the cardioprotective actions of low- and high-dose aspirin have not been performed. However, indirect comparisons across placebo controlled trials do not suggest an increasing benefit with dose; in fact, they suggest an inverse dose-response relationship, perhaps reflecting increasing inhibition of PGI_2 synthesis at higher doses of aspirin. Platelet COX-1-derived thromboxane synthesis is irreversibly inhibited by chronic dosing with aspirin in low doses. Macrophage COX-2 appears to contribute roughly 10% of the increment in TX biosynthesis observed in smokers, while the rest is derived from platelets.

KIDNEY

Both the medulla and the cortex of the kidney synthesize prostaglandins, the medulla substantially more than the cortex. The kidney also synthesizes several hydroxyeicosatetraenoic acids, leukotrienes, cytochrome P450 products, and epoxides. These compounds play important autoregulatory roles in renal function by modifying renal hemodynamics and glomerular and tubular function. This regulatory role is especially important in marginally functioning kidneys, as shown by the decline in kidney function caused by COX inhibitors in elderly patients and those with renal disease.

The major eicosanoid products of the renal cortex are PGE_2 and PGI_2 . Both compounds increase renin release; normally, however, renin release is more directly under β_1 -adrenoceptor control.

PGE_2 and PGI_2 increase glomerular filtration through their vasodilating effects. These prostaglandins also increase water and sodium excretion. The increase in water clearance probably results from an attenuation of the action of antidiuretic hormone (ADH) on adenylyl cyclase. It is uncertain whether the natriuretic effect is caused by the direct inhibition of sodium reabsorption in the distal tubule or by increased medullary blood flow. Loop diuretics, eg, furosemide, produce some of their effect by stimulating COX activity. In the normal kidney, this increases the synthesis of the vasodilator prostaglandins. Therefore, patient response to a loop diuretic is diminished if a COX inhibitor is administered concurrently (see Chapter 15).

TXA_2 causes intrarenal vasoconstriction (and perhaps an ADH-like effect), resulting in a decline in renal function. The normal kidney synthesizes only small amounts of TXA_2 . However, in renal conditions involving inflammatory cell infiltration (such as glomerulonephritis and renal transplant rejection), the inflammatory cells (monocyte-macrophages) release substantial amounts of TXA_2 . Theoretically, TXA_2 synthase inhibitors or receptor antagonists should improve renal function in these patients, but no such drug is clinically available.

Hypertension is associated with increased TXA_2 and decreased PGE_2 and PGI_2 synthesis in some animal models, eg, the Goldblatt kidney model. It is not known whether these changes are primary contributing factors or secondary responses. Similarly, increased TXA_2 formation has been reported in cyclosporine-induced nephrotoxicity, but no causal relationship has been established.

REPRODUCTIVE ORGANS

Female Reproductive Organs

Uterine muscle is contracted by PGF_2 , TXA_2 , and low concentrations of PGE_2 ; PGI_2 and high concentrations of PGE_2 cause relaxation. PGF_2 , together with oxytocin, is essential for the onset of parturition. The effects of prostaglandins on uterine function are discussed below. (See Clinical Pharmacology of Eicosanoids.)

Male Reproductive Organs

The role of prostaglandins in semen is still conjectural. The major source of these prostaglandins is the seminal vesicle; the prostate—despite the name "prostaglandin"—and the testes synthesize only small amounts. The factors that regulate the concentration of prostaglandins in human seminal plasma are not known in detail, but testosterone does promote prostaglandin production. Thromboxane and leukotrienes have not been found in seminal plasma. Men with a low seminal fluid concentration of prostaglandins are relatively infertile.

Smooth muscle–relaxing prostaglandins such as PGE_1 enhance penile erection by relaxing the smooth muscle of the corpora cavernosa. (See Clinical Pharmacology of the Eicosanoids.)

CENTRAL AND PERIPHERAL NERVOUS SYSTEMS

Fever

PGE_2 increases body temperature, probably via EP_3 receptors, especially when administered directly into the cerebral ventricles. Exogenous PGF_2 and PGI_2 induce fever, whereas PGD_2 and TXA_2 do not, but none of these contributes to the natural pyretic response. Instead, pyrogens release interleukin-1, which in turn promotes the synthesis and release of PGE_2 . This synthesis is blocked by aspirin and other antipyretic compounds.

Sleep

When infused into the cerebral ventricles, PGD_2 induces natural sleep (as determined by electroencephalographic analysis) via activation of DP_1 receptors and secondary release of adenosine.

Neurotransmission

PGE compounds inhibit the release of norepinephrine from postganglionic sympathetic nerve endings. Moreover, NSAIDs increase norepinephrine release in vivo, suggesting that the prostaglandins play a physiologic role in this process. Thus, vasoconstriction observed during treatment with COX inhibitors may be due, in part, to increased release of norepinephrine as well as to inhibition of the endothelial synthesis of the vasodilators PGE_2 and PGI_2 . PGE_2 and PGI_2 sensitize the peripheral nerve endings to painful stimuli by lowering the threshold of nociceptors. Centrally, PGE_2 can increase excitability in neuronal pain transmission pathways in the spinal cord. Hyperalgesia is also produced by LTB_4 . The release of these eicosanoids during the inflammatory process thus serves to amplify nociception.

NEUROENDOCRINE ORGANS

Both in vitro and in vivo tests have shown that some of the eicosanoids affect the secretion of anterior pituitary hormones. PGE_2 promotes the release of growth hormone, prolactin, TSH, ACTH, FSH, and LH. However, endocrine changes reflecting significant release of these hormones have not been reported in patients receiving PGE compounds. In parturition PGF_2 induces an oxytocin-dependent decline in progesterone levels. LOX metabolites also have endocrine effects. LTC_4 and LTD_4 stimulate LHRH and LH secretion (see below). 12-HETE stimulates the release of aldosterone from the adrenal cortex and mediates a portion of the aldosterone release stimulated by angiotensin II but not that by ACTH.

BONE METABOLISM

Prostaglandins are abundant in skeletal tissue and are produced by osteoblasts and adjacent hematopoietic cells. The major effect of prostaglandins (especially PGE_2 , acting on EP_4 receptors) in vivo is to increase bone turnover, ie, stimulation of bone resorption and formation. Deletion of the EP_4 receptors in mice results in an imbalance between bone resorption and formation, leading to a negative balance of bone mass and density in older animals. Prostaglandins may mediate the effects of mechanical forces on bones and changes in bone during inflammation. EP_4 -receptor deletion and inhibition of prostaglandin biosynthesis have both been associated with impaired fracture healing in animal models. COX inhibitors can also slow skeletal muscle healing by interfering with prostaglandin effects on myocyte proliferation, differentiation, and fibrosis in response to injury. Prostaglandins may contribute to the bone loss that occurs at menopause; it has been speculated that NSAIDs may be of therapeutic value in osteoporosis and bone loss prevention in older women. However, controlled evaluation of such therapeutic interventions remains to be carried out.

EYE

PGE and PGF derivatives lower intraocular pressure. The mechanism of this action is unclear but probably involves increased outflow of aqueous humor from the anterior chamber via the uveoscleral pathway (see Clinical Pharmacology of Eicosanoids).

Effects of Lipoxygenase & Cytochrome P450-Derived Metabolites

The actions of lipoxygenases generate compounds that can regulate specific cellular responses important in inflammation and immunity. Cytochrome P450-derived metabolites affect nephron transport functions either directly or via metabolism to active compounds (see below). The biologic functions of the various forms of hydroxy- and hydroperoxyeicosaenoic acids are largely unknown, but their pharmacologic potency is impressive.

BLOOD CELLS AND INFLAMMATION

LTB_4 is a potent chemoattractant for PMNs, eosinophils, and monocytes; LTC_4 and LTD_4 are potent chemoattractants for eosinophils. At higher concentrations, these leukotrienes also promote eosinophil adherence, degranulation, and oxygen radical formation.

The leukotrienes have been strongly implicated in the pathogenesis of inflammation, especially in chronic diseases such as asthma and inflammatory bowel disease. Prostaglandins, on the other hand, generally inhibit lymphocyte function and proliferation, suppressing the immunological response. PGE_2 inhibits the differentiation of B lymphocytes into antibody-secreting plasma cells and depress the humoral antibody response. It also inhibits mitogen-stimulated proliferation of T lymphocytes and the release of lymphokines by sensitized T lymphocytes. PGE_2 and TXA_2 may also play a role in T-lymphocyte development by regulating apoptosis of immature thymocytes. PGD_2 , a major product of mast cells, is a potent chemoattractant for eosinophils and induces chemotaxis and migration of T H 2 lymphocytes. Its degradation product, 15d-PGJ_2 , at concentrations actually formed in vivo, may also activate eosinophils via the DP_2 (CRT H 2) receptor.

Lipoxins have diverse effects on leukocytes, including activation of monocytes and macrophages and inhibition of neutrophil, eosinophil, and lymphocyte activation. Both lipoxin A and lipoxin B inhibit natural killer cell cytotoxicity.

HEART AND SMOOTH MUSCLE

Cardiovascular

12*(S)* -HETE is a potent chemoattractant for smooth muscle cells, causing migration at low concentrations; it may play a role in myointimal proliferation that occurs after vascular injury such as that caused by angioplasty. Its stereoisomer, 12*(R)* -HETE, is not a chemoattractant, but is a potent inhibitor of the Na^+ /K^+ ATPase in the cornea. LTC_4 and LTD_4 reduce myocardial contractility and coronary blood flow, leading to cardiac depression. Lipoxin A and lipoxin B exert coronary vasoconstrictor effects in vitro.

Gastrointestinal

Human colonic epithelial cells synthesize LTB_4 , a chemoattractant for neutrophils. The colonic mucosa of patients with inflammatory bowel disease contains substantially increased amounts of LTB_4 .

Airways

The cysteinyl leukotrienes, particularly LTC_4 and LTD_4 , are potent bronchoconstrictors and cause increased microvascular permeability, plasma exudation, and mucus secretion in the airways. Controversies exist over whether the pattern and specificity of the leukotriene receptors differ in animal models and humans. LTC_4 -specific receptors have not been found in human lung tissue, whereas both high- and low-affinity LTD_4 receptors are present.

RENAL SYSTEM

The roles of leukotrienes and cytochrome P450 products in the human kidney are currently speculative, but the 5,6-epoxide has been shown to be a powerful vasodilator in animal experiments.

CANCER

There has been significant interest in the role of prostaglandins and COX-2 in the development of malignancies. Angiogenesis, which is required for multistage carcinogenesis, is promoted by COX-2-derived TXA_2 , as well as PGE_2 and PGI_2 . COX inhibitors reduce colon tumor formation in experimental animals. In large epidemiologic studies, the incidental use of NSAIDs is associated with a 40–50% reduction in relative risk for developing colon cancer. Furthermore, in patients with familial polyposis coli, COX inhibitors significantly decrease polyp formation. A polymorphism in COX-2 has been associated with increased risk of colon cancer. Several studies have suggested that COX-2 expression is associated with markers of tumor progression in breast cancer. In mouse mammary tissue, COX-2 is pro-oncogenic whereas aspirin use is associated with a reduced risk of breast cancer in women, especially for hormone receptor-positive tumors.

MISCELLANEOUS

The effects of these products on the reproductive organs remain to be elucidated. Similarly, actions on the nervous system have been suggested but not confirmed. 12-HETE stimulates the release of aldosterone from the adrenal cortex and mediates a portion of the aldosterone release stimulated by angiotensin II but not that by ACTH. Very low concentrations of LTC_4 increase and higher concentrations of arachidonate-derived epoxides augment LH and LHRH release from isolated rat anterior pituitary cells.

INHIBITION OF EICOSANOID SYNTHESIS

Corticosteroids block all the known pathways of eicosanoid synthesis, perhaps by stimulating the synthesis of several inhibitory proteins collectively called **annexins** or **lipocortins**. They inhibit phospholipase A_2 activity, probably by interfering with phospholipid binding and thus preventing the release of arachidonic acid.

The NSAIDs (eg, indomethacin, ibuprofen) block both prostaglandin and thromboxane formation by reversibly inhibiting COX activity. The traditional NSAIDs are not selective for COX-1 or COX-2. Selective COX-2 inhibitors, which were developed more recently, vary in their degree of selectivity. Aspirin is an irreversible COX inhibitor. In platelets, which are anuclear, COX cannot be restored via protein biosynthesis resulting in extended inhibition of TXA_2 biosynthesis.

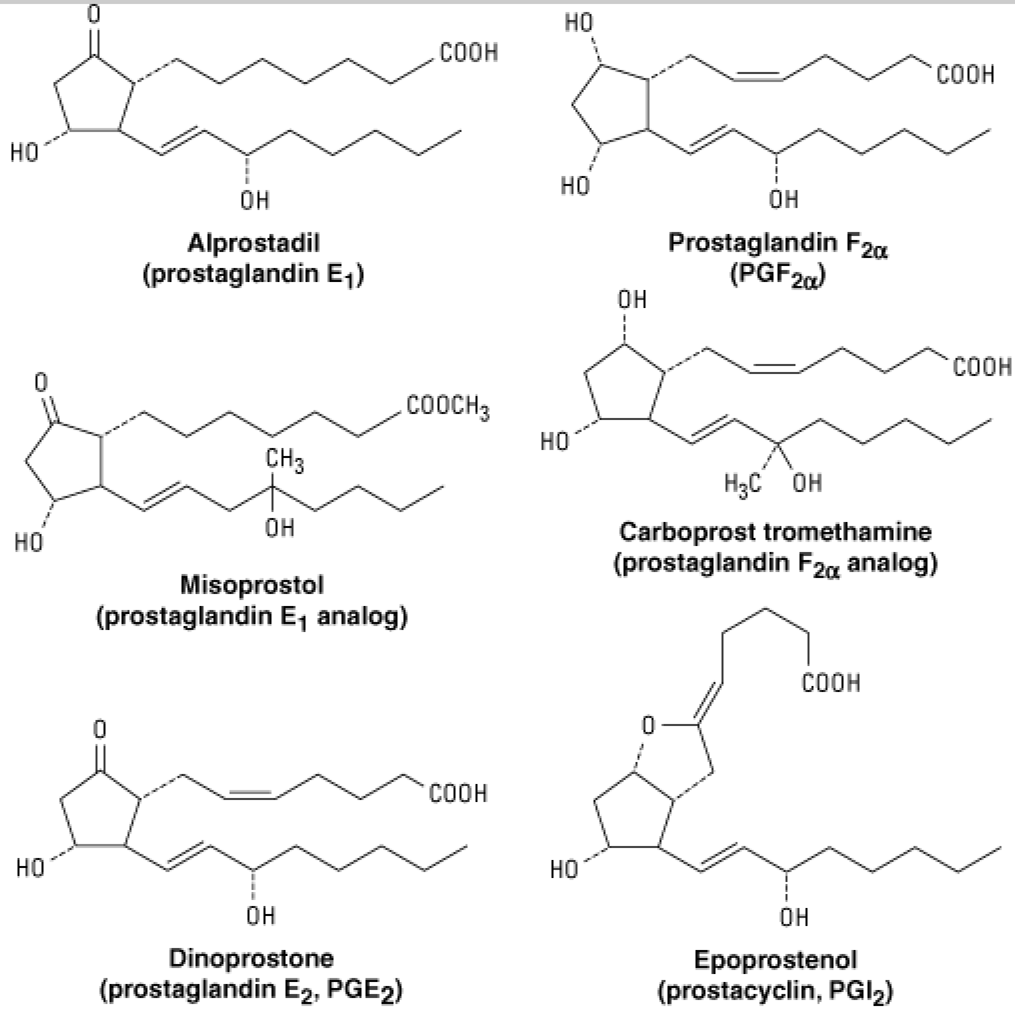
EP-receptor agonists and antagonists are under evaluation in the treatment of bone fracture and osteoporosis, whereas TP-receptor antagonists are being investigated for usefulness in treatment of cardiovascular syndromes.

Selective inhibitors of the lipoxygenase pathway are also mainly investigational. With a few exceptions, NSAIDs do not inhibit lipoxygenase activity at concentrations that markedly inhibit COX activity. In fact, by preventing arachidonic acid conversion via the COX pathway, NSAIDs may cause more substrate to be metabolized through the lipoxygenase pathways, leading to an increased formation of the inflammatory leukotrienes. Even among the COX-dependent pathways, inhibiting the synthesis of one derivative may increase the synthesis of an enzymatically related product. Therefore, drugs that inhibit both COX and lipoxygenase are being developed.

CLINICAL PHARMACOLOGY OF EICOSANOIDS

Several approaches have been used in the clinical application of eicosanoids. First, stable oral or parenteral long-acting analogs of the naturally occurring prostaglandins have been developed. Several such compounds have been approved for clinical use overseas and are being introduced in the USA (Figure 18–4). Second, enzyme inhibitors and receptor antagonists have been developed to interfere with the synthesis or effects of the eicosanoids. The discovery of COX-2 as a major source of inflammatory prostanoids led to the development of selective COX-2 inhibitors in an effort to preserve the gastrointestinal and renal functions directed through COX-1, thereby reducing toxicity. Third, dietary manipulation—to change the polyunsaturated fatty acid precursors in the cell membrane phospholipids and so change eicosanoid synthesis—is used extensively in over-the-counter products and in diets emphasizing increased consumption of cold water fish.

Figure 18–4.



Chemical structures of some prostaglandins and prostaglandin analogs currently in clinical use.

Female Reproductive System

Studies with knockout mice have confirmed a role for prostaglandins in reproduction and parturition. COX-1-derived PGF_2 appears important for luteolysis, consistent with delayed parturition in COX-1-deficient mice. A complex interplay between PGF_2 and oxytocin is critical to the onset of labor. EP_2 receptor-deficient mice demonstrate a preimplantation defect, which underlies some of the breeding difficulties seen in COX-2 knockouts.

ABORTION

PGE_2 and PGF_2 have potent oxytocic actions. The ability of the E and F prostaglandins and their analogs to terminate pregnancy at any stage by promoting uterine contractions has been adapted to common clinical use. Many studies worldwide have established that prostaglandin administration efficiently terminates pregnancy. The drugs are used for first- and second-trimester abortion and for priming or ripening the cervix before abortion. These prostaglandins appear to soften the cervix by increasing proteoglycan content and changing the biophysical properties of collagen.

Dinoprostone, a synthetic preparation of PGE_2 , is administered vaginally for oxytocic use. In the USA, it is approved for inducing abortion in the second trimester of pregnancy, for missed abortion, for benign hydatidiform mole, and for ripening of the cervix for induction of labor in patients at or near term.

Dinoprostone stimulates the contraction of the uterus throughout pregnancy. As the pregnancy progresses, the uterus increases its contractile response, and the contractile effect of oxytocin is potentiated as well. Dinoprostone also directly affects the collagenase of the cervix, resulting in softening. The vaginal dose enters the maternal circulation, and a small amount is absorbed directly by the uterus via the cervix and the lymphatic system. Dinoprostone is metabolized in local tissues and on the first pass through the lungs (about 95%). The metabolites are mainly excreted in the urine. The plasma half-life is 2.5–5 minutes.

For the induction of labor, dinoprostone is used either as a gel (0.5 mg PGE_2) or as a controlled-release formulation (10 mg PGE_2) that releases PGE_2 in vivo at a rate of about 0.3 mg/h over 12 hours. An advantage of the controlled-release formulation is a lower incidence of gastrointestinal side effects (< 1%).

For abortifacient purposes, the recommended dosage is a 20-mg dinoprostone vaginal suppository repeated at 3- to 5-hour intervals depending on the response of the uterus. The mean time to abortion is 17 hours, but in more than 25% of cases the abortion is incomplete and requires additional intervention.

For softening of the cervix at term, the preparations used are either a single vaginal insert containing 10 mg PGE_2 or a vaginal gel containing 0.5 mg PGE_2 administered every 6 hours. The softening of the cervix for induction of labor substantially shortens the time to onset of labor and the delivery time.

The use of PGE analogs for "menstrual regulation" or very early abortions—within 1–2 weeks after the last menstrual period—has been explored extensively. There are two problems: prolonged vaginal bleeding and severe menstrual cramps.

Antiprogestins (eg, mifepristone, RU486) have been combined with an oral oxytocic prostaglandin (eg, misoprostol) to produce early abortion. This regimen is available in the USA and Europe (see Chapter 39). The ease of use and the effectiveness of the combination have aroused considerable opposition in some quarters. The major toxicities are cramping pain and diarrhea. The oral and vaginal routes of administration of misoprostol are equally effective, but the vaginal route has been associated with an increased incidence of sepsis, so the oral route is now recommended by all authorities.

PGF_2 is available for clinical gynecologic use. This drug, carboprost tromethamine (15-methyl-PGF_2 ; the 15-methyl group prolongs the duration of action) is used to induce second-trimester abortions and to control postpartum hemorrhage that is not responding to conventional methods of management. The success rate is approximately 80%. It is administered as a single 250-mcg intramuscular injection, repeated if necessary. Vomiting and diarrhea occur commonly, probably because of gastrointestinal smooth muscle stimulation. Transient elevations in temperature are seen in approximately one eighth of patients.

FACILITATION OF LABOR

Numerous studies have shown that PGE_2 , PGF_2 , and their analogs effectively initiate and stimulate labor, but PGF_2 is one tenth as potent as PGE_2 . There appears to be no difference in the efficacy of PGE_2 and PGF_2 when they are administered intravenously; however, they may be of more use locally to promote labor through ripening of the cervix. These agents and oxytocin have similar success rates and comparable induction-to-delivery intervals. The adverse effects of the prostaglandins are moderate, with a slightly higher incidence of nausea, vomiting, and diarrhea than that produced by oxytocin. PGF_2 has more gastrointestinal toxicity than PGE_2 . Neither drug has significant maternal cardiovascular toxicity in the recommended doses. In fact, PGE_2 must be infused at a rate about 20 times faster than that used for induction of labor to decrease blood pressure and increase heart rate. PGF_2 is a bronchoconstrictor and should be used with caution in women with asthma; however, neither asthma attacks nor bronchoconstriction have been observed during the induction of labor. Although both PGE_2 and PGF_2 pass the fetoplacental barrier, fetal toxicity is uncommon.

The effects of oral PGE_2 administration (0.5–1.5 mg/h) have been compared with those of intravenous oxytocin and oral demoxytocin, an oxytocin derivative, in the induction of labor. Oral PGE_2 is superior to the oral oxytocin derivative and in most studies is as efficient as intravenous oxytocin. Oral PGF_2 causes too much gastrointestinal toxicity to be useful by this route.

Theoretically, PGE_2 and PGF_2 should be superior to oxytocin for inducing labor in women with preeclampsia-eclampsia or cardiac and renal diseases because, unlike oxytocin, they have no antidiuretic effect. In addition, PGE_2 has natriuretic effects. However, the clinical benefits of these effects have not been documented. In cases of intrauterine fetal death, the prostaglandins alone or with oxytocin seem to cause delivery effectively.

DYSMENORRHEA

Primary dysmenorrhea is attributable to increased endometrial synthesis of PGE_2 and PGF_2 during menstruation, with contractions of the uterus that lead to ischemic pain. NSAIDs successfully inhibit the formation of these prostaglandins (see Chapter 36) and so relieve dysmenorrhea in 75–85% of cases. Some of these drugs are available over the counter. Aspirin is also effective in dysmenorrhea, but because it has low potency and is quickly hydrolyzed, large doses and frequent administration are necessary. In addition, the acetylation of platelet COX, causing irreversible inhibition of platelet TXA_2 synthesis, may increase the amount of menstrual bleeding.

Male Reproductive System

Intracavernosal injection or urethral suppository therapy with alprostadil (PGE_1) is a second line treatment for erectile dysfunction. Doses of 2.5–25 mcg are used. Penile pain is a frequent side effect, which may be related to the algesic effects of PGE derivatives; however, only a few patients discontinue the use because of pain. Prolonged erection and priapism are less frequent side effects that occur in less than 4% of patients and are minimized by careful titration to the minimal effective dose. When given by injection, alprostadil may be used as monotherapy or in combination with either papaverine or phentolamine.

Renal System

Increased biosynthesis of prostaglandins has been associated with one form of Bartter's syndrome. This is a rare disease characterized by low-to-normal blood pressure, decreased sensitivity to angiotensin, hyperreninemia, hyperaldosteronism, and excessive loss of K^+ . There also is an increased excretion of prostaglandins, especially PGE, in the urine. After long-term administration of COX inhibitors, sensitivity to angiotensin, plasma renin values, and the concentration of aldosterone in plasma return to normal. Although plasma K^+ rises, it remains low, and urinary wasting of K^+ persists. Whether an increase in prostaglandin biosynthesis is the cause of Bartter's syndrome or a reflection of a more basic physiologic defect is not yet known.

Cardiovascular System

The vasodilator effects of PGE compounds have been studied extensively in hypertensive patients. These compounds also promote sodium diuresis. Practical application will require derivatives with oral activity, longer half-lives, and fewer adverse effects.

PULMONARY HYPERTENSION

Prostacyclin lowers peripheral, pulmonary, and coronary resistance. It has been used to treat both primary pulmonary hypertension and secondary pulmonary hypertension, which sometimes occurs after mitral valve surgery. In addition, prostacyclin has been used successfully to treat portopulmonary hypertension, which arises secondary to liver disease. A commercial preparation of prostacyclin (epoprostenol) is approved for treatment of primary pulmonary hypertension, in which it appears to improve symptoms, prolong survival, and delay or prevent the need for lung or lung-heart transplantation. However, because of its extremely short plasma half-life, the drug must be administered as a continuous intravenous infusion through a central line. Several prostacyclin analogs with longer half-lives have been developed, and treprostinil is approved for use in pulmonary hypertension. This drug is administered by continuous subcutaneous infusion.

PERIPHERAL VASCULAR DISEASE

A number of studies have investigated the use of PGE and PGI_2 compounds in Raynaud's phenomenon and peripheral atherosclerosis. In the latter case, prolonged infusions have been used to permit remodeling of the vessel wall and to enhance regression of ischemic ulcers.

PATENT DUCTUS ARTERIOSUS

Patency of the fetal ductus arteriosus depends on COX-2–derived PGE_2 acting on the EP_4 receptor. At birth, reduced PGE_2 levels, a consequence of increased PGE_2 metabolism, allow ductus arteriosus closure. In certain types of congenital heart disease (eg, transposition of the great arteries, pulmonary atresia, pulmonary artery stenosis), it is important to maintain the patency of the neonate's ductus arteriosus before corrective surgery. This is done with alprostadil, PGE_1 . Like PGE_2 , PGE_1 is a vasodilator and an inhibitor of platelet aggregation, and it contracts uterine and intestinal smooth muscle. Adverse effects include apnea, bradycardia, hypotension, and hyperpyrexia. Because of rapid pulmonary clearance, the drug must be continuously infused at an initial rate of 0.05–0.1 mcg/kg/min, which may be increased to 0.4 mcg/kg/min. Prolonged treatment has been associated with ductal fragility and rupture.

In delayed closure of the ductus arteriosus, COX inhibitors are often used to inhibit synthesis of PGE_2 and so close the ductus. Premature infants in whom respiratory distress develops due to failure of ductus closure can be treated with a high degree of success with indomethacin. This treatment often precludes the need for surgical closure of the ductus.

Blood

As noted above, eicosanoids are involved in thrombosis because TXA_2 promotes platelet aggregation and PGI_2 inhibits it. Low-dose aspirin selectively inhibits platelet COX-1. TXA_2 , in addition to activating platelets amplifies the response to other platelet agonists; hence inhibition of its synthesis inhibits secondary aggregation of platelets induced by ADP, by low concentrations of thrombin and collagen, and by epinephrine.

Overview analyses have shown that low-dose aspirin reduces the secondary incidence of heart attack and stroke by about 25%. It elevates the low risk of serious GI bleeds about twofold over placebo. Low-dose aspirin also reduces the incidence of first myocardial infarction. However, in this case, the benefit versus risk of GI bleeding is less clear. The effects of aspirin on platelet function are discussed in greater detail in Chapter 34.

Respiratory System

PGE_2 is a powerful bronchodilator when given in aerosol form. Unfortunately, it also promotes coughing, and an analog that possesses only the bronchodilator properties has been difficult to obtain.

PGF_2 and TXA_2 are both strong bronchoconstrictors and were once thought to be primary mediators in asthma. Polymorphisms in the genes for PGD_2 synthase and the TP have been linked with asthma in humans, and deletion of DP_1 sharply reduces allergen-induced infiltration of lymphocytes and eosinophils and airway hyperreactivity. However, the cysteinyl leukotrienes—LTC_4 , LTD_4 , and LTE_4 —probably dominate during asthmatic constriction of the airway. As described in Chapter 20, leukotriene-receptor inhibitors (eg, zafirlukast, montelukast) are effective in asthma. A lipoxygenase inhibitor (zileuton) has also been used in asthma but is not as popular as the receptor inhibitors. It remains unclear whether leukotrienes are partially responsible for the acute respiratory distress syndrome.

Corticosteroids and cromolyn are also useful in asthma. Corticosteroids inhibit eicosanoid synthesis and thus limit the amounts of eicosanoid mediator available for release. Cromolyn appears to inhibit the release of eicosanoids and other mediators such as histamine and platelet-activating factor from mast cells.

Gastrointestinal System

The word "cytoprotection" was coined to signify the remarkable protective effect of the E prostaglandins against peptic ulcers in animals at doses that do not reduce acid secretion. Since then, numerous experimental and clinical investigations have shown that the PGE compounds and their analogs protect against peptic ulcers produced by either steroids or NSAIDs. Misoprostol is an orally active synthetic analog of PGE_1 . The FDA-approved indication is for prevention of NSAID-induced peptic ulcers. The drug is administered at a dosage of 200 mcg four times daily. This and other PGE analogs (eg, enprostil) are cytoprotective at low doses and inhibit gastric acid secretion at higher doses. The adverse effects are abdominal discomfort and occasional diarrhea; both effects are dose-related. More recently, dose-dependent bone pain and hyperostosis have been described in patients with liver disease who were given long-term PGE treatment.

Selective COX-2 inhibitors were developed in an effort to spare gastric COX-1 so that the natural cytoprotection by locally synthesized PGE_2 and PGI_2 is undisturbed (see Chapter 36). However, this benefit is seen only with highly selective inhibitors and may be offset by increased cardiovascular toxicity.

Immune System

Cells of the immune system contribute substantially to eicosanoid biosynthesis during an immune reaction. T and B lymphocytes are not primary synthetic sources; however, they may supply arachidonic acid to monocyte-macrophages for eicosanoid synthesis. In addition, there is evidence for eicosanoid-mediated cell-cell interaction by platelets, erythrocytes, PMNs, and endothelial cells.

The eicosanoids modulate the effects of the immune system, as illustrated by the cell-mediated immune response. PGE_2 and PGI_2 limit T-cell proliferation in vitro as corticosteroids do. T-cell clonal expansion is attenuated through inhibition of interleukin-1 and interleukin-2 and class II antigen expression by macrophages or other antigen-presenting cells. The leukotrienes, TXA_2 , and platelet-activating factor stimulate T-cell clonal expansion. These compounds stimulate the formation of interleukin-1 and interleukin-2 as well as the expression of interleukin-2 receptors. The leukotrienes also promote interferon-γ release and can replace interleukin-2 as a stimulator of interferon-γ. These in vitro effects of the eicosanoids agree with in vivo findings in animals with acute organ transplant rejection, as described below.

CELL-MEDIATED ORGAN TRANSPLANT REJECTION

Acute organ transplant rejection is a cell-mediated immune response (Chapter 56). Administration of PGI_2 to renal transplant patients has reversed the rejection process in some cases. Experimental in vitro and in vivo data show that PGE_2 and PGI_2 can attenuate T-cell proliferation and rejection, which can also be seen with drugs that inhibit TXA_2 and leukotriene formation. In organ transplant patients, urinary excretion of metabolites of TXA_2 increases during acute rejection. Corticosteroids, the first-line drugs used for treatment of acute rejection because of their lymphotoxic effects, inhibit both phospholipase and COX-2 activity.

INFLAMMATION

Aspirin has been used to treat arthritis for approximately 100 years, but its mechanism of action—inhibition of COX activity—was not discovered until 1971. Aspirin and other anti-inflammatory agents that inhibit COX are discussed in Chapter 36. COX-2 appears to be the form of the enzyme most associated with cells involved in the inflammatory process. With the exception of PGD_2 , the prostanoids are not chemoattractants, but the leukotrienes and some of the HETEs (eg, 12-HETE) are strong chemoattractants. PGE_2 inhibits both antigen-driven and mitogen-induced B-lymphocyte proliferation and differentiation to plasma cells, resulting in inhibition of IgM synthesis. The concomitant elevation of serum IgE and monocyte PGE_2 synthesis, seen in patients with severe trauma and patients with Hodgkin's disease, is explained by the ability of PGE_2 to enhance immunoglobulin class switching to IgE.

RHEUMATOID ARTHRITIS

In rheumatoid arthritis, immune complexes are deposited in the affected joints, causing an inflammatory response that is amplified by eicosanoids. Lymphocytes and macrophages accumulate in the synovium, whereas PMNs localize mainly in the synovial fluid. The major eicosanoids produced by PMNs are leukotrienes, which facilitate T-cell proliferation and act as chemoattractants. Human macrophages synthesize the COX products PGE_2 and TXA_2 and large amounts of leukotrienes.

INFECTION

The relationship of eicosanoids to infection is not well defined. The association between the use of the anti-inflammatory steroids and increased risk of infection is well established. However, NSAIDs do not seem to alter patient responses to infection.

Glaucoma

Latanoprost, a stable long-acting PGF_2 derivative, was the first prostanoid used for glaucoma. The success of latanoprost has stimulated development of similar prostanoids with ocular hypotensive effects, and bimatoprost, travaprost, and unoprostone are now available. These drugs act at the FP receptor and are administered as drops into the conjunctival sac once or twice daily. Adverse effects include irreversible brown pigmentation of the iris and eyelashes, drying of the eyes, and conjunctivitis.

DIETARY MANIPULATION OF ARACHIDONIC ACID METABOLISM

Because arachidonic acid is derived from dietary linoleic and α-linolenic acids, which are essential fatty acids, the effects of dietary manipulation on arachidonic acid metabolism have been extensively studied. Two approaches have been used. The first adds corn, safflower, and sunflower oils, which contain linoleic acid (C18:2), to the diet. The second approach adds oils containing eicosapentaenoic (C20:5) and docosahexaenoic acids (C22:6), so-called omega-3 fatty acids, from cold water fish. Both types of diet change the phospholipid composition of cell membranes by replacing arachidonic acid with the dietary fatty acids. It has been claimed that the synthesis of both TXA_2 and PGI_2 is reduced and that changes in platelet aggregation, vasomotor spasm, and cholesterol metabolism follow.

As indicated previously, there are many possible oxidation products of the different polyenoic acids. It is probably naive to ascribe the effects of dietary intervention reported thus far to such metabolites. However, subjects on diets containing highly saturated fatty acids clearly show increased platelet aggregation when compared with other study groups. Such diets (eg, in Finland and the USA) are associated with higher rates of myocardial infarction than are more polyunsaturated diets (eg, in Italy).

PREPARATIONS AVAILABLE

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS ARE LISTED IN CHAPTER 36.

Alprostadil

Penile injection (Caverject, Edex): 5, 10, 20, 40 mcg sterile powder for reconstitution

Penile pellet (Muse): 125, 250, 500, 1000 mcg

Parenteral (Prostin VR Pediatric): 500 mcg/mL ampules

Bimatoprost (Lumigan)

Ophthalmic drops: 0.03% solution

Carboprost tromethamine (Hemabate)

Parenteral: 250 mcg carboprost and 83 mcg tromethamine per mL ampules

Dinoprostone [prostaglandin E_2] (Prostin E2, Prepidil, Cervidil)

Vaginal: 20 mg suppositories, 0.5 mg gel, 10 mg controlled-release system

Epoprostenol [prostacyclin] (Flolan)

Intravenous: 0.5, 1.5 mg powder to reconstitute

Latanoprost (Xalatan)

Topical: 0.005% ophthalmic solution

Misoprostol (generic, Cytotec)

Oral: 100 and 200 mcg tablets

Monteleukast (Singulair)

Oral: 4, 5 mg chewable tablets, 10 mg tablets, 4 mg granules

Travaprost (Travatan)

Ophthalmic solution: 0.004%

Treprostinil (Remodulin)

Parenteral: 1, 2.5, 5, 10 mg/mL for continuous subcutaneous infusion

Unoprostone (Rescula)

Ophthalmic solution 0.15%

Zafirleukast (Accolate)

Oral: 10, 20 mg tablets

Zileuton (Zyflo)

Oral: 600 mg tablets

NITRIC OXIDE: INTRODUCTION

Nitric oxide (NO) is a gaseous signaling molecule that readily diffuses across cell membranes and regulates a wide range of physiologic and pathophysiologic processes including cardiovascular, inflammation, immune, and neuronal functions. Nitric oxide should not be confused with nitrous oxide (N_2O), an anesthetic gas.

*The author acknowledges the contribution of the previous authors of this chapter, George Thomas, PhD, & Peter Ramwell, PhD.

DISCOVERY OF ENDOGENOUSLY GENERATED NITRIC OXIDE

The first observations of the biologic role of endogenously generated NO were made in rodent macrophages and neutrophils: In vitro exposure of these cells to endotoxin lipopolysaccharide resulted in the accumulation of significant amounts of nitrite and nitrate in the cell culture medium. Furthermore, injection of endotoxin in animals elevated urinary nitrite and nitrate, the two oxidation products of NO.

The second observation was made by investigators in 1980 who found that the ability of acetylcholine to elicit relaxation of isolated strips of rabbit aorta was entirely dependent on the presence of the endothelium. If the endothelium was removed, the vessel still exhibited normal relaxation responses to nitroglycerin, but not to acetylcholine or carbachol. They discovered that following stimulation with acetylcholine or carbachol, the endothelium released a short-lived molecule that resulted in relaxation and dilation of surrounding vascular smooth muscle. The synthesis of this factor was not affected by cyclooxygenase inhibitors, indicating that it was distinct from endothelium-derived prostacyclin. They named this vasodilator endothelium-derived relaxing factor (EDRF), since it promoted relaxation of precontracted smooth muscle preparations. In 1987, by comparing the pharmacologic and biochemical properties of the suspect molecule, three independent groups reported that EDRF and NO are the same molecule. It was later reported that other vasodilator molecules may be a part of EDRF, but it is clear that NO provides the major part of its activity. Subsequent studies revealed that NO was generated by many cells and was, like the eicosanoids (see Chapter 18), found in almost all tissues. The finding that NO is endogenously generated and elicits specific biologic effects explains why pharmacologic reagents that release NO (nitrates, nitrites, nitroprusside; see Chapters 11 and 12) are potent vasodilators.

NITRIC OXIDE SYNTHESIS, SIGNALING MECHANISMS, & INACTIVATION

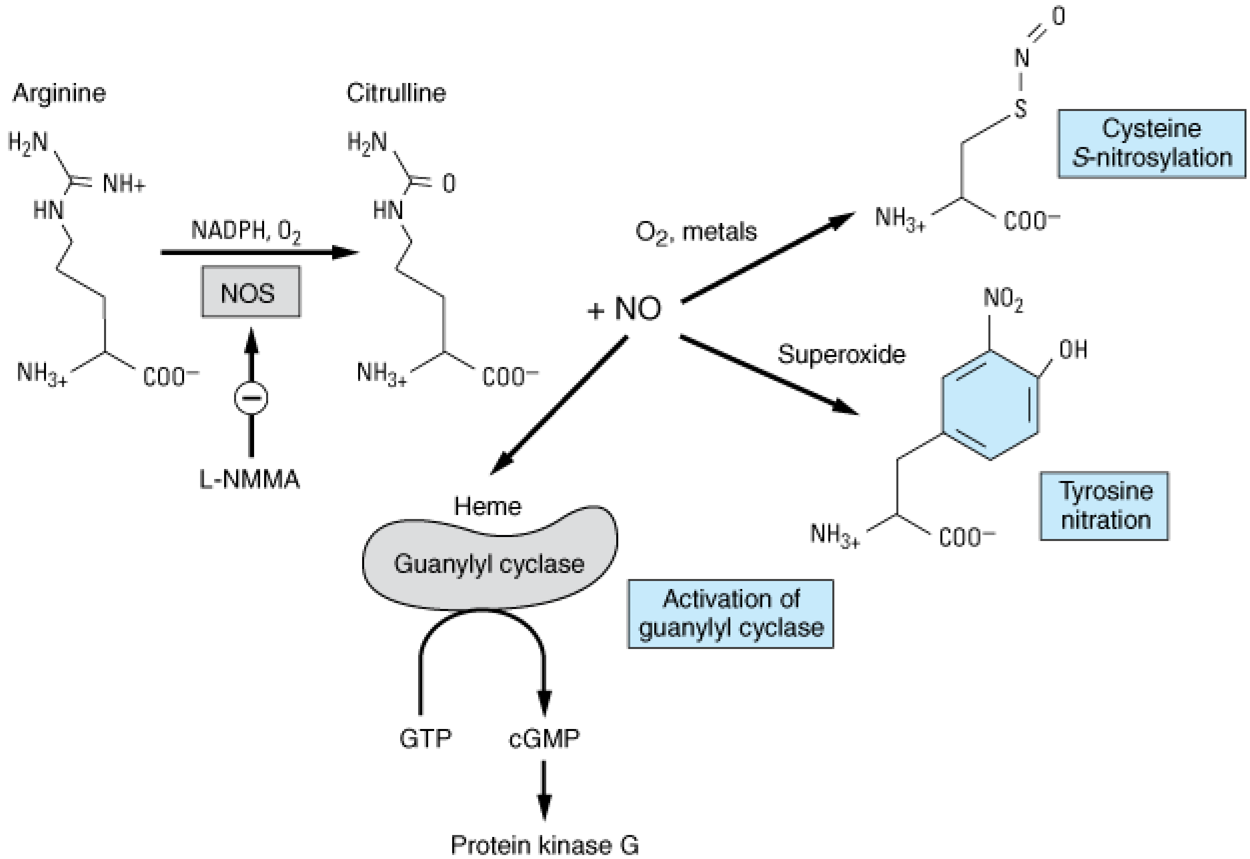
Synthesis

NO, written as NO to indicate an unpaired electron in its chemical structure, or simply NO, is a highly reactive signaling molecule that is made in a wide variety of cells, most prominently neurons, skeletal muscle, endothelial cells, and certain immune system cells. In these cells, NO is synthesized by one or more of three closely related NO synthase (NOS, EC 1.14.13.49) isoenzymes, each of which is encoded by a separate gene and named for the initial cell type in which it was isolated (Table 19–1). These enzymes, neuronal NOS (nNOS or NOS-1), macrophage or inducible NOS (iNOS or NOS-2), and endothelial NOS (eNOS or NOS-3), despite their names, are each expressed in a wide variety of cell types, often with an overlapping distribution. These isoforms generate NO from the amino acid L-arginine in an O_2- and NADPH-dependent reaction (Figure 19–1). This enzymatic reaction involves enzyme-bound cofactors, including heme, tetrahydrobiopterin, and flavin adenine dinucleotide. In the case of nNOS and eNOS, NO synthesis is evoked by agents and processes that increase cytosolic calcium concentrations. Binding of calcium-calmodulin complexes to eNOS and nNOS leads to enzyme activation. On the other hand, iNOS is not regulated by calcium, but is inducible. In macrophages and several other cell types, inflammatory mediators induce the transcriptional activation of the *iNOS* gene, resulting in accumulation of iNOS and generation of increased quantities of NO.

Table 19–1. Properties of the Three Isoforms of Nitric Oxide Synthase (NOS).

	Isoform Names		
Property	NOS-1	NOS-2	NOS-3
Other names	nNOS (neuronal NOS)	iNOS (inducible NOS)	eNOS (endothelial NOS)
Tissue	Neuronal, epithelial cells	Macrophages, smooth muscle cells	Endothelial cells
Expression	Constitutive	Transcriptional induction	Constitutive
Calcium regulation	Yes	No	Yes
Chromosome	12	17	7
Approximate mass	150–160 kDa	125–135 kDa	133 kDa

Figure 19–1.



Nitric oxide generation from L-arginine and nitric oxide donors and the formation of cGMP. L-NMMA inhibits nitric oxide synthase. Some of the nitric oxide donors such as furoxans and organic nitrates and nitrites require a thiol cofactor such as cysteine or glutathione to form nitric oxide.

Signaling Mechanisms

NO mediates its effects by covalent modification of proteins. There are three major effector targets of NO (Figure 19–1):

Metalloproteins

NO interacts with metals, especially iron in heme. Soluble guanylyl cyclase (sGC), an enzyme that generates cyclic GMP from guanosine triphosphate (GTP), contains heme, which binds readily to NO. NO binding to heme results in activation of sGC and elevation in intracellular cGMP levels. cGMP activates protein kinase G (PKG), which phosphorylates specific proteins. NO exerts vasodilatory effects (Chapter 12), which are largely mediated by NO-dependent elevations in cGMP and PKG activity. Several other metalloproteins are targets of NO. The affinity of NO for iron is also responsible for its inhibitory effect on enzymes that contain iron-sulfur clusters such as the tricarboxylic acid cycle enzyme aconitase. NO inhibits mitochondrial respiration by inhibition of cytochrome oxidase. Inhibition of the heme-containing cytochrome P450 enzymes by NO is a major pathogenic mechanism in inflammatory liver disease.

Thiols

NO reacts with thiols (compounds containing the –SH group) to form nitrosothiols. In proteins, the thiol moiety is found in the amino acid cysteine. Upon exposure to NO, certain proteins are found to accumulate nitrosothiols, which can activate or inhibit the activity of these proteins. This posttranslational modification, termed *S*-nitrosylation, is reversed by chemical reduction by intracellular reducing agents. The formation of nitrosothiols is not mediated by direct reaction of NO with thiols, but rather requires either metals or oxygen to catalyze the formation of this adduct. Indeed, NO undergoes both oxidative and reductive reactions, resulting in the formation of a variety of oxides of nitrogen that can nitrosylate thiols, nitrate tyrosines (below), or which are stable oxidation products (Table 19–2). H-ras, a regulator of cell proliferation, is activated by *S*-nitrosylation, while the metabolic enzyme glyceraldehyde-3-phosphate dehydrogenase is inhibited when it is *S*-nitrosylated. Glutathione, a major intracellular sulfhydryl-containing compound, also interacts with NO under physiologic conditions to generate *S*-nitrosoglutathione, a more stable form of NO. Nitrosoglutathione may serve as an endogenous long-lived adduct or carrier of NO. Vascular glutathione is decreased in diabetes mellitus and atherosclerosis, and this may account for the increased incidence of cardiovascular complications in these conditions.

Table 19–2. Oxides of Nitrogen.

Name	Symbol	Known Function
Nitric oxide	NO	Vasodilator, platelet inhibitor, immune regulator, neurotransmitter
Nitroxyl anion	NO^-	Smooth muscle relaxant
Nitrogen dioxide	NO_2	Free radical, nitrosating agent, lung irritant
Nitrous oxide	N_2O	Anesthetic
Dinitrogen trioxide	N_2O_3	Nitrosating agent
Dinitrogen tetraoxide	N_2O_4	Nitrosating agent
Nitrite	NO_2^-	Produces NO at acidic pH
Nitrate	NO_3^-	Stable oxidation product of NO

Tyrosine Nitration

NO reacts very efficiently with superoxide to form peroxynitrite ($ONOO^-$), a powerful oxidant that leads to DNA damage, irreversible nitration of tyrosine, and oxidation of cysteine to disulfides or to various oxides (SO_X). In several diseases, cellular degeneration, due to apoptotic mechanisms or due to ischemia, leads to excess superoxide production, and a consequent increase in peroxynitrite levels. Numerous proteins have been found to contain nitrotyrosines, and this modification can be associated with either activation or inhibition of protein function. However, it is not yet clear whether tyrosine nitration has essential roles in either physiologic signaling or in the pathology of any disease. Protein tyrosine nitration is also used as a marker for the presence of oxidative and nitrosative stress. Peroxynitrite-mediated protein modification is regulated by the cellular content of glutathione, which can protect against tissue damage by scavenging peroxynitrite. Factors that regulate the biosynthesis and decomposition of glutathione may have important consequences on the toxicity of NO.

Inactivation

The lability of NO is related to its rapid reactions with metals and reactive oxygen species. Thus, NO reacts with heme and hemoproteins, including oxyhemoglobin, which catalyzes NO oxidation to nitrate. NO reactions with hemoglobin may also result in partial *S*-nitrosylation of hemoglobin, resulting in transport of NO throughout the vasculature. NO is also inactivated by superoxide, and scavengers of superoxide anion such as superoxide dismutase may protect NO, enhancing its potency and prolonging its duration of action.

PHARMACOLOGIC MANIPULATION OF NITRIC OXIDE

Inhibitors of Nitric Oxide Synthesis

The primary strategy to inhibit the generation of NO in cells is to use NOS inhibitors. The majority of these inhibitors are arginine analogs that bind to the NOS arginine-binding site. Since each of the NOS isoforms has high sequence similarity, most of these inhibitors do not exhibit selectivity for any of the NOS isoforms. In many disorders, such as inflammation and sepsis (see below), inhibition of the iNOS isoform is desired, whereas in neurodegenerative conditions, nNOS-specific inhibitors are needed. However, administration of nonselective NOS inhibitors leads to concurrent inhibition of eNOS, which impairs its homeostatic signaling and also results in vasoconstriction and potential ischemic damage. Thus, newer NOS isoform-selective inhibitors are being designed that exploit subtle differences in substrate-binding sites between the isoforms, as well as newer inhibitors that prevent NOS dimerization, the conformation required for enzymatic activity. The efficacy of NOS isoform-selective inhibitors in medical conditions is under investigation.

Nitric Oxide Donors

NO donors, which release NO or related NO species, are used to elicit smooth muscle relaxation. Different classes of NO donors have differing biologic properties, related to the nature of the NO species that is released and the mechanism that relates to their release.

Organic Nitrates

Nitroglycerin, which dilates veins and coronary arteries, is metabolized to NO by mitochondrial aldehyde reductase, an enzyme enriched in venous smooth muscle, accounting for the potent venodilating activity of this molecule. Other organic nitrates, such as isosorbide dinitrate are metabolized to an NO-releasing species through a currently unidentified enzyme. Organic nitrates have less significant effects on aggregation of platelets, which appear to lack the enzymatic pathways necessary for rapid metabolic activation. Organic nitrates are limited by the loss of therapeutic effect during continuous administration. This nitrate tolerance may derive from NO-mediated inhibition of mitochondrial aldehyde reductase.

Organic Nitrites

Organic nitrites, such as the volatile antianginal isoamylnitrite, also require metabolic activation to elicit vasorelaxation, although the responsible enzyme has not been identified. Nitrites are arterial vasodilators and do not exhibit the rapid tolerance seen with nitrates.

Sodium Nitroprusside

Sodium nitroprusside, which is used for rapid pressure reduction in arterial hypertension, generates NO in response to light as well as chemical or enzymatic mechanisms in cell membranes. See Chapter 11 for additional details.

Hybrid NO Donors

A new strategy involves the incorporation of NO-donating moieties onto currently available cardiovascular drugs. This approach is being tested with drugs such as aspirin and the angiotensin-converting enzyme inhibitor captopril. SNOCap, which incorporates a nitrosothiol moiety on captopril, is currently being examined for its efficacy in cardiovascular disorders.

NO Gas Inhalation

NO itself can be used therapeutically. Inhalation of NO results in reduced pulmonary artery pressure and improved perfusion of ventilated areas of the lung. Inhaled NO has been used for acute respiratory distress syndrome, acute hypoxemia, and cardiopulmonary resuscitation with evidence for short-term improvements in pulmonary function.

Alternate Strategies

Another mechanism to enhance the activity of NO is to enhance the downstream NO signaling pathway. Sildenafil, an inhibitor of type 5 phosphodiesterase, results in prolongation of the duration of NO-induced cGMP elevations in a variety of tissues (see Chapter 12).

NITRIC OXIDE IN DISEASE

VASCULAR EFFECTS

NO has a significant effect on vascular smooth muscle tone and blood pressure. Numerous endothelium-dependent vasodilators, such as acetylcholine and bradykinin, act by increasing intracellular calcium levels, which induces NO synthesis. Mice with a knockout mutation in the *eNOS* gene display increased vascular tone and elevated mean arterial pressure, indicating that eNOS is a fundamental regulator of blood pressure. The effects of vasopressor drugs are increased by inhibition of NOS.

Apart from being a vasodilator, NO protects against thrombosis and atherogenesis through several mechanisms. A major mechanism involves the inhibition of proliferation and migration of vascular smooth muscle. In animal models, myointimal proliferation following angioplasty can be blocked by NO donors, by NOS gene transfer, and by NO inhalation.

The antithrombotic effects of NO are also mediated by NO-dependent inhibition of platelet aggregation. Both endothelial cells and platelets themselves contain eNOS, which acts to regulate thrombus formation. Thus, endothelial dysfunction and the associated decrease in NO generation may result in abnormal platelet function. As in vascular smooth muscle, cGMP mediates the effect of NO in platelets. NO may have an additional inhibitory effect on blood coagulation by enhancing fibrinolysis via an effect on plasminogen.

NO also reduces endothelial adhesion of monocytes and leukocytes, key features of the early development of atheromatous plaques. This effect is due to the inhibitory effect of NO on the expression of adhesion molecules on the endothelial surface. In addition, NO may act as an antioxidant, blocking the oxidation of low-density lipoproteins and thus preventing or reducing the formation of foam cells in the vascular wall. Plaque formation is also affected by NO-dependent reduction in endothelial cell permeability to lipoproteins. The importance of eNOS in cardiovascular disease is supported by experiments showing increased atherosclerosis in animals deficient in eNOS by pharmacologic inhibition. Atherosclerosis risk factors, such as smoking, hyperlipidemia, diabetes, and hypertension, are associated with decreased endothelial NO production, and thus enhance atherogenesis.

SEPTIC SHOCK

As mentioned previously, increased urinary excretion of nitrate, the oxidative product of NO, is a feature of gram-negative bacterial infection. Lipopolysaccharide components from the bacterial wall induce synthesis of iNOS, resulting in exaggerated hypotension, shock, and, in some cases, death. This hypotension is reversed by NOS inhibitors such as L-NMMA (Table 19–3) in humans as well as in animal models. A similar reversal of hypotension is produced by compounds that prevent the action of NO (such as methylene blue), as well as by scavengers of NO (such as hemoglobin). Furthermore, knockout mice lacking a functional *iNOS* gene are more resistant to endotoxin than wild-type mice. However, thus far there has been no correlation between the hemodynamic effects of relatively nonselective NOS inhibitors and survival rate in gram-negative sepsis. The absence of benefit may reflect the inability of the NOS inhibitors to differentiate between NOS isoforms or may reflect concurrent inhibition of beneficial aspects of iNOS signaling.

Table 19–3. Some Inhibitors of Nitric Oxide Synthesis or Action.		
Inhibitor	**Mechanism**	**Comment**
N^G–Monomethyl–L–arginine (L–NMMA)	NOS inhibition	May act as substrate in some tissues
N^G–Nitro–L–arginine methyl ester (L–NAME)	NOS inhibition	Less selective NOS inhibitor
7–Nitroindazole	NOS inhibition	Markedly selective for NOS–1 in vivo
S–Methylthiocitrulline	NOS inhibition	Partially selective for NOS–1
Heme	Nitric oxide scavenger	

NOS, nitric oxide synthase.

INFLAMMATION

The host response to infection or injury involves the recruitment of leukocytes and the release of inflammatory mediators, including NO. Numerous cytokines, such as tumor necrosis factor and interleukin-1, as well as bacterial-derived mediators, induce the transcription of iNOS in leukocytes, fibroblasts, and other cell types, accounting for enhanced levels of NO. NO is an important microbicide and may have important roles in tissue adapting to inflammatory states. However, overproduction of NO may exacerbate tissue injury in both acute and chronic inflammatory conditions. NO generated during inflammation is involved in the vasodilation associated with acute inflammation and can interact with superoxide to generate peroxynitrite and subsequently modify proteins, lipids, and nucleotides. In experimental models of acute inflammation, inhibitors of iNOS have a dose-dependent protective effect, suggesting that NO promotes edema and vascular permeability. NO has a detrimental effect in chronic models of arthritis; dietary L-arginine supplementation exacerbates arthritis, whereas protection is seen with iNOS inhibitors. Psoriasis lesions, airway epithelium in asthma, and inflammatory bowel lesions in humans all demonstrate elevated levels of NO and iNOS. Synovial fluid from patients with arthritis contains increased oxidation products of NO, particularly peroxynitrite. Recent studies have shown that NO stimulates the synthesis of inflammatory prostaglandins by activating cyclooxygenase isoenzyme II (COX-2). Thus, inhibition of the NO pathway may have a beneficial effect on inflammatory diseases, including joint diseases.

However, NO also appears to play an important protective role in the body via immune cell function. When challenged with foreign antigens, TH1 cells (see Chapter 56) respond by synthesizing NO. Inhibition of NOS and knockout of the *iNOS* gene can markedly impair the protective response to injected parasites in animal models.

THE CENTRAL NERVOUS SYSTEM

NO has been proposed to have a major role in the central nervous system—as a neurotransmitter, as a modulator of ligand-gated receptors, or both. NO synthesis is induced at postsynaptic sites in neurons upon activation of the NMDA subtype of glutamate receptor, which results in calcium influx and activation of nNOS. In several neuronal subtypes, eNOS is also present and activated by neurotransmitter pathways that lead to calcium influx. NO synthesized postsynaptically may function as a retrograde messenger and diffuse to the presynaptic terminal to enhance the efficiency of neurotransmitter release through a cGMP or *S*-nitrosylation-dependent mechanism. It has been suggested that a major role for NO is in the regulation of synaptic plasticity, the molecular process that underlies learning and behavior.

THE PERIPHERAL NERVOUS SYSTEM

Nonadrenergic, noncholinergic (NANC) neurons are widely distributed in peripheral tissues, especially the gastrointestinal and reproductive tracts (see Chapter 6). Considerable evidence implicates NO as a mediator of certain NANC actions, and some NANC neurons appear to release NO. Penile erection is thought to be caused by the release of NO from NANC neurons; it is well documented that NO promotes relaxation of the smooth muscle in the corpora cavernosa—the initiating factor in penile erection—and inhibitors of NOS have been shown to prevent erection caused by pelvic nerve stimulation in the rat. Thus, impotence is a possible clinical indication for the use of a NO donor, and trials have been carried out with nitroglycerin ointment and the nitroglycerin patch. An established approach is to inhibit the breakdown of cGMP by the phosphodiesterase (PDE isoform 5) present in the smooth muscle of the corpora cavernosa with drugs such as sildenafil (see Chapter 12).

RESPIRATORY DISORDERS

NO has been shown to improve cardiopulmonary function in adult patients with pulmonary artery hypertension and is approved for this indication (see Preparations Available). It is administered by inhalation. It has also been administered by inhalation to newborns with pulmonary hypertension and acute respiratory distress syndrome. The current treatment for severely defective gas exchange in the newborn is with extracorporeal membrane oxygenation (ECMO), which does not directly affect pulmonary vascular pressures. NO inhalation decreases pulmonary arterial pressure and improves blood oxygenation. Thus, when pulmonary resistance is elevated, it is possible to exploit the vasodilator properties of NO by administering it via inhalation of a few parts per million. Adults with respiratory distress syndrome also appear—in open trials—to benefit from NO inhalation. NO may have an additional role in relaxing airway smooth muscle and thus acting as a bronchodilator. For these reasons, NO inhalation therapy is being widely tested in both infants and adults with acute respiratory distress syndrome. The adverse effects of this use of NO are being assessed.

PREPARATIONS AVAILABLE

Nitric Oxide (INOmax)

Inhalation: 100, 800 ppm gas

DRUGS USED IN ASTHMA: INTRODUCTION

Asthma is characterized clinically by recurrent bouts of coughing, shortness of breath, chest tightness, and wheezing; physiologically by widespread, reversible narrowing of the bronchial airways and a marked increase in bronchial responsiveness to inhaled stimuli; and pathologically by lymphocytic, eosinophilic inflammation of the bronchial mucosa. It is also characterized pathologically by remodeling of the bronchial mucosa, with deposition of collagen beneath the epithelium's lamina reticularis and hyperplasia of the cells of all structural elements—vessels, smooth muscle, and secretory glands and goblet cells.

In mild asthma, symptoms occur only occasionally, as on exposure to allergens or certain pollutants, on exercise, or after a viral upper respiratory infection. More severe forms of asthma are associated with frequent attacks of wheezing dyspnea, especially at night, and may be associated with chronic airway narrowing, causing chronic respiratory impairment. These consequences of asthma are regarded as largely preventable, because effective treatments for relief of acute bronchoconstriction ("short term relievers") and for reduction in symptoms and prevention of attacks ("long-term controllers") are available (but underutilized).

The causes of airway narrowing in acute asthmatic attacks include contraction of airway smooth muscle, inspissation of thick, viscid mucus plugs in the airway lumen, and thickening of the bronchial mucosa from edema, cellular infiltration, and hyperplasia of secretory, vascular, and smooth muscle cells. Of these causes of airway obstruction, contraction of smooth muscle is most easily reversed by current therapy; reversal of the edema and cellular infiltration requires sustained treatment with anti-inflammatory agents.

Short-term relief is thus most effectively achieved by agents that relax airway smooth muscle, of which β-adrenoceptor stimulants (see Chapter 9) are the most effective and most widely used. Theophylline, a methylxanthine drug, and antimuscarinic agents (see Chapter 8) are also used for reversal of airway constriction.

Long-term control is most effectively achieved with an anti-inflammatory agent such as an inhaled corticosteroid. It can also be achieved, though less effectively, with a leukotriene pathway antagonist or an inhibitor of mast cell degranulation, such as cromolyn or nedocromil. Finally, clinical trials have established the efficacy of treatment for asthma with a humanized monoclonal antibody, omalizumab, which is specifically targeted against IgE, the antibody responsible for allergic sensitization.

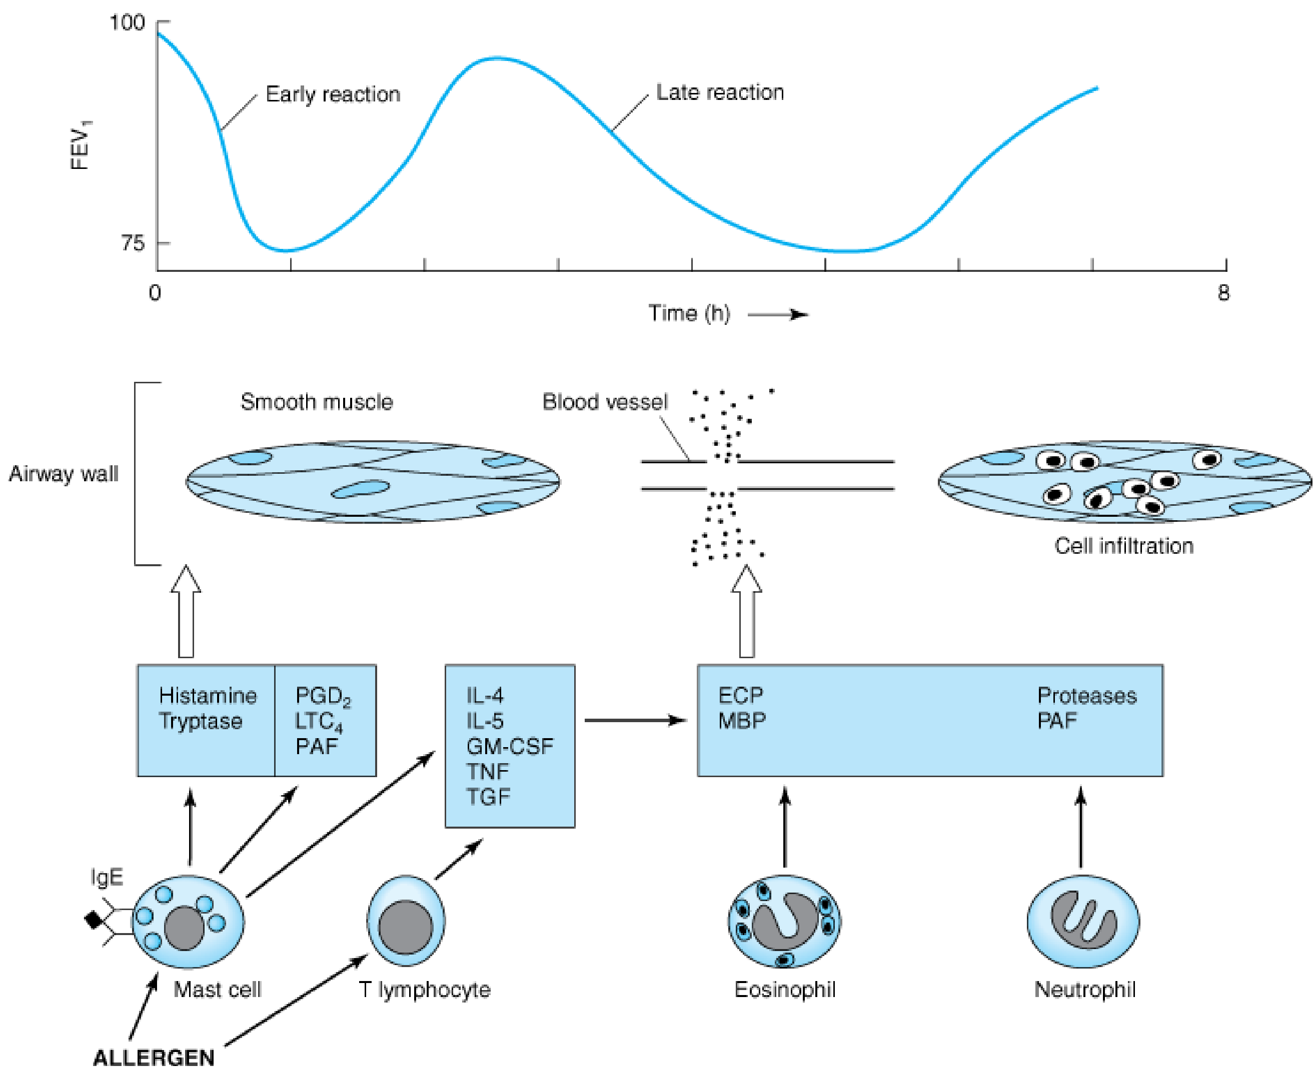
The distinction between "short-term relievers" and "long-term controllers" has become blurred. Theophylline, regarded as a bronchodilator, inhibits some lymphocyte functions and modestly reduces airway mucosal inflammation. Inhaled corticosteroids, regarded as long-term controllers, produce modest immediate bronchodilation. Two recently released long-acting β-adrenoceptor stimulants, salmeterol and formoterol, appear to be effective in improving asthma control when added to inhaled corticosteroid treatment.

This chapter presents the basic pharmacology of the methylxanthines, cromolyn, leukotriene pathway inhibitors, and monoclonal anti-IgE antibody—agents whose medical use is almost exclusively for pulmonary disease. The other classes of drugs listed above are discussed in relation to the therapy of asthma.

PATHOGENESIS OF ASTHMA

The classic immunologic model of asthma presents it as a disease mediated by reaginic immune globulin (IgE). Foreign materials that provoke IgE production are described as "allergens"; the most common are proteins from house dust mite, cockroach, cat dander, molds, and pollens. The tendency to produce IgE antibodies is genetically determined; asthma and other allergic diseases cluster in families. Once produced, IgE antibodies bind to mast cells in the airway mucosa (Figure 20–1). On reexposure to a specific allergen, antigen-antibody interaction on the surface of the mast cells triggers both the release of mediators stored in the cells' granules and the synthesis and release of other mediators. The histamine, tryptase, leukotrienes C_4 and D_4 , and prostaglandin D_2 , when released, diffuse through the airway mucosa triggering the muscle contraction and vascular leakage responsible for the acute bronchoconstriction of the "early asthmatic response." This response is often followed in 4–6 hours by a second, more sustained phase of bronchoconstriction, the "late asthmatic response," which is associated with an influx of inflammatory cells into the bronchial mucosa and with an increase in bronchial responsiveness that may last for several weeks after a single inhalation of allergen. The mediators responsible for this late response are thought to be cytokines characteristically produced by T_H2 lymphocytes, especially interleukins 5, 9, and 13. The cytokines are thought to attract and activate eosinophils, stimulate IgE production by B lymphocytes, and directly stimulate mucus production by bronchial epithelial cells. It is not clear whether lymphocytes or mast cells in the airway mucosa are the primary source of the mediators responsible for the late inflammatory response, but the benefits of corticosteroid therapy are attributed to their inhibition of cytokine production in the airways.

Figure 20–1.



Conceptual model for the immunopathogenesis of asthma. Exposure to allergen causes synthesis of IgE, which binds to mast cells in the airway mucosa. On reexposure to allergen, antigen-antibody interaction on mast cell surfaces triggers release of mediators of anaphylaxis: histamine, tryptase, prostaglandin D_2 (PGD_2), leukotriene C_4, and platelet-activating factor (PAF). These agents provoke contraction of airway smooth muscle, causing the immediate fall in FEV_1. Reexposure to allergen also causes the synthesis and release of a variety of cytokines: interleukins 4 and 5, granulocyte-macrophage colony stimulating factor (GM-CSF), tumor necrosis factor (TNF), and tissue growth factor (TGF) from T cells and mast cells. These cytokines in turn attract and activate eosinophils and neutrophils, whose products include eosinophil cationic protein (ECP), major basic protein (MBP), proteases, and platelet-activating factor. These mediators cause the edema, mucus hypersecretion, smooth muscle contraction, and increase in bronchial reactivity associated with the late asthmatic response, indicated by a fall in FEV_1 2–8 hours after the exposure.

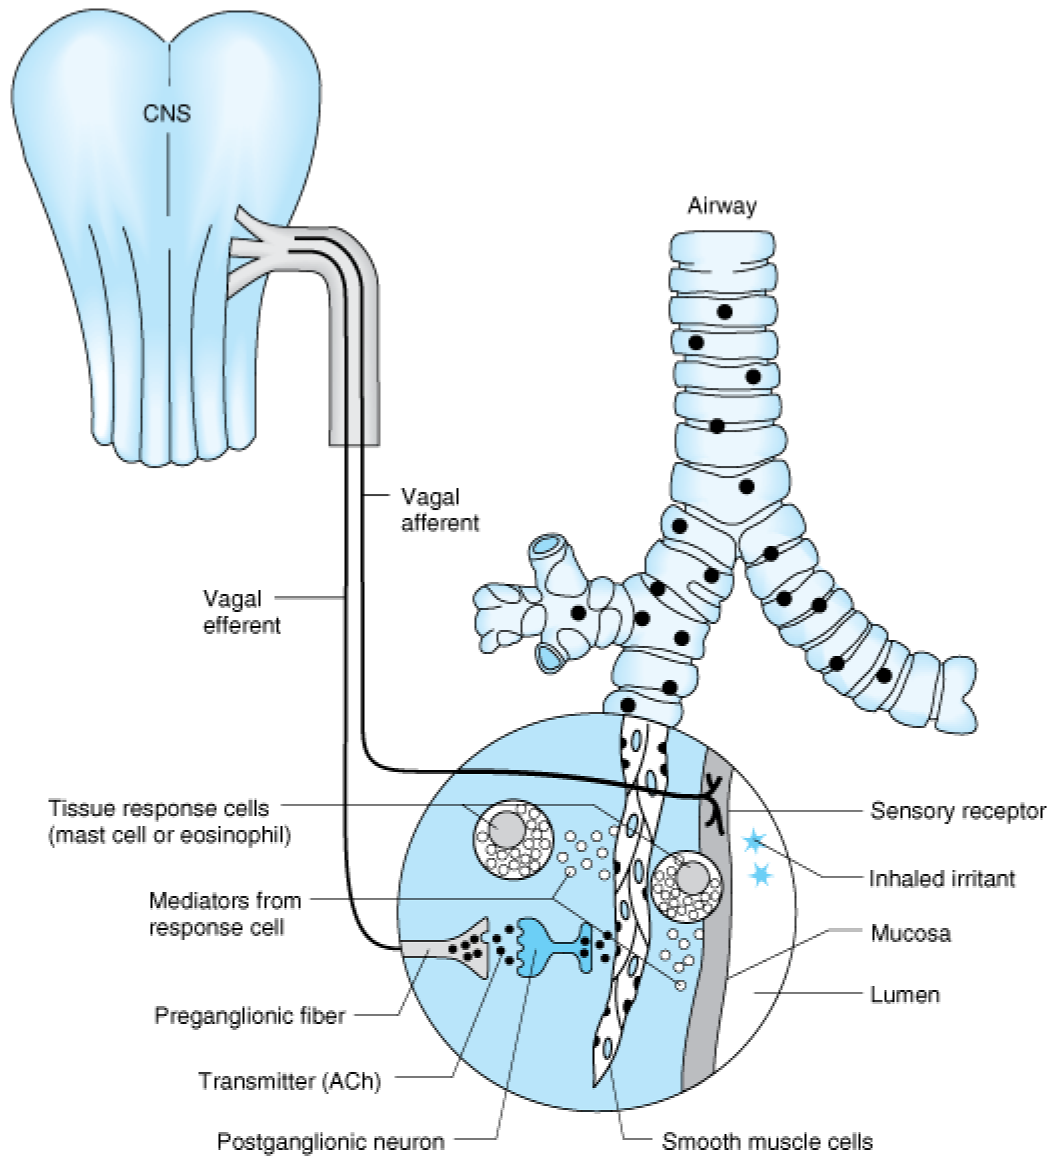
The allergen challenge model does not reproduce all the features of asthma. Most asthma attacks are not triggered by inhalation of allergens. They are triggered by viral respiratory infection. Some adults with asthma have no evidence of allergic sensitivity to allergens, and even in people with allergic sensitivity, the severity of symptoms correlates poorly with levels of allergen in the atmosphere. Moreover, bronchospasm can be provoked by nonallergenic stimuli such as distilled water, exercise, cold air, sulfur dioxide, and rapid respiratory maneuvers.

This tendency to develop bronchospasm on encountering stimuli that do not affect healthy nonasthmatic airways is characteristic of asthma and is sometimes called "nonspecific bronchial hyperreactivity" to distinguish it from bronchial responsiveness to specific antigens. Bronchial reactivity is assessed by measuring the fall in forced expiratory volume in 1 second (FEV_1) provoked by inhaling serially increasing concentrations of aerosolized methacholine. The exaggerated reactivity of the airways appears to be fundamental to asthma's pathogenesis, because it is nearly ubiquitous in patients with asthma and its degree correlates with the clinical severity of the disease.

The mechanisms underlying bronchial hyperreactivity are somehow related to inflammation of the airway mucosa. The agents that increase bronchial reactivity, such as ozone exposure, allergen inhalation, and infection with respiratory viruses, also cause airway inflammation. The increase in reactivity due to allergen inhalation is associated with an increase in both eosinophils and polymorphonuclear leukocytes in bronchial lavage fluid. The increase in reactivity that is associated with the late asthmatic response to allergen inhalation (Figure 20–1) is sustained and, because it is prevented by treatment with an inhaled corticosteroid, is thought to be caused by airway inflammation.

Whatever the mechanisms responsible for bronchial hyperreactivity, bronchoconstriction itself seems to result not simply from the direct effect of the released mediators but also from their activation of neural or humoral pathways. Evidence for the importance of neural pathways stems largely from studies of laboratory animals. The bronchospasm provoked in dogs by inhalation of histamine is reduced by pretreatment with an inhaled topical anesthetic agent, by transection of the vagus nerves, and by pretreatment with atropine. Studies of asthmatic humans, however, have shown that treatment with atropine causes only a reduction in—not abolition of—the bronchospastic responses to antigens and to nonantigenic stimuli. It is possible that activity in another neural pathway, such as the nonadrenergic, noncholinergic system, contributes to bronchomotor responses stimuli (Figure 20–2).

Figure 20–2.



Mechanisms of response to inhaled irritants. The airway is represented microscopically by a cross-section of the wall with branching vagal sensory endings lying adjacent to the lumen. Afferent pathways in the vagus nerves travel to the central nervous system; efferent pathways from the central nervous system travel to efferent ganglia. Postganglionic fibers release acetylcholine (ACh), which binds to muscarinic receptors on airway smooth muscle. Inhaled materials may provoke bronchoconstriction by several possible mechanisms. First, they may trigger the release of chemical mediators from mast cells. Second, they may stimulate afferent receptors to initiate reflex bronchoconstriction or to release tachykinins (eg, substance P) that directly stimulate smooth muscle contraction.

The hypothesis suggested by these studies—that asthmatic bronchospasm results from a combination of release of mediators and an exaggeration of responsiveness to their effects—predicts that asthma may be effectively treated by drugs with different modes of action. Asthmatic bronchospasm might be reversed or prevented, for example, by drugs that reduce the amount of IgE bound to mast cells (anti-IgE antibody), prevent mast cell degranulation (cromolyn or nedocromil, sympathomimetic agents, calcium channel blockers), block the action of the products released (antihistamines and leukotriene receptor antagonists), inhibit the effect of acetylcholine released from vagal motor nerves (muscarinic antagonists), or directly relax airway smooth muscle (sympathomimetic agents, theophylline).

The second approach to the treatment of asthma is aimed not only at preventing or reversing acute bronchospasm but at reducing the level of bronchial responsiveness. Because increased responsiveness appears to be linked to airway inflammation and because airway inflammation is a feature of late asthmatic responses, this strategy is implemented both by reducing exposure to the allergens that provoke inflammation and by prolonged therapy with anti-inflammatory agents, especially inhaled corticosteroids.

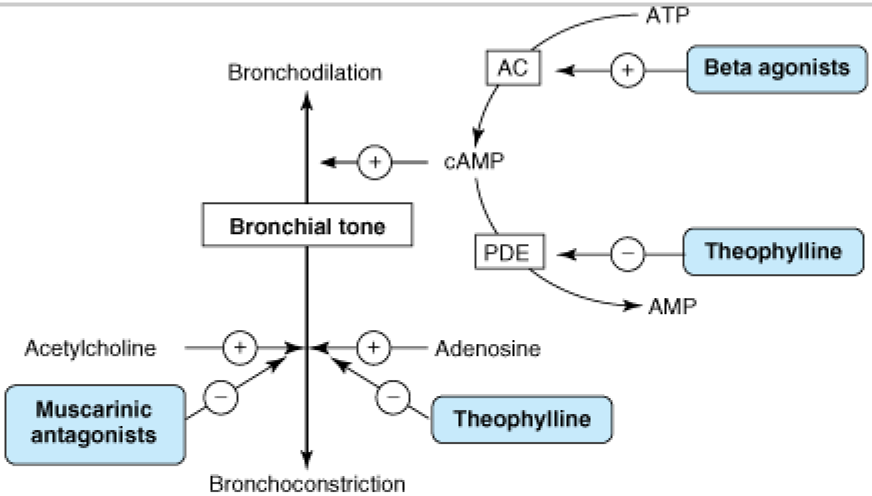
BASIC PHARMACOLOGY OF AGENTS USED IN THE TREATMENT OF ASTHMA

The drugs most used for management of asthma are adrenoceptor agonists, or sympathomimetic agents (used as "relievers" or bronchodilators) and inhaled corticosteroids (used as "controllers" or anti-inflammatory agents). Their basic pharmacology is presented elsewhere (see Chapters 9 and 39). In this chapter, we review their pharmacology relevant to asthma.

SYMPATHOMIMETIC AGENTS

The adrenoceptor agonists have several pharmacologic actions that are important in the treatment of asthma. They relax airway smooth muscle and inhibit release of bronchoconstricting mediators from mast cells. They may also inhibit microvascular leakage and increase mucociliary transport by increasing ciliary activity. As in other tissues, the β agonists stimulate adenylyl cyclase and increase the formation of intracellular cAMP (Figure 20–3).

Figure 20–3.

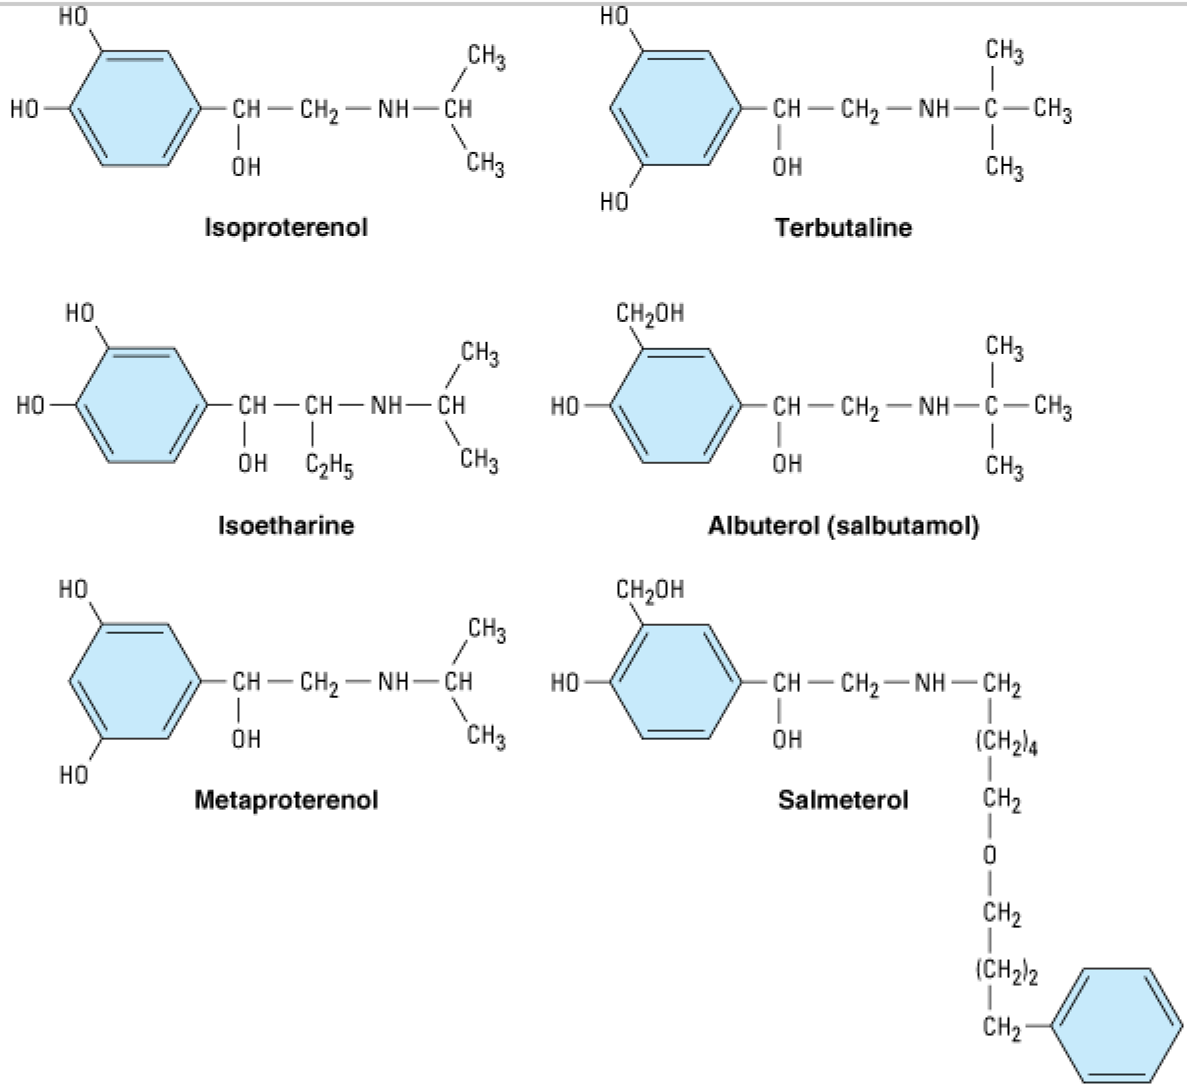


Bronchodilation is promoted by cAMP. Intracellular levels of cAMP can be increased by β-adrenoceptor agonists, which increase the rate of its synthesis by adenylyl cyclase (AC); or by phosphodiesterase (PDE) inhibitors such as theophylline, which slow the rate of its degradation. Bronchoconstriction can be inhibited by muscarinic antagonists and possibly by adenosine antagonists.

The best-characterized action of the adrenoceptor agonists in the airways is relaxation of airway smooth muscle. Although there is no evidence for significant sympathetic innervation of human airway smooth muscle, ample evidence exists for the presence of adrenoceptors on airway smooth muscle. In general, stimulation of β_2 receptors relaxes airway smooth muscle, inhibits mediator release, and causes tachycardia and skeletal muscle tremor as side effects.

The sympathomimetic agents that have been widely used in the treatment of asthma include epinephrine, ephedrine, isoproterenol, and albuterol and other β_2 -selective agents (Figure 20–4). Because epinephrine and isoproterenol increase the rate and force of cardiac contraction (mediated mainly by β_1 receptors), they are reserved for special situations (see below).

Figure 20–4.



Structures of isoproterenol and several β_2 -selective analogs.

In general, adrenoceptor agonists are best delivered by inhalation because this results in the greatest local effect on airway smooth muscle with the least systemic toxicity. Aerosol deposition depends on the particle size, the pattern of breathing (tidal volume and rate of airflow), and the geometry of the airways. Even with particles in the optimal size range of 2–5 mm, 80–90% of the total dose of aerosol is deposited in the mouth or pharynx. Particles under 1–2 μm remain suspended and may be exhaled. Deposition can be increased by holding the breath in inspiration.

Epinephrine is an effective, rapidly acting bronchodilator when injected subcutaneously (0.4 mL of 1:1000 solution) or inhaled as a microaerosol from a pressurized canister (320 mcg per puff). Maximal bronchodilation is achieved 15 minutes after inhalation and lasts 60–90 minutes. Because epinephrine stimulates α and β_1 as well as β_2 receptors, tachycardia, arrhythmias, and worsening of angina pectoris are troublesome adverse effects. The cardiovascular effects of epinephrine are of value for treating the acute vasodilation and shock as well as the bronchospasm of anaphylaxis, but its use in asthma has been displaced by other, more β_2 -selective agents.

Ephedrine was used in China for more than 2000 years before its introduction into Western medicine in 1924. Compared with epinephrine, ephedrine has a longer duration, oral activity, more pronounced central effects, and much lower potency. Because of the development of more efficacious and β_2 -selective agonists, ephedrine is now used infrequently in treating asthma.

Isoproterenol is a potent bronchodilator; when inhaled as a microaerosol from a pressurized canister, 80–120 mcg isoproterenol causes maximal bronchodilation within 5 minutes. Isoproterenol has a 60- to 90-minute duration of action. An increase in the asthma mortality rate that occurred in the United Kingdom in the mid 1960s was attributed to cardiac arrhythmias resulting from the use of high doses of inhaled isoproterenol. It is now rarely used for asthma.

Beta$_2$ -Selective Drugs

The β_2 -selective adrenoceptor agonist drugs are the most widely used sympathomimetics for the treatment of asthma at present (Figure 20–4). These agents differ structurally from epinephrine in having a larger substitution on the amino group and in the position of the hydroxyl groups on the aromatic ring. They are effective after inhaled or oral administration and have a long duration of action.

Albuterol, terbutaline, metaproterenol, and pirbuterol are available as metered-dose inhalers. Given by inhalation, these agents cause bronchodilation equivalent to that produced by isoproterenol. Bronchodilation is maximal within 15–30 minutes and persists for 3–4 hours. All can be diluted in saline for administration from a hand-held nebulizer. Because the particles generated by a nebulizer are much larger than those from a metered-dose inhaler, much higher doses must be given (2.5–5.0 mg vs 100–400 mcg) but are no more effective. Nebulized therapy should thus be reserved for patients unable to coordinate inhalation from a metered-dose inhaler.

Albuterol and terbutaline are also available in tablet form. One tablet two or three times daily is the usual regimen; the principal adverse effects of skeletal muscle tremor, nervousness, and occasional weakness may be reduced by starting the patient on half-strength tablets for the first 2 weeks of therapy, but this route of administration presents no advantage over inhaled treatment.

Of these agents, only terbutaline is available for subcutaneous injection (0.25 mg). The indications for this route are similar to those for subcutaneous epinephrine—severe asthma requiring emergency treatment when aerosolized therapy is not available or has been ineffective—but it should be remembered that terbutaline's longer duration of action means that cumulative effects may be seen after repeated injections.

A new generation of long-acting β_2 -selective agonists includes salmeterol and formoterol. Both drugs are potent selective β_2 agonists that achieve their long duration of action (12 hours or more) as a result of high lipid solubility. This permits them to dissolve in the smooth muscle cell membrane in high concentrations or, possibly, attach to "mooring" molecules in the vicinity of the adrenoceptor. These drugs appear to interact with inhaled corticosteroids to improve asthma control. They are not recommended as the sole therapy for asthma.

Toxicities

The use of sympathomimetic agents by inhalation at first raised fears about possible cardiac arrhythmias and about hypoxemia acutely and tachyphylaxis or tolerance when given repeatedly. It is true that the vasodilating action of β_2 -agonist treatment may increase perfusion of poorly ventilated lung units, transiently decreasing arterial oxygen tension (PaO_2). This effect is usually small, however, and may occur with any bronchodilator drug; the significance of such an effect depends on the initial PaO_2 of the patient. Administration of supplemental oxygen, routine in treatment of an acute severe attack of asthma, eliminates any concern over this effect. The other concern, that β-agonist treatment may cause lethal cardiac arrhythmias appears unsubstantiated. In patients presenting for emergency treatment of severe asthma, irregularities in cardiac rhythm *improve* with the improvements in gas exchange effected by bronchodilator treatment.

The concept that β-agonist drugs cause worsening of clinical asthma by inducing tachyphylaxis to their own action remains unestablished. Most studies have shown only a small change in the bronchodilator response to βstimulation after prolonged treatment with β-agonist drugs, but some studies have shown a loss in the ability of β-agonist treatment to inhibit the response to subsequent challenge with exercise, methacholine, or antigen challenge (referred to as a loss of bronchoprotective action).

Fears that heavy use of β-agonist inhalers could actually increase morbidity and mortality have not been borne out by careful epidemiologic investigations. Heavy use most often indicates that the patient should be receiving more effective prophylactic therapy with corticosteroids.

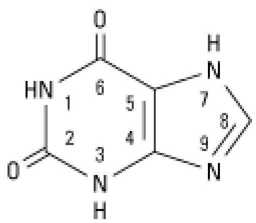
Although it is true that β_2 -adrenoceptor agonists appear to be safe and effective bronchodilators for most patients, there is some evidence that the risk of adverse effects from chronic treatment with long-acting β agonists may be greater for some individuals, possibly as a function of genetic variants for the βreceptor. Two retrospective and one prospective study have shown differences between patients homozygous for glycine versus arginine at the B-16 locus of the βreceptor. Among patients homozygous for arginine, a genotype found in 16% of the Caucasian population in the USA, but more commonly in African Americans, asthma control deteriorated with regular use of albuterol or salmeterol, whereas asthma control improved with this treatment among those homozygous for glycine at the same locus. These findings need to be replicated in larger studies, but it is tempting to speculate that a genetic variant may underlie the report of an increase in asthma mortality from regular use of a long-acting βagonist in studies involving very large numbers of patients.

METHYLXANTHINE DRUGS

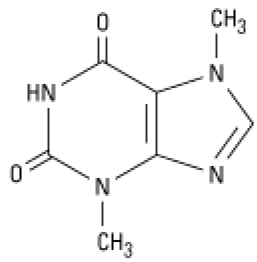
The three important methylxanthines are **theophylline**, **theobromine**, and **caffeine**. Their major source is beverages (tea, cocoa, and coffee, respectively). The importance of theophylline as a therapeutic agent in the treatment of asthma has waned as the greater effectiveness of inhaled adrenoceptor agents for acute asthma and of inhaled anti-inflammatory agents for chronic asthma has been established, but theophylline's very low cost is an important advantage for economically disadvantaged patients in societies in which health care resources are limited.

Chemistry

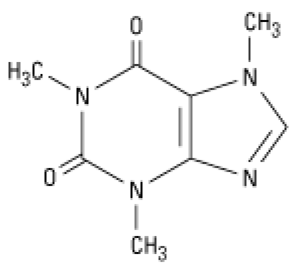
As shown below, theophylline is 1,3-dimethylxanthine; theobromine is 3,7-dimethylxanthine; and caffeine is 1,3,7-trimethylxanthine. A theophylline preparation commonly used for therapeutic purposes is **aminophylline**, a theophylline-ethylenediamine complex. The pharmacokinetics of theophylline are discussed below (see Clinical Use of Methylxanthines). The metabolic products, partially demethylated xanthines (not uric acid), are excreted in the urine.



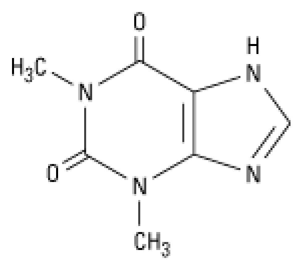
Xanthine



Theobromine



Caffeine



Theophylline

Mechanism of Action

Several mechanisms have been proposed for the actions of methylxanthines, but none has been firmly established. At high concentrations, they can be shown in vitro to inhibit several members of the phosphodiesterase (PDE) enzyme family (Figure 20–3). Because the phosphodiesterases hydrolyze cyclic nucleotides, this inhibition results in higher concentrations of intracellular cAMP and, in some tissues, cGMP. Cyclic AMP is responsible for a myriad of cellular functions including, but not limited to, stimulation of cardiac function, relaxation of smooth muscle, and reduction in the immune and inflammatory activity of specific cells.

Of the various isoforms of phosphodiesterase that have been identified, PDE4 appears to be the most directly involved in actions of methylxanthines on airway smooth muscle and on inflammatory cells. The inhibition of PDE4 in inflammatory cells reduces their release of cytokines and chemokines, which in turn results in a decrease in immune cell migration and activation.

In an effort to reduce toxicity while maintaining therapeutic efficacy, more selective inhibitors of different isoforms of PDE4 have been developed, particularly for the treatment of chronic obstructive pulmonary disease (COPD). Several are now in advanced stages of clinical development, (eg, roflumilast, cilomilast, tofimilast), but at the time of writing, none has been approved for clinical use by the FDA. Although several appear promising, none is entirely free of the major adverse effect of this class of drugs, nausea and vomiting.

Another proposed mechanism is inhibition of cell surface receptors for adenosine. These receptors modulate adenylyl cyclase activity, and adenosine has been shown to provoke contraction of isolated airway smooth muscle and histamine release from airway mast cells. It has been shown, however, that xanthine derivatives devoid of adenosine antagonism (eg, enprofylline) may be potent in inhibiting bronchoconstriction in asthmatic subjects.

Pharmacodynamics of Methylxanthines

The methylxanthines have effects on the central nervous system, kidney, and cardiac and skeletal muscle as well as smooth muscle. Of the three agents, theophylline is most selective in its smooth muscle effects, whereas caffeine has the most marked central nervous system effects.

CENTRAL NERVOUS SYSTEM EFFECTS

In low and moderate doses, the methylxanthines—especially caffeine—cause mild cortical arousal with increased alertness and deferral of fatigue. The caffeine contained in beverages—eg, 100 mg in a cup of coffee—is sufficient to cause nervousness and insomnia in sensitive individuals and slight bronchodilation in patients with asthma. The larger doses necessary for more effective bronchodilation commonly cause nervousness and tremor in some patients. Very high doses, from accidental or suicidal overdose, cause medullary stimulation and convulsions and may lead to death.

CARDIOVASCULAR EFFECTS

The methylxanthines have positive chronotropic and inotropic effects. At low concentrations, these effects appear to result from inhibition of presynaptic adenosine receptors in sympathetic nerves increasing catecholamine release at nerve endings. The higher concentrations (> 10 μmol/L, 2 mg/L) associated with inhibition of phosphodiesterase and increases in cAMP may result in increased influx of calcium. At much higher concentrations (> 100 μmol/L), sequestration of calcium by the sarcoplasmic reticulum is impaired.

The clinical expression of these effects on cardiovascular function varies among individuals. Ordinary consumption of coffee and other methylxanthine-containing beverages usually produces slight tachycardia, an increase in cardiac output, and an increase in peripheral resistance, raising blood pressure slightly. In sensitive individuals, consumption of a few cups of coffee may result in arrhythmias. In large doses, these agents also relax vascular smooth muscle except in cerebral blood vessels, where they cause contraction.

Methylxanthines decrease blood viscosity and may improve blood flow under certain conditions. The mechanism of this action is not well defined, but the effect is exploited in the treatment of intermittent claudication with pentoxifylline, a dimethylxanthine agent. However, no evidence suggests that this therapy is superior to other approaches.

EFFECTS ON GASTROINTESTINAL TRACT

The methylxanthines stimulate secretion of both gastric acid and digestive enzymes. However, even decaffeinated coffee has a potent stimulant effect on secretion, which means that the primary secretagogue in coffee is not caffeine.

EFFECTS ON KIDNEY

The methylxanthines—especially theophylline—are weak diuretics. This effect may involve both increased glomerular filtration and reduced tubular sodium reabsorption. The diuresis is not of sufficient magnitude to be therapeutically useful.

EFFECTS ON SMOOTH MUSCLE

The bronchodilation produced by the methylxanthines is the major therapeutic action in asthma. Tolerance does not develop, but adverse effects, especially in the central nervous system, may limit the dose (see below). In addition to their effect on airway smooth muscle, these agents—in sufficient concentration—inhibit antigen-induced release of histamine from lung tissue; their effect on mucociliary transport is unknown.

EFFECTS ON SKELETAL MUSCLE

The respiratory actions of the methylxanthines may not be confined to the airways, for they also strengthen the contractions of isolated skeletal muscle in vitro and improve contractility and reverse fatigue of the diaphragm in patients with COPD. This effect on diaphragmatic performance—rather than an effect on the respiratory center—may account for theophylline's ability to improve the ventilatory response to hypoxia and to diminish dyspnea even in patients with irreversible airflow obstruction.

Clinical Use of Methylxanthines

Of the xanthines, theophylline is the most effective bronchodilator, and it has been shown repeatedly both to relieve airflow obstruction in acute asthma and to reduce the severity of symptoms and time lost from work or school in patients with chronic asthma. Theophylline base is only slightly soluble in water, so it has been administered as several salts containing varying amounts of theophylline base. Most preparations are well absorbed from the gastrointestinal tract, but absorption of rectal suppositories is unreliable.

Improvements in theophylline preparations have come from alterations in the physical state of the drugs rather than from new chemical formulations. For example, the increased surface area of anhydrous theophylline in a microcrystalline form facilitates solubilization for complete and rapid absorption after oral administration. Numerous sustained-release preparations (see Preparations Available) are available and can produce therapeutic blood levels for 12 hours or more. These preparations offer the advantages of less frequent drug administration, less fluctuation of theophylline blood levels, and, in many cases, more effective treatment of nocturnal bronchospasm.

Theophylline should be used only where methods to measure theophylline blood levels are available because it has a narrow therapeutic window, and its therapeutic and toxic effects are related to its blood level. Improvement in pulmonary function is correlated with plasma concentration in the range of 5–20 mg/L. Anorexia, nausea, vomiting, abdominal discomfort, headache, and anxiety occur at concentrations of 15 mg/L in some patients and become common at concentrations greater than 20 mg/L. Higher levels (> 40 mg/L) may cause seizures or arrhythmias; these may not be preceded by gastrointestinal or neurologic warning symptoms.

The plasma clearance of theophylline varies widely. Theophylline is metabolized by the liver, so usual doses may lead to toxic concentrations of the drug in patients with liver disease. Conversely, clearance may be increased through the induction of hepatic enzymes by cigarette smoking or by changes in diet. In normal adults, the mean plasma clearance is 0.69 mL/kg/min. Children clear theophylline faster than adults (1–1.5 mL/kg/min). Neonates and young infants have the slowest clearance (see Chapter 60). Even when maintenance doses are altered to correct for the above factors, plasma concentrations vary widely.

Theophylline improves long-term control of asthma when taken as the sole maintenance treatment or when added to inhaled corticosteroids. It is inexpensive, and it can be taken orally. Its use, however, also requires occasional measurement of plasma levels; it often causes unpleasant minor side effects (especially insomnia); and accidental or intentional overdose can result in severe toxicity or death. For oral therapy with the prompt-release formulation, the usual dose is 3–4 mg/kg of theophylline every 6 hours. Changes in dosage result in a new steady-state concentration of theophylline in 1–2 days, so the dosage may be increased at intervals of 2–3 days until therapeutic plasma concentrations are achieved (10–20 mg/L) or until adverse effects develop.

ANTIMUSCARINIC AGENTS

Observation of the use of leaves from *Datura stramonium* for asthma treatment in India led to the discovery of atropine, a potent competitive inhibitor of acetylcholine at postganglionic "muscarinic" receptors, as a bronchodilator. Interest in the potential value of antimuscarinic agents increased with demonstration of the importance of the vagus nerves in bronchospastic responses of laboratory animals and by the development of a potent atropine analog that is poorly absorbed after aerosol administration and that is therefore relatively free of systemic atropine-like effects.

Mechanism of Action

Muscarinic antagonists competitively inhibit the effect of acetylcholine at muscarinic receptors (see Chapter 8). In the airways, acetylcholine is released from efferent endings of the vagus nerves, and muscarinic antagonists block the contraction of airway smooth muscle and the increase in secretion of mucus that occurs in response to vagal activity (Figure 20–2). Very high concentrations—well above those achieved even with maximal therapy—are required to inhibit the response of airway smooth muscle to nonmuscarinic stimulation. This selectivity of muscarinic antagonists accounts for their usefulness as investigative tools in examining the role of parasympathetic pathways in bronchomotor responses but limits their usefulness in preventing bronchospasm. In the doses given, antimuscarinic agents inhibit only that portion of the response mediated by muscarinic receptors, which varies by stimulus, and which further appears to vary among individuals in responses to the same stimulus.

Clinical Use of Muscarinic Antagonists

Antimuscarinic agents are effective bronchodilators. When given intravenously, atropine, the prototypical muscarinic antagonist, causes bronchodilation at a lower dose than that needed to cause an increase in heart rate. The selectivity of atropine's effect can be increased further by administering the drug by inhalation or by use of a more selective quaternary ammonium derivative of atropine, ipratropium bromide. Ipratropium can be delivered in high doses by this route because it is poorly absorbed into the circulation and does not readily enter the central nervous system. Studies with this agent have shown that the degree of involvement of parasympathetic pathways in bronchomotor responses varies among subjects. In some, bronchoconstriction is inhibited effectively; in others, only modestly. The failure of higher doses of the muscarinic antagonist to further inhibit the response in these individuals indicates that mechanisms other than parasympathetic reflex pathways must be involved.

Even in the subjects least protected by this antimuscarinic agent, however, the bronchodilation and partial inhibition of provoked bronchoconstriction are of potential clinical value, and antimuscarinic agents are valuable for patients intolerant of inhaled β-agonist agents. Although antimuscarinic drugs appear to be slightly less effective than β-agonist agents in reversing asthmatic bronchospasm, the addition of ipratropium enhances the bronchodilation produced by nebulized albuterol in acute severe asthma.

Ipratropium appears to be at least as effective in patients with COPD that includes a partially reversible component. A longer-acting, selective antimuscarinic agent, tiotropium, is approved as a treatment for COPD. This drug is also taken by inhalation, and a single dose of 18 mcg has 24-hour duration of action. Daily inhalation of tiotropium has been shown not only to improve functional capacity of patients with COPD, but also to reduce the frequency of exacerbations of their condition.

CORTICOSTEROIDS

Mechanism of Action

Corticosteroids have been used to treat asthma since 1950 and are presumed to act by their broad anti-inflammatory efficacy, mediated in part by inhibition of production of inflammatory cytokines (see Chapter 39). They do not relax airway smooth muscle directly but reduce bronchial reactivity and reduce the frequency of asthma exacerbations if taken regularly. Their effect on airway obstruction may be due in part to their contraction of engorged vessels in the bronchial mucosa and their potentiation of the effects of β-receptor agonists, but their most important action is inhibition of the lymphocytic, eosinophilic mucosal inflammation of asthmatic airways.

Clinical Use of Corticosteroids

Clinical studies of corticosteroids consistently show them to be effective in improving all indices of asthma control—severity of symptoms, tests of airway caliber and bronchial reactivity, frequency of exacerbations, and quality of life. Because of severe adverse effects when given chronically, oral and parenteral corticosteroids are reserved for patients who require urgent treatment, ie, those who have not improved adequately with bronchodilators or who experience worsening symptoms despite maintenance therapy. Regular or "controller" therapy is maintained with aerosol corticosteroids.

Urgent treatment is often begun with an oral dose of 30–60 mg prednisone per day or an intravenous dose of 1 mg/kg methylprednisolone every 6 hours; the daily dose is decreased after airway obstruction has improved. In most patients, systemic corticosteroid therapy can be discontinued in a week or 10 days, but in other patients symptoms may worsen as the dose is decreased to lower levels. Because adrenal suppression by corticosteroids is related to dose and because secretion of endogenous corticosteroids has a diurnal variation, it is customary to administer corticosteroids early in the morning after endogenous ACTH secretion has peaked. For prevention of nocturnal asthma, however, oral or inhaled corticosteroids are most effective when given in the late afternoon.

Aerosol treatment is the most effective way to avoid the systemic adverse effects of corticosteroid therapy. The introduction of corticosteroids such as beclomethasone, budesonide, flunisolide, fluticasone, mometasone, and triamcinolone has made it possible to deliver corticosteroids to the airways with minimal systemic absorption. An average daily dose of four puffs twice daily of beclomethasone (400 mcg/d) is equivalent to about 10–15 mg/d of oral prednisone for the control of asthma, with far fewer systemic effects. Indeed, one of the cautions in switching patients from oral to inhaled corticosteroid therapy is to taper oral therapy slowly to avoid precipitation of adrenal insufficiency. In patients requiring continued prednisone treatment despite inhalation of standard doses of an aerosol corticosteroid, higher doses appear to be more effective; inhaled dosages up to 2000 mcg/d of fluticasone are effective in weaning patients from chronic prednisone therapy. Although these high doses of inhaled steroids may cause adrenal suppression, the risks of systemic toxicity from chronic use appear negligible compared with those of the oral corticosteroid therapy they replace.

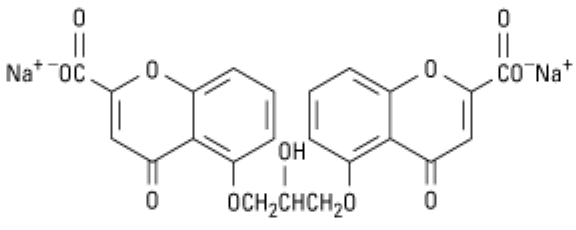
A special problem caused by inhaled topical corticosteroids is the occurrence of oropharyngeal candidiasis. The risk of this complication can be reduced by having patients gargle water and spit after each inhaled treatment. Hoarseness can also result from a direct local effect of inhaled corticosteroids on the vocal cords. These agents are remarkably free of other short-term complications in adults but may increase the risks of osteoporosis and cataracts over the long term. In children, inhaled corticosteroid therapy has been shown to slow the rate of growth, but this effect appears to be transient: Asthma itself delays puberty, and there is no evidence that inhaled corticosteroid therapy in childhood influences adult height.

A novel approach to minimizing the risk of toxicity from systemic absorption of an inhaled corticosteroid underlay the development of ciclesonide. This investigational corticosteroid is inhaled as a prodrug activated by cleavage by esterases in bronchial epithelial cells. When absorbed into the circulation, the active product is tightly bound to serum proteins, and so has little access to glucocorticoid receptors in skin, eye, and bone, minimizing its risk of causing cutaneous thinning, cataracts, osteoporosis, or temporary slowing of growth.

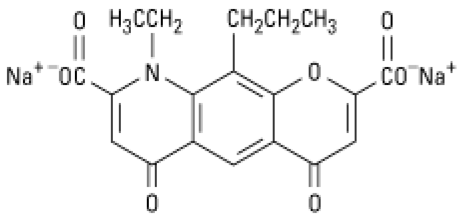
Chronic use of inhaled corticosteroids effectively reduces symptoms and improves pulmonary function in patients with mild asthma. Such use also reduces or eliminates the need for oral corticosteroids in patients with more severe disease. In contrast to β-stimulant agents and theophylline, chronic use of inhaled corticosteroids reduces bronchial reactivity. Because of the efficacy and safety of inhaled corticosteroids, they are now routinely prescribed for patients who require more than occasional inhalations of a β agonist for relief of symptoms. This therapy is continued for 10–12 weeks and then withdrawn to determine whether more prolonged therapy is needed. Inhaled corticosteroids are not curative. In most patients, the manifestations of asthma return within a few weeks after stopping therapy even if they have been taken in high doses for 2 years or longer.

CROMOLYN & NEDOCROMIL

Cromolyn sodium (disodium cromoglycate) and nedocromil sodium are stable but extremely insoluble salts (see structures below). When used as aerosols (by nebulizer or metered-dose inhaler), they effectively inhibit both antigen- and exercise-induced asthma, and chronic use (four times daily) slightly reduces the overall level of bronchial reactivity. However, these drugs have no effect on airway smooth muscle tone and are ineffective in reversing asthmatic bronchospasm; they are only of value when taken prophylactically.



Cromolyn sodium



Nedocromil sodium

Cromolyn is poorly absorbed from the gastrointestinal tract and must be inhaled as a microfine powder or aerosolized solution. Nedocromil also has a very low bioavailability and is available only in metered-dose aerosol form.

Mechanism of Action

Cromolyn and nedocromil differ structurally but are thought to share a common mechanism of action: an alteration in the function of delayed chloride channels in the cell membrane, inhibiting cell activation. This action on airway nerves is thought to be responsible for nedocromil's inhibition of cough; on mast cells, for inhibition of the early response to antigen challenge; and on eosinophils, for inhibition of the inflammatory response to inhalation of allergens. The inhibitory effect on mast cells appears to be specific for cell type, since cromolyn has little inhibitory effect on mediator release from human basophils. It may also be specific for different organs, since cromolyn inhibits mast cell degranulation in human and primate lung but not in skin. This in turn may reflect known differences in mast cells found in different sites, as in their neutral protease content.

Until recently, the idea that cromolyn inhibits mast cell degranulation was so well accepted that the inhibition of a response by cromolyn was thought to indicate the involvement of mast cells in the response. This simplistic idea has been overturned in part by the finding that cromolyn and nedocromil inhibit the function of cells other than mast cells and in part by the finding that nedocromil inhibits appearance of the late response even when given after the early response to antigen challenge, ie, after mast cell degranulation has occurred.

Clinical Use of Cromolyn & Nedocromil

In short-term clinical trials, pretreatment with cromolyn or nedocromil blocks the bronchoconstriction caused by allergen inhalation, by exercise, by sulfur dioxide, and by a variety of causes of occupational asthma. This acute protective effect of a single treatment makes cromolyn useful for administration shortly before exercise or before unavoidable exposure to an allergen.

When taken regularly (two to four puffs two to four times daily) by patients with perennial (nonseasonal) asthma, both agents modestly but significantly reduce symptomatic severity and the need for bronchodilator medications. These drugs are neither as potent nor as predictably effective as inhaled corticosteroids. In general, young patients with extrinsic asthma are most likely to respond favorably. At present, the only way of determining whether a patient will respond is by a therapeutic trial for 4 weeks. The addition of nedocromil to a standard dose of an inhaled corticosteroid appears to improve asthma control.

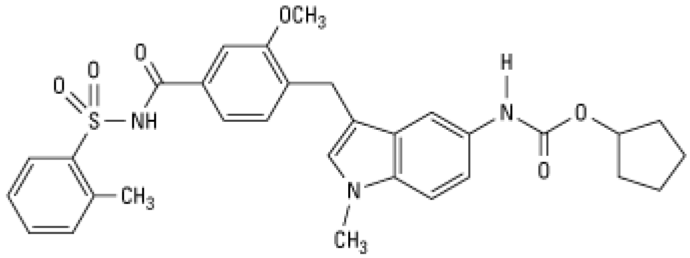
Cromolyn solution is also useful in reducing symptoms of allergic rhinoconjunctivitis. Applying the solution by nasal spray or eye drops several times a day is effective in about 75% of patients, even during the peak pollen season.

Because the drugs are so poorly absorbed, adverse effects of cromolyn and nedocromil are minor and are localized to the sites of deposition. These include such minor symptoms as throat irritation, cough, and mouth dryness, and, rarely, chest tightness, and wheezing. Some of these symptoms can be prevented by inhaling a β_2 -adrenoceptor agonist before cromolyn or nedocromil treatment. Serious adverse effects are rare. Reversible dermatitis, myositis, or gastroenteritis occurs in less than 2% of patients, and a very few cases of pulmonary infiltration with eosinophilia and anaphylaxis have been reported. This lack of toxicity accounts for cromolyn's widespread use in children, especially those at ages of rapid growth. For children who have difficulty coordinating the use of the inhaler device, cromolyn may be given by aerosol of a 1% solution.

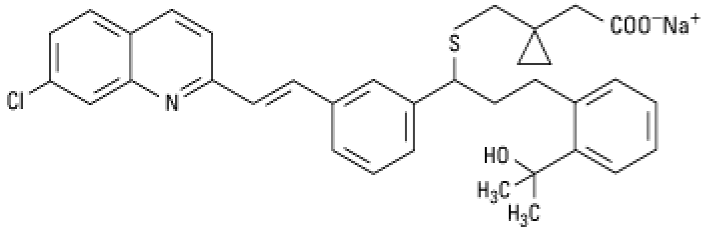
LEUKOTRIENE PATHWAY INHIBITORS

Because of the evidence of leukotriene involvement in many inflammatory diseases (see Chapter 18) and in anaphylaxis, considerable effort has been expended on the development of drugs that block the synthesis of these arachidonic acid derivatives or their receptors. Leukotrienes result from the action of 5-lipoxygenase on arachidonic acid and are synthesized by a variety of inflammatory cells in the airways, including eosinophils, mast cells, macrophages, and basophils. Leukotriene B_4 (LTB_4) is a potent neutrophil chemoattractant, and LTC_4 and LTD_4 exert many effects known to occur in asthma, including bronchoconstriction, increased bronchial reactivity, mucosal edema, and mucus hypersecretion. Early studies established that antigen challenge of sensitized human lung tissue results in the generation of leukotrienes, whereas other studies of human subjects have shown that inhalation of leukotrienes causes not only bronchoconstriction but also an increase in bronchial reactivity to histamine that persists for several days.

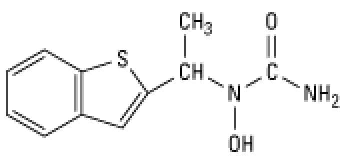
Two approaches to interrupting the leukotriene pathway have been pursued: inhibition of 5-lipoxygenase, thereby preventing leukotriene synthesis; and inhibition of the binding of LTD_4 to its receptor on target tissues, thereby preventing its action. Efficacy in blocking airway responses to exercise and to antigen challenge has been shown for drugs in both categories: zileuton, a 5-lipoxygenase inhibitor, and zafirlukast and montelukast, LTD_4 -receptor antagonists. All have been shown to improve asthma control and to reduce the frequency of asthma exacerbations in outpatient clinical trials. Their effects on symptoms, airway caliber, bronchial reactivity, and airway inflammation are less marked than the effects of inhaled corticosteroids, but they are more nearly equal in reducing the frequency of exacerbations. Their principal advantage is that they are taken orally; some patients—especially children—comply poorly with inhaled therapies. Montelukast is approved for children as young as 6 years of age.



Zafirlukast



Montelukast



Zileuton

Some patients appear to have particularly favorable responses, but no clinical features allow identification of "responders" before a trial of therapy. In the USA, zileuton is approved for use in an oral dosage of 400–800 mg for administration 2–4 times daily; zafirlukast, 20 mg twice daily; and montelukast, 10 mg (for adults) or 4 mg (for children) once daily.

Trials with leukotriene inhibitors have demonstrated an important role for leukotrienes in aspirin-induced asthma. It has long been known that 5–10% of asthmatics are exquisitely sensitive to aspirin, so that ingestion of even a very small dose causes profound bronchoconstriction and symptoms of systemic release of histamine, such as flushing and abdominal cramping. Because this reaction to aspirin is not associated with any evidence of allergic sensitization to aspirin or its metabolites and because it is produced by any of the nonsteroidal anti-inflammatory agents, it is thought to result from inhibition of prostaglandin synthetase (cyclooxygenase), shifting arachidonic acid metabolism from the prostaglandin to the leukotriene pathway. Support for this idea was provided by the demonstration that leukotriene pathway inhibitors impressively reduce the response to aspirin challenge and improve overall control of asthma on a day-to-day basis.

Of these agents, zileuton is the least prescribed because of the former requirement of four-times-daily dosing (a formulation for twice-daily use has recently been developed) and because of occasional liver toxicity. The receptor antagonists appear to be safe to use. Reports of Churg-Strauss syndrome (a systemic vasculitis accompanied by worsening asthma, pulmonary infiltrates, and eosinophilia) appear to have been coincidental, with the syndrome unmasked by the reduction in prednisone dosage made possible by the addition of zafirlukast or montelukast.

OTHER DRUGS IN THE TREATMENT OF ASTHMA

Anti-IgE Monoclonal Antibodies

An entirely new approach to the treatment of asthma exploits advances in molecular biology to target IgE antibody. From a collection of monoclonal antibodies raised in mice against IgE antibody itself, a monoclonal antibody was selected that appeared to be targeted against the portion of IgE that binds to its receptors (FCe-R1 and FCe-R2 receptors) on mast cells and other inflammatory cells. Omalizumab (an anti-IgE monoclonal antibody) inhibits the binding of IgE to mast cells but does not activate IgE already bound to these cells and thus does not provoke mast cell degranulation. It may also inhibit IgE synthesis by B lymphocytes. The murine antibody has been genetically humanized by replacing all but a small fraction of its amino acids with those found in human proteins, and it does not appear to cause sensitization when given to human subjects.

Studies of omalizumab in asthmatic volunteers showed that its administration over 10 weeks lowered plasma IgE to undetectable levels and significantly reduced the magnitude of both the early and the late bronchospastic responses to antigen challenge. Clinical trials have shown that repeated intravenous or subcutaneous injection of anti-IgE MAb lessens asthma severity and reduces the corticosteroid requirement in patients with moderate to severe disease, especially those with a clear environmental antigen precipitating factor, and improves nasal and conjunctival symptoms in patients with perennial or seasonal allergic rhinitis. Omalizumab's most important effect is reduction of the frequency and severity of asthma exacerbations, even while enabling a reduction in corticosteroid requirements. Combined analysis of several clinical trials has shown that the patients most likely to respond are, fortunately, those with the greatest need, ie, patients with a history of repeated exacerbations, a high requirement for corticosteroid treatment, and poor pulmonary function. Similarly, the exacerbations most prevented are the ones most important to prevent: Omalizumab treatment reduced exacerbations requiring hospitalization by 88%. These benefits justify the high cost of this treatment in selected individuals with severe disease characterized by frequent exacerbations.

Possible Future Therapies

The rapid advance in the scientific description of the immunopathogenesis of asthma has spurred the development of many new therapies targeting different sites in the immune cascade. These include monoclonal antibodies directed against cytokines (IL-4, IL-5, IL-13), antagonists of cell adhesion molecules, protease inhibitors, and immunomodulators aimed at shifting CD4 lymphocytes from the T_H2 to the T_H1 phenotype or at selective inhibition of the subset of T_H2 lymphocytes directed against particular antigens. There is evidence that asthma may be aggravated—or even caused—by chronic airway infection with *Chlamydia pneumoniae* or *Mycoplasma pneumoniae.* This may explain the reports of benefit from treatment with macrolide antibiotics and, if confirmed, would stimulate the development of new diagnostic methods and antimicrobial therapies.

CLINICAL PHARMACOLOGY OF DRUGS USED IN THE TREATMENT OF ASTHMA

Asthma is best thought of as a disease in two time domains. In the present domain, it is important for the distress it causes—cough, nocturnal awakenings, and shortness of breath that interferes with the ability to exercise or to pursue desired activities. For mild asthma, occasional inhalation of a bronchodilator may be all that is needed. For more severe asthma, treatment with a long-term controller, like an inhaled corticosteroid, is necessary to relieve symptoms and restore function. The second domain of asthma is the risk it presents of future events, such as exacerbations, or of progressive loss of pulmonary function. A patient's satisfaction with his or her ability to control symptoms and maintain function by frequent use of an inhaled β_2 agonist does not mean that the risk of future events is also controlled. In fact, use of two or more canisters of an inhaled βagonist per month is a marker of increased risk of asthma fatality.

The challenges of assessing severity and adjusting therapy for these two domains of asthma are different. For relief of distress in the present domain, the key information can be obtained by asking specific questions about the frequency and severity of symptoms, the frequency of use of an inhaled β_2 agonist for relief of symptoms, the frequency of nocturnal awakenings, and the ability to exercise. Estimating the risk for future exacerbations is more difficult. In general, patients with poorly controlled symptoms in the present have a heightened risk of exacerbations in the future, but some patients seem unaware of the severity of their underlying airflow obstruction (sometimes described as "poor perceivers") and can be identified only by measurement of pulmonary function, as by spirometry. Reductions in the FEV_1 correlate with heightened risk of attacks of asthma in the future. Other possible markers of heightened risk are unstable pulmonary function (large variations in FEV_1 from visit to visit, large change with bronchodilator treatment), extreme bronchial reactivity, or high numbers of eosinophils in sputum or of nitric oxide in exhaled air. Assessment of these features may identify patients who need increases in therapy for protection against exacerbations.

BRONCHODILATORS

Bronchodilators, such as inhaled albuterol, are rapidly effective, safe, and inexpensive. Patients with only occasional symptoms of asthma require no more than an inhaled β_2 -receptor agonist taken on an as-needed basis. If symptoms require this "rescue" therapy more than twice a week, if nocturnal symptoms occur more than twice a month, or if the FEV_1 is less than 80% predicted, additional treatment is needed. The treatment first recommended is a low dose of an inhaled corticosteroid, although treatment with a leukotriene receptor antagonist or with cromolyn may be used. Theophylline is now largely reserved for patients in whom symptoms remain poorly controlled despite the combination of regular treatment with an inhaled anti-inflammatory agent and as-needed use of a β_2 agonist. If the addition of theophylline fails to improve symptoms or if adverse effects become bothersome, it is important to check the plasma level of theophylline to be sure it is in the therapeutic range (10–20 mg/L).

An important caveat for patients with mild asthma is that although the risk of a severe, life-threatening attack is lower than in patients with severe asthma, it is not zero. All patients with asthma should be instructed in a simple action plan for severe, frightening attacks: to take up to four puffs of albuterol every 20 minutes over 1 hour. If they do not note clear improvement after the first four puffs, they should take the additional treatments while on their way to an Emergency Department or some other higher level of care.

MUSCARINIC ANTAGONISTS

Inhaled muscarinic antagonists have so far earned a limited place in the treatment of asthma. When adequate doses are given, their effect on baseline airway resistance is nearly as great as that of the sympathomimetic drugs. The airway effects of antimuscarinic and sympathomimetic drugs given in full doses have been shown to be additive only in patients with severe airflow obstruction who present for emergency care. Antimuscarinic agents appear to be of greater value in COPD—perhaps more so than in asthma. They are also useful as alternative therapies for patients intolerant of β_2 -adrenoceptor agonists.

Although it was predicted that muscarinic antagonists would dry airway secretions and interfere with mucociliary clearance, direct measurements of fluid volume secretion from single airway submucosal glands in animals show that atropine decreases baseline secretory rates only slightly. The drugs do, however, inhibit the increase in mucus secretion caused by vagal stimulation. No cases of inspissation of mucus have been reported following administration of these drugs.

CORTICOSTEROIDS

If asthmatic symptoms occur frequently or if significant airflow obstruction persists despite bronchodilator therapy, inhaled corticosteroids should be started. For patients with severe symptoms or severe airflow obstruction (eg, FEV_1 < 50% predicted), initial treatment with a combination of inhaled and oral corticosteroid (eg, 30 mg/d of prednisone for 3 weeks) treatment is appropriate. Once clinical improvement is noted, usually after 7–10 days, the oral dose should be discontinued or reduced to the minimum necessary to control symptoms.

An issue for inhaled corticosteroid treatment is patient compliance. Analysis of prescription renewals shows that corticosteroids are taken regularly by a minority of patients. This may be a function of a general "steroid phobia" fostered by emphasis in the lay press over the hazards of long-term oral corticosteroid therapy and by ignorance over the difference between corticosteroids and anabolic steroids, taken to enhance muscle strength by now-infamous athletes. This fear of corticosteroid toxicity makes it hard to persuade patients whose symptoms have improved after starting the treatment that they should continue it for protection against attacks. This context accounts for the interest in a recent report that instructing patients with mild but persistent asthma to initiate inhaled corticosteroid therapy only when their symptoms worsened was as effective in maintaining pulmonary function and preventing attacks as taking it twice each day.

In patients with more severe asthma, whose symptoms are inadequately controlled by a standard dose of an inhaled corticosteroid, two options may be considered: to double the dose of inhaled corticosteroid or to add a *long-acting* inhaled β_2 -receptor agonist (salmeterol or formoterol). Many studies have shown this combination therapy to be more effective than doubling the dose of the inhaled corticosteroid, but the FDA has issued a warning that the use of a long-acting βagonist is associated with a very small but statistically significant increase in the risk of death or near death from an asthma attack, especially in African Americans. This warning has not so far had much effect on prescriptions for a fixed-dose combination of inhaled fluticasone (a corticosteroid) and salmeterol (a long-acting βagonist), probably because their combination in a single inhaler offers several advantages. Combination inhalers are convenient; they ensure that the long-acting βagonist will not be taken as monotherapy (known not to protect against attacks); and they produce prompt, sustained improvements in clinical symptoms and pulmonary function and reduce the frequency of exacerbations requiring oral corticosteroid treatment. In patients prescribed such combination treatment, it is important to provide explicit instructions that a standard, short-acting inhaled β_2 agonist, such as albuterol, be used as needed for relief of acute symptoms.

CROMOLYN & NEDOCROMIL; LEUKOTRIENE ANTAGONISTS

Cromolyn or nedocromil by inhalation, or a leukotriene-receptor antagonist as an oral tablet, may be considered as alternatives to inhaled corticosteroid treatment in patients with symptoms occurring more than twice a week or who are wakened from sleep by asthma more than twice a month. Neither treatment is as effective as even a low dose of an inhaled corticosteroid, but both prevent the issue of "steroid phobia" described above.

Cromolyn and nedocromil may also be useful in patients whose symptoms occur seasonally or after clear-cut inciting stimuli such as exercise or exposure to animal danders or irritants. In patients whose symptoms are continuous or occur without an obvious inciting stimulus, the value of these drugs can be established only with a therapeutic trial of inhaled drug four times a day for 4 weeks. If the patient responds to this therapy, the dose can then be optimized.

Treatment with a leukotriene-receptor antagonist, particularly montelukast, is widely prescribed, especially by primary care providers. Taken orally, leukotriene-receptor antagonists are easy to use and appear to be taken more regularly than inhaled corticosteroids. They are rarely associated with troublesome side effects. Maintenance therapy with a leukotriene antagonist or with cromolyn or nedocromil appears to be roughly as effective as maintenance therapy with theophylline. Because of concerns over the possible long-term toxicity of systemic absorption of inhaled corticosteroids, this maintenance therapy has become widely used for treating children in the USA.

ANTI-IGE MONOCLONAL ANTIBODY

Treatment with omalizumab, the monoclonal humanized anti-IgE antibody, is reserved for patients with chronic severe asthma inadequately controlled by high-dose inhaled corticosteroid plus long-acting β-agonist combination treatment (eg, fluticasone 500 mcg plus salmeterol 50 mcg inhaled twice daily). This treatment reduces lymphocytic, eosinophilic bronchial inflammation and effectively reduces the frequency and severity of exacerbations. It is reserved for patients with demonstrated IgE-mediated sensitivity (by positive skin test or radioallergosorbent test [RAST] to common allergens) and an IgE level within a range that can be reduced sufficiently by twice weekly subcutaneous injection.

OTHER ANTI-INFLAMMATORY THERAPIES

Some reports suggest that agents commonly used to treat rheumatoid arthritis may also be used to treat patients with chronic steroid-dependent asthma. The development of an alternative treatment is important, because chronic treatment with oral corticosteroids may cause osteoporosis, cataracts, glucose intolerance, worsening of hypertension, and cushingoid changes in appearance. Initial studies suggested that oral methotrexate or gold salt injections were beneficial in prednisone-dependent asthmatics, but subsequent studies did not confirm this promise. In contrast, the benefit from treatment with cyclosporine seems real. However, this drug's great toxicity makes this finding only a source of hope that other immunomodulatory therapies will ultimately be developed for the small proportion of patients whose asthma can be managed only with high oral doses of prednisone. An immunomodulatory therapy recently reported to improve asthma is injection of etanercept, a TNF-α antagonist used for treatment of ankylosing spondylitis and severe rheumatoid arthritis.

MANAGEMENT OF ACUTE ASTHMA

The treatment of acute attacks of asthma in patients reporting to the hospital requires close, continuous clinical assessment and repeated objective measurement of lung function. For patients with mild attacks, inhalation of a β_2 -receptor agonist is as effective as subcutaneous injection of epinephrine. Both of these treatments are more effective than intravenous administration of aminophylline (a soluble salt of theophylline). Severe attacks require treatment with oxygen, frequent or continuous administration of aerosolized albuterol, and systemic treatment with prednisone or methylprednisolone (0.5 mg/kg every 6 hours). Even this aggressive treatment is not invariably effective, and patients must be watched closely for signs of deterioration. General anesthesia, intubation, and mechanical ventilation of asthmatic patients cannot be undertaken lightly but may be lifesaving if respiratory failure supervenes.

PROSPECTS FOR PREVENTION

The high prevalence of asthma in the developed world and its rapid increases in the developing world call for a strategy for primary prevention. Strict antigen avoidance during infancy, once thought to be sensible, has now been shown to be ineffective. In fact, growing up in a household where cats and dogs are kept as pets may *protect* against developing asthma. The best hope seems to lie in understanding the importance of microbial exposures during infancy in shaping a balanced immune response, and one study showing that feeding *Lactobacillus caseii* to infants born to allergic parents reduced the rate of allergic dermatitis at age 2 years offers reason for hope.

PREPARATIONS AVAILABLE

SYMPATHOMIMETICS USED IN ASTHMA

Albuterol (generic, Proventil, Ventolin)

Inhalant: 90 mcg/puff aerosol; 0.083, 0.5, 0.63% solution for nebulization

Oral: 2, 4 mg tablets; 2 mg/5 mL syrup

Oral sustained-release: 4, 8 mg tablets

Albuterol/Ipratropium (Combivent, DuoNeb)

Inhalant: 103 mcg albuterol + 18 mcg ipratropium/puff; 3 mg albuterol + 0.5 mg ipratropium/3 mL solution for nebulization

Bitolterol (Tornalate)

Inhalant: 0.2% solution for nebulization

Ephedrine (generic)

Oral: 25 mg capsules

Parenteral: 50 mg/mL for injection

Epinephrine (generic, Adrenalin)

Inhalant: 1, 10 mg/mL for nebulization; 0.22 mg/spray epinephrine base aerosol

Parenteral: 1:10,000 (0.1 mg/mL), 1:1000 (1 mg/mL)

Formoterol (Foradil)

Inhalant: 12 mcg/unit inhalant powder

Isoetharine (generic)

Inhalant: 1% solution for nebulization

Isoproterenol (generic, Isuprel)

Inhalant: 0.5, 1% for nebulization; 80, 131 mcg/puff aerosols

Parenteral: 0.02, 0.2 mg/mL for injection

Levalbuterol (Xenopex)

Inhalant: 0.31, 0.63, 1.25 mg/3 mL solution

Metaproterenol (Alupent, generic)

Inhalant: 0.65 mg/puff aerosol in 7, 14 g containers; 0.4, 0.6, 5% for nebulization

Pirbuterol (Maxair)

Inhalant: 0.2 mg/puff aerosol in 80 and 300 dose containers

Salmeterol (Serevent)

Inhalant aerosol: 25 mcg salmeterol base/puff in 60 and 120 dose containers

Inhalant powder: 50 mcg/unit

Salmeterol/Fluticasone (Advair Diskus)

Inhalant: 100, 250, 500 mcg fluticasone + 50 mcg salmeterol/unit

Terbutaline (generic, Brethine)

Oral: 2.5, 5 mg tablets

Parenteral: 1 mg/mL for injection

AEROSOL CORTICOSTEROIDS

(See also Chapter 39.)

Beclomethasone (QVAR)

Aerosol: 40, 80 mcg/puff in 100 dose containers

Budesonide (Pulmicort)

Aerosol powder (Turbuhaler): 160 mcg/activation

Inhalation suspension (Respules): 0.25, 0.5 mg/2 mL

Flunisolide (AeroBid, Aerospan)

Aerosol: 80, 250 mcg/puff in 80, 100, and 120 dose containers

Fluticasone (Flovent)

Aerosol: 44, 110, and 220 mcg/puff in 120 dose container; powder, 50, 100, 250 mcg/activation

Fluticasone/Salmeterol (Advair Diskus)

Inhalant: 100, 250, 500 mcg fluticasone + 50 mcg salmeterol/unit

Mometasone (Asmanex Twisthaler)

Inhalant: 220 mcg/actuation in 14, 30, 60, 120 dose units

Triamcinolone (Azmacort)

Aerosol: 100 mcg/puff in 240 dose container

LEUKOTRIENE INHIBITORS

Montelukast (Singulair)

Oral: 10 mg tablets; 4, 5 mg chewable tablets; 4 mg/packet granules

Zafirlukast (Accolate)

Oral: 10, 20 mg tablets

Zileuton (Zyflo)

Oral: 600 mg tablets

CROMOLYN SODIUM & NEDOCROMIL SODIUM

Cromolyn sodium

Pulmonary aerosol (generic, Intal): 800 mcg/puff in 200 dose container; 20 mg/2 mL for nebulization (for asthma)

Nasal aerosol (Nasalcrom): 5.2 mg/puff (for hay fever)

Oral (Gastrocrom): 100 mg/5 mL concentrate (for gastrointestinal allergy)

Nedocromil sodium (Tilade)

Pulmonary aerosol: 1.75 mg/puff in 104 metered-dose container

METHYLXANTHINES: THEOPHYLLINE & DERIVATIVES

Aminophylline (theophylline ethylenediamine, 79% theophylline) (generic)

Oral: 105 mg/5 mL liquid; 100, 200 mg tablets

Rectal: 250, 500 mg suppositories

Parenteral: 250 mg/10 mL for injection

Theophylline (generic, Elixophyllin, Slo-Phyllin, Uniphyl, Theo-Dur, Theo-24, others)

Oral: 100, 125, 200, 250, 300 mg tablets; 100, 200 mg capsules; 26.7, 50 mg/5 mL elixirs, syrups, and solutions

Oral sustained-release, 8–12 hours: 50, 60, 75, 100, 125, 200, 250, 300 mg capsules

Oral sustained-release, 8–24 hours: 100, 200, 300, 450 mg tablets

Oral timed-release, 12 hours: 125, 130, 250, 260, 300 mg capsules

Oral timed-release, 12–24 hours: 100, 200, 300 tablets

Oral timed-release, 24 hours: 100, 200, 300 mg tablets and capsules; 400, 600 mg tablets

Parenteral: 200, 400, 800 mg/container, theophylline and 5% dextrose for injection

OTHER METHYLXANTHINES

Dyphylline (generic)

Oral: 200, 400 mg tablets; 33.3 mg/5 mL elixir

Oxtriphylline (generic, Choledyl)

Oral: equivalent to 64, 127, 254, 382 mg theophylline tablets; 32, 64 mg/5 mL syrup

Pentoxifylline (generic, Trental)

Oral: 400 mg tablets and controlled-release tablets

Note: Pentoxifylline is labeled for use in intermittent claudication only.

ANTIMUSCARINIC DRUGS USED IN ASTHMA

Ipratropium (generic, Atrovent)

Aerosol: 17 (freon-free), 18 mcg/puff in 200 metered-dose inhaler; 0.02% (500 mcg/vial) for nebulization

Nasal spray: 21, 42 mcg/spray

Tiotropium (Spiriva)

Aerosol: 18 mcg/puff in 6 packs

ANTIBODY

Omalizumab (Xolair)

Powder for SC injection, 202.5 mg

INTRODUCTION TO THE PHARMACOLOGY OF CNS DRUGS: INTRODUCTION

Drugs acting in the central nervous system (CNS) were among the first to be discovered by primitive humans a are still the most widely used group of pharmacologic agents. In addition to their use in therapy, many drugs acting on the CNS are used without prescription to increase one's sense of well-being.

The mechanisms by which various drugs act in the CNS have not always been clearly understood. In the last three decades, however, dramatic advances have been made in the methodology of CNS pharmacology. It is n possible to study the action of a drug on individual cells and even single ion channels within synapses. The information obtained from such studies is the basis for several major developments in studies of the CNS.

First, it is clear that nearly all drugs with CNS effects act on specific receptors that modulate synaptic transmission. A very few agents such as general anesthetics and alcohol may have nonspecific actions on membranes (although these exceptions are not fully accepted), but even these nonreceptor-mediated actions result in demonstrable alterations in synaptic transmission.

Second, drugs are among the most important tools for studying all aspects of CNS physiology, from the mechanism of convulsions to the laying down of long-term memory. As described below, agonists that mimic natural transmitters (and in many cases are more selective than the endogenous substances) and antagonists extremely useful in such studies. Natural Toxins: Tools for Characterizing Ion Channels, describes a few of thes substances.

Third, unraveling the actions of drugs with known clinical efficacy has led to some of the most fruitful hypothese regarding the mechanisms of disease. For example, information on the action of antipsychotic drugs on dopami receptors has provided the basis for important hypotheses regarding the pathophysiology of schizophrenia. Studies of the effects of a variety of agonists and antagonists on γ-aminobutyric acid (GABA) receptors has resulted in new concepts pertaining to the pathophysiology of several diseases, including anxiety and epilepsy.

This chapter provides an introduction to the functional organization of the CNS and its synaptic transmitters as basis for understanding the actions of the drugs described in the following chapters.

Natural Toxins: Tools for Characterizing Ion Channels

Evolution is tireless in the development of natural toxins. A vast number of variations are possible with even a small number of amino acids in peptides, and peptides make up only one of a broad array of toxic compounds. For example, the predatory marine snail genus *Conus* is estimated to include at least 500 different species. Eac species kills or paralyzes its prey with a venom that contains 50–200 different peptides or proteins. Furthermor there is little duplication of peptides among *Conus* species. Other animals with useful toxins include snakes, fro spiders, bees, wasps, and scorpions. Plant species with toxic (or therapeutic) substances are too numerous to mention here; they are referred to in many chapters of this book.

Since many toxins act on ion channels, they provide a wealth of chemical tools for studying the function of thes channels. In fact, much of our current understanding of the properties of ion channels comes from studies utilizing only a small percentage of the highly potent and selective toxins that are now available. The toxins typically target voltage-sensitive ion channels, but a number of very useful toxins block ionotropic neurotransmitter receptors. Table 21–1 lists some of the toxins most commonly used in research, their mode o action, and their source.

Table 21–1. Some Toxins Used to Characterize Ion Channels.

Channel Types	Mode of Toxin Action	Source
Voltage-gated		
Sodium channels		
Tetrodotoxin (TTX)	Blocks channel from outside	Puffer fish
Batrachotoxin (BTX)	Slows inactivation, shifts activation	Colombian frog
Potassium channels		
Apamin	Blocks "small Ca-activated" K channel	Honeybee
Charybdotoxin	Blocks "big Ca-activated" K channel	Scorpion
Calcium channels		
Omega conotoxin (ω-CTX-GVIA)	Blocks N-type channel	Pacific cone snail
Agatoxin (ω-AGA-IVA)	Blocks P-type channel	

Funnel web spider

Ligand-gated

Nicotinic ACh receptor

α-Bungarotoxin

Irreversible antagonist

Marine snake

$GABA_A$ receptor

Picrotoxin

Blocks channel

South Pacific plant

Glycine receptor

Strychnine

Competitive antagonist

Indian plant

AMPA receptor

Philanthotoxin

Blocks channel

Wasp

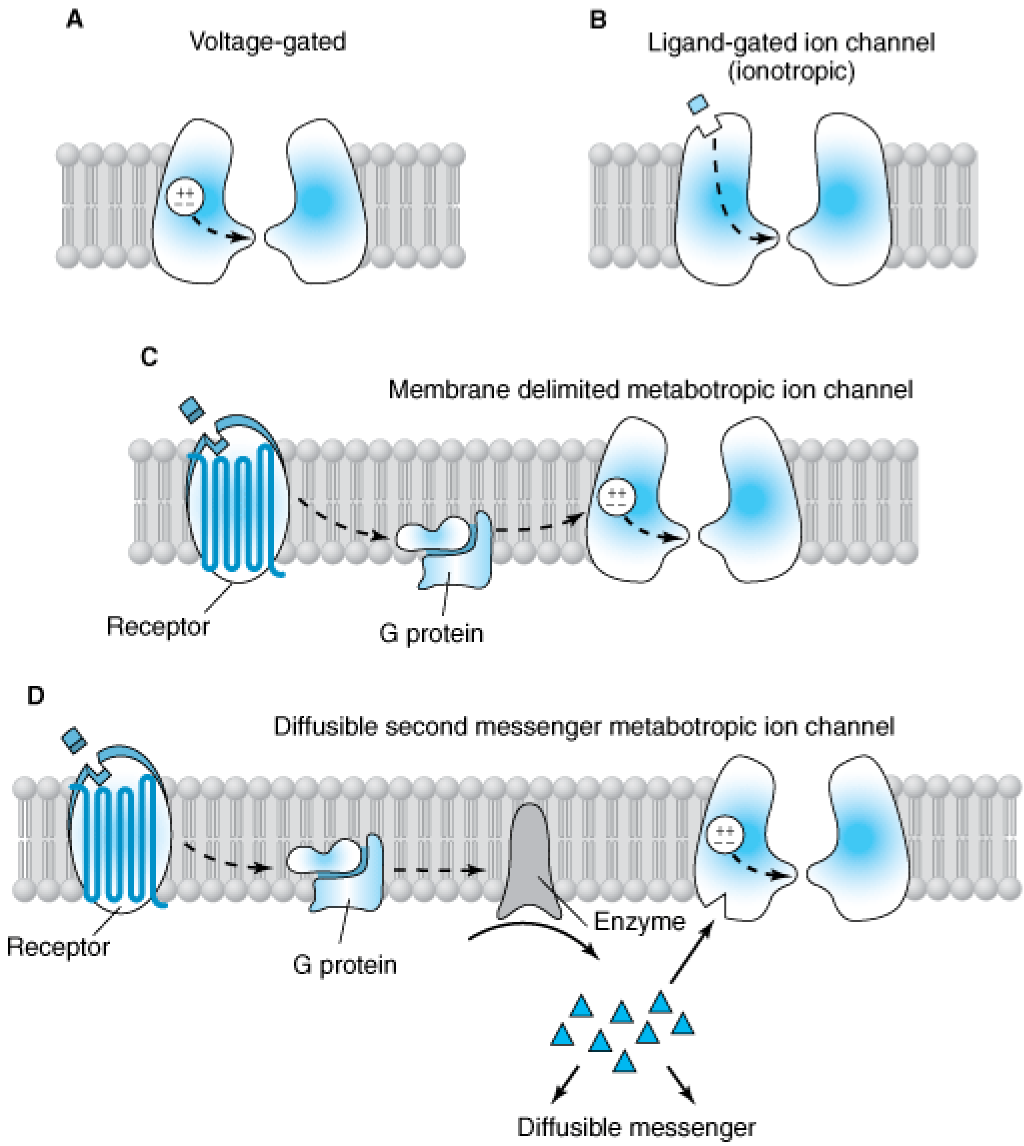
Methods for the Study of CNS Pharmacology

Like many areas of science, major progress in the study of CNS drugs has depended on the development of ne experimental techniques. The first detailed description of synaptic transmission was made possible by the invention of glass microelectrodes, which permit intracellular recording. The development of the brain slice technique permitted an analysis of the physiology and pharmacology of synapses. Detailed electrophysiologic studies of the action of drugs on both voltage- and transmitter-operated channels were further facilitated by th introduction of the patch clamp technique, which permits the recording of current through single channels. Histochemical, immunologic, and radioisotopic methods have made it possible to map the distribution of specifi transmitters, their associated enzyme systems, and their receptors. Molecular cloning has had a major impact our understanding of CNS receptors. These techniques make it possible to determine the precise molecular structure of the receptors and their associated channels. Finally, mice with mutated genes for specific receptor or enzymes (knockout mice) can provide important information regarding the physiologic and pharmacologic ro of these components.

ION CHANNELS & NEUROTRANSMITTER RECEPTORS

The membranes of nerve cells contain two types of channels defined on the basis of the mechanisms controllin their gating (opening and closing): voltage-gated and ligand-gated channels (Figure 21–1A and B). Voltage-gated channels respond to changes in the membrane potential of the cell. The voltage-gated sodium channel described in Chapter 14 for the heart is an example of the first type of channel. In nerve cells, these channels a concentrated on the initial segment and the axon and are responsible for the fast action potential, which transmits the signal from cell body to nerve terminal. There are many types of voltage-sensitive calcium and potassium channels on the cell body, dendrites, and initial segment, which act on a much slower time scale an modulate the rate at which the neuron discharges. For example, some types of potassium channels opened by depolarization of the cell result in slowing of further depolarization and act as a brake to limit further action potential discharge.

Figure 21–1.



Types of ion channels and neurotransmitter receptors in the CNS. A shows a voltage-gated channel in which a voltage senso component of the protein controls the gating (broken arrow) of the channel. B shows a ligand-gated channel in which the binding of the neurotransmitter to the ionotropic channel receptor controls the gating (broken arrow) of the channel. C show a G protein-coupled (metabotropic) receptor, which when bound, activates a G protein that then interacts directly with an io channel. D shows a G protein-coupled receptor, which when bound, activates a G protein that then activates an enzyme. Th activated enzyme generates a diffusible second messenger, eg, cAMP, which interacts with an ion channel.

Ligand-gated channels, also called ionotropic receptors, are opened by the binding of neurotransmitters to th channel. The receptor is formed of subunits, and the channel is an integral part of the receptor complex (see Figures 22–6 and 27–1). These channels are insensitive or only weakly sensitive to membrane potential. Activation of these channels typically results in a brief (a few milliseconds to tens of milliseconds) opening of th channel. Ligand-gated channels are responsible for fast synaptic transmission typical of hierarchical pathways i the CNS (see below).

It is now well established that the traditional view of completely separate voltage-gated and ligand-gated channels requires substantial modifications. As discussed in Chapter 2, most neurotransmitters, in addition to binding to ionotropic receptors, also bind to G protein-coupled receptors, often referred to as **metabotropic receptors**. Metabotropic receptors, via G proteins, modulate voltage-gated channels. This interaction can occu entirely within the membrane and is then referred to as a **membrane delimited** pathway (Figure 21–1C). In tl case, the G protein (often the $\beta\gamma$ subunit) interacts directly with the voltage-gated ion channel. In general, two types of voltage-gated ion channels are the targets of this type of signaling: calcium channels and potassium channels. When G proteins interact with calcium channels, they inhibit channel function. This mechanism accou for the presynaptic inhibition that occurs when presynaptic metabotropic receptors are activated. In contrast, when these receptors are postsynaptic, they activate (cause the opening of) potassium channels, resulting in a slow postsynaptic inhibition. Metabotropic receptors can also modulate voltage-gated channels less directly by generation of **diffusible second messengers** (Figure 21–1D). A classic example of this type of action is provided by the β adrenoceptor, which generates cAMP via the activation of adenylyl cyclase (see Chapter 2). Whereas membrane-delimited actions occur within microdomains in the membrane, second messenger-mediat effects can occur over considerable distances. Finally, an important consequence of the involvement of G protei in receptor signaling is that, in contrast to the brief effect of ionotropic receptors, the effects of metabotropic receptor activation can last tens of seconds to minutes. Metabotropic receptors predominate in the diffuse neuronal systems in the CNS (see below).

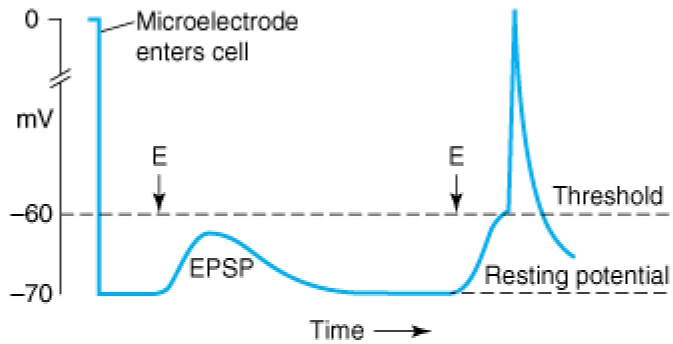
THE SYNAPSE & SYNAPTIC POTENTIALS

The communication between neurons in the CNS occurs through chemical synapses in the vast majority of case (A few instances of electrical coupling between neurons have been documented, and such coupling may play a role in synchronizing neuronal discharge. However, it is unlikely that these electrical synapses are an important site of drug action.) The events involved in synaptic transmission can be summarized as follows.

An action potential in the presynaptic fiber propagates into the synaptic terminal and activates voltage-sensitive calcium channels in the membrane of the terminal (see Figure 6–3). The calcium channels responsible for the release of transmitter are generally resistant to the calcium channel-blocking agents discussed in Chapter 12 (verapamil, etc) but are sensitive to blockade by certain marine toxins and metal ions (see Tables 12–4 and 21–1). Calcium flows into the terminal, and the increase in intraterminal calcium concentration promotes the fusion of synaptic vesicles with the presynaptic membrane. The transmitter contained in the vesicles is released into the synaptic cleft and diffuses to the receptors on the postsynaptic membrane. Binding of the transmitter t its receptor causes a brief change in membrane conductance (permeability to ions) of the postsynaptic cell. The time delay from the arrival of the presynaptic action potential to the onset of the postsynaptic response is approximately 0.5 ms. Most of this delay is consumed by the release process, particularly the time required for calcium channels to open.

The first systematic analysis of synaptic potentials in the CNS was in the early 1950s by Eccles and associates, who recorded intracellularly from spinal motoneurons. When a microelectrode enters a cell, there is a sudden change in the potential recorded by the electrode, which is typically about -70 mV (Figure 21–2). This is the resting membrane potential of the neuron. Two types of pathways—excitatory and inhibitory—impinge on the motoneuron.

Figure 21–2.

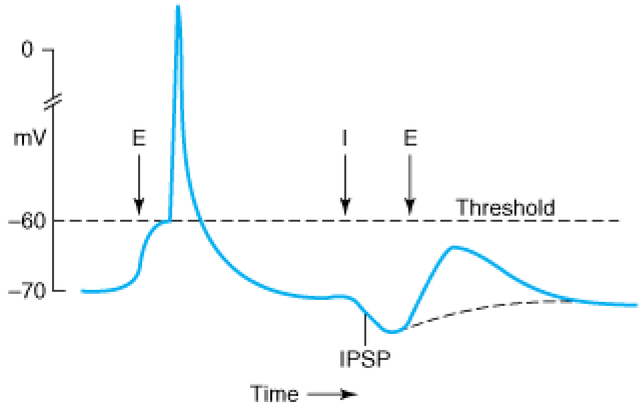


Excitatory synaptic potentials and spike generation. The figure shows entry of a microelectrode into a postsynaptic cell and subsequent recording of a resting membrane potential of -70 mV. Stimulation of an excitatory pathway (E) generates transie depolarization. Increasing the stimulus strength (second E) increases the size of the depolarization, so that the threshold for spike generation is reached.

When an excitatory pathway is stimulated, a small depolarization or excitatory postsynaptic potential (EPS is recorded. This potential is due to the excitatory transmitter acting on an ionotropic receptor, causing an increase in sodium and potassium permeability. Changing the stimulus intensity to the pathway and, therefore, the number of presynaptic fibers activated, results in a graded change in the size of the depolarization. When a sufficient number of excitatory fibers are activated, the EPSP depolarizes the postsynaptic cell to threshold, and an all-or-none action potential is generated.

When an inhibitory pathway is stimulated, the postsynaptic membrane is hyperpolarized owing to the selective opening of Cl^- channels, producing an inhibitory postsynaptic potential (IPSP) (Figure 21–3). However, because the equilibrium potential for Cl^- is only slightly more negative than the resting potential (~ –65 mV), tl hyperpolarization is small and contributes only modestly to the inhibitory action. The opening of the Cl^- channel during the IPSP makes the neuron "leaky" so that changes in membrane potential are more difficult to achieve. This shunting effect decreases the change in membrane potential during the excitatory postsynaptic potential (EPSP). As a result an EPSP that evoked an action potential under resting conditions fails to evoke an action potential during the IPSP (Figure 21–3). A second type of inhibition is termed presynaptic inhibition. It was first described for sensory fibers entering the spinal cord, where excitatory synaptic terminals receive synapses called axoaxonic synapses (described later). When activated, axoaxonic synapses reduce the amount of transmitter released from the terminals of sensory fibers. It is interesting that presynaptic inhibitory receptors present on virtually all presynaptic terminals in the brain even though axoaxonic synapses appear to be restrict to the spinal cord. In the brain, transmitter spills over to neighboring synapses to activate the presynaptic receptors.

Figure 21–3.

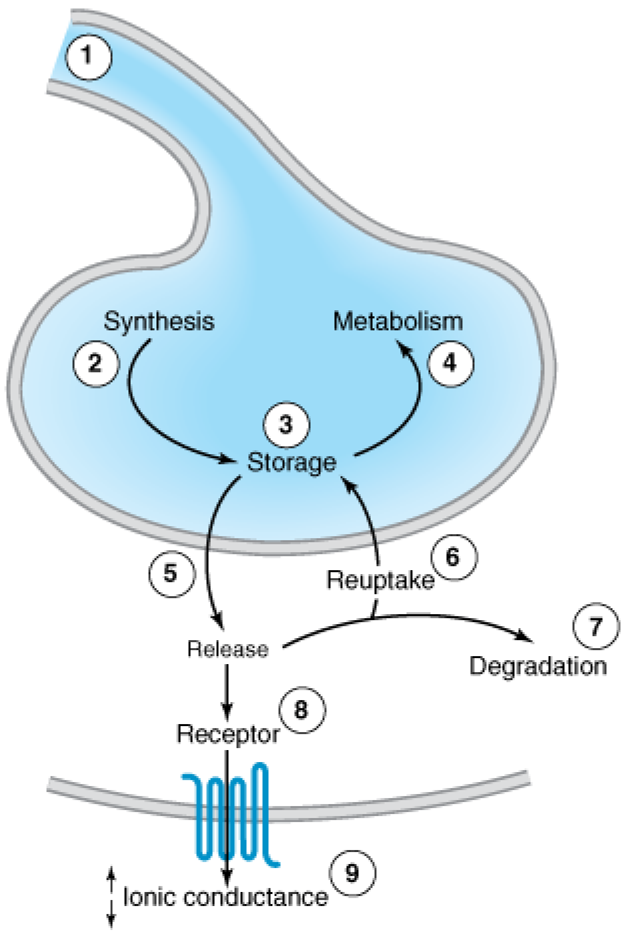


Interaction of excitatory and inhibitory synapses. On the left, a suprathreshold stimulus is given to an excitatory pathway (E and an action potential is evoked. On the right, this same stimulus is given shortly after activating an inhibitory pathway (I), which results in an inhibitory postsynaptic potential (IPSP) that prevents the excitatory potential from reaching threshold.

SITES OF DRUG ACTION

Virtually all of the drugs that act in the CNS produce their effects by modifying some step in chemical synaptic transmission. Figure 21–4 illustrates some of the steps that can be altered. These transmitter-dependent actior can be divided into presynaptic and postsynaptic categories.

Figure 21–4.



Sites of drug action. Schematic drawing of steps at which drugs can alter synaptic transmission. (1) Action potential in presynaptic fiber; (2) synthesis of transmitter; (3) storage; (4) metabolism; (5) release; (6) reuptake; (7) degradation; (8) receptor for the transmitter; (9) receptor-induced increase or decrease in ionic conductance.

Drugs acting on the synthesis, storage, metabolism, and release of neurotransmitters fall into the presynaptic category. Synaptic transmission can be depressed by blockade of transmitter synthesis or storage. For example reserpine depletes monoamine synapses of transmitter by interfering with intracellular storage. Blockade of transmitter catabolism inside the nerve terminal can increase transmitter concentrations and has been reported to increase the amount of transmitter released per impulse. Drugs can also alter the release of transmitter. The stimulant amphetamine induces the release of catecholamines from adrenergic synapses (Chapters 6 and 32). Capsaicin causes the release of the peptide substance P from sensory neurons, and tetanus toxin blocks the release of transmitters. After a transmitter has been released into the synaptic cleft, its action is terminated either by uptake or by degradation. For most neurotransmitters, there are uptake mechanisms into the synapti terminal and also into surrounding neuroglia. Cocaine, for example, blocks the uptake of catecholamines at adrenergic synapses and thus potentiates the action of these amines. However, acetylcholine is inactivated by enzymatic degradation, not reuptake. Anticholinesterases block the degradation of acetylcholine and thereby prolong its action. No uptake mechanism has been found for any of the numerous CNS peptides, and it has yet be demonstrated whether specific enzymatic degradation terminates the action of peptide transmitters.

In the postsynaptic region, the transmitter receptor provides the primary site of drug action. Drugs can act eith as neurotransmitter agonists, such as the opioids, which mimic the action of enkephalin, or they can block receptor function. Receptor antagonism is a common mechanism of action for CNS drugs. An example is strychnine's blockade of the receptor for the inhibitory transmitter glycine. This block, which underlies strychnine's convulsant action, illustrates how the blockade of inhibitory processes results in excitation. Drugs c also act directly on the ion channel of ionotropic receptors. For example, barbiturates can enter and block the channel of many excitatory ionotropic receptors. In the case of metabotropic receptors, drugs can act at any of the steps downstream of the receptor. Perhaps the best example is provided by the methylxanthines, which ca modify neurotransmitter responses mediated through the second-messenger cAMP. At high concentrations, the methylxanthines elevate the level of cAMP by blocking its metabolism and thereby prolong its action.

The selectivity of CNS drug action is based almost entirely on the fact that different transmitters are used by different groups of neurons. Furthermore, these transmitters are often segregated into neuronal systems that subserve broadly different CNS functions. Without such segregation, it would be impossible to selectively modif CNS function even if one had a drug that operated on a single neurotransmitter system. That such segregation does occur has provided neuroscientists with a powerful pharmacologic approach for analyzing CNS function an treating pathologic conditions.

IDENTIFICATION OF CENTRAL NEUROTRANSMITTERS

Because drug selectivity is based on the fact that different pathways utilize different transmitters, a primary go of neuropharmacologists is to identify the transmitters in CNS pathways. Establishing that a chemical substance a transmitter has been far more difficult for central synapses than for peripheral synapses. The following criteri have been established for transmitter identification.

Localization

Approaches that have been used to prove that a suspected transmitter resides in the presynaptic terminal of th pathway under study include biochemical analysis of regional concentrations of suspected transmitters and immunocytochemical techniques for enzymes and peptides.

Release

To determine whether the substance is released from a particular region, local collection (in vivo) of the extracellular fluid can sometimes be accomplished. In addition, slices of brain tissue can be electrically or chemically stimulated in vitro and the released substances measured. To determine whether the release is relevant to synaptic transmission, it is important to establish that the release is calcium-dependent.

Synaptic Mimicry

Finally, application of the suspected substance should produce a response that mimics the action of the transmitter released by nerve stimulation. Furthermore, application of a selective antagonist should block the response. Microiontophoresis, which permits highly localized drug administration, has been a valuable techniqu in assessing the action of suspected transmitters. Because of the complexity of the CNS, specific pharmacologic antagonism of a synaptic response provides a particularly powerful technique for transmitter identification.

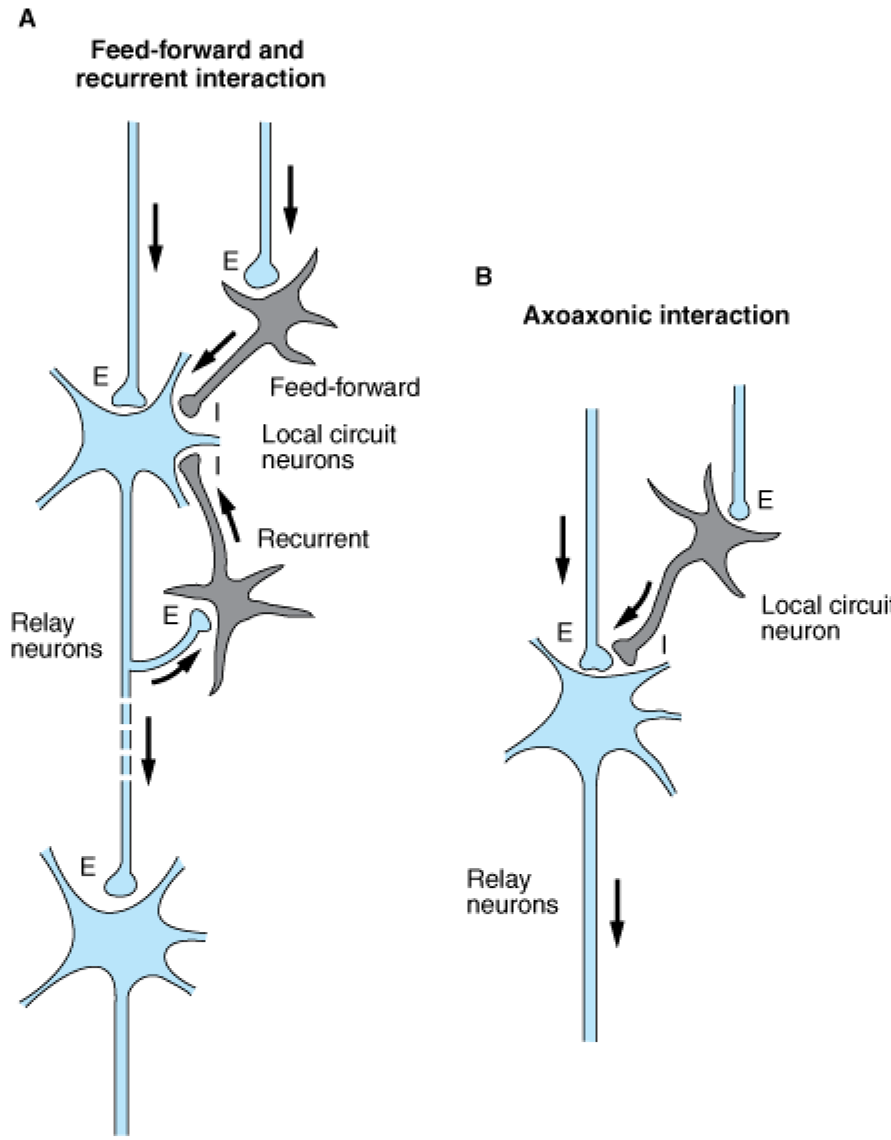
CELLULAR ORGANIZATION OF THE BRAIN

Most of the neuronal systems in the CNS can be divided into two broad categories: *hierarchical* systems and nonspecific or diffuse neuronal systems.

Hierarchical Systems

Hierarchical systems include all the pathways directly involved in sensory perception and motor control. The pathways are generally clearly delineated, being composed of large myelinated fibers that can often conduct action potentials at a rate in excess of 50 m/s. The information is typically phasic and occurs in bursts of action potentials. In sensory systems, the information is processed sequentially by successive integrations at each rela nucleus on its way to the cortex. A lesion at any link will incapacitate the system. Within each nucleus and in th cortex, there are two types of cells: relay or projection neurons and local circuit neurons (Figure 21–5A). The projection neurons that form the interconnecting pathways transmit signals over long distances. The cell bodies are relatively large, and their axons emit collaterals that arborize extensively in the vicinity of the neuro These neurons are excitatory, and their synaptic influences, which involve ionotropic receptors, are very short-lived. The excitatory transmitter released from these cells is, in most instances, glutamate. Local circuit neuro are typically smaller than projection neurons, and their axons arborize in the immediate vicinity of the cell body The majority of these neurons are inhibitory, and they release either GABA or glycine. They synapse primarily on the cell body of the projection neurons but can also synapse on the dendrites of projection neurons as well a with each other. Two common types of pathways for these neurons (Figure 21–5A) include recurrent feedback pathways and feed-forward pathways. A special class of local circuit neurons in the spinal cord forms axoaxonic synapses on the terminals of sensory axons (Figure 21–5B). In some sensory pathways such as the retina and olfactory bulb, local circuit neurons may actually lack an axon and release neurotransmitter from dendritic synapses in a graded fashion in the absence of action potentials.

Figure 21–5.



Pathways in the central nervous system. A shows parts of three relay neurons (color) and two types of inhibitory pathways, recurrent and feed-forward. The inhibitory neurons are shown in gray. B shows the pathway responsible for presynaptic inhibition in which the axon of an inhibitory neuron (gray) synapses on the axon terminal of an excitatory fiber (color).

Although there is a great variety of synaptic connections in these hierarchical systems, the fact that a limited number of transmitters are utilized by these neurons indicates that any major pharmacologic manipulation of th system will have a profound effect on the overall excitability of the CNS. For instance, selectively blocking GABA receptors with a drug such as picrotoxin results in generalized convulsions. Thus, although the mechanism of action of picrotoxin is specific in blocking the effects of GABA, the overall functional effect appears to be quite nonspecific, because GABA-mediated synaptic inhibition is so widely utilized in the brain.

Nonspecific or Diffuse Neuronal Systems

Neuronal systems that contain one of the monoamines—norepinephrine, dopamine, or 5-hydroxytryptamine (serotonin)—provide examples in this category. Certain other pathways emanating from the reticular formation and possibly some peptide-containing pathways also fall into this category. These systems differ in fundamenta ways from the hierarchical systems, and the noradrenergic systems serve to illustrate the differences.

Noradrenergic cell bodies are found primarily in a compact cell group called the locus ceruleus located in the caudal pontine central gray matter. The number of neurons in this cell group is small, approximately 1500 on each side of the brain in the rat.

Because these axons are fine and unmyelinated, they conduct very slowly, at about 0.5 m/s. The axons branch repeatedly and are extraordinarily divergent. Branches from the same neuron can innervate several functionall different parts of the CNS. In the neocortex, these fibers have a tangential organization and therefore can monosynaptically influence large areas of cortex. The pattern of innervation by noradrenergic fibers in the corte and nuclei of the hierarchical systems is diffuse, and these fibers form a very small percentage of the total number in the area. In addition, the axons are studded with periodic enlargements called varicosities, which contain large numbers of vesicles. In some instances, these varicosities do not form synaptic contacts, suggest that norepinephrine may be released in a rather diffuse manner, as occurs with the noradrenergic autonomic innervation of smooth muscle. This indicates that the cellular targets of these systems are determined largely b the location of the receptors rather than by the location of the release sites. Finally, most neurotransmitters utilized by diffuse neuronal systems, including norepinephrine, act—perhaps exclusively—on metabotropic receptors and therefore initiate long-lasting synaptic effects. Based on these observations, it is clear that the monoamine systems cannot be conveying topographically specific types of information; rather, vast areas of th CNS must be affected simultaneously and in a rather uniform way. It is not surprising, then, that these systems have been implicated in such global functions as sleeping and waking, attention, appetite, and emotional states

CENTRAL NEUROTRANSMITTERS

A vast number of small molecules have been isolated from the brain, and studies using a variety of approaches suggest that the agents listed in Table 21–2 are neurotransmitters. A brief summary of the evidence for some o these compounds follows.

Table 21–2. Summary of Neurotransmitter Pharmacology in the Central Nervous System. (Many Other Central Transmitters Have Been Identified [See Text].)

Transmitter	Anatomy	Receptor Subtypes and Preferred Agonists	Receptor Antagonists	Mechanisms
Acetylcholine	Cell bodies at all levels; long and short connections	Muscarinic (M_1): muscarine	Pirenzepine, atropine	Excitatory: ↓ in K^+ conductance; ↑ IP_3, DAG

Muscarinic (M_2): muscarine, bethanechol

Atropine, methoctramine

Inhibitory: ↑K^+ conductance; ↓cAMP

Motoneuron-Renshaw cell synapse

Nicotinic: nicotine

Dihydro-β-erythroidine, α-bungarotoxin

Excitatory: ↑cation conductance

Dopamine

Cell bodies at all levels; short, medium, and long connections

D_1

Phenothiazines

Inhibitory (?): ↑cAMP

D_2 : bromocriptine

Phenothiazines, butyrophenones

Inhibitory (presynaptic): ↓Ca^{2+} ; Inhibitory (postsynaptic): ↑in K^+ conductance, ↓cAMP

GABA

Supraspinal and spinal interneurons involved in pre- and postsynaptic inhibition

$GABA_A$: muscimol

Bicuculline, picrotoxin

Inhibitory: ↑Cl^- conductance

$GABA_B$: baclofen

2-OH saclofen

Inhibitory (presynaptic): ↓Ca^{2+} conductance

Inhibitory (postsynaptic): ↑K^+ conductance

Glutamate

Relay neurons at all levels and some interneurons

N -Methyl- D -aspartate (NMDA): NMDA

2-Amino-5-phosphonovalerate, dizocilpine

Excitatory: $\uparrow$cation conductance, particularly Ca^{2+}

AMPA: AMPA

CNQX

Excitatory: $\uparrow$cation conductance

Kainate: kainic acid, domoic acid

Metabotropic: ACPD, quisqualate

MCPG

Inhibitory (presynaptic): $\downarrow Ca^{2+}$ conductance; $\downarrow$cAMP

Excitatory: $\downarrow K^+$ conductance, $\uparrow IP_3$, DAG

Glycine

Spinal interneurons and some brain stem interneurons

Taurine, β-alanine

Strychnine

Inhibitory: $\uparrow Cl^-$ conductance

5-Hydroxytryptamine (serotonin)

Cell bodies in midbrain and pons project to all levels

$5\text{-}HT_{1A}$: LSD

Metergoline, spiperone

Inhibitory: $\uparrow K^+$ conductance, $\downarrow$cAMP

$5\text{-}HT_{2A}$: LSD

Ketanserin

Excitatory: $\downarrow K^+$ conductance, IP_3 , DAG

$5\text{-}HT_3$: 2-methyl-5-HT

Ondansetron

Excitatory: $\uparrow$cation conductance

$5\text{-}HT_4$

Excitatory: ↓K^+ conductance

Norepinephrine

Cell bodies in pons and brain stem project to all levels

α_1 : phenylephrine

Prazosin

Excitatory: ↓K^+ conductance, ↑IP_3 , DAG

α_2 : clonidine

Yohimbine

Inhibitory (presynaptic): ↓Ca^{2+} conductance

Inhibitory: ↑K^+ conductance, ↓cAMP

β_1 : isoproterenol, dobutamine

Atenolol, practolol

Excitatory: ↓K^+ conductance, ↑cAMP

β_2 : albuterol

Butoxamine

Inhibitory: may involve ↑in electrogenic sodium pump; ↑cAMP

Histamine

Cells in ventral posterior hypothalamus

H_1 : 2(*m* -fluorophenyl)-histamine

Mepyramine

Excitatory: ↓K^+ conductance, ↑IP_3 , DAG

H_2 : dimaprit

Ranitidine

Excitatory: ↓K^+ conductance, ↑cAMP

H_3 : *R* -α-methyl-histamine

Thioperamide

Inhibitory autoreceptors

Opioid peptides

Cell bodies at all levels; long and short connections

Mu: bendorphin

Naloxone

Inhibitory (presynaptic): ↓Ca^{2+} conductance, ↓cAMP

Delta: enkephalin

Naloxone

Inhibitory (postsynaptic): ↑K^+ conductance, ↓cAMP

Kappa: dynorphin

Naloxone

Tachykinins

Primary sensory neurons, cell bodies at all levels; long and short connections

NK1: Substance P methylester

Excitatory: ↓K^+ conductance, ↑IP_3 , DAG

NK2

NK3

Endocannabinoids

Widely distributed

CB1: Anandamide, 2-arachidonylglyerol

Rimonabant

Inhibitory (presynaptic): ↓Ca^{2+} conductance, ↓cAMP

ACPD, *trans* -1-amino-cyclopentyl-1,3-dicarboxylate; AMPA, DL -α-amino-3-hydroxy-5-methylisoxazole-4-propionate; cAMP, cyclic adenosine monophosphate; CQNX, 6-cyano-7-nitroquinoxaline-2,3-dione; DAG, diacylglycerol; IP_3 , inositol trisphosphate; LSD, lysergic acid diethylamide; MCPG, α-methyl-4-carboxyphenylglycine.

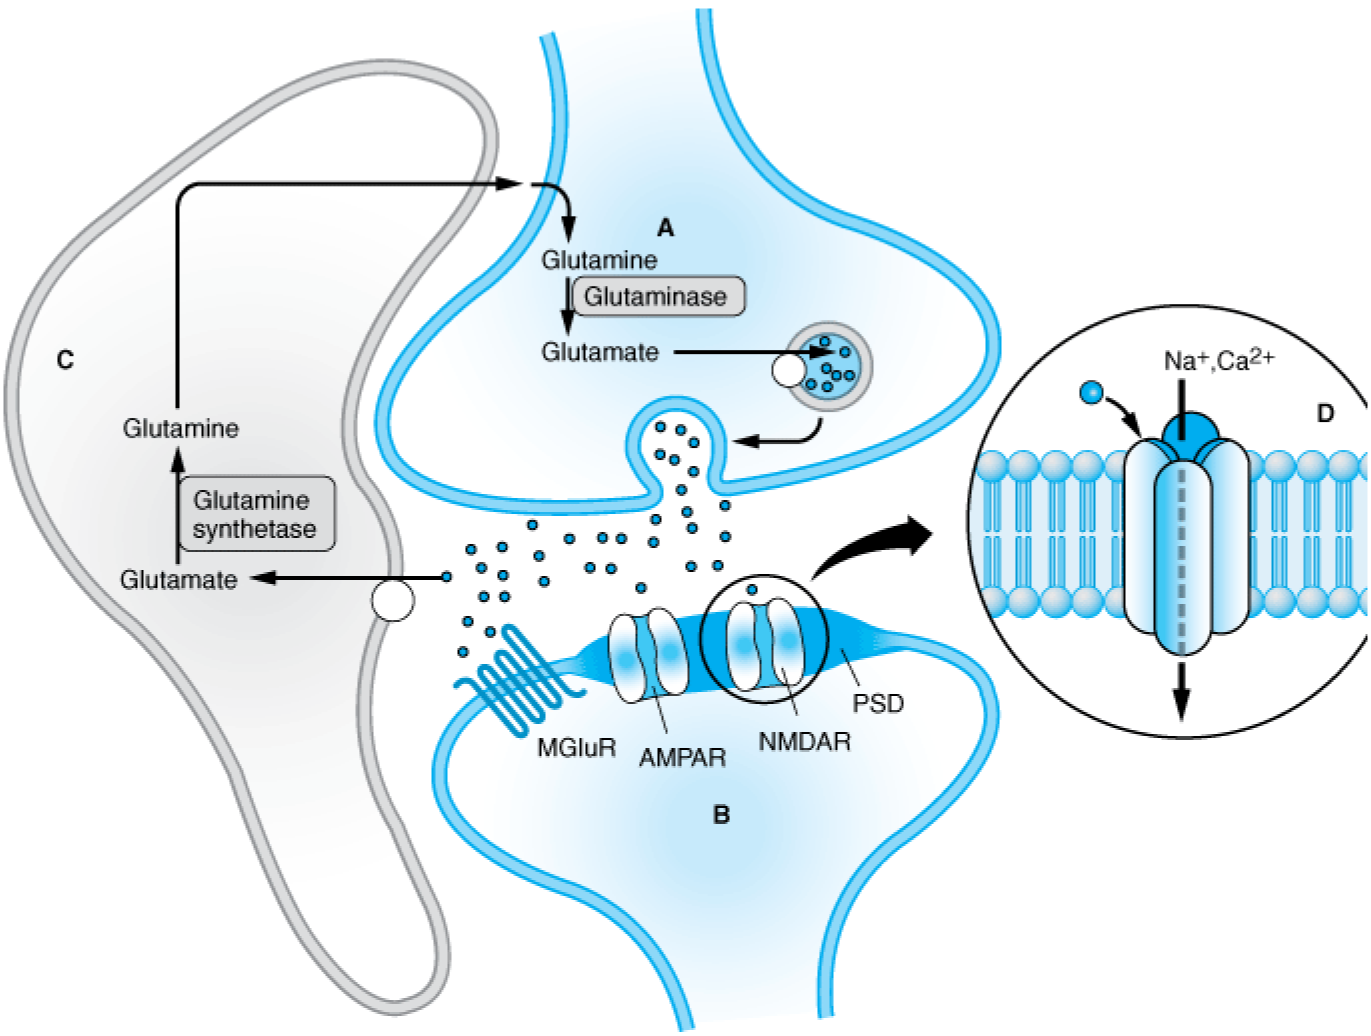
Amino Acids

The amino acids of primary interest to the pharmacologist fall into two categories: the acidic amino acid glutamate and the neutral amino acids glycine and GABA. All of these compounds are present in high concentrations in the CNS and are extremely potent modifiers of neuronal excitability.

GLUTAMATE

Excitatory synaptic transmission is mediated by glutamate, which is present in very high concentrations in excitatory synaptic vesicles (~ 100 mM). Glutamate is released into the synaptic cleft by Ca^{2+} -dependent exocytosis (Figure 21–6). The released glutamate acts on postsynaptic glutamate receptors and is cleared by glutamate transporters present on surrounding glia. In glia, glutamate is converted to glutamine by glutamine synthetase, released from the glia, taken up by the nerve terminal, and converted back to glutamate by the enzyme glutaminase. The high concentration of glutamate in synaptic vesicles is achieved by the vesicular glutamate transporter (VGLUT).

Figure 21–6.



Schematic diagram of a glutamate synapse. Glutamine is imported into the glutamatergic neuron (A) and converted into glutamate by glutaminase. The glutamate is then concentrated in vesicles by the vesicular glutamate transporter (VGLUT). Upon release into the synapse, glutamate can interact with AMPA and NMDA ionotropic receptor channels (AMPAR, NMDAR) the postsynaptic density (PSD) and with metabotropic receptors (MGluR) on the postsynaptic cell (B) . Synaptic transmissio terminated by active transport of the glutamate into a neighboring glial cell (C) by a glutamate transporter. It is synthesized into glutamine by glutamine synthetase and exported into the glutamatergic axon. (D) shows a model NMDA receptor chann complex consisting of a tetrameric protein that becomes permeable to Na^+ and Ca^{2+} when it binds a glutamate molecule.

Virtually all neurons that have been tested are strongly excited by glutamate. This excitation is caused by the activation of both ionotropic and metabotropic receptors, which have been extensively characterized by molecu cloning. The ionotropic receptors can be further divided into three subtypes based on the action of selective agonists: α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), kainic acid (KA) and *N* -methyl- D - aspartate (NMDA). All of the ionotropic receptors are composed of four subunits. AMPA receptors, which are present on all neurons, are heterotetramers assembled from four subunits (GluR1-GluR4). The majority of AMP receptors contain the GluR2 subunit and are permeable to Na^+ and K^+ , but not to Ca^{2+} . Some AMPA receptors typically present on inhibitory interneurons, lack the GluR2 subunit and are also permeable to Ca^{2+} .

Kainate receptors are not as uniformly distributed as AMPA receptors, being expressed at high levels in the hippocampus, cerebellum, and spinal cord. They are formed from a number of subunit combinations (GluR5-GluR7, and KA1 and KA2). Although KA1 and KA2 are unable to form channels on their own, their presence in t receptor changes the receptor's affinity and kinetics. Similar to AMPA receptors, kainate receptors are permeab to Na^{+} and K^{+} and in some subunit combinations can also be permeable to Ca^{2+} .

NMDA receptors are as ubiquitous as AMPA receptors, being present on essentially all neurons in the CNS. All NMDA receptors require the presence of the subunit NR1. The channel also contains one or two NR2 subunits (NR2A-D). Unlike AMPA and kainate receptors, all NMDA receptors are highly permeable to Ca^{2+} as well as to N and K^{+} . NMDA receptor function is controlled in a number of intriguing ways. In addition to glutamate binding, the channel also requires the binding of glycine to a separate site. The physiologic role for glycine binding is unclear because the glycine site appears to be saturated at normal ambient levels of glycine. Another key difference between AMPA and kainate receptors on the one hand, and NMDA receptors on the other, is that AMI and kainate receptor activation results in channel opening at resting membrane potential, whereas NMDA receptor activation does not. This is due to the voltage-dependent block of the NMDA pore by extracellular Mg^{2} When the neuron is strongly depolarized, as occurs with intense activation of the synapse or by activation of neighboring synapses, the Mg^{2+} ion is expelled and the channel opens. Thus, there are two requirements for NMDA receptor channel opening: Glutamate must bind the receptor and the membrane must be depolarized. Tl rise in intracellular Ca^{2+} that accompanies channel opening results in a long-lasting enhancement in synaptic strength that is referred to as *long-term potentiation* (LTP). The change can last for many hours or even da and is generally accepted as an important cellular mechanism underlying learning and memory.

The metabotropic glutamate receptors are G protein-coupled receptors that act indirectly on ion channels via G proteins. Metabotropic receptors (mGluR1-mGluR8) have been divided into three groups (I, II, and III). A varie of agonists and antagonists have been developed that interact selectively with the different groups. Group I receptors are typically located postsynaptically and are thought to cause neuronal excitation by activating a nonselective cation channel. These receptors also activate phospholipase C, leading to IP_3 -mediated intracellul Ca^{2+} release. In contrast, group II and group III receptors are typically located on presynaptic nerve terminals and act as inhibitory autoreceptors. Activation of these receptors causes the inhibition of Ca^{2+} channels resultin in inhibition of transmitter release. These receptors are activated only when the concentration of glutamate rise to high levels during repetitive stimulation of the synapse. Activation of these receptors causes the inhibition of adenylyl cyclase and decreases cAMP generation.

The postsynaptic membrane at excitatory synapses is thickened and referred to as the *postsynaptic density* (PSD; Figure 21–6). This is a highly complex structure containing glutamate receptors, signaling proteins, scaffolding proteins, and cytoskeletal proteins. A typical excitatory synapse contains AMPA receptors, which ten to be located toward the periphery, and NMDA receptors, which are concentrated in the center. Kainate recepto are present at a subset of excitatory synapses, but their exact location is unknown. Metabotropic glutamate receptors (group I), which are localized just outside the PSD, are also present at some excitatory synapses.

GABA AND GLYCINE

Both GABA and glycine are inhibitory neurotransmitters, which are typically released from local interneurons. Interneurons that release glycine are restricted to the spinal cord and brain stem, whereas interneurons releasi GABA are present throughout the CNS, including the spinal cord. It is interesting that some interneurons in the spinal cord can release both GABA and glycine. Glycine receptors are pentameric structures that are selectively permeable to Cl^{-} . Strychnine, which is a potent spinal cord convulsant and has been used in some rat poisons, selectively blocks glycine receptors.

GABA receptors are divided into two main types: $GABA_A$ and $GABA_B$. IPSPs in many areas of the brain have a fa and slow component. The fast component is mediated by $GABA_A$ receptors and the slow component by $GABA_B$ receptors. The difference in kinetics stems from the differences in coupling of the receptors to ion channels. $GABA_A$ receptors are inotropic receptors and, like glycine receptors, are pentameric structures that are selective permeable to Cl^- . These receptors are selectively inhibited by picrotoxin and bicuculline, both of which cause generalized convulsions. A great many subunits for $GABA_A$ receptors have been cloned; this accounts for the lar diversity in the pharmacology of $GABA_A$ receptors, making them key targets for clinically useful agents (see Chapter 22). $GABA_B$ receptors are metabotropic receptors that are selectively activated by the antispastic drug baclofen. These receptors are coupled to G proteins that, depending on their cellular location, either inhibit Ca^2 channels or activate K^+ channels. The $GABA_B$ component of the IPSP is due to a selective increase in K^+ conductance. This IPSP is long-lasting and slow because the coupling of receptor activation to K^+ channel openi is indirect and delayed. $GABA_B$ receptors are localized to the perisynaptic region and thus require the spillover o GABA from the synaptic cleft. $GABA_B$ receptors are also present on the axon terminals of many excitatory and inhibitory synapses. In this case, GABA spills over onto these presynaptic $GABA_B$ receptors, inhibiting transmitte release by inhibiting Ca^{2+} channels. In addition to their coupling to ion channels, $GABA_B$ receptors also inhibit adenylyl cyclase and decrease cAMP generation.

Acetylcholine

Acetylcholine was the first compound to be identified pharmacologically as a transmitter in the CNS. Eccles showed in the early 1950s that excitation of Renshaw cells by motor axon collaterals in the spinal cord was blocked by nicotinic antagonists. Furthermore, Renshaw cells were extremely sensitive to nicotinic agonists. These experiments were remarkable for two reasons. First, this early success at identifying a transmitter for a central synapse was followed by disappointment because it remained the sole central synapse for which the transmitter was known until the late 1960s, when comparable data became available for GABA and glycine. Second, the motor axon collateral synapse remains one of the best-documented examples of a cholinergic nicotinic synapse in the mammalian CNS, despite the rather widespread distribution of nicotinic receptors as defined by in situ hybridization studies. Most CNS responses to acetylcholine are mediated by a large family of G protein-coupled muscarinic receptors. At a few sites, acetylcholine causes slow inhibition of the neuron by activating the M_2 subtype of receptor, which opens potassium channels. A far more widespread muscarinic actio in response to acetylcholine is a slow excitation that in some cases is mediated by M_1 receptors. These muscari effects are much slower than either nicotinic effects on Renshaw cells or the effect of amino acids. Furthermore this M_1 muscarinic excitation is unusual in that acetylcholine produces it by *decreasing* the membrane permeability to potassium, ie, the opposite of conventional transmitter action.

A number of pathways contain acetylcholine, including neurons in the neostriatum, the medial septal nucleus, a the reticular formation. Cholinergic pathways appear to play an important role in cognitive functions, especially memory. Presenile dementia of the Alzheimer type is reportedly associated with a profound loss of cholinergic neurons. However, the specificity of this loss has been questioned because the levels of other putative transmitters, eg, somatostatin, are also decreased.

Monoamines

Monoamines include the catecholamines (dopamine and norepinephrine) and 5-hydroxytryptamine. Although these compounds are present in very small amounts in the CNS, they can be localized using extremely sensitive histochemical methods. These pathways are the site of action of many drugs; for example, the CNS stimulants cocaine and amphetamine appear to act primarily at catecholamine synapses. Cocaine blocks the reuptake of dopamine and norepinephrine, whereas amphetamines cause presynaptic terminals to release these transmitte

DOPAMINE

The major pathways containing dopamine are the projection linking the substantia nigra to the neostriatum anc the projection linking the ventral tegmental region to limbic structures, particularly the limbic cortex. The therapeutic action of the antiparkinsonism drug levodopa is associated with the former area (Chapter 28), whereas the therapeutic action of the antipsychotic drugs is thought to be associated with the latter (Chapter 2 Dopamine-containing neurons in the tuberobasal ventral hypothalamus play an important role in regulating hypothalamohypophysial function. Five dopamine receptors have been identified, and they fall into two categories: D_1 -like (D_1 and D_5) and D_2 -like (D_2 , D_3 , D_4). All dopamine receptors are metabotropic. Dopamir generally exerts a slow inhibitory action on CNS neurons. This action has been best characterized on dopamine-containing substantia nigra neurons, where D_2 -receptor activation opens potassium channels via the G_i couplin protein.

NOREPINEPHRINE

Most noradrenergic neurons are located in the locus ceruleus or the lateral tegmental area of the reticular formation. Although the density of fibers innervating various sites differs considerably, most regions of the CNS receive diffuse noradrenergic input. All noradrenergic receptor subtypes are metabotropic. When applied to neurons, norepinephrine can hyperpolarize them by increasing potassium conductance. This effect is mediated α_2 receptors and has been characterized most thoroughly on locus ceruleus neurons. In many regions of the CN norepinephrine actually enhances excitatory inputs by both indirect and direct mechanisms. The indirect mechanism involves disinhibition; that is, inhibitory local circuit neurons are inhibited. The direct mechanism involves blockade of potassium conductances that slow neuronal discharge. Depending on the type of neuron, t effect is mediated by either α_1 or β receptors. Facilitation of excitatory synaptic transmission is in accordance wi many of the behavioral processes thought to involve noradrenergic pathways, eg, attention and arousal.

5-HYDROXYTRYPTAMINE

Most 5-hydroxytryptamine (5-HT, serotonin) pathways originate from neurons in the raphe or midline regions o the pons and upper brain stem. 5-HT is contained in unmyelinated fibers that diffusely innervate most regions c the CNS, but the density of the innervation varies. 5-HT acts on more than a dozen receptor subtypes. Except f the 5-HT_3 receptor, all of these receptors are metabotropic. The ionotropic 5-HT_3 receptor exerts a rapid excitatory action at a very limited number of sites in the CNS. In most areas of the CNS, 5-HT has a strong inhibitory action. This action is mediated by 5-HT_{1A} receptors and is associated with membrane hyperpolarizatic caused by an increase in potassium conductance. It has been found that 5-HT_{1A} receptors and $GABA_B$ receptors share the same potassium channels. Some cell types are slowly excited by 5-HT owing to its blockade of potassium channels via 5-HT_2 or 5-HT_4 receptors. Both excitatory and inhibitory actions can occur on the same neuron. It has often been speculated that 5-HT pathways may be involved in the hallucinations induced by LSD since this compound can antagonize the peripheral actions of 5-HT. However, LSD does not appear to be a 5-H antagonist in the CNS, and typical LSD-induced behavior is still seen in animals after raphe nuclei are destroye Other proposed regulatory functions of 5-HT-containing neurons include sleep, temperature, appetite, and neuroendocrine control.

Peptides

A great many CNS peptides have been discovered that produce dramatic effects both on animal behavior and o the activity of individual neurons. Many of the peptides have been mapped with immunohistochemical techniqu and include opioid peptides (eg, enkephalins, endorphins), neurotensin, substance P, somatostatin, cholecystokinin, vasoactive intestinal polypeptide, neuropeptide Y, and thyrotropin-releasing hormone. As in the peripheral autonomic nervous system, peptides often coexist with a conventional nonpeptide transmitter in the same neuron. A good example of the approaches used to define the role of these peptides in the CNS comes fr studies on substance P and its association with sensory fibers. Substance P is contained in and released from small unmyelinated primary sensory neurons in the spinal cord and brain stem and causes a slow EPSP in targe neurons. These sensory fibers are known to transmit noxious stimuli, and it is therefore surprising that—althou substance P receptor antagonists can modify responses to certain types of pain—they do not block the respons Glutamate, which is released with substance P from these synapses, presumably plays an important role in transmitting pain stimuli. Substance P is certainly involved in many other functions, because it is found in many areas of the CNS that are unrelated to pain pathways.

Many of these peptides are also found in peripheral structures, including peripheral synapses. They are describ in Chapters 6 and 17.

Nitric Oxide

The CNS contains a substantial amount of nitric oxide synthase (NOS), which is found within certain classes of neurons. This neuronal NOS is an enzyme activated by calcium-calmodulin, and activation of NMDA receptors, which increases intracellular calcium, results in the generation of nitric oxide. Although a physiologic role for nit oxide has been clearly established for vascular smooth muscle, its role in synaptic transmission and synaptic plasticity remains controversial.

Endocannabinoids

The primary psychoactive ingredient in cannabis, Δ^9 -tetrahydrocannabinol (Δ^9 -THC), affects the brain mainly l activating a specific cannabinoid receptor, CB1. CB1 is expressed at high levels in many brain regions, and several endogenous brain lipids, including anandamide and 2-arachidonylglycerol, have been identified as CB1 ligands. These ligands are not stored, as are classic neurotransmitters, but instead are rapidly synthesized by neurons in response to depolarization and consequent calcium influx. In further contradistinction to classic neurotransmitters, endogenous cannabinoids can function as retrograde synaptic messengers: They are release from postsynaptic neurons and travel backward across synapses, activating CB1 receptors on presynaptic neurons and suppressing transmitter release. Cannabinoids may affect memory, cognition, and pain perception by this mechanism.

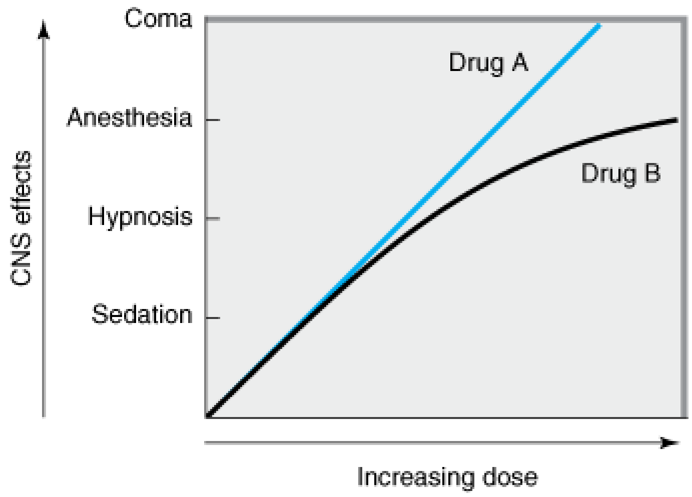
SEDATIVE-HYPNOTIC DRUGS: INTRODUCTION

Assignment of a drug to the sedative-hypnotic class indicates that it is able to cause sedation (with concomitant relief of anxiety) or to encourage sleep. Because there is considerable chemical variation within the group, this drug classification is based on clinical uses rather than on similarities in chemical structure. Anxiety states and sleep disorders are common problems, and sedative-hypnotics are widely prescribed drugs worldwide.

BASIC PHARMACOLOGY OF SEDATIVE-HYPNOTICS

An effective **sedative** (anxiolytic) agent should reduce anxiety and exert a calming effect. The degree of central nervous system depression caused by a sedative should be the minimum consistent with therapeutic efficacy. A **hypnotic** drug should produce drowsiness and encourage the onset and maintenance of a state of sleep. Hypnotic effects involve more pronounced depression of the central nervous system than sedation, and this can be achieved with many drugs in this class simply by increasing the dose. Graded dose-dependent depression of central nervous system function is a characteristic of most sedative-hypnotics. However, individual drugs differ in the relationship between the dose and the degree of central nervous system depression. Two examples of such dose-response relationships are shown in Figure 22–1. The linear slope for drug A is typical of many of the older sedative-hypnotics, including the barbiturates and alcohols. With such drugs, an increase in dose higher than that needed for hypnosis may lead to a state of general anesthesia. At still higher doses, these sedative-hypnotics may depress respiratory and vasomotor centers in the medulla, leading to coma and death. Deviations from a linear dose-response relationship, as shown for drug B, require proportionately greater dosage increments to achieve central nervous system depression more profound than hypnosis. This appears to be the case for benzodiazepines and for certain newer hypnotics that have a similar mechanism of action.

Figure 22–1.

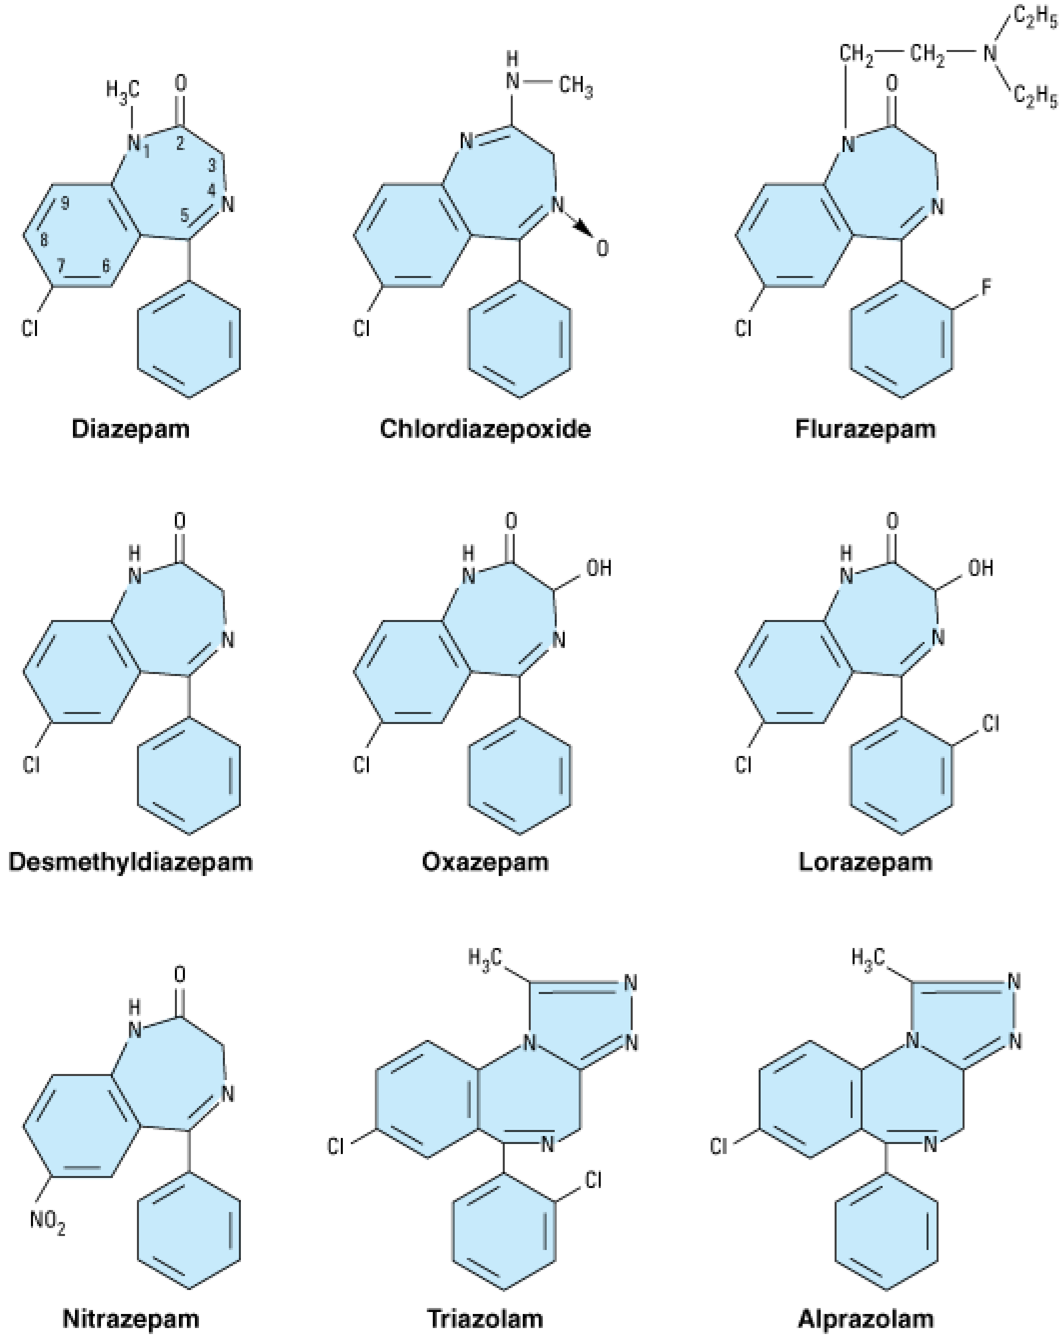


Dose-response curves for two hypothetical sedative-hypnotics.

CHEMICAL CLASSIFICATION

The benzodiazepines are widely used sedative-hypnotics. All of the structures shown in Figure 22–2 are 1,4-benzodiazepines, and most contain a carboxamide group in the 7-membered heterocyclic ring structure. A substituent in the 7 position, such as a halogen or a nitro group, is required for sedative-hypnotic activity. The structures of triazolam and alprazolam include the addition of a triazole ring at the 1,2-position.

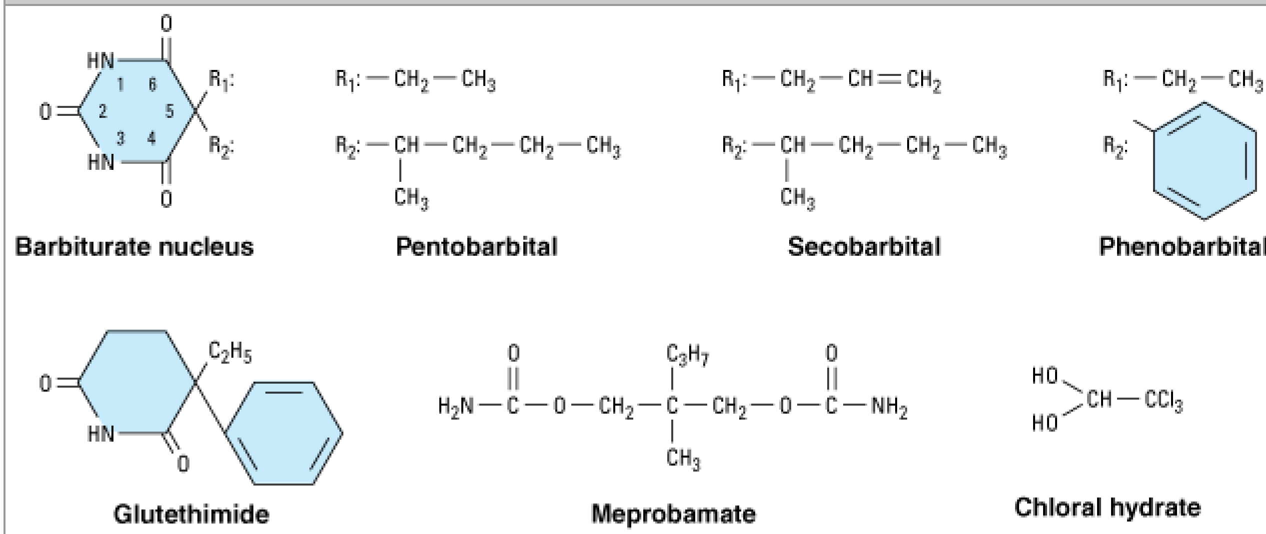
Figure 22–2.



Chemical structures of benzodiazepines.

The chemical structures of some older and less commonly used sedative-hypnotics, including several barbiturates, are shown in Figure 22–3. Glutethimide and meprobamate are of distinctive chemical structure but are practically equivalent to barbiturates in their pharmacologic effects. Their clinical use is rapidly declining. The sedative-hypnotic class also includes compounds of simpler chemical structure, including ethanol (see Chapter 23) and chloral hydrate.

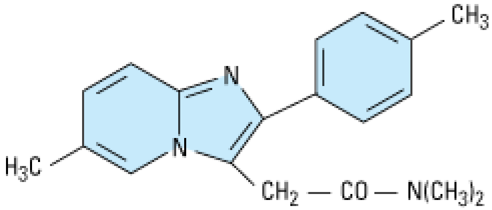
Figure 22–3.



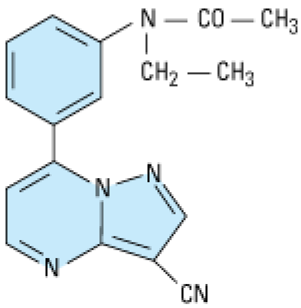
Chemical structures of barbiturates and other sedative-hypnotics.

Several drugs with novel chemical structures have been introduced more recently for use in sleep disorders. Zolpidem, an imidazopyridine, zaleplon, a pyrazolopyrimidine, and eszopiclone, a cyclopyrrolone (Figure 22–4), although structurally unrelated to benzodiazepines, share a similar mechanism of action, as described below. Eszopiclone is the *(S)*-enantiomer of zopiclone, a hypnotic drug that has been available outside the United States since 1989. Ramelteon, a melatonin receptor agonist, is a new hypnotic drug (see Ramelteon). Buspirone is a slow-onset anxiolytic agent whose actions are quite different from those of conventional sedative-hypnotics (see Buspirone).

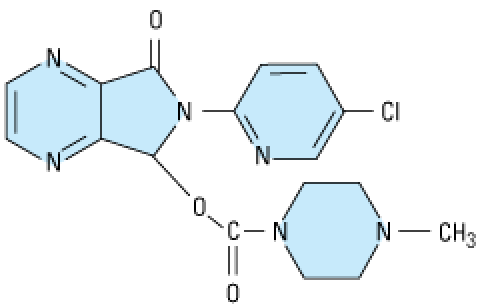
Figure 22–4.



Zolpidem



Zaleplon



Eszopiclone

Chemical structures of newer hypnotics.

Other classes of drugs that exert sedative effects include antipsychotics (Chapter 29), and many antidepressant drugs (Chapter 30). The latter are currently used widely in management of chronic anxiety disorders. Certain antihistaminic agents including hydroxyzine and promethazine (Chapter 16) are also sedating. These agents commonly also exert marked effects on the peripheral autonomic nervous system. Certain antihistaminics with sedative effects are available in over-the-counter sleep aids.

Ramelteon

Melatonin receptors are thought to be involved in maintaining circadian rhythms underlying the sleep-wake cycle (Chapter 16). Ramelteon, a novel hypnotic drug prescribed specifically for patients who have difficulty in falling asleep, is an agonist at MT_1 and MT_2 melatonin receptors located in the suprachiasmatic nuclei of the brain. The drug has no direct effects on GABAergic neurotransmission in the central nervous system. In polysomnography studies of patients with chronic insomnia, ramelteon reportedly reduced the latency to persistent sleep with no rebound insomnia or withdrawal symptoms. The drug is rapidly absorbed after oral administration and undergoes extensive first-pass metabolism, forming an active metabolite with longer half-life (2–5 hours) than the parent drug. The CYP1A2 isoform of cytochrome P450 is mainly responsible for the metabolism of ramelteon; the drug should not be used with fluvoxamine (an inhibitor of CYP1A2) and should be used with caution in patients with liver dysfunction. Adverse effects of ramelteon include dizziness, somnolence, fatigue, and endocrine changes as well as decreases in testosterone and increases in prolactin. Ramelteon is not a controlled substance.

Buspirone

Buspirone has selective anxiolytic effects, and its pharmacologic characteristics are different from those of other drugs described in this chapter. Buspirone relieves anxiety without causing marked sedative, hypnotic, or euphoric effects. Unlike benzodiazepines, the drug has no anticonvulsant or muscle relaxant properties. Buspirone does not interact directly with GABAergic systems. It may exert its anxiolytic effects by acting as a partial agonist at brain $5\text{-}HT_{1A}$ receptors, but it also has affinity for brain dopamine D_2 receptors. Buspirone-treated patients show no rebound anxiety or withdrawal signs on abrupt discontinuance. The drug is not effective in blocking the acute withdrawal syndrome resulting from abrupt cessation of use of benzodiazepines or other sedative-hypnotics. Buspirone has minimal abuse liability. In marked contrast to the benzodiazepines, the anxiolytic effects of buspirone may take more than a week to become established, making the drug unsuitable for management of acute anxiety states. The drug is used in generalized anxiety states but is less effective in panic disorders.

Buspirone is rapidly absorbed orally but undergoes extensive first-pass metabolism via hydroxylation and dealkylation reactions to form several active metabolites. The major metabolite is 1-(2-pyrimidyl)-piperazine (1-PP), which has α_2-adrenoceptor-blocking actions and which enters the central nervous system to reach higher levels than the parent drug. It is not known what role (if any) 1-PP plays in the central actions of buspirone. The elimination half-life of buspirone is 2–4 hours, and liver dysfunction may slow its clearance. Rifampin, an inducer of cytochrome P450, decreases the half-life of buspirone; inhibitors of CYP3A4 (eg, erythromycin, ketoconazole) increase its plasma levels.

Buspirone causes less psychomotor impairment than benzodiazepines and does not affect driving skills. The drug does not potentiate effects of conventional sedative-hypnotic drugs, ethanol, or tricyclic antidepressants, and elderly patients do not appear to be more sensitive to its actions. Tachycardia, palpitations, nervousness, gastrointestinal distress, and paresthesias and a dose-dependent pupillary constriction may occur. Blood pressure may be elevated in patients receiving MAO inhibitors.

Pharmacokinetics

ABSORPTION AND DISTRIBUTION

The rates of oral absorption of sedative-hypnotics differ depending on a number of factors, including lipophilicity. For example, the absorption of triazolam is extremely rapid, and that of diazepam and the active metabolite of clorazepate is more rapid than other commonly used benzodiazepines. Clorazepate, a prodrug, is converted to its active form, desmethyldiazepam (nordiazepam), by acid hydrolysis in the stomach. Most of the barbiturates and other older sedative-hypnotics, as well as the newer hypnotics (eszopiclone, zaleplon, zolpidem), are absorbed rapidly into the blood following oral administration.

Lipid solubility plays a major role in determining the rate at which a particular sedative-hypnotic enters the central nervous system. This property is responsible for the rapid onset of central nervous system effects of triazolam, thiopental (Chapter 25), and the newer hypnotics.

All sedative-hypnotics cross the placental barrier during pregnancy. If sedative-hypnotics are given during the predelivery period, they may contribute to the depression of neonatal vital functions. Sedative-hypnotics are also detectable in breast milk and may exert depressant effects in the nursing infant.

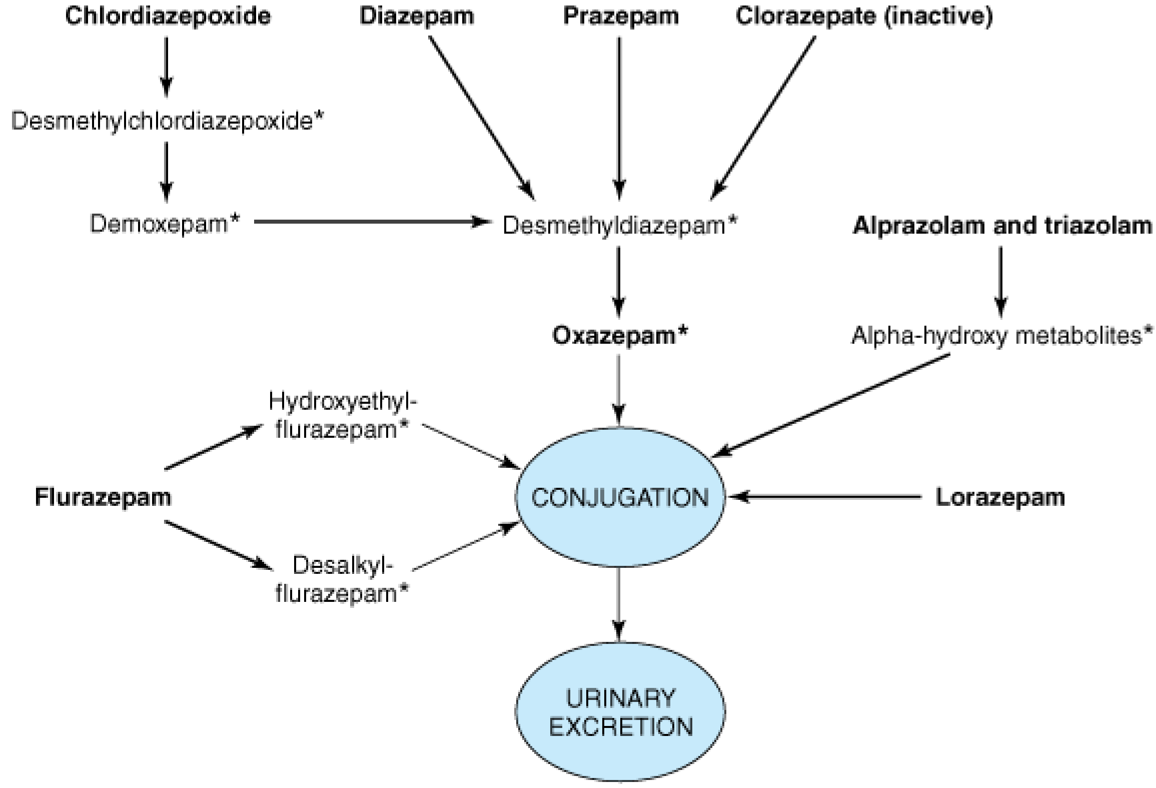
BIOTRANSFORMATION

Metabolic transformation to more water-soluble metabolites is necessary for clearance of sedative-hypnotics from the body. The microsomal drug-metabolizing enzyme systems of the liver are most important in this regard. Few sedative-hypnotics are excreted from the body in unchanged form, so elimination half-life depends mainly on the rate of metabolic transformation.

Benzodiazepines

Hepatic metabolism accounts for the clearance of all benzodiazepines. The patterns and rates of metabolism depend on the individual drugs. Most benzodiazepines undergo microsomal oxidation (phase I reactions), including *N*-dealkylation and aliphatic hydroxylation catalyzed by cytochrome P450 isozymes, especially CYP3A4. The metabolites are subsequently conjugated (phase II reactions) to form glucuronides that are excreted in the urine. However, many phase I metabolites of benzodiazepines are pharmacologically active, some with long half-lives (Figure 22–5). For example, desmethyldiazepam, which has an elimination half-life of more than 40 hours, is an active metabolite of chlordiazepoxide, diazepam, prazepam, and clorazepate. Alprazolam and triazolam undergo α-hydroxylation, and the resulting metabolites appear to exert short-lived pharmacologic effects because they are rapidly conjugated to form inactive glucuronides. The short elimination half-life of triazolam (2–3 hours) favors its use as a hypnotic rather than as a sedative drug.

Figure 22–5.



Biotransformation of benzodiazepines. (Boldface, drugs available for clinical use in various countries; *, active metabolite.)

The formation of active metabolites has complicated studies on the pharmacokinetics of the benzodiazepines in humans because the elimination half-life of the parent drug may have little relation to the time course of pharmacologic effects. Benzodiazepines for which the parent drug or active metabolites have long half-lives are more likely to cause cumulative effects with multiple doses. Cumulative and residual effects such as excessive drowsiness appear to be less of a problem with such drugs as estazolam, oxazepam, and lorazepam, which have relatively short half-lives and are metabolized directly to inactive glucuronides. Some pharmacokinetic properties of selected benzodiazepines are listed in Table 22–1. The metabolism of several commonly used benzodiazepines including diazepam, midazolam, and triazolam is affected by inhibitors and inducers of hepatic P450 isozymes (see Chapter 4).

Table 22–1. Pharmacokinetic Properties of Some Benzodiazepines and Newer Hypnotics in Humans.			
Drug	Peak Blood Level (hours)	Elimination Half-Life[1] (hours)	Comments
Alprazolam	1–2	12–15	Rapid oral absorption
Chlordiazepoxide	2–4	15–40	Active metabolites; erratic bioavailability from IM injection
Clorazepate	1–2 (nordiazepam)	50–100	Prodrug; hydrolyzed to active form in stomach
Diazepam	1–2	20–80	Active metabolites; erratic bioavailability from IM injection
Eszopiclone	1	6	Minor active metabolites
Flurazepam	1–2	40–100	Active metabolites with long half-lives
Lorazepam	1–6	10–20	No active metabolites
Oxazepam	2–4	10–20	No active metabolites
Temazepam	2–3	10–40	Slow oral absorption
Triazolam	1	2–3	Rapid onset; short duration of action
Zaleplon	< 1	1–2	Metabolized via aldehyde dehydrogenase
Zolpidem	1–3	1.5–3.5	No active metabolites

[1]Includes half-lives of major metabolites.

Barbiturates

With the exception of phenobarbital, only insignificant quantities of the barbiturates are excreted unchanged. The major metabolic pathways involve oxidation by hepatic enzymes to form alcohols, acids, and ketones, which appear in the urine as glucuronide conjugates. The overall rate of hepatic metabolism in humans depends on the individual drug but (with the exception of the thiobarbiturates) is usually slow. The elimination half-lives of secobarbital and pentobarbital range from 18 to 48 hours in different individuals. The elimination half-life of phenobarbital in humans is 4–5 days. Multiple dosing with these agents can lead to cumulative effects.

Newer Hypnotics

After oral administration of the standard formulation, zolpidem reaches peak plasma levels in 1.6 hours. A biphasic release formulation extends plasma levels by approximately 2 hours. Zolpidem is rapidly metabolized to inactive metabolites via oxidation and hydroxylation by hepatic cytochromes P450 including the CYP3A4 isozyme. The elimination half-life of the drug is 1.5–3.5 hours, with clearance decreased in elderly patients. Zaleplon is metabolized to inactive metabolites mainly by hepatic aldehyde oxidase and partly by the cytochrome P450 isoform CYP3A4. The half-life of the drug is about 1 hour. Dosage should be reduced in patients with hepatic impairment and in the elderly. Cimetidine, which inhibits both aldehyde dehydrogenase and CYP3A4, markedly increases the peak plasma level of zaleplon. Eszopiclone is metabolized by hepatic cytochromes P450 (especially CYP3A4) to form the inactive *N*-oxide derivative and weakly active desmethyleszopiclone. The elimination half-life of eszopiclone is approximately 6 hours and is prolonged in the elderly and in the presence of inhibitors of CYP3A4 (eg, ketoconazole). Inducers of CYP3A4 (eg, rifampin) increase the hepatic metabolism of eszopiclone.

EXCRETION

The water-soluble metabolites of sedative-hypnotics, mostly formed via the conjugation of phase I metabolites, are excreted mainly via the kidney. In most cases, changes in renal function do not have a marked effect on the elimination of parent drugs. Phenobarbital is excreted unchanged in the urine to a certain extent (20–30% in humans), and its elimination rate can be increased significantly by alkalinization of the urine. This is partly due to increased ionization at alkaline pH, since phenobarbital is a weak acid with a pK_a of 7.4.

FACTORS AFFECTING BIODISPOSITION

The biodisposition of sedative-hypnotics can be influenced by several factors, particularly alterations in hepatic function resulting from disease or drug-induced increases or decreases in microsomal enzyme activities (see Chapter 4).

In very old patients and in patients with severe liver disease, the elimination half-lives of these drugs are often increased significantly. In such cases, multiple normal doses of these sedative-hypnotics can result in excessive central nervous system effects.

The activity of hepatic microsomal drug-metabolizing enzymes may be increased in patients exposed to certain older sedative-hypnotics on a long-term basis (enzyme induction; see Chapter 4). Barbiturates (especially phenobarbital) and meprobamate are most likely to cause this effect, which may result in an increase in their hepatic metabolism as well as that of other drugs. Increased biotransformation of other pharmacologic agents as a result of enzyme induction by barbiturates is a potential mechanism underlying drug interactions (Appendix II). In contrast, benzodiazepines and the newer hypnotics do not change hepatic drug-metabolizing enzyme activity with continuous use.

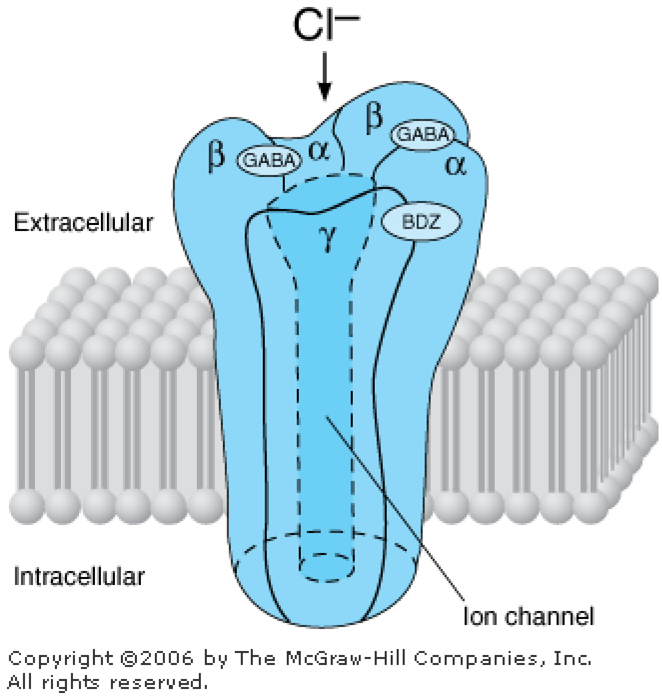
Pharmacodynamics of Benzodiazepines, Barbiturates, & Newer Hypnotics

MOLECULAR PHARMACOLOGY OF THE $GABA_A$ RECEPTOR

The benzodiazepines, the barbiturates, zolpidem, zaleplon, eszopiclone, and many other drugs bind to molecular components of the $GABA_A$ receptor in neuronal membranes in the central nervous system. This receptor, which functions as a chloride ion channel, is activated by the inhibitory neurotransmitter GABA (see Chapter 21).

The $GABA_A$ receptor has a pentameric structure assembled from five subunits (each with four transmembrane-spanning domains) selected from multiple polypeptide classes (α, β, γ, δ, ε, π, ρ, etc). Multiple subunits of several of these classes have been characterized, eg, six different α, four β, and three γ. A model of the hypothetical $GABA_A$ receptor-chloride ion channel macromolecular complex is shown in Figure 22–6.

Figure 22–6.



A model of the $GABA_A$ receptor-chloride ion channel macromolecular complex (others could be proposed). A heterooligomeric glycoprotein, the complex consists of five or more membrane-spanning subunits. Multiple forms of α, β, and γsubunits are arranged in different pentameric combinations so that $GABA_A$ receptors exhibit molecular heterogeneity. GABA appears to interact with αor βsubunits triggering chloride channel opening with resulting membrane hyperpolarization. Binding of benzodiazepines to γsubunits or to an area of the αunit influenced by the γunit facilitates the process of channel opening but does not directly initiate chloride current. (Modified and reproduced, with permission, from Zorumski CF, Isenberg KE: Insights into the structure and function of GABA receptors: Ion channels and psychiatry. Am J Psychiatry 1991;148:162.)

A major isoform of the $GABA_A$ receptor that is found in many regions of the brain consists of two α_1 and two β_2 subunits and one γ_2 subunit. In this isoform, the binding sites for GABA are located between adjacent α_1 and β_2 subunits, and the binding pocket for benzodiazepines (the BZ site of the $GABA_A$ receptor) is between an α_1 and the γ_2 subunit. However, $GABA_A$ receptors in different areas of the central nervous system consist of various combinations of the essential subunits, and the benzodiazepines bind to many of these, including receptor isoforms containing α_2, α_3, and α_5 subunits. Barbiturates also bind to multiple isoforms of the $GABA_A$ receptor but at different sites from those with which benzodiazepines interact. In contrast to benzodiazepines, zolpidem, zaleplon, and eszopiclone bind more selectively because these drugs interact only with $GABA_A$-receptor isoforms that contain α_1

subunits. The heterogeneity of $GABA_A$ receptors may constitute the molecular basis for the varied pharmacologic actions of benzodiazepines and related drugs (see GABA Receptor Heterogeneity & Pharmacologic Selectivity).

In contrast to GABA itself, benzodiazepines and other sedative-hypnotics have a low affinity for $GABA_B$ receptors, which are activated by the spasmolytic drug baclofen (see Chapters 21 and 27).

NEUROPHARMACOLOGY

GABA (gamma-aminobutyric acid) is the major inhibitory neurotransmitter in the central nervous system (Chapter 21). Electrophysiologic studies have shown that benzodiazepines potentiate GABAergic inhibition at all levels of the neuraxis, including the spinal cord, hypothalamus, hippocampus, substantia nigra, cerebellar cortex, and cerebral cortex. Benzodiazepines appear to increase the efficiency of GABAergic synaptic inhibition. The benzodiazepines do not substitute for GABA but appear to enhance GABA's effects allosterically without directly activating $GABA_A$ receptors or opening the associated chloride channels. The enhancement in chloride ion conductance induced by the interaction of benzodiazepines with GABA takes the form of an increase in the *frequency* of channel-opening events.

Barbiturates also facilitate the actions of GABA at multiple sites in the central nervous system, but—in contrast to benzodiazepines—they appear to increase the *duration* of the GABA-gated chloride channel openings. At high concentrations, the barbiturates may also be GABA-mimetic, directly activating chloride channels. These effects involve a binding site or sites distinct from the benzodiazepine binding sites. Barbiturates are less selective in their actions than benzodiazepines, because they also depress the actions of excitatory neurotransmitters (eg, glutamic acid) and exert nonsynaptic membrane effects in parallel with their effects on GABA neurotransmission. This multiplicity of sites of action of barbiturates may be the basis for their ability to induce full surgical anesthesia (see Chapter 25) and for their more pronounced central depressant effects (which result in their low margin of safety) compared with benzodiazepines and the newer hypnotics.

GABA Receptor Heterogeneity & Pharmacologic Selectivity

Studies involving genetically engineered mice have demonstrated that the specific pharmacologic actions elicited by benzodiazepines and other drugs that modulate GABA actions are influenced by the composition of the subunits assembled to form the $GABA_A$ receptor. Benzodiazepines interact only with brain $GABA_A$ receptors in which the α subunits (1,2,3, and 5) have a conserved histidine residue in the N-terminal domain. Strains of mice, in which a point mutation has been inserted converting histidine to arginine in the α_1 subunit, show resistance to both the sedative and amnestic effects of benzodiazepines, but anxiolytic and muscle-relaxing effects are largely unchanged. These animals are also unresponsive to the hypnotic actions of zolpidem and zaleplon, drugs that bind selectively to $GABA_A$ receptors containing α_1 subunits. In contrast, mice with selective histidine-arginine mutations in the α_2 subunit of $GABA_A$ receptors show selective resistance to the antianxiety effects of benzodiazepines. Based on studies of this type, it has been suggested that α_1 subunits in $GABA_A$ receptors mediate sedation, amnesia, and possibly antiseizure effects of benzodiazepines, whereas α_2 subunits are involved in their anxiolytic and muscle-relaxing actions. Other mutation studies have led to suggestions that an α_5 subtype is involved in at least some of the memory impairment caused by benzodiazepines. It should be noted that these studies involving genetic manipulations of the $GABA_A$ receptor utilize rodent models of the anxiolytic and amnestic actions of drugs.

BENZODIAZEPINE BINDING SITE LIGANDS

The components of the $GABA_A$ receptor-chloride ion channel macromolecule that function as benzodiazepine binding sites exhibit heterogeneity (see The Versatility of the Chloride Channel GABA Receptor Complex). Three types of ligand-benzodiazepine receptor interactions have been reported: (1) Agonists facilitate GABA actions, and this occurs at multiple BZ binding sites in the case of the benzodiazepines. As noted above, the nonbenzodiazepines zolpidem, zaleplon, and eszopiclone are selective agonists at the BZ sites that contain an α_1 subunit. Endogenous agonist ligands for the BZ binding sites have been proposed, because benzodiazepine-like chemicals have been isolated from brain tissue of animals never exposed to these drugs. Nonbenzodiazepine molecules that have affinity for BZ sites on the $GABA_A$ receptor have also been detected in human brain. (2) Antagonists are typified by the synthetic benzodiazepine derivative flumazenil, which blocks the actions of benzodiazepines, eszopiclone, zaleplon, and zolpidem but does not antagonize the actions of barbiturates, meprobamate, or ethanol. Certain endogenous neuropeptides are also capable of blocking the interaction of benzodiazepines with BZ binding sites. (3) Inverse agonists act as negative allosteric modulators of GABA-receptor function. Their interaction with BZ sites on the $GABA_A$ receptor can *produce* anxiety and seizures, an action that has been demonstrated for several compounds, especially the β-carbolines, eg, *n*-butyl-β-carboline-3-carboxylate (β-CCB). In addition to their direct actions, these molecules can block the effects of benzodiazepines.

The physiologic significance of endogenous modulators of the functions of GABA in the central nervous system remains unclear. To date, it has not been established that the putative endogenous ligands of BZ binding sites play a role in the control of states of anxiety, sleep patterns, or any other characteristic behavioral expression of central nervous system function.

The Versatility of the Chloride Channel GABA Receptor Complex

The $GABA_A$-chloride channel macromolecular complex is one of the most versatile drug-responsive machines in the body. In addition to the benzodiazepines, barbiturates, and the newer hypnotics (eg, zolpidem), many other drugs with central nervous system effects can modify the function of this important ionotropic receptor. These include alcohol; alphaxolone, etomidate, and propofol (intravenous anesthetics); volatile anesthetics (eg, halothane); several anticonvulsants (eg, gabapentin, vigabatrin); and ivermectin (an anthelmintic agent). Most of these agents facilitate or mimic the action of GABA. (It has not been shown that these drugs act exclusively or even primarily by this mechanism.) Central nervous system excitatory agents that act on the chloride channel include picrotoxin and bicuculline. These convulsant drugs block the channel directly (picrotoxin) or interfere with GABA binding (bicuculline).

ORGAN LEVEL EFFECTS

Sedation

Benzodiazepines, barbiturates, and most older sedative-hypnotic drugs exert calming effects with concomitant reduction of anxiety at relatively low doses. In most cases, however, the anxiolytic actions of sedative-hypnotics are accompanied by some depressant effects on psychomotor and cognitive functions. In experimental animal models, benzodiazepines and older sedative-hypnotic drugs are able to disinhibit punishment-suppressed behavior. This disinhibition has been equated with antianxiety effects of sedative-hypnotics, and it is not a characteristic of all drugs that have sedative effects, eg, the tricyclic antidepressants and antihistamines. However, the disinhibition of previously suppressed behavior may be more related to behavioral disinhibitory effects of sedative-hypnotics, including euphoria, impaired judgment, and loss of self-control, which can occur at dosages in the range of those used for management of anxiety. The benzodiazepines also exert dose-dependent anterograde amnesic effects (inability to remember events occurring during the drug's duration of action).

Hypnosis

By definition, all of the sedative-hypnotics induce sleep if high enough doses are given. The effects of sedative-hypnotics on the stages of sleep depend on several factors, including the specific drug, the dose, and the frequency of its administration. The general effects of benzodiazepines and older sedative-hypnotics on patterns of normal sleep are as follows: (1) the latency of sleep onset is decreased (time to fall asleep); (2) the duration of stage 2 NREM sleep is increased; (3) the duration of REM sleep is decreased; and (4) the duration of stage 4 NREM slow-wave sleep is decreased. The newer hypnotics all decrease the latency to persistent sleep. Zolpidem decreases REM sleep but has minimal effect on slow-wave sleep. Zaleplon decreases the latency of sleep onset with little effect on total sleep time, NREM, or REM sleep. Eszopiclone increases total sleep time, mainly via increases in stage 2 NREM sleep, and at low doses has little effect on sleep patterns. At the highest recommended dose, eszopiclone decreases REM sleep.

More rapid onset of sleep and prolongation of stage 2 are presumably clinically useful effects. However, the significance of sedative-hypnotic drug effects on REM and slow-wave sleep is not clear. Deliberate interruption of REM sleep causes anxiety and irritability followed by a rebound increase in REM sleep at the end of the experiment. A similar pattern of "REM rebound" can be detected following abrupt cessation of drug treatment with older sedative-hypnotics, especially when drugs with short durations of action (eg, triazolam) are used at high doses. With respect to zolpidem and the other newer hypnotics, there is little evidence of REM rebound when these drugs are discontinued after use of recommended doses. However, rebound insomnia occurs with both zolpidem and zaleplon if used at higher doses. Despite possible reductions in slow-wave sleep, there are no reports of disturbances in the secretion of pituitary or adrenal hormones when either barbiturates or benzodiazepines are used as hypnotics. The use of sedative-hypnotics for more than 1–2 weeks leads to some tolerance to their effects on sleep patterns.

Anesthesia

As shown in Figure 22–1, high doses of certain sedative-hypnotics depress the central nervous system to the point known as stage III of general anesthesia (see Chapter 25). However, the suitability of a particular agent as an adjunct in anesthesia depends mainly on the physicochemical properties that determine its rapidity of onset and duration of effect. Among the barbiturates, thiopental and methohexital are very lipid-soluble, penetrating brain tissue rapidly following intravenous administration, a characteristic favoring their use for the induction of anesthesia. Rapid tissue redistribution (not rapid elimination) accounts for the short duration of action of these drugs, a feature useful in recovery from anesthesia.

Benzodiazepines—including diazepam, lorazepam, and midazolam—are used intravenously in anesthesia (see Chapter 25), often in combination with other agents. Not surprisingly, benzodiazepines given in large doses as adjuncts to general anesthetics may contribute to a persistent postanesthetic respiratory depression. This is probably related to their relatively long half-lives and the formation of active metabolites. However, such depressant actions of the benzodiazepines are usually reversible with flumazenil.

Anticonvulsant Effects

Many sedative-hypnotics are capable of inhibiting the development and spread of epileptiform electrical activity in the central nervous system. Some selectivity exists in that some members of the group can exert anticonvulsant effects without marked central nervous system depression (although psychomotor function may be impaired). Several benzodiazepines—including clonazepam, nitrazepam, lorazepam, and diazepam—are sufficiently selective to be clinically useful in the management of seizures (see Chapter 24). Of the barbiturates, phenobarbital and metharbital (converted to phenobarbital in the body) are effective in the treatment of generalized tonic-clonic seizures. Zolpidem, zaleplon, and eszopiclone lack anticonvulsant activity, presumably because of their more selective binding than that of benzodiazepines to $GABA_A$ receptor isoforms.

Muscle Relaxation

Some sedative-hypnotics, particularly members of the carbamate (eg, meprobamate) and benzodiazepine groups, exert inhibitory effects on polysynaptic reflexes and internuncial transmission and at high doses may also depress transmission at the skeletal neuromuscular junction. Somewhat selective actions of this type that lead to muscle relaxation can be readily demonstrated in animals and have led to claims of usefulness for relaxing contracted voluntary muscle in muscle spasm (see Clinical Pharmacology). Muscle relaxation is not a characteristic action of zolpidem, zaleplon, and eszopiclone.

Effects on Respiration and Cardiovascular Function

At hypnotic doses in healthy patients, the effects of sedative-hypnotics on respiration are comparable to changes during natural sleep. However, even at therapeutic doses, sedative-hypnotics can produce significant respiratory depression in patients with pulmonary disease. Effects on respiration are dose-related, and depression of the medullary respiratory center is the usual cause of death due to overdose of sedative-hypnotics.

At doses up to those causing hypnosis, no significant effects on the cardiovascular system are observed in healthy patients. However, in hypovolemic states, heart failure, and other diseases that impair cardiovascular function, normal doses of sedative-hypnotics may cause cardiovascular depression, probably as a result of actions on the medullary vasomotor centers. At toxic doses, myocardial contractility and vascular tone may both be depressed by central and peripheral effects, leading to circulatory collapse. Respiratory and cardiovascular effects are more marked when sedative-hypnotics are given intravenously.

Tolerance; Psychologic & Physiologic Dependence

Tolerance—decreased responsiveness to a drug following repeated exposure—is a common feature of sedative-hypnotic use. It may result in the need for an increase in the dose required to maintain symptomatic improvement or to promote sleep. It is important to recognize that partial cross-tolerance occurs between the sedative-hypnotics described here and also with ethanol (Chapter 23)—a feature of some clinical importance, as explained below. The mechanisms responsible for tolerance to sedative-hypnotics are not well understood. An increase in the rate of drug metabolism (metabolic tolerance) may be partly responsible in the case of chronic administration of barbiturates, but changes in responsiveness of the central nervous system (pharmacodynamic tolerance) are of greater importance for most sedative-hypnotics. In the case of benzodiazepines, the development of tolerance in animals has been associated with down-regulation of brain benzodiazepine receptors. Tolerance has been reported to occur with the extended use of zolpidem. Minimal tolerance was observed with the use of zaleplon over a 5-week period and eszopiclone over a 6-month period.

The perceived desirable properties of relief of anxiety, euphoria, disinhibition, and promotion of sleep have led to the compulsive misuse of virtually all sedative-hypnotics. (See Chapter 32 for a detailed discussion.) For this reason, most sedative-hypnotic drugs are classified as Schedule III or Schedule IV drugs for prescribing purposes. The consequences of abuse of these agents can be defined in both psychologic and physiologic terms. The psychologic component may initially parallel simple neurotic behavior patterns difficult to differentiate from those of the inveterate coffee drinker or cigarette smoker. When the pattern of sedative-hypnotic use becomes compulsive, more serious complications develop, including physiologic dependence and tolerance.

Physiologic dependence can be described as an altered physiologic state that requires continuous drug administration to prevent an abstinence or withdrawal syndrome. In the case of sedative-hypnotics, this syndrome is characterized by states of increased anxiety, insomnia, and central nervous system excitability that may progress to convulsions. Most sedative-hypnotics—including benzodiazepines—are capable of causing physiologic dependence when used on a long-term basis. However, the severity of withdrawal symptoms differs among individual drugs and depends also on the magnitude of the dose used immediately before cessation of use. When higher doses of sedative-hypnotics are used, abrupt withdrawal leads to more serious withdrawal signs. Differences in the severity of withdrawal symptoms resulting from individual sedative-hypnotics relate in part to half-life, since drugs with long half-lives are eliminated slowly enough to accomplish gradual withdrawal with few physical symptoms. The use of drugs with very short half-lives for hypnotic effects may lead to signs of withdrawal even between doses. For example, triazolam, a benzodiazepine with a half-life of about 4 hours, has been reported to cause daytime anxiety when used to treat sleep disorders. The abrupt cessation of zolpidem, zaleplon, or eszopiclone may also result in withdrawal symptoms, though usually of less intensity than those seen with benzodiazepines.

BENZODIAZEPINE ANTAGONISTS: FLUMAZENIL

Flumazenil is one of several 1,4-benzodiazepine derivatives with a high affinity for the benzodiazepine binding site on the $GABA_A$ receptor that act as competitive antagonists. It blocks many of the actions of benzodiazepines, zolpidem, zaleplon, and eszopiclone, but does not antagonize the central nervous system effects of other sedative-hypnotics, ethanol, opioids, or general anesthetics. Flumazenil is approved for use in reversing the central nervous system depressant effects of benzodiazepine overdose and to hasten recovery following use of these drugs in anesthetic and diagnostic procedures. Although the drug reverses the sedative effects of benzodiazepines, antagonism of benzodiazepine-induced respiratory depression is less predictable. When given intravenously, flumazenil acts rapidly but has a short half-life (0.7–1.3 hours) due to rapid hepatic clearance. Because all benzodiazepines have a longer duration of action than flumazenil, sedation commonly recurs, requiring repeated administration of the antagonist.

Adverse effects of flumazenil include agitation, confusion, dizziness, and nausea. Flumazenil may cause a severe precipitated abstinence syndrome in patients who have developed physiologic benzodiazepine dependence. In patients who have ingested benzodiazepines with tricyclic antidepressants, seizures and cardiac arrhythmias may follow flumazenil administration.

CLINICAL PHARMACOLOGY OF SEDATIVE-HYPNOTICS

TREATMENT OF ANXIETY STATES

The psychologic, behavioral, and physiologic responses that characterize anxiety can take many forms. Typically, the psychic awareness of anxiety is accompanied by enhanced vigilance, motor tension, and autonomic hyperactivity. Anxiety is often secondary to organic disease states—acute myocardial infarction, angina pectoris, gastrointestinal ulcers, etc—which themselves require specific therapy. Another class of secondary anxiety states (situational anxiety) results from circumstances that may have to be dealt with only once or a few times, including anticipation of frightening medical or dental procedures and family illness or other stressful event. Even though situational anxiety tends to be self-limiting, the short-term use of sedative-hypnotics may be appropriate for the treatment of this and certain disease-associated anxiety states. Similarly, the use of a sedative-hypnotic as premedication prior to surgery or some unpleasant medical procedure is rational and proper (Table 22–2).

Table 22–2. Clinical Uses of Sedative-Hypnotics.
For relief of anxiety
For insomnia
For sedation and amnesia before and during medical and surgical procedures
For treatment of epilepsy and seizure states
As a component of balanced anesthesia (intravenous administration)
For control of ethanol or other sedative-hypnotic withdrawal states
For muscle relaxation in specific neuromuscular disorders
As diagnostic aids or for treatment in psychiatry

Excessive or unreasonable anxiety about life circumstances (generalized anxiety disorder, GAD), panic disorders, and agoraphobia are also amenable to drug therapy, sometimes in conjunction with psychotherapy. The benzodiazepines continue to be widely used for the management of acute anxiety states and for rapid control of panic attacks. They are also used in the long-term management of GAD and panic disorders. Anxiety symptoms may be relieved by many benzodiazepines, but it is not always easy to demonstrate the superiority of one drug over another. However, alprazolam is particularly effective in the treatment of panic disorders and agoraphobia and appears to be more selective in these conditions than other benzodiazepines. The choice of benzodiazepines for anxiety is based on several sound pharmacologic principles: (1) a relatively high therapeutic index (see drug B in Figure 22–1), plus availability of flumazenil for treatment of overdose; (2) a low risk of drug interactions based on liver enzyme induction; (3) minimal effects on cardiovascular or autonomic functions.

Disadvantages of the benzodiazepines include the risk of dependence, depression of central nervous system functions, and amnestic effects. In addition, the benzodiazepines exert additive central nervous system depression when administered with other drugs, including ethanol. The patient should be warned of this possibility to avoid impairment of performance of any task requiring mental alertness and motor coordination. In the treatment of generalized anxiety disorders and certain phobias, newer antidepressants, including selective serotonin reuptake inhibitors, are now considered by many authorities to be drugs of first choice (see Chapter 30). However, these agents have minimal effectiveness in acute anxiety states.

Sedative-hypnotics should be used with appropriate caution so as to minimize adverse effects. A dose should be prescribed that does not impair mentation or motor functions during waking hours. Some patients may tolerate the drug better if most of the daily dose is given at bedtime, with smaller doses during the day. Prescriptions should be written for short periods, since there is little justification for long-term therapy (defined as use of therapeutic doses for 2 months or longer). The physician should make an effort to assess the efficacy of therapy from the patient's subjective responses. Combinations of antianxiety agents should be avoided, and people taking sedatives should be cautioned about the consumption of alcohol and the concurrent use of over-the-counter medications containing antihistaminic or anticholinergic drugs (see Chapter 64).

TREATMENT OF SLEEP PROBLEMS

Sleep disorders are common and often result from inadequate treatment of underlying medical conditions or psychiatric illness. True primary insomnia is rare. Nonpharmacologic therapies that are useful for sleep problems include proper diet and exercise, avoiding stimulants before retiring, ensuring a comfortable sleeping environment, and retiring at a regular time each night. In some cases, however, the patient will need and should be given a sedative-hypnotic for a limited period. It should be noted that the abrupt discontinuance of many drugs in this class can lead to rebound insomnia.

Benzodiazepines can cause a dose-dependent decrease in both REM and slow-wave sleep, though to a lesser extent than the barbiturates. The newer hypnotics zolpidem, zaleplon, and eszopiclone are less likely than the benzodiazepines to change sleep patterns. However, so little is known about the clinical impact of these effects that statements about the desirability of a particular drug based on its effects on sleep architecture have more theoretical than practical significance. Clinical criteria of efficacy in alleviating a particular sleeping problem are more useful. The drug selected should be one that provides sleep of fairly rapid onset (decreased sleep latency) and sufficient duration, with minimal "hangover" effects such as drowsiness, dysphoria, and mental or motor depression the following day. Older drugs such as chloral hydrate, secobarbital, and pentobarbital continue to be used, but benzodiazepines, zolpidem, zaleplon, or eszopiclone are generally preferred. Daytime sedation is more common with benzodiazepines that have slow elimination rates (eg, lorazepam) and those that are biotransformed to active metabolites (eg, flurazepam, quazepam). If benzodiazepines are used nightly, tolerance can occur, which may lead to dose increases by the patient to produce the desired effect. Anterograde amnesia occurs to some degree with all benzodiazepines used for hypnosis.

Eszopiclone, zaleplon, and zolpidem have efficacies similar to those of the hypnotic benzodiazepines in the management of sleep disorders. Favorable clinical features of zolpidem and the other newer hypnotics include rapid onset of activity and modest day-after psychomotor depression with few amnestic effects. Zolpidem, currently the most frequently prescribed hypnotic drug in the United States, is available in a biphasic release formulation that provides sustained drug levels for sleep maintenance. Zaleplon acts rapidly, and because of its short half-life, the drug appears to have value in the management of patients who awaken early in the sleep cycle. At recommended doses, zaleplon and eszopiclone (despite its relatively long half-life) appear to cause less amnesia or day-after somnolence than zolpidem or benzodiazepines. The drugs commonly used for sedation and hypnosis are listed in Table 22–3 together with recommended doses. *Note:* Long-term use of hypnotics is an irrational and dangerous medical practice.

Table 22–3. Dosages of Drugs Used Commonly for Sedation and Hypnosis.

Sedation		Hypnosis	
Drug	Dosage	Drug	Dosage (at Bedtime)
Alprazolam (Xanax)	0.25–0.5 mg 2–3 times daily	Chloral hydrate	500–1000 mg
Buspirone (BuSpar)	5–10 mg 2–3 times daily	Estazolam (ProSom)	0.5–2 mg
Chlordiazepoxide (Librium)	10–20 mg 2–3 times daily	Eszopiclone (Lunesta)	1–3 mg
Clorazepate (Tranxene)	5–7.5 mg twice daily	Lorazepam (Ativan)	2–4 mg
Diazepam (Valium)	5 mg twice daily	Quazepam (Doral)	7.5–15 mg
Halazepam (Paxipam)	20–40 mg 3–4 times daily	Secobarbital	100–200 mg
Lorazepam (Ativan)	1–2 mg once or twice daily	Temazepam (Restoril)	7.5–30 mg
Oxazepam	15–30 mg 3–4 times daily	Triazolam (Halcion)	0.125–0.5 mg
Phenobarbital	15–30 mg 2–3 times daily	Zaleplon (Sonata)	5–20 mg
		Zolpidem (Ambien)	5–10 mg

OTHER THERAPEUTIC USES

Table 22–2 summarizes several other important clinical uses of drugs in the sedative-hypnotic class. Drugs used in the management of seizure disorders and as intravenous agents in anesthesia are discussed in Chapters 24 and 25.

For sedative and possible amnestic effects during medical or surgical procedures such as endoscopy and bronchoscopy—as well as for premedication prior to anesthesia—oral formulations of shorter-acting drugs are preferred.

Long-acting drugs such as chlordiazepoxide and diazepam and, to a lesser extent, phenobarbital are administered in progressively decreasing doses to patients during withdrawal from physiologic dependence on ethanol or other sedative-hypnotics. Parenteral lorazepam is used to suppress the symptoms of delirium tremens.

Meprobamate and, more recently, the benzodiazepines have frequently been used as central muscle relaxants, though evidence for general efficacy without accompanying sedation is lacking. A possible exception is diazepam, which has useful relaxant effects in skeletal muscle spasticity of central origin (see Chapter 27).

Psychiatric uses of benzodiazepines other than treatment of anxiety states include the initial management of mania, the control of drug-induced hyperexcitability states (eg, phencyclidine intoxication), and possibly the treatment of major depressive disorders with alprazolam. Sedative-hypnotics are also used occasionally as diagnostic aids in neurology and psychiatry.

CLINICAL TOXICOLOGY OF SEDATIVE-HYPNOTICS

Direct Toxic Actions

Many of the common adverse effects of sedative-hypnotics result from dose-related depression of the central nervous system. Relatively low doses may lead to drowsiness, impaired judgment, and diminished motor skills, sometimes with a significant impact on driving ability, job performance, and personal relationships. Benzodiazepines may cause a significant dose-related anterograde amnesia; they can significantly impair ability to learn new information, particularly that involving effortful cognitive processes, while leaving the retrieval of previously learned information intact. This effect is utilized for uncomfortable clinical procedures, eg, endoscopy, because the patient is able to cooperate during the procedure but amnesic regarding it afterward. The criminal use of benzodiazepines in cases of "date rape" is based on their dose-dependent amnestic effects. Hangover effects are not uncommon following use of hypnotic drugs with long elimination half-lives. Because elderly patients are more sensitive to the effects of sedative-hypnotics, doses approximately half of those used in younger adults are safer and usually as effective. The most common reversible cause of confusional states in the elderly is overuse of sedative-hypnotics. At higher doses, toxicity may present as lethargy or a state of exhaustion or, alternatively, as gross symptoms equivalent to those of ethanol intoxication. The physician should be aware of variability among patients in terms of doses causing adverse effects. An increased sensitivity to sedative-hypnotics is more common in patients with cardiovascular disease, respiratory disease, or hepatic impairment and in older patients. Sedative-hypnotics can exacerbate breathing problems in patients with chronic pulmonary disease and in those with symptomatic sleep apnea.

Sedative-hypnotics are the drugs most frequently involved in deliberate overdoses, in part because of their general availability as very commonly prescribed pharmacologic agents. The benzodiazepines are considered to be safer drugs in this respect, since they have flatter dose-response curves. Epidemiologic studies on the incidence of drug-related deaths support this general assumption—eg, 0.3 deaths per million tablets of diazepam prescribed versus 11.6 deaths per million capsules of secobarbital in one study. Alprazolam is purportedly more toxic in overdose than other benzodiazepines. Of course, many factors other than the specific sedative-hypnotic could influence such data—particularly the presence of other central nervous system depressants, including ethanol. In fact, most serious cases of drug overdosage, intentional or accidental, do involve polypharmacy; and when combinations of agents are taken, the practical safety of benzodiazepines may be less than the foregoing would imply.

The lethal dose of any sedative-hypnotic varies with the patient and the circumstances (see Chapter 59). If discovery of the ingestion is made early and a conservative treatment regimen is started, the outcome is rarely fatal, even following very high doses. On the other hand, for most sedative-hypnotics—with the exception of benzodiazepines and possibly the newer hypnotic drugs that have a similar mechanism of action—a dose as low as ten times the hypnotic dose may be fatal if the patient is not discovered or does not seek help in time. With severe toxicity, the respiratory depression from central actions of the drug may be complicated by aspiration of gastric contents in the unattended patient—an even more likely occurrence if ethanol is present. Cardiovascular depression further complicates successful resuscitation. In such patients, treatment consists of ensuring a patent airway, with mechanical ventilation if needed, and maintenance of plasma volume, renal output, and cardiac function. Use of a positive inotropic drug such as dopamine, which preserves renal blood flow, is sometimes indicated. Hemodialysis or hemoperfusion may be used to hasten elimination of some of these drugs.

Flumazenil reverses the sedative actions of benzodiazepines, and probably those of eszopiclone, zaleplon, and zolpidem, although experience with its use in overdose of the newer hypnotics is limited. However, its duration of action is short, its antagonism of respiratory depression is unpredictable, and there is a risk of precipitation of withdrawal symptoms in long-term users of benzodiazpines (see below). Consequently, the use of flumazenil in benzodiazepine overdose remains controversial and *must* be accompanied by adequate monitoring and support of respiratory function. The extensive clinical use of triazolam has led to reports of serious central nervous system effects including behavioral disinhibition, delirium, aggression, and violence. Although behavioral disinhibition may occur with sedative-hypnotic drugs, it does not appear to be more prevalent with triazolam than with other benzodiazepines. Disinhibitory reactions during benzodiazepine treatment are more clearly associated with the use of very high doses and the pretreatment level of patient hostility.

Adverse effects of the sedative-hypnotics that are not referable to their central nervous system actions occur infrequently. Hypersensitivity reactions, including skin rashes, occur only occasionally with most drugs of this class. Reports of teratogenicity leading to fetal deformation following use of piperidinediones and certain benzodiazepines justify caution in the use of these drugs during pregnancy. Because barbiturates enhance porphyrin synthesis, they are *absolutely contraindicated* in patients with a history of acute intermittent porphyria, variegate porphyria, hereditary coproporphyria, or symptomatic porphyria.

Alterations in Drug Response

Depending on the dosage and the duration of use, tolerance occurs in varying degrees to many of the pharmacologic effects of sedative-hypnotics. However, it should not be assumed that the degree of tolerance achieved is identical for all pharmacologic effects. There is evidence that the lethal dose range is not altered significantly by the long-term use of sedative-hypnotics. Cross-tolerance between the different sedative-hypnotics, including ethanol, can lead to an unsatisfactory therapeutic response when standard doses of a drug are used in a patient with a recent history of excessive use of these agents. However, there have been very few reports of tolerance development when eszopiclone, zolpidem, or zaleplon was used for less than 4 weeks.

With the long-term use of sedative-hypnotics, especially if doses are increased, a state of physiologic dependence can occur. This may develop to a degree unparalleled by any other drug group, *including the opioids.* Withdrawal from a sedative-hypnotic can have severe and life-threatening manifestations. Withdrawal symptoms range from restlessness, anxiety, weakness, and orthostatic hypotension to hyperactive reflexes and generalized seizures. Symptoms of withdrawal are usually more severe following discontinuance of sedative-hypnotics with shorter half-lives. However, eszopiclone, zolpidem, and zaleplon appear to be exceptions to this, because withdrawal symptoms are minimal following abrupt discontinuance of these newer short-acting agents. Symptoms are less pronounced with longer-acting drugs, which may partly accomplish their own "tapered" withdrawal by virtue of their slow elimination. Cross-dependence, defined as the ability of one drug to suppress abstinence symptoms from discontinuance of another drug, is quite marked among sedative-hypnotics. This provides the rationale for therapeutic regimens in the management of withdrawal states: Longer-acting drugs such as chlordiazepoxide, diazepam, and phenobarbital can be used to alleviate withdrawal symptoms of shorter-acting drugs, including ethanol.

Drug Interactions

The most common drug interactions involving sedative-hypnotics are interactions with other central nervous system depressant drugs, leading to additive effects. These interactions have some therapeutic usefulness when these drugs are used as adjuvants in anesthesia practice. However, if not anticipated, such interactions can lead to serious consequences, including enhanced depression with concomitant use of many other drugs. Additive effects can be predicted with concomitant use of alcoholic beverages, opioid analgesics, anticonvulsants, and phenothiazines. Less obvious but just as important is enhanced central nervous system depression with a variety of antihistamines, antihypertensive agents, and antidepressant drugs of the tricyclic class.

Interactions involving changes in the activity of hepatic drug-metabolizing enzyme systems have been discussed (see also Chapter 4 and Appendix II).

PREPARATIONS AVAILABLE

BENZODIAZEPINES

Alprazolam (generic, Xanax)

Oral: 0.25, 0.5, 1, 2 mg tablets, extended-release tablets, and orally disintegrating tablets; 1.0 mg/mL solution

Chlordiazepoxide (generic, Librium)

Oral: 5, 10, 25 mg capsules

Parenteral: 100 mg powder for injection

Clorazepate (generic, Tranxene)

Oral: 3.75, 7.5, 15 mg tablets and capsules

Oral sustained-release: 11.25, 22.5 mg tablets

Clonazepam (generic, Klonopin)

Oral: 0.5, 1, 2 mg tablets; 0.125, 0.25, 0.5, 1, 2 mg orally disintegrating tablets

Diazepam (generic, Valium)

Oral: 2, 5, 10 mg tablets; 1, 5 mg/mL solutions

Parenteral: 5 mg/mL for injection

Estazolam (generic, ProSom)

Oral: 1, 2 mg tablets

Flurazepam (generic, Dalmane)

Oral: 15, 30 mg capsules

Lorazepam (generic, Ativan)

Oral: 0.5, 1, 2 mg tablets; 2 mg/mL solution

Parenteral: 2, 4 mg/mL for injection

Midazolam (Versed)

Oral: 2 mg/mL syrup

Parenteral: 1, 5 mg/mL in 1, 2, 5, 10 mL vials for injection

Oxazepam (generic)

Oral: 10, 15, 30 mg capsules

Quazepam (Doral)

Oral: 7.5, 15 mg tablets

Temazepam (generic, Restoril)

Oral: 7.5, 15, 22.5, 30 mg capsules

Triazolam (generic, Halcion)

Oral: 0.125, 0.25 mg tablets

BENZODIAZEPINE ANTAGONIST

Flumazenil (Romazicon)

Parenteral: 0.1 mg/mL for IV injection

BARBITURATES

Amobarbital (Amytal)

Parenteral: powder in 250, 500 mg vials to reconstitute for injection

Mephobarbital (Mebaral)

Oral: 32, 50, 100 mg tablets

Pentobarbital (generic, Nembutal Sodium)

Oral: 50, 100 mg capsules; 4 mg/mL elixir

Rectal: 30, 60, 120, 200 mg suppositories

Parenteral: 50 mg/mL for injection

Phenobarbital (generic, Luminal Sodium)

Oral: 15, 16, 30, 60, 90, 100 mg tablets; 16 mg capsules; 15, 20 mg/5 mL elixirs

Parenteral: 30, 60, 65, 130 mg/mL for injection

Secobarbital (generic, Seconal)

Oral: 100 mg capsules

MISCELLANEOUS DRUGS

Buspirone (generic, BuSpar)

Oral: 5, 7.5, 10, 15, 30 mg tablets

Chloral hydrate (generic, Aquachloral Supprettes)

Oral: 500 mg capsules; 250, 500 mg/5 mL syrups

Rectal: 324, 648 mg suppositories

Eszopiclone (Lunesta)

Oral: 1, 2, 3 mg tablets

Hydroxyzine (generic, Atarax, Vistaril)

Oral: 10, 25, 50, 100 mg tablets; 25, 50, 100 mg capsules; 10 mg/5 mL syrup; 25 mg/5 mL suspension

Parenteral: 25, 50 mg/mL for injection

Meprobamate (generic, Equanil, Miltown)

Oral: 200, 400 mg tablets

Paraldehyde (generic)

Oral, rectal liquids: 1 g/mL

Ramelteon (Rozerem)

Oral: 8 mg tablets

Zaleplon (Sonata)

Oral: 5, 10 mg capsules

Zolpidem (Ambien, Ambien-CR)

Oral: 5, 10 mg tablets; 6.25, 12.5 mg extended-release tablets

Bottom of Form

Top of Form

THE ALCOHOLS: INTRODUCTION

Alcohol, primarily in the form of ethyl alcohol (ethanol), has occupied an important place in the history of humankind for at least 8000 years. In Western society, beer and wine were a main staple of daily life until the 19th century. These relatively dilute alcoholic beverages were preferred over water, which was known to be associated with acute and chronic illness. They provided important calories and nutrients and served as a main source of daily liquid intake. As systems for improved sanitation and water purification were introduced in the 1800s, beer and wine became less important components of the human diet, and the consumption of alcoholic beverages, including distilled preparations with higher concentrations of alcohol, shifted toward their present-day role, in many societies, as a socially acceptable form of recreation.

Today, alcohol is widely consumed. Like other sedative-hypnotic drugs, alcohol in low to moderate amounts relieves anxiety and fosters a feeling of well-being or even euphoria. However, alcohol is also the most commonly abused drug in the world, and a cause of vast medical and societal costs. In the United States, approximately 75% of the adult population drinks alcohol regularly. The majority of this drinking population are able to enjoy the pleasurable effects of alcohol without allowing their alcohol consumption to become a health risk. However, about 10% of the general population in the United States are unable to limit their ethanol consumption, a condition known as alcohol abuse. People who continue to drink alcohol in spite of adverse medical or social consequences related directly to their alcohol consumption suffer from alcoholism, a complex disorder that appears to have genetic as well as environmental determinants.

The societal and medical costs of alcohol abuse are staggering. It is estimated that about 30% of all people admitted to hospitals have coexisting alcohol problems. Once in the hospital, people with chronic alcoholism generally have poorer outcomes. In addition, each year thousands of children are born in the USA with morphologic and functional defects resulting from prenatal exposure to ethanol. Despite the investment of many resources and much basic research, alcoholism remains a common chronic disease that is difficult to treat.

Ethanol and many other alcohols with potentially toxic effects are used in industry, some in enormous quantities. In addition to ethanol, methanol and ethylene glycol toxicity occur with sufficient frequency to warrant discussion in this chapter.

BASIC PHARMACOLOGY OF ETHANOL

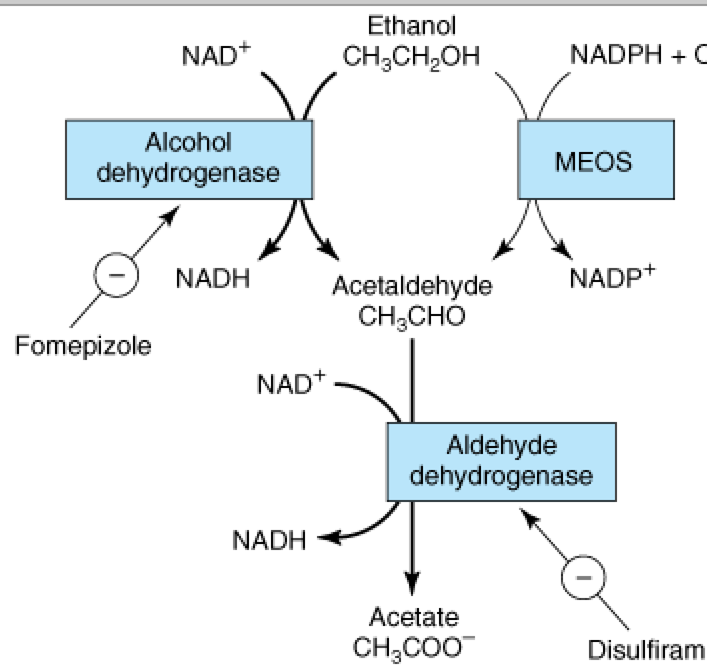
Pharmacokinetics

Ethanol is a small water-soluble molecule that is absorbed rapidly from the gastrointestinal tract. After ingestion of alcohol in the fasting state, peak blood alcohol concentrations are reached within 30 minutes. The presence of food in the gut delays absorption by slowing gastric emptying. Distribution is rapid, with tissue levels approximating the concentration in blood. The volume of distribution for ethanol approximates total body water (0.5–0.7 L/kg). For an equivalent oral dose of alcohol, women have a higher peak concentration than men, in part because women have a lower total body water content. In the central nervous system, the concentration of ethanol rises quickly since the brain receives a large proportion of total blood flow and ethanol readily crosses biologic membranes.

Over 90% of alcohol consumed is oxidized in the liver; much of the remainder is excreted through the lungs and in the urine. The excretion of a small but consistent proportion of alcohol by the lungs is utilized for breath alcohol tests that serve as a basis for a legal definition of "driving under the influence" in many countries. At levels of ethanol usually achieved in blood, the rate of oxidation follows zero-order kinetics; that is, it is independent of time and concentration of the drug. The typical adult can metabolize 7–10 g (150–220 mmol) of alcohol per hour, the equivalent of approximately one "drink" (10 oz of beer, 3.5 oz of wine, or 1 oz of distilled 80 proof spirits).

Two major pathways of alcohol metabolism to acetaldehyde have been identified (Figure 23–1). Acetaldehyde is then oxidized by a third metabolic process.

Figure 23–1.



Metabolism of ethanol by alcohol dehydrogenase and the microsomal ethanol-oxidizing system (MEOS). Alcohol dehydrogenase and aldehyde dehydrogenase are inhibited by fomepizole and disulfiram, respectively.

ALCOHOL DEHYDROGENASE PATHWAY

The primary pathway for alcohol metabolism involves alcohol dehydrogenase (ADH), a cytosolic enzyme that catalyzes the conversion of alcohol to acetaldehyde (Figure 23–1, left). This enzyme is located mainly in the liver, but it is also found in other organs such as the brain and stomach. In some Asian populations with polymorphisms in ADH that affect enzyme activity, a form of ADH with reduced activity is associated with an increased risk of alcoholism.

A significant amount of ethanol metabolism by gastric ADH occurs in the stomach in men, but a smaller amount occurs in women, who appear to have lower levels of the gastric enzyme. This difference in gastric metabolism of alcohol in women probably contributes to the sex-related differences in blood alcohol concentrations noted above.

During conversion of ethanol to acetaldehyde, hydrogen ion is transferred from alcohol to the cofactor nicotinamide adenine dinucleotide (NAD^+) to form NADH. As a net result, alcohol oxidation generates an excess of reducing equivalents in the liver, chiefly as NADH. The excess NADH production appears to contribute to a number of metabolic disorders that accompany chronic alcoholism.

MICROSOMAL ETHANOL OXIDIZING SYSTEM (MEOS)

This enzyme system, also known as the mixed function oxidase system, uses NADPH as a cofactor in the metabolism of ethanol (Figure 23–1, right) and consists primarily of cytochrome P450 2E1, 1A2, and 3A4 (see Chapter 4).

At blood concentrations below 100 mg/dL (22 mmol/L), the MEOS system, which has a relatively high K_m for alcohol, contributes little to the metabolism of ethanol. However, when large amounts of ethanol are consumed, the alcohol dehydrogenase system becomes saturated owing to depletion of the required cofactor, NAD^+. As the concentration of ethanol increases above 100 mg/dL, there is increased contribution from the MEOS system, which does not rely upon NAD^+ as a cofactor.

During chronic alcohol consumption, MEOS activity is induced. As a result, chronic alcohol consumption results in significant increases not only in ethanol metabolism but also in the clearance of other drugs eliminated by the cytochrome P450s that constitute the MEOS system and the generation of the toxic byproducts of cytochrome P450 reactions (toxins, free radicals, H_2O_2).

ACETALDEHYDE METABOLISM

Much of the acetaldehyde formed from alcohol appears to be oxidized in the liver in a reaction catalyzed by mitochondrial NAD-dependent aldehyde dehydrogenase (ALDH). The product of this reaction is acetate (Figure 23–1), which can be further metabolized to CO_2 and water.

Oxidation of acetaldehyde is inhibited by disulfiram, a drug that has been used to deter drinking by alcohol-dependent patients undergoing treatment. When ethanol is consumed in the presence of disulfiram, acetaldehyde accumulates and causes an unpleasant reaction of facial flushing, nausea, vomiting, dizziness, and headache. Several other drugs (eg, metronidazole, cefotetan, trimethoprim) inhibit ALDH and can cause a disulfiram-like reaction if combined with ethanol.

Some people, primarily of Asian descent, have a genetic deficiency in the activity of the mitochondrial form of ALDH. When these individuals drink alcohol, they develop high blood acetaldehyde concentrations and experience a flushing reaction similar to that seen with the combination of disulfiram and ethanol. Although the presence of the form of ALDH with reduced activity appears to protect against alcoholism, its presence in alcoholics is associated with increased risk of severe liver disease, presumably owing to the toxic effects of aldehyde.

Pharmacodynamics of Acute Ethanol Consumption

CENTRAL NERVOUS SYSTEM

The central nervous system (CNS) is markedly affected by acute alcohol consumption. Alcohol causes sedation and relief of anxiety and, at higher concentrations, slurred speech, ataxia, impaired judgment, and disinhibited behavior, a condition usually called intoxication or drunkenness (Table

23–1). These CNS effects are most marked as the blood level is rising, because acute tolerance to the effects of alcohol occurs after a few hours of drinking. For chronic drinkers who are tolerant to the effects of alcohol, much higher concentrations are needed to elicit these central nervous system effects. For example, a chronic alcoholic may appear sober or only slightly intoxicated with a blood alcohol concentration of 300–400 mg/dL, whereas this level is associated with marked intoxication or even coma in a nontolerant individual. The propensity of moderate doses of alcohol to inhibit the attention and information-processing skills as well as the motor skills required for operation of motor vehicles has profound effects. Approximately half of all traffic accidents resulting in a fatality in the United States involve at least one person with blood alcohol near or above the legal level of intoxication, and drunken driving is a leading cause of death in young adults.

Table 23–1. Blood Alcohol Concentration (BAC) and Clinical Effects in Nontolerant Individuals.

BAC (mg/dL)[1]	Clinical Effect
50–100	Sedation, subjective "high," slower reaction times
100–200	Impaired motor function, slurred speech, ataxia
200–300	Emesis, stupor
300–400	Coma
> 500	Respiratory depression, death

[1] In many parts of the USA, a blood level above 80–100 mg/dL for adults or 10 mg/dL for persons under 21 is sufficient for conviction of driving while "under the influence."

Like other sedative-hypnotic drugs, alcohol is a central nervous system depressant. At high blood concentrations, it induces coma, respiratory depression, and death.

Ethanol affects a large number of membrane proteins that participate in signaling pathways, including neurotransmitter receptors for amines, amino acids, and opioids; enzymes such as Na^+/K^+ ATPase, adenylyl cyclase, phosphoinositide-specific phospholipase C, and ion channels. Much attention has focused on alcohol's effects on neurotransmission by glutamate and GABA, the main excitatory and inhibitory neurotransmitters in the CNS. Acute ethanol exposure enhances the action of GABA at $GABA_A$ receptors, which is consistent with the ability of GABA-mimetics to intensify many of the acute effects of alcohol and of $GABA_A$ antagonists to attenuate some of the actions of ethanol. Ethanol inhibits the ability of glutamate to open the cation channel associated with the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors. The NMDA receptor is implicated in many aspects of cognitive function, including learning and memory. "Blackouts"—periods of memory loss that occur with high levels of alcohol—may result from inhibition of NMDA receptor activation. Experiments that use modern genetic approaches eventually will yield a more precise definition of ethanol's direct and indirect targets. In recent years, experiments with mutant strains of worms and flies have focused attention on several key genes, including a calcium-regulated and voltage-gated potassium channel that may be one of ethanol's direct targets (see What Can Drunken Worms, Flies, and Mice Tell Us About Alcohol?).

What Can Drunken Worms, Flies, and Mice Tell Us About Alcohol?

For a drug like ethanol, which exhibits low potency and specificity and modifies complex behaviors, the identification of direct molecular targets is difficult and has thus far proved elusive. Increasingly, ethanol researchers are employing genetic approaches to complement standard neurobiologic experimentation. Three experimental animal systems for which powerful genetic techniques exist—mice, flies, and worms—have yielded intriguing results.

Strains of mice with abnormal sensitivity to ethanol were identified many years ago by breeding and selection programs. Using sophisticated genetic mapping and sequencing techniques, researchers have made progress in identifying the genes that confer these traits. A more targeted approach is the use of transgenic mice to test hypotheses about specific genes. For example, after earlier experiments suggested a link between brain neuropeptide Y (NPY) and ethanol, researchers used two transgenic mouse models to further investigate the link. They found that a strain of mice that lacks the gene for NPY—NPY knockout mice—consume more ethanol than control mice and are less sensitive to ethanol's sedative effects. As would be expected if increased concentrations of NPY in the brain make mice more sensitive to ethanol, a strain of mice that overexpresses NPY drinks less alcohol than the controls even though their total consumption of food and liquid is normal. Work with other transgenic knockout mice have also implicated the dopamine D_2 and D_4 receptors and a subtype of protein kinase C with altered sensitivity to ethanol.

It is easy to imagine mice having measurable behavioral responses to alcohol but drunken worms and fruit flies are harder to imagine. Actually, both invertebrates respond to ethanol in ways that parallel mammalian responses. *Drosophila melanogaster* fruit flies that are exposed to ethanol vapor show increased locomotion at low concentrations but at higher concentrations, become poorly coordinated, sedated, and finally immobile. The behaviors can be monitored by sophisticated laser or video tracking methods or with an ingenious "chromatography" column that separates relatively insensitive flies from inebriated flies that drop to the bottom of the column. The worm *Caenorhabditis elegans* similarly exhibits increased locomotion at low ethanol concentrations and, at higher concentrations, reduced locomotion, sedation, and—something that can be turned into an effective screen for mutant worms that are resistant to ethanol—impaired egg laying. The advantage of using flies and worms as genetic models for ethanol research is their relatively simple neuroanatomy, well-established techniques for genetic manipulation, an extensive library of well-characterized mutants, and completely or nearly completely solved genetic code. Already, much information has accumulated about candidate proteins involved with the effects of ethanol in flies. In an elegant study on *C elegans*, researchers found evidence that a calcium-activated, voltage-gated BK potassium channel is a direct target of ethanol. This channel, which is activated by ethanol, has close homologs in flies and vertebrates, and evidence is accumulating that ethanol has similar effects in these homologs. Genetic experiments in these model systems should provide information that will help narrow and focus research into the complex and important effects of ethanol in humans.

HEART

Significant depression of myocardial contractility has been observed in individuals who acutely consume moderate amounts of alcohol, ie, at a blood concentration above 100 mg/dL.

SMOOTH MUSCLE

Ethanol is a vasodilator, probably as a result of both central nervous system effects (depression of the vasomotor center) and direct smooth muscle relaxation caused by its metabolite, acetaldehyde. In cases of severe overdose, hypothermia—caused by vasodilation—may be marked in cold environments. Ethanol also relaxes the uterus and—before the introduction of more effective and safer uterine relaxants (eg, calcium blockers, magnesium ion, and β_2-adrenoceptor stimulants)—was used intravenously for the suppression of premature labor.

Consequences of Chronic Alcohol Consumption

Chronic alcohol consumption profoundly affects the function of several vital organs—particularly the liver and skeletal muscle—and the nervous, gastrointestinal, cardiovascular, and immune systems. Since ethanol has low potency, it requires concentrations thousands of times higher than other misused drugs (eg, cocaine, opiates, amphetamines) to produce its intoxicating effects. As a result, ethanol is consumed in quantities that are unusually large for a pharmacologically active drug. The tissue damage caused by chronic alcohol ingestion results from a combination of the direct effects of ethanol and the metabolic consequences of processing a heavy load of a metabolically active substance. Specific mechanisms implicated in tissue damage include increased oxidative stress coupled with depletion of glutathione, damage to mitochondria, growth factor dysregulation, and potentiation of cytokine-induced injury.

Chronic consumption of large amounts of alcohol is associated with an increased risk of death. Deaths linked to alcohol consumption are caused by liver disease, cancer, accidents, and suicide.

LIVER AND GASTROINTESTINAL TRACT

Liver disease is the most common medical complication of alcohol abuse; an estimated 15–30% of chronic heavy drinkers eventually develop severe liver disease. Alcoholic fatty liver, a reversible condition, may progress to alcoholic hepatitis and finally to cirrhosis and liver failure. In the USA, chronic alcohol abuse is the leading cause of liver cirrhosis and of the need for liver transplantation. The risk of developing liver disease is related both to the average amount of daily consumption and to the duration of alcohol abuse. Women appear to be more susceptible to alcohol hepatotoxicity than men. Concurrent infection with hepatitis B or C virus increases the risk of severe liver disease.

The pathogenesis of alcoholic liver disease is a multifactorial process involving metabolic repercussions of ethanol oxidation in the liver, dysregulation of fatty acid oxidation and synthesis, and activation of the innate immune system by a combination of direct effects of ethanol and its metabolites and by bacterial endotoxins that access the liver as a result of ethanol-induced changes in the intestinal tract. Tumor necrosis factor-α, a pro-inflammatory cytokine that is consistently elevated in animal models of alcoholic liver disease and in patients with alcoholic liver disease, appears to play a pivotal role in the progression of alcoholic liver disease and may be a fruitful therapeutic target.

Other portions of the gastrointestinal tract can also be injured. Chronic alcohol ingestion is by far the most common cause of chronic pancreatitis in the Western world. In addition to its direct toxic effect on pancreatic acinar cells, alcohol alters pancreatic epithelial permeability and promotes the formation of protein plugs and calcium carbonate-containing stones.

Chronic alcoholics are prone to gastritis and have increased susceptibility to blood and plasma protein loss during drinking, which may contribute to anemia and protein malnutrition. Alcohol also reversibly injures the small intestine, leading to diarrhea, weight loss, and multiple vitamin deficiencies.

Malnutrition from dietary deficiency and vitamin deficiencies due to malabsorption are common in alcoholic individuals. Malabsorption of water-soluble vitamins is especially severe.

NERVOUS SYSTEM

Tolerance and Physical Dependence

The consumption of alcohol in high doses over a long period results in tolerance and in physical and psychologic dependence. Tolerance to the intoxicating effects of alcohol is a complex process involving poorly understood changes in the nervous system as well as the metabolic changes described earlier. As with other sedative-hypnotic drugs, there is a limit to tolerance, so that only a relatively small increase in the lethal dose occurs with increasing alcohol use.

Chronic alcohol drinkers, when forced to reduce or discontinue alcohol, experience a withdrawal syndrome, which indicates the existence of physical dependence. Alcohol withdrawal symptoms classically consist of hyperexcitability in mild cases and seizures, toxic psychosis, and *delirium tremens* in severe ones. The dose, rate, and duration of alcohol consumption determine the intensity of the withdrawal syndrome. When consumption has been very high, merely reducing the rate of consumption may lead to signs of withdrawal.

Psychologic dependence upon alcohol is characterized by a compulsive desire to experience the rewarding effects of alcohol and, for current drinkers, a desire to avoid the negative consequences of withdrawal. People who have recovered from alcoholism and become abstinent still experience periods of intense craving for alcohol that can be set off by environmental cues associated in the past with drinking, such as familiar places, groups of people, or events.

The molecular basis of alcohol tolerance and dependence is not known, nor is it known if the two phenomena reflect opposing effects upon a shared molecular pathway. Tolerance may result from ethanol-induced up-regulation of a pathway in response to the continuous presence of ethanol. Dependence may result from overactivity of that same pathway after the ethanol effect dissipates and before the system has time to return to a normal ethanol-free state. Chronic exposure of animals or cultured cells to alcohol elicits a multitude of adaptive responses involving neurotransmitters and their receptors, ion channels, and enzymes that participate in signal transduction pathways. Up-regulation of the NMDA subtype of glutamate receptors and voltage-sensitive Ca^{2+} channels may underlie the seizures that accompany the alcohol withdrawal syndrome. Based on the ability of sedative-hypnotic drugs that enhance GABAergic neurotransmission to substitute for alcohol during alcohol withdrawal and evidence of down-regulation of $GABA_A$-mediated responses with chronic alcohol exposure, changes in GABA neurotransmission are believed to play a central role in tolerance and withdrawal.

Neurotransmission events involved in the sensation of reward are also important. Alcohol affects local concentrations of serotonin, opioids, and dopamine—neurotransmitters involved in brain reward circuits (see Chapter 32). Alcohol also has complex effects on the expression of receptors for these neurotransmitters and their signaling pathways. The discovery that naltrexone, a nonselective opioid receptor antagonist, helps patients who are recovering from alcoholism abstain from drinking supports the idea that a common neurochemical reward system is shared by very different drugs associated with physical and psychological dependence.

Neurotoxicity

Consumption of large amounts of alcohol over extended periods (usually years) often leads to neurologic deficits. The most common neurologic abnormality in chronic alcoholism is generalized symmetric peripheral nerve injury, which begins with distal paresthesias of the hands and feet. Chronic alcoholics may also exhibit gait disturbances and ataxia that are due to degenerative changes in the central nervous system. Other neurologic disturbances associated with alcoholism include dementia and, rarely, demyelinating disease.

Wernicke-Korsakoff syndrome is a relatively uncommon but important entity characterized by paralysis of the external eye muscles, ataxia, and a confused state that can progress to coma and death. It is associated with thiamin deficiency but is rarely seen in the absence of alcoholism. Because of the importance of thiamin in this pathologic condition and the absence of toxicity associated with thiamine administration, all patients suspected of having Wernicke-Korsakoff syndrome (including virtually all patients who present to the emergency department with altered consciousness, seizures, or both) should receive thiamine therapy. Often, the ocular signs, ataxia, and confusion improve promptly upon administration of thiamine. However, most patients are left with a chronic disabling memory disorder known as Korsakoff's psychosis.

Alcohol may also impair visual acuity, with painless blurring that occurs over several weeks of heavy alcohol consumption. Changes are usually bilateral and symmetric and may be followed by optic nerve degeneration. Ingestion of ethanol substitutes such as methanol (see Pharmacology of Other Alcohols) causes severe visual disturbances.

CARDIOVASCULAR SYSTEM

Cardiomyopathy and Heart Failure

Alcohol has complex effects on the cardiovascular system. Heavy alcohol consumption of long duration is associated with a dilated cardiomyopathy with ventricular hypertrophy and fibrosis. In animals and humans, alcohol induces a number of changes in heart cells that may contribute to cardiomyopathy. They include membrane disruption, depressed function of mitochondria and sarcoplasmic reticulum, intracellular accumulation of phospholipids and fatty acids, and up-regulation of voltage-dependent calcium channels. There is evidence that patients with alcohol-induced dilated cardiomyopathy do significantly worse than patients with idiopathic dilated cardiomyopathy, even though cessation of drinking is associated with a reduction in cardiac size and improved function. The poorer prognosis for patients who continue to drink appears to be due in part to interference by ethanol with the beneficial effects of β-blockers and ACE inhibitors.

Arrhythmias

Heavy drinking—and especially "binge" drinking—are associated with both atrial and ventricular arrhythmias. Patients undergoing alcohol withdrawal syndrome can develop severe arrhythmias that may reflect abnormalities of potassium or magnesium metabolism as well as enhanced release of catecholamines. Seizures, syncope, and sudden death during alcohol withdrawal may be due to these arrhythmias.

Hypertension

A link between heavier alcohol consumption (more than three drinks per day) and hypertension has been firmly established in epidemiologic studies. Alcohol is estimated to be responsible for approximately 5% of cases of hypertension, making it one of the most common causes of reversible hypertension. This association is independent of obesity, salt intake, coffee drinking, and cigarette smoking. A reduction in alcohol intake appears to be effective in lowering blood pressure in hypertensives who are also heavy drinkers; the hypertension seen in this population is also responsive to standard blood pressure medications.

Coronary Heart Disease

Although the deleterious effects of excessive alcohol use on the cardiovascular system are well established, there is controversy over the effects of moderate drinking (one to three drinks per day) on the incidence of coronary heart disease (CHD). A number of observational studies concluded that moderate alcohol consumption actually prevents CHD and even reduces mortality. This type of relationship between mortality and the dose of a drug is called a "J-shaped" relationship. Results of these clinical studies are supported by ethanol's ability to raise serum levels of high-density lipoprotein (HDL) cholesterol (the form of cholesterol that appears to protect against atherosclerosis; see Chapter 35), its ability to inhibit some of the inflammatory processes that underlie atherosclerosis, and the presence in alcoholic beverages (especially red wine) of antioxidants and other substances that may protect against atherosclerosis. More recently, the relationship between moderate drinking and CHD has been called into question based on further investigation of confounders that affected the outcome of earlier epidemiologic studies. For example, moderate drinkers, especially wine drinkers, come from a higher socioeconomic level and may have healthier dietary habits; consumption tends to decrease with age; abstinence often is associated with ill health; and documenting precise amounts of consumption is difficult. Therefore, definitive conclusions regarding a cardioprotective effect of alcohol must await better clinical evidence.

BLOOD

Alcohol indirectly affects hematopoiesis through metabolic and nutritional effects and may also directly inhibit the proliferation of all cellular elements in bone marrow. The most common hematologic disorder seen in chronic drinkers is mild anemia resulting from alcohol-related folic acid deficiency. Iron deficiency anemia may result from gastrointestinal bleeding. Alcohol has also been implicated as a cause of several hemolytic syndromes, some of which are associated with hyperlipidemia and severe liver disease.

ENDOCRINE SYSTEM AND ELECTROLYTE BALANCE

Chronic alcohol use has important effects on the endocrine system and on fluid and electrolyte balance. Clinical reports of gynecomastia and testicular atrophy in alcoholics with or without cirrhosis suggest a derangement in steroid hormone balance.

Alcoholics with chronic liver disease may have disorders of fluid and electrolyte balance, including ascites, edema, and effusions. Alterations of whole body potassium induced by vomiting and diarrhea, as well as severe secondary aldosteronism, may contribute to muscle weakness and can be worsened by diuretic therapy. Some alcoholic patients develop hypoglycemia, probably as a result of impaired hepatic gluconeogenesis. Some alcoholics also develop ketosis, caused by excessive lipolytic factors, especially increased cortisol and growth hormone.

FETAL ALCOHOL SYNDROME

Chronic maternal alcohol abuse during pregnancy is associated with teratogenic effects, and alcohol appears to be a leading cause of mental retardation and congenital malformation. The abnormalities that have been characterized as fetal alcohol syndrome include (1) intrauterine growth retardation, (2) microcephaly, (3) poor coordination, (4) underdevelopment of midfacial region (appearing as a flattened face), and (5) minor joint anomalies. More severe cases may include congenital heart defects and mental retardation. While the level of alcohol intake required for causing serious neurologic deficits appears quite high, the threshold for causing more subtle neurologic deficits is uncertain.

The mechanisms that underlie ethanol's teratogenic effects are unknown. Ethanol rapidly crosses the placenta and reaches concentrations in the fetus that are similar to those in maternal blood. The fetal liver has little or no alcohol dehydrogenase activity, so the fetus must rely on maternal and placental enzymes for elimination of alcohol.

The neuropathologic abnormalities seen in humans and in animal models of fetal alcohol syndrome indicate that ethanol triggers apoptotic neurodegeneration and also causes aberrant neuronal and glial migration in the developing nervous system. In tissue culture systems, ethanol causes a striking reduction in neurite outgrowth.

IMMUNE SYSTEM

The effects of alcohol on the immune system are complex; immune function in some tissues is inhibited (eg, the lung), whereas pathologic, hyperactive immune function in other tissues is triggered (eg, liver, pancreas). In addition, acute and chronic exposure to alcohol have widely different effects on immune function. The types of immunologic changes reported for the lung include suppression of the function of alveolar macrophages, inhibition of chemotaxis of granulocytes, and reduced number and function of T cells. In the liver, there is enhanced function of key cells of the innate immune system (eg, Kupffer cells, hepatic stellate cells) and increased cytokine production. In addition to the inflammatory damage that chronic heavy alcohol use precipitates in the liver and pancreas, it predisposes to the development of infections, especially of the lung, and worsens the morbidity and increases the mortality risk of patients with pneumonia.

INCREASED RISK OF CANCER

Chronic alcohol use increases the risk for cancer of the mouth, pharynx, larynx, esophagus, and liver. Evidence also points to a small increase in the risk of breast cancer in women. Much more information is required before a threshold level for alcohol consumption as it relates to cancer can be established. Alcohol itself does not appear to be a carcinogen in most test systems. However, its primary metabolite, acetaldehyde, can damage DNA, as can the reactive oxygen species produced by increased cytochrome P450 activity. Other factors implicated in the link between alcohol and cancer include changes in folate metabolism and the growth-promoting effects of chronic inflammation.

Alcohol-Drug Interactions

Interactions between ethanol and other drugs can have important clinical effects that result from alterations in the pharmacokinetics or pharmacodynamics of the second drug.

The most frequent pharmacokinetic alcohol-drug interactions occur as a result of alcohol-induced increases of drug-metabolizing enzymes, as described in Chapter 4. Thus, prolonged intake of alcohol without damage to the liver may enhance the metabolic biotransformation of other drugs. Ethanol-mediated induction of hepatic cytochrome P450 enzymes is particularly important with regard to acetaminophen. Chronic consumption at the level of three or more drinks per day increases the risk of hepatotoxicity due to toxic or even high therapeutic levels of acetaminophen. This is probably due to increased P450-mediated conversion of acetaminophen to reactive hepatotoxic metabolites (see Figure 4–4). In 1998, the FDA announced that all OTC products containing acetaminophen must carry a warning about the relationship between chronic ethanol consumption and acetaminophen-induced hepatotoxicity.

In contrast, *acute* alcohol use may inhibit metabolism of other drugs. This inhibition may be due to decreased enzyme activity or decreased liver blood flow. Phenothiazines, tricyclic antidepressants, and sedative-hypnotic drugs are the most important drugs that may interact with alcohol by this pharmacokinetic mechanism.

Pharmacodynamic alcohol interactions are also of great clinical significance. Additive central nervous system depression with other central nervous system depressants, particularly sedative-hypnotics, is most important. Alcohol also potentiates the pharmacologic effects of many nonsedative drugs, including vasodilators and oral hypoglycemic agents.

CLINICAL PHARMACOLOGY OF ETHANOL

Ethanol is the cause of more preventable morbidity and mortality than all other drugs combined with the exception of tobacco. The search for specific etiologic factors or the identification of significant predisposing variables for alcohol abuse has generally led to disappointing results. Personality type, severe life stresses, psychiatric disorders, and parental role models are not reliable predictors of alcohol abuse. Although environmental factors clearly play a role, evidence suggests that there is a large genetic contribution to the development of alcoholism. Not surprisingly, polymorphisms in alcohol dehydrogenase and aldehyde dehydrogenase that lead to increased aldehyde accumulation (and therefore more severe hangover symptoms) appear to protect against alcoholism. Much attention in genetic mapping experiments has focused on membrane-signaling proteins known to be affected by ethanol and on protein constituents of reward pathways in the brain. Early reports of an association of an allele of the dopamine D_2 receptor with alcohol dependence have not been confirmed. Other candidate genes for susceptibility to alcoholism identified in genome-wide screens in humans include the dopamine D_4 receptor, the β_1 subunit of the $GABA_A$ receptor, and tyrosine hydroxylase, an enzyme involved in the synthesis of dopamine, norepinephrine, and epinephrine (see Chapter 6).

MANAGEMENT OF ACUTE ALCOHOL INTOXICATION

Nontolerant individuals who consume alcohol in large quantities develop typical effects of acute sedative-hypnotic drug overdose along with the cardiovascular effects described above (vasodilation, tachycardia) and gastrointestinal irritation. Since tolerance is not absolute, even chronic alcoholics may become severely intoxicated if sufficient alcohol is consumed.

The most important goals in the treatment of acute alcohol intoxication are to prevent severe respiratory depression and to prevent aspiration of vomitus. Even with very high blood ethanol levels, survival is probable as long as the respiratory and cardiovascular systems can be supported. The average blood alcohol concentration in fatal cases is above 400 mg/dL; however, the lethal dose of alcohol varies because of varying degrees of tolerance.

Metabolic alterations may require treatment of hypoglycemia and ketosis by administration of glucose. Thiamine is given to protect against the Wernicke-Korsakoff syndrome. Alcoholic patients who are dehydrated and vomiting should also receive electrolyte solutions. If vomiting is severe, large amounts of potassium may be required as long as renal function is normal. Especially important is recognition of decreased serum concentrations of phosphate, which may be aggravated by glucose administration.

MANAGEMENT OF ALCOHOL WITHDRAWAL SYNDROME

Abrupt alcohol withdrawal leads to a characteristic syndrome of motor agitation, anxiety, insomnia, and reduction of seizure threshold. The severity of the syndrome is usually proportionate to the degree and duration of alcohol abuse. However, this can be greatly modified by the use of other sedatives as well as by associated factors (eg, diabetes, injury). In its mildest form, the alcohol withdrawal syndrome of tremor, anxiety, and insomnia occurs 6–8 hours after alcohol consumption is stopped. These effects usually abate in 1–2 days. In some patients, more severe withdrawal reactions occur in which visual hallucinations, total disorientation, and marked abnormalities of vital signs occur. Alcohol withdrawal is one of the most common causes of seizures in adults.

The major objective of drug therapy in the alcohol withdrawal period is prevention of seizures, delirium, and arrhythmias. Potassium, magnesium, and phosphate balance should be restored as rapidly as is consistent with renal function. Thiamine therapy is initiated in all cases. Persons in mild alcohol withdrawal do not need any other pharmacologic assistance.

Specific drug treatment for detoxification in severe cases involves two basic principles: substituting a long-acting sedative-hypnotic drug for alcohol and then gradually reducing ("tapering") the dose of the long-acting drug. Because of their wide margin of safety, benzodiazepines are preferred, though barbiturates such as phenobarbital were used in the past. Since any benzodiazepine will prevent symptoms of alcohol withdrawal, the choice of a specific agent in this class is generally based on pharmacokinetic or economic considerations. Long-acting benzodiazepines, including chlordiazepoxide, clorazepate, and diazepam, have the advantage of requiring less frequent dosing. Since their pharmacologically active metabolites are eliminated slowly, the long-acting drugs provide a built-in tapering effect. A disadvantage of the long-acting drugs is that they and their pharmacologically active metabolites may accumulate, especially in patients with compromised liver function. Short-acting drugs such as lorazepam and oxazepam are rapidly converted to inactive water-soluble metabolites that will not accumulate, and for this reason the short-acting drugs are especially useful in alcoholic patients with liver disease. Benzodiazepines can be administered orally in mild or moderate cases, or parenterally for patients with more severe withdrawal reactions.

After the alcohol withdrawal syndrome has been treated acutely, sedative-hypnotic medications must be tapered slowly over several weeks. Complete detoxification is not achieved with just a few days of alcohol abstinence. Several months may be required for restoration of normal nervous system function, especially sleep.

TREATMENT OF ALCOHOLISM

Following detoxification, psychosocial therapy either in intensive inpatient or in outpatient rehabilitation programs serves as the primary treatment for alcohol dependence. Other psychiatric problems, most commonly depressive or anxiety disorders, often coexist with alcoholism and, if untreated, can contribute to the tendency of detoxified alcoholics to relapse. Treatment of these associated disorders with counseling and drugs can help decrease the rate of relapse for alcoholic patients.

Three drugs—disulfiram, naltrexone, and acamprosate—have FDA approval for adjunctive treatment of alcohol dependence.

Naltrexone

Naltrexone is an orally active opioid receptor antagonist that blocks the effects at μ-opioid receptors of exogenous and endogenous opioids (see Chapter 31). Studies in experimental animals first suggested a link between alcohol consumption and opioids. Injection of small amounts of opioids was followed by an increase in alcohol drinking, whereas administration of opioid antagonists inhibited self-administration of alcohol.

Naltrexone, a relatively long-acting oral opioid antagonist, has been shown in a number of short–term (12-week) placebo-controlled trials to reduce craving for alcohol and to reduce the rate of relapse to either drinking or alcohol dependence. Longer trials (6–12 months) have failed to show evidence to support long-term treatment. Naltrexone was approved in 1994 by the FDA for treatment of alcohol dependence.

Naltrexone is taken once a day in a dose of 50 mg for treatment of alcoholism. The drug should be used with caution in alcoholic patients with evidence of mild abnormalities in serum aminotransferase activity. The combination of naltrexone plus disulfiram should be avoided since both drugs are potential hepatotoxins. Administration of naltrexone to patients who are physically dependent on opioids will precipitate an acute withdrawal syndrome, so patients must be opioid-free before initiating naltrexone therapy. Naltrexone also blocks the therapeutic effects of usual doses of opioids.

Acamprosate

Acamprosate has been used in Europe for a number of years to treat alcohol dependence and was approved for this use by the FDA in 2004. Like ethanol itself, acamprosate has many molecular effects including effects on GABA, glutamate, serotonergic, noradrenergic, and dopaminergic effects. Probably its best characterized actions are as a weak NMDA-receptor antagonist and a $GABA_A$-receptor activator. In clinical trials, acamprosate reduces short-term and long-term (more than 6 months) relapse rates when combined with psychotherapy.

Acamprosate is administered as 1–2 enteric-coated 333-mg tablets three times per day. It is poorly absorbed, and food reduces its absorption even further. Acamprosate is widely distributed and is eliminated renally. It does not participate in drug-drug interactions. The most common adverse effects are gastrointestinal (nausea, vomiting, diarrhea) and rash. It is contraindicated in patients with severe renal impairment.

Disulfiram

Disulfiram causes extreme discomfort in patients who drink alcoholic beverages. Disulfiram given by itself to nondrinkers has little effect; however, flushing, throbbing headache, nausea, vomiting, sweating, hypotension, and confusion occur within a few minutes after drinking alcohol. The effect may last 30 minutes in mild cases or several hours in severe ones. Disulfiram acts by inhibiting aldehyde dehydrogenase. Thus, alcohol is metabolized as usual, but acetaldehyde accumulates.

Disulfiram is rapidly and completely absorbed from the gastrointestinal tract; however, a period of 12 hours is required for its full action. Its elimination rate is slow, so that its action may persist for several days after the last dose. The drug inhibits the metabolism of many other therapeutic agents, including phenytoin, oral anticoagulants, and isoniazid. It should not be administered with medications that contain alcohol, including nonprescription medications such as those listed in Table 64–3. Disulfiram can cause small increases in liver function tests. Its safety in pregnancy has not been demonstrated.

Because compliance with disulfiram therapy is low and because the evidence from clinical trials for its effectiveness is weak, disulfiram is no longer commonly used.

Other Drugs

There is some evidence that topiramate, a drug used for partial and generalized tonic-clonic seizures (Chapter 24), and ondansetron, a serotonin 5-HT_3-receptor antagonist (Chapters 16, 63), are effective in reducing craving in chronic alcoholics.

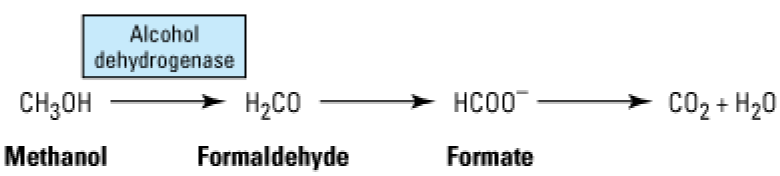
PHARMACOLOGY OF OTHER ALCOHOLS

Other alcohols related to ethanol have wide applications as industrial solvents and occasionally cause severe poisoning. Of these, methanol and ethylene glycol are two of the most common causes of intoxication.

Methanol

Methanol (methyl alcohol, wood alcohol) is widely used in the industrial production of synthetic organic compounds and as a constituent of many commercial solvents. In the home, methanol is most frequently found in the form of "canned heat" or in windshield-washing products. Poisonings occur from accidental ingestion of methanol-containing products or when it is used by alcoholics as an ethanol substitute.

Methanol can be absorbed through the skin or from the respiratory or gastrointestinal tract and is then distributed in body water. The primary mechanism of elimination of methanol in humans is by oxidation to formaldehyde, formic acid, and CO_2:



Animal species show great variability in mean lethal doses of methanol. The special susceptibility of humans to methanol toxicity is probably due to folate-dependent production of formate and not to methanol itself or to formaldehyde, the intermediate metabolite.

The most characteristic symptom in methanol poisoning is a visual disturbance, frequently described as "like being in a snowstorm." A complaint of blurred vision with a relatively clear sensorium should strongly suggest the diagnosis of methanol poisoning. Since much of the toxicity is due to metabolites of methanol, there is often a delay of up to 30 hours before development of visual disturbances and other signs of severe intoxication.

Physical findings in methanol poisoning are generally nonspecific. In severe cases, the odor of formaldehyde may be present on the breath or in the urine. Changes in the retina may sometimes be detected on examination, but these are usually late. The development of bradycardia, prolonged coma, seizures, and resistant acidosis all imply a poor prognosis. The cause of death in fatal cases is sudden cessation of respiration.

It is critical that the blood methanol level be determined as soon as possible if the diagnosis is suspected. Methanol concentrations higher than 50 mg/dL are thought to be an absolute indication for hemodialysis and ethanol treatment, though formate blood levels are a better indication of clinical pathology. Additional laboratory evidence includes metabolic acidosis with an elevated anion gap and osmolar gap (see Chapter 59). A decrease in serum bicarbonate is a uniform feature of severe methanol poisoning.

The first treatment for methanol poisoning, as in all critical poisoning situations, is support of respiration.There are three specific modalities of treatment for severe methanol poisoning: suppression of metabolism by alcohol dehydrogenase to toxic products, hemodialysis to enhance removal of methanol and its toxic products, and alkalinization to counteract metabolic acidosis.

The enzyme chiefly responsible for methanol oxidation in the liver is alcohol dehydrogenase. Ethanol has a higher affinity than methanol for alcohol dehydrogenase; thus, saturation of the enzyme with ethanol reduces formate production. Ethanol is often used intravenously as treatment for methanol poisoning. The dose-dependent characteristics of ethanol metabolism and the variability of ethanol metabolism require frequent monitoring of blood ethanol levels to ensure appropriate alcohol concentration. Fomepizole, an alcohol dehydrogenase inhibitor, is approved for the treatment of ethylene glycol poisoning (see next section) and methanol poisoning.

Hemodialysis rapidly eliminates both methanol and formate. However, ethanol is also eliminated in the dialysate, requiring alterations in the dose of ethanol. Hemodialysis is discussed in Chapter 59.

Two other measures are commonly taken. Because of profound metabolic acidosis in methanol poisoning, treatment with bicarbonate often is necessary. Since folate-dependent systems are responsible for the oxidation of formic acid to CO_2 in humans, it is probably useful to administer folic acid to patients poisoned with methanol, though this has never been fully tested in clinical studies.

Ethylene Glycol

Polyhydric alcohols such as ethylene glycol (CH_2OHCH_2OH) are used as heat exchangers, in antifreeze formulations, and as industrial solvents. Young children and animals are sometimes attracted by the sweet taste of ethylene glycol and, rarely, it is ingested intentionally as an ethanol substitute or in attempted suicide. While ethylene glycol itself is relatively harmless and eliminated by the kidney, it is metabolized to toxic aldehydes and oxalate.

Three stages of ethylene glycol overdose occur. Within the first few hours after ingestion, there is transient excitation followed by central nervous system depression. After a delay of 4–12 hours, severe metabolic acidosis develops from accumulation of acid metabolites and lactate. Finally, delayed renal insufficiency follows deposition of oxalate in renal tubules. The key to the diagnosis of ethylene glycol poisoning is recognition of anion gap acidosis, osmolar gap, and oxalate crystals in the urine in a patient without visual symptoms.

As with methanol poisoning, early ethanol infusion and hemodialysis are standard treatments for ethylene glycol poisoning. Fomepizole, an inhibitor of alcohol dehydrogenase, has FDA approval for treatment of ethylene glycol poisoning in adults based on its ability to decrease concentrations of toxic metabolites in blood and urine and to prevent renal injury. Intravenous treatment with fomepizole is initiated immediately and continued until the patient's serum ethylene glycol concentration drops below a toxic threshold (20 mg/dL). Adverse effects associated with fomepizole are not severe. Headache, nausea, and dizziness are most frequently reported, and a few patients experience minor allergic reactions. Fomepizole is classified as an orphan drug (see Chapter 5) because ethylene glycol poisoning is relatively uncommon. Its cost—estimated to be $4000 per patient—is much higher than the cost of infusible ethanol, but fomepizole offers some advantages over ethanol as an antidote for this potentially fatal poisoning.

PREPARATIONS AVAILABLE

DRUGS FOR THE TREATMENT OF ACUTE ALCOHOL WITHDRAWAL SYNDROME

Diazepam (generic, Valium, others)

Oral: 2, 3, 10 mg tablets; 5 mg/5 mL solutions (see also Chapter 22)

Parenteral: 5 mg/mL for injection

Lorazepam (generic, Alzapam, Ativan)

Oral: 0.5, 1, 2 mg tablets

Parenteral: 2, 4 mg/mL for injection

Oxazepam (generic, Serax)

Oral: 10, 15, 30 mg capsules, 15 mg tablets

Thiamine (generic)

Parenteral: 100 mg/mL for IV injection

DRUGS FOR THE PREVENTION OF ALCOHOL ABUSE

Acamprosate (Campral)

Oral: 333 mg delayed-release tablets

Disulfiram (Antabuse)

Oral: 250 mg tablets

Naltrexone (generic, ReVia)

Oral: 50 mg tablets

Parenteral (Vivitrol): 380 mg for IM injection once per month

DRUGS FOR THE TREATMENT OF ACUTE METHANOL OR ETHYLENE GLYCOL POISONING

Ethanol (generic)

Parenteral: 5% or 10% ethanol and 5% dextrose in water for IV infusion

Fomepizole (Antizol)

Parenteral: 1 g/mL for IV injection

ANTISEIZURE DRUGS: INTRODUCTION

Approximately 1% of the world's population has epilepsy, the second most common neurologic disorder after stroke. Although standard therapy permits control of seizures in 80% of these patients, millions (500,000 people in the USA alone) have uncontrolled epilepsy. Epilepsy is a heterogeneous symptom complex—a chronic disorder characterized by recurrent seizures. Seizures are finite episodes of brain dysfunction resulting from abnormal discharge of cerebral neurons. The causes of seizures are many and include the full range of neurologic diseases—from infection to neoplasm and head injury. In some subgroups, heredity has proved to be a predominant factor.

The antiseizure drugs described in this chapter are also used in patients with febrile seizures or with seizures occurring as part of an acute illness such as meningitis. The term "epilepsy" is not usually applied to such patients unless chronic seizures develop later. Seizures are occasionally caused by an acute underlying toxic or metabolic disorder, in which case appropriate therapy should be directed toward the specific abnormality, eg, hypocalcemia. In most cases of epilepsy, however, the choice of medication depends on the empiric seizure classification.

Drug Development for Epilepsy

For a long time it was assumed that a single drug could be developed for the treatment of all forms of epilepsy, but the causes of epilepsy are extremely diverse, encompassing genetic and developmental defects and infective, traumatic, neoplastic, and degenerative disease processes. Drug therapy to date shows little evidence of etiologic specificity. There is, however, some specificity according to seizure type (Table 24–1). This is most clearly seen with generalized seizures of the absence type. These are typically seen with 2–3 Hz spike-and-wave discharges on the electroencephalogram, which respond to ethosuximide and valproate but can be exacerbated by phenytoin and carbamazepine. Drugs acting selectively on absence seizures can be identified by animal screens, using either threshold pentylenetetrazol clonic seizures in mice or rats or mutant mice showing absence-like episodes (so-called lethargic, star-gazer, or tottering mutants). In contrast, the maximal electroshock (MES) test, with suppression of the tonic extensor phase, identifies drugs such as phenytoin, carbamazepine, and lamotrigine that are active against generalized tonic-clonic seizures and complex partial seizures. Use of the maximal electroshock test as the major initial screen for new drugs has probably led to the identification of drugs with a common mechanism of action involving prolonged inactivation of the voltage-sensitive sodium channel. Limbic seizures induced in rats by the process of electrical kindling (involving repeated episodes of focal electrical stimulation) probably provide a better screen for predicting efficacy in complex partial seizures.

Table 24–1. Classification of Seizure Types.
Partial seizures
Simple partial seizures
Complex partial seizures
Partial seizures secondarily generalized
Generalized seizures
Generalized tonic-clonic (grand mal) seizures
Absence (petit mal) seizures
Tonic seizures
Atonic seizures
Clonic and myoclonic seizures
Infantile spasms[1]

[1]An epileptic syndrome rather than a specific seizure type; drugs useful in infantile spasms will be reviewed separately.

Existing antiseizure drugs provide adequate seizure control in about two thirds of patients. A fraction of the epileptic population is resistant to all available drugs, and this may be due to increased expression of the multidrug transporter P-glycoprotein 170, a product of the *ABCB1* gene. In children, some severe seizure syndromes associated with progressive brain damage are very difficult to treat. In adults, some focal seizures are refractory to medications. Some, particularly in the temporal lobe, are amenable to surgical resection. Some of the drug-resistant population may respond to vagus-nerve stimulation (VNS), a nonpharmacologic treatment for epilepsy now widely approved for treatment of patients with partial seizures. VNS is indicated for refractory cases or for patients in whom antiseizure drugs are poorly tolerated. Stimulating electrodes are implanted in the left vagus nerve, and the pacemaker is implanted in the chest wall or axilla. Use of this device may permit seizure control with lower doses of drugs.

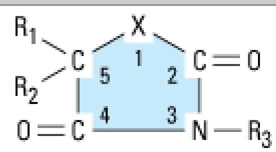
New antiseizure drugs are being sought not only by the screening tests noted above but also by more rational approaches. Compounds are sought that act by one of three mechanisms: (1) enhancement of GABAergic (inhibitory) transmission, (2) diminution of excitatory (usually glutamatergic) transmission, or (3) modification of ionic conductances.

BASIC PHARMACOLOGY OF ANTISEIZURE DRUGS

Chemistry

Until 1990, approximately 16 antiseizure drugs were available, and 13 of them can be classified into five very similar chemical groups: barbiturates, hydantoins, oxazolidinediones, succinimides, and acetylureas. These groups have in common a similar heterocyclic ring structure with a variety of substituents (Figure 24–1). For drugs with this basic structure, the substituents on the heterocyclic ring determine the pharmacologic class, either anti-MES or antipentylenetetrazol. Very small changes in structure can dramatically alter the mechanism of action and clinical properties of the compound. The remaining drugs—carbamazepine, valproic acid, and the benzodiazepines—are structurally dissimilar, as are the newer compounds marketed since 1990, ie, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, vigabatrin, and zonisamide.

Figure 24–1.



Antiseizure heterocyclic ring structure. The "X" varies as follows: hydantoin derivatives, –N–; barbiturates, –C–N–; oxazolidinediones, –O–; succinimides, –C–; acetylureas, $–NH_2$ (N connected to C_2). R_1, R_2, and R_3 vary within each subgroup.

Pharmacokinetics

The antiseizure drugs exhibit many similar pharmacokinetic properties—even those whose structural and chemical properties are quite diverse—because most have been selected for oral activity and all must enter the central nervous system. Although many of these compounds are only slightly soluble, absorption is usually good, with 80–100% of the dose reaching the circulation. Most antiseizure drugs are not highly bound to plasma proteins.

Antiseizure drugs are cleared chiefly by hepatic mechanisms, although they have low extraction ratios (see Chapter 3). Many are converted to active metabolites that are also cleared by the liver. These drugs are predominantly distributed into total body water. Plasma clearance is relatively slow; many anticonvulsants are therefore considered to be medium- to long-acting. Some have half-lives longer than 12 hours. Many of the older antiseizure drugs are potent inducers of hepatic microsomal enzyme activity.

Drugs Used in Partial Seizures & Generalized Tonic-Clonic Seizures

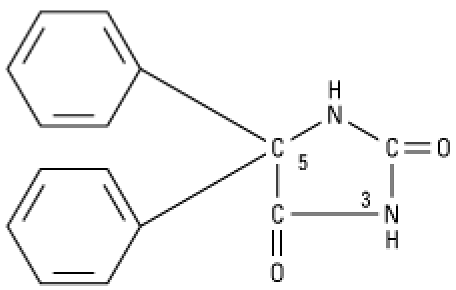
The classic major drugs for partial and generalized tonic-clonic seizures are phenytoin (and congeners), carbamazepine, valproate, and the barbiturates. However, the availability of newer drugs—lamotrigine, levetiracetam, gabapentin, oxcarbazepine, pregabalin, topiramate, vigabatrin, and zonisamide is altering clinical practice in countries where these compounds are available.

PHENYTOIN

Phenytoin is the oldest nonsedative antiseizure drug, introduced in 1938, after a systematic evaluation of compounds such as phenobarbital that altered electrically induced seizures in laboratory animals. It was known for decades as diphenylhydantoin.

Chemistry

Phenytoin is a diphenyl-substituted hydantoin with the structure shown below. It has much lower sedative properties than compounds with alkyl substituents at the 5 position. A more soluble prodrug of phenytoin, fosphenytoin, is available for parenteral use; this phosphate ester compound is rapidly converted to phenytoin in the plasma.

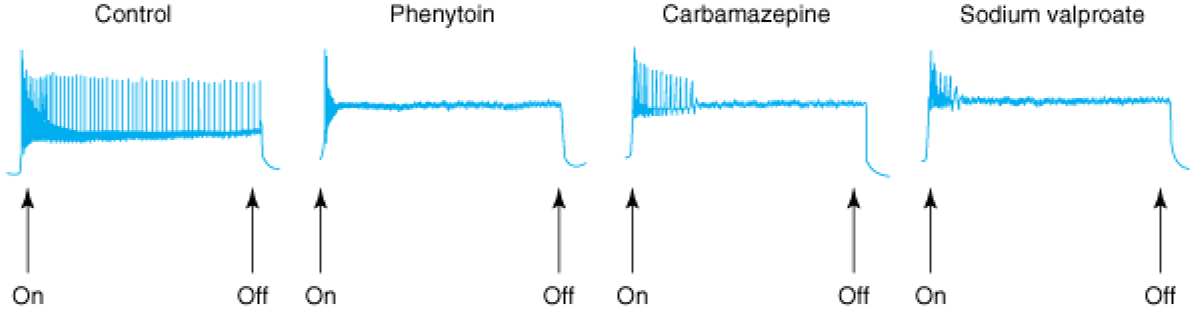


Phenytoin

Mechanism of Action

Phenytoin has major effects on several physiologic systems. It alters Na^+, K^+, and Ca^{2+} conductance, membrane potentials, and the concentrations of amino acids and the neurotransmitters norepinephrine, acetylcholine, and γ-aminobutyric acid (GABA). Studies with neurons in cell culture show that phenytoin blocks sustained high-frequency repetitive firing of action potentials (Figure 24–2). This effect is seen at therapeutically relevant concentrations. It is a use-dependent effect (see Chapter 14) on Na^+ conductance, arising from preferential binding to—and prolongation of—the inactivated state of the Na^+ channel. This effect is also seen with therapeutically relevant concentrations of carbamazepine, lamotrigine, and valproate and probably contributes to their antiseizure action in the electroshock model and in partial seizures.

Figure 24–2.



Effects of three antiseizure drugs on sustained high-frequency firing of action potentials by cultured neurons. Intracellular recordings were made from neurons while depolarizing current pulses, approximately 0.75 s in duration, were applied (on-off step changes indicated by arrows). In the absence of drug, a series of high-frequency repetitive action potentials filled the entire duration of the current pulse. Phenytoin, carbamazepine, and sodium valproate all markedly reduced the number of action potentials elicited by the current pulses. (Modified and reproduced, with permission, from Macdonald RL, Meldrum BS: Principles of antiepileptic drug action. In: Levy RH, et al [editors]: *Antiepileptic Drugs,* 4th ed. Raven Press, 1995.)

In addition, phenytoin paradoxically causes excitation in some cerebral neurons. A reduction of calcium permeability, with inhibition of calcium influx across the cell membrane, may explain the ability of phenytoin to inhibit a variety of calcium-induced secretory processes, including release of hormones and neurotransmitters. Recording of excitatory and inhibitory postsynaptic potentials show that phenytoin decreases the synaptic release of glutamate and enhances the release of GABA. The mechanism of phenytoin's action probably involves a combination of actions at several levels. At therapeutic concentrations, the major action of phenytoin is to block sodium channels and inhibit the generation of rapidly repetitive action potentials. Presynaptic actions on glutamate and GABA release probably arise from actions other than those on voltage-gated Na^+ channels.

Clinical Use

Phenytoin is effective against partial seizures and generalized tonic-clonic seizures. In the latter, it appears to be effective against attacks that are either primary or secondary to another seizure type.

Pharmacokinetics

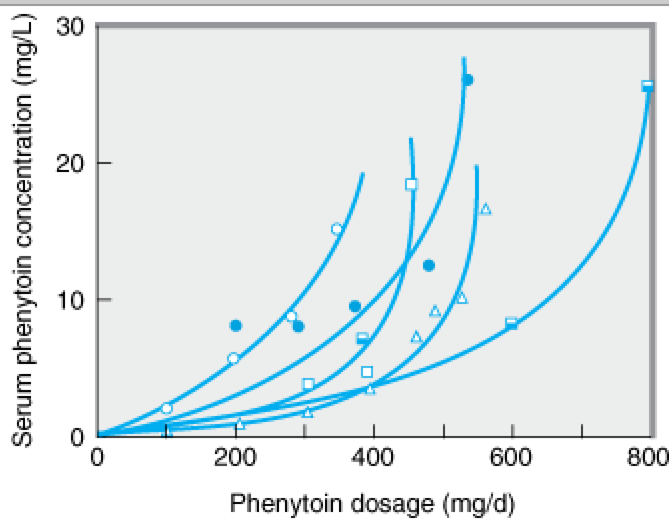
Absorption of phenytoin is highly dependent on the formulation of the dosage form. Particle size and pharmaceutical additives affect both the rate and the extent of absorption. Absorption of phenytoin sodium from the gastrointestinal tract is nearly complete in most patients, although the time to peak may range from 3 hours to 12 hours. Absorption after intramuscular injection is unpredictable, and some drug precipitation in the muscle occurs; this route of administration is not recommended for phenytoin. In contrast, fosphenytoin, a more soluble phosphate prodrug of phenytoin, is well absorbed after intramuscular administration.

Phenytoin is highly bound to plasma proteins. The total plasma level decreases when the percentage that is bound decreases, as in uremia or hypoalbuminemia, but correlation of free levels with clinical states remains uncertain. Drug concentration in cerebrospinal fluid is proportionate to the free plasma level. Phenytoin accumulates in brain, liver, muscle, and fat.

Phenytoin is metabolized to inactive metabolites that are excreted in the urine. Only a very small proportion of phenytoin is excreted unchanged.

The elimination of phenytoin is dose-dependent. At very low blood levels, phenytoin metabolism follows first-order kinetics. However, as blood levels rise within the therapeutic range, the maximum capacity of the liver to metabolize phenytoin is approached (Figure 24–3). Further increases in dosage, even though relatively small, may produce very large changes in phenytoin concentrations. In such cases, the half-life of the drug increases markedly, steady state is not achieved in routine fashion (since the plasma level continues to rise), and patients quickly develop symptoms of toxicity.

Figure 24–3.



Nonlinear relationship of phenytoin dosage and plasma concentrations. Five different patients (identified by different symbols) received increasing dosages of phenytoin by mouth, and the steady-state serum concentration was measured at each dosage. The curves are not linear, since, as the dosage increases, the metabolism is saturable. Note also the marked variation among patients in the serum levels achieved at any dosage. (Modified, with permission, from Jusko WJ: Bioavailability and disposition kinetics of phenytoin in man. In: Kellaway P, Peterson I [editors]: *Quantitative Analytic Studies in Epilepsy.* Raven Press, 1977.)

The half-life of phenytoin varies from 12 hours to 36 hours, with an average of 24 hours for most patients in the low to mid therapeutic range. Much longer half-lives are observed at higher concentrations. At low blood levels, it takes 5–7 days to reach steady-state blood levels after every dosage change; at higher levels, it may be 4–6 weeks before blood levels are stable.

Therapeutic Levels & Dosage

The therapeutic plasma level of phenytoin for most patients is between 10 and 20 mcg/mL. A loading dose can be given either orally or intravenously; the latter, using fosphenytoin, is the method of choice for convulsive status epilepticus (discussed later). When oral therapy is started, it is common to begin adults at a dosage of 300 mg/d, regardless of body weight. This may be acceptable in some patients, but it frequently yields steady-state blood levels below 10 mcg/mL, which is the minimum therapeutic level for most patients. If seizures continue, higher doses are usually necessary to achieve plasma levels in the upper therapeutic range. Because of its dose-dependent kinetics, some toxicity may occur with only small increments in dosage. The phenytoin dosage should be increased each time by only 25–30 mg in adults, and ample time should be allowed for the new steady state to be achieved before further increasing the dosage. A common clinical error is to increase the dosage directly from 300 mg/d to 400 mg/d; toxicity frequently occurs at a variable time thereafter. In children, a dosage of 5 mg/kg/d should be followed by readjustment after steady-state plasma levels are obtained.

Two types of oral phenytoin sodium are currently available in the USA, differing in their respective rates of dissolution; one is absorbed rapidly and one more slowly. Only the slow-release extended-action formulation can be given in a single daily dosage, and care must be used when changing brands (see Preparations Available). Although a few patients being given phenytoin on a long-term basis have been proved to have low blood levels from poor absorption or rapid metabolism, the most common cause of low levels is poor compliance. Fosphenytoin sodium is available for intravenous or intramuscular use and replaces intravenous phenytoin sodium, a much less soluble form of the drug.

Drug Interactions & Interference with Laboratory Tests

Drug interactions involving phenytoin are primarily related to protein binding or to metabolism. Since phenytoin is 90% bound to plasma proteins, other highly bound drugs, such as phenylbutazone and sulfonamides, can displace phenytoin from its binding site. In theory, such displacement may cause a transient increase in free drug. A decrease in protein binding—eg, from hypoalbuminemia—results in a decrease in the total plasma concentration of drug but not the free concentration. Intoxication may occur if efforts are made to maintain total drug levels in the therapeutic range by increasing the dose. The protein binding of phenytoin is decreased in the presence of renal disease. The drug has an affinity for thyroid-binding globulin, which confuses some tests of thyroid function; the most reliable screening test of thyroid function in patients taking phenytoin appears to be measurement of thyroid-stimulating hormone (TSH).

Phenytoin has been shown to induce microsomal enzymes responsible for the metabolism of a number of drugs. Autostimulation of its own metabolism, however, appears to be insignificant. Other drugs, notably phenobarbital and carbamazepine, cause decreases in phenytoin steady-state concentrations through induction of hepatic microsomal enzymes. On the other hand, isoniazid inhibits the metabolism of phenytoin, resulting in increased steady-state concentrations when the two drugs are given together.

Toxicity

Dose-related adverse effects caused by phenytoin are unfortunately similar to other antiseizure drugs in this group, making differentiation difficult in patients receiving multiple drugs. Nystagmus occurs early, as does loss of smooth extraocular pursuit movements, but neither is an indication for decreasing the dose. Diplopia and ataxia are the most common dose-related adverse effects requiring dosage adjustment; sedation usually occurs only at considerably higher levels. Gingival hyperplasia and hirsutism occur to some degree in most patients; the latter can be especially unpleasant in women. Long-term use is associated in some patients with coarsening of facial features and with mild peripheral neuropathy, usually manifested by diminished deep tendon reflexes in the lower extremities. Long-term use may also result in abnormalities of vitamin D metabolism, leading to osteomalacia. Low folate levels and megaloblastic anemia have been reported, but the clinical importance of this observation is unknown.

Idiosyncratic reactions to phenytoin are relatively rare. A skin rash may indicate hypersensitivity of the patient to the drug. Fever may also occur, and in rare cases the skin lesions may be severe and exfoliative. Lymphadenopathy may be difficult to distinguish from malignant lymphoma, and although some studies suggest a causal relationship between phenytoin and Hodgkin's disease, the data are far from conclusive. Hematologic complications are exceedingly rare, although agranulocytosis has been reported in combination with fever and rash.

MEPHENYTOIN, ETHOTOIN, & PHENACEMIDE

Many congeners of phenytoin have been synthesized, but only three have been marketed recently in the USA, and one of these (phenacemide) has been withdrawn from the market. The other two congeners, mephenytoin and ethotoin, like phenytoin, appear to be most effective against generalized tonic-clonic seizures and partial seizures. No well-controlled clinical trials have documented their effectiveness. The incidence of severe reactions such as dermatitis, agranulocytosis, or hepatitis is higher for mephenytoin than for phenytoin.

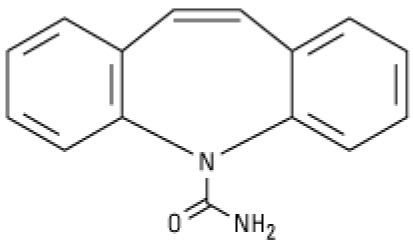
Ethotoin may be recommended for patients hypersensitive to phenytoin, but larger doses are required. The adverse effects and toxicity are generally less severe than those associated with phenytoin, but the drug appears to be less effective.

Both ethotoin and mephenytoin share with phenytoin the property of saturable metabolism within the therapeutic dosage range. Careful monitoring of the patient during dosage alterations with either drug is essential. Mephenytoin is metabolized to 5,5-ethylphenylhydantoin via demethylation. This metabolite, nirvanol, contributes most of the antiseizure activity of mephenytoin. Both mephenytoin and nirvanol are hydroxylated and undergo subsequent conjugation and excretion. Therapeutic levels for mephenytoin range from 5 mcg/mL to 16 mcg/mL, and levels above 20 mcg/mL are considered toxic.

Therapeutic blood levels of nirvanol are between 25 and 40 mcg/mL. A therapeutic range for ethotoin has not been established.

CARBAMAZEPINE

Closely related to imipramine and other antidepressants, carbamazepine is a tricyclic compound effective in treatment of bipolar depression. It was initially marketed for the treatment of trigeminal neuralgia but has proved useful for epilepsy as well.



Carbamazepine

Chemistry

Although not obvious from a two-dimensional representation of its structure, carbamazepine has many similarities to phenytoin. The ureide moiety (–N–CO–NH_2) present in the heterocyclic ring of most antiseizure drugs is also present in carbamazepine. Three-dimensional structural studies indicate that its spatial conformation is similar to that of phenytoin.

Mechanism of Action

The mechanism of action of carbamazepine appears to be similar to that of phenytoin. Like phenytoin, carbamazepine shows activity against maximal electroshock seizures. Carbamazepine, like phenytoin, blocks sodium channels at therapeutic concentrations and inhibits high-frequency repetitive firing in neurons in culture (Figure 24–2). It also acts presynaptically to decrease synaptic transmission. These effects probably account for the anticonvulsant action of carbamazepine. Binding studies show that carbamazepine interacts with adenosine receptors, but the functional significance of this observation is not known.

Clinical Use

Although carbamazepine has long been considered a drug of choice for both partial seizures and generalized tonic-clonic seizures, some of the newer antiseizure drugs are beginning to displace it from this role. Carbamazepine is not sedative in its usual therapeutic range. The drug is also very effective in some patients with trigeminal neuralgia, although older patients may tolerate higher doses poorly, with ataxia and unsteadiness. Carbamazepine is also useful in some patients with mania (bipolar disorder).

Pharmacokinetics

The rate of absorption of carbamazepine varies widely among patients, although almost complete absorption apparently occurs in all. Peak levels are usually achieved 6–8 hours after administration. Slowing absorption by giving the drug after meals helps the patient tolerate larger total daily doses.

Distribution is slow, and the volume of distribution is roughly 1 L/kg. The drug is only 70% bound to plasma proteins; no displacement of other drugs from protein binding sites has been observed.

Carbamazepine has a very low systemic clearance of approximately 1 L/kg/d at the start of therapy. The drug has a notable ability to induce microsomal enzymes. Typically, the half-life of 36 hours observed in subjects following an initial single dose decreases to as short as 8–12 hours in subjects receiving continuous therapy. Considerable dosage adjustments are thus to be expected during the first weeks of therapy. Carbamazepine also alters the clearance of other drugs (see below).

Carbamazepine is completely metabolized in humans to several derivatives. One of these, carbamazepine-10,11-epoxide, has been shown to have anticonvulsant activity. The contribution of this and other metabolites to the clinical activity of carbamazepine is unknown.

Therapeutic Levels & Dosage

Carbamazepine is available only in oral form. The drug is effective in children, in whom a dosage of 15–25 mg/kg/d is appropriate. In adults, daily doses of 1 g or even 2 g are tolerated. Higher dosage is achieved by giving multiple divided doses daily. Extended-release preparations permit twice-daily dosing for most patients. In patients in whom the blood is drawn just before the morning dose (trough level), the therapeutic level is usually 4–8 mcg/mL. Although many patients complain of diplopia at drug levels above 7 mcg/mL, others can tolerate levels above 10 mcg/mL, especially with monotherapy.

Drug Interactions

Drug interactions involving carbamazepine are almost exclusively related to the drug's enzyme-inducing properties. As noted previously, the increased metabolic capacity of the hepatic enzymes may cause a reduction in steady-state carbamazepine concentrations and an increased rate of metabolism of other drugs, eg, primidone, phenytoin, ethosuximide, valproic acid, and clonazepam. Other drugs such as propoxyphene, troleandomycin, and valproic acid may inhibit carbamazepine clearance and increase steady-state carbamazepine blood levels. Other anticonvulsants, however, such as phenytoin and phenobarbital, may decrease steady-state concentrations of carbamazepine through enzyme induction. No clinically significant protein-binding interactions have been reported.

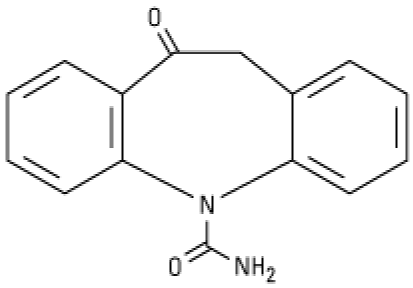
Toxicity

The most common dose-related adverse effects of carbamazepine are diplopia and ataxia. The diplopia often occurs first and may last less than an hour during a particular time of day. Rearrangement of the divided daily dose can often remedy this complaint. Other dose-related complaints include mild gastrointestinal upsets, unsteadiness, and, at much higher doses, drowsiness. Hyponatremia and water intoxication have occasionally occurred and may be dose-related.

Considerable concern exists regarding the occurrence of idiosyncratic blood dyscrasias with carbamazepine, including fatal cases of aplastic anemia and agranulocytosis. Most of these have been in elderly patients with trigeminal neuralgia, and most have occurred within the first 4 months of treatment. The mild and persistent leukopenia seen in some patients is not necessarily an indication to stop treatment but requires careful monitoring. The most common idiosyncratic reaction is an erythematous skin rash; other responses such as hepatic dysfunction are unusual.

OXCARBAZEPINE

Oxcarbazepine is closely related to carbamazepine and useful in the same seizure types, but it may have an improved toxicity profile. Oxcarbazepine has a half-life of only 1–2 hours. Its activity, therefore, resides almost exclusively in the 10-hydroxy metabolite, to which it is rapidly converted and which has a half-life similar to that of carbamazepine, ie, 8–12 hours. The drug is mostly excreted as the glucuronide of the 10-hydroxy metabolite. Oxcarbazepine is less potent than carbamazepine, both in animal models of epilepsy and in epileptic patients; clinical doses of oxcarbazepine may need to be 50% higher than those of carbamazepine to obtain equivalent seizure control. Some studies report fewer hypersensitivity reactions to oxcarbazepine, and cross-reactivity with carbamazepine does not always occur. Furthermore, the drug appears to induce hepatic enzymes to a lesser extent than carbamazepine, minimizing drug interactions. Although hyponatremia may occur more commonly with oxcarbazepine than with carbamazepine, most adverse effects that occur with oxcarbazepine are similar in character to reactions reported with carbamazepine.



Oxcarbazepine

PHENOBARBITAL

Aside from the bromides, phenobarbital is the oldest of the currently available antiseizure drugs. Although it has long been considered one of the safest of the antiseizure agents, the use of other medications with lesser sedative effects has been urged. Many consider the barbiturates the drugs of choice for seizures only in infants.

Chemistry

The four derivatives of barbituric acid clinically useful as antiseizure drugs are phenobarbital, mephobarbital, metharbital, and primidone. The first three are so similar that they are considered together. Metharbital is methylated barbital, and mephobarbital is methylated phenobarbital; both are demethylated in vivo. The pKas of these three weak acid compounds range from 7.3 to 7.9. Slight changes in the normal acid-base balance, therefore, can cause significant fluctuation in the ratio of the ionized to the un-ionized species. This is particularly important for phenobarbital, the most commonly used barbiturate, whose pKa is similar to the plasma pH of 7.4.

The three-dimensional conformations of phenobarbital and *N*-methylphenobarbital are similar to that of phenytoin. Both compounds possess a phenyl ring and are active against partial seizures.

Mechanism of Action

The exact mechanism of action of phenobarbital is unknown, but enhancement of inhibitory processes and diminution of excitatory transmission probably contribute significantly. Recent data indicate that phenobarbital may selectively suppress abnormal neurons, inhibiting the spread and suppressing firing from the foci. Like phenytoin, phenobarbital suppresses high-frequency repetitive firing in neurons in culture through an action on Na^+ conductance, but only at high concentrations. Also at high concentrations, barbiturates block some Ca^{2+} currents (L-type and N-type). Phenobarbital binds to an allosteric regulatory site on the $GABA_A$ receptor, and it enhances the GABA receptor-mediated current by prolonging the openings of the chloride channels. Phenobarbital also blocks excitatory responses induced by glutamate, principally those mediated by activation of the AMPA receptor (see Chapter 21). Both the enhancement of GABA-mediated inhibition and the reduction of glutamate-mediated excitation are seen with therapeutically relevant concentrations of phenobarbital.

Clinical Use

Phenobarbital is useful in the treatment of partial seizures and generalized tonic-clonic seizures, although the drug is often tried for virtually every seizure type, especially when attacks are difficult to control. There is little evidence for its effectiveness in generalized seizures such as absence, atonic attacks, and infantile spasms; it may worsen certain patients with these seizure types.

Some physicians prefer either metharbital or mephobarbital—especially the latter—to phenobarbital because of supposed decreased adverse effects. Only anecdotal data are available to support such comparisons.

Pharmacokinetics

See Chapter 22.

Therapeutic Levels & Dosage

The therapeutic levels of phenobarbital in most patients range from 10 mcg/mL to 40 mcg/mL. Documentation of effectiveness is best in febrile seizures, and levels below 15 mcg/mL appear ineffective for prevention of febrile seizure recurrence. The upper end of the therapeutic range is more difficult to define, because many patients appear to tolerate chronic levels above 40 mcg/mL.

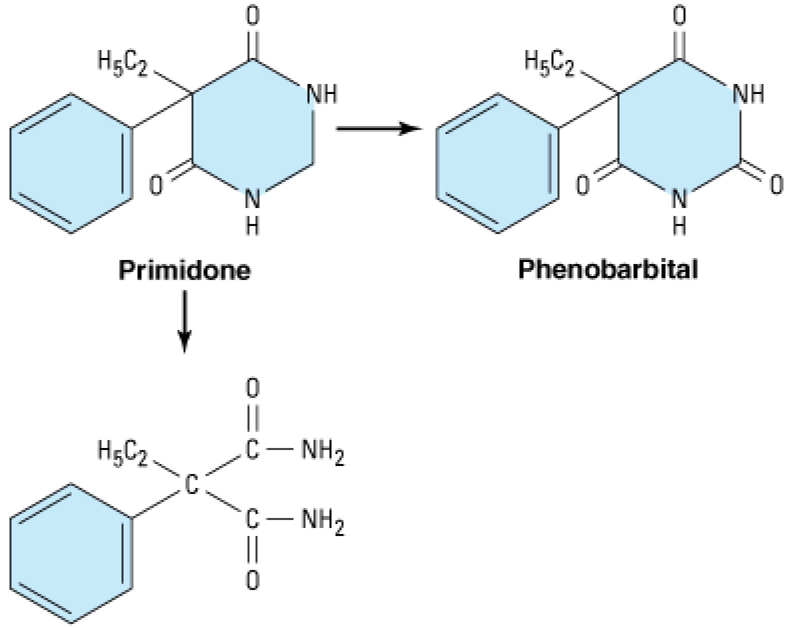
Drug Interactions & Toxicity

See Chapter 22.

PRIMIDONE

Primidone, or 2-desoxyphenobarbital (Figure 24–4), was first marketed in the early 1950s. It was later reported that primidone was metabolized to phenobarbital and phenylethylmalonamide (PEMA). All three compounds are active anticonvulsants.

Figure 24–4.



Phenylethylmalonamide (PEMA)

Primidone and its active metabolites.

Mechanism of Action

Although primidone is converted to phenobarbital, the mechanism of action of primidone itself may be more like that of phenytoin.

Clinical Use

Primidone, like its metabolites, is effective against partial seizures and generalized tonic-clonic seizures and may be more effective than phenobarbital. It was previously considered to be the drug of choice for complex partial seizures, but the latest studies of partial seizures in adults strongly suggest that carbamazepine and phenytoin are superior to primidone. Attempts to determine the relative potencies of the parent drug and its two metabolites have been conducted in newborn infants, in whom drug-metabolizing enzyme systems are very immature and in whom primidone is only slowly metabolized. Primidone has been shown to be effective in controlling seizures in this group and in older patients beginning treatment with primidone; older patients show seizure control before phenobarbital concentrations reach the therapeutic range. Finally, studies of maximal electroshock seizures in animals suggest that primidone has an anticonvulsant action independent of its conversion to phenobarbital and PEMA (the latter is relatively weak).

Pharmacokinetics

Primidone is completely absorbed, usually reaching peak concentrations about 3 hours after oral administration, although considerable variation has been reported. Primidone is generally confined to total body water, with a volume of distribution of 0.6 L/kg. It is not highly bound to plasma proteins; approximately 70% circulates as unbound drug.

Primidone is metabolized by oxidation to phenobarbital, which accumulates very slowly, and by scission of the heterocyclic ring to form PEMA (Figure 24–4). Both primidone and phenobarbital also undergo subsequent conjugation and excretion.

Primidone has a larger clearance than most other antiseizure drugs (2 L/kg/d), corresponding to a half-life of 6–8 hours. PEMA clearance is approximately half that of primidone, but phenobarbital has a very low clearance. The appearance of phenobarbital corresponds to the disappearance of primidone. Phenobarbital therefore accumulates very slowly but eventually reaches therapeutic concentrations in most patients when therapeutic doses of primidone are administered. During chronic therapy, phenobarbital levels derived from primidone are usually two to three times higher than primidone levels. PEMA, which probably makes a minimal contribution to the efficacy of primidone, has a half-life of 8–12 hours and therefore reaches steady state more rapidly than phenobarbital.

Therapeutic Levels & Dosage

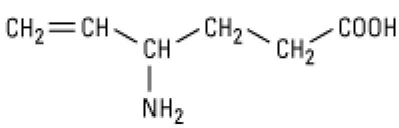
Primidone is most efficacious when plasma levels are in the range of 8–12 mcg/mL. Concomitant levels of its metabolite, phenobarbital, at steady state usually vary from 15 mcg/mL to 30 mcg/mL. Dosages of 10–20 mg/kg/d are necessary to obtain these levels. It is very important, however, to start primidone at low doses and gradually increase over days to a few weeks to avoid prominent sedation and gastrointestinal complaints. When adjusting doses of the drug, it is important to remember that the parent drug reaches steady state rapidly (30–40 hours), but the active metabolites phenobarbital (20 days) and PEMA (3–4 days) reach steady state much more slowly.

Toxicity

The dose-related adverse effects of primidone are similar to those of its metabolite, phenobarbital, except that drowsiness occurs early in treatment and may be prominent if the initial dose is too large. Gradual increments are indicated when starting the drug in either children or adults.

VIGABATRIN

Current investigations that seek drugs to enhance the effects of GABA include efforts to find GABA agonists and prodrugs, GABA transaminase inhibitors, and GABA uptake inhibitors. Vigabatrin (γ-vinyl-GABA) is one of these drugs and has been registered in Canada, Europe, and South America.



Vigabatrin

Mechanism of Action

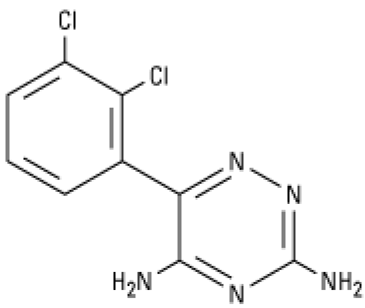
Vigabatrin is an irreversible inhibitor of GABA aminotransferase (GABA-T), the enzyme responsible for the degradation of GABA. It apparently acts by increasing the amount of GABA released at synaptic sites, thereby enhancing inhibitory effects. A decrease in brain glutamine synthetase activity is probably secondary to the increased GABA concentrations. It is effective in a wide range of seizure models. Vigabatrin is marketed as a racemate; the *S*(+) enantiomer is active and the *R*(–) enantiomer appears to be inactive.

Clinical Use

Vigabatrin is useful in the treatment of partial seizures and West's syndrome. The half-life is approximately 6–8 hours, but considerable evidence suggests that the pharmacodynamic activity of the drug is more prolonged and not well correlated with the plasma half-life. In adults, vigabatrin should be started at an oral dosage of 500 mg twice daily; a total of 2–3 g (rarely more) daily may be required for full effectiveness. Typical toxicities include drowsiness, dizziness, and weight gain. Less common but more troublesome adverse reactions are agitation, confusion, and psychosis; preexisting mental illness is a relative contraindication. The drug was delayed in its worldwide introduction by the appearance in rats and dogs of a reversible intramyelinic edema; this phenomenon has not been observed in any patient to date. More recently, unfortunately, long-term therapy with vigabatrin has been associated with development of visual field defects in up to one third of patients. This adverse effect may not be reversible, and vigabatrin may therefore be relegated to use in patients—such as those with infantile spasms—who are refractory to other treatments.

LAMOTRIGINE

Lamotrigine was developed when some investigators thought that the antifolate effects of certain antiseizure drugs (eg, phenytoin) may contribute to their effectiveness. Several phenyltriazines were developed, and although their antifolate properties were weak, some were active in seizure screening tests.



Lamotrigine

Mechanism of Action

Lamotrigine, like phenytoin, suppresses sustained rapid firing of neurons and produces a voltage- and use-dependent inactivation of sodium channels. This action probably explains lamotrigine's efficacy in focal epilepsy. It appears likely that lamotrigine has another mechanism of action to account for its efficacy in primary generalized seizures in childhood, including absence attacks; this mechanism may involve actions on voltage-activated Ca^{2+} channels. Lamotrigine also decreases the synaptic release of glutamate.

Clinical Use

Although most controlled studies have evaluated lamotrigine as add-on therapy, some suggest that the drug is effective as monotherapy for partial seizures, and the drug is now widely prescribed for this indication. Some authorities feel that the drug is also active against absence and myoclonic seizures in children. Adverse effects include dizziness, headache, diplopia, nausea, somnolence, and skin rash.

The rash is considered a typical hypersensitivity reaction. Although the risk of rash may be diminished by introducing the drug slowly, pediatric patients are at high risk; some studies suggest that a potentially life-threatening dermatitis will develop in 1–2% of pediatric patients.

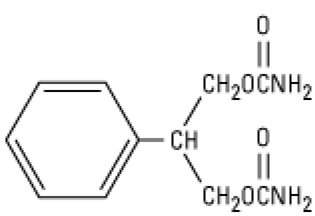
Pharmacokinetics & Dosage

Lamotrigine is almost completely absorbed and has a volume of distribution in the range of 1–1.4 L/kg. Protein binding is only about 55%. The drug has linear kinetics and is metabolized primarily by glucuronidation to the 2-*N*-glucuronide, which is excreted in the urine. Lamotrigine has a half-life of approximately 24 hours in normal volunteers; this decreases to 13–15 hours in patients taking enzyme-inducing drugs. Lamotrigine is effective against partial seizures in adults, with dosages typically between 100 and 300 mg/d and with a therapeutic blood level near 3 mcg/mL. Valproate causes a twofold increase in the drug's half-life; in patients receiving valproate, the initial dosage of lamotrigine must be reduced to 25 mg every other day.

FELBAMATE

Felbamate has been approved and marketed in the USA and in some European countries. Although it is effective in some patients with partial seizures, the drug causes aplastic anemia and severe hepatitis at unexpectedly high rates and has been relegated to the status of a third-line drug for refractory cases.

Felbamate appears to have multiple mechanisms of action. It produces a use-dependent block of the NMDA receptor, with selectivity for the NR1-2B subtype. It also potentiates $GABA_A$ receptor responses. Felbamate has a half-life of 20 hours (somewhat shorter when administered with either phenytoin or carbamazepine) and is metabolized by hydroxylation and conjugation; a significant percentage of the drug is excreted unchanged in the urine. When added to treatment with other antiseizure drugs, felbamate increases plasma phenytoin and valproic acid levels but decreases levels of carbamazepine.

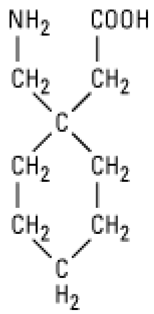


Felbamate

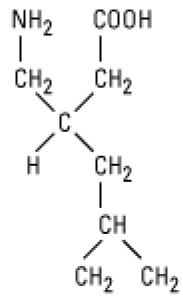
In spite of the seriousness of the adverse effects, thousands of patients worldwide remain on the medication. Usual dosages are 2000–4000 mg/d in adults, and effective plasma levels range from 30 mcg/mL to 100 mcg/mL. In addition to its usefulness in partial seizures, felbamate has proved effective against the seizures that occur in Lennox-Gastaut syndrome.

GABAPENTIN & PREGABALIN

Gabapentin is an amino acid, an analog of GABA, that is effective against partial seizures. Originally planned as a spasmolytic, it was found to be more effective as an antiseizure drug. Pregabalin is another GABA analog, closely related to gabapentin. This drug was recently approved in the USA for both antiseizure activity and for its analgesic properties.



Gabapentin



Pregabalin

Mechanism of Action

In spite of their close structural resemblance to GABA, gabapentin and pregabalin do not act directly on GABA receptors. They may, however, modify the synaptic or nonsynaptic release of GABA. An increase in brain GABA concentration is observed in patients receiving gabapentin. Gabapentin is transported into the brain by the L-amino acid transporter. Gabapentin and pregabalin bind avidly to the $\alpha 2\delta$ subunit of voltage-gated Ca^{2+} channels. Gabapentin and pregabalin also act presynaptically to decrease the release of glutamate; this effect is probably dependent on reduced presynaptic entry of Ca^{2+} via voltage-activated channels.

Clinical Use & Dosage

Gabapentin is effective as an adjunct against partial seizures and generalized tonic-clonic seizures at dosages that range up to 2400 mg/d in controlled clinical trials. Open follow-on studies permitted dosages up to 4800 mg/d, but data are inconclusive on the effectiveness or tolerability of such doses. Monotherapy studies also document some efficacy. Some clinicians have found that very high dosages are needed to achieve improvement in seizure control. Effectiveness in other seizure types has not been well demonstrated. Gabapentin has also been found effective in the treatment of neuropathic pain and is now indicated for postherpetic neuralgia in adults at doses of 1800 mg and above. The most common adverse effects are somnolence, dizziness, ataxia, headache, and tremor.

Pregabalin is approved (as an adjunct) for the treatment of partial seizures, with or without secondary generalization; controlled clinical trials have documented its effectiveness. It is available only in oral form, and the daily dose ranges from 150 mg/d to 600 mg/d, usually in two or three divided administrations. Pregabalin is also approved for use in neuropathic pain, including painful diabetic peripheral neuropathy and postherpetic neuralgia.

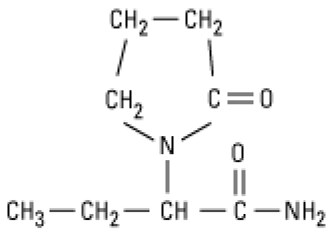
Pharmacokinetics

Gabapentin is not metabolized and does not induce hepatic enzymes. Absorption is nonlinear and dose-dependent at very high doses, but otherwise the elimination kinetics are linear. The drug is not bound to plasma proteins. Drug-drug interactions are negligible. Elimination is via renal mechanisms; the drug is excreted unchanged. The half-life is short, ranging from 5 hours to 8 hours; the drug is typically administered two or three times per day.

Pregabalin, like gabapentin, is not metabolized and is almost entirely excreted unchanged in the urine. It is not bound to plasma proteins and has virtually no drug-drug interactions, again resembling the characteristics of gabapentin. Likewise, other drugs do not affect the pharmacokinetics of pregabalin. The half-life of pregabalin ranges from about 4.5 hours to 7.0 hours, thus requiring more than once-per-day dosing in most patients.

LEVETIRACETAM

Levetiracetam is a piracetam analog that is ineffective against seizures induced by maximum electroshock or pentylenetetrazol but has prominent activity in the kindling model.



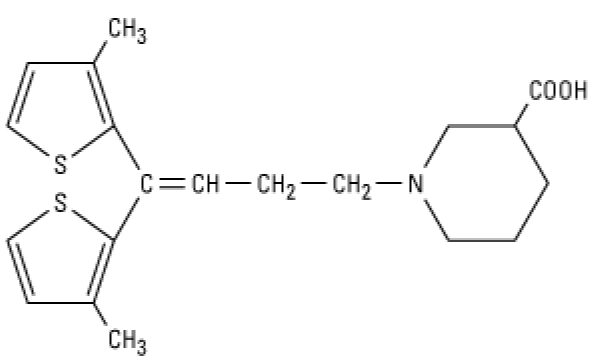
Levetiracetam

Levetiracetam binds selectively to a synaptic vesicular protein SV2A. The function of this protein is not understood but it is likely that levetiracetam modifies the synaptic release of glutamate and GABA through an action on vesicular function.

The drug is marketed for the treatment of partial seizures. Oral absorption is nearly complete; it is rapid and unaffected by food, with peak plasma concentrations in 1.3 hours. Kinetics are linear. Protein binding is less than 10%. The plasma half-life is 6–8 hours and may be longer in the elderly. Two thirds of the drug is excreted unchanged in the urine. Drug interactions are minimal; levetiracetam is not metabolized by cytochrome P450. Dosing can begin with 500 mg orally twice daily; some patients require up to 3000 mg/d. Adverse effects include somnolence, asthenia, and dizziness. Idiosyncratic reactions are rare.

TIAGABINE

Tiagabine is a derivative of nipecotic acid and was "rationally designed" as an inhibitor of GABA uptake (as opposed to discovery through random screening).



Tiagabine

Mechanism of Action

Tiagabine is an inhibitor of GABA uptake in both neurons and glia. It preferentially inhibits the transporter isoform 1 (GAT-1) rather than GAT-2 or GAT-3 and increases extracellular GABA levels in the forebrain and hippocampus. It prolongs the inhibitory action of synaptically released GABA. In rodents, it is potent against kindled seizures but weak against the maximum electroshock model.

Clinical Use

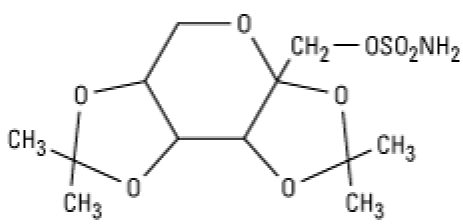
Tiagabine is indicated for the adjunctive treatment of partial seizures and is effective in doses ranging from 16 mg/d to 56 mg/d. Divided doses as often as four times per day are sometimes required. Some patients appear to do well with tiagabine monotherapy, which is generally well tolerated. Minor adverse events are dose-related and include nervousness, dizziness, tremor, difficulty in concentrating, and depression. Excessive confusion, somnolence, or ataxia may require discontinuation. Psychosis occurs rarely. Rash is an uncommon idiosyncratic adverse effect. Laboratory studies are usually normal.

Pharmacokinetics

Tiagabine is 90–100% bioavailable, has linear kinetics, and is highly protein-bound. The half-life is 5–8 hours and decreases in the presence of enzyme-inducing drugs. Food decreases the peak plasma concentration but not the area under the concentration curve (see Chapter 3). Hepatic impairment causes a slight decrease in clearance (and may necessitate a lower dose), but the drug does not cause inhibition or induction of hepatic enzymes. The drug is oxidized in the liver by CYP3A. Elimination is primarily in the feces (60–65%) and urine (25%).

TOPIRAMATE

Topiramate is a substituted monosaccharide that is structurally different from all other antiseizure drugs.



Topiramate

Mechanism of Action

Topiramate blocks repetitive firing of cultured spinal cord neurons, as do phenytoin and carbamazepine. Its mechanism of action, therefore, is likely to involve blocking of voltage-gated sodium channels. Topiramate also appears to potentiate the inhibitory effect of GABA, acting at a site different from the benzodiazepine or barbiturate sites. Topiramate also depresses the excitatory action of kainate on glutamate receptors. It is possible that all three of these actions contribute to topiramate's anticonvulsant effect.

Clinical Use

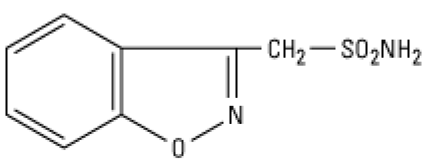
Clinical trials of topiramate demonstrated a dose-response relationship, and monotherapy trials showed the drug to be effective against partial and generalized tonic-clonic seizures. Good evidence suggests that the drug has a broader spectrum, with effectiveness against Lennox-Gestaut syndrome, West's syndrome, and even absence seizures. Topiramate is also approved for the treatment of migraine headaches. Dosages typically range from 200 mg/d to 600 mg/d, with a few patients tolerating dosages higher than 1000 mg/d. Most clinicians begin at a low dose (50 mg/d) and increase slowly to avoid adverse effects. Although no idiosyncratic reactions have been noted, dose-related adverse effects occur most frequently in the first 4 weeks and include somnolence, fatigue, dizziness, cognitive slowing, paresthesias, nervousness, and confusion. Acute myopia and glaucoma may require prompt drug withdrawal. Urolithiasis has also been reported. However, the discontinuation rate is apparently only about 15%. The drug is teratogenic in animal models, and hypospadias has been reported in male infants exposed in utero to topiramate; however, no causal relationship could be established.

Pharmacokinetics

Topiramate is rapidly absorbed (about 2 hours) and is 80% bioavailable. There is no food effect on absorption, minimal (15%) plasma protein binding, and only moderate (20–50%) metabolism; no active metabolites are formed. The drug is primarily excreted unchanged in the urine. The half-life is 20–30 hours. Although increased levels are seen with renal failure and hepatic impairment, there is no age or gender effect, no autoinduction, no inhibition of metabolism, and kinetics are linear. Drug interactions do occur and can be complex, but the major effect is on topiramate levels rather than on the levels of other antiseizure drugs. Birth control pills may be less effective in the presence of topiramate, and higher estrogen doses may be required.

ZONISAMIDE

Zonisamide is a sulfonamide derivative. Its primary site of action appears to be the sodium channel; it may also act on voltage-gated calcium channels. The drug is effective against partial and generalized tonic-clonic seizures and may also be useful against infantile spasms and certain myoclonias. It has good bioavailability, linear kinetics, low protein-binding, renal excretion, and a half-life of 1–3 days. Doses range from 100 mg/d to 600 mg/d in adults and from 4 mg/d to 12 mg/d in children. Adverse effects include drowsiness, cognitive impairment, and potentially serious skin rashes. Zonisamide does not interact with other antiseizure drugs.



Zonisamide

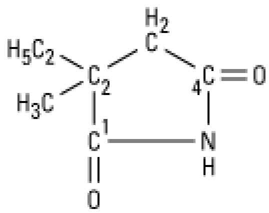
Drugs Used in Generalized Seizures

ETHOSUXIMIDE

Ethosuximide was introduced in 1960 as the third of three marketed succinimides in the USA. Ethosuximide has very little activity against maximal electroshock but considerable efficacy against pentylenetetrazol seizures, and it was introduced as a "pure petit mal" drug. Its continued popularity is based on its safety and efficacy, and its role as the first choice anti-absence drug remains undiminished—in part because of the idiosyncratic hepatotoxicity of the alternative drug, valproic acid.

Chemistry

Ethosuximide is the last antiseizure drug to be marketed whose origin is in the cyclic ureide structure. The three antiseizure succinimides marketed in the USA are ethosuximide, phensuximide, and methsuximide. Methsuximide and phensuximide have phenyl substituents, whereas ethosuximide is 2-ethyl-2-methylsuccinimide.



Ethosuximide

Mechanism of Action

Ethosuximide has an important effect on Ca^{2+} currents, reducing the low-threshold (T-type) current. This effect is seen at therapeutically relevant concentrations in thalamic neurons. The T-type calcium currents are thought to provide a pacemaker current in thalamic neurons responsible for generating the rhythmic cortical discharge of an absence attack. Inhibition of this current could therefore account for the specific therapeutic action of ethosuximide.

Clinical Use

As predicted from its activity in laboratory models, ethosuximide is particularly effective against absence seizures, but has a very narrow spectrum of clinical activity. Documentation of its effectiveness in human absence seizures was achieved with long-term electroencephalographic recording techniques.

Pharmacokinetics

Absorption is complete following administration of the oral dosage forms. Peak levels are observed 3–7 hours after oral administration of the capsules. Ethosuximide is not protein-bound.

Ethosuximide is completely metabolized, principally by hydroxylation, to inactive metabolites. The drug has a very low total body clearance (0.25 L/kg/d). This corresponds to a half-life of approximately 40 hours, although values from 18 to 72 hours have been reported.

Therapeutic Levels & Dosage

Therapeutic levels of 60–100 mcg/mL can be achieved in adults with dosages of 750–1500 mg/d, although lower or higher dosages and blood levels may be necessary and tolerated (up to 125 mcg/mL) in some patients. Ethosuximide has a linear relationship between dose and steady-state plasma levels. The drug might be administered as a single daily dose were it not for its adverse gastrointestinal effects; twice-a-day dosage is common.

Drug Interactions

Administration of ethosuximide with valproic acid results in a decrease in ethosuximide clearance and higher steady-state concentrations owing to inhibition of metabolism. No other important drug interactions have been reported for the succinimides.

Toxicity

The most common dose-related adverse effect of ethosuximide is gastric distress, including pain, nausea, and vomiting. When an adverse effect does occur, temporary dosage reductions may allow adaptation. Ethosuximide is a highly efficacious and safe drug for absence seizures; the appearance of relatively mild, dose-related adverse effects should not immediately call for its abandonment. Other dose-related adverse effects include transient lethargy or fatigue and, much less commonly, headache, dizziness, hiccup, and euphoria. Behavioral changes are usually in the direction of improvement.

Non-dose-related or idiosyncratic adverse effects of ethosuximide are extremely uncommon. Skin rashes have been reported, including at least one case of Stevens-Johnson syndrome. The development of systemic lupus erythematosus has also been reported, but other drugs may have been involved.

PHENSUXIMIDE & METHSUXIMIDE

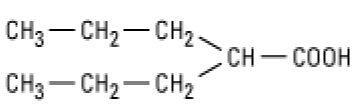
Phensuximide and methsuximide are phenylsuccinimides that were developed and marketed before ethosuximide. They are used primarily as anti-absence drugs. Methsuximide is generally considered more toxic, and phensuximide less effective, than ethosuximide. Unlike ethosuximide, these two compounds have some activity against maximal electroshock seizures, and methsuximide has been used for partial seizures by some investigators. The desmethyl metabolite of methsuximide has a half-life of 25 hours or more and exerts the major antiseizure effect. The toxicity and reduced effectiveness of phensuximide when compared with methsuximide has been investigated, and the failure of the desmethyl metabolite to accumulate in the former probably explains its relatively weak effect.

VALPROIC ACID & SODIUM VALPROATE

Sodium valproate, also used as the free acid, valproic acid, was found to have antiseizure properties when it was used as a solvent in the search for other drugs effective against seizures. It was marketed in France in 1969 but was not licensed in the USA until 1978. Valproic acid is fully ionized at body pH, and for that reason the active form of the drug may be assumed to be the valproate ion regardless of whether valproic acid or a salt of the acid is administered.

Chemistry

Valproic acid is one of a series of fatty carboxylic acids that have antiseizure activity; this activity appears to be greatest for carbon chain lengths of five to eight atoms. The amides and esters of valproic acid are also active antiseizure agents.



Valproic acid

Mechanism of Action

The time course of valproate's anticonvulsant activity appears to be poorly correlated with blood or tissue levels of the parent drug, an observation giving rise to considerable speculation regarding both the active species and the mechanism of action of valproic acid. Valproate is active against both pentylenetetrazol and maximal electroshock seizures. Like phenytoin and carbamazepine, valproate blocks sustained high-frequency repetitive firing of neurons in culture at therapeutically relevant concentrations. Its action against partial seizures may be a consequence of this effect on Na^+ currents. Blockade of NMDA receptor-mediated excitation may also be important. Much attention has been paid to the effects of valproate on GABA. Several studies have shown increased levels of GABA in the brain after administration of valproate, although the mechanism for this increase remains unclear. An effect of valproate to facilitate glutamic acid decarboxylase (GAD), the enzyme responsible for GABA synthesis, has been described. An inhibitory effect on the GABA transporter GAT-1 may contribute. At very high concentrations, valproate inhibits GABA transaminase in the brain, thus blocking degradation of GABA. However, at the relatively low doses of valproate needed to abolish pentylenetetrazol seizures, brain GABA levels may remain unchanged. Valproate produces a reduction in the aspartate content of rodent brain, but the relevance of this effect to its anticonvulsant action is not known.

Valproic acid is a potent inhibitor of histone deacetylase and through this mechanism changes the transcription of many genes. A similar effect, but to a lesser degree, is shown by some other antiseizure drugs (topiramate, carbamazepine, and a metabolite of levetiracetam).

Clinical Use

Valproate is very effective against absence seizures. Although ethosuximide is the drug of choice when absence seizures occur alone, valproate is preferred when the patient has concomitant generalized tonic-clonic attacks. The reason for preferring ethosuximide for uncomplicated absence seizures is valproate's idiosyncratic hepatotoxicity, described below. Valproate is unique in its ability to control certain types of myoclonic seizures; in some cases the effect is very dramatic. The drug is effective in generalized tonic-clonic seizures, especially those which are primarily generalized. A few patients with atonic attacks may also respond, and some evidence suggests that the drug is effective in partial seizures.

Other uses of valproate include management of bipolar disorder and migraine prophylaxis.

Pharmacokinetics

Valproate is well absorbed following an oral dose, with bioavailability greater than 80%. Peak blood levels are observed within 2 hours. Food may delay absorption, and decreased toxicity may result if the drug is given after meals.

Valproic acid is 90% bound to plasma proteins, although the fraction bound is somewhat reduced at blood levels greater than 150 mcg/mL. Since valproate is both highly ionized and highly protein-bound, its distribution is essentially confined to extracellular water, with a volume of distribution of approximately 0.15 L/kg.

Clearance for valproate is low; its half-life varies from 9 hours to 18 hours. Approximately 20% of the drug is excreted as a direct conjugate of valproate.

The sodium salt of valproate is marketed in Europe as a tablet and is quite hygroscopic. In Central and South America, the magnesium salt is available, which is considerably less hygroscopic. The free acid of valproate was first marketed in the USA in a capsule containing corn oil; the sodium salt is also available in syrup, primarily for pediatric use. An enteric-coated tablet of divalproex sodium is also marketed in the USA. This improved product, a 1:1 coordination compound of valproic acid and sodium valproate, is as bioavailable as the capsule but is absorbed much more slowly and is preferred by many patients. Peak concentrations following administration of the enteric-coated tablets are seen in 3–4 hours.

Therapeutic Levels & Dosage

Dosages of 25–30 mg/kg/d may be adequate in some patients, but others may require 60 mg/kg/d or even more. Therapeutic levels of valproate range from 50 mcg/mL to 100 mcg/mL.

Drug Interactions

The clearance of valproate is dose-dependent, caused by changes in both the intrinsic clearance and protein binding. At higher doses, there is an increased free fraction of valproate, resulting in lower total drug levels than expected. It may be clinically useful, therefore, to measure both total and free drug levels. Valproate also displaces phenytoin from plasma proteins. In addition to binding interactions, valproate inhibits the metabolism of several drugs, including phenobarbital, phenytoin, and carbamazepine, leading to higher steady-state concentrations of these agents. The inhibition of phenobarbital metabolism, for example, may cause levels of the barbiturate to rise steeply, causing stupor or coma.

Toxicity

The most common dose-related adverse effects of valproate are nausea, vomiting, and other gastrointestinal complaints such as abdominal pain and heartburn. The drug should be started gradually to avoid these symptoms. Sedation is uncommon with valproate alone but may be striking when valproate is added to phenobarbital. A fine tremor is frequently seen at higher levels. Other reversible adverse effects, seen in a small number of patients, include weight gain, increased appetite, and hair loss.

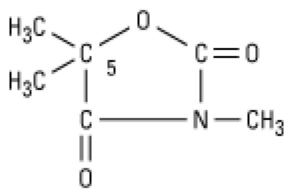
The idiosyncratic toxicity of valproate is largely limited to hepatotoxicity, but this may be severe; there seems little doubt that the hepatotoxicity of valproate has been responsible for more than 50 fatalities in the USA alone. The risk is greatest for patients under the age of 2 years and for those taking multiple medications. Initial aspartate aminotransferase values may not be elevated in susceptible patients, although these levels do eventually become abnormal. Most fatalities have occurred within 4 months after initiation of therapy. Some clinicians recommend treatment with oral or intravenous L-carnitine as soon as severe hepatotoxicity is suspected. Careful monitoring of liver function is recommended when starting the drug; the hepatotoxicity is reversible in some cases if the drug is withdrawn. The other observed idiosyncratic response with valproate is thrombocytopenia, although documented cases of abnormal bleeding are lacking. It should be noted that valproate is an effective and popular antiseizure drug and that only a very small number of patients have had severe toxic effects from its use.

Several epidemiologic studies of valproate have confirmed an increased incidence of spina bifida in the offspring of women who took valproate during pregnancy. In addition, an increased incidence of cardiovascular, orofacial, and digital abnormalities has been reported. These observations must be strongly considered in the choice of drugs during pregnancy.

OXAZOLIDINEDIONES

Trimethadione, the first oxazolidinedione, was introduced as an antiseizure drug in 1945 and remained the drug of choice for absence seizures until the introduction of succinimides in the 1950s. The use of the oxazolidinediones (trimethadione, paramethadione, and dimethadione) is now very limited.

The oxazolidinediones contain an oxazolidine heterocyclic ring (Figure 24–1) and are similar in structure to other antiseizure drugs introduced before 1960. The structure includes only short-chain alkyl substituents on the heterocyclic ring, with no attached phenyl group.



Trimethadione

These compounds are active against pentylenetetrazol-induced seizures. Trimethadione raises the threshold for seizure discharges following repetitive thalamic stimulation. It—or, more notably, its active metabolite dimethadione—has the same effect on thalamic Ca^{2+} currents as ethosuximide (reducing the T-type calcium current). Thus, suppression of absence seizures is likely to depend on inhibiting the pacemaker action of thalamic neurons.

Trimethadione is rapidly absorbed, with peak levels reached within an hour after drug administration. It is not bound to plasma proteins. Trimethadione is completely metabolized in the liver by demethylation to dimethadione, which may exert the major antiseizure activity. Dimethadione has an extremely long half-life (240 hours).

The therapeutic plasma level range for trimethadione has never been established, although trimethadione blood levels above 20 mcg/mL and dimethadione levels above 700 mcg/mL have been suggested. A dosage of 30 mg/kg/d of trimethadione is necessary to achieve these levels in adults.

The most common and bothersome dose-related adverse effect of the oxazolidinediones is sedation. Trimethadione has been associated with many other toxic adverse effects, some of which are severe. These drugs should not be used during pregnancy.

Other Drugs Used in Management of Epilepsy

Some drugs not classifiable by application to seizure type are discussed in this section.

BENZODIAZEPINES

Six benzodiazepines play prominent roles in the therapy of epilepsy (see also Chapter 22). Although many benzodiazepines are similar chemically, subtle structural alterations result in differences in activity. They have two different mechanisms of antiseizure action, which are shown to different degrees by the six compounds. This is evident from the fact that diazepam is relatively more potent against electroshock and clonazepam against pentylenetetrazol (the latter effect correlating with an action at the GABA-benzodiazepine allosteric receptor sites). Possible mechanisms of action are discussed in Chapter 22.

Diazepam given intravenously or rectally is highly effective for stopping continuous seizure activity, especially generalized tonic-clonic status epilepticus (see below). The drug is occasionally given orally on a long-term basis, although it is not considered very effective in this application, probably because of the rapid development of tolerance. A rectal gel is available for refractory patients who need acute control of bouts of seizure activity. Lorazepam appears in some studies to be more effective and longer-acting than diazepam in the treatment of status epilepticus and is preferred by some experts.

Clonazepam is a long-acting drug with documented efficacy against absence seizures; on a milligram basis, it is one of the most potent antiseizure agents known. It is also effective in some cases of myoclonic seizures and has been tried in infantile spasms. Sedation is prominent, especially on initiation of therapy; starting doses should be small. Maximal tolerated doses are usually in the range of 0.1–0.2 mg/kg, but many weeks of gradually increasing daily doses may be needed to achieve these dosages in some patients. Nitrazepam is not marketed in the USA but is used in many other countries, especially for infantile spasms and myoclonic seizures. It is less potent than clonazepam, and its clinical advantages over that drug have not been documented.

Clorazepate dipotassium is approved in the USA as an adjunct to treatment of complex partial seizures in adults. Drowsiness and lethargy are common adverse effects, but as long as the drug is increased gradually, dosages as high as 45 mg/d can be given.

Clobazam is not available in the USA but is marketed in most countries and is widely used in a variety of seizure types. It is a 1,5-benzodiazepine (other marketed benzodiazepines are 1,4-benzodiazepines) and reportedly has less sedative potential than benzodiazepines marketed in the USA. Whether the drug has significant clinical advantages is not clear. It has a half-life of 18 hours and is effective at dosages of 0.5–1 mg/kg/d. It does interact with some other antiseizure drugs and causes adverse effects typical of the benzodiazepines; efficacy, in some patients, is limited by the development of tolerance.

Pharmacokinetics

The pharmacokinetic properties of the benzodiazepines in part determine their clinical use. In general, the drugs are well absorbed, widely distributed, and extensively metabolized, with many active metabolites. The rate of distribution of benzodiazepines within the body is different from that of other antiseizure drugs. Diazepam and lorazepam in particular are rapidly and extensively distributed to the tissues, with volumes of distribution between 1 L/kg and 3 L/kg. The onset of action is very rapid. Total body clearances of the parent drug and its metabolites are low, corresponding to half-lives of 20–40 hours.

Limitations

Two prominent aspects of benzodiazepines limit their usefulness. The first is their pronounced sedative effect, which is unfortunate both in the treatment of status epilepticus and in chronic therapy. Children may manifest a paradoxical hyperactivity, as with barbiturates. The second problem is tolerance, in which seizures may respond initially but recur within a few months. The remarkable antiseizure potency of these compounds often cannot be realized because of these limiting factors.

ACETAZOLAMIDE

Acetazolamide is a diuretic whose main action is the inhibition of carbonic anhydrase (see Chapter 15). Mild acidosis in the brain may be the mechanism by which the drug exerts its antiseizure activity;

alternatively, the depolarizing action of bicarbonate ions moving out of neurons via GABA receptor ion channels may be diminished by carbonic anhydrase inhibition. Acetazolamide has been used for all types of seizures but is severely limited by the rapid development of tolerance, with return of seizures usually within a few weeks. The drug may have a special role in epileptic women who experience seizure exacerbations at the time of menses; seizure control may be improved and tolerance may not develop because the drug is not administered continuously. The usual dosage is approximately 10 mg/kg/d to a maximum of 1000 mg/d.

Another carbonic anhydrase inhibitor, **sulthiame**, was not found to be effective as an anticonvulsant in clinical trials in the USA. It is marketed in some other countries.

CLINICAL PHARMACOLOGY OF ANTISEIZURE DRUGS

SEIZURE CLASSIFICATION

The type of medication utilized for epilepsy depends on the empiric nature of the seizure. For this reason, considerable effort has been expended to classify seizures so that clinicians will be able to make a "seizure diagnosis" and on that basis prescribe appropriate therapy. Errors in seizure diagnosis cause use of the wrong drugs, and an unpleasant cycle ensues in which poor seizure control is followed by increasing drug doses and medication toxicity. As noted above, seizures are divided into two groups: partial and generalized. Drugs used for partial seizures are more or less the same for the entire group, but drugs used for generalized seizures are determined by the individual seizure type. A summary of the international classification of epileptic seizures is presented in Table 24–1.

Partial Seizures

Partial seizures are those in which a localized onset of the attack can be ascertained, either by clinical observation or by electroencephalographic recording; the attack begins in a specific locus in the brain. There are three types of partial seizures, determined to some extent by the degree of brain involvement by the abnormal discharge.

The least complicated partial seizure is the **simple partial seizure**, characterized by minimal spread of the abnormal discharge such that normal consciousness and awareness are preserved. For example, the patient may have a sudden onset of clonic jerking of an extremity lasting 60–90 seconds; residual weakness may last for 15–30 minutes after the attack. The patient is completely aware of the attack and can describe it in detail. The electroencephalogram may show an abnormal discharge highly localized to the involved portion of the brain.

The **complex partial seizure** also has a localized onset, but the discharge becomes more widespread (usually bilateral) and almost always involves the limbic system. Most complex partial seizures arise from one of the temporal lobes, possibly because of the susceptibility of this area of the brain to insults such as hypoxia or infection. Clinically, the patient may have a brief warning followed by an alteration of consciousness during which some patients stare and others stagger or even fall. Most, however, demonstrate fragments of integrated motor behavior called **automatisms** for which the patient has no memory. Typical automatisms are lip smacking, swallowing, fumbling, scratching, or even walking about. After 30–120 seconds, the patient makes a gradual recovery to normal consciousness but may feel tired or ill for several hours after the attack.

The last type of partial seizure is the secondarily generalized attack, in which a partial seizure immediately precedes a generalized tonic-clonic (grand mal) seizure. This seizure type is described in the text that follows.

Generalized Seizures

Generalized seizures are those in which there is no evidence of localized onset. The group is quite heterogeneous.

Generalized tonic-clonic (grand mal) seizures are the most dramatic of all epileptic seizures and are characterized by tonic rigidity of all extremities, followed in 15–30 seconds by a tremor that is actually an interruption of the tonus by relaxation. As the relaxation phases become longer, the attack enters the clonic phase, with massive jerking of the body. The clonic jerking slows over 60–120 seconds, and the patient is usually left in a stuporous state. The tongue or cheek may be bitten, and urinary incontinence is common. Primary generalized tonic-clonic seizures begin without evidence of localized onset, whereas secondary generalized tonic-clonic seizures are preceded by another seizure type, usually a partial seizure. The medical treatment of both primary and secondary generalized tonic-clonic seizures is the same and uses drugs appropriate for *partial* seizures.

The absence (petit mal) seizure is characterized by both sudden onset and abrupt cessation. Its duration is usually less than 10 seconds and rarely more than 45 seconds. Consciousness is altered; the attack may also be associated with mild clonic jerking of the eyelids or extremities, with postural tone changes, autonomic phenomena, and automatisms. The occurrence of automatisms can complicate the clinical differentiation from complex partial seizures in some patients. Absence attacks begin in childhood or adolescence and may occur up to hundreds of times a day. The electroencephalogram during the seizure shows a highly characteristic 2.5–3.5 Hz spike-and-wave pattern. Atypical absence patients have seizures with postural changes that are more abrupt, and such patients are often mentally retarded; the electroencephalogram may show a slower spike-and-wave discharge, and the seizures may be more refractory to therapy.

Myoclonic jerking is seen, to a greater or lesser extent, in a wide variety of seizures, including generalized tonic-clonic seizures, partial seizures, absence seizures, and infantile spasms. Treatment of seizures that include myoclonic jerking should be directed at the primary seizure type rather than at the myoclonus. Some patients, however, have myoclonic jerking as the major seizure type, and some have frequent myoclonic jerking and occasional generalized tonic-clonic seizures without overt signs of neurologic deficit. Many kinds of myoclonus exist, and much effort has gone into attempts to classify this entity.

Atonic seizures are those in which the patient has sudden loss of postural tone. If standing, the patient falls suddenly to the floor and may be injured. If seated, the head and torso may suddenly drop forward. Although most often seen in children, this seizure type is not unusual in adults. Many patients with atonic seizures wear helmets to prevent head injury.

Infantile spasms are an epileptic syndrome and not a seizure type. The attacks, although sometimes fragmentary, are most often bilateral and are included for pragmatic purposes with the generalized seizures. These attacks are most often characterized clinically by brief, recurrent myoclonic jerks of the body with sudden flexion or extension of the body and limbs; the forms of infantile spasms are, however, quite heterogeneous. Ninety percent of affected patients have their first attack before the age of 1 year. Most patients are mentally retarded, presumably from the same cause as the spasms. The cause is unknown in many patients, but such widely disparate disorders as infection, kernicterus, tuberous sclerosis, and hypoglycemia have been implicated. In some cases, the electroencephalogram is characteristic. Drugs used to treat infantile spasms are effective only in some patients; there is little evidence that the mental retardation is alleviated by therapy, even when the attacks disappear.

THERAPEUTIC STRATEGY

For most of the older antiseizure drugs, relationships between blood levels and therapeutic effects have been characterized to a high degree. The same is true for the pharmacokinetics of these drugs. These relationships provide significant advantages in the development of therapeutic strategies for the treatment of epilepsy. The therapeutic index for most antiseizure drugs is low, and toxicity is not uncommon. Thus, effective treatment of seizures often requires an awareness of the therapeutic levels and pharmacokinetic properties as well as the characteristic toxicities of each agent. Measurements of antiseizure drug plasma levels can be very useful when combined with clinical observations and pharmacokinetic data (Table 24–2). The relationship between seizure control and plasma drug levels is variable and often less clear for the drugs marketed since 1990.

Table 24–2. Effective Plasma Levels of Six Antiseizure Drugs.

Drug	Effective Level (mcg/mL)	High Effective Level[1] (mcg/mL)	Toxic Level (mcg/mL)
Carbamazepine	4–12	7	> 8
Primidone	5–15	10	< 12
Phenytoin	10–20	18	> 20
Phenobarbital	10–40	35	> 40
Ethosuximide	50–100	80	> 100
Valproate	50–100	80	> 100

[1]Level that should be achieved, if possible, in patients with refractory seizures, assuming that the blood samples are drawn before administration of the morning medication. Higher levels are often possible—without toxicity—when the drugs are used alone, ie, as monotherapy.

Management of Epilepsy

PARTIAL SEIZURES & GENERALIZED TONIC-CLONIC SEIZURES

Until the last 15 years, the choice of drugs for partial and tonic-clonic seizures was usually limited to phenytoin, carbamazepine, or barbiturates. There has been a strong tendency in the past few decades to limit the use of sedative antiseizure drugs such as barbiturates and benzodiazepines to patients who cannot tolerate other medications. Thus, in the 1980s, the trend was to increase the use of carbamazepine. Although carbamazepine and phenytoin are still very widely used, all of the newer drugs (marketed after 1990) have shown effectiveness against these same seizure types. An effort has been made to define the role for these new drugs (French et al, 2004). With the older drugs, the efficacy and the long-term adverse effects are well established; this creates a "confidence level" in spite of questionable tolerability. For the newer drugs, most have a broader spectrum of activity, and most are well tolerated, but the same "confidence level" is not yet present. These issues (plus the issues of drug cost) are the determining factors in choosing a drug for these seizure types.

GENERALIZED SEIZURES

The issues (described above) related to choosing between old and new drugs apply to the generalized group of seizures as well.

The drugs used for generalized tonic-clonic seizures are the same as for partial seizures; in addition, valproate is clearly useful.

At least three drugs are effective against absence seizures. Two are nonsedating and therefore preferred: ethosuximide and valproate. Clonazepam is also highly effective but has disadvantages of dose-related adverse effects and development of tolerance. Lamotrigine and topiramate may also be useful.

Specific myoclonic syndromes are usually treated with valproate; an intravenous formulation can be used acutely as needed. It is nonsedating and can be dramatically effective. Other patients respond to clonazepam, nitrazepam, or other benzodiazepines, although high doses may be necessary, with accompanying drowsiness. Zonisamide and levetiracetam may be useful. Another specific myoclonic syndrome, juvenile myoclonic epilepsy, can be aggravated by phenytoin or carbamazepine; valproate is the drug of choice followed by lamotrigine and topiramate.

Atonic seizures are often refractory to all available medications, although some reports suggest that valproate may be beneficial, as may lamotrigine. Benzodiazepines have been reported to improve seizure control in some of these patients but may worsen the attacks in others. Felbamate has been demonstrated to be effective in some patients, although the drug's idiosyncratic toxicity limits its use. If the loss of tone appears to be part of another seizure type (such as absence or complex partial seizures), every effort should be made to treat the other seizure type vigorously, hoping for simultaneous alleviation of the atonic component of the seizure. The ketogenic diet may also be useful.

DRUGS USED IN INFANTILE SPASMS

The treatment of infantile spasms is unfortunately limited to improvement of control of the seizures rather than other features of the disorder, such as retardation. Most patients receive a course of intramuscular corticotropin, although some clinicians note that prednisone may be equally effective and can be given orally. Clinical trials have been unable to settle the matter. In either case, therapy must often be discontinued because of adverse effects. If seizures recur, repeat courses of corticotropin or corticosteroids can be given, or other drugs may be tried. Other drugs widely used are the benzodiazepines such as clonazepam or nitrazepam; their efficacy in this heterogeneous syndrome may be nearly as good as that of corticosteroids. Vigabatrin may also be effective. The mechanism of action of corticosteroids or corticotropin in the treatment of infantile spasms is unknown. Further details may be sought in more specialized texts.

STATUS EPILEPTICUS

There are many forms of status epilepticus. The most common, generalized tonic-clonic status epilepticus, is a life-threatening emergency, requiring immediate cardiovascular, respiratory, and metabolic management as well as pharmacologic therapy. The latter virtually always requires intravenous administration of antiseizure medications. Diazepam is the most effective drug in most patients for stopping the attacks and is given directly by intravenous push to a maximum total dose of 20–30 mg in adults. Intravenous diazepam may depress respiration (less frequently, cardiovascular function), and facilities for resuscitation must be immediately at hand during its administration. The effect of diazepam is not lasting, but the 30- to 40-minute seizure-free interval allows more definitive therapy to be initiated. Some physicians prefer lorazepam, which is equivalent to diazepam in effect and perhaps somewhat longer-acting. For patients who are not actually in the throes of a seizure, diazepam therapy can be omitted and the patient treated at once with a long-acting drug such as phenytoin.

Until the introduction of fosphenytoin, the mainstay of continuing therapy for status epilepticus was intravenous phenytoin, which is effective and nonsedating. It can be given as a loading dose of 13–18 mg/kg in adults; the usual error is to give too little. Administration should be at a maximum rate of 50 mg/min. It is safest to give the drug directly by intravenous push, but it can also be diluted in saline; it precipitates rapidly in the presence of glucose. Careful monitoring of cardiac rhythm and blood pressure is necessary, especially in elderly people. At least part of the cardiotoxicity is from the propylene glycol in which the phenytoin is dissolved. Fosphenytoin, which is freely soluble in intravenous solutions without the need for propylene glycol or other solubilizing agents, is a safer parenteral agent. Because of its greater molecular weight, this prodrug is two thirds to three quarters as potent as phenytoin on a milligram basis.

In previously treated epileptic patients, the administration of a large loading dose of phenytoin may cause some dose-related toxicity such as ataxia. This is usually a relatively minor problem during the acute status episode and is easily alleviated by later adjustment of plasma levels.

For patients who do not respond to phenytoin, phenobarbital can be given in large doses: 100–200 mg intravenously to a total of 400–800 mg. Respiratory depression is a common complication, especially if benzodiazepines have already been given, and there should be no hesitation in instituting intubation and ventilation.

Although other drugs such as lidocaine have been recommended for the treatment of generalized tonic-clonic status epilepticus, general anesthesia is usually necessary in highly resistant cases.

For patients in absence status, benzodiazepines are still drugs of first choice. Rarely, intravenous valproate may be required.

Special Aspects of the Toxicology of Antiseizure Drugs

TERATOGENICITY

The potential teratogenicity of antiseizure drugs is controversial and important. It is important because teratogenicity resulting from long-term drug treatment of millions of people throughout the world may have a profound effect even if the effect occurs in only a small percentage of cases. It is controversial because both epilepsy and antiseizure drugs are heterogeneous, and few epileptic patients are available for study who are not receiving these drugs. Furthermore, patients with severe epilepsy, in whom genetic factors rather than drug factors may be of greater importance in the occurrence of fetal malformations, are often receiving multiple antiseizure drugs in high doses.

In spite of these limitations, it appears—from whatever cause—that children born to mothers taking antiseizure drugs have an increased risk, perhaps twofold, of congenital malformations. Phenytoin has been implicated in a specific syndrome called fetal hydantoin syndrome, although not all investigators are convinced of its existence and a similar syndrome has been attributed both to phenobarbital and to carbamazepine. Valproate, as noted above, has also been implicated in a specific malformation, spina bifida. It is estimated that a pregnant woman taking valproic acid or sodium valproate has a 1–2% risk of having a child with spina bifida. Topiramate has shown some teratogenicity in animal testing and, as noted earlier, in the human male fetus.

In dealing with the clinical problem of a pregnant woman with epilepsy, most epileptologists agree that although it is important to minimize exposure to antiseizure drugs, both in numbers and dosages, it is also important not to allow maternal seizures to go unchecked.

WITHDRAWAL

Withdrawal of antiseizure drugs, whether by accident or by design, can cause increased seizure frequency and severity. The two factors to consider are the effects of the withdrawal itself and the need for continued drug suppression of seizures in the individual patient. In many patients, both factors must be considered. It is important to note, however, that the abrupt discontinuance of antiseizure drugs ordinarily does not cause seizures in nonepileptic patients, provided that the drug levels are not above the usual therapeutic range when the drug is stopped.

Some drugs are more easily withdrawn than others. In general, withdrawal of anti-absence drugs is easier than withdrawal of drugs needed for partial or generalized tonic-clonic seizures. Barbiturates and benzodiazepines are the most difficult to discontinue; weeks or months may be required, with very gradual dosage decrements, to accomplish their complete outpatient removal.

Because of the heterogeneity of epilepsy, complete discontinuance of antiseizure drug administration is an especially difficult problem. If a patient is seizure-free for 3 or 4 years, a trial of gradual discontinuance is often warranted.

OVERDOSE

Antiseizure drugs are central nervous system depressants but are rarely lethal. Very high blood levels are usually necessary before overdoses can be considered life-threatening. The most dangerous effect of antiseizure drugs after large overdoses is respiratory depression, which may be potentiated by other agents, such as alcohol. Treatment of antiseizure drug overdose is supportive; stimulants should not be used. Efforts to hasten removal of antiseizure drugs, such as alkalinization of the urine (phenytoin is a weak acid), are usually ineffective.

PREPARATIONS AVAILABLE

Carbamazepine(generic, Tegretol)

Oral: 200 mg tablets; 100 mg chewable tablets; 100 mg/5 mL suspension

Oral extended-release: 100, 200, 400 mg tablets; 200, 300 mg capsules

Clonazepam (generic, Klonopin)

Oral: 0.5, 1, 2 mg tablets

Clorazepate dipotassium (generic, Tranxene)

Oral: 3.75, 7.5, 15 mg tablets, capsules

Oral sustained-release (Tranxene-SD): 11.25, 22.5 mg tablets

Diazepam (generic, Valium, others)

Oral: 2, 5, 10 mg tablets; 5 mg/5 mL, 5 mg/mL solutions

Parenteral: 5 mg/mL for IV injection

Rectal: 2.5, 5, 10, 15, 20 mg viscous rectal solution

Ethosuximide (generic, Zarontin)

Oral: 250 mg capsules; 250 mg/5 mL syrup

Ethotoin (Peganone)

Oral: 250, 500 mg tablets

Felbamate (Felbatol)

Oral: 400, 600 mg tablets; 600 mg/5 mL suspension

Fosphenytoin (Cerebyx)

Parenteral: 75 mg/mL for IV or IM injection

Gabapentin (Neurontin)

Oral: 100, 300, 400 mg capsules; 600, 800 mg filmtabs; 50 mg/mL solution

Lamotrigine (Lamictal)

Oral: 25, 100, 150, 200 mg tablets; 2, 5, 25 mg chewable tablets

Levetiracetam (Keppra)

Oral: 250, 500, 750 mg tablets

Lorazepam (generic, Ativan)

Oral: 0.5, 1, 2 mg tablets; 2 mg/mL solution

Parenteral: 2, 4 mg/mL for IV or IM injection

Mephenytoin (Mesantoin)

Oral: 100 mg tablets

Mephobarbital (Mebaral)

Oral: 32, 50, 100 mg tablets

Oxcarbazepine (Trileptal)

Oral: 100, 300, 600 mg tablets; 60 mg/mL suspension

Pentobarbital sodium (generic, Nembutal)

Parenteral: 50 mg/mL for IV or IM injection

Phenobarbital (generic, Luminal Sodium, others)

Oral: 15, 16, 30, 60, 90, 100 mg tablets; 16 mg capsules; 15, 20 mg/5 mL elixirs

Parenteral: 30, 60, 65, 130 mg/mL for IV or IM injection

Phenytoin (generic, Dilantin, others)

Oral (prompt-release): 100 mg capsules; 50 mg chewable tablets; 30, 125 mg/5 mL suspension

Oral extended-action: 30, 100 mg capsules

Oral slow-release (Phenytek): 200, 300 mg capsules

Parenteral: 50 mg/mL for IV injection

Pregabalin(Lyrica)

Oral: 75, 150, 300 mg capsules

Primidone (generic, Mysoline)

Oral: 50, 250 mg tablets; 250 mg/5 mL suspension

Tiagabine (Gabitril)

Oral: 4, 12, 16, 20 mg tablets

Topiramate (Topamax)

Oral: 25, 100, 200 mg tablets; 15, 25 mg sprinkle capsules

Trimethadione (Tridione)

Oral: 150 mg chewable tablets; 300 mg capsules; 40 mg/mL solution

Valproic acid (generic, Depakene)

Oral: 250 mg capsules; 250 mg/5 mL syrup (sodium valproate)

Oral sustained-release (Depakote): 125, 250, 500 mg tablets (as divalproex sodium)

Parenteral (Depacon): 100 mg/mL in 5 mL vial for IV injection

Zonisamide (Zonegran)

Oral: 25, 50, 100 mg tablets

Bottom of Form

GENERAL ANESTHETICS: INTRODUCTION

The physiologic state induced by general anesthetics typically includes analgesia, amnesia, loss of consciousness, inhibition of sensory and autonomic reflexes, and skeletal muscle relaxation. The extent to which any individual anesthetic agent can exert these effects varies depending on the drug, the dosage, and the clinical situation.

An ideal anesthetic drug would induce loss of consciousness smoothly and rapidly, while allowing for prompt recovery of cognitive function after its administration is discontinued. The drug would also possess a wide margin of safety and be devoid of adverse effects. No single anesthetic agent is capable of achieving all of these desirable effects without some disadvantages when used alone. The modern practice of anesthesiology most commonly involves the use of combinations of intravenous and inhaled drugs, taking advantage of their individual favorable properties while minimizing their adverse reactions.

The anesthetic technique will vary according to the proposed type of diagnostic, therapeutic, or surgical intervention. For minor procedures, oral or parenteral sedatives may be used in conjunction with local anesthetics (see Chapter 26). These techniques provide profound analgesia, but with retention of the patient's ability to maintain a patent airway and to respond to verbal commands. For more extensive surgical procedures, anesthesia frequently includes preoperative benzodiazepines, induction of anesthesia with an intravenous anesthetic (eg, thiopental or propofol), and maintenance of anesthesia with a combination of inhaled (eg, volatile agents, nitrous oxide) and intravenous (eg, propofol, opioid analgesics) drugs.

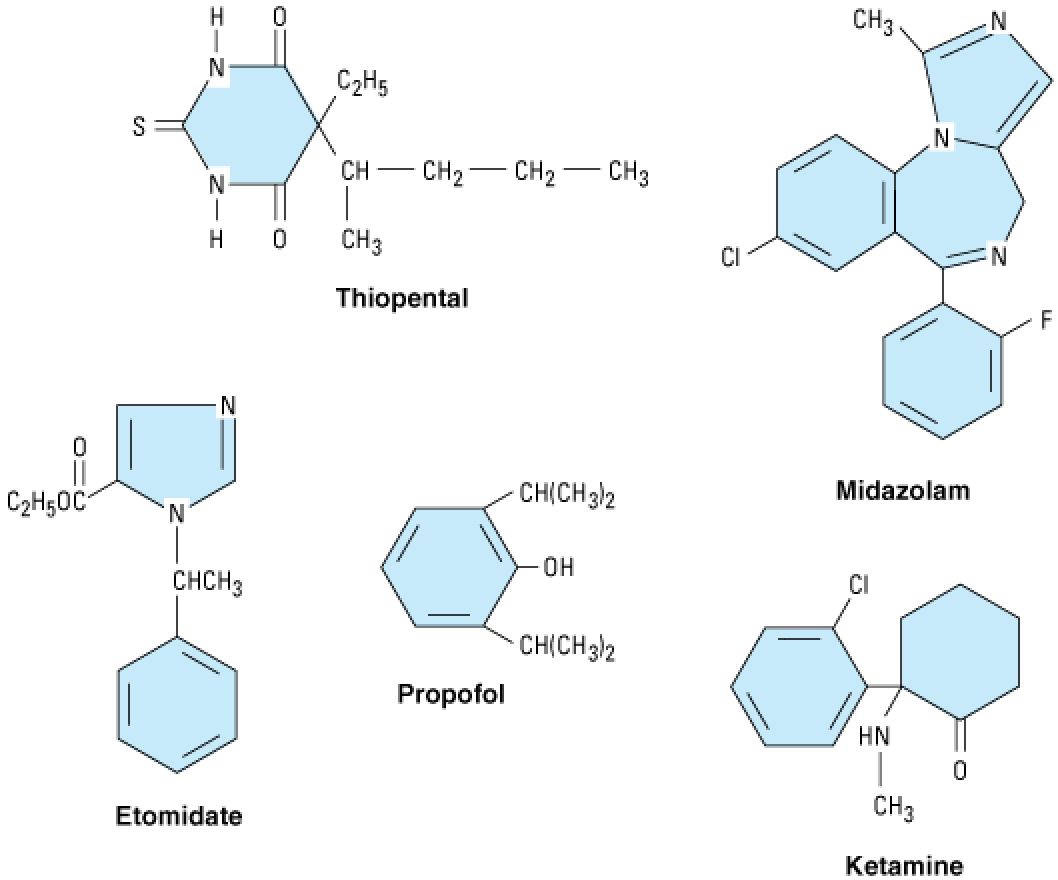
TYPES OF GENERAL ANESTHESIA

General anesthetics are usually administered by intravenous injection or by inhalation. For many years, inhalation anesthesia was used for all major procedures. Recently, intravenous anesthesia has become the more commonly used technique.

Intravenous Anesthetics

Several drugs are administered intravenously, alone or in combination with other anesthetic drugs, to achieve an anesthetic state or to sedate patients in intensive care units (ICUs) who must be mechanically ventilated. These drugs include the following: (1) barbiturates (eg, thiopental, methohexital); (2) benzodiazepines (eg, midazolam, diazepam); (3) propofol (4) ketamine; (5) opioid analgesics (morphine, fentanyl, sufentanil, alfentanil, remifentanil); and (6) miscellaneous sedative-hypnotics (eg, etomidate, dexmedetomidine). Figure 25–1 shows the structures of some commonly used intravenous anesthetics.

Figure 25–1.

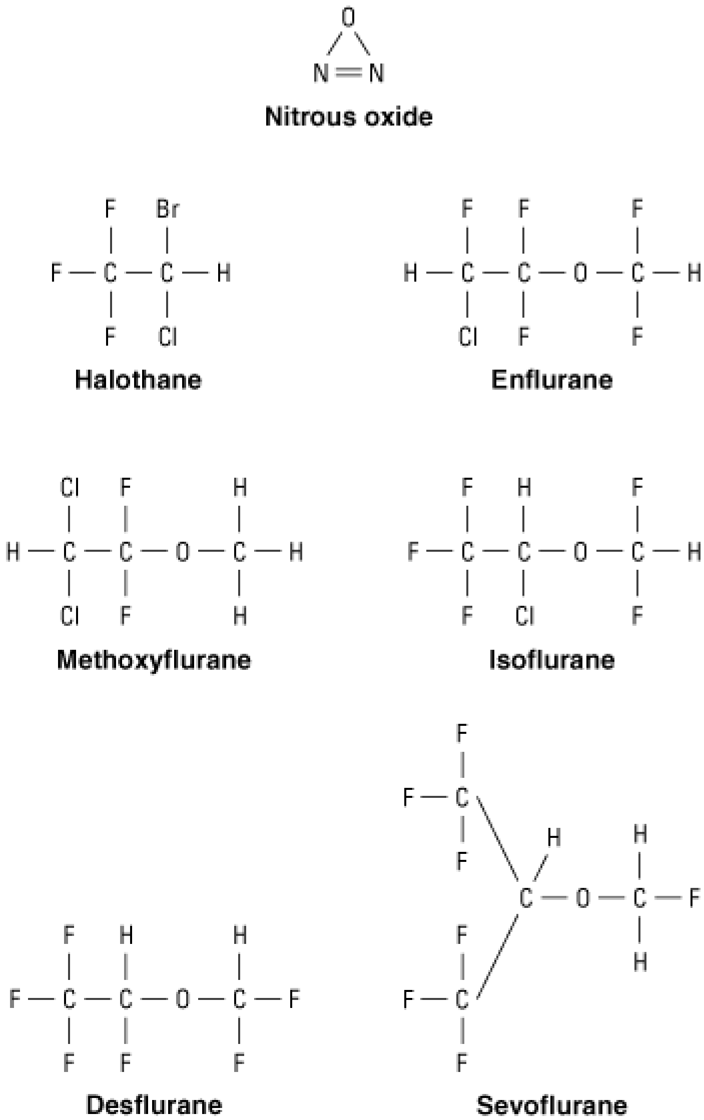


Intravenous anesthetics.

Inhaled Anesthetics

The chemical structures of the currently available inhaled anesthetics are shown in Figure 25–2. The most commonly used inhaled anesthetics are isoflurane, desflurane, and sevoflurane. These compounds are volatile liquids. Nitrous oxide, a gas at ambient temperature and pressure, continues to be an important adjuvant to the volatile agents.

Figure 25–2.



Inhaled anesthetics.

Balanced Anesthesia

Although general anesthesia can be produced using only intravenous or only inhaled anesthetic drugs, modern anesthesia typically involves a combination of intravenous (eg, for induction of anesthesia) and inhaled (eg, for maintenance of anesthesia) drugs. Muscle relaxants are commonly used to facilitate tracheal intubation and optimize surgical conditions (see Chapter 27). Local anesthetics are often administered by tissue infiltration and peripheral nerve blocks to provide perioperative analgesia (see Chapter 26). In addition, potent opioid analgesics and cardiovascular drugs (eg, βblockers, α_2

agonists, calcium channel blockers) are used to control autonomic responses to noxious (painful) surgical stimuli.

STAGES OF ANESTHESIA

The traditional description of the stages of anesthesia (the so-called Guedel's signs) were derived from observations of the effects of diethyl ether, which has a slow onset of central action owing to its high solubility in blood. Using these signs, anesthetic drug effects can be divided into four stages of increasing depth of central nervous system depression:

> I. Stage of analgesia: The patient initially experiences analgesia without amnesia. Later in Stage I, both analgesia and amnesia are produced.
>
> II. Stage of excitement: During this stage, the patient often appears to be delirious and may vocalize but is definitely amnesic. Respiration is irregular both in volume and rate, and retching and vomiting may occur if the patient is stimulated. For these reasons, efforts are made to limit the duration and severity of this stage, which ends with the reestablishment of regular breathing.
>
> III. Stage of surgical anesthesia: This stage begins with the recurrence of regular respiration and extends to complete cessation of spontaneous respiration (apnea). Four planes of stage III have been described in terms of changes in ocular movements, eye reflexes, and pupil size, which under specified conditions may represent signs of increasing depth of anesthesia.
>
> IV. Stage of medullary depression: This deep stage of anesthesia includes severe depression of the vasomotor center in the medulla, as well as the respiratory center. Without circulatory and respiratory support, death rapidly ensues.

In current anesthesia practice, the distinctive signs of each of the four stages described above are usually obscured because of the more rapid onset of action of modern intravenous and inhaled anesthetics (compared with ether), and the fact that ventilation is often controlled mechanically. In addition, the practice of administering other pharmacologic agents preoperatively (eg, preanesthetic medication) or intraoperatively (eg, opioid analgesics, cardiovascular drugs) can also alter the clinical signs of anesthesia. The anticholinergic drugs, atropine and glycopyrrolate, are used to decrease secretions and to treat bradycardia; however, they also dilate the pupils. Muscle relaxants reduce muscle tone and prevent purposeful movements, whereas the opioid analgesics exert depressant effects on both the respiratory and heart rates. The most reliable indication that stage III (surgical anesthesia) has been achieved is loss of responsiveness to noxious stimuli (eg, trapezius muscle squeeze) and reestablishment of a regular respiratory pattern. The adequacy of the depth of anesthesia for a specific surgical stimulus is assessed by monitoring changes in respiratory and cardiovascular responses to the surgical stimulation, as well as electroencephalographic (EEG-based) cerebral indices.

Although vital sign monitoring remains the most common method of assessing depth of anesthesia during surgery, techniques involving computer-assisted monitoring of cerebral function using EEG activity appear to offer some advantages. Automated techniques use processed variables derived from established effects of anesthetics on EEG activity and include the bispectral index (BIS), the physical state index (PSI), and the cerebral state index (CSI). The application of cerebral monitoring techniques has been shown to reduce the anesthetic requirement, contributing to a more rapid recovery from general anesthesia.

INHALED ANESTHETICS

PHARMACOKINETICS

Ensuring an adequate depth of anesthesia depends on achieving a therapeutic concentration of the anesthetic in the central nervous system. The rate at which an effective brain concentration is achieved (ie, time to induction of general anesthesia) depends on multiple pharmacokinetic factors that influence the brain uptake and tissue distribution of the anesthetic agent. The pharmacokinetic properties of the intravenous anesthetics (Table 25–1) and the physicochemical properties of the inhaled agents (Table 25–2) directly influence the pharmacodynamic effects of these drugs. These factors also influence the rate of recovery when the anesthetic is discontinued.

Table 25–1. Characteristics of Intravenous Anesthetics.

Drug	Induction and Recovery	Comments
Etomidate	Rapid onset and moderately fast recovery	Cardiovascular stability; decreased steroidogenesis; involuntary muscle movements
Ketamine	Moderately rapid onset and recovery	Cardiovascular stimulation; increased cerebral blood flow; emergence reactions impair recovery
Midazolam	Slow onset and recovery; flumazenil reversal available	Used in balanced anesthesia and conscious sedation; cardiovascular stability; marked amnesia
Propofol	Rapid onset and rapid recovery	Used in induction and for maintenance; hypotension; useful antiemetic action
Thiopental	Rapid onset and rapid recovery (bolus dose)—slow recovery following infusion	Standard induction agent; cardiovascular depression; avoid in porphyrias
Fentanyl	Slow onset and recovery; naloxone reversal available	Used in balanced anesthesia and conscious sedation; marked analgesia

Table 25–2. Properties of Inhaled Anesthetics.					
Anesthetic	Blood:Gas Partition Coefficient[1]	Brain:Blood Partition Coefficient[1]	Minimal Alveolar Conc (MAC) (%)[2]	Metabolism	Comments
Nitrous oxide	0.47	1.1	> 100	None	Incomplete anesthetic; rapid onset and recovery
Desflurane	0.42	1.3	6–7	< 0.05%	Low volatility; poor induction agent; rapid recovery
Sevoflurane	0.69	1.7	2.0	2–5% (fluoride)	Rapid onset and recovery; unstable in soda-lime
Isoflurane	1.40	2.6	1.40	< 2%	Medium rate of onset and recovery
Enflurane	1.80	1.4	1.7	8%	Medium rate of onset and recovery
Halothane	2.30	2.9	0.75	> 40%	Medium rate of onset and recovery
Methoxyflurane	12	2.0	0.16	> 70% (fluoride)	Very slow onset and recovery

[1]Partition coefficients (at 37 °C) are from multiple literature sources.

[2]MAC is the anesthetic concentration that produces immobility in 50% of patients exposed to a noxious stimulus.

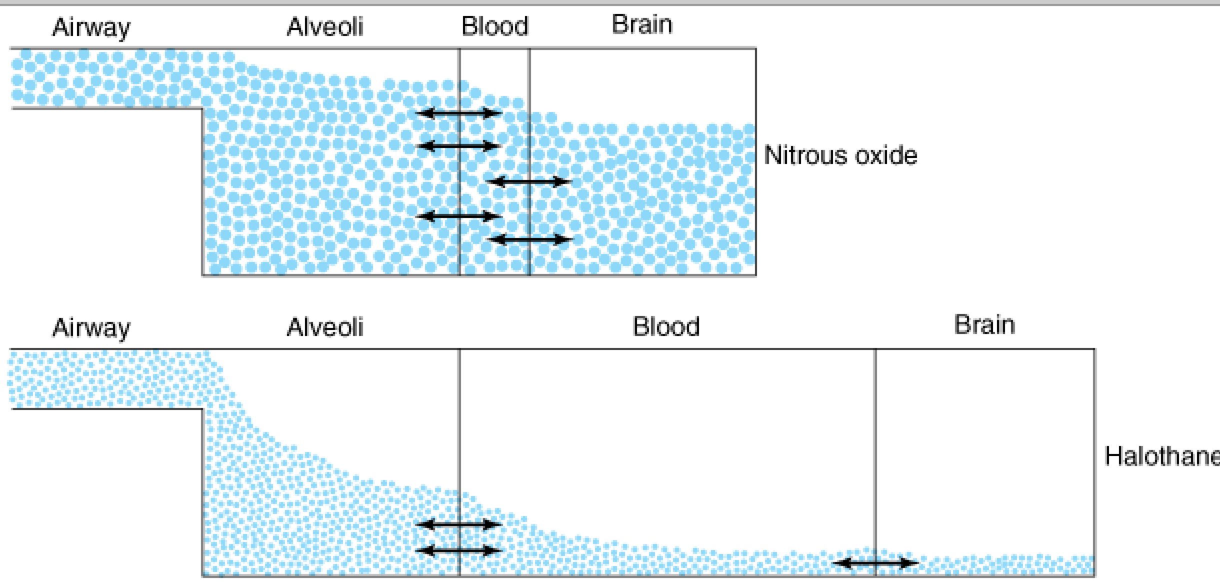
Uptake & Distribution of Inhaled Anesthetics

The concentration of an inhaled anesthetic in a mixture of gases is proportional to its partial pressure (or tension). These terms are often used interchangeably in discussing the various transfer processes involving anesthetic gases in the body. Achievement of a brain concentration of an inhaled anesthetic to provide adequate anesthesia requires transfer of the anesthetic from the alveolar air to the blood and from the blood to the brain. The rate at which a therapeutic concentration of the anesthetic is achieved in the brain depends on the solubility properties of the anesthetic, its concentration in the inspired air, the volume of pulmonary ventilation, the pulmonary blood flow, and the partial pressure gradient between arterial and mixed venous blood anesthetic concentrations.

SOLUBILITY

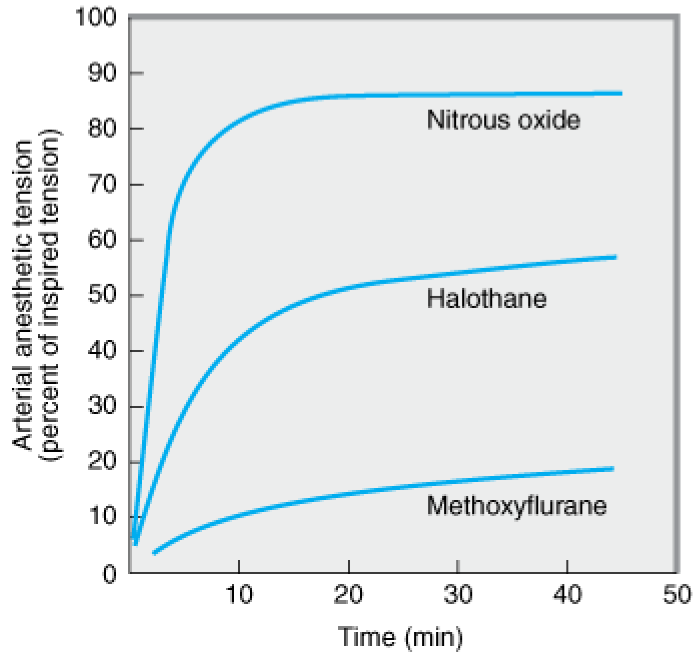
One of the most important factors influencing the transfer of an anesthetic from the lungs to the arterial blood is its solubility characteristics (Table 25–2). The blood:gas partition coefficient is a useful index of solubility and defines the relative affinity of an anesthetic for the blood compared with that of inspired gas. The partition coefficients for desflurane and nitrous oxide, which are relatively insoluble in blood, are extremely low. When an anesthetic with low blood solubility diffuses from the lung into the arterial blood, relatively few molecules are required to raise its partial pressure, and therefore the arterial tension rises rapidly (Figure 25–3, top, nitrous oxide). Conversely, for anesthetics with moderate-to-high solubility (eg, halothane, isoflurane), more molecules dissolve before partial pressure changes significantly, and arterial tension of the gas increases less rapidly (Figure 25–3, bottom, halothane). This inverse relationship between the blood solubility of an anesthetic and the rate of rise of its tension in arterial blood is illustrated in Figure 25–4. Nitrous oxide, with low solubility in blood, reaches high arterial tensions rapidly, which in turn results in rapid equilibration with the brain and fast onset of action. A rapid onset of anesthetic action is also characteristic of desflurane and, to a lesser extent, sevoflurane, volatile anesthetics that have low blood:gas partition coefficients.

Figure 25–3.



Why induction of anesthesia is slower with more soluble anesthetic gases. In this schematic diagram, solubility in blood is represented by the relative size of the blood compartment (the more soluble, the larger the compartment). Relative partial pressures of the agents in the compartments are indicated by the degree of filling of each compartment. For a given concentration or partial pressure of the two anesthetic gases in the inspired air, it will take much longer for the blood partial pressure of the more soluble gas (halothane) to rise to the same partial pressure as in the alveoli. Since the concentration of the anesthetic agent in the brain can rise no faster than the concentration in the blood, the onset of anesthesia will be slower with halothane than with nitrous oxide.

Figure 25–4.



Tensions of three anesthetic gases in arterial blood as a function of time after beginning inhalation. Nitrous oxide is relatively insoluble (blood:gas partition coefficient = 0.47); methoxyflurane is much more soluble (coefficient = 12); and halothane is intermediate (2.3).

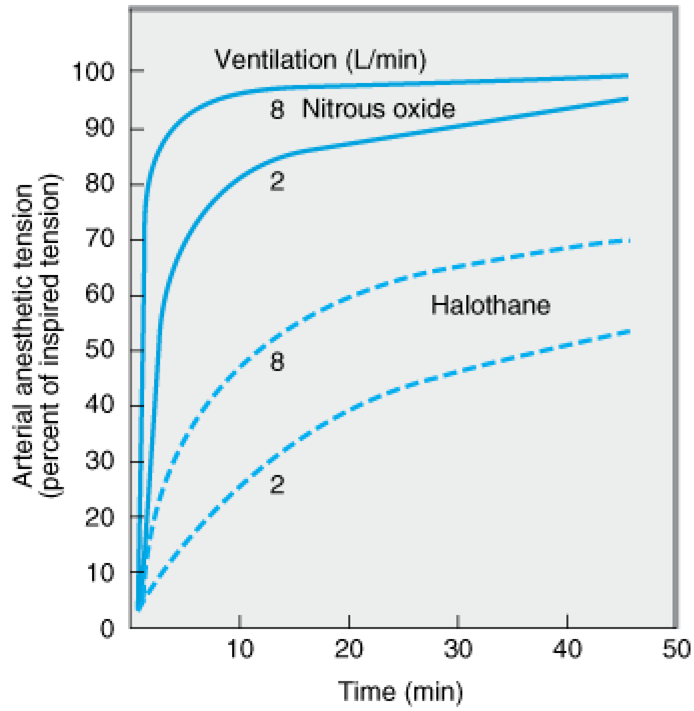
ANESTHETIC CONCENTRATION IN THE INSPIRED AIR

The concentration of an inhaled anesthetic in the inspired gas mixture has direct effects on both the maximum tension that can be achieved in the alveoli and the rate of increase in its tension in arterial blood. Increases in the inspired anesthetic concentration increase the rate of induction of anesthesia by increasing the rate of transfer into the blood according to Fick's law (see Chapter 1). Advantage is taken of this effect in anesthetic practice with inhaled anesthetics that possess moderate blood solubility (eg, enflurane, isoflurane, and halothane). For example, a 1.5% concentration of isoflurane may be administered initially to increase the rate of induction; this is reduced to 0.75–1% for maintenance when adequate anesthesia is achieved. In addition, moderately soluble anesthetics are often administered in combination with a less soluble agent (eg, nitrous oxide) to reduce the time required for loss of consciousness and achievement of a surgical depth of anesthesia.

PULMONARY VENTILATION

The rate of rise of anesthetic gas tension in arterial blood is directly dependent on both the rate and depth of ventilation (ie, minute ventilation). The magnitude of the effect varies according to the blood:gas partition coefficient. An increase in pulmonary ventilation is accompanied by only a slight increase in arterial tension of an anesthetic with low blood solubility or low coefficient but can significantly increase tension of agents with moderate-to-high blood solubility (Figure 25–5). For example, a fourfold increase in ventilation rate almost doubles the arterial tension of halothane during the first 10 minutes of anesthesia but increases the arterial tension of nitrous oxide by only 15%. Therefore, hyperventilation increases the speed of induction of anesthesia with inhaled anesthetics that would normally have a slow onset. Depression of respiration by opioid analgesics slows the onset of anesthesia of inhaled anesthetics if ventilation is not manually or mechanically assisted.

Figure 25–5.



Ventilation rate and arterial anesthetic tensions. Increased ventilation (8 versus 2 L/min) has a much greater effect on equilibration of halothane than nitrous oxide.

PULMONARY BLOOD FLOW

Changes in blood flow to and from the lungs influence transfer processes of the anesthetic gases. An increase in pulmonary blood flow (ie, increased cardiac output) slows the rate of rise in arterial tension, particularly for those anesthetics with moderate-to-high blood solubility. Increased pulmonary blood flow exposes a larger volume of blood to the anesthetic; thus, blood "capacity" increases and the anesthetic tension rises slowly. A decrease in pulmonary blood flow has the opposite effect, increasing the rate of rise of arterial tension of inhaled anesthetics. In patients with circulatory shock, the combined effects of decreased cardiac output (resulting in decreased pulmonary flow) and increased ventilation will accelerate induction of anesthesia with halothane and isoflurane. However, this is not likely to occur with less soluble agents such as nitrous oxide and desflurane.

ARTERIOVENOUS CONCENTRATION GRADIENT

The anesthetic concentration gradient between arterial and mixed venous blood is dependent mainly on uptake of the anesthetic by the tissues, including nonneural tissues. Depending on the rate and extent of tissue uptake, venous blood returning to the lungs may contain significantly less anesthetic than arterial blood. The greater this difference in anesthetic gas tensions, the more time it will take to achieve equilibrium with brain tissue. Anesthetic entry into tissues is influenced by factors similar to those that determine transfer from lung to blood, including tissue:blood partition coefficients, rates of blood flow to the tissues, and concentration gradients.

During the induction phase of anesthesia, the tissues that exert greatest influence on the arteriovenous anesthetic concentration gradient are those which are highly perfused (eg, brain, heart, liver, kidneys, and splanchnic bed). These tissues receive over 75% of the resting cardiac output. In the case of anesthetics with relatively high solubility in highly perfused tissues, venous blood concentration will initially be very low, and equilibrium with arterial blood is achieved slowly.

During maintenance of anesthesia with inhaled anesthetics, the drug continues to be transferred between various tissues at rates dependent on solubility and blood flow. Although muscle and skin constitute 50% of the total body mass, anesthetics accumulate more slowly in them than in highly perfused tissues (eg, brain) because they receive only one-fifth of the resting cardiac output. Although most anesthetic gases are highly soluble in adipose tissues, low blood perfusion to these tissues delays accumulation, and equilibrium is unlikely to occur with most anesthetics during an operation.

Elimination

The time to recovery from inhalation anesthesia depends on the rate of elimination of anesthetics from the brain. Many of the processes of anesthetic transfer during recovery are simply the reverse of those that occur during induction of anesthesia. One of the most important factors governing rate of recovery is the blood:gas partition coefficient of the anesthetic agent. Other factors controlling rate of recovery include the pulmonary blood flow, the magnitude of ventilation, and the tissue solubility of the anesthetic. Two features of recovery, however, are different from what happens during induction of anesthesia. First, although transfer of an anesthetic from the lungs to blood can be enhanced by increasing its concentration in inspired air, the reverse transfer process cannot be enhanced, because the concentration in the lungs cannot be reduced below zero. Second, at the beginning of recovery, the anesthetic gas tension in different tissues may be quite variable, depending on the specific agent and the duration of anesthesia. In contrast, with induction of anesthesia the initial anesthetic tension is zero in all tissues.

Inhaled anesthetics that are relatively insoluble in blood (ie, low blood:gas partition coefficient) and brain are eliminated at faster rates than more soluble anesthetics. The washout of nitrous oxide, desflurane, and sevoflurane occurs at a rapid rate, which leads to a more rapid recovery from their anesthetic effects compared with halothane and isoflurane. Halothane is approximately twice as soluble in brain tissue and five times more soluble in blood than nitrous oxide and desflurane; its elimination therefore takes place more slowly, and recovery from halothane anesthesia is predictably less rapid.

The duration of exposure to the anesthetic can also have a marked effect on recovery time, especially in the case of more soluble anesthetics (eg, isoflurane). Accumulation of anesthetics in muscle, skin, and fat increases with prolonged inhalation (especially in obese patients), and blood tension may decline slowly during recovery as the anesthetic is gradually eliminated from these tissues. Thus, if exposure to the anesthetic is short, recovery may be rapid even with the more soluble agents. However, after prolonged administration, recovery can be delayed even with anesthetics of moderate solubility (eg, isoflurane).

Clearance of inhaled anesthetics via the lungs is the major route of elimination from the body. However, hepatic metabolism may also contribute to the elimination of some volatile anesthetics. For example, the elimination of halothane during recovery is more rapid than that of enflurane, which would not be predicted from their respective tissue solubilities. However, over 40% of inspired halothane is metabolized during an average anesthetic procedure, whereas less than 10% of enflurane is metabolized over the same period. Oxidative metabolism of halothane results in the formation of trifluoroacetic acid and release of bromide and chloride ions. Under conditions of low oxygen tension, halothane is metabolized to the chlorotrifluoroethyl free radical, which is capable of reacting with hepatic membrane components and on rare occasions producing halothane hepatitis. Isoflurane and desflurane are the least metabolized of the fluorinated anesthetics; only traces of trifluoroacetic acid appear in the urine even after prolonged administration.

The metabolism of enflurane and sevoflurane results in the formation of fluoride ion; however, in contrast to the rarely used volatile anesthetic methoxyflurane, renal fluoride levels do not reach toxic levels under normal circumstances. In addition, sevoflurane is degraded by contact with the carbon dioxide absorbent in anesthesia machines, yielding a vinyl ether called "compound A," which can cause renal damage if high concentrations are absorbed. (See Do We Need Another Inhaled Anesthetic?) Seventy percent of the absorbed methoxyflurane is metabolized by the liver, and released fluoride ions can very readily produce nephrotoxicity. In terms of the extent of hepatic metabolism, the rank order for the inhaled anesthetics is methoxyflurane > halothane > enflurane > sevoflurane > isoflurane > desflurane > nitrous oxide (Table 25–2). Nitrous oxide is not metabolized by human tissues. However, bacteria in the gastrointestinal tract may be able to break down the nitrous oxide molecule.

DO WE NEED ANOTHER INHALED ANESTHETIC?

After its introduction in 1956, halothane was the standard of comparison for inhaled anesthetics. However, the onset and recovery from its anesthetic action were slow compared with the commonly used intravenous agents (eg, thiopental). In addition, its hepatic metabolism can result in a reactive compound that may lead to halothane-associated hepatitis.

The newer volatile anesthetics, desflurane and sevoflurane, have physicochemical characteristics (ie, low blood:gas partition coefficients) that are favorable to a more rapid onset and shorter duration of anesthetic actions compared with isoflurane and halothane. However, both of these newer agents also have certain limitations. The low volatility of desflurane necessitates the use of a specialized heated vaporizer, and the pungency of the drug leads to a high incidence of coughing and sympathomimetic side effects that make it less than ideally suited for induction of anesthesia.

Anesthesia is achieved rapidly and smoothly with sevoflurane, and recovery is more rapid than with isoflurane. However, sevoflurane is chemically unstable when exposed to carbon dioxide absorbents in anesthesia machines, degrading to an olefinic compound (fluoromethyl-2,2-difluoro-1-[trifluoromethyl]vinyl ether, also known as compound A) that is potentially nephrotoxic. In addition, sevoflurane is metabolized by the liver to release fluoride ions, raising concerns about potential renal damage.

Sevoflurane comes close to having the characteristics of an ideal inhaled anesthetic; however, a more insoluble compound that lacks the pungency of desflurane and has greater chemical stability than sevoflurane could be a useful alternative to the currently available inhaled agents.

PHARMACODYNAMICS

Mechanism of Action

Both the inhaled and the intravenous anesthetics can depress spontaneous and evoked activity of neurons in many regions of the brain. Older concepts of the mechanism of anesthesia evoked nonspecific interactions of these agents with the lipid matrix of the nerve membrane (the Meyer-Overton principle)—interactions that were thought to lead to secondary changes in ion flux. More recently, evidence has accumulated suggesting that the modification of ion currents by anesthetics results from more direct interactions with specific nerve membrane components. The ionic mechanisms involved for different anesthetics may vary, but at clinically relevant concentrations they appear to involve interactions with members of the ligand-gated ion channel family.

In the past decade, considerable evidence has accumulated that a primary molecular target of general anesthetics is the $GABA_A$ receptor-chloride channel, a major mediator of inhibitory synaptic transmission. Inhaled anesthetics, barbiturates, benzodiazepines, etomidate, and propofol facilitate GABA-mediated inhibition at $GABA_A$ receptor sites. These receptors are sensitive to clinically relevant concentrations of the anesthetic agents and exhibit the appropriate stereospecific effects in the case of enantiomeric drugs. The $GABA_A$ receptor-chloride channel is a pentameric assembly of five proteins derived from several polypeptide subclasses (see Chapter 22). Combinations of three major subunits—α, β, and γ—are necessary for normal physiologic and pharmacologic functions. $GABA_A$ receptors in different areas of the central nervous system contain different subunit combinations, conferring different pharmacologic properties on each receptor subtype. Both inhaled and intravenous anesthetics with sedative-hypnotic properties directly activate $GABA_A$ receptors, but at low concentrations they can also facilitate the action of GABA to increase chloride ion flux. In contrast, sedative benzodiazepines that lack general anesthetic properties (eg, diazepam, lorazepam) facilitate GABA action but have no direct actions on $GABA_A$ receptors even at high concentrations in the absence of GABA.

Reconstitution studies with transfected cells utilizing chimeric and mutated $GABA_A$ receptors reveal that anesthetic molecules do not interact directly with the GABA binding site but with specific sites in the transmembrane domains of both α and β subunits. Two specific amino acid residues in transmembrane segments 2 and 3 of the $GABA_A$ receptor α_2 subunit, Ser270 and Ala291, are critical for the enhancement of $GABA_A$ receptor function by inhaled anesthetics. One consequence of the interaction of isoflurane with this domain is an alteration in the gating of the chloride ion channel. However, differences occur in the precise binding sites of individual anesthetics. For example, a specific aspartate residue within transmembrane segment 2 of the $GABA_A$ receptor α_2 subunit is required for etomidate activity but is not essential for the activity of barbiturates or propofol.

Ketamine does not produce its effects via facilitation of $GABA_A$ receptor functions, but it may function via antagonism of the action of the excitatory neurotransmitter glutamic acid on the *N*-methyl-D-aspartate (NMDA) receptor. This receptor may also be a target for nitrous oxide.

In addition to their action on $GABA_A$ chloride channels, certain general anesthetics have been reported to cause membrane hyperpolarization (ie, an inhibitory action) via their activation of potassium channels. These channels are ubiquitous in the central nervous system and some are linked to neurotransmitters, including acetylcholine, dopamine, norepinephrine, and serotonin. Electrophysiologic analyses of membrane ion flux in cultured cells have shown that inhaled anesthetics decrease the duration of opening of nicotinic receptor-activated cation channels—an action that decreases the excitatory effects of acetylcholine at cholinergic synapses. Most inhaled anesthetics inhibit nicotinic acetylcholine receptor isoforms, particularly those containing the α_4 subunit, though such actions do not appear to be involved in their immobilizing actions. The strychnine-sensitive glycine receptor is another ligand-gated ion channel that may function as a target for inhaled anesthetics, which can elicit channel opening directly and independently of their facilitatory effects on neurotransmitter binding.

The neuropharmacologic basis for the effects that characterize the stages of anesthesia appears to be differential sensitivity of specific neurons or neuronal pathways to the anesthetic drugs. Neurons in the substantia gelatinosa of the dorsal horn of the spinal cord are very sensitive to relatively low anesthetic concentrations. Interaction with neurons in this region interrupts sensory transmission in the spinothalamic tract, including transmission of nociceptive (pain) stimuli. These effects contribute to stage I analgesia and conscious sedation. The disinhibitory effects of general anesthetics (stage II), which occur at higher brain concentrations, result from complex neuronal actions, including blockade of many small inhibitory neurons such as Golgi type II cells, together with a paradoxical facilitation of excitatory neurotransmitters. A progressive depression of ascending pathways in the reticular activating system occurs during stage III of anesthesia; also occurring is suppression of spinal reflex activity, which contributes to muscle relaxation. Neurons in the respiratory and vasomotor centers of the medulla are relatively insensitive to the effects of general anesthetics, but at high concentrations their activity is depressed, leading to cardiorespiratory collapse (stage IV). It remains to be determined whether regional variation in anesthetic actions corresponds to the regional variation in the subtypes of $GABA_A$ receptors. The differential sensitivity of specific neurons or neuronal pathways to anesthetics could reflect their interactions with other molecules in the fast ligand-gated ion channel family or could represent the existence of other molecular targets that have yet to be characterized.

Dose-Response Characteristics: The Concept of Minimum Alveolar Anesthetic Concentration

Inhaled anesthetics are delivered to the lungs in gas mixtures in which concentrations and flow rates are easy to measure and control. However, dose-response characteristics of gaseous anesthetics are difficult to measure. Although achievement of an anesthetic state depends on the concentration of the anesthetic in the brain (ie, effect site), concentrations in the brain tissue are obviously impossible to measure under clinical conditions. Furthermore, neither the lower nor the upper ends of the graded dose-response curve defining the effect on the central nervous system can be ethically determined because at very low gas concentrations awareness of pain may occur. Moreover, at high concentrations there is a high risk of severe cardiovascular and respiratory depression. Nevertheless, a useful estimate of anesthetic potency can be obtained using quantal dose-response principles.

During general anesthesia, the partial pressure of an inhaled anesthetic in the brain equals that in the lung when steady state is reached. Therefore, at a given level of anesthesia, measurements of the steady-state alveolar concentrations of different anesthetics provide a comparison of their relative potencies. The volatile anesthetic concentration is the percentage of the alveolar gas mixture, or partial pressure of the anesthetic as a percentage of 760 mm Hg (atmospheric pressure at sea level). The minimum alveolar anesthetic concentration (MAC) is defined as the *median concentration that results in immobility in 50% of patients when exposed to a noxious stimulus* (eg, surgical incision). Therefore, the MAC represents one point (the ED_{50}) on a conventional quantal dose-response curve (see Figure 2–16). Table 25–2 shows MAC values of the inhaled anesthetics, permitting comparison of their relative anesthetic potencies. The MAC value greater than 100% for nitrous oxide demonstrates that it is the least potent inhaled anesthetic. At normal barometric pressure, even 760 mm Hg partial pressure of nitrous oxide (100% of the inspired gas) is still less than 1 MAC, so it must be supplemented with other agents to achieve full surgical anesthesia (see below).

The dose of anesthetic gas that is being administered can be stated in multiples of MAC. A dose of 1 MAC of any anesthetic prevents movement in response to surgical incision in 50% of patients; however, individual patients may require 0.5–1.5 MAC. Unfortunately, MAC gives no information about the slope of the dose-response curve. In general, however, the dose-response relationship for inhaled anesthetics is very steep. Therefore, over 95% of patients may fail to respond to a noxious stimulus at 1.1 MAC.

The measurement of MAC values under controlled conditions has permitted quantitation of the effects of a number of variables on anesthetic requirements. For example, MAC values decrease in elderly patients and with hypothermia, but are not affected greatly by sex, height, and weight. Of particular importance is the presence of adjuvant drugs, which can change anesthetic requirement significantly. When intravenous drugs (eg, opioid analgesics, sympatholytics, or sedative-hypnotics) are administered as adjuvants to the volatile anesthetics, MAC is decreased in a dose-related fashion. The inspired concentration of anesthetic should be decreased in these situations.

MAC values of the inhaled anesthetics are additive. For example, nitrous oxide (60–70%) can be used as a "carrier" gas producing 40% of a MAC, thereby decreasing the anesthetic requirement of inhaled volatile and intravenous anesthetics. The addition of nitrous oxide (60% tension, 40% MAC) to 70% of a volatile agent's MAC would yield a total of 110% of a MAC, a value sufficient for surgical anesthesia in most patients.

Organ System Effects of Inhaled Anesthetics

EFFECTS ON THE CARDIOVASCULAR SYSTEM

Halothane, desflurane, enflurane, sevoflurane, and isoflurane all decrease mean arterial pressure in direct proportion to their alveolar concentration. With halothane and enflurane, the reduced arterial pressure appears to be caused by a reduction in cardiac output because there is little change in systemic vascular resistance despite marked changes in individual vascular beds (eg, an increase in cerebral blood flow). In contrast, isoflurane, desflurane, and sevoflurane have a depressant effect on arterial pressure as a result of a decrease in systemic vascular resistance with minimal effect on cardiac output.

Inhaled anesthetics change heart rate either directly by altering the rate of sinus node depolarization or indirectly by shifting the balance of autonomic nervous system activity. Bradycardia can be seen with halothane, probably because of direct vagal stimulation. In contrast, enflurane, and sevoflurane have little effect, and both desflurane and isoflurane increase heart rate. In the case of desflurane, transient sympathetic activation with elevations in catecholamine levels can lead to marked increases in heart rate and blood pressure when high inspired gas concentrations are administered.

All inhaled anesthetics tend to increase right atrial pressure in a dose-related fashion, which reflects depression of myocardial function. In general, enflurane and halothane have greater myocardial depressant effects than isoflurane and the newer, less soluble halogenated anesthetics. Inhaled anesthetics reduce myocardial oxygen consumption, primarily by decreasing the variables that control oxygen demand, such as arterial blood pressure and contractile force (see Chapter 12). Although it produces less depression than the volatile anesthetics, nitrous oxide has also been found to depress the myocardium in a dose-dependent manner. However, administration of nitrous oxide in combination with the more potent inhaled (volatile) anesthetics can minimize cardiac depressant effects owing to its anesthetic-sparing effect.

Several factors influence the cardiovascular effects of inhaled anesthetics. Surgical stimulation, intravascular volume status, ventilatory status, and duration of anesthesia alter the cardiovascular depressant effects of these drugs. Hypercapnia releases catecholamines, which attenuate the decrease in blood pressure. As a result, the blood pressure decrease after 5 hours of anesthesia is less than it is after 1 hour; however, concomitant use of β-blockers reduces this adaptive effect. Halothane and, to a lesser extent, isoflurane sensitize the myocardium to circulating catecholamines. Ventricular arrhythmias may occur in patients with cardiac disease who are given sympathomimetic drugs or have high circulating levels of endogenous catecholamines (eg, anxious patients, those given epinephrine-containing local anesthetics, and those with pheochromocytoma). However, the less soluble inhaled anesthetics appear to be less arrhythmogenic.

EFFECTS ON THE RESPIRATORY SYSTEM

With the exception of nitrous oxide, all inhaled anesthetics in current use cause a dose-dependent decrease in tidal volume and an increase in respiratory rate. However, the increase in rate is insufficient to compensate for the decrease in volume, resulting in a decrease in minute ventilation. All volatile anesthetics are respiratory depressants, as indicated by a reduced response to increased levels of carbon dioxide. The degree of ventilatory depression varies among the volatile agents, with isoflurane and enflurane being the most depressant. All volatile anesthetics in current use increase the resting level of Pa_{CO_2} (the partial pressure of carbon dioxide in arterial blood).

Volatile anesthetics increase the apneic threshold (Pa_{CO_2} level below which apnea occurs through lack of CO_2-driven respiratory stimulation) and decrease the ventilatory response to hypoxia. The latter effect is especially important because subanesthetic concentrations during the early recovery period can depress the normal compensatory increase in ventilation that occurs during hypoxic states. The respiratory depressant effects of anesthetics are overcome by assisting (or controlling) ventilation mechanically. Furthermore, the ventilatory depressant effects of inhaled anesthetics are counteracted by surgical stimulation.

Inhaled anesthetics also depress mucociliary function in the airway. Thus, prolonged anesthesia may lead to pooling of mucus and then result in atelectasis and postoperative respiratory infections.

However, volatile anesthetics possess varying degrees of bronchodilating properties), an effect of value in the treatment of active wheezing and status asthmaticus. The bronchodilating action of halothane and sevoflurane makes them the induction agents of choice in patients with underlying airway problems (eg, asthma, bronchitis, chronic obstructive pulmonary disease). Airway irritation, which may provoke coughing or breath-holding, is rarely a problem with halothane and sevoflurane. However, the pungency of desflurane make this agent less suitable for induction of anesthesia despite its low blood:gas partition coefficient.

EFFECTS ON THE BRAIN

Inhaled anesthetics decrease the metabolic rate of the brain. Nevertheless, the more soluble volatile agents increase cerebral blood flow because they decrease cerebral vascular resistance. The increase in cerebral blood flow is clinically undesirable in patients who have increased intracranial pressure because of a brain tumor or head injury. Volatile anesthetic-induced increases in cerebral blood flow increase cerebral blood volume and further increase intracranial pressure.

Of the inhaled anesthetics, nitrous oxide is the least likely to increase cerebral blood flow. At low concentrations, all of the halogenated agents have similar effects on cerebral blood flow. However, at higher concentrations, the increase in cerebral blood flow is less with the more insoluble agents such as desflurane and sevoflurane. If the patient is hyperventilated before the volatile agent is started, the increase in intracranial pressure can be minimized.

Halothane, isoflurane, and enflurane have similar depressant effects on the EEG up to doses of 1–1.5 MAC. At higher doses, the cerebral irritant effects of enflurane may lead to development of a spike-and-wave pattern and mild generalized muscle twitching (ie, myoclonic activity). However, this seizure-like activity has not been found to have any adverse clinical consequences. Seizure-like EEG activity has also been described after sevoflurane, but not desflurane. Although nitrous oxide has a very low anesthetic potency, it does possess both analgesic and amnesic properties when used alone or in combination with other agents as part of a balanced anesthesia technique.

EFFECTS ON THE KIDNEY

Depending on the concentration, volatile anesthetics decrease the glomerular filtration rate and renal blood flow, and increase the filtration fraction. Since renal blood flow decreases during general anesthesia in spite of well-maintained or even increased perfusion pressures (due to increased renal vascular resistance), autoregulation of renal flow may be impaired.

EFFECTS ON THE LIVER

Volatile anesthetics cause a concentration-dependent decrease in hepatic blood flow ranging from 15% to 45% below the preinduction (baseline) value. Despite transient intraoperative changes in liver function tests, permanent changes in liver enzyme function are rare.

EFFECTS ON UTERINE SMOOTH MUSCLE

Nitrous oxide appears to have little effect on uterine musculature. However, the halogenated anesthetics are potent uterine muscle relaxants and produce this effect in a concentration-dependent fashion. This pharmacologic effect can be used to advantage when profound uterine relaxation is required for an intrauterine fetal manipulation or manual extraction of a retained placenta during delivery.

Toxicity

HEPATOTOXICITY (HALOTHANE)

Postoperative hepatic dysfunction is typically associated with factors such as blood transfusions, hypovolemic shock, and other surgical stresses rather than volatile anesthetic toxicity. However, a small subset of individuals who have been previously exposed to halothane may develop potentially life-threatening hepatitis. The incidence of severe hepatotoxicity following exposure to halothane is in the range of one in 20,000–35,000. Obese patients who have had more than one exposure to halothane during a short time interval may be the most susceptible. There is no specific treatment for halothane hepatitis, and therefore liver transplantation may ultimately be required.

The mechanisms underlying hepatotoxicity from halothane remain unclear, but studies in animals have implicated the formation of reactive metabolites that either cause direct hepatocellular damage (eg, free radicals) or initiate immune-mediated responses. With regard to the latter mechanism, serum from patients with halothane hepatitis contains a variety of autoantibodies against hepatic proteins. Trifluoroacetylated (TFA) proteins in the liver could be formed in the hepatocyte during the biotransformation of halothane by liver drug-metabolizing enzymes. It is interesting that TFA proteins have also been identified in the sera of patients who did not develop hepatitis after halothane anesthesia.

NEPHROTOXICITY

Metabolism of methoxyflurane, enflurane, and sevoflurane leads to the formation of fluoride ions, and this has raised questions concerning the nephrotoxicity of these three volatile anesthetics. Changes in renal concentrating ability have been observed with prolonged exposure to both methoxyflurane and enflurane but not sevoflurane. Differences between the agents may be related to the fact that methoxyflurane and enflurane (but not sevoflurane) are metabolized in part by renal enzymes (eg, β-lyase), generating fluoride ions intrarenally. Sevoflurane degradation by carbon dioxide absorbents in anesthesia machines leads to formation of a haloalkene, compound A, which is metabolized by renal β-lyase to form thioacylhalide and causes a proximal tubular necrosis when administered to rats. However, there have been no reports of renal injury in humans receiving sevoflurane anesthesia. Moreover, the anesthetic does not appear to change standard markers of renal function. Renal dysfunction following methoxyflurane is caused by inorganic fluoride released during the extensive metabolism of this anesthetic by hepatic and renal enzymes. As a result, methoxyflurane, though still available, is no longer used in clinical practice.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia is an autosomal dominant genetic disorder of skeletal muscle that occurs in susceptible individuals undergoing general anesthesia with volatile agents and muscle relaxants (eg, succinylcholine). The malignant hyperthermia syndrome consists of the rapid onset of tachycardia and hypertension, severe muscle rigidity, hyperthermia, hyperkalemia, and acid-base imbalance with acidosis that follows exposure to a triggering agent (see Table 16–4). Malignant hyperthermia is a rare but important cause of anesthetic morbidity and mortality. The specific biochemical abnormality is an increase in free calcium concentration in skeletal muscle cells. Treatment includes administration of dantrolene (to reduce calcium release from the sarcoplasmic reticulum) and appropriate measures to reduce body temperature and restore electrolyte and acid-base balance.

Malignant hyperthermia susceptibility is characterized by genetic heterogeneity, and several predisposing clinical myopathies have been identified. It has been associated with mutations in the gene loci corresponding to the skeletal muscle ryanodine receptor (RyRl), the calcium release channel on the sarcoplasmic reticulum. Mutations in the *RyR1* gene are inherited as mendelian dominant characteristics. Other chromosomal loci for malignant hyperthermia susceptibility include mutant alleles of the gene encoding the α_1 subunit of the human skeletal muscle dihydropyridine-sensitive L-type voltage-dependent calcium channel. However, the genetic loci identified to date account for no more than 50% of malignant hyperthermia-susceptible individuals. Given the degree of genetic heterogeneity, it is premature to use genetic testing methods for malignant hyperthermia susceptibility. Currently, the most reliable test to establish such susceptibility is the in vitro caffeine-halothane contracture test using skeletal muscle biopsy tissue.

CHRONIC TOXICITY

Mutagenicity

Under normal conditions, inhaled anesthetics (including nitrous oxide) are neither mutagens nor carcinogens in patients.

Carcinogenicity

Epidemiologic studies suggested an increase in the cancer rate in operating room personnel who were exposed to trace concentrations of anesthetic agents. However, no study has demonstrated the existence of a causal relationship between anesthetics and cancer. Many other factors might account for the questionably positive results seen after a careful review of epidemiologic data. Most operating rooms now use scavenging systems to remove trace concentrations of anesthetics released from anesthetic machines.

Effects on Reproductive Organs

The most consistent finding reported in surveys conducted to determine the reproductive success of female operating room personnel has been a questionably higher than expected incidence of miscarriages. However, there are several problems in interpreting these studies.

The association of obstetrical problems with surgery and anesthesia in pregnant patients is also an important consideration. In the USA, at least 50,000 pregnant women each year undergo anesthesia and surgery for indications unrelated to pregnancy. The risk of abortion is clearly higher following this experience. It is not obvious, however, whether the underlying disease, surgery, anesthesia, or a combination of these factors is the cause of the increased risk.

Hematotoxicity

Prolonged exposure to nitrous oxide decreases methionine synthase activity and theoretically can cause megaloblastic anemia, a potential occupational hazard for staff working in inadequately ventilated dental operating suites.

Clinical Use of Inhaled Anesthetics

Volatile anesthetics are rarely used as the sole agents for both induction and maintenance of anesthesia. Most commonly, they are combined with intravenous agents as part of a balanced anesthesia technique. Of the inhaled anesthetics, nitrous oxide, desflurane, sevoflurane, and isoflurane are the most commonly used in the USA. Use of less soluble volatile anesthetics (especially desflurane and sevoflurane) has increased during the last decade as more surgical procedures are performed on an ambulatory ("short-stay") basis. The low blood:gas coefficients of desflurane and sevoflurane afford a more rapid recovery and fewer postoperative adverse effects than halothane, enflurane, and isoflurane. Although halothane is still used in pediatric anesthesia, sevoflurane is rapidly replacing halothane in this setting. As indicated previously, nitrous oxide lacks sufficient potency to produce surgical anesthesia by itself and therefore is used with volatile or intravenous anesthetics to produce a state of balanced general anesthesia. Despite the obvious advantages of the less soluble inhaled anesthetics, there is reason to believe that better ones might be developed (see Do We Need Another Inhaled Anesthetic?).

INTRAVENOUS ANESTHETICS

In the last two decades there has been increasing use of intravenous anesthetics in anesthesia, both as adjuncts to inhaled anesthetics and as part of techniques that do not include any inhaled anesthetics (eg, total intravenous anesthesia). The properties of some of the commonly used intravenous anesthetics are summarized in Table 25–1. Unlike inhaled anesthetics, intravenous agents do not require specialized vaporizer equipment for their delivery or facilities for the disposal of exhaled gases. Intravenous drugs such as thiopental, methohexital, etomidate, ketamine, and propofol have an onset of anesthetic action faster than the most rapid inhaled agents (eg, desflurane and sevoflurane). Therefore, intravenous agents are commonly used for induction of general anesthesia.

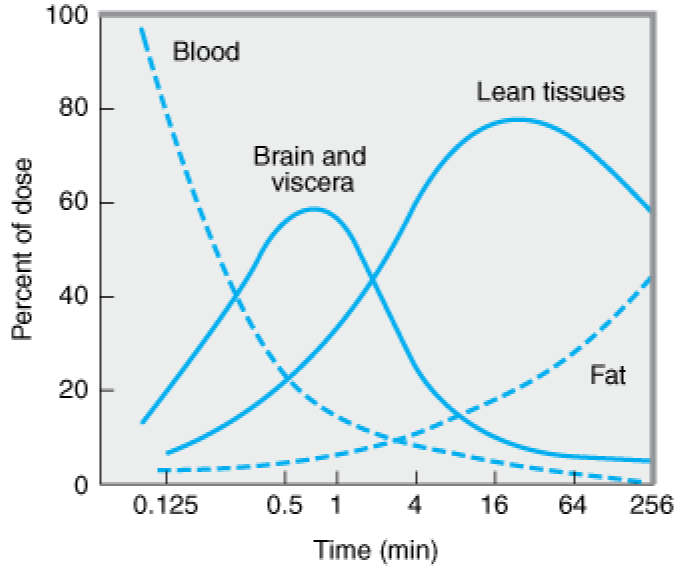
Recovery is sufficiently rapid with most intravenous drugs to permit their use for short ambulatory (outpatient) surgical procedures. In the case of propofol, recovery times are similar to those seen with sevoflurane and desflurane. The anesthetic potency of intravenous anesthetics is adequate to permit their use as the sole anesthetic in short surgical procedures when combined with nitrous oxide. Adjunctive use of potent opioids (eg, fentanyl and sufentanil; see Chapter 31) contributes cardiovascular stability, enhanced sedation, and profound perioperative analgesia. Benzodiazepines (eg, midazolam, diazepam) have a slower onset and slower recovery than the barbiturates or propofol and are rarely used for induction of anesthesia. However, preanesthetic administration of benzodiazepines (eg, midazolam) can be used to provide anxiolysis, sedation, and amnesia when used in conjunction with other anesthetic agents.

BARBITURATES

The general pharmacology of the barbiturates is discussed in Chapter 22. Thiopental is a barbiturate commonly used for induction of anesthesia. Thiamylal is structurally almost identical to thiopental and has the same pharmacokinetic and pharmacodynamic profile.

After an intravenous bolus injection, thiopental rapidly crosses the blood-brain barrier and, if given in sufficient dosage, produces loss of consciousness (hypnosis) in one circulation time. Similar effects occur with the shorter-acting barbiturate, methohexital. With both of these barbiturates, plasma:brain equilibrium occurs rapidly (< 1 minute) because of their high lipid solubility. Thiopental rapidly diffuses out of the brain and other highly vascular tissues and is redistributed to muscle and fat (Figure 25–6). Because of this rapid removal from brain tissue, a single dose of thiopental produces only a brief period of unconsciousness. Thiopental is metabolized at the rate of only 12–16% per hour in humans following a single dose and less than 1% of the administered dose of thiopental is excreted unchanged by the kidney.

Figure 25–6.



Redistribution of thiopental after an intravenous bolus administration. Note that the time axis is not linear.

With large doses (or a continuous infusion), thiopental produces dose-dependent decreases in arterial blood pressure, stroke volume, and cardiac output. These hemodynamic effects are due primarily to a myocardial depressant effect and increased venous capacitance; there is little change in total peripheral resistance. Thiopental is also a potent respiratory depressant, producing transient apnea and lowering the sensitivity of the medullary respiratory center to carbon dioxide.

Cerebral metabolism and oxygen utilization are decreased after barbiturate administration in proportion to the degree of cerebral depression. Cerebral blood flow is also decreased, but less than oxygen consumption. Because intracranial pressure and blood volume are not increased (in contrast to the volatile anesthetics), thiopental is a desirable drug for patients with cerebral swelling (eg, head trauma, brain tumors). Methohexital can cause central excitatory activity (eg, myoclonus) and has been useful for neurosurgical procedures involving ablation of seizure foci. However, it also has antiseizure activity and is the drug of choice for providing anesthesia in patients undergoing electroconvulsive therapy (ECT). Given its more rapid elimination, methohexital is also preferred over thiopental for short ambulatory procedures.

Barbiturates reduce hepatic blood flow and glomerular filtration rate, but these drugs produce no adverse effects on hepatic or renal function. Barbiturates can exacerbate acute intermittent porphyria by inducing the production of hepatic α-aminolevulinic acid (ALA) synthase (see Chapter 22). On rare occasions, thiopental has precipitated porphyric crisis when used as an induction agent in susceptible patients.

BENZODIAZEPINES

Diazepam, lorazepam, and midazolam are used in anesthetic procedures. The primary indication is for premedication because of their sedative, anxiolytic, and amnestic properties, and to control acute agitation. (The basic pharmacology of benzodiazepines is discussed in Chapter 22.) Diazepam and lorazepam are not water-soluble, and their intravenous use necessitates nonaqueous vehicles, which cause pain and local irritation. Midazolam is water-soluble and is the benzodiazepine of choice for parenteral administration. It is important that the drug becomes lipid-soluble at physiologic pH and can readily cross the blood-brain barrier to produce its central effects.

Compared with the intravenous barbiturates, benzodiazepines produce a slower onset of central nervous system depressant effects which reach a plateau at a depth of sedation that is inadequate for surgical anesthesia. Using large doses of benzodiazepines to achieve deep sedation prolongs the postanesthetic recovery period and can produce a high incidence of anterograde amnesia. Because it possesses sedative-anxiolytic properties and causes a high incidence of amnesia (> 50%), midazolam is frequently administered intravenously before patients enter the operating room. Midazolam has a more rapid onset, a shorter elimination half-life (2–4 hours), and a steeper dose-response curve than do the other available benzodiazepines.

The benzodiazepine antagonist flumazenil can be used to accelerate recovery when excessive doses of intravenous benzodiazepines are administered (especially in elderly patients). However, reversal of benzodiazepine-induced respiratory depression is less predictable. The short duration of action (< 90 minutes) of flumazenil may necessitate multiple doses to prevent recurrence of the central nervous system depressant effects of the longer-acting benzodiazepines (eg, lorazepam, diazepam).

OPIOID ANALGESICS

Large doses of opioid analgesics have been used in combination with large doses of benzodiazepines to achieve a general anesthetic state, particularly in patients undergoing cardiac surgery or other major surgery when the patient's circulatory reserve is limited. Although intravenous morphine, 1–3 mg/kg, was used many years ago, the high-potency opioids fentanyl, 100–150 mcg/kg, and sufentanil, 0.25–0.5 mcg/kg IV, have been used more recently in such patients. More recently also, remifentanil, a potent and extremely short-acting opioid, has been used to minimize residual ventilatory depression.

Despite the use of high doses of potent opioids (see Table 31–2), awareness during anesthesia and unpleasant postoperative recall can occur. Furthermore, high doses of opioids during surgery can cause chest wall (and laryngeal) rigidity, thereby acutely impairing ventilation, as well as increasing postoperative opioid requirements owing to the development of acute tolerance. Therefore, lower doses of fentanyl and sufentanil have been used as premedication and as an adjunct to both intravenous and inhaled anesthetics to provide perioperative analgesia. The shorter-acting alfentanil and remifentanil have been used as co-induction agents with intravenous sedative-hypnotic anesthetics because they have a rapid onset of action. Remifentanil is rapidly metabolized by esterases in the blood (not plasma cholinesterase) and muscle tissues, contributing to an extremely rapid recovery from its opioid effects. The metabolism of remifentanil is not subject to genetic variability, and the drug does not interfere with the clearance of other compounds metabolized by plasma cholinesterase (eg, esmolol, mivacurium, or succinylcholine). Opioid analgesics can also be administered in very low doses by the epidural and subarachnoid (spinal) routes of administration to produce excellent postoperative analgesia. Fentanyl and droperidol (a butyrophenone related to haloperidol) administered together produce analgesia and amnesia and combined with nitrous oxide provide a state referred to as neuroleptanesthesia.

PROPOFOL

Propofol (2,6-diisopropylphenol) has become the most popular intravenous anesthetic. Its rate of onset of action is similar to that of the intravenous barbiturates but recovery is more rapid and patients are able to ambulate earlier after general anesthesia. Furthermore, patients subjectively "feel better" in the immediate postoperative period because of the reduction in postoperative nausea and vomiting. Propofol is used for both induction and maintenance of anesthesia as part of total intravenous or balanced anesthesia techniques and is the agent of choice for ambulatory surgery. The drug is also effective in producing prolonged sedation in patients in critical care settings (see Conscious & Deep Sedation). When administered by prolonged infusion for sedation or ventilatory management in the intensive care unit, cumulative effects can lead to delayed arousal. In addition, prolonged administration of conventional emulsion formulations can elevate serum lipid levels. Use of propofol for the sedation of critically ill young children has led to severe acidosis in the presence of respiratory infections and to possible neurologic sequelae upon withdrawal.

After intravenous administration of propofol, the distribution half-life is 2–8 minutes, and the redistribution half-life is approximately 30–60 minutes. The drug is rapidly metabolized in the liver at a rate ten times faster than thiopental. Propofol is excreted in the urine as glucuronide and sulfate conjugates, with less than 1% of the parent drug excreted unchanged. Total body clearance of the anesthetic is greater than hepatic blood flow, suggesting that its elimination includes extrahepatic mechanisms in addition to metabolism by liver enzymes. This property can be useful in patients with impaired ability to metabolize other sedative-anesthetic drugs.

Effects on respiratory function are similar to those of thiopental at usual anesthetic doses and include dose-related depression of central ventilatory drive and apnea. However, propofol causes a marked decrease in blood pressure during induction of anesthesia through decreased peripheral arterial resistance and venodilation. In addition, propofol has greater direct negative inotropic effects than other intravenous anesthetics. Pain at the site of injection is the most common adverse effect of bolus administration. Muscle movements, hypotonus, and (rarely) tremors have also been reported after prolonged use. Clinical infections due to bacterial contamination of the propofol emulsion have led to the addition of antimicrobial adjuvants (eg, ethylenediaminetetraacetic acid [EDTA] and metabisulfite). Newer formulations of propofol have been developed that contain less lipid for prolonged administration (eg, Ampofol). However, pain on injection is increased when the lipid content is reduced. Admixture or pretreatment with lidocaine (20–50 mg) is the most effective approach to minimizing the pain on injection of propofol.

Conscious & Deep Sedation

Many diagnostic and minor therapeutic surgical procedures can be performed without general anesthesia. In this setting, regional or local anesthesia supplemented with midazolam or propofol and opioid analgesics (or ketamine) may be a more appropriate and safer approach than general anesthesia.

Another approach has led to the development of conscious sedation or drug-induced alleviation of anxiety and pain in combination with an altered level of consciousness associated with minimal sedation and retention of the ability of the patient to maintain a patent airway and to respond to verbal commands. A wide variety of intravenous anesthetic agents have proved to be useful drugs in conscious sedation techniques (eg, diazepam, midazolam, propofol). For example, intravenous midazolam, propofol, and a potent opioid analgesic can provide amnestic, sedative, and analgesic effects without loss of consciousness as part of a monitored anesthesia care (MAC) technique. Use of benzodiazepines and opioid analgesics in conscious sedation protocols has the advantage of being reversible by the specific receptor antagonist drugs (flumazenil and naloxone, respectively).

A specialized form of conscious sedation is occasionally required in the ICU, when patients are under severe stress and require mechanical ventilation for prolonged periods. In this situation, sedative-hypnotic drugs or low doses of intravenous anesthetics, neuromuscular blocking drugs, and dexmedetomidine may be combined. Dexmedetomidine is an α_2 agonist with sedative and analgesic effects. It has a half-life of 2–3 hours and is metabolized in the liver and excreted mainly as inactive urinary metabolites.

Deep sedation is similar to a light state of general anesthesia involving decreased consciousness from which the patient is not easily aroused. Because deep sedation is often accompanied by a loss of protective reflexes, an inability to maintain a patent airway, and lack of verbal responsiveness to surgical stimuli, this state may be indistinguishable from general anesthesia. Intravenous agents used in deep sedation protocols include thiopental, methohexital, ketamine, propofol, and the potent opioid analgesics.

ETOMIDATE

Etomidate is a carboxylated imidazole that can be used for induction of anesthesia in patients with limited cardiovascular reserve. Its major advantage over other intravenous anesthetics is that it causes minimal cardiovascular and respiratory depression. Etomidate produces a rapid loss of consciousness, with minimal hypotension even in elderly patients with poor cardiovascular reserve. The heart rate is usually unchanged, and the incidence of apnea is low. The drug has no analgesic effects, and coadministration of opioids may be required to decrease cardiac responses during tracheal intubation and to lessen spontaneous muscle movements. Following an induction dose, initial recovery with etomidate is less rapid (< 10 minutes) compared with recovery with propofol.

Distribution of etomidate is rapid, with a biphasic plasma concentration curve showing initial and intermediate distribution half-lives of 3 and 29 minutes, respectively. Redistribution of the drug from brain to highly perfused tissues appears to be responsible for the relatively short duration of its anesthetic effects. Etomidate is extensively metabolized in the liver and plasma to inactive metabolites, with only 2% of the drug excreted unchanged in the urine.

Etomidate causes a high incidence of pain on injection, myoclonic activity, and postoperative nausea and vomiting. The involuntary muscle movements are not associated with electroencephalographic epileptiform activity. Etomidate may also cause adrenocortical suppression via inhibitory effects on steroidogenesis, with decreased plasma levels of cortisol after a single dose. Prolonged infusion of etomidate in critically ill patients may result in hypotension, electrolyte imbalance, and oliguria because of its adrenal suppressive effects.

KETAMINE

Ketamine is a racemic mixture of two optical isomers, *S*(+) and *R*(-) ketamine. The drug produces a dissociative anesthetic state characterized by catatonia, amnesia, and analgesia, with or without loss of consciousness (hypnosis). The drug is an arylcyclohexylamine chemically related to phencyclidine (PCP), a drug with a high abuse potential owing to its psychoactive properties. The mechanism of action of ketamine may involve blockade of the membrane effects of the excitatory neurotransmitter glutamic acid at the NMDA receptor subtype (see Chapter 21). Ketamine is a highly lipophilic drug and is rapidly distributed into well-perfused organs, including the brain, liver, and kidney. Subsequently ketamine is redistributed to less well perfused tissues with concurrent hepatic metabolism followed by both urinary and biliary excretion.

Ketamine is the only intravenous anesthetic that possesses both analgesic properties and the ability to produce dose-related cardiovascular stimulation. Heart rate, arterial blood pressure, and cardiac output can be significantly increased above baseline values. These variables reach a peak 2–4 minutes after an intravenous bolus injection, then slowly decline to normal values over the next 10–20 minutes. Ketamine produces its cardiovascular effects by stimulating the central sympathetic nervous system and, to a lesser extent, by inhibiting the reuptake of norepinephrine at sympathetic nerve terminals. Increases in plasma epinephrine and norepinephrine levels occur as early as 2 minutes after an intravenous bolus of ketamine and return to baseline levels in less than 15 minutes.

Ketamine markedly increases cerebral blood flow, oxygen consumption, and intracranial pressure. Similar to the volatile anesthetics, ketamine is a potentially dangerous drug when intracranial pressure is elevated. Although ketamine decreases the respiratory rate, upper airway muscle tone is well maintained and airway reflexes are usually preserved.

Use of ketamine has been associated with postoperative disorientation, sensory and perceptual illusions, and vivid dreams (so-called emergence phenomena). Diazepam, 0.2–0.3 mg/kg, or midazolam, 0.025–0.05 mg intravenously, given before the administration of ketamine reduce the incidence of these adverse effects. Because of the high incidence of postoperative psychic phenomena associated with its use, ketamine fell into disfavor. However, use of low doses of ketamine in combination with other intravenous and inhaled anesthetics has become an increasingly popular alternative to opioid analgesics to minimize ventilatory depression. In addition, ketamine is very useful for poor-risk geriatric patients and high-risk patients in cardiogenic or septic shock because of its cardiostimulatory properties. It is also used in low doses for outpatient anesthesia in combination with propofol and in children undergoing painful procedures (eg, dressing changes for burns). In an effort to enhance ketamine's efficacy and reduce its side-effect profile, investigators separated the isomers and demonstrated that the *S*(+) ketamine possessed greater anesthetic and analgesic potency. However, even the *S*(+) isomer of ketamine possesses psychotomimetic side effects.

PREPARATIONS AVAILABLE*

Desflurane (Suprane)

Liquid: 240 mL for inhalation

Dexmedetomidine (Precedex)

Parenteral: 100 mcg/mL for IV infusion

Diazepam (generic, Valium)

Oral: 2, 5, 10 mg tablets; 1 mg/mL and 5 mg/mL solution

Oral sustained-release: 15 mg capsules

Rectal: 2.5, 5, 15, 19, 20 mg gel

Parenteral: 5 mg/mL for injection

Droperidol (generic, Inapsine)

Parenteral: 2.5 mg/mL for IV or IM injection

Enflurane (Enflurane, Ethrane)

Liquid: 125, 250 mL for inhalation

Etomidate (Amidate)

Parenteral: 2 mg/mL for injection

Halothane (generic, Fluothane)

Liquid: 125, 250 mL for inhalation

Isoflurane (Isoflurane, Forane)

Liquid: 100 mL for inhalation

Ketamine (generic, Ketalar)

Parenteral: 10, 50, 100 mg/mL for injection

Lorazepam (generic, Ativan)

Parenteral: 2, 4 mg/mL for injection

Methohexital (Brevital)

Parenteral: 0.5, 2.5, 5 g powder to reconstitute for injection

Methoxyflurane (Penthrane)

Liquid: 15, 125 mL for inhalation

Midazolam (generic, Versed)

Parenteral: 1, 5 mg/mL for injection in 1, 2, 5, 10 mL vials

Oral: 2 mg/mL syrup for children

Nitrous oxide (gas, supplied in blue cylinders)

Propofol (generic, Diprivan)

Parenteral: 10 mg/mL for IV injection

Sevoflurane (Ultane)

Liquid: 250 mL for inhalation

Thiopental (generic, Pentothal)

Parenteral: powder to reconstitute 20, 25 mg/mL for IV injection

*See Chapter 31 for formulations of opioid agents used in anesthesia.

Bottom of Form

LOCAL ANESTHETICS: INTRODUCTION

Local anesthetics reversibly block impulse conduction along nerve axons and other excitable membranes that utilize sodium channels as the primary means of action potential generation. Clinically, local anesthetics are use to block pain sensation from—or sympathetic vasoconstrictor impulses to—specific areas of the body. The first local anesthetic introduced into medical practice, cocaine, was isolated by Niemann in 1860 and introduced into practice by Koller in 1884 as an ophthalmic anesthetic. Despite the fact that its chronic use was associated with psychological dependence (addiction), cocaine was used clinically because it was the only local anesthetic drug available for 30 years. In an attempt to improve upon the clinical properties of cocaine, Einhorn in 1905 synthesized procaine, which became the dominant local anesthetic for the next 50 years. Subsequently, newer local anesthetics were introduced with the goal of reducing local tissue irritation, minimizing systemic cardiac ar central nervous system (CNS) toxicity, and achieving a faster onset and longer duration of action. Lidocaine, which is still the most widely used local anesthetic, was synthesized in 1943 by Löfgren.

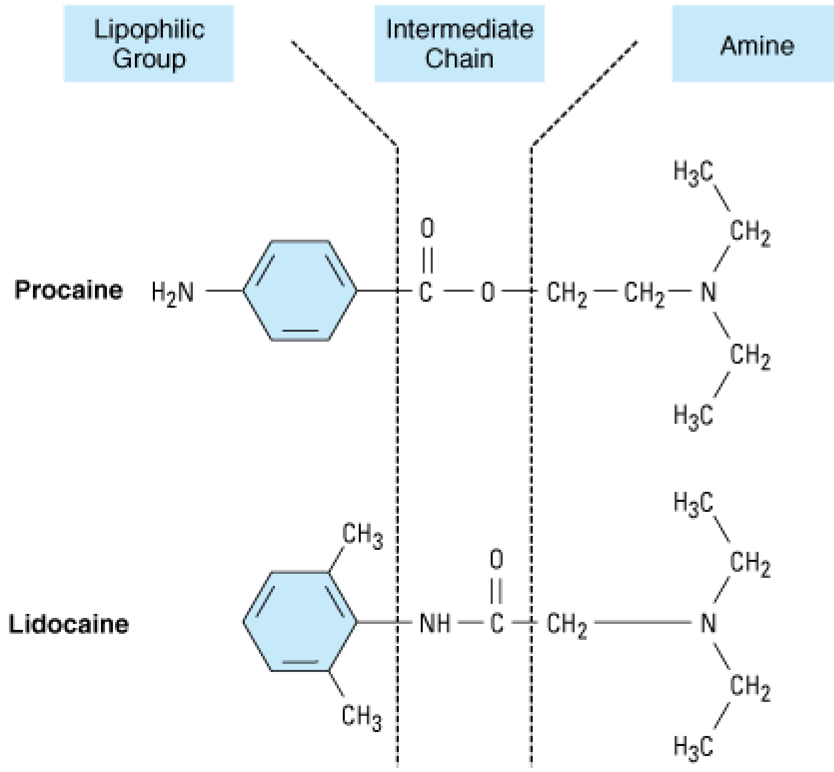
The development of newer agents continues because it is relatively easy to synthesize chemicals with local anesthetic properties. Unfortunately, it is difficult to reduce the toxicity of these compounds because the comm side effects of local anesthetics represent extensions of their therapeutic effects. New research into the mechanisms of local anesthetic-induced cardiac and spinal toxicity and identification of alternative drug targets for spinal analgesia (eg, opioid receptors, α_2 adrenoceptors, NMDA receptors, N-type calcium channels, and adenosine receptors) suggest that it may be possible to develop safer drugs in the future. To extend the durati of the local anesthetic action, a variety of novel delivery systems are in development (eg, polymers, suspensions). Transdermal local anesthetic delivery systems have also been successfully introduced into clinical practice for providing topical analgesia.

BASIC PHARMACOLOGY OF LOCAL ANESTHETICS

Chemistry

Most local anesthetic agents consist of a lipophilic group (eg, an aromatic ring) connected by an intermediate chain via an ester or amide to an ionizable group (eg, a tertiary amine) (Figure 26–1; Table 26–1). In addition t the general physical properties of the molecules, specific stereochemical configurations are associated with differences in the potency of stereoisomers (eg, bupivacaine, ropivacaine). Because ester links are more prone hydrolysis than amide links, esters usually have a shorter duration of action.

Figure 26-1.



Structures of two prototypical local anesthetics, the aminoester procaine and the aminoamide lidocaine. In both drugs, a lipophilic aromatic group is joined to a more hydrophilic tertiary amine base, by an intermediate amide or ester bond.

[1] Other chemical types are available including ethers (pramoxine), ketones (dyclonine), and phenetidin derivatives (phenacaine).

Local anesthetics are weak bases and are usually made available clinically as salts to increase solubility and stability. In the body, they exist either as the uncharged base or as a cation. The relative proportions of these two forms is governed by their pK_a and the pH of the body fluids according to the Henderson-Hasselbalch equation:

$$\log \frac{\text{Cationic form}}{\text{Uncharged form}} = pK_a - pH$$

Because the pK_a of most local anesthetics is in the range of 8.0–9.0, the larger percentage in body fluids at physiologic pH will be the charged, cationic form. The cationic form is the most active form at the receptor site because it cannot readily exit from closed channels. However, the uncharged form is important for rapid penetration of biologic membranes and producing a clinical effect, since the local anesthetic receptor is not readily accessible from the external side of the cell membrane. Therefore, local anesthetics are much less effective when they are injected into infected tissues because a smaller percentage of the local anesthetic is nonionized and available for diffusion across the membrane in an environment with a low extracellular pH.

Pharmacokinetics

The pharmacokinetic properties of the commonly used amide local anesthetics are summarized in Table 26–2. The pharmacokinetics of the ester-based local anesthetics have not been extensively studied owing to their rap breakdown in plasma (elimination half-life < 1 minute). Local anesthetics are usually administered by injection into dermis and soft tissues located in the area of nerves. Thus, absorption and distribution are not as importan in controlling the onset of effect as in determining the rate of offset of local analgesia, and the likelihood of CNS and cardiac toxicity. Topical application of local anesthetics (eg, transmucosal or transdermal) requires drug diffusion for both onset and offset of anesthetic effect.

ABSORPTION

Systemic absorption of injected local anesthetic from the site of administration is determined by several factors including dosage, site of injection, drug-tissue binding, local blood flow, use of vasoconstrictors (eg, epinephrin and the physicochemical properties of the drug itself. Application of a local anesthetic to a highly vascular area such as the tracheal mucosa or the tissue surrounding intercostal nerves results in more rapid absorption and thus higher blood levels than if the local anesthetic had been injected into a poorly perfused tissue such as tendon, dermis, or subcutaneous fat. For regional anesthesia involving block of large nerves, maximum blood levels of local anesthetic decrease according to the site of administration in the following order: intercostal (highest) > caudal > epidural > brachial plexus > sciatic nerve (lowest).

Vasoconstrictor substances such as epinephrine reduce systemic absorption of local anesthetics from the injecti site by decreasing blood flow in these areas. This is important for drugs with intermediate or short durations of action such as procaine, lidocaine, and mepivacaine (but not prilocaine).

Since blood levels are lowered up to 30% when vasoconstrictors are added to local anesthetics, localized neuronal uptake is enhanced because of higher local tissue concentrations in the region of drug administration, and the systemic toxic effects are reduced. Furthermore, when used in spinal anesthesia, epinephrine acts directly on the cord to both enhance and prolong local anesthetic-induced spinal anesthesia by acting on α_2 adrenoceptors, which inhibit release of substance P (neurokinin-1) and reduce sensory neuron firing. The recognition of this fact has led to the use of clonidine and dexmedetomidine to augment local anesthetic effect the subarachnoid space and on peripheral nerves. The combination of reduced systemic absorption, enhanced local neuronal anesthetic uptake, and α_2 activation by epinephrine in the CNS is responsible for prolonging the local anesthetic effect by up to 50%. Vasoconstrictors are less effective in prolonging anesthetic action of the more lipid-soluble, long-acting drugs (eg, bupivacaine and ropivacaine), possibly because these molecules are highly tissue-bound. Finally, cocaine is unique owing to its intrinsic sympathomimetic properties.

DISTRIBUTION

The amide local anesthetics are widely distributed after intravenous bolus administration. There is also evidenc that sequestration can occur in lipophilic storage sites (eg, fat). After an initial rapid distribution phase, which consists of uptake into highly perfused organs such as the brain, liver, kidney, and heart, a slower distribution phase occurs with uptake into moderately well-perfused tissues, such as muscle and the gastrointestinal tract. a result of the extremely short plasma half-lives of the ester type agents, their tissue distribution has not been extensively studied.

METABOLISM AND EXCRETION

The local anesthetics are converted in the liver (amide type) or in plasma (ester type) to more water-soluble metabolites and then excreted in the urine. Since local anesthetics in the uncharged form diffuse readily throug lipid membranes, little or no urinary excretion of the neutral form occurs. Acidification of urine promotes ionization of the tertiary amine base to the more water-soluble charged form, which is more readily excreted.

Ester-type local anesthetics are hydrolyzed very rapidly in the blood by circulating butyrylcholinesterase (pseudocholinesterase) to inactive metabolites. Therefore, procaine and chloroprocaine have very short plasma half-lives (< 1 minute).

The amide linkage of amide local anesthetics is hydrolyzed by liver microsomal cytochrome P450 isozymes. The is considerable variation in the rate of liver metabolism of individual amide compounds, the approximate order being prilocaine (fastest) > lidocaine > mepivacaine > ropivacaine > bupivacaine and levobupivacaine (slowest As a result, toxicity from amide-type local anesthetics is more likely to occur in patients with hepatic disease. F example, the average elimination half-life of lidocaine may be increased from 1.6 hours in normal patients ($t_{1/2}$ Table 26–2) to more than 6 hours in patients with severe liver disease. Many other drugs used in anesthesia ar metabolized by the same P450 isozymes, and concomitant use of these competing drugs may slow the hepatic metabolism of the local anesthetics.

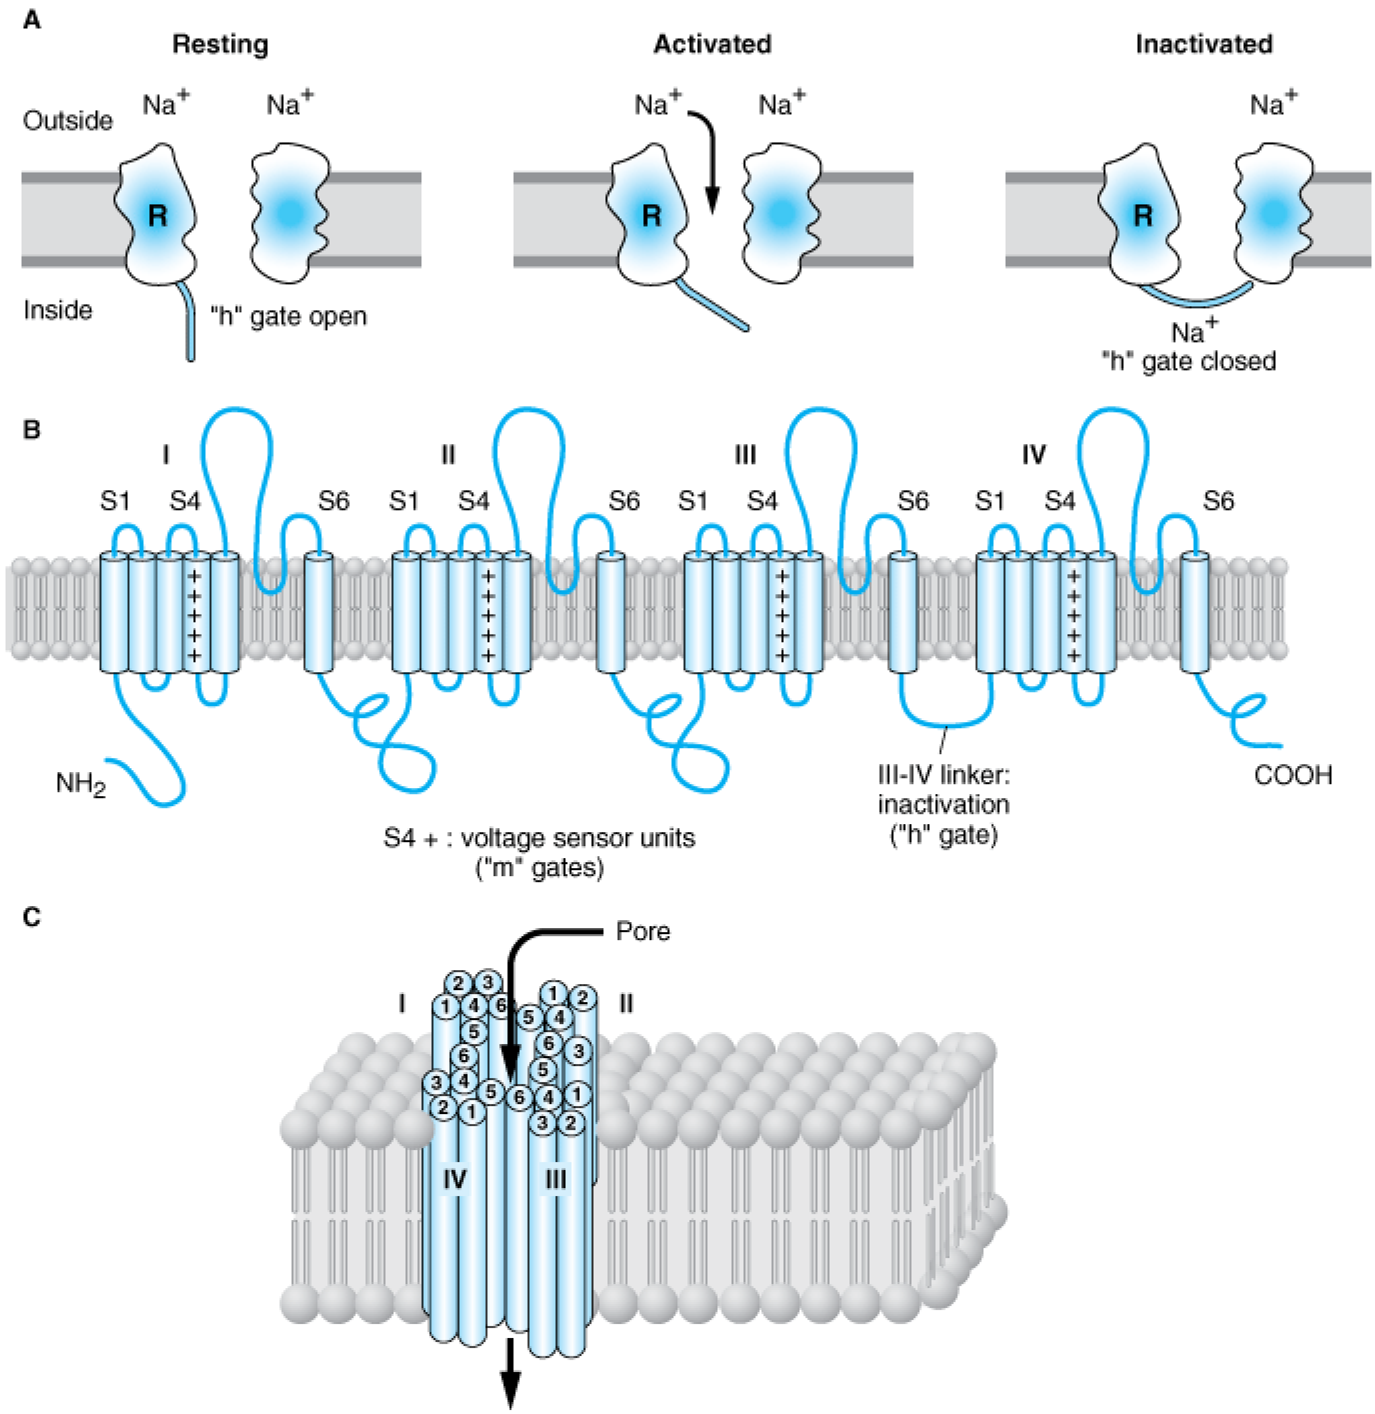
Decreased hepatic elimination of local anesthetics would also be anticipated in patients with reduced hepatic blood flow. For example, the hepatic elimination of lidocaine in patients anesthetized with volatile anesthetics (which reduce liver blood flow) is slower than in patients anesthetized with intravenous anesthetics.

Pharmacodynamics

MECHANISM OF ACTION

The primary mechanism of action of local anesthetics is **blockade of voltage-gated sodium channels** (Figure 26–2). The excitable membrane of nerve axons, like the membrane of cardiac muscle (see Chapter 14) and neuronal cell bodies (see Chapter 21), maintains a resting transmembrane potential of –90 to –60 mV. During excitation, the sodium channels open, and a fast inward sodium current quickly depolarizes the membrane toward the sodium equilibrium potential (+40 mV). As a result of depolarization, the sodium channels close (inactivate) and potassium channels open. The outward flow of potassium repolarizes the membrane toward the potassium equilibrium potential (about –95 mV); repolarization returns the sodium channels to the rested state. The transmembrane ionic gradients are maintained by the sodium pump. These ionic fluxes are similar to those heart muscle, and local anesthetics have similar effects in both tissues.

Figure 26-2.



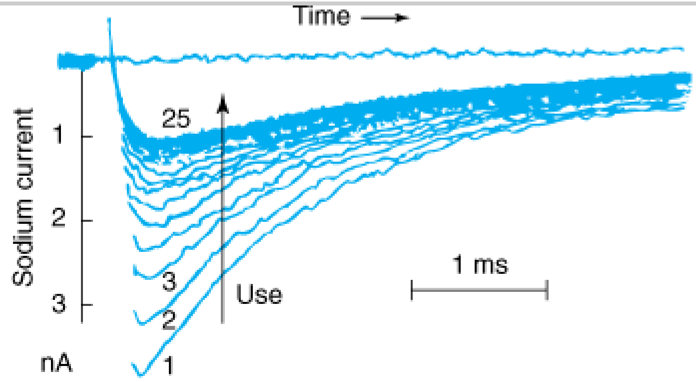
Functional and structural features of the Na^+ channel that determine local anesthetic (LA) interactions. A: Cartoon of the sodium channel in an axonal membrane in the resting (h gate open), activated (h gate open), and inactivated states (h gate closed). Recovery from the inactivated, refractory state requires opening of the h gate. Local anesthetics bind to a receptor (within the channel and access it via the membrane phase or from the cytoplasm. B: Molecular arrangement of the 6 membrane-spanning peptides, four of which combine to form the channel around a central pore. The S4 segments (marked with "+" signs) are thought to constitute the voltage-sensing "m" gates of the channel. The linker peptide connecting the III and IV hexamers acts as the inactivation "h" gate. Ions travel through an open channel along a pore defined at its narrowes dimension by partial membrane penetration of the four extracellular loops of protein connecting S5 and S6 in each domain. Local anesthetic binding occurs on S6 segments and at other regions of the channel. C: Three-dimensional cartoon showing the configuration of the four hexamers around the central pore in the membrane.

The function of sodium channels can be disrupted in several ways. Biologic toxins such as batrachotoxin, aconitine, veratridine, and some scorpion venoms bind to receptors within the channel and prevent inactivation. This results in prolonged influx of sodium through the channel and depolarization of the resting potential. The marine toxins tetrodotoxin (TTX) and saxitoxin block sodium channels by binding to channel receptors near the extracellular surface. Their clinical effects superficially resemble those of local anesthetics (ie block of conduction without a change in the resting potential) even though their receptor site is quite different. Spinal neurons can be differentiated on the basis of tetrodotoxin effect into TTX-sensitive and TTX-resistant neurons. Some evidence suggests that the TTX-resistant neurons are responsible for pain transmission and are the primary targets for local anesthetics in producing spinal anesthesia. Local anesthetics bind to receptors nea the intracellular end of the sodium channel and block the channel in a time- and voltage-dependent fashion (se below). The sodium channel has been cloned, its primary structure has been characterized, and mutational analysis has allowed identification of parts of the local anesthetic binding site.

When progressively increasing concentrations of a local anesthetic are applied to a nerve fiber, the threshold fo excitation increases, impulse conduction slows, the rate of rise of the action potential declines, the action potential amplitude decreases, and, finally, the ability to generate an action potential is completely abolished. These progressive effects result from binding of the local anesthetic to more and more sodium channels. If the sodium current is blocked over a critical length of the nerve, propagation across the blocked area is no longer possible. In myelinated nerves, the critical length is 2 to 3 nodes of Ranvier. At the minimum dose required to block propagation, the resting potential is not significantly altered.

The blockade of sodium channels by most local anesthetics is both *voltage-* and *time-dependent:* Channels in tl rested state, which predominate at more negative membrane potentials, have a much lower affinity for local anesthetics than activated (open state) and inactivated channels, which predominate at more positive membra potentials (see Figure 14–8). Thus, the effect of a given drug concentration is more marked in rapidly firing axo than in resting fibers (Figure 26–3).

Figure 26–3.



Effect of repetitive activity on the block of sodium current produced by a local anesthetic in a myelinated axon. A series of 25 pulses was applied, and the resulting sodium currents (downward deflections) are superimposed. Note that the current produced by the pulses rapidly decreased from the first to the 25th pulse. A long rest period following the train resulted in recovery from block, but the block could be reinstated by a subsequent train. (nA, nanoamperes.) (Modified and reproduced with permission, from Courtney KR: Mechanism of frequency-dependent inhibition of sodium currents in frog myelinated ner by the lidocaine derivative GEA. J Pharmacol Exp Ther 1975;195:225.)

Between successive action potentials, a portion of the sodium channels will recover from the local anesthetic block (see Figure 14–8). The recovery from drug-induced block is 10 to 1000 times slower than the recovery of channels from normal inactivation (as shown for the cardiac membrane in Figure 14–4). As a result, the refractory period is lengthened and the nerve conducts fewer impulses.

Elevated extracellular calcium partially antagonizes the action of local anesthetics owing to the calcium-induced increase in the surface potential on the membrane (which favors the low-affinity rested state). Conversely, increases in extracellular potassium depolarize the membrane potential and favor the inactivated state, enhancing the effect of local anesthetics.

Local anesthetics can be shown to block a variety of other ion channels, including nicotinic acetylcholine channe in the spinal cord. However, there is no convincing evidence that this mechanism is important in the clinical effects of these drugs. High concentrations of local anesthetics can interfere with intra-axonal transport and calcium homeostasis in the nerve terminal, contributing to potential spinal toxicity.

STRUCTURE-ACTIVITY CHARACTERISTICS OF LOCAL ANESTHETICS

The smaller and more lipophilic the local anesthetic, the faster the rate of interaction with the sodium channel receptor. Potency is also positively correlated with lipid solubility as long as the agent retains sufficient water solubility to diffuse to the site of action on the neuronal membrane. Lidocaine, procaine, and mepivacaine are more water-soluble than tetracaine, bupivacaine, and ropivacaine. The latter agents are more potent and have longer durations of local anesthetic action. These long-acting local anesthetics also bind more extensively to proteins and can be displaced from these binding sites by other protein-bound drugs. In the case of optically active agents (eg, bupivacaine), the *S* (+)isomer can usually be shown to be moderately more potent than the (-) isomer.

OTHER ACTIONS ON NERVES

Since local anesthetics are capable of blocking all nerves, their actions are not limited to the desired loss of sensation from sites of noxious (painful) stimuli. Although motor paralysis can be desirable during surgery, it m also limit the ability of the patient to cooperate during obstetric delivery or ambulate after outpatient surgery. During spinal anesthesia, motor paralysis may impair respiratory activity and autonomic nerve blockade can lea to hypotension upon ambulation. Residual autonomic blockade interferes with bladder function resulting in urina retention and the need for catheterization.

Nerve fibers differ significantly in their susceptibility to local anesthetic blockade on the basis of differences in si and degree of myelination (Table 26–3). Upon direct application of a local anesthetic to a nerve root, the smalle B and C fibers are blocked first, followed by other sensations, and motor function is the last to be blocked.

Table 26–3. Relative Size and Susceptibility of Different Types of Nerve Fibers to Local Anesthetics.

Fiber Type

	Function	Diameter (μm)	Myelination	Conduction Velocity (m/s)	Sensitivity to Block
Type A					
Alpha	Proprioception, motor	12–20	Heavy	70–120	+
Beta	Touch, pressure	5–12	Heavy	30–70	++

Effect of Fiber Diameter

Local anesthetics preferentially block small fibers because the distance over which such fibers can passively propagate an electrical impulse is shorter. During the onset of local anesthesia, when short sections of the nerv are blocked, the small-diameter fibers are the first to fail to conduct. For myelinated nerves, at least two and preferably three successive nodes of Ranvier must be blocked by the local anesthetic to halt impulse propagatic With larger and thicker nerve fibers (eg, motor neurons), the nodes are farther apart, creating greater resistan to blockade. Myelinated nerves tend to become blocked before unmyelinated nerves of the same diameter. For this reason, the preganglionic B fibers are blocked before the smaller unmyelinated C fibers involved in pain transmission.

Effect of Firing Frequency

Another important reason for preferential blockade of sensory fibers follows directly from the state- and use-dependent mechanism of action of local anesthetics. Blockade by these drugs is more marked at higher frequencies of depolarization. Sensory (pain) fibers have a high firing rate and a relatively long action potential duration. Motor fibers fire at a slower rate and have a shorter action potential duration. Type A delta and C fibe are smaller-diameter fibers that participate in high-frequency pain transmission. Therefore, these fibers are blocked earlier with lower concentrations of local anesthetics than are the large A alpha fibers.

Effect of Fiber Position in the Nerve Bundle

An anatomic circumstance that sometimes creates exceptions to the above rules for differential nerve block is t location of the fibers in the peripheral nerve bundle. In large nerve trunks, motor nerves are usually located circumferentially, and for that reason they are the first to be exposed to the local anesthetic when it is administered into the tissue surrounding the nerve. Therefore, it is not uncommon for motor nerve block to occ before sensory block in large mixed nerves. In the extremities, proximal sensory fibers are located in the outer portion of the nerve trunk, whereas the distal sensory innervation is in the core of the nerve. Thus, during infiltration block of a large nerve, sensory analgesia first develops proximally and then spreads distally as the drug penetrates into the core of the nerve.

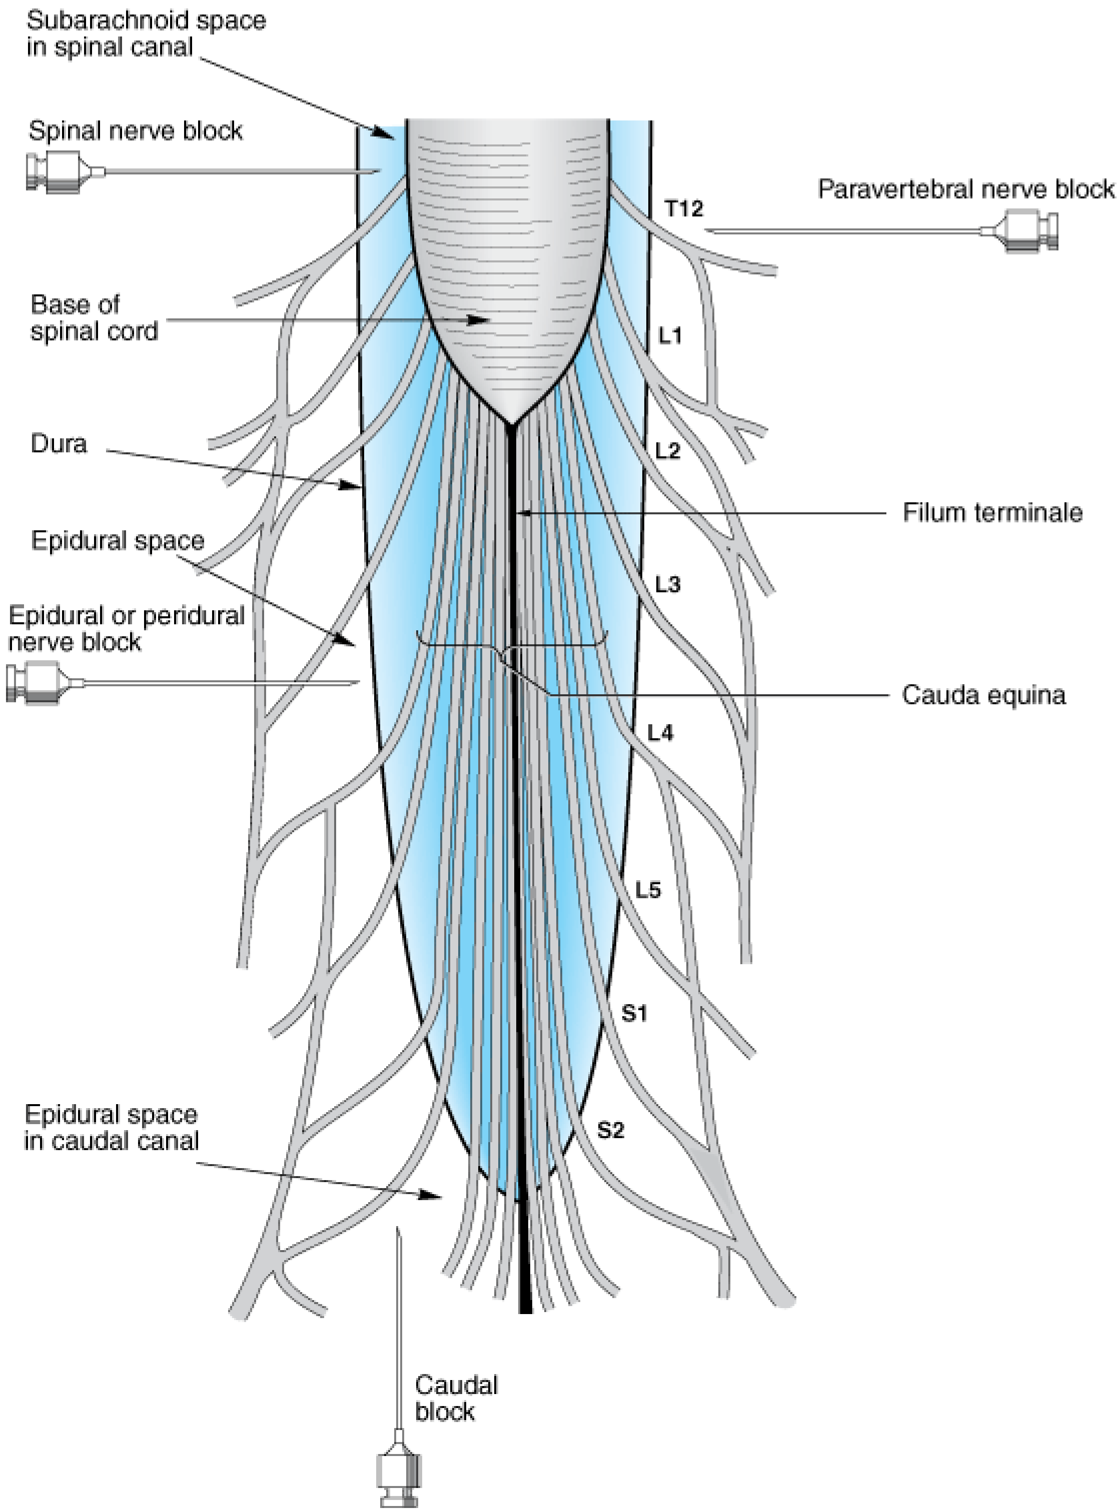
EFFECTS ON OTHER EXCITABLE MEMBRANES

Local anesthetics have weak neuromuscular blocking effects that are of little clinical importance. However, their effects on cardiac cell membranes are of major clinical significance, and some local anesthetics are useful antiarrhythmic agents (see Chapter 14) at concentrations lower than those required to produce nerve block. Others (eg, bupivacaine, ropivacaine) can *cause* lethal arrhythmias in high concentrations.

CLINICAL PHARMACOLOGY OF LOCAL ANESTHETICS

Local anesthetics can provide highly effective analgesia in well-defined regions of the body. The usual routes of administration include topical application (eg, nasal mucosa, wound margins), injection in the vicinity of peripheral nerve endings (infiltration) and major nerve trunks (blocks), and injection into the epidural or subarachnoid spaces surrounding the spinal cord (Figure 26–4). Intravenous regional anesthesia (so-called Bier block) is used for short surgical procedures (< 60 minutes) involving the upper and lower extremities. This is accomplished by intravenous injection of the anesthetic agent into a distal vein while the circulation of the limb isolated with a proximally placed tourniquet. Finally, an infiltration block of autonomic sympathetic fibers can be used to evaluate the role of sympathetic tone in patients with peripheral vasospastic disorders.

Figure 26–4.



Schematic diagram of sites of injection of local anesthetics in and near the spinal canal.

The choice of local anesthetic for infiltration, peripheral nerve blocks, and central neuraxis blockade is usually based on the duration of action required. Procaine and chloroprocaine are short-acting; lidocaine, mepivacaine, and prilocaine have an intermediate duration of action; and tetracaine, bupivacaine, levobupivacaine, and ropivacaine are long-acting local anesthetics (Table 26–1).

The anesthetic effect of the agents with short and intermediate durations of action can be prolonged by increasing the dose or adding a vasoconstrictor agent (eg, epinephrine or phenylephrine). The vasoconstrictor slows the removal of the local anesthetic from the injection site. In addition, it decreases the blood level and th probability of CNS toxicity.

The onset of local anesthesia can be accelerated by the addition of sodium bicarbonate (1–2 mL) to the local anesthetic solution. This maximizes the amount of drug in the more lipid-soluble form.

Repeated injections of local anesthetics can result in loss of effectiveness (ie, tachyphylaxis) due to extracellula acidosis. Local anesthetics are commonly marketed as hydrochloride salts (pH 4.0–6.0). After injection, the sal are buffered in the tissue to physiologic pH, thereby providing sufficient free base concentration for diffusion through the axonal membrane. However, repeated injections of the local anesthetic can deplete the buffering capacity of the local tissues. The ensuing acidosis increases the extracellular cationic form, which diffuses poorl and results in tachyphylaxis. Tachyphylaxis to local anesthetics is common in areas with a limited buffer capacit (eg, the cerebrospinal fluid).

Pregnancy appears to increase susceptibility to local anesthetic toxicity, with reductions in the median doses required for neural blockade and to induce toxicity. Cardiac arrest leading to death following the epidural administration of 0.75% bupivacaine to women in labor resulted in the temporary withdrawal of the high concentration of this widely used long-acting local anesthetic. The subsequent introduction of purportedly less cardiotoxic alternatives to bupivacaine (ie, ropivacaine and levobupivacaine) has led to controversy because the evidence supporting enhanced safety is based on animal models. It is not clear whether the increased sensitivit to bupivacaine during pregnancy is due to elevated levels of estrogen, progesterone, or some other unrecogniz factor.

Topical local anesthesia is often used for eye, ear, nose, and throat procedures and for cosmetic surgery. Satisfactory topical local anesthesia requires an agent capable of rapid penetration across the skin or mucosa, and with limited tendency to diffuse away from the site of application. Cocaine, because of its excellent penetration and local vasoconstrictor effects, has been used extensively for ear, nose and throat (ENT) procedures. Cocaine is somewhat irritating and therefore is less popular for ophthalmic procedures. Recent concern about its potential cardiotoxicity when combined with epinephrine has led most otolaryngologists and plastic surgeons to switch to a combination containing lidocaine and epinephrine. Other drugs used for topical anesthesia include tetracaine, pramoxine, dibucaine, benzocaine, and dyclonine.

Since local anesthetics have membrane-stabilizing effects, both parenteral (eg, intravenous lidocaine) and oral (eg, mexiletine, tocainide) formulations of local anesthetics have been used to treat patients with neuropathic pain syndromes because these syndromes are thought to involve uncontrolled, rapid, sensory fiber firing. Systemic local anesthetic drugs are commonly used as adjuvants to the combination of a tricyclic antidepressar (eg, amitriptyline) and an anticonvulsant (eg, carbamazepine) in patients who fail to respond to the combinatio of antidepressant and anticonvulsant. A period of 1–3 weeks may be required to observe a therapeutic effect after introduction of the local anesthetic in patients with neuropathic pain.

Toxicity

The two major forms of local anesthetic toxicity are: (1) systemic effects following absorption of the local anesthetic from their site of administration and (2) direct neurotoxicity from the local effects of these drugs wh administered in close proximity to the spinal cord and other major nerve trunks. When blood levels of local anesthetics rise rapidly, adverse effects on several major organ systems may be observed.

CENTRAL NERVOUS SYSTEM

All Local Anesthetics

At low concentrations, all local anesthetics have the ability to produce sleepiness, light-headedness, visual and auditory disturbances, and restlessness. An early symptom of local anesthetic toxicity is circumoral and tongue numbness and a metallic taste. At higher concentrations, nystagmus and muscular twitching occur, followed by overt tonic-clonic convulsions. Local anesthetics apparently cause depression of cortical inhibitory pathways, thereby allowing unopposed activity of excitatory neuronal pathways. This transitional stage of unbalanced excitation (ie, seizure activity) is then followed by generalized CNS depression.

Convulsions due to excessive blood levels can usually be prevented by administering the smallest effective dos of the local anesthetic required for adequate surgical analgesia and by avoiding inadvertent intravascular injection, or injection into highly perfused tissues. When large doses of a local anesthetic are required (eg, for major peripheral nerve block), premedication with a parenteral benzodiazepine (eg, diazepam or midazolam) provides significant prophylaxis against local anesthetic-induced CNS toxicity by raising the seizure threshold.

If seizures do occur, it is important to prevent hypoxemia and acidosis. Although administration of oxygen does not prevent seizure activity, hyperoxemia may be beneficial after onset of seizures. Hypercapnia and acidosis may lower the seizure threshold, and so hyperventilation is recommended during treatment of seizures. In addition, hyperventilation increases blood pH, which in turn lowers extracellular potassium. This action hyperpolarizes the transmembrane potential of axons, which favors the rested (or low-affinity) state of the sodium channels, resulting in decreased local anesthetic toxicity.

Seizures induced by local anesthetics can also be treated with intravenous anesthetic drugs (eg, thiopental 1–2 mg/kg, propofol 0.5–1 mg/kg, midazolam 0.03–0.06 mg/kg, or diazepam 0.1–0.2 mg/kg). The muscular manifestations of a seizure can be blocked using a short-acting neuromuscular relaxant drug (eg, succinylcholir 0.5–1 mg/kg IV). It should be emphasized that succinylcholine does not obliterate CNS manifestations of seizu activity. Rapid tracheal intubation and mechanical ventilation can prevent pulmonary aspiration of gastric contents and facilitate hyperventilation.

Cocaine

Since prehistoric times, the natives of Peru and Bolivia have chewed the leaves of the indigenous plant *Erythroxylon coca,* the source of cocaine, to obtain a feeling of well-being and reduce fatigue. Intense CNS effe can be achieved by sniffing cocaine powder and smoking cocaine base ("free basing"). Cocaine has become one of the most widely abused drugs (see Chapter 32). High doses of inhaled and injected cocaine have all of the toxicities described for other local anesthetics. In addition, cocaine can produce severe cardiovascular toxicity, including hypertension, arrhythmias, and myocardial failure.

NEUROTOXICITY

When applied at excessively high concentrations, all local anesthetics can produce direct neural toxicity. Chloroprocaine and lidocaine appear to be more neurotoxic than other local anesthetics when used for spinal anesthesia, with high local concentrations producing so-called transient radicular irritation (or transient neuropathic symptoms). It has been suggested that this toxicity results from pooling of high concentrations of the local anesthetic in the cauda equina (Figure 26–4). Although the precise mechanism of this neurotoxic actio has not been established, both interference with axonal transport and disruption of calcium homeostasis have been implicated. Spinal neurotoxicity does not result from excessive sodium channel blockade.

CARDIOVASCULAR SYSTEM

The cardiovascular effects of local anesthetics result partly from direct effects on the cardiac and smooth muscl membranes and partly from indirect effects on the autonomic nervous system. As described in Chapter 14, loca anesthetics block cardiac sodium channels and thus depress abnormal cardiac pacemaker activity, excitability, and conduction. At extremely high concentrations, local anesthetics can also block calcium channels. With the notable exception of cocaine, local anesthetics also depress the strength of cardiac contraction and cause arteriolar dilation, leading to systemic hypotension. Cardiovascular collapse is rare, but has been reported after large doses of bupivacaine and ropivacaine.

Cocaine differs from the other local anesthetics with respect to its cardiovascular effects. Cocaine's blockade of norepinephrine reuptake results in vasoconstriction and hypertension, as well as cardiac arrhythmias. The vasoconstriction produced by cocaine can lead to local ischemia and, in chronic abusers who use the nasal rout ulceration of the mucous membrane and damage to the nasal septum have been reported. The vasoconstrictor properties of cocaine can be used clinically to decrease bleeding from mucosal damage in the nasopharynx.

It has been suggested that bupivacaine may be more cardiotoxic than other long-acting local anesthetics. This reflects the fact that bupivacaine-induced blockade of sodium channels is potentiated by the long action potenti duration of cardiac cells compared with nerve fibers. The most common electrocardiographic finding in patients with bupivacaine intoxication is a slow idioventricular rhythm with broad QRS complexes and eventually electromechanical dissociation.

Resuscitation from bupivacaine cardiovascular toxicity is extremely difficult even for experienced clinicians. The *(S)* -isomer, levobupivacaine, appears to have a lower propensity for cardiovascular toxicity than the racemic mixture or the *(R)* -isomer and has been approved for clinical use. Ropivacaine has clinical (pharmacodynamic) effects similar to those of bupivacaine, but is allegedly associated with a lower potential for cardiovascular toxicity. Ropivacaine is available only as the *(S)* -stereoisomer, which has inherently less affinity for the cardiac sodium channel. However, both cardiac toxicity and CNS toxicity have been reported when ropivacaine was use for peripheral nerve blocks.

HEMATOLOGIC EFFECTS

The administration of large doses (> 10 mg/kg) of prilocaine during regional anesthesia may lead to accumulati of the metabolite *o* -toluidine, an oxidizing agent capable of converting hemoglobin to methemoglobin. When sufficient methemoglobin is present (3–5 mg/dL), the patient may appear cyanotic and the blood "chocolate-colored." Although moderate levels of methemoglobinemia are well tolerated by healthy individuals, elevated methemoglobinemia may cause decompensation in patients with preexisting cardiac or pulmonary disease. The treatment of methemoglobinemia involves the intravenous administration of a reducing agent (eg, methylene blue or ascorbic acid), which rapidly converts methemoglobin to hemoglobin.

ALLERGIC REACTIONS

The ester-type local anesthetics are metabolized to *p*- aminobenzoic acid derivatives. These metabolites are responsible for allergic reactions in a small percentage of the patient population. Amides are not metabolized to *p*- aminobenzoic acid, and allergic reactions to amide local anesthetics are extremely rare.

PREPARATIONS AVAILABLE

Articaine (Septocaine)

Parenteral: 4% with 1:100,000 epinephrine

Benzocaine (generic)

Topical: 5, 6% creams; 15, 20% gels; 5, 20% ointments; 0.8% lotion; 20% liquid; 20% spray

Bupivacaine (generic, Marcaine, Sensorcaine)

Parenteral: 0.25, 0.5, 0.75% for injection; 0.25, 0.5, 0.75% with 1:200,000 epinephrine

Butamben picrate (Butesin Picrate)

Topical: 1% ointment

Chloroprocaine (generic, Nesacaine)

Parenteral: 1, 2, 3% for injection

Cocaine (generic)

Topical: 40, 100 mg/mL regular and viscous solutions; 5, 25 g powder

Dibucaine (generic, Nupercainal)

Topical: 0.5% cream; 1% ointment

Dyclonine (Dyclone)

Topical: 0.5, 1% solution

Levobupivacaine (Chirocaine)

Parenteral: 2.5, 5, 7.5 mg/mL

Lidocaine (generic, Xylocaine)

Parenteral: 0.5, 1, 1.5, 2, 4% for injection; 0.5, 1, 1.5, 2% with 1:200,000 epinephrine; 1, 2% with 1:100,000 epinephrine, 2% with 1:50,000 epinephrine

Topical: 2.5, 5% ointments; 0.5, 4% cream; 0.5, 2.5% gel; 2, 2.5, 4% solutions; 23, 46 mg/2 cm^2 patch

Lidocaine and bupivacaine mixture (Duocaine)

Parenteral: 10 mg/mL lidocaine plus 3.75 mg/mL bupivacaine for injection

Lidocaine and prilocaine eutectic mixture (EMLA cream)

Topical: lidocaine 2.5% plus prilocaine 2.5%

Mepivacaine (generic, Carbocaine)

Parenteral: 1, 1.5, 2, 3% for injection; 2% with 1:20,000 levonordefrin

Pramoxine (generic, Tronothane)

Topical: 1% cream, lotion, spray, and gel

Procaine (generic, Novocain)

Parenteral: 1, 2, 10% for injection

Proparacaine (generic, Alcain, others)

0.5% solution for ophthalmic use

Ropivacaine (Naropin)

Parenteral: 0.2, 0.5, 0.75, 1.0% solution for injection

Tetracaine (generic, Pontocaine)

Parenteral: 1% for injection; 0.2, 0.3% with 6% dextrose for spinal anesthesia

Topical: 1% ointment; 0.5% solution (ophthalmic); 1, 2% cream; 2% solution for nose and throat; 2% gel

SKELETAL MUSCLE RELAXANTS: INTRODUCTION

Drugs that affect skeletal muscle function as two very different therapeutic groups: those used during surgical procedures and in intensive care units to produce muscle paralysis for patients requiring ventilatory assistance (ie, neuromuscular blockers) and those used to reduce spasticity in a variety of neurologic conditions (ie, spasmolytics). Neuromuscular blocking drugs interfere with transmission at the neuromuscular end plate and lack central nervous system activity. These compounds are used primarily as adjuncts during general anesthesi to facilitate tracheal intubation and optimize surgical conditions while ensuring adequate ventilation. Drugs in the spasmolytic group have traditionally been called "centrally acting" muscle relaxants and are used primarily to treat chronic back pain and fibromyalgic conditions. Dantrolene, a spasmolytic agent that has no significant central effects and is used primarily to treat malignant hyperthermia, is also discussed in this chapter.

NEUROMUSCULAR BLOCKING DRUGS

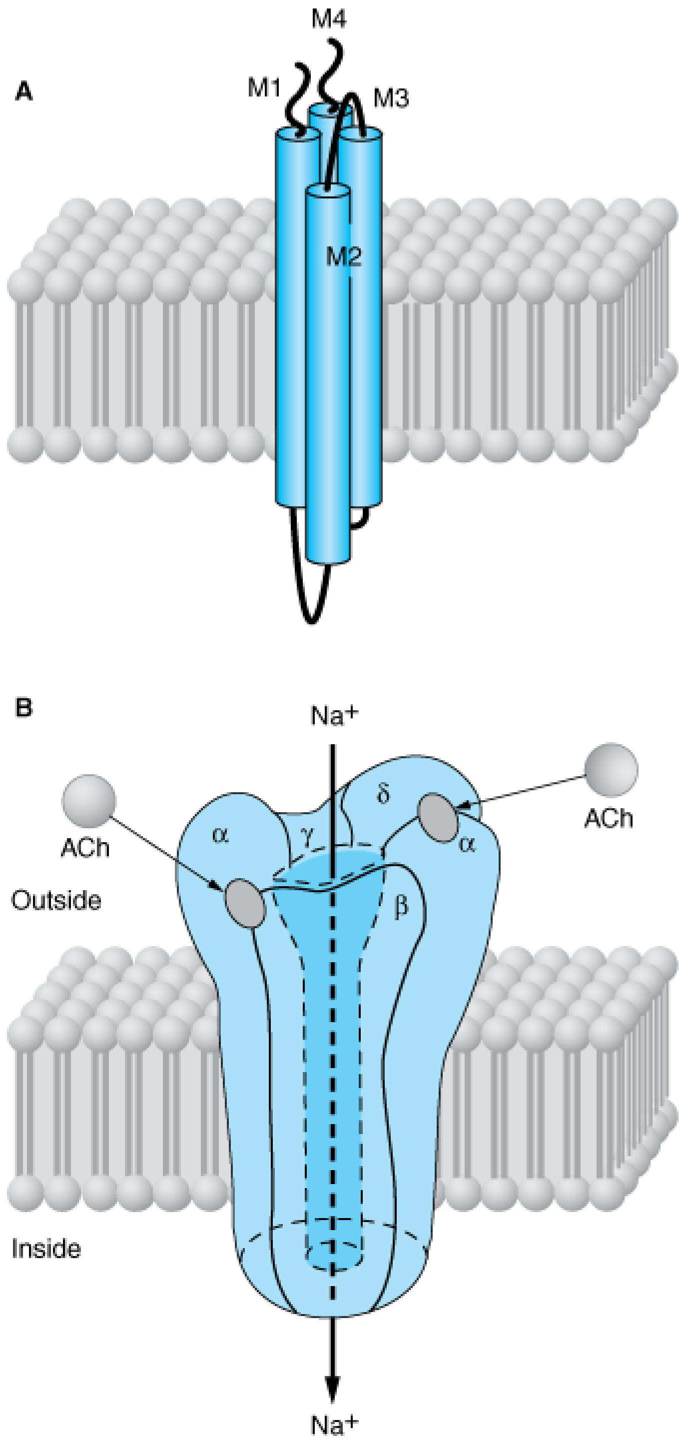
History

During the 16th century, European explorers found that natives in the Amazon Basin of South America used curare, an arrow poison, to produce death by skeletal muscle paralysis. The active compound, *d*- tubocurarine, and its modern synthetic derivatives have had a significant influence on the practice of anesthesia and surgery and have proved useful in defining normal neuromuscular physiologic mechanisms.

Normal Neuromuscular Function

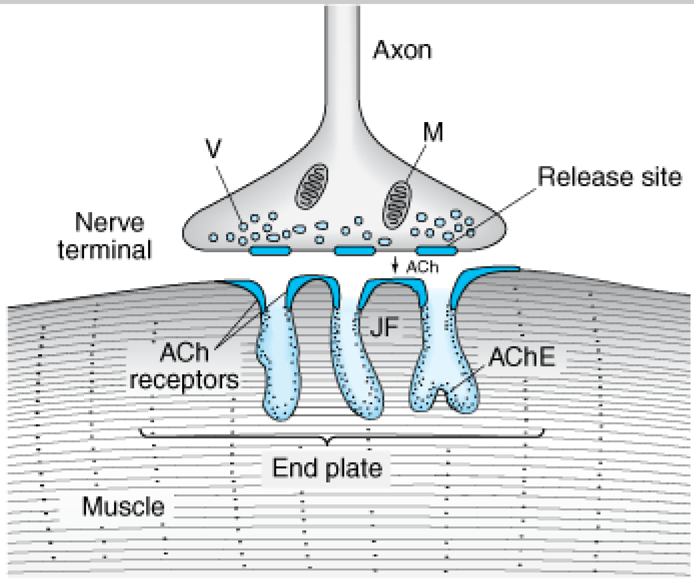
The mechanism of neuromuscular transmission at the motor end plate is similar to that described for preganglionic cholinergic nerves in Chapter 6. With the arrival of an electrical impulse at the motor nerve terminal, there is an influx of calcium and release of acetylcholine. Acetylcholine then diffuses across the synaptic cleft to the nicotinic receptor located on the motor end plate. As noted in Chapter 7, the adult N_M receptor is composed of five peptides: two alpha peptides, one beta, one gamma, and one delta peptide (Figur 27–1). The binding of two acetylcholine molecules to receptors on the α- β and δ- α subunits causes opening o the channel. The subsequent movement of sodium and potassium is associated with a graded depolarization of the end plate membrane (Figure 27–2). This change in voltage is termed the motor end plate potential. The magnitude of the end plate potential is directly related to the amount of acetylcholine released. If the potential is small, the permeability and the end plate potential return to normal without an impulse being propagated from the end plate region to the rest of the muscle membrane. However, if the end plate potential is large, the adjacent muscle membrane is depolarized, and an action potential will be propagated along the entire muscle fiber. Muscle contraction is then initiated by excitation-contraction coupling. The released acetylcholine is quickl removed from the end plate region by diffusion and enzymatic destruction by the local acetylcholinesterase enzyme.

Figure 27–1.



The adult nicotinic acetylcholine receptor (nAChR) is an intrinsic membrane protein with five distinct subunits ($\alpha_2 \beta \delta \gamma$). A: Cartoon of the one of five subunits of the AChR in the end plate surface of adult mammalian muscle. Each subunit contains four helical domains labeled M1 to M4. The M2 domains line the channel pore. B: Cartoon of the full AChR. The N termini of two subunits cooperate to form two distinct binding pockets for acetylcholine (ACh). These pockets occur at the α-β and the δ-α subunit interfaces.

Figure 27–2.



Schematic representation of the neuromuscular junction. (ACh, acetylcholine; AChE, acetylcholinesterase; JF, junctional folds; M, mitochondrion; V, transmitter vesicle.) (Reproduced, with permission, from Drachman DB: Myasthenia gravis. N Engl J Med 1978;298:135.)

At least two additional types of acetylcholine receptors are associated with the neuromuscular apparatus. One type is located on the presynaptic motor axon terminal, and activation of these receptors mobilizes additional transmitter for subsequent release by moving more acetylcholine vesicles toward the synaptic membrane. The second type of receptor is found on perijunctional cells and is not normally involved in neuromuscular transmission. However, under certain conditions (eg, prolonged immobilization, thermal burns), these receptor may proliferate sufficiently to affect subsequent neuromuscular transmission.

Skeletal muscle relaxation and paralysis can occur from interruption of function at several sites along the pathway from the central nervous system to myelinated somatic nerves, unmyelinated motor nerve terminals, nicotinic acetylcholine receptors, the motor end plate, the muscle membrane, and the intracellular contractile apparatus itself.

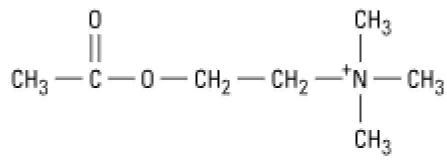
In practice, blockade of end plate function is accomplished by two basic mechanisms. Pharmacologic blockade of the physiologic agonist acetylcholine is characteristic of the *antagonist* neuromuscular blocking drugs. These drugs prevent access of the transmitter to its receptor and thereby prevent depolarization. The prototype of thi *nondepolarizing* subgroup is *d*- tubocurarine. The second mechanism of blockade can be produced by an excess of a depolarizing *agonist,* such as acetylcholine. This paradoxical effect of acetylcholine also occurs at th ganglionic nicotinic acetylcholine receptor. The prototypical *depolarizing* blocking drug is succinylcholine. A similar depolarizing block can be produced by acetylcholine itself when high local concentrations are achieved ir the synaptic cleft (eg, by cholinesterase inhibitor intoxication) and by nicotine and other nicotinic agonists. However, the neuromuscular block produced by these depolarizing drugs (other than succinylcholine) cannot be precisely controlled and is of no clinical value.

BASIC PHARMACOLOGY OF NEUROMUSCULAR BLOCKING DRUGS

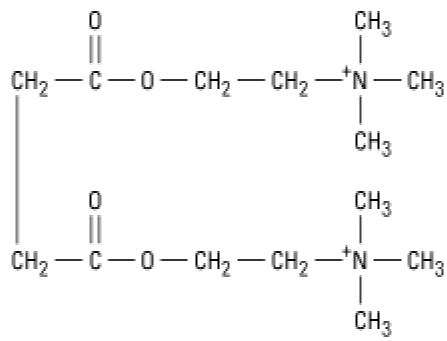
Chemistry

All of the available neuromuscular blocking drugs bear a structural resemblance to acetylcholine. For example, succinylcholine is two acetylcholine molecules linked end-to-end (Figure 27–3). In contrast to the single linear structure of succinylcholine and other depolarizing drugs, the nondepolarizing agents (eg, pancuronium) conceal the "double-acetylcholine" structure in one of two types of bulky, semi-rigid ring systems (Figure 27–3). The two major families of nondepolarizing blocking drugs—the isoquinoline and steroid derivatives—are shown in Figures 27–4 and 27–5. Another feature common to all currently used neuromuscular blockers is the presence of one or two quaternary nitrogens, which makes them poorly lipid-soluble and limits entry into the central nervous system.

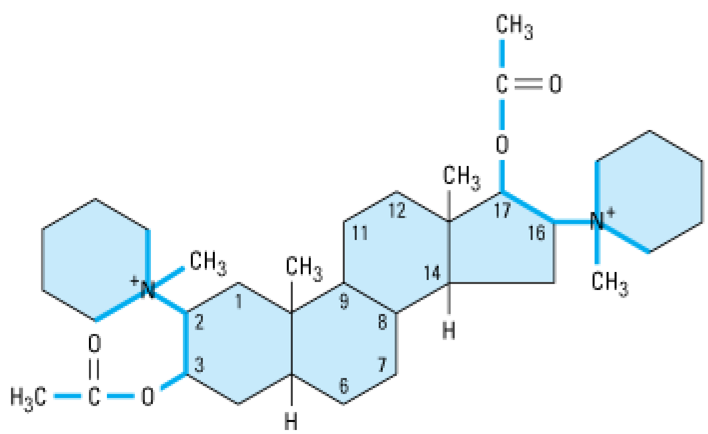
Figure 27–3.



Acetylcholine



Succinylcholine



Pancuronium

Structural relationship of succinylcholine, a depolarizing agent, and pancuronium, a nondepolarizing agent, to acetylcholine, the neuromuscular transmitter. Succinylcholine, originally called diacetylcholine, is simply two molecules of acetylcholine linked through the acetate methyl groups. Pancuronium may be viewed as two acetylcholine-like fragments (outlined in colo oriented on a steroid nucleus.

Pharmacokinetics of Neuromuscular Blocking Drugs

All of the neuromuscular blocking drugs are highly polar and inactive orally and must be administered parenterally.

NONDEPOLARIZING RELAXANT DRUGS

The rate of disappearance of a nondepolarizing neuromuscular blocking drug from the blood is characterized by a rapid initial distribution phase followed by a slower elimination phase. Neuromuscular blocking drugs are high ionized and do not readily cross cell membranes. Therefore, their volume of distribution is only slightly larger than the blood volume (80–140 mL/kg).

The elimination half-life strongly correlates with the duration of action of nondepolarizing relaxants. Drugs that are excreted by the kidney typically have longer half-lives, leading to longer durations of action (> 60 minutes). Drugs eliminated by the liver tend to have shorter half-lives and durations of action (Table 27–1). All steroidal muscle relaxants are metabolized to their 3-hydroxy, 17-hydroxy, or 3,17-dihydroxy products in the liver. The 3 hydroxy metabolites are usually 40–80% as potent as the parent drug. Under normal circumstances, metabolites are not formed in sufficient quantities to produce a significant degree of neuromuscular blockade during or after anesthesia. However, if the parent compound is administered for several days in the intensive care setting, the 3-hydroxy metabolite may accumulate and cause prolonged paralysis because it has a longer half-life than the parent compound. The remaining metabolites possess minimal neuromuscular blocking properties.

Table 27–1. Some Properties of Neuromuscular Blocking Drugs.

Drug	Elimination	Clearance (mL/kg/min)	Approximate Duration of Action (minutes)	Approximate Potency Relative to Tubocurarine
Isoquinoline derivatives				
Atracurium	Spontaneous[1]	6.6	20–35	1.5
Cisatracurium	Mostly spontaneous	5–6	25–44	1.5

Doxacurium	Kidney	2.7	> 35	6
Metocurine	Kidney (40%)	1.2	> 35	4
Mivacurium	Plasma ChE[2]	70–95	10–20	4
Tubocurarine	Kidney (40%)	2.3–2.4	> 35	1
Steroid derivatives				
Pancuronium	Kidney (80%)	1.7–1.8	> 35	6
Pipecuronium	Kidney (60%) and liver	2.5–3.0	> 35	6

Rocuronium	Liver (75–90%) and kidney	2.9	20–35	0.8
Vecuronium	Liver (75–90%) and kidney	3–5.3	20–35	6
Depolarizing agent				
Succinylcholine	Plasma ChE[2] (100%)	>100	< 8	0.4

[1] Nonenzymatic and enzymatic hydrolysis of ester bonds.

[2] Butyrylcholinesterase (pseudocholinesterase).

The intermediate-acting steroid muscle relaxants (eg, vecuronium and rocuronium) tend to be more dependent on biliary excretion or hepatic metabolism for their elimination. These muscle relaxants are more commonly used clinically than the long-acting steroid-based drugs (eg, pancuronium, pipecuronium).

Atracurium (Figure 27–4) is an intermediate-acting isoquinoline nondepolarizing muscle relaxant. In addition to hepatic metabolism, atracurium is inactivated by a form of spontaneous breakdown known as Hofmann elimination. The main breakdown products are laudanosine and a related quaternary acid, neither of which possesses neuromuscular blocking properties. Laudanosine is slowly metabolized by the liver and has a long elimination half-life (ie, 150 minutes). It readily crosses the blood-brain barrier, and high blood concentrations may cause seizures and an increase in the volatile anesthetic requirement. During surgical anesthesia, blood levels of laudanosine range from 0.2 to 1 mcg/mL. However, with prolonged infusions of atracurium in the intensive care unit, laudanosine blood levels may exceed 5 mcg/mL.

Atracurium has several stereoisomers, and one of the more potent isomers, **cisatracurium**, has been approved for clinical use. It resembles atracurium but has even less dependence on hepatic inactivation, forms less laudanosine, and is less likely to release histamine. From the clinical perspective, cisatracurium has all the advantages of atracurium with fewer side effects. Therefore, cisatracurium has largely replaced atracurium in clinical practice.

Mivacurium, another isoquinoline compound, has the shortest duration of action of all nondepolarizing muscle relaxants (Table 27–1). However, its onset of action is significantly slower than that of succinylcholine. In addition, the use of a larger dose to speed the onset can be associated with profound histamine release leading to hypotension, flushing, and bronchospasm. Clearance of mivacurium by plasma cholinesterase is rapid and independent of the liver or kidney (Table 27–1). However, because patients with renal failure often have decreased levels of plasma cholinesterase, the short duration of action of mivacurium may be prolonged in patients with impaired renal function.

DEPOLARIZING RELAXANT DRUGS

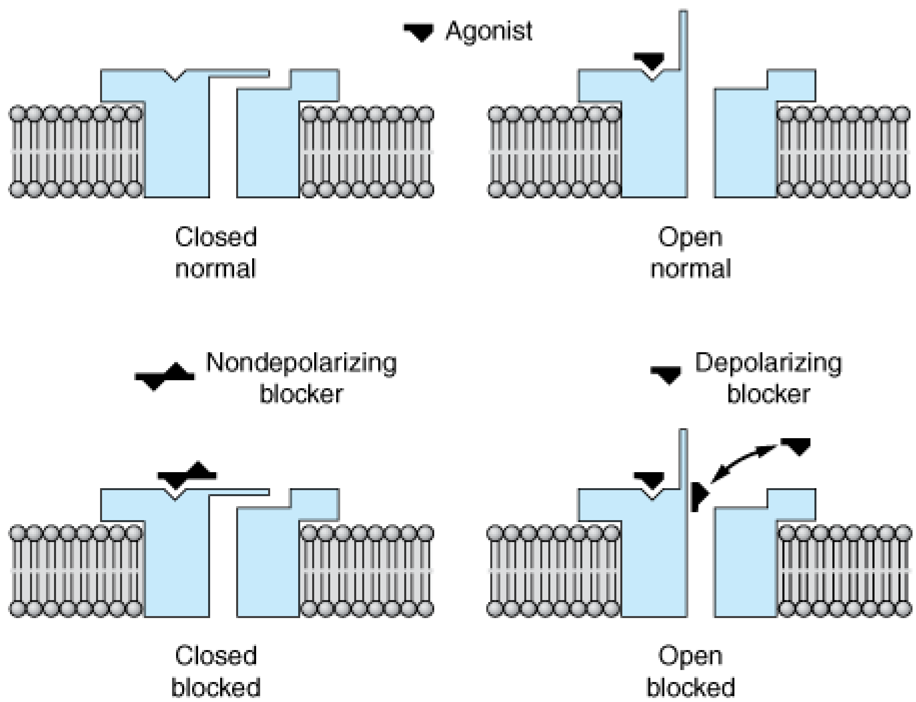
The extremely short duration of action of succinylcholine (5–10 minutes) is due to its rapid hydrolysis by cholinesterases (eg, butyrylcholinesterase and pseudocholinesterase) in the liver and plasma. Plasma cholinesterase metabolizes succinylcholine more rapidly than mivacurium, and consequently the duration of action of succinylcholine is shorter than that of mivacurium (Table 27–1). The primary metabolite, succinylmonocholine, is rapidly broken down to succinic acid and choline. Because plasma cholinesterase has an enormous capacity to hydrolyze succinylcholine, only a small percentage of the original intravenous dose ever reaches the neuromuscular junction. There is little if any plasma cholinesterase at the motor end plate, and a succinylcholine-induced blockade is terminated by its diffusion away from the end plate into extracellular fluid. Therefore, circulating levels of plasma cholinesterase influence the duration of action of succinylcholine by determining the amount of the drug that reaches the motor end plate.

Neuromuscular blockade produced by succinylcholine and mivacurium can be prolonged in patients with a genetically abnormal variant of plasma cholinesterase. The *dibucaine number* is a measure of the ability of a patient to metabolize succinylcholine and can be used to identify at-risk patients. Under standardized test conditions, dibucaine inhibits the normal enzyme by 80% and the abnormal enzyme by only 20%. Many genetic variants of plasma cholinesterase have been identified, though the dibucaine-related variants are the most important. Given the rarity of these genetic variants, plasma cholinesterase testing is not a routine clinical procedure.

Mechanism of Action

The interactions of drugs with the acetylcholine receptor-end plate channel have been described at the molecular level. Several modes of action of drugs on the receptor are illustrated in Figure 27–6.

Figure 27–6.



Schematic diagram of the interactions of drugs with the acetylcholine receptor on the end plate channel (structures are purely symbolic). Top: The action of the normal agonist, acetylcholine, in opening the channel. Bottom, left: A nondepolarizing blocker, eg, rocuronium, is shown as preventing the opening of the channel when it binds to the receptor. Right: A depolarizing blocker, eg, succinylcholine, both occupying the receptor and blocking the channel. Normal closure of the channel gate is prevented and the blocker may move rapidly in and out of the pore. Depolarizing blockers may desensitiz the end plate by occupying the receptor and causing persistent depolarization. An additional effect of drugs on the end plate channel may occur through changes in the lipid environment surrounding the channel (not shown). General anesthetics and alcohols may impair neuromuscular transmission by this mechanism.

NONDEPOLARIZING RELAXANT DRUGS

All the neuromuscular blocking drugs in use in the USA except succinylcholine are classified as nondepolarizing agents. Tubocurarine is considered the prototype neuromuscular blocker. When small doses of nondepolarizin muscle relaxants are administered, they act predominantly at the nicotinic receptor site by competing with acetylcholine. The least potent nondepolarizing relaxants (eg, rocuronium) have the fastest onset and the shortest duration of action. In larger doses, nondepolarizing drugs can enter the pore of the ion channel (Figure 27–1) to cause a more intense motor blockade. This action further weakens neuromuscular transmission and diminishes the ability of acetylcholinesterase inhibitors (eg, neostigmine, edrophonium, pyridostigmine) to antagonize the effect of nondepolarizing muscle relaxants.

Nondepolarizing relaxants can also block prejunctional sodium channels. As a result of this action, muscle relaxants interfere with the mobilization of acetylcholine at the nerve ending. One consequence of the surmountable nature of the postsynaptic blockade produced by nondepolarizing muscle relaxants is the fact tha tetanic stimulation, by releasing a large quantity of acetylcholine, is followed by transient posttetanic facilitatior (ie, relief of blockade) of the twitch strength. An important clinical consequence of the same principle is the reversal of residual blockade by cholinesterase inhibitors. The characteristics of a nondepolarizing neuromuscul blockade are summarized in Table 27–2 and Figure 27–7.

Table 27–2. Comparison of a Typical Nondepolarizing Muscle Relaxant (Rocuronium) and a Depolarizing Muscle Relaxant (Succinylcholine).

		Succinylcholine	
	Rocuronium	Phase I	Phase II
Administration of tubocurarine	Additive	Antagonistic	Augmented[1]
Administration of succinylcholine	Antagonistic	Additive	Augmented[1]
Effect of neostigmine	Antagonistic	Augmented[1]	Antagonistic
Initial excitatory effect on skeletal muscle	None	Fasciculations	None
Response to a tetanic stimulus	Unsustained (fade)	Sustained[2] (no fade)	Unsustained (fade)
Posttetanic facilitation	Yes

Yes

Rate of recovery

30–60 min[3]

4–8 min

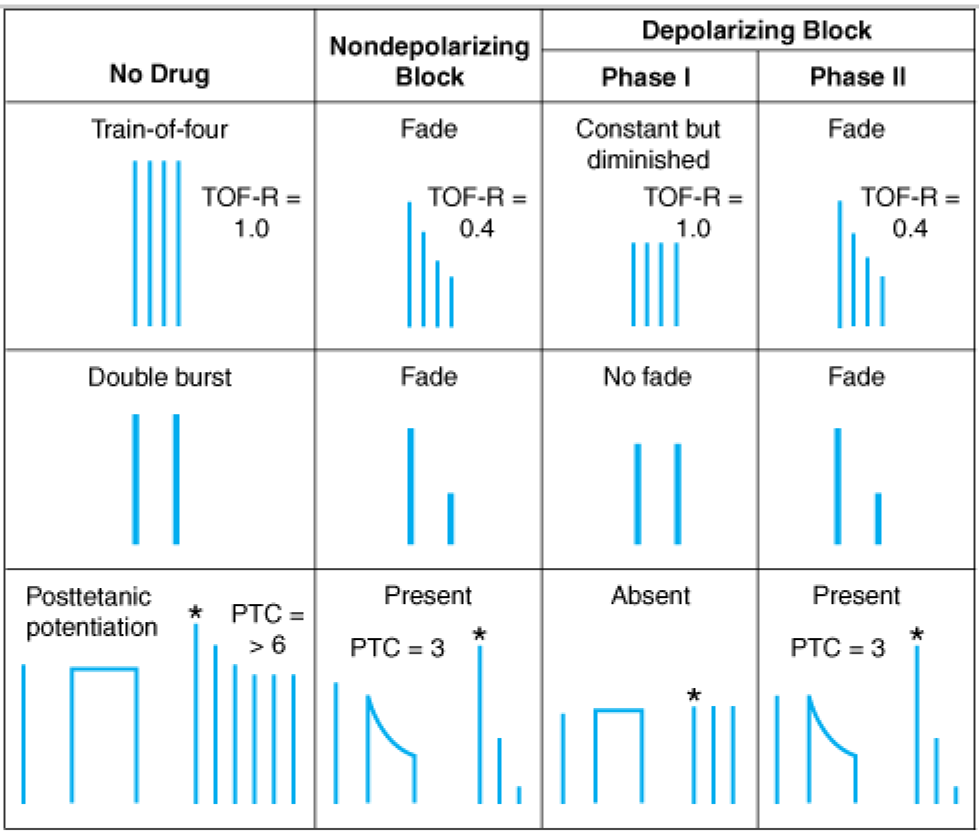
> 20 min[3]

[1] It is not known whether this interaction is additive or synergistic (superadditive).

[2] The amplitude is decreased, but the response is sustained.

[3] The rate depends on the dose and on the completeness of neuromuscular blockade.

Figure 27–7.



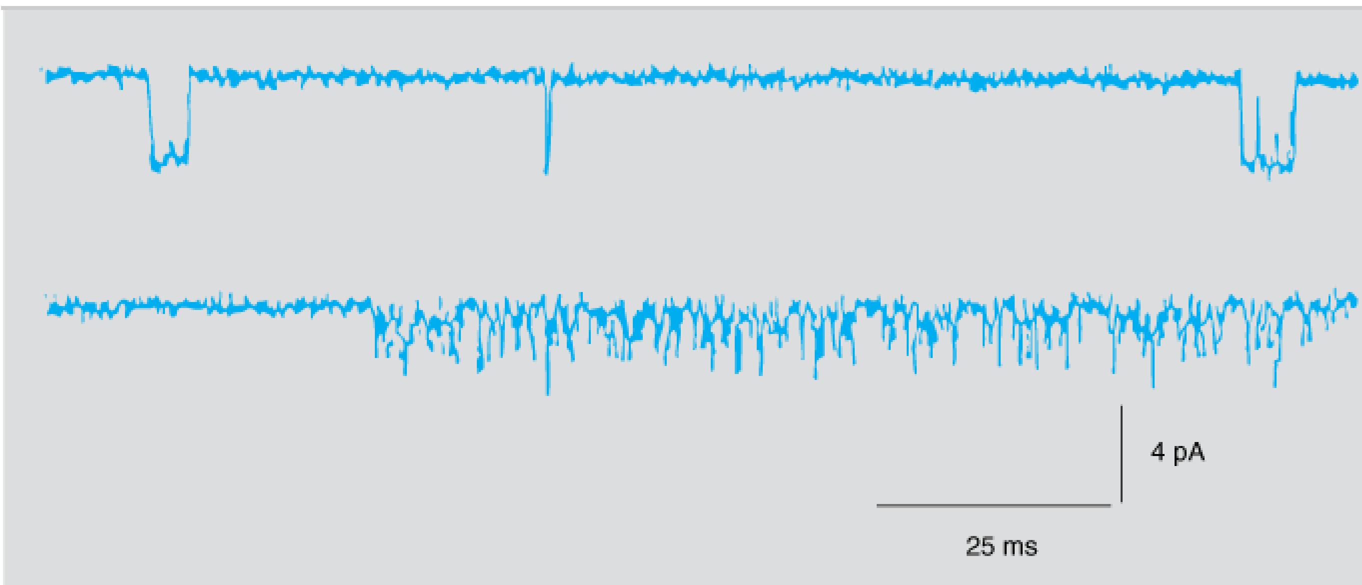
Muscle responses to different patterns of nerve stimulation used in monitoring skeletal muscle relaxation. The alterations produced by a nondepolarizing blocker and depolarizing and desensitizing blockade by succinylcholine are shown. In the trai of four (TOF) pattern, four stimuli are applied at 2 Hz. The TOF ratio (TOF-R) is calculated from the strength of the fourth contraction divided by that of the first. In the double burst pattern, three stimuli are applied at 50 Hz, followed by a 700 ms rest period and then repeated. In the posttetanic potentiation pattern, several seconds of 50 Hz stimulation are applied, followed by several seconds of rest and then by single stimuli at a slow rate (eg, 0.5 Hz). The number of detectable posttetanic twitches is the posttetanic count (PTC). (*, first posttetanic contraction.)

DEPOLARIZING RELAXANT DRUGS

Phase I Block (Depolarizing)

Succinylcholine is the only clinically useful depolarizing blocking drug. Its neuromuscular effects are like those o acetylcholine except that succinylcholine produces a longer effect at the myoneural junction. Succinylcholine reacts with the nicotinic receptor to open the channel and cause depolarization of the motor end plate, and this in turn spreads to the adjacent membranes, causing contractions of muscle motor units. Data from single-channel recordings indicate that depolarizing blockers can enter the channel to produce a prolonged "flickering" of the ion conductance (Figure 27–8). Because succinylcholine is not metabolized effectively at the synapse, th depolarized membranes remain depolarized and unresponsive to subsequent impulses (ie, in a state of depolarizing block). Furthermore, because excitation-contraction coupling requires end plate repolarization ("repriming") and repetitive firing to maintain muscle tension, a flaccid paralysis results. This so-called phase I (depolarizing) block is thus augmented, not reversed, by cholinesterase inhibitors.

Figure 27–8.



Action of succinylcholine on single-channel end plate receptor currents in frog muscle. Currents through a single AchR channel were recorded using the patch clamp technique. The upper trace was recorded in the presence of a low concentratic of succinylcholine; the downward deflections represent two openings of the channel and passage of inward (depolarizing) current. The lower trace was recorded in the presence of a much higher concentration of succinylcholine and shows prolonged "flickering" of the channel as it repetitively opens and closes or is "plugged" by the drug.

(Reproduced, with permission, from Marshall CG, Ogden DC, Colquhoun D: The actions of suxamethonium (succinyldicholine as an agonist and channel blocker at the nicotinic receptor of frog muscle. J Physiol [Lond] 1990;428:155.)

The characteristics of a depolarizing neuromuscular blockade are summarized in Table 27–2 and Figure 27–7.

Phase II Block (Desensitizing)

With continued exposure to succinylcholine, the initial end plate depolarization decreases and the membrane becomes repolarized. Despite this repolarization, the membrane cannot easily be depolarized again because it i *desensitized* . The mechanism for this desensitizing phase is unclear, but some evidence indicates that channel block may become more important than agonist action at the receptor in phase II of succinylcholine's neuromuscular blocking action. Regardless of the mechanism, the channels behave as if they are in a prolonge closed state (Figure 27–7). Later in phase II, the characteristics of the blockade are nearly identical to those of nondepolarizing block (ie, a nonsustained twitch response to a tetanic stimulus) (Figure 27–7), with reversal by acetylcholinesterase inhibitors.

CLINICAL PHARMACOLOGY OF NEUROMUSCULAR BLOCKING DRUGS

Skeletal Muscle Paralysis

Before the introduction of neuromuscular blocking drugs, profound skeletal muscle relaxation for intracavitary operations could be achieved only by producing deep levels of anesthesia that are accompanied by profound depressant effects on the cardiovascular and respiratory systems. The adjunctive use of neuromuscular blockin drugs makes it possible to achieve adequate muscle relaxation for all types of surgical procedures without the cardiorespiratory depressant effects produced by deep anesthesia.

Assessment of Neuromuscular Transmission

Monitoring the effect of muscle relaxants during surgery (and recovery following the administration of cholinesterase inhibitors) typically involves the use of a device that produces transdermal electrical stimulation of one of the peripheral nerves to the hand (or face) and recording of the evoked contractions (ie, twitches). Th motor responses to different patterns of peripheral nerve stimulation are measured (Figure 27–7). The three most commonly used patterns include (1) single-twitch stimulation, (2) train-of-four (TOF) stimulation, and (3) tetanic stimulation. Two newer modalities are also available to monitor neuromuscular transmission: double-burst stimulation and posttetanic count.

With single-twitch stimulation, a single supramaximal electrical stimulus is applied to a peripheral nerve at frequencies from 0.1 Hz to 1.0 Hz. The higher frequency is often used during induction and reversal to more accurately determine the peak (maximal) drug effect. TOF stimulation involves four successive supramaximal stimuli given at intervals of 0.5 second (2 Hz). Each stimulus in the TOF causes the muscle to contract, and the relative magnitude of the response of the fourth twitch compared with the first twitch is the TOF ratio. With a depolarizing block, all four twitches are reduced in a dose-related fashion. With a nondepolarizing block, the TO ratio decreases ("fades") and is inversely proportional to the degree of blockade. During recovery from nondepolarizing block, the amount of fade decreases and the TOF ratio approaches 1.0. Fade in the TOF response after administration of succinylcholine signifies the development of a phase II block.

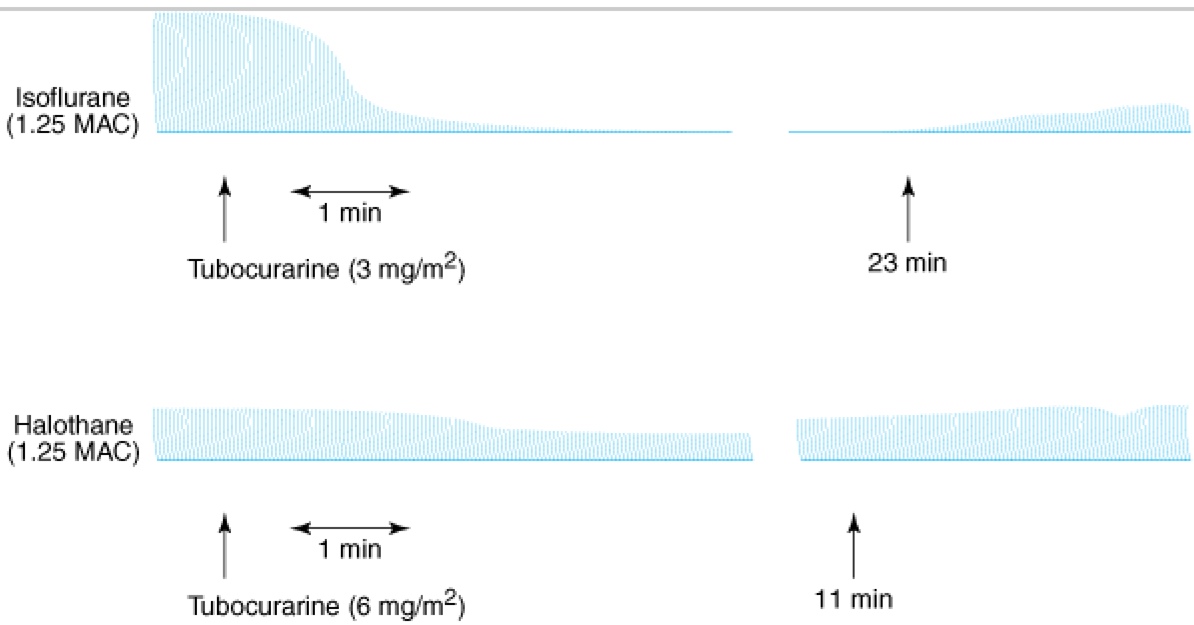
Tetanic stimulation consists of very rapid (30–100 Hz) delivery of electrical stimuli for several seconds. During a nondepolarizing block (and a phase II block after succinylcholine), the response is not sustained and fade is observed. Fade in response to tetanic stimulation is normally considered a presynaptic event. However, the degree of fade depends primarily on the degree of neuromuscular blockade. During a partial nondepolarizing blockade, tetanic nerve stimulation is followed by an increase in the posttetanic twitch response, so-called posttetanic facilitation of neuromuscular transmission. During intense neuromuscular blockade, there is no response to either tetanic or posttetanic stimulation. As the intensity of the block diminishes, the response to posttetanic twitch stimulation reappears. The time to reappearance of the first response to TOF stimulation is related to the posttetanic count.

The double-burst stimulation pattern is a newer mode of electrical nerve stimulation developed with the goal of allowing for manual detection of residual neuromuscular blockade when it is not possible to record the response to single-twitch, TOF, or tetanic stimulation. In this pattern, three nerve stimuli are delivered at 50 Hz followed by a 700 ms rest period and then, by two or three additional stimuli at 50 Hz. It is easier to detect fade in the responses to double-burst stimulation than to TOF stimulation. The absence of fade in response to double-burst stimulation implies that clinically significant residual neuromuscular blockade does not exist.

NONDEPOLARIZING RELAXANT DRUGS

During anesthesia, administration of tubocurarine, 0.1–0.4 mg/kg IV, initially causes motor weakness, followed by the skeletal muscles becoming flaccid and inexcitable to electrical stimulation (Figure 27–9). In general, larger muscles (eg, abdominal, trunk, paraspinous, diaphragm) are more resistant to blockade and recover more rapidly than smaller muscles (eg, facial, foot, hand). The diaphragm is usually the last muscle to be paralyzed. Assuming that ventilation is adequately maintained, no adverse effects occur. When administration of muscle relaxants is discontinued, recovery of muscles usually occurs in reverse order, with the diaphragm regaining function first. The pharmacologic effect of tubocurarine, 0.3 mg/kg IV, usually lasts 45–60 minutes. However, subtle evidence of residual muscle paralysis detected using a neuromuscular monitor may last for another hour.

Figure 27–9.



Neuromuscular blockade from tubocurarine during equivalent levels of isoflurane and halothane anesthesia in patients. Note that isoflurane augments the block far more than does halothane.

Potency and duration of action of the other nondepolarizing drugs are shown in Table 27–1. In addition to the duration of action, the most important property distinguishing the nondepolarizing relaxants is the time to onse of effect, which determines how rapidly the patient's trachea can be intubated. Of the currently available nondepolarizing drugs, rocuronium (60–120 seconds) is the most rapid.

DEPOLARIZING RELAXANT DRUGS

Following the administration of succinylcholine, 0.75–1.5 mg/kg IV, transient muscle fasciculations occur over the chest and abdomen within 30 seconds, although general anesthesia tends to attenuate them. As paralysis develops rapidly (< 90 seconds), the arm, neck, and leg muscles are initially relaxed followed by the respirator muscles. As a result of succinylcholine's rapid hydrolysis by cholinesterase in the plasma and liver, the duration of neuromuscular block typically lasts less than 10 minutes (Table 27–1).

Cardiovascular Effects

Vecuronium, pipecuronium, doxacurium, cisatracurium, and rocuronium all have minimal, if any, cardiovascular effects. The other nondepolarizing muscle relaxants (ie, pancuronium, atracurium, mivacurium) produce cardiovascular effects that are mediated by either autonomic or histamine receptors (Table 27–3). Tubocurarin and, to a lesser extent, metocurine, mivacurium, and atracurium can produce hypotension as a result of systemic histamine release, and with larger doses ganglionic blockade may occur with tubocurarine and metocurine. Premedication with an antihistaminic compound attenuates tubocurarine- and mivacurium-induced hypotension. Pancuronium causes a moderate increase in heart rate and a smaller increase in cardiac output, with little or no change in systemic vascular resistance. Although pancuronium-induced tachycardia is primarily due to a vagolytic action, release of norepinephrine from adrenergic nerve endings and blockade of neuronal uptake of norepinephrine may be secondary mechanisms. Although bronchospasm may be produced by neuromuscular blockers that release histamine (eg, mivacurium), insertion of a tracheal tube is the most common reason for bronchospasm after induction of general anesthesia.

[1] Allergic reactions have been reported.

Succinylcholine can cause cardiac arrhythmias when administered during halothane anesthesia. The drug stimulates autonomic cholinoceptors, including the nicotinic receptors at both sympathetic and parasympathetic ganglia and muscarinic receptors in the heart (eg, sinus node). The negative inotropic and chronotropic responses to succinylcholine can be attenuated by administration of an anticholinergic drug (eg, glycopyrrolate, atropine). With large doses of succinylcholine, positive inotropic and chronotropic effects may be observed. On the other hand, bradycardia has been repeatedly observed when a second dose of succinylcholine is given less than 5 minutes after the initial dose. This transient bradycardia can be prevented by thiopental, atropine, ganglionic-blocking drugs, and even nondepolarizing muscle relaxants (eg, pancuronium). Direct myocardial effects, increased muscarinic stimulation, and ganglionic stimulation contribute to this bradycardic response.

Other Adverse Effects of Depolarizing Blockade

HYPERKALEMIA

Patients with burns, nerve damage or neuromuscular disease, closed head injury, and other trauma can respond to succinylcholine by releasing potassium into the blood, which, on rare occasions, results in cardiac arrest.

INCREASED INTRAOCULAR PRESSURE

Administration of succinylcholine may be associated with the rapid onset of an increase in intraocular pressure (< 60 seconds), peaking at 2–4 minutes, and declining after 5 minutes. The mechanism may involve tonic contraction of myofibrils or transient dilation of ocular choroidal blood vessels. Despite the increase in intraocul pressure, the use of succinylcholine for ophthalmologic operations is not contraindicated unless the anterior chamber is open ("open globe") due to trauma.

INCREASED INTRAGASTRIC PRESSURE

In heavily muscled patients, the fasciculations associated with succinylcholine may cause an increase in intragastric pressure ranging from 5 to 40 cm H_2O, increasing the risk for regurgitation and aspiration of gastri contents. This complication is more likely to occur in patients with delayed gastric emptying (eg, those with diabetes), traumatic injury, esophageal dysfunction, and morbid obesity.

MUSCLE PAIN

Myalgias are a common postoperative complaint of heavily muscled patients and those who receive large doses of succinylcholine. The true incidence of myalgias related to muscle fasciculations is difficult to establish becaus of confounding factors, including the type of surgery and positioning during the operation. However, the incidence of myalgias has been reported to vary from less than 1% to 20%. It occurs more frequently in ambulatory than in bedridden patients. The pain is thought to be secondary to the unsynchronized contractions of adjacent muscle fibers just before the onset of paralysis. However, there is controversy over whether the incidence of muscle pain following succinylcholine is actually higher than with nondepolarizing muscle relaxants when other potentially confounding factors are taken into consideration.

Interactions with Other Drugs

ANESTHETICS

Inhaled (volatile) anesthetics potentiate the neuromuscular blockade produced by nondepolarizing muscle relaxants in a dose-dependent fashion. Of the general anesthetics that have been studied, volatile anesthetics augment the effects of muscle relaxants in the following order: isoflurane (most); sevoflurane, desflurane, enflurane, and halothane; and nitrous oxide (least) (Figure 27–9). The most important factors involved in this interaction are the following: (1) nervous system depression at sites proximal to the neuromuscular junction (ie central nervous system); (2) increased muscle blood flow (ie, due to peripheral vasodilation produced by volatil anesthetics), which allows a larger fraction of the injected muscle relaxant to reach the neuromuscular junction and (3) decreased sensitivity of the postjunctional membrane to depolarization.

A rare interatction of succinylcholine with volatile anesthetics results in malignant hyperthermia, a condition caused by abnormal release of calcium from stores in skeletal muscle. This condition is treated with dantrolene and is discussed below under Spasmolytic Drugs and in Chapter 16.

ANTIBIOTICS

Numerous reports have described enhancement of neuromuscular blockade by antibiotics (eg, aminoglycosides Many of the antibiotics have been shown to cause a depression of evoked release of acetylcholine similar to tha caused by magnesium. The mechanism of this prejunctional effect appears to be blockade of specific P-type calcium channels.

LOCAL ANESTHETICS AND ANTIARRHYTHMIC DRUGS

In small doses, local anesthetics depress posttetanic potentiation via a prejunctional neural effect. In large doses, local anesthetics can block neuromuscular transmission. With higher doses, local anesthetics block acetylcholine-induced muscle contractions as a result of blockade of the nicotinic receptor ion channels.

Experimentally, similar effects can be demonstrated with sodium channel-blocking antiarrhythmic drugs such as quinidine. However, at the doses used for cardiac arrhythmias, this interaction is of little or no clinical significance. Higher concentrations of bupivacaine (0.75%) have been associated with cardiac arrhythmias independent of the muscle relaxant used.

OTHER NEUROMUSCULAR BLOCKING DRUGS

The end plate-depolarizing effect of succinylcholine can be antagonized by administering a small dose of a nondepolarizing blocker. To prevent the fasciculations associated with succinylcholine administration, a small nonparalyzing dose of a nondepolarizing drug can be given before succinylcholine (eg, *d* -tubocurarine 2 mg IV or pancuronium 0.5 mg IV). Although this dose usually reduces fasciculations and postoperative myalgias, it can increase the amount of succinylcholine required for relaxation by 50–90% and can produce a feeling of weakness in awake patients. Therefore, "pre-curarization" before succinylcholine is no longer widely practiced.

Effects of Diseases & Aging on the Neuromuscular Response

Several diseases can diminish or augment the neuromuscular blockade produced by nondepolarizing muscle relaxants. Myasthenia gravis enhances the neuromuscular blockade produced by these drugs. Advanced age is associated with a prolonged duration of action from nondepolarizing relaxants as a result of decreased clearance of the drugs by the liver and kidneys. As a result, the dosage of neuromuscular blocking drugs should be reduced in elderly patients (> 70 years).

Conversely, patients with severe burns and those with upper motor neuron disease are resistant to nondepolarizing muscle relaxants. This desensitization is probably caused by proliferation of extrajunctional receptors, which results in an increased dose requirement for the nondepolarizing relaxant to block a sufficient number of receptors.

Reversal of Nondepolarizing Neuromuscular Blockade

The cholinesterase inhibitors effectively antagonize the neuromuscular blockade caused by nondepolarizing drugs. Their general pharmacology is discussed in Chapter 7. Neostigmine and pyridostigmine antagonize nondepolarizing neuromuscular blockade by increasing the availability of acetylcholine at the motor end plate, mainly by inhibition of acetylcholinesterase. To a lesser extent, these cholinesterase inhibitors also increase release of transmitter from the motor nerve terminal. In contrast, edrophonium antagonizes neuromuscular blockade purely by inhibiting acetylcholinesterase. Edrophonium may be less effective than neostigmine in reversing the effects of nondepolarizing blockers in the presence of a profound degree of neuromuscular blockade. These differences are important in determining recovery from *residual block* , the neuromuscular blockade remaining after completion of surgery and movement of the patient to the recovery room. Unsuspected residual block may result in hypoventilation, leading to hypoxia and even apnea, especially if patients receive central depressant medications during the early recovery period.

Since mivacurium is metabolized by plasma cholinesterase, the interaction with the reversal drugs is less predictable. On the one hand, the neuromuscular blockade is antagonized because of increased acetylcholine concentrations in the synapse. On the other hand, mivacurium concentration may be higher because of decreased plasma cholinesterase breakdown of the muscle relaxant.

A novel cyclodextrin reversal drug, sugammadex, has been recently introduced. It can rapidly inactivate steroidal neuromuscular blocking drugs by forming an inactive complex, which is excreted in the urine. This chelation process allows the practitioner to rapidly reverse even profound degrees of neuromuscular blockade at the end of surgery.

Uses of Neuromuscular Blocking Drugs

SURGICAL RELAXATION

By far the most important application of the neuromuscular blockers is in facilitating intracavitary surgery. This especially important in intra-abdominal and intrathoracic procedures.

TRACHEAL INTUBATION

By relaxing the pharyngeal and laryngeal muscles, neuromuscular blocking drugs facilitate laryngoscopy and placement of the tracheal tube. Placement of a tracheal tube ensures an adequate airway and minimizes the ris of pulmonary aspiration during general anesthesia.

CONTROL OF VENTILATION

In critically ill patients who have ventilatory failure from various causes (eg, severe bronchospasm, pneumonia, chronic obstructive airway disease), it may be necessary to control ventilation to provide adequate gas exchange and to prevent atelectasis. Muscle paralysis is produced by neuromuscular blocking drugs to reduce chest wall resistance (ie, improve thoracic compliance) and ineffective spontaneous ventilation.

TREATMENT OF CONVULSIONS

Neuromuscular blocking drugs are occasionally used to attenuate the peripheral manifestations of convulsions associated with status epilepticus or local anesthetic toxicity. Although this approach is effective in eliminating the muscular manifestations of the seizures, it has no effect on the central processes because neuromuscular blocking drugs do not cross the blood-brain barrier.

SPASMOLYTIC DRUGS

Spasticity is characterized by an increase in tonic stretch reflexes and flexor muscle spasms (ie, increased basa muscle tone) together with muscle weakness. It is often associated with cerebral palsy, multiple sclerosis, and stroke. These conditions often involve abnormal function of the bowel and bladder as well as skeletal muscle. The mechanisms underlying clinical spasticity appear to involve not only the stretch reflex arc itself but also higher centers in the central nervous system (ie, upper motor neuron lesion), with damage to descending pathways in the spinal cord resulting in hyperexcitability of the alpha motoneurons in the cord. Pharmacologic therapy may ameliorate some of the symptoms of spasticity by modifying the stretch reflex arc or by interfering directly with skeletal muscle (ie, excitation-contraction coupling). The important components involved in these processes are shown in Figure 27–10.

Figure 27–10.

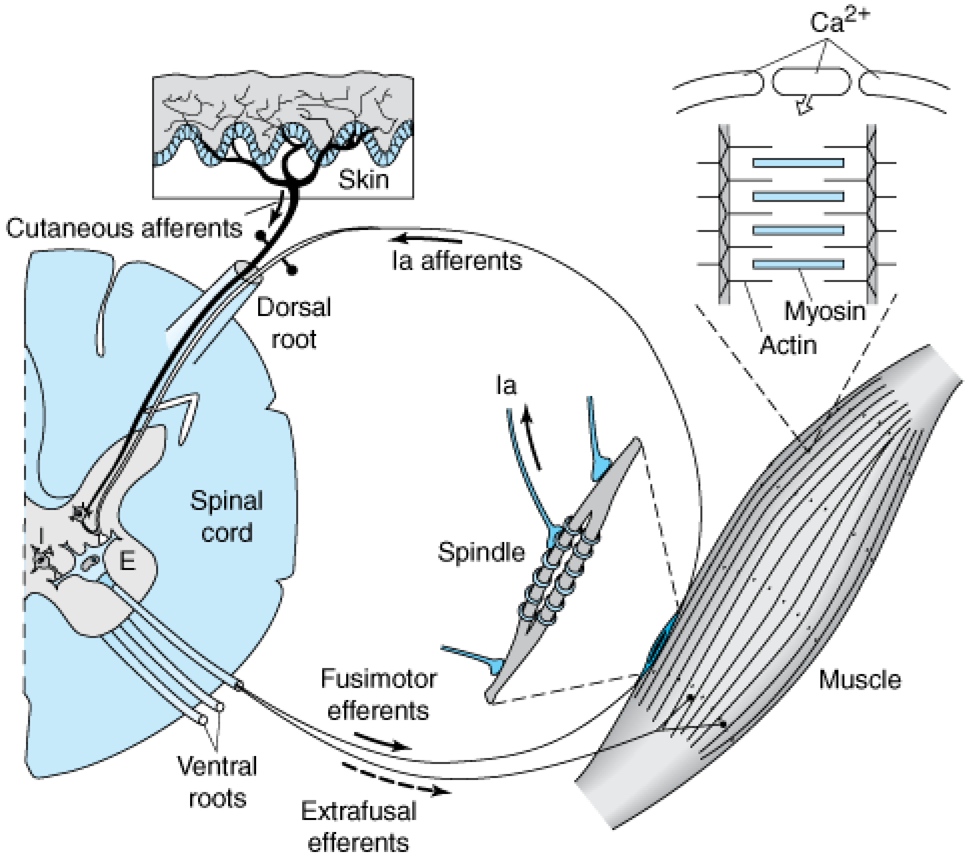

Diagram of the structures involved in the stretch reflex arc. *I* is an inhibitory interneuron; *E* indicates an excitatory presynaptic terminal; *Ia* is a primary intrafusal afferent fiber; *Ca* $^{2+}$ denotes activator calcium stored in the sarcoplasmic reticulum of skeletal muscle. (Reproduced, with permission, from Young RR, Delwaide PJ: Drug therapy: Spasticity. N Engl J Med 1981;304:28.)

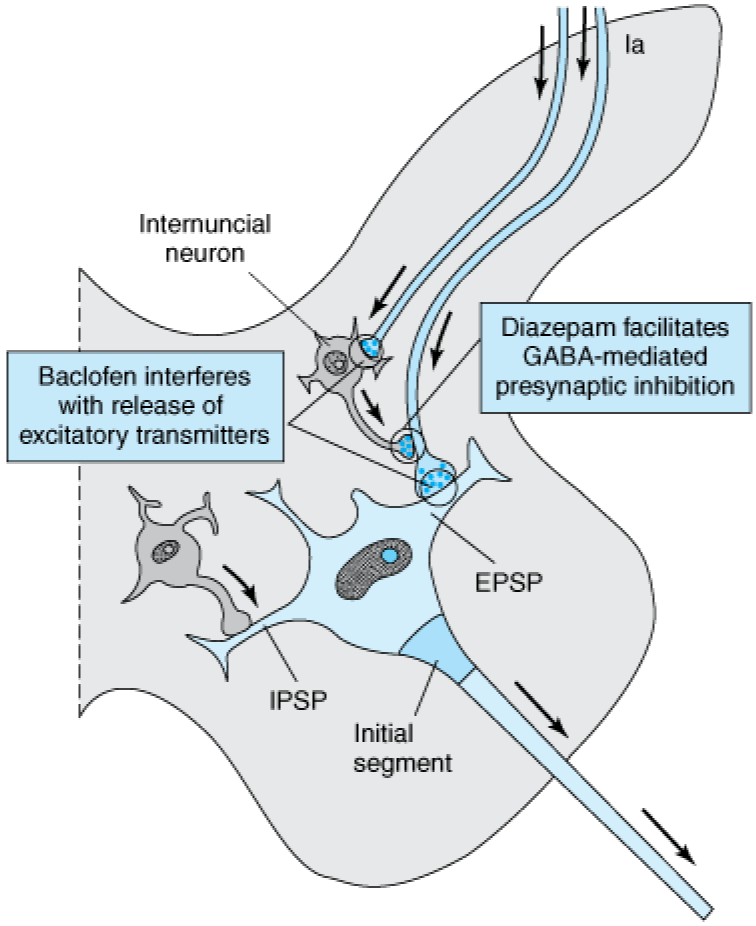
Drugs that modify this reflex arc may modulate excitatory or inhibitory synapses (see Chapter 21). Thus, to reduce the hyperactive stretch reflex, it is desirable to reduce the activity of the Ia fibers that excite the primar motoneuron or to enhance the activity of the inhibitory internuncial neurons. These structures are shown in greater detail in Figure 27–11.

Figure 27–11.



Postulated sites of spasmolytic action of diazepam and baclofen in the spinal cord. (Reproduced, with permission, from Youn RR, Delwaide PJ: Drug therapy: Spasticity. N Engl J Med 1981;304:28.)

A variety of pharmacologic agents described as depressants of the spinal "polysynaptic" reflex arc (eg, barbiturates [phenobarbital] and glycerol ethers [mephenesin]) have been used to treat these conditions of excess skeletal muscle tone. However, as illustrated in Figure 27–11, nonspecific depression of synapses involved in the stretch reflex could reduce the desired inhibitory activity, as well as the excitatory transmission. Currently available drugs can provide significant relief from painful muscle spasms, but they are less effective ir improving meaningful function (eg, mobility and return to work).

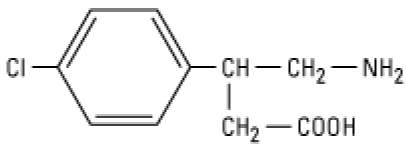
DIAZEPAM

As described in Chapter 22, benzodiazepines facilitate the action of γ-aminobutyric acid (GABA) in the central nervous system. Diazepam acts at $GABA_A$ synapses, and its action in reducing spasticity is at least partly mediated in the spinal cord because it is somewhat effective in patients with cord transection. Although diazepam can be used in patients with muscle spasm of almost any origin (including local muscle trauma), it produces sedation at the doses required to reduce muscle tone. The initial dosage is 4 mg/d, and it is gradually increased to a maximum of 60 mg/d. Other benzodiazepines have been used as spasmolytics (eg, midazolam), but clinical experience with them is limited.

BACLOFEN

Baclofen (*p*- chlorophenyl-GABA) was designed to be an orally active GABA-mimetic agent.

Baclofen exerts its spasmolytic activity at $GABA_B$ receptors. Activation of these receptors by baclofen results in hyperpolarization, probably by increased K^+ conductance. It has been suggested that hyperpolarization causes presynaptic inhibition by reducing calcium influx (Figure 27–11) and reduces the release of excitatory transmitters in both the brain and the spinal cord. Baclofen may also reduce pain in patients with spasticity, perhaps by inhibiting the release of substance P (neurokinin-1) in the spinal cord.



Baclofen

Baclofen is at least as effective as diazepam in reducing spasticity while producing less sedation. In addition, baclofen does not reduce overall muscle strength as much as dantrolene. It is rapidly and completely absorbed after oral administration and has a plasma half-life of 3–4 hours. Dosage is started at 15 mg twice daily, increasing as tolerated to 100 mg daily. Adverse effects of this drug include drowsiness; however, patients become tolerant to the sedative effect with chronic administration. Increased seizure activity has been reportec in epileptic patients. Therefore, withdrawal from baclofen must be done very slowly.

Studies have confirmed that intrathecal administration of baclofen can control severe spasticity and muscle pai that is not responsive to medication by other routes of administration. Owing to the poor egress of baclofen fro the spinal cord, peripheral symptoms are rare. Therefore, higher central concentrations of the drug may be tolerated. Partial tolerance to the effect of the drug may occur after several months of therapy, but can be overcome by upward dosage adjustments to maintain the beneficial effect. Excessive somnolence, respiratory depression, and even coma have been described. Although a major disadvantage of this therapeutic approach i the difficulty of maintaining the drug delivery catheter in the subarachnoid space, long-term intrathecal baclofe therapy can improve the quality of life for patients with severe spastic disorders.

Oral baclofen has been studied in several other medical conditions. Preliminary studies suggest that it may be effective in reducing "craving" in recovering alcoholics (see Chapter 32). It has also been found to be effective i preventing migraine headaches in some patients.

TIZANIDINE

As noted in Chapter 11, α agonists such as clonidine and other imidazoline compounds have a variety of effects on the central nervous system that are not fully understood. Among these effects is the ability to reduce muscl spasm. Tizanidine is a congener of clonidine that has been studied for its spasmolytic actions. Tizanidine has significant α_2 -adrenoceptor agonist effects, but it reduces spasticity in experimental models at doses that caus fewer cardiovascular effects than clonidine. Neurophysiologic studies in animals and humans suggest that tizanidine reinforces both presynaptic and postsynaptic inhibition in the cord. It also inhibits nociceptive transmission in the spinal dorsal horn.

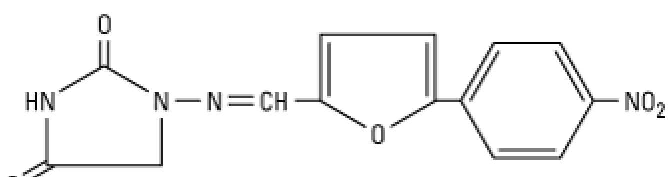
Clinical trials with oral tizanidine report comparable efficacy in relieving muscle spasm to diazepam, baclofen, and dantrolene. However, tizanidine produces a different spectrum of adverse effects, including drowsiness, hypotension, dry mouth, and asthenia. The dosage requirements vary markedly among patients, suggesting that individual dosage titration is necessary to achieve an optimal clinical effect.

OTHER CENTRALLY ACTING SPASMOLYTIC DRUGS

Gabapentin is an antiepileptic drug (see Chapter 24) that has shown considerable promise as a spasmolytic agent in several studies involving patients with multiple sclerosis. Pregabalin is a new analog of gabapentin that may also prove useful. Progabide and glycine have also been found in preliminary studies to reduce spasticity. Progabide is a $GABA_A$ and $GABA_B$ agonist and has active metabolites, including GABA itself. Glycine is another inhibitory amino acid neurotransmitter (see Chapter 21). It appears to possess pharmacologic activity when given orally and readily passes the blood-brain barrier. Idrocilamide and riluzole are newer drugs for the treatment of amyotrophic lateral sclerosis that appear to have spasm-reducing effects, possibly through inhibition of glutamatergic transmission in the central nervous system.

DANTROLENE

Dantrolene is a hydantoin derivative related to phenytoin that has a unique mechanism of spasmolytic activity. In contrast to the centrally acting drugs, dantrolene reduces skeletal muscle strength by interfering with excitation-contraction coupling in the muscle fibers. The normal contractile response involves release of calcium from its stores in the sarcoplasmic reticulum (see Figures 13–2 and 27–10). This activator calcium brings about the tension-generating interaction of actin with myosin. Calcium is released from the sarcoplasmic reticulum via a calcium channel, called the ryanodine receptor (RyR) channel because the plant alkaloid ryanodine combines with a receptor on the channel protein. In the case of the skeletal muscle RyR channel, ryanodine facilitates the open configuration.



Dantrolene

Dantrolene interferes with the release of activator calcium through this sarcoplasmic reticulum calcium channel by binding to the RyR and blocking the opening of the channel. Motor units that contract rapidly are more sensitive to the drug's effects than are slower-responding units. Cardiac muscle and smooth muscle are minimally depressed because the release of calcium from their sarcoplasmic reticulum involves a different RyR channel.

Treatment with dantrolene is usually initiated with 25 mg daily as a single dose, increasing to a maximum of 10 mg four times daily as tolerated. Only about one third of an oral dose of dantrolene is absorbed, and the elimination half-life of the drug is approximately 8 hours. Major adverse effects are generalized muscle weakness, sedation, and occasionally hepatitis.

A special application of dantrolene is in the treatment of malignant hyperthermia, a rare heritable disorder that can be triggered by a variety of stimuli, including general anesthetics (eg, volatile anesthetics) and neuromuscular blocking drugs (eg, succinylcholine; see also Chapter 16). Patients at risk for this condition have a hereditary impairment in the ability of the sarcoplasmic reticulum to sequester calcium (Figure 27–10). After administration of one of the triggering agents, there is a sudden and prolonged release of calcium, with massiv muscle contraction, lactic acid production, and increased body temperature. Prompt treatment is essential to control acidosis and body temperature and to reduce calcium release. The latter is accomplished with intravenous dantrolene, starting with a dose of 1 mg/kg IV, and repeating as necessary to a maximum dose of 10 mg/kg.

BOTULINUM TOXIN

The therapeutic use of botulinum toxin for ophthalmic purposes and for local muscle spasm was mentioned in Chapter 6. Local facial injections of botulinum toxin are widely used for the short-term treatment (1–3 months per treatment) of wrinkles around the eyes and mouth. Local injection of botulinum toxin has also become a useful treatment for generalized spastic disorders (eg, cerebral palsy). Most clinical studies to date have involved administration in one or two limbs, and the benefits appear to persist for weeks to several months afte a single treatment. Most studies have used type A botulinum toxin, but type B is also available.

DRUGS USED TO TREAT ACUTE LOCAL MUSCLE SPASM

A large number of drugs (eg, carisoprodol, chlorphenesin, chlorzoxazone, cyclobenzaprine, metaxalone methocarbamol, and orphenadrine) are promoted for the relief of acute muscle spasm caused by local tissu trauma or muscle strains. It has been suggested that these drugs act primarily at the level of the brainstem. Cyclobenzaprine may be regarded as the prototype of the group. Cyclobenzaprine is structurally related to the tricyclic antidepressants and possesses antimuscarinic effects. It is ineffective in treating muscle spasm due to cerebral palsy or spinal cord injury. The drug has strong antimuscarinic actions and may cause significant sedation, as well as confusion and transient visual hallucinations. The dosage of cyclobenzaprine for acute injury-related muscle spasm is 20–40 mg/d in divided doses.

PREPARATIONS AVAILABLE

NEUROMUSCULAR BLOCKING DRUGS

Atracurium (Tracrium)

Parenteral: 10 mg/mL for injection

Cisatracurium (Nimbex)

Parenteral: 2, 10 mg/mL for IV injection

Doxacurium (Nuromax)

Parenteral: 1 mg/mL for IV injection

Metocurine (generic, Metubine Iodide)

Parenteral: 2 mg/mL for injection

Mivacurium (Mivacron)

Parenteral: 0.5, 2 mg/mL for injection

Pancuronium (generic)

Parenteral: 1, 2 mg/mL for injection

Pipecuronium (Arduan)

Parenteral: powder for 1 mg/mL for IV injection

Rocuronium (Zemuron)

Parenteral: 10 mg/mL for IV injection

Succinylcholine (generic, Anectine)

Parenteral: 20, 50, 100 mg/mL for injection; 500, 1000 mg per vial powders to reconstitute for injection

Tubocurarine (generic)

Parenteral: 3 mg (20 units)/mL for injection

Vecuronium (generic, Norcuron)

Parenteral: 10, 20 mg powder to reconstitute for injection

MUSCLE RELAXANTS (SPASMOLYTICS)

Baclofen (generic, Lioresal)

Oral: 10, 20 mg tablets

Intrathecal: 0.05, 0.5, 2 mg/mL

Botulinum toxin type A (Botox)

Parenteral: Powder for solution, 100 units/vial

Botulinum toxin type B (Myobloc)

Parenteral: 5000 units/mL for injection

Carisoprodol (generic, Soma)

Oral: 350 mg tablets

Chlorphenesin (Maolate)

Oral: 400 mg tablets

Chlorzoxazone (generic, Paraflex)

Oral: 250, 500 mg tablets, caplets

Cyclobenzaprine (generic, Flexeril)

Oral: 10 mg tablets

Dantrolene (Dantrium)

Oral: 25, 50, 100 mg capsules

Parenteral: 20 mg per vial powder to reconstitute for injection

Diazepam (generic, Valium)

Oral: 2, 5, 10 mg tablets; 5 mg/5 mL, 5 mg/mL solutions

Parenteral: 5 mg/mL for injection

Gabapentin (Neurontin)

Oral: 100, 300, 400 mg capsules; 600, 800 mg tablets; 50 mg/mL oral solution

Note: This drug is labeled for use only in epilepsy and postherpetic neuralgia

Metaxalone (Skelaxin)

Oral: 400 mg tablets

Methocarbamol (generic, Robaxin)

Oral: 500, 750 mg tablets

Parenteral: 100 mg/mL for IM, IV injection

Orphenadrine (generic, Norflex)

Oral: 100 mg tablets; 100 mg sustained-release tablets

Parenteral: 30 mg/mL for IM, IV injection

Riluzole (Rilutek)

Oral: 50 mg tablets

Note: This drug is labeled only for use in amyotrophic lateral sclerosis.

Tizanidine (Zanaflex)

Oral: 2, 4 mg tablets, capsules; 6 mg capsules

PHARMACOLOGIC MANAGEMENT OF PARKINSONISM & OTHER MOVEMENT DISORDERS: INTRODUCTION

Several types of abnormal movement are recognized. Tremor consists of a rhythmic oscillatory movement around a joint and is best characterized by its relation to activity. Tremor at rest is characteristic of parkinsonism, when it is often associated with rigidity and an impairment of voluntary activity. Tremor may occur during maintenance of sustained posture (postural tremor) or during movement (intention tremor). A conspicuous postural tremor is the cardinal feature of benign essential or familial tremor. Intention tremor occurs in patients with a lesion of the brainstem or cerebellum, especially when the superior cerebellar peduncle is involved, and may also occur as a manifestation of toxicity from alcohol or certain other drugs.

Chorea consists of irregular, unpredictable, involuntary muscle jerks that occur in different parts of the body and impair voluntary activity. In some instances, the proximal muscles of the limbs are most severely affected, and because the abnormal movements are then particularly violent, the term *ballismus* has been used to describe them. Chorea may be hereditary or may occur as a complication of a number of general medical disorders and of therapy with certain drugs.

Abnormal movements may be slow and writhing in character (athetosis) and in some instances are so sustained that they are more properly regarded as abnormal postures (dystonia). Athetosis or dystonia may occur with perinatal brain damage, with focal or generalized cerebral lesions, as an acute complication of certain drugs, as an accompaniment of diverse neurologic disorders, or as an isolated inherited phenomenon of uncertain cause known as idiopathic torsion dystonia or dystonia musculorum deformans. Its physiologic basis is uncertain, and treatment is unsatisfactory.

Tics are sudden coordinated abnormal movements that tend to occur repetitively, particularly about the face and head, especially in children, and can be suppressed voluntarily for short periods of time. Common tics include repetitive sniffing or shoulder shrugging. Tics may be single or multiple and transient or chronic. Gilles de la Tourette's syndrome is characterized by chronic multiple tics; its pharmacologic management is discussed at the end of this chapter.

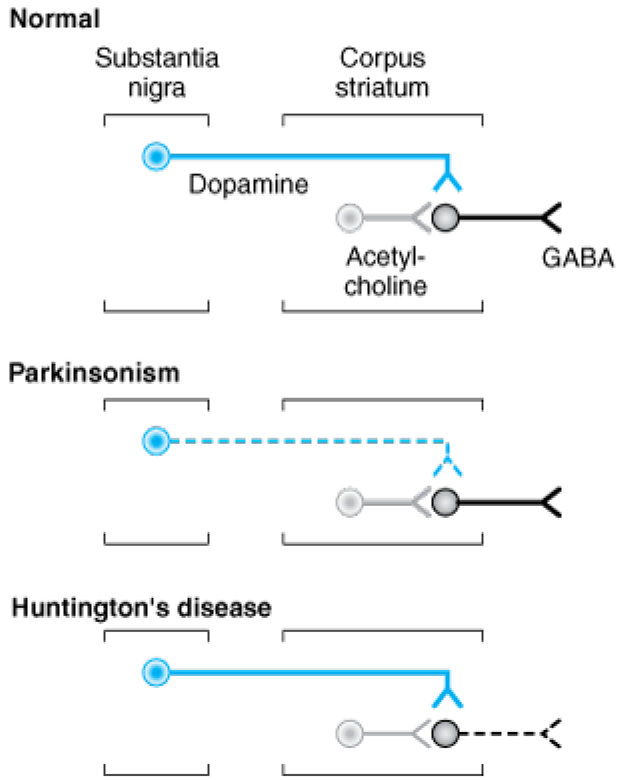
Many of the movement disorders have been attributed to disturbances of the basal ganglia, but the precise function of these anatomic structures is not yet fully understood, and it is not possible to relate individual symptoms to involvement at specific sites.

PARKINSONISM (PARALYSIS AGITANS)

Parkinsonism is characterized by a combination of rigidity, bradykinesia, tremor, and postural instability that can occur for a variety of reasons but is usually idiopathic. The pathophysiologic basis of the idiopathic disorder may relate to exposure to some unrecognized neurotoxin or to the occurrence of oxidation reactions with the generation of free radicals. Studies in twins suggest that genetic factors may also be important, especially when the disease occurs in patients under age 50. Parkinson's disease is generally progressive, leading to increasing disability unless effective treatment is provided.

The normally high concentration of dopamine in the basal ganglia of the brain is reduced in parkinsonism, and pharmacologic attempts to restore dopaminergic activity with levodopa and dopamine agonists have been successful in alleviating many of the clinical features of the disorder. An alternative but complementary approach has been to restore the normal balance of cholinergic and dopaminergic influences on the basal ganglia with antimuscarinic drugs. The pathophysiologic basis for these therapies is that in idiopathic parkinsonism, dopaminergic neurons in the substantia nigra that normally inhibit the output of GABAergic cells in the corpus striatum are lost (Figure 28–1). (In contrast, Huntington's chorea involves the loss of some cholinergic neurons and an even greater loss of the GABAergic cells that exit the corpus striatum.) Drugs that induce parkinsonian syndromes either are dopamine receptor antagonists (eg, antipsychotic agents; see Chapter 29) or lead to the destruction of the dopaminergic nigrostriatal neurons (eg, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine [MPTP]; see below).

Figure 28–1.



Schematic representation of the sequence of neurons involved in parkinsonism and Huntington's chorea. Top: Dopaminergic neurons (color) originating in the substantia nigra normally inhibit the GABAergic output from the striatum, whereas cholinergic neurons (gray) exert an excitatory effect. Middle: In parkinsonism, there is a selective loss of dopaminergic neurons (dashed, color). Bottom: In Huntington's chorea, some cholinergic neurons may be lost (gray), but even more GABAergic neurons (black) degenerate.

LEVODOPA

Dopamine does not cross the blood-brain barrier and if given into the peripheral circulation has no therapeutic effect in parkinsonism. However, (–)-3-(3,4-dihydroxyphenyl)-l-alanine (levodopa), the immediate metabolic precursor of dopamine, does enter the brain (via an L-amino acid transporter, LAT), where it is decarboxylated to dopamine (see Figure 6–5). Several noncatecholamine dopamine receptor agonists have also been developed and may lead to clinical benefit, as discussed below.

Dopamine receptors are discussed in detail in Chapters 21 and 29. Dopamine receptors of the D_1 type are located in the zona compacta of the substantia nigra and presynaptically on striatal axons coming from cortical neurons and from dopaminergic cells in the substantia nigra. The D_2 receptors are located postsynaptically on striatal neurons and presynaptically on axons in the substantia nigra belonging to neurons in the basal ganglia. The benefits of dopaminergic antiparkinsonism drugs appear to depend mostly on stimulation of the D_2 receptors, but D_1-receptor stimulation may also be required for maximal benefit and one of the newer drugs is D_3-selective. Dopamine agonist or partial agonist ergot derivatives such as lergotrile and bromocriptine that are powerful stimulators of the D_2 receptors have antiparkinsonism properties, whereas certain dopamine blockers that are selective D_2 antagonists can induce parkinsonism.

Chemistry

As discussed in Chapter 6, dopa is the amino acid precursor of dopamine and norepinephrine. Its structure is shown in Figure 28–2. Levodopa is the levorotatory stereoisomer of dopa.

Figure 28–2.

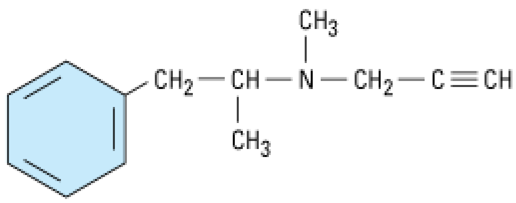
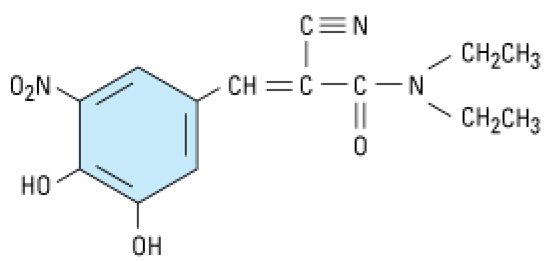
Carbidopa



Selegiline



Entacapone

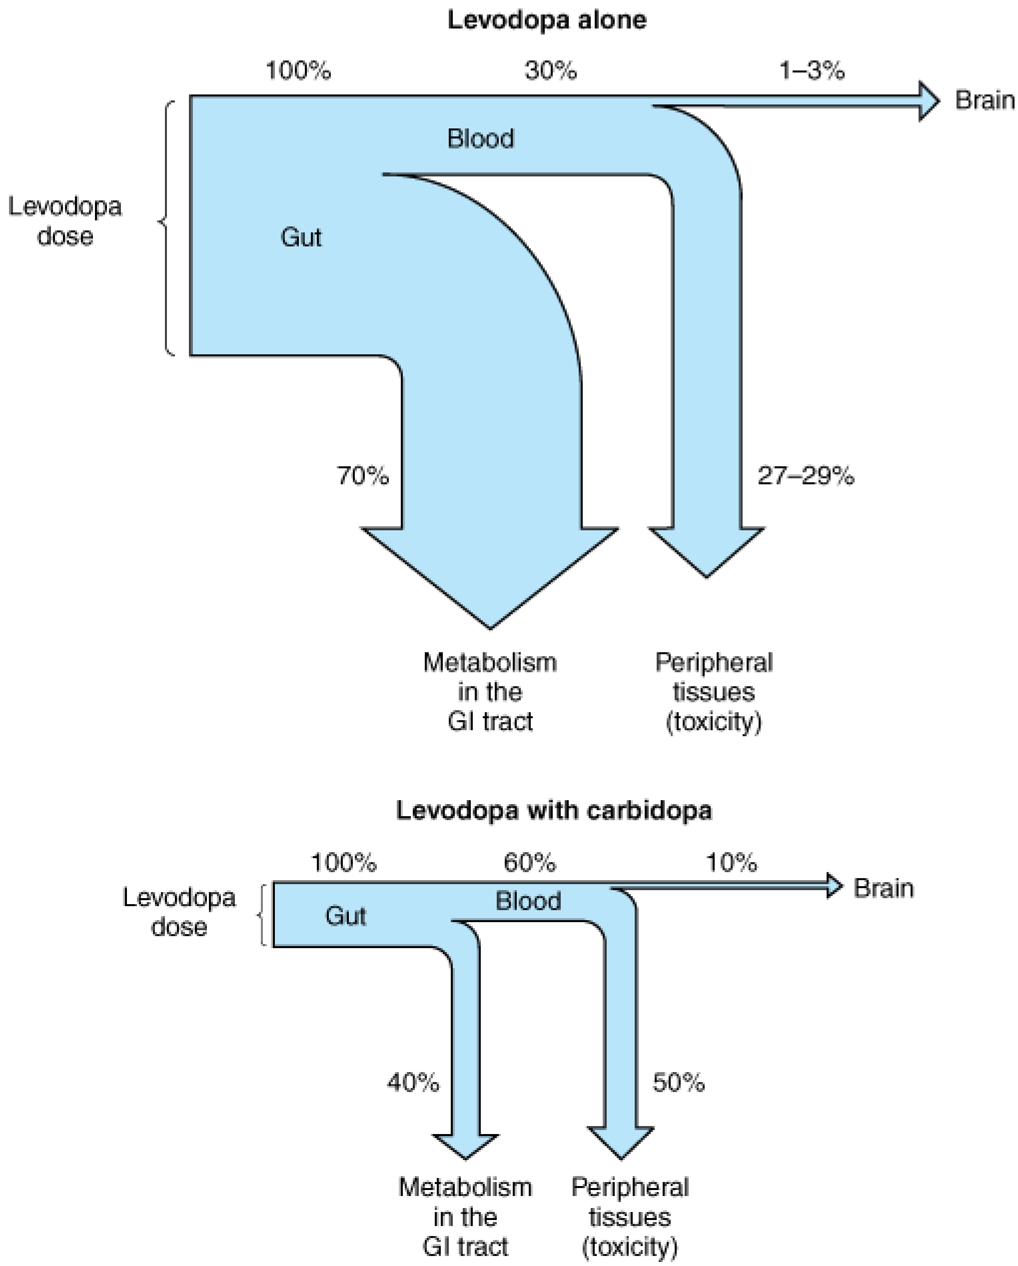
Some drugs used in the treatment of parkinsonism.

Pharmacokinetics

Levodopa is rapidly absorbed from the small intestine, but its absorption depends on the rate of gastric emptying and the pH of the gastric contents. Ingestion of food delays the appearance of levodopa in the plasma. Moreover, certain amino acids from ingested food can compete with the drug for absorption from the gut and for transport from the blood to the brain. Plasma concentrations usually peak between 1 and 2 hours after an oral dose, and the plasma half-life is usually between 1 and 3 hours, although it varies considerably among individuals. About two thirds of the dose appears in the urine as metabolites within 8 hours of an oral dose, the main metabolic products being 3-methoxy-4-hydroxyphenyl acetic acid (homovanillic acid, HVA) and dihydroxyphenylacetic acid (DOPAC).

Unfortunately, only about 1–3% of administered levodopa actually enters the brain unaltered; the remainder is metabolized extracerebrally, predominantly by decarboxylation to dopamine, which does not penetrate the blood-brain barrier. This means that levodopa must be given in large amounts when it is used alone. However, when it is given in combination with a dopa decarboxylase inhibitor that does not penetrate the blood-brain barrier, the peripheral metabolism of levodopa is reduced, plasma levels of levodopa are higher, plasma half-life is longer, and more dopa is available for entry into the brain (Figure 28–3). Indeed, concomitant administration of a peripheral dopa decarboxylase inhibitor such as carbidopa may reduce the daily requirements of levodopa by approximately 75%.

Figure 28–3.



Fate of orally administered levodopa and the effect of carbidopa, estimated from animal data. The width of each pathway indicates the absolute amount of the drug at each site, whereas the percentages shown denote the relative proportion of the administered dose. The benefits of coadministration of carbidopa include reduction of the amount of levodopa diverted to peripheral tissues and an increase in the fraction of the dose that reaches the brain. (GI, gastrointestinal.)

(Data from Nutt JG, Fellman JH: Pharmacokinetics of levodopa. Clin Neuropharmacol 1984;7:35.)

Clinical Use

The best results of levodopa treatment are obtained in the first few years of treatment. This is sometimes because the daily dose of levodopa must be reduced over time to avoid side effects at doses that were well tolerated at the outset. Some patients also become less responsive to levodopa, so that previously effective doses eventually fail to produce any therapeutic benefit. Responsiveness to levodopa may ultimately be lost completely, perhaps because of the disappearance of dopaminergic nigrostriatal nerve terminals or some pathologic process directly involving the striatal dopamine receptors. For such reasons, the benefits of levodopa treatment often begin to diminish after about 3 or 4 years of therapy regardless of the initial therapeutic response. Although levodopa therapy does not stop the progression of parkinsonism, its early initiation lowers the mortality rate. However, long-term therapy may lead to a number of problems in management such as the on-off phenomenon discussed below. The most appropriate time to introduce levodopa therapy must therefore be determined individually.

When levodopa is used, it is generally given in combination with carbidopa (Figure 28–2), a peripheral dopa decarboxylase inhibitor, which reduces peripheral conversion to dopamine. Sinemet treatment is started with a small dose, eg, Sinemet-25/100 (carbidopa 25 mg, levodopa 100 mg) three times daily, and gradually increased. It should be taken 30–60 minutes before meals. Most patients ultimately require Sinemet-25/250 (carbidopa 25 mg, levodopa 250 mg) three or four times daily. It is generally preferable to keep treatment with this agent at a low level (eg, Sinemet-25/100 three times daily) and to increase dopaminergic therapy by the addition of a dopamine agonist, if necessary, to reduce the risk of development of response fluctuations. A controlled-release formulation of Sinemet is available and may be helpful in patients with established response fluctuations or as a means of reducing dosing frequency. A commercially available combination (Stalevo) of levodopa, carbidopa, and a catechol-*O*-methyltransferase (COMT) inhibitor (entacapone) is discussed in a later section.

Levodopa can ameliorate all of the clinical features of parkinsonism, but it is particularly effective in relieving bradykinesia and any disabilities resulting from it. When it is first introduced, about one third of patients respond very well and one third less well. Most of the remainder either are unable to tolerate the medication or simply do not respond at all.

Adverse Effects

GASTROINTESTINAL EFFECTS

When levodopa is given without a peripheral decarboxylase inhibitor, anorexia and nausea and vomiting occur in about 80% of patients. These adverse effects can be minimized by taking the drug in divided doses, with or immediately after meals, and by increasing the total daily dose very slowly; antacids taken 30–60 minutes before levodopa may also be beneficial. The vomiting has been attributed to stimulation of the chemoreceptor trigger zone located in the brainstem but outside the blood-brain barrier. Fortunately, tolerance to this emetic effect develops in many patients. Antiemetics such as phenothiazines should be avoided because they reduce the antiparkinsonism effects of levodopa and may exacerbate the disease.

When levodopa is given in combination with carbidopa, adverse gastrointestinal effects are much less frequent and troublesome, occurring in less than 20% of cases, so that patients can tolerate proportionately higher doses.

CARDIOVASCULAR EFFECTS

A variety of cardiac arrhythmias have been described in patients receiving levodopa, including tachycardia, ventricular extrasystoles and, rarely, atrial fibrillation. This effect has been attributed to increased catecholamine formation peripherally. The incidence of such arrhythmias is low, even in the presence of established cardiac disease, and may be reduced still further if the levodopa is taken in combination with a peripheral decarboxylase inhibitor.

Postural hypotension is common, but often asymptomatic, and tends to diminish with continuing treatment. Hypertension may also occur, especially in the presence of nonselective monoamine oxidase inhibitors or sympathomimetics or when massive doses of levodopa are being taken.

DYSKINESIAS

Dyskinesias occur in up to 80% of patients receiving levodopa therapy for long periods. The form and nature of dopa dyskinesias vary widely among patients but tend to remain constant in character in individual patients. Choreoathetosis of the face and distal extremities is the most common presentation. The development of dyskinesias is dose-related, but there is considerable individual variation in the dose required to produce them.

BEHAVIORAL EFFECTS

A wide variety of adverse mental effects have been reported, including depression, anxiety, agitation, insomnia, somnolence, confusion, delusions, hallucinations, nightmares, euphoria, and other changes in mood or personality. Such adverse effects are more common in patients taking levodopa in combination with a decarboxylase inhibitor rather than levodopa alone, presumably because higher levels are reached in the brain. They may be precipitated by intercurrent illness or operation. It may be necessary to reduce or withdraw the medication. Several atypical antipsychotic agents (clozapine, olanzapine, quetiapine, and risperidone; see Chapter 29) are now available and may be particularly helpful in counteracting the behavioral complications of levodopa.

FLUCTUATIONS IN RESPONSE

Certain fluctuations in clinical response to levodopa occur with increasing frequency as treatment continues. In some patients, these fluctuations relate to the timing of levodopa intake, and they are then referred to as wearing-off reactions or end-of-dose akinesia. In other instances, fluctuations in clinical state are unrelated to the timing of doses (on-off phenomenon). In the on-off phenomenon, off-periods of marked akinesia alternate over the course of a few hours with on-periods of improved mobility but often marked dyskinesia. The phenomenon is most likely to occur in patients who responded well to treatment initially. The exact mechanism is unknown. For patients with severe off-periods who are unresponsive to other measures, subcutaneously injected apomorphine may provide temporary benefit.

MISCELLANEOUS ADVERSE EFFECTS

Mydriasis may occur and may precipitate an attack of acute glaucoma in some patients. Other reported but rare adverse effects include various blood dyscrasias; a positive Coombs test with evidence of hemolysis; hot flushes; aggravation or precipitation of gout; abnormalities of smell or taste; brownish discoloration of saliva, urine, or vaginal secretions; priapism; and mild—usually transient—elevations of blood urea nitrogen and of serum transaminases, alkaline phosphatase, and bilirubin.

Drug Holidays

A drug holiday (discontinuance of the drug for 3–21 days) may temporarily improve responsiveness to levodopa and alleviate some of its adverse effects but is usually of little help in the management of the on-off phenomenon. Furthermore, a drug holiday carries the risks of aspiration pneumonia, venous thrombosis, pulmonary embolism, and depression resulting from the immobility accompanying severe parkinsonism. For these reasons and because of the temporary nature of any benefit, drug holidays are no longer recommended.

Drug Interactions

Pharmacologic doses of pyridoxine (vitamin B_6) enhance the extracerebral metabolism of levodopa and may therefore prevent its therapeutic effect unless a peripheral decarboxylase inhibitor is also taken. Levodopa should not be given to patients taking monoamine oxidase A inhibitors or within 2 weeks of their discontinuance, because such a combination can lead to hypertensive crises.

Contraindications

Levodopa should not be given to psychotic patients because it may exacerbate the mental disturbance. It is also contraindicated in patients with angle-closure glaucoma, but those with chronic open-angle glaucoma may be given levodopa if intraocular pressure is well controlled and can be monitored. It is best given combined with carbidopa to patients with cardiac disease; even so, the risk of cardiac dysrhythmia is slight. Patients with active peptic ulcer must also be managed carefully, since gastrointestinal bleeding has occasionally occurred with levodopa. Because levodopa is a precursor of skin melanin and conceivably may activate malignant melanoma, its use should be avoided in patients with a history of melanoma or with suspicious undiagnosed skin lesions.

DOPAMINE RECEPTOR AGONISTS

Drugs acting directly on dopamine receptors may have a beneficial effect in addition to that of levodopa. Unlike levodopa, they do not require enzymatic conversion to an active metabolite, have no potentially toxic metabolites, and do not compete with other substances for active transport into the blood and across the blood-brain barrier. Moreover, drugs selectively affecting certain (but not all) dopamine receptors may have more limited adverse effects than levodopa. A number of dopamine agonists have antiparkinsonism activity. The older dopamine agonists (bromocriptine and pergolide) are ergot (ergoline) derivatives (see Chapter 16), and their side effects are of more concern than those of the newer agents (pramipexole and ropinirole). There is no evidence that one agonist is superior to another; individual patients, however, may respond to one but not another of these agents. Apomorphine is a potent dopamine agonist but is discussed separately in a later section in this chapter because it is used primarily as a rescue drug for patients with disabling response fluctuations to levodopa.

Dopamine agonists have an important role as first-line therapy for Parkinson's disease, and their use is associated with a lower incidence of the response fluctuations and dyskinesias that occur with long-term levodopa therapy. In consequence, dopaminergic therapy may best be initiated with a dopamine agonist. Alternatively, a low dose of carbidopa plus levodopa (eg, Sinemet-25/100 three times daily) is introduced and a dopamine agonist is then added. In either case, the dose of the dopamine agonist is built up gradually depending on response and tolerance. Dopamine agonists may also be given to patients with parkinsonism who are taking levodopa and who have end-of-dose akinesia or on-off phenomenon or are becoming resistant to treatment with levodopa. In such circumstances, it is generally necessary to lower the dose of levodopa to prevent intolerable adverse effects. The response to a dopamine agonist is generally disappointing in patients who have never responded to levodopa.

Bromocriptine

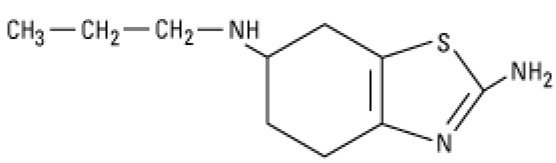
Bromocriptine is a D_2 agonist; its structure is shown in Table 16–4. This drug has been widely used to treat Parkinson's disease and has also been used to treat certain endocrinologic disorders, especially hyperprolactinemia (see Chapter 37), but in lower doses than for parkinsonism. Bromocriptine is absorbed to a variable extent from the gastrointestinal tract; peak plasma levels are reached within 1–2 hours after an oral dose. It is excreted in the bile and feces. The usual daily dose of bromocriptine in the treatment of parkinsonism is between 7.5 and 30 mg, depending on response and tolerance. To minimize adverse effects, the dose is built up slowly over 2 or 3 months from a starting level of 1.25 mg twice daily after meals; the daily dose is then increased by 2.5 mg every 2 weeks depending on the response or the development of adverse reactions.

Pergolide

Pergolide, another ergot derivative, directly stimulates both D_1 and D_2 receptors. It too has been widely used for parkinsonism, and comparative studies suggest that it is more effective than bromocriptine in relieving the symptoms and signs of the disease, increasing "on-time" among response fluctuators, and permitting the levodopa dose to be reduced. Because the use of pergolide has recently been associated with clinical or subclinical valvular heart disease in about one third of patients, one of the newer non-ergot agents is preferred when a dopamine agonist is required.

Pramipexole

Pramipexole, which is not an ergot derivative, has preferential affinity for the D_3 family of receptors. It is effective when used as monotherapy for mild parkinsonism. It is also helpful in patients with advanced disease, permitting the dose of levodopa to be reduced and smoothing out response fluctuations. It may ameliorate affective symptoms. A possible neuroprotective effect has been suggested by its ability to scavenge hydrogen peroxide and enhance neurotrophic activity in mesencephalic dopaminergic cell cultures.

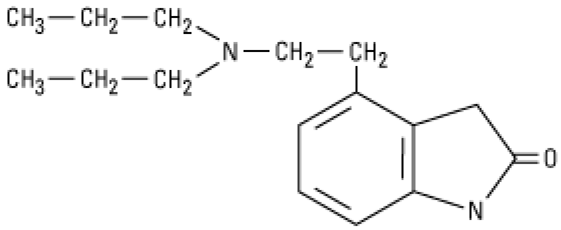


Pramipexole

Pramipexole is rapidly absorbed after oral administration, reaching peak plasma concentrations in approximately 2 hours, and is excreted largely unchanged in the urine. It is started at a dosage of 0.125 mg three times daily, doubled after 1 week, and again after another week. Further increments in the daily dose are by 0.75 mg at weekly intervals, depending on response and tolerance. Most patients require between 0.5 and 1.5 mg three times daily. Renal insufficiency may necessitate dosage adjustment.

Ropinirole

Another nonergoline derivative, ropinirole is a relatively pure D_2 receptor agonist that is effective as monotherapy in patients with mild disease and as a means of smoothing the response to levodopa in patients with more advanced disease and response fluctuations. It is introduced at 0.25 mg three times daily, and the total daily dose is then increased by 0.75 mg at weekly intervals until the fourth week and by 1.5 mg thereafter. In most instances, a dose of between 2 and 8 mg three times daily is necessary. Ropinirole is metabolized by CYP1A2; other drugs metabolized by this isoform may significantly reduce its clearance.



Ropinirole

Adverse Effects of Dopamine Agonists

GASTROINTESTINAL EFFECTS

Anorexia and nausea and vomiting may occur when a dopamine agonist is introduced and can be minimized by taking the medication with meals. Constipation, dyspepsia, and symptoms of reflux esophagitis may also occur. Bleeding from peptic ulceration has been reported.

CARDIOVASCULAR EFFECTS

Postural hypotension may occur, particularly at the initiation of therapy. Painless digital vasospasm is a dose-related complication of long-term treatment with the ergot derivatives (bromocriptine or pergolide). When cardiac arrhythmias occur, they are an indication for discontinuing treatment. Peripheral edema is sometimes problematic. Cardiac valvulopathy may occur with pergolide.

DYSKINESIAS

Abnormal movements similar to those introduced by levodopa may occur and are reversed by reducing the total dose of dopaminergic drugs being taken.

MENTAL DISTURBANCES

Confusion, hallucinations, delusions, and other psychiatric reactions are other complications of dopaminergic treatment and are more common and severe with dopamine receptor agonists than with levodopa. They clear on withdrawal of the offending medication.

MISCELLANEOUS

Headache, nasal congestion, increased arousal, pulmonary infiltrates, pleural and retroperitoneal fibrosis, and erythromelalgia are other reported side effects of the ergot-derived dopamine agonists. Erythromelalgia consists of red, tender, painful, swollen feet and, occasionally, hands, at times associated with arthralgia; symptoms and signs clear within a few days of withdrawal of the causal drug. In rare instances, an uncontrollable tendency to fall asleep at inappropriate times has occurred, particularly in patients receiving pramipexole or ropinirole, requiring the discontinuation of medication.

Contraindications

Dopamine agonists are contraindicated in patients with a history of psychotic illness or recent myocardial infarction, or with active peptic ulceration. The ergot-derived agonists are best avoided in patients with peripheral vascular disease.

MONOAMINE OXIDASE INHIBITORS

Two types of monoamine oxidase have been distinguished in the nervous system. Monoamine oxidase A metabolizes norepinephrine and serotonin; monoamine oxidase B metabolizes dopamine. Selegiline (deprenyl) (Figure 28–2), a selective irreversible inhibitor of monoamine oxidase B at normal doses (at higher doses it inhibits MAO-A as well), retards the breakdown of dopamine; in consequence, it enhances and prolongs the antiparkinsonism effect of levodopa (thereby allowing the dose of levodopa to be reduced) and may reduce mild on-off or wearing-off phenomena. It is therefore used as adjunctive therapy for patients with a declining or fluctuating response to levodopa. The standard dose of selegiline is 5 mg with breakfast and 5 mg with lunch. Selegiline may cause insomnia when taken later during the day. It should not be taken by patients receiving meperidine, tricyclic antidepressants, or serotonin reuptake inhibitors because of the risk of acute toxic interactions of the serotonin syndrome type (see Chapter 16). The adverse effects of levodopa may be increased by selegiline.

Selegiline has only a minor therapeutic effect on parkinsonism when given alone, but studies in animals suggest that it may reduce disease progression. Such an effect of antioxidative therapy on disease progression may be expected if Parkinson's disease is associated with the oxidative generation of free radicals. However, any neuroprotective effect of selegiline may relate to its metabolite, desmethylselegiline, and involve antiapoptotic mechanisms. Studies to test the effect of selegiline on the progression of parkinsonism in humans have yielded ambiguous results. The findings in a large multicenter study have been taken to suggest a beneficial effect in slowing disease progression but may simply have reflected a symptomatic response.

Rasagiline, another monoamine oxidase B inhibitor, is more potent than selegiline in preventing MPTP-induced parkinsonism and is being used as a neuroprotective agent and for early symptomatic treatment. The standard dose is 0.5 mg/d.

The combined administration of levodopa and an inhibitor of both forms of monoamine oxidase must be avoided, because it may lead to hypertensive crises, probably because of the peripheral accumulation of norepinephrine.

CATECHOL-*O*-METHYLTRANSFERASE INHIBITORS

Inhibition of dopa decarboxylase is associated with compensatory activation of other pathways of levodopa metabolism, especially catechol-*O*-methyltransferase (COMT), and this increases plasma levels of 3-*O*-methyldopa (3OMD). Elevated levels of 3OMD have been associated with a poor therapeutic response to levodopa, perhaps in part because 3OMD competes with levodopa for an active carrier mechanism that governs its transport across the intestinal mucosa and the blood-brain barrier. Selective COMT inhibitors such as tolcapone and entacapone also prolong the action of levodopa by diminishing its peripheral metabolism. Levodopa clearance is decreased, and relative bioavailability of levodopa is thus increased. Neither the time to reach peak concentration nor the maximal concentration of levodopa is increased. These agents may be helpful in patients receiving levodopa who have developed response fluctuations—leading to a smoother response, more prolonged "on-time," and the option of reducing total daily levodopa dose. Tolcapone and entacapone are both widely available, but entacapone is generally preferred because it has not been associated with hepatotoxicity.

The pharmacologic effects of tolcapone and entacapone are similar, and both are rapidly absorbed, bound to plasma proteins, and metabolized prior to excretion. However, tolcapone has both central and peripheral effects, whereas the effect of entacapone is peripheral. The half-life of both drugs is approximately 2 hours, but tolcapone is slightly more potent and has a longer duration of action. Tolcapone is taken in a standard dosage of 100 mg three times daily; some patients require a daily dose of twice that amount. By contrast, entacapone (200 mg) needs to be taken with each dose of levodopa, up to five times daily.

Adverse effects of the COMT inhibitors relate in part to increased levodopa exposure and include dyskinesias, nausea, and confusion. It is often necessary to lower the daily dose of levodopa by about 30% in the first 48 hours to avoid or reverse such complications. Other side effects include diarrhea, abdominal pain, orthostatic hypotension, sleep disturbances, and an orange discoloration of the urine. Tolcapone may cause an increase in liver enzyme levels and has been rarely associated with death from acute hepatic failure; accordingly, its use in the USA requires signed patient consent (as provided in the product labeling) plus monitoring of liver function tests every 2 weeks during the first year and less frequently thereafter. No such toxicity has been reported with entacapone.

A commercial preparation named Stalevo consists of a combination of levodopa with both carbidopa and entacapone. Use of this preparation simplifies the drug regimen and requires the consumption of a lesser number of tablets than otherwise; Stalevo is priced at or below the price of its individual components.

APOMORPHINE

Subcutaneous injection of apomorphine hydrochloride (Apokyn), a potent dopamine agonist, is effective for the temporary relief of off-periods of akinesia in patients on dopaminergic therapy. It is rapidly taken up in the blood and then the brain, leading to clinical benefit that begins within about 10 minutes of injection and persists for up to 2 hours. The optimal dose is identified by administering increasing test doses until adequate benefit is achieved or a maximum of 10 mg is reached. Most patients require a dose of 3–6 mg, and this should be given no more than about three times daily.

Nausea is often troublesome, especially at the initiation of apomorphine treatment; accordingly, pretreatment with the antiemetic trimethobenzamide (300 mg three times daily) for 3 days is recommended before apomorphine is introduced and is then continued for at least 1 month, if not indefinitely. Other adverse effects include dyskinesias, drowsiness, sweating, hypotension, and bruising at the injection site.

AMANTADINE

Amantadine, an antiviral agent, was by chance found to have antiparkinsonism properties. Its mode of action in parkinsonism is unclear, but it may potentiate dopaminergic function by influencing the synthesis, release, or reuptake of dopamine. Release of catecholamines from peripheral stores has been documented.

Pharmacokinetics

Peak plasma concentrations of amantadine are reached 1–4 hours after an oral dose. The plasma half-life is between 2 and 4 hours, most of the drug being excreted unchanged in the urine.

Clinical Use

Amantadine is less potent than levodopa, and its benefits may be short-lived, often disappearing after only a few weeks of treatment. Nevertheless, during that time it may favorably influence the bradykinesia, rigidity, and tremor of parkinsonism. The standard dosage is 100 mg orally twice or three times daily. Amantadine may also help in reducing iatrogenic dyskinesias in patients with advanced disease.

Adverse Effects

Amantadine has a number of undesirable central nervous system effects, all of which can be reversed by stopping the drug. These include restlessness, depression, irritability, insomnia, agitation, excitement, hallucinations, and confusion. Overdosage may produce an acute toxic psychosis. With doses several times higher than recommended, convulsions have occurred.

Livedo reticularis sometimes occurs in patients taking amantadine and usually clears within a month after the drug is withdrawn. Other dermatologic reactions have also been described. Peripheral edema, another well-recognized complication, is not accompanied by signs of cardiac, hepatic, or renal disease and responds to diuretics. Other adverse reactions include headache, heart failure, postural hypotension, urinary retention, and gastrointestinal disturbances (eg, anorexia, nausea, constipation, and dry mouth).

Amantadine should be used with caution in patients with a history of seizures or heart failure.

ACETYLCHOLINE-BLOCKING DRUGS

A number of centrally acting antimuscarinic preparations are available that differ in their potency and in their efficacy in different patients. Some of these drugs were discussed in Chapter 8. These agents may improve the tremor and rigidity of parkinsonism but have little effect on bradykinesia. Some of the more commonly used drugs are listed in Table 28–1.

Table 28–1. Some Drugs with Antimuscarinic Properties Used in Parkinsonism.

Drug	Usual Daily Dose (mg)
Benztropine mesylate	1–6
Biperiden	2–12
Orphenadrine	150–400
Procyclidine	7.5–30
Trihexyphenidyl	6–20

Clinical Use

Treatment is started with a low dose of one of the drugs in this category, the level of medication gradually being increased until benefit occurs or adverse effects limit further increments. If patients do not respond to one drug, a trial with another member of the drug class is warranted and may be successful.

Adverse Effects

Antimuscarinic drugs have a number of undesirable central nervous system and peripheral effects (see Chapter 8). Dyskinesias occur in rare cases. Acute suppurative parotitis sometimes occurs as a complication of dryness of the mouth.

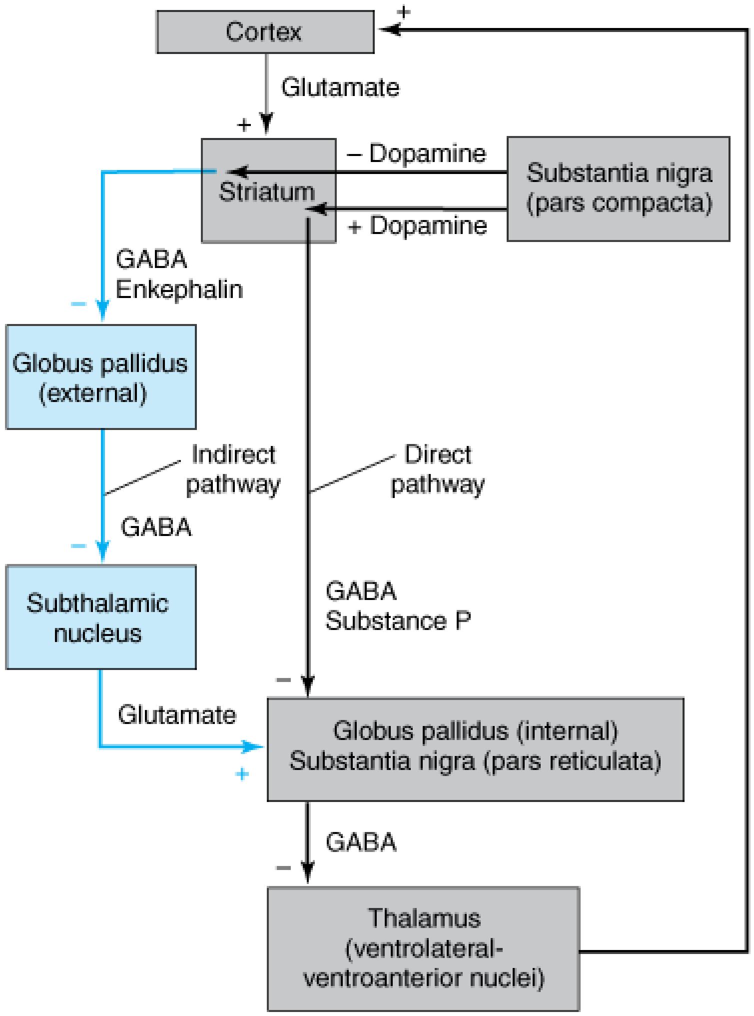
If medication is to be withdrawn, this should be accomplished gradually rather than abruptly to prevent acute exacerbation of parkinsonism. For contraindications to their use, see Chapter 8.

SURGICAL PROCEDURES

In patients with advanced disease that is poorly responsive to pharmacotherapy, worthwhile benefit may follow thalamotomy (for conspicuous tremor) or posteroventral pallidotomy. Ablative surgical procedures, however, are being replaced by functional, reversible lesions induced by high-frequency deep-brain stimulation, which has a lower morbidity.

Thalamic stimulation by an implanted electrode and stimulator is very effective for the relief of tremor, and stimulation of the subthalamic nucleus or globus pallidus internus has yielded good results for management of the clinical fluctuation occurring in advanced parkinsonism. The anatomic substrate for such therapy is indicated in Figure 28–4. Such procedures are contraindicated in patients with secondary or atypical parkinsonism.

Figure 28–4.



Functional circuitry between the cortex, basal ganglia, and thalamus. The involved neurotransmitters are indicated. In Parkinson's disease, there is degeneration of the pars compacta of the substantia nigra, leading to overactivity in the indirect pathway (color) and increased glutamatergic activity by the subthalamic nucleus.

Transplantation of dopaminergic tissue (fetal substantia nigra tissue) has been reported to confer benefit in some parkinsonism patients, but the results are conflicting. In one controlled trial, symptomatic benefit occurred in younger (less than 60 years old) but not older patients. In another trial, benefits were inconsequential. Furthermore, uncontrollable dyskinesias occurred in some patients in both studies. This was attributed to a relative excess of dopamine from continued fiber outgrowth from the transplant. Further basic studies are required before other trials of cellular therapies are undertaken, and such approaches therefore remain investigational.

NEUROPROTECTIVE THERAPY

A number of different compounds are under investigation as potential neuroprotective agents that may slow disease progression. These compounds include antioxidants, antiapoptotic agents, glutamate antagonists, intraparenchymally administered glial-derived neurotrophic factor, coenzyme Q10, creatine, and anti-inflammatory drugs. The role of these agents remains to be established, however, and their use for therapeutic purposes is not indicated at this time.

GENERAL COMMENTS ON DRUG MANAGEMENT OF PATIENTS WITH PARKINSONISM

Parkinson's disease generally follows a progressive course. Moreover, the benefits of levodopa therapy often diminish with time, and serious adverse effects may complicate long-term levodopa treatment. Nevertheless, dopaminergic therapy at a relatively early stage may be most effective in alleviating symptoms of parkinsonism and may also favorably affect the mortality rate due to the disease. Symptomatic treatment of mild parkinsonism is probably best avoided until there is some degree of disability or until symptoms begin to have a significant impact on the patient's lifestyle. When treatment becomes necessary, a trial of amantadine or an antimuscarinic drug (or both) may be worthwhile. With disease progression, dopaminergic therapy becomes necessary. This can conveniently be initiated with a dopamine agonist, either alone or in combination with low-dose Sinemet therapy. Physical therapy is helpful in improving mobility. In patients with severe parkinsonism and long-term complications of levodopa therapy such as the on-off phenomenon, a trial of treatment with a COMT inhibitor may be worthwhile. Regulation of dietary protein intake may also improve response fluctuations. Deep-brain stimulation may be helpful in patients who fail to respond adequately to these measures. Treating patients who are young or have mild parkinsonism with selegiline or rasagiline may delay disease progression and merits consideration.

DRUG-INDUCED PARKINSONISM

Reserpine and the related drug tetrabenazine deplete biogenic monoamines from their storage sites, whereas haloperidol and the phenothiazines block dopamine receptors. These drugs may therefore produce a parkinsonian syndrome, usually within 3 months after introduction. This is related to high dosage and clears over a few weeks or months after withdrawal. If treatment is necessary, antimuscarinic agents are preferred. Levodopa is of no help if neuroleptic drugs are continued and may in fact aggravate the mental disorder for which antipsychotic drugs were prescribed originally.

In 1983, a drug-induced form of parkinsonism was discovered in individuals who attempted to synthesize and use a narcotic drug related to meperidine but actually synthesized and self-administered MPTP, as discussed in MPTP & Parkinsonism.

MPTP & Parkinsonism

Reports in the early 1980s of a rapidly progressive form of parkinsonism in young persons opened a new area of research in the etiology and treatment of parkinsonism. The initial report described apparently healthy young people who attempted to support their opioid habit with a meperidine analog synthesized by an amateur chemist. They unwittingly self-administered 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and subsequently developed a very severe form of parkinsonism.

MPTP is a protoxin that is converted by monoamine oxidase B to *N*-methyl-4-phenylpyridinium (MPP+). MPP+ is selectively taken up by cells in the substantia nigra through an active mechanism normally responsible for dopamine reuptake. MPP+ inhibits mitochondrial complex I, thereby inhibiting oxidative phosphorylation. The interaction of MPP+ with complex I probably leads to cell death and thus to striatal dopamine depletion and parkinsonism.

Recognition of the effects of MPTP suggested that spontaneously occurring Parkinson's disease may result from exposure to an environmental toxin that is similarly selective in its target. However, no such toxin has yet been identified. It also suggested a successful means of producing an experimental model of Parkinson's disease in animals, especially nonhuman primates. This model is assisting in the development of new antiparkinsonism drugs. Pretreatment of exposed animals with a monoamine oxidase B inhibitor such as selegiline prevents the conversion of MPTP to MPP+ and thus protects against the occurrence of parkinsonism. This observation has provided one reason to believe that selegiline or rasagiline may retard the progression of Parkinson's disease in humans.

OTHER MOVEMENT DISORDERS

Tremor

Tremor consists of rhythmic oscillatory movements. Physiologic postural tremor, which is a normal phenomenon, is enhanced in amplitude by anxiety, fatigue, thyrotoxicosis, and intravenous epinephrine or isoproterenol. Propranolol reduces its amplitude and, if administered intra-arterially, prevents the response to isoproterenol in the perfused limb, presumably through some peripheral action. Certain drugs—especially the bronchodilators, valproate, tricyclic antidepressants, and lithium—may produce a dose-dependent exaggeration of the normal physiologic tremor that is reversed by discontinuing the drug. Although the tremor produced by sympathomimetics such as terbutaline (a bronchodilator) is blocked by propranolol, which antagonizes both β_1 and β_2 receptors, it is not blocked by metoprolol, a β_1-selective antagonist; this suggests that such tremor is mediated mainly by the β_2 receptors.

Essential tremor is a postural tremor, sometimes familial, which is clinically similar to physiologic tremor. Dysfunction of β_1 receptors has been implicated in some instances, since the tremor may respond dramatically to standard doses of metoprolol as well as to propranolol. The most useful approach is with propranolol, but whether the response depends on a central or peripheral action is unclear. The pharmacokinetics, pharmacologic effects, and adverse reactions of propranolol are discussed in Chapter 10. Daily doses of propranolol on the order of 120 mg (range, 60–240 mg) are usually required, and reported adverse effects have been few. Propranolol should be used with caution in patients with heart failure, heart block, asthma, and hypoglycemia. Patients can be instructed to take their own pulse and call the physician if significant bradycardia develops. Metoprolol is sometimes useful in treating tremor when patients have concomitant pulmonary disease that contraindicates use of propranolol. Primidone (an antiepileptic drug; see Chapter 24), in gradually increasing doses up to 250 mg three times daily, is also effective in providing symptomatic control in some cases. Patients with tremor are very sensitive to primidone and often cannot tolerate the doses used to treat seizures; they should be started on 50 mg once daily and the daily dose increased by 50 mg every 2 weeks depending on response. Topiramate, another antiepileptic drug, may also be helpful in a dose of 400 mg daily, built up gradually. Small quantities of alcohol may suppress essential tremor but only for a short time and by an unknown mechanism. Alprazolam (in doses up to 3 mg daily) is helpful in some patients. Others are helped by intramuscular injections of botulinum toxin. Thalamic stimulation (discussed earlier) is often worthwhile in advanced cases refractory to pharmacotherapy. Diazepam, chlordiazepoxide, mephenesin, and antiparkinsonism agents have been advocated in the past but are generally worthless. Anecdotal reports of benefit from mirtazapine were not confirmed in a double-blind study, which found no effect on the tremor in most patients.

Intention tremor is present during movement but not at rest; sometimes it occurs as a toxic manifestation of alcohol or drugs such as phenytoin. Withdrawal or reduction in dosage provides dramatic relief. There is no satisfactory pharmacologic treatment for intention tremor due to other neurologic disorders.

Rest tremor is usually due to parkinsonism.

Huntington's Disease

Huntington's disease is an autosomal dominant inherited disorder caused by an abnormality in chromosome 4. It is characterized by progressive chorea and dementia that usually begin in adulthood. The development of chorea seems to be related to an imbalance of dopamine, acetylcholine, GABA, and perhaps other neurotransmitters in the basal ganglia (Figure 28–1). Pharmacologic studies indicate that chorea results from functional overactivity in dopaminergic nigrostriatal pathways, perhaps because of increased responsiveness of postsynaptic dopamine receptors or deficiency of a neurotransmitter that normally antagonizes dopamine. Drugs that impair dopaminergic neurotransmission, either by depleting central monoamines (eg, reserpine, tetrabenazine) or by blocking dopamine receptors (eg, phenothiazines, butyrophenones), often alleviate chorea, whereas dopamine-like drugs such as levodopa tend to exacerbate it.

Both GABA and the enzyme (glutamic acid decarboxylase) concerned with its synthesis are markedly reduced in the basal ganglia of patients with Huntington's disease, and GABA receptors are usually implicated in inhibitory pathways. There is also a significant decline in concentration of choline acetyltransferase, the enzyme responsible for synthesizing acetylcholine, in the basal ganglia of these patients. These findings may be of pathophysiologic significance and have led to attempts to alleviate chorea by enhancing central GABA or acetylcholine activity. Unfortunately, such pharmacologic manipulations have been disappointing, yielding no consistently beneficial response. As a consequence, the most commonly used drugs for controlling dyskinesia in patients with Huntington's disease are still those that interfere with dopamine activity. With all the latter drugs, however, reduction of abnormal movements may be associated with iatrogenic parkinsonism.

Reserpine depletes cerebral dopamine by preventing intraneuronal storage (see Chapter 6); it is introduced in low doses (eg, 0.25 mg daily), and the daily dose is then built up gradually (eg, by 0.25 mg every week) until benefit occurs or adverse effects become troublesome. A daily dose of 2–5 mg is often effective in suppressing abnormal movements, but adverse effects may include hypotension, depression, sedation, diarrhea, and nasal congestion. Tetrabenazine resembles reserpine in depleting cerebral dopamine and has less troublesome adverse effects, but it is not available in the USA. Treatment with postsynaptic dopamine receptor blockers such as phenothiazines and butyrophenones may also be helpful. Haloperidol is started in a small dose, eg, 1 mg twice daily, and increased every 4 days depending on the response. If haloperidol is not helpful, treatment with increasing doses of perphenazine up to a total of about 20 mg daily sometimes helps. Several recent reports suggest that olanzapine may also be useful; the dose varies with the patient, but 10 mg daily is often sufficient although doses as high as 30 mg daily are sometimes required. The pharmacokinetics and clinical properties of these drugs are considered in greater detail elsewhere in this book.

Other Forms of Chorea

Treatment is directed at the underlying cause when chorea occurs as a complication of general medical disorders such as thyrotoxicosis, polycythemia vera rubra, systemic lupus erythematosus, hypocalcemia, and hepatic cirrhosis. Drug-induced chorea is managed by withdrawal of the offending substance, which may be levodopa, an antimuscarinic drug, amphetamine, lithium, phenytoin, or an oral contraceptive. Neuroleptic drugs may also produce an acute or tardive dyskinesia (discussed below). Sydenham's chorea is temporary and usually so mild that pharmacologic management of the dyskinesia is unnecessary, but dopamine-blocking drugs are effective in suppressing it.

Ballismus

The biochemical basis of ballismus is unknown, but the pharmacologic approach to management is the same as for chorea. Treatment with haloperidol, perphenazine, or other dopamine-blocking drugs may be helpful.

Athetosis & Dystonia

The pharmacologic basis of these disorders is unknown, and there is no satisfactory medical treatment for them. Occasional patients with dystonia may respond to diazepam, amantadine, antimuscarinic drugs (in high dosage), levodopa, carbamazepine, baclofen, haloperidol, or phenothiazines. A trial of these pharmacologic approaches is worthwhile even though often not successful. Patients with focal dystonias such as blepharospasm or torticollis may benefit from injection of botulinum toxin into the overactive muscles.

Tics

The pathophysiologic basis of tics is unknown. Chronic multiple tics (Gilles de la Tourette's syndrome) may require symptomatic treatment if the disorder is severe or is having a significant impact on the patient's life. The most effective pharmacologic approach is with haloperidol, and patients are better able to tolerate this drug if treatment is started with a small dosage (eg, 0.25 or 0.5 mg daily) and then increased very gradually over the following weeks. Most patients ultimately require a total daily dose of 3–8 mg. Adverse effects include extrapyramidal movement disorders, sedation, dryness of the mouth, blurred vision, and gastrointestinal disturbances. Pimozide, another dopamine-receptor antagonist, may be helpful in patients who are either unresponsive to or intolerant of haloperidol. Treatment is started at 1 mg/d, and the dosage is increased by 1 mg every 5 days; most patients require 7–16 mg/d.

If these measures fail, fluphenazine, clonazepam, clonidine, or carbamazepine should be tried. The pharmacologic properties of these drugs are discussed elsewhere in this book. Clonidine reduces motor or vocal tics in about 50% of children so treated. It may act by reducing activity in noradrenergic neurons in the locus caeruleus. It is introduced in a dose of 2–3 mcg/kg/d, increasing after 2 weeks to 4 mcg/kg/d and then, if required, to 5 mcg/kg/d. It may cause an initial transient fall in blood pressure. The most common side effect is sedation; other side effects include reduced or excessive salivation and diarrhea. Phenothiazines such as fluphenazine sometimes help the tics, as do dopamine agonists. The role of the newer atypical antipsychotic agents, such as risperidone, is unclear.

Injection of botulinum toxin A at the site of problematic tics is sometimes helpful. Treatment of any associated attention deficit disorder or obsessive-compulsive disorder may be required. Bilateral thalamic stimulation is sometimes worthwhile in otherwise intractable cases.

Drug-Induced Dyskinesias

The pharmacologic basis of the acute dyskinesia or dystonia sometimes precipitated by the first few doses of a phenothiazine is not clear. In most instances, parenteral administration of an antimuscarinic drug such as benztropine (2 mg intravenously), diphenhydramine (50 mg intravenously), or biperiden (2–5 mg intravenously or intramuscularly) is helpful, whereas in other instances diazepam (10 mg intravenously) alleviates the abnormal movements.

Tardive dyskinesia, a disorder characterized by a variety of abnormal movements, is a common complication of long-term neuroleptic drug treatment (see Chapter 29). Unfortunately, its precise pharmacologic basis is unclear. A reduction in dose of the offending medication, a dopamine receptor blocker, commonly worsens the dyskinesia, whereas an increase in dose may suppress it. The drugs most likely to provide immediate symptomatic benefit are those interfering with dopaminergic function, either by depletion (eg, reserpine, tetrabenazine) or receptor blockade (eg, phenothiazines, butyrophenones). Paradoxically, the receptor-blocking drugs are the very ones that also cause the dyskinesia.

Because tardive dyskinesia that develops in adults is often irreversible and has no satisfactory treatment, care must be taken to reduce the likelihood of its occurrence. Antipsychotic medication should be prescribed only when necessary and should be withheld periodically to assess the need for continued treatment and to unmask incipient dyskinesia. Thioridazine, a phenothiazine with a piperidine side chain, is an effective antipsychotic that seems less likely than most to cause extrapyramidal reactions, perhaps because it has little effect on dopamine receptors in the striatal system. Finally, antimuscarinic drugs should not be prescribed routinely in patients receiving neuroleptics, because the combination may increase the likelihood of dyskinesia.

Restless Legs Syndrome

Restless legs syndrome is characterized by an unpleasant creeping discomfort that seems to arise deep within the legs and occasionally the arms. Symptoms occur particularly when patients are relaxed, especially when they are lying down or sitting, and they lead to an urge to move about. Such symptoms may delay the onset of sleep. A sleep disorder associated with periodic movements during sleep may also occur. The cause is unknown, but the disorder is especially common among pregnant women and also among uremic or diabetic patients with neuropathy. In most patients, no obvious predisposing cause is found.

Symptoms may resolve with correction of coexisting iron-deficiency anemia and often respond to dopamine agonists, levodopa, diazepam, clonazepam, or opiates. Dopaminergic therapy is the preferred treatment for restless legs syndrome and should be initiated with long-acting dopamine agonists to avoid the complications associated with levodopa. Ropinirole has recently been approved for this condition. When opiates are required, those with long half-lives or low addictive potential should be used.

Wilson's Disease

A recessively inherited disorder of copper metabolism, Wilson's disease is characterized biochemically by reduced serum copper and ceruloplasmin concentrations, pathologically by markedly increased concentration of copper in the brain and viscera, and clinically by signs of hepatic and neurologic dysfunction. Neurologic signs include tremor, choreiform movements, rigidity, hypokinesia, and dysarthria and dysphagia. Treatment involves the removal of excess copper, followed by maintenance of copper balance. A commonly used agent for this purpose is penicillamine (dimethylcysteine), a chelating agent that forms a ring complex with copper. It is readily absorbed from the gastrointestinal tract and rapidly excreted in the urine. A common starting dose in adults is 500 mg three or four times daily. After remission occurs, it may be possible to lower the maintenance dose, generally to not less than 1 g daily, which must thereafter be continued indefinitely. Adverse effects include nausea and vomiting, nephrotic syndrome, a lupus-like syndrome, pemphigus, myasthenia, arthropathy, optic neuropathy, and various blood dyscrasias. Treatment should be monitored by frequent urinalysis and complete blood counts. Dietary copper should also be kept below 2 mg daily. Potassium disulfide, 20 mg three times daily with meals, reduces the intestinal absorption of copper and should also be prescribed.

For those patients who are unable to tolerate penicillamine, trientine, another chelating agent, may be used in a daily dose of 1–1.5 g. Trientine appears to have few adverse effects other than mild anemia due to iron deficiency in a few patients. Zinc acetate administered orally increases the fecal excretion of copper and is sometimes used for maintenance therapy. The dose is 50 mg three times a day. Zinc sulfate (200 mg/d orally) has also been used to decrease copper absorption. Zinc blocks copper absorption from the gastrointestinal tract by induction of intestinal cell metallothionein. Its main advantage is its low toxicity compared with that of other anticopper agents, although it may cause gastric irritation when introduced.

PREPARATIONS AVAILABLE

Amantadine (Symmetrel, others)

Oral: 100 mg capsules; 10 mg/mL syrup

Apomorphine (Apokyn)

Subcutaneous injection titration kit, 10 mg/mL

Benztropine (Cogentin, others)

Oral: 0.5, 1, 2 mg tablets

Parenteral: 1 mg/mL for injection

Biperiden (Akineton)

Oral: 2 mg tablets

Parenteral: 5 mg/mL for injection

Bromocriptine (Parlodel)

Oral: 2.5 mg tablets; 5 mg capsules

Carbidopa (Lodosyn)

Oral: 25 mg tablets

Carbidopa/levodopa (Sinemet, others)

Oral: 10 mg carbidopa and 100 mg levodopa, 25 mg carbidopa and 100 mg levodopa, 25 mg carbidopa and 250 mg levodopa tablets

Oral sustained-release (Sinemet CR): 25 mg carbidopa and 100 mg levodopa; 50 mg carbidopa and 200 mg levodopa

Carbidopa/levodopa/entacapone (Stalevo)

Oral: 12.5 mg carbidopa, 200 mg entacapone and 50 mg levodopa; 25 mg carbidopa, 200 mg entacapone, and 100 mg levodopa; 37.5 mg carbidopa, 200 mg entacapone, and 150 mg levodopa

Entacapone (Comtan)

Oral: 200 mg tablets

Levodopa (Dopar, Larodopa)

Oral: 100, 250, 500 mg tablets, capsules

Orphenadrine (various)

Oral: 100 mg tablets

Oral sustained-release: 100 mg tablets

Parenteral: 30 mg/mL for injection

Penicillamine (Cuprimine, Depen)

Oral: 125, 250 mg capsules; 250 mg tablets

Pergolide (Permax, other)

Oral: 0.05, 0.25, 1 mg tablets

Pramipexole (Mirapex)

Oral: 0.125, 0.25, 1, 1.5 mg tablets

Procyclidine (Kemadrin)

Oral: 5 mg tablets

Rasagiline (Azilect)

Oral: 0.5, 1 mg tablets

Ropinirole (Requip)

Oral: 0.25, 0.5, 1, 2, 5 mg tablets

Selegiline (deprenyl) (generic, Eldepryl)

Oral: 5 mg tablets, capsules

Tolcapone (Tasmar)

Oral: 100, 200 mg tablets

Trientine (Syprine)

Oral: 250 mg capsules

Trihexyphenidyl (Artane, others)

Oral: 2, 5 mg tablets; 2 mg/5 mL elixir

Oral sustained-release (Artane Sequels): 5 mg capsules

Top of Form

ANTIPSYCHOTIC AGENTS

The terms *antipsychotic* and *neuroleptic* have been used interchangeably to denote a group of drugs that have been used mainly for treating schizophrenia but are also effective in some other psychoses and agitated states.

History

Antipsychotic drugs have been used in Western medicine for more than 50 years. Reserpine and chlorpromazine were the first drugs found to be useful in schizophrenia. Although chlorpromazine is still sometimes used for the treatment of psychoses, these forerunner drugs have been superseded by many newer agents. Their impact on psychiatry, however—especially on the treatment of schizophrenia—has been enormous: The number of patients hospitalized in mental institutions has markedly decreased, and schizophrenia is now recognized as a biologic illness.

Nature of Psychosis & Schizophrenia

The term "psychosis" denotes a variety of mental disorders. Schizophrenia is a particular kind of psychosis characterized mainly by a clear sensorium but a marked thinking disturbance.

The pathogenesis of schizophrenia is unknown. Largely as a result of research stimulated by the discovery of antipsychotic drugs, a genetic predisposition has been proposed as a necessary but not always sufficient condition underlying psychotic disorder. This assumption has been supported by the observed familial incidence of schizophrenia. At least one gene—that encoding neuregulin 1—is associated with schizophrenia in Icelandic and northern European populations. Additional genes associated with schizophrenia continue to be identified that may contribute to understanding the molecular basis for schizophrenia. Based on the efficacy of antipsychotic drugs, efforts continue to link the disorder with abnormalities of amine neurotransmitter function, especially that of dopamine (see The Dopamine Hypothesis of Schizophrenia). The defects of this hypothesis are significant, and it is now appreciated that schizophrenia is far more complex than originally supposed.

THE DOPAMINE HYPOTHESIS OF SCHIZOPHRENIA

The dopamine hypothesis for schizophrenia is the most fully developed of several hypotheses and is the basis for much of the rationale for drug therapy. Several lines of circumstantial evidence suggest that excessive dopaminergic activity plays a role in the disorder: (1) many antipsychotic drugs strongly block postsynaptic D_2 receptors in the central nervous system, especially in the mesolimbic-frontal system; (2) drugs that increase dopaminergic activity, such as levodopa (a precursor), amphetamines (releasers of dopamine), and apomorphine (a direct dopamine receptor agonist), either aggravate schizophrenia or produce psychosis de novo in some patients; (3) dopamine receptor density has been found postmortem to be increased in the brains of schizophrenics who have not been treated with antipsychotic drugs; (4) positron emission tomography (PET) has shown increased dopamine receptor density in both treated and untreated schizophrenics when compared with such scans of nonschizophrenic persons; and (5) successful treatment of schizophrenic patients has been reported to change the amount of homovanillic acid (HVA), a metabolite of dopamine, in the cerebrospinal fluid, plasma, and urine.

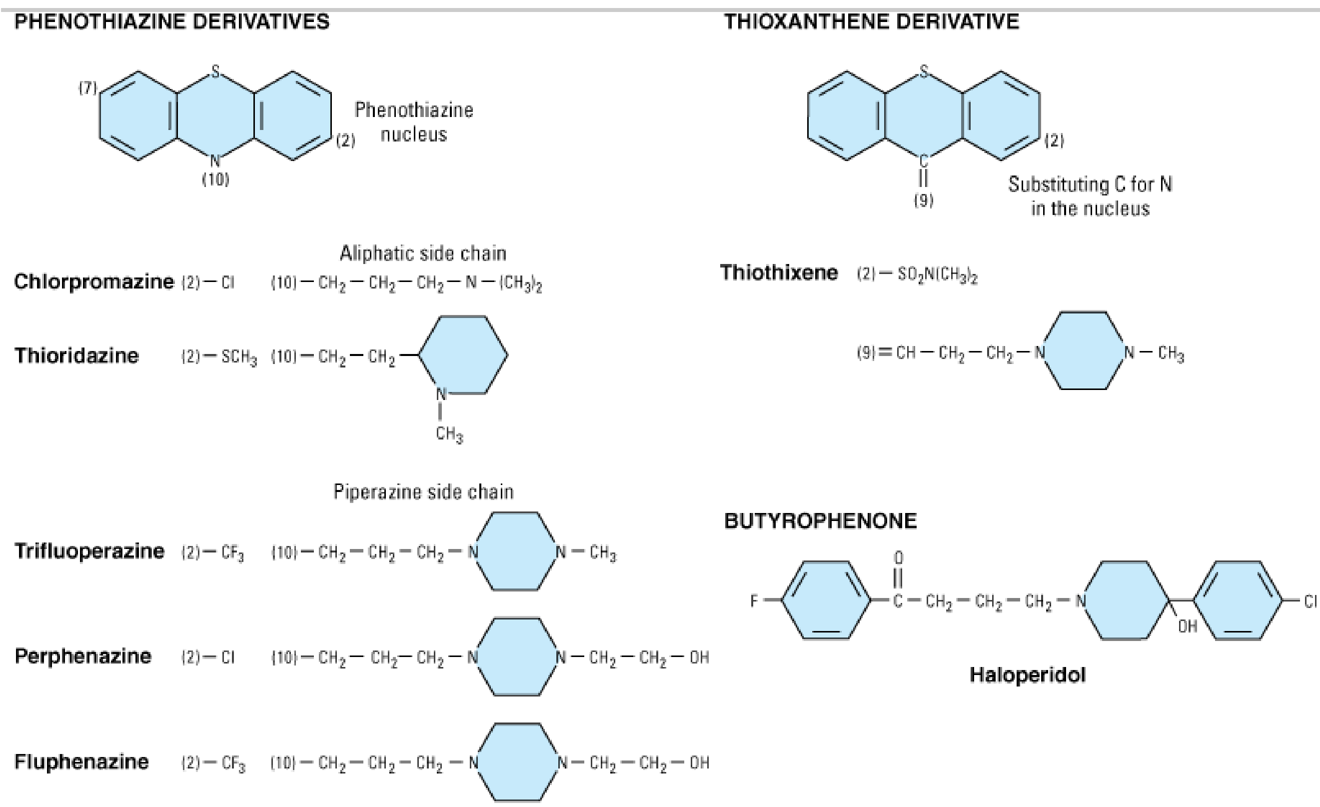
The dopamine hypothesis is far from complete, however. If an abnormality of dopamine physiology were completely responsible for the pathogenesis of schizophrenia, antipsychotic drugs would do a much better job of treating patients—but they are only partially effective for most and ineffective for some patients. Moreover, it appears that antagonists of the NMDA receptor such as phencyclidine, when administered to nonpsychotic subjects, produce much more "schizophrenia-like" symptoms than do dopamine agonists. The cloning and characterization of multiple dopamine receptor types may permit more direct testing of the dopamine hypothesis if drugs can be developed that act more selectively on each receptor type. The traditional antipsychotics bind D_2 50 times more avidly than D_1 or D_3 receptors. Until recently, the main thrust in drug development was to find agents that were more potent and more selective in blocking D_2 receptors. The fact that several of the atypical antipsychotic drugs have much less effect on D_2 receptors and yet are effective in schizophrenia has redirected attention to the role of other dopamine receptors and to nondopamine receptors, especially serotonin receptor subtypes that may mediate synergistic effects or protect against the extrapyramidal consequences of D_2 antagonism. As a result of these considerations, the direction of research has changed to a greater focus on compounds that may act on several transmitter-receptor systems. The great hope is to produce drugs with greater efficacy and fewer adverse effects, especially extrapyramidal toxicity.

Basic Pharmacology of Antipsychotic Agents

Chemical Types

A number of chemical structures have been associated with antipsychotic properties. The drugs can be classified into several groups as shown in Figures 29–1 and 29–2.

Figure 29–1.



Structural formulas of some older antipsychotic drugs: phenothiazines, thioxanthenes, and butyrophenones. Only representative members of each type are shown.

Figure 29–2.

PHENOTHIAZINE DERIVATIVES

Three subfamilies of phenothiazines, based primarily on the side chain of the molecule, were once the most widely used of the antipsychotics. Aliphatic derivatives (eg, chlorpromazine) and piperidine derivatives (eg, thioridazine) are the least potent. Piperazine derivatives are more potent (effective in lower doses) but not necessarily more efficacious. The piperazine derivatives are also more selective in their pharmacologic effects (Table 29–1).

THIOXANTHENE DERIVATIVES

This group of drugs is exemplified primarily by thiothixene. In general, these compounds are slightly less potent than their phenothiazine analogs.

BUTYROPHENONE DERIVATIVES

This group, of which haloperidol is the most widely used, has a very different structure from those of the two preceding groups. Diphenylbutylpiperidines are closely related compounds. The butyrophenones and congeners tend to be more potent and to have fewer autonomic effects but greater extrapyramidal effects (Table 29–1).

MISCELLANEOUS STRUCTURES

The newer drugs, not all of which are available in the USA, have a variety of structures and include pimozide, molindone, loxapine, clozapine, olanzapine, quetiapine, risperidone, ziprasidone, and aripiprazole (Figure 29–2).

Pharmacokinetics

ABSORPTION AND DISTRIBUTION

Most antipsychotic drugs are readily but incompletely absorbed. Furthermore, many of these drugs undergo significant first-pass metabolism. Thus, oral doses of chlorpromazine and thioridazine have systemic availability of 25% to 35%, whereas haloperidol, which is less likely to be metabolized, has an average systemic availability of about 65%.

Most antipsychotic drugs are highly lipid-soluble and protein-bound (92–99%). They tend to have large volumes of distribution (usually > 7 L/kg). Probably because these drugs are sequestered in lipid compartments of the body and have a very high affinity for selected neurotransmitter receptors in the central nervous system, they generally have a much longer clinical duration of action than would be estimated from their plasma half-lives. This is paralleled by prolonged occupancy of dopamine D_2 receptors in brain. Metabolites of chlorpromazine may be excreted in the urine weeks after the last dose of chronically administered drug. Similarly, full relapse may not occur until 6 weeks or more after discontinuation of many antipsychotic drugs.

METABOLISM

Most antipsychotic drugs are almost completely metabolized by a variety of processes. Although some metabolites retain activity, eg, 7-hydroxychlorpromazine and reduced haloperidol, metabolites are not considered to be highly important to the action of these drugs. The sole exception is mesoridazine, the major metabolite of thioridazine, which is more potent than the parent compound and accounts for most of the effect. This compound has been marketed as a separate entity. Very little of these antipsychotic drugs is excreted unchanged, because they are almost completely metabolized to more polar substances.

Pharmacologic Effects

The first phenothiazine antipsychotic drugs, with chlorpromazine as the prototype, proved to have a wide variety of central nervous system, autonomic, and endocrine effects. These actions were traced to blocking effects at a wide range of receptors, including dopamine and α adrenoceptor, muscarinic, H_1 histaminic, and serotonin (5-HT_2) receptors. Dopamine receptor effects quickly became the major focus of interest.

DOPAMINERGIC SYSTEMS

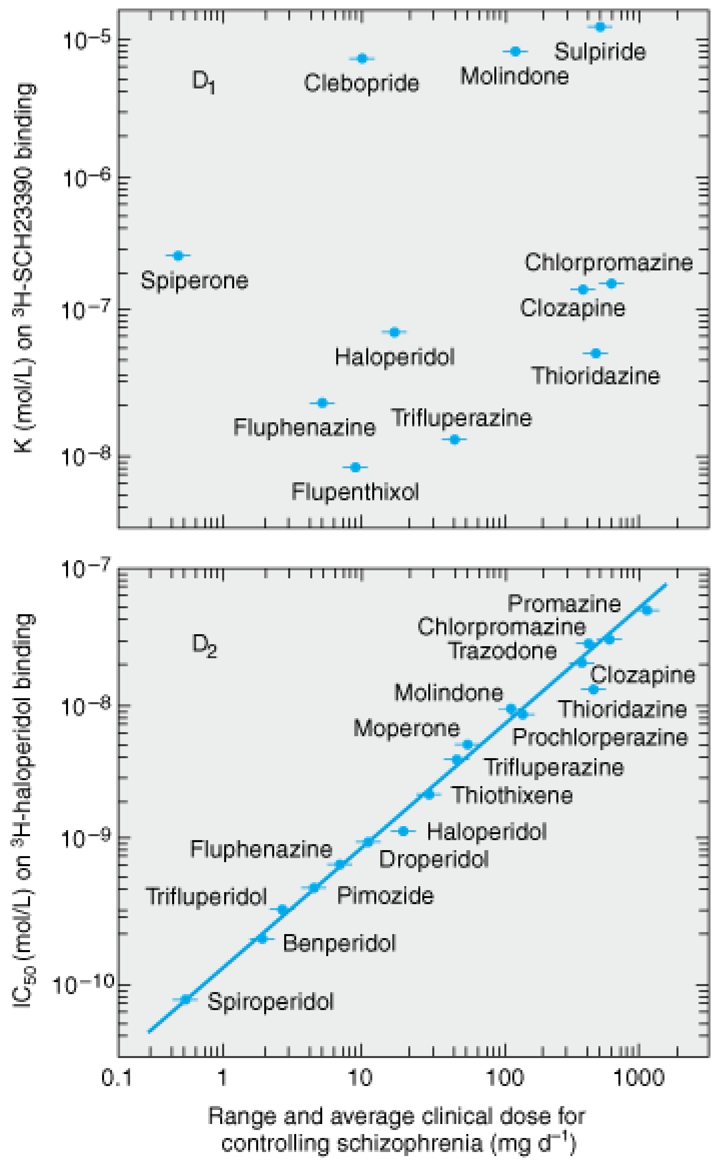
Five important dopaminergic systems or pathways are now recognized in the brain. The first pathway—the one most closely related to behavior—is the *mesolimbic-mesocortical* pathway, which projects from cell bodies near the substantia nigra to the limbic system and neocortex. The second system—the *nigrostriatal* pathway—consists of neurons that project from the substantia nigra to the caudate and putamen; it is involved in the coordination of voluntary movement. The third pathway—the *tuberoinfundibular* system—connects arcuate nuclei and periventricular neurons to the hypothalamus and posterior pituitary. Dopamine released by these neurons physiologically inhibits prolactin secretion. The fourth dopaminergic system—the *medullary-periventricular* pathway—consists of neurons in the motor nucleus of the vagus whose projections are not well defined. This system may be involved in eating behavior. The fifth pathway—the *incertohypothalamic* pathway—forms connections from the medial zona incerta to the hypothalamus and the amygdala. It appears to regulate the anticipatory motivational phase of copulatory behavior in rats.

After dopamine was recognized as a neurotransmitter in 1959, investigators showed that its effects on electrical activity in central synapses and on production of cAMP by adenylyl cyclase could be blocked by most antipsychotic drugs. This evidence led to the conclusion in the early 1960s that these drugs should be considered *dopamine antagonists*. The antipsychotic action is now thought to be produced (at least in part) by their ability to block dopamine in the mesolimbic and mesocortical systems. Furthermore, the antagonism of dopamine in the nigrostriatal system explains the unwanted effect of parkinsonism produced by these drugs. The hyperprolactinemia that follows treatment with antipsychotics is caused by blockade of dopamine's tonic inhibitory effect on prolactin release from the pituitary. Thus, the same pharmacodynamic action may have distinct psychiatric, neurologic, and endocrinologic consequences.

DOPAMINE RECEPTORS AND THEIR EFFECTS

At present, five dopamine receptors have been described, consisting of two separate families, the D_1 -like and D_2 -like receptor groups. The D_1 receptor is coded by a gene on chromosome 5, increases cAMP by G_s -coupled activation of adenylyl cyclase, and is located mainly in the putamen, nucleus accumbens, and olfactory tubercle. The second member of this family, D_5 , is coded by a gene on chromosome 4, also increases cAMP, and is found in the hippocampus and hypothalamus. The therapeutic potency of antipsychotic drugs does not correlate with their affinity for binding the D_1 receptor (Figure 29–3, top) but for most, correlates strongly with D_2 affinity. The D_2 receptor is coded on chromosome 11, decreases cAMP (by G_i -coupled inhibition of adenylyl cyclase), and inhibits calcium channels but opens potassium channels. It is found both pre- and postsynaptically on neurons in the caudate-putamen, nucleus accumbens, and olfactory tubercle. A second member of this family, the D_3 receptor, also coded by a gene on chromosome 11, is thought to decrease cAMP and is located in the frontal cortex, medulla, and midbrain. D_4 receptors also decrease cAMP.

Figure 29–3.



Correlations between the therapeutic potency of antipsychotic drugs and their affinity for binding to dopamine D_1 *(top)* or D_2 receptors *(bottom)* . Potency is indicated on the horizontal axes; it decreases to the right. Binding affinity for D_1 receptors was measured by displacing the selective D_1 ligand SCH 23390; affinity for D_2 receptors was similarly measured by displacing the selective D_2 ligand haloperidol. Binding affinity decreases upward. (Modified and reproduced, with permission, from Seeman P: Dopamine receptors and the dopamine hypothesis of schizophrenia. Synapse 1987;1:133.)

The activation of D_2 receptors by a variety of direct or indirect agonists (eg, amphetamines, levodopa, apomorphine) causes increased motor activity and stereotyped behavior in rats, a model that has been extensively used for antipsychotic drug screening. When given to humans, the same drugs aggravate schizophrenia. The antipsychotic agents block D_2 receptors stereoselectively for the most part, and their binding affinity is very strongly correlated with clinical antipsychotic and extrapyramidal potency (Figure

29–3, bottom). Continuous treatment with antipsychotic drugs has been reported in some studies to produce a transient increase in levels of a dopamine metabolite, homovanillic acid (HVA), in the cerebrospinal fluid, plasma, and urine.

These findings have been incorporated into the dopamine hypothesis of schizophrenia. However, many questions have not been satisfactorily answered, and many observations have not been fully confirmed. For example, dopamine receptors exist in both high- and low-affinity forms, and it is not known whether schizophrenia or the antipsychotic drugs alter the proportions of receptors in these two forms. With the introduction of aripiprazole, which in preclinical studies shows partial agonism at D_2 and 5-HT_{1A} receptors, the relevance of the proportion of receptors in various affinity states may prove especially important for understanding the degree of response to this agent.

Furthermore, the drug-induced progression of extrapyramidal changes—from diminished function (resembling parkinsonism) to increased activity (manifested by dyskinesias)—often occurs over a period of months to years. This time scale is much longer than that described for other drug-induced changes in receptor function. Of most importance, newer drugs—clozapine, olanzapine, quetiapine, and aripiprazole—do not have very high affinity for the D_2 receptor, which suggests that additional actions are critical to their antipsychotic effects.

It has not been convincingly demonstrated that antagonism of any dopamine receptor other than the D_2 receptor plays a role in the action of antipsychotic drugs. Selective D_3 -receptor antagonists may prove therapeutic but are not yet available. Most of the newer "atypical" antipsychotic agents and some of the traditional ones have significant affinity for the 5-HT_{2A} receptor (Table 29–1), suggesting an important role for the serotonin system. Participation of glutamate, GABA, and acetylcholine receptors in the pathophysiology of schizophrenia has also been proposed. Agents targeted at glutamatergic and cholinergic systems are just beginning to be evaluated in schizophrenia.

DIFFERENCES AMONG ANTIPSYCHOTIC DRUGS

Although all effective antipsychotic drugs block D_2 receptors, the degree of this blockade in relation to other actions on receptors varies considerably between drugs. Vast numbers of ligand-receptor binding experiments have been performed in an effort to discover a single receptor action that would best predict antipsychotic efficacy. A summary of the relative receptor-binding affinities of several key agents in such comparisons illustrates the difficulty in drawing simple conclusions from such experiments:

Chlorpromazine: $\alpha_1 = 5\text{-}HT_{2A} > D_2 > D_1$
Haloperidol: $D_2 > \alpha_1 > D_4 > 5\text{-}HT_{2A} > D_1 > H_1$
Clozapine: $D_4 = \alpha_1 > 5\text{-}HT_{2A} > D_2 = D_1$
Olanzapine: $5\text{-}HT_{2A} > H_1 > D_4 > D_2 > \alpha_1 > D_1$
Aripiprazole: $D_2 = 5\text{-}HT_{2A} > D_4 > \alpha_1 = H_1 >> D_1$
Quetiapine: $H_1 > \alpha_1 > M_{1,3} > D_2 > 5\text{-}HT_{2A}$

Thus, most of the atypical antipsychotic agents are at least as potent in inhibiting 5-HT_2 receptors as they are in inhibiting D_2 receptors. The newest, aripiprazole, appears to be a partial agonist of D_2 receptors. Varying degrees of antagonism of α_2 adrenoceptors are also seen with risperidone, clozapine, olanzapine, quetiapine, and aripiprazole. The clinical relevance of these actions remains to be ascertained.

Current research is directed toward discovering atypical antipsychotic compounds that are either more selective for the mesolimbic system (to reduce their effects on the extrapyramidal system) or have effects on central neurotransmitter receptors—such as those for acetylcholine and excitatory amino acids—that have been proposed as new targets for antipsychotic action.

In contrast to the search for *efficacy,* such differences in the receptor effects of various antipsychotics do explain many of their *toxicities* (Tables 29–1 and 29–2). In particular, extrapyramidal toxicity appears to be associated with high D_2 potency.

Table 29–2. Adverse Pharmacologic Effects of Antipsychotic Drugs.

Type	Manifestations	Mechanism
Autonomic nervous system	Loss of accommodation, dry mouth, difficulty urinating, constipation	Muscarinic cholinoceptor blockade
	Orthostatic hypotension, impotence, failure to ejaculate	Alpha adrenoceptor blockade
Central nervous system	Parkinson's syndrome, akathisia, dystonias	Dopamine receptor blockade
	Tardive dyskinesia	Supersensitivity of dopamine receptors
	Toxic-confusional state	Muscarinic blockade
Endocrine system	Amenorrhea-galactorrhea, infertility, impotence	Dopamine receptor blockade resulting in hyperprolactinemia
Other	Weight gain	Possibly combined H_1 and 5-HT_2 blockade

PSYCHOLOGICAL EFFECTS

Most antipsychotic drugs cause unpleasant subjective effects in nonpsychotic individuals; the combination of sleepiness, restlessness, and autonomic effects creates experiences unlike those associated with more familiar sedatives or hypnotics. Nonpsychotic persons also experience impaired performance as judged by a number of psychomotor and psychometric tests. Psychotic individuals, however, may actually show improvement in their performance as the psychosis is alleviated.

ELECTROENCEPHALOGRAPHIC EFFECTS

Antipsychotic drugs produce shifts in the pattern of electroencephalographic frequencies, usually slowing them and increasing their synchronization. The slowing (hypersynchrony) is sometimes focal or unilateral, which may lead to erroneous diagnostic interpretations. Both the frequency and the amplitude changes induced by psychotropic drugs are readily apparent and can be quantitated by sophisticated electrophysiologic techniques. Some of the neuroleptic agents lower the seizure threshold and induce EEG patterns typical of seizure disorders; however, with careful dosage titration, most can be used safely in epileptic patients.

ENDOCRINE EFFECTS

Older antipsychotic drugs produce striking adverse effects on the reproductive system. Amenorrhea-galactorrhea, false-positive pregnancy tests, and increased libido have been reported in women, whereas men have experienced decreased libido and gynecomastia. Some of these effects are secondary to blockade of dopamine's tonic inhibition of prolactin secretion; others may be due to increased peripheral conversion of androgens to estrogens. Absent or minimal increases of prolactin after some of the newer antipsychotics such as olanzapine, quetiapine, and aripiprazole may be a marker of diminished D_2 antagonism and hence reduced risks of extrapyramidal system dysfunction and tardive dyskinesia as well as endocrine dysfunction.

CARDIOVASCULAR EFFECTS

Orthostatic hypotension and high resting heart rates frequently result from use of the low-potency phenothiazines. Mean arterial pressure, peripheral resistance, and stroke volume are decreased, and heart rate is increased. These effects are predictable from the autonomic actions of these agents (Table 29–2). Abnormal ECGs have been recorded, especially with thioridazine. Changes include prolongation of QT interval and abnormal configurations of the ST segment and T waves. These changes are readily reversed by withdrawing the drug.

Among the newest antipsychotics, prolongation of the QT or QT_c interval—with increased risk of dangerous arrhythmias—has been of such concern that the atypical drug sertindole was withdrawn shortly after being marketed. Ziprasidone carries a warning about the risk of significant QT_c prolongation.

ANIMAL SCREENING TESTS

Inhibition of conditioned (but not unconditioned) avoidance behavior is one of the most predictive tests of antipsychotic action. Another is the inhibition of amphetamine- or apomorphine-induced stereotyped behavior. This inhibition is undoubtedly related to the D_2 receptor-blocking action of the drugs, countering these two dopamine agonists. Other tests that may predict antipsychotic action are reduction of exploratory behavior without undue sedation, induction of a cataleptic state, inhibition of intracranial self-stimulation of reward areas, and prevention of apomorphine-induced vomiting. Most of these tests are difficult to relate to any model of clinical psychosis.

The psychosis produced by phencyclidine (PCP) has been used as a model for schizophrenia. Because this drug is an antagonist of the NMDA glutamate receptor, attempts have been made to develop antipsychotics that work as NMDA agonists. Sigma opioid and cholecystokinin type b (CCK_b) antagonism have also been suggested as potential targets. Thus far, NMDA receptor-based models have pointed to agents that modulate glutamate release as potential antipsychotics.

Clinical Pharmacology of Antipsychotic Agents

Indications

PSYCHIATRIC INDICATIONS

Schizophrenia is the primary indication for antipsychotic agents, which remain the mainstay of treatment for this condition. Unfortunately, many patients show little response and virtually none show a complete response.

Antipsychotics are also indicated for schizoaffective disorders, which share characteristics of both schizophrenia and affective disorders. The psychotic aspects of the illness require treatment with antipsychotic drugs, which may be used with other drugs such as antidepressants, lithium, or valproic acid. The manic phase in bipolar affective disorder often requires treatment with antipsychotic agents, though lithium or valproic acid supplemented with high-potency benzodiazepines (eg, lorazepam or clonazepam) may suffice in milder cases. Recent controlled trials support the efficacy of monotherapy with atypical antipsychotics in the acute phase (up to 4 weeks) of mania, and olanzapine has been approved for this indication.

As mania subsides, the antipsychotic drug may be withdrawn, although maintenance treatment with atypical antipsychotics has become more common. Nonmanic excited states may also be managed by antipsychotics, often in combination with benzodiazepines.

Other indications for the use of antipsychotics include Tourette's syndrome, disturbed behavior in patients with Alzheimer's disease, and, with antidepressants, psychotic depression. Antipsychotics are not indicated for the treatment of various withdrawal syndromes, eg, opioid withdrawal. In small doses antipsychotics have been promoted (wrongly) for the relief of anxiety associated with minor emotional disorders. The antianxiety sedatives (see Chapter 22) are preferred in terms of both safety and acceptability to patients.

NONPSYCHIATRIC INDICATIONS

Most older antipsychotic drugs, with the exception of thioridazine, have a strong antiemetic effect. This action is due to dopamine receptor blockade, both centrally (in the chemoreceptor trigger zone of the medulla) and peripherally (on receptors in the stomach). Some drugs, such as prochlorperazine and benzquinamide, are promoted solely as antiemetics.

Phenothiazines with shorter side chains have considerable H_1 -receptor-blocking action and have been used for relief of pruritus or, in the case of promethazine, as preoperative sedatives. The butyrophenone droperidol is used in combination with an opioid, fentanyl, in neuroleptanesthesia. The use of these drugs in anesthesia practice is described in Chapter 25.

Drug Choice

Choice among antipsychotic drugs is based mainly on differences in adverse effects and possible differences in efficacy. Since use of the older drugs is still widespread, especially for patients treated in the public sector, knowledge of such agents as chlorpromazine and haloperidol remains relevant. Thus, one should be familiar with one member of each of the three subfamilies of phenothiazines, a member of the thioxanthine and butyrophenone group, and all of the newer compounds—clozapine, risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole. Each may have special benefits for selected patients. A representative group of antipsychotic drugs is presented in Table 29–3.

Table 29–3. Some Representative Antipsychotic Drugs.

Drug Class

Drug	Advantages	Disadvantages
Phenothiazines		
Aliphatic		
Chlorpromazine[1]	Generic, inexpensive	Many adverse effects, especially autonomic
Piperidine		
Thioridazine[2]	Slight extrapyramidal syndrome; generic	800 mg/d limit; no parenteral form; cardiotoxicity
Piperazine		
Fluphenazine[3]	Depot form also available (enanthate, decanoate)	(?) Increased tardive dyskinesia
Thioxanthene		
Thiothixene	Parenteral form also available; (?) decreased tardive dyskinesia	Uncertain
Butyrophenone		
Haloperidol	Parenteral form also available; generic	Severe extrapyramidal syndrome
Dibenzoxazepine		
Loxapine	(?) No weight gain	Uncertain

Dibenzodiazepine

Clozapine

May benefit treatment-resistant patients; little extrapyramidal toxicity

May cause agranulocytosis in up to 2% of patients; dose-related lowering of seizure threshold

Benzisoxazole

Risperidone

Broad efficacy; little or no extrapyramidal system dysfunction at low doses

Extrapyramidal system dysfunction and hypotension with higher doses

Thienobenzodiazepine

Olanzapine

Effective against negative as well as positive symptoms; little or no extrapyramidal system dysfunction

Weight gain; dose-related lowering of seizure threshold

Dibenzothiazepine

Quetiapine

Similar to olanzapine; perhaps less weight gain

May require high doses if there is associated hypotension; short $t_{1/2}$ and twice-daily dosing

Dihydroindolone

Ziprasidone

Perhaps less weight gain than clozapine, parenteral form available

QT_c prolongation

Dihydrocarbostyril

Aripiprazole

Lower weight gain liability, long half-life, novel mechanism potential

Uncertain, novel toxicities possible

[1] Other aliphatic phenothiazines: promazine, triflupromazine.

[2] Other piperidine phenothiazines: piperacetazine, mesoridazine.

[3] Other piperazine phenothiazines: acetophenazine, perphenazine, carphenazine, prochlorperazine, trifluoperazine.

New antipsychotic drugs have been shown in some trials to be more effective than older ones for treating negative symptoms (emotional blunting, social withdrawal, lack of motivation). The floridly psychotic form of the illness accompanied by uncontrollable behavior probably responds equally well to all potent antipsychotics but is still frequently treated with older drugs that offer intramuscular formulations for acute and chronic treatment. Moreover, the low cost of the older drugs contributes to their widespread use despite their clear disadvantages in terms of extrapyramidal side effects and hyperprolactinemia. Several of the newer antipsychotics, including clozapine, risperidone, and olanzapine, show superiority over haloperidol in terms of overall response in some controlled trials. More comparative studies with aripiprazole are needed to evaluate its relative efficacy. Moreover, the superior side-effect profile of the newer agents and low to absent risk of tardive dyskinesia suggest that these should provide the first line of treatment.

It is not necessary for practitioners to know all the drugs intimately, but they should be familiar with the effects—including the adverse effects—of one or two drugs in each class. The best guide for selecting a drug for an individual patient is the patient's past responses to drugs. Within the older group, the trend has been away from low-potency agents such as chlorpromazine and thioridazine toward the high-potency drugs such as haloperidol. At present, clozapine is limited to those patients who have failed to respond to substantial doses of conventional antipsychotic drugs. The agranulocytosis and seizures associated with this drug prevent more widespread use. Risperidone's superior side-effect profile (compared with haloperidol) at dosages of 6 mg/d or less and the lower risk of tardive dyskinesia have contributed to its widespread use. Olanzapine and quetiapine may have even lower risk and have achieved widespread use. Whether any of the other recently introduced antipsychotic drugs can substitute for clozapine remains to be established.

Dosage

The range of effective dosages among various antipsychotics is quite broad. Therapeutic margins are substantial. Assuming that dosages are appropriate, antipsychotics, with the exception of clozapine and perhaps olanzapine, are of equal efficacy in broadly selected groups of patients. However, some patients who fail to respond to one drug may respond to another; for this reason, several drugs may have to be tried to find the one most effective for an individual patient. This phenomenon might be due to the differing profiles of receptor actions of the various drugs. Patients who have become refractory to two or three antipsychotic agents given in substantial doses now become candidates for treatment with clozapine. This drug, in dosages up to 900 mg/d, salvages about 30–50% of patients previously refractory to 60 mg/d of haloperidol. In such cases, the increased risk of clozapine can well be justified. Risperidone does not appear to substitute for clozapine, although reports are mixed. Whether other antipsychotics will show efficacy similar to that of clozapine remains to be determined.

Some dosage relationships between various antipsychotic drugs, as well as possible therapeutic ranges, are shown in Table 29–4.

Table 29–4. Dose Relationships of Antipsychotics.

	Minimum Effective Therapeutic Dose (mg)	Usual Range of Daily Doses (mg)
Chlorpromazine (Thorazine)	100	100–1000

Thioridazine (Mellaril)

100

100–800

Trifluoperazine (Stelazine)

5

5–60

Perphenazine (Trilafon)

10

8–64

Fluphenazine (Permitil, Prolixin)

2

2–60

Thiothixene (Navane)

2

2–120

Haloperidol (Haldol)

2

2–60

Loxapine (Loxitane)

10

20–160

Molindone (Lidone, Moban)

10

20–200

Clozapine (Clozaril)

50

300–600

Olanzapine (Zyprexa)

5

10–30

Quetiapine (Seroquel)

150

150–800

Risperidone (Risperdal)

4

4–16

Ziprasidone (Zeldox)

40

80–160

Aripiprazole (Abilify)

10

10–30

Parenteral Preparations

Well-tolerated parenteral forms of the high-potency older drugs are available for rapid initiation of treatment as well as for maintenance treatment in noncompliant patients. Since the parenterally administered drugs may have much greater bioavailability than the oral forms, doses should be only a fraction of what might be given orally, and the manufacturer's literature should be consulted. Fluphenazine decanoate and haloperidol decanoate are suitable for long-term parenteral maintenance therapy in patients who cannot or will not take oral medication.

Dosage Schedules

Antipsychotic drugs are often given in divided daily doses, titrating to an effective dosage. After an effective daily dosage has been defined for an individual patient, doses can be given less frequently. Once-daily doses, usually given at night, are feasible for many patients during chronic maintenance treatment. Simplification of dosage schedules leads to better compliance.

Maintenance Treatment

A very small minority of schizophrenic patients may recover from an acute episode and require no further drug therapy for prolonged periods. In most cases, the choice is between "as needed" increased doses or addition of other drugs for exacerbations versus continual maintenance treatment with full therapeutic doses. The choice depends on social factors such as the availability of family or friends familiar with the symptoms of early relapse and ready access to care.

Drug Combinations

Combining antipsychotic drugs confounds evaluation of the efficacy of the drugs being used. Use of combinations, however, is widespread, with more emerging experimental data supporting such practices. Tricyclic antidepressants or, more often, selective serotonin reuptake inhibitors may be used with antipsychotics for clear symptoms of depression complicating schizophrenia. Lithium or valproic acid is sometimes added to antipsychotic agents with benefit to patients who do not respond to the latter drugs alone. It is uncertain whether such instances represent misdiagnosed cases of mania or schizoaffective disorder. Sedative drugs may be added for relief of anxiety or insomnia not controlled by antipsychotics.

Adverse Reactions

Most of the unwanted effects of antipsychotics are extensions of their known pharmacologic actions (Tables 29–1 and 29–2), but a few effects are allergic and some are idiosyncratic.

BEHAVIORAL EFFECTS

The older typical antipsychotic drugs are unpleasant to take. Many patients stop taking these drugs because of the adverse effects, which may be mitigated by giving small doses during the day and the major portion at bedtime. A "pseudodepression" that may be due to drug-induced akinesia usually responds to treatment with antiparkinsonism drugs. Other pseudodepressions may be due to higher doses than needed in a partially remitted patient, in which case decreasing the dose may relieve the symptoms. Toxic-confusional states may occur with very high doses of drugs that have prominent antimuscarinic actions.

NEUROLOGIC EFFECTS

Extrapyramidal reactions occurring early during treatment with older agents include typical Parkinson's syndrome, akathisia (uncontrollable restlessness), and acute dystonic reactions (spastic retrocollis or torticollis). Parkinsonism can be treated, when necessary, with conventional antiparkinsonism drugs of the antimuscarinic type or, in rare cases, with amantadine. (Levodopa should never be used in these patients.) Parkinsonism may be self-limiting, so that an attempt to withdraw antiparkinsonism drugs should be made every 3–4 months. Akathisia and dystonic reactions also respond to such treatment, but many prefer to use a sedative antihistamine with anticholinergic properties, eg, diphenhydramine, which can be given either parenterally or orally.

Tardive dyskinesia, as the name implies, is a late-occurring syndrome of abnormal choreoathetoid movements. It is the most important unwanted effect of antipsychotic drugs. It has been proposed that it is caused by a relative cholinergic deficiency secondary to supersensitivity of dopamine receptors in the caudate-putamen. The prevalence varies enormously, but tardive dyskinesia is estimated to have occurred in 20–40% of chronically treated patients prior to the introduction of the newer atypical antipsycotics. Early recognition is important, since advanced cases may be difficult to reverse. Many treatments have been proposed, but their evaluation is confounded by the fact that the course of the disorder is variable and sometimes self-limited. Most authorities agree that the first step would be to try to discontinue or reduce the dose of the current antipsychotic or switch to one of the newer atypical agents. A logical second step would be to eliminate all drugs with central anticholinergic action, particularly antiparkinsonism drugs and tricyclic antidepressants. These two steps are often enough to bring about improvement. If they fail, the addition of diazepam in doses as high as 30–40 mg/d may add to the improvement by enhancing GABAergic activity.

Seizures, though recognized as a complication of chlorpromazine treatment, were so rare with the high-potency older drugs as to merit little consideration. However, de novo seizures may occur in 2–5% of patients treated with clozapine.

AUTONOMIC NERVOUS SYSTEM EFFECTS

Most patients are able to tolerate the antimuscarinic adverse effects of antipsychotic drugs. Those who are made too uncomfortable or who develop urinary retention or other severe symptoms can be switched to an agent without significant antimuscarinic action. Orthostatic hypotension or impaired ejaculation—common complications of therapy with chlorpromazine or mesoridazine—should be managed by switching to drugs with less marked adrenoceptor-blocking actions.

METABOLIC AND ENDOCRINE EFFECTS

Weight gain is very common, especially with clozapine and olanzapine, and requires monitoring of food intake, especially carbohydrates. Hyperglycemia may develop, but whether secondary to weight gain-associated insulin resistance or due to other potential mechanisms remains to be clarified. Hyperprolactinemia in women results in the amenorrhea-galactorrhea syndrome and infertility; in men, loss of libido, impotence, and infertility may result.

TOXIC OR ALLERGIC REACTIONS

Agranulocytosis, cholestatic jaundice, and skin eruptions occur rarely with the high-potency antipsychotic drugs currently used.

In contrast to other antipsychotic agents, clozapine causes agranulocytosis in a small but significant number of patients—approximately 1–2% of those treated. This serious, potentially fatal effect can develop rapidly, usually between the 6th and 18th weeks of therapy. It is not known whether it represents an immune reaction, but it appears to be reversible upon discontinuance of the drug. *Because of the risk of agranulocytosis, patients receiving clozapine must have weekly blood counts for the first 6 months of treatment and every 3 weeks thereafter.*

OCULAR COMPLICATIONS

Deposits in the anterior portions of the eye (cornea and lens) are a common complication of chlorpromazine therapy. They may accentuate the normal processes of aging of the lens. Thioridazine is the only antipsychotic drug that causes retinal deposits, which in advanced cases may resemble retinitis pigmentosa. The deposits are usually associated with "browning" of vision. The maximum daily dose of thioridazine has been limited to 800 mg/d to reduce the possibility of this complication.

CARDIAC TOXICITY

Thioridazine in doses exceeding 300 mg daily is almost always associated with minor abnormalities of T waves that are easily reversible. Overdoses of thioridazine are associated with major ventricular arrhythmias, cardiac conduction block, and sudden death; it is not certain whether thioridazine can cause these same disorders when used in therapeutic doses. In view of possible additive antimuscarinic and quinidine-like actions with various tricyclic antidepressants, thioridazine should be combined with the latter drugs only with great care. Among the atypical agents, ziprasidone carries the greatest risk of QT prolongation and therefore should not be combined with other drugs that prolong the QT interval, including thioridazine, pimozide, and quinidine.

USE IN PREGNANCY; DYSMORPHOGENESIS

Although the antipsychotic drugs appear to be relatively safe in pregnancy, a small increase in teratogenic risk could be missed. Questions about whether to use these drugs during pregnancy and whether to abort a pregnancy in which the fetus has already been exposed must be decided individually.

NEUROLEPTIC MALIGNANT SYNDROME

This life-threatening disorder occurs in patients who are extremely sensitive to the extrapyramidal effects of antipsychotic agents (see also Chapter 16). The initial symptom is marked muscle rigidity. If sweating is impaired, as it often is during treatment with anticholinergic drugs, fever may ensue, often reaching dangerous levels. The stress leukocytosis and high fever associated with this syndrome may erroneously suggest an infectious process. Autonomic instability, with altered blood pressure and pulse rate, is often present. Creatine kinase isozymes are usually elevated, reflecting muscle damage. This syndrome is believed to result from an excessively rapid blockade of postsynaptic dopamine receptors. A severe form of extrapyramidal syndrome follows. Early in the course, vigorous treatment of the extrapyramidal syndrome with antiparkinsonism drugs is worthwhile. Muscle relaxants, particularly diazepam, are often useful. Other muscle relaxants, such as dantrolene, or dopamine agonists, such as bromocriptine, have been reported to be helpful. If fever is present, cooling by physical measures should be tried. Various minor forms of this syndrome are now recognized.

Drug Interactions

Antipsychotics produce more important pharmacodynamic than pharmacokinetic interactions because of their multiple effects. Additive effects may occur when these drugs are combined with others that have sedative effects, α-adrenoceptor-blocking action, anticholinergic effects, and—for thioridazine and ziprasidone—quinidine-like action.

A variety of pharmacokinetic interactions have been reported, but none are of major clinical significance.

Overdoses

Poisonings with antipsychotics (unlike tricyclic antidepressants) are rarely fatal, with the exception of those due to mesoridazine and thioridazine. In general, drowsiness proceeds to coma, with an intervening period of agitation. Neuromuscular excitability may be increased and proceed to convulsions. Pupils are miotic, and deep tendon reflexes are decreased. Hypotension and hypothermia are the rule, though fever may be present later in the course. The lethal effects of mesoridazine and thioridazine are related to induction of ventricular tachyarrhythmias. Patients should be given the usual "ABCD" treatment for poisonings (see Chapter 59) and treated supportively. Management of overdoses of thioridazine and mesoridazine, which are complicated by cardiac arrhythmias, is similar to that for tricyclic antidepressants (see Chapter 30).

Benefits & Limitations of Drug Treatment

As noted at the beginning of this chapter, antipsychotics have had a major impact on psychiatric treatment. First, they have shifted the care of patients from mental institutions to the community. For many patients, this shift has provided a better life under more humane circumstances and in many cases has made possible life without frequent use of physical restraints. For others, the tragedy of an aimless existence is now being played out in the streets of our communities rather than in mental institutions.

Second, these drugs have markedly shifted psychiatric thinking to a more biologic orientation. Partly because of research stimulated by the effects of these drugs on schizophrenia, we now know much more about central nervous system physiology and pharmacology than we did before the introduction of these agents. However, despite a great amount of research, schizophrenia remains a scientific mystery and a personal disaster for the patient. Although most schizophrenic patients obtain some degree of benefit from these drugs—in some cases substantial benefit—none are made well by them.

*Chapter author Leo E. Hollister, MD, is deceased.

LITHIUM & OTHER MOOD-STABILIZING DRUGS

Lithium carbonate is often referred to as an "antimanic" drug, but in many parts of the world it is considered a "mood-stabilizing" agent because of its primary action of preventing mood swings in patients with bipolar affective (manic-depressive) disorder. Carbamazepine has also been recognized as effective in some groups of manic-depressive patients despite not being formally approved for such use. Valproate has recently been approved for the treatment of mania and is being evaluated as a mood stabilizer. Atypical antipsychotics, beginning with olanzapine, are being investigated and approved as antimanic agents and potential mood stabilizers.

Nature of Bipolar Affective Disorder

Bipolar affective (manic-depressive) disorder is a frequently diagnosed and very serious psychiatric disorder. Patients with cyclic attacks of mania have many symptoms of paranoid schizophrenia (grandiosity, bellicosity, paranoid thoughts, and overactivity). The ability to treat bipolar disorder effectively has made such diagnostic distinctions important.

The cause of the mood swings characteristic of bipolar affective disorder is unknown, although a preponderance of catecholamine-related activity may be present. Drugs that increase this activity tend to exacerbate mania, whereas those that reduce activity of dopamine or norepinephrine relieve mania. Acetylcholine or glutamate may also be involved. The nature of the abrupt switch from mania to depression experienced by some patients is uncertain. Bipolar disorder has a strong familial component. Genetic studies have identified at least three possible linkages to different chromosomes.

Basic Pharmacology of Lithium

Pharmacokinetics

Lithium is a small monovalent cation. Its pharmacokinetics are summarized in Table 29–5.

Table 29–5. Pharmacokinetics of Lithium.

Absorption	Virtually complete within 6–8 hours; peak plasma levels in 30 minutes to 2 hours
Distribution	In total body water; slow entry into intracellular compartment. Initial volume of distribution is 0.5 L/kg, rising to 0.7–0.9 L/kg; some sequestration in bone. No protein binding.
Metabolism	None
Excretion	Virtually entirely in urine. Lithium clearance about 20% of creatinine. Plasma half-life about 20 hours.
Target plasma concentration	0.6–1.4 mEq/L
Dosage	0.5 mEq/kg/d in divided doses

Pharmacodynamics

Despite considerable investigation, the mode of action of lithium remains unclear. The major possibilities being investigated include (1) effects on electrolytes and ion transport; (2) effects on neurotransmitters and their release; and (3) effects on second messengers and intracellular enzymes that mediate transmitter action. The last of these three approaches appears to be the most promising.

EFFECTS ON ELECTROLYTES AND ION TRANSPORT

Lithium is closely related to sodium in its properties. It can substitute for sodium in generating action potentials and in Na^+ -Na^+ exchange across the membrane. It inhibits the latter process, ie, Li^+ -Na^+ exchange is gradually slowed after lithium is introduced into the body. At therapeutic concentrations (around 1 mmol/L), it does not significantly affect the Na^+ /Ca^{2+} exchange process or the Na^+ /K^+ ATPase sodium pump.

EFFECTS ON NEUROTRANSMITTERS

Lithium appears to enhance some of the actions of serotonin, though findings have been contradictory. Its effects on norepinephrine are variable. The drug may decrease norepinephrine and dopamine turnover, and these effects, if confirmed, might be relevant to its antimanic action. Lithium also appears to block the development of dopamine receptor supersensitivity that may accompany chronic therapy with antipsychotic agents. Finally, lithium may augment the synthesis of acetylcholine, perhaps by increasing choline uptake into nerve terminals.

EFFECTS ON SECOND MESSENGERS

Some of the enzymes affected by lithium are listed in Table 29–6. One of the best-defined effects of lithium is its action on inositol phosphates. Early studies of lithium demonstrated changes in brain inositol phosphate levels, but the significance of these changes was not appreciated until the second-messenger roles of inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) were discovered. As described in Chapter 2, IP_3 and DAG are important second messengers for both α-adrenergic and muscarinic transmission. Lithium inhibits several important enzymes in the normal recycling of membrane phosphoinositides, including conversion of IP_2 to IP_1 (inositol monophosphate) and the conversion of IP_1 to inositol (Figure 29–4). This block leads to a depletion of phosphatidylinositol-4,5-bisphosphate (PIP_2), the membrane precursor of IP_3 and DAG. Over time, the effects of transmitters on the cell diminish in proportion to the amount of activity in the PIP_2 -dependent pathways. Before therapy, such activity might be greatly increased in mania; thus, lithium could cause a selective depression of the overactive circuits.

Table 29–6. Enzymes Affected by Lithium at Therapeutic Concentrations.

Enzyme	Enzyme Function; Action of Lithium
Inositol monophosphatase	The rate-limiting enzyme in inositol recycling; inhibited by lithium, resulting in depletion of substrate for IP_3 production (see Figure 29–4)
Inositol polyphosphate 1-phosphatase	Another enzyme in inositol recycling; inhibited by lithium, resulting in depletion of substrate for IP_3 production (see Figure 29–4)
Bisphosphate nucleotidase	

Involved in AMP production; inhibited by lithium; may be target that results in lithium-induced nephrogenic diabetes insipidus

Fructose 1,6-biphosphatase

Involved in gluconeogenesis; inhibition by lithium of unknown relevance

Phosphoglucomutase

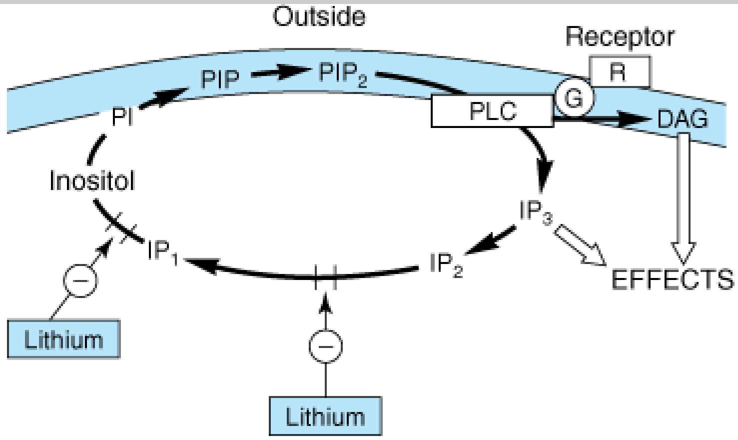
Involved in glycogenolysis; inhibition by lithium of unknown relevance

Glycogen synthase kinase-3

Constitutively active enzyme that appears to limit neurotrophic and neuroprotective processes; lithium inhibits

AMP, adenosine monophosphate; IP_3 , inositol 1,4,5-trisphosphate

Figure 29–4.



Effect of lithium on the IP_3 and DAG second-messenger system. The schematic diagram shows the synaptic membrane of a neuron. (PIP_2 , phosphatidylinositol-4,5-bisphosphate; PLC, phospholipase-C; G, coupling protein; EFFECTS, activation of protein kinase C, mobilization of intracellular Ca^{2+} , etc.) Lithium, by inhibiting the recycling of inositol substrates, may cause depletion of the second-messenger source PIP_2 and therefore reduce the release of IP_3 and DAG. Lithium may also act by other mechanisms.

Studies of noradrenergic effects in isolated brain tissue indicate that lithium can inhibit norepinephrine-sensitive adenylyl cyclase. Such an effect could relate to both its antidepressant and its antimanic effects. The relationship of these effects to lithium's actions on IP_3 mechanisms is currently unknown.

Because lithium affects second-messenger systems involving both activation of adenylyl cyclase and phosphoinositol turnover, it is not surprising that G proteins are also found to be affected. Several studies suggest that lithium may uncouple receptors from their G proteins; indeed, two of lithium's most common side effects, polyuria and subclinical hypothyroidism, may be due to uncoupling of the vasopressin and thyroid-stimulating hormone (TSH) receptors from their G proteins.

The major current working hypothesis for lithium's therapeutic mechanism of action supposes that its effects on phosphoinositol turnover, leading to an early relative reduction of myoinositol in human brain, are part of an initiating cascade of intracellular changes. Effects on specific isoforms of protein kinase C may be most relevant. Alterations of protein kinase C-mediated signaling alter gene expression and the production of proteins implicated in long-term neuroplastic events that could underlie long-term mood stabilization.

Clinical Pharmacology of Lithium

Bipolar Affective Disorder

Until recently, lithium carbonate was the universally preferred treatment for bipolar disorder, especially in the manic phase. With the approval of valproate, olanzapine, and other newer antipsychotics for this indication, a smaller percentage of bipolar patients now receive lithium. This trend is reinforced by the slow onset of action of lithium, which has often been supplemented with concurrent use of antipsychotic drugs or potent benzodiazepines in severely manic patients. The overall success rate for achieving remission from the manic phase of bipolar disorder can be as high as 80%. However, among patients who require hospitalization, success rates are considerably lower. A similar situation applies to maintenance treatment, which is about 60% effective overall but less in severely ill patients. These considerations have led to increased use of combined treatment in severe cases. After mania is controlled, the antipsychotic drug may be stopped, then the benzodiazepine and lithium continued as maintenance therapy.

The depressive phase of manic-depressive disorder often requires concurrent use of an antidepressant drug (see Chapter 30). Tricyclic antidepressant agents have been linked to precipitation of mania, with more rapid cycling of mood swings, although most patients do not show this effect. Selective serotonin reuptake inhibitors are less likely to induce mania but may have limited efficacy. Bupropion has shown some promising effects but—like tricyclic antidepressants—may induce mania at higher doses. As shown in recent controlled trials, the anticonvulsant lamotrigine is effective for many patients with bipolar depression. For some patients, however, one of the older monoamine oxidase inhibitors may be the antidepressant of choice.

Unlike antipsychotic or antidepressant drugs, which exert several actions on the central or autonomic nervous system, lithium ion at therapeutic concentrations is devoid of autonomic blocking effects and of activating or sedating effects, though it can produce nausea and tremor. Most important is that the prophylactic use of lithium can prevent both mania and depression. Many experts believe that the aggressive marketing of newer drugs has inappropriately produced a shift to drugs that are less effective than lithium for substantial numbers of patients.

Other Applications

Recurrent endogenous depression with a cyclic pattern is controlled by either lithium or imipramine, both of which are superior to a placebo.

Schizoaffective disorder, another condition with an affective component characterized by a mixture of schizophrenic symptoms and depression or excitement, is treated with antipsychotic drugs alone or combined with lithium. Various antidepressants are added if depression is present.

Lithium alone is rarely successful in treating schizophrenia, but adding it to an antipsychotic may salvage an otherwise treatment-resistant patient. Carbamazepine may work equally well when added to an antipsychotic.

An interesting application of lithium that is relatively well supported by controlled studies is as an adjunct to tricyclic antidepressants and selective serotonin reuptake inhibitors in patients with unipolar depression who do not respond fully to monotherapy with the antidepressant. For this application, concentrations of lithium at the lower end of the recommended range for manic depressive illness appear to be adequate.

Monitoring Treatment

Clinicians rely on measurements of serum lithium concentrations for assessing both the dosage required for treatment of acute mania and for prophylactic maintenance. These measurements are customarily taken 10–12 hours after the last dose, so all data in the literature pertaining to these concentrations reflect this interval.

An initial determination of serum lithium concentration should be obtained about 5 days after the start of treatment, at which time steady-state conditions should have been attained. If the clinical response suggests a change in dosage, simple arithmetic (new dose equals present dose times desired blood level divided by present blood level) should produce the desired level. The serum concentration attained with the adjusted dosage can be checked in another 5 days. Once the desired concentration has been achieved, levels can be measured at increasing intervals unless the schedule is influenced by intercurrent illness or the introduction of a new drug into the treatment program.

Maintenance Treatment

The decision to use lithium as *prophylactic* treatment depends on many factors: the frequency and severity of previous episodes, a crescendo pattern of appearance, and the degree to which the patient is willing to follow a program of indefinite maintenance therapy. If the present attack was the patient's first or if the patient is unreliable, one might prefer to terminate treatment after the episode has subsided. Patients who have one or more episodes of illness per year are candidates for maintenance treatment. Although some patients can be maintained with serum levels as low as 0.6 mEq/L, the best results have been obtained with higher levels, such as 0.9 mEq/L.

Drug Interactions

Renal clearance of lithium is reduced about 25% by diuretics (eg, thiazides), and doses may need to be reduced by a similar amount. A similar reduction in lithium clearance has been noted with several of the newer nonsteroidal anti-inflammatory drugs that block synthesis of prostaglandins. This interaction has not been reported for either aspirin or acetaminophen. All neuroleptics tested to date, with the possible exception of clozapine and the newer antipsychotics, may produce more severe extrapyramidal syndromes when combined with lithium.

Adverse Effects & Complications

Many adverse effects associated with lithium treatment occur at varying times after treatment is started. Some are harmless, but it is important to be alert to adverse effects that may signify impending serious toxic reactions.

NEUROLOGIC AND PSYCHIATRIC ADVERSE EFFECTS

Tremor is one of the most common adverse effects of lithium treatment, and it occurs with therapeutic doses. Propranolol and atenolol, which have been reported to be effective in essential tremor, also alleviate lithium-induced tremor. Other reported neurologic abnormalities include choreoathetosis, motor hyperactivity, ataxia, dysarthria, and aphasia. Psychiatric disturbances at toxic concentrations are generally marked by mental confusion and withdrawal. Appearance of any new neurologic or psychiatric symptoms or signs is a clear indication for temporarily stopping treatment with lithium and close monitoring of serum levels.

DECREASED THYROID FUNCTION

Lithium probably decreases thyroid function in most patients exposed to the drug, but the effect is reversible or nonprogressive. Few patients develop frank thyroid enlargement, and fewer still show symptoms of hypothyroidism. Although initial thyroid testing followed by regular monitoring of thyroid function has been proposed, such procedures are not cost-effective. Obtaining a serum TSH concentration every 6–12 months, however, is prudent.

NEPHROGENIC DIABETES INSIPIDUS AND OTHER RENAL ADVERSE EFFECTS

Polydipsia and polyuria are common but reversible concomitants of lithium treatment, occurring at therapeutic serum concentrations. The principal physiologic lesion involved is loss of responsiveness to antidiuretic hormone (nephrogenic diabetes insipidus). Lithium-induced diabetes insipidus is resistant to vasopressin but responds to amiloride.

An extensive literature has accumulated concerning other forms of renal dysfunction during long-term lithium therapy, including chronic interstitial nephritis and minimal-change glomerulopathy with nephrotic syndrome. Some instances of decreased glomerular filtration rate have been encountered but no instances of marked azotemia or renal failure.

Patients receiving lithium should avoid dehydration and the associated increased concentration of lithium in urine. Periodic tests of renal concentrating ability should be performed to detect changes.

EDEMA

Edema is a common adverse effect of lithium treatment and may be related to some effect of lithium on sodium retention. Although weight gain may be expected in patients who become edematous, water retention does not account for the weight gain observed in up to 30% of patients taking lithium.

CARDIAC ADVERSE EFFECTS

The bradycardia-tachycardia ("sick sinus") syndrome is a definite contraindication to the use of lithium because the ion further depresses the sinus node. T-wave flattening is often observed on ECG but is of questionable significance.

USE DURING PREGNANCY

Renal clearance of lithium increases during pregnancy and reverts to lower levels immediately after delivery. A patient whose serum lithium concentration is in a good therapeutic range during pregnancy may develop toxic levels following delivery. Special care in monitoring lithium levels is needed at these times. Lithium is transferred to nursing infants through breast milk, in which it has a concentration about one-third to one-half that of serum. Lithium toxicity in newborns is manifested by lethargy, cyanosis, poor suck and Moro reflexes, and perhaps hepatomegaly.

The issue of dysmorphogenesis is not settled. An earlier report suggested an increase in the frequency of cardiac anomalies, especially Ebstein's anomaly, in lithium babies, and it is listed as such in Table 60–1 in this book. However, more recent data suggest that lithium carries a relatively low risk of teratogenic effects. Further research is needed in this important area.

MISCELLANEOUS ADVERSE EFFECTS

Transient acneiform eruptions have been noted early in lithium treatment. Some of them subside with temporary discontinuance of treatment and do not recur with its resumption. Folliculitis is less dramatic and probably occurs more frequently. Leukocytosis is always present during lithium treatment, probably reflecting a direct effect on leukopoiesis rather than mobilization from the marginal pool. This adverse effect has now become a therapeutic effect in patients with low leukocyte counts.

Overdoses

Therapeutic overdoses of lithium are more common than those due to deliberate or accidental ingestion of the drug. Therapeutic overdoses are usually due to accumulation of lithium resulting from some change in the patient's status, such as diminished serum sodium, use of diuretics, or fluctuating renal function. Since the tissues will have already equilibrated with the blood, the plasma concentrations of lithium may not be excessively high in proportion to the degree of toxicity; any value over 2 mEq/L must be considered as indicating likely toxicity. Because lithium is a small ion, it is dialyzed readily. Both peritoneal dialysis and hemodialysis are effective, though the latter is preferred. Dialysis should be continued until the plasma concentration falls below the usual therapeutic range.

Valproic Acid

Valproic acid (valproate), discussed in detail in Chapter 24 as an antiepileptic, has been demonstrated to have antimanic effects and is now being widely used for this indication in the USA. Gabapentin is not effective, leaving the mechanism of action of valproate unclear. Overall, it shows efficacy equivalent to that of lithium during the early weeks of treatment. It is significant that valproic acid has been effective in some patients who have failed to respond to lithium. Moreover, its side-effect profile is such that one can rapidly increase the dosage over a few days to produce blood levels in the apparent therapeutic range, with nausea being the only limiting factor in some patients. The starting dosage is 750 mg/d, increasing rapidly to the 1500–2000 mg range with a recommended maximum dosage of 60 mg/kg/d.

Combinations of valproic acid with other psychotropic medications likely to be used in the management of either phase of bipolar illness are generally well tolerated. Valproic acid is becoming recognized as an appropriate first-line treatment for mania, although it is not clear that it will be as effective as lithium as a maintenance treatment in all subsets of patients. Many clinicians argue for combining valproic acid and lithium in patients who do not fully respond to either agent alone.

Carbamazepine

Carbamazepine has been considered to be a reasonable alternative to lithium when the latter is less than optimally efficacious. The mode of action of carbamazepine is unclear, and oxcarbazepine is not effective. Carbamazepine may be used to treat acute mania and also for prophylactic therapy. Adverse effects (discussed in Chapter 24) are generally no greater and sometimes less than those associated with lithium. Carbamazepine may be used alone or, in refractory patients, in combination with lithium or, rarely, valproate.

The use of carbamazepine as a mood stabilizer is similar to its use as an anticonvulsant (see Chapter 24). Dosage usually begins with 200 mg twice daily, with increases as needed. Maintenance dosage is similar to that used for treating epilepsy, ie, 800–1200 mg/d. Plasma concentrations between 3 and 14 mg/L are considered desirable, although no therapeutic range has been established. Blood dyscrasias have figured prominently in the adverse effects of carbamazepine when it is used as an anticonvulsant, but they have not been a major problem with its use as a mood stabilizer. Overdoses of carbamazepine are a major emergency and should generally be managed like overdoses of tricyclic antidepressants.

Other Drugs

Lamotrigine has been reported to be useful in preventing the depression that often follows the manic phase of bipolar disorder.

PREPARATIONS AVAILABLE

ANTIPSYCHOTIC AGENTS

Aripiprazole (Abilify)

Oral: 5, 10, 15, 20, 30 mg tablets; 1 mg/mL solution

Chlorpromazine (generic, Thorazine)

Oral: 10, 25, 50, 100, 200 mg tablets; 100 mg/mL concentrate

Rectal: 100 mg suppositories

Parenteral: 25 mg/mL for IM injection

Clozapine (generic, Clozaril)

Oral: 12.5, 25, 100 mg tablets; 25, 100 mg orally disintegrating tablets

Fluphenazine (generic, Prolixin)

Oral: 1, 2.5, 5, 10 mg tablets; 2.5 mg/5 mL elixir

Parenteral: (fluphenazine HCl): 2.5 mg/mL for IM injection

Fluphenazine decanoate (generic, Prolixin)

Parenteral: 25 mg/mL for IM or SC injection

Haloperidol (generic, Haldol)

Oral: 0.5, 1, 2, 5, 10, 20 mg tablets; 2 mg/mL concentrate

Parenteral: 5 mg/mL for IM injection

Haloperidol ester (Haldol Decanoate)

Parenteral: 50, 100 mg/mL for IM injection

Loxapine (generic, Loxitane)

Oral: 5, 10, 25, 50 mg capsules

Molindone (Moban)

Oral: 5, 10, 25, 50 mg tablets

Olanzapine (Zyprexa)

Oral: 2.5, 5, 7.5, 10, 15, 20 mg tablets; 5, 10, 15, 20 mg orally disintegrating tablets

Parenteral: 10 mg powder for injection

Perphenazine (generic)

Oral: 2, 4, 8, 16 mg tablets; 16 mg/5 mL concentrate

Pimozide (Orap)

Oral: 1, 2 mg tablets

Prochlorperazine (generic, Compazine)

Oral: 5, 10 mg tablets; 5 mg/5 mL syrup

Oral sustained-release: 10, 15 mg capsules

Rectal: 2.5, 5, 25 mg suppositories

Parenteral: 5 mg/mL for IM injection

Quetiapine (Seroquel)

Oral: 25, 100, 200, 300 mg tablets

Risperidone (Risperdal)

Oral: 0.25, 0.5, 1, 2, 3, 4 mg tablets; 0.5, 1, 2 mg orally disintegrating tablets; 1 mg/mL oral solution

Parenteral: 25, 37.5, 50 mg powder for injection

Thioridazine (generic, Mellaril)

Oral: 10, 15, 25, 50, 100, 150, 200 mg tablets; 30 mg/mL concentrate

Thiothixene (generic, Navane)

Oral: 1, 2, 5, 10, 20 mg capsules

Trifluoperazine (generic)

Oral: 1, 2, 5, 10 mg tablets

Ziprasidone (Geodon)

Oral: 20, 40, 60, 80 mg capsules

Parenteral: 20 mg powder for IM injection

MOOD STABILIZERS

Carbamazepine (generic, Tegretol)

Oral: 200, 300, 400 mg tablets, 100 mg chewable tablets; 100 mg/5 mL oral suspension

Oral extended-release: 100, 200, 400 mg tablets; 200, 300 mg capsules

Divalproex (Depakote)

Oral: 125, 250, 500 mg delayed-release tablets

Lithium carbonate (generic, Eskalith) (*Note:* 300 mg lithium carbonate = 8.12 mEq Li^+ .)

Oral: 150, 300, 600 mg capsules; 300 mg tablets; 8 mEq/5 mL syrup

Oral sustained-release: 300, 450 mg tablets

Valproic acid (generic, Depakene)

Oral: 250 mg capsules; 250 mg/5 mL syrup

Top of Form

ANTIDEPRESSANT AGENTS: INTRODUCTION

Major depression is one of the most common psychiatric disorders. At any given moment, about 3–5% of the population is depressed (point prevalence), and an estimated 10% of people may become depressed during their lives (lifetime prevalence). The symptoms of depression are often subtle and unrecognized both by patients and by physicians. Patients with vague complaints that resist explanation as manifestations of somatic disorders and those who might be simplistically described as "neurotic" should be suspected of being depressed.

Depression is a heterogeneous disorder that has been characterized and classified in a variety of ways. According to the American Psychiatric Association's modified fourth edition (2000) of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR),* several diagnoses of affective disorders are possible. Major depression and dysthymia (minor) are pure depressive syndromes, whereas bipolar disorder and cyclothymic disorder signify depression in association with mania. A simplified classification based on presumed origin is as follows: (1) brief reactive or secondary depression (most common), occurring in response to real stimuli such as grief, illness, etc; (2) melancholic and recurrent depression, a genetically determined biochemical disorder manifested by an inability to experience ordinary pleasure or to cope with ordinary life events; and (3) depression associated with bipolar affective (manic-depressive) disorder. Because safe antidepressants are now available, almost any individual with several symptoms of depression that persist beyond a few weeks is a candidate for pharmacologic treatment. Intensive efforts to formalize guidelines for the treatment of depression have been pursued for more than a decade, resulting in guidelines from the American Psychiatric Association, the Agency for Health Care Policy and Research, and the World Federation of Societies of Biological Psychiatry. Pharmacologic treatment is emphasized, although a continuing role for electroconvulsive therapy for delusional or severe forms of life-threatening depression is also noted.

The Pathogenesis of Major Depression: The Amine Hypothesis and Subsequent Developments

Soon after the introduction of reserpine in the early 1950s, it became apparent that the drug could induce depression. Studies revealed that the principal mechanism of action of reserpine was to inhibit the neuronal storage of amine neurotransmitters such as serotonin and norepinephrine. Reserpine induced depression and depleted stores of amine neurotransmitters; therefore, it was reasoned, depression must be associated with decreased functional amine-dependent synaptic transmission. This idea provided the basis for what became known as the amine hypothesis of depression. By extension, drugs that increased amine function in appropriate synaptic areas would relieve depression. A major puzzle in applying this hypothesis was the fact that although the pharmacologic actions of both tricyclic and monoamine oxidase (MAO) inhibitor classes of antidepressants are prompt, the clinical effects require weeks to become manifest. Attempts have been made to explain this observation by invoking slow compensatory responses to the initial blockade of amine reuptake or MAO inhibition (see below).

Current brain imaging and biochemical studies in patients do not support a single biologic abnormality as common to most depressions. Rather, prevailing hypotheses emphasize an underlying role for several brain circuits that have a propensity to become dysfunctional, especially following certain stressors, in individuals with a range of genetic predispositions. It is likely that several pathophysiologic processes will ultimately be identified to account for the presentation of what is now termed *major depression* .

Nevertheless, the amine hypothesis has provided the major experimental models for the discovery of new antidepressant drugs. As a result, all currently available antidepressants, except bupropion, are classified as having their primary actions on the metabolism, reuptake, or selective receptor antagonism of serotonin, norepinephrine, or both.

*Chapter author Leo E. Hollister, MD, is deceased.

BASIC PHARMACOLOGY OF ANTIDEPRESSANTS

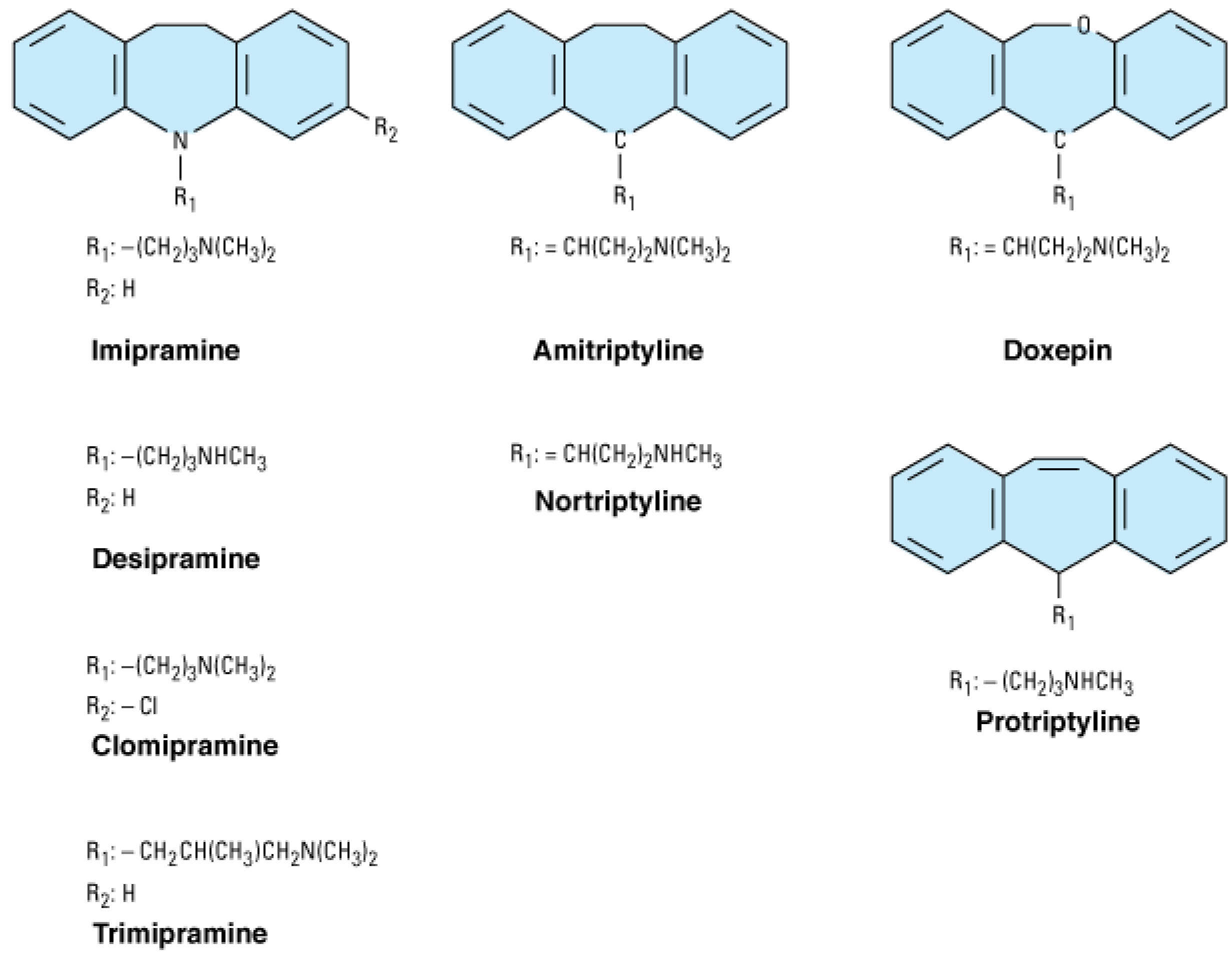
Chemistry

A variety of chemical structures have been found to have antidepressant activity. With the exception of bupropion, however, the core antidepressant action of even the newest agents derives from mechanisms proposed for antidepressants that were introduced four decades ago.

TRICYCLIC ANTIDEPRESSANTS (TCAS)

Tricyclic antidepressants—so called because of the characteristic three-ring nucleus (Figure 30–1)—have been used clinically for four decades. They closely resemble the phenothiazines chemically and, to a lesser extent, pharmacologically. Like the phenothiazines, tricyclics were first thought to be useful as antihistamines with sedative properties. The discovery of their antidepressant properties was a fortuitous clinical observation. Imipramine and amitriptyline are the prototypical drugs of the class as mixed norepinephrine and serotonin uptake inhibitors, although they also have several other effects.

Figure 30–1.

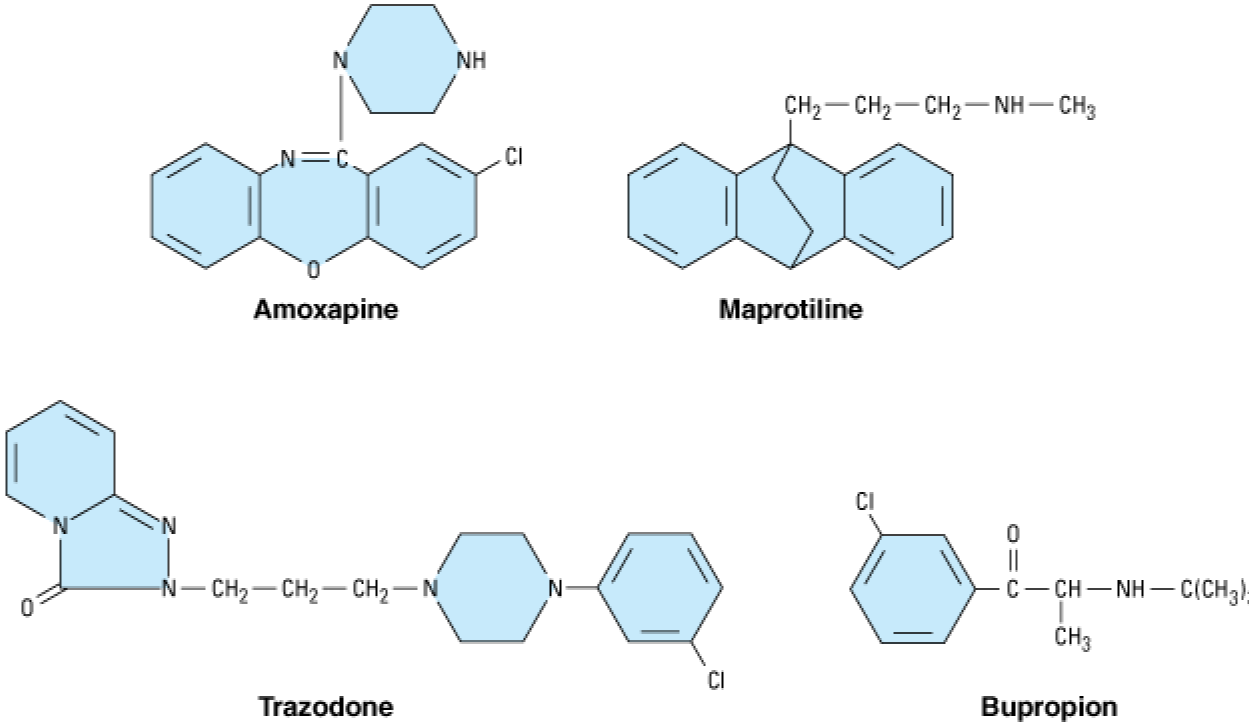


Structural relationships between various tricyclic antidepressants (TCAs).

SECOND-GENERATION AND SUBSEQUENT AGENTS

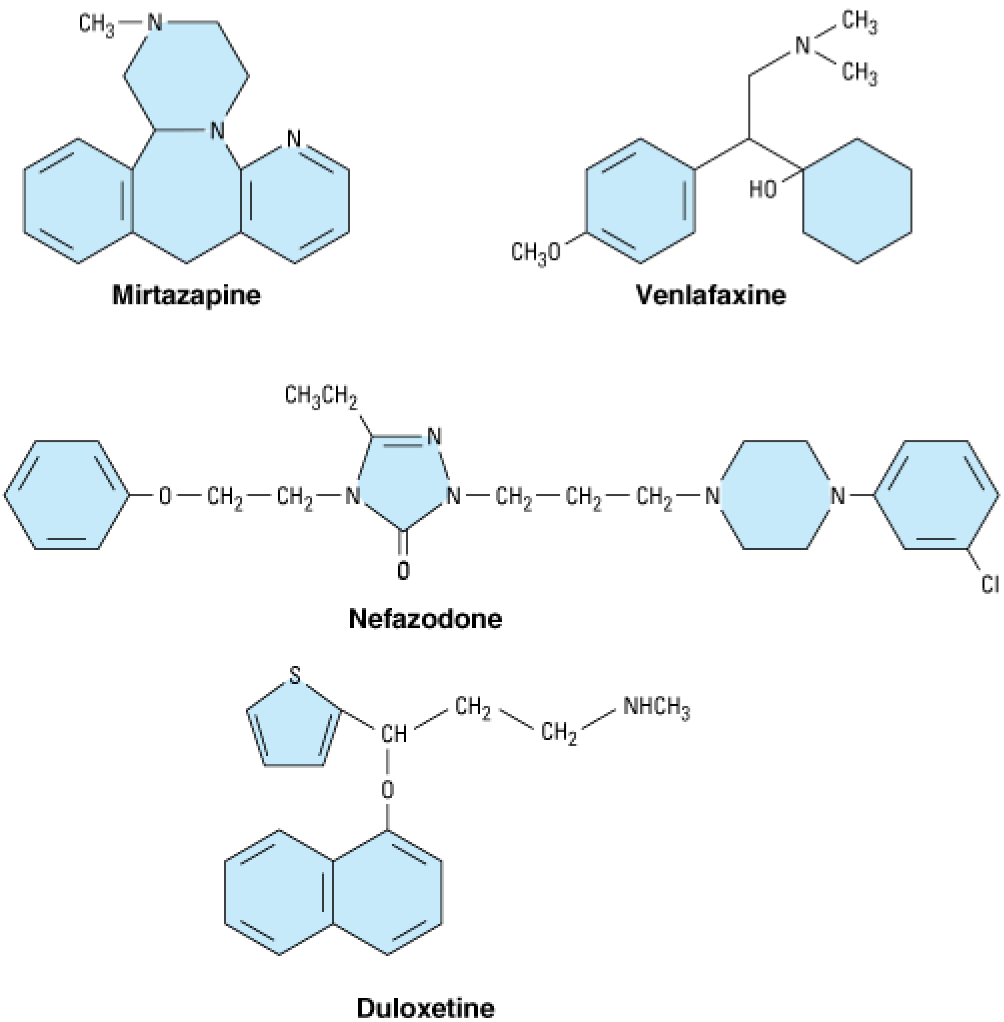
Between 1980 and 2005, thirteen structurally unique antidepressants and one isomeric variation were introduced. The agents classified as second generation and available for clinical use in the USA are shown in Figure 30–2. Amoxapine and maprotiline resemble the structure of the tricyclic agents, whereas trazodone and bupropion are distinctive. Newer, third generation drugs include venlafaxine, mirtazapine, nefazodone, and duloxetine. The structures of these compounds are shown in Figure 30–3. Six additional agents that work mainly through serotonin uptake inhibition are classified together in the following section.

Figure 30–2.



Second-generation antidepressants.

Figure 30–3.

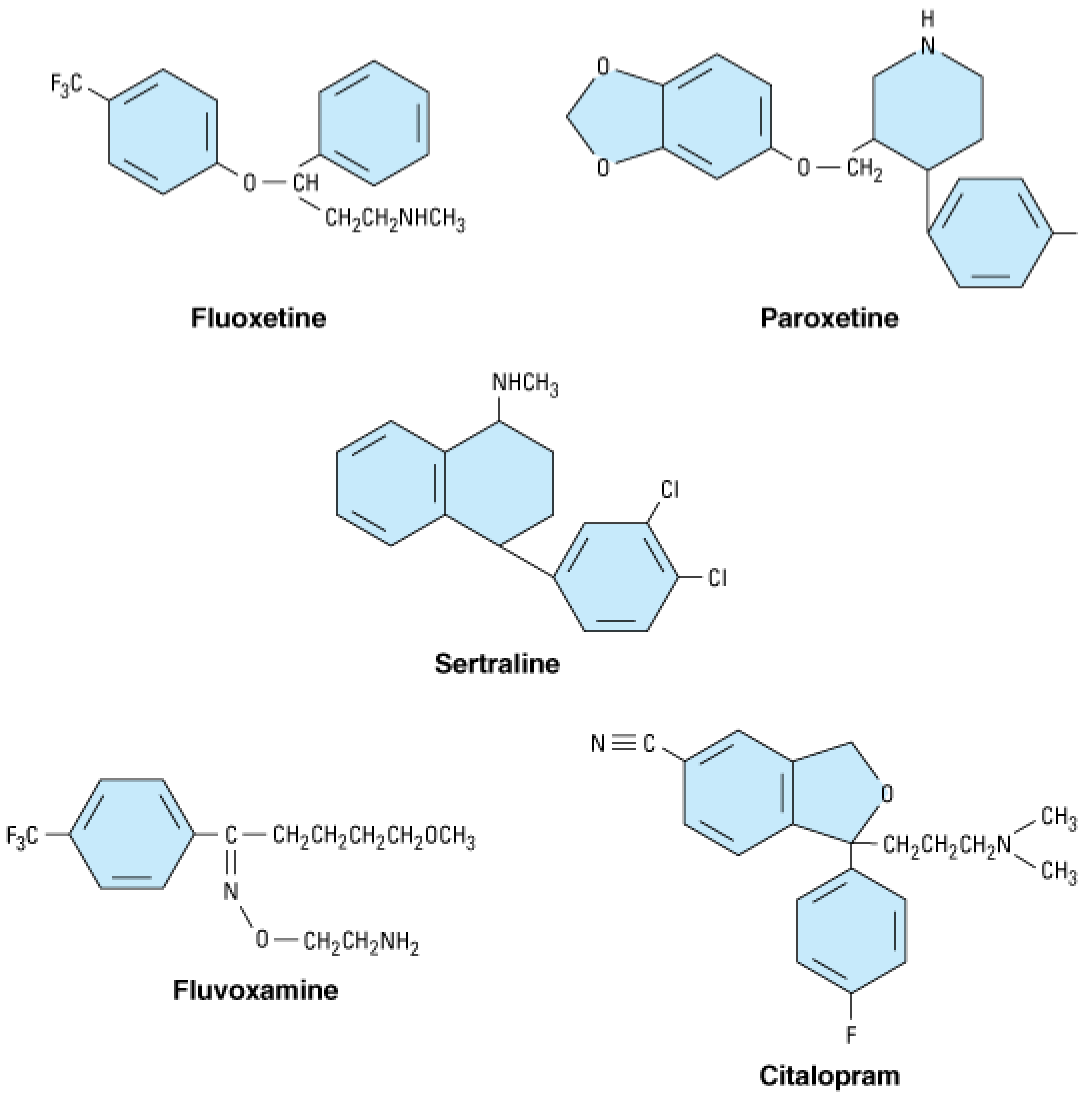


Newer (third-generation) antidepressants.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIS)

Search for molecules with greater selectivity for the serotonin transporter led to the introduction of fluoxetine —an effective and more selective antidepressant with minimal autonomic toxicity. Since that time, four more SSRIs have been introduced as well as the active enantiomeric form of one, *(S)* -citalopram. All are structurally distinct from the tricyclic molecules (Figure 30–4). These drugs have fewer adverse effects than the tricyclics and have become very popular.

Figure 30–4.

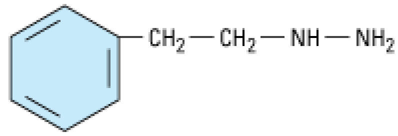


Selective serotonin reuptake inhibitors (SSRIs).

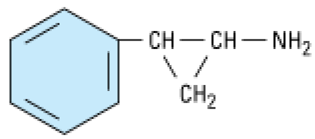
MONOAMINE OXIDASE (MAO) INHIBITORS

MAO inhibitors may be classified as hydrazides, exemplified by the C–N–N moiety, as is the case with phenelzine and isocarboxazid (no longer marketed); or nonhydrazides, which lack such a moiety, as with tranylcypromine (Figure 30–5).

Figure 30–5.



Phenelzine



Tranylcypromine

Some monoamine oxidase inhibitors. Phenelzine is the hydrazide of phenylethylamine (see Figure 9–3), whereas tranylcypromine has a cyclopropyl amine side chain and closely resembles dextroamphetamine (see Figure 9–4). These agents are unselective and produce an extremely long-lasting inhibition of the enzyme. Selegiline, which is partially selective for MAO-B, is shown in Figure 28–2.

Tranylcypromine closely resembles dextroamphetamine, which is itself a weak inhibitor of MAO. Tranylcypromine retains some of the sympathomimetic characteristics of the amphetamines. The hydrazides appear to combine irreversibly with the enzyme, whereas tranylcypromine has a prolonged duration of effect even though it is not bound irreversibly. These older MAO inhibitors are nonselective inhibitors of both MAO-A and MAO-B. Selegiline, an MAO inhibitor used in Parkinson's disease that is selective for MAO-B at low doses but less selective at higher doses, has been approved for the treatment of major depression.

Pharmacokinetics

TRICYCLIC ANTIDEPRESSANTS

Most tricyclics are incompletely absorbed and undergo significant first-pass metabolism. As a result of high tissue protein binding and relatively high lipid solubility, volumes of distribution tend to be very large. Tricyclics are metabolized by two major routes: transformation of the tricyclic nucleus and alteration of the aliphatic side chain. Monodemethylation of tertiary amines leads to active metabolites such as desipramine and nortriptyline (which are themselves available as drugs; Figure 30–1). The pharmacokinetic parameters of various antidepressants are summarized in Table 30–1.

Table 30–1. Pharmacokinetic Parameters of Various Antidepressants.

SECOND-GENERATION AND SUBSEQUENT ANTIDEPRESSANTS

The pharmacokinetics of these drugs are similar to those of the TCAs (Table 30–1). Some have active metabolites. Trazodone and venlafaxine have short plasma half-lives, which mandates divided doses during the day when beginning treatment, although once-a-day dosing may be possible later. Extended-release forms of bupropion and venlafaxine allow for once-a-day dosing in some patients from the outset.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

The pharmacokinetic parameters of these drugs are summarized in Table 30–1. Fluoxetine is notable for the long half-life of its active metabolite, norfluoxetine (7–9 days at steady state). This long $t_{1/2}$ has allowed the introduction of a formulation for once-weekly dosing. Sertraline and paroxetine have pharmacokinetic parameters similar to those of tricyclics. Citalopram and fluvoxamine resemble fluoxetine.

MAO INHIBITORS

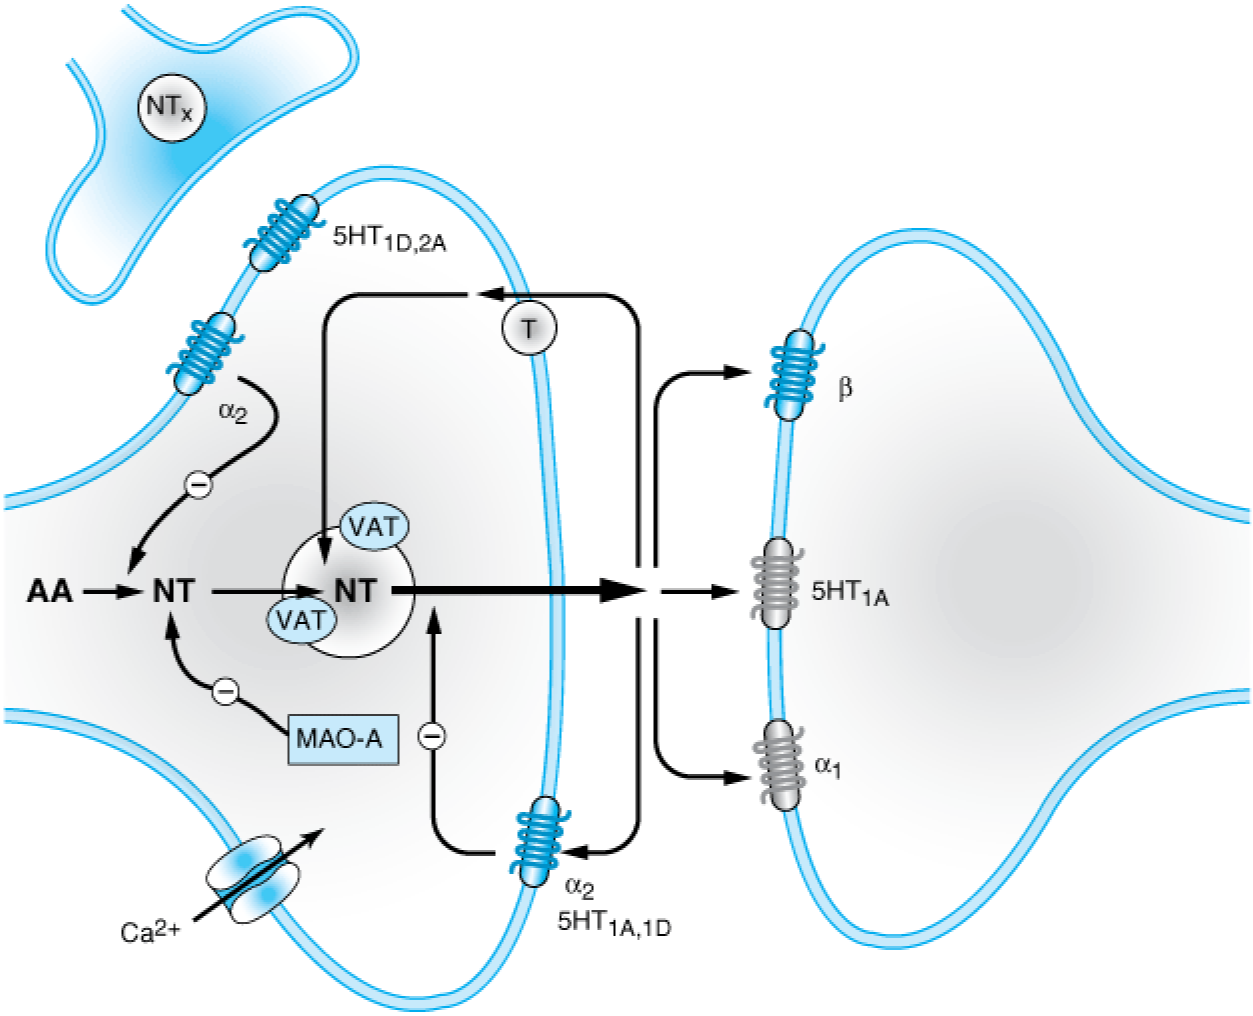
The monoamine oxidase inhibitors (MAOIs) are readily absorbed from the gastrointestinal tract. The hydrazide inhibitor phenelzine is acetylated in the liver and manifests differences in elimination, depending on the acetylation phenotype of the individual (see Chapter 4). However, inhibition of MAO persists even after these drugs (including selegiline) are no longer detectable in plasma. Therefore, conventional pharmacokinetic parameters (half-life, etc) are not very helpful in governing dosage. It is prudent to assume that the drug effect will persist for 7 days (tranylcypromine) to 2 or 3 weeks (phenelzine, selegiline) after discontinuance of the drug.

Pharmacodynamics

ACTIONS OF ANTIDEPRESSANTS ON AMINE NEUROTRANSMITTERS

The amine hypothesis was buttressed by studies on the mechanism of action of various types of antidepressant drugs. Tricyclics block the amine transporters (uptake pumps; Figure 30–6) known as the norepinephrine and serotonin transporters, NET and SERT, respectively. These transporters terminate amine neurotransmission (see Table 30–2 and Chapter 6). Blockade of these transporters presumably permits a longer sojourn of neurotransmitter in the intrasynaptic space at the receptor site. MAO inhibitors block a major intraneuronal degradative pathway for the amine neurotransmitters, which permits more amines to accumulate in presynaptic stores (Figure 30–6) and more to be released. Some of the second-generation antidepressants have similar strong effects on amine transporters, whereas others have only moderate or minimal effects on reuptake or metabolism. Countering this simple model of increased synaptic activity is increasing evidence of alterations in presynaptic regulation of neurotransmitter release. Presynaptic autoreceptors respond to increased synaptic transmitter by down-regulating transmitter synthesis and release. Furthermore, some (but not all) of these regulatory receptors may themselves be down-regulated. These changes occur on a slower time scale more in keeping with the clinically observed effects.

Figure 30–6.



Schematic diagram showing some of the potential sites of action of antidepressant drugs. The primary neuron is shown as releasing a transmitter amine (NT). A modulating neuron may release a second transmitter (NT_x), regulating the activity of the primary neuron. The most consistent observed effect of the antidepressants (other than MAO inhibitors) is inhibition of the reuptake transporters (T) for norepinephrine or serotonin. The MAO inhibitors increase the vesicular stores of both NE and 5-HT. Other direct or indirect effects include initial increase in activation of pre- and postsynaptic receptors and subsequent desensitization or down-regulation of transmitter synthesis from an amino acid (AA), receptor numbers, or postreceptor mechanisms. Desensitization resulting from antidepressant use has been reported for α_2, β, and 5-HT_{1A} systems (color). VAT denotes a vesicle-associated transporter.

[2] Significant α_2 -adrenoceptor antagonism.

Trazodone, nefazodone, and mirtazapine stand out as agents in which antagonism of subtypes of serotonin receptors (5-HT_{2A} or 5-HT_{2C}) may be important in their action. Mirtazapine is unique in including antagonism of α_2 norepinephrine receptors as presumably contributing to its therapeutic effects. Bupropion has been found to alter the output of norepinephrine in humans following chronic administration through some as yet unidentified primary mechanism as well as occupying about 25% of dopamine uptake transporters (DAT) in the brain as revealed by positron emission tomography. (Since it has been shown that effective doses of SSRIs occupy 80% of serotonin uptake sites, the clinical relevance of 25% DAT occupancy is uncertain.) Thus, even the newest antidepressants can still be categorized as possibly working through serotonergic and noradrenergic effects with the additional possibility of a role for dopamine. Increased synaptic dopamine has often been invoked as relevant to the efficacy of MAOIs.

RECEPTOR AND POSTRECEPTOR EFFECTS

Considerable attention has been paid to the long-term postsynaptic effects of increased neurotransmitters in the synapses. In tests of postsynaptic effects, especially of the tricyclics, cAMP concentrations have consistently *decreased* rather than increased. In addition, the number of receptors for the neurotransmitters can decrease over the same time course as clinical improvement in patients. Thus, the initial increase in neurotransmitter seen with some antidepressants appears to produce, over time, a compensatory decrease in receptor activity, ie, down-regulation of certain postsynaptic as well as presynaptic receptors.

It has long been thought that enhanced serotonergic transmission, albeit mediated through diverse mechanisms, might be a common effect of antidepressants even without an increase in synaptic serotonin. Moreover, selective antagonism of either norepinephrine or serotonin receptors as opposed to that of the 5-HT transporter may lead to enhanced extracellular serotonin due to the complex manner in which these neurotransmitters are regulated.

Most recently, long-term intracellular changes involving phosphorylation of various regulatory elements, including those within the nucleus, have been implicated as relevant to antidepressant action. It is possible that effects on certain neurotrophic factors—factors critical to sustained survival and function of neurons in the adult nervous system—may be central to the actions of antidepressants.

Clinical studies have indirectly tested the relevance of findings from animals for norepinephrine or serotonin function. The approach has been to reduce the amino acid precursor of serotonin, tryptophan, in the diet and, by implication, the amount of available neurotransmitter in the brain, since tryptophan availability can be rate-limiting in the formation of serotonin. Severely tryptophan-depleted diets reduce plasma tryptophan and acutely reverse antidepressant responses to SSRIs but not to NET inhibitors. Similarly, depletion of the norepinephrine amino acid precursor tyrosine can reverse antidepressant effects of the relatively selective NET inhibitor, desipramine. These findings support the hypothesis that enhanced serotonin and norepinephrine throughput is necessary for the antidepressant actions of the respective transporter inhibitors. However, tryptophan depletion does not consistently worsen the condition of unmedicated depressed patients. Thus, there is still no clear relationship between serotonin and depression or antidepressant mechanisms in general.

EFFECTS OF SPECIFIC ANTIDEPRESSANTS

Tricyclics

The first-generation antidepressants demonstrate varying degrees of selectivity for the reuptake pumps for norepinephrine and serotonin (Table 30–2) but selectivity is much lower than for the SSRIs. They also have numerous autonomic actions, as described below under Adverse Effects.

Second-Generation Agents

Amoxapine is a metabolite of the antipsychotic drug loxapine and retains some of its antipsychotic action and dopamine receptor antagonism (see Chapter 29). A combination of antidepressant and antipsychotic actions might make it a suitable drug for depression in psychotic patients. However, the dopamine antagonism may cause akathisia, parkinsonism, amenorrhea-galactorrhea syndrome, and perhaps tardive dyskinesia.

Maprotiline (a tetracyclic drug) is most like desipramine in terms of its potent norepinephrine uptake inhibition. Like desipramine, it has fewer sedative and antimuscarinic actions than the older tricyclics.

Clinical experience with trazodone has indicated unpredictable efficacy for depression, although it has proved very useful as a hypnotic, sometimes being combined with MAOIs, which disturb sleep.

Subsequent Non-SSRI Agents

Four antidepressants—nefazodone, venlafaxine, duloxetine, and mirtazapine—are all related to earlier agents in either structure or mechanism of action. Nefazodone is closely related to trazodone but is less sedating. It produces fewer adverse sexual effects than the SSRIs (see below) but is a potent inhibitor of CYP3A4. (Fluvoxamine causes the same inhibition of CYP3A4.)

Venlafaxine is a potent inhibitor of serotonin transport and a weaker inhibitor of norepinephrine transport. At lower therapeutic doses, venlafaxine behaves like an SSRI. At high doses (more than 225 mg/d), it produces mild to moderate increases of heart rate and blood pressure attributable to norepinephrine transporter inhibition. Doses in the range of 225 mg/d or more may confer broader therapeutic effects than SSRIs, but titration up to these doses is needed to control adverse effects.

Mirtazapine is a potent antihistaminic with greater sedating effects than the other second- and third-generation antidepressants. Its use is also more likely to be associated with weight gain. The hypothesized mechanism of action of mirtazapine combines 5-HT_2 receptor and α-adrenoceptor antagonism and, if established in humans, would be unique among available drugs. Thus, mirtazapine may prove beneficial in patients who can tolerate its sedative effects and do not respond well to SSRIs or cannot tolerate their sexual adverse effects.

Selective Serotonin Reuptake Inhibitors

These drugs achieve high ratios of SERT versus NET inhibition of 300 to 7000 (Table 30–2). Fluoxetine was the first SSRI to reach general clinical use. Paroxetine and sertraline differ mainly in having shorter half-lives and different potencies as inhibitors of specific P450 isoenzymes. Racemic citalopram and *(S)* -citalopram (escitalopram), the most selective SSRIs of all, have achieved very widespread use. Although the SSRIs have not been shown to be more effective overall than prior drugs, they lack many of the toxicities of the tricyclic and heterocyclic antidepressants. Thus, patient acceptance has been high despite their own adverse effects.

MAO Inhibitors

MAO-A (isoform A) is the amine oxidase primarily responsible for norepinephrine, serotonin, and tyramine metabolism. MAO-B is more selective for dopamine. The irreversible inhibitors available in the USA are nonselective and at the doses used block both forms of the enzyme. Irreversible block of MAO, characteristic of the older MAO inhibitors, allows significant accumulation of tyramine and loss of the first-pass metabolism that protects against tyramine in foods (see Adverse Effects). Because they result in replacement of the normal transmitter (norepinephrine) stored in noradrenergic nerve terminal vesicles with a false transmitter (octopamine), they may cause significant hypotension.

CLINICAL PHARMACOLOGY OF ANTIDEPRESSANTS

Clinical Indications

The major indication for antidepressant drugs is to treat depression, but a number of other uses have been established by clinical experience and controlled trials.

DEPRESSION

This indication has been kept broad deliberately, even though evidence from clinical studies strongly suggests that the drugs are specifically useful only in major depressive episodes. Major depressive episodes are diagnosed primarily on the basis of the persistent degree and quality of depressed mood or loss of interest and pleasure in most activities, usually accompanied by disturbances of sleep, appetite, sexual drive, activity, or ability to concentrate. The diagnosis of major depression may be uncertain in individual patients, so that on balance this condition is underdiagnosed and undertreated. The depressed phase of bipolar illness definitely requires pharmacologic treatment given the high rate of suicide in persons with this disorder. Standard antidepressants are usually added to lithium or another antimanic agent; SSRIs are less likely to induce mania than the older tricyclic agents. There are, however, few controlled studies on their relative efficacy or proper duration of use. Finally, recent controlled studies support the additional labeling of the anticonvulsant lamotrigine for maintenance and prophylaxis of the depressed phase of bipolar illness.

ANXIETY DISORDERS: PANIC, GENERALIZED ANXIETY, AND SOCIAL PHOBIA

Imipramine was first shown in 1962 to have a beneficial effect in the acute episodes of anxiety that have come to be known as panic attacks. It has also been demonstrated that SSRIs, venlafaxine, and duloxetine are effective in panic, generalized anxiety disorder (GAD), and social phobia, but they require 6–8 weeks of treatment. Since there is considerable comorbidity between depression and anxiety disorders, it is advantageous for many patients to use a treatment that is helpful for both conditions. In some instances, because they are well tolerated and their clinical effects become evident promptly, benzodiazepines remain the preferred drugs for anxiety disorders despite the physiologic dependence associated with long-term use.

OBSESSIVE-COMPULSIVE DISORDERS

Potent SSRIs are uniquely effective for treating these disorders. Recent studies have focused on fluoxetine and other SSRIs, although clomipramine, the most potent mixed serotonin and norepinephrine transporter inhibitor, may be especially effective. Fluvoxamine is marketed exclusively for this disorder in the United States.

ENURESIS

Enuresis is an established indication for tricyclics. Proof of efficacy for this indication is substantial, but drug therapy is not the preferred approach, especially given the risks of cardiovascular effects and the dangers from overdoses.

CHRONIC PAIN

Clinicians in pain clinics have found tricyclics to be useful for treating a variety of chronically painful states that often cannot be definitively diagnosed. It is likely that tricyclics and other combined serotonin-norepinephrine transporter inhibitors work directly on pain pathways and do not work simply on depressive equivalents secondary to chronic pain.

In addition to TCAs, controlled studies of higher doses of venlafaxine show efficacy in pain. Duloxetine has similar effects at doses closer to standard antidepressant doses. SSRIs, however, are not effective for chronic pain.

OTHER INDICATIONS

Certain antidepressants have been shown to be effective for eating disorders, especially bulimia (fluoxetine), premenstrual dysphoric disorder (fluoxetine), and attention deficit hyperkinetic disorder (imipramine, desipramine). Atomoxetine was recently introduced for the treatment of attention deficit hyperactivity disorder (ADHD). This selective NET inhibitor does not appear to have the abuse liability of the standard drugs for this condition (methylphenidate and amphetamine; see Chapter 9).

Drug Choice

Controlled comparisons of the available antidepressants have usually led to the conclusion that they are roughly equivalent in efficacy. Although this may be true for groups of patients, individual patients may respond better to one drug than to another. European studies show that patients depressed enough to be hospitalized respond better to classic tricyclics than to monotherapy with SSRIs. Meta-analyses of outpatient studies also show a greater efficacy of tricyclics over SSRIs in patients who complete trials. The greater tolerability of the SSRIs, however, makes them the preferred agent for most patients. At high doses (> 225 mg), venlafaxine also shows greater efficacy than the SSRIs. Thus, finding the right drug and the right dose for the individual patient must be accomplished empirically. The history of the patient's drug experience is the most valuable guide.

Tricyclics and the second- and third-generation agents differ mainly in the degree of sedation they produce (greatest with amitriptyline, doxepin, trazodone, and mirtazapine) and their antimuscarinic effects (greatest with amitriptyline and doxepin; Table 30–2). SSRIs are generally free of sedative effects and safe in overdose. Combined with their mild adverse effects, these qualities account for the popularity of SSRIs as the most widely prescribed antidepressants.

In contrast, amoxapine and maprotiline seem to have as many sedative and autonomic actions as most tricyclics; more recently introduced antidepressants such as bupropion, venlafaxine, and duloxetine are, like SSRIs, mostly free of such effects, whereas nefazodone and mirtazapine are very sedating. Amoxapine and maprotiline are at least as dangerous as the tricyclics when taken in overdose; the other newer agents seem to be safer.

No special indications for particular types of depression have been found for SSRIs or other newer antidepressants. The popularity of these drugs, despite their higher cost, is due principally to their greater acceptance by patients. A provocative clinical report that fluoxetine use increased suicidal or aggressive ideation was not supported by subsequent analyses of massive databases. In 2004, however, because of an apparent increase in suicidal thoughts and behaviors in children on SSRIs, the FDA issued a general warning about increased risk of suicide with newer antidepressants. Studies of concurrent epidemiologic data involving much larger numbers than the trials cited by the FDA came to the opposite conclusion—any increase in suicide risk is seen only with older antidepressants (primarily tricyclics).

Clinical reports, prescription databases, and a few trials support the use of SSRIs in combination with the older tricyclics, especially desipramine; with bupropion; and, most recently, with mirtazapine in patients who do not show an adequate response to a single agent.

MAO inhibitors remain helpful despite their adverse effects but are reserved for patients who have failed to respond to at least two courses of monotherapy or combination treatment with different classes of antidepressants.

Lithium, a mood stabilizer (see Chapter 29), in combination with an antidepressant may achieve a favorable response not obtained by the antidepressant alone.

Dosages

The usual daily dose ranges of antidepressants are shown in Table 30–3. Doses are almost always determined empirically; the patient's acceptance of adverse effects is the usual limiting factor. Tolerance to some of the objectionable effects may develop, so that the usual pattern of treatment has been to start with small doses, increasing either to a predetermined daily dose, or to one that produces relief of depression, or to the maximum tolerated dose (except in the case of nortriptyline, which loses efficacy at plasma concentrations over 150 ng/mL).

Table 30–3. Usual Daily Doses of Antidepressant Drugs.

Drug	Dose (mg)
Tricyclics	
Amitriptyline	75–200
Clomipramine	75–300
Desipramine	75–200
Doxepin	75–300
Imipramine	75–200
Nortriptyline	75–150
Protriptyline	20–40
Trimipramine	75–200

Second- and third-generation agents	
Amoxapine	150–300
Bupropion	200–400
Duloxetine	40–120
Maprotiline	75–300
Mirtazapine	15–60
Nefazodone	200–600
Trazodone	50–600
Venlafaxine	75–225
Monoamine oxidase inhibitors	
Phenelzine	45–75
Tranylcypromine	10–30
Selective serotonin reuptake inhibitors	
Citalopram	20–60
Fluoxetine	10–60
Fluvoxamine	100–300

Paroxetine	20–50
Sertraline	50–200

MAO inhibitors, bupropion, fluoxetine, sertraline, paroxetine, citalopram, and venlafaxine are customarily given early in the day when initiating treatment, because they can be somewhat stimulating and may cause insomnia if given late. After a few weeks on the drug, however, any such effects should disappear, and time of day administered is rarely important. Virtually all the other antidepressants have varying degrees of sedative effects and are best given near bedtime. Autonomic adverse effects also tend to be less troublesome if the dose is given late.

Maintenance Treatment

Whether or not to undertake long-term maintenance treatment of a depressed patient depends entirely on the actual history of the disorder in that individual. If the depressive episode was the patient's first and if the patient responded quickly and satisfactorily to drug therapy, it is reasonable to gradually withdraw treatment over a period of a few weeks after treating for 6–9 months. If relapse does not occur, drug treatment can be stopped until another episode occurs, which is unpredictable but highly probable. Pooled data from randomized trials covering 6–36 months reveal a more than 50% reduction in relapses or recurrences if patients are maintained on an antidepressant. Thus, a patient who has had previous episodes of depression—especially if each succeeding one was more severe and more difficult to treat—is a candidate for maintenance therapy. Maintenance therapy requires the full dosage used to obtain the initial response. The duration of treatment varies, though many patients require maintenance treatment indefinitely.

Unresponsive Patients

One third or more of patients do not respond (defined as 50% or more improvement) to treatment, and almost two thirds fail to achieve or maintain full remission on any single regimen. In evaluating any patient's limited response to a treatment, one should consider the five D's: diagnosis, drug, dose, duration of treatment, and different treatment.

Diagnosis might be reassessed if the patient shows little response over a period of 2–3 weeks of adequate dosage or plasma concentrations. Whether or not the patient is bipolar, lithium might be added (see Chapter 29); if psychotic, treatment might be augmented with an antipsychotic agent. Combination of an SSRI with desipramine, bupropion, or mirtazapine is safe and effective for some patients. There is no good pharmacologic rationale for combining venlafaxine or duloxetine with SSRIs because they are full serotonin reuptake inhibitors at doses that inhibit norepinephrine uptake; rather, they might be combined with bupropion or mirtazapine. At least 6–8 weeks should be tried before giving up on a drug or combination as long as there is some evidence of improvement by 3–4 weeks.

One strategy is to begin treatment with an SSRI in mild to moderate outpatient depression and then augment by adding a drug of a different class for more impaired patients. Otherwise, switch to a drug of a different class. Most experts would move through various antidepressant drug classes in the search for the right drug rather than through various drugs within a class.

Dose and duration of treatment for depression must be considered. Many treatment failures are due to inadequate dosage, which should be pushed to the limits of the patient's tolerance in refractory cases. Duration of treatment is even more important. In over 50% of patients, full response does not occur until there has been at least 8 weeks of treatment.

Finally, some patients may need a completely different type of treatment, such as electroconvulsive therapy (ECT). ECT is often viewed as a treatment of last resort, but it should not be withheld from patients with depression who cannot be helped by drug therapy. For patients with psychotic depression, ECT may be a treatment of first choice.

Noncompliance is an important cause of lack of response to drugs. Patients should be warned also that noticeable improvement may be slow, with the first clear signs taking perhaps 3 weeks or more. Inability to tolerate adverse effects and discouragement with treatment are two major causes for noncompliance and for failure of antidepressants to show efficacy.

Adverse Effects

Adverse effects of various antidepressants are summarized in Table 30–4. Most common unwanted effects are minor, but they may seriously affect patient compliance. Seriously depressed patients, however, can tolerate unwanted effects, perhaps because they are too depressed to care. In healthy volunteers, even moderate doses of the tricyclics—amitriptyline, imipramine, clomipramine, and doxepin—are poorly tolerated. With the SSRIs, transient nausea is the most frequent complaint, and decreased libido and sexual dysfunction create the greatest concerns in patients during maintenance treatment. Concerns about teratogenic potential recently led to revised labeling of paroxetine.

Table 30–4. Adverse Effects of Antidepressants.

Tricyclics	
Sedation	Sleepiness, additive effects with other sedative drugs
Sympathomimetic	Tremor, insomnia
Antimuscarinic	Blurred vision, constipation, urinary hesitancy, confusion
Cardiovascular	Orthostatic hypotension, conduction defects, arrhythmias
Psychiatric	Aggravation of psychosis, withdrawal syndrome
Neurologic	

Seizures

Metabolic-endocrine

Weight gain, sexual disturbances

Monoamine oxidase inhibitors

Headache, drowsiness, dry mouth, weight gain, postural hypotension, sexual disturbances, interactions[1]

Amoxapine

Similar to the tricyclics with the addition of some effects associated with the antipsychotics (Chapter 29)

Maprotiline

Similar to tricyclics; seizures are dose-related

Mirtazapine

Somnolence, increased appetite, weight gain, dizziness

Trazodone, nefazadone

Drowsiness, dizziness, insomnia, nausea, agitation

Venlafaxine

Nausea, somnolence, sweating, dizziness, anxiety, sexual disturbances, hypertension

Duloxetine

Nausea, dry mouth, decreased appetite, insomnia, dizziness, sweating

Bupropion

Dizziness, dry mouth, sweating, tremor, aggravation of psychosis, potential for seizures at high doses

Fluoxetine and other serotonin reuptake inhibitors

Anxiety, insomnia, gastrointestinal symptoms, decreased libido, sexual dysfunction, teratogenic potential with paroxetine

[1] Interactions with tyramine-containing foods; interactions that cause serotonin syndrome (see Chapter 16).

Among the major drawbacks of most first-generation antidepressants are their many "irrelevant" pharmacologic actions, a trait inherited from the phenothiazine antipsychotic agents. It appears that the antimuscarinic, antihistaminic, and α-adrenoceptor-blocking actions of tricyclic antidepressants contribute only to the undesirable effects of these agents. Blurred vision, dry mouth, urinary hesitancy or retention, and constipation represent the most common antimuscarinic complaints. Postural hypotension is a significant and potentially dangerous manifestation of the α-blocking action, especially in the elderly.

Drug Interactions

PHARMACODYNAMIC INTERACTIONS

The pharmacodynamic interactions of antidepressants with other drugs depend on their class. Those with sedative effects may be additive with other sedatives, especially alcohol. Patients taking tricyclics or mirtazapine should be warned that use of alcohol may lead to greater than expected impairment of driving ability. MAO inhibitors, by increasing stores of catecholamines, sensitize the patient to indirectly acting sympathomimetics such as tyramine, which is found in some fermented foods and beverages, and to sympathomimetic drugs such as diethylpropion, phenylpropanolamine, or botanicals containing ephedrine. Such sensitization can result in dangerous and—rarely—fatal hypertensive reactions. A pharmacodynamic interaction may occur when fluoxetine or another SSRI is used in the presence of an MAO inhibitor. The combination of increased stores of 5-HT plus inhibition of reuptake after release is thought to result in a marked increase of serotonin in the synapses, leading to a serotonin syndrome. This sometimes fatal syndrome includes hyperthermia, muscle rigidity, myoclonus, and rapid changes in mental status and vital signs (see Chapter 16).

PHARMACOKINETIC INTERACTIONS

The most likely pharmacokinetic interactions are between the potent inhibitors of P450 2D6, paroxetine and fluoxetine, and those drugs highly dependent on this pathway for clearance (eg, desipramine, nortriptyline, flecainide; see also Chapter 4). Actual instances of clinically significant interactions are extremely rare, and there are only a handful of case reports after cumulative exposure of more than 50 million patients to these SSRI drugs. Inhibition of P450 3A4 could possibly occur at high concentrations of nefazodone and fluvoxamine and block the metabolism of the many substrates of this isoform.

Overdoses

TRICYCLICS

Tricyclics are extremely dangerous when taken in overdose quantities, and depressed patients are more likely than others to be suicidal. Prescriptions should therefore be limited to amounts less than 1.25 g, or 50 dose units of 25 mg, on a "no refill" basis. If suicide is a serious possibility, the tablets should be entrusted to a family member. The drugs must be kept away from children. Both accidental and deliberate overdoses continue to occur and are serious medical emergencies. Major effects and management of overdosage are discussed in Chapter 59.

SECOND- AND THIRD-GENERATION DRUGS

Overdoses of amoxapine are characterized by severe neurotoxicity, with seizures that are difficult to control. Overdoses of maprotiline also have a tendency to cause seizures as well as cardiotoxicity. Overdoses of the other heterocyclic drugs appear to create only minor problems and can usually be managed with purely supportive measures.

MAO INHIBITORS

Intoxication with MAO inhibitors is unusual. Agitation, delirium, and neuromuscular excitability are followed by obtunded consciousness, seizures, shock, and hyperthermia. Supportive treatment is usually all that is required, though sedative phenothiazines with α-adrenoceptor-blocking action, such as chlorpromazine, may be useful.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

A few deaths have occurred during overdosage of SSRIs when other drugs were also being taken. The likelihood of fatalities from SSRI overdoses is extremely low. In case of overdose, only supportive treatment can be offered, since the high volume of distribution, as with other antidepressants, rules out removal of drug by dialysis. As much as 2.6 g of sertraline has been taken with survival. Overdoses of paroxetine are relatively benign: Up to 850 mg has been taken with no evidence of cardiotoxicity.

PREPARATIONS AVAILABLE

TRICYCLICS

Amitriptyline (generic, Elavil)

Oral: 10, 25, 50, 75, 100, 150 mg tablets

Parenteral: 10 mg/mL for IM injection

Amoxapine (generic)

Oral: 25, 50, 100, 150 mg tablets

Clomipramine (generic, Anafranil; labeled only for obsessive-compulsive disorder)

Oral: 25, 50, 75 mg capsules

Desipramine (generic, Norpramin)

Oral: 10, 25, 50, 75, 100, 150 mg tablets

Doxepin (generic, Sinequan)

Oral: 10, 25, 50, 75, 100, 150 mg capsules; 10 mg/mL concentrate

Imipramine (generic, Tofranil)

Oral: 10, 25, 50 mg tablets (as hydrochloride); 75, 100, 125, 150 mg capsules (as pamoate)

Nortriptyline (generic, Aventyl, Pamelor)

Oral: 10, 25, 50, 75 mg capsules; 10 mg/5 mL solution

Protriptyline (generic, Vivactil)

Oral: 5, 10 mg tablets

Trimipramine (Surmontil)

Oral: 25, 50, 100 mg capsules

SECOND-GENERATION & SUBSEQUENT DRUGS

Amoxapine (generic, Asendin)

Oral: 25, 50, 100, 150 mg tablets

Bupropion (generic, Wellbutrin)

Oral: 75, 100 mg tablets; 100, 150, 200 mg 12-hour sustained-release tablets; 150, 300 mg 24-hour sustained-release tablets

Duloxetine (Cymbalta)

Oral: 20, 30, 50 mg capsules

Maprotiline (generic)

Oral: 25, 50, 75 mg tablets

Mirtazapine (generic, Remeron)

Oral: 7.5, 15, 30, 45 mg tablets; 15, 30, 45 mg disintegrating tablets

Nefazodone (Serzone)

Oral: 50, 100, 150, 200, 250 mg tablets

Trazodone (generic, Desyrel)

Oral: 50, 100, 150, 300 mg tablets

Venlafaxine (Effexor)

Oral: 25, 37.5, 50, 75, 100 mg tablets; 37.5, 75, 150 mg extended-release capsules

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Citalopram (generic, Celexa)

Oral: 10, 20, 40 mg tablets; 10 mg/5 mL solution

Escitalopram (Lexapro)

Oral: 5, 10, 20 mg tablets; 5 mg/5 mL solution

Fluoxetine (generic, Prozac)

Oral: 10, 20, 40 mg capsules; 10, 20 mg tablets; 20 mg/5 mL liquid
Oral delayed-release (Prozac Weekly): 90 mg capsules

Fluvoxamine (generic, labeled only for obsessive-compulsive disorder)

Oral: 25, 50, 100 mg tablets

Paroxetine (generic, Paxil)

Oral: 10, 20, 30, 40 mg tablets; 10 mg/5 mL suspension; 12.5, 25, 37.5 mg controlled-release tablets

Sertraline (Zoloft)

Oral: 25, 50, 100 mg tablets; 20 mg/mL oral concentrate

MONOAMINE OXIDASE INHIBITORS

Phenelzine (Nardil)

Oral: 15 mg tablets

Tranylcypromine (Parnate)

Oral: 10 mg tablets

OTHER

Atomoxetine (Strattera)

Oral: 10, 18, 25, 40, 60 mg capsules

Top of Form

OPIOID ANALGESICS & ANTAGONISTS: INTRODUCTION

Morphine, the prototypical opioid agonist, has long been known to relieve severe pain with remarkable efficacy. The opium poppy is the source of crude opium from which Sertürner in 1803 isolated morphine, the pure alkaloid and named it after Morpheus, the Greek god of dreams. It remains the standard against which all drugs that have strong analgesic action are compared. These drugs are collectively known as opioid analgesics and include not only the natural and semisynthetic alkaloid derivatives from opium but also include synthetic surrogates, other opioid-like drugs whose actions are blocked by the nonselective antagonist naloxone, plus several endogenous peptides that interact with the several subtypes of opioid receptors.

BASIC PHARMACOLOGY OF THE OPIOID ANALGESICS

Source

Opium, the source of morphine, is obtained from the poppy, *Papaver somniferum* and *P album.* After incision, the poppy seed pod exudes a white substance that turns into a brown gum that is crude opium. Opium contains many alkaloids, the principle one being morphine, which is present in a concentration of about 10%. Codeine is synthesized commercially from morphine.

Classification & Chemistry

Opioid drugs include full agonists, partial agonists, and antagonists (see Chapter 2 for definitions). Morphine is a full agonist at the μ(mu) opioid receptor, the major analgesic opioid receptor (Table 31–1). In contrast, codeine functions as a partial (or "weak") μ-receptor agonist. Simple substitution of an allyl group on the nitrogen of the full *agonist* morphine plus addition of a single hydroxyl group results in naloxone, a strong μ-receptor *antagonist.* The structures of some of these compounds are shown later in this chapter. Some opioids, eg, nalbuphine, are capable of producing an agonist (or partial agonist) effect at one opioid receptor subtype and an antagonist effect at another. Not only can the activating properties of opioid analgesics be manipulated by pharmaceutical chemistry, certain opioid analgesics are modified in the liver, resulting in compounds with greater analgesic action (see Pharmacokinetics, Metabolism).

Table 31–1. Opioid Receptor Subtypes, Their Functions, and Their Endogenous Peptide Affinities.

Receptor Subtype	Functions	Endogenous Opioid Peptide Affinity
μ(mu)	Supraspinal and spinal analgesia; sedation; inhibition of respiration; slowed GI transit; modulation of hormone and neurotransmitter release	Endorphins > enkephalins > dynorphins
δ(delta)	Supraspinal and spinal analgesia; modulation of hormone and neurotransmitter release	

		Enkephalins > endorphins and dynorphins
κ(kappa)	Supraspinal and spinal analgesia; psychotomimetic effects; slowed GI transit	Dynorphins > > endorphins and enkephalins

GI, gastrointestinal.

Endogenous Opioid Peptides

Opioid alkaloids (eg, morphine) produce analgesia through actions at regions in the central nervous system (CNS) that contain peptides with opioid-like pharmacologic properties. The general term currently used for these endogenous substances is **endogenous opioid peptides**.

Three families of endogenous opioid peptides have been described in detail: the **endorphins**, the pentapeptides methionine-enkephalin (**met-enkephalin**) and leucine-enkephalin (**leu-enkephalin**), and the **dynorphins**. The three families of opioid receptors have overlapping affinities for these endogenous peptides (Table 31–1).

The endogenous opioid peptides are derived from three precursor proteins: prepro-opiomelanocortin (POMC), preproenkephalin (proenkephalin A), and preprodynorphin (proenkephalin B). POMC contains the met-enkephalin sequence, β-endorphin, and several nonopioid peptides, including adrenocorticotropic hormone (ACTH), β-lipotropin, and melanocyte-stimulating hormone. Preproenkephalin contains six copies of met-enkephalin and one copy of leu-enkephalin. Leu- and met-enkephalin have slightly higher affinity for the δ(delta) than for the μopioid receptor (Table 31–1). Preprodynorphin yields several active opioid peptides that contain the leu-enkephalin sequence. These are **dynorphin A**, **dynorphin B**, and α and β **neoendorphins**. More recently, the endogenous peptides **endomorphin-1** and **endomorphin-2** have been found to possess many of the properties of opioid peptides, notably analgesia and high-affinity binding to the μ-receptor. Research is focused on whether endomorphins selectively activate μ-receptor subtypes and much remains unknown, including the identity of their gene. Both the endogenous opioid precursor molecules and the endomorphins are present at CNS sites that have been implicated in pain modulation. Evidence suggests that they can be released during stressful conditions such as pain or the anticipation of pain to diminish the sensation of noxious stimuli.

In contrast to the analgesic role of leu- and met-enkephalin, an analgesic action of dynorphin A—through its binding to κ(kappa) opioid receptors—remains controversial. Dynorphin A is also found in the dorsal horn of the spinal cord, where it plays a critical role in the *sensitization* of nociceptive neurotransmission. Increased levels of dynorphin can be found in the dorsal horn after tissue injury and inflammation. This elevated dynorphin level is believed to increase pain and induce a state of long-lasting hyperalgesia. The pronociceptive action of dynorphin in the spinal cord appears to be independent of the opioid receptor system. Rather, dynorphin A can bind and activate the *N*-methyl-D-aspartate (NMDA) receptor complex, a site of action that is the focus of intense therapeutic development.

Recently, a novel receptor-ligand system homologous to the opioid peptides has been found. The principle receptor for this system is the G protein-coupled **orphanin opioid-receptor-like subtype 1 (ORL1)**. Its endogenous ligand has been termed **nociceptin** by one group of investigators and **orphanin FQ** by another group. This ligand-receptor system is currently known as the N/OFQ system. Nociceptin is structurally similar to dynorphin except for the absence of an N-terminal tyrosine; it acts only at the ORL1 receptor. Although widely expressed in the CNS and periphery, this system has a diverse pharmacology, capable of opposing classic μ-receptor–mediated analgesia as well as modulating drug reward, reinforcement, learning, and memory processes.

Pharmacokinetics

Some properties of clinically important opioids are summarized in Table 31–2.

[1] Available in sustained-release forms, morphine (MSContin); oxycodone (OxyContin).

[2] Administered as an infusion at 0.025-0.2 mcg/kg/min.

[3] Duration is dependent on a context-sensitive half-time of 3–4 minutes.

[4] Available in tablets containing acetaminophen (Norco, Vicodin, Lortab, others).

[5] Available in tablets containing acetaminophen (Percocet); aspirin (Percodan).

[6] Analgesic efficacy at this dose not equivalent to 10 mg of morphine. See text for explanation.

ABSORPTION

Most opioid analgesics are well absorbed when given by subcutaneous, intramuscular, and oral routes. However, because of the first-pass effect, the oral dose of the opioid (eg, morphine) may need to be much higher than the parenteral dose to elicit a therapeutic effect. Considerable interpatient variability exists in first-pass opioid metabolism, making prediction of an effective oral dose difficult. Certain analgesics such as codeine and oxycodone are effective orally because they have reduced first-pass metabolism. Nasal insufflation of certain opioids can result in rapid therapeutic blood levels by avoiding first-pass metabolism. Other routes of opioid administration include oral mucosa via lozenges, and transdermal via transdermal patches. The latter can provide delivery of potent analgesics over days.

DISTRIBUTION

The uptake of opioids by various organs and tissues is a function of both physiologic and chemical factors. Although all opioids bind to plasma proteins with varying affinity, the drugs rapidly leave the blood compartment and localize in highest concentrations in tissues that are highly perfused such as the brain, lungs, liver, kidneys, and spleen. Drug concentrations in skeletal muscle may be much lower, but this tissue serves as the main reservoir because of its greater bulk. Even though blood flow to fatty tissue is much lower than to the highly perfused tissues, accumulation can be very important, particularly after frequent high-dose administration or continuous infusion of highly lipophilic opioids that are slowly metabolized, eg, fentanyl.

METABOLISM

The opioids are converted in large part to polar metabolites (mostly glucuronides), which are then readily excreted by the kidneys. For example, morphine, which contains free hydroxyl groups, is primarily conjugated to morphine-3-glucuronide (M3G), a compound with neuroexcitatory properties. The neuroexcitatory effects of M3G do not appear to be mediated by μ receptors but rather by the GABA/glycinergic system. In contrast, approximately 10% of morphine is metabolized to morphine-6-glucuronide (M6G), an active metabolite with analgesic potency four to six times that of its parent compound. However, these relatively polar metabolites have limited ability to cross the blood-brain barrier and probably do not contribute significantly to the usual CNS effects of morphine given acutely. Nevertheless, accumulation of these metabolites may produce unexpected adverse effects in patients with renal failure or when exceptionally large doses of morphine are administered or high doses are administered over long periods. This can result in M3G-induced CNS excitation (seizures) or enhanced and prolonged opioid action produced by M6G. CNS uptake of M3G and, to a lesser extent, M6G can be enhanced by coadministration with probenecid or with drugs that inhibit the P-glycoprotein drug transporter. Like morphine, hydromorphone is metabolized by conjugation, yielding hydromorphone-3-glucuronide (H3G), which has CNS excitatory properties. However, hydromorphone has not been shown to form significant amounts of a 6-glucuronide metabolite.

The effects of these active metabolites should be considered before the administration of morphine or hydromorphone, especially when given at high doses.

Esters (eg, heroin, remifentanil) are rapidly hydrolyzed by common tissue esterases. Heroin (diacetylmorphine) is hydrolyzed to monoacetylmorphine and finally to morphine, which is then conjugated with glucuronic acid.

Hepatic oxidative metabolism is the primary route of degradation of the phenylpiperidine opioids (meperidine, fentanyl, alfentanil, sufentanil) and eventually leaves only small quantities of the parent compound unchanged for excretion. However, accumulation of a demethylated metabolite of meperidine, normeperidine, may occur in patients with decreased renal function and in those receiving multiple high doses of the drug. In high concentrations, normeperidine may cause seizures. In contrast, no active metabolites of fentanyl have been reported. The P450 isozyme CYP3A4 metabolizes fentanyl by N-dealkylation in the liver. CYP3A4 is also present in the mucosa of the small intestine and contributes to the first-pass metabolism of fentanyl when it is taken orally. Codeine, oxycodone, and hydrocodone undergo metabolism in the liver by P450 isozyme CYP2D6, resulting in the production of metabolites of greater potency. For example, codeine is demethylated to morphine. Genetic polymorphism of CYP2D6 has been documented and linked to the variation in analgesic response seen among patients. Nevertheless, the metabolites of oxycodone and hydrocodone may be of minor consequence because the parent compounds are currently believed to be directly responsible for the majority of their analgesic actions. In the case of codeine, conversion to morphine may be of greater importance because codeine itself has relatively low affinity for opioid receptors.

EXCRETION

Polar metabolites, including glucuronide conjugates of opioid analgesics, are excreted mainly in the urine. Small amounts of unchanged drug may also be found in the urine. In addition, glucuronide conjugates are found in the bile, but enterohepatic circulation represents only a small portion of the excretory process.

Pharmacodynamics

MECHANISM OF ACTION

Opioid agonists produce analgesia by binding to specific G protein-coupled receptors that are located in brain and spinal cord regions involved in the transmission and modulation of pain.

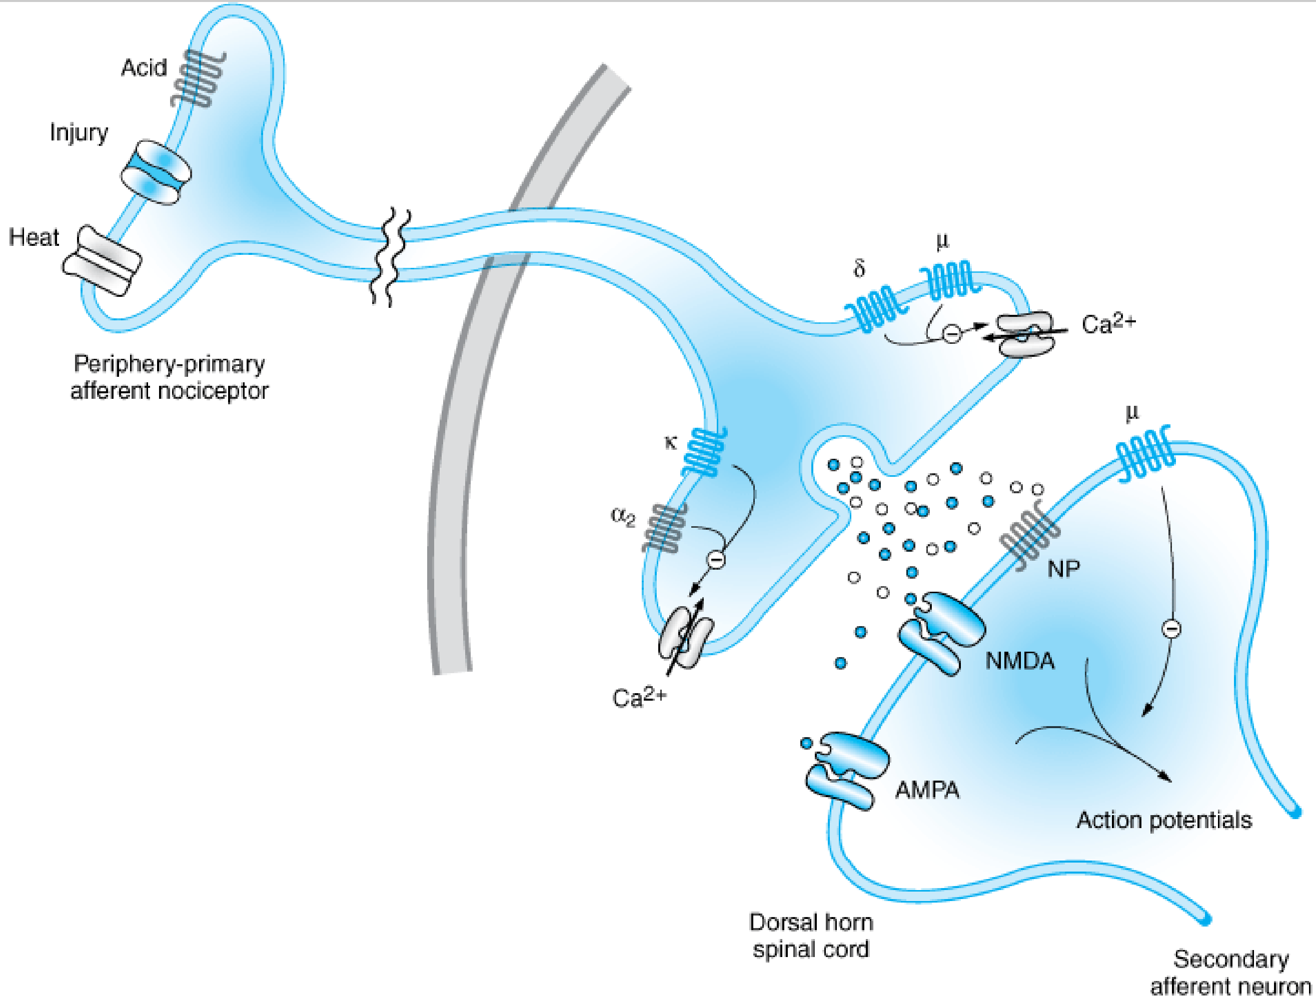
Receptor Types

As noted, three major classes of opioid receptors (μ, δ, and κ) have been identified in various nervous system sites and in other tissues (Table 31–1). Each of the three major receptors has now been cloned. All are members of the G protein-coupled family of receptors and show significant amino acid sequence homologies. Multiple receptor subtypes have been proposed based on pharmacologic criteria, including μ_1, μ_2; δ_1, δ_2; and κ_1, κ_2, and κ_3. However, genes encoding only one subtype from each of the μ, δ, and κ receptor families have been isolated and characterized thus far. One plausible explanation is that μ-receptor subtypes arise from alternate splice variants of a common gene. Since an opioid drug may function with different potencies as an agonist, partial agonist, or antagonist at more than one receptor class or subtype, it is not surprising that these agents are capable of diverse pharmacologic effects. The N/OFQ-ORL1 receptor has not been as extensively studied.

Cellular Actions

At the molecular level, opioid receptors form a family of proteins that physically couple to G proteins and through this interaction affect ion channel gating, modulate intracellular Ca^{2+} disposition, and alter protein phosphorylation (see Chapter 2). The opioids have two well-established direct G protein-coupled actions on neurons: (1) they close voltage-gated Ca^{2+} channels on presynaptic nerve terminals and thereby reduce transmitter release, and (2) they hyperpolarize and thus inhibit postsynaptic neurons by opening K^+ channels. Figure 31–1 schematically illustrates the presynaptic action at all three receptor types and the postsynaptic effect at μ receptors on nociceptive afferents in the spinal cord. The presynaptic action—depressed transmitter release—has been demonstrated for release of a large number of neurotransmitters including glutamate, the principle excitatory amino acid released from nociceptive nerve terminals, as well as acetylcholine, norepinephrine, serotonin, and substance P.

Figure 31–1.



Spinal sites of action of opioids and some other analgesic agents. Mu (μ), delta (δ), and kappa (κ) agonists reduce transmitter release (often glutamate and excitatory neuropeptides) from presynaptic terminals of nociceptive primary afferents (cell body omitted). Mu agonists also hyperpolarize second-order pain transmission neurons by increasing K^+ conductance, evoking an inhibitory postsynaptic potential. $Alpha_2$ agonists appear to act on adrenoceptors on the presynaptic terminal of the primary afferent neuron and ziconotide may act by blocking the calcium channels on this structure (see text).

Relation of Physiologic Effects to Receptor Type

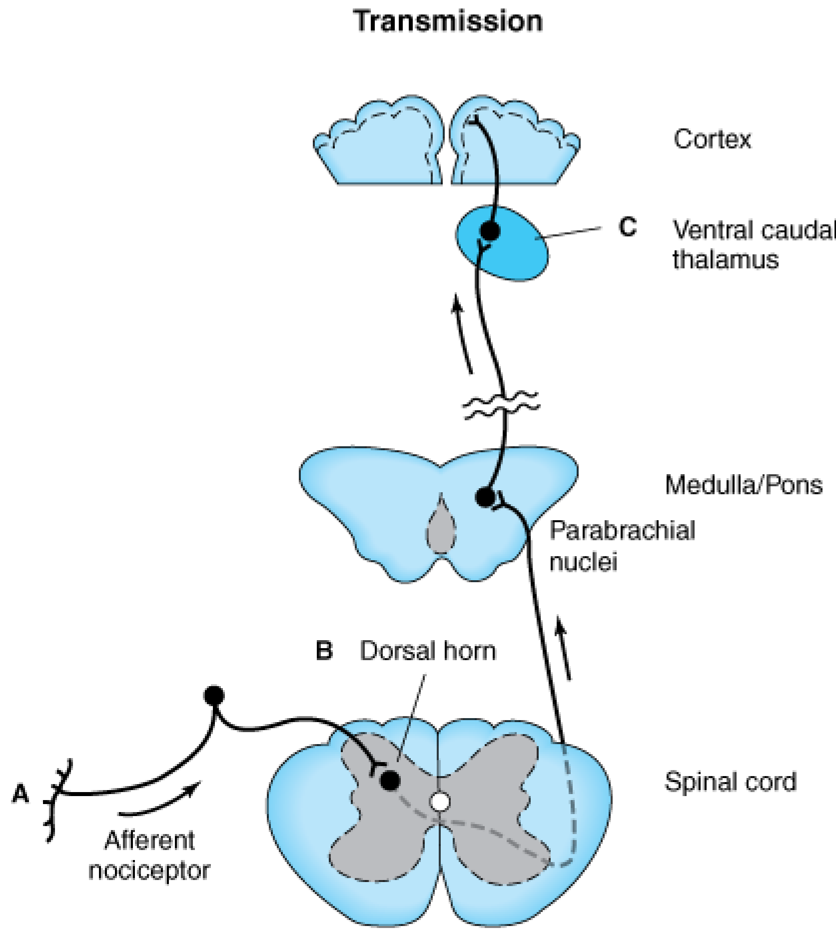
The majority of currently available opioid analgesics act primarily at the μ opioid receptor. Analgesia, as well as the euphoriant, respiratory depressant, and physical dependence properties of morphine result principally from actions at μ receptors. In fact, the μ receptor was originally defined using the relative potencies for clinical analgesia of a series of opioid alkaloids. However, opioid analgesic effects are complex and include interaction with δ and κ receptors. This is supported by the study of genetic knockouts of the μ, δ, and κ genes in mice. Delta-receptor agonists retain analgesic properties in μ receptor knockout mice. The development of δ-receptor-selective agonists could be clinically useful if their side-effect profiles (respiratory depression, risk of dependence) were more favorable than those found with current μ-receptor agonists, such as morphine. Although morphine does act at κ and δ receptor sites, it is unclear to what extent this contributes to its analgesic action. The endogenous opioid peptides differ from most of the alkaloids in their affinity for the δ and κ receptors (Table 31–1).

In an effort to develop opioid analgesics with a reduced incidence of respiratory depression or propensity for addiction and dependence, compounds that show preference for κ opioid receptors have been developed. Butorphanol and nalbuphine have shown some clinical success as analgesics, but they can cause dysphoric reactions and have limited potency. It is interesting that butorphanol has also been shown to cause significantly greater analgesia in women than in men. The reason for this difference is not known.

Receptor Distribution and Neural Mechanisms of Analgesia

Opioid receptor binding sites have been localized autoradiographically with high-affinity radioligands and with antibodies to unique peptide sequences in each receptor subtype. All three major receptors are present in high concentrations in the dorsal horn of the spinal cord. Receptors are present both on spinal cord pain transmission neurons and on the primary afferents that relay the pain message to them (Figure 31–2, sites A and B). Opioid agonists inhibit the release of excitatory transmitters from these primary afferents, and they directly inhibit the dorsal horn pain transmission neuron. Thus, opioids exert a powerful analgesic effect directly on the spinal cord. This spinal action has been exploited clinically by direct application of opioid agonists to the spinal cord, which provides a regional analgesic effect while reducing the unwanted respiratory depression, nausea and vomiting, and sedation that may occur from the supraspinal actions of systemically administered opioids.

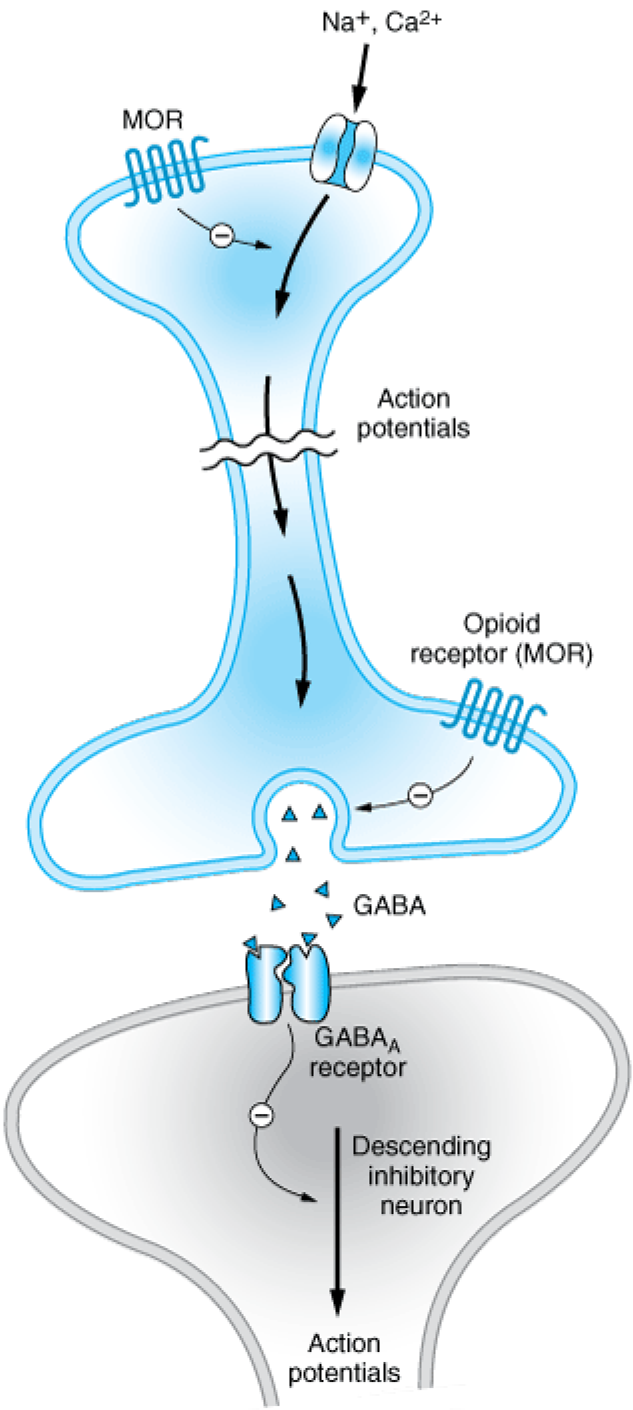
Figure 31–2.



Putative sites of action of opioid analgesics. Sites of action on the afferent pain transmission pathway from the periphery to the higher centers are shown. A: Direct action of opioids on inflamed or damaged peripheral tissues (see Figure 31–1 for detail). B: Inhibition also occurs in the spinal cord. C: Possible sites of action in the thalamus.

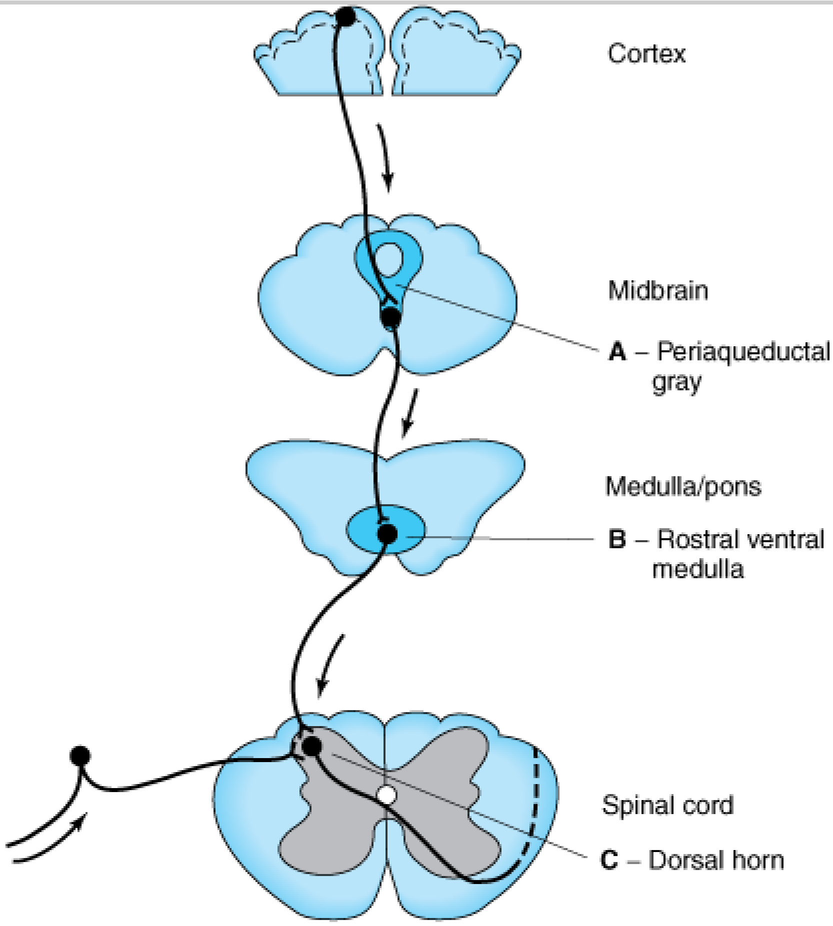
Under most circumstances, opioids are given systemically and so act simultaneously at multiple sites. These include not only the ascending pathways of pain transmission beginning with specialized peripheral sensory terminals that transduce painful stimuli (Figure 31–2) but also descending (modulatory) pathways (Figure 31–3). At these sites as at others, opioids directly inhibit neurons; yet this action results in the *activation* of descending inhibitory neurons that send processes to the spinal cord and inhibit pain transmission neurons. This activation has been shown to result from the inhibition of inhibitory neurons in several locations (Figure 31–4). Taken together, interactions at these sites increase the overall analgesic effect of opioid agonists.

Figure 31–3.



Brainstem local circuitry underlying the modulating effect of descending pathways by μ-opioid receptor (MOR)–mediated analgesia. The pain inhibitory neuron is indirectly activated by opioids (exogenous or endogenous) that inhibit an inhibitory (GABAergic) interneuron. This results in enhanced inhibition of nociceptive processing in the dorsal horn of the spinal cord.

Figure 31–4.



Opioid analgesic action on the descending inhibitory pathway. Sites of action of opioids on pain-modulating neurons in the midbrain and medulla including the midbrain periaqueductal gray area (A), rostral ventral medulla (B), and the locus caeruleus indirectly control pain transmission pathways by enhancing descending inhibition to the dorsal horn (C).

When pain-relieving opioid drugs are given systemically, they presumably act upon brain circuits normally regulated by endogenous opioid peptides. Part of the pain-relieving action of exogenous opioids involves the release of endogenous opioid peptides. An exogenous opioid agonist (eg, morphine) may act primarily and directly at the μ receptor, but this action may evoke the release of endogenous opioids that additionally act at δ and κ receptors. Thus, even a receptor-selective ligand can initiate a complex sequence of events involving multiple synapses, transmitters, and receptor types.

Animal and human clinical studies demonstrate that both endogenous and exogenous opioids can also produce opioid-mediated analgesia at sites *outside* the CNS. Pain associated with inflammation seems especially sensitive to these peripheral opioid actions. The identification of functional μ receptors on the peripheral terminals of sensory neurons supports this hypothesis. Furthermore, activation of peripheral μ receptors results in a decrease in sensory neuron activity and transmitter release. Peripheral administration of opioids, eg, into the knees of patients following arthroscopic knee surgery, has shown clinical benefit up to 24 hours after administration. If they can be developed, opioids selective for a peripheral site would be useful adjuncts in the treatment of inflammatory pain (see Ion Channels & Novel Analgesic Targets). Moreover, new peripherally acting dynorphins may provide a novel means to treat visceral pain. Such compounds could have the additional benefit of reducing unwanted effects such as constipation.

ION CHANNELS & NOVEL ANALGESIA TARGETS

Even the most severe *acute* pain (lasting hours to days) can usually be well controlled—with significant but tolerable adverse effects—with currently available analgesics, especially the opioids. *Chronic* pain (lasting weeks to months), however, is not very satisfactorily managed with opioids. It is now known that in chronic pain, presynaptic receptors on sensory nerve terminals in the periphery contribute to increased excitability of sensory nerve endings (peripheral sensitization). The hyperexcitable sensory neuron bombards the spinal cord, leading to increased excitability and synaptic alterations in the dorsal horn (central sensitization). Such changes appear to be important in chronic inflammatory and neuropathic pain states.

In the effort to discover better analgesic drugs for chronic pain, renewed attention is being paid to synaptic transmission in nociception and peripheral sensory transduction. Potentially important ion channels associated with these processes in the periphery include members of the transient receptor potential family such as the capsaicin receptor, TRPV1 (which is activated by multiple noxious stimuli such as heat, mechanical injury, protons, and products of inflammation) as well as P2X receptors (which are responsive to purines released from tissue damage). A special type of tetrodotoxin-resistant voltage-gated sodium channel (Nav1.8), also known as the PN3/SNS channel, is apparently uniquely associated with nociceptive neurons in dorsal root ganglia. Lidocaine and mexiletine, which are useful in some chronic pain states, may act by blocking this channel. Given the importance of their peripheral sites of action, therapeutic strategies that deliver agents that block peripheral pain transduction or transmission have been introduced in the form of transdermal patches and balms. Such products that specifically target peripheral capsaicin receptors and sodium channel function are becoming available.

Ziconotide, a blocker of voltage-gated N-type calcium channels, has recently been approved for intrathecal analgesia in patients with refractory chronic pain. It is a synthetic peptide related to the marine snail toxin ω-conotoxin, which selectively blocks these calcium channels. Gabapentin, an anticonvulsant analog of GABA (see Chapter 24), is an effective treatment for neuropathic (nerve injury) pain. It has recently been shown to block the pain and hyperalgesia associated with inflammation. Potential sites of action of gabapentin include the $\alpha_2\delta$ family of calcium channels.

N-methyl-D-aspartate (NMDA) receptors appear to play a very important role in central sensitization at both spinal and supraspinal levels. Although certain NMDA antagonists have demonstrated analgesic activity (eg, ketamine), it has been difficult to find agents with an acceptably low profile of adverse effects or neurotoxicity. However, ketamine at very small doses appears to improve analgesia and reduce opioid requirements under conditions of opioid tolerance. GABA and acetylcholine (through nicotinic receptors) appear to control the central synaptic release of several transmitters involved in nociception. Nicotine itself and certain nicotine analogs cause analgesia, and their use for postoperative analgesia is under investigation. Finally, work on cannabinoids and vanilloids and their receptors suggest that Δ^9-tetrahydrocannabinol, which acts primarily on CB1 cannabinoid receptors, can interact with the TRPV1 capsaicin receptor to produce analgesia under certain circumstances.

As our understanding of peripheral and central pain transduction improves, additional therapeutic targets and strategies will become available. Combined with our present knowledge of opioid analgesics, a "multimodal" approach to pain therapy is emerging, which allows the use of complementary compounds resulting in improved analgesia with fewer adverse effects.

Tolerance and Physical Dependence

With frequently repeated therapeutic doses of morphine or its surrogates, there is a gradual loss in effectiveness, ie, tolerance. To reproduce the original response, a larger dose must be administered. Along with tolerance, physical dependence develops. Physical dependence is defined as a characteristic withdrawal or abstinence syndrome when a drug is stopped or an antagonist is administered (see also Chapter 32).

The mechanism of development of tolerance and physical dependence is poorly understood, but persistent activation of μ-receptors such as occurs with the treatment of severe chronic pain appears to play a primary role in its induction and maintenance. Current concepts have shifted away from tolerance being driven by a simple up-regulation of the cyclic adenosine monophosphate (cAMP) system. Although this process is associated with tolerance, it is not sufficient to explain it. A second hypothesis for tolerance was based on the proposal that repeated exposure to agonist caused μ-receptors to be down-regulated by endocytosis. However, emerging research now implicates the *failure* of morphine to induce endocytosis of the μ-opioid receptor as an important component of tolerance development. This suggests that maintenance of normal sensitivity of μ-receptors requires reactivation by endocytosis and recycling (see Chapter 2). Another area of research suggests that the δ-opioid receptor functions as an independent component in the maintenance of tolerance. In addition, the concept of receptor uncoupling has gained prominence. Under this hypothesis, tolerance is due to a dysfunction of structural interactions between the μ-receptor and G proteins, second-messenger systems, and their target ion channels. Moreover, a particular ion channel complex, the NMDA receptor, has been shown to play a critical role in tolerance development and maintenance because NMDA-receptor antagonists such as ketamine can block tolerance development. The development of novel NMDA-receptor antagonists or other strategies to recouple μ-receptors to their target ion channels provides hope for achieving a clinically effective means to prevent or reverse opioid analgesic tolerance.

In addition to the development of tolerance, persistent administration of opioid analgesics has been observed to *increase* the sensation of pain leading to a state of hyperalgesia. This phenomenon has been observed with several opioid analgesics, including morphine, fentanyl, and remifentanyl. Spinal dynorphin has emerged as one important candidate for the mediation of opioid-induced pain and hyperalgesia.

ORGAN SYSTEM EFFECTS OF MORPHINE AND ITS SURROGATES

The actions described below for morphine, the prototypic opioid agonist, can also be observed with other opioid agonists, partial agonists, and those with mixed receptor effects. Characteristics of specific members of these groups are discussed below.

Central Nervous System Effects

The principal effects of opioid analgesics with affinity for μ-receptors are on the CNS; the more important ones include analgesia, euphoria, sedation, and respiratory depression. With repeated use, a high degree of tolerance occurs to all of these effects (Table 31–3).

Table 31–3. Degrees of Tolerance that May Develop to Some of the Effects of the Opioids.

ANALGESIA

Pain consists of both sensory and affective (emotional) components. Opioid analgesics are unique in that they can reduce both aspects of the pain experience, especially the affective aspect.

EUPHORIA

Typically, patients or intravenous drug users who receive intravenous morphine experience a pleasant floating sensation with lessened anxiety and distress. However, dysphoria, an unpleasant state characterized by restlessness and malaise, may sometimes occur.

SEDATION

Drowsiness and clouding of mentation are common concomitants of opioid action. There is little or no amnesia. Sleep is induced by opioids more frequently in the elderly than in young, healthy individuals. Ordinarily, the patient can be easily aroused from this sleep. However, the combination of morphine with other central depressant drugs such as the sedative-hypnotics may result in very deep sleep. Marked sedation occurs more frequently with compounds closely related to the phenanthrene derivatives and less frequently with the synthetic agents such as meperidine and fentanyl. In standard analgesic doses, morphine (a phenanthrene) disrupts normal REM and non-REM sleep patterns. This disrupting effect is probably characteristic of all opioids. In contrast to humans, a number of species (cats, horses, cows, pigs) may manifest excitation rather than sedation when given opioids. These paradoxic effects are at least partially dose-dependent.

RESPIRATORY DEPRESSION

All of the opioid analgesics can produce significant respiratory depression by inhibiting brainstem respiratory mechanisms. Alveolar P_{CO_2} may increase, but the most reliable indicator of this depression is a depressed response to a carbon dioxide challenge. The respiratory depression is dose-related and is influenced significantly by the degree of sensory input occurring at the time. For example, it is possible to partially overcome opioid-induced respiratory depression by stimulation of various sorts. When strongly painful stimuli that have prevented the depressant action of a large dose of an opioid are relieved, respiratory depression may suddenly become marked. A small to moderate decrease in respiratory function, as measured by Pa_{CO_2} elevation, may be well tolerated in the patient without prior respiratory impairment. However, in individuals with increased intracranial pressure, asthma, chronic obstructive pulmonary disease, or cor pulmonale, this decrease in respiratory function may not be tolerated. Opioid-induced respiratory depression remains one of the most difficult clinical challenges in the treatment of severe pain. Research is ongoing to understand and develop analgesic agents and adjuncts that avoid this effect. Research to overcome this problem is focused on δ receptor pharmacology and serotonin signaling pathways in the brainstem respiratory control centers.

COUGH SUPPRESSION

Suppression of the cough reflex is a well-recognized action of opioids. Codeine in particular has been used to advantage in persons suffering from pathologic cough and in patients in whom it is necessary to maintain ventilation via an endotracheal tube. However, cough suppression by opioids may allow accumulation of secretions and thus lead to airway obstruction and atelectasis.

MIOSIS

Constriction of the pupils is seen with virtually all opioid agonists. Miosis is a pharmacologic action to which little or no tolerance develops (Table 31–3); thus, it is valuable in the diagnosis of opioid overdose. Even in highly tolerant addicts, miosis is seen. This action, which can be blocked by opioid antagonists, is mediated by parasympathetic pathways, which, in turn, can be blocked by atropine.

TRUNCAL RIGIDITY

An intensification of tone in the large trunk muscles has been noted with a number of opioids. It was originally believed that truncal rigidity involved a spinal cord action of these drugs, but there is now evidence that it results from an action at supraspinal levels. Truncal rigidity reduces thoracic compliance and thus interferes with ventilation. The effect is most apparent when high doses of the highly lipid-soluble opioids (eg, fentanyl, sufentanil, alfentanil, remifentanil) are rapidly administered intravenously. Truncal rigidity may be overcome by administration of an opioid antagonist, which of course will also antagonize the analgesic action of the opioid. Preventing truncal rigidity while preserving analgesia requires the concomitant use of neuromuscular blocking agents.

NAUSEA AND VOMITING

The opioid analgesics can activate the brainstem chemoreceptor trigger zone to produce nausea and vomiting. There may also be a vestibular component in this effect because ambulation seems to increase the incidence of nausea and vomiting.

Temperature

Homeostatic regulation of body temperature is mediated in part by the action of endogenous opioid peptides in the brain. This has been supported by experiments demonstrating that μ-opioid receptor agonists such as morphine administered to the anterior hypothalamus produces hyperthermia, whereas administration of κ-agonists induce hypothermia.

Peripheral Effects

CARDIOVASCULAR SYSTEM

Most opioids have no significant *direct* effects on the heart and, other than bradycardia, no major effects on cardiac rhythm. Meperidine is an exception to this generalization because its antimuscarinic action can result in tachycardia. Blood pressure is usually well maintained in subjects receiving opioids unless the cardiovascular system is stressed, in which case hypotension may occur. This hypotensive effect is probably due to peripheral arterial and venous dilation, which has been attributed to a number of mechanisms including central depression of vasomotor-stabilizing mechanisms and release of histamine. No consistent effect on cardiac output is seen, and the electrocardiogram is not significantly affected. However, caution should be exercised in patients with decreased blood volume, because the above mechanisms make these patients susceptible to hypotension. Opioid analgesics affect cerebral circulation minimally except when P_{CO_2} rises as a consequence of respiratory depression. Increased P_{CO_2} leads to cerebral vasodilation associated with a decrease in cerebral vascular resistance, an increase in cerebral blood flow, and an increase in intracranial pressure.

GASTROINTESTINAL TRACT

Constipation has long been recognized as an effect of opioids, an effect that does not diminish with continued use; that is, tolerance does not develop to opioid-induced constipation (Table 31–3). Opioid receptors exist in high density in the gastrointestinal tract, and the constipating effects of the opioids are mediated through an action on the enteric nervous system (see Chapter 6) as well as the CNS. In the stomach, motility (rhythmic contraction and relaxation) may decrease but tone (persistent contraction) may increase—particularly in the central portion; gastric secretion of hydrochloric acid is decreased. Small intestine resting tone is increased, with periodic spasms, but the amplitude of nonpropulsive contractions is markedly decreased. In the large intestine, propulsive peristaltic waves are diminished and tone is increased; this delays passage of the fecal mass and allows increased absorption of water, which leads to constipation. The large bowel actions are the basis for the use of opioids in the management of diarrhea.

BILIARY TRACT

The opioids contract biliary smooth muscle, which can result in biliary colic. The sphincter of Oddi may constrict, resulting in reflux of biliary and pancreatic secretions and elevated plasma amylase and lipase levels.

RENAL

Renal function is depressed by opioids. It is believed that in humans this is chiefly due to decreased renal plasma flow. In addition, μ opioids have been found to have an antidiuretic effect in humans. Mechanisms may involve both the CNS and peripheral sites. Opioids also enhance renal tubular sodium reabsorption. The role of opioid-induced changes in antidiuretic hormone (ADH) release is controversial. Ureteral and bladder tone are increased by therapeutic doses of the opioid analgesics. Increased sphincter tone may precipitate urinary retention, especially in postoperative patients. Occasionally, ureteral colic caused by a renal calculus is made worse by opioid-induced increase in ureteral tone.

UTERUS

The opioid analgesics may prolong labor. The mechanism for this action is unclear, but both peripheral and central actions of the opioids can reduce uterine tone.

NEUROENDOCRINE

Opioid analgesics stimulate the release of ADH, prolactin, and somatotropin but inhibit the release of luteinizing hormone. These effects suggest that endogenous opioid peptides, through effects in the hypothalamus, regulate these systems (Table 31–1).

PRURITUS

Therapeutic doses of the opioid analgesics produce flushing and warming of the skin accompanied sometimes by sweating and itching; CNS effects and peripheral histamine release may be responsible for these reactions. Opioid-induced pruritus and occasionally urticaria appear more frequently when opioid analgesics are administered parenterally. In addition, when opioids such as morphine are administered to the neuraxis by the spinal or epidural route, their usefulness may be limited by intense pruritus over the lips and torso.

MISCELLANEOUS

The opioids modulate the immune system by effects on lymphocyte proliferation, antibody production, and chemotaxis. Natural killer cell cytolytic activity and lymphocyte proliferative responses to mitogens are usually inhibited by opioids. Although the mechanisms involved are complex, activation of central opioid receptors could mediate a significant component of the changes observed in peripheral immune function. In general, these effects are mediated by the sympathetic nervous system in the case of acute administration and by the hypothalamic-pituitary-adrenal system in the case of prolonged administration of opioids.

EFFECTS OF OPIOIDS WITH BOTH AGONIST AND ANTAGONIST ACTIONS

Buprenorphine is an opioid agonist that displays high binding affinity but low intrinsic activity at the μ receptor. Its slow rate of dissociation from the μ receptor has also made it an attractive alternative to methadone for the management of opioid withdrawal. It functions as an *antagonist* at the δ and κ receptors and for this reason is referred to as a "mixed agonist-antagonist." Although buprenorphine is used as an analgesic, it can antagonize the action of more potent μ agonists such as morphine. Buprenorphine also binds to ORL1, the orphanin receptor. Whether this property also participates in opposing μ receptor function is under study. Pentazocine and nalbuphine are other examples of opioid analgesics with mixed agonist-antagonist properties. Psychotomimetic effects, with hallucinations, nightmares, and anxiety, have been reported after use of drugs with mixed agonist-antagonist actions.

CLINICAL PHARMACOLOGY OF THE OPIOID ANALGESICS

Successful treatment of pain is a challenging task that begins with careful attempts to assess the source and magnitude of the pain. The amount of pain experienced by the patient is often measured by means of a numeric visual analog scale (VAS) with word descriptors ranging from no pain (0) to excruciating pain (10). A similar scale can be used with children and with patients who cannot speak; this scale depicts five faces ranging from smiling (no pain) to crying (maximum pain).

For a patient in severe pain, the administration of an opioid analgesic is usually considered a primary part of the overall management plan. Determining the route of administration (oral, parenteral, neuraxial), duration of drug action, ceiling effect (maximal intrinsic activity), duration of therapy, potential for adverse effects, and the patient's past experience with opioids all should be addressed. One of the principal errors made by physicians in this setting is failure to adequately assess a patient's pain and to match its severity with an appropriate level of therapy. Just as important is the principle that following delivery of the therapeutic plan, its effectiveness must be reevaluated and the plan modified, if necessary, if the response was excessive or inadequate.

Use of opioid drugs in acute situations may be contrasted with their use in chronic pain management, in which a multitude of other factors must be considered, including the development of tolerance to and physical dependence on opioid analgesics.

Clinical Use of Opioid Analgesics

ANALGESIA

Severe, *constant* pain is usually relieved with opioid analgesics with high intrinsic activity (see Table 31–2); whereas sharp, intermittent pain does not appear to be as effectively controlled.

The pain associated with cancer and other terminal illnesses must be treated aggressively and often requires a multidisciplinary approach for effective management. Such conditions may require continuous use of potent opioid analgesics and are associated with some degree of tolerance and dependence. However, this should not be used as a barrier to providing patients with the best possible care and quality of life. Research in the hospice movement has demonstrated that fixed-interval administration of opioid medication (ie, a regular dose at a scheduled time) is more effective in achieving pain relief than dosing on demand. New dosage forms of opioids that allow slower release of the drug are now available, eg, sustained-release forms of morphine (MSContin) and oxycodone (OxyContin). Their purported advantage is a longer and more stable level of analgesia.

If disturbances of gastrointestinal function prevent the use of oral sustained-release morphine, the fentanyl transdermal system (fentanyl patch) can be used over long periods. Furthermore, buccal transmucosal fentanyl can be used for episodes of breakthrough pain (see Alternative Routes of Administration). Administration of strong opioids by nasal insufflation has been shown to be efficacious, and nasal preparations are now available in some countries. Approval of such formulations in the USA is growing. In addition, stimulant drugs such as the amphetamines have been shown to enhance the analgesic actions of the opioids and thus may be very useful adjuncts in the patient with chronic pain.

Opioid analgesics are often used during obstetric labor. Because opioids cross the placental barrier and reach the fetus, care must be taken to minimize neonatal depression. If it occurs, immediate injection of the antagonist naloxone will reverse the depression. The phenylpiperidine drugs (eg, meperidine) appear to produce less depression, particularly respiratory depression, in newborn infants than does morphine; this may justify their use in obstetric practice.

The acute, severe pain of renal and biliary colic often requires a strong agonist opioid for adequate relief. However, the drug-induced increase in smooth muscle tone may cause a paradoxical *increase* in pain secondary to increased spasm. An increase in the dose of opioid is usually successful in providing adequate analgesia.

ACUTE PULMONARY EDEMA

The relief produced by intravenous morphine in dyspnea from pulmonary edema associated with left ventricular failure is remarkable. Proposed mechanisms include reduced anxiety (*perception* of shortness of breath), and reduced cardiac preload (reduced venous tone) and afterload (decreased peripheral resistance). Morphine can be particularly useful when treating painful myocardial ischemia with pulmonary edema.

COUGH

Suppression of cough can be obtained at doses lower than those needed for analgesia. However, in recent years the use of opioid analgesics to allay cough has diminished largely because a number of effective synthetic compounds have been developed that are neither analgesic nor addictive. These agents are discussed below.

DIARRHEA

Diarrhea from almost any cause can be controlled with the opioid analgesics, but if diarrhea is associated with infection such use must not substitute for appropriate chemotherapy. Crude opium preparations (eg, paregoric) were used in the past to control diarrhea, but now synthetic surrogates with more selective gastrointestinal effects and few or no CNS effects, eg, diphenoxylate, are used. Several preparations are available specifically for this purpose (Chapter 63).

SHIVERING

Although all opioid agonists have some propensity to reduce shivering, meperidine is reported to have the most pronounced anti-shivering properties. It is interesting that meperidine apparently blocks shivering through its action on subtypes of the α_2 adrenoceptor.

APPLICATIONS IN ANESTHESIA

The opioids are frequently used as premedicant drugs before anesthesia and surgery because of their sedative, anxiolytic, and analgesic properties. They are also used intraoperatively both as adjuncts to other anesthetic agents and, in high doses (eg, 0.02–0.075 mg/kg of fentanyl), as a primary component of the anesthetic regimen (see Chapter 25). Opioids are most commonly used in cardiovascular surgery and other types of high-risk surgery in which a primary goal is to minimize cardiovascular depression. In such situations, mechanical respiratory assistance must be provided.

Because of their direct action on the superficial neurons of the spinal cord dorsal horn, opioids can also be used as regional analgesics by administration into the epidural or subarachnoid spaces of the spinal column. A number of studies have demonstrated that long-lasting analgesia with minimal adverse effects can be achieved by epidural administration of 3–5 mg of morphine, followed by slow infusion through a catheter placed in the epidural space. It was initially assumed that the epidural application of opioids might selectively produce analgesia without impairment of motor, autonomic, or sensory functions other than pain. However, respiratory depression can occur after the drug is injected into the epidural space and may require reversal with naloxone. Effects such as pruritus and nausea and vomiting are common after epidural and subarachnoid administration of opioids and may also be reversed with naloxone if necessary.

Currently, the epidural route is favored because adverse effects are less common. Morphine is the most frequently used agent, but the use of low doses of local anesthetics in combination with fentanyl infused through a thoracic epidural catheter has also become an accepted method of pain control in patients recovering from major upper abdominal surgery. In rare cases, chronic pain management specialists may elect to surgically implant a programmable infusion pump connected to a spinal catheter for continuous infusion of opioids or other analgesic compounds.

ALTERNATIVE ROUTES OF ADMINISTRATION

Rectal suppositories of morphine and hydromorphone have long been used when oral and parenteral routes are undesirable. The *transdermal patch* provides stable blood levels of drug and better pain control while avoiding the need for repeated parenteral injections. Fentanyl has been the most successful opioid in transdermal application and finds great use in patients experiencing chronic pain. The *intranasal* route avoids repeated parenteral drug injections and the first-pass metabolism of orally administered drugs. Butorphanol is the only opioid currently available in the USA in a nasal formulation, but more are expected. Another alternative to parenteral administration is the *buccal transmucosal* route, which uses a fentanyl citrate lozenge or a "lollipop" mounted on a stick.

Another type of pain control called *patient-controlled analgesia* (PCA) is now in widespread use for the management of breakthrough pain. With PCA, the patient controls a parenteral (usually intravenous) infusion device by depressing a button to deliver a preprogrammed dose of the desired opioid analgesic. Claims of better pain control using less opioid are supported by well-designed clinical trials, making this approach very useful in postoperative pain control. However, health care personnel must be very familiar with the use of PCAs to avoid overdosage secondary to misuse or improper programming. There is a proven risk of respiratory depression with hypoxia that requires careful monitoring of vital signs and sedation level.

Toxicity & Undesired Effects

Direct toxic effects of the opioid analgesics that are extensions of their acute pharmacologic actions include respiratory depression, nausea, vomiting, and constipation (Table 31–4). In addition, tolerance and dependence, diagnosis and treatment of overdosage, as well as contraindications must be considered.

Table 31–4. Adverse Effects of the Opioid Analgesics.

Behavioral restlessness, tremulousness, hyperactivity (in dysphoric reactions)
Respiratory depression
Nausea and vomiting
Increased intracranial pressure
Postural hypotension accentuated by hypovolemia
Constipation
Urinary retention
Itching around nose, urticaria (more frequent with parenteral and spinal administration)

TOLERANCE AND DEPENDENCE

Drug dependence of the opioid type is marked by a relatively specific withdrawal or abstinence syndrome. Just as there are pharmacologic differences between the various opioids, there are also differences in psychologic dependence and the severity of withdrawal effects. For example, withdrawal from dependence on a strong agonist is associated with more severe withdrawal signs and symptoms than withdrawal from a mild or moderate agonist. Administration of an opioid *antagonist* to an opioid-dependent person is followed by brief but severe withdrawal symptoms (see antagonist-precipitated withdrawal, below). The potential for physical and psychologic dependence of the partial agonist-antagonist opioids appears to be less than that of the agonist drugs.

Tolerance
